In **mammals**, the glycerol-3-phosphate acyltransferase that catalyses the first step exists in four isoforms, two in the mitochondrial outer membrane (designated GPAT1 and 2) and two in the endoplasmic reticulum (GPAT3 and 4); all are membrane-bound enzymes, which are believed to span the membranes. GPAT1 is highly expressed in the liver and adipose tissue, where it is responsive to changes in feeding status via the sterol regulatory element binding protein-1 (SREBP-1), a master transcriptional regulator of lipogenic enzymes. It is essential in directing fatty acyl-CoA esters towards glycerolipid synthesis as opposed to β-oxidation. GPAT3 is especially important for

triacylglycerol storage in adipocytes, while GPAT4 is the main contributor to lysophosphatidic acid synthesis in liver and brown adipose tissue.

For the second step in phosphatidic acid biosynthesis, five mammalian acyl-CoA:lysophosphatidic acid acyltransferases are known of which three are in the endoplasmic reticulum (LPAAT or LPAT or AGPAT1, 2 and 3), with a further two (LPAT4 and 5) on the outer mitochondrial membrane. While LPAT1 and 2 have strict specificity for lysophosphatidic acid as acyl acceptor, other isoforms can esterify other lysophospholipids. Human LPAT1 showed higher activity with 14:0-, 16:0- and 18:2-CoAs, while LPAT2 prefers 20:4-CoA and LPAT3 produces phosphatidic acid containing docosahexaenoic acid (22:6(*n*-3)); the last is especially important in retina and testes. LPAT4 and 5 have a preference for oleoyl-CoA and polyunsaturated acyl-CoAs as the acyl donor, suggesting a dual role in glycerolipid synthesis and remodeling. The activity in the endoplasmic reticulum predominates in adipose tissue, but the mitochondrial forms are believed to be responsible for half the activity in liver. However, as there is traffic of phosphatidic acid between the mitochondria and endoplasmic reticulum for remodeling or for synthesis of other lipids, the relative contributions of the two can be difficult to assess.

In **plants**, the *sn*-glycerol-3-phosphate pathway exists both in plastids and at the endoplasmic reticulum with multiple isoforms of the two acyltransferases as well as differences in the acyl substrates. In brief most plant lipid biosynthesis begins with fatty acid biosynthesis in the chloroplasts. In plastids, the acyltransferase ATS1 transfers 18:1 acyl groups from acyl-acyl carrier protein (acyl-ACP) to position *sn*-1 of glycerol 3-phosphate, before ATS2 transfers a palmitoyl group from ACP to position *sn*-2, producing phosphatidic acid at the inner leaflet of the chloroplast inner envelope membrane (IEM). Fatty acids intended for the endoplasmic reticulum are released from ACP in the chloroplast stroma by IEM-associated thioesterases, exported and then activated by acyl-CoA synthetases of the outer envelope membrane to produce species with C_{18} fatty acids in both positions. Thus, acyl-CoAs are used for phosphatidic acid biosynthesis in the endoplasmic reticulum with marked differences in the specificity of the acyl substrates. Subsequently, phosphatidic acid in the plastids is utilized for biosynthesis of galactosyldiacylglycerols, while that in the endoplasmic reticulum is used for synthesis of triacylglycerols and phospholipids.

In **bacteria**, two families of enzymes are responsible for acylation of position *sn*-1 of glycerol-3-phosphate. One present in *Escherichia coli*, for example, utilizes the acyl-acyl carrier protein (acyl-ACP) products of fatty acid synthesis as acyl donors as well as acyl-CoA derived from exogenous fatty acids. In a second wider group of bacteria, including cyanobacteria, there are enzymes (PlsX and PlsY) that make use of the unique acyl donors, **acyl-phosphates** derived in part from acyl-ACP, to acylate position *sn*-1. Acylation of position *sn*-2 in this instance is performed by a further family of enzymes (PlsC) that uses acyl-ACP as the acyl donor, although some bacterial species may use acyl-CoA also.

In animals, a second biosynthetic pathway utilizes dihydroxyacetone phosphate (DHAP) as the primary precursor for the peroxisomal enzyme, DHAP acyltransferase, which produces acyl-DHAP. This intermediate is converted to lysophosphatidic acid in a NADPH-dependent reaction catalyzed by acyl-DHAP reductase, and this is in turn acylated to form phosphatidic acid by the same LPAT as in the previous mechanism. This pathway is of particular importance in the biosynthesis of **ether lipids**. The synthesis of phosphatidic acid from dihydroxyacetone phosphate is shown in Figure 21.3.3.

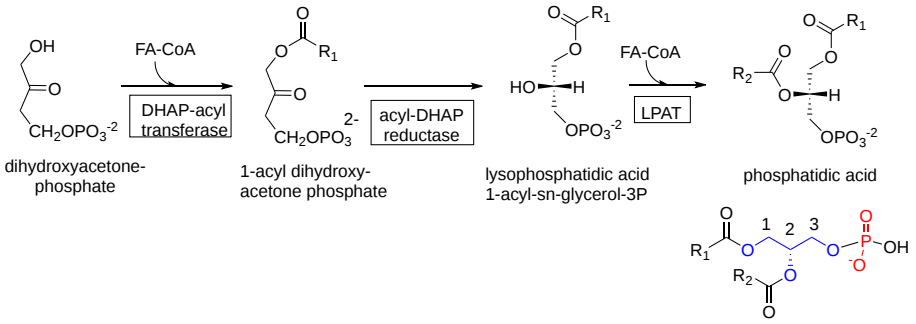

Figure 21.3.3:Synthesis of phosphatidic acid from dihydroacetone phosphate

A third important route to phosphatidic acid is via hydrolysis of other phospholipids, but especially phosphatidylcholine, by the enzyme phospholipase D (or by a family or related enzymes of this kind). The enzyme is readily available for study in plants, where the special functions of phosphatidic acid have long been known (see **below**), but it is now recognized that phospholipase D is present in bacteria, yeasts and most animal cells. In the last, it exists in two main isoforms with differing specificities and cellular locations; PLD1 is found mainly in the Golgi-lysosome continuum, while PLD2 is present mainly in the plasma membrane. They are phosphoproteins, the activity of which is regulated by kinases and phosphatases and by binding to phosphatidylinositol-4,5-bisphosphate. In mitochondria, a distinctive enzyme of this type utilizes cardiolipin as substrate. The mechanism involves the use of water as the nucleophile to catalyse the hydrolysis of phosphodiester bonds in phospholipids. Phospholipase D activity is dependent on and regulated by neurotransmitters, hormones, small monomeric GTPases and lipids. The hydrolysis of phosphatidylcholine to phosphatidic acids by phospholipase D is shown in Figure 21.3.4.

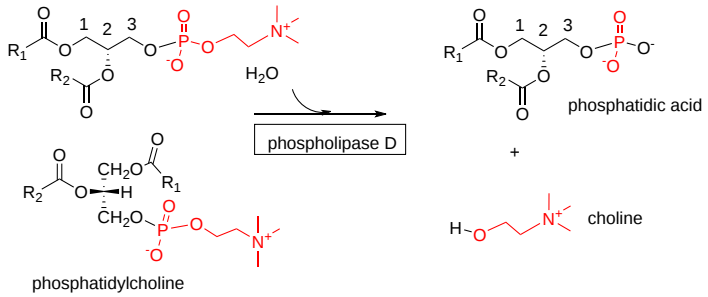

Figure 21.3.4: hydrolysis of phosphatidylcholine to phosphatidic acids by phospholipase D

In addition to its function in generating phosphatidic acid mainly for signaling purposes but also for the maintenance of membrane composition, phospholipase D is involved in intracellular protein trafficking, cytoskeletal dynamics, cell migration, and cell proliferation, partly through protein-protein interactions; it is considered to be important in inflammation and in cancer growth and metastasis as a downstream transcriptional target of proteins involved in the pathophysiology of these diseases. It also has an unusual activity as a guanine nucleotide exchange factor. By a transphosphatidylation reaction with ethanol, it generates **phosphatidylethanol**, a useful biomarker for ethanol consumption in humans.

Under some conditions, phosphatidic acid can be generated from 1,2-diacyl-*sn*-glycerols by the action of **diacylglycerol kinases**, for example those produced from other phospholipids by the action of phospholipase C. Such enzymes appear to be ubiquitous in nature, although those in bacteria and yeast are structurally different from the mammalian enzymes. Diacylglycerol kinases, of which at least ten isoforms (DGKα to DGKκ) exist with different sub-cellular locations and functions in animals, use ATP as the phosphate donor. While the epsilon isoform (DGKε) utilizes the 1-stearoyl-2-arachidonoyl species of diacyl-*sn*-glycerols preferentially to produce phosphatidic acid for the biosynthesis of **phosphatidylinositol**, other isoenzymes phosphorylate diverse diacylglycerol species. Aside from producing phosphatidic acid for phospholipid production or signaling , these enzymes may attenuate the signaling effects of diacylglycerols. For example, diacylglycerol kinases can contribute to cellular asymmetry and control the polarity of cells by regulating the gradients in diacylglycerol and phosphatidic acid concentrations. Figure 21.3.5 shows the synthesis of phosphatidic acid via diacylglycerols and the reverse reaction.

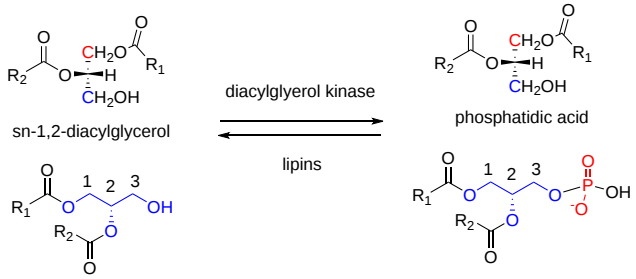

Figure 21.3.5: Synthesis of phosphatidic acid via diacylglycerols and the reverse reaction

The reverse reaction, hydrolysis, is catalyzed by lipins. These enzymes are of importance in regulating the local concentrations of phosphatidic acid and thence its biological activity.

A further possible route to phosphatidic acid production for signaling specifically is via acylation of lysophosphatidic acid, which can be produced independently for signaling purposes as discussed below. This pathway may be especially relevant in membranes, where the protein endophilin has LPAT activity and is believed to generate phosphatidic acid from lysophosphatidic acid in order to alter the curvature of the membrane bilayer.

21.3.2.2: PHOSPHATIDIC ACID - ROLE AS A LIPID PRECURSOR

In summary, phosphatidic acid generated via 1-acyl-*sn*-glycerol-3-phosphate is the primary precursor of other glycerolipids, although other pathways may be more important for generating the lipid for signaling functions. Whether separate pools of this lipid for specific purposes really exist is not certain since dynamic changes of intracellular distribution occur under various cellular conditions. These are attributed to inter-organelle transfer via vesicular transport or at membrane contact sites by lipid transfer proteins. Control of its concentration in membranes, especially in the endoplasmic reticulum, is therefore of great importance, and a transcriptional repressor 'Opi1', which binds specifically to phosphatidic acid in membranes, is a key regulatory factor. However, many other phosphatidic acid-binding proteins have been identified that influence how phosphatidic acid is used either as a biosynthetic precursor or for signaling purposes. The mechanisms for phosphatidic acid homeostasis differ among animals, plants, yeasts, and bacteria in response to the differing functional requirements in these organisms. Figure 21.3.6 shows the pathways for biosynthesis of complex glycerolipids.

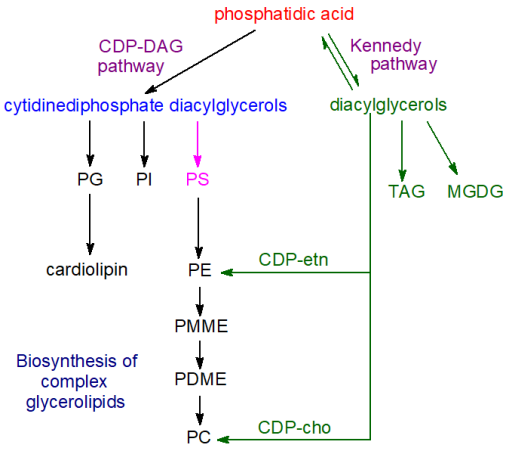

Figure 21.3.6: Biosynthesis of complex glycerolipids

In addition to dietary, hormonal and tissue-specific factors in animals, the extent to which fatty acids are channeling either into triacylglycerol synthesis for storage in lipid droplets and secretion in lipoproteins or into glycerophospholipids for membrane formation depends to a large extent upon the enzymes of glycerol-3-phosphate pathway, their isoform expression, activities and locations. On the other hand, phosphatidic acid is not only a biosynthetic precursor of other lipids but also a regulatory molecule in the transcriptional control of the genes for glycerolipid synthesis, and regulation of its concentration in cells for this purpose is similarly essential. For example, the local concentration of phosphatidic acid in the endoplasmic reticulum is an important factor in the biogenesis of lipid droplets.

The subsequent steps in the utilization of phosphatidic acid in the biosynthesis of triacylglycerols and of the various glycerophospholipids are described in separate documents of this website. Thus, hydrolysis of phosphatidic acid by phosphatidate phosphatase enzymes (including lipins 1, 2, and 3) is the source of most other glycerolipids, e.g. ***sn*-1,2-diacylglycerols** (DG), which are the precursors for the biosynthesis of **triacylglycerols** (TAG), **phosphatidylcholine** (PC) and **phosphatidylethanolamine** (PE) via the so-called Kennedy pathway (also of **monogalactosyldiacylglycerols** in plants). Via reaction with cytidine triphosphate, phosphatidic acid is the precursor of **cytidine diphosphate diacylglycerol**, which is the key intermediate in the synthesis of **phosphatidylglycerol** (PG), and thence of **cardiolipin** (CL), and of **phosphatidylinositol** (PI), and in prokaryotes and yeast but not animals **phosphatidylserine** (PS). Depending on the organism and other factors, phosphatidylserine can be a precursor for phosphatidylethanolamine, while the latter can give rise to phosphatidylcholine by way of mono- and dimethyl-phosphatidylethanolamine intermediates. The cytidine diphosphate diacylglycerol synthase is another enzyme that consumes phosphatidic acid and is important for modulating the concentration of phosphatidic acid in cells and for regulating processes mediated by this lipid.

While the fatty acid composition of phosphatidic acid can resemble that of the eventual products, the latter are generally much altered by re-modeling after synthesis via deacylation-reacylation reactions.

21.3.2.3: PHOSPHATIDIC ACID - BIOLOGICAL FUNCTIONS IN ANIMALS

In addition to its role as an intermediate in lipid biosynthesis, phosphatidic acid and especially that generated by the action of phospholipase D and by diacylglycerol kinases may have signaling functions as a second messenger, although it is not certain whether all the activities suggested by studies *in vitro* operate *in vivo*. Nonetheless, phosphatidic acid has been implicated in many aspects of animal cell biochemistry and physiology.

Some of the observed effects may be explained simply by the physical properties of phosphatidic acid, which has a propensity to form a hexagonal II phase, especially in the presence of calcium ions. Thus, hydrolysis of phosphatidylcholine, a cylindrical non-fusogenic lipid, converts it into cone-shaped phosphatidic acid, which promotes negative membrane curvature and fusion of membranes. It differs from other anionic phospholipids in that its small anionic phosphomonoester head group lies very close to the hydrophobic interior of the lipid bilayer. In model systems, phosphatidic acid can effect membrane fusion, probably because of its ability to form non-bilayer phases. For example, the phosphatidic acid biosynthesis is believed to favor intraluminal budding of endosomal membranes with the formation of exosomes, and in many cell types, vesicle trafficking, secretion and endocytosis may require phosphatidic acid derived by the action of phospholipase D.

Also of relevance in this context is its overall negative charge, and it is not always clear whether some of the observed biological effects are specific to phosphatidic acid or simply to negatively charged phospholipids in general. In contrast to phosphoinositide-interacting proteins, which have defined structural folds, the binding motifs of effector proteins with phosphatidic acid are not highly conserved. However, it has been demonstrated that the positively charged lysine and arginine residues on proteins can bind with some specificity to phosphatidic acid through hydrogen bonding with the phosphate group thus distinguishing it from other phospholipids. An ‘electrostatic-hydrogen bond switch model’ has been proposed in which the head group of phosphatidic acid forms a hydrogen bond to amino acid residues leading to de-protonation of the head group, increasing its negative charge from -1 to -2 and thus enabling stronger interactions with basic residues and

tight docking with the membrane interacting protein. In this way, phosphatidic acid can tether certain proteins to membranes, and it can simultaneously induce conformational changes, hinder ligand binding and/or oligomerize proteins to alter their catalytic activity, stability and interactions with other molecules. It functions as a cellular pH sensor in effect in that binding to proteins is dependent on intracellular pH and the protonation state of its phosphate head group.

One key target of the lipid is mTOR, a serine/threonine protein kinase with a signaling cascade that regulates cell growth, proliferation, motility and survival, together with protein synthesis and transcription, by integrating both nutrient and growth factor signals. This forms two distinct complexes of accessory proteins that regulate downstream targets. Of these, mTORC1 interacts directly with phosphatidic acid and this interaction allosterically activates the enzyme complex to regulate protein synthesis, mitochondrial metabolism and the transcription of enzymes involved in lipid synthesis. In contrast, phosphatidic acid appears to inhibit mTORC2 activity, for example in relation to insulin signaling .

Phosphatidic acid is believed to regulate membrane trafficking events, and it is involved in activation of the enzyme NADPH oxidase, which operates as part of the defence mechanism against infection and tissue damage during inflammation. By binding to targeted proteins, including protein kinases, protein phosphatases and G-proteins, it may increase or inhibit their activities. Effects on gene transcription have been observed that are linked to inhibition of peroxisome proliferator-activated receptor (PPAR) activity. In yeast, phosphatidic acid in the endoplasmic reticulum binds directly to a specific transcriptional repressor to keep it inactive outside the nucleus; when the lipid precursor inositol is added, this phosphatidic acid is rapidly depleted, releasing the transcriptional factor so that it can be translocated to the nucleus where it is able to repress target genes. The overall effect is a mechanism to control phospholipid synthesis.

In addition, phosphatidic acid regulates many aspects of phosphoinositide function. For example, the murine phosphatidylinositol 4-phosphate 5-kinase, the main enzyme generating the lipid second messenger **phosphatidylinositol-4,5-bisphosphate**, does not appear to function unless phosphatidic acid is bound to it; this lipid, generated by the action of phospholipase D, recruits the enzyme to the membrane and induces a conformational change that regulates its activity. It may have a role in promoting phospholipase A_2 activity, a key enzyme in eicosanoid production from phosphoinositide precursors.

In relation to signaling activities, it should be noted that phosphatidic acid can be metabolized to ***sn*-1,2-diacylglycerols** or to lysophosphatidic acid (see next section), both of which have distinctive signaling functions in their own right. Conversely, both of these compounds can be in effect be de-activated by conversion back to phosphatidic acid.

Phospholipase D isoforms and phosphatidic acid have been implicated in a variety of pathologies including neurodegenerative diseases, blood disorders, late-onset Alzheimer's disease and cancer, leading to attempts to develop specific inhibitors of the enzyme for therapeutic purposes. Similarly, the expression of LPAT isoforms can enhance the proliferation and chemoresistance of some cancer cells. Diacylglycerol kinase alpha (DGKα) is highly expressed in several refractory cancer cells, where it attenuates apoptosis, and promotes proliferation. In addition, DGKα is highly abundant in T cells and induces a nonresponsive state, which enables advanced cancers to escape immune action. Inhibition of this enzyme also is seen as a promising treatment strategy.

21.3.2.4: PHOSPHATIDIC ACID - BIOLOGICAL FUNCTIONS IN PLANTS

Phosphatidic acid is present at higher levels in roots of plants in comparison to leaves and is believed to have a function in root architecture. Similarly, its concentration is elevated in flowers and reproductive tissues, but the significance of this is not known. In addition to its role as one of the central molecules in lipid biosynthesis, it facilitates the transport of lipids across plant membranes, and it is also the key plant lipid second messenger, which is rapidly and transiently generated in response to many different biotic and abiotic stresses. In contrast to animal metabolism, the **diacylglycerol** signaling pathway is believed to be relatively insignificant in plants.

The main source of phosphatidic acid for these purposes is the action of phospholipase D (PLD) on membrane phospholipids, such as phosphatidylcholine and phosphatidylethanolamine. Plants contain numerous related enzymes of this type, 12 in Arabidopsis and 17 in rice, in comparison with two in humans and one in yeast, and individual iso-enzymes may elicit specific responses. In the former, the isoforms are grouped into six classes, based on the genic architecture, sequence similarities, domain structures and biochemical properties. These depend mainly on their lipid-binding domains, with some homologous to the human and yeast enzymes and with most containing a characteristic ‘C2’ (calcium- and lipid-binding) domain. The most widespread of these is PLDα, which does not require binding to phosphatidylinositol 4,5-bisphosphate, in contrast to other PLD isoforms and the mammalian enzyme, but millimolar levels of Ca^{2+} are necessary. Studies with fluorescent biosensors suggest that phosphatidic acid accumulates in the subapical region of the cytosolic leaflet of the plasma membrane.

Phosphatidic acid can also be produced by the sequential action of phospholipase C and diacylglycerol kinase on membrane inositol phospholipids, with diacylglycerols as an intermediate (there are 7 isoenzymes in *A. thaliana*). One difference from animal metabolism is that diacylglycerol pyrophosphate can be synthesized from phosphatidic acid in plants (see below).

Phosphatidic acid is required to bind and allosteric activate the **monogalactosyldiacylglycerol synthase (MGDG1)**, located in the inner envelope membrane of the chloroplast, and it may be a regulator of the biosynthesis of thylakoid membranes. Phospholipase D activity and the phosphatidic acid produced have long been recognized as of importance during germination and senescence, and they have an essential role in the response to stress damage and pathogen attack, both in higher plants and in green algae. A high content of phosphatidic acid

induced by phospholipase D action during wounding or senescence brings about a loss of the membrane bilayer phase, because of the conical shape of this negatively charged phospholipid in comparison to the cylindrical shape of structural phospholipids. This change in ionization properties has crucial effects upon lipid-protein interactions, "the electrostatic-hydrogen bond switch model" described above. By promoting negative curvature at the plasma membrane and binding to clathrin proteins, it is believed to facilitate the process of endocytosis. Similar phenomena may explain why phosphatidic acid is important in the response to other forms of stress, including osmotic stress (salinity or drought), cold and oxidation. Although much remains to be learned of the mechanism by which it exerts its effects, it is believed to promote the response to the plant hormone abscisic acid. In addition, phosphatidic acid may interact with salicylic acid to mediate defence responses.

In plants, phosphatidic acid is involved in many different cell responses induced by hormones, stress and developmental processes. In relation to cellular signaling, it often acts in concert with **phosphatidylinositol 4,5-bisphosphate** by binding to specific proteins rather than acting via a receptor. As in mammalian cells, targets for such signaling include protein kinases and phosphatases in addition to proteins involved in membrane trafficking and the organization of the cytoskeleton. It can both activate or inhibit enzymes. If the target protein is soluble, binding to phosphatidic acid can cause the protein to be sequestered into a membrane with effects upon downstream targets. For example, it is involved in promoting the growth of pollen-tubes and root hairs, decreasing peroxide-induced cell death, and mediating the signaling processes that lead to responses to ethylene and again to the hormone abscisic acid. Thus, in the 'model' plant *Arabidopsis*, phosphatidic acid interacts with a protein phosphatase to signal the closure of stomata promoted by abscisic acid; it interacts also with a further enzyme to mediate the inhibition of stomatal opening effected by abscisic acid. Together these reactions constitute a signaling pathway that regulates water loss from plants.

It is noteworthy that phosphatidic acid production can be initiated by opposing stress factors, such as cold and heat, as well as by hormones that are considered to be antagonistic, such as abscisic acid and salicylic acid. It is possible that phosphatidic acid molecules synthesized by the two main pathways differ in composition and cellular distributions and so may produce different responses, but this is an open question. Certainly, during low temperature stress, phosphatidic acid is generated by the action of diacylglycerol kinase. It also seems likely that these differing activities are controlled by the cellular environment where the lipid is produced and by the availability of target proteins or other molecules with which it can act synergistically. Genes encoding enzymes involved in phosphatidic acid metabolism have been manipulated to explore their potential application for crop improvements, based on effects on plant growth, development, and stress responses.

As in animals, phosphatidic acid is catabolized and its signaling functions are terminated by lipid phosphate phosphatases and phosphatidic acid hydrolases, and by acyl-hydrolases and lipoxygenases with the production of fatty acids and other small molecules, which are subsequently absorbed and recycled.

21.3.2.5: LYSOPHOSPHATIDIC ACID

Figure 21.3.7 shows the structure of a lysophosphatidic acid (note the absence of an acyl group at C2).

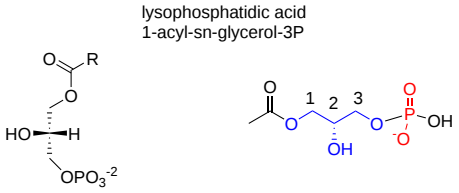

Figure 21.3.7: lysophosphatidic acid

Lysophosphatidic acid (LPA) or 1-acyl-*sn*-glycerol-3-phosphate differs structurally from phosphatidic acid in having only one mole of fatty acid per mole of lipid. As such, it is one of the simplest possible glycerophospholipids. It exists in the form of many different molecular species, i.e., esterified to 16:0 to 22:6 fatty acids, and there is preliminary evidence that saturated and polyunsaturated species may differ in their biological properties in some circumstances. As the *sn*-1-acylated form is more stable thermodynamically, facile isomerization ensures that this tends to predominate. As it lacks one fatty acid in comparison to phosphatidic acid, it is a much more hydrophilic molecule, while the additional hydroxyl group strengthens hydrogen bonding within membranes, properties that may be important for its function in cells.

Although lysophosphatidic acid is present at very low levels only in animal tissues, it is extremely important biologically, influencing many biochemical processes. It is a biosynthetic precursor of phosphatidic acid, but there is particular interest in its role as a lipid mediator with growth factor-like activities. For example, it is rapidly produced and released from activated platelets to influence target cells.

Biosynthesis: In the circulation, the most important source of lysophosphatidic acid is the activity of an enzyme with lysophospholipase D-like activity and known as '**autotaxin**' on **lysophosphatidylcholine** (200 μM in plasma) to yield LPA in an albumin-bound form mainly, although it is relatively soluble in aqueous media because of its polarity and small size. This lipid is more abundant in serum (1 to 5 μM) than in plasma (100 nM), because of the release of its main precursor, lysophosphatidylcholine, from activated platelets during coagulation. Autotaxin is a member of the nucleotide pyrophosphatase-phosphodiesterase family and is also present in cerebrospinal and seminal fluids and many other tissues including cancer cell lines from which it was first isolated and characterized. Indeed, the name derives from the

finding that it promoted chemo*taxis* on melanoma cells in an *auto*crine fashion. It binds to target cells via integrin and heparan sulfate proteoglycans and this may assist the delivery of lysophosphatidic acid to its receptors. Genetic deletion of the enzyme in mice results in aberrant vascular and neuronal development and soon leads to death of the embryos. However, the overexpression of autotaxin causes physical defects also and is eventually lethal to embryos.

Figure 21.3.8 shows the pathways for synthesis of lysophosphatidic acid.

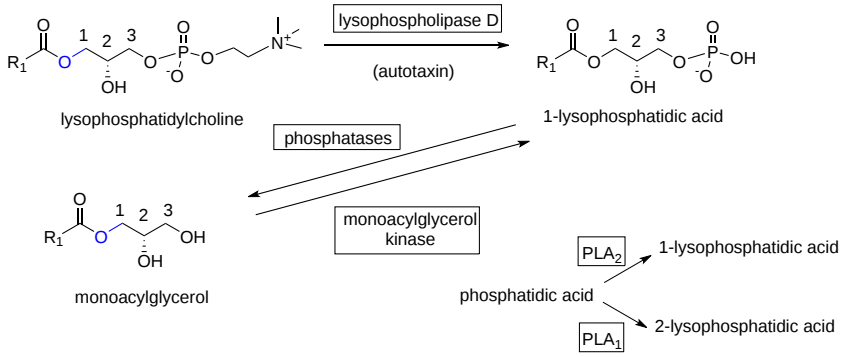

Figure 21.3.8: Pathways for synthesis of lysophosphatidic acid.

While autotaxin is the primary source of extracellular lysophosphatidic acid, it is now established that it is produced intracellularly by a wide variety of cell types by various mechanisms often with phosphatidic acid, derived from other phospholipids by the action of phospholipase D, as the primary precursor. For example, hydrolysis of phosphatidic acid by a phospholipase A_2 (PLA_2) is the main mechanism in platelets, but other cellular enzymes involved include a phosphatidic acid-selective phospholipase A_1 (PLA_1) producing *sn*-2-acyl-lysophosphatidic acid, a monoacylglycerol kinase (utilizing monoacylglycerols produced by the action of lipid phosphate phosphatases) and glycerol-3-phosphate acyltransferase (the first step in phosphatidic acid biosynthesis). In particular, secretory PLA_2-IIA (sPLA2-IIA) is able to induce the release of LPA from phosphatidic acid exposed on the surface of extracellular vesicles derived from platelets and Ca^{2+}-loaded erythrocytes upon stimulation by pro-inflammatory cytokines.

General function: Although lysophospholipids are relatively small molecules, they carry a high content of information through the nature of the phosphate head group, the positional distribution of the fatty acids on the glycerol moiety, the presence of ether or ester linkages to the glycerol backbone, and the chain-length and degree and position of saturation of the fatty acyl chains. Lysophosphatidic acid acts upon nearly all cell types, often as a proliferative and pro-survival signal, inducing cellular invasion, migration and differentiation, while stimulating smooth muscle and fibroblast contraction, cytoskeletal rearrangement, secretion of cytokines/chemokines and numerous other effects. Many of these activities are displayed also by the 1-*O*-alkyl- and alkenyl-ether forms, which can be derived from **platelet activating factor**. On the other hand, it is possible that much of the lysophosphatidic acid produced intracellularly is used for synthesis of other phospholipids rather than for signaling purposes.

Receptors: The informational content of the lysophosphatidic acid molecule leads to selectivity in the functional relationship with cell receptors. As most mammalian cells express receptors for lysophosphatidic acid, this lipid may initiate signaling in the cells in which it is produced, as well as affecting neighboring cells. Characterization of cloned lysophosphatidic acid receptors in combination with strategies of molecular genetics has allowed determination of both signaling and biological effects that are dependent on receptor mechanisms. At least six G protein-coupled receptors that are specific for lysophosphatidic acid have now been identified in vertebrates, each found in particular organs and coupled to at least one or more of the four heterotrimeric G_α proteins and designated $LPAR_1$ to $LPAR_6$, of which $LPAR_1$ is virtually ubiquitous in tissues. These vary appreciably amino acid sequences but are classified into two subgroups, the EDG (LPAR1-3) and P2Y (LPAR4-6) families, with differing tissue distributions. Most cell types express these receptors in different combinations. There is also some interaction with transient receptor potential cation channel V1 (TRPV1), peroxisome proliferator-activated receptor gamma (PPARγ) and other proteins. Plasma lysophosphatidic acid binds to its receptors while it is bound to albumin.

Experimental activation of the LPAR receptors has shown that a range of downstream signaling cascades are mediated by lysophosphatidic acid signaling via these various receptors. These include activation of adenylyl cyclase, cAMP production, intracellular Ca^{2+} and K^+ production (by activating ion channels), protein kinases, phospholipase C, phosphatidylinositol 3-kinase, small GTPases (Ras, Rho, Rac), release of arachidonic acid, and much more. In this way, lysophosphatidic acid regulates cell survival, proliferation, cytoskeleton re-arrangement, motility, cytokine secretion, cell differentiation and many other vital cellular processes. Sometimes, lysophosphatidic acid appears to function in contradictory ways, and there is evidence that it is involved in cell survival in some circumstances and in programmed cell death in others, for example.

Signaling by lysophosphatidic acid has regulatory functions in the mammalian reproductive system, both male and female, facilitating oocyte maturation and spermatogenesis through the action of the receptors $LPAR_1$ to $LPAR_3$. During early gestation, it regulates vascular remodeling at the maternal-fetal interface. There is also evidence that the lipid is involved in brain development, through its activity in

neural progenitor cells, neurons, and glia, and in vascular remodeling. In the central nervous system, these receptors are thought to play a central role in both triggering and maintaining neuropathic pain by mechanisms that may involve demyelination of damaged nerves.

Lysophosphatidic acid has been found in saliva in significant amounts, and it has been suggested that it is involved in wound healing in the upper digestive organs such as the mouth, pharynx, and oesophagus. When applied topically to skin wounds, it has similar effects probably by stimulating proliferation of new cells to seal the wound. Receptor $LPAR_6$ together with the phospholipase A_1 is required for the development of hair follicles, and this receptor is also involved in the regulation of endothelial blood-brain barrier function. The proliferation and survival of stem cells and their progenitors is regulated by lysophosphatidic acid signaling, while in bone cells, acting via $LPAR_1$, lysophosphatidic acid is important for bone mineralization and repair.

Disease: There is particular interest in the activity of lysophosphatidic acid in various disease states and **cancer** especially, as increased expression of autotaxin and the subsequent increased levels of lysophosphatidic acid have been reported in several primary tumors. For example, a finding that lysophosphatidic acid is markedly elevated in the plasma and peritoneal fluid (ascites) of ovarian cancer patients compared to healthy controls may be especially significant. Also, elevated plasma levels were found in patients in the first stage of ovarian cancer, suggesting that it may represent a useful marker for the early detection of the disease. It is believed that the secretory form of phospholipase A_2 acts preferentially on lipids from damaged membranes or microvesicles, such as those produced by malignant cells, and this eventually results in increased levels of this lipid. Lysophosphatidic acid has been shown to stimulate the expression of genes for many different enzymes that lead to the proliferation of ovarian and other cancer cells and may induce cell migration via receptors $LPAR_1$ to $LPAR_3$ and possibly $LPAR_6$, while $LPAR_4$ and $LPAR_5$ have opposing effects. Autotaxin and LPARs have been implicated in resistance to chemotherapy and radiation treatment in cancer therapy.

As lysophosphatidic acid has growth-factor-like activities for many cell types that induce cell proliferation and migration, changes in cellular shape and increasing of endothelial permeability, it is perhaps not surprising that it is relevant to tumor biology. Treatment of various cancer cell types with lysophosphatidic acid promotes the expression and release of interleukin 8 (IL-8), which is a potent angiogenic factor, and thus it has a critical role in the growth and spread of cancers by enhancing the availability of nutrients and oxygen. There is evidence that signaling by lysophosphatidic acid is causally linked to hyperactive lipogenesis in cancer. For example, it activates the sterol regulatory element-binding protein (SREBP) together with the fatty acid synthase and AMP-activated protein kinase–ACC lipogenic cascades leading to elevated synthesis of lipids *de novo*. Increased autotaxin expression has been demonstrated in many different cancer cell lines, and the expression of many of the surface receptors for lysophosphatidic acid in cancer cells is aberrant. Cancer cells must evade the immune system during metastasis, and lysophosphatidic acid facilitates this process by inhibiting the activation of T cells. Therefore, lysophosphatidic acid metabolism is a target of the pharmaceutical industry in the search for new drugs for cancer therapy, aided by a knowledge of the crystal structures of three of the receptors.

Signaling by lysophosphatidic acid has been implicated in many aspects of chronic inflammation, which it promotes by affecting the endothelium in several ways, for example by stimulating endothelial cell migration, the secretion of chemokines-cytokines and regulating the integrity of the endothelial barrier. Problems with lysophosphatidic acid signaling together with changes in autotaxin expression are believed to be factors in such metabolic and inflammatory disorders as obesity, insulin resistance, non-alcoholic fatty liver disease, rheumatoid arthritis, multiple sclerosis and cardiovascular disease. Further, there is evidence it contributes to neurological disorders, such as Alzheimer's disease and neuropathic pain, and to asthma, fibrosis and bone malfunction. Drugs that interact with the lysophosphatidic acid receptors are reported to be effective in attenuating symptoms of several diseases in animal models, and three have passed phase I and II clinical trials for idiopathic pulmonary fibrosis and systemic sclerosis in human patients. Drugs that target autotaxin production and catabolism of lysophosphatidic acid are also in development, and the steroidal anti-inflammatory agent, dexamethasone, appears to be especially useful.

Under certain conditions, lysophosphatidic acid can become athero- and thrombogenic and might aggravate cardiovascular disease. As oxidized low-density lipoproteins promote the production of lysophosphatidic acid, its content in atherosclerotic plaques is high, suggesting that it might serve as a biomarker for cardiovascular disease. Indeed, lysophosphatidic acid promotes pro-inflammatory events that lead to the development of atheroma as well encouraging progression of the disease. By mediating platelet aggregation, it could lead to arterial thrombus formation.

Related lipids: The sphingolipid analogue, **sphingosine-1-phosphate**, shows a similar range of activities to lysophosphatidic acid and the two lipids are often discussed together in the same contexts, although they may sometimes have opposing effects. Acute leukemia cells produce **methyl-lysophosphatidic acids** (the polar head-group is methylated). As these act as antigens to which a specific group of human T cells react strongly, it is possible that they might be a target for the immunotherapy of hematological malignancies. Other lysophospholipids are known to have distinctive biological functions.

Catabolism: Deactivation of lysophosphatidic acid is accomplished by dephosphorylation to produce monoacylglycerols by a family of three lipid phosphate phosphatases (LPP1, 2 and 3), which also de-phosphorylate sphingosine-1-phosphate, phosphatidic acid and ceramide 1-phosphate in a non-specific manner. These are integral membrane proteins with the active site in the plasma membrane facing the extracellular environment, enabling them to access and hydrolyse extracellular lysophosphatidic acid and other phospholipids. Mice with a constitutive LPP3 deficiency are not viable, but this is not true for LPP1 and LPP2 knockout mice. Lysophosphatidic acid can be converted

back to phosphatidic acid by a membrane-bound *O*-acyltransferase (MBOAT2) specific for lysophosphatidic acid (and lysophosphatidylethanolamine) with a preference for oleoyl-CoA as substrate.

21.3.3: PHOSPHATIDYLCHOLINE AND RELATED LIPIDS

21.3.3.1: PHOSPHATIDYLCHOLINE - STRUCTURE AND OCCURRENCE

Phosphatidylcholine or 1,2-diacyl-*sn*-glycero-3-phosphocholine (once given the trivial name 'lecithin') is a neutral or zwitterionic phospholipid over a pH range from strongly acid to strongly alkaline. It is usually the most abundant phospholipid in animals and plants, often amounting to almost 50% of the total complex lipids, and as such it is obviously a key building block of membrane bilayers. In particular, it makes up a very high proportion of lipids of the outer leaflet of the plasma membrane in animals. Virtually all the phosphatidylcholine in human erythrocyte membranes is present in the outer leaflet, for example, while in the plasma membranes of nucleated cells, 80 to 90% of this lipid is located on the outer leaflet. Phosphatidylcholine is also the principal phospholipid circulating in plasma, where it is an integral component of the **lipoproteins**, especially the HDL. On the other hand, it is less often found in bacterial membranes, perhaps ~10% of species, but there is none in the 'model' organisms *Escherichia coli* and *Bacillus subtilis*. In animal tissues, some of its membrane functions appear to be shared with the structurally related sphingolipid, **sphingomyelin**, although the latter has many unique properties of its own.

Figure 21.3.9 shows the structure of phosphatidylcholine

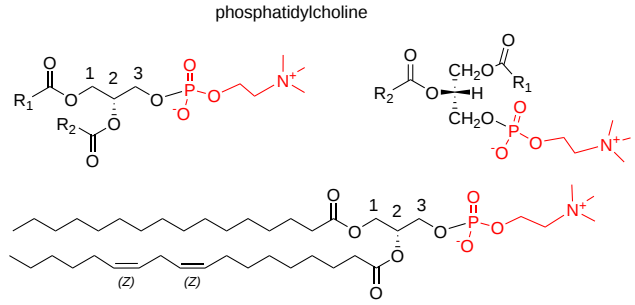

Figure 21.3.9: Phosphatidylcholine

In animal tissues, phosphatidylcholine tends to exist in mainly in the diacyl form, but small proportions (in comparison to phosphatidylethanolamine and phosphatidylserine) of alkyl,acyl and alkenylacyl forms may also be present. As a generalization, animal phosphatidylcholine tends to contain lower proportions of arachidonic and docosahexaenoic acids and more of the C_{18} unsaturated fatty acids than the other zwitterionic phospholipid, phosphatidylethanolamine. Saturated fatty acids are most abundant in position *sn*-1, while polyunsaturated components are concentrated in position *sn*-2. Indeed, C_{20} and C_{22} polyenoic acids are exclusively in position *sn*-2, yet in brain and retina the unusual very-long-chain polyunsaturated fatty acids (C_{30} to C_{38}) of the *n*-6 and *n*-3 families occur in position *sn*-1. Dietary factors obviously influence fatty acid compositions, but in comparing animal species, it would be expected that the structure of the phosphatidylcholine in the same metabolically active tissue would be somewhat similar in terms of the relative distributions of fatty acids between the two positions. Table 21.3.1 lists some representative data.

Table 21.3.1. **Positional distribution of fatty acids in the phosphatidylcholine of some animal tissues.**

There are some exceptions to the rule as the phosphatidylcholine in some tissues or organelles contains relatively high proportions of disaturated molecular species. For example, it is well known that lung phosphatidylcholine in most if not all animal species studied to date contains a high proportion (50% or more) of dipalmitoylphosphatidylcholine.

The positional distributions of fatty acids in phosphatidylcholine in representative plants and yeast are listed in Table 21.3.2. In the leaves of the model plant *Arabidopsis thaliana*, saturated fatty acids are concentrated in position *sn*-1, but monoenoic fatty acids are distributed approximately equally between the two positions, and there is a preponderance of di- and triunsaturated fatty acids in position *sn*-2; the same is true for soybean ‘lecithin’. In the yeast *Lipomyces lipoferus*, the pattern is somewhat similar except that much of the 16:1 is in position *sn*-1.

Table 21.3.2: **Composition of fatty acids (mol %) in positions *sn*-1 and *sn*-2 in the phosphatidylcholine from plants and yeast.**

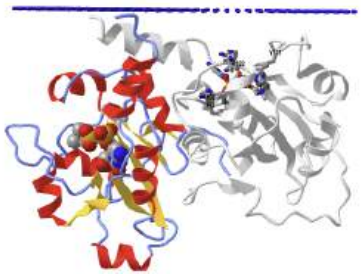
21.3.3.2: PHOSPHATIDYLCHOLINE – BIOSYNTHESIS

There are several mechanisms for the biosynthesis of phosphatidylcholine in animals, plants and micro-organisms. Choline itself is not synthesized as such by animal cells and is an essential nutrient, not only for phospholipid synthesis but also for cholinergic neurotransmission (acetylcholine synthesis) and as a source for methyl groups for numerous other metabolites. It must be obtained from dietary sources or by degradation of existing choline-containing lipids, for example those produced by the second pathway described below. Once taken across membranes and into cells by specific transporters, choline is immediately phosphorylated by a choline kinase (1) in the cytoplasm of the cell to produce phosphocholine, which is reacted with cytidine triphosphate (CTP) by the enzyme **CTP:phosphocholine cytidylyltransferase (CCT)** (2) to form cytidine diphosphocholine (CDP-choline).

$$CTP + PC \rightarrow CDP\text{-}choline + Pi$$

The latter enzyme exists in two isoforms of which CCTα is the more important and is a soluble protein found first in the nucleoplasm, but then in the nucleoplasmic reticulum. This is considered to be the rate-limiting step in phosphatidylcholine biosynthesis, and the activity of the enzyme is regulated by signals from a sensor in the membrane that reports on the relative abundance of the final product. However, choline kinase (ChoKα) also has regulatory functions.

Figure 21.3.10 shows an interactive iCn3D model of the mammalian (rat) CTP: Phosphocholine cytidylyltransferase catalytic domain (3HL4).



NCBI iCn3D Figure 21.3.10: Mammalian (rat) CTP-Phosphocholine cytidylyltransferase catalytic domain (3HL4). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...tBYRYk7vPKD7f6

The biologically active homodimer is shown. The B chain is colored by secondary structure and the A chain is shown in gray. Key active site residues (only shown in the A chain) are in CPK-colored sticks and labeled. A bound CDP-choline analog ((2-cytidylate-O'-phosphonyloxy)-ethyl-trimethylammonium) is shown in spacefill CPK colors.

This enzyme (CCT) catalyzes the key regulatory and rate-limiting step in PC synthesis. The C-terminal domain binds membrane lipids and regulates the enzyme. The iCn3D model above is for the catalytic domain with the regulatory domain deleted. Two nonconserved active site side chains, His 168 and Tyr 173 interact with and position the phosphocholine. Other active site residues include Arg-196 in L6, Lys-122 in L2, and Asp-94. Figure 21.3.11 shows a simplified mechanism for the reaction

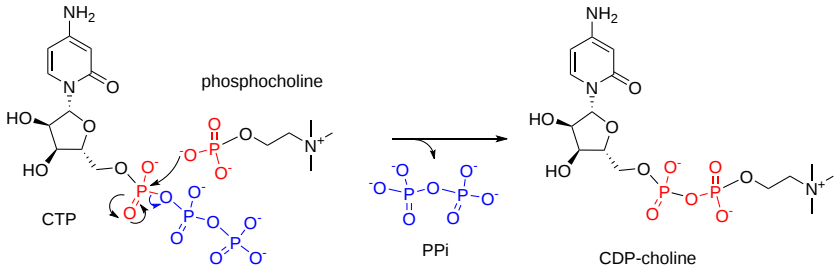


Figure 21.3.11: Simplified mechanism for CTP-Phosphocholine cytidylyltransferase

In plants, nematodes and certain parasites, most phosphocholine is synthesized by sequential methylation of phosphoethanolamine by phospho-base *N*-methyltransferases, but phosphatidylethanolamine is only methylated in this way in a few plant species. This is also the main route to free choline and betaine in plants.

The CDP-choline produced is acted upon by the membrane-bound enzyme CDP-choline:1,2-diacylglycerol choline/ethanolamine-phosphotransferase in the endoplasmic reticulum (CEPT1), and a related choline phosphotransferase 1 (CPT1) in the *trans*-Golgi, which catalyse the reaction with *sn*-1,2-diacylglycerols to form phosphatidylcholine. The first of these is responsible for most phosphatidylcholine biosynthesis but with a somewhat different molecular species composition from the second, which has a preference for 1-alkyl precursors. This is the main pathway for the synthesis of phosphatidylcholine in animals and plants, and it is analogous to that for a major route to **phosphatidylethanolamine**; it is also found in a few bacterial species (e.g. *Sinorhizobium meliloti*). Phosphatidylcholine in mitochondria is obtained by transfer from the endoplasmic reticulum.

Figure 21.3.12 shows the main pathways for PC synthesis in plants and animals.

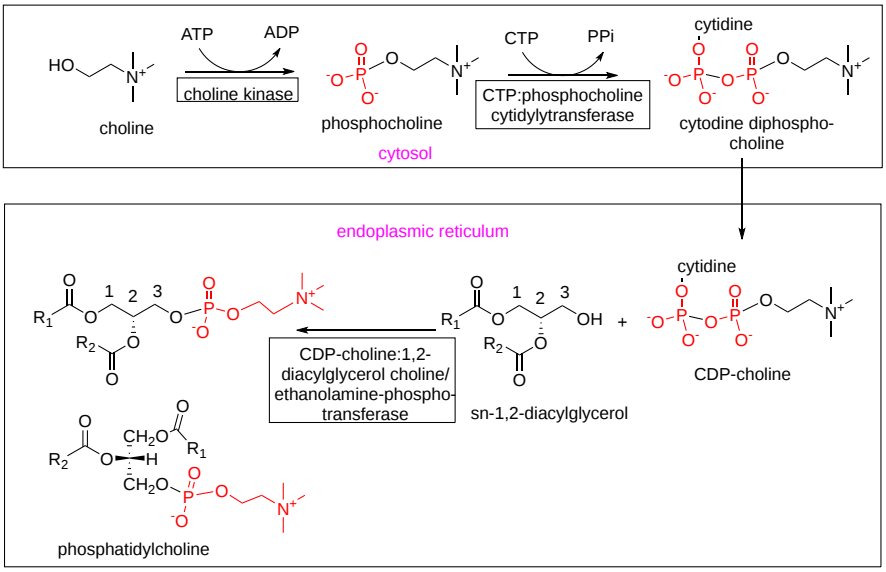

Figure 21.3.172: Main pathways for PC synthesis in plants and animals.

The discovery of the importance of this pathway depended a little on serendipity in that in experiments in the laboratory of Professor Eugene Kennedy, samples of adenosine triphosphate (ATP) contained some cytidine triphosphate (CTP) as an impurity. However, luck is of little value without receptive minds, and Kennedy and co-workers demonstrated that the impurity was an important metabolite that was essential for the formation of phosphatidylcholine.

The above reaction, together with the biosynthetic mechanism for phosphatidylethanolamine, is significantly different from that for phosphatidylglycerol, phosphatidylinositol and cardiolipin. Both make use of nucleotides, but with the latter, the nucleotide is covalently linked directly to the lipid intermediate, i.e., **cytidine diphosphate diacylglycerol**. However, a comparable pathway to the latter for biosynthesis of phosphatidylcholine occurs in bacteria (see below).

The source of the *sn*-1,2-diacylglycerol precursor, which is also a key intermediate in the formation of phosphatidylethanolamine and phosphatidylserine, and of triacylglycerols, is **phosphatidic acid**. In this instance, the important enzyme is phosphatidic acid phosphatase (also known as lipin or phosphatidate phosphatase' or 'lipid phosphate phosphatase' or 'phosphatidate phosphohydrolase').

Figure 21.3.13 shows the biosynthesis of the diacyl precursor of PC

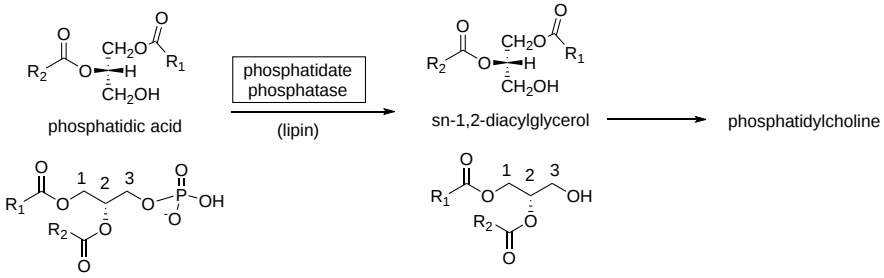

Figure 21.3.13: Synthesis of the diacyl precursor of PC

This enzyme is also important for the production of diacylglycerols as essential intermediates in the biosynthesis of triacylglycerols and of **phosphatidylethanolamine**. Yeasts contain two such enzymes, one of which is Mg^{2+}-dependent (PAP1) and the other Mg^{2+}-independent (PAP2). In mammals, much of the phosphatidic acid phosphatase activity resides in three related cytoplasmic proteins, termed lipins-1, -2, and -3. Lipin-1 is found mainly in adipose tissue, while lipin-2 is present mainly in liver. They are unique among biosynthetic enzymes for glycerolipids in that they can transit among cellular membranes rather than remain tethered to membranes. Of these lipin-1 is most important and exists in three isoforms, lipin-1α, lipin-1β and lipin-1γ with lipin-1α located mainly in the nucleus and lipin-1β in the cytoplasm. Lipin-1γ is present primarily in brain.

The second pathway for biosynthesis of phosphatidylcholine involves sequential methylation of phosphatidylethanolamine, with *S*-adenosylmethionine (SAM) as the source of methyl groups, with **mono- and dimethylphosphatidylethanolamine** as intermediates and catalyzed by the enzyme phosphatidylethanolamine *N*-methyltransferase. A single enzyme (~20 KDa) in two isoforms catalyses all three reactions in hepatocytes; the main form is located in the endoplasmic reticulum (ER) where it spans the membrane, while the second is found in the mitochondria-associated ER membrane. At least two *N*-methyltransferases are present in yeasts. This is a major pathway in the liver, generating one third of the phosphatidylcholine in this organ, but not in other animal tissues or in general in higher organisms. It may be the main route to phosphatidylcholine in those bacterial species that produce this lipid and in yeasts, but it appears to operate in only a few species of higher plants. When choline is deficient in the diet, this liver pathway is especially important.

Figure 21.3.14 shows the synthesis of PC via methylation of PE.

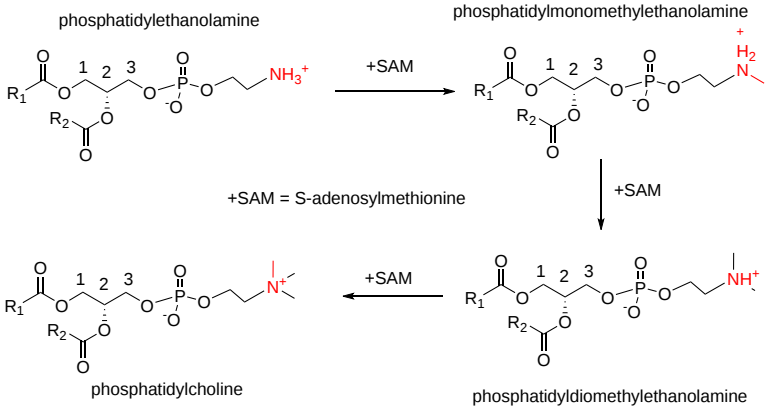

Figure 21.3.14: synthesis of PC via methylation of PE

A by-product of the biosynthesis of phosphatidylcholine from phosphatidylethanolamine is the conversion of *S*-adenosylmethionine to *S*-adenosylhomocysteine, which is hydrolyzed in the liver to adenosine and homocysteine. An elevated level of the latter in plasma is a risk factor for cardiovascular disease and myocardial infarction.

Phosphatidylcholine biosynthesis by both pathways in the liver is necessary for normal secretion of the plasma lipoproteins (VLDL and HDL), and it is relevant to a number of human physiological conditions. It should be noted that all of these pathways for the biosynthesis of diacylphosphatidylcholine are very different and are separated spatially from that producing **alkyl, acyl- and alkenylacyl-phosphatidylcholines** *de novo*. Also, synthesis of phosphatidylcholine does not occur uniformly throughout the endoplasmic reticulum but is located at membrane interfaces or where it meets other organelles, and especially where the membrane is expanding dynamically.

The enzymes in the endoplasmic reticulum responsible for the synthesis of all phospholipids are orientated in such a manner that their active sites are exclusively facing the cytosol. Problems would arise if there were a rapid expansion of the cytosolic leaflet while the luminal leaflet did not change, but a phospholipid transporter known as a scramblase enables a rapid bidirectional flip-flop of phospholipids between leaflets of the bilayer in an energy-independent manner. Compositional asymmetry in first seen in the *trans*-Golgi and is completed before the plasma membrane is formed with phosphatidylcholine and sphingolipids present mainly in the exofacial (outer) leaflet while phosphatidylethanolamine and phosphatidylserine are enriched in the cytosolic leaflet.

Dietary phosphatidylcholine is rapidly hydrolyzed in the proximal small intestine by pancreatic enzymes with formation of lysophosphatidylcholine (and free fatty acids). Further hydrolysis can occur in the jejuno-ileal brush-border by the action of the membrane phospholipases, with the release of glycerophosphocholine, but much of the lysophosphatidylcholine is reacylated by the lyso-PC-acyl-CoA-acyltransferase 3 for export in chylomicrons.

In **plant** cells, phosphatidylcholine biosynthesis occurs mainly in the endoplasmic reticulum, and it is a major component of most membranes other than the internal membranes of plastids; it is absent from the thylakoids and the inner envelope membrane, but is the main glycerolipid of the outer monolayer of the outer envelope membrane. Further complications arise in plants in that turnover or partial synthesis via lysophosphatidylcholine occurs in different organelles from different fatty acid pools or with enzymes with differing specificities, and in addition, fatty acids esterified to phosphatidylcholine serve as substrates for desaturases. The result is that an appreciable pool of the diacylglycerols for the biosynthesis of **triacylglycerols**, **galactosyldiacylglycerols,** and other glycerolipids pass through phosphatidylcholine as an intermediate so that the fatty acid compositions in different membranes change after the initial synthetic process. This mechanism has obvious differences from the remodeling of molecular species in animal tissues discussed next, although a comparable exchange of acyl groups does occur in part catalyzed by acyl transferases (see next section). Some transfer of phosphatidylcholine *per se* from the endoplasmic reticulum to plastids may occur via contact points between the two membranes or may be facilitated by specific transport proteins.

While phosphatidylcholine is a major lipid in yeasts, recent work suggests that it is not essential if suitable alternative growth substrates are available, unlike higher organisms where perturbation of phosphatidylcholine synthesis can lead to inhibition of growth or even cell death.

21.3.3.3: REMODELING OF PHOSPHATIDYLCHOLINE - THE LANDS' CYCLE

Whatever the mechanism of biosynthesis of phosphatidylcholine in animal tissues, it is apparent that the fatty acid compositions and positional distributions on the glycerol moiety are determined post synthesis by extensive re-modeling involving orchestrated reactions of hydrolysis (phospholipase A_2 mainly) to lysophosphatidylcholine, acyl-CoA synthesis and re-acylation by lysophospholipid acyltransferases or transacylases, a series of reactions that is sometimes termed the 'Lands' Cycle' after its discoverer W.E.M. (Bill) Lands. Similar processes occur with all glycerophospholipid classes.

The final composition of the lipid is achieved by a mixture of synthesis *de novo* and the remodeling pathway. There are at least fifteen different groups of enzymes in the phospholipase A_2 super-family, which differ in calcium dependence, cellular location and structure. All hydrolyze the *sn*-2 ester bond of phospholipids specifically, generating a fatty acid and lysophospholipid, both of which have important functions in their own right in addition to their role in the Lands cycle. There is also a phospholipase A_1 family of enzymes, which are esterases that are able to cleave the *sn*-1 ester bond but are less important in this context.

Figure 21.3.15 shows Land's cycle

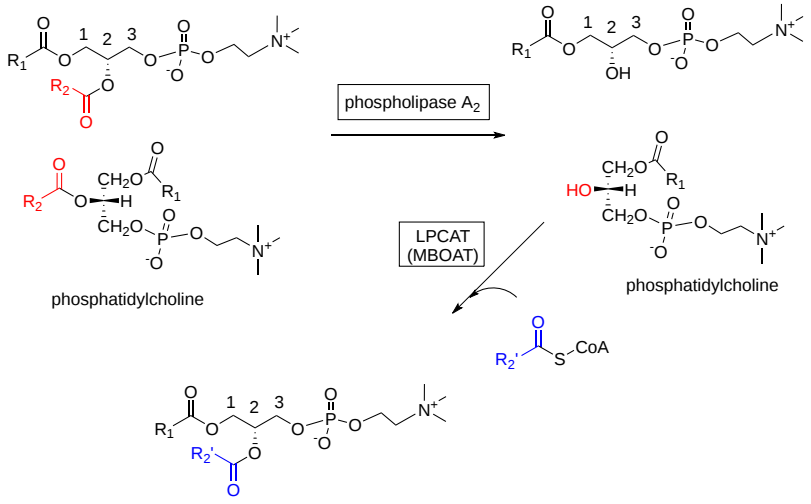

Figure 21.3.15 Land's cycle - 1

The re-acylation step is catalyzed by membrane-bound coenzyme A-dependent lysophosphatidylcholine acyltransferases such as LPCAT3 (also designated ‘MBOAT5’), which is located chiefly within the endoplasmic reticulum, though also in mitochondria and the plasma membrane in organs such as the liver, adipose tissue and pancreas. It maintains systemic lipid homeostasis by regulating lipid absorption and composition in the intestines, the secretion of lipoproteins, and lipogenesis *de novo* in liver, and is notable in that it incorporates linoleoyl and arachidonoyl chains specifically into lysophosphatidylcholine (as does a related enzyme LPCAT2). There is also a CoA-independent acyltransferase in inflammatory cells that transfers arachidonic acid from phosphatidylcholine to ethanolamine-containing phospholipids. While LPCAT3 prefers 1-acyl lysophosphatidylcholine as an acyl acceptor, LPCAT2 utilizes both 1-acyl and 1-alkyl precursors. LPCAT2 is highly expressed in inflammatory cells such as macrophages and neutrophils, which contain ether-phospholipids,

where it contributes to the production of eicosanoid lipid mediators. The highly saturated molecular species of phosphatidylcholine found in lung surfactant are formed from species with a more conventional composition by remodeling by an acyltransferase with a high specificity for palmitoyl-CoA acid (LPCAT1). In other tissues, those species containing high proportions of polyunsaturated fatty acids depend more on synthesis *de novo*. These and further related enzymes are involved in remodeling of all other phospholipids. Over-expression of the genes for these enzymes is associated with the progression of many different cancers and may be involved in other pathological conditions.

Phosphatidylcholine has a central role in glycerolipid metabolism in plants and remodeling occurs for reasons and by mechanisms that are rather different from those in animal cells as described briefly above. For example, there is extensive remodeling as a site of fatty acid desaturation and as the main entry point for acyl groups exported from the plastid into the endoplasmic reticulum. In addition, the remodeling of phosphatidylcholine provides fatty acids for triacylglycerol synthesis in developing seeds and diacylglycerols for the synthesis of thylakoid lipids such as **galactosyldiacylglycerols**. In Arabidopsis, two lysophosphatidylcholine acyltransferases, LPCAT1 and LPCAT2, are involved in remodeling in developing seeds and leaves, with some preference for position *sn*-2 using fatty acids exported from the plastid. In some plant species, there is a strong preference for C_{18}-unsaturated acyl chains over 16:0. However, the lipases that generate lysophosphatidylcholine from phosphatidylcholine for this purpose are not yet known. Some remodeling in plant membranes occurs in response to stress.

The yeast *Saccharomyces cerevisiae* is able to reacylate glycerophosphocholine, generated endogenously by the action of phospholipase B (an enzyme with both phospholipase A_1 and A_2 activities) on phosphatidylcholine, with acyl-CoA in the microsomal membranes by means of a glycerophosphocholine acyltransferase (Gpc1) to produces lysophosphatidylcholine, which can be converted back to phosphatidylcholine by the lysophospholipid acyltransferase (Ale1) with appreciable changes in the molecular species composition. The process is regulated in coordination with the other main lipid pathways and affects yeast growth. The enzyme Gpc1 does not affect other phospholipids in yeasts. A similar mechanism appears to operate in some plant species. Figure 21.3.16 shows variants of the Land's cycle.

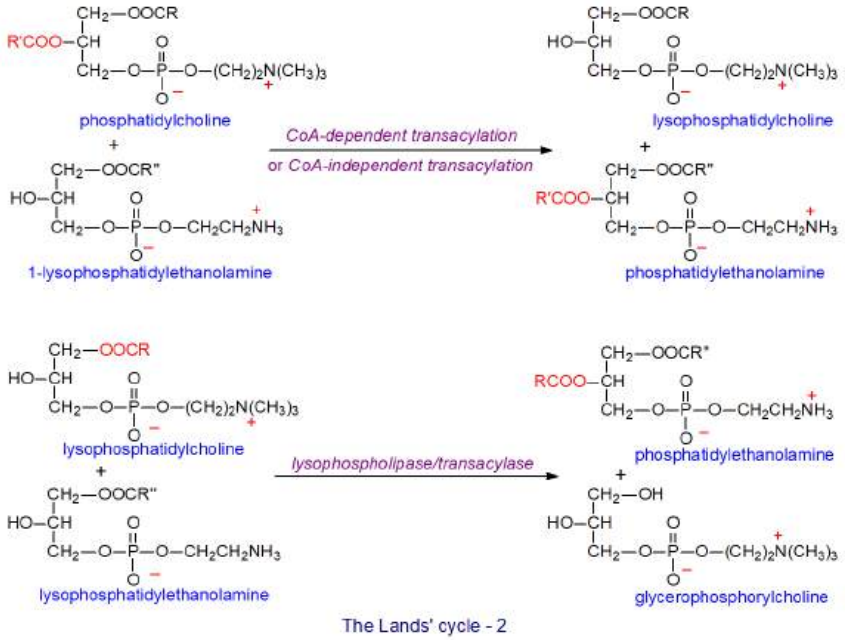

Figure 21.3.16: Variants of the Land's cycle - 2

21.3.3.4: CATABOLISM

Phosphatidylcholine (and most other glycerophospholipids) in membranes can be metabolized by lipolytic enzymes, especially phospholipases, some isoforms of which are specific for particular lipid classes in humans. For example, in addition to the action of phospholipase A (discussed above), phospholipase C (six families in mammals differing in expression and subcellular distribution) yields **diacylglycerols** together with phosphocholine by hydrolyzing glycerophospholipids at the phosphodiester bond, a process that is especially important in relation to **phosphoinositide** metabolism. The **sphingomyelin synthases** also have phospholipase C activity (in the absence of ceramide). Phospholipase D generates **phosphatidic acid** and choline, while phospholipase B removes both fatty acids to yield glycerophosphocholine.

Figure 21.3.17 shows the activities of phospholipases on phosphatidyl choline.

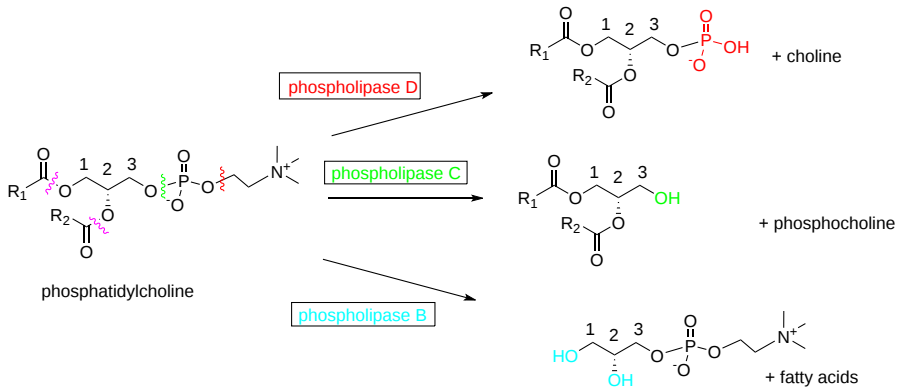

Figure 21.3.17: Activities of phospholipases on phosphatidyl choline

On catabolism in this way, the lipid components are re-cycled or they may have signaling functions, while much of the choline is re-used for phosphatidylcholine biosynthesis, often after being returned to the liver (the CDP-choline cycle). Some choline is oxidized in the kidney and liver to betaine, which serves as a donor of methyl groups for *S*-adenosylmethionine production, and some is lost through excretion of phosphatidylcholine in bile. A proportion is used in nervous tissues for production of acetylcholine, a neurotransmitter of importance to learning, memory and sleep. Phosphatidylcholine in the high-density lipoproteins of plasma is taken up by the liver, and perhaps surprisingly a high proportion of this is eventually converted to triacylglycerols via diacylglycerol intermediates.

21.3.3.5: PHOSPHATIDYLCHOLINE – BIOLOGICAL FUNCTIONS

Because of the generally cylindrical shape of the molecule, phosphatidylcholine organizes spontaneously into bilayers, so it is ideally suited to serve as the bulk structural element of biological membranes, and as outlined above it is makes up a high proportion of the lipids in the outer leaflet of the plasma membrane. The unsaturated acyl chains are kinked and confer fluidity on the membrane. Such properties are essential to act as a balance to those lipids that do not form bilayers or that form specific micro-domains such as **rafts**. While phosphatidylcholine does not induce curvature of membranes, as may be required for membrane transport and fusion processes, it can be metabolized to form lipids that do.

In contrast, dipalmitoyl phosphatidylcholine is the main surface-active component of human lung surfactant, although in other animals the lung surfactant can be enriched in some combination of short-chain disaturated and monounsaturated species, mainly palmitoylmyristoyl- and palmitoylpalmitoleoyl- in addition to the dipalmitoyl-lipid. This is believed to provide alveolar stability by decreasing the surface tension at the alveolar surface to a very low level during inspiration while preventing alveolar collapse at the end of expiration. Also, the internal lipids of the animal cell nucleus (after the external membrane has been removed) contain a high proportion of disaturated phosphatidylcholine. This is synthesized entirely within the nucleus, unlike phosphatidylinositol for example, and in contrast to other cellular lipids its composition cannot be changed by extreme dietary manipulation; it has been suggested that it may have a role in stabilizing or regulating the structure of the chromatin, as well as being a source of diacylglycerols with a signaling function. A further unique molecular species, 1-oleoyl-2-palmitoyl-phosphatidylcholine, is located specifically at the protrusion tips of neuronal cells and appears to be essential for their function, while 1-palmitoyl-2-arachidonoyl-phosphatidylcholine is important in the regulation of the progression of the cell cycle and cell proliferation, and this is independent of eicosanoid production.

Phosphatidylcholine is present bound non-covalently in the crystal structures of a number of membrane proteins, including cytochrome c oxidase and yeast cytochrome bc_1. The ADP/ATP carrier protein has two binding sites for phosphatidylcholine, one on each side. In addition, it is known that the enzyme 3-hydroxybutyrate dehydrogenase must be bound to phosphatidylcholine before it can function optimally. Both the head group and the acyl chains may be involved in the interactions depending on the protein.

As noted above, phosphatidylcholine is by far the most abundant phospholipid component in plasma and in all plasma **lipoprotein** classes. Although it is especially abundant in high density lipoproteins (HDL), it influences strongly the levels of all circulating lipoproteins and especially of the very-low-density lipoproteins (VLDL), which are surrounded by a phospholipid monolayer. Indeed, phosphatidylcholine with polyunsaturated fatty acids in position *sn*-2 is essential for the assembly and secretion of VLDLs and chylomicrons in liver and the intestines, and it must be synthesized *de novo* in the latter. Similarly, phosphatidylcholine synthesis is required to stabilize the surface of lipid droplets in tissues where **triacylglycerols** are stored.

Some of the phosphatidylcholine synthesized in the liver is secreted into bile by a specific flippase together with bile acids where it assists in the emulsification of dietary triacylglycerols in the intestinal lumen to facilitate their hydrolysis and uptake. Eventually, it is absorbed across the intestinal brush border membrane after hydrolysis to lysophosphatidylcholine, which may then be involved in the initiation of chylomicron formation in the endoplasmic reticulum of enterocytes by activation of a protein kinase. In addition, phosphatidylcholine produced in enterocytes is secreted into the intestinal lumen and forms part of the hydrophobic mucus layer that protects the intestinal surface.

Phosphatidic acid generated from phosphatidylcholine by the action of phospholipase D in plants has key signaling functions. Similarly, phosphatidic acid generated in this way from phosphatidylcholine in animals is involved in the metabolism and signaling function of phosphoinositides by activating phosphatidylinositol 4-phosphate 5-kinase, the main enzyme generating the lipid second messenger **phosphatidylinositol-4,5-bisphosphate**. The plasmalogen form of phosphatidylcholine may also have a signaling function, as thrombin treatment of endothelial cells activates a selective hydrolysis (phospholipase A_2) of molecular species containing arachidonic acid in the *sn*-2 position, releasing this fatty acid for eicosanoid production, while the diacyl form of phosphatidylcholine may have a related function in signal transduction in other tissues. In addition, phosphatidylcholine may have a role in signaling via the generation of **diacylglycerols** by phospholipase C, especially in the nucleus. Although the pool of the precursor is so great in many tissues that turnover is not easily measured, the presence of phospholipases C and D that are specific for phosphatidylcholine and are activated by a number of agonists suggests such a function especially in the cell nucleus. Diacylglycerols formed in this way would be much more saturated than those derived from phosphatidylinositol, and would not be expected to be as active in some functions.

Phosphatidylcholine is the biosynthetic precursor of **sphingomyelin** and as such must have some influence on the many metabolic pathways that constitute the sphingomyelin cycle. It is also a precursor for phosphatidic acid, lysophosphatidylcholine and **platelet-activating factor**, each with important signaling functions, and of **phosphatidylserine**.

Because of the increased demand for membrane constituents, there is enhanced synthesis of phosphatidylcholine in cancer cells and solid tumours; the various biosynthetic and catabolic enzymes are seen as potential targets for the development of new therapeutic agents. Impaired phosphatidylcholine biosynthesis has been observed in a number of pathological conditions in the liver in humans, including the development of non-alcoholic fatty liver disease, liver failure and impaired liver regeneration. Similarly, a deficiency in phosphatidylcholine or an imbalance in the ratio of phosphatidylcholine to phosphatidylethanolamine has negative effects upon insulin sensitivity and glucose homeostasis in skeletal muscle.

Plants and bacteria: In addition to its structural role in plant membranes, phosphatidylcholine levels at the shoot apex correlate with flowering time, and this lipid is believed to bind to the Flowering Locus T, a master regulator of flowering. Molecular species containing relatively low levels of α-linolenic acid are involved. Diacylglycerols formed by the action of a family of enzymes of the phospholipase C type on phosphatidylcholine, as opposed to phosphatidylinositol, may be more important in plants and especially during phosphate deprivation for the generation of precursors for galactolipid biosynthesis and perhaps for lipid re-modeling more generally. In prokaryotes, phosphatidylcholine is essential for certain symbiotic and pathogenic microbe-host interactions. For example, in human pathogens such as *Brucella abortus* and *Legionella pneumophila*, this lipid is necessary for full virulence, and the same is true for plant pathogens, such as *Agrobacterium tumefaciens*. Bacteria symbiotic with plants, e.g. the rhizobial bacterium *Bradyrhizobium japonicum*, require it to establish efficient symbiosis and root nodule formation.

21.3.3.6: LYSOPHOSPHATIDYLCHOLINE

Figure 21.3.18 shows the structure of lysophosphatidylcholine

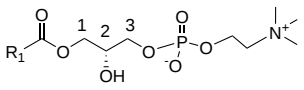

Figure 21.3.18 Lysophosphatidylcholine

Lysophosphatidylcholine (LPC), with one mole of fatty acid per mole of lipid in position *sn*-1, is found in trace amounts in most animal tissues, although there are relatively high concentrations in plasma (150–500μM). It is produced by hydrolysis of dietary and biliary phosphatidylcholine and is absorbed as such in the intestines, but it is re-esterified before being exported in the lymph. In addition, it is formed in most tissues by hydrolysis of phosphatidylcholine by means of the superfamily of **phospholipase A_2** enzymes as part of the de-acylation/re-acylation cycle that controls the overall molecular species composition of the latter, as discussed above. Much of the LPC in the plasma of animal species is secreted by hepatocytes into plasma in a complex with albumin, but an appreciable amount is formed in plasma by the action of the enzyme **lecithin:cholesterol acyltransferase (LCAT)**, which is secreted from the liver. This catalyses the transfer of fatty acids from position *sn*-2 of phosphatidylcholine to free cholesterol in plasma, with formation of cholesterol esters and of course of lysophosphatidylcholine, which consists of a mixture of molecular species with predominately saturated and mono- and dienoic fatty acid constituents. Some LPC is formed by the action of an endothelial lipase on phosphatidylcholine in HDL.

At high concentrations, lysophosphatidylcholine can disrupt membranes, while some biological effects at low concentrations may be simply due to its ability to diffuse readily into membranes, altering their curvature and indirectly affecting the properties of membrane proteins. In plasma, it is bound to albumin and lipoproteins so that its effective concentration is reduced to a relatively safe level.

Lysophosphatidylcholine is considered to be an important factor in cardiovascular and neurodegenerative diseases. It is usually considered to have pro-inflammatory properties and it is known to be a pathological component of oxidized lipoproteins (LDL) in plasma and of atherosclerotic lesions, when it is generated by over-expression or enhanced activity of phospholipase A_2. Its concentration is elevated in joint fluids from patients with rheumatoid arthritis. In addition, it is a major component of platelet-derived microvesicles and activates a

specific receptor in platelets that ultimately leads to vascular inflammation, increasing the instability of atherosclerotic plaques. The intracellular acyltransferase LPCAT cannot remove lysophosphatidylcholine directly from plasma or lipoproteins, nor do there appear to be any enzymes with lysophospholipase A_1 activity in the circulation. Lysophosphatidylcholine blocks the formation of early hemifusion intermediates required for cell-cell fusions. Lysophosphatidylcholine in insect bites attracts inflammatory cells to the site, enhances parasite invasion, and inhibits the production of nitric oxide, for example in Chagas disease. Elevated levels of 26:0-lysophosphatidylcholine in blood are reported to be characteristic of Zellweger spectrum disorders (the result of a defect in peroxisome biogenesis).

Elevated levels of lysophosphatidylcholine have been identified in cervical cancer and may be diagnostic for the disease. On the other hand, reduced concentrations of lysophosphatidylcholine are observed in some malignant cancers, and it has protective effects in patients undergoing chemotherapy. Stearoyl-lysophosphatidylcholine has an anti-inflammatory role in that it is protective against lethal sepsis in experimental animals by various mechanisms, including stimulation of neutrophils to eliminate invading pathogens through a peroxide-dependent reaction. Similarly, there are reports that lysophosphatidylcholine may have beneficial effects in rheumatoid arthritis and a number of other diseases. However, there are suggestions that some experimental studies *in vitro* of the activity of lysophosphatidylcholines may be flawed because insufficient levels of carrier proteins were used. A further point for consideration is that lysophosphatidylcholine is the precursor of the key lipid mediator **lysophosphatidic acid** via the action of the enzyme autotaxin in plasma, and this may be the true source of some of the effects described for the former, especially on cell migration and survival.

There is evidence to suggest that lysophosphatidylcholine containing docosahexaenoic (DHA) and eicosapentaenoic (EPA) acids, presumably in position *sn*-2, in plasma targets more of these fatty acids into the brain, via a specific receptor/transporter at the blood-brain barrier known as the sodium-dependent LPC symporter 1 (MFSD2A), than occurs from the corresponding fatty acids in unesterified form. Hepatic lipase is especially important for generation of these lipids. This finding is now being explored in relation to potential therapeutic applications for neurological diseases, cognitive decline and dementia. Similarly, at the maternal plasma/placental interface, phosphatidylcholine is taken up and hydrolyzed to *sn*-2-lysophosphatidylcholine, presumably by the endothelial lipase, to facilitate transfer of polyunsaturated fatty acids across the basal membrane into the fetal circulation with the aid of the same LPC transporter.

Lysophosphatidylcholine has been found to have some functions in cell signaling , and specific receptors (coupled to G proteins) have been identified, i.e., GPR119, GPR40 and GPR55. It activates the specific phospholipase C that releases diacylglycerols and inositol triphosphate with resultant increases in intracellular Ca^{2+} and activation of protein kinase C. Increased glucose-stimulated insulin secretion has been observed in different cell systems. Lysophosphatidylcholine also activates the mitogen-activated protein kinase in certain cell types, and it promotes demyelination in the nervous system. By interacting with the TRPV4 ion channels of skin keratinocytes, it causes persistent itching. Identification of a highly specific phospholipase $A_{2\gamma}$ in peroxisomes that is unique in generating *sn*-2-arachidonoyl lysophosphatidylcholine suggests that this may be of relevance to eicosanoid generation and signaling . For example, there is reportedly an enrichment of 2-arachidonoyl-lysophosphatidylcholine in carotid atheroma plaque from type 2 diabetic patients. In vascular endothelial cells, it induces the important pro-inflammatory mediator **cyclooxygenase-2 (COX-2)**, a key enzyme in prostaglandin synthesis. However, it has beneficial effects on the innate immune system as it is able to activate macrophages and increase their phagocytic activity in the presence of T lymphocytes.

As lysophospholipids in general and lysophosphatidylcholine in particular are important signaling molecules within mammalian cells, their levels are closely regulated, mainly by the action of the lysophospholipases A_1 and A_2 (LYPLA1 and LYPLA2), depending on the position to which the fatty acid is esterified; these are cytosolic serine hydrolases with esterase and thioesterase activity. The glycerophosphocholine produced can enter the Lands' cycle or be further degraded.

In relation to plants, amylose-rich starch granules of cereal grains contain lysophosphatidylcholine as virtually the only lipid in the form of inclusion complexes or lining channels in the starch macromolecules.

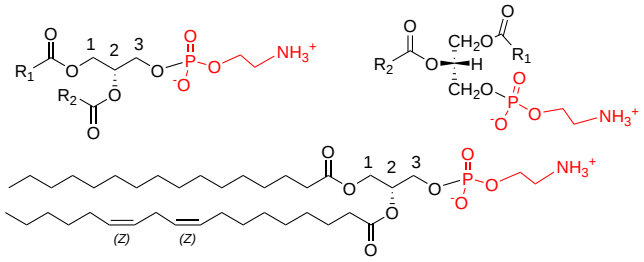
21.3.4: PHOSPHATIDYLETHANOLAMINE AND RELATED LIPIDS

21.3.4.1: PHOSPHATIDYLETHANOLAMINE – STRUCTURE AND OCCURRENCE

Phosphatidylethanolamine or 1,2-diacyl-*sn*-glycero-3-phosphoethanolamine (once given the trivial name 'cephalin') is usually the second most abundant phospholipid in animal and plant lipids, after phosphatidylcholine, and it is frequently the main lipid component of microbial membranes. It can amount to 20% of liver phospholipids and as much as 45% of those of brain; higher proportions are found in mitochondria than in other organelles. As such, it is obviously a key building block of membrane bilayers, and it is present exclusively in the inner leaflet of the plasma membrane in animal cells, for example. It is a neutral or zwitterionic phospholipid (at least in the pH range 2 to 7), with the structure shown (with one specific molecular species illustrated as an example).

Figure 21.3.19 shows the structure of phosphatidylethanolamine.

phosphatidylethanolamine



1-hexadecanoyl,2-(9Z,12Z)-octadecadienoyl-sn-glycero-3-phosphoethanolamine

Figure 21.3.19: Phosphatidylethanolamine

In animal tissues, phosphatidylethanolamine tends to exist in diacyl, alkyl,acyl and alkenyl, acyl forms. As much as 70% of the phosphatidylethanolamine in some cell types (especially inflammatory cells, neurons and tumor cells) can have an ether linkage, but in liver, the plasmalogen form of phosphatidylethanolamine, i.e., with an O-alk-1'-enyl linkage, accounts for only 0.8% of total phospholipids. Generally, there is a much higher proportion of phosphatidylethanolamine with ether linkages than of phosphatidylcholine. If biosynthesis of the plasmalogen form is inhibited by physiological conditions, it is replaced by the diacyl form so that the overall content of the phospholipid remains constant.

In general, animal phosphatidylethanolamine tends to contain higher proportions of arachidonic and docosahexaenoic acids than the other zwitterionic phospholipid, phosphatidylcholine. These polyunsaturated components are concentrated in position *sn*-2 with saturated fatty acids most abundant in position *sn*-1, as illustrated for rat liver and chicken egg in Table 21.3.3. In most other species, it would be expected that the structure of the phosphatidylethanolamine in the same metabolically active tissues would exhibit similar features.

Table 21.3.3: **Positional distribution of fatty acids in phosphatidylethanolamine in animal tissues.**

Position	Fatty acid						
	14:0	16:0	18:0	18:1	18:2	20:4	22:6
			Rat liver [1]

The *O*-alkyl and *O*-alkenyl chains at the *sn*-1 position of the analogous ether lipids generally consist of 16:0, 18:0 or 18:1 chains, whereas arachidonic and docosahexaenoic acids are the most abundant components at the *sn*-2 position.

The positional distributions of fatty acids in phosphatidylethanolamine from the leaves of the model plant *Arabidopsis thaliana* are listed in Table 21.3.4. Here also saturated fatty acids are concentrated in position *sn*-1, and there is a preponderance of di- and triunsaturated in position *sn*-2. The pattern is somewhat different for the yeast *Lipomyces lipoferus*, where the compositions of the two positions are relatively similar.

Table 21.3.4: **Composition of fatty acids (mol %) in positions *sn*-1 and *sn*-2 in the phosphatidylethanolamine from leaves of *Arabidopsis thaliana* and from *Lipoferus lipoferus* .**

21.3.4.2: PHOSPHATIDYLETHANOLAMINE – BIOSYNTHESIS

The two main pathways employed by mammalian cells for the biosynthesis of phosphatidylethanolamine are the CDP-ethanolamine pathway, i.e., one of the general routes to phospholipid biosynthesis *de novo* in plants and animals, and the phosphatidylserine decarboxylase pathway, which occur in two spatially separated organelles - the endoplasmic reticulum and mitochondria, respectively. Ethanolamine is obtained by decarboxylation of serine in plants, and in animals most must come from dietary sources and requires facilitated transport into cells. A small amount of ethanolamine phosphate comes from catabolism of **sphingosine-1-phosphate**, and this is essential for the survival of the protozoon *Trypanosoma brucei*. The initial steps in phosphatidylethanolamine biosynthesis occur in the cytosol with first the phosphorylation of ethanolamine by two specific ethanolamine kinases to produce ethanolamine phosphate; the reverse reaction can occur by means of the enzyme ethanolamine phosphate phosphorylase and this may have a regulatory function in some tissues. The second step is rate-limiting, i.e., reaction of the product with cytidine triphosphate (CTP) to form cytidine diphosphoethanolamine catalyzed by CTP:phosphoethanolamine cytidylyltransferase.

In the final step, a membrane-bound enzyme CDP-ethanolamine:diacylglycerol ethanolaminephosphotransferase catalyses the reaction of cytidine diphosphoethanolamine with diacylglycerol to form phosphatidylethanolamine. There are two such enzymes, ethanolamine phosphotransferase 1 (EPT1) in the Golgi and choline/EPT1 (CEPT1) in the endoplasmic reticulum, but EPT1 is more important for the biosynthesis of the **plasmalogen form**, 1-alkenyl-2-acyl-glycerophosphoethanolamine, and especially molecular species containing polyunsaturated fatty acids, while CEPT1 produced species with shorter-chain fatty acids. The diacylglycerol precursor is formed from phosphatidic acid via the action of the enzyme phosphatidic acid phosphohydrolase.

Figure 21.3.20 shows the synthesis of phosphatidyethanolamine in the ER/Golgi.

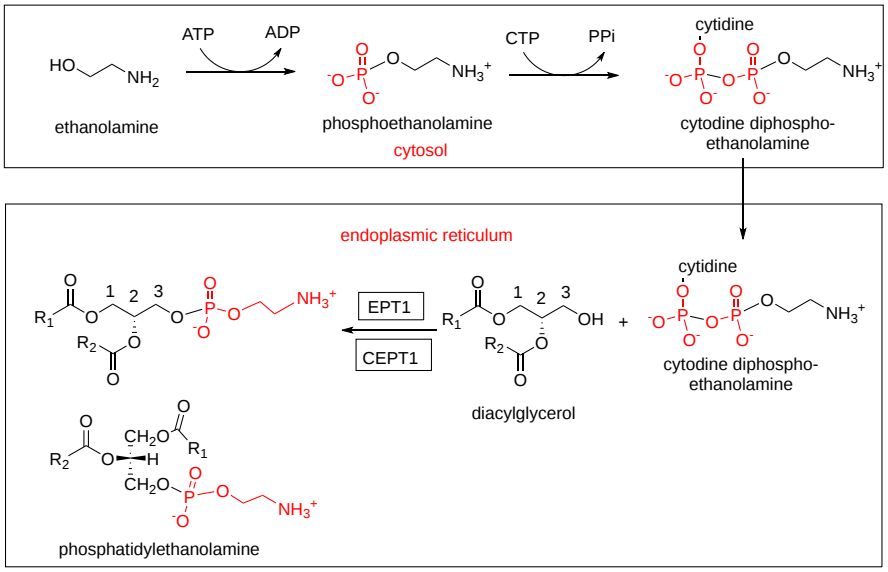

Figure 21.3.20: Synthesis of phosphatidyethanolamine in the ER/Golgi

The second major pathway is the conversion (decarboxylation) of phosphatidylserine to form phosphatidylethanolamine in mitochondria. Conservation of the this pathway from bacteria to humans suggests that it has been preserved to optimize mitochondrial performance. Mitochondria are not connected with the rest of the cell's membrane network by classical vesicular routes, but must receive and export small molecules through the nonvesicular transport at zones of close proximity with other organelles at membrane contact sites, such as a specific domain of the endoplasmic reticulum termed the mitochondria-associated membrane (MAM). Lipid transport of phosphatidylserine is then enabled by tethers that bridge two membranes, lipid transfer proteins and recruitment proteins. In this process, the lipid must traverse two aqueous compartments, the cytosol and the mitochondrial intermembrane space, to reach the inner mitochondrial membrane.

The phosphatidylserine decarboxylase is located on the external aspect of the mitochondrial inner membrane, and most of the phosphatidylethanolamine in mitochondria is derived from this pathway. While various isoforms of the phosphatidylserine decarboxylation exist in prokaryotes, yeasts and mammals, the main forms designated 'PSD1' are found only in mitochondria and are related structurally. An isoform designated 'PSD2' is located in the endosomal membranes of yeasts, and the phosphatidylethanolamine formed is the preferred substrate for phosphatidylcholine biosynthesis. It is evident that cellular concentrations of phosphatidylethanolamine and phosphatidylserine are closely related and tightly regulated.

Figure 21.3.21 shows the synthesis of phosphatidyethanolamine in mitochondria.

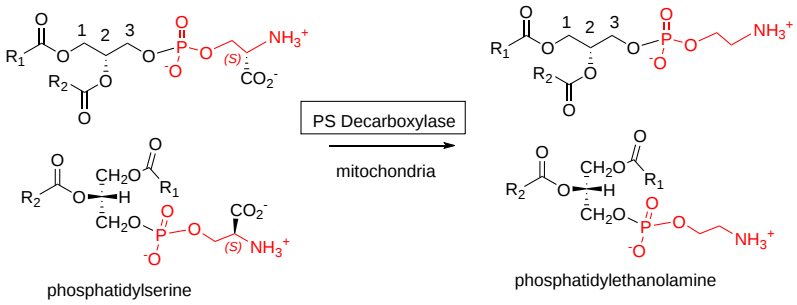

Figure 21.3.21: Synthesis of phosphatidyethanolamine in mitochondria

In prokaryotic cells, such as *E. coli*, in which phosphatidylethanolamine is the most abundant membrane phospholipid, all of it is derived from phosphatidylserine decarboxylation. In this instance, the enzyme undergoes auto-cleavage for activation and utilizes a pyruvoyl moiety to form a Schiff base intermediate with phosphatidylserine to facilitate decarboxylation. This pathway is also important in mammalian cells and yeasts, although the relative contributions of the two main pathways for phosphatidylethanolamine synthesis in mammalian cells appears to depend on the cell type. In cells in culture, more than 80% of the phosphatidylethanolamine is reported to be derived from the phosphatidylserine decarboxylase pathway, but in hamster heart and rat hepatocytes, only ~5% of phosphatidylethanolamine synthesis comes from this route and most is from the CDP-ethanolamine pathway. In yeasts, 70% of the phosphatidylethanolamine is generated by PSD1. The spatially distinct pools within the cell are functionally distinct, but both are essential to life. For example, disruption of the phosphatidylserine decarboxylase gene causes misshapen mitochondria and has lethal consequences in embryonic mice, although phosphatidylethanolamine synthesis continues for a time in other cellular regions. Similarly, elimination of the endoplasmic reticulum route is embryonically lethal.

Three additional minor biosynthetic pathways are known. Phosphatidylethanolamine can be formed by the enzymatic exchange reaction of ethanolamine with phosphatidylserine, or by re-acylation of lysophosphatidylethanolamine. The second of these is associated with the mitochondria-associated membrane where the phosphatidylserine synthase II is located. Finally, the bacterial plant pathogen *Xanthomonas campestris* is able to synthesize phosphatidylethanolamine by condensation of **cytidine diphosphate diacylglycerol** with ethanolamine.

Ether lipids: It should be noted that all of these pathways for the biosynthesis of diacyl-phosphatidylethanolamine are very different and are separated spatially from that producing **alkyl,acyl- and alkenyl,acyl-phosphatidylethanolamines**, suggesting that there may be functional differences. In the protozoon *T. brucei*, for example, it has been demonstrated that the diacyl and ether pools of phosphatidylethanolamine have separate functions and cannot substitute for each other.

Lands' cycle: The various mechanisms produce different pools of phosphatidylethanolamine species, which are often in different cellular compartments and have distinctive compositions. Studies with mammalian cell types *in vitro* suggest that the CDP-ethanolamine pathway produces molecular species with mono- or di-unsaturated fatty acids on the *sn*-2 position preferentially, while the phosphatidylserine decarboxylation reaction generates species with polyunsaturated fatty acids on the *sn*-2 position mainly. However, as with other phospholipids, the final fatty acid composition in animal tissues is attained by a process of remodeling known as the Lands' cycle . The first step is hydrolysis by a phospholipase A_2 to lysophosphatidylethanolamine, followed by reacylation by means of various acyl-CoA:lysophospholipid acyltransferases. The enzymes LPCAT1, 2 and 3, which are involved in phosphatidylcholine biosynthesis, are also active with phosphatidylethanolamine, while LPEAT1 utilizes lysophosphatidylethanolamine mainly and is specific for oleoyl-CoA. Some of these isoforms appear to be confined to particular tissues. There is also a CoA-independent acyltransferase in macrophages that transfers arachidonic acid from phosphatidylcholine to ethanolamine-containing phospholipids.

21.3.4.3: PHOSPHATIDYLETHANOLAMINE – BIOLOGICAL FUNCTION

Physical properties: Although phosphatidylethanolamine has sometimes been equated with phosphatidylcholine in biological systems, there are significant differences in the chemistry and physical properties of these lipids, and they have different functions in biochemical processes. Both are key components of membrane bilayers and the ratio of the two may be important to many cellular functions. However, phosphatidylethanolamine has a smaller head group, which gives the lipid a cone shape. On its own, it does not form bilayers but inverted hexagonal phases. With other lipids in a bilayer, it is believed to exert a lateral pressure that modulates membrane curvature and stabilizes membrane proteins in their optimum conformations. It can hydrogen bond to adjacent lipids and to proteins through its polar head group. For example, the phosphate can be stabilized at the binding site by interactions with lysine and arginine side chains, or with hydroxyls from tyrosine side chains. There can also be strong interactions with acyl chains of the phospholipid.

In contrast to phosphatidylcholine, phosphatidylethanolamine is concentrated with phosphatidylserine in the inner leaflet of the plasma membrane. On the other hand, it is present in both the inner and outer membranes of mitochondria, but especially the former, where it is present at much higher levels than in other organelles and facilitates membrane fusion and protein movement across membranes in addition to many other essential mitochondrial functions, including oxidative phosphorylation via the electron transport chain. It is an important functional component of membrane contact sites between the endoplasmic reticulum and mitochondria. In eukaryotic cells, especially those

of insects, studies suggest that it has a similar function to cholesterol in membranes in that it increases the rigidity of the bilayer to maintain membrane fluidity. In bacterial membranes, it appears that a primary role for phosphatidylethanolamine is simply to dilute the high negative charge density of the anionic phospholipids.

Protein Interactions: Membrane proteins amount to 30% of the genome, and they carry out innumerable biochemical functions, including transport, energy production, biosynthesis, signaling and communication. Within a membrane, most integral proteins consist of hydrophobic α-helical trans-membrane domains that zigzag across it and are connected by hydrophilic loops. Of those parts of the proteins outwith the bilayer, positively charged residues are much more abundant on the cytoplasmic side of membrane proteins as compared to the trans side (the positive-inside rule). Phosphatidylethanolamine is believed to have a key function in that it inhibits location of negative amino acids on the cytoplasmic side, supporting the positive-inside rule, and it has an appropriate charge density to balance that of the membrane surface and the protein. However, it can also permit the presence of negatively charged residues on the cytosolic surface in some circumstances in support of protein function.

Phosphatidylethanolamine is vital for mitochondrial functionality, as demonstrated by defects in the operation of oxidative phosphorylation in the absence of PSD1, and by the role of the lipid in the regulation of mitochondrial dynamics in general and the biogenesis of proteins in the outer mitochondrial membrane. Synthesis of phosphatidylethanolamine in the inner membrane of mitochondria is critical for the function of the cytochrome bc_1 complex (III), where there is a conserved binding site for the lipid in a specific subunit.

Phosphatidylethanolamine binds non-covalently to a superfamily of cytosolic proteins with multiple functions termed 'phosphatidylethanolamine-binding proteins'. While four members have been identified in mammals (PEBP1-4), more than 400 members of the family that are conserved during evolution are known from bacteria to higher eukaryotes. These have many different functions including lipid binding, neuronal development, serine protease inhibition, and the regulation of several signaling pathways; in plants, they control shoot growth and flowering. PEBP4 is of particular interest as it is highly expressed in many different cancers and can increase their resistance to therapy. In animal tissues, phosphatidylethanolamine is especially important in the sarcolemmal membranes of the heart during ischemia, it is involved in the secretion of the nascent very-low-density lipoproteins from the liver and it has functions in membrane fusion and fission. It has a functional role in the Ca^{2+}-ATPase in that one molecule of phosphatidylethanolamine is bound in a cavity between two transmembrane helices, acting as a wedge to keep them apart. This is displaced when Ca^{2+} is bound to the enzyme. Many other important proteins bind non-covalently to phosphatidylethanolamine in a similar way, including rhodopsin and aquaporins.

The content of phosphatidylethanolamine in newly secreted VLDL particles and in apoB-containing particles isolated from the lumen of the Golgi is much higher than that in circulating VLDLs, suggesting that this lipid is involved in VLDL assembly and/or secretion. However, it is rapidly and efficiently removed from the VLDL in the circulation. With lipid droplets in cells, phosphatidylethanolamine is believed to promote coalescence of smaller droplets into larger ones.

Although the mechanism has yet to be fully elucidated, effects on protein conformation are believed to be behind a finding that phosphatidylethanolamine is the primary factor in the brain required for the propagation and infectivity of mammalian prions. Host defense peptides are antimicrobial agents produced by both prokaryotic and eukaryotic organisms, and many of these have a high affinity for phosphatidylethanolamine as a lipid receptor to modulate their activities. For example, the peptide antibiotics cinnamycin and duramycins from Streptomyces have a hydrophobic pocket that fits around phosphatidylethanolamine such that the binding is stabilized by ionic interaction between the ethanolamine group of the lipid and the carboxylate moiety of the peptide; this complex exhibits activity against other Gram-positive organisms, such as *Bacillus* species.

Much of the evidence for the unique properties of phosphatidylethanolamine comes from studies of the biochemistry of the bacterium *E. coli*, where this lipid is a major component of the membranes. Gram-negative bacteria have two membrane bilayers in the cell wall, and as much as 90% of the phospholipid in the inner leaflet of the outer membrane is phosphatidylethanolamine, with a high proportion in the cytoplasmic leaflet of the inner membrane also. In particular, phosphatidylethanolamine has a specific involvement in supporting the active transport of lactose by the lactose permease, and other transport systems may require or be stimulated by it. There is evidence that phosphatidylethanolamine acts as a 'chaperone' during the assembly of this and other membrane proteins to guide the folding path for the proteins and to aid in the transition from the cytoplasmic to the membrane environment, although in contrast it inhibits the folding of some multi-helical proteins. In the absence of this lipid, the transport membranes may not have the correct tertiary structure and so will not function correctly. Whether the lipid is required once the protein is correctly assembled is not fully understood in all cases, but it may be needed to orient enzymes correctly in the inner membrane. Some studies suggest that life in this organism can be maintained without phosphatidylethanolamine, but that life processes are inhibited.

Autophagy and ferroptosis: A covalent conjugate of phosphatidylethanolamine with a protein designated 'Atg8' is formed by the action of cysteine protease ATG4 (belonging to the caspase family) and various other proteins, and is involved in the process of autophagy (controlled degradation of cellular components) in yeast by promoting the formation of membrane vesicles containing the components to be degraded (**phosphatidylinositol 3-phosphate** is also essential to this process). Similarly, oxidatively modified phosphatidylethanolamine is an important factor in **ferroptosis**, a form of apoptosis in which disturbances to iron metabolism lead to an accumulation of hydroperoxides.

Precursor of other lipids: Phosphatidylethanolamine is a precursor for the synthesis of *N*-acyl-phosphatidylethanolamine (see below) and thence of **anandamide** (*N*-arachidonoylethanolamine), and it is the donor of ethanolamine phosphate during the synthesis of the

glycosylphosphatidylinositol anchors that attach many signaling proteins to the surface of the plasma membrane. In bacteria, it functions similarly in the biosynthesis of **lipid A** and other lipopolysaccharides. It is also the substrate for the hepatic enzyme phosphatidylethanolamine *N*-methyltransferase, which provides about a third of the **phosphatidylcholine** in the liver.

Miscellaneous other functions: Phosphatidylethanolamine is the precursor of an ethanolamine phosphoglycerol moiety bound to two conserved glutamate residues in eukaryotic elongation factor 1A, which is an essential component in protein synthesis. This unique modification appears to be of great importance for the resistance of plants to attack by pathogens. *Francisella tularensis* bacteria, the cause of tularemia, suppresses host inflammation and the immune response when infecting mouse cells. The effect is due to a distinctive phosphatidylethanolamine species containing 10:0 and 24:0 fatty acids, and the synthetic lipid produces the same effects *in vitro* in human cells infected with dengue fever virus. It is hoped that this lipid will prove to be a potent anti-inflammatory therapeutic agent.

Plants: In the seeds of higher plants, a deficiency of phosphorylethanolamine cytidylyltransferase, a rate-limiting enzyme in the biosynthesis of phosphatidylethanolamine, has profound effects on the viability and maturation of embryos.

21.3.4.4: LYSOPHOSPHATIDYLETHANOLAMINE

Figure 21.3.22 shows the the structure of lysophosphatidyethanolamine

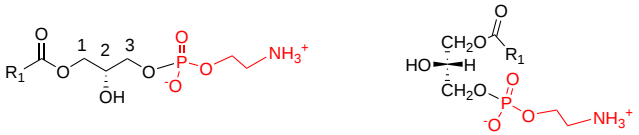

Figure 21.3.22: Lysophosphatidyethanolamine

Lysophosphatidylethanolamine (LPE), with one mole of fatty acid per mole of lipid, is found in trace amounts only in animal tissues, other than plasma (10 to 50μM, or ~1% of total serum phospholipids). It is formed by hydrolysis of phosphatidylethanolamine by the enzyme phospholipase A_2, as part of a de-acylation/re-acylation cycle that controls its overall molecular species composition as discussed above. A membrane-bound *O*-acyltransferase (MBOAT2) specific for LPE (and lysophosphatidic acid) has been characterized with a preference for oleoyl-CoA as substrate. There are reports of the involvement of LPE in cellular functions, such as differentiation and migration of certain neuronal cells, but also of various cancer cells. For example, oleoyl-LPE in the brain stimulates neurite outgrowth and protects against glutamate toxicity.

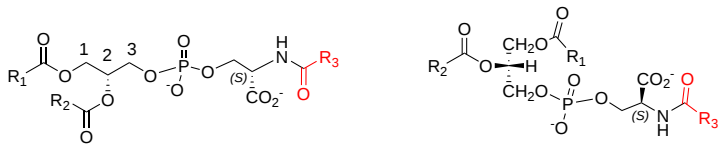
In plants, lysophosphatidylethanolamine is a specific inhibitor of phospholipase D, a key enzyme in the degradation of membrane phospholipids during the early stages of plant senescence. Through this action, it retards the senescence of leaves, flowers, and post-harvest fruits. Indeed, it has a number of horticultural applications when applied externally, e.g., to stimulate ripening and extend the shelf-life of fruit, delay senescence, and increase the vase life of cut flowers. In bacteria, lysophosphatidylethanolamine displays chaperone-like properties, promoting the functional folding of citrate synthase and other enzymes. Some biological properties have been reported in animal tissues *in vitro*, but a specific receptor has yet to be identified.

Lysophospholipids and especially lysophosphatidylethanolamines are produced in the envelope membranes of bacteria by many different endogenous and exogenous factors and must be transported back into the bacterial cell by flippases for conversion back to the diacyl forms by the action of a peripheral enzyme, acyl-ACP synthetase/LPL acyltransferase. Lysophosphatidylethanolamines produced by certain bacteria act synergistically with the **sulfonolipid** rosette-inducing factors (RIFs) to maximize the activity of the latter to induce choanoflagellates to move from a unicellular to a multicellular state.

21.3.4.5: *N*-ACYL PHOSPHATIDYLETHANOLAMINE

In *N*-Acyl phosphatidylethanolamine, the free amino group of phosphatidylethanolamine is acylated by a further fatty acid. This lipid has been detected in rather small amounts in several animal tissues (~0.01%), but especially brain, nervous tissues, and the epidermis, when the *N*-acyl chain is often palmitic or stearic acid (human plasma: N16:0-PE (40%), N18:1-PE (23.3%), N18:0-PE (19%), N18:2-PE (16.6%) and N20:4-PE (1.4%)). Under conditions of degenerative stress, it can accumulate in significant amounts, for example as the result of ischemic injury, infarction, or cancer. It is present in plasma after feeding a high-fat diet to rats, and then it can cross into the brain where it accumulates in the hypothalamus.

Figure 21.3.23 shows the structures of *N*-Acyl Phosphatidylethanolamine.



N-acylphosphatidylethanolamine

Figure 21.3.23: *N*-Acyl Phosphatidylethanolamine

In animals, *N*-Acyl phosphatidylethanolamine is of particular importance as the precursor of **anandamide**, and of other biologically important ethanolamides (e.g., ***N*-oleoylethanolamide**) in brain and other tissues, but especially the intestines. In brief, it is formed

biosynthetically by the action of a transferase (cytosolic phospholipase $A_2\varepsilon$) exchanging a fatty acid from the *sn*-1 position of a phospholipid (probably phosphatidylcholine) to the primary amine group of phosphatidylethanolamine (without a hydrolytic step). Both diacyl- and alkenylacyl-species of phosphatidylethanolamine can serve as acceptors. In addition, some transfer can also occur from phosphatidylethanolamine *per se* by an intramolecular reaction. However, it should be noted that some *N*-acyl phosphatidylethanolamine can be formed artefactually as a result of faulty extraction procedures during analysis.

In plants, *N*-acyl phosphatidylethanolamine is a common constituent of cereal grains (e.g., wheat, barley and oats) and of some other seeds (1.9% of the phospholipids of cotton seeds, but 10-12% of oats). In other plant tissues, it is detected most often under conditions of physiological stress. In contrast to animals, synthesis involves direct acylation of phosphatidylethanolamine with a free fatty acid, catalyzed by a membrane-bound transferase in a reverse serine-hydrolase catalytic mechanism. Activation of *N*-acyl phosphatidylethanolamine metabolism in plants with the release of *N*-acylethanolamines and phosphatidic acid formation seems to be associated with cellular stresses, but research is at an early stage. However, both *N*-acyl lipid classes have been implicated in such physiological processes as the elongation of main and lateral roots, regulation of seed germination, seedling growth, and defense from attacks by pathogens.

N-Acyl phosphatidylethanolamine has been found in a number of microbial species, while *N*-acetyl phosphatidylethanolamine was detected in a filamentous fungus, *Absidia corymbifera*, where it comprised 6% of the total membrane lipids. It was accompanied by an even more unusual lipid 1,2-diacyl-*sn*-glycero-3-phospho(*N*-ethoxycarbonyl)-ethanolamine.

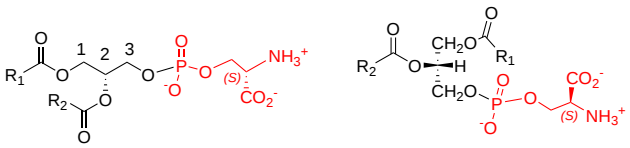
21.3.5: PHOSPHATIDYLSERINE AND RELATED LIPIDS

Phosphatidylserine or 1,2-diacyl-*sn*-glycero-3-phospho-L-serine is an important anionic phospholipid, which brings essential physical properties to membranes in both eukaryotes and prokaryotes. Independently of this, it has many biological functions in cells, including effects on blood coagulation and apoptosis, and it is the biosynthetic precursor for phosphatidylethanolamine in prokaryotes and in eukaryote mitochondria. Its metabolite lysophosphatidylserine has signaling functions and operates through specific receptors. Also, there is increasing interest in a structurally related lipid phosphatidylthreonine, and other phospholipids linked to amino acids.

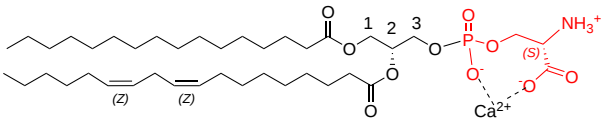
21.3.5.1: PHOSPHATIDYLSERINE - STRUCTURE AND OCCURRENCE

Although phosphatidylserine is distributed widely among animals, plants, and microorganisms, it is usually less than 10% of the total phospholipids, the greatest concentration being in myelin from brain tissue. For example, mouse brain and liver contain 14 and 3% phosphatidylserine, respectively. However, it may comprise 10 to 20 mol% of the total phospholipids in the plasma membrane, where under normal conditions it is concentrated in the inner leaflet, and in the endoplasmic reticulum of cells. In the yeast *Saccharomyces cerevisiae*, it is a minor component of most cellular organelles other than the plasma membrane, where surprisingly it can amount to more than 30% of the total lipids. In most bacteria, it is a minor membrane constituent, although it is important as an intermediate in phosphatidylethanolamine biosynthesis. The 1-octadecanoyl-2-docosahexaenoyl molecular species, which is especially important in brain tissue, is illustrated here.

Figure 21.3.24 shows the structure of phosphatidylserine



phosphatidylserine



1-hexadecanoyl,2-(9Z,12Z)-octadecadienoyl-sn-glycero-3-phosphoserine

Figure 21.3.24 Phosphatidylserine

Phosphatidylserine is an acidic (anionic) phospholipid with three ionizable groups, i.e., the phosphate moiety, the amino group, and the carboxyl function. As with other acidic lipids, it exists in nature in salt form, but it has a high propensity to chelate to calcium via the charged oxygen atoms of both the carboxyl and phosphate moieties, modifying the conformation of the polar head group. This interaction may be of considerable relevance to the biological function of phosphatidylserine, especially during bone formation for example.

In animal cells, the fatty acid composition of phosphatidylserine varies from tissue to tissue, but it does not appear to resemble the precursor phospholipids, either because of selective utilization of specific molecular species for biosynthesis or because of the re-modeling of the lipid via deacylation-reacylation reactions with lysophosphatidylserine as an intermediate (see below). In human plasma, 1-stearoyl-2-oleoyl and 1-stearoyl-2-arachidonoyl species predominate, but in the brain (especially grey matter), retina and many other tissues 1-stearoyl-2-docosahexaenoyl species are especially abundant and appear to be essential for normal functioning of the nervous system. Indeed, the ratio

of *n*-3 to *n*-6 fatty acids in brain phosphatidylserine is much higher than in most other lipids. The positional distribution of fatty acids in phosphatidylserine from rat liver and bovine brain are listed in Table 21.3.5. As with most phospholipids, saturated fatty acids are concentrated in position *sn*-1 and polyunsaturated in position *sn*-2.

Table 21.3.5: **Positional distribution of fatty acids in phosphatidylserine from rat liver and bovine brain**

Position	Fatty acid					
	16:0	18:0	18:1	18:2	20:4	22:6
			Rat liver [1]			
***sn*-1**	5	93	1			
***sn*-2**	6	29	8	4	32	19
			Bovine brain [2]			
***sn*-1**	3	81	13			
***sn*-2**	2	1	25	trace	1	60

1. Wood, R. and Harlow, R.D. *Arch. Biochem. Biophys*., **135**, 272-281 (1969); DOI.
2. Yabuuchi, H. and O'Brien, J.S. *J. Lipid Res*., **9**, 65-67 (1968); DOI.

In leaves of *Arabidopsis thaliana*, used as a 'model' plant in many studies, the fatty acid composition of phosphatidylserine resembles that of **phosphatidylethanolamine**. There is an intriguing report that the chain lengths of the acyl groups increase with age and stress in phosphatidylserine quite specifically, and 22:0 and 24:0 fatty acids have been reported to occur in this lipid in the plasma membrane of some plant species.

In marked contrast to phosphatidylethanolamine, phosphatidylserines with ether-linked moieties (alkyl and alkenyl) are not common in animal tissues, although they are reported to be relatively abundant in human retina and macrophages (they were first found in rat lung). As a generality, the concentration of phosphatidylserine is highest in plasma membranes and endosomes but is very low in mitochondria. As it is located entirely on the inner monolayer surface of the plasma membrane (and of other cellular membranes) and it is the most abundant anionic phospholipid, it may make the largest contribution to interfacial effects in membranes involving non-specific electrostatic interactions. This normal distribution is disturbed during platelet activation and cellular apoptosis.

***N*-Acylphosphatidylserine** is reportedly present in the frontal cortex of patients with schizophrenia, as a minor component of the lipids of sheep erythrocytes, bovine brain, and the central nervous system of freshwater fish, and Bryozoans amongst others. The *N*-arachidonoyl form may be the precursor of the endocannabinoid ***N*-arachidonoylserine**.

21.3.5.2: BIOSYNTHESIS OF PHOSPHATIDYLSERINE

L-Serine is a non-essential amino acid that is actively synthesized by most organisms. In animals, it is produced in nearly all cell types, although in brain it is synthesized by astrocytes but not by neurons, which must be supplied with this amino acid for the biosynthesis of phosphatidylserine (and of sphingoid bases).

In animal tissues, phosphatidylserine is synthesized solely by calcium-dependent base-exchange reactions in which the polar head-group of an existing phospholipid is exchanged for L-serine. There are two routes involving distinct enzymes (PS synthase I and II) with 30% homology and several membrane-spanning domains that can utilize different substrates. Phosphatidylserine is synthesized by both enzymes on the cytosolic face of the endoplasmic reticulum (ER) of the cell, but mainly in a specific domain of this termed the mitochondria-associated membrane ('MAM'), because it is tethered transiently to the mitochondrial outer membrane, presumably by a protein bridge. In yeast, a complex of integrated proteins ('ERMES') has been characterized with a similar function. The reaction involves the exchange of L-serine with either phosphatidylcholine or phosphatidylethanolamine, catalyzed by PS synthase I (although it was long thought that only phosphatidylcholine was a substrate for this enzyme), while PS synthase II catalyzes a similar exchange with diacyl-phosphatidylethanolamine and its the plasmalogen form. Both enzymes are subject to feedback regulation by their product phosphatidylserine, thereby maintaining the correct amounts of this lipid. Figure 21.3.25 shows the synthesis and metabolism of phosphatidylserine in animals.

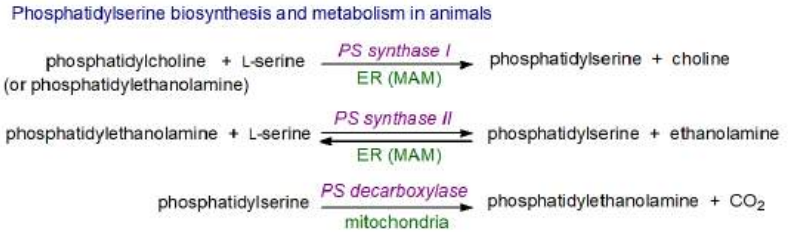


Figure 21.3.25: Synthesis and metabolism of phosphatidylserine in animals.

Phosphatidylserine synthase I is expressed in all mouse tissues, but especially the kidney, liver, and brain, while phosphatidylserine synthase II is most active in the brain and testis and much less so in other tissues. The latter enzyme has a high specificity for molecular species containing docosahexaenoic acid. It is not known why such a complex series of coupled reactions is necessary, or why there should be two enzymes, but one virtue is that the free ethanolamine and choline formed are rapidly re-utilized for phospholipid synthesis. Thus, both phosphatidylserine and phosphatidylethanolamine are produced without a reduction in the amount of phosphatidylcholine. Elimination of both enzymes is embryonically lethal in knock-out mice, but each of them can be knocked out separately and the mice survive, even though they have substantially reduced levels of phosphatidylserine and phosphatidylethanolamine.

As with other phospholipids, the final fatty acid composition in animal tissues is attained by a process of remodeling known as the Lands' cycle. The first step is hydrolysis by a phospholipase A_2 to lysophosphatidylserine, followed by the reacylation by various acyl-CoA:lysophospholipid acyltransferases. One membrane-bound *O*-acyltransferase (LPCAT4 or MBOAT2) with a preference for oleoyl-CoA has been characterized, while a second (LPCAT3 or MBOAT5) incorporates linoleoyl and arachidonoyl chains (and also utilizes lysophosphatidylcholine).

Following synthesis, phosphatidylserine molecules can diffuse laterally in a concentration-dependent manner to different regions of the membrane to fulfill their physiological functions. In humans, cytosolic transport proteins transfer phosphatidylserine and other acidic phospholipids between membranes, and this can also occur by a vesicular transport mechanism.

Some of the newly synthesized phosphatidylserine is transferred to the plasma membrane, while a proportion is transported to the mitochondria, probably again via transient membrane contact (MAM), where it is decarboxylated to produce **phosphatidylethanolamine** by a specific decarboxylase in the inner mitochondrial membrane. In yeast, there is a preference for molecular species containing two monoenoic fatty acids for transport and metabolism; this process occurs also at the Golgi/endosome membranes. All the phosphatidylethanolamine in mitochondria is formed in this way, but some can return to the endoplasmic reticulum where it may be converted back to phosphatidylserine by the action of the PS synthases. Mitochondrial production of phosphatidylethanolamine from phosphatidylserine is not fully complemented by the CDP-ethanolamine pathway, as mice lacking the enzyme do not survive for long. Evidently, cellular concentrations of these two lipids are intimately related and tightly regulated. Figure 21.3.26 shows the mitochondrial metabolism of phosphatidylserine

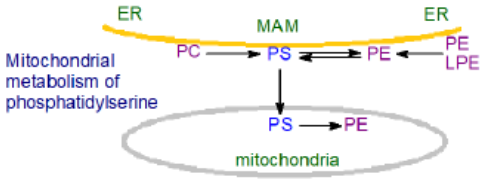

Figure 21.3.26: Mitochondrial metabolism of phosphatidylserine

Much of the phosphatidylserine thus formed is decarboxylated to phosphatidylethanolamine, and this may be the major route to the latter in bacteria. As phosphatidylcholine in yeast is produced via methylation of phosphatidylethanolamine, phosphatidylserine is the primary precursor for this phospholipid in these organisms.

Bacteria and plants: In bacteria and other prokaryotic organisms and in yeast, phosphatidylserine is synthesized by a mechanism comparable to that of most other phospholipids, i.e., by reaction of L-serine with CDP-diacylglycerol, and depends on Mg^{2+} or Mn^{2+}. Phosphatidylserine synthases belong to two different families: type I (non-integral membrane form) in the phospholipase D-like family as in *E. coli*, and type II (integral membrane form) in the CDP-alcohol phosphotransferase family as in *Bacillus* sp. and the yeast *S. cerevisiae*, although the latter shows no homology with the bacterial enzymes.

In many plants, including in the model plant Arabidopsis, much of the phosphatidylserine is produced by a calcium-dependent base-exchange reaction in which the head group of an existing phospholipid is exchanged for L-serine in the luminal leaflet of the endoplasmic reticulum (i.e., mechanistically similar to PS synthase I). It is transferred to the cytoplasmic membrane leaflet by flippases and thence to the post-Golgi compartments before eventually accumulating at the plasma membrane. However, some vesicular transport may occur or there may be direct transfer at membrane contact sites. A CDP-diacylglycerol (prokaryotic-like) biosynthetic pathway exists in some species, e.g. wheat.

Let's explore the mechanism of the *Methanocaldococcus jannaschii* phosphatidylserine synthase (**MjPSS**). The organism is a hyperthermophilic methanogen. Figure 21.3.27 shows substrate binding by MjPSS.

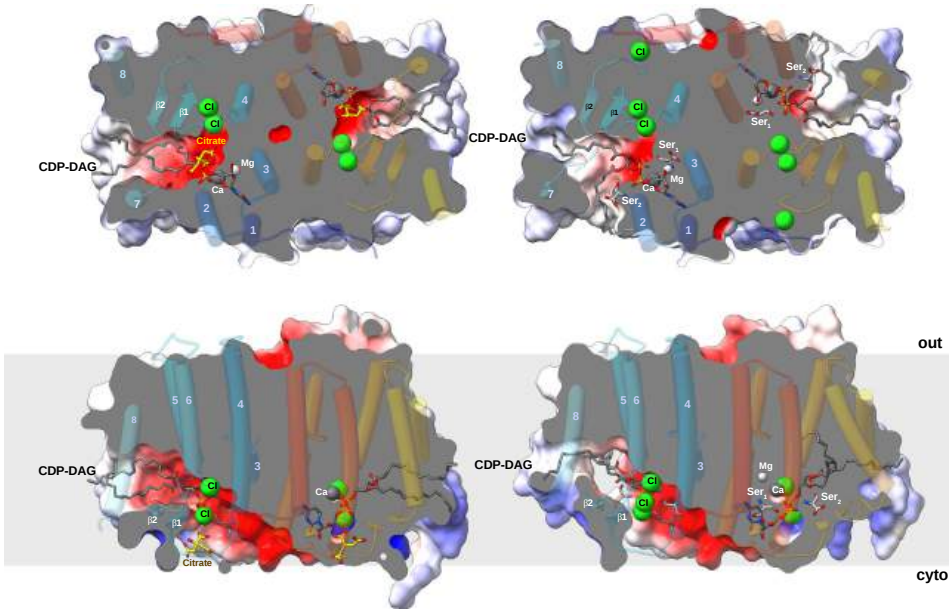

Figure 21.3.27: Substrate binding by MjPSS. Centola, M., van Pee, K., Betz, H. *et al.* Crystal structures of phosphatidyl serine synthase PSS reveal the catalytic mechanism of CDP-DAG alcohol O-phosphatidyl transferases. *Nat Commun* **12,** 6982 (2021). https://doi.org/10.1038/s41467-021-27281-w. Creative Commons Attribution 4.0 International License, http://creativecommons.org/licenses/by/4.0/.

The large binding pocket for CDP-DAG in MjPSS extends from the hydrophobic membrane core to the active site near the cytoplasmic surface in the center of the dimer. In the closed structures (left), both CDP-DAG alkyl chains adopt similar conformations within the binding pocket, whereas the positions of helix 7 and 8 in the open structures (right) allow one alkyl chain to reach the membrane via a different path. Serine molecules are only found in open structures (right). In one closed conformation, there is a citrate near the substrate-binding site, whereas in the other closed structures this position is empty. A chain of three chloride ions extends parallel to the dimer interface from the active site to the cytoplasmic interface with the N-terminal helix hH from the other protomer.

Figure 21.3.28 shows the reaction cycle of MjPSS during the synthesis of PS from CDP-DAG and serine in the presence of Mg^{2+} and Ca^{2+}.

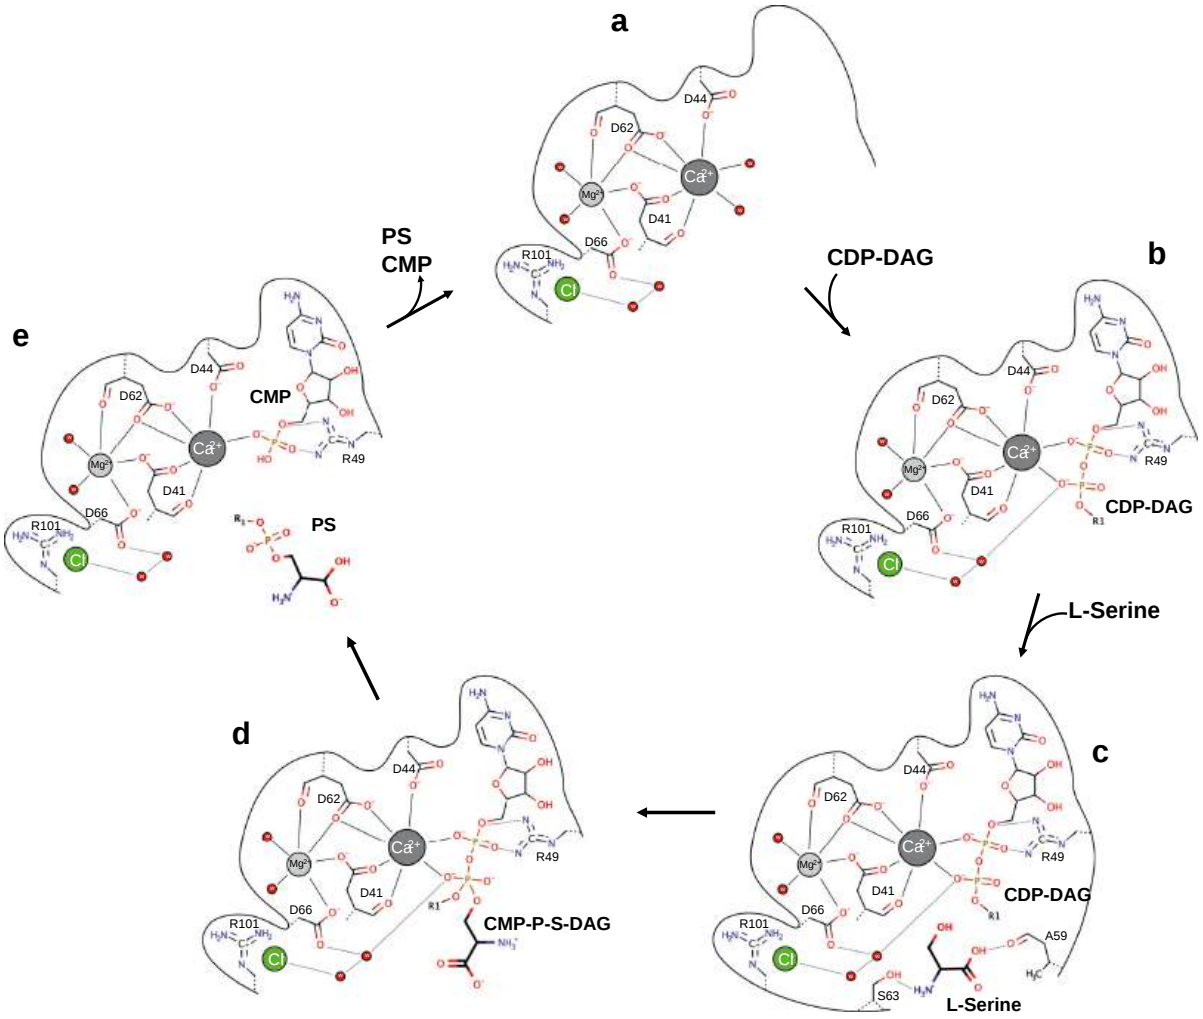

Figure 21.3.28 Reaction mechanism for MjPss. Centola, M. et al., ibid

The CDPDAG binding site in MjPSS of is formed and stabilized by the divalent cations Mg2+ and Ca2+ (a). In the absence of CDP-DAG, Ca2+ most likely is coordinated by water molecules, as shown in a, or by residues in nearby loops that would be flexible in the absence of CDP-DAG. The binding of CDP-DAG (b) is driven by the coordination of Ca2+ by the negatively charged phosphates. Serine binds to the binding pocket after CDP-DAG (c). For the nucleophilic attack, the serine molecule is positioned with its hydroxyl group near the β-phosphate of CDP-DAG. The serine molecule is activated by deprotonation, attacks the β-phosphate, and forms the penta-coordinated transition state (d). The proton of serine is probably removed by one of the water molecules located in the interaction network of Asp66, Arg101, and the nearby chloride ions. Hydrolysis of the CDP-DAG/serine complex from the transition state leads to the complex of MjPSS with the products PS and CMP (e). The next cycle starts after release of the products and binding of CDP-DAG. Structural data are available for the state with bound CDP-DAG (b), CDP-DAG, and serine (c), and for the transition state of the CDP-DAG/serine complex (d).

Figure 21.3.29 shows an interactive iCn3D model of the Methanocaldococcus jannaschii phosphatidyl serine synthase (PSS) in the open state with bound CDP-DAG and serine (7B1L). The enzyme is also named CDP-diacylglycerol--serine O-phosphatidyltransferase.

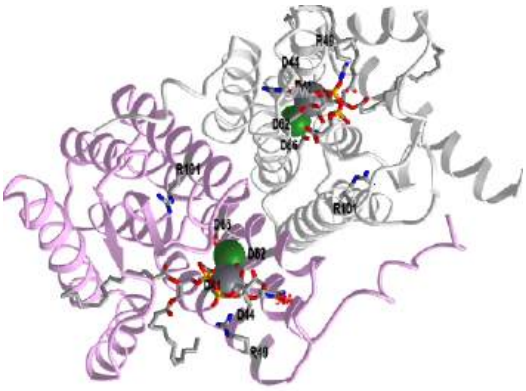

Figure 21.3.29: Bacterial phosphatidyl serine synthase (PSS) in the open state with bound CDP-DAG and serine (7B1L) (Note the actual PDB file title names state that this is the closed state which it is not.) Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...B3Rn3gVN4c4ge6

The A chain of the homodimer is shown in gray and the B in plum. The active site residues in the A chain in the above mechanism are shown in stick, CPK colors, and labeled. Hover over the large ligand (58A) in the gray subunit. Two free serines are shown near it but only one is probably the substrate.

21.3.5.3: PHOSPHATIDYLSERINE – BIOLOGICAL FUNCTION

Membrane location: Phosphatidylserine modulates membrane charge locally, enabling the recruitment of soluble cations and proteins, and so it contributes to the organization of processes within cell membranes. Its distribution within membranes is tightly controlled as it facilitates signaling within the various cellular compartments. Thus, it undergoes a transition from the lumenal leaflet of the endoplasmic reticulum to the cytosolic leaflet in the trans-Golgi network, probably by the activity of flippases and scramblases in the Golgi, and it is highly enriched on the inner leaflet of the plasma membrane. Transport to the plasma membrane against a concentration gradient is aided in part by proteins designated 'ORP5' and 'ORP8' in humans (Osh 6 and Osh7 in yeast) with a 'PH' binding domain for **phosphatidylinositol 4,5-bisphosphate** and an 'ORD' domain for phosphatidylserine. At a membrane contact site between the endoplasmic reticulum and plasma membrane, phosphatidylserine is exchanged for phosphatidylinositol 4-phosphate. Such transfer requires an input of energy, which can be supplied in the form of ATP or by phosphoinositides Although it does not take part in membrane **raft** formation, phosphatidylserine is present in **caveolae**, where it is believed to interact with caveolin-1. It is also present in appreciable amounts in the endosomal compartment.

The asymmetric structure of the plasma membrane with high concentrations of anionic lipids such as phosphatidylserine in the cytosolic leaflet with zwitterionic lipids in the extracellular leaflet generates two surfaces with greatly different electrostatic potentials that influence the association of proteins with the membrane surface and the activities of integral membrane proteins. This distribution is maintained and can be altered, after specific activation, by various flippases (transfer back into the cytoplasmic leaflet), floppases (transfer out of the cytoplasmic leaflet), and scramblases (bidirectional transfer), including ATP-dependent translocases selective for phosphatidylserine. Phosphatidylserine is highly enriched in the cytosolic leaflet of the membranes of recycling endosomes, which replenish the lipids and proteins of the plasma membrane, and it is essential for their function.

Enzyme activation: In addition to its function as a component of cellular membranes and as a precursor for other phospholipids, phosphatidylserine is an essential cofactor that binds to and activates a large number of proteins, especially those with signaling activities. The negative charge on the lipid facilitates the binding to proteins through electrostatic interactions or Ca^{2+} bridges. For example, the presence of appreciable amounts of phosphatidylserine on the cytosolic leaflet of endosomes and lysosomes enables these compartments to dock with proteins that possess specific phosphatidylserine-binding domains including several important signaling and fusogenic effectors. The cytoskeletal protein spectrin binds to phosphatidylserine in this way, and it is also required by enzymes such as the neutral sphingomyelinase and the Na^+/K^+ ATPase, where the 18:0/18:1 molecular species is especially important. It is believed that the fatty acyl components of this species in the inner leaflet of the plasma membrane (and potentially other intracellular membranes) may interact (interdigitation or "hand-shake") with the very-long chains of sphingolipids in the outer leaflet in raft microdomains, resulting in a high local concentration of the anionic phospholipid and an accumulation of negative surface charge to which specific poly-cationic proteins in the membranes can bind. This may then enable the transfer of signals across the membrane to the cytosol.

Similarly, phosphatidylserine participates directly in key signaling pathways in the brain by binding to the cytosolic proteins involved in neuronal signaling and thereby activating them. At least three major pathways are affected, including those involving phosphatidylinositol 3-kinase and protein kinase C. For example, most enzymes of the protein kinase C family contain a 'C2' calcium-dependent cysteine-rich region that recognizes phosphatidylserine, and in coordination with the 'C1' domain that binds to **diacylglycerols**, is essential for activating and locating them to the plasma membrane of appropriately stimulated cells. Phosphatidylserine is not involved in cell signaling through the formation of metabolites, as is the case with phosphatidylinositol.

Blood coagulation: Phosphatidylserine is an important element of the blood coagulation process in platelets, where it is transported from the inner to the outer surface of the plasma membrane in platelets activated by exposure to fibrin-binding receptors, for example. Here, the exposed phosphatidylserine enhances the activation of prothrombin to thrombin (the key molecule in the blood clotting cascade) by triggering a cascade of reactions and providing the negatively charged platform that enables calcium ions to form bridges with γ-carboxyglutamic acid-containing domains on the coagulation factors. Membrane vesicles with phosphatidylserine exposed on the surface can also be released from platelets and promote the coagulation process. Apolipoprotein A-1 in high-density lipoproteins has a controlling function in that it neutralizes these procoagulant properties by arranging the phospholipid in surface areas that are too small to accommodate the prothrombinase complex. Blood coagulation is beneficial when it prevents the loss of blood from the circulatory system, but it is detrimental when it causes thrombosis, and the action of phosphatidylserine is essential to the regulation of the process.

Apoptosis: In addition in response to particular calcium-dependent stimuli, phosphatidylserine is known to have an important role in the regulation of apoptosis or programmed cell death, the natural process by which aged or damaged cells are removed from tissues before they can exert harmful effects. When cells are damaged, a mechanism is initiated in which the normal distribution of this lipid on the inner leaflet of the plasma membrane bilayer is disrupted by stimulation of scramblases, which are ATP-independent and can move the lipid across the membrane to the outer leaflet. This occurs together with the inhibition of aminophospholipid translocases, which return the lipid to the inner side of the membrane. In erythrocytes, phosphatidylserine is located in the inner leaflet of the membrane bilayer under low Ca^{2+} conditions when a phospholipid scramblase is suppressed by membrane cholesterol, but it is exposed to the outer leaflet under elevated Ca^{2+} concentrations which activate the scramblase. After the collapse of this asymmetry and transfer of phosphatidylserine to the outer leaflet of an effete cell, it is believed that it is recognized by a cohort of receptors, either directly or indirectly, through bridging ligands on the surface of macrophages and related scavenger cells. These activate a family of cysteine-dependent aspartate-specific proteases, the caspases, and other enzymes to facilitate the engulfment of the apoptotic cells and their potentially toxic or immunogenic contents in a non-inflammatory manner. It is noteworthy that the transition from a pro-inflammatory to an anti-inflammatory state is defined by phagocytosis of neutrophils by macrophages via this phosphatidylserine-dependent process.

During apoptosis, the generation of reactive oxygen species occurs, mainly hydrogen peroxide, which together with the enzyme cytochrome c brings about rapid oxidation of the fatty acids in phosphatidylserine before this lipid is externalized. Indeed, it is now apparent that molecular species of phosphatidylserine with an oxidatively truncated *sn*-2 acyl group that incorporates terminal γ-hydroxy(or oxo)-α,β-unsaturated acyl moieties are especially potent signals for scavenger receptors in macrophages as a prerequisite for engulfment of apoptotic cells.

This has been described as "a dominant and evolutionarily conserved immunosuppressive signal that promotes tolerance and prevents local and systemic immune activation" or more succinctly as an "eat-me signal" (externalized phosphatidylinositol 3,4,5-trisphosphate (PI(3,4,5)P) may have a similar function). The binding of phosphatidylserine to specific proteins, such as apolipoprotein H (β2-glycoprotein 1), enhances the recognition and clearance. This process is essential for the development of the lung and brain, and it is also relevant to clinical situations where apoptosis plays an important part, such as cancer, chronic autoimmunity, and infections. For example, phosphatidylserine is a necessary component of the TAM family of receptor tyrosine kinases and the receptor-ligand complex of particular importance in cancer cells, where phosphatidylserine-TAM signaling regulates many aspects of inflammation and immune resolution and is seen as a target for therapeutic intervention. Exposure of phosphatidylserine is increased substantially on the surface of tumor cells or tumor cell-derived microvesicles, which have innate immunosuppressive properties and facilitate tumor growth and metastasis. Targeting phosphatidylserine is considered to be a promising strategy in cancer immunotherapy. In relation to atherosclerosis, phosphatidylserine is believed to have anti-inflammatory and protective effects as a component of the high-density lipoproteins, probably mediated by the apoptosis mechanism. In contrast, as this mechanism is important for the turnover of erythrocytes, it is relevant to thrombus formation and the stabilization of blood clots. The innate immunosuppressive effect of externalized phosphatidylserine has been hijacked by numerous viruses and bacteria to facilitate infection.

A similar apoptotic mechanism operates in retinal pigment epithelial cells to remove the large amounts of photoreceptor cell debris that are generated continuously. In addition, appreciable amounts of phosphatidylserine are translocated by an analogous mechanism to the surface of T lymphocytes that express low levels of the trans-membrane enzyme tyrosine phosphatase. This change in distribution acts then as a signaling mechanism to modulate the activities of several membrane proteins. The anti-coagulant protein annexin V binds with high specificity to phosphatidylserine and is used as a probe to detect apoptotic cells. It is noteworthy that phosphatidylserine is a major component of the membranes of microvesicles in animal cells, and translocation to the outer leaflet upon cellular activation is essential for their biogenesis. In addition, exposure of phosphatidylserine on the cell surface is reported to be a factor in non-apoptotic forms of regulated inflammatory cell death, such as necroptosis.

Role in infections: Unfortunately, viruses such as Ebola and HIV viruses can hijack this apoptosis machinery by incorporating phosphatidylserine into their viral envelopes so conning cells into engulfing them; the viral glycoprotein/cellular receptor complex may then facilitate the entry of foreign organisms into other cells. Similarly, parasites ingested in this manner, including *Leishmania* and *Trypanosoma* species, utilize host phosphatidylserine to establish infections and facilitate disease progression as they do not then elicit the production of proinflammatory cytokines. This mechanism has been termed 'apoptotic mimicry' and is critical for the survival of parasites within the macrophage.

Other activities: Phosphatidylserine is required for the transmembrane movement of excess cholesterol, derived initially from the lysosomal degradation of low-density lipoproteins, from the plasma membrane to the endoplasmic reticulum thereby maintaining membrane integrity and ensuring cell survival. It is therefore an important element in **cholesterol homeostasis**. The mechanism is believed to involve proteins known as GRAMD1s embedded in the endoplasmic reticulum membrane at sites in contact with the plasma membrane. These have two functional domains: the StART-like domain that binds cholesterol and the GRAM domain that binds anionic lipids, such as phosphatidylserine, and so forms a link between the two membranes that enables the transfer of cholesterol.

A further unusual function of phosphatidylserine is that it is a key component of the lipid-calcium-phosphate complexes that act as nucleation centers for hydroxyapatite formation and initiate mineral deposition during the formation of bone. It has been established that phosphatidylserine and inorganic phosphate must be present, before calcium ions are introduced, when the high affinity of phosphatidylserine for calcium ions becomes important. Nucleation is facilitated by the protein annexin V. Similarly, during bone repair and maintenance, the fusion of osteoclasts requires the non-apoptotic exposure of phosphatidylserine at the surface of fusion-committed cells with the aid of a transmembrane protein (DC-STAMP) expressed in dendrocytes. This activity is relevant to cardiovascular disease and in particular to the phenomenon of "hardening of the arteries," where atherosclerotic plaques can undergo mineralization with the deposition of hydroxyapatite.

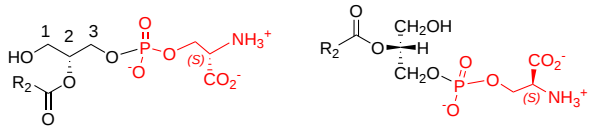
Among many other functions of phosphatidylserine, it is believed to be an essential surface membrane component for the fusion of cell types other than osteoclasts, including during the formation of fibers in muscle cells, and the fusion of macrophages into inflammatory giant cells and myoblasts into myotubes. Such cell fusions require the non-apoptotic exposure of phosphatidylserine at the surface of fusing cells, where it interacts with phosphatidylserine-recognizing proteins to regulate the time and place of cell fusion. Phosphatidylserine provides stable membrane domains in spermatozoa that are essential for fertilization, and it is also an essential component of the plasma membrane microdomains known as **caveolae**, where it is required both for their formation and stability possibly through specific binding to the cavin proteins.

The high concentrations of docosahexaenoic acid (DHA) in the brain and retinal phosphatidylserine are certainly important for the development and function of these tissues. Accumulation of phosphatidylserine in neuronal membranes is promoted by DHA, and this is important for the maintenance of neuronal survival. Phosphatidylserine may also be a reservoir of DHA for **protectin** formation in neuronal tissue. On the other hand, the Food and Drug Administration in the USA considers that there is little scientific evidence to support claims that dietary supplements of phosphatidylserine reduce the risk of dementia or cognitive dysfunction in the elderly, and other nutritional claims appear to be dubious also. Antibodies to phosphatidylserine are formed in some disease states, including thrombosis and recurrent spontaneous pregnancy loss. The rare genetic disease Lenz-Majewski syndrome is caused by a mutation in the phosphatidylserine synthase I gene that greatly increases the activity of the enzyme while preventing feedback inhibition, and abnormal metabolism of phosphatidylserine has been implicated in other diseases.

In yeasts such as *Candida albicans*, phosphatidylserine and the enzyme phosphatidylserine decarboxylase, which generates phosphatidylethanolamine, are both essential for the virulence of the organism towards a host species.

21.3.5.4: LYSOPHOSPHATIDYLSERINE

Figure 21.3.30 shows the structure of lysophosphatidylserine



lysophosphatidylserine

Figure 21.3.30 lysophosphatidylserine

Lysophosphatidylserine, i.e., with a fatty acid in one position only, is known to be a mediator of a number of biological processes, especially in the context of the immune system in animal tissues. It has been found in the thymus, peripheral lymphoid tissues, central nervous system, and colon, but is barely detectable in plasma. Deacylation of the diacyl lipid by phospholipases is the primary source. For example, a secreted isoform that is phosphatidylserine-specific (PLA1A) removes the *sn*-1 acyl group of phosphatidylserine to generate *sn*-2-lysophosphatidylserine containing unsaturated fatty acids, and this is upregulated greatly by various inflammatory stimuli. This extracellular enzyme utilizes phosphatidylserine exposed on the cell membrane as a substrate, although other phospholipases may operate intracellularly and produce *sn*-1-lysophosphatidylserine. In addition, platelets in some species (not significantly in humans) secrete a phospholipase A_2 group IIA (ABHD16A), which generates saturated *sn*-1-lysophosphatidylserine (and other lysophospholipids).

Lysophosphatidylserine has been detected after injury to animal tissues (tumor growth, graft rejection, burns), and it may have a similar function to **lysophosphatidic acid** in cell signaling, for example in regulating calcium flux and stimulating immune cells through G protein-coupled receptors of which three (GPR34, P2Y10 and GPR174, LPS1-3) have been detected in mice and humans. For example, GPR174 mediates the suppression of T-cell proliferation induced *in vitro* by lysophosphatidylserine. When cells are damaged, lysophosphatidylserine can be generated by a reaction dependent on the activation of the NADPH oxidase. It can diffuse and transmit the information to other cells,

especially mast cells, and it is produced to enhance the clearance of activated and dying neutrophils. It thus has a role in the resolution of inflammation. One specific molecular species, i.e., 1-(11*Z*-eicosenoyl)-glycero-3-phosphoserine, is reported to be a true agonist of the Toll-like receptor 2/6 heterodimer of importance to the immune response to pathogens; both its polar head group and the length of the acyl chain are required for this activity. On the other hand, *sn*-2-lysophosphatidylserine has proinflammatory reactions in that it augments mast cell degranulation and mast cell-dependent anaphylactic shock; most other lysophospholipids have no such activity.

Deregulated lysophosphatidylserine metabolism has been linked to certain cancers, cardio-metabolic disorders, night blindness, and the human genetic neurological disorder PHARC. High serum levels of PLA1A are associated with such autoimmune disorders as Graves' disease and systemic lupus erythematosus, and there is increased expression of the enzyme in metastatic melanomas. It is necessary for the assembly of the hepatitis C virus, and it can play a role in the antivirus innate immune response. In Schistosome infections, lysophosphatidylserine from the parasite is believed to be a key activator molecule in the host.

Negatively charged lysophosphatidylserine species tend to organize in non-bilayer structures and are believed to facilitate the folding of certain membrane proteins *in situ* better than bilayer-forming lipids.

21.3.6: PHOSPHATIDYLINOSITOL AND RELATED PHOSPHOINOSITIDES

Although it had long been recognized that phosphatidylinositol or 1,2-diacyl-*sn*-glycero-3-phospho-(1'-*myo*-inositol) was a key membrane constituent, it was initially something of a surprise when the manifold biological activities of this lipid, and then of the derived phosphatidylinositol phosphates and their hydrolysis products, were discovered in animals, plants, and microorganisms. Many years after the initial discoveries in the 1950s, these lipids continue to be a major focus for research efforts around the world with considerable relevance to human health. Phosphatidylinositol and its various metabolites and relevant enzymes can be located and function within different membrane regions in cells, and they form part of what have been termed phosphoinositide and phosphatidylinositol cycles, their versatility stemming from the inositol head group, a six-carbon the hexahydroxy ring, which can be reversibly phosphorylated on the 3, 4 and 5 positions. In addition to their structural role in membranes, these lipids are intimately involved in innumerable aspects of membrane trafficking and signaling in eukaryotic cells, functions that are essential to cell growth and metabolism. Only a brief overview of such a highly complex topic is possible here. **Glycosyl-phosphatidylinositol (GPI)** is a related lipid that serves as an anchor for proteins.

21.3.6.1: PHOSPHATIDYLINOSITOL

Structure and Occurrence: Phosphatidylinositol is an important lipid, both as a membrane constituent and as a participant in essential metabolic processes in all plants and animals, both directly and via a number of its metabolites. It is an acidic (anionic) phospholipid that in essence consists of a phosphatidic acid backbone, linked via the phosphate group to inositol (hexahydroxycyclohexane). In most organisms, the stereochemical form of the last is *myo*-D-inositol (with one axial hydroxyl in position 2 with the remainder equatorial, i.e. a chair-like structure), although other forms (*scyllo*- and *chiro*-) have been found on occasion in plants. The 1-stearoyl,2-arachidonoyl molecular species, which is of considerable biological importance in animals, is illustrated.

Figure 21.3.31 shows the structure of phosphatidylinositol.

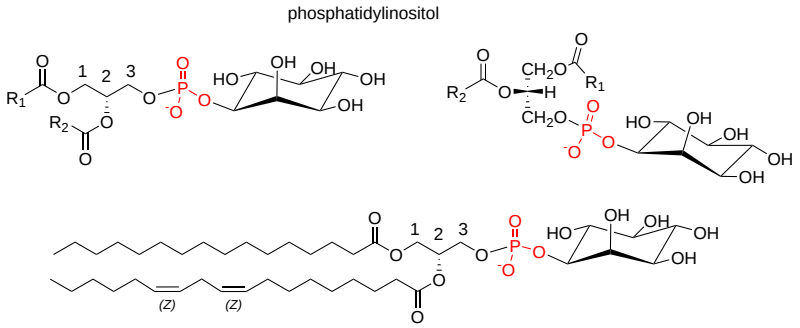


Figure 21.3.31: Phosphatidylinositol

Phosphatidylinositol is especially abundant in brain tissue, where it can amount to 10% of the phospholipids, but it is present in all tissues, cell types, and membranes at relatively low levels in comparison to many other phospholipids. In rat liver, it amounts to 1.7 micromoles/g., i.e. less than phosphatidylcholine, phosphatidylethanolamine, and phosphatidylserine. Under normal conditions, it is present entirely in the inner leaflet of the erythrocyte membrane and of the plasma membrane in nucleated cells. Phosphatidylinositol *per se* is rarely found in prokaryotes other than the *Actinomycetales*, although the thermophilic α-proteobacterium *Rhodothermus marinus* contains dialkylether glycerophosphoinositides.

The fatty acid composition of phosphatidylinositol is rather distinctive as shown in Table 21.3.6. Thus, in almost all animal tissues, the characteristic feature is a high content of stearic and arachidonic acids. All the stearic acid is linked to position *sn*-1 and all the arachidonic acid to position *sn*-2, and as much as 78% of the total lipid may consist of the single molecular species *sn*-1-stearoyl-*sn*-2-arachidonoyl-

glycerophosphorylinositol (see Table 21.3.7 below). Although 1-alkyl- and alkenyl- forms of phosphatidylinositol are known, they tend to be much less abundant than the diacyl form. In plant phosphatidylinositol, e.g. *Arabidopsis thaliana* as listed, palmitic acid is the main saturated fatty acid in position *sn*-1, while linoleic and linolenic acids are the main unsaturated components in position *sn*-2. Similarly in yeast, palmitic acid is in position *sn*-1 with oleic and palmitoleic acids in position *sn*-2 predominantly; the Amoebozoa have a C_{16} alkyl group in position *sn*-1 and *cis*-vaccenic acid in position *sn*-2.

Table 21.3.6: **Fatty acid composition of phosphatidylinositol (wt % of the total) in animal and plant tissues.**

Tissue	Fatty acids									
	16:0	18:0	18:1	18:2	18:3	20:3	20:4	22:3	22:5	22:6

Biosynthesis: The basic mechanism for the biosynthesis of phosphatidylinositol and phosphatidylglycerol is sometimes termed a branch point in phospholipid synthesis, as phosphatidylcholine and phosphatidylethanolamine are produced by a somewhat different route.

Phosphatidylinositol is found in all eukaryotes, which are in general able to synthesize inositol *de novo* via glucose-6-phosphate. As with **phosphatidylglycerol** (and hence cardiolipin), phosphatidylinositol is formed biosynthetically from **phosphatidic acid** via the intermediate **cytidine diphosphate diacylglycerol**, which is produced by the action of a CDP-diacylglycerol synthase believed to be the rate-limiting enzyme in phosphatidylinositol biosynthesis. Then, the enzyme CDP-diacylglycerol inositol phosphatidyltransferase ('phosphatidylinositol synthase' or 'PIS') catalyzes a reaction with *myo*-inositol to produce phosphatidylinositol.

Figure 21.3.32 shows the synthesis of phosphatidylinositol in eukaryotes.

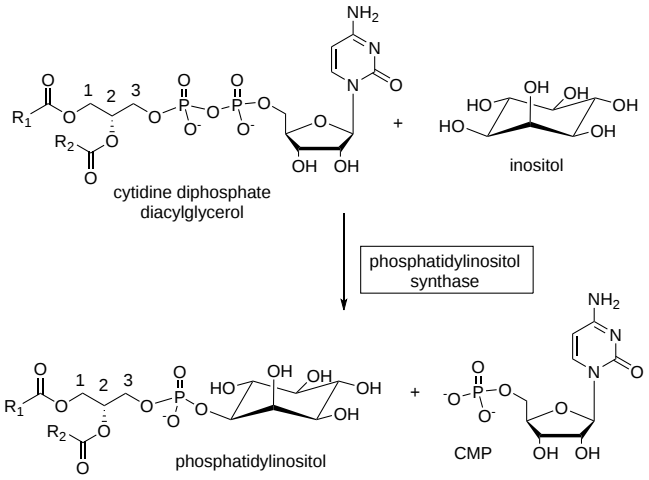

Figure 21.3.32 Synthesis of phosphatidylinositol in eukaryotes

Only isoform of PIS exists in mammals and it is located in the endoplasmic reticulum, in part in a subcompartment of this associated with mitochondria (mitochondria-associated membranes - MAM) and in mitochondria *per se*. Indeed, it is reported that PIS is present in a mobile ER-derived subcompartment that makes transient contacts with other organelles, including the plasma membrane, and facilitates the distribution of phosphatidylinositol to other subcellular compartments. The other product of the reaction is cytidine monophosphate (CMP). As PIS catalyzes the reverse reaction also, the rate of phosphatidylinositol synthesis is determined by the relative concentrations of the precursors and product, and the latter must be transported away from the site of synthesis for the reaction to continue. Much of the phosphatidylinositol is delivered to other membranes by vesicular transport, but a family of soluble phosphatidylinositol transfer proteins (PITPα, PITPβ and PITPNC1) provides phosphatidylinositol from the ER to kinases for phosphorylation (see below).

Molecular species specificity: The phosphatidylinositol synthase *per se* does not exhibit the fatty acyl specificity observed in the final product, but earlier in the biosynthetic process 1-stearoyl-2-arachidonoyl species of diacyl-*sn*-glycerols are converted preferentially into **phosphatidic acid** by the epsilon isoform of **diacylglycerol kinase** (DGKε), anchored to the membrane via its N-terminal hydrophobic helix segment; ATP is the phosphate donor. In addition, one of the CDP-diacylglycerol synthases (CDS2) has similar specificity in the generation of the immediate precursor CDP-diacylglycerols from phosphatidic acid, while some specificity may be introduced via lysophosphatidylinositol, formed as a by-product of eicosanoid formation (see below) or as an intermediate as part of the normal cycle of

deacylation-acylation of phosphatidylinositol in tissues in which the fatty acid composition is remodeled to give the final distinctive composition. A membrane-bound *O*-acyltransferase (MBOAT7 or LPIAT1) specific for position *sn*-2 of lysophosphatidylinositol with a marked preference for arachidonoyl-CoA is ubiquitously expressed in animal tissues, and this may be one means by which free arachidonic acid and eicosanoid levels are regulated.

In macrophages subjected to inflammatory stimuli, phosphatidylinositol containing two molecules of arachidonate is produced by remodeling reactions, and there is evidence that it is a novel bioactive phospholipid regulating innate immune responses in these cells. Further specificity may be introduced by lysocardiolipin acyltransferase (LYCAT; also known as LCLAT1 or ALCAT1), which exhibits a preference for lysophosphatidylinositol and lysophosphatidylglycerol over other phospholipids *in vitro*, and incorporates 18:0 rather than shorter chain fatty acids into position *sn*-1 of phosphatidylinositol and other phosphoinositides, especially phosphatidylinositol-4,5-bisphosphate and phosphatidylinositol-3-phosphate; this enzyme may be located adjacent to the phosphatidylinositol synthase in the endoplasmic reticulum. Some of the phosphatidylinositol in membranes is derived from recycling of polyphosphoinositides via the phosphatidylinositol cycle, and this could influence the molecular species composition (see below).

The highly specific distribution of fatty acids on the glycerol moiety of phosphatidylinositol breaks down in some cancer cells, especially those with a mutation on the transcription factor p53 gene, which is one of the most highly mutated genes in cancers.

Plants and bacteria: In contrast to animals, **plants** have two phosphatidylinositol synthase isoforms, PIS1 and PIS2, which display specificities for particular species of the CDP-diacylglycerol substrate. PIS1 generates phosphatidylinositol with saturated or monounsaturated fatty acids preferentially, while PIS2 generates polyunsaturated species, the two forms possibly having different functions. In protozoan parasites, such as *Trypanosoma brucei*, the active site of phosphatidylinositol synthase may be the lumen of the endoplasmic reticulum and Golgi. There is evidence for two distinct pools of product in this organism, the bulk membrane form derived from inositol imported from the environment, and a second used for the synthesis of GPI anchors, which uses *myo*-inositol synthesized *de novo*. In yeasts, some biosynthesis may occur on the cytosolic side of the plasma membrane.

The enzyme is a transmembrane protein.and use CDP-diacylglycerol as a donor and either inositol (eukaryotes) or inositol phosphate (prokaryotes) as the acceptor alcohol. The structure of a similar enzyme, phosphatidylinositol-phosphate synthase from *Renibacterium salmoninarum*, is shown in Figure 21.3.33.

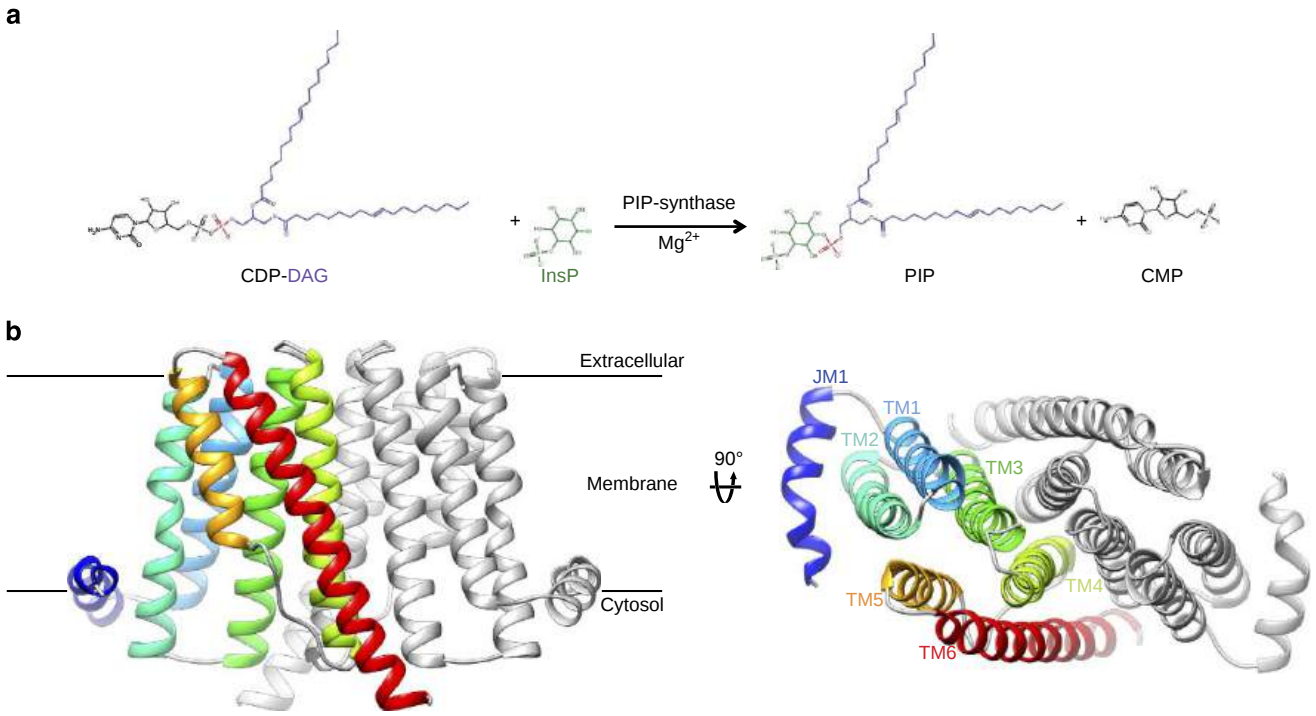

Figure 21.3.33: Structure and reaction of phosphatidylinositol-phosphate synthase from *Renibacterium salmoninarum.* Clarke, O., Tomasek, D., Jorge, C. *et al.* Structural basis for phosphatidylinositol-phosphate biosynthesis. *Nat Commun* **6,** 8505 (2015). https://doi.org/10.1038/ncomms9505. Panel A shows the reaction for PIP synthases which involves the transfer of a diacylglycerol-substituted phosphate group (purple/red) from the CDP-DAG donor to the inositol phosphate acceptor (green), generating PIP and CMP. Panel B shows the structure of the *Rs*PIPS-Δ6N homodimer in ribbon representation viewed from two orthogonal orientations (in the plane of the membrane on the left; towards the cytosol

down the dimer axis on the right). One protomer is colored grey, and the helices of the other are depicted in spectral coloring, from blue (JM1) to red (TM6). The *Af*2299 extramembrane domain used to facilitate crystallization is not shown here.

Figure 21.3.34 shows a large cavity that contains the active site of RsPIPS.

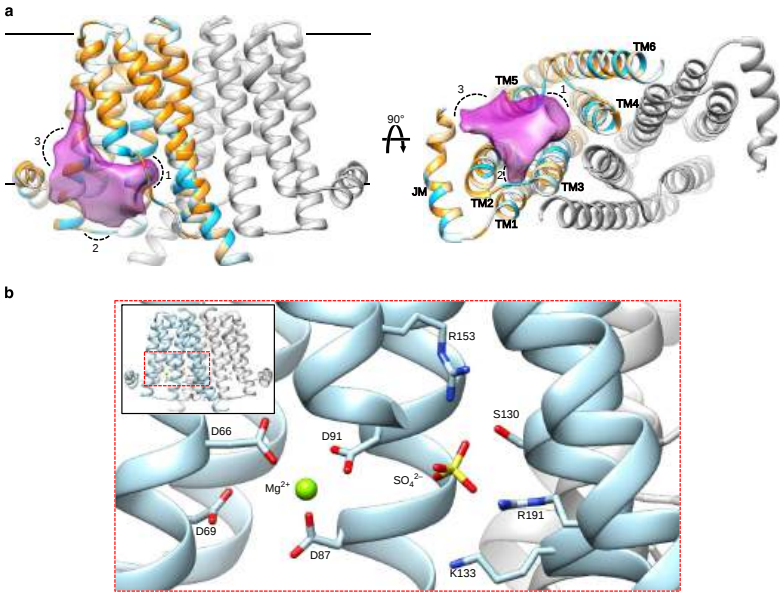

Figure 21.3.34 Large cavity containing the active site of RsPIPS . Clarke, O., Tomasek, D., Jorge, C. *et al.* ibid.

Panel (**a**) shows the structure of *Rs*PIPS-Δ6N is shown in ribbon representation, with one protomer colored grey and the other colored by the Kyte–Doolitle hydrophobicity scale, from −4.5 (most polar, light blue) to 4.5 (most hydrophobic, orange). Two orthogonal representations are shown, on the left is a view in the plane of the membrane, and on the right is a view from the cytosol along the dimer axis. A transparent purple surface delineates the borders of the interfacial cavity, which contains three subregions as follows: 1, the inositol phosphate acceptor-binding pocket; 2, the nucleotide-binding pocket between TM2 and TM3; and 3, a hydrophobic groove between TM2 and JM1. (**b**) Detail of the active site viewed in the plane of the membrane, with side chains that contact the bound Mg^{2+} and SO_4^{2-} ions labeled and depicted in stick representation.

A nucleotide-binding site formed from transmembrane segments 1, 2, and 3 contains 8 conserved residues (D_1xx$D_2$$G_1$xxAR… G_2xxxD_3xxxD_4). The first 3 aspartic acid side chains coordinate a metal ion while the 4th is likely a general base in catalysis.

Figure 21.3.35 shows an interactive iCn3D model of the phosphatidylinositolphosphate (PIP) synthase with bound CDP-DAG from Renibacterium salmoninarum (5D92).

The two identical subunits of the homodimer are shown in gray and plum. The two CDP-DAGs are shown in spacefill and CPK colors

Function: In addition to functioning as negatively charged building blocks of membranes, the inositol phospholipids (including the phosphatidylinositol phosphates or 'polyphosphoinositides' discussed below) have crucial roles in the interfacial binding of proteins and in the regulation of protein activity at the cell interface. As phosphoinositides are polyanionic, they can be very effective in non-specific

electrostatic interactions with proteins. However, they are especially efficient in specific binding to so-called 'PH' domains of cellular proteins. At least three phosphatidylinositol molecules are present in the crystal structure of human erythrocyte glycophorin, for example, and they are believed to influence binding to other proteins via their head groups. The lipid is a structural component of yeast cytochrome bc_1.

In animal tissues, phosphatidylinositol is the primary source of the arachidonic acid required for the biosynthesis of **eicosanoids**, including prostaglandins, via the action of the enzyme phospholipase A_2, which releases the fatty acids from position *sn*-2. The reverse reaction also occurs.

Figure 21.3.36s shows the generation of arachidonic acid and eicosanoids from PI by means of phospholipase A2

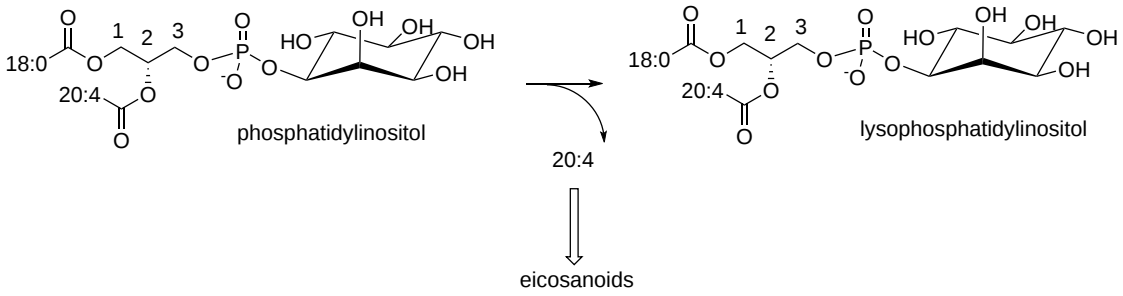

Figure 21.3.36: Generation of arachidonic acid and eicosanoids from PI by means of phospholipase A2.

Similarly, phosphatidylinositol and the phosphatidylinositol phosphates are the main sources of diacylglycerols that serve as signaling molecules in animal and plant cells, via the action of a family of highly specific enzymes collectively known as phospholipase C. In brief, diacylglycerols regulate the activity of a group of at least a dozen related enzymes known as protein kinase C, which in turn control many key cellular functions, including differentiation, proliferation, metabolism, and apoptosis. Indeed, the biological actions of the various components released have been the subject of intensive study over many years. **2-Arachidonoylglycerol**, an endogenous cannabinoid receptor ligand, may also be a product of phosphatidylinositol catabolism.

21.3.6.2: PHOSPHATIDYLINOSITOL PHOSPHATES (POLYPHOSPHOINOSITIDES) IN ANIMALS

Structure and Occurrence: The pioneering work of Mable and Lowell Hokin in the 1950s led to the discovery that phosphatidylinositol was converted to polyphosphoinositides with important signaling and other functional activities, including cell communication via signal transduction, cell survival and proliferation, membrane trafficking and modulation of gene expression. Phosphatidylinositol is now known to be phosphorylated by a number of substrate-selective kinases that place the phosphate moiety on positions 3, 4, and 5 of the inositol ring with the balance among them maintained by distinct phosphatases and phospholipases. Seven different isomers are known (mono-, bis-, and tris-phosphorylated), which are produced in a tightly coordinated manner, and all of these have characteristic biological activities. They each turn over much more rapidly than the parent phosphatidylinositol molecule. In addition, there can be an array of molecular species of each of these isomers that differ in the nature of the fatty acyl groups. Although the most significant in quantitative and possibly biological terms were long thought to be **phosphatidylinositol 4-phosphate** and **phosphatidylinositol 4,5-bisphosphate**, it is now recognized that **phosphatidylinositol 3-phosphate** and its metabolites are as important biologically at least.

Figure 21.3.37 shows the structures of phosphatidylinositol phosphates

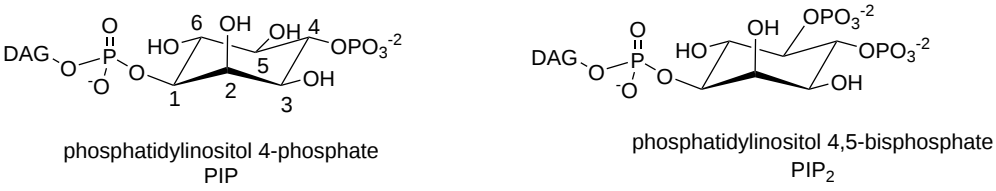

Figure 21.3.37: Structures of phosphatidylinositol phosphates in animals

These lipids are usually present at low levels only in tissues, typically at about 0.5 to 1% of the total lipids of the inner leaflet of the plasma membrane, so they are unlikely to have an appreciable structural role. On the other hand, static measurements of lipids that turn over very rapidly do not provide a meaningful assessment of their cellular functions. The positional distributions of fatty acids in the phosphatidylinositol, phosphatidylinositol 4-phosphate, and phosphatidylinositol 4,5-bisphosphate of ox brain are listed in Table 21.3.7. In each the saturated fatty acids are concentrated in position *sn*-1 and polyunsaturated, especially arachidonate, in position *sn*-2; there are few differences among the three lipids in this instance.

Table 21.3.7: **Distribution of fatty acids (mol % of the total) in positions *sn*-1 and *sn*-2 in phosphatidylinositol (PI) and the phosphatidylinositol mono- and diphosphates of ox brain.**

Fatty acids	PI		PI monophosphate		PI diphosphate	
	sn-1	*sn*-2	*sn*-1	*sn*-2	*sn*-1	*sn*-2

Biosynthesis: Phosphatidylinositol *per se* is the ultimate precursor of all phosphoinositides, the head groups of which have different charges and structures that impact directly on membrane properties and via metabolic interactions can function as chemical switches. The individual phosphoinositides are maintained at steady state levels in membranes by a continuous and sequential series of phosphorylation and dephosphorylation reactions by specific kinases, phosphatases, and phospholipase C enzymes, which are regulated and/or relocated through cell surface receptors for extracellular ligands, the phosphoinositide cycle. While this has been termed a 'futile cycle', which can consume a significant proportion of cellular ATP production, it is only part of a wider pattern of reactions - the **phosphatidylinositol cycle** (see below). Controlled synthesis of these different phosphoinositides occurs in different intracellular compartments for distinct and independently regulated functions with spacially distinct target enzymes or receptors. In mammals, the complexity is such that 18 phosphoinositide inter-conversion reactions have been identified to date, and these are mediated by at least 20 phosphoinositide kinases and 34 phosphoinositide phosphatases that span 8 and 10 classes, respectively; some have yet to be characterized. Most of these enzymes are conserved across all of the eukaryota, and each has distinct functions and specificities that cannot be replaced by the activity of related isoforms.

As a generality, most mono-phosphorylations occur in endomembranes, such as the endosomes and the Golgi network, while second and third phosphorylations occur primarily at the plasma membrane, and this is reflected in the lipid composition of each membrane. While these enzymes are believed to work independently and sequentially to produce a specific product, there remains a possibility that some participate in protein complexes to coordinate their activities. Specific transporters, especially the 'Nir2' protein, facilitate the exchange of phosphoinositides between membranes. It should be noted that there are links to the metabolism of **phosphatidylcholine**, which can be hydrolyzed by phospholipase D to phosphatidic acid, an important activator of key kinases. Figure 21.3.38 shows an overview of polyphosphoinositide metabolism in animal tissues.

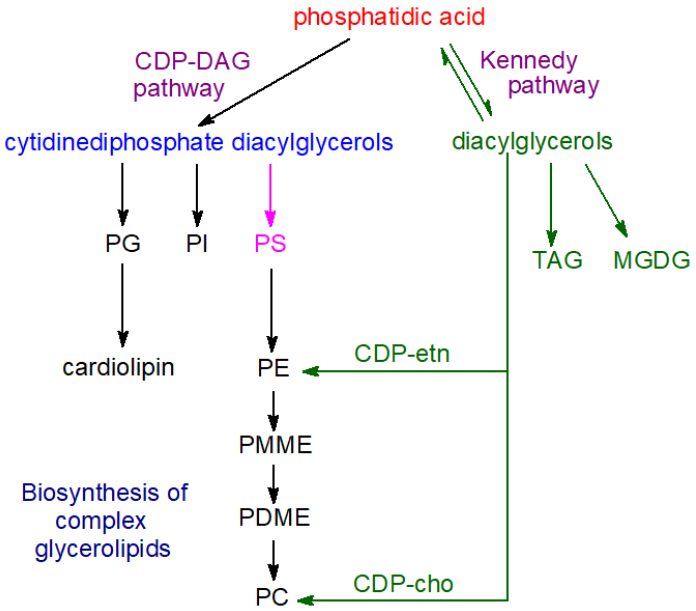

Figure 21.3.38 Overview of polyphosphoinositide metabolism in animal tissues

Thus as an example, phosphatidylinositol 4-phosphate (PI(4)P) is produced by the action of a phosphatidylinositol 4-kinase (PI4K) in the Golgi, and is in turn phosphorylated by a phosphatidylinositol phosphate 5-kinase (PIPK I) to form phosphatidylinositol 4,5-bisphosphate (PI(4,5)P) at the plasma membrane, although this can also be formed by phosphorylation of phosphatidylinositol 5-phosphate by a specific 4-kinase (PIPK II). Four isoforms of PI4K in two structural families are known that each operate in different subcellular membrane compartments to produce phosphatidylinositol 4-phosphate for particular signaling functions. Some selectivity in the formation of molecular species or remodeling may occur to further enrich the arachidonic acid content.

Subsequently, it was discovered that phosphatidylinositol is also phosphorylated by a 3-kinase (PI3K III or the VPS 34 complex) to produce phosphatidylinositol 3-phosphate (PI(3)P) in the early endosomes. In fact, three phosphatidylinositol 3-kinases families (eight isoforms) have been described, each with distinct substrate specificities. A second phosphoinositide signaling pathway involves activation of two of these 3-kinases, stimulated by growth factors and hormones, which phosphorylate phosphatidylinositol 4,5-bisphosphate (by PI3K I - four isoforms) and phosphatidylinositol 4-phosphate (by PI3K II - three isoforms) to produce phosphatidylinositol 3,4,5-trisphosphate (PI(3,4,5)P) and phosphatidylinositol 3,4-bisphosphate (PI(3,4)P), respectively. While phosphatidylinositol 3-phosphate and other 3-phosphorylated metabolites amount to only about 0.5% of the total phosphoinositides in resting mammalian cells, they are now recognized to be of profound importance for cellular metabolism.

In addition to the activity of kinases, the amounts of these various metabolites are regulated by the activities of specific phosphoinositide phosphatases, which are highly conserved in eukaryotes and dephosphorylate phosphoinositides at the 3, 4, and 5 positions of the inositol ring. For example, so-called ‘SHIP’ phosphatases convert phosphatidylinositol 4,5-bisphosphate back to phosphatidylinositol 4-phosphate by hydrolysis of the 5-phosphate group. 3-Phosphorylated phosphoinositides are only degraded by phosphatases, especially those of the PTEN family, and not by phospholipase C (see below).

The various organelles in cells have membranes with distinct functions and molecular compositions. Yet, all the phosphatidylinositol precursor is formed primarily at the endoplasmic reticulum, and the different membrane lipids must be transported between membrane sites via specific trafficking processes/proteins. There is selective recruitment of effector proteins to particular membranes by binding only to a single type of phosphoinositide, and this is followed by interactions between the phosphoinositide-binding proteins and various enzymes to channel phosphoinositide production to the required biological outcomes and to regulate signaling. For example, much of the phosphatidylinositol 4-phosphate and phosphatidylinositol 4,5-bisphosphate involved in signaling is believed to be formed at contact sites between the endoplasmic reticulum and plasma membrane.

A concept has emerged in which each phosphoinositide has its own role – **the ‘lipid code’ hypothesis**, in which defined lipids act as labels for each cellular membrane to organize cells into dynamic and responsive membrane-bound compartments and maintain the orderly flow required for the complexities of membrane trafficking and spatio-temporal signaling reactions. Thus, phosphatidylinositol 4-phosphate, phosphatidylinositol 4,5-bisphosphate, phosphatidylinositol 3-phosphate and phosphatidylinositol 3,5-bisphosphate are found mainly on the Golgi, plasma membrane, early endosomes, and late endocytic organelles, respectively, where they are sometimes regarded as landmarks for these compartments. For example, phosphatidylinositol 4,5-bisphosphate is present throughout the plasma membrane and is considered a general marker for this, while phosphatidylinositol 3,4,5-triphosphate, is a characteristic component of the basolateral region of this membrane in a polarized cell but is absent from the apical part. On the other hand, it should be noted that this map of phosphoinositides to specific organelles is derived from their steady state distributions, but the highly dynamic generation and consumption of different phosphoinositides in response to different stimuli in the various sub-cellular compartments in living cells by the action of kinases and phosphatases together with lipase reactions, may lead to the formation of transient pools of distinct molecular forms. There must be a continuous replenishment of the precursors by new synthesis.

Function: The distinctive subcellular location of the different phosphoinositide species, together with the rapid and reversible nature of phosphorylation, gives them a central and general position in the fields of cell signaling cascades and intracellular membrane trafficking. The precise locations of particular phosphoinositides are factors that contribute a specific identity to each organelle and sometimes even to each face of an organelle, such as the *cis* and *trans* faces of the Golgi apparatus, and this enables directional transport of cellular constituents between organelles or membranes. Phosphoinositides are able to achieve signaling effects directly by binding to specific cytosolic domains of membrane proteins via their polar head groups, thereby triggering downstream signaling cascades, often in conjunction with an acidic phospholipid, such as phosphatidylserine or phosphatidic acid at an adjacent-binding site. The term 'lipidon' has been coined to describe the unique collection of co-located lipids that distinguish biological membrane nano-environments and which provide the context for PI recognition *in vivo*. In this way, they can regulate the function of innumerable proteins integral to membranes, for example by relocating a protein from one area of the cell to another, e.g., from the cytosol to the inner leaflet of the plasma membrane, or they can attract cytoskeletal and signaling components to the membrane. Amongst the proteins that bind to phosphoinositides in this way are phospholipases, protein kinases, regulators of membrane trafficking, and cytoskeletal, scaffold, and ion channel proteins. Dysregulation of phosphoinositide metabolism and signaling is a factor in a number of diseases, including cancer.

Binding usually involves electrostatic interactions with the negative charges of the phosphate groups on the inositol ring with characteristic clusters of basic amino acid residues in proteins to recruit them to intracellular membranes, while often leading to specific folding and thence increased activity of unstructured peptides. At least 70 distinct types of binding sites for phosphoinositides have been identified in

proteins. In particular, a binding region termed the pleckstrin homology (PH) domain, consisting of ~100 amino acids, is the most abundant lipid-binding domain with more than 225 examples identified, and this can exhibit great specificity for particular polyphosphoinositides, often binding simultaneously with other proteins. While the interaction is driven by non-specific electrostatic interactions initially, it is followed by specific binding to increase the membrane residence time. The phox homology (PX) domain family with 49 members in humans is unique in that it can recognize all seven phosphoinositide forms, while proteins with a FYVE domain, which is enriched in cysteine and is stabilized by two zinc atoms, bind specifically to phosphatidylinositol 3-phosphate (PI(3)P). The protein kinase C family have C1 or C2 domains which recognize phosphatidylinositol 4,5-bisphosphate and phosphatidylinositol 3,4,5-trisphosphate specifically (and sometimes other lipids). The distinctive phosphoinositide composition of membranes in different organelles adds strength and specificity to the interactions by cooperative binding with other membrane proteins.

Phosphatidylinositol 3-phosphate and the other phosphatidylinositol monophosphates are present in cells at low levels only, although their levels do not appear to fluctuate greatly. PI(3)P has been implicated in membrane trafficking through its interactions with certain proteins in endosomes. In particular, it plays a pivotal role in the initiation of autophagy, i.e. the controlled internal degradation and turnover of cellular constituents, while PI(3,5)P_2 is important in the autophagosome–lysosome fusion step and in the subsequent acidification of this organelle. After sorting of the lysosomal contents, components of the internalized cargo are recycled to the plasma membrane and PI(3)P is dephosphorylated to phosphatidylinositol by a specific phosphatase, and this is in turn phosphorylated to PI(4)P. Thus the processes of internalization, sorting, and trafficking of membrane proteins depend on the interconversion of phosphoinositide species by coordinated phosphorylation-dephosphorylation reactions.

In general, PI(3)P controls cellular processes by recruiting effector proteins through low to moderate affinity interaction with specific PI(3)P binding domains. A protein designated Akt (protein kinase B) is recognized as a direct effector of the PI3K signaling cascade with receptor tyrosine kinases as the main upstream activators, for example, but it is now known that every phosphatidylinositol phosphate has a specific set of effector proteins that are recruited to target membranes or are allosterically regulated by the specific receptors; each function may require a different effector. A further function of PI(3)P is in the regulation of the final stage of cell division (cytokinesis), and the lipid is known to accumulate where cells divide. As the class I PI3K isoforms especially have been implicated in the etiology and maintenance of various diseases and metabolic disorders, including cancer, inflammation, and autoimmunity, drug companies are actively pursuing the development of inhibitors. In particular, they mediate insulin-independent glucose transport and many of the physiological actions of insulin. In relation to lung cancer especially, RAS proteins, which are key signaling switches essential for the control of proliferation, differentiation, and survival of eukaryotic cells, regulate the activity of type I phosphatidylinositol 3-kinase (PI3K); this is essential for tumor initiation and maintenance.

Phosphatidylinositol 4-phosphate is the precursor for the 4,5-bisphosphate, but it binds to a protein on the cytoskeleton of the cell and has its own characteristic functions. It is the most widely distributed of the phosphoinositides, and in addition to the Golgi and the plasma membrane, it is present in late endosomes, lysosomes, secretory vesicles, and autophagosomes. As a part of protein-lipid complexes, it is believed to have a role in essential nuclear processes. In yeast, it has a function in the anterograde transport from the trans-Golgi and the retrograde transport from the Golgi to the endoplasmic reticulum; it is also necessary for the formation of secretory vesicles in the Golgi that are targeted to the plasma membrane. Some of that in the plasma membrane is exchanged for phosphatidylserine by the action of specific transport proteins at junctions with the endoplasmic reticulum.

In addition, PI(4)P is essential for the structure and function of the late endosomes, where it is required for the recruitment of specific proteins that control cargo exit (following hydrolysis of PI(3)P). Some of these participate in vesicle formation, while others like the oxysterol binding protein (OSBP) are involved in lipid transfer. After initiation of the process by PI(3)P, PI(4)P, PI(4,5)P_2 and their binding proteins are modulators of autophagy at most stages of the process. PI(4)P has been called the 'fuel' that drives cholesterol transport, as its hydrolysis provides the energy that enables the establishment of active sterol concentration gradients across membrane-bound compartments with the aid of OSBP, which is a key regulator of cholesterol, oxysterol, and PI(4)P concentrations in membranes. In the plasma membrane, PI(4)P can support the functions of ion channels, and it contributes to the anchoring of proteins with polybasic domains, although it is not utilized for the synthesis of PI(4,5)P_2 in this membrane. On the other hand, PI(4)P derived from PI(4,5)P_2 in the membrane of primary cilia in the retina is important for vision. PI(4)P has an important influence on the progression of many diseases, especially virus replication, cancer, and various inflammatory diseases, and inhibitors of PI4-kinase are under study for their therapeutic potential.

While the biological properties of **phosphatidylinositol 5-phosphate** have taken longer to unravel, because of the difficulties of separation of this isomer, it is now apparent that it is involved in osmoregulation both in plants and animals. It also has signaling functions, and although it is the least abundant phosphatidylinositol monophosphate, it is involved in signaling at the nucleus and in the cytoplasm, modulating cellular responses to various stresses, hormones and growth factors. In the endosomes, it is a regulator of protein sorting.

Although **phosphatidylinositol 4,5-bisphosphate** (PI(4,5)P_2) is found primarily in the inner leaflet of the plasma membrane, where it may define membrane identity in eukaryotic cells, it is also present in endosomes, the endoplasmic reticulum and nucleus. It is an essential precursor of lipid second messengers such as diacylglycerols with vital signaling functions that operate through plasma membrane G-protein coupled receptors, receptor tyrosine kinases, and immune receptors. Because of its large head group and multivalent negative charge, PI(4,5)P_2 has been described as an "electrostatic beacon" that interacts in various ways with membrane proteins, other lipids and

cellular cations. In consequence and in spite of its relatively low concentration, it is a key regulator of innumerable events at the plasma membrane, including cell adhesion and motility, vesicle endocytosis and exocytosis, and the function of ion channels, especially those for potassium, calcium, and sodium. With ion channels, for example, it appears to be an obligatory factor, increasing their activity by activating key proteins, while its hydrolysis by phospholipase C reduces such activity.

$PI(4,5)P_2$ interacts with cationic residues of a large array of proteins in concert with cholesterol to form localized membrane domains that are distinct from the sphingolipid-enriched **rafts**. Indeed, it has a much higher concentration than other phosphoinositide species in cells, although most of this is in effect sequestered by binding proteins. Also, phosphatidylinositol 4,5-bisphosphate and its diacylglycerol metabolites are important for vesicle formation in membranes. For example, a major pathway in cells for the internalization of cell surface proteins such as transferrin is the clathrin-coated vesicle pathway. $PI(4,5)P_2$ is essential to this process in that it binds to the machinery involved in the membrane, increasing the number of clathrin-coated pits and permitting the internalization of proteins. It has a related function in **caveolae**, where it is concentrated at the rim.

Through its attachment to the apical plasma membrane, phosphatidylinositol 4,5-bisphosphate is intimately involved in the development of the actin cytoskeleton and thereby controls cell shape, motility, and many other processes. In particular, it binds with high specificity to effectors such as vinculin, a membrane-cytoskeletal protein that is involved in the linkage of integrin adhesion molecules to the actin cytoskeleton. Dysregulation of this function has been implicated in the migration and metastasis of tumor cells. In yeasts, it appears that the presence of stearic acid in position *sn*-1 is essential for this function. In the cell nucleus, this lipid is believed to be involved in maintaining chromatin, the complex combination of DNA, RNA, and protein that makes up chromosomes in a transcriptionally active conformation, as well as being a precursor for further signaling molecules. It has a role in gene transcription, and RNA processing, especially in the modulation of RNA polymerase activity, and in other nuclear processes.

Via its binding to specific proteins, the lipid is an essential component of the immune response of animal tissues to toxic bacterial **lipopolysaccharides**. It is also involved in the pathophysiology of the HIV virus via an interaction with the Tat protein secreted by infected cells.

$PI(4,5)P_2$ is the primary precursor of the endocannabinoid **2-arachidonoylglycerol** in neurons, and it is also an essential cofactor for phospholipase D and so affects the cellular production of **phosphatidic acid** with its specific signaling functions. By binding specifically to ceramide kinase, the enzyme responsible for the synthesis of **ceramide-1-phosphate**, it has an influence on sphingolipid metabolism. Like ceramide-1-phosphate, it binds to and activates the Ca^{2+}-dependent phospholipase A_2, which generates the arachidonate for eicosanoid production. One molecule of phosphatidylinositol 4,5-bisphosphate is bound to each subunit of the protein in the X-ray crystal structures of mammalian GIRK2 potassium channel, where it enables a conformational change that assists the transport function of the protein.

Perhaps, the best characterized of the phosphoinositide signaling functions results from the hydrolysis of phosphatidylinositol phosphates by phospholipase C isoforms, in this instance to produce ***sn*-1,2-diacylglycerols** and inositol 3,4,5-trisphosphate (see below), which act as second messengers. Only those polyunsaturated diacylglycerol species derived from $PI(4,5)P_2$ are able to bind and activate protein kinase C (α, ε, δ) isoforms both *in vitro* and *in vivo*. This lipid is doubly important as it binds strongly to these enzymes via a basic patch distal to a Ca^{2+} binding site, and this targets them selectively to the plasma membrane. Aberrant expression of phospholipase Cγ2 may be a factor in neurodegenerative diseases. Via the action of PI3 kinase, $PI(4,5)P_2$ is the precursor of $PI(3,4,5)P_3$ with its own distinctive signaling properties.

Phosphatidylinositol 3,4-bisphosphate can be produced by two routes and regulates a variety of cellular processes with relevance to health and disease that include B cell activation and autoantibody production, insulin sensitivity, neuronal dynamics, endocytosis, and cell migration. It is known to bind selectively to a number of proteins, and it acts as a secondary messenger by recruiting the protein kinases Akt (protein kinase B) and so may influence the cell cycle, cell survival, angiogenesis, and glucose metabolism. During endocytosis in the endolysosomal system, it is produced from $PI(4,5)P_2$ and controls the maturation of endocytic-coated pits. Its synthesis and turnover of are spatially segregated within the endocytic pathway. In epithelial cells, it is located on the apical membrane, i.e. facing the lumen, as opposed to the basolateral membranes, and it is believed to be is a determinant of the identity and function of the apical membrane.

Phosphatidylinositol 3,5-bisphosphate is present at low levels only in cells (0.04-0.1% of the total phosphatidylinositides) unless stimulated by growth factors, but it is important in membrane and protein trafficking, especially in the late endosomes in eukaryotes and in yeast vacuoles. For example, the conversion of PI(3)P to $PI(3,5)P_2$ promotes endosomal maturation and degradative sorting. It is involved in the mediation of signaling in response to stress and hormonal cues and in the control of ion transport in membranes, while genetic studies confirm that it is essential for healthy embryonic development, especially in the nervous system.

Phosphatidylinositol 3,4,5-trisphosphate ($PI(3,4,5)P_3$) is almost undetectable in quiescent cells, but its intracellular level rises very rapidly from synthesis at the plasma membrane in response to agonists such as extracellular growth factors and hormonal stimuli. By recruiting proteins with pleckstrin homology (PH) domains to the plasma membrane, it has been implicated in a variety of cellular functions that include growth, cell survival, proliferation, cytoskeletal rearrangement, intracellular vesicle trafficking, and cell metabolism. In particular, it is an important component of a signaling pathway in the cell nucleus. In epithelial cells, it is located on the basolateral membrane, i.e. facing adjacent cells, where it may be a determinant of the identity and function of this membrane. In contrast to phosphatidylinositol 3-phosphate, it opposes autophagy by binding to and activating the PH domain of Akt, so inducing cell proliferation. During feeding, various

physiological responses lead to the secretion of insulin, which stimulates the phosphorylation of phosphatidylinositol 4,5-bisphosphate to phosphatidylinositol 3,4,5-trisphosphate and triggers a signaling cascade that leads to the suppression of autophagy. When this pathway is impaired it has deleterious effects on insulin resistance associated with various metabolic diseases including obesity and diabetes. It has been implicated in tumor cell migration and metastasis. PI(3,4,5)P_3 is also present in the nucleus and nucleoli of cells where it is believed to have functions in RNA processing/splicing, cytokinesis, protein folding, and DNA repair. In complete contrast, like **phosphatidylserine**, it is reportedly transferred to the outer leaflet of the plasma membrane in aged or damaged cells as an 'eat-me' signal for phagocytes and apoptosis.

The human immune system utilizes neutrophils, which are highly mobile cells, to eliminate pathogens from infected tissue. The first step is to track and then pursue molecular signals, such as cytokines, emitted by pathogens. It has been established that two phospholipids operate in sequence to point the neutrophils in the correct direction. The first of these is phosphatidylinositol 3,4,5-trisphosphate, which binds to a specific protein DOCK2 and enables it to translocate to the plasma membrane. Then phosphatidic acid, generated by the action of phospholipase D on phosphatidylcholine, takes over and directs the DOCK2 to the leading edge of the plasma membrane. This causes the polymerization of actin within the cell and in effect reshapes the neutrophil and points it in the direction from which the pathogens signals are coming. On the other hand, *Mycobacterium tuberculosis* is able to subvert phosphoinositide signaling to arrest phagosome maturation by dephosphorylation of phosphatidylinositol 3-phosphate.

21.3.6.3: WATER-SOLUBLE INOSITOL PHOSPHATES

As mentioned briefly above, hydrolysis of phosphatidylinositol phosphates by calcium-dependent phospholipase C (or 'phosphoinositidase C') leads to the generation of ***sn*-1,2-diacylglycerols**, which act as second messengers in animal cells and are of enormous metabolic importance. There are many different enzymes of this type, but the activity of the phosphoinositide-specific phospholipase C constitutes an essential step in the inositide signaling pathways. The enzyme exists in six families consisting of at least 13 isoenzymes, all of which have conserved regions such as the plekstrin homology (PH) binding domain. Each one has a distinctive role and can have a characteristic cell distribution that is linked to a specific function. The activity of these enzymes is stimulated by signaling molecules such as G-protein coupled receptors, receptor tyrosine kinases, Ras-like GTPases, and calcium ions, thus linking the hydrolysis of phosphatidylinositol phosphates to a wide range of other cellular signals. As phospholipase C is a soluble protein located mainly in the cytosol, translocation to the plasma membrane is a crucial step in signal transduction. Regulation of these isoenzymes and the form PLCγ1 in particular is vital for health as they are associated with the activation or inhibition of important pathophysiological processes, especially in relation to cancer.

Some phosphatidic acid is synthesized from the diacylglycerols produced within the plasma membrane through the activity of diacylglycerol kinases, and this is transported back to the endoplasmic reticulum and ultimately can be re-utilized for phosphatidylinositol biosynthesis.

The other products of the phospholipase C reaction that are of special relevance because of their many essential functions are **water-soluble inositol phosphates**. Up to 60 different compounds of this type are possible, and at least 37 of these have been found in nature at the last count, all of which are extremely important biologically. However, polyphosphoinositides with a phosphate in position 3 are not substrates for phospholipase C.

Figure 21.3.39 shows the generation of inositol phosphates by phospholipase C.

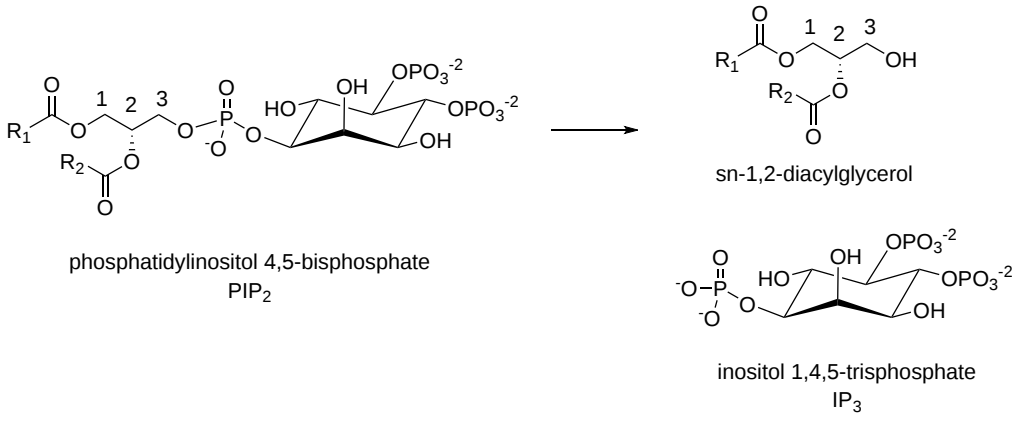

Figure 21.3.39: Generation of inositol phosphates by phospholipase C

For example, under the action of various physiological stimuli in animals, including sphingosine-1-phosphate, and acting via various G-protein-coupled receptors, phosphatidylinositol 4,5-bisphosphate in the plasma membrane is hydrolyzed to release inositol 1,4,5-trisphosphate, an important cellular messenger that diffuses into the cytosol and stimulates calcium release from an ATP-loaded store in the endoplasmic reticulum via ligand-gated calcium channels (the diacylglycerols remain in the membrane to recruit and activate members of the protein kinase C family). The increase in calcium concentration, together with the altered phosphorylation status, activates or de-

activates many different protein targets, enabling cells to respond in an appropriate manner to the extracellular stimulus. To enable rapid replenishment of the phosphatidylinositol 4,5-bisphosphate used in this way, a cycle of reactions - the phosphatidylinositol cycle - must occur (see below). On the other hand, a recent publication suggests that phosphatidylinositol 4-phosphate in the plasma membrane may be a more important source of diacylglycerols following stimulation of G protein–coupled receptors.

All of the various inositol phosphates appear to be involved in the control of cellular events in very specific ways, but especially in the organization of key signaling pathways, the rearrangement of the actin cytoskeleton, or intracellular vesicle trafficking. They have been implicated in gene transcription, RNA editing, nuclear export, and protein phosphorylation. As these remarkable compounds can be rapidly synthesized and degraded in discrete membrane domains or even sub-nuclear structures, they are considered to be ideal regulators of dynamic cellular mechanisms. From structural studies of inositol polyphosphate-binding proteins, it is believed that the inositides may act in part at least by modifying protein function by acting as structural cofactors, ensuring that proteins adopt their optimum conformations. In addition, phosphoinositides and the inositol polyphosphates are key components of the nucleus of the cell, where they have many essential functions, including DNA repair, transcription regulation, and RNA dynamics. It is believed that they may be activity switches for the nuclear complexes responsible for such processes, with the phosphorylation state of the inositol ring being of primary importance. As different isomers appear to have specific functions at each level of gene expression, extracellular events must coordinate the production of these compounds in a highly synchronous manner.

In organisms from plants to mammals, an extra tier of regulatory mechanisms is produced by kinases that generate energetic diphosphate (pyrophosphate)-containing molecules from inositol phosphates. Conversely, these can be dephosphorylated by polyphosphate phosphohydrolase enzymes to regenerate the original inositol phosphates. These inositol pyrophosphates and the enzymes involved in their metabolism are also involved in the regulation of cellular processes by modulating the activity of proteins by a variety of mechanisms.

It should be noted that the phospholipase C isoenzymes regulate the concentration of phosphatidylinositol 4,5-bisphosphate and related lipids and thence their activities in addition to the generation of new biologically active metabolites.

21.3.6.4: PHOSPHATIDYLINOSITIDES IN PLANTS

In plants as in animals, phosphatidylinositol and polyphosphoinositides have essential biological functions, exerting their regulatory effects by acting as ligands that bind to protein targets via specific lipid-binding domains and so alter the location of proteins and their enzymatic activities. However, it appears that polyphosphoinositide metabolism developed in different ways after the divergence of the animal and plant kingdoms so the details of the processes in each are very different, not least because the subcellular locations of phosphoinositides differ appreciably between plants and animals. Phosphatidylinositol *per se* is of course the precursor of the phosphorylated forms and determines their fatty acid compositions. It also has a role in inhibiting programmed cell death by acting as the biosynthetic precursor of the sphingolipid **ceramide phosphoinositol** and so reducing the levels of ceramide.

As in animals, the various phosphoinositides (five in total) are produced and inter-converted rapidly by a series of kinases and phosphatases (in many isoforms) in different cellular membranes in response to environmental or developmental cues. For example, phosphatidylinositol is generated mainly in the endoplasmic reticulum, while PI 4-kinases and their product are located in the trans-Golgi network and nucleus, and PI4P 5-kinases and product are present in the plasma membrane. During the biosynthesis of polyphosphoinositides, the first phosphorylation occurs at the hydroxyl group at positions 3 or 4 of the inositol ring, catalyzed by the appropriate kinases, while the second phosphorylation then takes place at position 5; PI 5-phosphate is produced by the action of a phosphatase on PI 3,5-bisphosphate. Most other metabolites are produced via phosphatidylinositol 3-phosphate, and reports that some phosphatidylinositol 3,4,5-trisphosphate may be produced from phosphatidylinositol 4,5-bisphosphate require confirmation. In contrast to mammalian phosphatidylinositol 3-kinases, which accept both phosphatidylinositol and its monophosphates as substrates, the plant enzyme acts only on the former.

Figure 21.3.40 shows polyphosphoinositide metabolism in plants

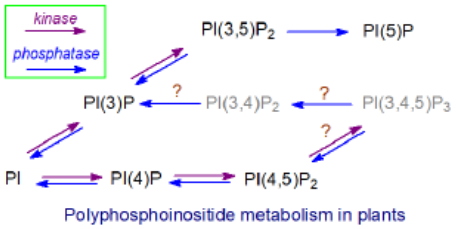

Figure 21.3.40: Polyphosphoinositide metabolism in plants

The reverse reaction in plants is accomplished by phosphoinositide phosphatases, which can be grouped into three main families, the phosphatase/tensin (PTEN) family, 5-phosphatases (5-PTases) and phosphatases containing Suppressor of Actin (SAC) domains, each with differing subcellular locations, substrate specificities and regulatory mechanisms.

Although what might be considered normal levels of phosphatidylinositol 4-phosphate are present, the concentrations of phosphatidylinositol 4,5-bisphosphate and other phosphoinositides are extremely low in plants (10 to 20-fold lower than in mammalian cells), although they still have vital functions. There are differences between cell types, but in Arabidopsis epidermal root cells, $PI(4,5)P_2$ is

present at the highest concentration in the plasma membrane (apex region) and nucleus, while PI4P slowly distributes between the plasma membrane and Golgi, with the highest concentration in the former. Multivesicular bodies/late endosomes accumulate both PI3P and PI(3,5)P_2, and the tonoplast and autophagosomes contain PI3P. How the various metabolites are transported between membranes has yet to be determined, but non-vesicular transport is believed to occur at membrane contact sites and vesicular transport probably occurs also.

Highly polarized distributions of phosphoinositides are found within membranes, generally oriented toward the cytosolic leaflet, and they are believed to be organized in nanoclusters together with other lipids and proteins. For example, phosphatidylinositol-4-phosphate is an important constituent of the plasma membrane in plant cells, where it controls the electrostatic state and is involved in cell division. It may control the location and function of many membrane proteins, including those required for development, reproduction, immunity, nutrition, and signaling. PI(4)P is the only phosphoinositide present at the cell plate, i.e. the membrane separating two daughter cells during cell division. In addition, PI(4)P may interact with salicylic acid in the plant immune response, and it is produced during salt stress. However, specific functions are now being discovered for each of the plant phosphoinositides, which are produced rapidly in response to osmotic and heat stress, and it has become evident that a continuous turnover is essential for cell growth and development. For example, they have marked effects on the growth of many cell types and on guard cell function. In the nucleus, proteins have been identified that bind to phosphoinositides via the acyl chains, leaving the head group exposed for enzymatic modifications and signal transduction.

Phosphoinositides are of special importance in microdomains at the tip of growing tissues such as the shoot apical meristem, pollen tubes, and root hairs where phosphatidylinositol 4,5-bisphosphate functions in stem cell maintenance and organogenesis. In the plasma membrane, it is enriched in the detergent-resistant component commonly equated with '**rafts**'. Although its concentration is low, PI(4,5)P_2 has been shown to have signaling functions by binding to a number of different target proteins, which have characteristic binding domains. For example, together with phosphatidic acid, PI(4,5)P_2 regulates the activity of a number of actin-binding proteins, which in turn control the activity of the actin cytoskeleton. This has a key role in plant growth, the movement of subcellular organelles, cell division and differentiation, and plant defense. In addition, this lipid exerts control over ion channels, ATPases, and phospholipase C-mediated lipid degradation and the production of further second messengers. It is an important factor in both clathrin-mediated endocytosis and exocytosis. The specificity of the interactions may be dependent on the fatty acid composition of the lipid and on the activity of phosphatidylinositol 4-phosphate 5-kinase.

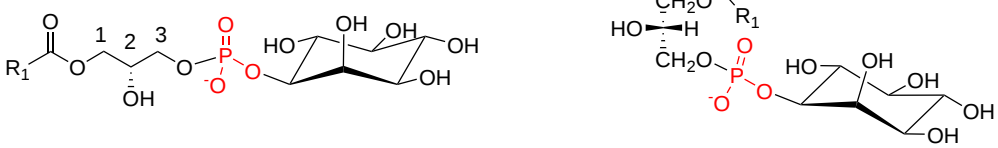
As in animals, phosphoinositides have a role in endosomal sorting but through the central vacuole, which is a plant-specific organelle with both lytic and storage functions. Phosphatidylinositol 3,5-bisphosphate is the least abundant of the phosphoinositides, but it is a crucial lipid for membrane trafficking systems. The PI to PI(3)P to PI(3,5)P_2 cascade, the second step requiring a kinase designated FAB1, is required for endosomal sorting events leading to membrane protein degradation or retrieval, vacuolar morphogenesis and autophagy. PI(3,5)P_2 is involved in stomatal closure and the growth of root hairs, and it is also induced in salt stress.

A number of different enzymes of the phospholipase C type that are specific for polyphosphoinositides have been isolated from higher plants; they are activated by Ca^{2+} and unlike their mammalian counterparts, they are not regulated by G proteins. It is not certain whether phosphatidylinositol is itself a substrate for these enzymes *in vivo*. Less is known of the metabolism of the water-soluble inositol phosphates produced in comparison to animals, and plants appear to lack a receptor for inositol 1,4,5-trisphosphate (IP_3), although it is the most abundant metabolite of this type and is reported to induce the release of calcium ions to trigger stomatal closure. However, there is increasing evidence for lipid signaling mediated by phospholipase C in abiotic stress tolerance and development in plants. There is a general if contested belief that inositol hexakisphosphate (phytic acid or IP_6), produced at least in part by sequential phosphorylation of inositol 1,4,5-trisphosphate, is a more important cellular messenger in plants and mobilizes an endomembrane store of calcium ions. Inositol-1,2,4,5,6-pentakisphosphate (IP_5) is a structural co-factor of the **jasmonic acid** receptor coronatine insensitive 1, linking phosphoinositide signaling with phytohormone-controlled pathways.

In plants in contrast to animals, **diacylglycerols**, the other product of phospholipase C hydrolysis of phosphoinositides, are rapidly converted to **phosphatidic acid** by diacylglycerol kinases and have not been considered important in signal transduction. Plants lack protein kinase C but they do have proteins with related properties that appear to be influenced by diacylglycerols. Via the action of phospholipase D, inositol phospholipids are a source of phosphatidic acid with its well-characterized signaling functions in plants, especially in defence.

21.3.6.5: LYSO-PHOSPHOINOSITIDES

Figure 21.3.41 shows the structure of lysophosphatidylinositol



lysophosphatidylinositol

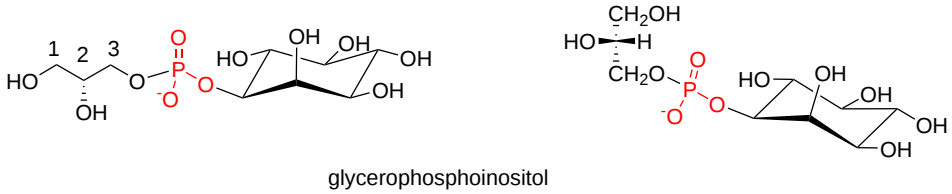
Figure 21.3.41: Lysophosphatidylinositol

Lysophosphatidylinositols: Lysophosphatidylinositols (LPI), i.e. with a single fatty acid only linked to the glycerol moiety, are formed as intermediates in the remodeling of the fatty acid compositions of the lipids by the action of phospholipase A_1 or phospholipase A_2 (e.g. $cPLA_2\alpha$), and when arachidonic acid is released for eicosanoid biosynthesis (see above). In ovarian cancer, LPI is elevated appreciably to around 15µM in ascites, and it is also present at high levels in obese subjects.

It has become apparent relatively recently that like other lysophospholipids, phosphatidylinositol, and polyphospho-analogues may have messenger functions. For example, it has long been known to stimulate the release of insulin from pancreatic cells, suggesting a role in glucose homeostasis. *sn*-2-Arachidonoyl-lysophosphatidylinositol, in particular, is an endogenous ligand for a G protein-coupled receptor GPR55, and thereby can induce rapid phosphorylation of certain enzymes, including a protein kinase, which promote cancer cell proliferation, migration, and metastasis. Indeed, lysophosphatidylinositol is a biomarker for poor prognosis in cancer patients, and its concentration is elevated significantly in highly proliferative cancer cells *in vitro*. GPR55 is expressed in many regions of the brain, the intestines, endocrine pancreas and islets (where it may stimulate insulin release). It has been implicated in macrophage activation and inflammation. In addition to its role in cancer, lysophosphatidylinositol has been implicated in a number of metabolic diseases. It is reported to be a precursor of the endocannabinoid **2-arachidonoylglycerol** by the action of human glycerophosphodiesterase 3 as a lysophospholipase C. This enzyme suppresses the receptor for lysophosphatidylinositol, and so acts as a switch between GPR55 and endocannabinoid (CB2) signaling.

Glycerophosphoinositol: Sequential removal of both fatty acids from phosphatidylinositol by a specific phospholipase A_2 ($PLA_2IV\alpha$) with both phospholipase A_2 and lysophospholipase activities releases water-soluble glycerophosphoinositol. While this can be hydrolyzed by a glycerophosphodiester phosphodiesterase to inositol 1-phosphate, glycerophosphoinositol *per se* has distinctive biological activities and functions, as do related compounds derived from the phosphatidylinositol phosphates. In particular, glycerophosphoinositol has anti-inflammatory activity in that it inhibits the inflammatory and thrombotic responses induced by bacterial lipopolysaccharides (endotoxins).

Figure 21.3.42 shows the structure of glycerophosphoinositol



glycerophosphoinositol

Figure 21.3.42 Glycerolphosphoinositol

21.3.6.6: THE PHOSPHATIDYLINOSITOL CYCLE

Phosphatidylinositol can be considered to be at the center of a cycle of reactions and intermediates that are involved in innumerable aspects of cellular signaling in animals (a similar cycle could be described for plants). These are discussed individually at length above, but it is useful to point out how each component forms part of a larger pattern. In brief as illustrated, the various synthetic and hydrolytic reactions involved in phosphoinositide metabolism can be considered to constitute a **phosphatidylinositol cycle** with enzymes located both in the endoplasmic reticulum and plasma membrane, so lipids have to be transferred across the cytosol in both directions between the two to complete the cycle, probably via adjacent membrane structures and facilitated by proteins of the phosphatidylinositol transfer protein membrane-associated family (PITPNM or nir2), which may channel phosphoinositide production to specific biological outcomes. Phospholipase C and phosphatidylinositol-4-phosphate 5-kinase (PI4P 5K) are located in the plasma membrane, while the cytidine diphosphate-diacylglycerol synthase (CDS2) and phosphatidylinositol synthase are in the endoplasmic reticulum. The epsilon isoform of diacylglycerol kinase (DGKε) is located at contact sites between the endoplasmic reticulum and plasma membrane, but there are nine further isoforms with differing cellular and subcellular locations that may be involved in the cycle. Each turn of the cycle uses a great deal of energy and consumes three moles of ATP, together with cytidine triphosphate and inositol. If it is assumed that the pyrophosphate is hydrolyzed by endogenous pyrophosphatases to inorganic phosphate, the cycle can proceed in one direction only.

Figure 21.3.43 shows the phosphatidylinositol cycle.

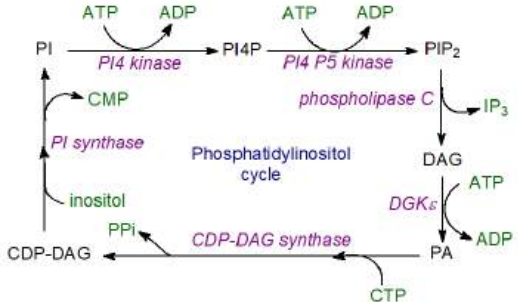


Figure 21.3.43 Phosphatdylionositol cycle

Factors such as membrane curvature must be taken into account, and the diagram is of necessity a considerable over-simplification. In addition to participating in this cycle, many of the lipid intermediates can be precursors for other lipids, and for example, diacylglycerols are potential precursors for triacylglycerols, while phosphatidic acid is a precursor for phosphatidylcholine and phosphatidylethanolamine. Each lipid intermediate is subject to remodeling of the acyl chains via the Lands cycle, and polyunsaturated fatty acids released can be utilized for eicosanoid production. A further by-product of the cycle is inositol triphosphate, which contributes to the regulation of intracellular calcium levels.

It has been suggested that the unique molecular species composition of phosphoinositides (18:0-20:4) could influence their selective recycling back into phosphatidylinositol as many of the enzymes involved have a preference for this substrate. A further proposal is that the phosphatidylinositol cycle could act to enrich this species through multiple passages around the cycle.

21.4: BIOSYNTHESIS OF MEMBRANE SPHINGOLIPIDS

by William (Bill) W. Christie and Henry Jakubowski.

This section is an abbreviated and modified version of material from the Lipid Web, an introduction to the chemistry and biochemistry of individual lipid classes, written by William Christie.

21.4.1: SPHINGOLIPIDS

21.4.1.1: INTRODUCTION:

The sphingolipids comprise a wide range of complex lipids in which the defining component is a long-chain or sphingoid base, which in living tissues is usually linked to a fatty acid via an amide bond. J.L.W. Thudichum, a German chemist working in London, first coined the root term “sphingo-” in 1884 following his discovery of the first glycosphingolipids, because the enigmatic nature of the molecules reminded him of the riddle of the sphinx. Regretfully, the importance of his work was not recognized until 25 years after his death, and it was 1947 before the term “sphingolipide” was introduced by Herbert Carter and colleagues. While they are much less enigmatic than they once were, sphingolipids are extremely versatile molecules that continue to fascinate as new knowledge is gained of their functions in healthy (and diseased) animal and plant tissues. They are found in only a few bacterial genera, but they are present in *Sphingomonas*, *Sphingobacterium* and a few other species, and many pathogenic species utilize host sphingolipids to promote infections. Novel sphingolipid structures continue to be reported, and as an example at the last count, 188 of the complex sphingolipids classified as **gangliosides**, with variations in the complex carbohydrate component alone, had been characterized in vertebrates.

Long-chain or sphingoid bases, of which sphingosine is typical, are the basic elements and are the simplest possible functional sphingolipids. They vary in chain length and in the presence of various functional groups including double bonds of both the *cis*- and *trans*-configuration at different locations in the aliphatic chain. **Ceramides**, which contain sphingoid bases linked to fatty acids by amide bonds, vary appreciably in the compositions of both aliphatic components, depending on their biological origins. The structure of sphingosine and ceramide, the sphingolipid building blocks, are shown in Figure 21.4.1 .

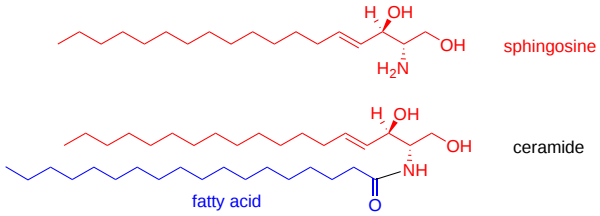

Figure 21.4.1: Sphingolipid building blocks

Long-chain bases and ceramides have important biological properties in their own right, for example in relation to intra- and inter-cellular molecular signaling, especially in animal cells, while another relatively simple sphingolipid, **sphingosine-1-phosphate**, is now recognized as a key factor in countless aspects of animal metabolism. The concentrations of these bioactive lipids respond rapidly to the action of specific stimuli and then regulate downstream effectors and targets.

Ceramides are the precursors of a multitude of sphingo-phospho- and sphingo-glycolipids with an immense range of functions in tissues. The properties and functions of these complex sphingolipids are quite distinct from those of the comparable glycerophospho- and glyceroglycolipids. For example in animals, **sphingomyelin** has structural similarities to phosphatidylcholine, but has very different physical and biological properties, while the complex **oligoglycosylceramides** and **gangliosides**(glycosphingolipids, of which **glucosylceramide** is the precursor, have no true parallels among the glyceroglycolipids. Figure 21.4.2 shows the structure of the complex sphingolipids sphingomyelin and glucosylceramide.

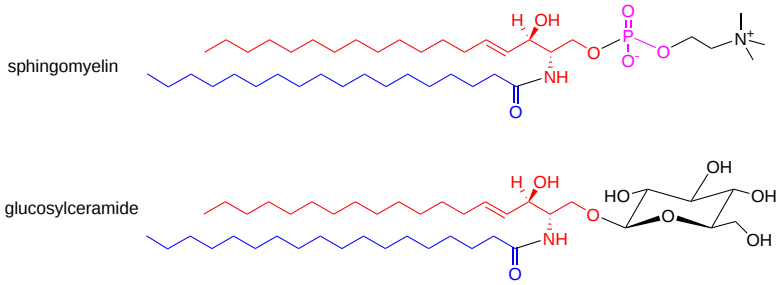

Figure 21.4.2: Complex Sphingolipids

Complex sphingolipids are synthesized in the endoplasmic reticulum and Golgi, but are located mainly in the plasma membrane of most mammalian cells where they have a structural function and also serve as adhesion sites for proteins from the extracellular tissue. The glycosphingolipids are especially important for myelin formation in the brain. However, sphingolipids have intracellular functions in all

cellular compartments, including the nucleus. The first five carbon atoms of the sphingoid base in sphingolipids have a highly specific stereochemistry and constitute a key feature that has been termed the ‘sphingoid motif’, which in comparison to other lipid species facilitates a relatively large number of noncovalent interactions with other membrane lipids, via hydrogen-bonding, ion-ion interactions and induced dipole-induced dipole interactions. A distinctive property of sphingolipids in membranes is that they spontaneously form transient nanodomains termed '**rafts**', usually in conjunction with cholesterol, where such proteins as enzymes and receptors congregate to carry out their signaling and other functions. Thus, in addition to their direct effects on metabolism, sphingolipids affect innumerable aspects of biochemistry indirectly via their physical properties.

While it may be obvious that a well-balanced sphingolipid metabolism is important for health in animals, increasing evidence has been acquired to demonstrate that impaired sphingolipid metabolism and function are involved in the pathophysiology of many of the more common human diseases. These include diabetes, various cancers, microbial infections, Alzheimer's disease and other neurological syndromes, and diseases of the cardiovascular and respiratory systems. In humans, a number of important genetic defects in sphingolipid metabolism or sphingolipidoses have been detected, especially storage diseases associated with the lysosomal compartment where sphingolipids are catabolized. Sphingolipids and their metabolism are therefore likely to prove of ever increasing interest to scientists.

There are appreciable differences in sphingolipid compositions and metabolism between animal and plant cells, both with respect to the aliphatic components and especially the polar head groups, although there are also some important similarities. While sphingomyelin is the most abundant sphingolipid in animals, it does not occur in plants and fungi. Although less is known of the role they play in plants, it has become apparent that complex sphingolipids are much more abundant in plant membranes than was once believed, and it is now recognized that they are key components of the plasma membrane and endomembrane system.

21.4.1.2: SOME GENERAL COMMENTS ON SPHINGOLIPID METABOLISM

The biosynthesis and catabolism of sphingolipids involves a large number of intermediate metabolites, all of which have distinctive biological activities of their own. In animals, the relationships between these metabolites have been rationalized in terms of a ‘sphingomyelin, sphingolipid or ceramide cycle’, as shown in Figure 21.4.3.

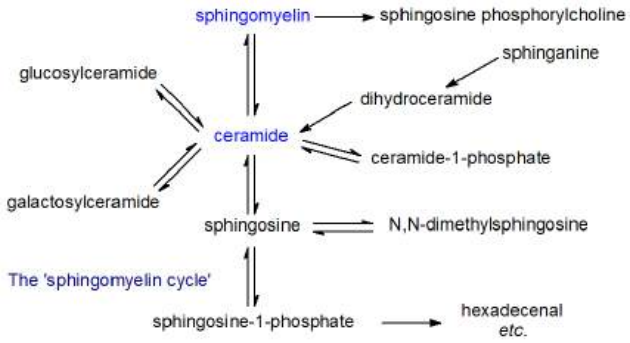

Figure 21.4.3: Sphingomyelin, sphingolipid or ceramide cycle

Many different enzymes (and their isoforms) are involved, and their activities depend on a number of factors, including intracellular locations and mechanisms of activation. Each of the various compounds in these pathways has characteristic metabolic properties. Thus, free sphingosine and other **long-chain bases**, which are the primary precursors of ceramides and thence of all the complex sphingolipids, function as mediators of many cellular events, for example by inhibiting the important enzyme protein kinase C. **Ceramides** are involved in cellular signaling, and especially in the regulation of apoptosis, and cell differentiation, transformation and proliferation, and most stress conditions. In contrast, **sphingosine-1-phosphate** and **ceramide-1-phosphate** promote cellular division (mitosis) as opposed to apoptosis, so that the balance between these lipids and ceramide and/or sphingosine levels in cells is critical and necessitates exquisite control in each cellular compartment.

Similarly, the ‘structural’ sphingolipids, such as **sphingomyelin**, **monoglycosylceramides**, **oligoglycosylceramides** and **gangliosides**, all have unique and characteristic biological functions, some of which are due to their physical properties and location within **rafts,** nanodomains of membranes. Most of the reactions in the sphingomyelin cycle are reversible and the relevant enzymes are located in the endoplasmic reticulum, Golgi, plasma membrane, and mitochondria, but the more complex sphingolipids are catabolized in the lysosomal compartment. Sphingolipids are especially important in providing the permeability barrier in the **skin**, where they are characterized by the presence of ultra-long fatty acyl components as well as fatty acyl groups linked to a hydroxyl group at the terminal end of the *N*-linked fatty acids (thereby generating a three-chain rather than a two-chain molecule).

Metabolic pathways that are comparable to those of the sphingomyelin cycle are believed to occur in plants, as shown in Figure 21.4.4, although they have not been studied as extensively as those in animals.

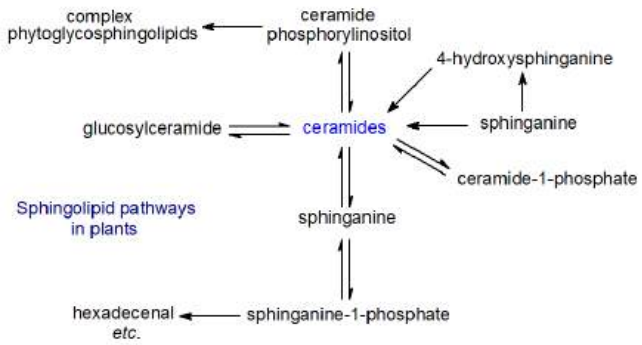

Figure 21.4.4: Sphingomyelin, sphingolipid or ceramide cycle in plants

However, sphingolipid metabolites such as sphingosine-1-phosphate (or analogues) have been linked to programmed cell death, signal transduction, membrane stability, host-pathogen interactions and stress responses, for example. Plants also have a unique range of complex sphingolipids in their membranes, such as **ceramide phosphorylinositol and the phytoglycosphingolipids**, and these are now known to constitute a higher proportion of the total lipids than had hitherto been supposed, although their functions have hardly been explored. While sphingolipids are produced by relatively few bacterial species, sulfono-analogues of long-chain bases and ceramides (capnoids) are produced by some specie.

21.4.1.3: FATTY ACID COMPONENTS OF SPHINGOLIPIDS

The **fatty acids** of sphingolipids are very different from those of glycerolipids, consisting of very-long-chain (up to C_{26}) odd- and even-numbered saturated or monoenoic and related **2(*R*)-hydroxy** components, while even longer fatty acids (C_{28} to C_{36}) occur in spermatozoa and the epidermis. The dienoic acid 15,18-tetracosadienoate (24:2(*n*-6)), derived from elongation of linoleic acid, is found in the ceramides and other sphingolipids of a number of different tissues, but at relatively low levels. Polyunsaturated fatty acids are only rarely present, although sphingomyelins of testes and spermatozoa are exceptions in that they contain such fatty acids, which are even longer in chain-length (up to 34 carbon atoms) and include 28:4(*n*-6) and 30:5(*n*-6). Skin ceramides also contain unusual very-long-chain fatty acids, while yeast sphingolipids are distinctive in containing mainly C_{26} fatty acids. In plants and yeasts, a similar range of chain-lengths occur as in animals, but 2-hydroxy acids predominate sometimes accompanied by small amounts of 2,3-dihydroxy acids; saturated fatty acids are most abundant, but monoenes are present in higher proportions in the Brassica family (including Arabidopsis) and a few other species. Some fungal species contain monoenoic fatty acids with a *trans*-3 double bond and/or a hydroxyl group. Figure 21.4.5 shows typical sphingolipid fatty acids.

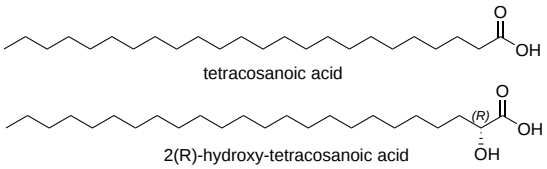

Figure 21.4.5: Typical sphingolipid fatty acids

Very-long-chain saturated and monoenoic fatty acids for sphingolipid biosynthesis are produced from medium-chain precursors by **elongases (ELOVL)** in the endoplasmic reticulum of cells in mammals, and there is increasing evidence that specific isoforms are involved in the biosynthesis of certain ceramides. For example, ELOVL1 has been linked to the production of ceramides with C_{24} fatty acids (saturated and unsaturated), while ELOVL4 is responsible for the ultra-long-chain fatty acids in skin. Yeasts possess three elongation enzymes: Elo1 (for medium to long-chain fatty acids), Elo2 (up to C_{22}) and Elo3 (up to C_{26}).

The hydroxyl group is believed to add to the hydrogen-bonding capacity of the sphingolipids, and it helps to stabilize membrane structures and strengthen the interactions with membrane proteins. Hydroxylation is effected by a fatty acid 2-hydroxylase in mammals, i.e. an NAD(P)H-dependent monooxygenase, which is an integral membrane protein of the endoplasmic reticulum. It converts unesterified long-chain fatty acids to 2-hydroxy acids *in vitro* and probably also *in vivo*. For example, experimental evidence has been obtained that is consistent with 2-hydroxylation occurring at the fatty acid level prior to incorporation into ceramides in the brain of mice where the enzyme is expressed at high levels. A second enzyme of this kind is known to exist but has yet to be characterized, and it is possible that a proportion of the odd-chain fatty acids in brain are synthesized by Peroxisomal α-oxidation of the 2-hydroxy acids. Similarly, in skin, 2-hydroxy and non-hydroxy fatty acids as their CoA esters are used with equal facility for ceramide biosynthesis by ceramide synthases. As mutations in the fatty acid 2-hydroxylase in humans and mice give rise to demyelination disorders, such as leukodystrophy, it is evident that sphingolipids containing 2-hydroxy acids have unique functions in membranes that cannot be substituted by non-hydroxy analogues.

In plants, it appears that 2-hydroxyl groups are inserted into fatty acyl chains while they are linked to ceramide, as ceramide synthase does not accept hydroxy fatty acids *in vitro* at least. Two fatty acid 2-hydroxylases (di-iron-oxo enzymes) have been found in Arabidopsis, with

one specific for very-long-chain fatty acids and one for palmitic acid. In fungi, a hydroxyl group is inserted at C2 of the fatty acid in a dihydroceramide intermediate.

Although the fatty acids are only occasionally considered in terms of the biological functions of sphingolipids, their influence is considerable, especially but not only in relation to their physical properties and function in membranes. For example, very-long-chain fatty acids may play a role in stabilizing highly curved membrane domains as is required during cell division. The hydrophobic nature of the fatty acyl groups (together with the long-chain bases) enables the hydrogen bonding that is essential for the formation of **raft nanodomains** in membranes. As a general rule, lipid bilayers containing sphingolipids with 2-hydroxy-fatty acyl or 4-hydroxy-sphingoid base moieties, tend to generate condensed and more stable gel phases with higher melting temperatures than their non-hydroxylated equivalents, because they have a more extended and strengthened intermolecular hydrogen bonding network. Changes in fatty acid composition are seen in some disease states, and for example increased concentrations of fatty acids $>C_{24}$ are a feature of adrenoleukodystrophy, an X-linked genetic disorder.

Removal of very-long-chain fatty acids from sphingolipids in mutants of the model plant Arabidopsis inhibits completely the development of seedlings. As example of a more specific interaction, it has been demonstrated that synthetic glycerolipids must contain very-long-chain fatty acids (C_{26}) to allow growth in yeast mutants lacking sphingolipids, probably by stabilizing the proton-pumping enzyme H^+-ATPase. Similarly, ceramides containing different fatty acids can be used in highly specific ways. Thus in fungi, C_{16} or C_{18} hydroxy acids are used exclusively for synthesis of glucosylceramide, while those containing very-long-chain C_{24} and C_{26} hydroxy acids are used only for synthesis of **glycosyl inositol phosphorylceramide** anchors for proteins. In plants, sphingolipids containing 2-hydroxy acids are protective against oxidative and other biotic stresses.

21.4.1.4: LINKS BETWEEN GLYCEROLIPID AND SPHINGOLIPID METABOLISM

Sphingolipid metabolism and glycerolipid metabolism have been widely treated as separate sciences until relatively recently, partly for historical reasons and partly because the analysis of the two lipid groups required different approaches and skills. However, there are many areas where the two overlap, not least because phosphatidylcholine is the biosynthetic precursor of **sphingomyelin** in animal cells, while in plants and fungi, phosphatidylinositol is the biosynthetic precursor of **ceramide phosphorylinositol**. In contrast, ethanolamine phosphate derived from the catabolism of sphingolipids via **sphingosine 1-phosphate** is recycled for the biosynthesis of **phosphatidylethanolamine**, and this is essential for survival in the protozoan parasite *Trypanosoma brucei*. In studies in vitro, sphingosine 1-phosphate has been shown to be an activator of the phospholipase C involved in the hydrolysis of the lipid mediator **phosphatidylinositol 4,5-bisphosphate** with formation of diacylglycerols and inositol triphosphate. The location and functions of glycerophospholipids in membranes is influenced both positively and negatively by sphingolipid-rich domains or **rafts** in membranes.

In addition, there are several examples of phosphoinositides and other complex lipids binding to enzymes of sphingolipid metabolism, either as part of a regulatory function that controls their activity or to facilitate their location to various membranes. Thus, sphingosine kinase 2, one of the enzymes responsible for the biosynthesis of sphingosine 1-phosphate, binds to phosphatidylinositol monophosphates, while the ceramide kinase responsible for the biosynthesis of **ceramide 1-phosphate** requires phosphatidylinositol 4,5-bisphosphate to function. Similarly, the CERT protein involved in **ceramide** transport has a binding site for phosphatidylinositol 4-phosphate. Sphingomyelin production at the trans-Golgi network triggers a signaling pathway leading to dephosphorylation of phosphatidylinositol 4-phosphate, interrupting transport of cholesterol and sphingomyelin. Again, the interactions are not solely in one direction as ceramide 1-phosphate (with phosphatidylinositol 4,5-bisphosphate) binds to the specific **phospholipase A_2 ($cPLA_2\alpha$)** responsible for the hydrolysis of phosphatidylinositol and thence the release arachidonic acid for eicosanoid production. Other than the phosphoinositides, phosphatidylserine activates the neutral sphingomyelinase in brain.

21.4.2: LONG-CHAIN (SPHINGOID) BASES

Long-chain/sphingoid bases are the characteristic and defining structural unit of the sphingolipids, which are important structural and signaling lipids of animals and plants and of a few bacterial species. These are long-chain aliphatic amines, containing two or three hydroxyl groups, and often a distinctive *trans*-double bond in position 4. To be more precise, they are 2-amino-1,3-dihydroxy-alkanes or alkenes with (2*S*,3*R*)-*erythro* stereochemistry, often with various further structural modifications in the alkyl chain. They are important for the physical and biological properties of all of the more complex sphingolipids, but free sphingoid bases are also bioactive and interact with specific receptors and target molecules. As discussed below, the mechanisms for biosynthesis of sphingoid bases and of the *N*-acylated form (ceramides) are intimately linked.

21.4.2.1: STRUCTURES AND OCCURRENCE

In animal tissues, the most common or abundant of the sphingoid bases is **sphingosine** ((2*S*,3*R*,4*E*)-2-amino-4-octadecene-1,3-diol) or sphing-4*E*-enine, i.e., with a C_{18} aliphatic chain, hydroxyl groups in positions 1 and 3 and an amine group in position 2; the double bond in position 4 has the *trans* (or *E*) configuration. This was first characterized in 1947 by Professor Herbert Carter, who was also the first to propose the term “sphingolipides” for those lipids containing sphingosine. It is usually accompanied by the saturated analogue dihydrosphingosine (or sphinganine). Sphingoid bases are illustrated in Figure 21.4.6.

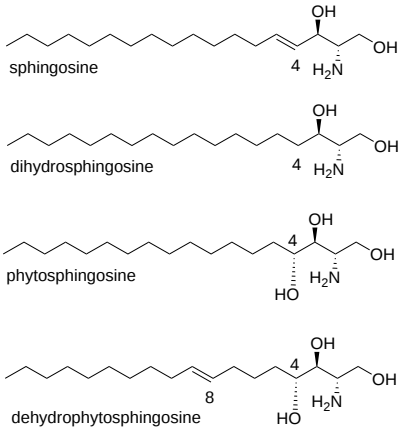

Figure 21.4.6: Sphingoid Bases

For shorthand purposes, a nomenclature similar to that for fatty acids can be used; the chain length and number of double bonds are denoted in the same manner with the prefix 'd' or 't' to designate di- and trihydroxy bases, respectively. Thus, sphingosine is denoted as d18:1 and phytosphingosine is t18:0. The position of the double bond may be indicated by a superscript, i.e., 4-sphingenine is d18:1$^{\Delta 4t}$ or 4*E*-d18:1. While alternative nomenclatures are occasionally seen in publications, they are not recommended.

The number of different long-chain bases that has been found in animals, plants and microorganisms now amounts to over one hundred, and many of these may occur in a single tissue or organism, but almost always as part of a complex lipid with an *N*-acyl-linked fatty acid and often phosphate or carbohydrate functional groups, as opposed to in the free form. The aliphatic chains can contain from 14 to as many as 28 carbon atoms, and most often they are saturated, monounsaturated or diunsaturated, with double bonds of either the *cis* or *trans* configuration. For example, the main dienoic long-chain base (sphingadienine) in human plasma is D-erythro-1,3-dihydroxy-2-amino-4-*trans*,14-*cis*-octadecadiene, and this is especially abundant in kidney, with more in women than in men. It is not present in zebra fish, widely used as a model species. Forms with three double bonds, such as sphinga-4*E*,8*E*,10*E*-trienine, sometimes with a methyl group in position 9, have been found the sphingolipids of some marine invertebrates and in a dinoflagellate. In addition, long-chain bases can have branched chains with methyl substituents in the *omega*-1 (*iso*), *omega*-2 (*anteiso*) or other positions, hydroxyl groups in positions 4, 5 or 6, ethoxy groups in position 3, and even a cyclopropane ring in the aliphatic chain in some organisms. *N*-Methyl, *N*,*N*-dimethyl and *N*,*N*,*N*-trimethyl derivatives of sphingoid bases have been detected in mouse brain.

The main C_{18} components of long-chain bases of sphingomyelins of some animal tissues are accompanied by small amounts of C_{16} to C_{19} dihydroxy bases, although the latter attain higher proportions in tissues of ruminant animals. In gangliosides from human brain and intestinal tissues, eicosasphingosine (2*S*,3*R*,4*E*-d20:1) occurs in appreciable concentrations with variable amounts in different regions and membranes. However, human skin contains an especially wide range of isomers, including saturated, monoenoic and 6-hydroxy bases and phytosphingosines from C_{16} to C_{28} in chain-length. Shorter-chain bases are found in many insect species, and in the fruit fly, *Drosophila melanogaster*, which is widely used as a model species in genetic and metabolic experiments, the main components are C_{14} bases. In contrast to higher animals, nematodes such as *Caenorhabditis elegans* produce C_{17} *iso*-methyl-branched sphingoid bases, which are essential for normal sphingolipid function in the organism.

The long-chain base composition of individual lipids can vary markedly between species, tissues, organelles and even different membranes within a single organelle. For example, the data in Table 21.4.1 is perhaps from an extreme example, but it illustrates that remarkable differences that can exist among lipids in one cellular component (rat liver mitochondria). Only part of the data from the paper cited is listed, but it illustrates that 3-keto-sphinganine, produced in the first step of sphingosine biosynthesis (see below) and normally a minor component of sphingolipids - often not detectable, can vary from 28 to 100% of the sphingoid bases depending on the lipid class and membrane within the organelle.

Table 21.4.1: **Long chain base composition of some lipid components of mitochondria from rat liver.**

Type	Base (%)			
	d18:1	d18:0-3keto	t21:1 (phyto)	Unidentified

Glucosylceramides[a]	3	95	-	3
Lactosylceramides[b]	100			

[a] whole mitochondria; [b] mitochondrial inner membrane
Data from Ardail, D. *et al. FEBS Letts*, **488**, 160-164 (2001).

Phytosphingosine or 4D-hydroxy-sphinganine ((2*S*,3*R*,4*R*)-2-amino-octadecanetriol) is a common long-chain base of mainly plant origin. It is a saturated C_{18}-trihydroxy compound, although unsaturated analogues, for example with a *trans* (or occasionally a *cis* (*Z*)) double bond in position 8, i.e., dehydrophytosphingosine or 4D-hydroxy-8-sphingenine, tend to be much more abundant. In many plant species, there are

lipid class preferences also, and dihydroxy long-chain bases are more enriched in glucosylceramides than in glycosylinositolphosphoceramides, for example. This is true in the model plant *Arabidopsis thaliana*, where the data listed for whole tissue is probably representative largely of the latter lipid, as shown in Table 21.4.2 below.

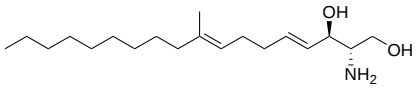
Table 21.4.2: **Sphingolipid long-chain base composition of whole tissue and glucosylceramides from *Arabidopsis thaliana*.**

	Base (%)					
	t18:1 (8*Z*)	t18:1 (8*E*)	t18:0	d18:1 (8*Z*)	d18:1 (8*E*)	d18:0
Whole tissue	12	70	13		4	1
Glucosylceramides	44	22		5	28	2
Data from Sperling, P. *et al*. *Plant Physiol. Biochem*., **43**, 1032-1038 (2005)						

Other plant long-chain bases have double bonds in position 4, which can be of either the *cis* or *trans* configuration, although *trans*-isomers are by far the more common, while the base d18:2$\Delta^{4E,8Z/E}$ is relatively abundant in most plant species. In *A. thaliana* and related species, Δ^4 long-chain bases are found mainly in the flowers and pollen and then exclusively as a component of the glucosylceramides. In general outwith Brassica species, the composition is dependent on species, but typically it is composed of up to eight different C_{18}-sphingoid bases, with variable geometry of the double bond in position 8, i.e., (*E/Z*)-sphing-8-enine (d18:1Δ^8), (4*E*,8*E/Z*)-sphinga-4,8-dienine (d18:2$\Delta^{4,8}$) and (8*E/Z*)-4-hydroxy-8-sphingenine (t18:1Δ^8); d18:1Δ^4, d18:0 and t18:0 tend to be present in small amounts only.

Phytosphingosine is not restricted to plants, but is found in significant amounts in intestinal cells and skin of animals, with much smaller relative proportions in kidney. Although non-mammalian sphingoid bases in general tend to be poorly absorbed from the intestines, a small proportion of the phytosphingosine and related sphingoid bases found in animal tissues may enter via the food chain.

Yeasts and fungi tend to have distinctive and characteristic long-chain base compositions. For example, filamentous fungi have 9-methyl-4*E*,8*E*-sphingadienine as the main sphingoid base in the glucosylceramides, as shown in Figure 21.4.7, but not in the ceramide phosphoinositol glycosides, while yeasts contain mainly the saturated C_{18} bases sphinganine and phytosphingosine, although some *trans*-4/8-unsaturated forms are usually present. Only a few bacterial species synthesize sphingolipids, but the family Bacteroidetes, which is abundant in the human gut is an important exception; they usually contain saturated (and branched) long-chain bases. Other pathogenic bacteria may utilize sphingolipids and sphingoid bases from their hosts.



(4E,8E)-9-methylsphinga-4,8-dienine

Figure 21.4.7: Main sphingoid base in filamentous fungi

Sphingoid bases are surface-active amphiphiles with critical micellar concentrations of about 20 μM in aqueous solutions; they probably exist in the gel phase at physiological temperatures. In that they bear a small positive charge at neutral pH, they are unusual amongst lipids, although their pK_a (9.1) is lower than in simple amines as a consequence of intra-molecular hydrogen bonding. Together with their relatively high solubility (> 1μM), this enables them to cross membranes or move between membranes with relative ease. In so doing, they increase the permeability of membranes to small solutes. In esterified form in complex lipids, they participate in the formation of ordered lipid domains in membranes such as **rafts**.

In the complex sphingolipids, the sphingoid base is linked via the amine group to a fatty acid, including very-long-chain saturated or monoenoic and 2-hydroxy components, i.e., to form **ceramides**, which can be attached a polar head group, such as phosphate or a carbohydrate, via the primary hydroxyl moiety. An important exception is **sphingosine-1-phosphate**, which is not acylated and has signaling functions in cells akin to those of lysophospholipids.

21.4.2.2: BIOSYNTHESIS AND METABOLISM

Sphinganine biosynthesis

The basic mechanism for the biosynthesis of **sphinganine** involves condensation of palmitoyl-coenzyme A with L-serine, catalyzed by the membrane-bound enzyme **serine palmitoyltransferase**, requiring pyridoxal 5'-phosphate as a cofactor, which binds to a specific lysine residue on the enzyme. The reaction occurs on the cytosolic side of the endoplasmic reticulum in animal, plant and yeast cells with formation of 3-keto-sphinganine as illustrated in Figure 21.4.8.

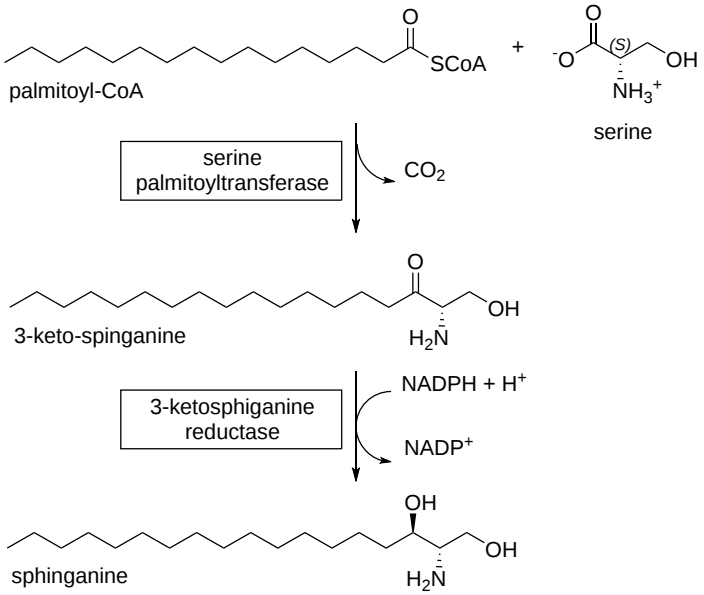


Figure 21.4.8: Sphinganine synthesis

This is believed to be the key regulatory or rate-limiting step in sphingolipid biosynthesis and is conserved in all organisms studied to date. Elimination of this enzyme is embryonically fatal in mammals and fruit flies. In mammals, serine palmitoyltransferase is a heterotrimer composed of two main subunits, designated SPTLC1 with either SPTLC2 or SPTLC3 (sometimes termed SPTLC2a and SPTLC2b, respectively). SPTLC1 is essential for activity, and it is ubiquitously expressed as is SPTLC2, while SPTLC3 is present in a relatively limited range of tissues and is most abundant in skin and placental tissue. In addition, there are two small subunits ssSPTA and ssSPTB (again other nomenclatures exist), which differ in a single amino acid residue, and may have regulatory functions; the active site is at the interface between the two main subunits. ssSPTA is essential for serine palmitoyltransferase function during development and hematopoiesis.

A possible mechanism for the 1st step in the pathway, catalyzed by serine palmitotyltransferase, is shown in Figure 21.4.9.

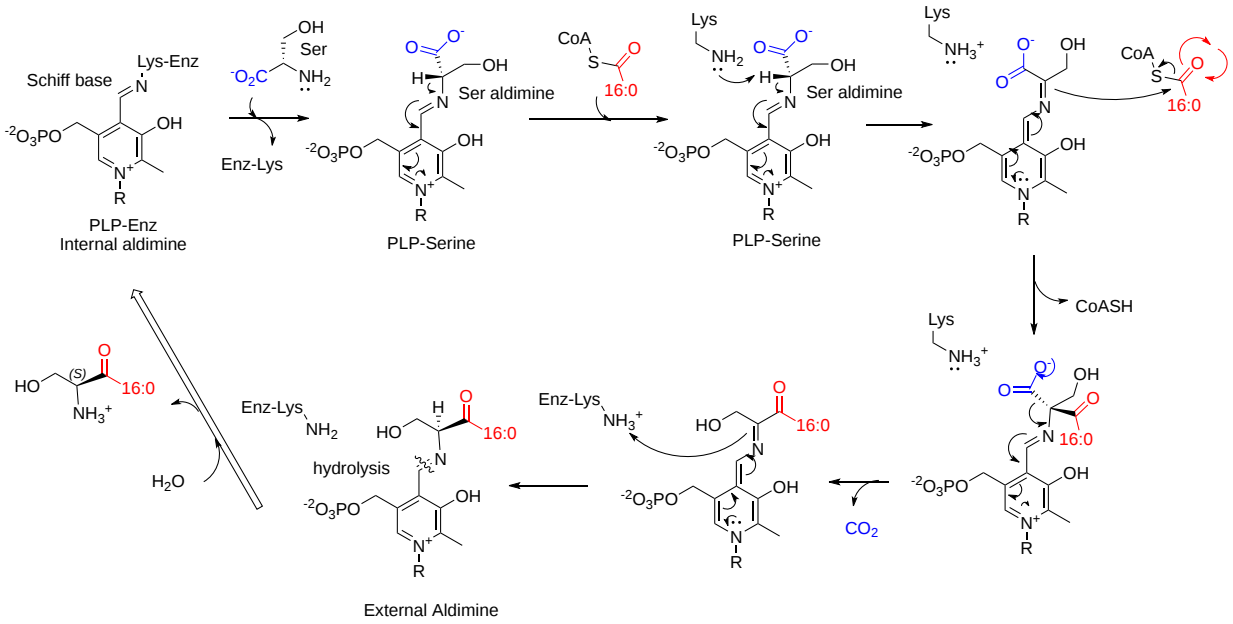

Figure 21.4.9: Mechanism for serine palmitotyltransferase, the key regulatory step in sphingolipid metabolism

The addition of either of the two small subunits to the complexes changes the substrate preferences substantially and enables the synthesis of the wide range of homologs found in nature. In mammals, the SPTLC1-SPTLC2 complex forms C_{18} sphingoid bases specifically (with some C_{19}, and C_{20}), while the combination of SPTLC1 and SPTLC3 gives a broader product spectrum, including an *anteiso*-methylbranched-C_{18} isomer (from *anteiso*-methyl-palmitate as the precursor). Such branched bases are synthesized to a limited extent in human skin, but they are the main forms in lower invertebrates such as *C. elegans*. The activity of the serine palmitoyltransferase is governed by negative feedback and partly by orosomucoid (ORM-like or ORMDL) proteins, three in mammals (ORMDL1 to 3) and two in

yeast (Orm1/2), which are ubiquitously expressed trans-membrane proteins located in the endoplasmic reticulum. The availability of serine is also an important factor.

Figure 21.4.10 shows an interactive iCn3D model of the human serine palmitoyltransferase complex (7K0M).

- Light Blue and Blue (SPT2 B and F Chains)
- Light Brown (small subunit A - ssA, C and G chains)
- Yellow (ORM D and H)

The second step in sphinganine biosynthesis is reduction of the keto group to a hydroxyl in an NADPH-dependent manner by a specific 3-ketodihydrosphingosine reductase ('3KSR'), also on the cytosolic side of the endoplasmic reticulum, a step that must occur rapidly as the intermediate is rarely encountered in tissues. The enzymes are presumed to be in similar subcellular locations in plant cells.

In plants, serine palmitoyltransferase is a heterodimer composed of LCB1 and LCB2 subunits with some homology to the mammalian enzymes, while in the yeast *Saccharomyces cerevisiae*, there are three subunits: Lcb1, Lcb2, and Tsc3. In the few bacteria that synthesize sphingoid bases, serine palmitoyltransferase is a water-soluble homodimer. The enzyme in the apicomplexan parasite *Toxoplasma gondii* is a homodimer also in contrast to other eukaryotes, but it is located in the endoplasmic reticulum.

Free sphinganine formed in this way is rapidly *N*-acylated by acyl-coA to form dihydroceramides by dihydroceramide synthases, which in animals are located primarily on the endoplasmic reticulum, presumably on the cytoplasmic surface. Animals and plants have multiple isoforms of this enzyme, for which the abbreviated term ‘ceramide synthase’ is now widely applied as they utilize most other sphingoid bases, such as those produced by hydrolysis of sphingolipids, as substrates. They are unique gene products with each located on a different chromosome and with considerable variation in the expression of the enzymes in different cell types within each tissue. Each isoenzyme has distinct specificities for the chain-length of the fatty acyl-CoA moieties but to a limited extent only for the base, suggesting that ceramides containing different fatty acids have differing roles in cellular physiology. All of these enzymes have six membrane spanning regions, but the only substantial difference is in an 11-residue sequence in a loop between the last two putative transmembrane domains. **Ceramides** are central to all elements of sphingolipid biochemistry. These steps are illustrated in Figure 21.4.11.

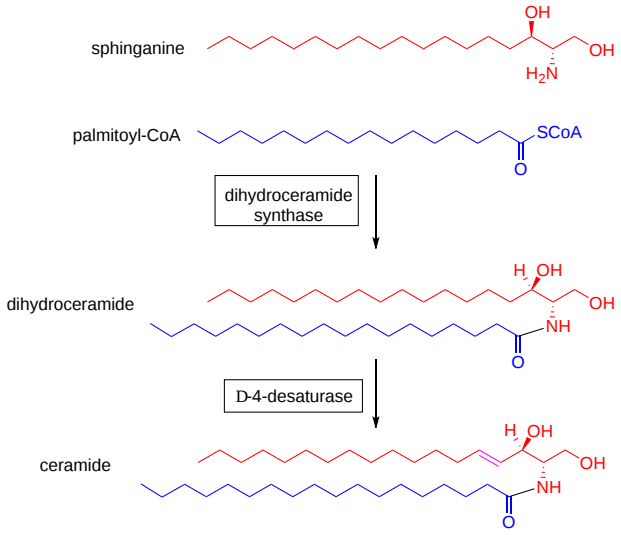

Figure 21.4.11: Synthesis of ceramide from sphinganine.

Humans and mice have six ceramide synthases, which utilize subsets of acyl-CoAs and thus producing ceramides with specific acyl chain lengths. Of these, ceramide synthase 2 is most abundant and is specific for coA esters of very-long-chain fatty acids (C_{20} to C_{26}); it is most active in lung, liver and kidney. Ceramide synthase 1 is specific for 18:0 and is located mainly in brain with lower levels in skeletal muscle and testes. Ceramide synthase 3 is responsible for the unusual ceramides of skin and testes and uses C_{26}-CoA and higher including polyunsaturated-CoAs with the latter tissue, while ceramide synthase 4 (skin, liver, heart, adipose tissue and leukocytes) uses C_{18} to C_{22}-CoAs. Ceramide synthases 5 (lung epithelia and brain gray and white matter) generates C_{16} (mainly) and C_{18} ceramides, and ceramide synthase 6 (intestine, kidney and lymph nodes) produces C_{14} and C_{16} ceramides. However, hydroxylation and the presence or otherwise of double bonds in the acyl-coAs do not appear to influence the specificity of the ceramide synthases. Also, the expression of mRNA expression for ceramide synthases does not always correlate with the fatty acid composition of sphingolipids in a particular tissue, suggesting that other factors are involved in determining which molecular species are formed. One such is acyl-coenzyme A-binding protein (ACBP), which facilitates the synthesis of ceramides containing very-long fatty acids and stimulates ceramide synthases 2 and 3 especially.

Insertion of the *trans*-double bond in position 4 to produce sphingosine occurs only **after** the sphinganine has been esterified in this way to form a ceramide as illustrated in Figure 21.4.11, with desaturation occurring at the cytosolic surface of the endoplasmic reticulum also. The desaturases were first characterized in plants, and this subsequently simplified the isolation of the appropriate enzymes in humans and other organisms. Two dihydroceramide desaturases have now been identified in animals and designated 'DEGS1 and DEGS2'. Both enzymes insert *trans* double bonds in position 4, but DEGS2 is a dual function enzyme that also acts as a hydroxylase to generate phytoceramides, i.e., to add a hydroxyl group on position 4. Distribution of the enzymes in tissues is very different, with DEGS1 expressed ubiquitously but highest in liver, Harderian gland, kidney and lung. DEGS2 expression is largely restricted to skin, intestine and kidney, where phytoceramides are more important. A considerable family of Δ^4-sphingolipid desaturases has now been identified, and an early study by Stoffel and colleagues demonstrated that Δ^4-desaturation involves first *syn*-removal of the C(4)- H_R and then the C(5)-H_S hydrogens. This appears to have been the first evidence that desaturases in general operate in this stepwise fashion.

The enzyme responsible for the insertion of the *cis*-14 double bond into sphinga-4-*trans*,14-*cis*-dienine is the fatty acid desaturase 3 (FADS3), which utilizes ceramides containing sphingosine as the precursor. The only other known activity of this enzyme is to insert a *cis*-double bond in position 13 of the CoA ester of vaccenic acid (11*t*-18:1) to produce the conjugated diene 11*t*,13*c*-18:2.

Synthesis of sphingoid bases *de novo* is essential in most organisms and inhibition of the biosynthetic pathways affects growth and viability. However, this can be tissue specific, as deletion of the liver-specific SPTLC2 in mice, was found to have no effect on liver function, while a comparable deletion of adipocyte-specific SPTLC1 caused major tissue defects. Presumably, the latter tissue is unable to take up enough sphingolipid from the circulation to remedy the problem. Deficiencies in SPTLC3 are related to dermal pathologies, and genetic variant of SPTLC3 are associated with dyslipidemia and atherosclerosis. The essentiality of sphingoid base synthesis in plants has been demonstrated in a similar manner in studies with mutants in which specific enzymes have been deleted.

Phytosphingosine and plant ceramides: Phytosphingosine is formed from sphinganine, produced as above, by hydroxylation in position 4, possibly via the free base in plants, although it can be formed both from sphinganine and a ceramide substrate in yeasts. A single sphinganine C4-hydroxylase is present in yeast, but Arabidopsis has two such enzymes (SBH1 and 2), which are critical for growth and viability. Much remains to be learned of the processes involved, but it is known that the enzyme responsible is closely related to a Δ^4 desaturase. Indeed, it has been shown that there are bifunctional Δ^4-desaturase/Δ^4-hydroxylases in *Candida albicans* and mammals, especially in keratinocytes (DEGS2 discussed above) with which either 4-hydroxylation or Δ^4-desaturation is initiated by removal of the pro*R* C-4 hydrogen. Sphinganine linked to ceramide is the substrate for 4-hydroxylation in intestinal cells.

In *Arabidopsis thaliana* leaves, 90% of the sphingoid bases are phytosphingosine with a Δ^8-double bond. In plants in general, in addition to Δ^4-desaturation, two distinct types (20 gene products) of sphingoid Δ^8-desaturase have been characterized that catalyse the introduction of a double bond at position 8,9 of phytosphingosine. These are evolutionarily distinct from the Δ^4-desaturases. One type produces the *trans (E)*-8 isomer mainly and the other mostly the *cis (Z)*-8 isomer, with overall the *trans*-isomer tending to predominate but dependent upon plant species. It appears that the *trans* isomer is formed when the hydrogen on carbon 8 is removed first, and the *cis* when carbon 9 is the point of attack. While the main group of Δ^8-desaturases requires a 4-hydroxysphinganine moiety as substrate, the second does not.

In Arabidopsis, three different isoforms of ceramide synthase have been identified and denoted LOH1, LOH2 and LOH3. Phytosphingosine is used efficiently by LOH1 and LOH3 (class II synthases), but only LOH2 (class I synthase) uses sphinganine efficiently; LOH2 and 3 prefer unsaturated long-chain bases. Marked fatty acid specificity is also observed with LOH2 showing almost completely specific for palmitoyl-CoA and dihydroxy bases, while LOH1 shows greatest activity for 24:0- and 26:0-CoAs and trihydroxy bases; none utilize unsaturated acyl-CoA esters efficiently. In plants, fatty acid desaturases and hydroxylases are also closely related, and sphingolipid fatty acid α-hydroxylation is believed to occur on the ceramide, as opposed to the free acyl chain. It is believed that the Δ^8-desaturase utilizes ceramide as the substrate and the channels the products selectively into the synthesis of complex sphingolipids, while Δ^4-desaturation channels ceramides for synthesis of glucosylceramide.

It has been established that long-chain bases with 4-hydroxyl groups are necessary for the viability of the filamentous fungus *Aspergillus nidulans* and for growth in plants such as *A. thaliana*. The presence of an 8*E* double bond confers aluminium tolerance to yeasts and plants, and it is important for chilling resistance in tomatoes. However, a *trans*-4 double bond in the sphingoid base does not appear to be essential for growth and development in *Arabidopsis*.

Fungal sphingoid bases: Fungi produce *trans* Δ^8-isomers only, but Δ^4- and Δ^8-desaturases do not occur in the widely studied yeast *S. cerevisiae*. In the biosynthesis of sphingoid bases in fungi, the double bonds in positions 4 and 8 and the methyl group in position 9 are inserted sequentially into the sphinganine portion of a ceramide, the last by means of an *S*-adenosylmethionine-dependent methyltransferase similar to plant and bacterial **cyclopropane fatty acid synthases**. In *S. cerevisiae* the ceramide synthase is a heteromeric protein complex, containing three subunits, Lag1, Lac1, and Lip1, of which the first two are homologous proteins that feature eight transmembrane domains. In the yeast *Pichia pastoris*, there is a distinct ceramide synthase, which utilizes dihydroxy sphingoid bases and C_{16}/C_{18} acyl-coenzyme A as substrates to produce ceramides. The long-chain-base components of the ceramide are then desaturated *in situ* by a Δ^4-desaturase and the fatty acid components are hydroxylated in position 2. Further desaturation of the long-chain base component by a Δ^8-(*trans*)- desaturase occurs before the methyl group in position 9 is introduced by an *S*-adenosylmethionine-dependent sphingolipid C-9 methyltransferase. As a final step a *trans*-double bond may be introduced into position 3 of the fatty acid component. These ceramides are used exclusively for the production of **glucosylceramides**, and it is believed that a separate ceramide synthase encoded by a different gene produces the ceramide precursors for **ceramide phosphorylinositol mannosides**.

Viral sphingoid bases: The genome of an important marine virus (EhV) encodes for a novel serine palmitoyltransferase, which hijacks the metabolism of algal hosts to produce unusual hydroxylated C_{17} sphingoid bases; these accumulate in lytic cells of infected algae such as the important bloom-forming species *Emiliania huxleyi*. While this may seem a rather esoteric topic, viruses constitute a high proportion of the marine biome, and their control of the growth of algal blooms has global consequences.

Unesterified sphingosine: A cycle of reactions occurs in tissues by which sphingoid bases are incorporated via ceramide intermediates into sphingolipids, which are utilized for innumerable functions, before being broken down again to their component parts. It is worth noting that all the free sphingosine in tissues must arise by this route, in particular by the action of ceramidases on **ceramides**. Five such ceramidases are known with differing pH optima and varying subcellular locations. The levels of free sphingoids and their capacities to function as lipid mediators, as shown in Figure 21.4.12, are controlled mainly by enzymic re-acylation to form ceramides, although some is acted upon by sphingosine kinases to produce sphingosine-1-phosphate.

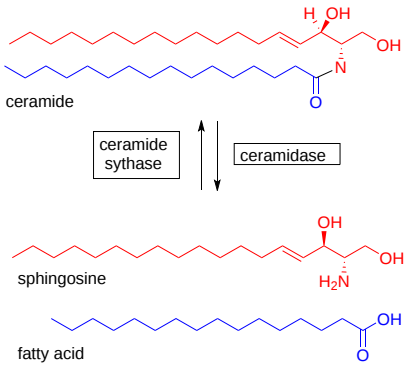

Figure 21.4.12 Ceramide hydrolysis and resynthesis

Free sphingoid bases are absorbed by enterocytes following digestion of dietary sphingolipids in animals (including some from gut microorganisms), and while some of this is converted to complex sphingolipids, much is catabolized with the eventual formation of palmitic

acid.

Catabolism of sphingosine and other long-chain bases occurs after conversion to **sphingosine-1-phosphate** and analogues. In yeasts, an alternative means of detoxification has been reported in which an excess of phytosphingosine is first acetylated and then converted to a vinyl ether prior to export from the cells.

21.4.2.3: BIOLOGICAL FUNCTIONS OF UNESTERIFIED SPHINGOID BASES

The primary function of sphingoid bases is to serve as a basic component of ceramides and complex sphingolipids, where variations in their compositions can influence the physical and biological properties of these lipids. Independently of this in their free (unesterified) form, they are important mediators of many cellular events even though they are present at low levels only in tissues (typically 25 and 50 nM in plasma), with intracellular levels determined by hydrolysis by ceramidases or by the action of sphingosine kinases (sphingosine-1-phosphate production). In animal cells, they inhibit protein kinase C indirectly, possibly by a mechanism involving interference with the binding of activators of the enzyme, such as diacylglycerols or phorbol esters. In addition, sphingoid bases are known to be potent inhibitors of cell growth, although they stimulate cell proliferation and DNA synthesis. They are involved in the process of apoptosis in a manner distinct from that of ceramides by binding to specific proteins and regulating their phosphorylation. While sphingosine does not appear to participate in raft formation in membranes, it may rigidify pre-existing gel domains in mixed bilayers, although any such effects will be dependent on local concentrations and pH. It should be noted that some of the biological effects observed experimentally may be due to conversion to sphingosine-1-phosphate.

Free sphingosine has been implicated in various pathological conditions, and for example, plasma sphingosine levels are increased in hyperthyroidism and in patients with type 2 diabetes. Lysosomal storage of the lipid is an initiating factor in Niemann Pick type C disease, a neurodegenerative disorder, where it causes a change in calcium release leading to a buildup of cholesterol and sphingolipids. In the human adrenal cortex, sphingosine produced *in situ* by the acid ceramidase has a function in steroid production by serving as a ligand for steroidogenic factor 1 at the cell nucleus, which controls the transcription of genes involved in the conversion of cholesterol to steroid hormones. Unesterified sphingoid bases may have a protective role against cancer of the colon in humans. Thus, *N*,*N*-dimethylsphingosine and dihydrosphingosine, like the deoxysphingoid bases, are known to induce cell death in a variety of different types of malignant cells. There is evidence that sphingadienes of plant and animal origin inhibit colorectal cancer in mouse models by reducing sphingosine-1-phosphate levels. In consequence, synthetic analogues of long-chain bases are being tested for their pharmaceutical properties.

Free sphingosine is believed to have a signaling role in plants by controlling pH gradients across membranes. In addition, free long chain bases (and the balance with the 1-phosphate derivatives) are essential for the regulation of apoptosis in plants.

21.4.3: CERAMIDES

21.4.3.1: STRUCTURE AND OCCURRENCE

The structure of ceramide is shown again in Figure 21.4.13.

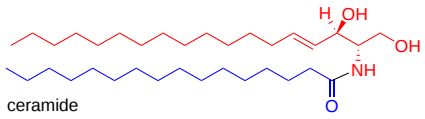

Figure 21.4.13: Structure of ceramides (with varying fatty acids in ester link)

Ceramides consist of a long-chain or **sphingoid base** linked to a fatty acid via an amide bond. They are essential intermediates in the biosynthesis and metabolism of all sphingolipids including the complex sphingolipids in which the terminal primary hydroxyl group is linked to carbohydrate, phosphate, and so forth (sphingomyelin, glycosphingolipids and gangliosides) as shown in Figure 21.4.14.

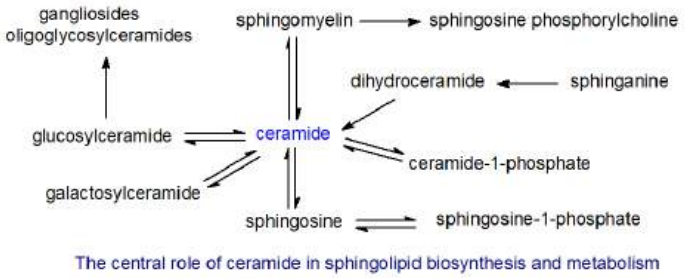

Figure 21.4.14 Central role of ceramkin in sphingolipid biosynthesis and metabolism

They are also the primary source of unesterified sphingoid bases and of the important biological mediators sphingosine-1-phosphate and ceramide-1-phosphate. At the last count, 33 different enzymes were known to participate in ceramide metabolism. While ceramides are rarely found as such at greater than trace amounts in tissues other than skin, they can exert important biological effects of their own at these low levels. They are present in membranes where they participate in the formation of raft domains.

Each organism and indeed each tissue may synthesize ceramides in which there are a variety of di- and trihydroxy long-chain bases linked to fatty acids. As discussed previously, the fatty acids consisting mainly of longer-chain (up to C_{24} or greater) saturated and monoenoic (mainly (*n*-9)) components, sometimes with a hydroxyl group in position 2. Other than in certain testicular cells, polyunsaturated fatty acids do not occur. More than 200 structurally distinct molecular species of ceramides have been characterized from mammalian cells. In plants, 2-hydroxy acids predominate sometimes accompanied by small amounts of 2,3-dihydroxy acids. Although small amounts of free ceramides are produced in all tissues as required for the specific biological functions described below, most is converted rapidly to more complex sphingolipids, including sphingomyelin (in animals) and the various glycosylceramides. The ceramides in skin are a remarkable exception to this rule, and as such they are discussed separately below.

A shorthand nomenclature simply combines those used conventionally for fatty acids and long-chain bases to denote molecular species of ceramides, including those as components of more complex lipids, e.g. *N*-palmitoyl-sphingosine is d18:1-16:0. Ceramides containing sphinganine are sometimes termed 'dihydroceramides'.

21.4.3.2: CERAMIDE BIOSYNTHESIS

Ceramide production is complex and involves at least three pathways. Biosynthesis *de novo* takes place in the endoplasmic reticulum with palmitoyl-CoA and serine as the precursors for the long-chain base component, which is subsequently converted to ceramide. Biosynthesis of the very specific fatty acids in ceramides involving various chain elongases (ELOVL) requires consideration also. Alternative routes for ceramide production involve regeneration from complex sphingolipids. For example, in animals in the sphingomyelinase pathway, conversion of sphingomyelin into ceramides (and *vice versa*) occurs in the plasma membrane, Golgi and mitochondria. Finally, the polar moieties of complex glycosphingolipids can be removed by various hydrolytic enzymes in the lysosomal compartment to recover the ceramides (or their component parts) in a re-cycling/catabolic process. As these biosynthetic or metabolic pathways are located in different organelles, specific pools of ceramide and sphingolipids result with differing biological properties and functions.

Ceramide synthesis *de novo*: The first of these pathways is described in mechanistic. In brief in animals, sphinganine is coupled to a long-chain fatty acid to form dihydroceramide by means of one of six ceramide synthases in the endoplasmic reticulum mainly, before the double bond is introduced into position 4 of the sphingoid base. Of these, ceramide synthase 2 is most abundant and is specific for CoA esters of very-long-chain fatty acids (C_{20} to C_{26}); it is most active in the central nervous system. Ceramide synthase 1 is specific for 18:0 and is located exclusively in brain and skeletal muscle, ceramide synthases 5 and 6 generate 16:0-containing ceramides, and ceramide synthase 3 is responsible for the unusual ceramides of skin and testes.

Figure 21.4.15 shows again the synthesis of ceramide from sphinganine and palmitoyl-CoA (a repeat of Figure 21.4.11

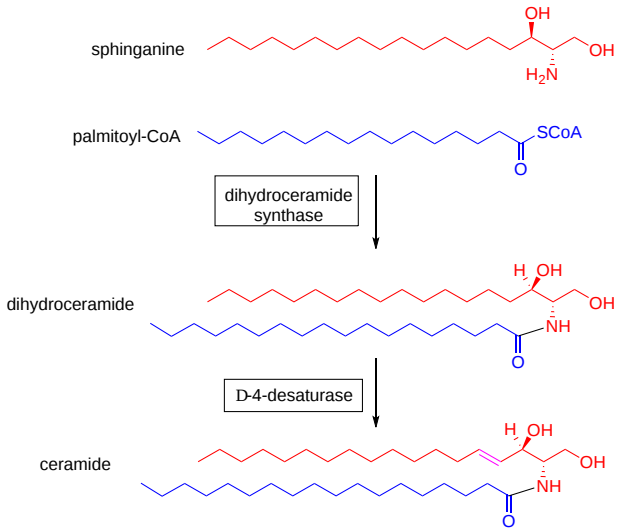

Figure 21.4.15: Synthesis of ceramide from sphinganine and palmitoyl-CoA

Each synthase has six membrane-spanning domains and contains a characteristic motif with the specific structures required for catalysis and substrate binding that are essential for its activity, and they have been shown to differ primarily in an 11-residue sequence in a loop between the last two putative transmembrane domains. In addition to separate transcriptional regulation of each of these enzymes, ceramide synthase activity is modulated by many different factors including reversible dimerization, while ceramide synthase 2 has a **sphingosine-1-phosphate** binding motif and this lipid may inhibits its activity. Acyl-coenzyme A-binding protein (ACBP) facilitates the synthesis of ceramides containing very-long fatty acids and stimulates ceramide synthases 2 and 3 especially.

Most of the ceramides generated in this way are rapidly utilized for synthesis of complex sphingolipids, especially sphingomyelin and hexosylceramides, to ensure that cellular ceramide concentrations are regulated to control their biological activities. In mammalian cells, most complex glycerolipids are synthesized in the endoplasmic reticulum prior to their transport to their final subcellular locations, but the

process is rather different for sphingolipids. Ceramide is synthesized on the cytoplasmic leaflet of the endoplasmic reticulum, but subsequent formation of complex sphingolipids occurs in the Golgi apparatus, and a key cytoplasmic protein, ceramide transporter or '**CERT**' (CERamide Trafficking), mediates the transport of ceramide between these organelles in a non-vesicular manner. It has a number of distinct functional domains, including an N-terminal **phosphatidylinositol-4-monophosphate (PI(4)P)**-binding or Pleckstrin homology (PH) domain, which targets the Golgi apparatus, and a C-terminal 'START' domain, which can recognize ceramide species with the natural D-*erythro* stereochemistry, including dihydroceramide and phytoceramide (but not sphingosine), and holds them within in a long amphiphilic cavity by hydrogen bonding with all three polar atoms of the sphingoid motif. There is also a short peptide motif (FFAT) that recognizes a specific protein in the endoplasmic reticulum. There is sufficient flexibility in the body of the protein to enable transfer of ceramide from the endoplasmic reticulum to the Golgi without free movement through the cytosol.

Very-long-chain ceramides containing 24:0 or 24:1 fatty acids turn over much more rapidly in animal cells than those containing 16:0 or 18:0 fatty acids, because of the more rapid conversion of the former into complex sphingolipids, where they may regulate the levels and perhaps the biological functions of the latter. In contrast, ceramides containing d16:1 and d18:1 sphingoid bases turnover at similar rates so do not affect the flux of ceramides through these pathways. The CERT protein is a major factor in this specificity, as it extracts ceramides from membrane bilayers with a preference for those required for synthesis of complex sphingolipids. Removal of ceramide by this process provides the gradient that enables the process to continue, and prevents an accumulation of ceramide in the endoplasmic reticulum that might otherwise be disruptive to the membrane and even cause cell death. While the transfer process itself is not dependent on ATP, the overall process requires ATP, possibly to keep PI(4)P in a phosphorylated form, and the multiple factors that control the biosynthesis of this lipid must also influence sphingolipid metabolism.

As a neutral lipid, ceramide can flip readily across membrane leaflets, and this is also necessary for the synthesis of sphingomyelin, which occurs on the lumen of the Golgi. The pool of ceramide utilized for the synthesis of **glycosylceramide** is delivered to the Golgi by a separate transport mechanism that also does not require ATP. In addition, some ceramide synthesis occurs in mitochondria although this has the potential to lead to cell death. Regulation of ceramide and subsequent sphingolipid biosynthesis is crucial as an excess of sphingolipids can be toxic, while reduced synthesis can inhibit cell proliferation.

Some ceramides are transported from the liver to other tissues in plasma **lipoproteins**, but especially subclasses HDL_2 and HDL_3, i.e. those containing apolipoprotein B. There is a suggestion that transport of ceramides via lipoproteins could be a paracrine mechanism to regulate the metabolism of other cells.

Ceramides are also produced during the catabolism of other complex sphingolipids, and especially by the action of one or other of the sphingomyelinases or of phospholipase C on **sphingomyelin** in animal tissues as part of the 'sphingomyelin cycle' as shown in Figure 21.4.16.

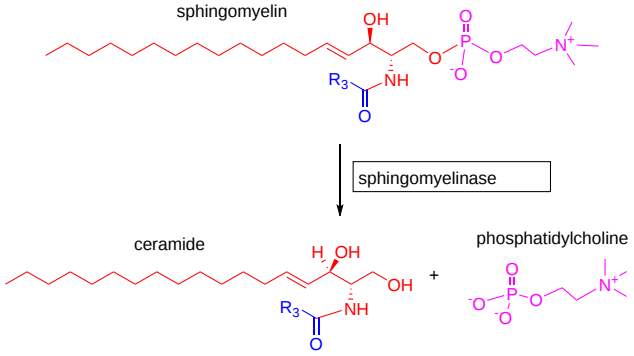

Figure 21.4.16: Ceramide formation from sphinogmyelin

Many agonists including chemotherapeutic agents, tumor necrosis factor-alpha, 1,25-dihydroxy-vitamin D_3, endotoxin, gamma-interferon, interleukins, nerve growth factor, ionizing radiation and heat stimulate hydrolysis of sphingomyelin to produce ceramide. In addition, reversal of the sphingomyelin synthesis reaction may generate ceramide, and some may be produced by operation of the enzyme ceramidase in reverse (see next section). Such reactions are much more rapid than synthesis *de novo*, so they are of special relevance in relation to the signaling functions of ceramides, especially when they occur at the plasma membrane. For example, in this context, the acid sphingomyelinase may be especially important by generating the ceramides that initiate the train of events that leads to apoptosis (see below).

Glycosphingolipids can be hydrolyzed by glycosidases to ceramides also in tissues, but the process tends to be less important in quantitative terms (other than in skin). The key enzymes of sphingolipid metabolism were first characterized from the yeast *Saccharomyces cerevisiae*, and these were found to be sufficiently similar to the corresponding enzymes in mammals to facilitate their study in the latter.

As discussed above, there are specific ceramide synthases that utilize specific fatty acids for ceramide biosynthesis in animals, and knowledge is slowly being acquired of how these are compartmentalized and regulated within cells. Thus, the synthesis and subsequent catabolism of ceramides involves a complex web of at least 28 distinct enzymes, including six ceramide synthases and five

sphingomyelinases, which are all products of different genes. Each of these enzymes may produce distinctive molecular species of ceramides with their own characteristic biological properties. It has been determined that ceramide species containing very-long-chain fatty acids (C_{24}) turnover more rapidly than those containing $C_{16/18}$ components.

21.4.3.3: CERAMIDE CATABOLISM

In animals, ceramide metabolism and function are controlled in part by the action of **ceramidases**, which cause hydrolysis forming sphingoid bases and free fatty acids, and indeed this is the only route to the formation of unesterified sphingosine. This is illustrated in Figure 21.4.17.

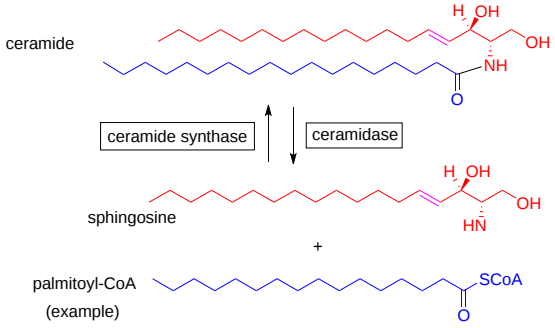

Figure 21.4.17: Ceramide hydrolysis-resynthesis

Five such enzymes are known in humans, classified according to their pH optima, i.e. acid ('ASAH1'), neutral ('ASAH2', which differs between humans and animals), and alkaline (three enzymes - 'ACER1 to ACER3'), with differing cellular locations and fatty acid specificities and with the potential to affect distinct signaling and metabolic events. The acid ceramidase is of particular importance, and aberrations in its synthesis or activity is involved in several human disease states, including the rare autosomal-recessive **Farber disease** where there is a deficiency in the enzyme so ceramide accumulates; ceramide containing 26:0 in the blood is considered to be a biomarker for diagnosis of the disease. ASAH1 is located in the lysosomes and hydrolyses ceramides with small to medium-chain fatty acid components (C_6 to C_{18}) most efficiently. The neutral ceramidase is located in the plasma membrane and Golgi, especially of intestinal epithelial cells and colorectal tissues, and prefers long-chain components (C_{16} to C_{18}); it also catalyzes the reverse reaction, and this may be a means of ceramide synthesis in mitochondria. ACER1 and ACER2 are found in the endoplasmic reticulum and Golgi, respectively, and they prefer species with very-long-chain acyl groups. ACER3 is present in both the endoplasmic reticulum and Golgi; it has a marked specificity for ceramides, dihydroceramides, and phytoceramides linked to unsaturated long-chain fatty acids (18:1, 20:1 or 20:4) *in vitro* at least. Neutral/alkaline ceramidase activity has also been found in mitochondria and nuclei.

In Arabidopsis, an alkaline ceramidase (AtACER) can hydrolyze phytosphingosine-containing ceramides, and a related enzyme from rice has a preference for d18:1Δ4-ceramide; the latter can function in reverse to increase the content of C_{26}- and C_{28}-phytoceramides. Several neutral ceramidases (AtNCERs) have been identified, but there does not appear to be an equivalent to the acid ceramidase in plants. Ceramidases are also present in lower organisms such as *Pseudomonas aeruginosa* and slime molds, where they are secreted proteins rather than integral membrane enzymes. A neutral ceramidase only is found in prokaryotes, including some pathogenic bacteria.

Sphingoid bases released by the action of acid ceramidase can escape from the lysosomes and be re-utilized for ceramide biosynthesis through the action of a ceramide synthase. This has been termed the 'salvage' pathway and is important in both quantitative and biological terms. For example, it has been estimated that it contributes from 50 to 90% of sphingolipid biosynthesis. The biological functions of ceramides are discussed below, but there are reasons to believe that ceramides derived from the salvage pathway are spacially and thence functionally distinct from those synthesized *de novo*. In addition, sphingoid bases released in this way have their own biological functions, which includes utilization for the synthesis of the biologically important metabolite **sphingosine-1-phosphate**. Therefore, regulation of ceramidase action is central to innumerable biological processes in animals.

21.4.3.4: BIOLOGICAL FUNCTIONS OF CERAMIDES

The role of ceramides in the biosynthesis of complex glyco- and phospho-sphingolipids are discussed elsewhere in this text. Ceramides, like other lipid second messengers in signal transduction, are produced rapidly and transiently in response to specific stimuli in order to target specific proteins, for example to activate certain serine/threonine protein kinases or phosphatases. They may also regulate cellular processes by influencing membrane properties. While they can be produced by synthesis *de novo* for such functions, activation of one of the sphingomyelinases under physiological stress or other agents is a more rapid means of generation in animal tissues at least. In fact, ceramides appear to be formed under all conditions of cellular stress by a multiplicity of activators in eukaryotic organisms. However, it should be noted that ceramides with different fatty acid and long-chain base (molecular species) compositions are formed in different compartments or membranes of the cell by various mechanisms over different time scales and potentially with distinct functions. The biological functions of those ceramides containing medium-chain (up to C_{14}), long-chain (C_{16} and C_{18}), and very-long-chain (C_{20} and longer) fatty acids, in particular, may have to be considered separately.

Physical properties: Unsaturation in the sphingoid backbone augments intramolecular hydrogen bonding in the polar region, which permits a close packing of ceramide molecules and a tight intramolecular interaction in membranes. A further important factor in this context is the length of the fatty acyl moiety, as shorter-chain ceramides tend to produce a positive curvature in a lipid monolayer, while long-chain molecules have the opposite effect and possess a marked intrinsic negative curvature that facilitates the formation of inverted hexagonal phases as well as increasing the order of the acyl chains in bilayers. By their interactions with ion channels, ceramides influence the permeability of membranes and render bilayers and cell membranes permeable to solutes that vary from small- up to protein-size molecules.

While ceramides are minor components of membranes in general, their physical properties ensure that they are concentrated preferentially into lateral liquid-ordered microdomains (a distinct form of '**raft**' termed 'ceramide-rich platforms'), although these effects are again chain-length specific. These domains differ appreciably in composition from those rafts enriched in **sphingomyelin** and cholesterol, and ceramides containing C_{12} to C_{18} fatty acids can in fact displace cholesterol from rafts to modify their physical properties. Ceramides are generated within rafts by the action of acid sphingomyelinase, causing small rafts to merge into larger units and modifying the membrane structure in a manner that is believed to permit oligomerization of specific proteins such as cytokines and death receptors. Ceramides are also essential for the formation and/or secretion of exosomes by facilitating or inducing membrane curvature. In contrast, sphingosine, sphingosine-1-phosphate and ceramide-1-phosphate do not facilitate raft formation.

Through the medium of these modified rafts, ceramides are able to function in signal transduction. Specific receptor molecules and signaling proteins are recruited and cluster within such domains, thereby excluding potential inhibitory signals, while initiating and greatly amplifying primary signals. It is believed that ceramide-rich platforms amplify both receptor- and stress-mediated signaling events and thence may influence various disease states. Ceramide-enriched membrane domains formed in response to sphingomyelinase activity are sites for endocytic uptake of pathogens because of a concentration of pathogen receptors and signaling complexes, and in particular these can enhance viral infections, including Norovirus, Japanese encephalitis virus, Ebola and possibly SARS-CoV-2. However, elevated levels of ceramide inhibit cellular uptake of the HIV virus.

Although ceramides and diacylglycerols have structural similarities, their occurrence, location, and behavior in membranes are different. Ceramides cross synthetic lipid bilayers relatively quickly *in vitro*, but it is not clear whether they can flip across more complex biological membranes equally readily, especially in the ceramide-rich platforms. Restricted flipping could have important effects on the signaling role of ceramides in that those generated by different enzymes on each side of a membrane could have distinct functions.

Enzyme activation: In general, ceramides tend to modify intracellular signaling pathways to slow anabolism and promote catabolism. Amongst a wide range of biological functions in relation to cellular signaling, ceramides are especially important in triggering apoptosis, and they have also been implicated in the activation of various protein kinase cascades, dependent on the site of generation. The mechanism of these interactions is the subject of intensive study at present, but in relation to the latter, two intracellular targets for ceramide action of special importance have been discovered – at least two protein phosphatases (ceramide-activated protein phosphatases) and a family of protein kinases (ceramide-activated protein kinases). For example, the phosphatase may be involved in the regulation of glycogen synthesis, insulin resistance, and response to apoptotic stimuli. Ceramides generated by the action of sphingomyelinase and by synthesis *de novo* are both important to the process, while ceramidases have contrasting effects in these and other biological effects of ceramides.

Apoptosis: The role of ceramides in the regulation of **apoptosis**, and cell differentiation, transformation, and proliferation has received special attention. Apoptosis is a normal process, which occurs in response to oxidative stress in particular, in which a cell can be considered to actively 'commit suicide'. It is essential for many aspects of normal development and is required for maintaining tissue homeostasis. There are two pathways - 'extrinsic' initiated in the plasma membrane by ligation of so-called 'death factors', such as the tumor necrosis factor-α (TNF-α), and 'intrinsic' induced by external actions in mitochondria, e.g. by DNA damage, oxidation or radiation injury. Although the mechanism of the ceramide interaction with these pathways is uncertain, it is clear that a cascade of reactions is initiated that culminates in the release of intracellular proteases of the caspase family to promote apoptosis. In dysfunctional mitochondria, one mechanism involves the formation of channels in the membrane that enable the release of specific mitochondrial proteins that include caspases. Ceramides with fatty acids of differing chain lengths are believed to function in different ways, and 16:0-ceramide generated by ceramide synthase 6 is especially pro-apoptotic, for example, while ceramides with very-long-chain fatty acids accumulate in necroptosis, a form of apoptosis. On the other hand, ceramides containing 2-hydroxy acids in keratinocytes appear to be protective against apoptosis. Ceramides induce the related process of cellular senescence also.

Failure to properly regulate apoptosis can have catastrophic consequences, and many disease states, including cancer, diabetes, neuropathies, Alzheimer's disease, Parkinson's disease, and atherosclerosis, are thought to arise from the deregulation of apoptosis. For example, ceramides have been implicated in the actions of TNF-α and in the cytotoxic responses to amyloid Aβ peptide, which are involved in Alzheimer's disease and neurodegeneration. In addition, ceramides appear to be involved in many aspects of the biology of aging and of male and female fertility. These effects may hold implications for diseases associated with obesity and insulin resistance, including again diabetes and cardiovascular disease.

Similarly, ceramides are intimately involved in the induction of autophagy, the 'maintenance' process by which cellular proteins and excess or damaged organelles are removed from cells by engulfing them in a membrane-enclosed cellular compartment called the phagosome. In

particular, maturing phagosomes are enriched in very-long-chain ceramides. While this process is beneficial in that it aids the recycling of cellular nutrients, the presence of excess ceramide can lead to unnecessary apoptosis.

As animals and plants have multiple isoforms of ceramide synthase that are specific for the chain length of the base and fatty acid, it has been suggested that ceramides containing different fatty acids have distinct roles in cellular physiology. In particular, C_{16} ceramide appears to be especially important in apoptosis in non-neuronal tissues, while C_{18} ceramide has growth-arresting properties and may be involved in apoptosis in some carcinomas treated with chemotherapy agents. In addition, a transferase has been identified that transfers the acetyl group from **platelet-activating factor** to sphingosine with a high specificity. The product, *N*-acetylsphingosine - the simplest of all ceramide molecules, has signaling functions that are distinct from those of the parent lipids or of other ceramides; it does not enter the salvage pathway in cancer cells *in vitro* and is cytotoxic.

In contrast, the ceramide metabolite, **sphingosine-1-phosphate**, has opposing effects on cell survival and proliferation. As ceramide and sphingosine-1-phosphate are inter-convertible via sphingosine as an intermediate, which also has pro-apoptopic activity, the balance between these lipids and with ceramide-1-phosphate is obviously of great metabolic importance. It has been termed the 'sphingolipid-rheostat', as illustrated in Figure 21.4.18.

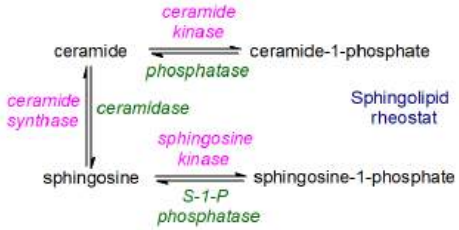

Figure 21.4.18 Sphingolipid rheostat

Plants: Comparatively little information is available on the role of ceramides in cell signaling in plants, but there are suggestions that sphingolipid catabolic products may be linked to programmed cell death, signal transduction, membrane stability, host-pathogen interactions, and stress responses. For example, there is evidence that enhanced synthesis of ceramides with very-long-chain fatty acids and trihydroxy sphingoid bases by ceramide synthases LOH1 and LOH3 promotes cell division and growth, while in contrast, accumulation of the ceramide species C_{16} fatty acid with a dihydroxy sphingoid base, due to LOH2 overexpression, leads to plant dwarfing and programmed cell death. Ceramides aggregate in rafts in plant membranes, together with other sphingolipids and sterols, as in animal tissues. Similarly, in the yeast *S. cerevisiae*, widely used as a model organism, it has been reported that ceramide species with different *N*-acyl chains and sphingoid bases are involved in the regulation of different sets of functionally related genes.

21.4.3.5: SKIN CERAMIDES

The mammalian skin forms the protective barrier between the internal tissues of the host and the hostile external environment, which can include chemicals, ultraviolet light, mechanical damage, and pathogenic microorganisms, while preventing the loss of water and electrolytes. It consists of stratified layers of increasingly differentiated cells or keratinocytes of which the basal layer is responsible for the renewal of the tissue but begins to migrate upwards and differentiate, while accumulating specific lipids and proteins that change the cellular architecture. Eventually, the keratinocytes lose their nucleus and become flattened structures of insoluble protein surrounded by lipids termed 'corneocytes' in the outermost impermeable layer or stratum corneum. By secreting peptides and proteins that possess antimicrobial activity, keratinocytes add to the defensive capability of skin against commensal microorganisms and opportunistic pathogens, and this is reinforced by lipid mediators such as free sphingoid bases and eicosanoids in the stratum corneum and free fatty acids in sebum.

The stratum corneum contains high levels of ceramides (as much as 50% of the total lipids), including *O*-acylceramides, which exist both in the free form and linked by ester bonds to structural proteins. They are present mainly in the extracellular domains (interstices) and are accompanied by nearly equimolar amounts of cholesterol and free fatty acids, a ratio that is believed to be essential for the normal organization of the tissue into the membrane structures that are responsible for the functioning of the epidermal barrier. In contrast to other biological membranes, the lipid organization in the membranes of skin consists of two lamellar phases, which form crystalline lateral phases mainly, with repeat distances of approximately 6 and 13 nm. Small sub-domains of lipids in a liquid phase may also exist.

Some of these skin ceramides have distinctive structures not seen in other tissues, and many different forms are commonly recognized. They can contain the normal range of longer-chain fatty acids (a), e.g. formula 1 in the figure, some with hydroxyl groups in position 2 (a*), e.g. formula 2, linked both to dihydroxy bases with *trans*-double bonds in position 4 or to trihydroxy bases. This is illustrated in Figure 21.4.18.

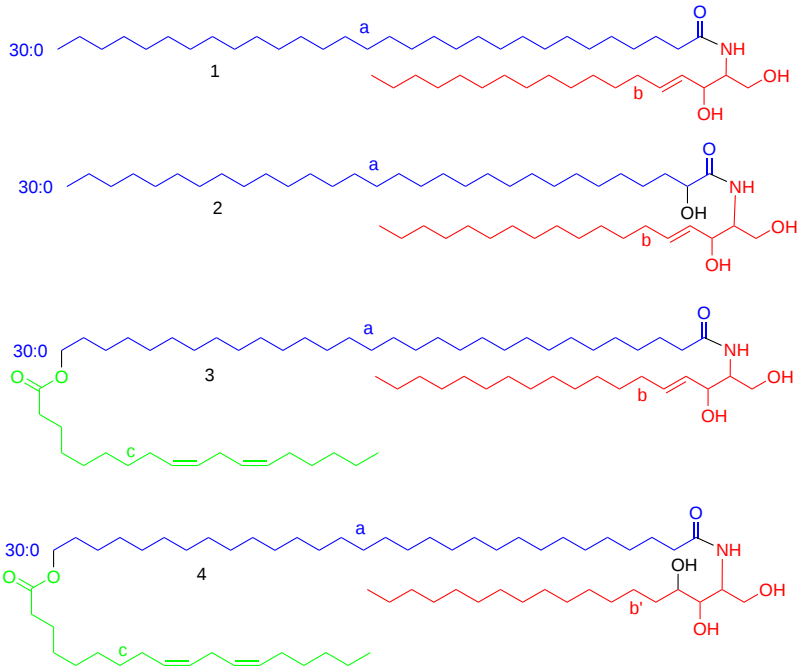

Figure 21.4.18 Skin ceramides

In addition, there are *O*-acyl ceramides in which a unique very-long-chain fatty acid component (typically C_{30} or C_{32}) has a terminal hydroxyl group, and this may be in the free form or esterified with linoleate (**c**), e.g., formulae 3 and 4; the sphingoid base can be either di- (**b**) or trihydroxy (**b***), e.g., formula 4; the latter is not a common feature in sphingolipids of animal origin, and can include both phytosphingosine and the unique 6-hydroxy-4-sphingenine in human epidermis. Ceramides of type 1 in which the 1-*O*-hydroxyl group of the sphingoid base is acylated by a very-long-chain fatty acid are also present (1-*O*-acylceramides - illustrated above); these comprise 5% of the total ceramides in the epidermis of mice and humans and comprise as much as 700 molecular species. In all, 15 classes of free ceramides and 3 classes of covalently bound ceramides with up to 1700 distinct molecular species have been identified. Such lipids were first studied in detail in the skin of the pig as a convenient experimental model, but they have been characterized in humans and rats. In addition, several molecular forms of **glucosylceramide**, based on similar ceramide structures, have been characterized in skin, and these are also essential for its proper function.

Depending on the particular layer of the skin (keratinocytes, stratum corneum, *etc*.), the lipid composition can vary. These lipids have an obvious role in the barrier properties of the skin, limiting the loss of water and solutes and at the same time preventing the ingress of harmful substances. As the aliphatic chains in the ceramides and the fatty acids are mainly non-branched long-chain saturated compounds with a high melting point and a small polar head group, the lipid chains are mostly in a solid crystalline or gel state, which exhibits low lateral diffusional properties and low permeability at physiological temperatures. There is a report that the stratum corneum layer of the skin has a water permeability only one-thousandth that of other biomembranes, for example. Natural and synthetic ceramides are now commonly added to cosmetics and other skin care preparations.

Most steps in the biosynthesis of ceramides linked to ω-*O*-acylated fatty acids occur in the endoplasmic reticulum of keratinocytes. First, fatty acid synthesis of very-long-chain (and ultra-long-chain, $\geq C_{26}$) acyl-CoA *de novo* must take place, requiring the chain-elongation enzymes **ELOVL1 and ELOVL4**. Desaturation can occur, and importantly oxidation in the 2 (α) and terminal (ω) positions. The ω-hydroxylation step requires an enzyme of the cytochrome P450 family, designated CYP4F22, of the kind involved in the synthesis of **hydroxy-eicosatetraenoic acids** (HETE). Mutations are a cause of lamellar ichthyosis, and knockout mice deficient in the equivalent enzyme were found to die within 8 hours of birth.

Biosynthesis of very-long chain ω-hydroxy fatty acids

Ceramides are first synthesized by ceramide synthase 3 (CERS3), which has a high specificity for very-long-chain fatty acids ($>C_{26}$) with the incorporation of the ω-hydroxy fatty acid. This is acylated with linoleate by the action of an unusual enzyme related to the phospholipase A family, PNPLA1, which catalyzes esterification by first releasing linoleate from triacylglycerols in the skin while acting as an acyltransferase to link the linoleate directly to the ω-hydroxyl moiety of the ultra-long chain fatty acid. PNPLA1 is unique among phospholipases in that it is involved in the metabolism of sphingolipids rather than glycerophospholipids and catalyzes transacylation rather than hydrolysis. In addition, some linoleate for this purpose is released from triacylglycerols by the action of the adipose tissue lipase aided

by a protein ABHD5. This process is vital for proper skin barrier function and keratinocyte differentiation, as mice with defective triacylglycerol biosynthesis and metabolism, including a deficiency of the acyl-CoA synthase ACSL1, are unable to synthesis ω-*O*-acylceramides and have an impaired skin barrier. Mutations in the human *PNPLA1* gene are believed to be the cause of autosomal recessive disease congenital ichthyosis.

The resulting ceramides are converted to the complex sphingolipids **sphingomyelin** and especially **glucosylceramide**, which are transferred with the aid of ATP-binding cassette (ABC) transporters together with degradative enzymes into the stratum corneum via specific organelles termed 'lamellar bodies.' These organelles must fuse with the apical plasma membrane of the outermost cell layer of the epidermis in order that their contents can be secreted. It is only then that the final step of hydrolysis of the lipid precursors occurs in the extracellular spaces of the stratum corneum, i.e. ceramides are generated from sphingomyelin by the action of acid sphingomyelinase and from glucosylceramides by β-glucocerebrosidase. This mechanism ensures that ceramides, with their potentially harmful biological activities, never accumulate within nucleated cells.

Eventually, ceramides with a terminal ω-hydroxyl group in the fatty acyl moiety are bound covalently to the proteins of the cornified envelope, especially to involucrin. This is illustrated in Figure 21.4.19.

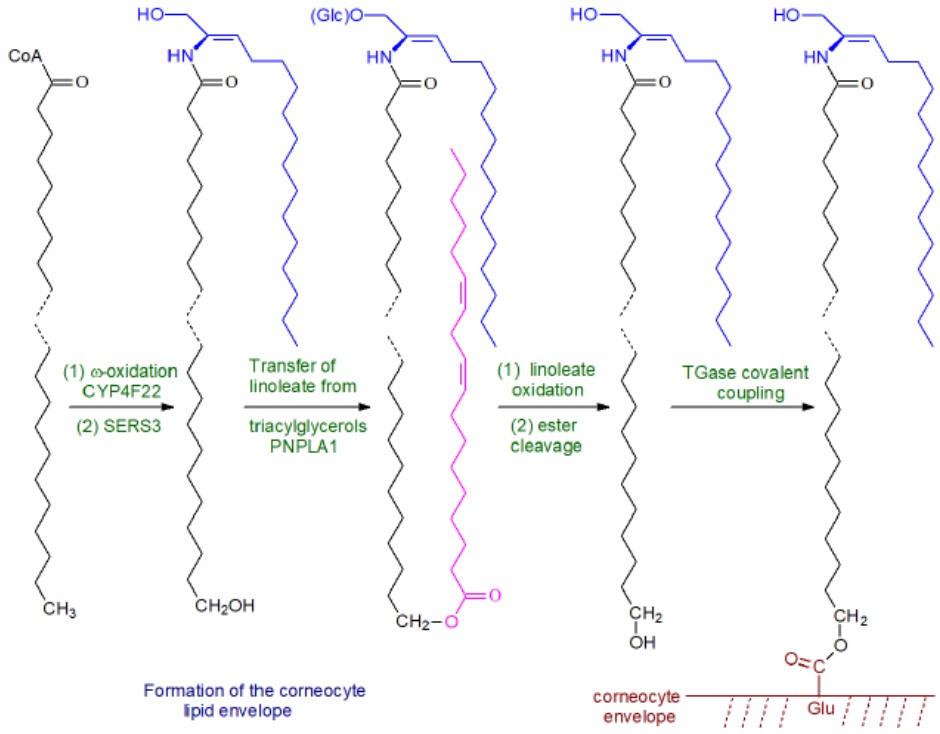

Figure 21.4.19: Formation of the corneocyte lipid envelope

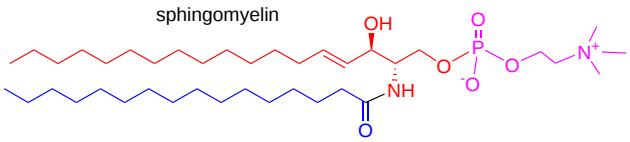
21.4.4: SPHINGOMYELIN AND RELATED SPHINGOPHOSPHOLIPIDS

21.4.4.1: STRUCTURE AND OCCURRENCE OF SPHINGOMYELIN

Sphingomyelin or ceramide 1-phosphocholine consists of a **ceramide** unit with a phosphorylcholine moiety attached to position 1 of the **sphingoid base** component. It is thus the sphingolipid analog of **phosphatidylcholine**, and like that lipid it is zwitterionic. The d18:1/16:0 molecular species is illustrated as an example in Figure 21.4.20.



N-(hexadecanolyl)-sphing-4-enine-1-phosphocholine

Figure 21.4.20: Example of a sphingolipid

Sphingomyelin is primarily of animal origin and is a ubiquitous component of all animal cell membranes, from mammals to nematodes (and in a few protozoa), where it is by far the most abundant sphingolipid. Indeed, it can comprise as much as 50% or more of the lipids in certain tissues, though it is usually lower in concentration than phosphatidylcholine. For example, it makes up about 10% of the lipids of the brain, where it is a key constituent of myelin, but 70% of the phospholipids of the human lens. Like phosphatidylcholine, sphingomyelin

tends to be in greatest concentration in the plasma membrane of cells (up to 20%), and in the endocytic recycling compartment and *trans* Golgi network. It is also abundant in the nucleus where it is the main phospholipid associated with chromatin, but there is very little in the endoplasmic reticulum (2 to 4%) and even less in mitochondria. All the sphingomyelin in human erythrocyte membranes is in the outer leaflet, and ~90% of that in the plasma membrane of nucleated cells is in the outer leaflet. All lipoprotein fractions in plasma contain appreciable amounts of sphingomyelin with a higher proportion in the VLDL/LDL. Sphingomyelin is the single most abundant lipid in erythrocytes of most ruminant animals, where it replaces phosphatidylcholine entirely. In this instance, there is known to be a highly active phospholipase A that breaks down the glycerophospholipids, but not sphingomyelin.

Sphingomyelin is not synthesized in plants or fungi, which produce the sphingophospholipid **ceramide phosphoinositol** and related lipids instead, or in bacteria, and its evolutionary significance is a matter for speculation. However, a number of bacteria and viruses utilize sphingomyelin or its metabolism in their hosts for growth and viability.

Sphingosine is usually the most abundant **long-chain base** constituent, together with sphinganine and C_{20} homologues, although other bases can be present, especially in ruminant animals. In contrast, sphinganine is the major sphingoid base in the sphingomyelin of human lens membranes, linked mainly to 16:0. Typically, the fatty acids are very-long-chain saturated and monounsaturated, including odd-numbered components. In comparison to the glycosphingolipids, 2-hydroxy acids are only rarely detected and then in small amounts, but they are found in testes, spermatozoa, kidney and skin sphingomyelin, for example. The absolute proportions of each fatty acid and sphingoid base can vary markedly between tissues and species, and some of the variability in compositions can be seen from the data in Table 21.4.3 and Table 21.4.4 below.

Table 21.4.3: Fatty acid compositions of sphingomyelin (wt % of the total) in some animal tissues.

Palmitic acid (16:0) is the most common fatty acid component of sphingomyelin in peripheral cells of mammals, while stearic acid (18:0) is more abundant in neural tissue, but this only hints at the potential complexity as there can be variability within tissues. For example, about 60% of the fatty acids of the sphingomyelin of the grey matter of the human brain consist of stearic acid (18:0), while lignoceric (24:0) and nervonic (24:1) acids make up 60% of the corresponding lipid of white matter, although this is dependent on the stage of development. During the first two years of life, the 18:0 concentration in sphingomyelin of white matter decreases from 82% to 33%, while the proportions of 24:0 and 24:1 increase. This pronounced shift from long-chain to very-long-chain sphingomyelins is not observed in the cerebral cortex. Approximately 100 molecular species of sphingomyelin have been detected in human plasma. Although polyunsaturated fatty acids such as arachidonic acid are rarely present, they have sometimes been mistakenly identified in the literature. Exceptions are the sphingomyelins of testes and spermatozoa, which contain very-long-chain polyunsaturated fatty acids (up to 34 carbon atoms), the major components being 28:4(*n*-6) and 30:5(*n*-6) with a proportion having hydroxyl groups in position 2.

21.4.4.2: BIOSYNTHESIS, METABOLISM AND FUNCTION OF SPHINGOMYELIN

The biosynthesis of sphingomyelin is distinct from that of **phosphatidylcholine** and indeed depends upon it, as it involves the transfer of phosphorylcholine from phosphatidylcholine to ceramide, synthesized in the endoplasmic reticulum, with the liberation of 1,2-diacyl-*sn*-glycerols. as illustrated in Figure 21.4.21.

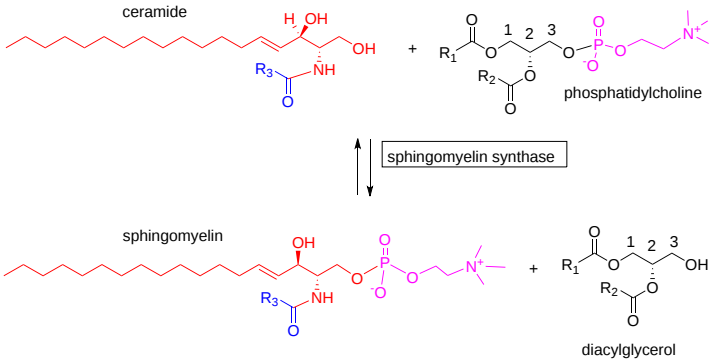

Figure 21.4.21: Synthesis of sphingomyelin

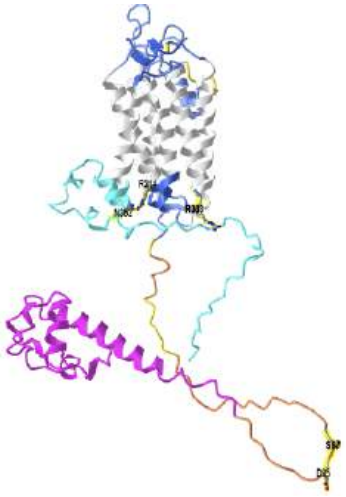
The reaction is catalyzed by a ceramide choline-phosphotransferase (sphingomyelin synthase or SMS) and takes place primarily on the luminal side of the *trans*-Golgi but also in the plasma membrane, with two related enzymes each with six transmembrane domains and their N- and C-termini facing the cytosol, i.e., SMS1 and SMS2. Both enzymes are present in the Golgi, but only SMS2 is in the plasma membrane (facing the extra-cellular space in this instance) and may be necessary for the formation of raft domains (see below). SMS2 is also present in the membranes of nuclei from rat liver cells. It is noteworthy that in the absence of ceramide, both SMS1 and 2 have phospholipase C activity, and so may regulate the steady-state levels of phosphatidylcholine and diacylglycerols as well as that of sphingomyelin. The reaction does not use free phosphorylcholine or CDP-choline as a donor.

Figure 21.4.22 shows an interactive iCn3D model of the AlphaFold model of human Golgi membrane phosphatidylcholine:ceramide cholinephosphotransferase 1, also called sphingomyelin synthase 1 (Q86VZ5).



NCBI iCn3D Figure 21.4.22: . Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...v6s5wHRgPXKJC6

The gray helices are the transmembrane helices. A cytoplasmic protein:protein interaction domain called SAM (sterile alpha motif) is shown in magenta. The other cytoplasmic C-terminal domain is shown in cyan Obviously much of the cytoplasmic domain is disordered in this computational structure. Side chains involved in binding phosphatidylcholine are shown as sticks colored CPK. Note that two, D95 and S97 are located in a disordered section in this model but would close in the actual active site in the actual structure.

It has been proposed that Asp101 (95 in the AlphaFold structure) deprotonates Arg220 (214 in the model), which then acts as a nucleophile which attacks the phosphate group of phosphatidylcholine. Given the very high pKa of arginine, this mechanism, if true, is somewhat unique. Phosphocholine is linked to ceramide to produce sphingomyelin. Three key and extremely conserved amino acids in the active site are Asp101, Arg220 and Asn358.

A specific ceramide transport molecule (CERT) is important to the reaction with SMS1 in that it transfers ceramide from the cytosolic surface of the endoplasmic reticulum to the *trans*-Golgi in an ATP-dependent and non-vesicular manner. Much of the sphingomyelin produced in the Golgi is then delivered to the apical plasma membrane by a vesicular transport mechanism. Sphingomyelin synthesis is regulated in part by phosphatidylinositide metabolism and is connected to sterol homeostasis through the oxysterol binding protein (OSBP).

SMS2 in the plasma membrane is not dependent on CERT-mediated ceramide delivery, but is believed to convert ceramide produced locally by a sphingomyelinase back to sphingomyelin; this may be an important protective mechanism for the cell. The location of the enzymes explains the enrichment of sphingomyelin in specific membranes and the sidedness, i.e., the luminal *trans*-Golgi and the outer leaflet of the plasma membrane, while ceramide reaching the *cis*-Golgi is utilized for the synthesis of **glucosylceramide**. As the nature of the molecular

species of sphingomyelins produced differs appreciably from that of the ceramide precursors, the sphingomyelin synthases must have considerable substrate specificity. The reaction can be reversible, using sphingomyelin to generate ceramide for specific signaling functions. It is evident that sphingomyelin biosynthesis forms a link between the sphingolipid signaling pathway (pro-apoptotic - see below) and that of glycerolipids via the mitogenic **diacylglycerol** by-products. Although the importance of this production relative to that via **phosphatidylinositol** is not known, it is possible that it is significant locally at the external leaflet of the plasma membrane.

An alternative pathway of sphingomyelin synthesis has been demonstrated in the endoplasmic reticulum in which ceramide is first converted to ceramide phosphoethanolamine via transfer of the head group from phosphatidylethanolamine, followed by stepwise methylation of the ethanolamine moiety. However, the physiological significance of this pathway has yet to be established.

It was long thought that the only function of sphingomyelin was to serve as a substitute for phosphatidylcholine as a building block of membranes, i.e., by forming a stable and chemically resistant outer leaflet of the plasma membrane lipid bilayer. For example, it may limit the ingress of oxygen and thence oxidation of adjacent unsaturated acyl chains. While this is certainly one of its functions, the apparent similarity between phosphatidylcholine and sphingomyelin is superficial, and there are great differences in the hydrogen bonding capacities and physical properties of the two lipids. For example, sphingomyelin has an amide bond at position 2 and a hydroxyl at position 3 of the sphingoid base, both of which can participate in hydrogen bonding, while the *trans* double bond also appears to assist intermolecular interactions in membranes. Indeed, the first five carbon atoms of the sphingoid base in sphingolipids constitute a key feature that has been termed the ‘sphingoid motif’, which facilitates a relatively large number of molecular interactions with other membrane lipids, via hydrogen-bonding, charge-pairing, hydrophobic and van der Waals forces. With phosphatidylcholine, in contrast, the two ester carbonyl groups can act only as hydrogen acceptors. The degree of unsaturation of the alkyl moieties in each lipid is very different, and this gives them dissimilar packing properties in membranes.

It is now recognized that sphingomyelin and other sphingolipids have a strong tendency to interact with proteins and cholesterol, often via strong van der Waals interactions and hydrogen bonding, to form transient nano-domains in membranes known as '**rafts**' and on the surface of lipoprotein particles. Initially, there was a view that saturated sphingomyelin formed a liquid-ordered phase with cholesterol or a gel phase with saturated ceramides to lead to lateral segregation within the membrane, and that sphingomyelin and cholesterol metabolism were closely integrated, even that the sphingomyelin concentration might control the distribution of cholesterol in cells. On the other hand, the understanding of the mechanism of raft formation in membranes has changed substantially in recent years, and while an interaction with cholesterol is certainly important, it may not be the major factor *in vivo*. Ceramide can displace cholesterol from its association with sphingomyelin, when formed in membranes by hydrolysis of the latter.

Other functions: Sphingomyelin *per se* is generally considered to be a relatively inert molecule, although modern molecular biology methods are uncovering potential regulatory functions via interactions with particular proteins. For example, it has been shown to inhibit the activity of **phospholipase $A_2\alpha$**, a key enzyme in eicosanoid production. Sphingomyelin in the plasma membrane may be essential for the internalization of transferrin and thence of iron into cells, and it appears to be required for the activity of a number of membrane-bound proteins, including those of certain ion channels and receptors. As the most abundant sphingolipid in the nucleus, it is intimately involved in chromatin assembly and dynamics as well as being an integral component of the nuclear matrix. A single molecular species of sphingomyelin with a C_{18} acyl chain binds specifically to a coat protein designated 'p24' to enable it to form membrane vesicles. In addition, sphingomyelin is selectively recognized and acts as a receptor for the actinoporins, which are pore-forming toxins produced by sea anemones.

There is a specific binding site for sphingomyelin on the amyloid beta-peptide (Aβ) in brain, and there is evidence from studies *in vitro* that this may promote the aggregation of these proteins in Alzheimer's disease. In turn, this leads to depletion of brain sphingomyelin by activation of acid sphingomyelinase with disruption of many protein–lipid interactions and thence of downstream signaling pathways. In contrast, the ganglioside GM1 may have a protective role towards Aβ aggregation

As well as its role in membranes, it serves as a precursor for ceramides, long-chain bases, sphingosine-1-phosphate, and many other biologically important sphingolipids, as part of the 'sphingomyelin cycle' (also termed the ‘sphingolipid’ or ‘ceramide’ cycles depending on the context). Some of these metabolites are intra- and inter-cellular messengers, and others are essential membrane constituents. The sphingomyelin cycle extends to other sphingolipids via the action of sphingomyelinases and enzymes such as glycosylhydrolases and glycosyltransferases in cells to produce innumerable new oligoglycosylceramides. It can also give rise to ***sn*-1,2-diacylglycerols**, which are central to many metabolic and signaling pathways. These molecular relationships are illustrated only briefly in Figure 21.4.23.

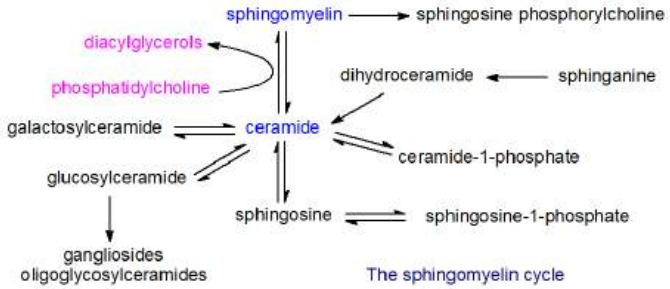


Figure 21.4.23: The sphingomyelin cycle

In particular, sphingomyelin is a major source of **ceramides** in most cellular organelles, including the nucleus and even mitochondria, via the action of sphingomyelinases (see next section), and in addition to being a source of other sphingolipids these are required to trigger apoptosis and other metabolic changes. As ceramides do not mix well with glycerophospholipids and cholesterol, this conversion results in the formation of new membrane domains enriched in ceramide that exclude cholesterol and so differ in composition from other sphingolipid rafts. This has profound effects on membrane function, especially of the plasma membrane, in that different proteins may be recruited or excluded depending on their relative affinities for cholesterol and ceramides. It may also influence disease states such as cancer.

Chlamydiae, widespread bacterial pathogens, acquire sphingomyelin from the Golgi apparatus and plasma membrane of their hosts and this is necessary for the viability and growth of the organisms. Other pathogenic bacteria, notably *Pseudomonas aeruginosa* and *Neisseria gonorrhoeae*, can hijack sphingomyelin catabolic enzymes with deleterious effects upon the host. Likewise, human immunodeficiency virus (HIV) and the hepatitis C virus utilize host sphingomyelin for their own nefarious purposes.

Nutrition: Although there is no known nutritional requirement for sphingomyelin and other sphingolipids, they are a component of any diet containing egg, meat or dairy products. Thus, it has been estimated that *per capita* sphingolipid consumption in the United States, for example, is of the order of 0.3-0.4 g/d. As sphingolipids constitute an appreciable proportion of the polar lipid constituents of milk, they may be significant if minor nutrients for infants and beneficial effects upon their development have been claimed. From animal experiments, there is evidence that dietary sphingolipids can reduce the intestinal absorption of cholesterol and other lipids, leading to reductions in serum lipid concentrations. Feeding sphingolipids inhibits colon carcinogenesis and may alleviate some of the symptoms of inflammatory bowel disease. 2-Hydroxyoleic acid suppresses the growth and induces autophagy in cancer cells by stimulating the synthesis of sphingomyelin and increasing the amount of this lipid in the plasma membrane. On the other hand, plasma sphingomyelin levels are considered to be an independent risk factor for atherosclerosis, possibly as a result of its ability to retain cholesterol in cells and the arterial wall with consequent diminished reverse cholesterol transfer via HDL.

21.4.4.3: SPHINGOMYELIN CATABOLISM

In contrast to the glycerolipids, dietary sphingolipids are not hydrolyzed by pancreatic enzymes only. Rather, most of the sphingomyelin in the diet is hydrolyzed in the brush border of the intestines by an **alkaline sphingomyelinase** (at a pH of 8.5–9 optimally) to ceramide and thence by a neutral ceramidase to free fatty acids and sphingosine. Some of this enzyme is also present in liver from which it is secreted in bile into the intestinal lumen where it can hydrolyze sphingomyelin and other phospholipids with the aid of bile salts. The sphingosine released at the brush border is absorbed, some is re-*N*-acylated to form ceramides, and the remainder is converted via sphingosine-1-phosphate to palmitic acid, which is esterified into the triacylglycerol component of chylomicrons. In the process, some of these sphingolipid intermediates may have signaling functions and anti-inflammatory properties in intestinal cells. The alkaline sphingomyelinase is unusual in that is very different in its structure and other properties from intracellular enzymes with a related function; it is part of the (ecto)nucleotidepyrophosphatase-phosphodiesterase protein family (NPP) that includes **autotaxin**. The enzyme is believed to have a role in the production of sphingolipid metabolites within the intestines and colon especially, which may influence a number of disease states. For example, it appears to inhibit colon cancer by generating ceramides. In addition, alkaline sphingomyelinase has phospholipase C activity towards the pro-inflammatory metabolite **platelet-activating factor** and towards lysophosphatidylcholine with potentially further beneficial effects. By reducing the level of endogenous sphingomyelin and increasing that of ceramides in the membranes of intestinal cells, it is believed to reduce the uptake of dietary cholesterol.

Catabolism in other tissues: The key enzymes for the degradation of sphingomyelin to ceramides in most tissues are also sphingomyelinases (phosphodiesterases), as shown in Figure 21.4.24.

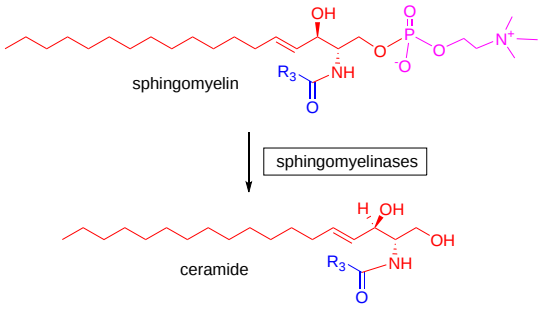

Figure 21.4.24: Sphingomyelin catabolism

These are similar in function to phospholipase C and generate ceramides with their innumerable and important signaling properties as the main product. There are many such enzymes with different pH optima and metal ion requirements that operate in different regions of the cell with potentially distinct biochemical roles. Thus, there is an acid sphingomyelinase in the endo-lysosomes, and different neutral sphingomyelinases in the plasma membrane, endoplasmic reticulum, Golgi, and mitochondria in addition to the alkaline sphingomyelinase in the intestines. It should not be forgotten that the other product of the reaction is phosphocholine, which has importance as a nutrient. Bacterial sphingomyelinases are known to lyse red blood cells, although intriguingly, there is a sphingomyelinase in the bacterium *Pseudomonas aeruginosa* that can also act as a sphingomyelin synthase *in vitro* at least.

The lysosomal **acid sphingomyelinase** (pH optimum ca. 5) is expressed ubiquitously and has a key housekeeping role in maintaining normal membrane turnover and remodeling of the sphingolipid constituents, especially those of lipoproteins. While other lysosomal sphingolipid hydrolases require a **saposin** activator protein for full activity, the acid sphingomyelinase incorporates a built-in N-terminal saposin domain so does not require an external activator. Under resting conditions, acid sphingomyelinase is stored inside lysosomes, but upon stimulation, it undergoes vesicular transport to the plasma membrane where it docks with a specific protein and is exposed on the outer leaflet. It then generates ceramide by hydrolysis of sphingomyelin and initiates the train of events that leads to apoptosis. There are reports that acid sphingomyelinase, by acting at the plasma membrane to produce ceramides, regulates the localization and trafficking of palmitoylated proteins from the Golgi, and it may also facilitate bacteria-host interactions. Experiments *in vitro* have demonstrated that the enzyme can be considered as a phospholipase C that is active against a wide range of phospholipids, including **ceramide-1-phosphate** and the unique lysosomal phospholipid **bis(monoacylglycero)phosphate**.

There is a related secreted acid sphingomyelinase (Zn^{2+}-dependent), which can be transported to the outer membrane of the cell and is especially important in endothelial cells of the human coronary artery. This enzyme is produced by the same gene but differs from the lysosomal enzyme as it requires Zn^{2+} ions for activation and has a different glycosylation pattern. It can also operate at neutral pH and has multiple functions in that it is involved in many aspects of cellular signaling as well as in membrane sphingomyelin turnover. By acting at the plasma membrane to produce ceramides, it is believed to regulate the trafficking of **palmitoylated proteins** from the Golgi to their new location.

Neutral sphingomyelinases (pH optima 7.4), of which four quite distinct enzymes are known, are located in membranes of the endoplasmic reticulum, Golgi, and plasma membrane with one in mitochondria (MA-NSM), where they have signaling functions by generating ceramides and thence other biologically active sphingolipids. Human NSM-1 has 423 amino acid residues and a molecular weight of 47.6 kDa; it has two putative transmembrane domains in the C-terminus and resides mainly in the nucleus and endoplasmic reticulum. It has a broad specificity for choline phospholipids, but it is most active with sphingomyelin and may not have a significant role in cellular signaling. In contrast, NSM-2 which is located in the Golgi apparatus and plasma membrane is activated by phosphatidylserine and is important for ceramide signaling. It is especially important in brain and nervous tissue, where it is required for the secretion of hypothalamic-sssreleasing hormones, although it is relevant to many cellular functions and physiological processes in most other tissues. Dysregulation of NMS-2 is reported to be a factor in many inflammation-related pathologies. Neutral sphingomyelinases-3 is found mainly in the plasma membrane of bone and cartilage, where it is vital for the process of mineralization; it is also important in striated and cardiac muscle. Little seems to be known of the function of the mitochondrial enzyme. Losses, mutation, and poor expression of the gene encoding neutral sphingomyelinase have been observed in several cancers, but exposure to ionizing irradiation led to rapid hydrolysis of sphingomyelin to ceramide by this enzyme, and thence to cancer cell death.

A diverse range of factors activates the enzymes, including chemotherapeutic agents, tumor necrosis factor-alpha, 1,25-dihydroxy-vitamin D_3, endotoxin, gamma-interferon, interleukins, nerve growth factor, and most conditions known to induce cellular stress, especially in relation to inflammation. As they utilize by far the most abundant sphingolipid in animal tissues to generate ceramides and other sphingolipid metabolites that have important signaling functions, sphingomyelinases are believed to function as regulators of signaling mechanisms, especially in the nucleus of the cell. Thus, they have a much wider metabolic role than simply catabolism of sphingomyelin.

The **type A and B forms of Niemann-Pick disease** are lysosomal lipid storage disorders that are a consequence of a deficiency of acid sphingomyelinase with a resulting accumulation of sphingomyelin and smaller amounts of other sphingolipids, including gangliosides, in cells and tissues and especially in the monocyte/macrophage system to form the so-called “foam cells” that characterize the disease. A

consequent lack of ceramide production may be involved in the pathology of the disease. Increasing sphingomyelin levels in turn result in elevated cholesterol concentrations. It is noteworthy that membranes containing ceramides have a much lower binding capacity for cholesterol, so sphingomyelin degradation may play a part in cholesterol homeostasis. **Type C Niemann-Pick** disease differs from the A and B forms and is caused by defects in two distinct cholesterol-binding proteins (NPC1 and NPC2).

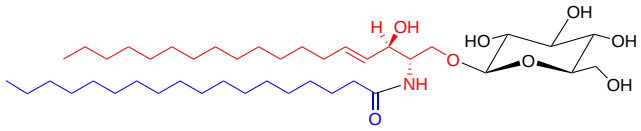
21.4.5: GLUCOSYL- AND GALACTOSYLCERAMIDES (CEREBROSIDES)

There are two natural monoglycosylceramides of special importance in animals, i.e., glucosylceramide and galactosylceramide. Both have biological functions in their own right, but especially as structural components of membranes, as in the brain, for example, where galactosylceramide is required for the maintenance of the structure and stability of myelin and the differentiation of oligodendrocytes. Glucosylceramide is a vital component of all cell types, and is most abundant in human skin; it is the key intermediate in the biosynthesis of lactosylceramide and thence of complex oligoglycosphingolipids, including gangliosides. This monoglycosylceramide is also a major component of the membranes of plants and fungi. Although the two lipids have very similar structures in that D-galactose is an epimer of D-glucose and they differ only in the configuration at C4, they have very different biological properties. A few other monoglycosylceramides are produced in nature, for example by some bacteria of the order *Sphingomonadales* of α-proteobacteria.

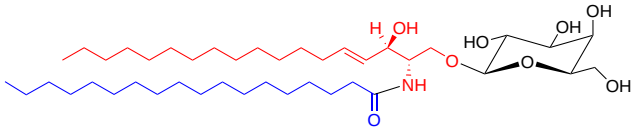
21.4.5.1: STRUCTURE AND OCCURRENCE

β-D-Galactosylceramide (Galβ1-1'Cer) is the principal glycosphingolipid in brain tissue, hence the trivial name "cerebroside", which was first conferred on it in 1874, although it was much later before it was properly characterized. In fact, galactosylceramides are found in all nervous tissues and indeed at low levels in all organs, but in they brain they can amount to 2% of the dry weight of grey matter and 12% of white matter or 23% of myelin lipids, where they insulate the axons of neuronal cells and constitute a substantial component of the extended plasma membrane of oligodendrocytes. It is also present in some fungal species. While galactosylceramide can be sulfated to form a sulfatide or sialylated to form ganglioside GM_4, only a small proportion is subjected to further galactosylation to form Gal_2Cer as the precursor for the limited gala-series of oligoglycosphingolipids.

β-D-Glucosylceramide (Glcβ1-1'Cer), with the trivial name "glucocerebroside", is a major constituent of skin lipids, where it is essential for the maintenance of the water permeability barrier of the skin. Otherwise, it is most abundant in animal tissues such as the spleen and erythrocytes as well as in nervous tissues, especially in the neurons if at low levels, and it is also found in plants. Higher than normal concentrations of this glycosphingolipid have been reported for the apical plasma membrane domain of epithelial cells from the intestines (especially the absorptive villous cells) and urinary bladder. The d18:1/16:0 molecular species of the two lipids are illustrated in Figure 21.4.25.



glucosylceramide



b- galactosylceramide

Figure 21.4.25: gluco- and galactoceramides (cerebrosides)

However, of equal or greater importance to the natural occurrence of glucosylceramide *per se* is its role as the biosynthetic precursor of lactosylceramide in animals, and thence of most of the complex **neutral oligoglycolipids** and **gangliosides**. In contrast, glucosylceramide is the end-product of the biosynthetic pathway in plants and fungi.

Interestingly, the proportion of galactosylceramides relative to glucosylceramides in myelin glycolipids increases greatly in the ascending phylogenic tree, and the ratio of hydroxy- to nonhydroxy fatty acids in cerebrosides increases with the complexity of the central nervous system. There is also an intriguing sex difference in the kidney, where it has been shown that galactosylceramide rather than glucosylceramide occurs in male mice only (or androgen-treated adult females). Only glucosylceramide is present in the nerves of the most primitive animals (protostomes).

In the brain, the galactosylceramides are enriched in very-long-chain fatty acids (C_{22}–C_{26}). The fatty acid and long-chain base compositions of cerebrosides from the intestines of the Japanese quail are listed in Table 21.4.5 for illustrative purposes. The fatty acid components resemble those of other sphingolipids, although the percentage of 2-hydroxy acids is higher than that in sphingomyelin, for example. They are exclusively saturated in this instance, though a small proportion of monoenoic components may also be found in other tissues.

Glucosylceramides tend to contain mainly non-hydroxylated fatty acids that are of relatively shorter chain length. The proportion of trihydroxy bases listed is perhaps higher than in other many other tissues or species studied, probably reflecting the diet. Usually, sphingosine is the main long-chain base in cerebrosides of animal tissues.

Table 21.4.5: **Composition of fatty acids and long-chain bases (wt % of the total) in cerebrosides of intestines from the Japanese quail.***

Plants: Glucosylceramide is the only glycosphingolipid common to plants, fungi, and animals. It has often been described incorrectly as the main sphingolipid in plants, but this has been because the more polar complex **glycosylinositol phosphoceramides** are not easily extracted and until relatively recently were missed in conventional analyses. Nonetheless, glucosylceramide is abundant in photosynthetic tissues and constitutes approximately a third of the total sphingolipids, where the main long-chain bases are C_{18} 4,8-diunsaturated (*Z*/*Z* and *E*/*Z*) (not sphingosine as illustrated above); it is a major component of the outer layer of the plasma membrane and is also enriched in the late endosomes and plant tonoplast. Small amounts of monoglycosylceramides containing a β-D-mannopyranosyl unit may be present in non-photosynthetic tissues, but galactosylceramides have not been found in plants. Glucosylceramide is a common component of the lipids of yeast and other fungi, including most fungal pathogens. However, it does not occur in the yeast *Saccharomyces cerevisiae*, which is widely used as an experimental model, although trace levels of galactosylceramide have been detected.

The fatty acid and long-chain base compositions of glucosylceramides from two plant sources are listed in Table 21.4.6. Perhaps surprisingly, the fatty acid components are not very different in nature from those in animal tissues, comprising mainly longer-chain saturated and monoenoic acids, with a high proportion being saturated and having a hydroxyl group in position 2. In the examples selected for the table here, both di- and tri-hydroxy long-chain bases were found, mainly diunsaturated (*Z*/*Z* and *E*/*Z*) and almost entirely C_{18} in chain length. Much higher concentrations of glucosylceramides are found in pollen than in leaves, with substantial compositional differences. For example, the long-chain bases in Arabidopsis leaves consist mainly of t18:1, with relatively little d18:1, t18:0 and d18:0 (with 16:0, 24:0 and 24:1 hydroxy fatty acids mainly), but no d18:2 base although this is 50% of those in pollen. While saturated 2-hydroxy acids predominate in most plants, some cereal glucosylceramides contain high proportions of mono-unsaturated very-long-chain fatty acids of the *n*-9 family. Glucosylceramides from algae tend to resemble those from higher plants, although some novel structures have been reported from microalgae.

21.4.5.2: BIOSYNTHESIS

Ceramides synthesized both *de novo* and by catabolism of sphingomyelin are used for the biosynthesis of monoglycosylceramides in animal tissues. The biosynthetic mechanism resembles that for **glycosyldiacylglycerols**, i.e., there is a direct transfer of the carbohydrate moiety from a sugar-nucleotide, e.g. uridine 5-diphosphate(UDP)-galactose, UDP-glucose, etc, to a ceramide unit synthesized in the endoplasmic reticulum. This is illustrated in Figure 21.4.26.

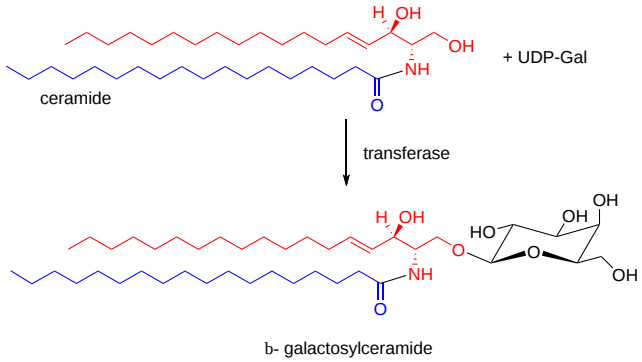

Figure 21.4.25: Synthesis of galactosylceramide

During the transfer, which is catalyzed by specific glycosyl-transferases, inversion of the glycosidic bond occurs from the *alpha* to *beta* configuration. Synthesis of β-D-galactosylceramide takes place on the lumenal surface of the endoplasmic reticulum, although it has free access to the cytosolic surface by an energy-independent flip-flop process. Expression of the UDP-galactose:ceramide galactosyl transferase (galactosylceramide synthase) is restricted to oligodendrocytes, Schwann cells, kidneys, and testes. Prior to **sulfation**, galactosylceramide is transported to the *trans*-Golgi compartment.

In contrast, after the transfer of the precursor **ceramides** from the endoplasmic reticulum to the cytosolic side of the early Golgi membranes with the aid of the CERT protein, glucosylceramide is produced by a glucosylceramide synthase present in this membrane (with the possible exception of neuronal tissues). If it is to be converted to more complex **oligoglycosylceramides**, this must be translocated to the luminal leaflet of the *trans*-Golgi membranes, a process that occurs both by vesicular and by non-vesicular transport. The latter is mediated by a conserved clade of integral membrane proteins, i.e., phospholipid flippases (P4-ATPases) designated ATP10A and ATP10D, together with the four phosphate adapter protein-2 (FAPP2) and glycolipid transfer protein (GLTP) in humans with related enzymes in fungi, which utilize the energy from ATP catalysis to translocate lipids across cellular membranes. The human enzymes are entirely specific for glucosylceramide and not galactosylceramide. Indeed, the galactosyl- and glycosylceramide synthases have no significant sequence homology, indicating different evolutionary origins.

For their functions in protein interactions and signaling, both galactosyl- and glucosylceramide must be transported to and then across the plasma membrane. Some glucosylceramide is carried by lipoproteins (VLDL, LDL, and HDL) in the circulation and presumably requires active transport for absorption and distribution across the membranes of target tissues.

In plants, glucosylceramides are also formed by an evolutionarily conserved glucosylceramide synthase involving UDP-glucose in the endoplasmic reticulum, although an alternative mechanism has been described that utilizes sterol glucoside as the immediate glucose donor to ceramide. There is also evidence for a requirement for ceramides containing Δ^4 *trans*-double bonds for synthesis of glucosylceramides but not other sphingolipids in some plant and fungal tissues. However, there is a distinct ceramide synthase in the yeast *Pichia pastoris*, which produces ceramides of defined composition exclusively for the production of glucosylceramides. A separate ceramide synthase with different specificities produces the ceramide precursors for **ceramide phosphorylinositol**, which contains only phytosphingosine as the long-chain base. In fungi, glucosylceramide synthases have been characterized, but a galactosylceramide synthase has yet to be identified. Enzymes responsible for the biosynthesis of glucuronosylceramide and α-galactosylceramide in some bacterial species have been characterized.

21.4.5.3: FUNCTION

Galactosylceramides: A remarkable property of cerebrosides is that their 'melting point' is well above physiological body temperature, so that glycolipids have a para-crystalline structure at this temperature. Each cerebroside molecule may form up to eight inter- or intramolecular hydrogen bonds by lateral interaction between the polar hydrogens of the sugar and the hydroxy and amide groups of the sphingosine base of the ceramide moiety, and this dense network of hydrogen bonds is believed to contribute to the high transition temperature and the compact alignment of cerebrosides in membranes. As with sphingomyelin, monoglycosylceramides tend to be concentrated in the outer leaflet of the plasma membrane together with cholesterol and thence in myelin in the specific membrane domains termed '**rafts**'. Indeed, the latter appear to facilitate segregation to a greater extent than sphingomyelin via the combination of hydrogen bonds and hydrophobic interactions, and these forces are also of great importance for binding to the wide range of proteins, including enzymes and receptors, which are found in raft domains.

Galactosylceramide is essential to myelin structure and function and it is involved in oligodendrocytes differentiation. While molecular species with 2'-hydroxy fatty acid constituents are not essential for myelin formation, they are critical for the long-term stability of myelin, presumably because increased hydrogen bonding with neighboring lipids in membranes stabilizes the phase structure. Galactosylceramide is important as a precursor of **3'-sulfo-galactosylceramide**, which is also essential to brain development in addition to numerous functions in other tissues. By interacting with sulfatide located in the membrane of opposing layers in the myelin sheath by carbohydrate-carbohydrate interaction, it forms what is known as a glycosynapse, which provides a necessary contribution to the long-term stability of myelin.

Glucosylceramides: Glucosylceramides have similar physical properties in membranes to the galactose analog, and they are also concentrated in raft domains in the outer leaflet of the plasma membrane. As mentioned briefly above, they are the primary precursor for most of the more complex oligoglycosphingolipids in animal tissues, especially in brain, where synthesis is vital for the production of most neuronal oligoglycosphingolipids, while glucosylceramide *per se* is essential for axonal growth. They are major constituents of skin lipids, where they are essential for lamellar body formation in the stratum corneum and to maintain the water permeability barrier of the skin. In addition, the epidermal glucosylceramides (together with sphingomyelin) are the source of the unusual complex **ceramides** that are found in the stratum corneum including those with terminal hydroxyl groups and estolide-linked fatty acids. Some of the glucosylceramide in the skin is linked covalently to proteins via terminal hydroxyl groups, presumably to strengthen the epidermal barrier.

Much of the evidence for the function of glycosylceramides in animals has been derived from cell lines in which synthesis of the lipid has been suppressed by various means *in vitro*. It appears that glucosylceramide is not essential for the viability of certain cell lines in culture, but disruption of the global synthase gene in mice results in the death of embryos. It is essential for the survival of cancer cells, and deletion from other cell types can lead to abnormalities. In addition to being an intermediate in the biosynthesis of more complex glycosphingolipids and its role in the permeability barrier of the skin (discussed above), glucosylceramide is believed to be required for intracellular membrane transport, cell proliferation, and survival, and for various functions in the immune system. In contrast, there are indications that it may have adverse implications for various disease states. For example, over-expression of glucosylceramide synthase in cancer cells has been linked to tumour progression with a reduction in ceramide concentration, resulting in increased resistance to chemotherapy. The lipid has also been associated with drug resistance in a wider context. In the nematode *Caenorhabditis elegans*, glucosylceramide containing the fatty acid 22:0 is reported to be a longevity metabolite that functions through the membrane localization of clathrin, a protein that regulates membrane budding.

In Arabidopsis, glucosylceramides are critical for cell differentiation and organogenesis, but not necessarily for the viability of cells. It has been proposed that glycosphingolipids could impose positive curvature to membranes, thereby facilitating vesicle fusion. There is evidence that glycosylceramides (but not glycosyldiacylglycerols) together with sterols are located in 'rafts' in plant membranes in an analogous manner to sphingolipids in animal tissues, and that they are associated with specific proteins. Correlative studies suggest that glucosylceramides help the plasma membrane in plants to withstand stresses brought about by cold and drought. For example, glycosylceramides containing 2-hydroxy monounsaturated very-long-chain fatty acids and long-chain bases with 4-*cis* double bonds appear to be present in higher concentrations in plants that are more tolerant of chilling and freezing. While fungal glucosylceramides with a 9-methyl group within the sphingosine backbone elicit defence responses in rice, cerebrosides with double bonds in positions 4 and/or 8 of the long-chain base appear to be involved in the defense of some plant species against fungal attack.

Less is known of the function of glucosylceramides in fungi, although they are certainly major constituents of the plasma membrane and cell wall. They are believed to be involved in such processes as cell wall assembly, cell division and differentiation, and signaling. The presence of the methyl branch in the long-chain base is essential for cell division and alkali tolerance. In the case of fungal pathogens, glucosylceramides are recognized by the host immune system and regulate virulence, often after export into the external environment as extracellular vesicles. In contrast to animals, ceramide monohexosides are not precursors for oligoglycosylceramides in fungi. Some molecular species of this lipid from plants (a Δ^8 double bond in the long-chain base is essential) show fruiting-inducing activity in the fungus *Schizophyllum commune*.

α-D-Galactosylceramides: Cerebrosides linked to an α-D- rather than a β-D-galactosyl unit such as that found in the marine sponge *Agelas mauritianus*, in human gut microflora, and even in cow's milk are potent stimulators of mammalian immune systems by binding to the protein CD1d on the surface of antigen-presenting cells and activating invariant natural killer T cells. Indeed this was one of the first pieces of evidence to show that glycolipids, like glycoproteins, could invoke an immune response. Subsequently, it was demonstrated that α-galactosylceramide with a 24:1 fatty acid, though present in very small amounts, is loaded onto the CD1d or CD40 protein and is presented as the natural endogenous ligand for NKT cells in the thymus and the periphery. Once activated, NKT cells secrete a range of pro-and anti-inflammatory cytokines to modulate innate and adaptive immune responses. The α-glucosyl and α-psychosine analogs show similar activity.

It is not certain whether α-galactosylceramide is synthesized in animal tissues, and it is likely that is derived primarily from members of the gut microbiome such as *Bacteroides fragilis* and related species (although in general, few bacterial species produce sphingolipids). Ceramide-galactosyltransferases responsible for the synthesis of this lipid in two species of bacteria from the intestinal microbiome have been identified. In mouse gut, the main molecular form consisted of a 2-(*R*)-hydroxylated hexadecanoyl chain linked to C_{18}-sphinganine, while that in *B. fragilis* contained longer-chain components with *iso*-methyl-branches in the sphingoid base and often fatty acid moieties. The sphinganine chain branching is a critical determinant of NKT cell activation by the bacterial enzyme. A decrease in the production of

this lipid was observed in mice exposed to stress conditions that alter the composition of the gut microbiota, including Western-type diet, colitis, and influenza A virus infection with potential consequences upon the systemic immune responses. Its concentration within animal tissues is controlled by catabolic enzymes in a two-step mechanism: removal of the acyl chain by an acid ceramidase followed by hydrolysis of the sugar residue by an α-glycosidase. Initial studies with animal models suggest that treatment with α-D-galactosylceramides is effective against lung and colorectal cancers, melanomas and leukemia, and pre-clinical trials of this lipid and synthetic analogs so far have shown that these are safe and effective as an anti-tumour immunotherapeutic agents and vaccine adjuvants. Indeed, a phase I trial with high-risk melanoma patients has given promising preliminary results.

21.4.5.4: CATABOLISM OF GLYCOSPHINGOLIPIDS

In animal tissues, the main sites for the degradation of **all** glycosphingolipids, including the monoglycosylceramides, oligoglycosphingolipids and gangliosides, are the lysosomes. These are membrane-bound organelles that comprise a limiting external membrane and internal lysosomal vesicles, which contain soluble digestive enzymes that are active at the acidic pH of this organelle. All membrane components are actively transported to the lysosomes to be broken down into their various primary components. In the case of glycosphingolipids, this means to fatty acids, sphingoid bases, and monosaccharides, which can be recovered for re-use or further degraded. Thus, sections of the plasma membrane enter the cell by a process of endocytosis, and they are then transported through the endosomal compartment to the lysosomes. The compositional and physical arrangement of the lysosomal membranes is such that they are themselves resistant to digestion with **bis(monoacylglycero)phosphate** (lysobisphosphatidic acid) as a characteristic component of the inner membrane. A glycocalyx of highly *N*-glycosylated integral membrane proteins protects the perimeter membrane with the aid of the ganglioside GM3, which is resistant to degradation. This glycocalix forms an efficient hydrophilic barrier at the luminal surface of the lysosomal perimeter membrane to protect it from degradation by proteases and hydrolases, and to prevent lipids and their hydrolysis products from escaping from the lumen of the lysosome.

Degradation of oligoglycosylceramides and gangliosides occurs by sequential removal of monosaccharide units via the action of specific exohydrolases from the non-reducing end until a monoglycosylceramide unit is reached when glucosylceramide β-glucosidases or an analogous β-galactosidase (one isoform) removes the final carbohydrate moiety. Several glucosylceramidases are known; GBA1 is a lysosomal hydrolase, GBA2 is a ubiquitous non-lysosomal enzyme and GBA3 is a cytosolic β-glucosidase. The last is found in the kidney, liver, spleen and a few other tissues of mammals, but its function is not clear.

As glycolipids with fewer than four carbohydrate residues are embedded in intralysosomal membranes, while the degradative enzymes are soluble, the process requires the presence of negatively charged lipids and specific activator proteins, which are water-soluble glycoproteins of low molecular weight. These are not themselves active catalytically but are required as cofactors either by directing the enzyme to the substrate or by activating the enzyme by binding to it in some manner. Five such proteins are known, the GM_2-activator protein (specific for gangliosides) and Sphingolipid Activator Proteins or **saposins A, B, C and D**, which perturb the membranes sufficiently to enable the degradative enzymes to reach the glycolipid substrates. The four saposins are derived by proteolytic processing from a single precursor protein, prosaposin, which is synthesized in the endoplasmic reticulum, transported to the Golgi for glycosylation, and then to the lysosomes. Of these, saposin C is essential for the degradation of galactosyl- and glucosylceramide, while saposin B is required for the hydrolysis of sulfatide, globotriaosylceramide, and digalactosylceramide. The products of the hydrolysis reaction with monoglycosylceramides are ceramides and monosaccharides with net retention of the stereochemistry of the latter in the process. This is illustrated in Figure 21.4.26.

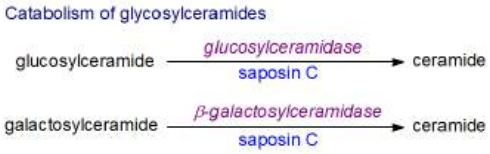

Figure 21.4.26: Catabolism of glycosylceramide

The reactions are aided by the presence of anionic lipids such as bis(monoacylglycero)phosphate. In particular, this increases the ability of the GM2-activator to solubilize lipids and stimulates the hydrolysis of membrane-bound GM1, GM2, and some of the kidney sulfatides. Saposin D stimulatesthe degradation of lysosomal ceramide by acid ceramidase, and it is also involved in the solubilization of negatively charged lipids at an appropriate pH. Eventually, the ceramides can in turn be hydrolyzed by an acid ceramidase to fatty acids and sphingoid bases.

β-Glucosylceramidase and saposin C are also required for the generation of the structural **ceramides** from glucosylceramide in the outer region of the skin, a process essential for optimal skin barrier function and survival. Some glucosylceramide is hydrolyzed by the enzyme GBA2 at the plasma membrane, where the ceramide formed is rapidly converted to sphingomyelin by the sphingomyelinase 2, which may be co-located with the glucosidase. In addition, it has been established that cellular β-glucosidases are able to transfer the glucose moiety from glucosylceramide to and from other lipids as in the formation of **cholesterol glucoside**.

Small but significant amounts of glucosyl- and galactosylceramides are ingested as part of the human diet. They are not hydrolyzed by pancreatic enzymes but are degraded in the brush border of the intestines by the enzyme lactase-phlorizin hydrolase (which also hydrolyses

the lactose in milk) to ceramides and thence to sphingosine.

An Arabidopsis homolog of human glucosylceramidase (AtGCD3) preferentially hydrolyses glucosylceramides that contain long acyl chains, and three further isoforms may exist based on sequence homology.

21.4.5.5: GENETIC DISORDERS AND DISEASE

Harmful quantities of glucosylceramide accumulate in the spleen, liver, lungs, bone marrow, and, in rare cases, the brain of patients with **Gaucher disease**, the most common of the inherited metabolic disorders (autosomal recessive) involving storage of excessive amounts of complex sphingolipids. Three clinical forms (phenotypes) of the disease are commonly recognized of which by far the most dangerous are those affecting the brain (Types 2 and 3). All of the patients exhibit a deficiency in the activity of the lysosomal glucosylceramide-β-glucosidase (GBA1), which catalyzes the first step in the catabolism of glucosylceramide. The enzyme may be present, but a mutation prevents it from forming its correct conformation, although other factors may be involved as patients with a defective saposin C, the lysosomal activator protein, develop similar symptoms.

In the brain, glucosylceramide accumulates when complex lipids turn over during brain development and during the formation of the myelin sheath of nerves. Other than in the brain, the excess glucosylceramide arises mainly from the biodegradation of old red and white blood cells. The result is that the glucosylceramide remains stored within the lysosomes of macrophages, i.e., the specialized cells that remove worn-out cells by degrading them to simple molecules for recycling, thus preventing them from functioning normally and often leading to chronic inflammation. The enlarged macrophages containing undigested glucosylceramide are termed Gaucher cells. They over-express and secrete certain proteins into the circulation, and some of these are used as biomarkers. In addition, glucosylceramide is converted more rapidly to **gangliosides** in these cells, leading to an increase in ganglioside GM3 in the plasma and spleen of patients with Gaucher disease. Fortunately, there are now effective enzyme replacement therapies for patients with the milder (non-neurological or Type 1) form of Gaucher disease that successfully reverse most manifestations of the disorder, including decreasing liver and spleen size and reducing skeletal abnormalities. Two oral drugs that inhibit glucosylceramide synthesis have also been approved.

Defective GBA1 enzyme activity in humans has been implicated in an increased risk of multiple myeloma and other cancers. Oligoglycosylceramides and gangliosides in particular are known to be involved in the pathology of a number of cancers, and glucosylceramide is an important precursor of these. Inhibition of glucosylceramide synthase, which is overexpressed in many human tumors lead to a marked arrest of cell growth in cancer cells *in vitro*, so this is believed to have the potential for the treatment of colorectal and other cancers.

A deficiency in glucocerebrosidase activity may predispose individuals to more common disorders such as Parkinson's disease and Lewy body dementia. Excess glucosylceramide production and thence of more complex glycosphingolipids is a factor in polycystic kidney disease. It appears to be a general rule that the mere process of lysosomal substrate accumulation in all lysosomal storage disorders impairs lysosome integrity and results in more general disruptions to lipid metabolism and membrane structure and function. On the other hand, inhibition of glucosylceramidases may be of benefit in cystic fibrosis. Krabbe disease is discussed in the next section.

Galactosylceramide is believed to function as an initial receptor for the human immunodeficiency virus (HIV) in mucosal epithelial cells and controls the early infection-independent phase of HIV transfer to T cells. Glucosylceramide levels regulate the uptake of viruses that rely upon the late endosomal compartment for fusion, including the influenza A and Ebola viruses.

21.4.6: GANGLIOSIDES

The name **ganglioside** was first applied by the German scientist Ernst Klenk in 1942 to a mixture of complex glycosphingolipids newly isolated from ganglion cells of brain. Subsequently, he demonstrated that as part of an oligosaccharide chain, they contained an acidic carbohydrate component, which he named "neuraminic acid" - later termed "sialic acid" from the Greek "sialon" for saliva, from which they were first isolated. However, it was not until 1963 that the first ganglioside species was fully characterized. Innumerable sphingolipids are now known that differ in the nature of both the glycan (glucose, galactose, *N*-acetylgalactosamine, and sialic acid residues) and **ceramide** structures. They are present throughout the animal kingdom, from echinoderms up to higher animals, but not in plants. Such highly polar, acidic and relatively hydrophilic molecules have distinctive physical properties, which are essential for the vital functions of gangliosides in the membranes of the central nervous system and other tissues.

21.4.6.1: SIALIC ACIDS AND GANGLIOSIDES

Sialic acids: Gangliosides are oligoglycosylceramides derived as a first step from lactosylceramide, and they are defined by the presence of one to as many as five **sialic acid** residues, i.e. carbohydrate molecules with a nine-carbon backbone and a carboxylic acid group, a subclass of the superfamily of naturally occurring non-2-ulosonic acids. Of the many forms that have been characterized, only a few are relevant to gangliosides, and the most important of these is *N*-acetylneuraminic acid (‘NANA’ or ‘SA’ or 'Neu5Ac' or 'NeuAc'). Less often the sialic acid component is *N*-glycolylneuraminic acid (Neu5Gc), which differs by only one oxygen atom at the C-5 *N*-acetyl group, or it can be a Neu5Ac analogue in which the amide group is replaced by a hydroxyl group, i.e. 3-deoxy-D-glycero-D-galacto-nonulosonic acid (ketodeoxynonulosonic acid or ‘KDN’). The sialic acids are joined via α-glycosidic linkages to one or more of the monosaccharide units,

e.g. via the hydroxyl group on position 2, or to another sialic acid residue. The polar head groups of the lipids carry a net-negative charge at pH 7.0 and they are acidic. Their structures are shown in Figure 21.4.27.

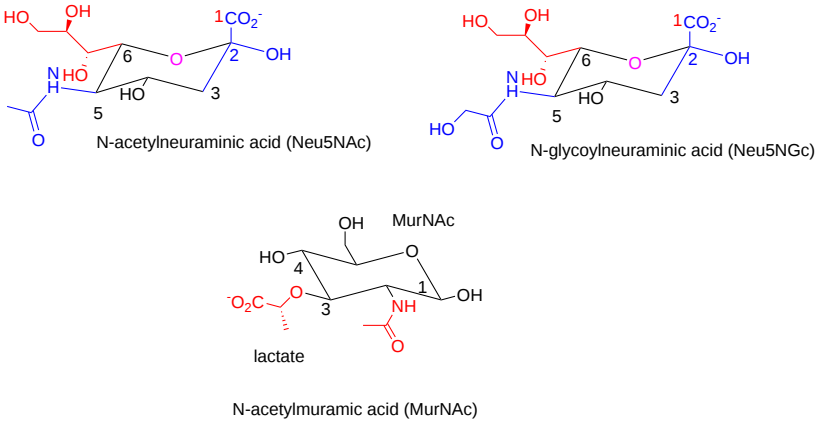

Figure 21.4.27: Sialic acids

Humans lack Neu5Gc: Neu5Ac is the biosynthetic precursor of Neu5Gc, a component of gangliosides from most animal species, including mice, horse, sheep, and goats, via the action of the enzyme CMP–*N*-acetylneuraminic acid hydroxylase (CMAH). However, NeuGc is not synthesized in humans (or birds and New World monkeys), although it is present in other primates such as the great apes, and indeed as it is a xeno-antigen, anti-NeuGc antibodies are produced normally in healthy humans (and especially after injection of NeuGc-containing glycoconjugates). The absence or irreversible inactivation of a number of relevant genes, but especially a critical exon in the *CMAH* gene, both for sialolipids and peptides in humans suggests that this may have been a major biochemical branch-point in human evolution that occurred ~2 to 3 million years ago after the divergence of humans and chimpanzees from a common ancestor. It may even be a factor in the superior performance of the human brain as the overexpression of Neu5Gc in the brains of transgenic mice was found to result in abnormal development. It could also mean that there might have been a fertility barrier between us and other hominids during evolution.

While these are speculations, there is some evidence that the loss of Neu5Gc in humans had complex effects on immunity, providing greater capabilities to clear sublethal bacterial challenges. Some NeuGc may be obtained from the diet in meat and milk, for example, and this may be incorporated into human gangliosides to a limited extent, especially in fetal tissues and some cancers. In the latter, preferential expression of dietary Neu5Gc has been ascribed to their higher metabolic rate.

21.4.6.2: 2. STRUCTURE AND OCCURRENCE OF GANGLIOSIDES

Most of the common range of gangliosides are derived from the ganglio- and neolacto-series of **neutral oligoglycosphingolipids (Table 1)**, and they should be named systematically in the same way with the position of the sialic acid residue(s) indicated as for branched structures. However, they are more conveniently defined by a short-hand nomenclature system proposed by Svennerholm in which M, D, T and Q refer to mono-, di-, tri- and tetrasialogangliosides, respectively, and the numbers 1, 2, 3, etc refer to the order of migration of the gangliosides on thin-layer chromatography. For example, the order of migration of monosialogangliosides is GM3 > GM2 > GM1 (sometimes defined by subscripts, e.g. G_{M1} or GM_1). To indicate variations within the basic structures, further terms are added, e.g. GM1a, GD1b, etc. Although alternatives have been proposed that are more systematic in structural terms, the Svennerholm nomenclature is that approved by IUPAC-IUB. Ganglio-series glycosphingolipids having 0, 1, 2 and 3 sialic acid residues linked to the inner galactose unit are termed asialo- (or 0-), a-, b- and c-series gangliosides, respectively, while gangliosides having sialic acid residues linked to the inner *N*-galactosamine residue are classified as α-series gangliosides. The structures for these groups are illustrated in the section on ganglioside **biosynthesis** below, for reasons of practical convenience.

As of 2020, more than 200 gangliosides with variations in the carbohydrate chain had been characterized in vertebrates alone. One of the most studied monosialo-gangliosides and the first to be fully characterized is ganglioside GM1a (Neu5Acα2-3(Galβ1-3GalNAcβ1-4)Galβ1-4Glcβ1Cer), a major brain ganglioside of mammals and the preferred ligand of cholera toxin, illustrated in Figure 21.4.28.

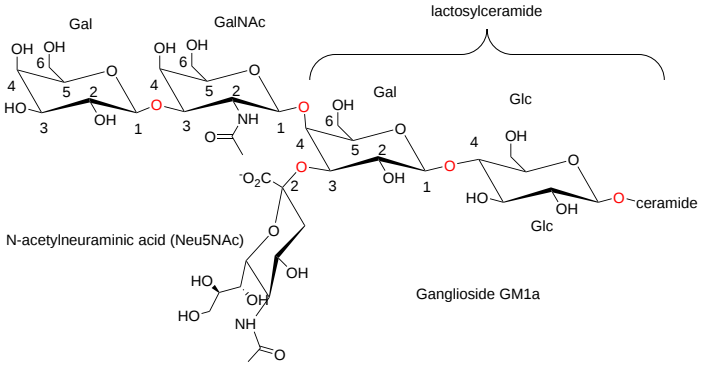

Figure 21.4.28: Ganglioside GM1a

It can also be depicted using the abbreviated structure shown in Figure 21.4.29.

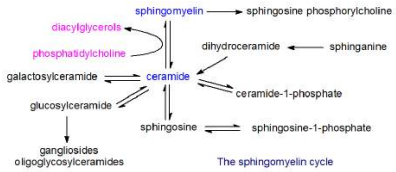

Figure 21.4.29: Abbreviated structure for Ganglioside GM1a

An alternative nomenclature, which is less used, is recommended by IUPAC-IUB and is based upon the ganglio (Gg) root structure; it employs Roman numerals to designate each hexose unit and the location of the Neu5Ac along the carbohydrate chain with Arabic superscripts to designate the hydroxyl group to which this is linked. By this system, GM1a is defined as II^3-α-Neu5Ac-Gg_4Cer.

Brain gangliosides: Gangliosides can amount to 6% of the weight of lipids from the brain (20 to 500 times more than in other tissues), where they constitute 10 to 12% of the total lipid content (20-25% of the outer layer) of neuronal membranes, for example. Aside from this, they are synthesized and are present at low levels (1 to 2% of the total lipids) in all animal tissues, where like the neutral oligoglycosphingolipids they are concentrated in the outer leaflet of the plasma membrane in the nanodomains known as '**rafts**' or in related structures. Mammalian neurons actively synthesize gangliosides of the ganglio-series primarily, but oligodendrocytes in the brain produce instead myelin-forming glycosphingolipids, such as galactosylceramide and sulfatide together with a minor amount of ganglioside GM4.

The brain contains as much as 20 to 500 times more gangliosides than most non-neural tissues, with three times as much in grey as in white matter. As the brain develops, there is an increase in the content of gangliosides and in their degree of sialylation. There are large differences between species and tissues. For example, during embryogenesis and the postnatal period in the human central nervous system, the total amount of gangliosides increases approximately threefold, while that of GM1 and GD1a increases 12 to 15-fold. During the same period, the hemato-series gangliosides GM3, GD3, and 9-OAc-GD3, which lack a hexosamine residue, are the predominant ganglioside species, but they are present in much lower amounts in adults and then in some areas of the brain only. In the mouse brain, the total amount of gangliosides is almost 8-fold greater in adults than in embryos, with a similar shift in composition from simple (GM3 and GD3) to more complex gangliosides. It is evident that the ganglioside changes during brain maturation are correlated with many neuro-developmental milestones, and there is no doubt that gangliosides play a crucial role in neuronal function and brain development, especially during infancy when there is high nutrient demand as the brain undergoes rapid restructuring.

The main gangliosides (~95%) of adult mammalian brain are ganglio series GM1, GD1a, GD1b, and GQ1b, while lactosyl series gangliosides such as GM3 (sialyllactosylceramide) are found mainly in the extra-neural tissues. The remaining ~5% consists of minor components in the brain include gangliosides GM4, GM3, GD3, GM2, GD2, Fuc-GM1, Fuc-GD1b, GT1a and GP1c, the proportions of which vary depending on species. On the other hand, modern mass spectrometric methodology (electrospray ionization ion mobility MS) has revealed a much higher degree of sialylation than was previously recognized, including a complete series of mono- to octasialylated gangliosides in fetal frontal lobe. Subsequently, many previously unknown acetylated gangliosides were found in fetal hippocampus by this methodology. The content and composition of gangliosides in the brain also change with aging, with a substantial fall in the content of lipid-bound sialic acid but an increase in the proportion of the more complex forms in terms of carbohydrate structures in the elderly.

Gangliosides in other tissues and species: Among the extraneural tissues, lactosyl series gangliosides such as GM3 (sialyllactosylceramide) and monosialogangliosides, in general, tend to predominate. Relatively high concentrations of ganglioside GD1a are present in erythrocytes, bone marrow, testis, spleen, and liver, while GM4 is more abundant in kidney, GM2 in bone marrow, GM1 in erythrocytes and GM3 in intestine. In germ cells of mice, there is a switch between gangliosides of the a- and 0-series upon differentiation when they are crossing the blood-testis barrier. Skin fibroblasts and many cells of visceral organs generate gangliosides of the globo series mainly. Similarly, glob-o and lacto series gangliosides are characteristic components of the stage-specific embryonic antigens (SSEA), which underlie the development and differentiation of human embryonic stem cells. A sialyl-lactotetraosylceramide is present in the latter

and in the brains of children under the age of two, but not in tissues of adult humans. Gangliosides can cross the placental barrier into the fetus and those in milk, derived from the apical plasma membrane of secretory cells of the mammary gland, may be of nutritional importance for the newborn. GD3 is the main ganglioside in human breast milk at an early stage of lactation, whereas GM3 is more abundant in the later stages (and in bovine milk). Unfortunately, gangliosides are poorly characterized and quantified in foods in general.

A 5-*N*-deacetylated form of ganglioside GM3 has been detected in human melanoma tumors. In addition, *O*-acetylation or lactonization of the sialic acid residue adds to the potential complexity. Gangliosides containing *O*-acetylated sialic acids, such as 9-*O*Ac-GD3, are expressed during embryonic development and in the retina and cerebellum of adult rats, but not other brain regions. They occur also in certain tumors and may protect them from apoptosis. It is possible that such gangliosides are even more widespread, but they are missed after treatment with mild alkali during the isolation procedure, a common analytical practice. A further complexity is the occurrence of gangliosides with sulfate groups, and these have been isolated from human, mouse, and monkey kidney cells. KDN-containing gangliosides are minor components of egg, ovarian fluid, sperm and testis of fish and of some mammalian tissues

Gangliosides from marine invertebrates (echinoderms), such as starfish and sea cucumbers, are very different in structure from those in vertebrates and do not have a shorthand nomenclature. They include forms with distinctive ceramide compositions, untypical carbohydrate residues, sialic acids within the oligosaccharide chain, or with glycosyl inositol-phosphoceramide structures. The mollusc, *Aplysia kurodai*, lacks gangliosides but produces complex oligoglycosylceramides with 2-aminoethylphosphonic acids and/or phosphoethanolamine groups attached that may serve as ganglioside surrogates.

Ceramide structures: In general, the ceramide structures of gangliosides tend to be relatively simple. Sphingosine is usually the main sphingoid base, accompanied by the C_{20} analog in gangliosides of the central nervous system. Stearic acid (18:0) can be 80 to 90% of the fatty acid constituents in the brain, accompanied by small amounts of 16:0, 20:0 and 22:0, but with little or no polyunsaturated or 2-hydroxy acids, other than in some exceptional circumstances (e.g. some carcinomas). Palmitic acid is more abundant in gangliosides of the intestines and liver, while 2-hydroxylated fatty acids are relatively abundant in the last and in the kidney. There are also differences in the composition of the base and fatty acid components in different cells or regions of the brain. During development, the nature and concentrations of these constituents change markedly, and for example, the ratio of C_{20}/C_{18}-sphingosine in ganglioside GD1a of cerebellum increases 16-fold from 8-day-old to 2-year-old rats. In gangliosides outwith the nervous system, C_{20}-sphingosine is barely detectable, and there is often a much wider range of fatty acid constituents (C_{14} to C_{24}).

The nature of the ceramide component is relevant to the biological function of gangliosides, and changing the fatty acid component to α-linolenic acid by synthetic means alters the biological activity of gangliosides dramatically *in vitro*. However, it is the carbohydrate moiety that has the primary importance for most of their functions, and detailed discussion of these structures would take us into realms of chemistry best left to carbohydrate experts (see the reading list below). In any given cell type, the number of different gangliosides may be relatively small, but their nature and compositions may be characteristic and in some way related to the function of the cell. It is noteworthy that some terminal glycan structures of gangliosides are also present in glycoproteins of membranes.

21.4.6.3: 3. BIOSYNTHESIS

There is evidence that the pool of **glucosylceramide** and thence of **lactosylceramide** that is utilized for ganglioside biosynthesis is different from that for the other neutral **oligoglycosylceramides**. This may explain some of the differences between the two groups in the fatty acid and sphingoid base components, which will also be dependent upon cell type. It is an open question how the ganglioside precursors enter the Golgi and trans-Golgi network where synthesis occurs at the luminal leaflet, but it appears that the regulation of intracellular sphingolipid traffic may be as important as the control of enzyme expression and activity in determining the final compositions of the various glycosphingolipid types.

In humans, sialic acid biosynthesis occurs by a series of reactions in the cytosol, but the Neu5Ac produced is transferred to the nucleus and activated by the cytosine 5'-monophosphate *N*-acetylneuraminic acid synthetase (CMAS) to form CMP-Neu5Ac, which is transported to the Golgi apparatus by a family of sialyltransferases specific for particular glycosidic linkages (α2,3, α2,6, α2,8, and α2,9).

Thereafter, the pathways for the biosynthesis of the common series of gangliosides of the ganglio-series, for example, involve sequential activities of distinct membrane-spanning sialyltransferases and glycosyltransferases as illustrated in Figure 21.4.29 for the four main 0-, a-, b- and c-series of gangliosides.

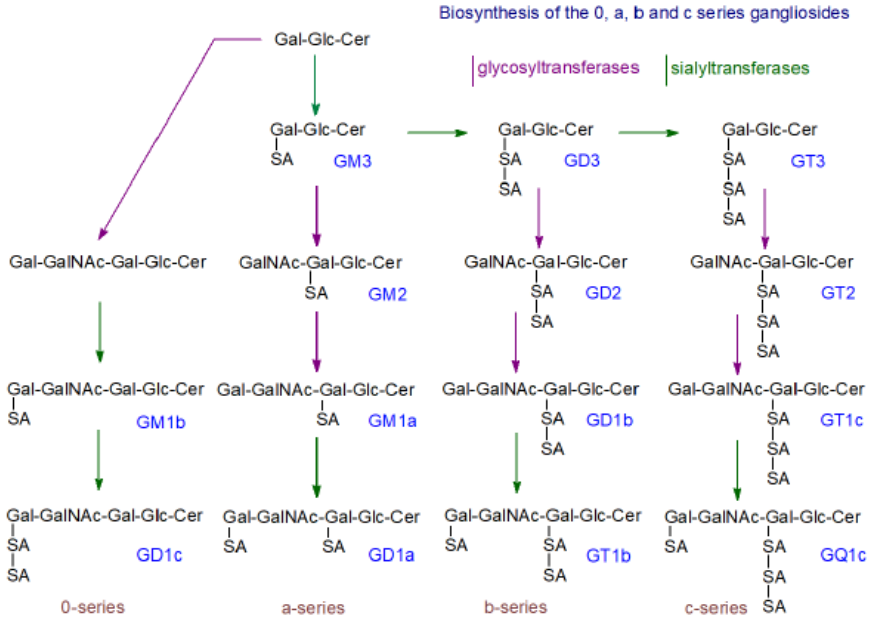

Figure 21.4.29: Biosynthesis of gangliosides

The required enzymes are bound to the membranes of the Golgi apparatus in a sequence that corresponds to the order of addition of the various carbohydrate components. Thus, the sialyltransferase that catalyzes the synthesis of the relatively simple ganglioside GM3 is located in the *cis*-region of the Golgi, while those that catalyse the terminal steps of ganglioside synthesis are located in the distal or *trans*-Golgi region. The GM3 synthase in particular, which catalyzes the transfer of Neu5Ac from cytidine monophosphate (CMP)-Neu5Ac onto the terminal galactose residue of lactosylceramide, has a unique specificity.

The simple ganglioside GM3 is synthesized by the addition of sialic acid to lactosylceramide by CMP:LacCer α2-3 sialyltransferase (or GM3 synthase), before GD3 and GT3 are produced in turn by the action of appropriate synthases. Subsequently, GM3, GD3 and GT3 serve as precursors of more complex gangliosides by the action of further glycosyl- and sialyl-transferases. An alternative theory with some supporting evidence proposes that a multiglycosyl-transferase complex is responsible for the synthesis of each individual ganglioside rather than a series of individual enzymes. Further sialylation of each of the a, b, and c series and in different positions in the carbohydrate chain can occur to give an increasingly complex and heterogeneous range of products, such as the α-series gangliosides with sialic acid residue(s) linked to the inner *N*-acetylgalactosamine residue (not illustrated). GM4 or NeuAcα2,3Gal-Ceramide, a minor component of the brain and present in a few other tissues at low levels, is an exception in that galactosylceramide is its precursor. Finally, the newly synthesized gangliosides are transferred to the external leaflet of the plasma membrane via the lumenal surface of transport vesicles. Gangliosides are also important constituents of nuclear membranes.

The changes that occur in ganglioside compositions of brain and other tissues in the embryonic and post-natal stages are governed mainly by changes in the expression level and activity of the glycosyl- and sialyl-transferases, although the former can also be regulated by glycosylation and phosphorylation.

The presence of distinctive sialidases that differ from the catabolic lysosomal enzymes (see below) in raft-like regions of the plasma membrane bring about further changes in the composition of the cell surface gangliosides that can be specific to particular cell types, causing a shift from poly-sialylated species involving a decrease of GM3 and formation of GM2 then GM1 by hydrolysis of terminal sialosyl residues linked either α2-8 on another sialic acid or α2-3 on galactose. As GM1 is resistant to most sialidases, it tends to increase in concentration relative to oligosialo species as developmental and other GM1-requiring processes come into play. This may have consequences for important cellular events, such as neuronal differentiation and apoptosis. Conversely, sialylation may occur in some neuronal membranes, increasing the proportions of poly-sialylated species. In particular, a CMP-NeuAc:GM3 sialyltransferase is able to sialylate GM3. Gangliosides GM1 and GD1a have been identified in both membranes of the nuclear envelope together with two neuraminidases.

Ganglioside lactones, where the sialic acids are linked together with ester linkages, have been detected as minor components in brain tissues, where lactonization occurs at the plasma membrane. As the process of lactonization profoundly influences the shape and biological properties of the original ganglioside, it is possible that lactonization-delactonization in a membrane might be a trigger for specific cellular reactions. Similarly, GD3 ganglioside can undergo *O*-acetylation at C9 of the outer sialic acid with important metabolic implications.

Gangliosides added to many types of cell preparations *in vitro* are rapidly taken up by the cells, while gangliosides injected into animals *in vivo* are rapidly internalized by tissues. They can cross the blood-brain barrier, and via the placenta, they can enter the fetus. Similarly, dietary gangliosides are absorbed intact by intestinal cells but are broken down to their lipid and carbohydrate constituents for re-use. The

sialic acids released by an intestinal sialidase are transported in plasma to the brain and other tissues where they influence ganglioside expression. Indeed, there is some experimental evidence that dietary gangliosides may improve cognitive functions in animals and humans.

21.4.6.4: CATABOLISM

Degradation of gangliosides takes place at the surface of intralysosomal luminal vesicles, generated by an inward budding of the endosomal membrane, and these are reached by a process of endocytosis. In brief in relation to gangliosides, soluble sialidases (neuraminidases) and exoglycohydrolases remove individual sialic acid and sugar residues sequentially from the non-reducing terminal unit, as illustrated for ganglioside GM1, with the eventual formation of ceramide, which is then split into long-chain base and fatty acids by ceramidases. This degradation occurs through the endocytosis-endosome-lysosome pathway with a requirement for an acidic pH inside the organelle. In addition to the sialidases and exoglycohydrolases, the various reactions have an absolute requirement for effector molecules, termed 'sphingolipid activator proteins', including saposins (Sap), and the specific GM2-activator protein (GM2-AP). Ganglioside GM3 is a component of the lysosomal perimeter membrane, but is protected from degradation by a glycocalix of the membrane facing the lysosol. Anionic lipids and especially **bis(monoacylglycero)phosphate** in the membranes stimulate ganglioside degradation while cholesterol is inhibitory. The catabolic pathway is shown in Figure 21.4.30.

Figure 21.4.30 Catabolism of gangliosides

This process constitutes a salvage mechanism that is important to the overall cellular economy since a high proportion of the various hydrolysis products are recycled for glycolipid biosynthesis. By generating ceramide and sphingosine, it may also be relevant to the regulatory and signaling functions of these lipids. In addition, some partial hydrolysis of gangliosides occurs in the plasma membrane as part of a biosynthetic remodeling process discussed above. Defects in catabolism lead to the gangliosidoses discussed later.

21.4.6.5: GANGLIOSIDE FUNCTION

Cell surface effects: In their natural biological environment, gangliosides have a negative charge because of the presence of sialic acids, which also add to the hydrophilicity of the polysaccharide constituent. This is balanced somewhat by the hydrophobic character of the ceramide moiety, so that over all the molecules are amphiphilic in nature, but very different from the glycerophospholipids, which are essential for the formation of membrane bilayers. Indeed, a ganglioside such as GM1 is virtually soluble in water, where it can form large aggregates though hydrophilic effects. The nature of the ceramide unit with its capacity to form hydrogen bonds with glycerophospholipids is important in ensuring that gangliosides are inserted in a stable manner into the outer layer of the plasma membrane.

Thus, gangliosides are anchored in membranes by their ceramide units with the double-tailed sialoglycan components extending out from the cell surface, where they can participate in intermolecular interactions by a network of hydrogen bonds and hydrophobic interactions. For example, the glucose-ceramide bond of GM1 is oriented in the outer leaflet of the plasma membrane such that the glycan extends perpendicularly to the plane of the lipid bilayer. All gangliosides, but especially the simplest GM3 or Neu5Acα2-3Galβ1-4Glcβ1Cer, have a structural role, and they a natural propensity to laterally segregate and to associate with each other and with other sphingolipids, phospholipids and cholesterol into **raft** nano-domains or in related structures, such as the **caveolae**, where the very large surface area occupied by the oligosaccharide chain imparts a strong positive curvature to the membrane. In this environment, gangliosides can interact with each other through side-by-side hydrogen bonds mediated by water molecules that act as bridges between the chains.

Further, molecules of GM3 and other gangliosides self-aggregate into clusters on the surface of lymphocytes of human peripheral blood, and there is evidence that the density of these clusters in membranes governs their reactivity as antigens. In addition, it is believed that gangliosides and other oligoglycosylceramides can cluster together through hydrogen donor-acceptor (*cis*) interactions because of the presence of hydroxyl and acetamide groups to form glycosynaptic domains, which are related to but functionally distinct from raft signaling platforms (with lower cholesterol concentrations). Many of the biological functions of gangliosides are mediated through their location in these nanodomains, where they may have specialized functions in cell adhesion, growth, and motility through interactions with specific proteins and signal transduction pathways. However, not all gangliosides are present in such raft-like structures.

Receptor/signaling functions: Gangliosides can bind to membrane proteins directly by carbohydrate-carbohydrate or carbohydrate-amino acid interactions, usually involving specific ganglioside head groups, resulting in changes to the location of proteins within membrane microdomains for recruitment of signaling partners, or to dimerization or other effects upon receptors. In rafts and caveolae especially, gangliosides can modulate cell signaling processes by their interactions with specific receptors, adhesion molecules, and ion channels. Cell–cell (*trans*) interactions occur by sialoglycans on one cell binding to complementary binding proteins (lectins) on adjacent cells, bringing

about adhesion of cells and enabling regulation of intracellular signaling pathways, e.g. myelin-associated glycoprotein on myelin sheaths binds to gangliosides present on axonal membranes.

In addition, gangliosides act as receptors of interferon, epidermal growth factor, nerve growth facto,r and insulin, and they may regulate cell signaling and control growth and differentiation of cells in this way. While intact gangliosides inhibit growth by rendering cells less sensitive to stimulation by epidermal growth factor, removal of the *N*-acetyl group of sialic acid enhances this reaction and stimulates growth. Gangliosides function as antigens or receptors by recognizing specific molecules (lectins), including bacterial toxins, at the cell surface and by modulating the charge density at the membrane surface (see the section on Gangliosides and Disease below). They also regulate the activities of proteins within the plasma membrane and especially receptor-type tyrosine kinases. For example, the phosphorylation state and activity of insulin receptors in caveolae and thence the insulin resistance of cells is controlled by the concentration of GM3, the main ganglioside in plasma and other extraneural tissues. GM3 interacts also with the epidermal growth factor receptor leading to cell growth inhibition. GM1 strongly influences specific neuronal functions by interacting with specific receptors such as the tropomyosin receptor kinase (Trk) A (TrkA) receptor by altering its conformation to enable interaction with the nerve growth factor (NGF) ligand.

GM3 (SA-Gal-Glc-Cer) is a serum ganglioside that is highly enriched in a type of membrane microdomain termed a 'glycosynapse', and it forms complexes with co-localized cell signaling molecules. It has a function in the innate immune function of macrophages and it has been demonstrated that molecular species of GM3 with differing acyl-chain structures and modifications can operate as pro- and anti-inflammatory modulators of Toll-like receptor 4 (TLR4); very-long-chain and α-hydroxy GM3 species increase TLR4 activation, while long-chain and unsaturated GM3 species have the opposite effect. In addition, gangliosides have been shown to be cell-type specific antigens that have key functions in immune defense. For example, a major immunological function of gangliosides and sialic acids is to protect cells from attack by our own immune system and from autoimmunity. They recognize and protect host organs and tissues from complement attack by binding to the complement regulatory protein factor H, which has the potential to exert strong cytotoxic and inflammation-inducing activity. In particular, sialic acids protect against complement killing of autologous cells by binding to this protein via the α2–3 linked sialic acid glycans of the GD3 ganglioside. On the other hand, the breakdown of this system can lead to autoimmune diseases.

Brain function: One of the first examples of a ganglioside influencing a signaling event to be studied in some detail concerns the simple ganglioside GD3, which has a central role in early neurogenesis. GD3 binds to the epidermal growth factor receptor (EGFR) via a protein-carbohydrate interaction involving its terminal *N*-acetylneuraminic acid and a lysine residue in the transmembrane domain of the receptor and also by a carbohydrate-carbohydrate interaction thereby maintaining the latter in its inactive monomeric state. EGFR then binds to the epidermal growth factor and stimulates the transition of the receptor from an inactive monomeric to an active homodimeric form, and this in turn triggers receptor auto-phosphorylation and activation of a signaling cascade that promotes cell proliferation. This has proven to be essential for the regulation of the stem cell self-renewal capacity in the brain. In contrast, the neutral oligoglycosphingolipid Gb4 exerts the opposite effect on EGFR by interacting directly with it to potentiate its auto-phosphorylation with activation of the downstream cascade.

The techniques of molecular biology such as targeted gene deletion, which enable specific enzymes to be eliminated from experimental animals, are now leading to a better understanding of the function of each ganglioside. It is evident that they are essential to central myelination, to maintain the integrity of axons and myelin, and for the transmission of nervous impulses. These effects may be mediated by interactions of the negatively charged sialic acid residues of gangliosides with calcium ions, which are critical for neuronal responses. For example, a variant of GD3, 9-*O*-acetyl GD3, appears to be involved in glial-guided neuronal migration during brain development in the rat, while GM1 may have a similar function in humans; it determines which growth cone of unpolarized neurons becomes the axon. By stabilizing neuronal circuits, gangliosides have a function in memory, and conversely, disturbances in ganglioside synthesis can lead to neurodegenerative disorders (see below). Ganglioside GM3 in raft domains has been shown to have an indispensable role for the development, function, and viability of cochlear hair cells and thence it is essential for hearing. On the other hand, mice that express GM3 primarily and are devoid of the typical complex gangliosides of the brain suffer weight loss, progressive motor and sensory dysfunction, and deterioration in spatial learning and memory with aging. GD3 is important for retinal structure and visual function in mice.

Changes in ganglioside composition can be induced by nerve stimulation, environmental factors, or drug treatments. The various interconvertible ganglioside types in the plasma membrane of neurons are particularly important for its development in that they regulate such processes as axonal determination and growth, signaling, and repair. In addition, gangliosides are believed to be functional ligands for the maintenance of myelin stability and the control of nerve regeneration by binding to a specific myelin-associated glycoprotein. The occurrence of gangliosides in cell nuclei suggests a possible involvement of gangliosides in the expression of genes relevant to neuronal function. For example, the monosialoganglioside **GM1** has been shown to promote the differentiation of various neuronal cell lines in culture. It has protective effects on the neural system by encouraging neural stem cell survival and proliferation, while facilitating the stability and regeneration of axons, and by inhibiting neurodegeneration through autophagy, for example after ischemic stroke. Within membrane rafts, this ganglioside has key roles in several signaling systems through association with specific proteins that have glycolipid-binding domains, including those that modulate mechanisms such as ion transport, neuronal differentiation, G protein-coupled receptors (GPCRs), immune system reactivities and neuroprotection. It is important for Ca^{2+} and Na^{+} homeostasis in the nucleus and plasma

membrane and in regulating the effects of platelet-derived growth factor. However, there have been unpleasant complications when GM1 has been administered for therapeutic purposes. GD1a is sometimes considered to be a reserve pool for GM1.

After nerve injury, toll-like receptor 2 (TLR2) signaling is important for the induction of neuropathic pain; ganglioside GT1b functions as a TLR2 agonist to produce mechanical and thermal hypersensitivity.

Other functions: The ganglioside GD3 is essential for the process of apoptosis by blocking the activation of specific transcription factors and thence disabling the induction of antiapoptotic genes. 9-*O*-Acetylation of the GD3 molecule prevents ganglioside oxidation and blocks its pro-apoptotic effects. Similarly, GD3 is a regulator of autophagy, i.e. the degradation and/or recycling of cellular components. Gangliosides are also important in reproduction, and in mice, GD1a has been shown to be important to oocyte maturation, monospermic fertilization, and embryonic development, while GM1 is important in sperm-oocyte interactions and sperm maturation processes. Deletion of the GM2/GD2 synthase leads to infertility in male mice and the production of a novel fucosylated ganglioside containing very-long-chain polyunsaturated fatty acids. Related studies with gene knockout mice have revealed that b-series gangliosides are important in leptin secretion from adipocytes, while a-series gangliosides interact with the leptin receptor in the hypothalamus to influence the balance of energy.

21.4.6.6: GANGLIOSIDES AND DISEASE

Bacterial toxins and viruses: In relation to adaptive immunity, a-series and o-series gangliosides in the plasma membrane are involved in the function and stimulation of receptors on certain subsets of T cells by acting as pattern-recognition receptors for invading pathogens. In particular, certain gangliosides bind specifically to viruses and to various bacterial toxins, such as those from botulinum, tetanus and cholera, and to blood merozoites of the deadliest malaria parasite *Plasmodium falciparum*, and they mediate interactions between microbes and host cells during infections, with NeuAc as the main recognition module. The best known example is cholera toxin, which is an enterotoxin produced by *Vibrio cholerae* where the specific cell surface receptor is ganglioside GM1; the five B-chains of cholera toxin each bind one molecule of GM1. Interestingly, the subsequent metabolism of the ganglioside-toxin complex is dependent on the nature of the fatty acid components of the ganglioside. It is believed that toxins utilize the gangliosides to hijack an existing retrograde transport pathway from the plasma membrane to the endoplasmic reticulum. For example, the passage of the cholera toxin through the epithelial barrier of the intestine is mediated by GM1, possibly by endocytosis of the toxin-GM1 complex via caveolae into the apical endosome and thence into the Golgi/endoplasmic reticulum, where the complex dissociates. The consequence is persistent activation of adenylate cyclase by the toxin and continuous production of cAMP that leads to the severe fluid loss typical of cholera infections. As a further example, the botulinus toxin binds to a complex of a polysialoganglioside with the protein synaptotagmin, which together act as a high-affinity receptor complex to enable the neurotoxic effects. Similarly, ganglioside GM2 binds to a toxin secreted by *Clostridium perfringens*.

Influenza viruses have two glycoproteins in their envelope membranes, hemagglutinins, which bind to cellular receptors such as gangliosides, and after entry into respiratory epithelial cells, the sialidase (neuraminidase) of the virus cleaves the sialic acid from the receptors to prevent entry of further viruses to the cell. Variations in the structure of these proteins force the development of new vaccines The carbohydrate moiety of gangliosides is essential for the initial binding of viruses, but the lipid moiety is believed to be important for controlling their intracellular transport.

Some gangliosides and GD1a especially have anti-inflammatory properties in that they inhibit the effects of bacterial lipopolysaccharides by preventing the activation of tumor necrosis factor (TNF) and other cytokines. In contrast, GM2 may increase cytokine production in similar circumstances, while the heat-labile toxins of *Escherichia coli* bind to several gangliosides in macrophages, thus activating an inflammatory response.

Gangliosidoses and other neurodegenerative diseases: It appears to be a general rule that the mere process of lysosomal substrate accumulation in all lysosomal storage disorders impairs lysosome integrity and results in more general disruptions to lipid metabolism and membrane structure and function, inevitably triggering pathologic mechanisms. Endogenous generation of antibodies to gangliosides is often a factor, and it has been argued that gangliosides and their sialic acids components are at the border of immune tolerance.

As with the neutral **oligoglycosylceramides** and **ceramide monohexosides**, a number of unpleasant lipidoses have been identified that involve the storage of excessive amounts of gangliosides in tissues because of failures in the catabolic mechanism. The most important of these are the **GM2 gangliosidoses**, i.e. **Tay-Sachs disease** (and the similar Sandhoff disease), a fatal genetic disorder found mainly in Jewish populations in which harmful quantities of ganglioside GM2 accumulate in the nerve cells in the brain and other tissues. Lyso-GM2 (non-acylated) in plasma may serve as a marker. A modified GM2 derivative that contains taurine in amide linkage to the sialic acid carboxyl group has been identified in the brain of such patients. As infants with the most common form of the disease develop, the nerve cells become distended and a relentless deterioration of mental and physical abilities occurs. The condition is caused by insufficient activity of specific enzymes, i.e. β-*N*-acetylhexosaminidase, which catalyzes the degradation of gangliosides by removing the terminal *N*-acetylgalactosamine residue from GM2, or the GM2 activator protein.

In addition, a generalized **GM1 gangliosidosis** (an autosomal recessive and neurodegenerative disease) has been characterized in which ganglioside GM1 accumulates in the nervous system leading to mental retardation and enlargement of the liver. The condition is a consequence of a deficiency of the lysosomal β-galactosidase enzyme, which hydrolyses the terminal β-galactosyl residues from GM1

ganglioside to produce GM2. It appears that storage of substantial amounts of unwanted lipids in the lysosomal system leads to a state of cellular starvation, so that essential elements such as iron are depleted in brain tissue. The presence of lyso-GM1 in plasma is now seen as a useful aid to diagnosis. Small amounts of some gangliosides accumulate as secondary storage compounds in **Niemann–Pick** disease. The **Guillain–Barré syndrome** is an acute inflammatory disorder, usually triggered by a severe infection, which affects the peripheral nervous system. Antibodies to gangliosides are produced by the immune system, leading to damage of the axons, which can result in paralysis of the patient. Huntington's disease is believed to involve disruption of the metabolic pathways between glycosylceramides and gangliosides, and there is a human autosomal recessive infantile-onset epilepsy syndrome caused by a mutation to a sialyl transferase. Impaired ganglioside metabolism is also relevant to Alzheimer's disease, because complexation with ganglioside GM1 may cause aggregation of the amyloid β-protein deposits that characteristically accumulate in the brain in this condition (this explanation does not appear to be universally accepted). In general, in ganglioside deficiencies, natural or induced, it appears that progressive inflammatory reactions take place, leading to neurodegeneration in part because of the deterioration of the architecture of lipid rafts.

On the other hand at normal tissue concentrations, gangliosides such as GM1 are believed to have an anti-inflammatory and neuroprotective role in certain types of neuronal injury, Parkinsonism, and some related diseases. For example in relation to Parkinson's disease, GM1 binds to α-synuclein and inhibits or eliminates fibril formation. It may have a protective role by preventing sphingomyelin-induced aggregation, although as the overall level of GM1 decreases during aging, its beneficial effect decreases. For these reasons, the therapeutic properties of ganglioside GM1, the most accessible species, and derived molecules are under clinical investigation. However, there is no approved therapy for any gangliosidosis, although a number of different therapeutic strategies are being studied, including hematopoietic stem cell transplantation and gene therapy. For the moment, the blood-brain barrier remains a challenge.

Cancer: Gangliosides have important functions in cancer, especially in the regulation of signal transduction induced by growth-factor receptors in a specific microdomain termed a 'glycosynapse' in the cancer cell membranes, and in interactions with glycan recognition molecules involved in cell adhesion and immune regulation. In particular, depending on tissue, certain distinctive gangliosides are expressed at much higher levels in tumors than in normal healthy tissues, mainly by aberrant expression of glycosyltransferases and glycohydrolases. This enables tumor cells to escape immune surveillance and retain their malignancy. GM3 is not expressed in melanocytes normally, but is detected in 60% of primary melanomas and in 75% of metastatic melanomas, for example. Gangliosides can be shed from the surface of tumor cells into the local environment where they can influence interactions between cancer cells, including the transition of tumors from a dormant to a malignant state (angiogenesis); when present in the circulation they can be useful diagnostic aids. For example, the ganglioside GM3 is elevated in the serum of patients with breast cancer and may be a biomarker for the disease, while disialylated gangliosides GD2 and GD3 (Figure 21.4.31) are considered to be markers of neuroectoderm origin in tumors (neuroblastoma).

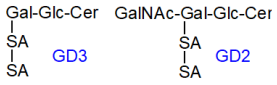

Figure 21.4.31: Structure GD2 and GD3

Specific gangliosides can have either positive or negative effects upon the regulation of the malignant properties of cancer cells. As a generality, disialyl glycosphingolipids or tandem-repeated sialic acid-structures confer malignant properties in various cancer systems; they are not merely markers. For example, the disialo-gangliosides GD2 and GD3 are present in trace amounts only in normal tissues, but are found at much higher concentrations in cancer cells, especially melanomas and neuroblastomas, with GD2 especially elevated in triple-negative breast cancer. These b-series gangliosides play a substantial part in the malignant properties of gliomas by mediating cell proliferation, migration, invasion, adhesion, and angiogenesis, and in preventing immunosuppression. They are considered to be tumor-associated antigens, and the GD2 and GD3 synthases are seen as important drug targets. In contrast, monosialyl gangliosides, such as GM1, GM2 and GM3, may suppress the malignant properties of various cancer cells. The mechanism is believed to involve complex formation at the cell surface with membrane proteins, such as growth factor receptors and adhesion receptors like those of the integrin family, leading to the modification of cell signals mediated by these receptors. Metastatic melanoma cells have high levels of GD3 in comparison to poorly metastatic cells or the normal counterpart, suggesting that GD3 may promote metastasis possibly by suppressing the anti-tumor immune response.

Ganglioside GM3(Neu5Gc), i.e. containing an abnormal sialic acid, is sometimes considered to be a tumor-specific antigen and a target for cancer immunotherapy. Aberrant sialylation is found in many malignant cancers, where the levels of neuraminidases are key factors for metastasis and survival of cancer cells, and there can be a significant accumulation of unusual gangliosides containing *N*-glycolyl sialic acid in some cancers. *N*-Glycolyl-GM3, normally absent from human tissues, is present in all stage II breast cancers, and it is accompanied by a number of other less common complex gangliosides. Similarly, the 5-*N*-deacetylated form of GM3 is expressed in metastatic melanomas, but not in healthy tissue or even in primary melanomas; it is considered to be a specific marker for the metastatic condition and a target for potential therapy. Increased synthesis of 9-*O*-acetyl-GD3, dependent on a sialyl-*O*-acetyltransferase - CAS1 Domain-Containing Protein 1, occurs in acute lymphoblastic leukemia and in malignant melanomas, and this appears to limit apoptosis, while *O*-acetylated GD2 (OAcGD2) is expressed in breast cancer and other tumors. A unique fucosyl-GM1 in which the terminal galactose is α-1,2-fucosylated at the non-reducing end is found circulating in the serum of patients with a number of cancers and especially with small-cell lung cancer but rarely in normal conditions, and it is also considered to be a potential indicator of cancer and a candidate for immunotherapy.

Clinical trials with an antibody to GD2 have been carried out successfully against the rare childhood cancer neuroblastoma, and the USDA has approved the use of this in combination with other drugs to treat this often lethal cancer. However, this antibody can have painful side effects due to an interaction with GD2 on neurons, and modified antibodies, which may be safer, are now being tested in multiple clinical trials. A phase I clinical trial with an antibody to GD3 has shown promising results in patients with malignant melanoma. Similarly, antibodies to OAcGD2 and fucosyl-GM1 have shown anti-tumour effects *in vitro*, and studies with human patients are underway.

Other diseases: Aberrant production of the ganglioside GM3 has been linked to pathophysiological changes associated with obesity, metabolic disorders, and type 2 diabetes mellitus through its effects on insulin receptors. It has a role in autoimmune disorders such as multiple sclerosis. In epilepsy, it is believed that a deficiency in the enzyme ceramide synthase 1, which produces 18:0 ceramides, leads to reduced ganglioside formation. By their presence in certain subsets of T cells, gangliosides influence allergic responses and auto-immune diseases. As gangliosides are present on the surface of vascular, vascular-associated, and inflammatory cells, they may have a role in atherosclerosis and in aging.

21.5: BIOSYNTHESIS OF CHOLESTEROL AND STEROIDS

By William (Bill) W. Christie and Henry Jakubowski.

This section is an abbreviated and modified version of material from the Lipid Web, an introduction to the chemistry and biochemistry of individual lipid classes, written by William Christie.

21.5.1: STEROLS: CHOLESTEROL AND CHOLESTEROL ESTERS

In animal tissues, **cholesterol** (cholest-5-en-3β-ol) is by far the most abundant member of a family of polycyclic compounds known as **sterols**. It can also be described as a polyisoprenoid or a triterpene from its biosynthetic origin. Cholesterol was first recognized as a component of gallstones as long ago as 1769, while the great French lipid chemist Chevreul isolated it from animal fats in 1815. However, it was well into the 20th century before the structure was fully defined by the German Chemist Heinrich Wieland, who received the Nobel Prize in Chemistry for his work in 1927, the first of thirteen so honored for research on cholesterol and its metabolism.

Cholesterol plays a vital role in animal life, and it is essential for the normal functioning of cells both as a structural component of cell membranes and as a precursor of steroid hormones and other key metabolites including vitamin D and bile acids. It is also important for cell signaling, transport processes, nerve conduction and the regulation of gene transcription. Every cell in vertebrates is able both to synthesize cholesterol and to metabolize it, and there is evidence that synthesis *de novo* is essential whatever the dietary intake; this is vital in the brain. However, excess cholesterol can contribute to the pathology of various diseases, notably cardiovascular disease, so cholesterol levels must be balanced to ensure an adequate but not excessive supply.

21.5.1.1: CHOLESTEROL – STRUCTURE, OCCURRENCE, AND FUNCTION IN MEMBRANES

The struture of cholesterol is shown below in Figure 21.5.1.

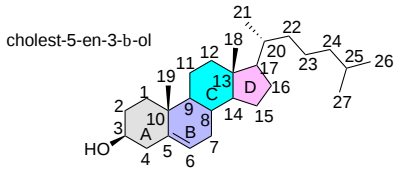

Figure 21.5.*xx*:

Cholesterol consists of a tetracyclic cyclopenta[a]phenanthrene structure with an *iso*-octyl side-chain at carbon 17. The four rings (A, B, C, D) have *trans* ring junctions, and the side chain and two methyl groups (C-18 and C-19) are at an angle to the rings above the plane with β stereochemistry (as for the hydroxyl group on C-3 also); there is a double bond between carbons 5 and 6. Thus, the molecule has a rigid planar four-ring nucleus with a flexible tail. Of the two recognized numbering systems in use, one originally described by Fieser and Fieser in 1959 and a second by IUPAC-IUB in 1989, the first appears to be preferred by most current authors.

Most of the atoms in cholesterol can be placed on the diamond lattice, which is the structure showing the position of each carbon atom in the network solid diamond. In that structure, each carbon is connected to four other carbons using sp^3-hybridized atomic orbitals and tetrahedral geometry. A representation of the diamond lattice is shown below. It consists of a series of interconnected boat conformations of cyclohexane propagating in the xyz direction. The structures of two different fused cyclohexanes, trans- and cis-decalins as well as the structure of three fused cyclohexanes, adamantane, are shown in Figure 21.5.2. Superimposing sp^3-connected atoms onto a diamond lattice allows improved visualization of the real and allowed structures of more complicated molecules.

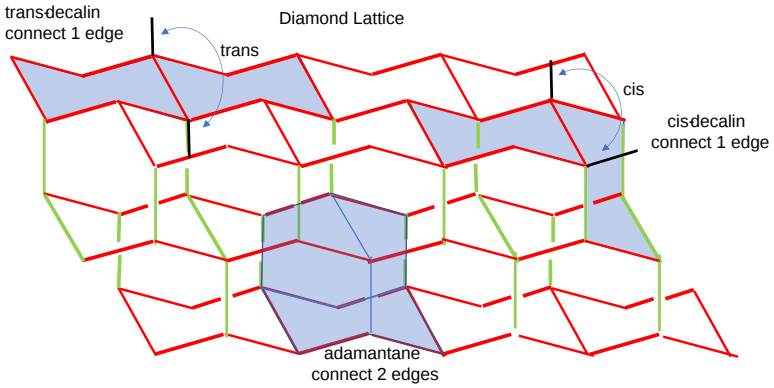

Figure 21.5.2: The diamond lattice showing decalins and adamantane

Figure 21.5.3 shows a superposition of 5-α-cholestane, a reduced and non-hydroxylated form of cholesterol, onto the diamond lattice. The pink cyclopentane D ring of 5-α-cholestane, which is distorted from the 109^0 bond angle for sp^3-hybridized carbon atoms, does not fit

exactly onto the lattice. Cholesterol, with its double bond, would also deviate from the ideal position on the diamond lattice given the two sp^2-hybridized carbons in the double bond.

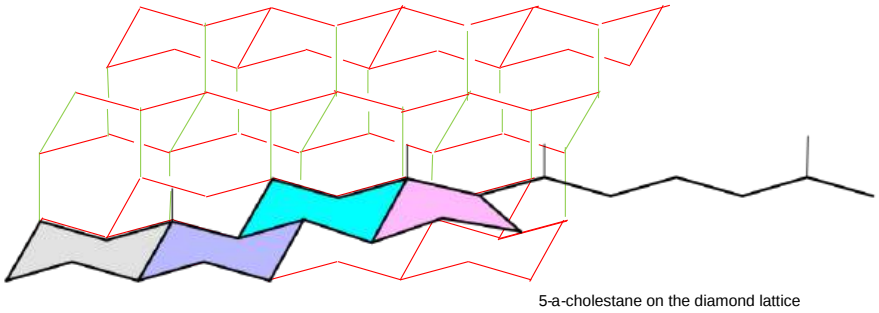

Figure 21.5.3: The diamond lattice showing 5-α-cholestane

Cholesterol is a ubiquitous component of all animal tissues (and of some fungi), produced by every nucleated animal cell, where much of it is located in the membranes, although it is not evenly distributed. The highest proportion of unesterified cholesterol is in the plasma membrane (roughly 30-50% of the lipid in the membrane or 60-80% of the cholesterol in the cell), while mitochondria and the endoplasmic reticulum have much less (~5% in the latter), and the Golgi contains an intermediate amount. Cholesterol is also enriched in early and recycling endosomes, but not in late endosomes. It may surprise some to learn that the brain contains more cholesterol than any other organ, where it comprises roughly a quarter of the total free cholesterol in the human body, 70-80% of which is in the myelin sheath. Of all the organic constituents of blood, only glucose is present in a higher molar concentration than cholesterol. In animal tissues, it occurs in the free form, esterified to long-chain fatty acids (**cholesterol esters**), and in other covalent and non-covalent linkages, including an association with the **plasma lipoproteins**. In plants, it tends to be a minor component only of a complex mixture of structurally related '**phytosterols**', although there are exceptions but it is nevertheless importance as a precursor of some plant hormones.

Animals in general synthesize a high proportion of their cholesterol requirement, but they can also ingest and absorb appreciable amounts from foods. On the other hand, many invertebrates, including insects, crustaceans and some molluscs cannot synthesize cholesterol and must receive it from the diet; for example, spiny lobsters must obtain exogenous cholesterol to produce essential sex hormones. Similarly, it must be supplied from exogenous sources to the primitive nematode *Caenorhabditis elegans*, where it does not appear to have a major role in membrane structure, other than perhaps in the function of ion channels, although it is essential the production of steroidal hormones required for larval development; its uptake is regulated by the novel lipid **phosphoethanolamine glucosylceramide**. Some species are able to convert dietary plant sterols such as β-sitosterol to cholesterol. Prokaryotes lack cholesterol entirely with the exception of some pathogens that acquire it from eukaryotic hosts to ensure their intracellular survival (e.g., *Borrelia sp.*); bacterial **hopanoids** are often considered to be sterol surrogates.

Cholesterol has vital structural roles in membranes and in lipid metabolism in general with an extraordinary diversity of biological roles, including cell signaling, morphogenesis, lipid digestion and absorption in the intestines, reproduction, stress responses, sodium and water balance, and calcium and phosphorus metabolism, and we can only touch on a few of these functions in this web page. It is a biosynthetic precursor of bile acids, vitamin D, and steroid hormones (glucocorticoids, estrogens, progesterones, androgens, and aldosterone), and it is found in covalent linkage to specific membrane proteins or **proteolipids** ('hedgehog' proteins), which have vital functions in embryonic development. In addition, it contributes substantially to the development and working of the central nervous system. On the other hand, excess cholesterol in cells can be toxic, and a complex web of enzymes is essential to maintain the optimum concentrations. Because plasma cholesterol levels can be a major contributory factor to atherogenesis, media coverage has created what has been termed a 'cholesterophobia' in the population at large.

One of the main functions of cholesterol is to modulate the fluidity of membranes by interacting with their complex lipid components, specifically the phospholipids such as phosphatidylcholine and sphingomyelin. As an amphiphilic molecule, cholesterol is able to intercalate between phospholipids in lipid bilayers to span about half a bilayer. In its three-dimensional structure, it is in essence a planar molecule that can interact on both sides. The tetracyclic ring structure is compact and very rigid. In addition, the location of the hydroxyl group facilitates the orientation of the molecule in a membrane bilayer, while the positions of the methyl groups appear to maximize interactions with other lipid constituents. The structure of cholesterol as it would appear on the diamond lattice is shown in Figure 21.5.4.

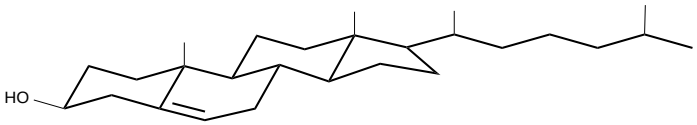

Figure 21.5.4: "Diamond" lattice structure of cholesterol

As the α-face of the cholesterol nucleus (facing down) is 'smooth', it can make good contact with the saturated fatty-acyl chains of phospholipids down to about their tenth methylene group; the β-face (facing up) is made 'rough' by the projection of methyl groups from carbons 10 and 13. The interaction is mainly via van der Waals and hydrophobic forces with a contribution from hydrogen bonding of the cholesterol hydroxyl group to the polar head group and interfacial regions of the phospholipids, especially sphingomyelin. Intercalated cholesterol may also disrupt electrostatic interactions between the ionic phosphocholine head groups of nearby membrane phospholipids, leading to increased mobility of the head groups. Indeed, there is evidence that cholesterol forms stoichiometric complexes with the saturated fatty acyl groups of sphingomyelin and to a lesser extent of phosphatidylcholine.

Experiments with mutant cell lines and specific inhibitors of cholesterol biosynthesis suggest that an equatorial hydroxyl group at C-3 of sterols is essential for the growth of mammalian cells. The Δ5 double bond ensures that the molecule adopts a planar conformation, and this feature also appears to be essential for cell growth, as is the flexible *iso*-octyl side-chain. The C-18 methyl group is crucial for the proper orientation of the sterol. While plant sterols appear to be able to substitute for cholesterol in supporting many of the bulk properties of membranes in mammalian cells *in vitro*, cholesterol is essential for other purposes.

In the absence of cholesterol, a membrane composed of unsaturated lipids is in a fluid state that is characterized by a substantial degree of lipid chain disorder, i.e., it constitutes a *liquid-disordered* phase. The function of cholesterol is to increase the degree of order (cohesion and packing) in membranes, leading to the formation of a *liquid-ordered* phase. In contrast, it renders bilayers composed of more saturated lipids, which would otherwise be in a solid gel state, more fluid. Thus, cholesterol is able to promote and stabilize a liquid-ordered phase over a substantial range of temperatures and sterol concentrations. Further, high cholesterol concentrations in membranes reduce their passive permeability to solutes. These effects enable membranes to bend or withstand mechanical stresses, and they permit the fine-tuning of membrane lipid composition and organization, and regulate critical cell functions. Simplistically, the higher cholesterol concentrations in the plasma membrane support its barrier function by increasing membrane thickness and reducing its permeability to small molecules. In contrast, the endoplasmic reticulum has increased membrane flexibility because of its lower cholesterol concentrations and thus enables the insertion and folding of proteins in its lipid bilayer. While mitochondrial membranes have a low cholesterol content in total, this may be concentrated in nanodomains at regions of high curvature in the inner mitochondrial membrane with links to nucleoprotein complexes (nucleoids).

In comparison to other lipids, it has been reported that cholesterol can flip rapidly between the leaflets in a bilayer, although this does not appear to be accepted universally, leading to doubts as to the trans-bilayer distribution of cholesterol in some biological membranes. However, much recent evidence suggests that the concentration of cholesterol in the inner leaflet of the plasma membrane is much lower than that in the outer leaflet in a range of mammalian cells. This distribution is important in that cholesterol promotes negative curvature of membranes and may be a significant factor in bringing about membrane fusion in the process of exocytosis. It may also be relevant for the regulation of various cellular signaling processes at the plasma membrane.

Cholesterol also has a key role in the lateral organization of membranes and their free volume distribution, factors permitting more intimate protein-cholesterol interactions that may regulate the activities of membrane proteins. Many membrane proteins bind strongly to cholesterol, including some that are involved in cellular cholesterol homeostasis or trafficking, and contain a conserved region termed the ‘sterol-sensing domain’. Some proteins bind to cholesterol deep within the hydrophobic core of the membrane via binding sites on the membrane-spanning surfaces or in cavities or pores in the proteins, driven by hydrogen bond formation. Cholesterol has an intimate interaction with G-protein-coupled receptors (GPCRs) to affect ligand binding and activation, either by direct high-affinity binding to the receptor, by changing their oligomerization state, or by inducing changes in the properties of the membrane. For example, it is essential for the stability and function of the β2-adrenergic, oxytocin and serotonin receptors by increasing the agonist affinities, while the inactive state of rhodopsin is stabilized both through indirect effects on plasma membrane curvature and by a direct interaction between lipid and protein. The GPCR neurotransmitter serotonin$_{1A}$ receptor has ten closely bound cholesterol molecules, and these control its organization and positioning; the receptor senses membrane cholesterol via a lysine residue in a so-called 'CRAC' motif in transmembrane helix 2.

Ion pumps such as the (Na^+-K^+)-ATPase, which have specific binding sites for cholesterol molecules, are the single most important consumer of ATP in cells and are responsible for the ion gradients across membranes that are essential for many cellular functions; depletion of cholesterol in the plasma membrane deactivates these ion pumps. In the brain in addition to being essential for the structure of the myelin sheath, cholesterol is a major component of synaptic vesicles and controls their shape and functional properties. In the nucleus of cells, cholesterol is intimately involved in chromatin structure and function.

The role of cholesterol together with sphingolipids in the formation of the transient membrane nano-domains known as **rafts** (see the specific web page for detailed discussion), is of crucial importance for the function of cells, while the interaction of cholesterol with **ceramides** is essential for the barrier function of the skin.

21.5.1.2: CHOLESTEROL BIOSYNTHESIS

Cholesterol biosynthesis involves a highly complex series of at least thirty different enzymatic reactions, which were unraveled in large measure by Konrad Bloch and Fyodor Lynen, who received the Nobel Prize for their work on the topic in 1964. When the various regulatory, transport, and genetic studies of more recent years are taken into account, it is obvious that this is a subject that cannot be treated in depth here. The bare bones of mechanistic aspects are therefore delineated, which with the references listed below should serve as a guide

to further study. In **plants**, cholesterol synthesis occurs by a somewhat different pathway with cycloartenol as the key intermediate. We'll explore the reaction mechanisms for several of the enzymes on this complicated pathway given its medical importance.

Almost all nucleated cells are able to synthesize their full complement of cholesterol. The first steps involve the synthesis of the important intermediate mevalonic acid from acetyl-CoA and acetoacetyl-CoA, both of which are in fact derived from acetate, in two enzymatic steps. These precursors are in the cytosol as is the first enzyme, **3-hydroxy-3-methyl-glutaryl(HMG)-CoA synthase**. The second enzyme **HMG-CoA reductase** is a particularly important control point, and is widely regarded as the rate-limiting step in the overall synthesis of sterols; its activity is regulated at the transcriptional level and by many more factors including a cycle of phosphorylation-dephosphorylation. This and subsequent enzymes are membrane-bound and are located in the endoplasmic reticulum. The enzyme HMG-CoA reductase is among the targets inhibited by the drugs known as 'statins' so that patients must then obtain much of their cholesterol from the diet. The first two reactions in the synthesis of cholesterol are shown in Figure 21.5.5.

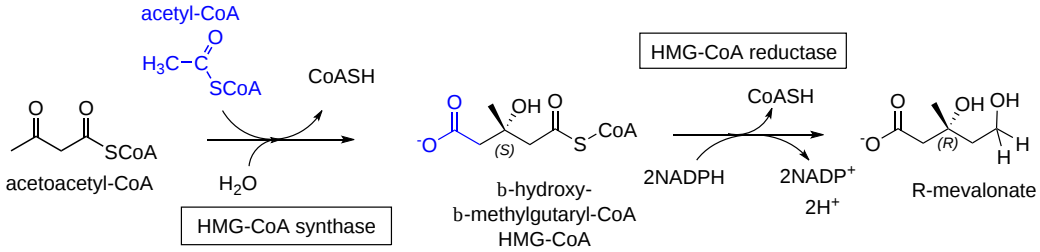

Figure 21.5.5: First two reaction in the synthesis of cholesterol

HMG-CoA Synthase

We saw this reaction in the synthesis of ketone bodies in Chapter 17. This enzyme catalyzes the condensation of acetoacetyl–CoA (AcAc–CoA) and acetyl–CoA (Ac-CoA) to form 3-hydroxy-3-methylglutaryl (HMG)–CoA, and requires the formation of a C-C bond. HMG-CoA synthase forms a C-C bond by activating the methyl group of **acetyl-cysteine**. The acetyl group comes from an acyl-CoA "donor". The enzyme catalyzes the first committed step in the formation of complex isoprenoids (like cholesterol) and ketone bodies. The product, 3-hydroxy-3-methylglutaryl HMG–CoA, can either be reduced by HMG-CoA reductase to form mevalonate, which leads to cholesterol synthesis, or cleaved by the enzyme HMG-CoA lyase, to produce acetoacetate, a ketone body.

HMG-CoA synthase catalyzes a bisubstrate reaction that displays ping-pong kinetics, characteristic of a covalent enzyme intermediate. The first substrate binds to the enzyme and transfers an acetyl group to a nucleophilic Cys 111 in the active site to form an acetyl-Cys 111 intermediate. Free CoA departs. Next the second substrate, acetoacetyl-CoA binds, and condenses with the acetyl group donated by acetyl-Cys 111. This condensation involves an enolate. A plausible reaction mechanism is shown in Figure 21.5.6.

Figure 21.5.6: Reaction mechanism for HMG-CoA synthase

Hence there are three parts of the reaction: acetylation/deacetylation, condensation/cleavage with an enolate intermediate, and C-C formation and hydrolysis/dehydration. Figure 21.5.7 shows an interactive iCn3D model of the Staphylococcus aureus HMG-COA Synthase with bound HMG-CoA and acetoacetyl-CoA (1XPK)

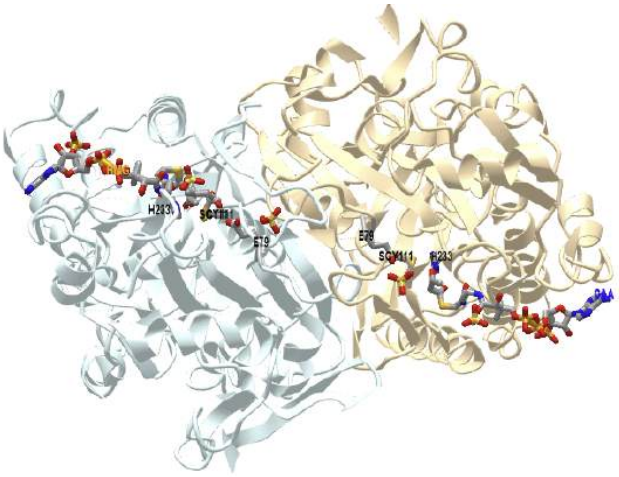

Figure 21.5.7: Staphylococcus aureus HMG-COA Synthase with bound HMG-CoA and acetoacetyl-CoA (1XPK). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...deiFs7JceE5H76

The biologically active unit (homodimer) is shown with each monomer shown in a different color. The A chain (light cyan) has bound HMG-CoA (HMG) while the B chain (light gold) has acetoacetyl-CoA (CAA) bound. The Glu 79, Cys 111, and His 233 in each subunit are shown in CPK sticks and labeled. Note that the Cys 111 is covalently modified in each subunit.

Figure 21.5.8 shows an interactive iCn3D model of the human 3-hydroxy-3-methylglutaryl CoA synthase I with bound CoASH (2P8U)

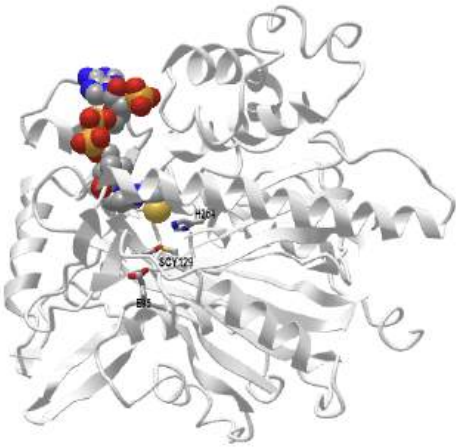

Figure 21.5.8: Human 3-hydroxy-3-methylglutaryl CoA synthase I (monomer) with bound CoASH (2P8U). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...xxEoUfecTk3eL6

The active site side chains are numbered differently (Glu 95, Cys 129, and His 264) compared to the S. aurus protein. Only the monomer is shown in this model.

HMG-CoA Reductase

In this key rate-limiting step that commits HMG to the sterol and isoprenoid synthetic pathways, HMG is converted to mevalonate. A reducing agent (NADPH) is required for this biosynthetic reaction. A plausible mechanism is shown in Figure 21.5.9.

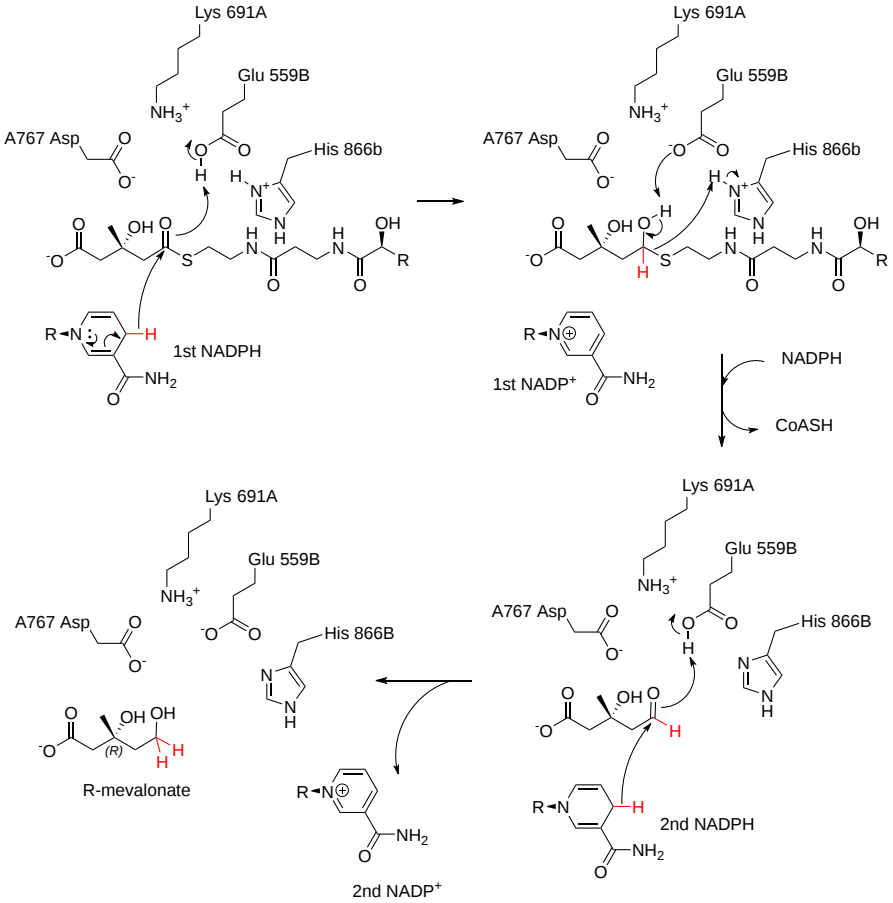

Figure 21.5.9: Reaction mechanism for HMG-CoA reductase. Adapted from https://www.ebi.ac.uk/thornton-srv/m-csa/entry/93/. Creative Commons Attribution 4.0 International (CC BY 4.0) License.

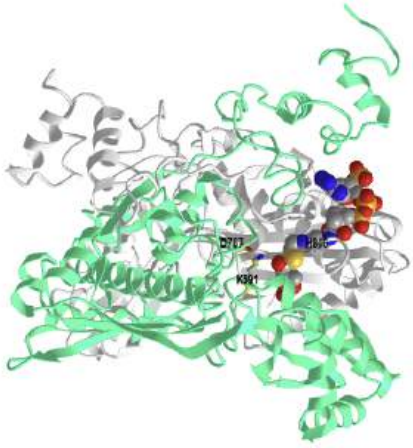
Figure 21.5.10 shows an interactive iCn3D model of the catalytic domain of human HMG-CoA reductase with bound HMG-CoA (1DQ9).



NCBI iCn3D Figure 21.5.10: Catalytic domain of human HMG-CoA reductase with bound HMG-CoA (1DQ9). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...dZvWzTocKhUzt8

Two of the four identical monomers in the biological unit, the C (gray) and D (cyan) chains are shown. HMG-CoA is shown in spacefill and CPK colors. Three key catalytic residues, His 866 in the C chain (b chain in the mechanism above) and Lys 691 and Asp 767 in the D chain (A chain in the mechanism above) are shown in sticks, CPK colors and labeled.

Synthesis of 5-isopentenyl and 2-isopentenyl pyrophosphate

The next sequence of reactions involves first the phosphorylation of mevalonic acid by a mevalonate kinase to form the 5-monophosphate ester, followed by further phosphorylation to yield an unstable pyrophosphate, which is rapidly decarboxylated to produce 5-isopentenyl

pyrophosphoric acid, the universal isoprene unit. An isomerase converts part of the latter to 3,3-dimethylallyl pyrophosphoric acid. These reactions are shown in Figure 21.5.11.

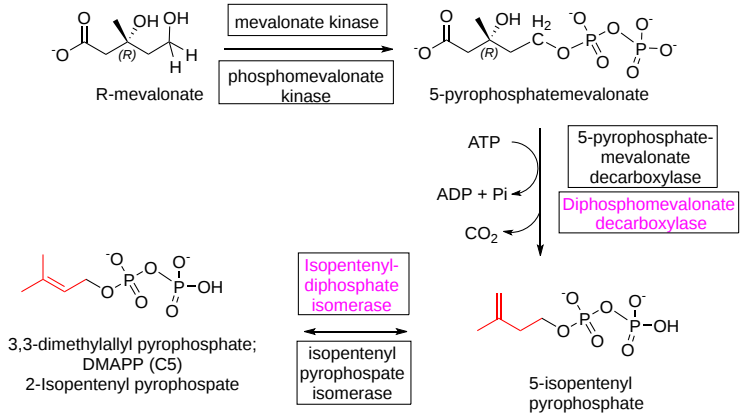


Figure 21.5.11: Reactions for the synthesis of 5-isopentenyl and 2-isopentenyl pyrophosphate for the synthesis of sterols and isoprenoids

Two phosphorylations are required, one by mevalonate kinase, which proceeds by an ordered sequential binding of mevalonate as the first reactant and its phosphomevalonate as the first product released. The enzyme is inhibited by two downstream products of the reaction pathway, farnesyl pyrophosphate, and geranyl pyrophosphate. A mechanism for mevalonate kinase is shown in Figure 21.5.12.

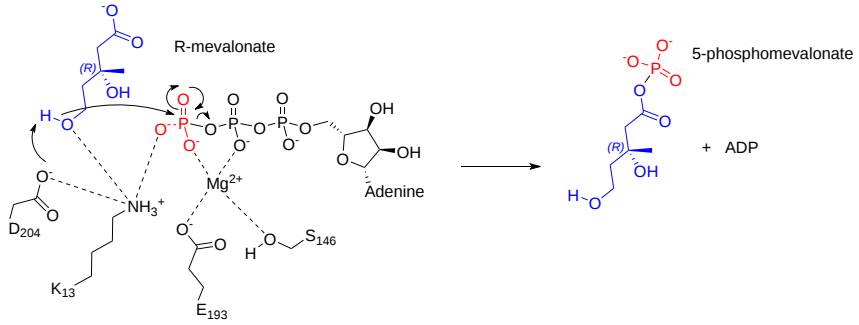

Figure 21.5.12: Mechanism of mevalonate kinase (adapted from Fu et al. JBC. 277 (2002). https://doi.org/10.1074/jbc.M200912200

A reaction mechanism for the second kinase, phosphomevalonate kinase, showing progression through the transition state, is shown in Figure 21.5.13. The reaction proceeds through direct phosphorylation through a dissociative mechanism.

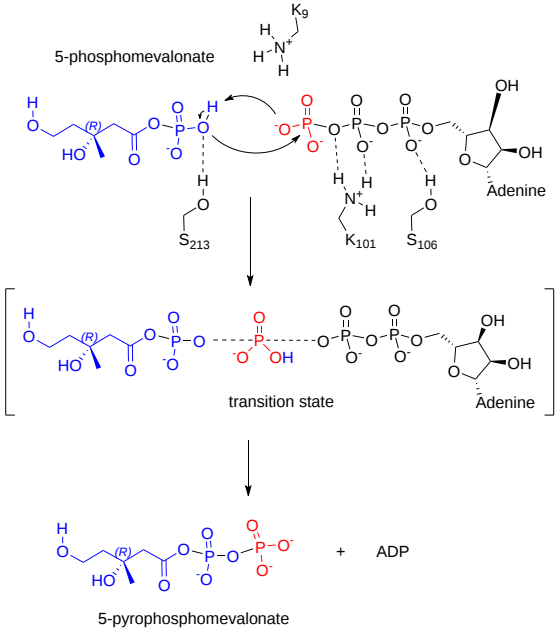

Figure 21.5.13: Reaction mechanism for phosphomevalonate kinase (after Huang et al. J. Phys. Chem. B 2016, 120. DOI: 10.1021/acs.jpcb.6b08480)

Mevalonate diphosphate decarboxylase

This enzyme catalyzes the decarboxylation of 5-pyrophosphate mevalonate to 5-isopentenylpyrophosphate as shown in Figure 21.5.14.

Figure 21.5.14: Conversion of 5-pyrophosphaemevalonate to 5-isopentyl pyrophosphate

The binding of the two substrates, pyrophosphatemevalonate (or mevalonate pyrophosphate - MVAPP) and ATP to the enzyme (A), and a reaction mechanism (B, are shown in Figure 21.5.15.

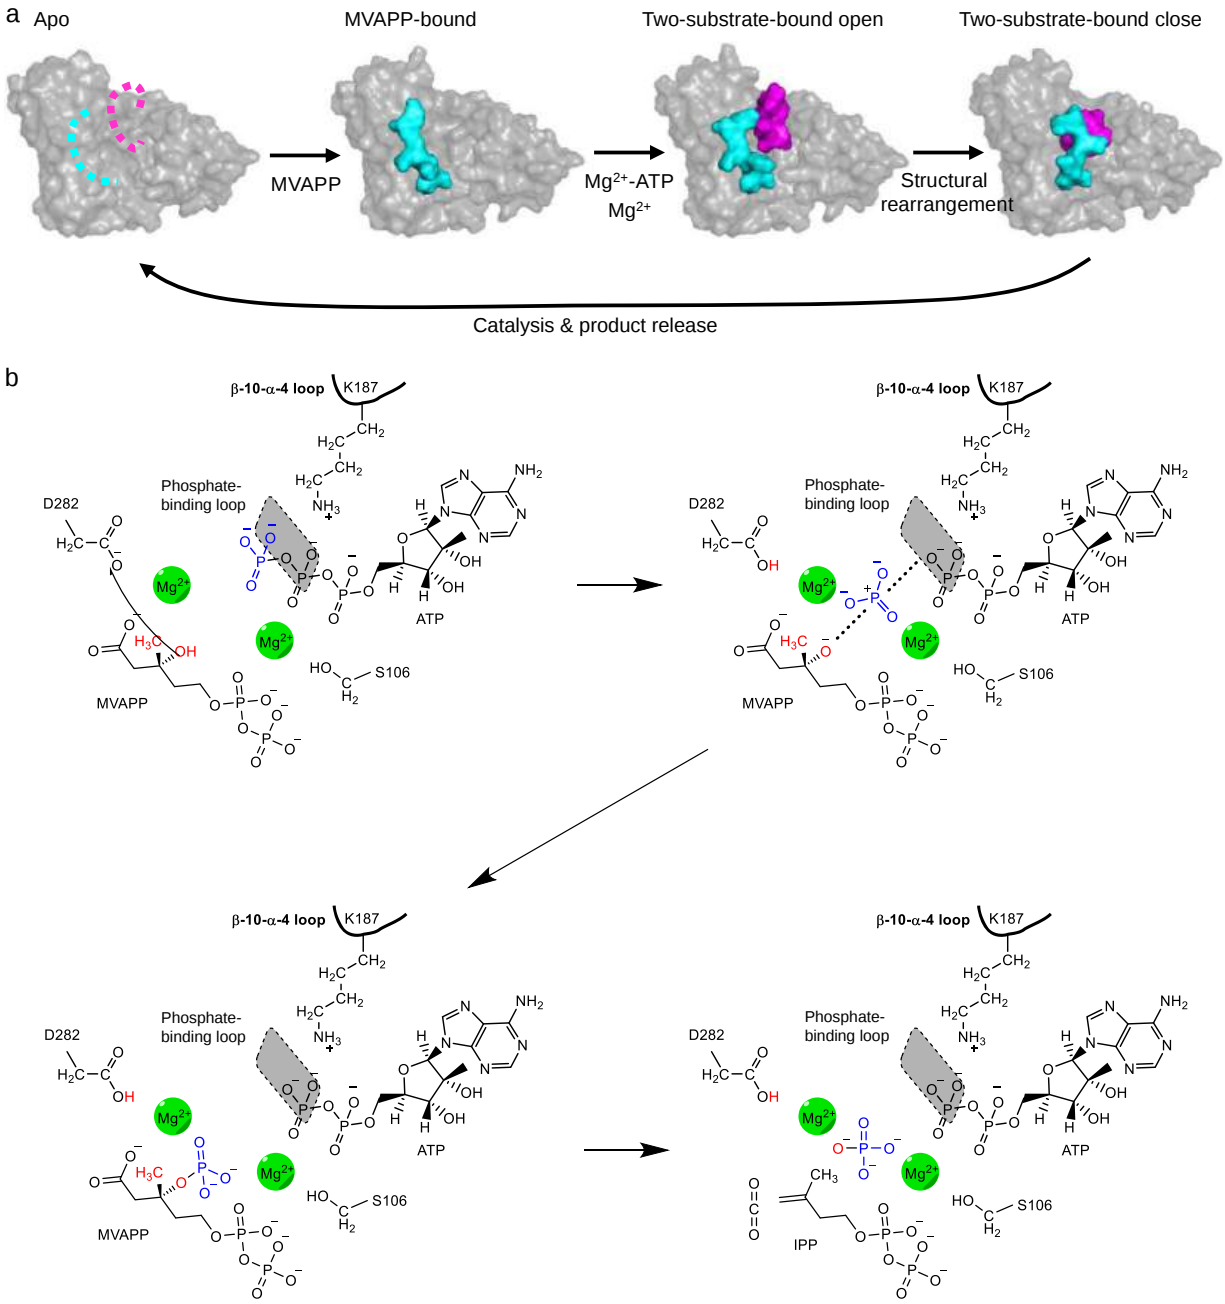

Figure 21.5.15: Proposed model for the detailed MDD enzyme mechanism. Chen et al. Nature Communications. (2020) 11:3969 |https://doi.org/10.1038/s41467-020-17733-0. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/.

Panel (a) shows changes in the enzyme structure upon substrate binding. The apo-enzyme is shown on the left. The middle structure shows the enzyme after binding of the first substrate, MVAPP. A key loop (β10-α4) is shown as a cyan surface. The enzyme is then shown in an open conformation with the second substrate (ATP) also bound. An additional phosphate-biding loop is shown in magenta. At the far right, the enzyme is shown in a closed conformation after conformational changes in both loops which traps substrates in the active site. These changes enable catalysis. Product release follows.

Panel (b) shows the dissociative phosphoryl transfer catalytic mechanism. At the top-left, D282 is shown interacting with the 3′-OH group of MVAPP (red). The top-right shows a dissociative phosphoryl (blue) transition state. In the bottom-left, the phosphate attaches to the 3′ oxygen (red) of MVAPP. The bottom-right shows the products after the dephosphorylation and decarboxylation to produce IPP, ADP, phosphate, and CO2. K187 from the β10-α4 loop and metal ions in the active site are involved in neutralizing the negatively charged environment and assists catalysis.

Figure 21.5.16 shows an interactive iCn3D model of mevalonate diphosphate decarboxylase with mevalonate-5-diphosphate, AMPPCP and Magnesium (6E2U).

NCBI iCn3D Figure 21.5.16: Mevalonate diphosphate decarboxylase with mevalonate-5-diphosphate, AMPPCP and Magnesium (6E2U) . (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...SukmP1BTyNhH26

The correctly positioned substrates interact with two Mg^{2+} ions in the initial steps of the reaction. The conserved lysine facilitates the phosphoryl transfer.

21.5.1.3: POLYMERIZATION OF ISOPRENE

Isoprene, a small branched alkadiene, which can polymerize into larger molecules containing isoprene monomer to form isoprenoids, often called terpenes. Instead of using isoprene as the polymerization monomer, either dimethylally pyrophosphate (DMAPP) or isopentenylpyrophosphate (IPP) are used biologically.

Figure 21.5.x below shows how DMAPP and IPP (both containing 5Cs) are used in a polymerization reaction to form geranyl-pyrophosphate (C10), farnesyl pyrophosphate (C15) and geranyl-geranyl pyrophosphate (C20). Figure 21.5.17:

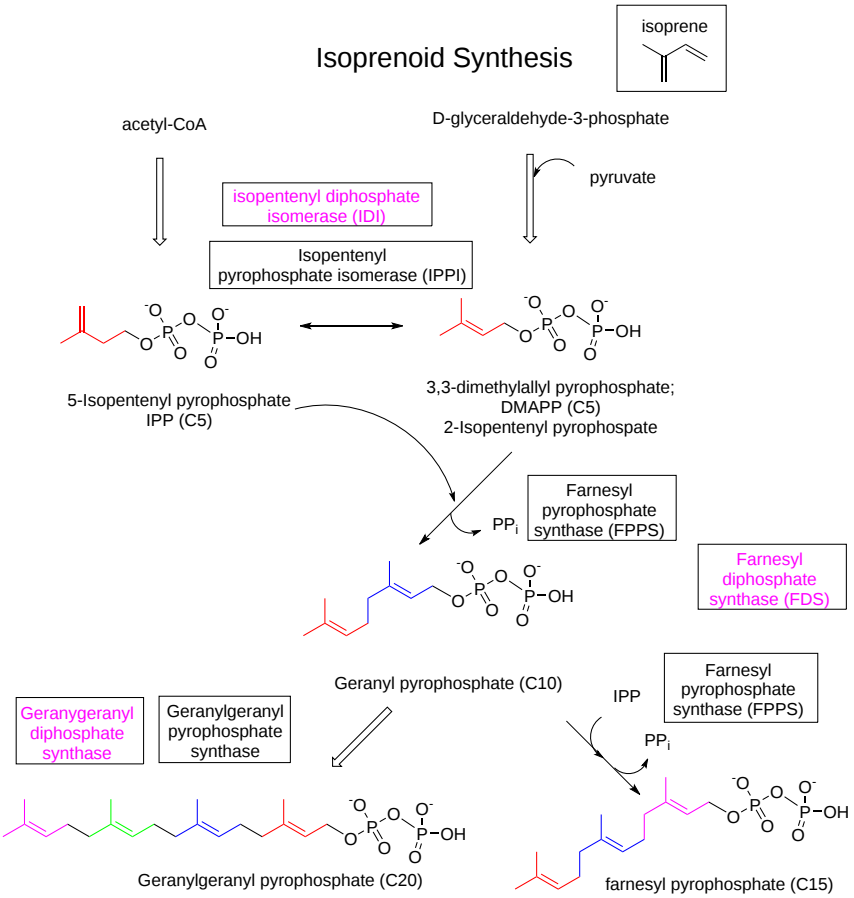

Figure 21.5.17: Synthesis of geranyl-pyrophosphate (C10), farnesyl pyrophosphate (C15) and geranyl-geranyl pyrophosphate (C20)

The condensation of IPP and DMAPP is a head-to-tail condensation reaction. Another IPP reacts with geranylpyrophosphate using the same enzyme to produce farnesylpyrophosphate. DMAPP is first formed by the isomerization of an IPP to DMAPP catalyzed by isopentenyl-diphosphate delta-isomerase. It catalyzes the 1,3-allylic rearrangement of the homoallylic substrate isopentenyl (IPP). 5-isopentenyl pyrophosphate is a nucleophile, but its isomer, DMAPP, is highly electrophilic, which promotes the condensation of the two molecules.

A mechanism for the next reaction, the first condensation of DMAPP and IPP to form geranylpyrophosphate by farnesyl pyrophosphate (diphosphate) synthase reaction, is shown in Figure 21.5.18.

Figure 21.5.18 Mechanism for the condensation of DMAPP and IPP to form geranylpyrophosphate by farnesyl pyrophosphate (diphosphate) synthase

The reaction appears to proceed using a carbocation transition state, followed by the transfer of a hydrogen atom (not ion) from IPP to pyrophosphate. Figure 21.5.19 shows an interactive iCn3D model of E. Coli farnesyl pyrophosphate synthase bound to isopentyl pyrophosphate and dimethylallyl S-thiolodiphosphate (1RQI).

Figure 21.5.19: Farnesyl pyrophosphate synthase Bound to isopentyl pyrophosphate (IPP) and dimethylallyl S-thiolodiphosphate (1RQI). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...kQBU5dNnKrCVt6

DST in the structure is dimethylallyl S-thiolodiphosphate, an analog of dimethylallyl diphosphate (DMAPP). Key conserved amino acids involved in substrate binding, transition state stabilization, and catalysis are shown as sticks, CPK colors. Thr203, Gln241, and Lys202 presumably stabilized the carbocation intermediate/transition state. Lys202 also forms a hydrogen bond with DMAPP. Two arginines (69, 116) form salt bridges with the pyrophosphates of IPP and DMAPP.

Many isoprenoid lipids are made from farnesyl pyrophosphate. For membrane purposes, the most important of these is cholesterol. Figure 21.5.20 shows an overview of the synthesis of cholesterol from two farnesyl pyrophosphates linking together in a "tail-to-tail" reaction to form squalene, a precursor of cholesterol. Each isoprene unit (5Cs) is shown in different colors to make it easier to see.

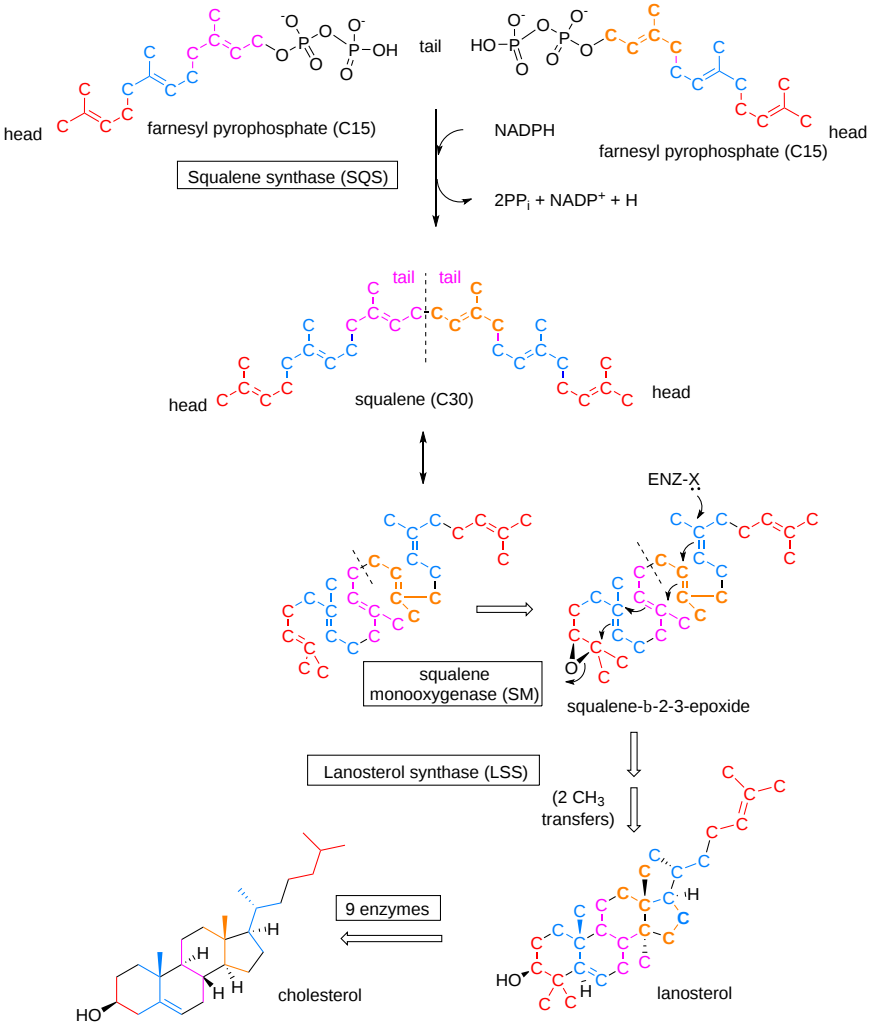

Figure 21.5.20: Synthesis of squalene from isoprene units Figure 21.5.21 shows reactants (two farnesyl pyrophosphate), intermediate (presqualene diphosphate) and product (squalene) in the reaction catalyzed by squalene synthase.

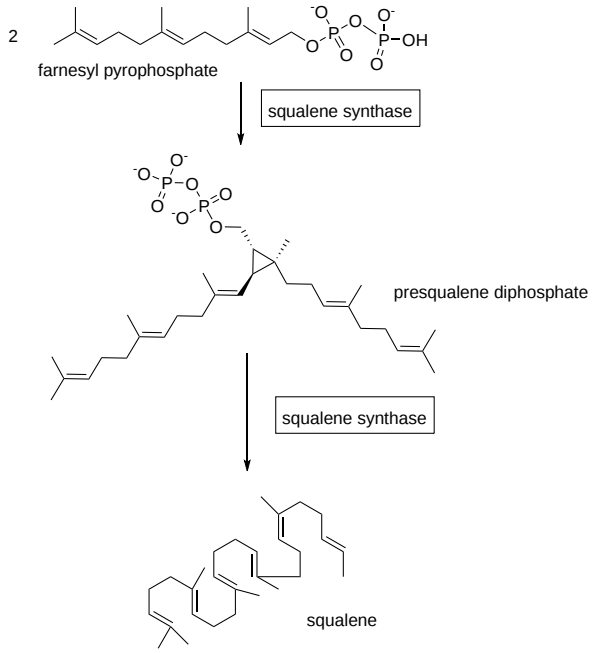

Figure 21.5.21:

In the squalene synthase reaction, two molecules of farnesyl pyrophosphate condense to yield presqualene pyrophosphate. In turn, this is reduced by NADPH to produce the key intermediate **squalene**. The enzyme squalene synthase, which regulates the flow of metabolites into either the sterol or non-sterol pathways (with farnesyl pyrophosphate as the branch point), is considered to be the first committed enzyme in cholesterol biosynthesis.

Given the importance of this reaction, we will explore the unique mechanism of squalene synthase in some detail.

Part 1: Formation of the cyclopropyl presqualene intermediate

Figure 21.5.22 shows the mechanism for the first part of the reaction in which the cyclopropyl intermediate presqualene form. The reaction proceeds through a series of carbocation intermediates.

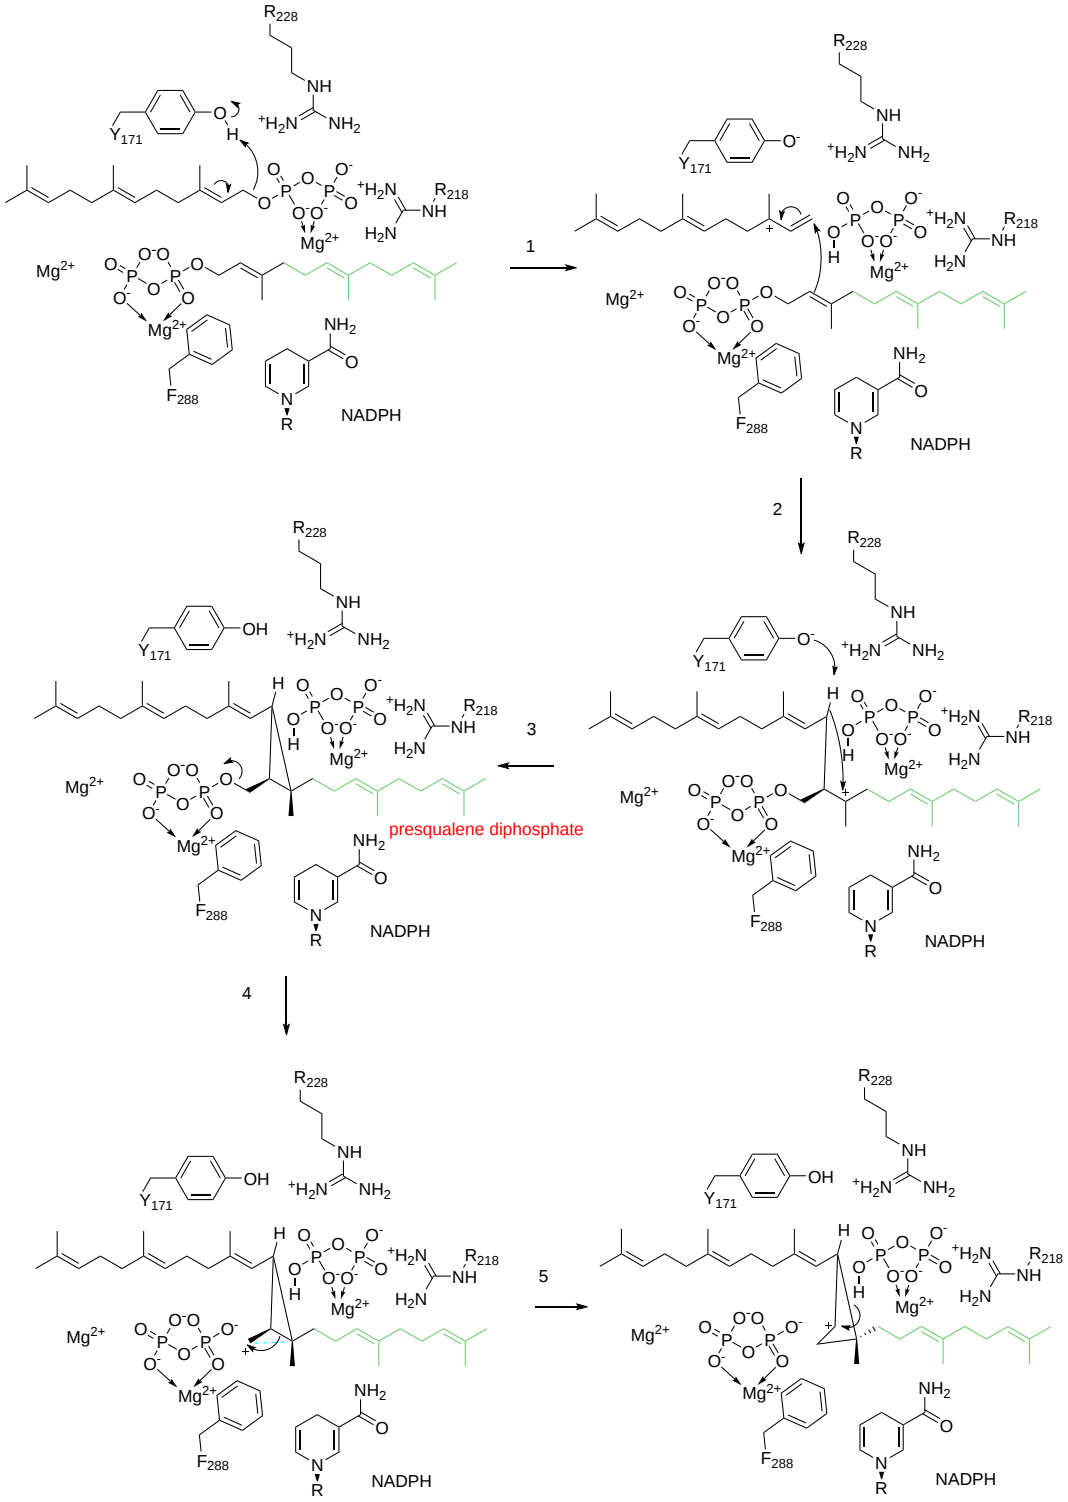

Figure 21.5.22 Mechanism for the synthesis of presqualene by squalene synthase. https://www.ebi.ac.uk/thornton-srv/m-csa/entry/264/. Creative Commons Attribution 4.0 International (CC BY 4.0) License

Part 2: Conversion of cyclopropyl intermediate to squalene - reduction

The next part of the reaction involves the reductive formation of squalene, as shown in Figure 21.5.23.

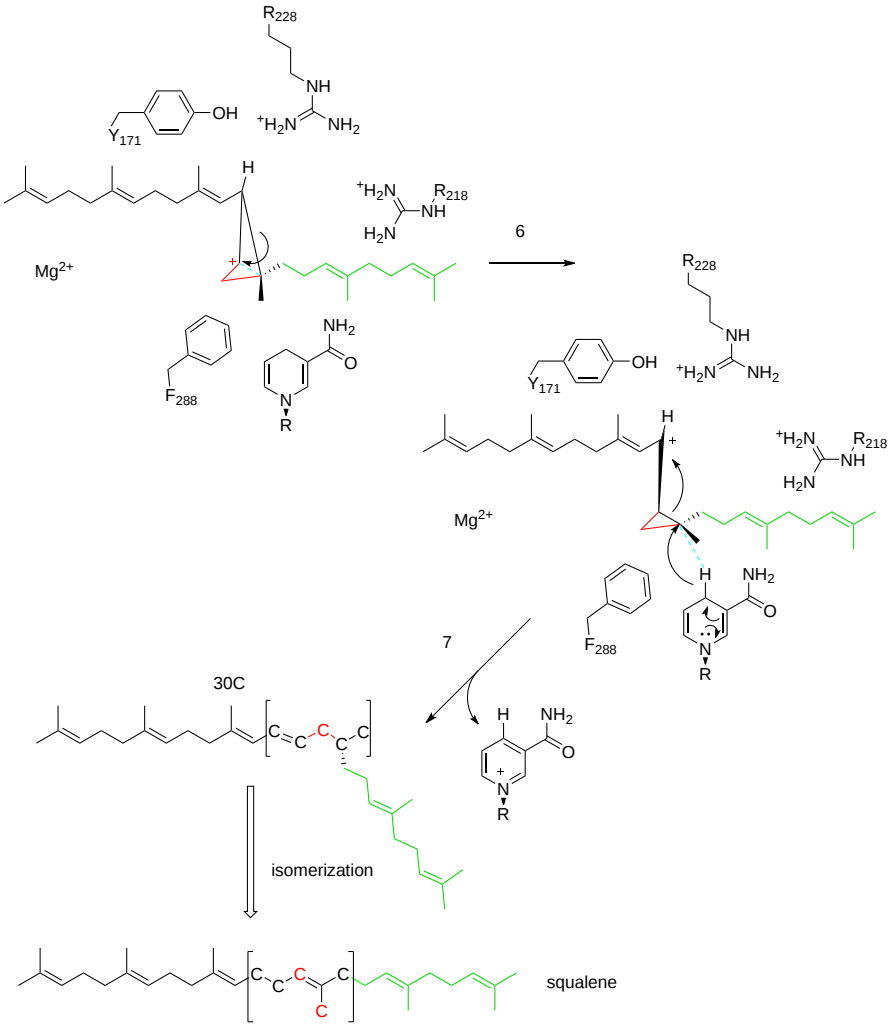

Figure 21.5.23: Mechanism for conversion of presqualene to squalene by squalene synthase. https://www.ebi.ac.uk/thornton-srv/m-csa/entry/264/. Creative Commons Attribution 4.0 International (CC BY 4.0) License

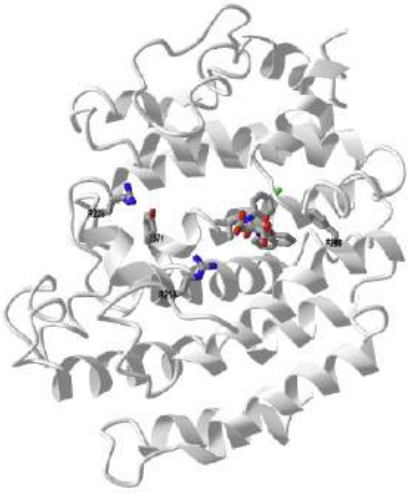
Figure 21.5.24 shows an interactive iCn3D model of human squalene synthase with bound inhibitor (1EZF).



NCBI iCn3D Figure 21.5.24: Human squalene synthase with bound inhibitor (1EZF). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...jLreHkvbftoFPA

Tyr 171 acts as a general acid/base in the first half of the reaction. Arg 218 and 228 stabilize the diphosphate in the transition state as it leaves. Phe 288 stabilizes the reactive carbocation.

The enzyme has a single domain that contains a large channel in one face of the enzyme which leads from a solvent-exposed to the hydrophobic interior. Two FPPs bind in the beginning of the channel where key side chains for the first reaction are located. The cyclopropyl intermediate then moves into the hydrophobic end of the channel where it reacts in the second half of the reaction without exposure to water.

In the next important step, squalene is oxidized by a squalene monooxygenase to squalene 2,3-epoxide, a key control point in the cholesterol synthesis pathway. This introduces the oxygen atom to squalene that becomes the signature oxygen of the hydroxyl group in cholesterol. The epoxide then undergoes cyclization catalyzed by the enzyme squalene epoxide lanosterol-cyclase to form the first steroidal intermediate lanosterol (or cycloartenol en route to **phytosterols** in photosynthetic organisms). This is illustrated in Figure 21.5.26.

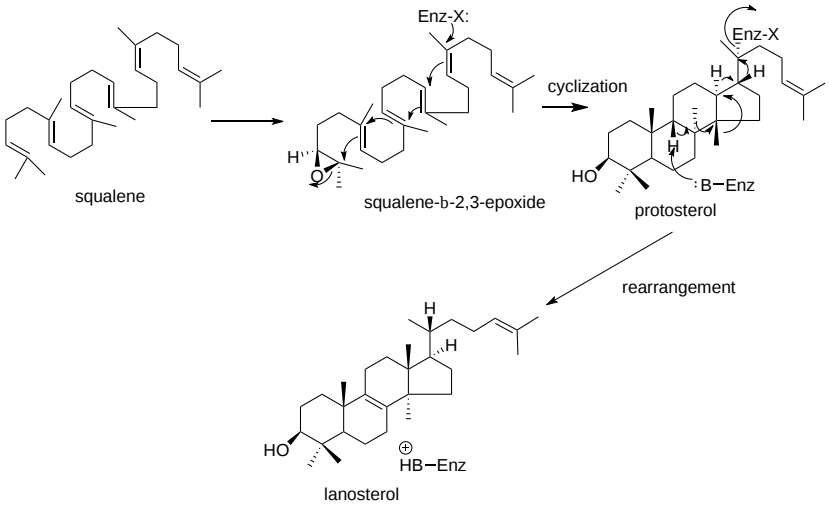


Figure 21.5.26: Conversion of squalene to lanosterol

In this remarkable reaction, there is a series of concerted 1,2-methyl group and hydride shifts along the chain of the squalene molecule to bring about the formation of the four rings. No intermediate compounds have been found. This is believed to be one of the most complex single enzymatic reactions ever to have been identified, although the enzyme involved is only 90 kDa in size. Again, the reaction takes place in the endoplasmic reticulum, but a cytosolic protein, sterol carrier protein 1, is required to bind squalene in an appropriate orientation in the presence of the cofactors NADPH, flavin adenine dinucleotide (FAD) and O_2; the reaction is promoted by the presence of phosphatidylserine.

The ring closure reaction starting with the epoxide involves a concerted flow of electrons from a source to the epoxide oxygen atom electron sink. This brings to mind a reaction known to all students who have ever studied chemistry, the reaction of the pH indicator phenolphthalein with a base to produce a pink colored-solution. That reaction which produces a more conjugated molecule that absorbs at 553 nm (green) which causes a magenta solution color, is illustrated for comparison (and fun) in Figure 21.5.27.

Figure 21.5.27: Reaction of phenolphthalein with base

In subsequent steps, lanosterol is converted to cholesterol by a series of demethylations, desaturations, isomerizations, and reductions, involving nineteen separate reactions as illustrated in Figure 21.5.28.

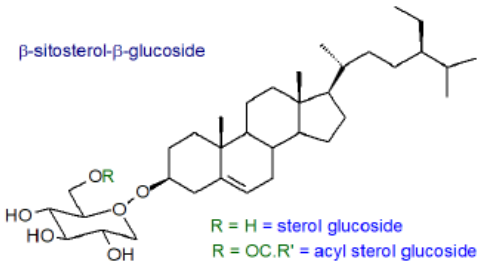

Figure 21.5.28: Production of cholesterol from lanosterol

Thus, demethylation reactions produce zymosterol as an intermediate, and this is converted to cholesterol via a series of intermediates, all of which have been characterized, and by at least two pathways that utilize essentially the same enzymatic machinery but differ in the order of the various reactions, mainly at the point at which the Δ24 double bond is reduced. Desmosterol is the key intermediate in the so-called 'Bloch' pathway, while 7-dehydrocholesterol is the immediate precursor in the 'Kandutsch-Russell' pathway. While some tissues, such as adrenal glands and testis, use the Bloch pathway mainly, the brain synthesizes much of its cholesterol by the 'Kandutsch-Russell' pathway. This may enable the production of a variety of other minor sterols for specific biological purposes in different cell types/locations.

The energy cost of the synthesis of one cholesterol molecule is roughly one hundred ATP equivalents, and eleven oxygen molecules are required. Synthesis occurs mainly in the liver, although the brain (see below), peripheral nervous system, and skin synthesize their own considerable supplies. Cholesterol is exported from the liver and transported to other tissues in the form of low-density **lipoproteins** (LDL) for uptake via specific receptors. In animals, cells can obtain the cholesterol they require either from the diet via the circulating LDL, or they can synthesize it themselves as outlined above. Cholesterol biosynthesis is highly regulated with rates of synthesis varying over hundreds of fold depending on the availability of any external sources of cholesterol, and cholesterol homeostasis requires the actions of a complex web of enzymes, transport proteins, and membrane-bound transcription factors, as discussed below.

21.5.1.4: REGULATION OF CHOLESTEROL HOMEOSTASIS

In humans, only about a third of the cholesterol is of dietary origin (mainly eggs and red meat), the remainder is produced by synthesis *de novo* in the endoplasmic reticulum. The latter must be tightly regulated as it is an energetically expensive process that requires appreciable amounts of acetyl-CoA, ATP, oxygen, and the reducing factors NADPH and NADH, especially since cholesterol cannot be catabolized for energy purposes (see below).

Many factors are involved in maintaining the large differences in cholesterol concentrations among the various membranes and organelles in cells within precise limits. In order to explain how cholesterol in the plasma membrane, where it is most abundant, can regulate cholesterol biosynthesis and uptake through enzymes in the endoplasmic reticulum, where it is least abundant, it has been suggested that a key to the process is that there are three pools of cholesterol in the plasma membrane with distinct functional roles. The first of these is “accessible” to receptor proteins for transport to the endoplasmic reticulum, while the second pool is sequestered by sphingomyelin and can be released by the action of sphingomyelinase if required. The third residual pool of cholesterol is essential for plasma membrane integrity. These correspond to about 16, 15, and 12 mol % of total plasma membrane lipids, respectively, in cholesterol-replete cells. Simplistically, when cholesterol in the plasma membrane is in excess for any reason, e.g., after LDL uptake by receptor-mediated endocytosis, there is a rise in accessible cholesterol, which is then transported to the endoplasmic reticulum to switch off cholesterol biosynthesis and expression of the LDL receptor. This process requires a host of regulatory proteins and mechanisms that can involve either vesicle formation or non-vesicular pathways that utilize specific transport proteins, such as the ABC transporters.

Ultimately, post-translational control of the many different enzymes involved provides a rapid means for modifying flux through the biosynthetic pathway in the endoplasmic reticulum; some are rapidly degraded in response to tissue levels of cholesterol and its intermediates, while others have their activity altered through phosphorylation or acetylation mechanisms. For example, the second rate-limiting enzyme in cholesterol biosynthesis is squalene monooxygenase, which undergoes cholesterol-dependent proteasomal degradation when cholesterol is in excess, guided by a 12-amino acid hydrophobic sequence on the enzyme that can serve as a degradation signal. When the cholesterol concentration in the endoplasmic reticulum is high, the degradation sequence detaches from the membrane and is exposed to provide the signal for the enzyme to be degraded. Similarly, HMG-CoA reductase is recognized as the key enzyme in the regulation of cholesterol biosynthesis, and this can be regulated by a feedback mechanism involving ubiquitin–proteasomal degradation. Further regulation of cholesterol biosynthesis is exerted by sterol intermediates in cholesterol biosynthesis, such as lanosterol and 24,25-dehydrolanosterol (dimethyl-sterols) by accelerating degradation of the biosynthetic enzymes such as HMG-CoA reductase. It is noteworthy that ceramide down-regulates cholesterol synthesis – another link between cholesterol and sphingolipid metabolism.

The regulatory element-binding proteins (mainly SREBP-1c and SREBP-2), which contain an N-terminal membrane domain and a C-terminal regulatory domain, are essential to the maintenance of cholesterol levels. Each is synthesized as an inactive precursor that is inserted into the endoplasmic reticulum where it can encounter an escort protein termed **SREBP cleavage-activating protein (SCAP)**, which is the cellular cholesterol sensor. When the latter recognizes that cellular cholesterol levels are inadequate, it binds to the regulatory domain of SREBP. The SCAP-SREBP complex then moves to the Golgi, where two specific proteases (designated site-1 and site-2 proteases) cleave the SREBP enabling the *C*-terminal regulatory domain to enter the nucleus. There it activates transcription factors, such as the nuclear liver X receptor (LXR), which stimulate the expression of the genes coding for the LDL receptor in the plasma membrane and for the key enzyme in cholesterol biosynthesis, HMG-CoA reductase. This in turn stimulates the rate of cholesterol uptake and synthesis. Conversely, when cholesterol in the endoplasmic reticulum exceeds a threshold, it binds to SCAP in such a way that it prevents the SCAP-SREBP complex from leaving the membrane for the nucleus, cholesterol synthesis and uptake are thereby repressed, and cholesterol homeostasis is restored. In effect, cholesterol exerts feedback inhibition by suppressing its own production by preventing the proteolytic cleavage and maturation of SREBP-2. **Oxysterols**, especially 25-hydroxycholesterol, are also inhibitors of this process.

Cholesterol in the endoplasmic reticulum is transferred to the Golgi and eventually to the plasma membrane by vesicular and non-vesicular transport mechanisms involving in part soluble sterol transport proteins, including the so-called 'START' domain proteins, and partly by binding to those proteins that are intimately involved in the transport and metabolism of polyphosphoinositides such as **phosphatidylinositol 4-phosphate (PI(4)P)**. In the latter mechanism, cholesterol is transported by binding to the ORD domain of oxysterol binding protein (OSBP) or Osh4 in yeast, before OSBP binds to PI(4)P in the plasma membrane to transfer its cargo. The key to this process is that cholesterol and PI(4)P are synthesized at two different locations, i.e., the endoplasmic reticulum for sterols and the trans-Golgi network and plasma membrane for PI(4)P, so the two lipids do not compete but rather can be exchanged. OSBP carries cholesterol in the forward direction to the trans-Golgi network and plasma membrane and PI(4)P, which binds to a C-terminal PH domain in the protein, in the

reverse direction. The subsequent hydrolysis of PI(4)P is the energy source for the reaction, and indeed PI(4)P has been termed "lipid ATP". As this reaction is irreversible, a gradient of cholesterol along organelles of the secretory pathway is established. OSBP is thus a lipid transfer protein that enables two organelles to exchange cholesterol rapidly between them at membrane contact sites in a cycle of reactions involving membrane tethering, cholesterol transport, PI(4)P counter transport, and PI(4)P hydrolysis. A similar mechanism is involved in the transport of phosphatidylserine from the endoplasmic reticulum to the inner leaflet of the plasma membrane.

Subsequently, the ATP binding cassette (ABC) transporters ABCA1 and ABCG1 in the plasma membrane, which contains much of the cellular cholesterol, are activated to export the excess. Nuclear factor erythroid 2 related factor-1 or NRF1 in the endoplasmic reticulum binds directly to cholesterol and senses when its level is high to bring about a de-repression of genes involved in cholesterol removal, also with mediation by the liver X receptor. Also, side-chain oxysterols, especially 25-hydroxycholesterol, can suppress the activation of SREBP by binding to an oxysterol-sensing protein in the endoplasmic reticulum.

Within cells, cholesterol derived initially from the lysosomal degradation of low-density lipoproteins is transferred first to the plasma membrane and thence to the endoplasmic reticulum, the latter step by a mechanism involving proteins known as GRAMD1s embedded in the endoplasmic reticulum membrane at sites in contact with the plasma membrane. These have two functional domains: the START-like domain that binds cholesterol and the GRAM domain that binds anionic lipids, such as phosphatidylserine, and so are able to form a link between the two membranes that enable the transfer of cholesterol.

In peripheral tissues, excess cholesterol is exported to high-density lipoproteins (HDL) in the circulation and returned to the liver, a process known as **reverse cholesterol transport**. The liver is important for cholesterol synthesis, but it is essential for its elimination from the body in bile. Also, some lipoproteins with their content of cholesterol and cholesterol esters are delivered to lysosomes by endocytosis for degradation. The cholesterol is transported to the inner surface of the lysosomal membrane through the glycocalyx, via a transglycocalyx tunnel, with the aid of Niemann-Pick C1, C2, and other proteins, and thence via contact sites between membranes to other organelles. Cholesterol in cellular membranes in excess of the stoichiometric requirement can escape back into the cell, where it may serve as a feedback signal to down-regulate cholesterol accumulation, while some is converted to the relatively inert storage form, i.e., cholesterol esters, and some is used for steroidogenesis.

The intestines play a major part in cholesterol homeostasis via the absorption of dietary cholesterol and fecal excretion of cholesterol and its metabolites. A specific transporter (Niemann-Pick C1-like 1 or NPC1L1)in the brush border membrane of enterocytes in the proximal jejunum of the small intestine is involved in the uptake of cholesterol from the intestinal contents, while the metabolism of sterols in the intestines is controlled mainly by an acetyl-CoA acetyltransferase (ACAT2), which facilitates intracellular cholesterol esterification, and the microsomal triglyceride transfer protein (MTTP), which is involved in the assembly of chylomicrons for export into lymph. Some cholesterol can be transferred in the opposite direction (trans-intestinal cholesterol excretion), but the quantitative importance of this process is not clear. There is evidence that dietary or synthesized cholesterol is necessary to maintain intestinal integrity, as cholesterol derived from circulating lipoproteins is not sufficient for the purpose.

In the intestines and especially the colon, the intestinal microflora are able to hydrogenate cholesterol from bile, diet, and desquamated cells to form coprostanol with an efficiency that is dependent on the composition of microbial species. Coprastanol is not absorbed by the intestinal tissue to a significant extent, and it may inhibit the uptake of residual cholesterol. There are two mechanisms for this conversion in bacteria, one involving direct reduction and another via cholestenone and coprostanone as intermediates, and as the relevant genes have now been identified the therapeutic potential is under investigation.

Brain: There are substantial differences in cholesterol synthesis and metabolism in brain in comparison to the liver and peripheral tissues. Trace amounts only of cholesterol are able to cross the blood-brain barrier via transport in low-density lipoproteins. Therefore, virtually all the cholesterol in the brain must be synthesized *de novo*, mainly in astrocytes (glial cells). During the perinatal and adolescent years especially, cholesterol is synthesized in large amounts to form the myelin that surrounds the axons, before this rate begins to decline to eventually reach about 10% of earlier values.

Cholesterol is transported to neurons in the form of Apo E complexes in discoidal HDL-like particles, for which seven main receptors have been identified in brain cells that take up cholesterol from these lipoproteins. Apo E is synthesized in the brain, and its transcription is regulated by 24-hydroxy-cholesterol concentrations. Similarly, in the brain and central nervous system, cholesterol synthesis is regulated independently of that in peripheral tissues, mainly by forms of the liver X receptor (LXR). As cholesterol and oxysterols are involved in providing neuroprotective effects and lowering neuroinflammation, dysregulation of their concentrations has been noted in many neurodegenerative disorders. Most of the lipoproteins in cerebrospinal fluid differ from the nascent poorly-lipidated HDL secreted by astrocytes, suggesting that the latter are modified during maturation.

21.5.1.5: CHOLESTEROL CATABOLISM

Cholesterol is not readily degraded in animal tissues so does not serve as a metabolic fuel to generate ATP. Only the liver possesses the enzymes to degrade significant amounts, and then via pathways that do not lead to energy production. Cholesterol and oxidized metabolites (oxysterols) are transferred back from peripheral tissues in lipoprotein complexes to the liver for catabolism by conversion to oxysterols and bile acids. The latter are exported into the intestines to aid in digestion, while leading to some loss that is essential for cholesterol

homeostasis. Until recently, it was believed that approximately 90% of cholesterol elimination from the body occurred via bile acids in humans. However, experiments with animal models now suggest that a significant amount is secreted directly into the intestines by a process known as trans-intestinal cholesterol efflux. How this occurs and its relevance to humans are under active investigation.

Gut bacteria reduce some of the cholesterol in the diet to highly insoluble 5β-cholestan-3β-ol (coprostanol), which is excreted and can be used as a biomarker for sewage in the environment. Certain bacterial species contain a 3β-hydroxysteroid:oxygen oxidoreductase (EC 1.1.3.6), commonly termed cholesterol oxidase, a flavoenzyme that catalyzes the oxidation of cholesterol to cholest-5-en-3-one which is then rapidly isomerized to cholest-4-en-3-one as the first essential step in the catabolism of sterols. The enzyme is widespread in organisms that degrade organic wastes, but it is also present in pathogenic organisms where it influences the virulence of infections (see below). In biotechnology, it has been used for the production of a number of steroids, and it is employed in a clinical procedure for the determination of cholesterol levels in serum.

21.5.1.6: CHOLESTEROL ESTERS

Cholesterol esters, i.e., with long-chain fatty acids linked to the hydroxyl group, are much less polar than free cholesterol and appear to be the preferred form for transport in plasma and as a biologically inert storage or detoxification form to buffer an excess. They do not contribute to membrane structures but are packed into intracellular lipid droplets. Cholesterol esters are major constituents of the adrenal glands, and they accumulate in the fatty lesions of atherosclerotic plaques. Similarly, esters of steroidal hormones are also present in the adrenal glands, where they are concentrated in cytosolic lipid droplets adjacent to the endoplasmic reticulum; 17β-estradiol, the principal estrogen in fertile women, is transported in lipoproteins in the form of a fatty acid ester.

Because of the mechanism of synthesis (see below), plasma cholesterol esters tend to contain relatively high proportions of the polyunsaturated components typical of phosphatidylcholine as shown in Table 21.5.1 below. Arachidonic and “adrenic” (20:4(n-6)) acids can be especially abundant in cholesterol esters from the adrenal gland.

Table 21.5.1. **Fatty acid composition of cholesterol esters (wt % of the total) from various tissues.**

Form	Fatty acids						
	16:0	18:0	18:1	18:2	18:3	20:4	22:4
Human							
plasma	12	2	27	45		8	
liver	23	10	28	22		6	
Sheep							
plasma	10	2	27	35	7	-	-

In plasma and in the high-density lipoproteins (HDL) in particular, cholesterol esters are synthesized largely by the transfer of fatty acids to cholesterol from position *sn*-2 of phosphatidylcholine (‘lecithin’) catalyzed by the enzyme **lecithin:cholesterol acyl transferase (LCAT)**; the other product is 1-acyl lysophosphatidylcholine. This is illustrated in Figure 21.5.29.

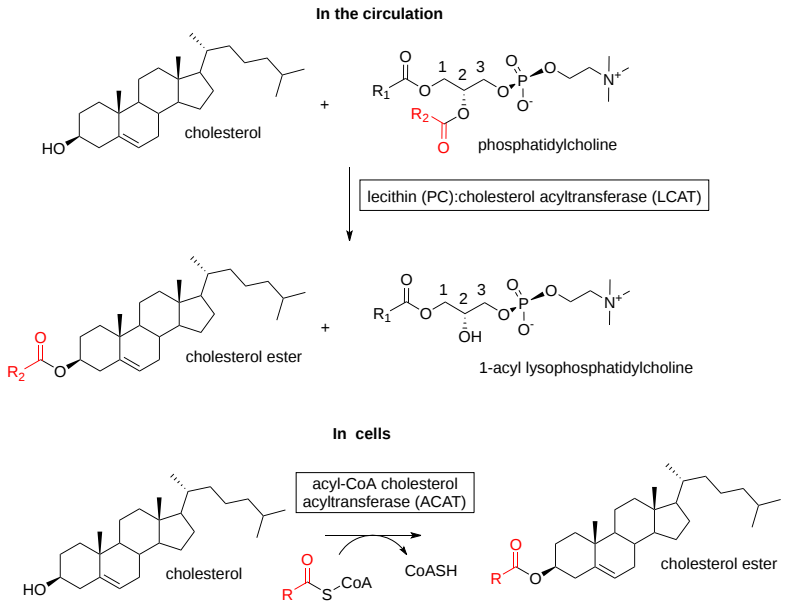

Figure 21.5.29 Synthesis of cholesterol esters

In fact, the reaction occurs in several steps. First, apoprotein A1 in the HDL acts to concentrate the lipid substrates near LCAT and present it in the optimal conformation; at the same time, it opens a lid on the enzyme that activates it by opening up the site of transesterification. Then, cleavage of the *sn*-2 ester bond of phosphatidylcholine occurs via the phospholipase activity of LCAT with the release of a fatty acyl moiety. This is transacylated to the sulfur atom of a cysteine residue forming a thioester, and ultimately it is donated to the 3β-hydroxyl group of cholesterol to form the cholesterol ester. Some LCAT activity has also been detected in apolipoprotein B100-containing particles (β-LCAT activity as opposed to α-LCAT with HDL).

It has been established that human LCAT is a relatively small glycoprotein with a polypeptide mass of 49 kDa, increased to about 60 kDa by four *N*-glycosylation and two *O*-glycosylation moieties. Most of the enzyme is produced in the liver and circulates in the bloodstream bound reversibly to HDL, where it is activated by the main protein component of HDL, apolipoprotein A1. As cholesterol esters accumulate in the lipoprotein core, cholesterol is removed from its surface thus promoting the flow of cholesterol from cell membranes into HDL. This in turn leads to morphological changes in HDL, which grow and become spherical. Subsequently, cholesterol esters are transferred to the other lipoprotein fractions LDL and VLDL, a reaction catalyzed by cholesterol ester transfer protein. This process promotes the efflux of cholesterol from peripheral tissues (‘reverse cholesterol transport’), especially from macrophages in the arterial wall, for subsequent delivery to the liver. LCAT is often stated to be the main driving force behind this process, and it is of great importance for cholesterol homeostasis and a suggested target for therapeutic intervention against cardiovascular disease.

The stereospecificity of LCAT changes with molecular species of phosphatidylcholine containing arachidonic or docosahexaenoic acid, when 2-acyl lysophosphatidylcholines are formed. This reaction may be especially important for the supply of these essential fatty acids to the brain in that such lysophospholipids are believed to cross the blood-brain barrier more readily than the free acids.

In other animal tissues, a further enzyme acyl-CoA:cholesterol acyltransferase (ACAT) synthesizes cholesterol esters from CoA esters of fatty acids and cholesterol. ACAT exists in two forms, both of which are intracellular enzymes found in the endoplasmic reticulum and are characterized by multiple transmembrane domains and a catalytic histidine residue in a hydrophobic domain; they are members of the *O*-acyltransferase (MBOAT) superfamily. ACAT1 is present in many tissues, but especially in macrophages and adrenal and sebaceous glands, which store cholesterol esters in the form of cytoplasmic lipid droplets; it is responsible for the synthesis of cholesterol esters in arterial foam cells in human atherosclerotic lesions. ACAT2 is found only in the liver and small intestine, and it is believed to be involved in the supply of cholesterol esters to the nascent lipoproteins. Analogous enzymes are found in yeast where ergosterol is the main sterol, but a very different process occurs in plants.

Oxidized Cholesterol Esters: All lipid classes containing polyunsaturated fatty acids are susceptible to oxidation. Under normal circumstances, cholesterol esters are considered to be relatively inert. However, when they contain oxidized polyunsaturated fatty acids, their properties change and they acquire biological activity. Such oxidized cholesterol esters may be formed by a reaction with 15-lipoxygenase, but they can be produced also through free radical-induced lipid peroxidation, and they have been detected in lipoproteins, LDL especially, in human blood and atherosclerotic lesions. Those oxidized cholesterol esters in plasma are trafficked into cells and metabolized by the same mechanisms as the corresponding unoxidized lipids.

Such "minimally oxidized LDL" do not bind to CD36 but rather to CD14, a receptor that recognizes bacterial lipopolysaccharides. The result is stimulation of toll-like receptor 4 (TLR4), although the response differs from that of lipopolysaccharides. In addition, oxidized

metabolites of cholesteryl arachidonate of this kind stimulate macrophages to express inflammatory cytokines of relevance to atherosclerosis among other effects. Oxidized cholesterol esters can be hydrolyzed to release their fatty acids, which can then be incorporated into phospholipids with a different repertoire of activities.

Hydrolysis of cholesterol esters: Cholesterol ester hydrolases in animals liberate cholesterol and free fatty acids when required for membrane and lipoprotein formation, and they also provide cholesterol for hormone synthesis in adrenal cells. Many cholesterol ester hydrolases have been identified, including a carboxyl ester hydrolase, a lysosomal acid cholesterol ester lipase, hormone-sensitive lipase, and hepatic cytosolic cholesterol ester hydrolase. These are located in many different tissues and organelles and have multiple functions. A neutral cholesterol ester hydrolase has received special study, as it is involved in the removal of cholesterol esters from macrophages so reducing the formation of foam cells and thence the development of fatty streaks within the arterial wall, a key event in the progression of atherosclerosis.

21.5.1.7: OTHER ANIMAL STEROLS

Cholesterol will oxidize slowly in tissues or foods to form a range of different products with additional hydroperoxy, epoxy, hydroxy or keto groups, and these can enter tissues via the diet. There is increasing interest in these from the standpoint of human health and nutrition since the accumulation of oxo-sterols in plasma is associated with inhibition of the biosynthesis of cholesterol and bile acids and with other abnormalities in plasma lipid metabolism.

A number of other sterols occur in small amounts in tissues, most of which are intermediates in the pathway from lanosterol to cholesterol, although some of them have distinct functions in their own right. **Lanosterol**, the first sterol intermediate in the biosynthesis of cholesterol, was first found in wool wax, both in free and esterified form, and this is still the main commercial source. It is found at low levels only in most other animal tissues (typically 0.1% of the cholesterol concentration). As oxygen is required, lanosterol cannot be produced by primitive organisms, hence its absence from prokaryotes, leading to some speculation on its evolutionary significance. When sterols became available to eukaryotes, much greater possibilities opened for their continuing evolution. The production of cholesterol from lanosterol is then seen as ‘molecular streamlining’ by evolution, removing protruding methyl groups that hinder the interaction between sterols and phospholipids in membranes.

Desmosterol (5,24-cholestadien-3β-ol), the last intermediate in the biosynthesis of cholesterol by the Bloch pathway, may be involved in the process of myelination, as it is found in relative abundance in the brains of young animals but not in those of adults, other than astrocytes. It is also found in appreciable amounts in testes and spermatozoa together with another cholesterol intermediate, testis meiosis-activating sterol. In addition, there is evidence that desmosterol activates certain genes involved in lipid biosynthesis in macrophages, and may deactivate others associated with the inflammatory response. There is a rare genetic disorder in which there is an impairment in the conversion of desmosterol to cholesterol, desmosterolosis, with serious consequences in terms of mental capacity. These and related sterols appear to be essential for human reproduction.

In human serum, the levels of **lathosterol** (5α-cholest-7-en-3β-ol) were found to be inversely related to the size of the bile acid pool, and in general, the concentration of serum lathosterol is strongly correlated with the cholesterol balance under most dietary conditions. The isomeric saturated sterols, **cholestanol,** and **coprastanol**, which differ in the stereochemistry of the hydrogen atom on carbon 5, are formed by microbial biohydrogenation of cholesterol in the intestines, and together with cholesterol are the main sterols in feces. Further examples of animal sterols include **7-dehydrocholesterol** (cholesta-5,7-dien-3β-ol) in the skin, which on irradiation with UV light is converted to **vitamin D_3** (cholecalciferol). These sterols are shown in Figure 21.5.30.

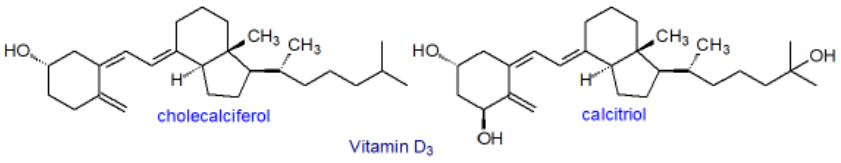

Figure 21.5.30: Other animal sterols

Marine invertebrates produce a large number of novel sterols, with both unusual nuclei and unconventional sidechains, some derived from cholesterol and others from plant sterols or alternative biosynthetic intermediates. For example, at least 80 distinct sterols have been isolated from echinoderms and 100 from sponges.

21.5.1.8: CHOLESTEROL AND DISEASE

Elevated cholesterol and cholesterol ester levels are associated with the pathogenesis of cardiovascular disease (atherosclerotic plaques, myocardial infarctions, and strokes), as is well known, and this is considered briefly on this website together with the metabolism of the **plasma lipoproteins**. The rate-limiting enzyme in the synthesis of cholesterol HMG-CoA reductase is the target of statins, but drugs that target other steps in the biosynthetic pathway, especially the squalene monooxygenase and lanosterol synthase, are under investigation. Further discussion of such a complex nutritional and clinical topic is best left to others better qualified than myself.

Cholelithiasis or the presence of 'stones' in the gallbladder or bile ducts, which consist largely of cholesterol (~85%), is one of the most prevalent and costly digestive diseases in developed countries. The primary cause is the excessive excretion of cholesterol from the liver. Excess accumulation of cholesterol associated with the metabolism of **bis(monoacylglycero)phosphate** and causing disturbances in glycosphingolipid trafficking in cell membranes is involved in the pathogenesis of **Niemann-Pick C disease**, a lysosomal storage disease in which endocytosed cholesterol becomes sequestered in late endosomes/lysosomes because of gene mutations affecting two binding proteins (NPC1 and NPC2) thereby causing neuronal and visceral atrophy. In addition, deficiencies in cholesterol transport and metabolism are associated with many forms of neurodegeneration, including Alzheimer's disease, Huntington's disease, and related conditions associated with old age. These proteins are also key virulence factors for several viral and bacterial pathogens.

Several genetic disorders of cholesterol biosynthesis have been identified in recent years that can result in developmental malformations including neurologic defects. As there is limited cholesterol transport across the placenta, the human fetus is highly dependent upon endogenous synthesis. While the molecular basis for the altered developmental pathways is not fully understood, impaired synthesis of the **hedgehog** family of signaling proteins, which require covalently linked cholesterol to function in membranes, is believed to be involved in many cases. In others, there are confirmed enzyme defects. For example, the recessive Smith-Lemli-Opitz syndrome in infants born with a decreased concentration of the enzyme 7-dihydrocholesterol reductase, produces symptoms varying from mild autism to severe mental and often fatal physical problems. The effects are due to a lack of cholesterol and the accumulation of 7-dehydrocholesterol and its 27-hydroxy metabolite, as brain tissue cannot utilize dietary cholesterol or that produced peripherally. In fact, at least eight different inherited disorders of cholesterol biosynthesis lead to congenital abnormalities in those afflicted. In animal models, deficiencies in SREBP-2 and genes encoding sterol biosynthetic enzymes display embryonic lethality. Deficiencies in the enzymes responsible for the hydrolysis of cholesterol esters, such as the lysosomal acid lipase, occur in Wolman disease and cholesterol ester storage disease.

Cholesterol and other sterols bind directly to several immune receptors, especially in macrophages and T cells, and dynamic changes in cholesterol biosynthesis impact directly upon innate and adaptive immune responses, such that functional coupling between sterol metabolism and immunity has implications for health and disease. For example, cholesterol binds directly to the αβ T cell antigen receptor (αβTCR) and has at least two opposing functions in its activation. By binding to the trans-membrane domain of this receptor, it is kept in an inactive, non-signaling conformation, but when required it can stimulate the formation of receptor nanoclusters to increase their avidity for the antigen. In cancer, there is a high demand for cholesterol in order to support the inherent nature of tumor cells to divide and proliferate, and perturbations of reverse cholesterol transport can have negative consequences. Drugs that lower cholesterol levels in cancer cells by inhibiting the mevalonate pathway are undergoing clinical trials.

When increased levels of sterols other than cholesterol are found in plasma, they usually serve as markers for abnormalities in lipid metabolism associated with disease states. For example, premature atherosclerosis and xanthomatosis occur in two rare lipid storage diseases, cerebrotendinous xanthomatosis, and sitosterolemia. In the former, cholestanol is present in all tissues, while in the latter, the dietary plant sterols campesterol and sitosterol accumulate in plasma and red blood cells. Inhibition of cholesterol biosynthesis may be associated with the appearance of some of the precursor sterols in the plasma.

In infections with *Mycobacterium tuberculosis*, the organism uses host cholesterol as the major carbon and energy source and thereby promotes persistent infection with appreciable effects on pathogenicity. Similarly, *Chlamydia trachomatis*, a gram-negative obligate intracellular bacterium and a major cause of sexually transmitted infections, requires host cholesterol for growth. Many viruses use cholesterol as part of their life cycle, and reduction in cellular cholesterol is sometimes seen as an anti-viral strategy, although this may not always be helpful. For example, an HIV protein has a binding site for cholesterol, which it utilizes to facilitate the fusion with raft regions in the membranes of the host cell.

21.5.2: STEROLS: 2. OXYSTEROLS AND OTHER CHOLESTEROL DERIVATIVES

Oxysterols as defined and discussed here are oxygenated derivatives of **cholesterol** and its precursors, i.e., with additional hydroxyl, epoxyl, or keto groups, that are found in all animal tissues. Many of these have vital functions in animals, while others are important as short-lived intermediates or end products in the catabolism or excretion of cholesterol or in the biosynthesis of steroid hormones, bile acids, and 1,25-dihydroxy-vitamin D_3. They are normally present in biological membranes and lipoproteins at trace levels only, though they can exert profound biological effects at these concentrations. However, they are always accompanied by a great excess (as much as 10^6-fold) of cholesterol *per se*.

A multiplicity of different oxysterols are synthesized in cells by sequential reactions with specific oxygenases. However, because of the presence of the double bond in the 5,6-position, oxysterols can also be formed rapidly by non-enzymatic oxidation (autoxidation) of cholesterol and cholesterol esters within tissues with the formation of many different oxygenated derivatives. Simplistically, non-enzymatic oxidation leads mainly to the generation of products in which the sterol ring system is oxidized, while enzymatic processes usually produce metabolites with an oxidized side chain (7-hydroxylation is an important exception). Oxidized cholesterol molecules can also be generated by the gut microflora and be taken up through the enterohepatic circulation. Once an oxygen function is introduced into cellular cholesterol, the product can act as a biologically active mediator by interacting with specific receptors before it is metabolized to **bile acids** or is degraded further, processes assisted by the fact that oxysterols are able to diffuse much more rapidly through membranes than is cholesterol

itself. Cholesterol metabolites of this kind are especially important in the brain, which is a major site for cholesterol synthesis *de novo*, and they are crucial elements of cholesterol homeostasis.

21.5.2.1: ENZYMATIC OXIDATION OF CHOLESTEROL

Within animal cells, the oxidation of sterols is mainly an enzymic process that is carried out by several enzymes that are primarily from the cytochrome P450 family of oxygenases (named for a characteristic absorption at 450 nm). These comprise a disparate group of proteins that contain a single heme group and have a similar structural fold, though the amino acid sequences can differ appreciably. They are all mono-oxygenases. Oxysterol biosynthesis can be considered in terms of different pathways that depend on the position of the initial oxidation, but these pathways tend to overlap and lead to a complex web of different oxysterols (and eventually to **bile acid** formation). As these enzymes, which include cytochrome P450, cholesterol hydroxylase, hydroxysteroid dehydrogenases, and squalene epoxidase, are specific to particular tissues and indeed animal species, there is considerable variation in oxysterol distributions between organs. A few examples only of the first steps in some of these pathways are illustrated in Figure 21.5.31.

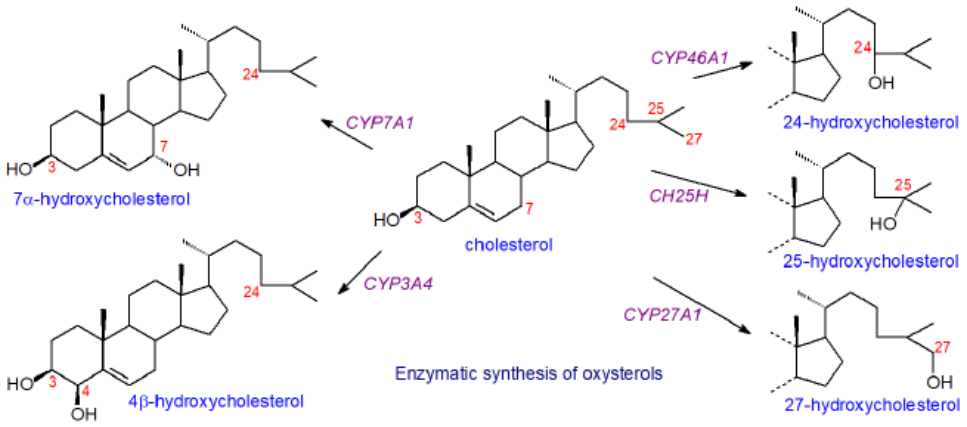

Figure 21.5.31: Enzymatic synthesis of oxysterols

As an example, a primary product is **7α-hydroxycholesterol**, which is an important intermediate in the biosynthesis of bile acids by the 'neutral' pathway and of many other oxysterols, and it is produced in the liver by the action of cholesterol 7α-hydroxylase (CYP7A1), an enzyme that has a critical role in cholesterol homeostasis. The reaction is under strict regulatory control, and the expression of CYP7A1 is controlled by the farnesoid X receptor (FXR) and is activated by cholic and chenodeoxycholic acids. Any circulating 7α-hydroxycholesterol represents leakage from the liver. Further oxidation of 7α-hydroxycholesterol can occur, and the action of CYP3A4 in humans generates 7α,25-dihydroxycholesterol as an important metabolite, for example, while oxidation by CYP27A1 yields 7α,27-dihydroxycholesterol; the latter is regarded as a key step in a further pathway to oxysterols and bile acids. On the other hand, the epimer **7β-hydroxycholesterol** is produced in the brain by the action of the toxic β-amyloid peptide and its precursor on cholesterol, but whether this is involved in the pathology of Alzheimer's disease has yet to be determined.

The hydroxysteroid 11-β-dehydrogenase 1 (HSD11B1) is responsible for the conversion of 7β-hydroxy-cholesterol to the important metabolite **7-keto-cholesterol**, while HS11B2 catalyzes the reverse reaction; 7-keto-cholesterol is also formed by autoxidation (see below). HSD11B1 is better known as the oxidoreductase that converts inactive cortisone to the active stress hormone cortisol in glucocorticoid target tissues.

An alternative ('acidic') pathway to bile acids starts with the synthesis of **27-hydroxycholesterol** (or more systematically named (25*R*)26-hydroxycholesterol), which is produced by the cytochrome P450 enzyme (CYP27A1) and introduces the hydroxyl group into the terminal methyl carbon (C27 or C26 - used interchangeably). While this enzyme is present in the liver, it is found in many extra-hepatic tissues and especially the lung, which provides a steady flux of 27-oxygenated metabolites to the liver. As a multifunctional mitochondrial P450 enzyme in the liver, it generates both 27-hydroxycholesterol and 3β-hydroxy-5-cholestenoic acid, the bile acid precursor, which occurs in small but significant amounts in plasma. 27-Hydroxycholesterol is the most abundant circulating oxysterol, and its concentration in plasma correlates with that of total cholesterol. It can be oxidized to 7α,27-dihydroxycholesterol by the enzyme CYP7B1. **4β-Hydroxycholesterol** is also abundant in plasma and is relatively stable; it is produced in humans by the action of the cytochromes CYP3A4 and CY3A5.

In humans, the specific cytochrome P450 that produces **24*S*-hydroxycholesterol** (cholest-5-ene-3β,24-diol) is cholesterol 24*S*-hydroxylase (CYP46A1) and is located almost entirely in the smooth endoplasmic reticulum of neurons in the brain, including those of the hippocampus and cortex, which are important for learning and memory. It is by far the most abundant oxysterol in the brain after parturition, but during development, many more many oxysterols are produced. 24*S*-hydroxycholesterol is responsible for 98-99% of the turnover of cholesterol in the central nervous system, which is the source of most of this oxylipin found in plasma. A small amount of it is converted in the brain directly into to 7α,24*S*-dihydroxycholesterol by the cytochrome CYP39A1 and thence via side-chain oxidation in peroxisomes to bile acids,

such as cholestanoic acid. It is evident that the blood-brain barrier is crossed by constant passive fluxes of oxysterols, but not of cholesterol *per se*, as a result of their permissive chemical structures and following their concentration gradients. In plasma, it is transported via high-density lipoproteins, as discussed further below. In contrast to humans, CYP46A1 is present in the liver of rodents as well as the brain.

25-Hydroxycholesterol is a relatively minor but biologically important cholesterol metabolite, which is produced rapidly by immune cells during the inflammation resulting from bacterial or viral infections. The dioxygenase enzyme cholesterol 25-hydroxylase (CH25H in humans), which utilizes a diiron cofactor to catalyze hydroxylation, is the most important route to this metabolite *in vivo*, although at least two cytochrome P450 enzymes, CYP27A1 and CYP3A4, can catalyze this conversion to a limited extent. Further oxidation by CYP7B1 is a second route to 7α,25-dihydroxycholesterol, and hence to further oxysterols.

24(*S*),25-Epoxycholesterol is not produced by the pathways described above but is synthesized in a shunt of the mevalonate pathway using the same enzymes that produce cholesterol, specifically squalene mono-oxygenase and lanosterol synthase, by means of which a second epoxy group is introduced on the other end of squalene from the initial epoxidation. A further mechanism in the brain is the action of CYP46A1 on desmosterol, another intermediate in cholesterol biosynthesis.

The oxysterols formed by both autoxidation and enzymatic routes can undergo further oxidation-reduction reactions, and they can be modified by many of the enzymes involved in the metabolism of cholesterol and steroidal hormones, such as esterification and sulfation of position 3, as illustrated for 7-keto-cholesterol as an example in Figure 21.5.32.

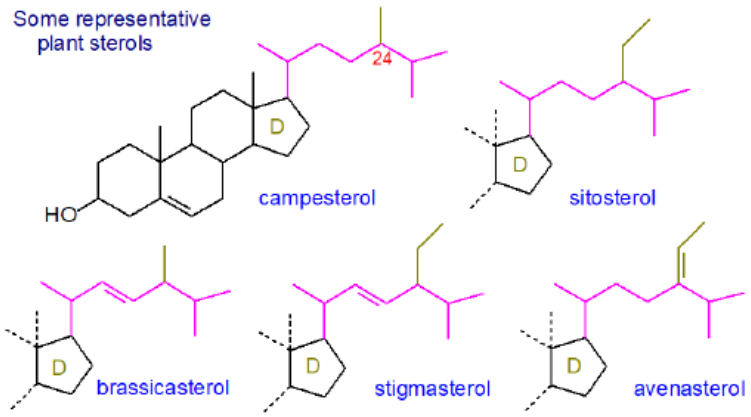

Figure 21.5.32 Metabolism of 7-keto-cholesterol

In most tissues, esterification of the 3β-hydroxyl group only occurs and requires the activity of sterol *O*-acyltransferases 1/2 (SOAT1/2 or ACAT1/2) with the participation of cytosolic phospholipase A_2 (cPLA$_2$α) to liberate the required fatty acids from phospholipids. In plasma, oxysterols can be esterified by the lecithin–cholesterol acyltransferase (LCAT) for transport in lipoproteins, but in this instance, a diester can be produced from 27-hydroxycholesterol specifically. Whether such esters are an inert storage form for oxysterols to be liberated on demand by esterases remains to be determined.

It is noteworthy that the important human pathogen, *Mycobacterium tuberculosis*, utilizes a cytochrome P450 enzyme (CYP125) to catalyze C26/C27 hydroxylation of cholesterol as an essential early step in its catabolism as part of the infective process.

Catabolism: Because of their increased polarity relative to cholesterol, oxysterols produced by both enzymatic and non-enzymatic means can exit cells relatively easily. A proportion is oxidized further and converted to **bile acids**, and some are converted to sulfate esters (especially at the 3-hydroxyl group) or glucuronides (see below) for elimination via the kidneys.

21.5.2.2: NON-ENZYMATIC OXIDATION OF CHOLESTEROL

In biological systems in which both cholesterol and fatty acids are present, it would be expected that autoxidation of polyunsaturated fatty acids by free radical mechanisms would be favored thermodynamically with the formation of isoprostanes from arachidonic acid in phospholipids. However, there are circumstances that can favor cholesterol oxidation *in vivo*, and, for example, the concentration of cholesterol in low-density lipoprotein particles (LDL) is about three times higher than that of phospholipids, and the rate of cholesterol-hydroperoxide formation can be higher than that of phospholipid hydroperoxides. The rate and specificity of the reaction can depend also on whether it is initiated by free radical species, such as those arising from the superoxide/hydrogen peroxide/hydroxyl radical system (Type I autoxidation), or whether it occurs by non-radical but highly reactive oxygen species such as singlet oxygen, HOCl or ozone (Type II autoxidation). As examples of the main types of products of non-enzymatic oxidation, the structures of a few of the more important of these oxysterols are illustrated in Figure 21.5.33.

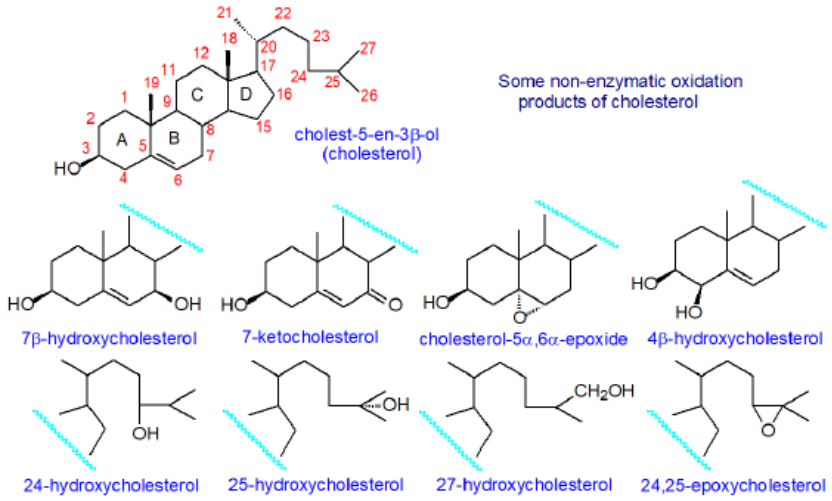

Figure 21.5.33: Some non-ezymatic oxidation products of cholesterol

Oxysterols produced by this means can vary in the type (hydroperoxy, hydroxy, keto, epoxy), number and position of the oxygenated functions introduced, and nature of their stereochemistry. Derivatives with the A and B rings and the *iso*-octyl side-chain oxidized are illustrated, but compounds with oxygen groups in position 15 (D ring) are also important biologically. Many are similar to those produced by enzymatic means, although the stereochemistry will usually differ. Like the enzymic products, they are named according to their relationship to cholesterol, rather than by the strict systematic terminology.

Mechanisms of autoxidation have been studied intensively in terms of unsaturated fatty acids, and it appears that similar mechanisms operate with sterols. The first event in lipid peroxidation by a radical mechanism is an initiation reaction in which a carbon with a labile hydrogen undergoes hydrogen abstraction by reaction with a free radical, which can be a non-lipid species such as a transition metal or hydroxyl or peroxynitrile radical, and this is followed by oxygen capture. The resulting reactive species recruits further non-oxidized lipids and starts a chain reaction termed the propagation phase. Finally, the reaction is terminated by the conversion of hydroperoxy intermediates to more stable hydroxy products by reaction with endogenous antioxidants such as tocopherols.

As an example, the reaction mechanism leading to the production of 7-oxygenated cholesterol derivatives is illustrated in Figure 21.5.34.

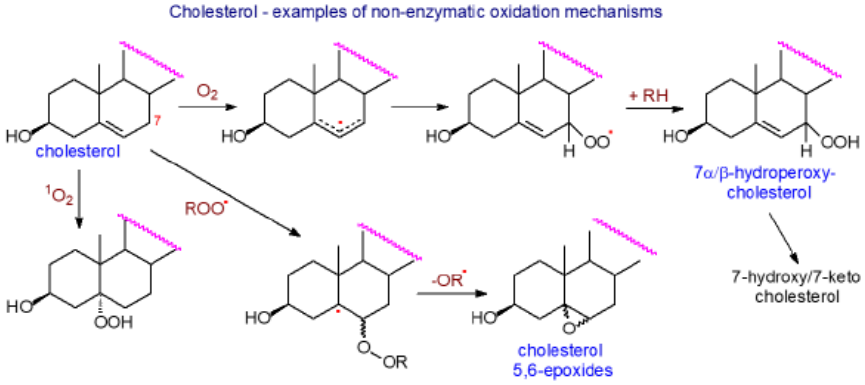

Figure 21.5.34: Cholesterol non-enzymatic oxidation mechanisms

In aqueous dispersions, oxidation is initiated by a radical attack from a reactive-oxygen species such as a hydroxyl radical with the abstraction of hydrogen from the C-7 position to form a delocalized three-carbon allylic radical, which reacts with oxygen to produce 7α-hydroperoxycholesterol, which gradually isomerizes to the more thermodynamically stable 7β-hydroperoxycholesterol. Subsequent enzymic and non-enzymic reactions lead to the 7-hydroxy and 7-keto analogs, which tend to be the most abundant non-enzymatically generated oxysterols in tissues, often accompanied by epoxy-ene and ketodienoic secondary products. Reaction with singlet oxygen ($^1O_2$) produces 5α-hydroperoxycholesterol mainly together with some 6α- or 6β-hydroperoxycholesterol. The reaction does not occur readily at the other allylic carbon 4, presumably because of steric hindrance. When cholesterol is in the solid state, the reaction occurs primarily at the tertiary carbon-25, though some products oxygenated at C-20 may also be produced.

Cholesterol hydroperoxides can be converted to stable diols only by the phospholipid hydroperoxide glutathione peroxidase - type 4 (GPx4) and then relatively slowly, but not by the type 1 glutathione peroxidase (GPx1) when in a membrane-bound state. However, in mammalian cells, monomeric GPx4 (~20 kDa), although present in several cellular compartments, including mitochondria, is much less abundant than tetrameric GPx1. Phospholipid-hydroperoxides are reduced most rapidly followed by cholesterol 6β-OOH > 7α/β-OOH >> 5α-OOH. The

result is that cholesterol hydroperoxides are expected to have a relatively long half-life and so can potentially be rather dangerous in biological systems. Of these, 5α-OOH with the lowest reduction rate is the most cytotoxic of the hydroperoxides, unfortunately.

Epimeric 5,6-epoxy-cholesterols may be formed by a non-radical reaction involving the non-enzymatic interaction of a hydroperoxide with the double bond, a process that is believed to occur in macrophages especially and in low-density lipoproteins (LDL). In this instance, the initial peroxidation product is a polyunsaturated fatty acid; the hydroperoxide transfers an oxygen atom to cholesterol to produce the epoxide, and in so doing is reduced to a hydroxyl. Other non-radical oxidation processes include reaction with singlet oxygen, which is especially important in the presence of light and photosensitizers and can generate 5-hydroxy- as well as 6- and 7-hydroxy products. In addition, the reaction with ozone in the lung can generate a family of distinctive oxygenated cholesterol metabolites.

Similarly, a diverse range of oxidation products are generated by peroxidation of the cholesterol and vitamin D precursor 7-dehydrocholesterol, which has the highest propagation rate constant known for any lipid toward free-radical chain oxidation, and these metabolites have important biological properties.

Oxysterols occur in tissues both in the free state and esterified with long-chain fatty acids. For example, in human atherosclerotic lesions, 80–95% of all oxysterols are esterified. Appreciable amounts of oxysterols can be present in foods, especially those rich in cholesterol such as meat, eggs, and dairy products, where they are most probably generated non-enzymically during cooking or processing when such factors as temperature, oxygen, light exposure, the associated lipid matrix, and the presence of antioxidants and water all play a part. Those present in foods can be absorbed from the intestines and transported into the circulation in chylomicrons, but the extent to which dietary sources contribute to tissue levels either of total oxysterols or of individual isomers is not known and is probably highly variable but relatively lower than of cholesterol *per se*.

21.5.2.3: OXYSTEROLS – BIOLOGICAL ACTIVITY

General Functions: In tissues *in vivo*, the very low oxysterol:cholesterol ratio means that oxysterols have little impact on the primary role of cholesterol in cell membrane structure and function, although it has been claimed that oxysterols could cause packing defects and thence atheroma formation in vascular endothelial cells. It is often argued that there are few reliable measurements of cellular or subcellular oxysterol concentrations, because of the technical difficulties in the analysis of the very low concentrations of oxysterols in the presence of a vast excess of native cholesterol; the average levels of 26-, 24- and 7α-hydroxy-cholesterol in human plasma that are often quoted are 0.36, 0.16 and 0.14 μM, respectively. Autoxidation products of cholesterol, especially 7-keto- and 7-hydroxy-cholesterol, are cytotoxic and may be useful markers of oxidative stress or for monitoring of the progression of various diseases. However, experts in the field caution that it can be difficult to extrapolate from experiments *in vitro* to the situation *in vivo*, because of the rapidity with which cholesterol can autoxidize in experimental systems and because of the difficulty of carrying out experiments with physiological levels of oxysterols.

Nonetheless, aside from their role as precursors of bile acids and some steroidal hormones, it is evident that oxysterols have a variety of roles in terms of maintaining cholesterol homeostasis and perhaps in signaling, where those formed enzymatically are most important. They can exert potent biological effects at physiologically relevant concentrations by binding to various receptors to elicit transcriptional programs, i.e., to regulate gene and hence protein expression. Among many cell membrane receptors for oxysterols to have been identified, nuclear receptors are especially important and include the liver X receptors (LXRs), retinoic acid receptor-related orphan receptors (RORs), estrogen receptors (ERs), and glucocorticoid receptors (GRs). In addition, *N*-methyl-D-aspartate receptors (NMDARs) are expressed in nerve cells and work over a short time scale to regulate excitatory synaptic function, while G protein-coupled receptors operate at cell membranes and are activated by molecules outside the cell to activate signaling pathways within the cell. As various isoforms of these receptors exist in different tissues, and these can interact with several oxysterols, only a brief summary of this complex topic is possible here.

A family of oxysterol-binding proteins (OSBP) transports and regulates the metabolism of sterols and targets oxysterols to specific membranes and especially to contact sites between organelles with the transport of **phosphatidylinositol 4-phosphate** in the reverse direction (see our web page on the latter). In this way, they can enable oxysterols to regulate membrane composition and function and mediate intracellular lipid transport. As with cholesterol, oxysterols can be eliminated from cells by transporters such as the ATP-binding cassette proteins ABCA1 and ABCG1, and they are transported in the blood-stream within lipoproteins, especially in association with HDL and LDL and mainly in the esterified form.

Cholesterol homeostasis: While cholesterol plays a key role in its own feedback regulation, there is some evidence that oxysterols are **regulators of cholesterol concentration** in cell membranes, and that **25-hydroxycholesterol** and **24(*S*),25-epoxycholesterol** may be especially effective, although the other side-chain oxysterols 22-, 24- and 27-hydroxycholesterol have been implicated. Several mechanisms appear to be involved, and it is suggested that 24(*S*),25-epoxycholesterol especially acts as a ligand for the liver X receptor, which forms a heterodimer with the retinoic X receptor, to inhibit the transcription of key genes in cholesterol biosynthesis, as well as directly inhibiting or accelerating the degradation of such important enzymes in the process as HMG-CoA reductase and squalene synthase. Similarly, both 26-hydroxylanosterol and 25-hydroxycholesterol inhibit HMG-CoA reductase. 25-Hydroxycholesterol inhibits the transfer of the 'sterol regulatory element binding protein' (SREBP-2) to the Golgi for processing to its active form as a transcription factor for the genes of the cholesterol biosynthesis pathway, and it stimulates the enzyme acyl-CoA:cholesterol acyl transferase in the endoplasmic reticulum to

esterify cholesterol. By such mechanisms, these oxysterols fine-tune cholesterol homeostasis and ensure smooth regulation rather than substantial fluctuations in tissue concentration.

Oxysterols and the immune system: Oxysterols and especially are known to have vital and diverse roles in immunity by regulating both the adaptive and innate immune responses to infection. For example, infection with viruses leads to the production of type I interferon, and in macrophages, this induces synthesis of **25-hydroxycholesterol**, which in general is regarded as anti-inflammatory and exerts broad antiviral activity by activating integrated stress response genes and reprogramming protein translation again via its interaction with LXR receptors. It is a potent inhibitor of SARS-CoV-2 replication, for example, possibly by a mechanism involving the blocking of cholesterol export from the late endosome/lysosome compartment and depletion of membrane cholesterol levels. However, the formation of 25-hydroxycholesterol may be harmful in the case of influenza infections, as it can lead to over production of inflammatory metabolites. Similarly, the biosynthesis of 25-hydroxycholesterol in macrophages is stimulated by the endotoxin **Kdo2-lipid A**, the active component of the lipopolysaccharide present on the outer membrane of Gram-negative bacteria, which acts as an agonist for Toll-like receptor 4 (TLR4). There is enhanced expression of the oxygenase CH25H in immune cells in response to bacterial and viral infection.

Many oxysterol species are active in a range of immune cells subsets, mediated through the control of LXR and SREBP signaling, but also by acting as ligands for RORs, and for the cell surface receptors G protein-coupled receptor 183 (GPR183) or CXCR2. Activation of LXR tends to dampen the immune response. In response to various stimuli, they can operate through ion channels to effect rapid changes in intracellular ion concentrations, especially of Ca^{2+}, to bring about changes in membrane potential, cell volume, cell death (apoptosis, autophagy, and necrosis), gene expression, secretion, endocytosis, or motility. For example, 27-hydroxycholesterol in human milk is reported to be active against the pathogenic human rotavirus and rhinovirus of importance in pediatrics, and 7-Dehydrocholesterol has anti-viral properties also. While they can exert their immune functions within the cell in which they are generated, oxysterols can also operate in a paracrine fashion towards other immune cells.

25-Hydroxycholesterol in particular can have either pro- or anti-inflammatory effects, depending upon the conditions, but the enzyme CH25H responsible for its biosynthesis is induced markedly in macrophages activated by inflammatory agents. It is reported to have a regulatory effect on the biosynthesis of sphingomyelin, which is required with cholesterol for the formation of **raft** sub-domains in membranes, where signaling molecules are concentrated, and together with other oxysterols, such as 24*S*,25-epoxycholesterol, to regulate the activities of the **hedgehog proteins** involved in embryonic development. Metabolites of 25-hydroxycholesterol, such as 7α,25-dihydroxycholesterol, and further oxidation products, are pro-inflammatory act as chemoattractants to lymphocytes; they have a role in the regulation of immunity in secondary lymphoid organs by interactions with the receptor GPR183.

Oxysterols in brain: Oxysterols are especially important for cholesterol homeostasis in the brain, which contains 25% of the total body cholesterol, virtually all of it in unesterified form, in only about 2% of the body volume. Cholesterol is a major component of the plasma membrane especially, where it serves to control fluidity and permeability. This membrane is produced in large amounts in the brain and is the basis of the compacted myelin, which is essential for the conductance of electrical stimuli and contains about 70% of brain cholesterol. While this pool is relatively stable, the remaining 30% is present in the membranes of neurons and glial cells of gray matter and is more active metabolically. Even in the fetus and the newborn infant, all the cholesterol required for growth is produced by synthesis *de novo* in the brain, not by transfer from the circulation across the blood-brain barrier, which consists of tightly opposed endothelial cells lining the extensive vasculature of the tissue. The fact that this pool of cholesterol in the brain is independent of circulating levels must reflect a requirement for constancy in the content of this lipid in membranes and myelin. In adults, although there is a continuous turnover of the membrane, the cholesterol is efficiently re-cycled and has a remarkably high half-life (up to 5 years). The rate of cholesterol synthesis is a little greater than the actual requirement so net movement of cholesterol out of the central nervous system must occur. An important component of this system is apolipoprotein E (Apo E), a 39-kDa protein, which is highly expressed in the brain and functions in the cellular transport of cholesterol and in cholesterol homeostasis. Apo E complexes with cholesterol are required for transport from the site of synthesis in astrocytes to neurons.

Hydroxylation by CYP46A1 of cholesterol to **24(*S*)-hydroxycholesterol** (cerebrosterol) is responsible for 50–60% of all cholesterol metabolism in the adult brain. If cholesterol itself cannot cross the blood-brain barrier, this metabolite is able to do so with relative ease. When the hydroxyl group is introduced into the side chain, this oxysterol causes a local re-ordering of membrane phospholipids such that it is more favorable energetically to expel it at a rate that is orders of magnitude greater than that of cholesterol *per se*, though still only 3-7 mg per day. There is a continuous flow of the metabolite from the brain into the circulation, much of it in the form of the inactive sterol ester, where it is transported by lipoprotein particles to the liver for further catabolism, i.e., it is hydroxylated in position 7 and then converted to **bile acids**. This is illustrated in Figure 21.5.35.

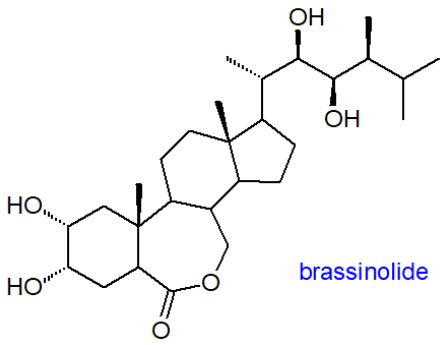

Figure 21.5.35: Brain/Liver 27-carboxy and 27-OH steroid metabolism.

Both 24(*S*)-hydroxycholesterol and 24(*S*),25-epoxycholesterol are believed to be important in regulating cholesterol homeostasis in the brain. They interact with the specific nuclear receptors involved in the expression and synthesis of proteins involved in sterol transport, and for example, 24-hydroxy-cholesterol regulates the transcription of Apo E. In particular, it is an agonist of the nuclear liver X receptors (LXRs), influencing the expression of those LXR target genes involved in cholesterol homeostasis and inflammatory responses. It is also a high-affinity ligand for the retinoic acid receptor-related orphan receptors α and γ (RORα and RORγ). In this way, it can act locally to affect the functioning of neurons, astrocytes, oligodendrocytes, and vascular cells.

24(*S*)-Hydroxycholesterol down-regulates the trafficking of the amyloid precursor protein and may be a factor in preventing neurodegenerative diseases. Especially high levels of 24(*S*)-hydroxycholesterol are observed in the plasma of human infants and in patients with brain trauma, while reduced levels are found in the plasma of patients with neurodegenerative diseases, including Parkinson's disease, multiple sclerosis, and Alzheimer's disease. In contrast, there are elevated levels in the brain and especially cerebrospinal fluid in patients with these conditions, where it may be a marker of neurodegeneration. Increased expression of cholesterol 24-hydroxylase (CYP46A1) is believed to improve cognition, while a reduction leads to poor cognitive performance, as occurs at advanced stages of the disease, probably reflecting a selective loss of neuronal cells, and it may be a factor in age-related macular degeneration. An excess of 24(*S*)-hydroxycholesterol and especially of its ester form can lead to neuronal cell death, and elevated levels in plasma are reported to be a potential marker for Autism Spectrum Disorders in children. On the other hand, it may be protective against glioblastoma, the most common primary malignant brain tumour in adults via activation of LXRs.

27-Hydroxy-cholesterol diffuses across the blood-brain barrier from the bloodstream into the brain (in the reverse direction to 24-hydroxycholesterol), where it does not accumulate but is further oxidized and then exported as steroidal acids. This flux may regulate certain key enzymes within the brain, and there are suggestions that the balance between the levels of 24- and 27-hydroxy-cholesterol, especially excess of the latter, may be relevant to the generation of β-amyloid peptides in Alzheimer's disease by reducing insulin-mediated glucose uptake by neurons. While 7β-hydroxycholesterol is pro-apoptotic, any links with Alzheimer's disease are unproven although there is a school of thought that other oxidized cholesterol metabolites may be major factors behind the development of this disease. For example, seco-sterols such as 3β-hydroxy-5-oxo-5,6-secocholestan-6-al and its stable aldolization product, the main ozonolysis metabolites derived from cholesterol, have been detected in brain samples of patients who have died from Alzheimer's disease and Lewy body dementia; they are also found in atherosclerotic lesions. Oxidation products of the cholesterol precursor 7-dehydrocholesterol and especially 3β,5-dihydroxycholest-7-ene-6-one are involved in the pathophysiology of the human disease Smith-Lemli-Opitz syndrome.

Cell differentiation: Oxysterols can influence the differentiation of many cell types and this was first studied in the skin, where 22(*R*)- and 25(*R*)-hydroxycholesterol were shown to induce human keratinocyte differentiation. Subsequently, by stimulating nuclear binding receptors, oxysterols were found to have similar effects on mesenchymal stem cells. There have been many reports of the involvement of oxysterols in disease processes, especially atherosclerosis and the formation of human atherosclerotic plaques, but also cytotoxicity, necrosis, inflammation, immuno-suppression, phospholipidosis and gallstone formation. They have been implicated in the development of cancers, especially those of the breast, prostate, colon, and bile duct. For example, **27-hydroxycholesterol** is an element in cholesterol elimination from macrophages and arterial endothelial cells, but it is also an endogenous ligand for the human nuclear estrogen receptor (ERα) and the liver X receptor, and it modulates their activities with effects upon various human disease states, including cardiovascular dysfunction and progression of cancer of the breast and prostate, as well as having an involvement in the regulation of bone mineralization (osteoporosis). It has been linked to cancer metastasis through effects on immune cells, and there is hope that pharmacological inhibition of CYP27A1 and thence the formation of 27-hydroxycholesterol may be a useful strategy in the treatment of breast cancer; *CYP7A1* gene polymorphism has been associated with colorectal cancer. In contrast, oxysterols can interfere in the proliferation of several types of cancer cell (glioblastoma, leukemia, colon, breast, and prostate cancer).

Cholesterol 5,6-epoxide (with either 5α or 5β stereochemistry) is formed non-enzymatically in tissues, but it is also believed to be produced by an unidentified cytochrome P450 enzyme in the adrenal glands. While it was for some time believed to be a causative agent in cancer, it is now recognized that downstream metabolites are responsible. Thus, cholesterol epoxide hydrolase converts cholesterol 5,6-epoxide into cholestane-3β,5α,6β-triol, which is transformed by 11β-hydroxysteroid-dehydrogenase-type-2 into the oncometabolite 3β,5α-

dihydroxycholestan-6-one (oncosterone). By binding to the glucocorticoid receptor, this oncosterone stimulates the growth of breast cancer cells, and it also acts as a ligand to the LXR receptors, which may mediate its pro-invasive effects. In contrast, in normal breast tissue, cholesterol 5,6-epoxide is metabolized to the tumor suppressor metabolite, a steroidal alkaloid designated dendrogenin A that is a conjugation product with histamine and controls a nuclear receptor to trigger lethal autophagy in cancers; its synthesis is greatly reduced in cancer cells. Tamoxifen, a drug that is widely used against breast cancer, binds to the cholesterol 5,6-epoxide hydrolase, which is also a microsomal anti-estrogen binding site (AEBS), to inhibit its activity.

7-Ketocholesterol is a major oxysterol produced during the oxidation of low-density lipoproteins, and is one of the most abundant in plasma and atherosclerotic lesions; it accumulates in erythrocytes of heart failure patients. It has a high pro-apoptotic potential and associates preferentially with membrane lipid **raft** domains. As it is not readily exported from macrophages, it impairs cholesterol efflux and promotes the foam cell phenotype. In cardiomyocytes, this accumulation can lead to cell hypertrophy and death, and it has been suggested that oxysterols are a major factor precipitating morbidity in atherosclerosis-induced cardiac diseases and inflammation-induced heart complications. Photoxidation in the retina via the action of free radicals or singlet oxygen generates unstable cholesterol hydroperoxides, which may be involved in age-related macular degeneration. For example, these compounds can quickly be converted to highly toxic 7α- and 7β-hydroxycholesterols and 7-ketocholesterol, depending on the status of tissue oxidases and reductases. Three separate enzymatic pathways have developed in the eye to neutralize their activities. These sterols are metabolized by novel branches of the acidic pathway of bile acid biosynthesis.

Those oxysterols formed non-enzymatically can be most troublesome in relation to disease in general. For example, they are enriched in pathologic cells and tissues, such as macrophage foam cells, atherosclerotic lesions, and cataracts. They may regulate some of the metabolic effects of cholesterol, but as cautioned above, effects observed *in vitro* may not necessarily be of physiological importance *in vivo*. Various oxysterols have been implicated in the differentiation of mesenchymal stem cells and the signaling pathways involved in this process. High levels of 7-hydroxycholesterol and cholestane-3β,5α,6β-triol are characteristic of the lysosomal storage diseases Niemann-Pick types B and C and of lysosomal acid lipase deficiency.

Cholesterol hydroperoxides: With the aid of START domain proteins, cholesterol hydroperoxides can translocate from a membrane of origin to another membrane such as mitochondria. Such transfer of free radical-generated 7-hydroperoxycholesterol, for example, has adverse consequences in that there is impairment of cholesterol utilization in steroidogenic cells, and of anti-atherogenic reverse-cholesterol transport in vascular macrophages. The antioxidant activity of GPx4 may be crucial for the maintenance of mitochondrial integrity and functionality in these cells.

21.5.2.4: VITAMIN D

Vitamin D encompasses two main sterol metabolites that are essential for the regulation of calcium and phosphorus levels and thence for bone formation in animals. However, these have many other functions, including induction of cell differentiation, inhibition of cell growth, immunomodulation, and control of other hormonal systems. Vitamin D (with calcium) deficiency is responsible for the disease rickets in children in which bones are weak and deformed, and it is associated with various cancers and autoimmune diseases. Ultraviolet light mediates cleavage of 7-dehydrocholesterol, an important intermediate in the biosynthesis of cholesterol, with the opening of the second (B) ring in the skin to produce pre-vitamin D, which rearranges spontaneously to form the secosteroid vitamin D_3 or cholecalciferol. Its structure is shown in Figure 21.5.36.

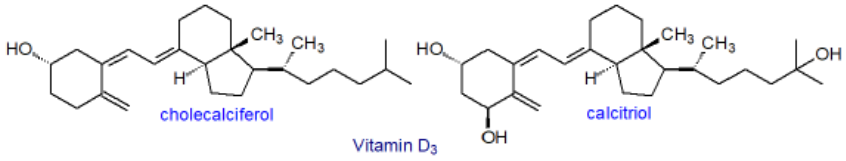

Figure 21.5.36: Structure of Vitamin D_3

The newly generated vitamin D_3 is transported to the liver where it is subject to 25-hydroxylation and thence to the kidney for 1α-hydroxylation to produce the active form 1α,25-dihydroxyvitamin D_3 (calcitriol); this is a true hormone and serves as a high-affinity ligand for the vitamin D receptor in distant tissues. For transportation in plasma, it is bound to a specific glycoprotein termed unsurprisingly, the 'vitamin D binding protein (BDP)'. Vitamin D_2 or ergocalciferol is derived from ergosterol, which is obtained from plant and fungal sources in the diet.

Vitamin D_3 functions by activating a cellular receptor (vitamin D receptor or VDR), a transcription factor binding to sites in the DNA called vitamin D response elements. There are thousands of such binding sites, which together with co-modulators regulate innumerable genes in a cell-specific fashion. In this way, it enhances bone mineralization by promoting dietary calcium and phosphate absorption, as well as having direct effects on bone cells. In addition, it functions as a general development hormone in many different tissues, while together with Vitamin D_2 it has profound effects on immune responses in the defense against microbes.

21.5.2.5: STEROIDAL HORMONES AND THEIR ESTERS

Steroidal hormones cannot be discussed in depth here as their structures, biosynthesis, and functions comprise a rather substantial and specialized topic. In brief, animal tissues produce small amounts of vital steroidal hormones from cholesterol as the primary precursor with 22*R*-hydroxycholesterol, produced by hydroxylation by the cholesterol side-chain cleavage enzyme (P450scc), as the first of its metabolites in the pathway. This step involves the 'STAR' protein which enables the transport of cholesterol into mitochondria where conversion to pregnenolone is rate-limiting and involves first hydroxylation and then cleavage of the side-chain. After export from the mitochondria, this can be converted directly to progesterone or in several steps to testosterone. 17β-Estradiol, for example, is the most potent and important of the endogenous estrogens; it is made mainly in the follicles of the ovaries and regulates menstrual cycles and reproduction, but it is also present in testicles, adrenal glands, fat, liver, breasts, and brain. Testosterone is the primary male sex hormone and an anabolic steroid, and it is produced mainly in the testes; it has a key function in the development of male reproductive tissues such as testes and prostate, in addition to promoting secondary sexual characteristics. Pregnane neurosteroids are synthesized in the central nervous system. Cholesterol homeostasis is therefore vital to fertility and a host of bodily functions. The structures of key steroidal hormones are shown in Figure 21.5.37.

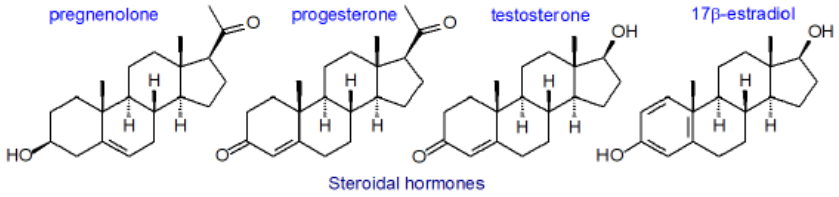

Figure 21.5.37: Structures of key steroidal hormones

Steroidal esters accumulate in tissues such as the adrenal glands, which synthesize corticosteroids such as cortisol and aldosterone and are responsible for releasing hormones in response to stress and other factors. It is also apparent that fatty acyl esters of estradiols, such as dehydroepiandrosterone, accumulate in adipose tissue in post-menopausal women. Small amounts of estrogens acylated with fatty acids at the C-17 hydroxyl are present in the plasma lipoproteins. In each instance, they appear to be biologically inert storage or transport forms of the steroid. Eventually, esterified steroids in low-density lipoproteins (LDL) particles are taken up by cells via lipoprotein receptors, and then are hydrolyzed to release the active steroid. Pharmaceutical interest in oleoyl-estrone, a naturally occurring hormone in humans, which was found to induce a marked loss of body fat while preserving protein stores in laboratory animals, has declined as clinical trials with humans were not successful.

21.5.3: STEROLS 3. STEROLS AND THEIR CONJUGATES FROM PLANTS AND LOWER ORGANISMS

21.5.3.1: PLANT STEROLS - STRUCTURES AND OCCURRENCE

Plants, algae, and fungi contain a rather different range of sterols from those in animals. Like **cholesterol**, to which they are related structurally and biosynthetically, plant sterols form a group of triterpenes with a tetracyclic cyclopenta[*a*]phenanthrene structure and a side chain at carbon 17, sometimes termed the $C_{30}H_{50}O$ triterpenome. The four rings (A, B, C, D) have *trans* ring junctions, and the side chain and two methyl groups (C-18 and C-19) are at an angle to the rings above the plane with β stereochemistry (as for a hydroxyl group commonly located on C-3 also). The basic sterol from which other sterol structures are defined is 5α-cholestan-3β-ol with the numbering scheme recommended by IUPAC as shown in Figure 21.5.38.

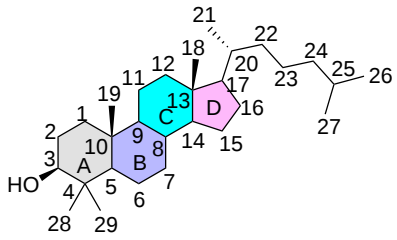

Figure 21.5.38: IUPAC sterol numbing system

The phytosterols (as opposed to zoosterols) include campesterol, β-sitosterol, stigmasterol, and Δ5-avenasterol, some of which are illustrated in Figure 21.5.39.

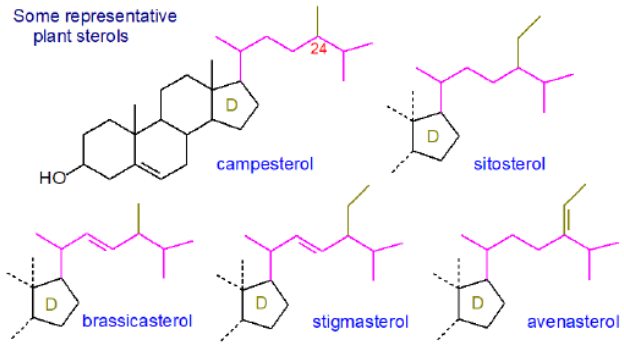

Figure 21.5.39: Some common plant sterols

These more common plant sterols have a double bond in position 5, and a definitive feature – a one- or two-carbon substituent with variable stereochemistry in the side chain at C-24, which is preserved during subsequent metabolism. For example, campesterol is a 24-methylsterol, while β-sitosterol and stigmasterol are 24-ethylsterols. Occasionally, there is a double bond in this chain that can be of the *cis* or *trans* configuration as in stigmasterol (at C22) or fucosterol (C24), the main sterol in green algae.

Phytosterols can be further classified on a structural or biosynthetic basis as 4-desmethyl sterols (i.e. with no substituent on carbon-4), 4α-monomethyl sterols and 4,4-dimethyl sterols. The most abundant group is the 4-desmethyl sterols, which may be subdivided into Δ5-sterols (illustrated above), Δ7-sterols (e.g. α-spinasterol) and Δ5,7-sterols depending on the position of the double bonds in the B ring. As the name suggests, brassicasterols (24-methyl-cholesta-5,22-dien-3β-ol and related sterols) are best known from the brassica family of plants, but they are also common constituents of marine algae (phytoplankton). Phytostanols (fully saturated) are normally present at trace levels only in plants, but they are relatively abundant in cereal grains.

Many different sterols may be present in photosynthetic organisms, and the amounts and relative proportions are dependent on the species. Over 250 different phytosterols have been recorded with 60 in corn (maize) alone, for example. As a rough generality, a typical plant sterol mixture would be 70% sitosterol, 20% stigmasterol, and 5% campesterol (or >70% 24-ethyl-sterols and <30% 24-methyl-sterols), although this will vary with the stage of development and in response to stress. **Table 1** contains data on the main components from some representative commercial seed oils.

Table 21.5.2. **Sterol composition in some seed oils of commercial importance (mg/Kg).**

	corn	cottonseed	olive	palm	rapeseed	safflower	soybean	sunflower
cholesterol	-	-	-	26	-	-	-	-
campesterol	2691	170	28	358	1530	452	720	313
stigmasterol	702	42	14	204	-	313	720	313
β-sitosterol	7722	3961	1310	1894	3549	1809	1908	2352
Δ5-avenasterol	468	85	29	51	122	35	108	156
Δ7-stigmasterol	117	-	58	25	306	696	108	588
Δ7-avenasterol	-	-	-	-	-	104	36	156
brassicasterol	-	-	-	-	612	-	-	-
other	-	-	-	-	-	69	-	39

Data adapted from Gunstone, F.D. *et al. The Lipid Handbook (Second Edition)* (Chapman & Hall, London) (1994).

Cholesterol is usually a minor component only of plant sterols (<1%), but it is unwise to generalize too much as it can be the main sterol component of red algae and of some families of higher plants such as in the Solanaceae, Liliaceae and Scrophylariaceae. It can also be a significant constituent sterol of chloroplasts, shoots, pollen and leaf surface lipids in other plant families; wheat roots contain 10% and Arabidopsis cells 19% of the sterols as cholesterol. Yeasts and fungi tend to contain ergosterol as their main sterol (see below). **Ecdysteroids** (phytoecdysteroids) are polyhydroxylated plant sterols that can occur in appreciable amounts in some species. Sterols are also found in some bacterial groups but not in archaea, and hopanoids in bacteria are considered to be functional triterpenic counterparts.

Sterols can occur in plants in the 'free' state, i.e. in which the sterol hydroxyl group is not linked to any other moiety, but they are usually present also as conjugates with the hydroxyl group covalently bound via an ester bond to a fatty acid, for example, i.e. as sterol esters, or via a glycosidic linkage to glucose (and occasionally other sugars), i.e. as steryl glycosides.

21.5.3.2: PLANT STEROLS - BIOSYNTHESIS

The biosynthetic route to plant sterols resembles that to cholesterol in many aspects in that it follows an isoprenoid biosynthetic pathway with isopentenyl pyrophosphate, derived primarily from mevalonate, as the key building block in the cytoplasm (but not plastids) at least. The main pathway for the biosynthesis of isopentenyl pyrophosphate and dimethylallyl pyrophosphate, the isoprene units, is described previously and so need not be repeated here. It is known as the 'mevalonic acid (MVA) pathway' and functions in the cytosol, endoplasmic reticulum and mitochondria.

However, an alternative pathway that does not use mevalonic acid as a precursor was established first for bacterial **hopanoids**, but has since been found in plant chloroplasts, algae, cyanobacteria, eubacteria, and some parasites (but not in animals). This route is variously termed the 'non-mevalonate', '1-deoxy-D-xylulose-5-phosphate' (DOXP) or better the **2*C*-methyl-D-erythritol 4-phosphate (MEP)** pathway as the last compound is presumed to be the first committed intermediate in sterol biosynthesis by this route. In the first step, pyruvate and glyceraldehyde phosphate are combined to form deoxyxylose phosphate, which is in turn converted to 2C-methyl-D-erythritol 4-phosphate. The pathway then proceeds via various erythritol intermediates until isopentenyl pyrophosphate and dimethylallyl pyrophosphate are formed. This pathway is illustrated in Figure 21.5.40.

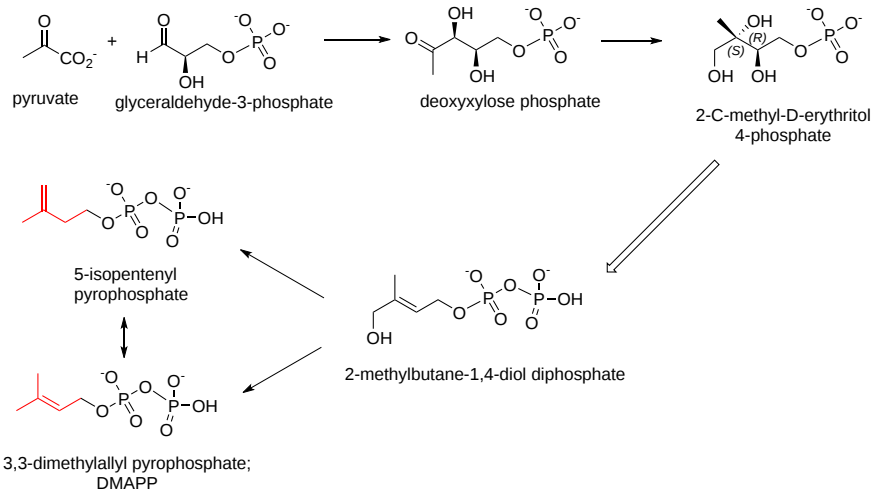

Figure 21.5.40: Alternative 2*C*-methyl-D-erythritol 4-phosphate (MEP) pathway for synthesis of sterol and isoprenoid precursors in chloroplasts.

There is evidence that some of the isoprene units are exchanged between the cytoplasm and plastids. In much of the plant kingdom, both the MVA and MEP pathways operate in parallel, but green algae use the MEP pathway only. Thereafter, sterol biosynthesis continues via squalene and (3*S*)-2,3-oxidosqualene.

In photosynthetic organisms (as opposed to yeast and fungi), the subsequent steps in the biosynthesis of plant sterols differ from that for cholesterol in that the important intermediate in the route from squalene via 2,3-oxidosqualene is **cycloartenol**, rather than lanosterol, and this is produced by the action of a 2,3(*S*)-oxidosqualene-cycloartenol cyclase (cycloartenol synthase). Then, the enzyme sterol methyltransferase 1 is of special importance in that it converts cycloartenol to 24-methylene cycloartenol, as the first step in introducing the methyl group onto C-24, while the enzyme cyclopropyl sterol isomerase is required to open the cyclopropane ring. Animals lack the sterol C24-methyltransferase gene. While this pathway is in essence linear up to the synthesis of 24-methylene lophenol, a bifurcation then occurs that results in two alternative pathways, one of which leads to the synthesis of sitosterol and stigmasterol and the other to that of campesterol. This pathway is shown in Figure 21.5.41.

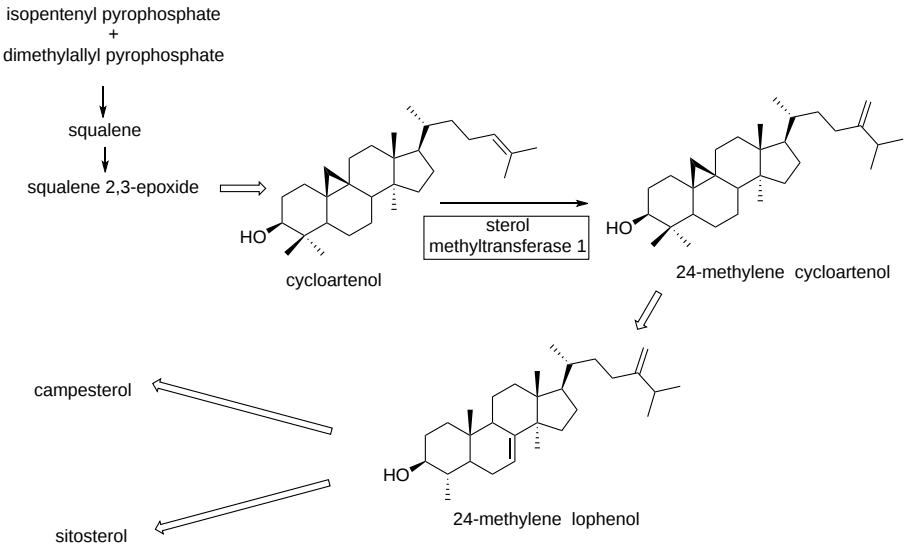

Figure 21.5.41: Synthesis of plant sterols via the cycloartenol intermediate

In fact, there are more than thirty enzyme-catalyzed steps in the overall process of plant sterol biosynthesis, each associated with membranes, and detailed descriptions are available from the reading list below. The 4,4-dimethyl- and 4α-methylsterols are part of the biosynthetic pathway, but are only minor if ubiquitous sterol components of plants. New biosynthetic pathways are now being discovered by genome analysis that reveal the complexity of sterol biosynthesis in different plant species.

Dinoflagellates produce a characteristic 4-methylsterol termed dinosterol and others like gorgosterol via lanosterol as precursor. Protozoans synthesize many different sterols related to those in plants. For example, some species of *Acanthamoeba* and *Naegleria* produce both lanosterol and cycloartenol, but only the latter is used for the synthesis of other sterols, especially ergosterol, but in other protozoan species, sterol biosynthesis occurs via lanosterol. The best studied bacterial pathway is that of the methylotroph *Methylococcus capsulatus*, which produces a number of unique Δ18(14)-sterols and is known to possess a squalene epoxidase and a lanosterol-14-demethylase.

Cholesterol in plants is produced from cycloartenol as the key intermediate with the Sterol Side Chain Reductase 2 (SSR2) as the key enzyme. It is now established that the cholesterol biosynthetic pathway in tomato plants comprises 12 enzymes acting in 10 steps. Of these, half evolved through gene duplication and divergence from phytosterol biosynthetic enzymes, whereas others act reciprocally in both cholesterol and phytosterol metabolism. Algae can also produce cholesterol in a multi-step process from cycloartenol, and many more sterols via 24-methylene lophenol as the key intermediate. It is hoped that genetic manipulation of these enzymes will lead to plants that synthesize high-value steroidal products.

Oxidation: Phytosterols can be subjected to non-enzymatic oxidation with the formation of **oxysterols** in a similar manner to that of cholesterol in animals, resulting in ring products such as hydroxy-, keto-, epoxy- and triol-derivatives, and further enzymic reactions can oxidize the side chain. However, photosensitized oxidation is more common in plants and is much faster (>1500 times); it starts with the *ene*-addition of singlet oxygen ($^1O_2$) on either side of the double bond in the B ring to generate 5α-/6α-/6β-hydroperoxysterols, of which 5α-OOH is the most abundant and rearranges to form the more stable 7α-OOH isomer. This is the main reaction in foods stored under LED lighting in food retailers.

21.5.3.3: PLANT STEROLS - FUNCTION

Like cholesterol, plant sterols are amphiphilic and are vital constituents of all membranes, and especially of the plasma membrane, the mitochondrial outer membrane and the endoplasmic reticulum. The three-dimensional structure of the plant sterols is such that there are planar surfaces at both the top and the bottom of the molecules, which permit multiple hydrophobic interactions between the rigid sterol and the other components of membranes. Indeed, they must determine the physical properties of membranes to an appreciable extent. It is believed that campesterol, β-sitosterol, and 24-methylcholesterol (in this order) are able to regulate membrane fluidity and permeability in plant membranes by restricting the mobility of fatty acyl chains in a similar manner to cholesterol in mammalian cells, but stigmasterol has much less effect on lipid ordering and no effect on the permeability of membranes. In the plasma membrane, plant sterols associate with the glycosphingolipids such as **glucosylceramide,** and **glycosylinositolphosphoceramides** in **raft**-like sub-domains, analogous to those in animal cells, and these support the membrane location and activities of many proteins with important functions in plant cells. The sterol glycosides are especially important in this context (see below).

Sterols (and their conjugates) are involved in plant membrane adaptations to changes in temperature and other biotic and abiotic stresses. For example, β-sitosterol is a precursor of stigmasterol via the action of a C22-sterol desaturase, and the ratio of these two sterols is important to the resistance of *A. thaliana* plants to low and high temperatures. In addition, plant sterols can modulate the activity of membrane-bound enzymes. Thus, stigmasterol and cholesterol regulate the activity of the Na^+/K^+-ATPase in plant cells, probably in a manner analogous to that of cholesterol in animal cells. Stigmasterol may be required specifically for cell differentiation and proliferation. As well as being the precursor of plant steroidal hormones, campesterol, is a signaling molecule that regulates growth, development, and stress adaptation.

Perhaps surprisingly, cholesterol is a precursor for the biosynthesis of some steroidal saponins and alkaloids in plants, for example, the well-known steroidal glycoalkaloid in potato (α-solanine), as well as of other steroids including the phytoecdysteroids (in some species they are derived from lathosterol). While the physiological roles of ecdysteroids in plants yet to be been confirmed, they are believed to enhance stress resistance by promoting health and vitality. Withanolides are complex oxysterols, which are believed to be defense compounds against insect herbivores.

21.5.3.4: STEROIDAL PLANT HORMONES

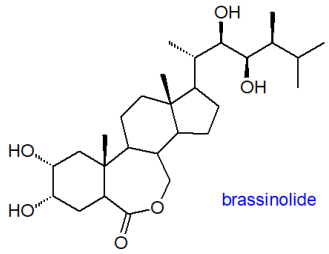

Figure 21.5.42 Structure of brassinolide

They have crucial importance for plant growth processes, including cell elongation, division, differentiation, immunity, and development of reproductive organs, and they are involved in the regulation of innumerable aspects of metabolism. Via signal transduction pathways, they interact with transcription factors through phosphorylation cascades to regulate the expression of target genes. Brassinosteroids are also signaling molecules in abiotic stress responses such as drought, salinity, high temperature, low temperature, and heavy metal stresses. Outwith plants, they may have biomedical applications as anticancer drugs for endocrine-responsive cancers to induce apoptosis and inhibit growth. Some plant species produce small amounts of steroid hormones that are often considered to be of animal origin only, including progesterone and testosterone, and these may have physiological roles in plants.

21.5.3.5: STEROL ESTERS IN HIGHER PLANTS

Sterol esters are present in all plant tissues, but they are most abundant in tapetal cells of anthers, pollen grains, seeds, and senescent leaves. In general, they are minor components relative to the free sterols other than in waxes. Usually, the sterol components of sterol esters are similar to the free sterols, although there may be relatively less of stigmasterol. The fatty acid components tend to resemble those of the other plant tissue lipids, but there can be significant differences on occasion. Sterol esters are presumed to serve as inert storage forms of sterols, as they are often enriched in the intermediates of sterol biosynthesis and can accumulate in **lipid droplets** within the cells. However, they have been found in some membranes, especially in microsomes and mitochondrial preparations, although their function there is uncertain. They may also have a role in transport within cells and between tissues, as they can be present in the form of soluble lipoprotein complexes.

Biosynthesis of sterol esters in *A. thaliana* is known to occur in the endoplasmic reticulum by the action of a phospholipid:sterol acyltransferase, which catalyzes the transfer of a fatty acyl group to the sterol from position *sn*-2 of phospholipids - mainly phosphatidylethanolamine; the enzyme is very different from those in animals and yeasts. However, an acyl CoA:sterol acyltransferase closer in structure to the animal enzyme has been characterized also; it prefers saturated fatty acyl-CoAs as acyl donors and cycloartenol as the acceptor molecule. The enzymes responsible for the hydrolysis of sterol esters in *A. thaliana* are not yet known. Certain distinctive phytosterol esters occur in the aleurone cells of cereal grains, including *trans*-hydroxycinnamate, ferulate (4-hydroxy-3-methoxycinnamate), and *p*-coumarate esters. Similarly, rice bran oil is a rich source of esters of ferulic acid and a mixture of sterols and triterpenols, termed 'γ-orizanol'', and an example of one of these compounds is illustrated in Figure 21.5.43.

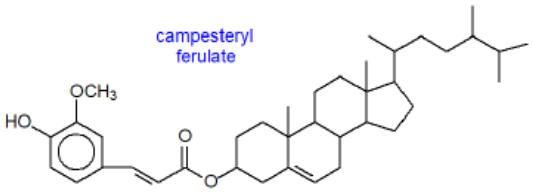

Figure 21.5.43 Structure of campesteryl ferulate

This is sold as a health food supplement, because of the claimed beneficial effects, including cholesterol-lowering and antioxidant activities, while enhancing muscle growth and sports performance. However, none of these effects have been confirmed by rigorous clinical testing.

21.5.3.6: STEROL GLYCOSIDES

Leaf and other tissue in plants contain a range of **sterol glycosides** and **sterol acyl-glycosides** in which the hydroxyl group at C3 on the sterol is linked to the sugar by a glycosidic bond. Other than in the genus *Solanum*, where they can represent up to 85% of sterol fraction in tomato fruit as an example, they tend to be minor components relative to other lipids. Typical examples (glucosides of β-sitosterol) are illustrated in Figure 21.5.44.

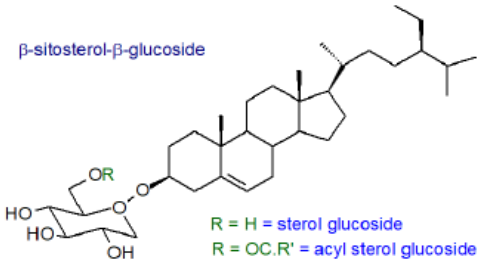

Figure 21.5.44 Structure of β-sitosterol-β-glucoside

Most of the common plant sterols occur in this form, but Δ5 sterols are preferred (Δ7 in some genera). Glucose is the most common carbohydrate moiety but galactose, mannose, xylose, arabinose can also be present depending on plant species; occasionally, complex carbohydrates with up to five hexose units linked in a linear fashion are present. Algae also contains sterol glycosides with a wide range of sterol and carbohydrate components. Plant, animal, fungal, and most bacterial steryl glycosides have a β-glycosidic linkage, but in a few bacterial species there is an α-linkage.

Similarly, the nature of the fatty acid component in the acyl sterol glycosides can vary as well as the hydroxyl group to which they are linked, although it is usually position 6 of the glucose moiety. In potato tubers, for example, the 6'-palmitoyl-β-D-glucoside of β-sitosterol is the major species, while the corresponding linoleate derivative predominates in soybeans. Usually, the sterol acyl-glycosides are present at concentrations that are two- to tenfold greater than those of the non-acylated forms. They are known to be located in the plasma membrane, tonoplasts and endoplasmic reticulum.

Biosynthesis involves the reaction of free sterols with a glucose unit catalyzed by a sterol glycosyltransferase, or by the reaction of the sterol with uridine diphosphoglucose (UDP-glucose) and UDP-glucose:sterol glucosyltransferase on the cytosolic side of the plasma membrane. The acyl donor for acyl sterol glycoside synthesis is not acyl-coenzyme A but is believed to be a glycerolipid. Steryl β-D-glycoside hydrolases have been characterized from plants that reverse this reaction, but no fatty acyl hydrolase activity for sterol acyl-glycosides is yet known. One route to the biosynthesis of **glucosylceramides** in plants involves the transfer of the glucose moiety of sterol glycosides to ceramide.

The functions of sterol glycosides and sterol acyl-glycosides are slowly being revealed, and they are believed to be significant components of the plasma membrane that associate with sphingolipids in **raft-like domains**; the esterified form especially may be involved in the adaptation of plant membranes to low temperatures and other stresses. It is possible that they have a role in signal transmission through membranes, and they are reported to be beneficial in the response to pathogens. It seems probable that sterol glycosides are oriented with the sterol moiety buried in the hydrophobic core of the lipid bilayer with the sugar located in the plane of the polar head groups of the membrane, while with sterol acyl-glycosides both the sterol moiety and the fatty acid chain are embedded in the hydrophobic core of the membrane. Sitosterol-β-D-glucoside in the plasma membrane is believed to be the primer molecule for cellulose synthesis in plants, as in cotton (*Gossypium arboreum*) fiber, where it may be required for the initiation of glucan polymerization. The sterol is eventually removed from the polymer by a specific cellulase enzyme (the multimeric cellulase synthase is believed to be stabilized by sterols in the plasma membrane).

Sterol glycosides appear to be essential for the pathogenicity of certain fungi and for some bacteria, and ergosterol glycosides especially are especially troublesome components of plant fungal pathogens. Sterol glycosides have only rarely been reported from organisms other than plants and fungi, although some bacteria, such as the gram-negative bacterium *Helicobacter pylori* and *Borrelia burgdorferi*, the causative agent of Lyme disease produce **cholesterol glucoside** from host cholesterol. On the other hand, cholesteryl glucoside has been found as a natural component of a few animal tissues, and through acting as immunoadjuvants, sterol glycosides are reported to be efficacious in protecting animal hosts against lethal Cryptococcal infections. In the human diet, sterol glycosides have potential benefits in that like free sterols they inhibit the absorption of cholesterol from the gut and reduce the plasma cholesterol levels. The fatty acids are removed from sterol acyl-glycosides by enzymes in the intestine.

A number of species of monocotyledons contain complex steroidal **saponins**, which consist of an aglycone based on a triterpenoid furostanol or spirostanol skeleton (derived from cholesterol) and an oligosaccharide chain of two to five hexose or pentose moieties attached to the 3β-hydroxyl group of the sterol. These can interact with cholesterol in plant membranes to form insoluble complexes, which increase membrane permeability.

21.5.3.7: ERGOSTEROL AND OTHER STEROLS IN YEASTS AND FUNGI

Yeasts and fungi, together with microalgae and protozoa, can contain a wide range of different sterols. However, **ergosterol** ((22*E*)-ergosta-5,7,22-trien-3β-ol) is the most common sterol in fungi and yeast, and is accompanied by other sterols not normally abundant in higher plants including cholesterol, 24-methyl cholesterol, 24-ethyl cholesterol, and brassicasterol, depending upon species. In *Saccharomyces cerevisiae*, which is widely studied as a model species of yeasts, ergosterol is the most abundant sterol (ca. 12% of all lipids), with the highest levels in the plasma membrane (up to 40% of the lipids or 90% of the total cell sterols). Its structure is shown in Figure 21.5.45.

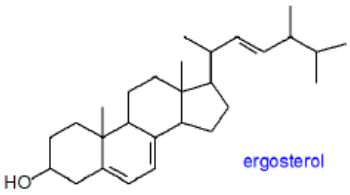

Figure 21.5.45: Strurture of ergosterol

Like cholesterol and in contrast to the plant sterols, it is synthesized in the endoplasmic reticulum via lanosterol as the key intermediate and then zymosterol, but the pathway diverges at this stage to produce fecosterol on the way to ergosterol (see the reading list below for further details). Ergosterol is transported to other organelles within the cell in a non-vesicular manner by two families of evolutionarily conserved sterol-binding proteins - 'Osh' and 'Lam', which are able to optimize the sterol composition of cell membranes rapidly under conditions of stress. As in humans, a Niemann-Pick protein NCR1 integrates sterols into the lysosomal membrane prior to further distribution as part of the mechanism of sterol homeostasis. Some antifungal drugs are targeted against ergosterol, either by binding to it to cause damaging cellular leakage, or to prevent its synthesis from lanosterol.

Many mutants defective in ergosterol biosynthesis have been isolated, and these have yielded a great deal of information on the features of the sterol molecule required for its structural role in membranes of yeast and fungi. Ergosterol stabilizes the liquid-ordered phase in the same manner as cholesterol and also forms raft microdomains with sphingolipids in membranes, whereas lanosterol does not. It is also evident that ergosterol has a multiplicity of functions in the regulation of yeast growth.

Under some conditions, especially those that retard growth, a high proportion of the sterols in yeasts can be in esterified form, where they are stored in lipid droplets. Ergosterol esters are synthesized in yeast by enzymes (ARE1 and ARE2), which are related to ACAT-1 and ACAT-2 that perform this function in animals, and both transfer an activated fatty acid to the hydroxyl group at the C3-position of a sterol molecule. In addition, specific sterol ester hydrolases that catalyze the reverse reaction have been characterized from yeasts, two in lipid droplets and one at the plasma membrane. Many fungal species and slime molds contain steryl glycosides (ergosteryl β-monoglucopyranosides in the former), but they are present at very low levels only in the widely studied yeast *Saccharomyces cerevisiae*.

Most fungi conjugate the 3β-hydroxyl group of ergosterol with aspartate in an RNA-dependent reaction catalyzed by an ergosteryl-3β-*O*-L-aspartate synthase, with the reverse reaction using a dedicated hydrolase. A phylogenomic study has shown that this pathway is conserved across higher fungi (except *S. cerevisiae*), including pathogens, and it has been suggested that these reactions constitute a homeostasis system with a potential impact upon membrane remodeling, trafficking, antimicrobial resistance, and pathogenicity.

21.5.3.8: BACTERIAL STEROLS

Hopanoids take the place of sterols in many species of bacteria, but it has long been recognized that some bacteria take up cholesterol and other sterols from host animals for use as membrane constituents. Indeed, an external source of sterols is required for growth in species of *Mycoplasma*. In addition, there have been a number of reports of the biosynthesis of sterols by various bacterial species, although a high proportion of these appears now to have been discounted because of fungal contamination. In particular, the possibility of sterol biosynthesis in cyanobacteria has been controversial, and molecular biology studies have yet to detect the presence of the required enzyme squalene epoxide cyclase.

That said, there is good evidence that a few species of prokaryotes at least have the capacity to synthesize sterols *de novo*. Among the eubacteria, certain methylotrophs (*Methylobacterium* and *Methylosphaera* species) produce mono- and dimethyl sterols, including lanosterol. Similarly, some soil bacteria produce 4-desmethylsterols. It has now been established from gene sequence studies that a few bacteria contain enzymes of the sterol biosynthesis pathway such as oxidosqualene cyclase, but as these have no obvious evolutionary link it seems probable that they were acquired via lateral transfer from eukaryotes.

21.5.3.9: PLANT STEROLS IN THE HUMAN DIET

The absorption of dietary plant sterols and stanols in humans is low (0.02-3.5%) compared to cholesterol (35-70%), although there are similar amounts in an average Western diet. The explanation is believed to be that the Niemann-Pick C1-like protein 1 (NPC1L1), which is responsible for cholesterol absorption in enterocytes does not take up plant sterols efficiently, while two transporters (ABCG5 and ABCG8) redirect any that are absorbed back into the intestinal lumen. In some rare cases, increased levels of plant sterols in plasma serve as markers for an inherited lipid storage disease (phytosterolemia) caused by mutations in the enterocyte transporters. Among many symptoms, accelerated atherosclerosis is often reported although the reasons for this are not clear. There is evidence that while plant sterols can substitute for cholesterol in maintaining membrane function in mammalian cells, they can exert harmful effects by disrupting cholesterol homeostasis. This may be relevant to the brain especially, since phytosterols are able to cross the blood-brain barrier, although they cannot be oxidized enzymatically because of the alkyl moiety on C24. In contrast, dietary supplements of plant sterols have been reported to have anti-cancer effects.

Substantial amounts of phytosterols are available as by-products of the refining of vegetable oils and of tall oil from the wood pulp industry. As it appears that they can inhibit the uptake of cholesterol from the diet and thereby reduce the levels of this in the plasma low-density lipoproteins, there is an increasing interest in such commercial sources of plant sterols to be added as "nutraceuticals" to margarines and other foods, Hydrogenated phytosterols or "**stanols**" are also used for this purpose, and studies suggest they are as effective as sterols in reducing LDL cholesterol. The consensus amongst experts in the field (including the FDA in the USA) is that such dietary supplements do indeed have the effects claimed and such claims can be used in advertising of commercial products, with the important caveat that there are no randomized, controlled clinical trial data that establish ensuing benefits to health, especially with respect to cardiovascular disease. Other pharmacological effects are under investigation, and there may be beneficial effects for the development of the human fetus and newborn, and for the treatment of non-alcoholic steatohepatitis, inflammatory bowel diseases ,and allergic asthma.

It is not clear whether oxy-phytosterols are generated in animal tissues, but those produced by enzymatic or non-enzymatic means can enter the food chain, especially when they are produced during cooking. Although they are not efficiently absorbed, 7-keto-sitosterol and 7-keto-campesterol have been detected in human plasma and have the potential to exert a variety of biological effects. For example, they have pro-atherogenic and pro-inflammatory properties in animal models.

21.6: BIOSYNTHESIS OF ISOPRENOIDS

By William (Bill) W. Christie and Henry Jakubowski.

This section is an abbreviated and modified version of material from the Lipid Web, an introduction to the chemistry and biochemistry of individual lipid classes, written by William Christie.

21.6.1: ISOPRENOIDS: 1. TOCOPHEROLS AND TOCOTRIENOLS (VITAMIN E)

Tocopherols and tocotrienols constitute a series of related benzopyranols (or methyltocols) that are synthesized in plants and other photosynthetic organisms, where they have many important functions but especially as part of a complex web of antioxidants that protect plants from the activities of reactive oxygen species (ROS). First described in 1922 as a dietary factor essential to prevent fetal reabsorption in rats, it was soon understood that plants contained a fat-soluble vitamin (vitamin E) that is essential for innumerable aspects of animal development. Of these many related molecules, only one form, i.e., **α-tocopherol**, is recognized as having vitamin E activity in humans in that it prevents a spectrum of human deficiency diseases termed 'ataxia', which is characterized by very low concentrations of α-tocopherol in plasma. The progression of the disease can be prevented by the administration of α-tocopherol only, although the pathogenic mechanism appears to be uncertain. While all tocopherols are known to be powerful lipid-soluble antioxidants *in vitro* at least, α-tocopherol has indirect roles in signal transduction and gene expression in animal tissues. On the other hand, specific functions (non-vitamin E) for other tocopherol forms and their metabolites in animal tissues are now being revealed. Vegetable oils are a major dietary source of vitamin E for humans.

21.6.1.1: STRUCTURE AND OCCURRENCE

In the tocopherols, the C_{16} side chain is saturated, and in the **tocotrienols** it contains three *trans* double bonds. Together, these two groups are termed the **tocochromanols.** In essence, the tocopherols have a 20-carbon phytyl tail (including the pyranol ring) and four chiral centers in total, with variable numbers of methyl groups attached to the benzene ring, while the tocotrienols have a 20-carbon geranylgeranyl tail with double bonds at the 3', 7' and 11' positions relative to the ring system. Tocopherols contain three chiral carbons, one at C2 in the chromanol ring and two in the side chain at C4′ and C8′ with *R,R,R* stereochemistry. The four main constituents of the two classes are termed - *alpha* (5,7,8-trimethyl), *beta* (5,8-dimethyl), *gamma* (7,8-dimethyl) and *delta* (8-methyl). In contrast to the tocopherols, the tocotrienols have only one chiral center. **Plastochromanol-8** is an analog of γ-tocotrienol with a much longer side-chain. Their structures are shown in Figure 21.6.1.

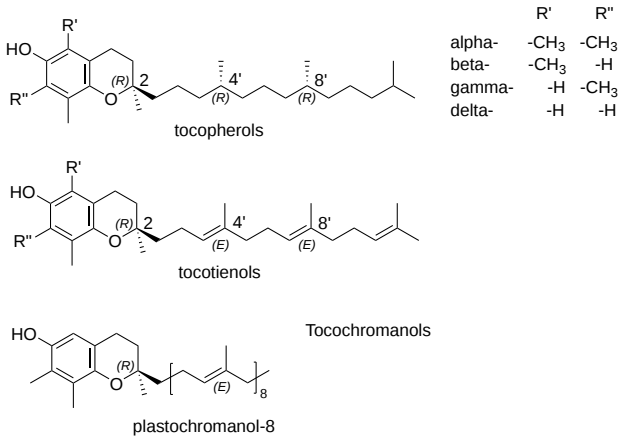

Figure 21.6.1: Tocochromanols

The tocochromanols are only synthesized by plants and other oxygenic photosynthetic organisms, such as algae and some cyanobacteria, but they are essential components of the diet of animals. Of these, only natural *R,R,R*-α-tocopherol is now designated ‘vitamin E’, as explained below, although the other tocopherols are sometimes termed ‘vitamers’ (some claim incorrectly - nor should all forms be termed isomers strictly speaking). In the USA, the current recommended dietary allowance (RDA) is 15 mg α-tocopherol daily for adults. In plants, there is a great range of tocochromanol contents and compositions, and photosynthetic plant tissues contain from 10 to 50 μg tocochromanols per g fresh weight. α-Tocopherol only is present in photosynthetic membranes of plant leaves, while γ-tocopherol and other forms are found principally in fruits, seeds, and nuts. While tocopherols are present in all photosynthetic organisms, the tocotrienols are found only in certain plant families.

Seed oils are a major source for the human diet and the compositions of tocopherols in some unrefined oils are listed in **Table 1**. Sunflower and olive oils are good sources of α-tocopherol and palm oil of the tocotrienols. In general, tocotrienols tend to be abundant only in seeds and fruits, especially of monocots such as wheat, rice, and barley, though a major commercial source is palm oil. In leaf tissue, α-tocopherol is often the main form, while γ-tocopherol is the primary tocopherol of many seeds. Plastochromanol-8 was first found in leaves of the rubber tree (*Hevea brasiliensis*) but has since been found in many other plants including rapeseed and maize, but usually at lower levels

than of the tocopherols. In addition, tocopherol esters of fatty acids occur in plant tissues, where they may be an inert storage form, but unesterified tocopherols are not released during digestion in animals so they may not make a contribution to vitamin E activity.

Table 21.6.1: **Tocopherol and tocotrienol contents (mg/Kg) in some seed oils.**

	α-T*	β-T	γ-T	δ-T	α-TT*	β-TT	γ-TT	δ-TT
palm	89	-	18	-	128	-	323	72
soybean	100	8	1021	421	-	-	-	-
maize	282	54	1034	54	49	8	161	6
sunflower	670	27	11	1	-	-	-	-
rapeseed	202	65	490	9	-	-	-	-

* Abbreviations: T, tocopherol; TT, tocotrienol

Data from: Gunstone, F.D., Harwood, J.L. and Padley, F.B. *The Lipid Handbook (Second Edition)* (Chapman & Hall, London)(1994).

An unusual tocopherol that has been termed marine-derived α-tocomonoenol is found together with α-tocopherol in a wide range of marine fish species, where it appears to be a more efficient scavenger of free radicals at low temperatures. A related isomer with a Δ11 double bond has been found in palm oil and kiwi fruit. While pumpkin seeds contain both α- and γ-tocomonoenols, other plant species contain β, γ- and δ-tocomonoenols with unsaturation in the terminal isoprene unit of the side chain. Tocochromenols or 3,4-dehydrotocopherols, i.e., with a double bond in the pyranol ring, are also known in addition to more complex tocopherol-like molecules. The structures of tocomonoenols are shown in Figure 21.6.2.

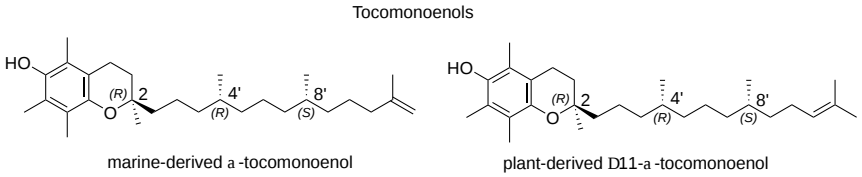

Figure 21.6.2: Tocomonoenols

α-Tocopherol is a minor but ubiquitous component of the lipid constituents of animal cell membranes (non-raft domains), with estimates ranging from one molecule of tocopherol to from 100 to 1000 molecules of phospholipids, depending on the membrane. The hydrophobic tail lies within the membrane, as might be expected, and the polar head group is orientated towards the surface but below the level of the phosphate moieties of the phospholipids. There may be some limited hydrogen bonding between the hydroxyl groups and phosphate depending on the degree of hydration of the membrane. On the other hand, there is a strong affinity of α-tocopherol for polyunsaturated fatty acids, where the chromanol unit may interact with the double bonds, suggesting that tocopherol is located deep within the membrane.

α-Tocopheryl phosphate has recently been detected at low levels in plasma, liver, and adipose tissue. Its structure is shown in Figure 21.6.3. Together with catabolic tocopherol metabolites, it has important biological properties.

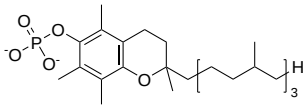

Figure 21.6.3: α-Tocopheryl phosphate

During the refining of vegetable oils, much of the natural tocopherols is lost or destroyed. Most commercial vitamin E is therefore prepared by chemical synthesis with trimethylhydroquinone and phytyl bromide as the precursors. The resulting product is a mixture of eight stereoisomers (from *R*,*R*,*R*- to *S*,*S*,*S*-methyl groups) of α-tocopherol, with the various stereoisomers differing by a factor of two in biologic activity, as a consequence of the stereochemistry of position 2 in the chromanol ring (i.e., 2*S*-α- compared to 2*R*-α-tocopherol). It is usually administered as the acetate derivative *in vivo*. Tocopherols are not usually regarded as effective antioxidants in the polyunsaturated seed oils of commerce, and at higher concentrations can even act as pro-oxidants, although the reasons for this are not understood.

21.6.1.2: BIOSYNTHESIS AND FUNCTIONS OF TOCOCHROMANOLS IN PLANTS

The mechanism of biosynthesis of tocopherols has been elucidated and involves the coupling of phytyl diphosphate with homogentisic acid (2,5-dihydroxyphenylacetic acid), followed by cyclization and methylation reactions. The plant chloroplast is the site of biosynthesis, and most of the enzymes are located on the inner membrane of the chloroplast envelope, although there is increasing evidence that **plastoglobules** associated with the thylakoid membrane may be involved. The pathway for biosynthesis of tocopherols is shown in Figure 21.6.4.

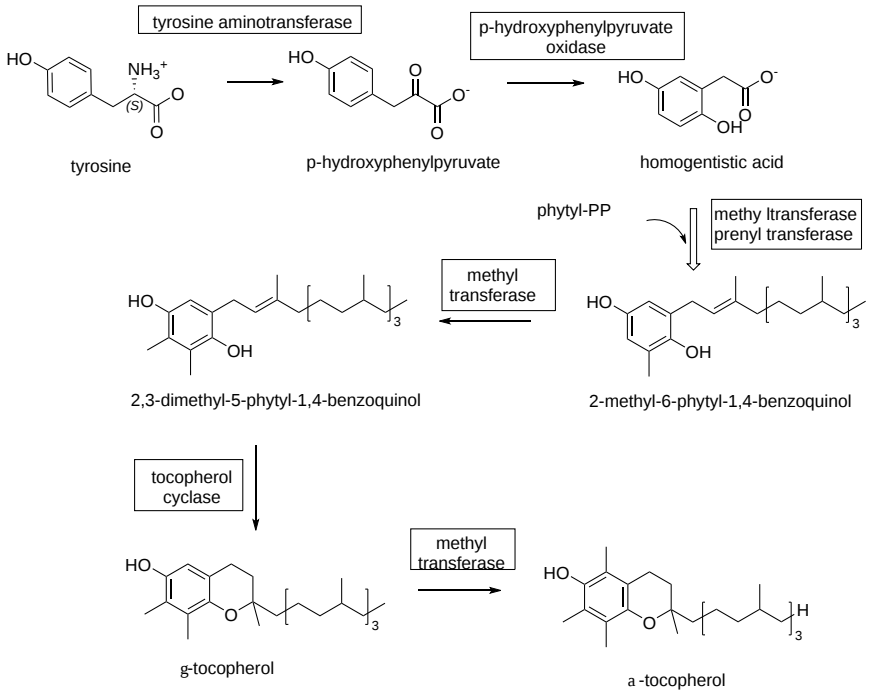

Figure 21.6.4: Synthesis of tocopherols

The aromatic amino acid tyrosine can be considered the basic precursor, and this is oxidized to *p*-hydroxypyruvic acid, which in the first committed step is converted to homogentisic acid by the enzyme *p*-hydroxyphenylpyruvate dioxygenase. Homogentisic acid is condensed with phytyl diphosphate, derived from **phytol** obtained from hydrolysis of chlorophyll, in a reaction catalyzed by a prenyl transferase to yield 2-methyl-6-phytyl-plastoquinol, which is first methylated to form 2,3-dimethyl-5-phytyl-1,4-benzoquinol and then converted by the enzyme tocopherol cyclase to γ-tocopherol. A further methylation reaction produces α-tocopherol, while modifications to the pathway produce β- and δ-tocopherols, together with **plastoquinones** and thence plastochromanol-8. Tocotrienols and tocomonoenols result from a similar series of reactions but with geranylgeranyl diphosphate and tetrahydro-geranylgeraniol diphosphate, respectively, as substrates in the condensation step. The isoprenoid precursors are synthesized in the plastid also by the non-mevalonate or 'MEP' pathway.

In plants, tocopherols are found mainly in the chloroplasts of green tissues, but they are also present in seeds, fruits, roots and tubers. They are especially important as antioxidant molecules, limiting the damage from photosynthesis-derived reactive oxygen species during conditions of oxidative stress, including high-intensity light stress, and the mechanisms for this antioxidant activity are discussed below. However, recent studies seem to suggest that they are just one of a number of different components that are involved in photoprotection. Certainly, any tocochromanol peroxy radicals formed must be converted back to the original compounds by the concerted action of other plant antioxidants, for example by ascorbate, glutathione, ubiquinol or lipoic acid, and antioxidant enzymes, including superoxide dismutase, catalase, and peroxidases. Tocopherols are essential for the control of non-enzymatic lipid peroxidation during seed dormancy and germination of seedlings. In their absence, elevated levels of malondialdehyde and phytoprostanes are formed, and there can be inappropriate activation of plant defense responses.

There is evidence that tocopherols play a part in intracellular signaling in plants in that they regulate the amounts of **jasmonic acid** in leaves, via modulating the extent of lipid peroxidation and gene expression, and so influence plant development and stress responses. Thus, by controlling the degree of lipid peroxidation in chloroplasts (redox regulation), they limit the accumulation of lipid hydroperoxides required for the synthesis of jasmonic acid, which in turn regulates the expression of genes that affect a number of abiotic stress conditions, including drought, salinity and extremes of temperature. The translocation of enzymes to the plasma membrane is regulated by tocopherols, possibly by modulating protein-membrane, altering membrane microdomains (lipid **rafts**), or by competing for common binding sites within lipid transport proteins. In addition, tocopherols are required for the development of the cell walls in phloem transfer cells under cold conditions. It appears that α- and γ-tocopherol and the tocotrienols may each have distinct functions. For example, γ-tocopherol is reportedly more potent than α-tocopherol in protecting plants from the harmful effects of osmotic stresses and is important for the longevity of seeds. Efforts are underway to increase the tocopherol levels in plants by selective breeding and genetic manipulation with the aim of producing crops with greater potential health benefits to consumers and perhaps for the plants *per se*.

21.6.1.3: TOCOPHEROLS METABOLISM IN ANIMALS

In animals, the first step in the digestion of tocopherols is their dissolution with other lipids in mixed micelles in the intestines. All tocopherol forms are absorbed to a similar extent in the intestines by means of transporters in the enterocyte apical membrane that have a broad specificity for hydrophobic molecules, such as cholesterol, vitamin D, and carotenoids. These include scavenger receptor class B type

I (SR-BI), the CD36 protein, and NPC1-like intracellular cholesterol transporter 1 (NPC1L1). However, some passive diffusion cannot be ruled out. Transport across the enterocyte may involve cytoplasmic transporters or clathrin-coated vesicles before the tocopherols are incorporated into chylomicrons in free form in the Golgi apparatus for release into the lymph. At the liver, α-tocopherol specifically is taken up from the chylomicrons by a receptor-mediated mechanism with the aid of a specific tocopherol-binding protein (the α-tocopherol transfer protein (α-TTP)), i.e., a 30,500 Da cytosolic protein that has a marked affinity for α-tocopherol and can enhance its transfer between membranes. This recognizes α-tocopherol by the three methyl groups and hydroxyl on the chromanol ring and by the structure and orientation of the phytyl side chain. It is the chief regulator of whole body α-tocopherol status and is expressed primarily in the cytosol of hepatocytes in the liver, but has been reported (in much lower concentrations) in other tissues, such as the placenta.

α-TTP ultimately regulates the egress of α-tocopherol selectively from hepatocytes with the aid of the ATP-binding cassette proteins ABCA1 and ABCG for conveyance in the plasma **lipoproteins**, mainly in the very-low-density lipoproteins or VLDL (and thence to LDL) and HDL in humans, to the peripheral tissues (together with much smaller amounts of γ-tocopherol). Most of the other tocopherol forms are directed toward catabolism. Once in the circulation, tocopherol can exchange spontaneously between membranes and lipoproteins, and no specific transport protein for vitamin E in plasma has yet been described. Transfer of tocopherols from the VLDL to peripheral tissues occurs as triacylglycerols are hydrolyzed by the enzyme lipoprotein lipase, while that in LDL is processed via the LDL receptor-mediated uptake pathway. Within cells of peripheral tissues, including the central nervous system, α-TTP functions in transporting α-tocopherol to wherever it is required in membranes, a process that appears to be aided by **phosphatidylinositol** metabolites. In the brain, tocopherol is transported by apo-E rich lipoproteins. Concentrations of tocopherols can vary appreciably amongst tissues, with most in adipose tissue and adrenals, less in kidney, heart, and liver, and least in the erythrocytes.

The "α-tocopherol salvage pathway" is partly due to this process and partly to selective oxidation (see below), and the result is a 20- to 30-fold enrichment of α-tocopherol in plasma (average concentration 22-28 μM) relative to the other tocopherols. Thus, the process of conservation of one specific tocopherol appears to determine the relative vitamin E activities of the tocopherols and tocotrienols *in vivo*, rather than their individual potencies as antioxidants as measured in model systems *in vitro*. Only α-tocopherol (including synthetic material) or natural mixtures containing this can be sold under the label 'Vitamin E'. γ-Tocopherol is the second most abundant form in plasma, and it is present in relatively greater proportions in the skin, adipose tissue, and skeletal muscle, where it has some specific biological properties that are distinct from those of α-tocopherol. Although tocotrienols are more potent antioxidants *in vitro*, they are not usually detected in tissues, although they are believed to have some important functions.

Catabolism: The unwanted surplus of tocochromanols other than α-tocopherol may be excreted in the urine and feces in the form of carboxy-chromanols, including the so-called 'Simon metabolites' - tocopheronic acids (carboxyethylhydroxychromans, CEHC) and tocopheronolactones, after oxidative cleavage of much of the phytyl tail, although these are normally detected in the form of conjugates as sulfate or glucuronidate esters, the forms in which they are excreted in feces and urine. For example for illustrative purposes in liver cells, the first step in the catabolism of γ-tocopherol is ω-hydroxylation by cytochrome P450 (CYP4F2) at the 13' carbon to form γ-13'-hydroxychromanol in the endoplasmic reticulum, followed by ω-oxidation in the peroxisomes to produce γ-13'-carboxychromanol, and finally by stepwise β-oxidation in the mitochondria to cut off two or three carbon moieties from the phytyl chain in each cycle. These steps are shown in Figure 21.6.5.

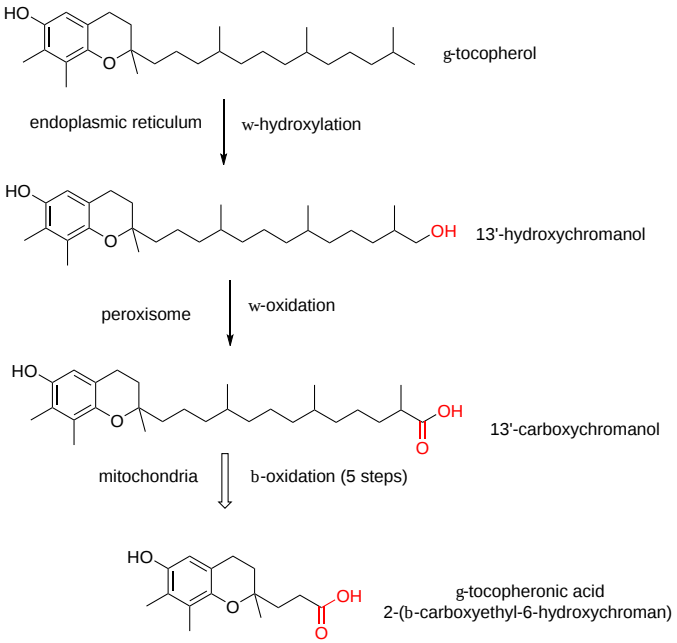

Figure 21.6.5: Catabolism of γ-tocopherol

Various carboxychromanol intermediates have been identified for all of the tocopherols together with forms in which the hydroxyl group is sulfated in human cell cultures *in vitro*; sulfated carboxychromanols are the main tocopherol metabolites in the plasma of rodents. As the vitamin E ω-hydroxylase has a high affinity for the tocopherols other than the α-form and does not attack that bound to the α-tocopherol transfer protein, this provides a further specific enhancement of the α-tocopherol concentration in plasma relative to the others. Some of these catabolic metabolites may have some biological activity in their own right. For example, carboxyethylhydroxychromans derived from γ-tocopherol were reported to induce apoptosis in cancer cells and to have anti-inflammatory effects by inhibition of cyclooxygenases and 5-lipoxygenase (see below). Tocotrienols are catabolized in a similar manner, but with additional steps in which the double bonds are reduced prior to oxidation; the final carboxyethylchromanols are the same as for tocopherols.

21.6.1.4: TOCOPHEROLS AS ANTIOXIDANTS

Although the syndrome associated with a lack of vitamin E in the diet of animals has been known for decades, the mode of action and specific location of tocopherols in cell membranes are not clearly understood. Several theories have been proposed to explain the functions of vitamin E in animal cells. From studies *in vitro*, it has long been believed that a major task is to act as an **antioxidant** to inhibit, decrease, delay, or prevent oxidative damage to unsaturated lipids or other membrane constituents and thence to tissues by scavenging free radicals. For example, vitamin E administration can prevent lipid peroxidation and hepatotoxicity upon exposure to the free radical-generating agent carbon tetrachloride. Lipid peroxidation is also a cause of **ferroptosis**, an iron-dependent form of nonapoptotic cell death. However, tocopherols have functions other than as antioxidants. In non-biological systems such as foods, cosmetics, pharmaceutical preparations, etc., tocopherols are invaluable as antioxidant additives.

Because of their lipophilic character, tocopherols are located in the membranes or with storage lipids where they may be available immediately to interact with lipid hydroperoxides, such as those described in more detail in our web pages on **isoprostanes**, **reactive aldehydes,** and **oxidized phospholipids**. In brief, **Reactive Oxygen Species (ROS)**, of which innumerable forms, exist can be derived by enzymatic or non-enzymatic means and produce superoxide anions and other peroxyl radicals. Superoxide radicals ($O_2^{\bullet-}$) ultimately generate highly toxic hydroxyl ($^{\bullet}OH$) or alkoxyl radicals, which can abstract a hydrogen atom from *bis*-allylic methylene groups of polyunsaturated fatty acids under aerobic conditions *in vivo* in animals and plants to generate lipid peroxyl radicals ($LOO^{\bullet}$) and hydroperoxy-fatty acids. **Singlet oxygen** ($^1O_2$ or O=O) is an especially important ROS (non-radical) in photosynthetic tissues of plants. As radical generation is not enzymatic, all methylene groups between two *cis* double bonds can potentially be involved in the reaction, although not necessarily to the same degree. Tocopherols react rapidly in a non-enzymic manner unlike many other cellular antioxidants, which are dependent on enzymes, to scavenge lipid peroxyl radicals, i.e., the chain-carrying species that propagate lipid peroxidation. In model systems *in vitro*, all the tocopherols (α > γ > β > δ) and tocotrienols are good antioxidants, with the tocotrienols being the most potent.

In general, the oxidation of lipids is known to proceed by a chain process mediated by such free radicals, in which the lipid peroxyl radical serves as a chain carrier. In the initial step of chain propagation, a hydrogen atom is abstracted from the target lipid by the peroxyl radical as shown in Figure 21.6.6.

$$LOO^{\bullet} + LH \longrightarrow LOOH + L^{\bullet} \quad (1)$$

$$L^{\bullet} + O_2 \longrightarrow LOO^{\bullet} \quad (2)$$

- where LH is a lipid, $LOO^{\bullet}$ is the lipid peroxyl radical and LOOH is the lipid hydroperoxide

Figure 21.6.6: Formation of lipid peroxyl radical

The main function of α-tocopherol is to scavenge the lipid peroxyl radical before it is able to react with the lipid substrate as shown in Figure 21.6.7.

$$LOO^{\bullet} + TOH \longrightarrow LOOH + TOO^{\bullet} \quad (3)$$

- where TOH is tocopherol and $TOO^{\bullet}$ is the tocopheroxyl radical

Figure 21.6.7: Scavenging of free radicals by tocopherol

The potency of an antioxidant is determined by the relative rates of reactions (1) and (2). When a tocopheroxyl radical is formed, it is stabilized by the delocalization of the unpaired electron about the fully substituted chromanol ring system rendering it relatively unreactive, thus preventing propagation of the chain reaction. This also explains the high first-order rate constant for hydrogen transfer from α-tocopherol to peroxyl radicals, as studies of the relative rates of chain propagation to chain inhibition by α-tocopherol in model systems have demonstrated that α-tocopherol is able to scavenge peroxyl radicals much more rapidly than the peroxyl radical can react with a lipid substrate.

In biological systems, oxidant radicals can spring from a number of sources, including singlet oxygen, alkoxyl radicals, superoxide, peroxynitrite, nitrogen dioxide, and ozone. α-Tocopherol is most efficient at providing protection against peroxyl radicals in a membrane environment.

The reaction of the tocopheroxyl radical with a lipid peroxyl radical, as illustrated, yields 8α-substituted tocopherones, which are readily hydrolyzed to 8α-hydroxy tocopherones that rearrange spontaneously to form α-tocopherol quinones. In an alternative pathway, the

tocopheroxyl radical reacts with the lipid peroxyl radical to form epoxy-8α-hydroperoxytocopherones, which hydrolyze and rearrange to epoxyquinones. Tocopherol dimers and trimers may also be formed as minor products. These reactions are shown in Figure 21.6.8.

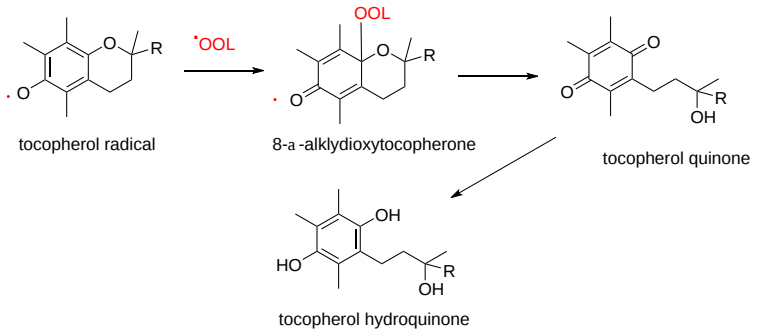

Figure 21.6.8: Reaction of the tocopherol radical

Free radical-mediated lipid peroxidation is the major pathway of lipid oxidation taking place in humans, and α-tocopherol is a major antioxidant, but it does not scavenge the nitrogen dioxide radical, carbonate anion radical, and hypochlorite efficiently. Vitamin E forms with an unsubstituted 5-position, such as γ-tocopherol, are an exception to the rule that the various tocopherols have similar antioxidant properties in that they are able to trap electrophiles, including **Reactive Nitrogen Species (RNS)**, which are enhanced during inflammation. The enzyme nitric oxide synthase is capable of continuously producing a large amount of nitric oxide ($NO^{\bullet}$), which can react with superoxide to produce peroxynitrite ($ONOO^-$), a potent and versatile oxidant that can attack a wide range of biological targets. It induces lipid peroxidation and nitrates aromatic compounds and unsaturated fatty acids while isomerizing *cis*-double bonds in fatty acids to the *trans*-configuration. γ-Tocopherol is superior to α-tocopherol in detoxifying the NO_2 radical and peroxynitrite with formation of 5-nitro-γ-tocopherol, as shown in Figure 21.6.9.

Figure 21.6.*xx*:

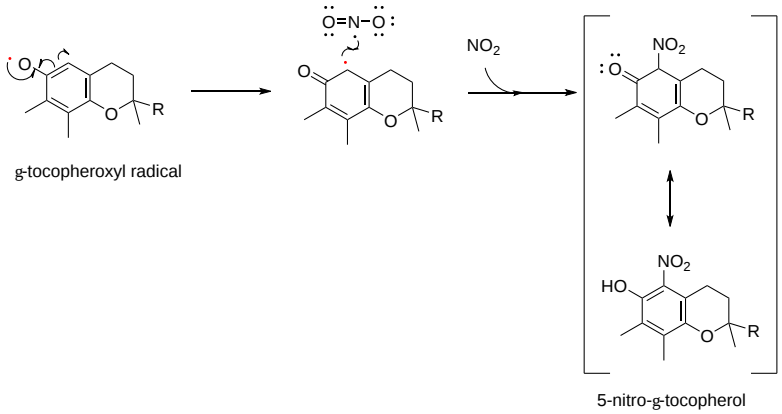

Figure 21.6.9: Radical reaction with γ-Tocopherol

This occurs *in vivo*, and the concentrations of 5-nitro-γ-tocopherol have been shown to be elevated in the plasma of subjects with coronary heart disease and in carotid-artery atherosclerotic plaque.

In plant and animal tissues, tocopherols can be regenerated from the tocopheroxyl radicals in a redox cycle mediated by a number of endogenous antioxidants, including vitamins A and C and coenzyme Q, and this must greatly extend their biological potency. Vitamin C (ascorbic acid) may be especially important in aqueous systems, although it may also act at the surface of membranes, to regenerate α-tocopherol, while in turn being oxidized to dehydroascorbic acid. This can be regenerated to the reduced form by glutathione (GSH) with the production of glutathione disulfide (GSSG), which can subsequently be enzymatically reduced by glutathione reductase with NAD(P)H as a cofactor. In plants, an NAD(P)H-dependent quinone oxidoreductase is involved at an early stage of the regeneration process, while tocopherol cyclase, an enzyme involved in the biosynthesis of tocopherols, re-introduces the chromanol ring. These linked cycles (the antioxidant network) are shown in Figure 21.6.10.

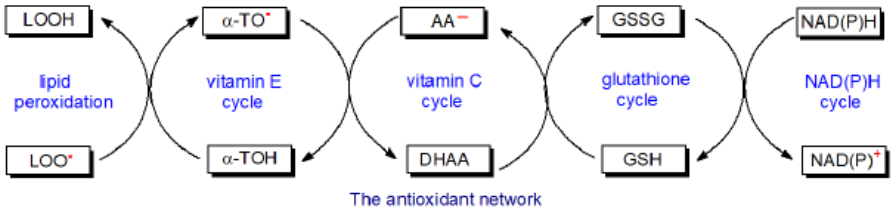

Figure 21.6.10: The antioxidant network

Thus, tocopherols are only one component of a complex web of metabolites and enzymes in tissues that have antioxidant activities and act by various mechanisms, including the stimulation of genes involved in signaling responses to environmental stresses. One antioxidant mechanism involves the removal of free radicals and reactive species by enzymes such as superoxide dismutase, catalase, and glutathione peroxidase, while electron donors, such as glutathione, tocopherols, ascorbic acid, vitamin K, coenzyme Q, and thioredoxin, scavenge free radicals also. Metal-binding proteins such as transferrin, metallothionein, haptoglobin, and ceruloplasmin have antioxidant activity by sequestering pro-oxidant metal ions, such as iron and copper, although some metals such as selenium and zinc are in fact antioxidants. Other antioxidants, including flavonoids, carotenoids, and phenolic acids in addition to tocopherols, enter animal tissues via the food chain. Although the discussion here has been limited to the effects upon lipids, free radicals can cause damage to proteins, DNA, and indeed virtually any native substance in living organisms.

21.6.1.5: BIOLOGICAL FUNCTIONS OF TOCOCHROMANOLS IN ANIMALS

Vitamin E deficiency has been detected in patients with fat malabsorption, cystic fibrosis, Crohn's disease, liver disease, and pancreatic insufficiency, and in premature infants. Impairment of the normal functions of the immune system has been demonstrated in animals and humans in vitamin E deficiency, and this can be corrected by vitamin E repletion. It also displays activity against nonalcoholic hepatosteatosis. Although there are various proposals for the pathogenic mechanism, none as yet appears to be generally accepted. After the discovery of the effects of vitamin E on fertility in studies with laboratory animals, its importance was documented for the development of tissues and organs such as brain and nerves, muscle and bones, skin, bone marrow, and blood, most of which are specific to α-tocopherol. However, there is no evidence for an effect of vitamin E on fertility in humans, as was originally found in the rat. The rare genetic disorder “Ataxia with Isolated Vitamin E Deficiency” or “AVED” is the result of mutations in the gene coding for α-TTP. It is caused by the death of cerebellar Purkinje cells, but administration of α-tocopherol prevents this and the subsequent development of clinical symptoms of the disease.

There appears to be little doubt that tocopherols inhibit many of the enzymes associated with inflammation *in vitro* in animals, and may contribute to the amelioration and treatment of some chronic diseases. However, it has been argued that data on the effects of vitamin E on biomarkers of oxidative stress *in vivo* are inconsistent. Oxidized metabolites of vitamin E, i.e., that have reacted as antioxidants, are barely detectable in tissues, and vitamin E maintenance *in vivo* does not appear to have been clearly associated with its regeneration. There appear to be significant differences between results obtained in studies with laboratory animals in comparison to those in humans. Thus, suggestions that dietary supplements of vitamin E may reduce the rate of oxidation of lipids in low-density lipoproteins in humans and thence the incidence or severity of atherosclerosis have not been confirmed by clinical intervention studies, although benefits in some conditions have been claimed. Indeed, there are suggestions that excessive vitamin E supplementation may even be harmful. One study has suggested that relatively high doses of natural α-tocopherol over a long period are required to demonstrate a significant reduction in the levels in the urine of F_2 **isoprostanes**, which are considered to be the most reliable marker for oxidative stress *in vivo*. While there are many fat-soluble antioxidants in the diet, only α-tocopherol is a vitamin. It has even been suggested that tocopherol may be protected from functioning as an antioxidant in some tissues *in vivo* through a network of cellular antioxidant defenses, such that tocopherols are utilized only when other antioxidants are exhausted, although there is no experimental proof of this hypothesis.

At the cellular level, *RRR*-α-tocopherol has been shown to inhibit protein kinase C, and in the process, it inhibits the assembly and radical-producing activity of NADPH oxidase in monocytes. Similarly, vitamin E suppresses the expression of xanthine oxidase, a source of reactive oxygen species, in the liver. It is thus possible that α-tocopherol is able to diminish the levels of free radicals by preventing their production and not by scavenging them. Its physical presence in membranes adjacent to polyunsaturated fatty acids may thus limit autoxidation.

With the discovery that the antioxidant effects of various tocopherols and tocotrienols have little relation to their vitamin E activities *in vivo* has come the realization that they have other functions in tissues, most of which are specific to α-tocopherol. Most current research is concerned with how vitamin E and its metabolites act in signaling and controversially in the regulation of gene activity. While it is certainly true that most other vitamins are essential cofactors for specific enzymes or transcription factors, no receptor that binds specifically to vitamin E has yet been discovered. By preventing the increase of peroxidized lipids that alter both metabolic pathways and gene expression profiles within tissues and cells, it may act indirectly as a regulator of genes connected with tocopherol catabolism, lipid uptake, collagen synthesis, cellular adhesion, inflammation, the immune response and cell signaling. Vitamin E affects a number of transcription factors in

this manner, including peroxisome proliferator-activated receptor gamma (PPARγ), nuclear factor erythroid-derived 2 (NRF2), nuclear factor kappa B (NFκB), RAR-related orphan receptor alpha (RORα), estrogen receptor beta (ERβ), and the pregnane X receptor (PXR).

α-Tocopherol and its metabolites are believed to modulate the activity of several enzymes involved in signal transduction, including protein kinases and phosphatases, lipid kinases and phosphatases, and other enzymes involved in lipid metabolism, but especially those with inflammatory properties such as lipoxygenases, cyclooxygenase-2, and phospholipase A_2. While the credentials of tocopherols as antioxidants *in vivo* have been doubted, this does not preclude a role in the inhibition of oxidative enzymes, especially in relation to the function of the immune system. For example, vitamin E regulates T cell function directly by its effects upon T cell membrane integrity, signal transduction, and cell division, and it also functions indirectly by affecting eicosanoids and related inflammatory mediators generated from other immune cells. Various tocopherols and tocotrienols have been shown to suppress COX-2 involvement in prostaglandin (PGD_2 and PGE_2) synthesis in lipopolysaccharide-activated macrophages.

In addition, it has been established that the 13'-carboxy metabolite of α-tocopherol (α-T-13'-COOH) and other tocopherol ω-carboxylates are potent allosteric inhibitors of 5-lipoxygenase, a key enzyme in the biosynthesis of the inflammatory **leukotrienes**. α-T-13'-COOH accumulates in immune cells and inflamed exudates both *in vitro* and *in vivo* in mice, and it has even been suggested that the immune regulatory and anti-inflammatory functions of α-tocopherol depend on this endogenous metabolite. The structure of α-T-13'-COOH is shown in Figure 21.6.11.

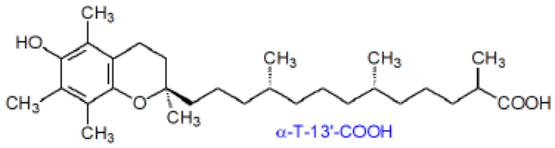

Figure 21.6.11: Structure of α-T-13'-COOH

α-Tocopherol has a stimulatory effect on the dephosphorylation enzyme, protein phosphatase 2A, which cleaves phosphate groups from protein kinase C, leading to its deactivation. The mechanism may involve the binding of vitamin E directly to enzymes in order to compete with their substrates, or it may change their activities by redox regulation. It may also compete for common binding sites within lipid transport proteins, and so may alter the traffic of lipid mediators indirectly with effects upon their signaling functions and enzymatic metabolism. For example, it binds to albumin as well as to a specific α-tocopherol-associated protein (TAP), and in the latter form especially it inhibits the phosphoinositide 3-kinase. It has been suggested that vitamin E may have a secondary role in stabilizing the structure of membranes, or it may interact with enzymes in membranes to interfere with binding to specific membrane lipids, or it may affect membrane microdomains such as lipid **rafts**.

Evidence suggests that the biological activities of β-, γ- and δ-tocopherols do not reflect their behavior as chemical antioxidants, but anti-inflammatory, antineoplastic, and natriuretic actions have been reported. Some non-antioxidant effects of **γ-tocopherol** in tissues in relation to reactive nitrogen oxide species have been observed, but the specificity of these *in vivo* is not yet certain. In addition, anti-inflammatory properties have been described that have been attributed to a chain-shortened metabolite. Beneficial effects against cancer cells *in vitro* have been observed that have been ascribed to scavenging of reactive nitrogen species, since such effects are not seen with α-tocopherol. On the other hand, vitamin E and its derivatives are believed to regulate tumor cells by activating the mitogen-activated protein kinase (MAPK) signaling pathway.

Tocotrienols have been shown to have neuroprotective effects and to inhibit cholesterol synthesis. They reduce the growth of breast cancer cells *in vitro*, possibly by influencing gene expression by interaction with the estrogen receptor-β. When administered in combination with either standard antitumor agents as in chemotherapy or with natural compounds with anticancer activity, they are reported to exert a synergistic antitumor effect on cancer cells. γ-Tocotrienol is reported to be an inducer of apoptosis via endoplasmic reticulum stress, while α-tocotrienol may be neuroprotective by inhibition of lipoxygenase activity. Although anti-obesity and anti-diabetic effects have been observed in mice, clinical trials with humans appear to have given inconclusive results. These properties are largely distinct from those of the tocopherols, and the pharmaceutical potential of tocotrienols against cancer, bone resorption, diabetes, and skin, cardiovascular and neurological diseases are currently being studied.

The biological functions of **α-tocopheryl phosphate** are slowly being revealed. In addition to being a possible storage or a transport (water-soluble) form of tocopherol, it is involved in cellular signaling and regulates a number of genes, including those involved in angiogenesis and vasculogenesis, in a different manner from α-tocopherol *per se*. As it lacks the free hydroxyl group, it cannot act directly as an antioxidant, and some consider it to be the biologically active form of the vitamin. It is certainly more active in a number of biological systems *in vitro* than α-tocopherol, so these effects cannot be ascribed to the hydrolyzed molecule, and in some instances, it is antagonistic to α-tocopherol, for example in its activity towards phosphatidylinositol 3-kinase. On the other hand, activation requires a kinase, while a phosphatase is needed to make the system reversible, but neither has yet been identified. Synthetic phosphate derivatives of γ-tocopherol and α-tocopheryl succinate are known to have potent anti-cancer properties.

21.6.2: ISOPRENOIDS: 2. RETINOIDS (VITAMIN A)

That a dietary factor was involved in visual acuity was known to the ancient Egyptians and Greeks, but it was the 1930s before the importance of the carotenoids and their metabolites was recognized, and β-carotene and retinol were fully characterized. It is now recognized that vitamin A activity now resides in the metabolites retinol, retinal and retinoic acid, and in several provitamin A carotenoids, most notably β-carotene. A share in the Nobel Prize for Medicine in 1967 was awarded to George Wald, who over many years showed how retinol derivatives (named for their function in the retina) constituted the chemical basis of vision. Now, it is recognized that retinol, retinoic acid, and their many metabolites have innumerable other functions in human metabolism from embryogenesis to adulthood, including growth and development, reproduction, cancer, and resistance to infection. They are important natural antioxidants with benefits to health, although some potentially harmful properties have been reported.

Carotenoids are a class of highly unsaturated terpenoids that occur in innumerable molecular forms (>1000). They are common colorful pigments of plants, fungi, and bacteria, of vital importance to photosynthesis, and as dietary constituents, they can add ornament to some animal species. Apart from acting as precursors of retinoids, carotenoids *per se* appear to have a relatively limited range of functions in animal tissues, but they are important to vision and as antioxidants, especially in the skin. They do of course have important functions in plants and lower organisms where they originate, but this topic can only be dealt with briefly here. Other fat-soluble vitamins **tocopherols (vitamin E)**, **vitamin K,** and **vitamin D** are discussed elsewhere.

21.6.2.1: OCCURRENCE AND BASIC METABOLISM OF CAROTENOIDS AND RETINOIDS

The term ‘vitamin A’ is used to denote **retinol** (or all-*trans*-retinol, sometimes termed 'vitamin A_1'), together with a family of biologically active C_{20} **retinoids** derived from this ('vitamers'). The structure of retinol is shown in Figure 21.6.12.

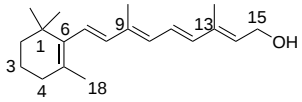

Figure 21.6.12: All-trans-retinol

These are only found in animal tissues, where they are essential to innumerable biochemical processes. However, they cannot be synthesized *de novo* in animals and their biosynthetic precursors are plant carotenoids with a β-ionone ring (provitamin A), C_{40} tetraterpenes of which β-carotene is most the efficient; it is an orange-red pigment that occurs in the photosynthetic tissues of plants and in seed oils. In the human diet in the developed world, plant sources tend to be less important than those from dairy products, meat, fish oils, and margarines, which provide vitamin A *per se*, although carrots and spinach are good sources of the provitamin. In the U.K., for example, all vegetable spreads must be supplemented with the same level of vitamin A (synthetic retinol or β-carotene) as is found in butter. While most research effort has been focused on retinoids, there is increasing interest in the biological activities of intact carotenoids in animal tissues.

The biosynthesis of carotenoids in plants via isopentenyl diphosphate and dimethylallyl diphosphate has much in common with that of the **plant sterols**, but this is too specialized a topic to be treated at length here. They have many important functions in plants, for example during photosynthesis or as precursors of plant hormones, and these are discussed below. Some crop plants with increased carotene levels are available with the aim of preventing vitamin A deficiency in the populations of developing countries, and further efforts are underway. Non-photosynthetic bacteria produce a different range of carotenoids, some with chain lengths other than C_{40} (C_{30} to C_{50}).

In animals (including humans), dietary carotenoids such as β-carotene are solubilized with other dietary lipids in mixed micelles with the aid of bile acids, and they are absorbed in the intestines in intact form by a process facilitated by specific receptor proteins. Dietary retinol and retinol esters are absorbed similarly in the intestines, but the latter are first hydrolyzed by pancreatic lipase. Conversion to retinoids leading ultimately to retinol esters occurs in the enterocytes, where dietary β-carotene is subjected to oxidative cleavage at its center, the first step of which is catalyzed by a cytosolic enzyme β-carotene-15,15'-oxygenase-1 (BCO1), which is specific for carotenes with a β-ionone ring, to yield two molecules of all-*trans*-retinal, which is reversibly reduced by a retinol reductase to retinol. Xanthophyll carotenoids are absorbed without cleavage mainly. These reactions are shown in Figure 21.6.13.

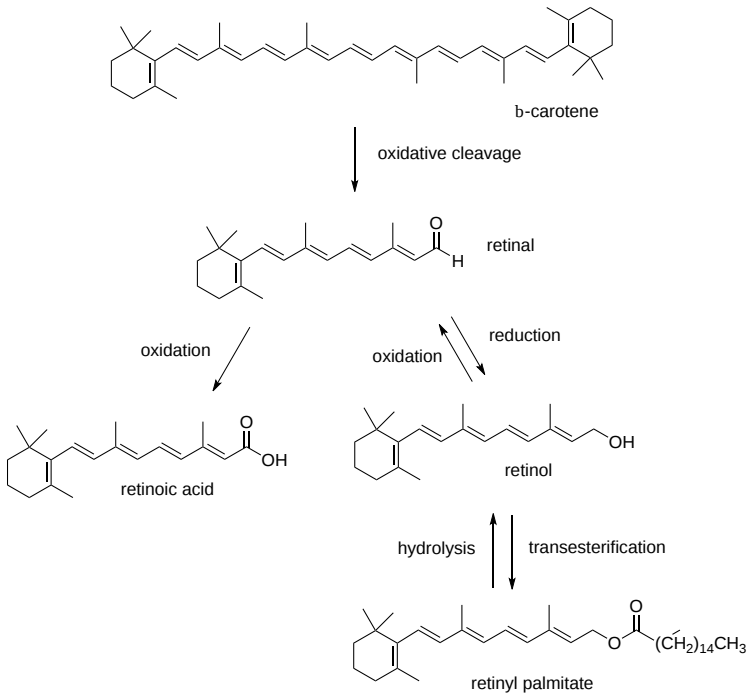

Figure 21.6.13: Synthesis of all-trans retinoids in the intestines and liver

jbc: https://www.jbc.org/article/S0021-92...842-6/fulltext

Based on the incorporation of ^{18}O into the products. it appears that the enzyme that introduces the oxygen atom, β-carotene-15,15'-oxygenase-1 (BCO1), into the cleavage products is a **dioxygenase** as both atoms of oxygen in dioxygen are incorporated into products. This is in contrast to a possible mechanism in which only one oxygen atom from dioxygen is added, with the other coming from H_2O if the enzyme acted as a monooxygenase. Figure 21.6.14 shows how oxygen could be introduced in the reaction catalyzed by BCO1 through both possible mechanisms.

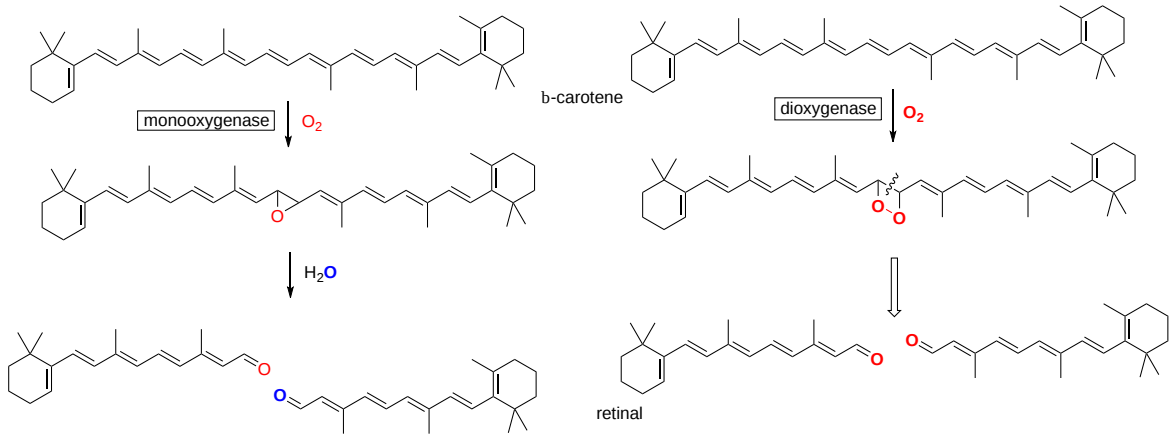

Figure 21.6.14: Introduction of oxygen atoms into retinal through either mono- and dioxygenase actions of β-carotene-15,15'-oxygenase-1 (BCO1).

The dioxygenase mechanism on the right best accounts for the incorporation of ^{18}O isotope of oxygen in dioxygen.

Figure 21.6.15 shows an interactive iCn3D model of the apocarotenoid cleavage oxygenase from Synechocystis, a Retinal-Forming Carotenoid Oxygenase (2BIW)

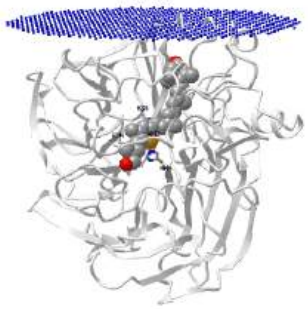

Figure 21.6.15: Retinal-Forming Carotenoid Oxygenase from Synechocystis (2BIW). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov...dttF958wFPAUP7

The enzyme has a bound carotene analog, (3R)-3-hydroxy-8'-apocarotenol. It contains an active site Fe^{2+} ion at the end of a hydrophobic tunnel. The ion is ligated by 4 histidine side chains. On binding, three of the trans C=C bonds convert to a distorted cis-trans-cis conformation. The middle trans bond is proximal to the Fe^{2+} which is ligated by dioxygen, the source of the incorporated oxygen atoms on cleavage.

Any unchanged β-carotene and newly formed retinol esters in the enterocytes are incorporated into **chylomicrons** and released into the lymphatic system and thence into the bloodstream, where some is taken up by peripheral tissues before most is absorbed by the liver. Some intact carotene and other carotenoids are transferred to lipoproteins (LDL and HDL) for transport in plasma, with assistance from specific binding and transport proteins, and for example, carotene can be absorbed at the placental barrier and transferred to the fetus for conversion to retinoids that are essential for development. Within the hepatocytes, retinol esters are hydrolyzed in the late endosomes with the release of free retinol into the cytosol, from which it can be released back into the circulation, converted to retinoids or transferred to hepatic stellate cells for storage in lipid droplets, the main body reservoir of vitamin A. In these specialized cells, retinol is esterified to form retinyl palmitate by the transfer of fatty acids from position *sn*-1 of phosphatidylcholine, mainly via the action of a membrane-bound lecithin:retinol acyltransferase (LRAT) in the endoplasmic reticulum. There are also lesser acyl-CoA dependent pathways, including an acyl CoA:retinol acyltransferase and even the enzyme diacylglycerol acyltransferase 1 (DGAT1); esterification is facilitated by binding to cellular retinol-binding protein type II (CRBP2).

Both retinol and retinoic acid are precursors of a number of metabolites (retinoids), which are required for specific purposes in tissues, by enzymatic modification of the functional groups and geometrical isomerization of the polyene chains. In the liver, activation of the retinol pathway involves first mobilization of the ester, followed by hydrolysis by retinol ester hydrolases, which includes carboxylesterase ES-10. Then, the reversible oxidation of retinol to retinal is carried out by one of several enzymes that include dehydrogenases and various cytochrome P450s, before some retinal is oxidized irreversibly to retinoic acid by enzymes with retinal dehydrogenase activity. On-demand conversion of retinol to retinoic acid occurs by the same mechanisms in other tissues, although for vision, retinol esters serve directly as the substrate for the formation of the visual chromophore 11-*cis*-retinal (see below). Retinyl-β-D-glucoside, retinyl-β-D-glucuronide, and retinoyl-β-D-glucuronide are naturally occurring and biologically active metabolites of vitamin A, which are found in fish and mammals. Indeed, the last has similar activity to all-*trans*-retinoic acid without any of the unwanted side effects in some circumstances.

Cleavage of β-carotene at double bonds other than that in the center or of a wider range of other carotenoids occurs by the action of a related enzyme β-carotene-9',10'-dioxygenase (β-carotene-oxygenase-2 or BCO2) in mitochondria, which leads to the formation of similar molecules, i.e. β-apocarotenals and β-apocarotenones of variable chain-length. While these may exert distinctive biological activities in their own right, there is evidence that they can also be metabolized to form retinal.

In the aqueous environment within cells, as well as in plasma, retinol, retinal and retinoic acid are bound to retinoid-binding proteins (RBP), which solubilize, protect and in effect detoxify them. These proteins also have a role in facilitating retinoid transport and metabolism; some are present only in certain tissues, and many are specific for particular retinoids and metabolic pathways. To prevent infiltration through the kidneys, retinol, and holo-RBP form an association in blood with a protein termed transthyretin (TTR), which also serves as a thyroid hormone carrier and is essential for secretion. Normally, vitamin A circulates in plasma as a retinol:RBP:TTR complex with a 1:1:1 molar ratio. Unesterified retinol is the main form of the vitamin that is exported from the liver upon demand, and it is transported in the blood in this bound form in VLDL, LDL, and HDL, with some directly from the diet in the chylomicrons and their remnants. Peripheral tissues have specific receptors to take up what they require, probably after hydrolysis of any esters to retinol by means of the enzyme lipoprotein lipase. Then, retinol dissociates from the protein as it forms a complex with a receptor (STRA6) at a target cell and diffuses through the plasma membrane, a process driven by retinol esterification.

The RBP-TTR complex does not bind to retinal and retinoic acid, although these do bind to RBP on its own, and most of the low levels of retinoic acid transported in the blood are bound to albumin. Local levels of retinoic acid are the result of an interplay between enzymes of

synthesis, binding, and catabolism. For example, within cells retinoic acid binding proteins (CRABP1 and CRABP2) bind to the newly synthesized retinoic acid, increase its rate of metabolism and protect cells from an excess.

In skin, 3,4-dehydroretinoids are synthesized from all-*trans* retinoids by the desaturase Cytochrome P450 27C1 with the assistance of cellular retinol-binding proteins (CRBPs). 3,4-Dehydroretinol, which is sometimes termed vitamin A_2, is shown in Figure 21.6.16.

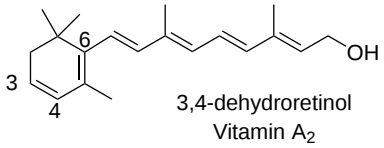

Figure 21.6.16: 3,4-dehydroretinol (Vitamin A_2)

Its derivative 3,4-dehydroretinal is used as a visual chromophore in many cold-blooded vertebrates including lampreys, fish, amphibians, and some reptiles (see below). Geranylgeranoic acid has structural similarities to retinoic acid and has been termed an acyclic retinoid, although it has no vitamin A activity. It is synthesized in animal tissues from mevalonate, and together with its 2,3-dihydro metabolite, has potent anticancer properties.

Retinol esters: A relatively small proportion of the cellular retinoids is located in membranes in tissues. Rather, retinol esters, mainly retinyl palmitate, are the main storage form of vitamin A, and they occur in many different organs, including adipose tissue and testes, but chiefly in stellate cells of the liver and pancreas. How the retinol is directed specifically to these cells and enters them prior to esterification is not known. Although hepatic stellate cells are much smaller and less abundant than hepatocytes (only 5 to 8% of all liver cells), they are characterized by cytoplasmic lipid droplets that contain 90-95% of the hepatic retinoids (and up to 80% of the body pool) in addition to other non-retinoid lipids; the lecithin:retinol acyltransferase is the only retinol ester synthase in this instance. In addition, specialized cells in the eye store retinoids essential for vision in the form of lipid droplets. When the supply of retinol in the diet is limited, hepatic stores of retinol esters are mobilized as retinol ester hydrolases are activated to maintain constant circulating retinol levels; hormone-sensitive lipase is the most important of these enzymes, although the adipose tissue triacylglycerol lipase and the lysosomal acid lipase are also involved.

Catabolism: All-*trans*-retinoic acid formation is irreversible, so its synthesis and degradation must be tightly regulated. As a first step in catabolism, the excess is cleared by conversion to more polar metabolites through oxidation by various enzymes of the cytochrome P450 family. Secondly, the water-soluble retinoic acid metabolites, including 4-hydroxy-, 4-oxo- and 18-hydroxy-retinoic acids, conjugate with glucuronic acid and then can be rapidly removed from circulation and eliminated from the body via the kidney.

21.6.2.2: RETINOIDS AND VISION

The structure of 11-cis-retinal, which we discussed in Chapter 11, is shown in Figure 21.6.17

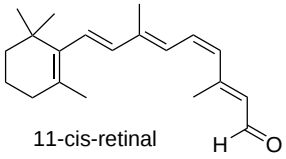

Figure 21.6.17: 11-cis-retinal

Retinoids are essential for vision, and there is now a good appreciation of how this works at the molecular level. In the eye, uptake of retinol from the circulation is mediated by the transmembrane cell-surface STRA6 receptor of the retinal pigment epithelium, a pigmented monolayer of cells located between the photoreceptors and choroid that nourishes retinal visual cells and catalyzes the release of retinol from retinol-binding proteins and transports it to the cytosol. The process by which light is converted to a signal recognized by the brain, sometimes termed the '**retinoid (visual) cycle**', requires a two-cell system beginning in the retinal pigment epithelium and continuing in photoreceptor cells, i.e. retinal rod and cone cells in the eye that contain membranous vesicles that serve as light receptors. Roughly half of the proteins in these vesicles consist of the protein conjugate, rhodopsin, which consists of a protein – opsin – with the retinoid **11-*cis*-retinal**. Each step in the visual process requires specific binding or transport proteins, and especially the interphotoreceptor retinoid-binding protein (IRBP).

All-*trans*-retinol is first converted to its ester by the enzyme lecithin:retinol acyltransferase as described above in the RPE, and the products coalesce into lipid droplets, i.e. dynamic organelles termed 'retinosomes'. The next step involves a dual-purpose enzyme (RPE65) in the endoplasmic reticulum, which cleaves the *O*-alkyl bond (not a conventional hydrolysis reaction) in the retinol ester and at the same time causes a change in the geometry of the double bond in position 11 of retinol from *trans* to *cis*. The 11-*cis*-retinol is then oxidized to 11-*cis*-retinal by 11-*cis*-retinal dehydrogenase (RDH5). The full cycle is shown in Figure \(\PageIndex{18}\) below.

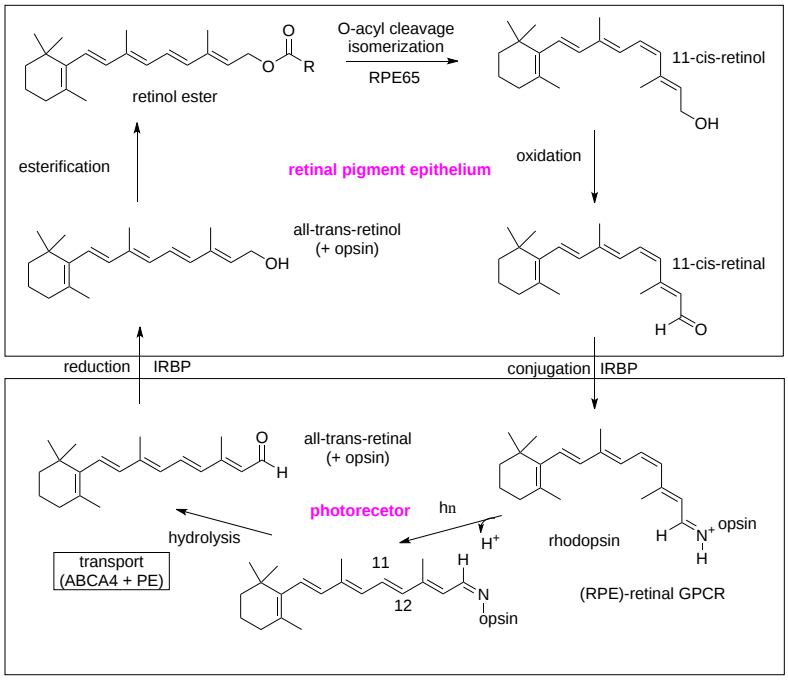

Figure 21.6.18: Retinoid visual cycle

The final part of the cycle occurs in the photoreceptor, where first the 11-*cis*-retinal is reacted with opsin to produce the protein conjugate rhodopsin in a protonated form. When rhodopsin is activated by light, the *cis*-double bond in the retinoid component is isomerized non-enzymatically by the energy of a photon to the 11-*trans* form with a change of conformation that in turn affects the permeability of the membrane and influences calcium transport. This results in further molecular changes that culminate in the release of opsin and all-*trans*-retinal, which is the trigger that sets off the nerve impulse so that the light is perceived by the brain.

A second mechanism for 11-*cis*-retinal formation that may function to ensure continuous visual responsiveness in bright light involves the (RPE)-retinal G protein-coupled receptor (RGR), which can function as a retinaldehyde photoisomerase. As the enzyme RPE65 functions optimally under low light conditions, it is believed that RGR prevents the saturation of photoreceptors under high light levels, and in this way facilitates vision in daylight. The isomerase, RPE65, and the photoisomerase, RGR, operate together to provide a sustained supply of the visual chromophore under different levels of illumination.

The all-*trans*-retinal is removed from the photoreceptor either by reduction to all-*trans*-retinol by all-*trans*-retinol dehydrogenase 8 expressed in the outer segments of photoreceptors or after transport by means of a specific transporter (ABCA4), which provides phosphatidylethanolamine (PE) for conversion to the Schiff-base adduct, i.e. *N*-retinylidene-phosphatidylethanolamine, as shown in Figure 21.6.19.

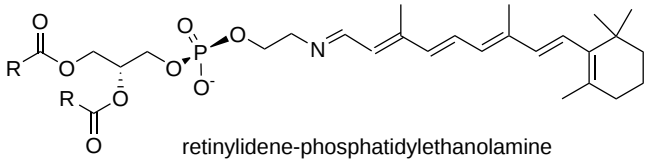

Figure 21.6.19: *N*-retinylidene-phosphatidylethanolamine

It flips from the lumen to the cytosolic leaflet of the disc membrane. This process prevents non-specific aldehyde activity with the effect of removing potentially toxic retinoid compounds from the photoreceptors. The adduct is a transient sink that dissociates so the retinal can be reduced back to all-*trans*-retinol by the cytoplasmic retinol dehydrogenase. All-trans-retinol exits the photoreceptor and enters the retinal pigment epithelium with the aid of binding to the retinoid-binding protein (IRBP) where it is converted back to a retinyl ester to complete the cycle and restore light sensitivity.

As a side-reaction, some troublesome bis-retinoid adducts of PE (and further byproducts) may be produced by non-enzymatic mechanisms, and these can accumulate with age to affect vision. **Lower organisms:** Bacteriorhodopsin is the best studied of a family of opsins, found in archaea, eubacteria, fungi, and algae. It is a protein with seven transmembrane helices that acts as an opto-electrical transducer or light-gated active ion pump to capture photon energy via its covalently bound chromophore, all-*trans*-retinal, converting it to 13-*cis*-retinal, and moves protons against their electrochemical gradient from the cytoplasm to the extracellular space. In Archaea, it is known as the "purple membrane" and can occupy a high proportion of the surface area of the organism.

21.6.2.3: OTHER FUNCTIONS OF RETINOIDS IN HEALTH AND DISEASE

In addition to their function in vision, it is now realized that retinoids have essential roles in growth and development, reproduction and resistance to infection. They are particularly important for the function of epithelial cells in the digestive tract, lungs, nervous system, immune system, skin, and bone at all stages of life. They are required for the regeneration of damaged tissues, including the heart, and they appear to have some potential as chemo-preventive agents for cancer and for the treatment of skin diseases such as acne. Under pathological conditions, stellate cells lose their retinoid content and transform into fibroblast-like cells, contributing to the fibrogenic response. Cirrhosis of the liver is accompanied by a massive loss of retinoids, but it is not clear whether this is a cause or a symptom, and there appears to be confusion as to when supplementation may be helpful in this and other diseases of the liver. Like retinol and retinoic acid, the metabolite 9-*cis*-retinoic acid also has valuable pharmaceutical properties.

With such a large number of double bonds in conjugation, it is not surprising that carotenoids in general, and retinoids in particular are efficient quenchers of singlet oxygen and scavengers of other reactive oxygen species. However, any direct antioxidant properties are not believed to be important in terms of general health *in vivo*, and it is not clear how relevant the physical properties of retinoids are to specific biochemical processes in comparison to their effects on signaling and gene transcription. There is a caveat that retinoids may stimulate some antioxidant genes and so have an indirect antioxidant function. In fact, nutritional studies with dietary supplements of carotenoids have sometimes suggested pro-oxidant activity. One explanation for detrimental effects may be that regeneration of the parent carotenoid or retinoid from the corresponding radical cation may be limited when concentrations of reductants such as ascorbic acid are low.

Many of the retinol metabolites function as ligands to activate specific transcription factors for particular receptors in the nucleus of the cell, and thus they control the expression of a large number of genes (>500), including those essential to the maintenance of normal cell proliferation and differentiation, embryogenesis, for a healthy immune system, and for male and female reproduction. In the innate immune system, vitamin A is required for the differentiation of cells such as macrophages, neutrophils and natural killer cells, while all-*trans*-retinoic acid is involved in differentiating the precursors of dendritic cells. **Retinoic acid** and its 9-*cis*-isomer are especially important in this context, and they are often considered the most important retinoids in terms of function other than in the eye. This structure of the cis-isomer is shown in Figure 21.6.20.

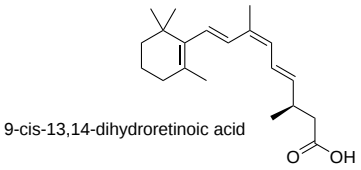

Figure 21.6.20: Cis isomer of retinoic acid

In essence, retinoic acid moves to the nucleus with the aid of small intracellular lipid-binding proteins (CRABP2 and FABP5), which channel it to specific nuclear receptors, the **retinoic acid receptors (RAR)** of which there are three, RAR-α, β and γ. These are ligand-dependent regulators of transcription and they function *in vivo* as heterodimers with **retinoid X receptors (RXR)** to process the retinoic acid signal by acting through polymorphic retinoic acid response elements (RAREs) within the promoter regions of responsive genes. Similarly, 9-*cis*-retinoic acid and 9-*cis*-13,14-dihydroretinoic acid are high-affinity ligands for RXR in mice. Together with retinoic acid, these are also ligands for the farnesoid X receptor (FXR), which forms a heterodimer with RXR. The latter receptor complex is involved primarily in **bile acid** homeostasis, and conversely, there are suggestions that bile acids may have regulatory effects on vitamin A homeostasis.

In addition, other nuclear receptors, such as the peroxisome proliferator-activated receptor PPARγ forms a heterodimer with the retinoid X receptor and is activated by retinoic acid to recruit cofactors. This complex in turn binds to the peroxisome proliferator response element (PPRE) gene promoter, leading to regulation mainly of those genes involved in lipid and glucose metabolism, including some involved in inflammation and cancer. To add to the complexity, retinoic acid has extra-nuclear, non-transcriptional effects, such as the activation of protein kinases and other signaling pathways.

It has also become evident that many of the functions of retinoids are mediated via the action of specific binding proteins (as discussed briefly above), which control their metabolism *in vivo* by reducing the effective or free retinoid concentrations, by protecting them from unwanted chemical attack, and by presenting them to enzyme systems in an appropriate conformation. With some tissues, retinol-bound RBP in the blood is recognized by the membrane protein STRA6, which transports retinol into cells where it binds to an intracellular retinol acceptor, cellular retinol-binding protein 1 (CRBP1), and is then able to activate a signaling cascade that targets specific genes. In addition, a specific retinol-binding protein secreted by adipose tissue (RPB4) is involved in the development of insulin resistance and type 2 diabetes, possibly by affecting glucose utilization by muscle tissue, with obvious application to controlling obesity. In the eye, the activity of retinoic acid during development is controlled by binding to apolipoprotein A1.

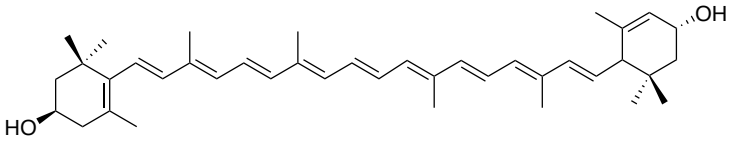
All-*trans*-retinoic acid has been shown to be effective against many different types of human cancers, especially in model systems but also in some clinical trials, because of its specific effects on cell proliferation, differentiation, and apoptosis (where its relatively low toxicity at normal tissue levels is a virtue). For example, it induces complete remission in most cases of acute promyelocytic leukemia when administered in combination with other chemotherapy techniques. Similarly, 13-*cis*-retinoic acid has been used successfully in the treatment

of children with high-risk neuroblastoma to reduce the risk of recurrence and increase long-term survival rates. However, the efficacy of similar treatments against other types of acute myeloid leukemia and solid tumors appears to be poor. It is hoped that current efforts to obtain a better understanding of the mechanism of the anti-cancer activities will lead to improved treatments. Synthetic analogs of retinoic acid, termed **rexinoids**, which activate retinoic X receptors, also hold promise as anti-cancer agents.

Vitamin A deficiency in children and adult patients is usually accompanied by impairment of the immune system, leading to a greater susceptibility to infection and an increased mortality rate, often with growth retardation and congenital malformations. However, vitamin A deficiency in malnourished children is the major reason for childhood mortality in the underdeveloped world, causing over 650,000 early childhood deaths annually and pediatric blindness. This is doubly tragic in that it is so easily prevented. In adults, vitamin A deprivation affects the reproductive system, inhibiting spermatogenesis in males and ovulation in females. Unfortunately, it is not always easy to distinguish between the effects of vitamin A deficiency and primary defects of retinoid signaling.

21.6.2.4: FUNCTIONS OF XANTHOPHYLLS AND OTHER CAROTENOIDS IN HUMANS

Xanthophylls are plant C_{40} tetraterpenes that differ from the carotenoids in having oxygen atoms in the ring structures (hydroxyl, oxo, or epoxyl). Lutein, zeaxanthin, and *meso*-zeaxanthin from dietary sources, such as green leafy vegetables and yellow and orange fruits and vegetables, are found specifically in the macula of the eye in humans and other primates, i.e. the functional center of the retina in a small central pit known as the *macula lutea*, where they enhance visual acuity and protect the eye from high-intensity, short-wavelength visible light. They are powerful antioxidants in a region vulnerable to light-induced oxidative stress. Binding proteins specific for lutein- and zeaxanthin mediate the highly selective uptake of these carotenoids into the retina, but *meso*-zeaxanthin is mainly a metabolite of dietary lutein. Macular xanthophylls decrease the risk of age-related macular degeneration. In the brain, they may stimulate and maintain cognitive function in the elderly, and assist with brain development in infants. Hydroxylated xanthophylls such as lutein, shown in Figure 21.6.21, occur both in the free form and esterified to fatty acids; the latter are hydrolyzed in the intestines when consumed by animals.



lutein

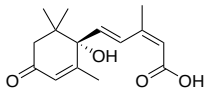
Figure 21.6.21: Leutin

Many other carotenoids are absorbed from the diet, and are subject to oxidative cleavage or other catabolic processes, partly in the intestines and partly in other tissues after transport in the lipoproteins. Some carotenoids remain intact and are believed to act as antioxidants, and some may have specific anti-inflammatory actions. For example, carotenoids accumulate in the skin of mammals, where they may have an antioxidant and photo-protective role as well as effects on the moisture content, texture, and elasticity. Lycopene may have protective effects against atherogenesis, coronary heart disease, and prostate cancer.

21.6.2.5: FUNCTIONS OF CAROTENOIDS IN PLANTS

As carotenoids have a polyene chain of 9 to 11 double bonds in conjugation, they are able to absorb light in the gap of chlorophyll absorption, and so function as additional light-harvesting pigments in plants. Their distinctive arrangement of electronic levels gives them the capacity to transfer excitation energy from the carotenoid excited state to chlorophyll in the light-harvesting complex (photosystem II). Energy can also be transferred back from chlorophyll to carotenoids as a photoprotection mechanism. During photosynthesis, damaging species are produced by both light and oxygen with reactive oxygen species (ROS) of special concern. The energy is transferred from chlorophyll to the polyene tail of the carotenoid where electrons are moved between the carotenoid bonds until the most balanced or lowest energy state (state) is reached. While there is therefore appreciable potential for carotenoids to act as antioxidants in plants, it is uncertain how important this is from a practical functional standpoint. The length of the polyene tail of carotenoids determines which wavelengths of light will be absorbed by the plant, and those not absorbed are reflected and so determine coloration. F

Carotenoids are precursors for two plant hormones and a diverse set of apocarotenoids. For example, **abscisic acid**, shown in Figure 21.6.21, is a C_{15} isoprenoid plant hormone, which is synthesized in plastids from the C_{40} carotenoid zeaxanthin.



abscisic acid

Figure 21.6.21:

A series of enzyme-catalyzed epoxidations and isomerizations is involved followed by cleavage of the intermediate product by a dioxygenation reaction and further oxidations to yield eventually abscisic acid. Functioning via signaling cascades, abscisic acid regulates innumerable biological effects in plants, especially in relation to developmental processes that include plant growth, seed and bud dormancy, embryo maturation and germination, cell division and elongation, floral growth and the control of stomatal closure. It is critical for the responses to environmental stresses that include drought, cold and heat stress, salinity, and tolerance of heavy metal ions. Similarly,

strigolactones are C_{15} oxidation products of carotenoids that are involved in the regulation of symbiosis between plants and arbuscular mycorrhizal fungi and in interactions with plant parasites.

21.6.3: ISOPRENOIDS: 3. OTHER MEMBRANE-ASSOCIATED ISOPRENOIDS

Terpenes (isoprenoids) are one of the most varied and abundant natural products produced by animals, plants, and bacteria. They are generally defined on the basis of their biosynthetic derivation from isoprene units (C_5H_8), with 55,000 different types characterized to date according to a recent estimate. By most definitions, all isoprenoids should be classified as 'lipids', from simple monoterpenes such as geraniol, which is derived from two prenol units, to complex polymers such as natural rubber. Only those isoprenoids that have a **functional** role in cellular membranes will be discussed here. These include plastoquinone, ubiquinone (coenzyme Q), phylloquinone and menaquinone (vitamin K), dolichol and polyprenols, undecaprenyl phosphate and lipid II, and farnesyl pyrophosphate, together with some key biosynthetic precursors. The nature and function of **tocopherols and tocotrienols (vitamin E)** and **retinoids (vitamin A)** are relevant here, but have been discussed previously. Of course, sterols are also isoprenoids.

There are two basic mechanisms for the biosynthesis of the isoprene units that are the precursors for the biosynthesis of isoprenoids, i.e., isopentenyl pyrophosphate and dimethylallyl pyrophosphate. These are the mevalonate pathway, which is located in the cytosol of the cell, and the non-mevalonate pathway, found mainly in the plastids of plants. These have been discussed previously.

21.6.3.1: PHYTOL

Phytol or (2*E*,7*R*,11*R*)-3,7,11,15-tetramethyl-2-hexadecen-1-ol, i.e., with 20 carbons in a 16-carbon chain and one double bond, is an acyclic diterpene alcohol, which is synthesized in large amounts in plants as an essential component of chlorophyll, the most important photosynthetic pigment in plants and algae. Geranylgeranyl-diphosphate synthesized in chloroplasts via the 4-methylerythritol-5-phosphate (non-mevalonate) pathway is the primary precursor of phytol following reduction of three double bonds by geranylgeranyl reductase, and this can occur before or after attachment to chlorophyll, depending upon species. Chlorophyll dephytylase (CLD1) is the enzyme in plants responsible for chlorophyll hydrolysis and the release of phytol. The reactions are shown in Figure 21.6.22.

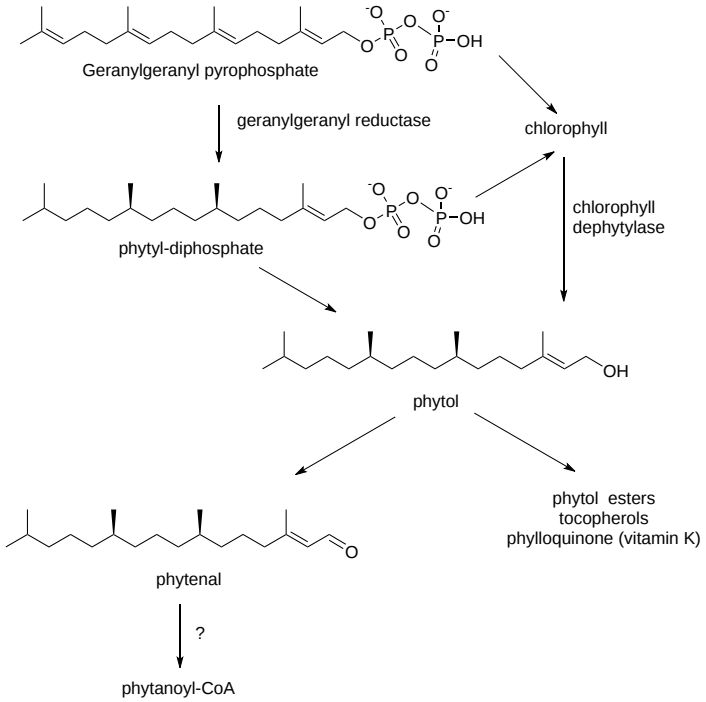


Figure 21.6.22 Phytol synthesis and metabolism in plants

Little free phytol is present in plant tissues, although some phytol esters of fatty acids may occur, especially when plants are stressed during nitrogen deprivation or in senescence, when chlorophyll is degraded, fatty acids are released from glycerolipids and a phytol ester synthase is induced as part of a detoxification and recycling process. Bell peppers and rocket salad are especially rich sources under normal conditions. In addition, phytol as its diphosphate is utilized for the synthesis of **tocopherols** (vitamin E) and phylloquinol (vitamin K - see below), and the precursor geranylgeraniol and its fatty acid ester occur in small amounts in some plant species. It is the biosynthetic precursor of tocotrienols and the highly unsaturated carotenoids (and hence of **retinoids**). Phytenal has been isolated as an intermediate in the catabolism of phytol in plants, but further steps are uncertain although phytanoyl-CoA has been detected in stressed plants. As phytenal is highly reactive and potentially toxic via its interaction with proteins, its accumulation must be kept at a low level by competing pathways.

In ruminant animals, chlorophyll is hydrolyzed by rumen microorganisms with the release of free phytol. This does not occur in humans, but some phytol may be ingested with plant foods either in free form or as phytol esters and can be absorbed from the intestines. Within animal tissues, phytol is oxidized to **phytanic acid**. Phytol and/or its metabolites have been reported to activate the transcription factors PPARα and retinoid X receptor. In mice, oral phytol induces a substantial proliferation of peroxisomes in many organs.

21.6.3.2: PLASTOQUINONE

A molecule that is related to the tocopherols, **plastoquinone**, is found in cyanobacteria and plant chloroplasts, and it is produced in plants by analogous biosynthetic pathways to those of tocopherols in the inner chloroplast envelope with solanesol diphosphate as the biosynthetic precursor of the side chain; there appears to be a somewhat different mechanism in cyanobacteria. The molecule is sometimes designated - 'plastoquinone-n' (or PQ-n), where 'n' is the number of isoprene units, which can vary from 6 to 9. It's structure is shown in Figure 21.6.23.

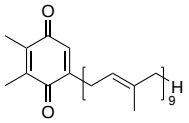

Figure 21.6.23: Plastoquinone

Plastoquinone has a key role in photosynthesis, by providing an electronic connection between photosystems I and II, generating an electrochemical proton gradient across the thylakoid membrane. This provides energy for the synthesis of adenosine triphosphate (ATP). The reduced dihydroplastoquinone (plastoquinol) that results in the transfers further electrons to the photosynthesis enzymes before being re-oxidized by a specific cytochrome complex; the redox state of the plastoquinone pool regulates the expression of many of the genes encoding photosystem proteins. X-Ray crystallography studies of photosystem II from cyanobacteria show two molecules of plastoquinone forming two membrane-spanning branches. In addition, plastoquinone has antioxidant activity comparable to that of the tocopherols, protecting especially against excess light energy and photooxidative damage. Similarly, in thylakoid membranes, plastoquinol is able to scavenge superoxide with the production of H_2O_2. Plastoquinone is a cofactor participating in desaturation of phytoene in carotenoid biosynthesis, and the biosynthetic precursor of plastochromanols. With these many different functions, plastoquinone connects photosynthesis in plants with metabolism, light acclimation, and stress tolerance.

Plastoquinone-9, together with phylloquinone, tocopherol, and plastochromanol-8, is stored in plastoglobuli, lipoprotein-like micro-compartments, which enable exchange with the thylakoid membrane and are also involved in chlorophyll catabolism and recycling. It has been suggested that the redox state of the plastoquinone pool is the main redox sensor in chloroplasts that initiates many physiological responses to changes in the environment and in particular to those related to light intensity by regulating the expression of chloroplast genes.

21.6.3.3: UBIQUINONE (COENZYME Q)

The **ubiquinones**, which are also known as coenzyme Q (CoQ) or mitoquinones, have obvious biosynthetic and functional relationships to plastoquinone and they are found in all the domains of life (hence the name). They have a 2,3-dimethoxy-5-methylbenzoquinone nucleus and a side chain of six to ten isoprenoid units; the human form illustrated below has ten such units (coenzyme Q_{10}), i.e., it is 2,3-dimethoxy-5-methyl-6-decaprenyl-1,4-benzoquinone, while that of the rat has nine, *Escherichia coli* has eight and *Saccharomyces cerevisiae* has six. In plants, ubiquinones tend to have nine or ten isoprenoid units. Forms with a second chromanol ring, resembling the structures of tocopherols, are also produced (ubichromanols), but not in animal tissues. They are generated on an industrial scale for pharmaceutical purposes by yeast fermentation. Because of their hydrophobic properties, ubiquinones are located entirely in membrane bilayers in most eukaryote organelles, probably at the mid-plane.

Ubiquinones are synthesized *de novo* in mitochondria in most cells in animal, plant, and bacterial tissues by a complex sequence of reactions from the essential amino acid phenylalanine and then tyrosine to generate *p*-hydroxybenzoic acid, which is the key precursor that is condensed with the polyprenyl unit (from the cholesterol synthesis pathway) via a specific transferase; this is followed by decarboxylation, hydroxylation, and methylation steps, depending on the specific organism, although some of the required enzymes have yet to be fully characterized. In *Escherichia coli*, biosynthesis does not occur in a membrane environment as had been thought. Rather, the seven proteins that catalyze the last six reactions of the biosynthetic pathway, following the attachment of the isoprenoid tail, form a stable complex or metabolon in the cytoplasm so enabling modification of the hydrophobic substrates in a hydrophilic environment.

In mitochondria, coenzyme Q is present both as the oxidized (ubiquinone) and reduced (ubiquinol) forms as shown in Figure 21.6.24.

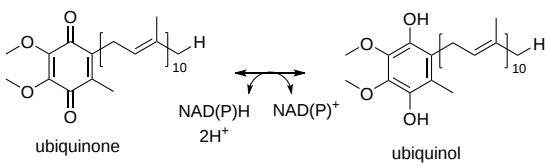

Figure 21.6.24: Ubiquinone-ubiquinol interconversion

Ubiquinones are essential components of the respiratory electron transport system, possibly as part of supramolecular complexes, taking part in the oxidation of succinate or NADH via the cytochrome system to generate the protonmotive force used by the mitochondrial ATPase to synthesize ATP. In this process, coenzyme Q transfers electrons from the various primary donors, including complex I, complex II, and the oxidation of fatty acids and branched-chain amino acids, to the oxidase system (complex III), while simultaneously transferring protons to the outside of the mitochondrial membrane with the result of a proton gradient across the membrane. As a consequence, it is reduced to ubiquinol. Thus, it is an essential component of the cycle that generates the proton motive force driving ATP production via oxidative phosphorylation. In yeast, one coenzyme Q binding protein (COQ10), and in humans two related proteins (COQ10A and COQ10B) may serve as chaperones or transporters during this process. Mitochondrial coenzyme Q is also implicated in the production of reactive oxygen species by a mechanism involving the formation of superoxide from ubisemiquinone radicals, and in this way is responsible for causing some of the oxidative damage behind many degenerative diseases. In this action, it is a pro-oxidant. It is most abundant in organs with a high metabolic rate such as the heart, kidneys, and liver.

In complete contrast in its reduced form (ubiquinol) in non-mitochondrial cellular membranes and plasma lipoproteins, it acts as an endogenous antioxidant, the only lipid-soluble antioxidant to be synthesized endogenously. It inhibits lipid peroxidation in biological membranes and serum low-density lipoproteins, and it may also protect membrane proteins and DNA against oxidative damage. The ferroptosis suppressor protein 1 (FSP1) replenishes ubiquinol, and this acts protectively by combating the lipid peroxidation that drives **ferroptosis**. The mechanism involves the recruitment of FSP1 to the plasma membrane following myristoylation, where this functions as an oxidoreductase that reduces ubiquinone to ubiquinol, which acts as a lipophilic radical-trapping antioxidant that halts the propagation of lipid peroxides. In this manner, it regulates cellular redox status and cytosolic oxidative stress, and thereby is a controlling factor in apoptosis. Other NAD(P)H dehydrogenases with CoQ reductase activity include cytochrome b5 reductase and NQo1 (NAD(P)H:quinone oxidoreductase).

Although ubiquinone has only about one-tenth of the antioxidant activity of **vitamin E** (α-tocopherol), it is able to stimulate the effects of the latter by regenerating it from its oxidized form back to its active fully reduced state (similarly with vitamin C). However, ubiquinones and tocopherols appear to exhibit both cooperative and competitive effects under different conditions. Similarly, in bacteria and other prokaryotes, ubiquinones participate a large number of redox reactions, notably in the respiratory electron transport system but also in other enzyme reactions that require electron donation, including the formation of disulfide bonds.

Coenzyme Q has many other functions that are not related directly to its antioxidant function. Some coenzyme Q is used in mitochondria by enzymes that link the mitochondrial respiratory chain to other metabolic pathways, including fatty acid β-oxidation as an electron acceptor, nucleotide biosynthesis *de novo*, amino acid oxidation (glycine, proline, glyoxylate, and arginine), and detoxification of sulfide. Via these activities, coenzyme Q may modulate metabolic pathways located outside the mitochondria indirectly. There are also suggestions that coenzyme Q may be involved in redox control of cell signaling and gene expression, and in particular to repress the expression of inflammatory genes. In relation to its anti-inflammatory properties, clinical studies suggest that supplementation with coenzyme Q_{10} reduces the levels of the inflammatory mediators C-reactive protein, interleukin-6, and tumor necrosis factor alpha (TNFα) to a significant degree. In addition, it is a regulator of mitochondrial permeability, and in relation to pyrimidine nucleotide biosynthesis, it is required for DNA replication and repair.

Dietary ubiquinone, i.e., that in food or dietary supplements, is absorbed by enterocytes via a process of “passive facilitated diffusion”, probably requiring a carrier molecule, before incorporation into chylomicrons for transport to the liver. This eventually leads to elevated levels of ubiquinol in blood, especially in the LDL and VLDL lipoproteins, presumably because of the reduction of the oxidized form in the lymphatic system. In consequence, there is reported to be enhanced protection against lipid peroxidation with beneficial effects on health, especially in relation to cardiac function, sperm motility, and neurodegenerative diseases. For example, CoQ levels in both plasma and the heart correlate with heart failure in patients, and clinical trials of dietary supplementation have shown promising results. This may be of particular importance in the elderly or in patients on statins, when endogenous synthesis declines. A CoQ_{10} deficiency syndrome is associated with inherited pathological diseases, defined by a decrease of the CoQ_{10} content in muscle and/or cultured skin fibroblasts. Early clinical trials with CoQ10 and a synthetic analog, idebenone, against various neurodegenerative diseases, including Alzheimer's disease, Parkinson's disease, Huntington's disease, and others, are encouraging.

21.6.3.4: PHYLLOQUINONE AND MENAQUINONES (VITAMIN K)

Phylloquinone or 2-methyl-3-phytyl-1,4-naphthoquinone is synthesized in the inner chloroplast envelope of cyanobacteria, algae, and higher plants by a mechanism analogous to that of the **tocopherols**, i.e., from chorismate in the shikimate pathway with a prenyl side chain derived from phytyldiphosphate. In this membrane, it is a key component of the photosystem I complex where it receives an electron from the chlorophyll a acceptor molecule and then donates an electron to the membrane-associated iron-sulfur protein acceptor cluster in the complex. In an obvious parallel to the plastoquinones (above), two molecules of phylloquinone form two membrane-spanning branches, as demonstrated by X-ray crystallography studies of photosystem I from cyanobacteria. Plastoglobules associated with the thylakoid membrane are believed to function as a reservoir for excess phylloquinone, and may also function in its metabolism. Edward A. Doisy and Henrik Dam received the Nobel Prize in Physiology or Medicine in 1943 for their discovery of vitamin K and its chemical structure. The structure of vitamin K is shown in Figure 21.6.25.

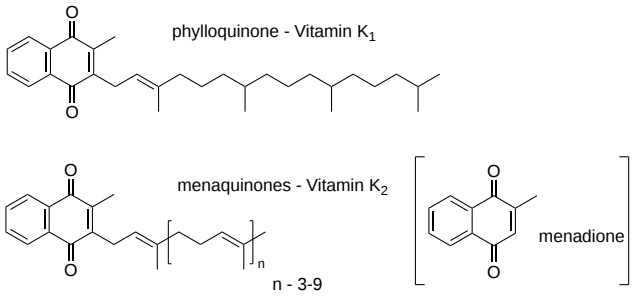

Figure 21.6.25: Vitamin K

The menaquinones are related bacterial products, which function in the respiratory and photosynthetic electron transport chains of bacteria. They have a variable number (4 to 10) of isoprenoid units in the tail, and they are sometimes designated ‘MK-4’ to ‘MK-10’. In contrast to phylloquinone, these are usually highly unsaturated. In some species, there are methyl or other groups attached to the naphthoquinone moiety. Remarkably high concentrations of menaquinones are present in membranes of some extremophiles such as the haloarchaea, where it has been suggested that they act as ion permeability barriers and as a powerful shield against oxidative stress in addition to their functions as electron and proton transporters.

Phylloquinone is an essential component of the diet of animals and has been termed '**vitamin K_1**'. It must be supplied by green plant tissues, where it occurs in the range 400-700 µg/100 g, or seed oils. The menaquinones, the main source of which in the human diet is cheese and yogurt, also have vitamin K activity and are termed '**vitamin K_2**'. They account for about 10-25% of the vitamin K content of the Western diet. A synthetic saturated form of this, which is used in animal feeds, is known as 'vitamin K_3 or menadione', though strictly speaking it is not a vitamin but a pro-vitamin in that it can be converted to the menaquinone MK-4 in animal tissues by addition of a phytyl unit; it is too toxic for human nutrition. Vitamin K forms are absorbed from the intestines and transported in plasma in the form of lipoproteins in a similar manner to the other fat-soluble vitamins. Different tissues have differ storage capacities and presumably requirements for the various forms of vitamin K. As a high proportion is excreted, there appears to be a requirement for a constant intake. Vitamin K_1 is taken up rapidly by the liver, but vitamin K_2 remains in the plasma for much longer and maybe the main source of the vitamin in peripheral tissues. In addition, it has been established that some dietary phylloquinone is converted to menaquinone-4 in animals, although the quantitative significance has still to be established; the mechanism involves conversion to menadione in the intestines followed by transport to tissues where a geranylgeranyl side-chain is attached by a specific prenyl transferase.

The primary role of vitamin K in animal tissues is to act as a cofactor specific to the vitamin K-dependent enzyme γ-glutamyl carboxylase in the endoplasmic reticulum in the liver mainly. Its function is the post-translational carboxylation of glutamate residues to form γ-carboxyglutamic acid in proteins, such as prothrombin. In this way, prothrombin and three related proteins are activated to promote blood clotting. The γ-carboxyglutamic acid residues are located at the binding site for Ca^{2+}, and are vital for the activity of the enzyme. Phylloquinone must first be converted to the reduced form, phylloquinol, which is the actual cofactor for the enzyme; molecular oxygen and carbon dioxide are both required also. Phylloquinol donates hydrogen to the glutamic acid residue and is oxidized in the process to 2,3-epoxyphylloquinone. A further enzyme, vitamin K epoxide reductase, regenerates phylloquinone by reduction of the epoxide in a dithiol-dependent reaction so that this can be re-utilized many times ("the vitamin K cycle", shown below in Figure 21.6.26).

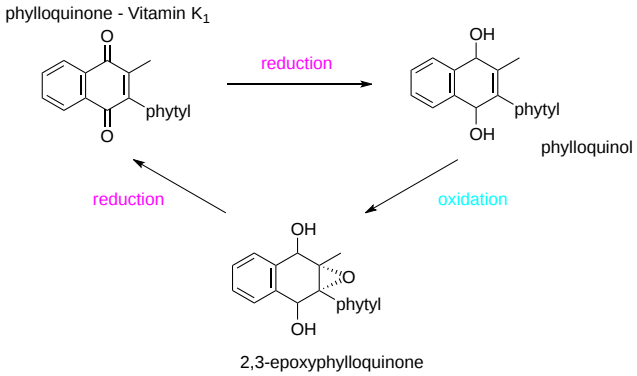

Figure 21.6.26: The Vitamin K cycle

Menaquinones undergo the same cycle of reaction. By interfering with the last step in the metabolic cycle, warfarin, the rodenticide, prevents blood clotting. In the same way, a deficiency in vitamin K results in the inhibition of blood clotting and can lead to brain hemorrhaging in malnourished newborn infants, though this is not seen in adult humans, presumably because intestinal bacteria produce sufficient for our needs. Vitamin K-dependent proteins are also known to have important functions in the central and peripheral nervous systems, and vitamin K influences sphingolipid biosynthesis in the brain.

Unsaturated isoprene units rather than phytol are used for the biosynthesis of menaquinones, and they differ from phylloquinone with respect to their chemical structure and pharmacokinetics. It is now apparent that vitamin K_2 (MK-4 especially) has a number of different actions, some with specificities for particular tissues. For example, osteocalcin is a γ-carboxyglutamic acid-containing protein, which forms a strong complex with the mineral hydroxyapatite (calcium phosphate) of bone; it must be carboxylated to function properly and vitamin K_2 appears to be of particular importance in this instance. Vitamin K_2 also regulates bone remodeling by osteoclasts to remove old or damaged bone and its replacement by new bone. In addition, vitamin K_2 is involved in vascular calcification, cell growth, and apoptosis. Side effects of the use of anticoagulants that bind to vitamin K can be osteoporosis and increased risk of vascular calcification. Although careful control of the dosage is necessary, vitamin K_2 may be a useful adjunct for the treatment of osteoporosis, and it may reduce morbidity and mortality in cardiovascular health by reducing vascular calcification.

Excess vitamin K_1 and the menaquinones are catabolized in the liver by a common degradative pathway in which the isoprenoid side chain is shortened to yield carboxylic acid aglycones such as menadiol, which can be excreted in bile and urine as glucuronides or sulfates.

21.6.3.5: DOLICHOLS AND POLYPRENOLS

Polyisoprenoid alcohols, such as dolichols, are ubiquitous if minor components, relative to the glycerolipids, of membranes of most living organisms from bacteria to mammals. They are hydrophobic linear polymers, consisting of up to twenty isoprene residues or a hundred carbon atoms (or many more in plants especially), linked head-to-tail, with a hydroxy group at one end (α-residue) and a hydrogen atom at the other (ω-end). In **dolichols** (or dihydropolyprenols), the double bond in the α-residue is hydrogenated, and this distinguishes them from the **polyprenols** with a double bond in the α-residue. Their structures are shown in Figure 21.6.27.

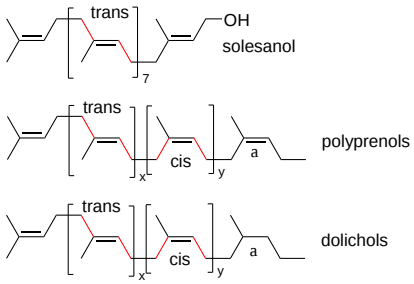

Figure 21.6.27: Polyprenols and dolichols

Polyisoprenoid alcohols are further differentiated by the geometrical configuration of the double bonds into three subgroups, i.e., di-*trans*-poly-*cis*, tri-*trans*-poly-*cis*, and all-*trans*. For many years, it was assumed that polyprenols were only present in bacteria and plants, especially photosynthetic tissues, while dolichols were found in mammals or yeasts, but it is now known that dolichols can also occur at low levels in bacteria and plants, while polyprenols have been detected in animal cells. **Solanesol** is a related and distinctive plant product with *trans* double bonds only and is a precursor of plastoquinone.

Within a given species, components of one chain length may predominate, but other homologs are usually present. The chain length of the main polyisoprenoid alcohols varies from 11 isoprene units in eubacteria, to 16 or 17 in Drosophila, 15 and 16 in yeasts, 19 in hamsters, and 20 in pigs and humans. In plants, the range is from 8 to 22 units, but some species of plant have an additional class of polyprenols with up to 40 units. In tissues, polyisoprenoid alcohols can be present in the free form, esterified with acetate or fatty acids, phosphorylated or monoglycosylated phosphorylated (various forms), depending on species and tissue. Polyisoprenoid alcohols *per se* do not form bilayers in aqueous solution, but rather a type of lamellar structure. However, they are found in most membranes, especially the plasma membrane of liver cells and the chloroplasts of plants.

Dolichoic acids, i.e., related molecules with a terminal carboxyl group and containing 14–20 isoprene units, have been isolated from the substantia nigra of the human brain. However, they were barely detectable in the pig brain.

Biosynthesis of the basic building block of dolichols, e.g. isopentenyl diphosphate, follows either the mevalonate pathway or a more recently described methylerythritol phosphate pathway discussed in relation to **cholesterol biosynthesis** previously. Farnesyl pyrophosphate is the primary precursor in the biosynthesis of polyprenols and is the branch point in sterol/isoprene biosynthesis, depending on the nature of the organism (see a further note below). Subsequent formation of the linear prenyl chain is accomplished by *cis*-prenyl transferases that catalyze the condensation of isopentenyl pyrophosphate and farnesyl pyrophosphate and then the growing the allylic prenyl diphosphate chain. The end products are polyprenyl pyrophosphates, which are dephosphorylated first to polyprenol phosphate and thence to the free alcohol. Finally, a specific reductase has been identified from human tissues that catalyzes the reduction of the double bond in position 2 to produce dolichols. There is a family of *cis*-prenyl transferases, present in both eukaryotes and bacteria, that in addition to the synthesis of dolichols can catalyze the formation of isoprenoid carbon skeletons from neryl pyrophosphate (C_{10}) to natural rubber ($C_{>10,000}$), including the polyisoprenoid phosphates involved in protein glycosylation as discussed in the next section. The reactions in the synthesis of dolichol are shown in Figure 21.6.28.

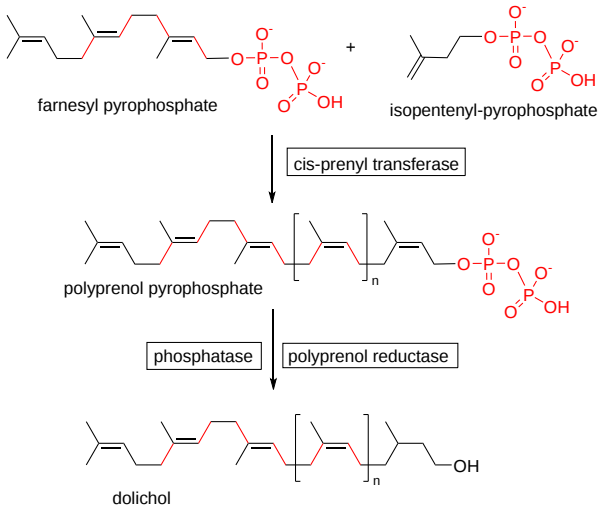

Figure 21.6.28: Synthesis of dolichol

Although polyprenols and dolichols were first considered to be simply secondary metabolites, they are now known to have important biological functions. Glycosylation of asparagine residues is the main protein modification in all three domains of life, and phosphorylated polyisoprenoids, including dolichols, are essential to this process (next section). There is also a suggestion that free dolichol may have a beneficial antioxidant function in cell membranes.

21.6.3.6: POLYISOPRENOID PHOSPHATES AND GLYCOSYLATION OF PROTEINS

Glycosylated phosphopolyisoprenoid alcohols are the carriers of oligosaccharide units for transfer to proteins and as glycosyl donors, i.e., they are substrates for glycosyl transferases for the biosynthesis of glycans in a similar manner to the cytosolic sugar nucleotides. They differ from the latter in their intracellular location, with the lipid portion in the membrane of the endoplasmic reticulum and the oligosaccharide portion specifically located either on the cytosolic or lumenal face of the membrane. The degree of unsaturation and chain length of the product is important for recognition by the enzymes in the next stage of the pathway.

Dolichol phosphates: In eukaryotes, *N*-glycosylation begins on the cytoplasmic side of the endoplasmic reticulum with the transfer of carbohydrate moieties from nucleotide-activated sugar donors, such as uridine diphosphate *N*-acetylglucosamine, onto dolichol phosphate. Then, *N*-acetylglucosamine phosphate is added to give dolichol-pyrophosphate linked to *N*-acetylglucosamine, to which a further *N*-acetylglucosamine unit is added followed by five mannose units, the last catalyzed by dolichol phosphate mannose synthase, which is also essential for **GPI-anchor** biosynthesis. The dolichol-PP glycan is shown in Figure 21.6.29.

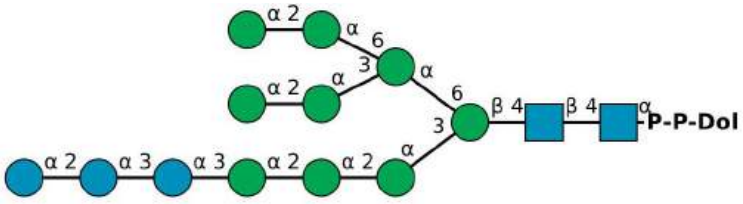

Figure 21.6.29: Dolichol-pyrophosphate glycan. Blue squares GlcNAc, Green circles Man, blue circles Glc. Cheng, K. et al., 'DrawGlycan-SNFG: a robust tool to render glycans and glycopeptides with fragmentation information', Glycobiology 27(3): 200-205, 2017

The resulting dolichol-pyrophosphate heptasaccharide is then flipped across the endoplasmic reticulum membrane to the luminal face with the aid of a “flippase”. Four further mannose and three glucose residues are added to the oligosaccharide chain by means of glycosyltransferases, which utilize as donors dolichol-phospho-mannose and dolichol-phospho-glucose, which are also synthesized on the cytosolic face of the membrane and flipped across to the luminal face. In humans, the final lipid product is a C_{95}-dolichol pyrophosphate-linked tetradecasaccharide, the oligosaccharide unit of which is transferred from the dolichol carrier onto specific asparagine residues on a developing polypeptide in the membrane. The carrier dolichol-pyrophosphate is dephosphorylated to dolichol-phosphate then diffuses or is flipped back across the endoplasmic reticulum to the cytoplasmic face.

The **Archaea** use dolichol in their synthesis of lipid-linked oligosaccharide donors with both dolichol phosphate (Euryarchaeota) and pyrophosphate (Crenarchaeota) as carriers; these can have variable numbers of isoprene units many of which can be saturated. In the haloarchaeon *Haloferax volcanii*, for example, a series of C_{55} and C_{60} dolichol phosphates with saturated isoprene subunits at the α- and ω-positions is involved in the glycosylation reaction of target proteins, while similar lipid carriers of oligosaccharide units appear to be present in methanogens. Archaea of course use **isoprenyl ethers linked to glycerol** as major membrane lipid components in addition to unusual carotenoids such as the C_{50} bacterioruberins. In many of these species, isoprenoid biosynthesis is via the 'classical' mevalonate pathway, but in other species, some aspects of this pathway differ.

Undecaprenylphosphate: Most other bacteria use undecaprenyl-diphosphate-oligosaccharide as a glycosylation agent in a similar way for the biosynthesis of peptidoglycan, the main component of most bacterial cell walls and a structure unique to bacteria, of many other cell-wall polysaccharides, including lipopolysaccharides, *O*-antigenic polysaccharides and capsular polysaccharides, and of *N*-linked protein glycosylation in both in Gram-negative and Gram-positive bacteria. **Undecaprenyl phosphate** (a C_{55} isoprenoid), also referred to as bactoprenol, is the essential lipid intermediate. Its structure is shown in Figure 21.6.30.

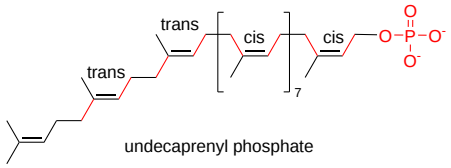

Figure 21.6.30: Undecaprenyl phosphate

It differs from the dolichol phosphates mainly in that the terminal unit is unsaturated, and is synthesized by the addition of eight units of isopentenyl pyrophosphate to farnesyl pyrophosphate, a reaction catalyzed by undecaprenyl pyrophosphate synthase in the cytoplasm, followed by the removal of a phosphate group. Undecaprenyl phosphate is required for the synthesis and transport of glycans for external polymer formation. Thus, glycans are covalently transferred to the carrier lipid by membrane-embedded or membrane-associated enzymes using nucleotide-activated precursors. For example, the carrier lipid with GlcNAc-MurNAc-peptide monomers, i.e., as lipid II, is hydrophilic and is then transported across the cytoplasmic membrane to external sites for peptidoglycan formation. Similarly, it is required for the synthesis of **lipoteichoic acids** and **lipopolysaccharide *O*-antigens**.

Lipid II: Undecaprenyl diphosphate-MurNAc-pentapeptide-GlcNAc, often simply termed **lipid II**, is the last significant lipid intermediate in the construction of the peptidoglycan cell wall in bacteria (Lipid I is the biosynthetic precursor lacking the *N*-acetylgluosamine residue). Its structure is shown below in Figure 21.6.31.

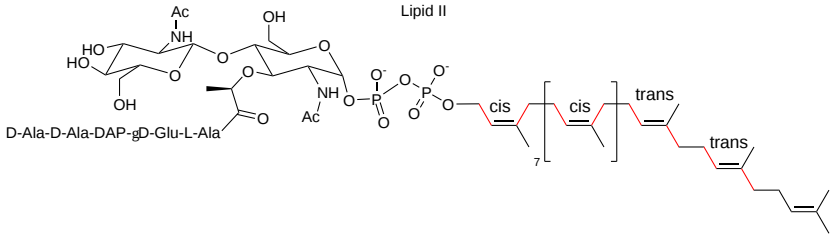

Figure 21.6.31: Lipid II

This molecule must be translocated from the cytosolic to the exterior membrane of the organism, and three different protein classes have been identified that can accomplish this of which ATP-binding cassette (ABC) transporters are best characterized. Once across the membrane, lipid II is cleaved to provide the MurNAc-pentapeptide-GlcNAc monomer, which undergoes polymerization and crosslinking to form the complex peptidoglycan polymer that provides strength and shape to bacteria. The undecaprenyl-pyrophosphate remaining is hydrolyzed to undecaprenyl phosphate by a membrane-integrated member of the type II phosphatidic acid phosphatase family and is recycled back to the interior of the membrane by an as yet unidentified transport mechanism. The turnover rate is very high so the lipid II cycle is considered to be the rate-limiting step in peptidoglycan biosynthesis. There is also some evidence that lipid II has a function on the inner leaflet of the cytoplasmic membrane in organizing the proteins of the cytoskeleton. Because of its highly conserved structure and accessibility on the surface membrane, the proteins involved in the synthesis and transport of lipid II are considered important targets for the development of novel antibiotics. Figure 21.6.*xx*:

In a few prokaryotes, the membrane intermediate has a polyprenyl-monophosphate-glycan structure instead of lipid II, and undecaprenyl-phosphate-L-4-amino-4-deoxyarabinose is involved in **lipid A** modification in Gram-negative bacteria, for example. There are obvious parallels with the involvement of glycosylated phosphopolyisoprenoid alcohols as carriers of oligosaccharide units for transfer to proteins and as glycosyl donors in higher organisms (see above).

β-D-Mannosyl phosphomycoketide is an isoprenoid phosphoglycolipid found in the cell walls of *Mycobacterium tuberculosis*, the lipid component of which is a C_{32}-mycoketide, consisting of a saturated oligoisoprenoid chain with five chiral methyl branches. It acts as a potent antigen to activate T-cells upon presentation by CD1c protein. Its structure is shown in Figure 21.6.32.

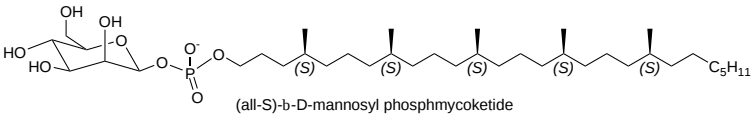

Figure 21.6.32 β-D-Mannosyl phosphomycoketide

21.6.3.7: FARNESYL PYROPHOSPHATE AND RELATED COMPOUNDS

Farnesyl pyrophosphate is a key intermediate in the biosynthesis of sterols such as **cholesterol**, and it is the donor of the farnesyl group in the biosynthesis of dolichols and polyprenols (see above) as well as for the isoprenylation of many proteins (see the web page on **proteolipids**). However, it is also known to mediate various biological reactions in its own right via interaction with a specific receptor. It is synthesized by two successive phosphorylation reactions of farnesol.

Presqualene diphosphate is unique among the isoprenoid phosphates in that it contains a cyclopropylcarbinyl ring. In addition to being a biosynthetic precursor of squalene, and thence of cholesterol, it is a natural anti-inflammatory agent, which functions by inhibiting the activity of phospholipase D and the generation of superoxide anions in neutrophils.

Their structures are shown in Figure 21.6.32.

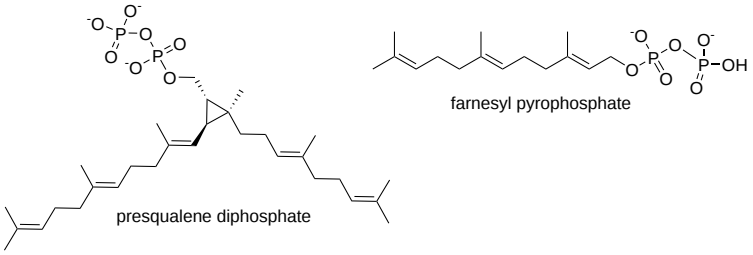

Figure 21.6.32 Structures of farnesyl pyrophosphate and presqualene diphosphate

CHAPTER OVERVIEW

22: BIOSYNTHESIS OF AMINO ACIDS, NUCLEOTIDES, AND RELATED MOLECULES

22.1: Overview of Nitrogen Metabolism
22.2: Biosynthesis of Amino Acids
22.3: Molecules Derived from Amino Acids
22.4: Biosynthesis and Degradation of Nucleotides

22.1: OVERVIEW OF NITROGEN METABOLISM

22.1.1: INTRODUCTION

Organic chemistry is usually described as the chemistry of carbon-containing molecules. But isn't that definition a bit carbon centric, especially since the prevalence of oxygen-containing molecules is staggering? What about nitrogen? We live in a dinitrogen-rich atmosphere (80%), and all classes of biomolecules (lipids, carbohydrates, nucleic acids, and proteins) contain nitrogen. Dinitrogen is very stable, given its triple bond and nonpolarity. We rely on a few organisms to fix N_2 from the atmosphere to form ammonium (NH_4^+), which through nitrification and denitrification can form nitrite (NO_2^-), nitrate (NO_2^-), nitric oxide (NO), and nitrous oxide (N_2O), the latter being a potent greenhouse gas. We'll concentrate on the metabolic fate of amino groups in amino acids and proteins in the next section. Before exploring their fates, look at Figure 22.1.1 which shows an overall view of the biological nitrogen cycle. The study of biochemistry should encompass more than homo sapiens and expand to the ecosystem in which we are such a small but damaging part.

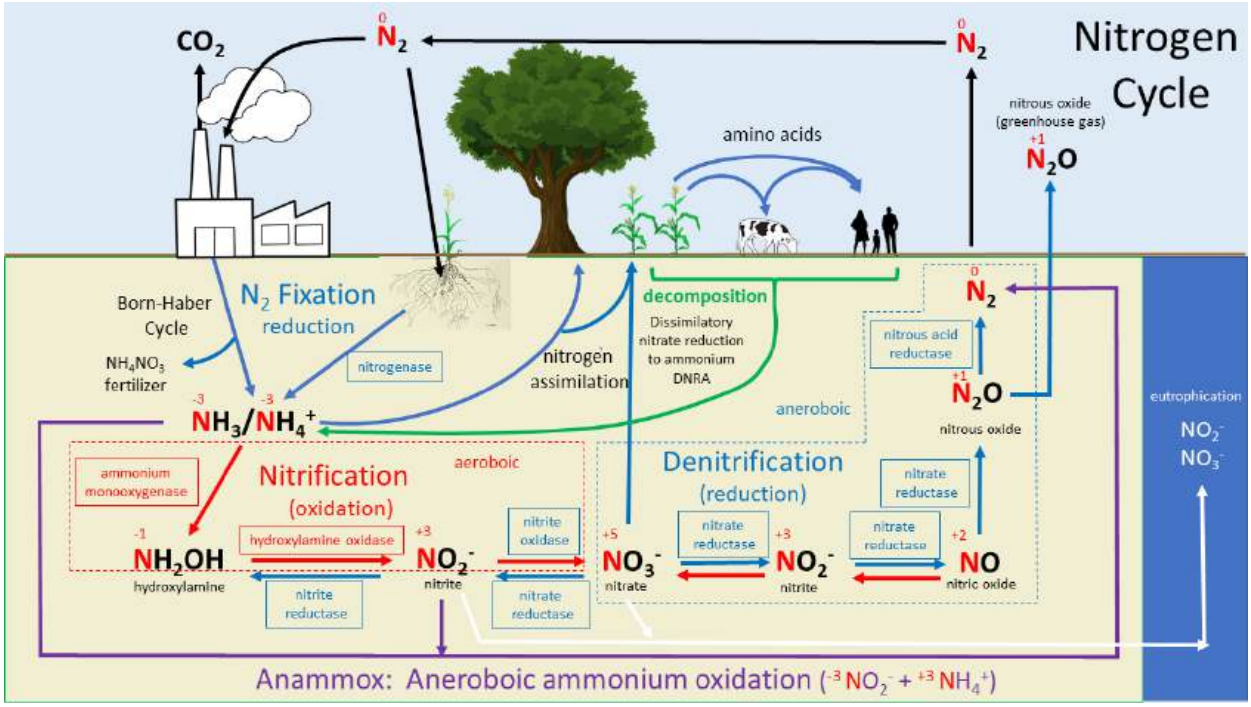

Figure 22.1.1: Nitrogen Cycle

Let's break down the diagram from a biochemical perspective. There are aerobic and anaerobic processes (conducted by bacteria). Nitrogen-containing substances include both inorganic (ammonium, nitrate, nitrite) and organic (amino acids, nucleotides, etc) molecules. The reactions shown are oxidative and reductive (note: the oxidation number of the nitrogen atoms in the molecules is shown in red). Most of the reactions are carried out underground by bacterial and Archaeal microorganisms.

Here are some of the major reactions:

- N_2 fixation (a reduction): N_2 from the air is converted by bacteria to ammonium (NH_4^+) by the enzyme nitrogenase of soil prokaryotes. The energetically disfavored reaction requires lots of ATPs. Ammonium once made can then be taken up by primary producers like plants and incorporated into biomolecules such as amino acids, which animals consume. For those who may still believe that people have marginal effects on our biosphere, consider this. We may soon fix more N_2 to NH_3 through the industrial Born-Haber reaction (used for fertilizer and explosive productions) that is all made by the biosphere. Much of the nitrogen in use comes from the Born-Haber reaction. The excess NH_4^+ (upwards of 50%) produced industrially and which enters the soil in fertilizers (mostly as NH_4NO_3) has overwhelmed nature's ability to balance the nitrogen cycle and is not taken up by plants. It is metabolized by microorganisms to nitrite and nitrate.
- Nitrification: Ammonium is converted to nitrite by ammonia-oxidizing aerobic microorganisms and further to nitrate by a separate group of nitrite-oxidizing aerobic bacteria. Here are the reactions (Rx 1 and 2) to produce nitrate through a hydroxylamine intermediate, followed by the formation of nitrate (Rx 3).

$$NH_3 + O_2 + 2e^- \rightarrow NH_2OH + H_2O \text{ Rx 1}$$

$$NH_2OH + H_2O \rightarrow NO_2^- + 5H^+ + 4e^- \text{ Rx 2}$$

$$NO_2^- + 1/2\ O_2 \rightarrow NO_3^-\ Rx\ 3$$

These added ions exceed soil capacity and end up runoff water, polluting our rivers and lakes.

- Denitrification: This anaerobic reaction pathway reproduces N_2 from nitrate Here is the net reaction:

$$2NO_3^- + 10e^- + 12H^+ \rightarrow 2N_2 + 6H_2O$$

- Anammox reaction: This more recently discovered bacterial anaerobic reaction pathway converts ammonium and nitrate to N_2. Here is the net reaction

$$NO_2^- + NH_3^+ \rightarrow N_2 + 2H_2O$$

- Ammonification (not to be confused with mummification) occurs when plants and animals decompose, which returns ammonium to the soil for reuse by plants and microbes.

These reactions are shown in the abbreviated Nitrogen Cycle shown in Figure 22.1.2.

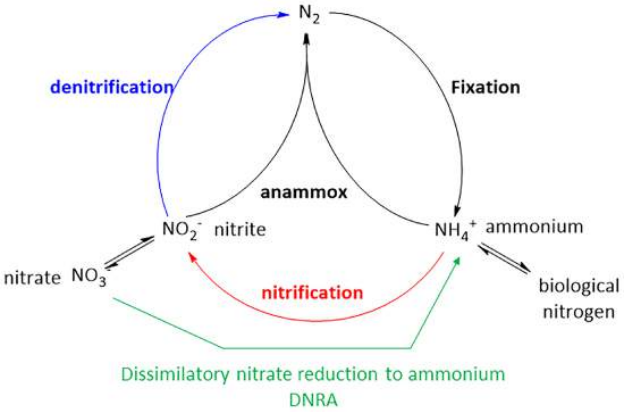

Figure 22.1.2: Abbreviated Nitrogen Cycle

Nitrogen metabolites are nutrients for plants and perhaps the most important nutrients in the regulation of plant growth (primary productivity) and in regulating life diversity in the biosphere. All living organisms require feedstocks to produce energy and as substrates for biosynthetic reactions. Which is used depends on the organism. Plants are primary producers so they use their synthesized carbohydrates for both energy production and biosynthesis. For carnivores, proteins and their derived amino acids are the source of energy (through oxidation) and serve as biosynthetic precursors. For omnivorous organisms, the source of energy depends on the "fed" state. With abundant food resources, carbohydrates, and lipids are the source of energy. Unlike carbohydrates and lipids, which can be stored as glycogen and triacylglycerols for future use, excess protein, and their associated amino acids can not be stored, so amino acids can be eliminated or used for oxidative energy.

In the fed state, carbohydrates are the main source, while in the unfed state, lipids take a predominant role. Under starving conditions, the organism's own proteins are broken down and used for oxidative energy production and for any biosynthesis that remains. In diseased states like diabetes, which can be likened to a starving state in the presence of abundant carbohydrates, both lipids and amino acids become the sources of energy.

How are amino acids in animals oxidatively metabolized? Many pathways could be used to do so but it would seem logical that NH_4^+ would be removed and the carbons in the remaining molecule would eventually enter glycolysis or the TCA cycle in the form of ketoacids. NH_4^+ is toxic in high concentrations. Ammonium is not oxidized to nitrite or nitrates in humans as occurs in the soil by microorganisms. It can be recycled back into nucleotides or amino acids, and excess amounts are eliminated from the organism. Both processes must be highly controlled. We will turn out attention to the oxidation of amino acids in the next section.

22.1.2: NITROGENASE: AN INTRODUCTION

Beauty is in the eye of the beholder.

As the domain of biochemistry covers the entire biological world, the extent of coverage of a given topic in textbooks can depend, in part, on the interest and experiences of the author(s) presenting the material. Is relevance a metric that should determine coverage? If so, books focused on human or medical biochemistry would surely omit photosynthesis. If topics are selected based on their importance for life, then photosynthesis must surely be covered. If so, then nitrogenase must also be included. If the degree of chemical difficulty for a chemical reaction and the amazing eloquence of the evolved biochemistry solution is considered, then both photosynthesis and nitrogen fixation must be presented. Even though nitrogen fixation is a reductive reaction, it shares strong similarities with the oxygen-evolving complex of photosynthesis. They catalyze enormously important redox reactions that involve an abundant atmospheric gas using a very complicated and unique inorganic metallic cofactor that evolution has selected as uniquely suited for the job.

Every first-year student of chemistry can draw the Lewis structure of dinitrogen, N_2, which contains a triple bond and a lone pair on each nitrogen. If Lewis structures speak to them, they should be able to state that the triple bond makes N_2 extraordinarily stable, thus explaining why we can breathe an atmosphere containing 80% N_2 and not die. If they have taken biology, they are also aware that very few biological organisms can utilize N_2 as a substrate, as this requires breaking bonds between the nitrogen atoms, a chemical process reserved for nitrogen "fixing" bacteria found in rhizomes of certain plants. Lastly, they probably memorized that high pressure and temperature are needed in the Haber-Bosch process used to convert N_2 and H_2 to ammonia, NH_3. As with any scientific advance, the Haber-Bosch process has brought both harm (it's used for explosive weapons) and good (fertilizers). This process now fixes enough N_2 in the form of fertilizers to support half of the world's population, with nitrogenase supporting the rest. Efforts are underway to genetically modify plants to make nitrogenase, eliminating the need for fertilizers but perhaps creating unforeseen problems of its own.

You might be surprised to find out that at room temperature the equilibrium constant favors ammonia formation, hence $\Delta G^0 < 0$. The reaction is favored enthalpically as it is exothermic at room temperature. It is disfavored entropically as should be evident from the balanced equation:

$$N_2(g) + 3\,H_2(g) \rightarrow 2\,NH_3(g).$$

The thermodynamic parameters for the reaction (per mol) are ΔH° = –46.2 kJ, ΔS° = –389 J K–1, and ΔG° = –16.4 kJ at 298 K

The entropy is negative since the reaction proceeds from 4 molecules to two molecules. From an enthalpy perspective, if you raise the temperature of an exothermic reaction, you drive it in a reverse direction. If you increase the pressure, you shift the equilibrium to the side that has the fewest number of molecules.

If the reaction is favored thermodynamically at room temperature, why doesn't it proceed? This story sounds familiar as this same descriptor applies to the oxidation of organic molecules with dioxygen. There we showed using MO theory that the reaction is kinetically slow. Same with NH_3 formation. A superficial way to see this is that we must break bonds in the stable N_2 to start the reaction, leading to a high activation energy, and making the reaction kinetics sluggish.

One could jump-start the reaction by raising the temperature, but that would slow an exothermic reaction. The Keq (or K_D) and ΔG^0 are functions of temperature and for this reaction, the reaction becomes disfavored at higher temperatures. The solution Haber found was high pressure, forcing the reaction to the side that has fewer molecules of gas, and high temperature to overcome the activation energy barrier and make the reaction kinetically feasible. A complex metal catalyst (magnetite - Fe_3O_4 -with metal oxides like CaO and Al_2O_3 which prevent reduction of the Fe with H_2) provides an absorptive surface to bring reagents together and facilitate bond breaking in H_2 and N_2.

In photosynthesis, the **oxygen-evolving complex** (OEC) with Mn, Fe, S, and Ca is used to oxidize another very stable and ubiquitous molecule, H_2O. Now we explore the amazing mechanisms behind the nitrogenase complex which fixes N_2 to form NH_3 in a reductive fashion.

What might be needed to drive this reaction biologically? You might surmise the list to include:

- a source of energy, most likely ATP, to facilitate this complex reaction;
- a source of electrons as the N atoms move from an oxidation state of 0 in elemental N to 3- in NH3; this source turns out to be a protein called flavodoxin or ferredoxin. Of course, these electrons also have interesting sources before they were in the electron carriers of these proteins;
- some pretty amazing metal centers to accept and donate electrons in a controlled way; these centers are mostly FeS clusters with an additional cluster containing molybdenum (Mo). The clusters are named F, P, and M
- a source of hydrogen; you might have guessed correctly that it's not H_2 gas (from where would that come?), but H^+ ions which are pretty ubiquitously available.
- a net reaction that is different that the Haber-Bausch process ($N_2 + 3H_2 \rightarrow 2\,NH_3$).

Here is the actual reaction catalyzed by nitrogenase:

$$N_2 + 8\,e^- + 16\,ATP + 8\,H^+ \rightarrow 2\,NH_3 + H_2 + 16\,ADP + 16\,Pi.$$

Let's think a bit about the reaction. As electrons are added the attraction between the nitrogen atoms must decrease. Eventually, bonds between them must be broken. Protons could be easily added to maintain charge neutrality. A basic mechanism might involve intermediates as shown in Figure 22.1.3.

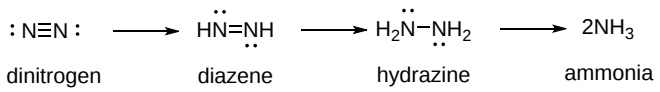

Figure 22.1.3: Possible intermediates in the conversion of dinitrogen to ammonia by nitrogenase

Nitrogenase can also other small molecules with triple bonds, including C≡O: and H-C≡C-H.

22.1.3: THE STRUCTURE OF NITROGENASE

Nitrogenase is a multiprotein complex in which the functional biological unit is built from **two** sets of the following dimeric structures:

- a homodimer of subunits, E and F, which have binding sites for the mobile carrier of electrons (the protein ferredoxin or flavodoxin), ATP, and an FeS cofactor (4Fe-4S, called the F cluster) which accept electrons. These subunits are hence called the nitrogenase reductase subunits
- a heterodimer of alpha and beta subunits. The a (alpha chain) binds the 8Fe-7S F cluster and the Fe-S-Mo M cluster. These subunits comprise the (di)nitrogenase catalytic subunits. The iron-molybdenum M cluster is in the α subunit and is where N_2 reduction occurs. The P-cluster is between the α and β subunits and facilitates electron flow between the Fe-protein (F cluster) and FeMo-cofactor (M cluster)

For clarity, one-half of the overall structure of the protein complex with bound ATP and metal centers is shown in Figure 22.1.4.

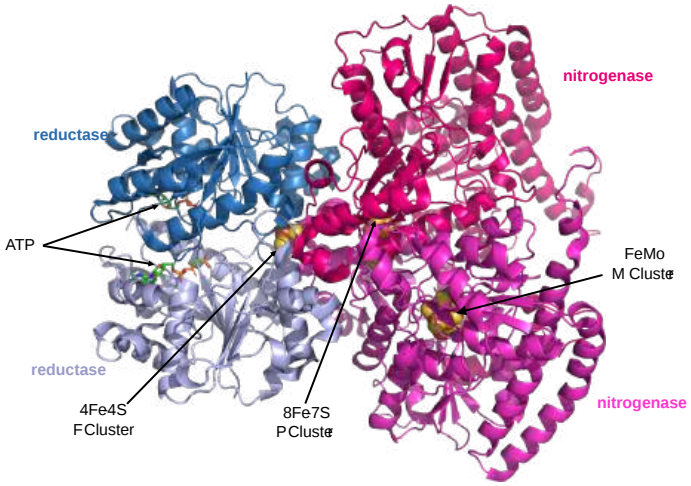

Figure 22.1.4: Nitrogenase structure (4wzb)

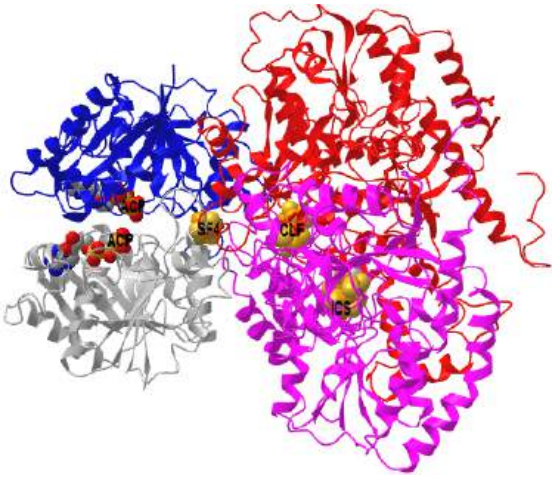
This half-structure consists of a homodimer of the reductase monomers and a heterodimer of nitrogenase subunits.

Figure 22.1.5 shows an interactive iCn3D model of the half structure of nitrogenase complex from Azotobacter vinelandii (4WZB) (long load).



NCBI iCn3D Figure 22.1.5: Nitrogenase complex from Azotobacter vinelandii (4WZB). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...zPNjfPRwq8MSeA (long load))

The structure is color-coded in a fashion similar to Figure 4. The F cluster is labeled as SF4, the P cluster as CLF (FE(8)-S(7) cluster), and the M cluster as ICS (iron-sulfur-molybdenum cluster with interstitial carbon).

The reductase subunits (called Av2 in *Azotobacter vinelandii*), accept electrons from ferredoxin and is where the ATP analog, ACP (phosphomethylphosphonic acid adenylate ester), and the 4Fe-4S F cluster is bound. The nitrogenase subunits (called Av1 in *Azotobacter vinelandii*) convert N_2 to NH_3 and is where the 8Fe-7S P cluster, FeMo (C Fe_7 Mo S_9) M Cluster is bound.

An enhanced view of the bound cofactors and ATP is shown in the same spatial orientation in Figure 22.1.6 below.

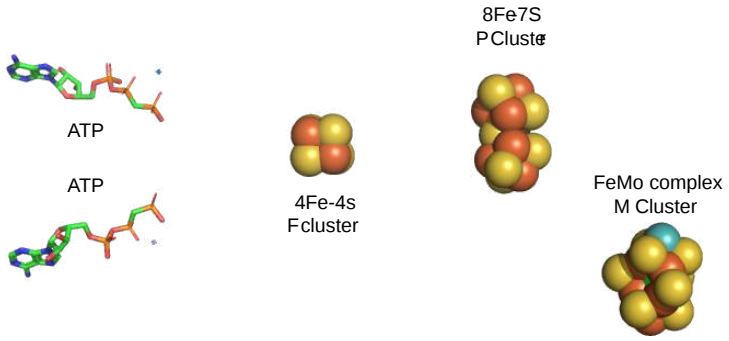


Figure 22.1.6: Bound cofactor metal clusters and ATP in nitrogenase

You can easily image the direction of the flow of electrons from the F cluster to the P cluster to the M cluster.

The metal centers are shown in Figure 22.1.7 in more detail in both line and space fill views.

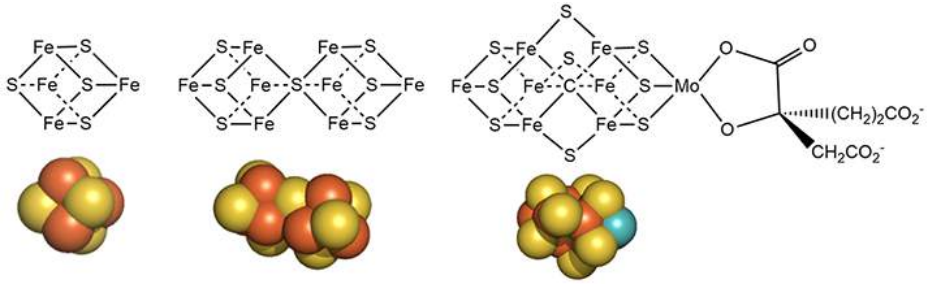

Figure 22.1.7: Detailed structures of the metal cofactors in nitrogenase

Mo is bound to 3 sulfur ions and oxygen from 3-hydroxy-3-carboxy-adipic acid as shown in Figure 7 above.

The M cluster has an interstitial carbide ion that derives from -CH_3 attached to the sulfur of S-adenosyl-methionine (SAM) allowing the carbide to be labeled with either ^{13}C or ^{14}C for mechanistic studies. These labeled carbides are not exchanged or used as a substrate when the enzyme undergoes catalytic turnover. Hence it seems that the carbide probably just stabilizes the M cluster. it won't be shown in the figures below showing more detailed mechanisms.

We'll focus on two features of the reaction mechanism, ATP hydrolysis and the flow of electrons and protons to N_2 as it is reduced to NH_3.

22.1.4: ATP HYDROLYSIS

ATP binds in the reductase subunit (AV2) where ferredoxin brings in electrons, and where the F metal cluster is bound. Much as GTP hydrolysis controls conformational change and subunit dissociation in the heterotrimeric $G_{\alpha\beta\gamma}$ in signal transductions, ATP hydrolysis in reductase (AV2) subunits, drives not only electron transfer but dissociation/reassociation of the reductase and nitrogenase catalytic subunits. It appears that 2 ATPs are hydrolyzed per electron transferred from the F cluster to the Mo M cluster. Since the oxidation numbers of N are 0 and -3 in N_2 and NH_3, respectively, sequential rounds of ATP hydrolysis and dissociation/reassociation occur. Note that the Fe-protein hydrolyzes ATP only when bound to the MoFe-protein.

The overall reaction involves the reduction of N_2 to two molecules of NH_3 at the FeMo cofactor. It involves a reductive elimination of hydrides that are bridged by Fe ions (Fe-H-Fe) in a reaction that also makes H_2 as a by-product. We'll describe this complex reaction next.

22.1.5: NITROGENASE REACTION: PART 1 - ADDITION OF ELECTRONS AND PROTONS

The sequential path of electrons from the reductase subunit containing the F cluster to the P and M clusters in the nitrogenase subunit should be apparent from the figures above. We will concentrate on the binding of N_2 and how it receives electrons from the M cluster. Figure 22.1.8 shows the FeMo-cofactor and some adjacent amino acid residues. Mo is labeled but not shown in spacefill. HCA is a bound molecule of 3-hydroxy-3-carboxy-adipic acid, which interacts with Mo. The carbide is shown in the middle as the green sphere and labeled CX.

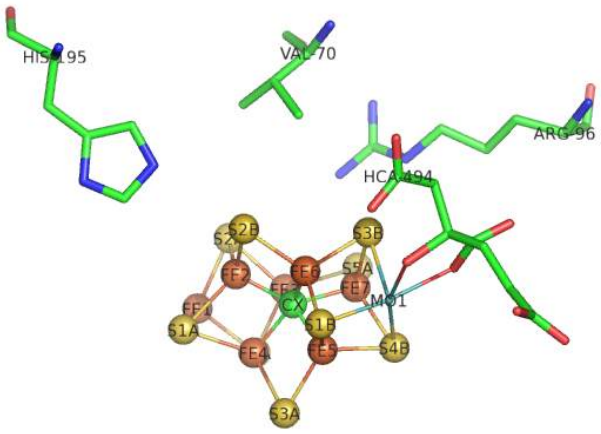

Figure 22.1.8: Side chains near the M cluster

If Val 70 is mutated to Ile, a substrate appears not to access the cluster suggesting that N_2 may interact with the top part of the structure with the residues shown acting as gatekeepers. His side chains are often found at enzyme active sites so you might expect His 195 to be a general acid/base. Mutations lead to drastic losses in the reduction of N_2. His 195 is involved in hydrogen bonds to sulfur S2B and bridges Fe2 and Fe3 in Figure 8, where reduction of N_2 likely occurs. If His 195 moves, it can form short H bonds between the imidazole N and an H bond to HFe2. If the ring is rotated 180^0, no proton transfer occurs from the surface. It appears that His195 might be involved in the first N_2 protonation event.

The Lowe and Thorneley (LT) model has been proposed as a mechanism for dinitrogen reduction. In this model, an electron and proton are added to the oxidized form of the enzyme (E_o) to produce E_1. This is repeated 3 more times to form sequentially, E_2, E_3, and E_4. Only then does N_2 bind and the reduction of N_2 occurs. Two of the added electrons are accepted by H^+ ions which form H_2, which is liberated on N_2 binding. Hence only 6 electrons are added to the actual N_2 molecule, in agreement with the change in oxidation numbers discussed above. The Lowe and Throneley model is shown in Figure 22.1.9.

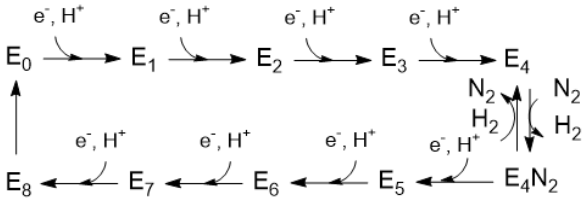

Figure 22.1.9: Lowe and Throneley model for electron and proton additions in nitrogenase

The crystal structure shows 2 ATP analogs bound to the reductase subunit. The stoichiometry of the reaction shows 16 ATP used. Simple math suggests that 2 ATP are cleaved to support the entry of one electron into the complex, assuming 8 transferred electrons (6 to N_2 and 2 to 2 protons to form H_2).

Part 1 - E1-E4: A potential structure for the E4 intermediate is shown in Figure 22.1.10.

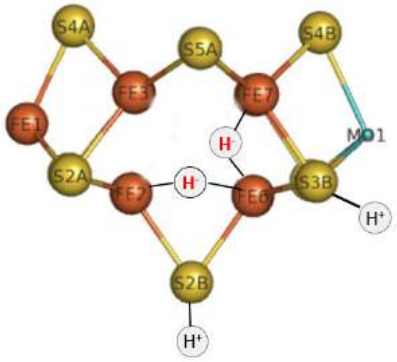

Figure 22.1.10: The E4 Janus intermediate in the reduction of N_2.

Note the central carbide is not shown. This is often called the **Janus intermediate** as it is halfway through the catalytic cycle. It is named for Janus, the Roman god of beginnings and transitions, and has been ascribed to gates, doors, doorways, and passages. Janus is typically

shown with two faces, one looking to the future and one to the past (image below: DOI:10.1590/2177-6709.21.1.018-023.oin. License CC BY 4.0 Creative Commons Attribution 4.0 International)

The hydrides bridge 2 Fe ions so these are examples of three-center, two-electron bonds. The H^+ ions in Figure 10 balance the charge from the hydrides.

How does this reaction occur? We must look to organometallic chemistry to help us understand the mechanism of this and subsequent steps. Hydride equivalents have been added to the metals, associated with the oxidation of metal ions in the center. This particular reaction is called an **oxidative addition**. Presumably, the sulfur ions act as Lewis bases as they gain protons from a Lewis acid, probably His 195.

Oxidative addition reactions

Figure 22.1.11 shows oxidative additions to metal centers for three different types of reactants.

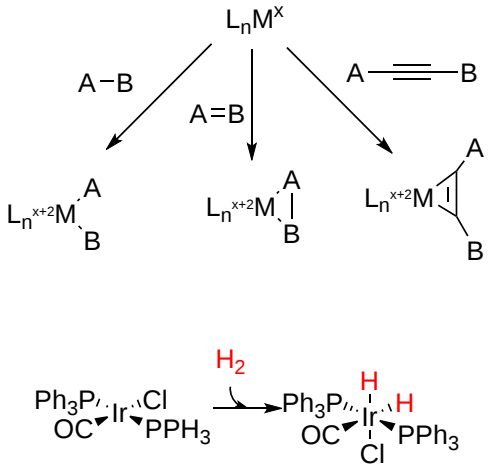

Figure 22.1.11: Three different types of oxidative addition reactions (after Schaller, http://employees.csbsju.edu/cschaller/ROBI1.htm)

In oxidative insertion, the oxidation state of the metal ion increases, hence the name oxidative. The hydrogens are now hydrides. Note the example for insertion of H_2, an example similar to the proposed hydride additions to the M cluster. Oxidative reduction occurs most readily when the two oxidation states of the metal ion are stable. It is likewise favored for metal centers that are not sterically hindered (makes sense if A-B is to be added) and if A-B has a low bond dissociation energy.

One way to study reaction intermediates is to trap them. If N_2 can't access the binding site and the temperature is reduced, the accumulated hydrides (and for charge balance the H+s) in E4 might leave in the opposite reaction, reductive elimination, which we will discuss below, as the reaction goes back to E1. In the elimination, they could form H_2 as metal gains back electrons in a reduction. The Val70Ile discussed above would allow an intermediate to be trapped.

22.1.6: NITROGENASE REACTION: PART 2 - REDUCTION OF N_2

Step E4 to E5 seems a bit bizarre as H_2 gas is released. This would seem to waste ATP but we should trust evolution has led to this mechanism for a reason. This mechanism, the reverse of oxidative addition, is another classic organometallic reaction, **reductive elimination**.

Reductive elimination reactions

In this reaction, a molecule is eliminated or expelled from the complex as the metal ion is reduced and adds two electrons. Figure 22.1.12 shows reductive elimination. Reductive elimination occurs most readily in higher oxidation state metal centers which can be stabilized on reduction. It occurs most readily from electron-rich ligands and if the other surrounding ligands are bulky. The dissociating species must also be cis to each other in the transition metal complex so they can form a bond with each other when they leave.

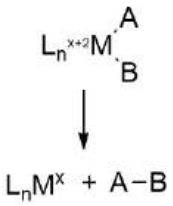

Figure 22.1.12: Reductive Elimination reaction (after Schaller, ibid)

Oxidative addition and reductive elimination (OA/RE) reactions at metal centers are often coupled together in organometallic **catalytic cycles**, in the same way as a histidine can act as a general acid and then accept a proton back as a general acid to complete the catalytic cycle. In the OA/RE reactions at metal centers, some rearrangements or other modifications can also occur. Think about it. The FeS clusters must return to their original oxidation state after the complete LT cycle. We will encounter another organometallic reaction after the addition of N_2, **migratory insertion**, in the second half of the reaction. Another advantage of coupling OA/RE is that the positive charge or oxidation state on the transition metal complex does not get too high, which is unstable. Making a cation with a positive charge more positive becomes more difficult, much as removing a second proton from a polyprotic acid is more difficult than removing the first (as reflected in the higher pKa for removal of the second proton).

Is H_2(g) really released? To study this, investigators have used alternative substrates like acetylene, HC≡CH (similar to N≡N), in the presence of D_2 and N_2 in an aqueous system. It helps to see Figure 22.1.9 again.

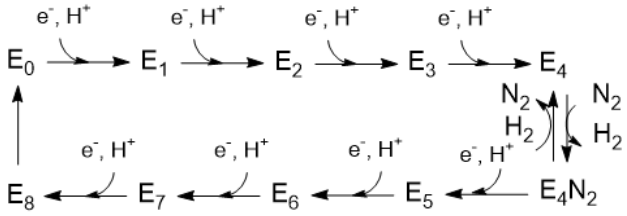

Figure 22.1.9: Lowe and Throneley model for electron and proton additions in nitrogenase

The acetylene was reduced and formed $C_2H_2D_2$ and C_2H_3D. Hence E4 must have had 2 Ds in it, and E2 probably 1. These results support the **reversible** reductive elimination mechanism for the E4 to E4:N_2 reaction above. Previously it had been shown that H^+ are reduced by D_2 in the presence of D_2 and N_2 in an aqueous system, so these results are consistent. In additional support, deuterium from D_2 is not incorporated into products ($C_2H_2D_2$, C_2H_3D, or HD) in the absence of N_2.

Let's return for a moment to the bridging hydrides as shown again Figure 22.1.10.

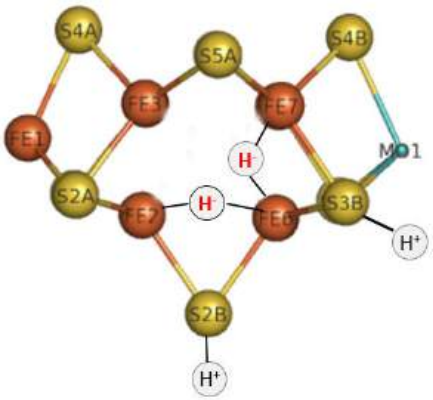

Figure 22.1.10: The E4 Janus intermediate in the reduction of N_2

To summarize, it appears likely that the reductive elimination of the two proximal bridging hydrides is the mechanism for the formation of H_2. The bridging hydrides, which are strong bases, are much less likely to be protonated than if the hydrides were terminal. A simple and competing protonation reaction could form H_2 as well, and if that occurred the reducing equivalents of the bridging hydrides would be lost. Hence the bridging hydrides (share by two metal centers) are more stable and hence can "wait" for the incoming N_2 reactants before their reducing equivalents are lost. They may convert to terminal hydrides eventually to facilitate substrate reduction (hydrogenation).

The Janus intermediate E4 is now in a position to bind N_2 and release H_2. For each H^- that binds to the M cluster, two H^+s bind to the M cluster sulfides for electrostatic stabilization.

Migratory Insertions

We need to consider one last common type of reaction at a metal center, **migratory insertions (MI)**. In a MI reaction, a group attached to a metal ion center is transferred to another group attached to the same metal. Figure 22.1.13 shows four examples of MI reactions.

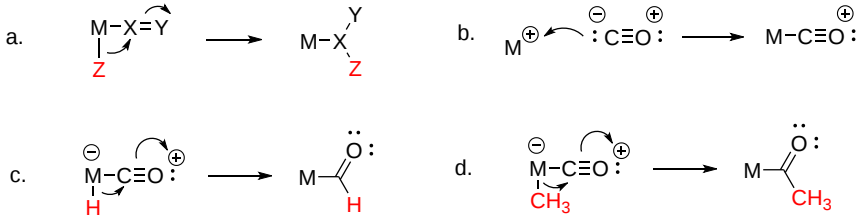

Figure 22.1.13: Migratory insertion reactions at metal centers

Panel (a) shows a generic MI reaction. Panel (b) shows the interaction of carbon monoxide, :C≡O: (isoelectronic and analogous to :N≡N:), with a metal center. Panel (c) shows how a hydride could engage in 1:1 insertion as it shifts and covalently bonds to the first atom of another ligand bound to the metal center. Note that metal does not have to have a negative charge. This could theoretically be important for the reduction of N_2 bound as a ligand through a coordinate covalent (dative) bond to the metal. Panel (d) shows the migration of an alkyl group.

We will see that the MI reaction is involved in adding Hs to N_2 starting not with N_2 but with the N_2H_2 stage as the intermediates insert into an Fe-H bond. N_2 is not reactive to the insertion of a hydride as is carbon monoxide, CO, which provides a positive oxygen to facilitate electron flow during the insertion. In addition, the oxygen become neutral after the reaction.

This offers a great explanation for how Nature chose the FeMo cluster for nitrogen fixation. The interaction of two hydrides requires a 4 Fe face (coordinated with the carbon) that allows for the storage of reducing equivalents for the initial reduction of N_2. The large M cluster is more stable and effectively held together by a central carbide anion. This also allows the metal centers to never change their oxidation state by more than 1 charge unit.

The source of the protons to form N_2H_2 comes directly from the two H_2 attached to the two sulfurs as they can't come from the hydrides which are released as H_2. The seeming wasteful reductive elimination of H_2 and energy is required to allow the kinetically unreactive N_2 molecule to bind to the reduced and activate 4Fe face which is also electrostatically facilitated by the 2 bound protons in what has been called a push (reductive)-pull (protonation) reaction. This first step in N_2 reduction to N_2H_2 is the hardest.

22.1.7: OXIDATION STATES OF NITROGENASE FE CENTERS

First Half: It would be difficult to assign specific oxidation states to each Fe ion in the M complex. Instead, we can assign relative changes in the oxidation states as the reaction proceeds from E0 to E4. In each step of the LT model, 1 electron is added. We will first assign this to an average Fe ion, M^0, with an arbitrarily assigned oxidation state of 0. On the addition of 1 electron, the oxidation state would go from M^0 to M^{-1} as the metal is reduced. The M^{-1} state is then oxidized as an electron is transferred to H^+, and when 2 electrons are transferred, a single H^- is made. The diagram in Figure 22.1.14 shows the change in oxidation state in going from E0 to E4.

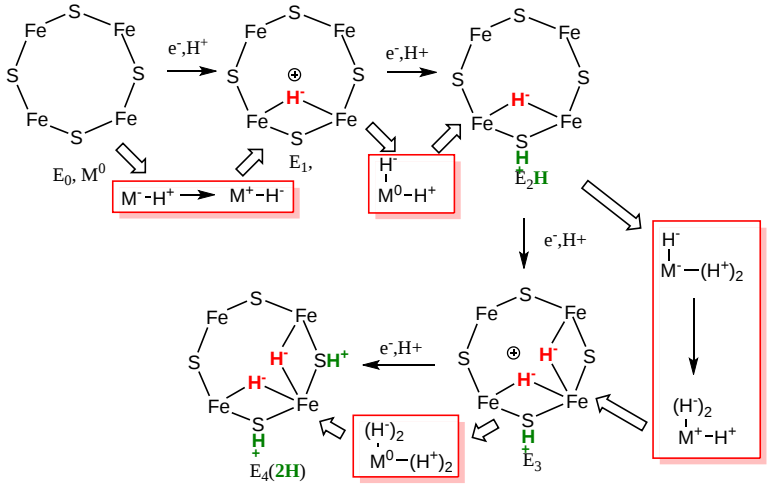

Figure 22.1.14: Change in oxidation state in going from E0 to E4

The red boxes highlight thermodynamic cycle-like steps which show how changes in the redox state of the Fe ions (M) could be visualized. Note that in going from E0 to E4, the actual oxidation state of M changes from 0 to +1 to 0 to +1 and back to 0. That is quite amazing given that 4 electrons have been added. Note also that in the red box going from step E0 to E1, M goes from -1 to +1 which corresponds to our

description of an oxidative addition when the metal center loses two electrons. This mechanism shows that nitrogenase could be considered a "hydride storage device".

Second Half (facing forward to production NH_3):

How does N_2 initially interact with E4? It must depend on how the hydrides are released as H_2, which evidence shows occurs by **reductive elimination** (re) and not hydride protonation (hp). On addition, the N_2 very quickly is converted to diazene, HN=NH, with the departing H_2 taking with it 2 H^+s and 2 electrons (or reducing equivalents). These events could occur as shown in Figure 22.1.15.

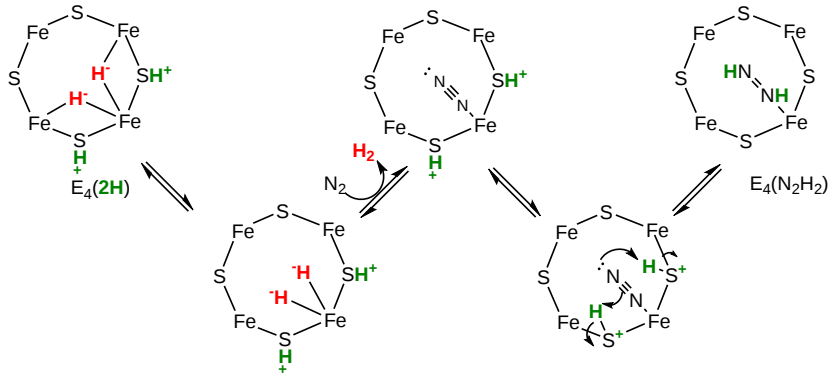

Figure 22.1.15: Reaction mechanism for the formation of N_2H_2

Now, with N_2 bound as diazene (N_2H_2) and H_2 released, the rest of the reaction could occur as shown below. One new step, a migratory insertion, is shown in Figure 22.1.16.

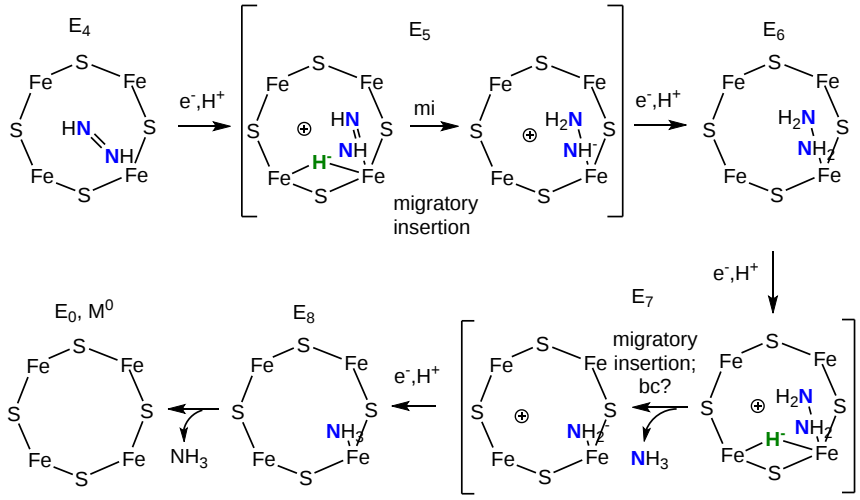

Figure 22.1.16: Reaction mechanism for the conversion N_2H_2 to NH_3.

The two halves of the reaction are similar with bridging hydrides utilized - the E4 Janus intermediate links the two halves together.

22.2: BIOSYNTHESIS OF AMINO ACIDS

22.2.1: INTRODUCTION

By the time many students get to the study of amino acid biosynthesis, they have seen so many pathways that learning new pathways for the amino acids seems daunting, even though they can be clustered into subpathways. Most know that from a nutrition perspective, amino acids can be divided into nonessential and essential (need external dietary supplementation) amino acids. These are shown for humans below.

- Nonessential amino acids: Alanine, Asparagine, Aspartate, Cysteine, Glutamate, Glutamine, Glycine, Proline, Serine, Tyrosine
- Essential amino acids: Arginine*, Histidine, Isoleucine, Leucine, Lysine, Methionine*, Phenylalanine*, Threonine, Tryptophan, Valine

Three of the essential amino acids can be made in humans but need significant supplementation. Arginine is depleted in processing through the urea cycle. When cysteine is low, methionine is used to replace it so its levels fall. If tyrosine is low, phenylalanine is used to replace it.

The amino acids can be synthesized from glycolytic and citric acid cycle intermediates as shown in Figure 22.2.1

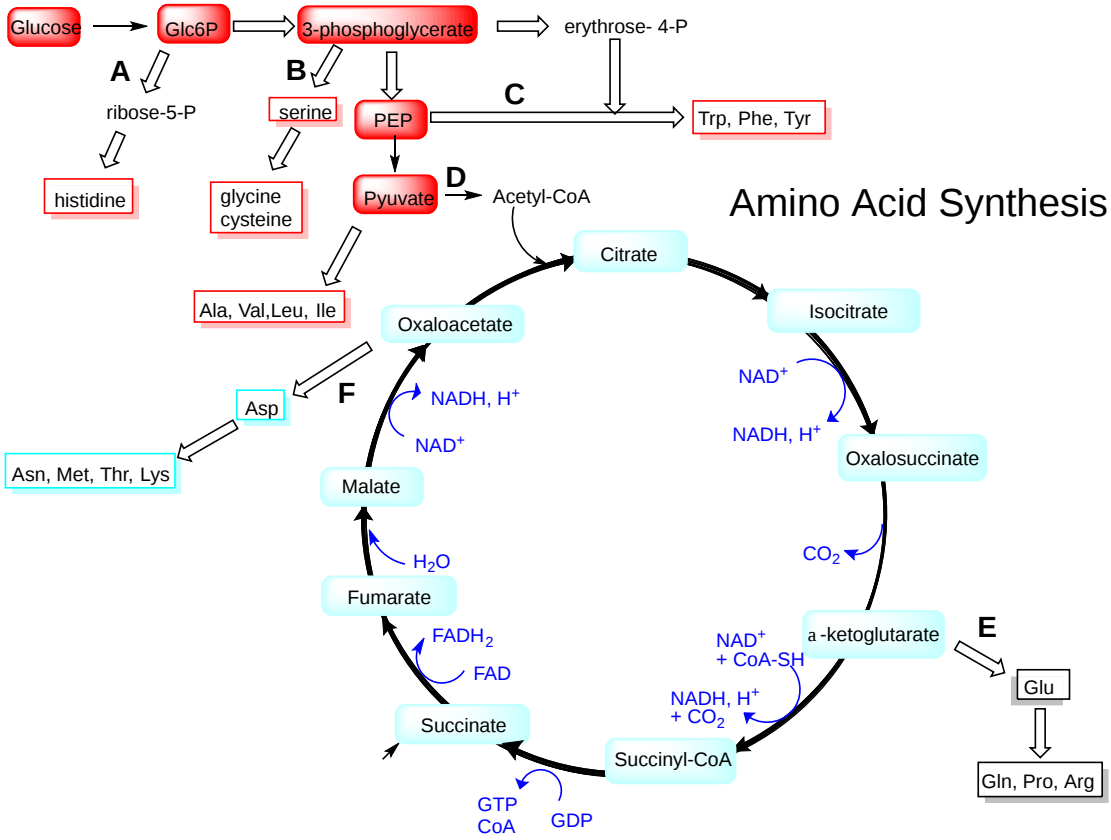

Figure 22.2.1: Summary amino acid synthesis from glycolytic and TCA intermediates

For this chapter subsection, we will provide only the basic synthetic pathways in abbreviated form without going into mechanistic or structural details

22.2.2: AMINO ACID SYNTHESIS FROM GLYCOLYTIC INTERMEDIATES

22.2.2.1: FROM GLUCOSE-6-PHOSPHATE: HISTIDINE

The synthesis of histidine from a phosphorylated form of ribose (derived from glucose-6-phosphate) is shown in Figure 22.2.2.

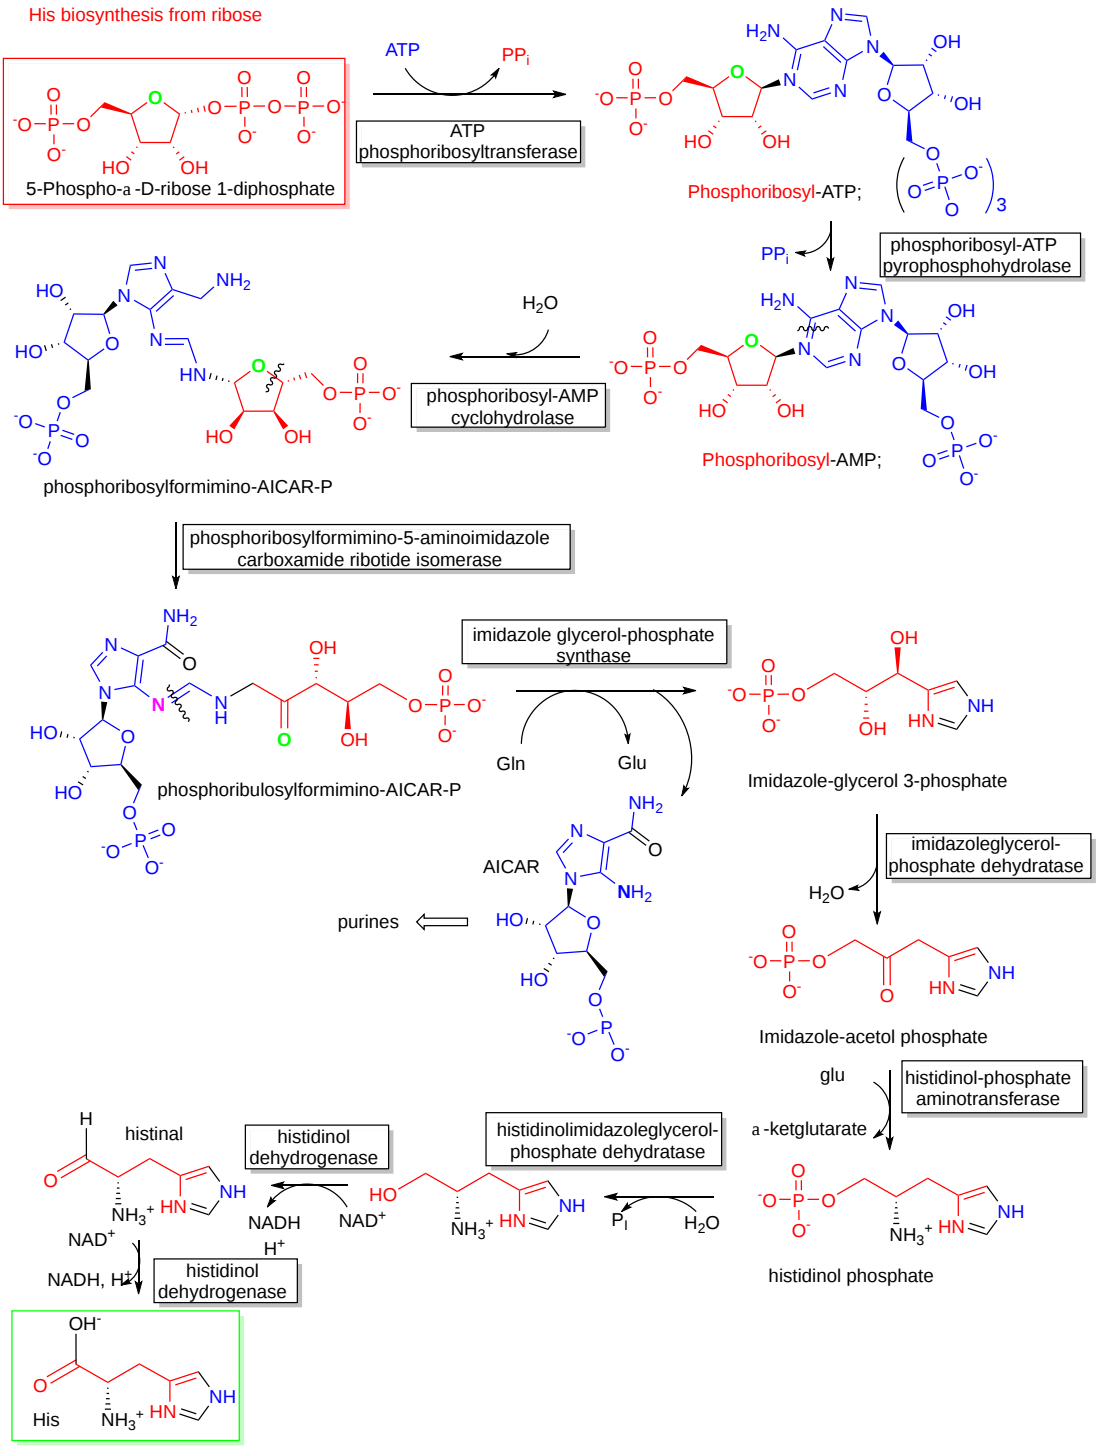

Figure 22.2.2: Synthesis of histidine from a phosphorylated form of ribose

22.2.2.2: FROM 3-PHOSPHOGLYCERATE: SERINE, GLYCINE, AND CYSTEINE

The synthesis of serine, glycine, and cysteine from 3-phosphoglycerate is shown in Figure 22.2.3.

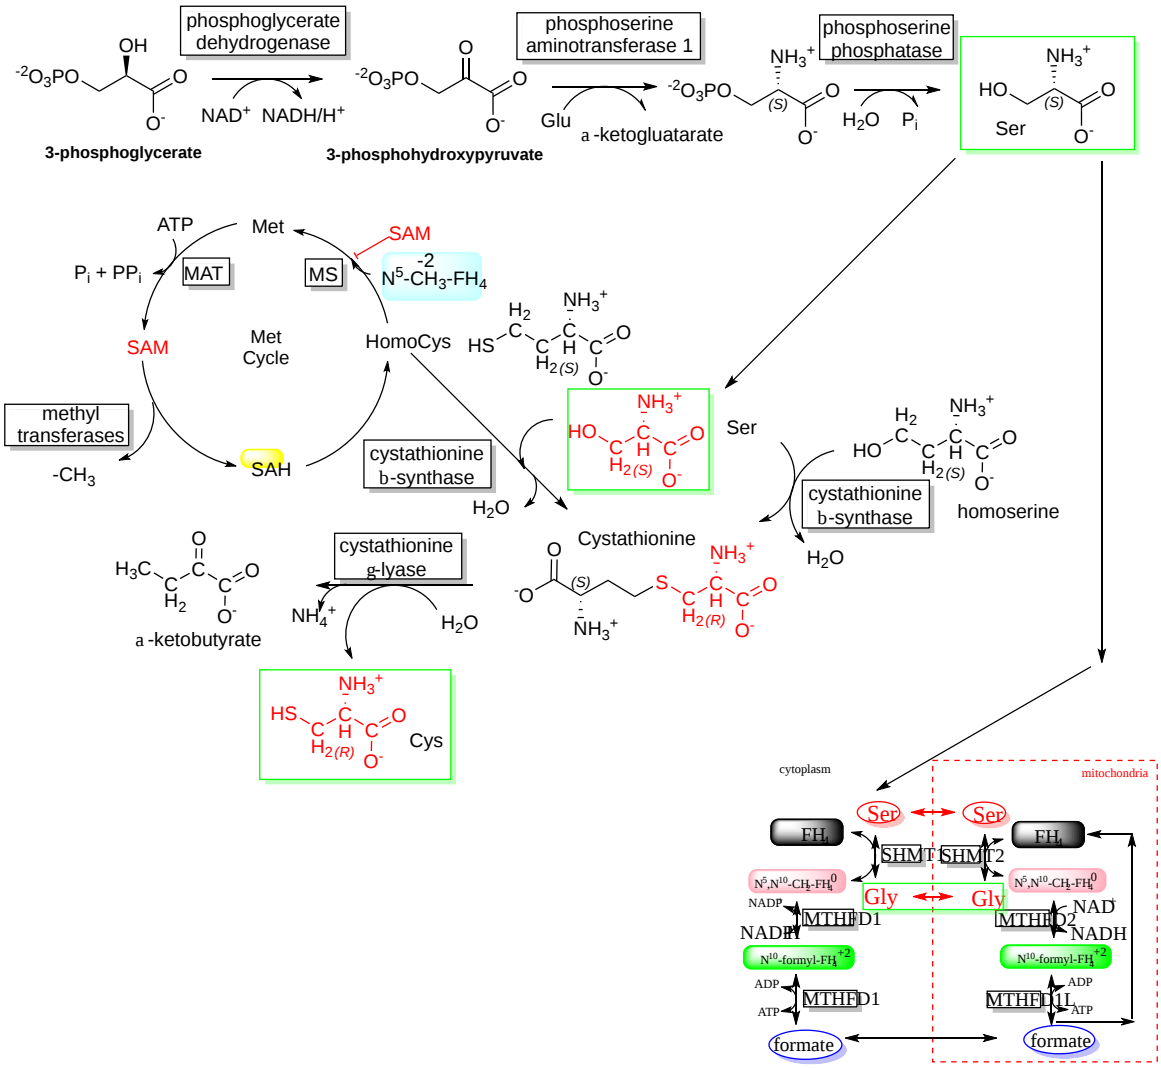

Figure 22.2.3: The synthesis of serine, glycine, and cysteine from 3-phosphoglycerate

22.2.2.3: FROM PHOSPHENOL PYRUVATE: THE AROMATICS - TRP, PHE, AND TYR

The synthesis of the first of the biosynthetic pathways for the aromatic amino acids phenylalanine, tryptophan, and tyrosine from phosphoenolpyruvate up to chorismate is shown in Figure 22.2.4.

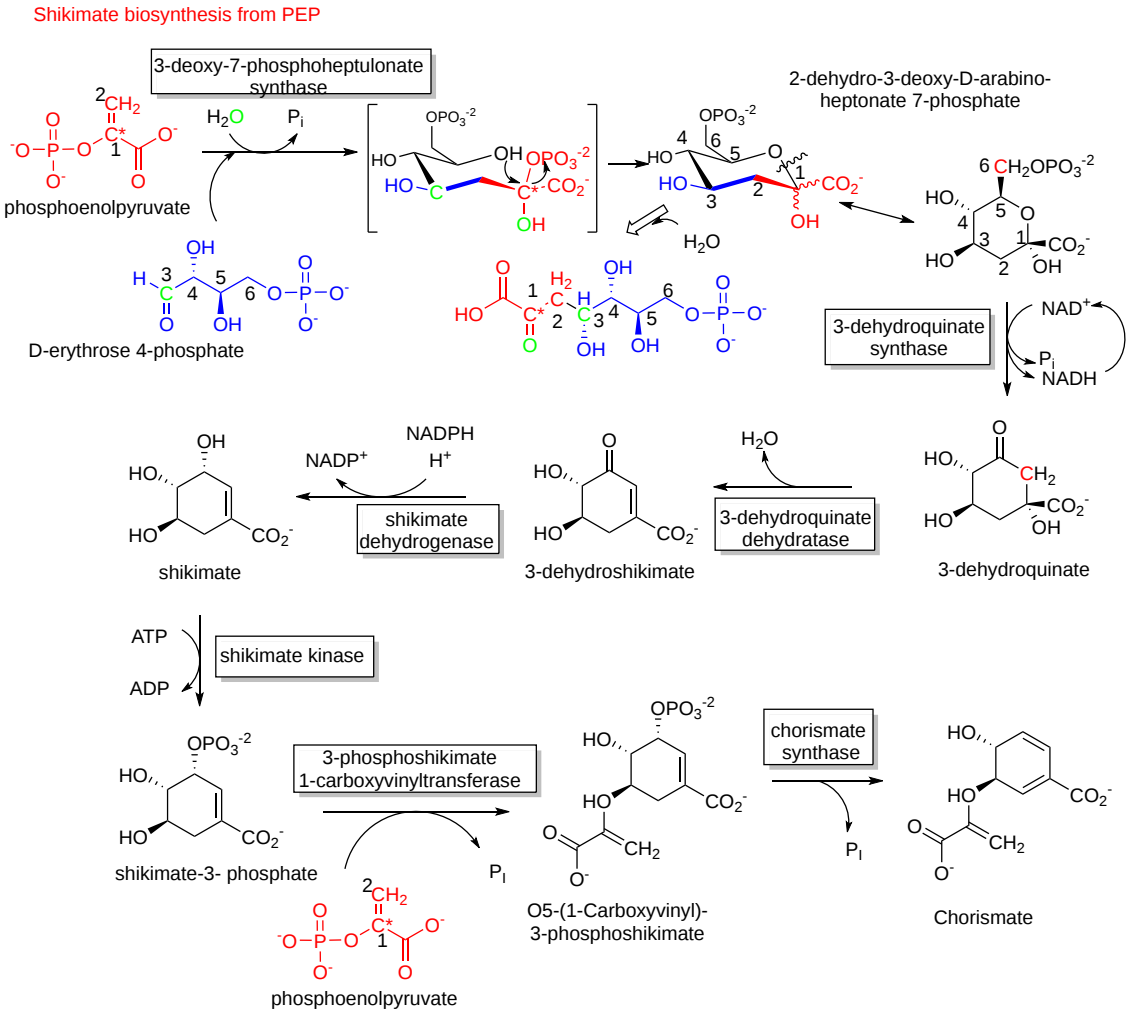

Figure 22.2.4: Synthesis of the first of the biosynthetic pathways for the aromatic amino acids phenylalanine, tryptophan, and tyrosine from phosphoenolpyruvate up to chorismate

Chorismate to tryptophan

The synthesis of the second half of the biosynthetic pathway for tryptophan from chorismate is shown in Figure 22.2.5

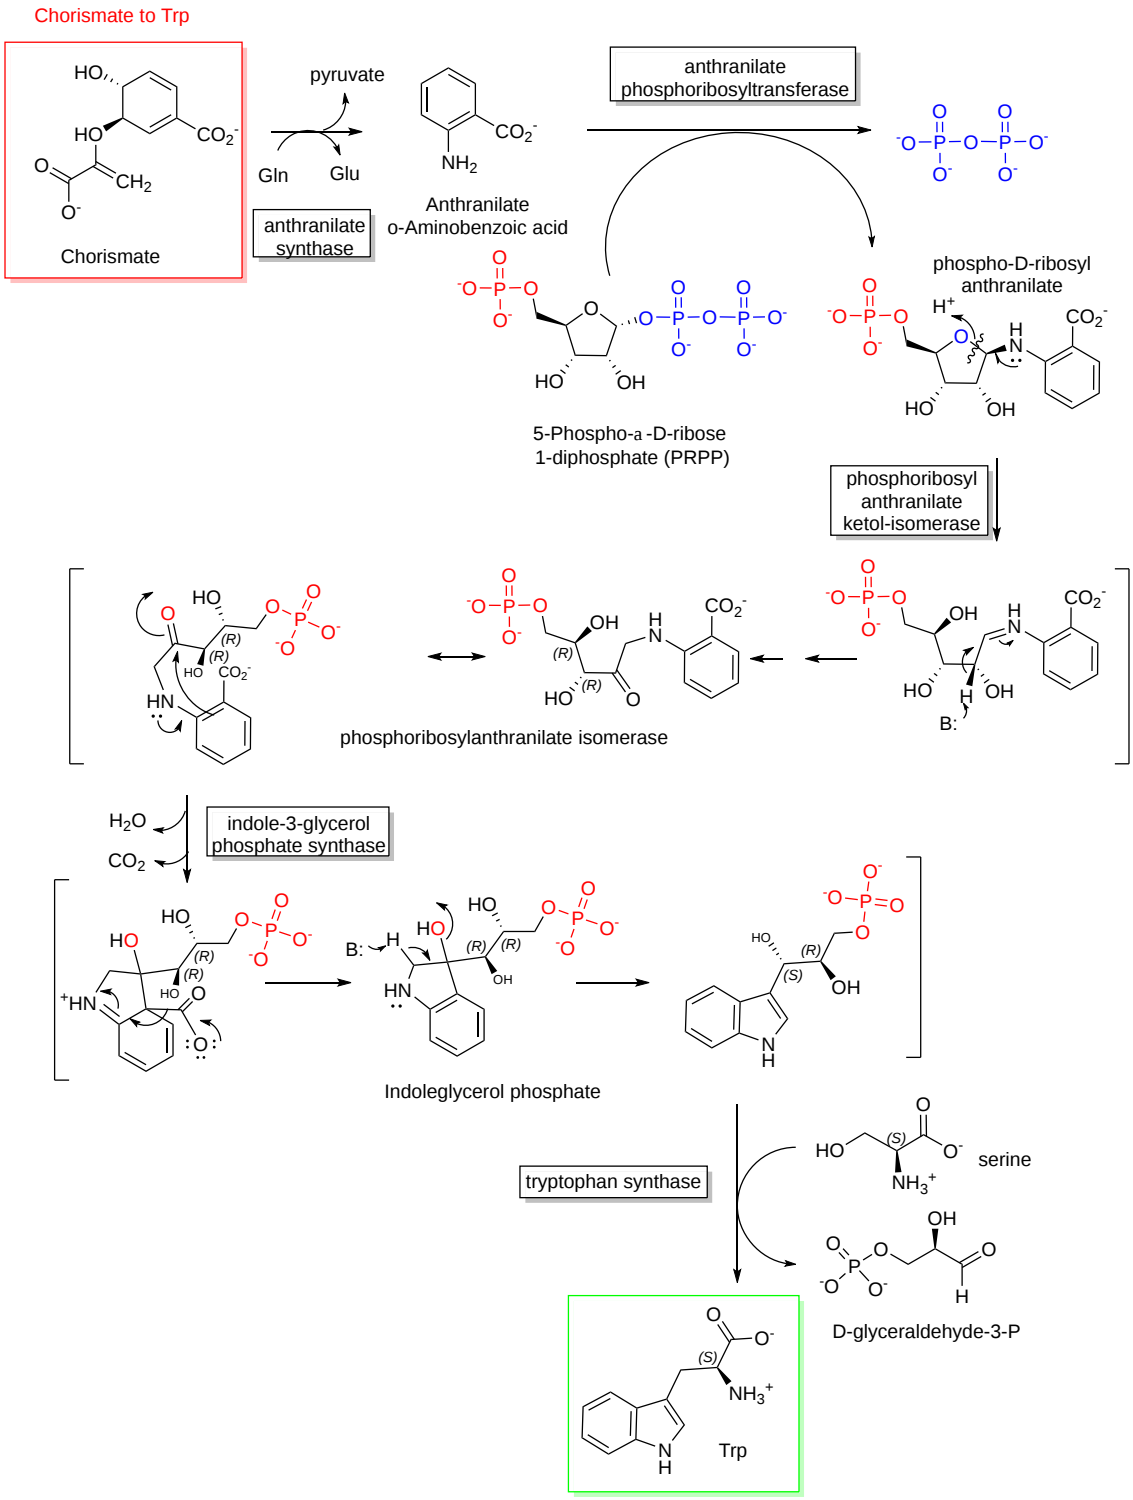

Figure (\PageIndex{5}\): Synthesis of the second half of the biosynthetic pathways for the aromatic amino acid tryptophan from chorismate

Chorismate to Phe and Tyr

The synthesis of the second half of the biosynthetic pathway for phenylalanine and tyrosine from chorismate is shown in Figure 22.2.6

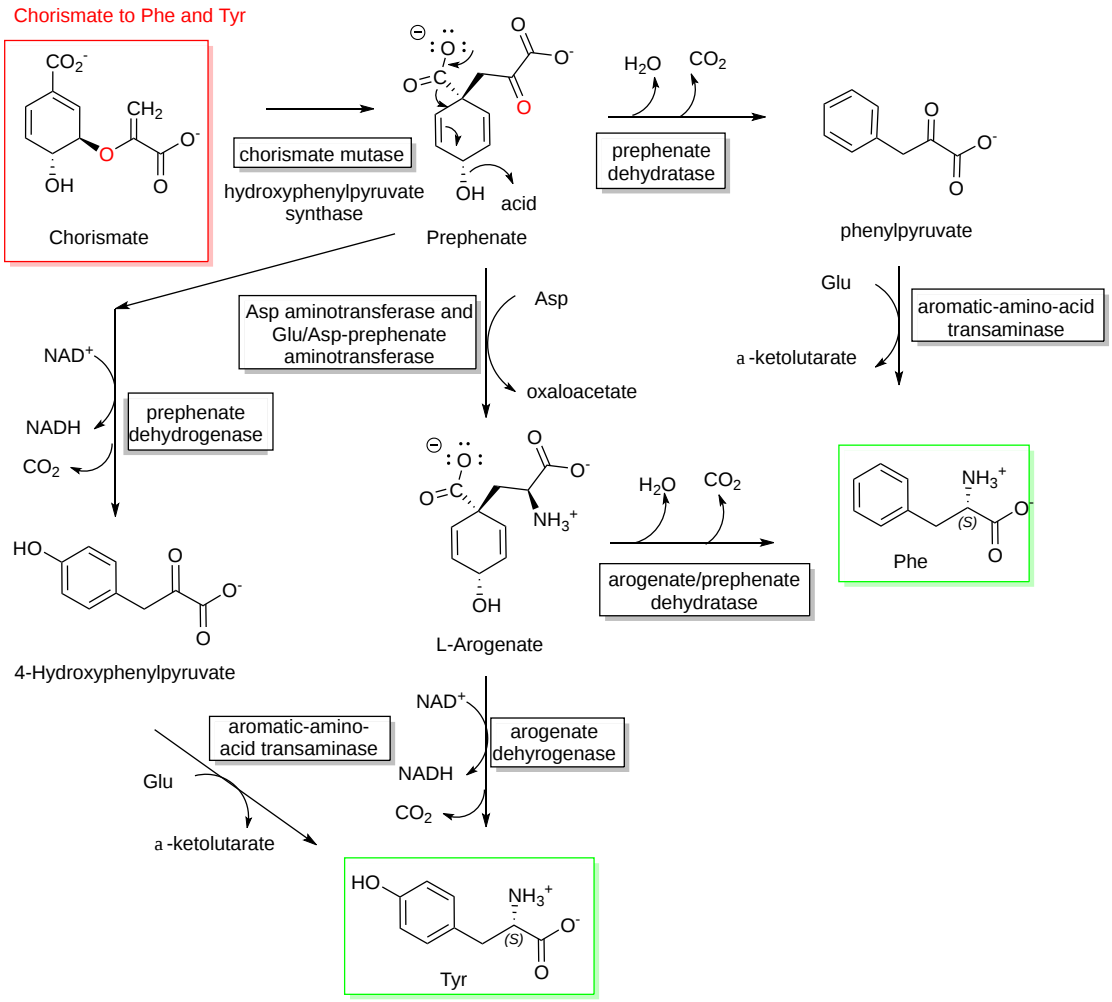

Figure 22.2.6: Synthesis of the second half of the biosynthetic pathway for phenylalanine and tyrosine from chorismate

22.2.2.4: FROM PYRUVATE: ALA, VAL, LEU, ILE

Ala can easily be synthesized from the alpha-keto acid pyruvate by a transamination reaction, so we will focus our attention on the others, the branched-chain nonpolar amino acids Val, Leu, and Ile.

The synthesis of valine, leucine, and isoleucine from pyruvate is shown in Figure 22.2.7.

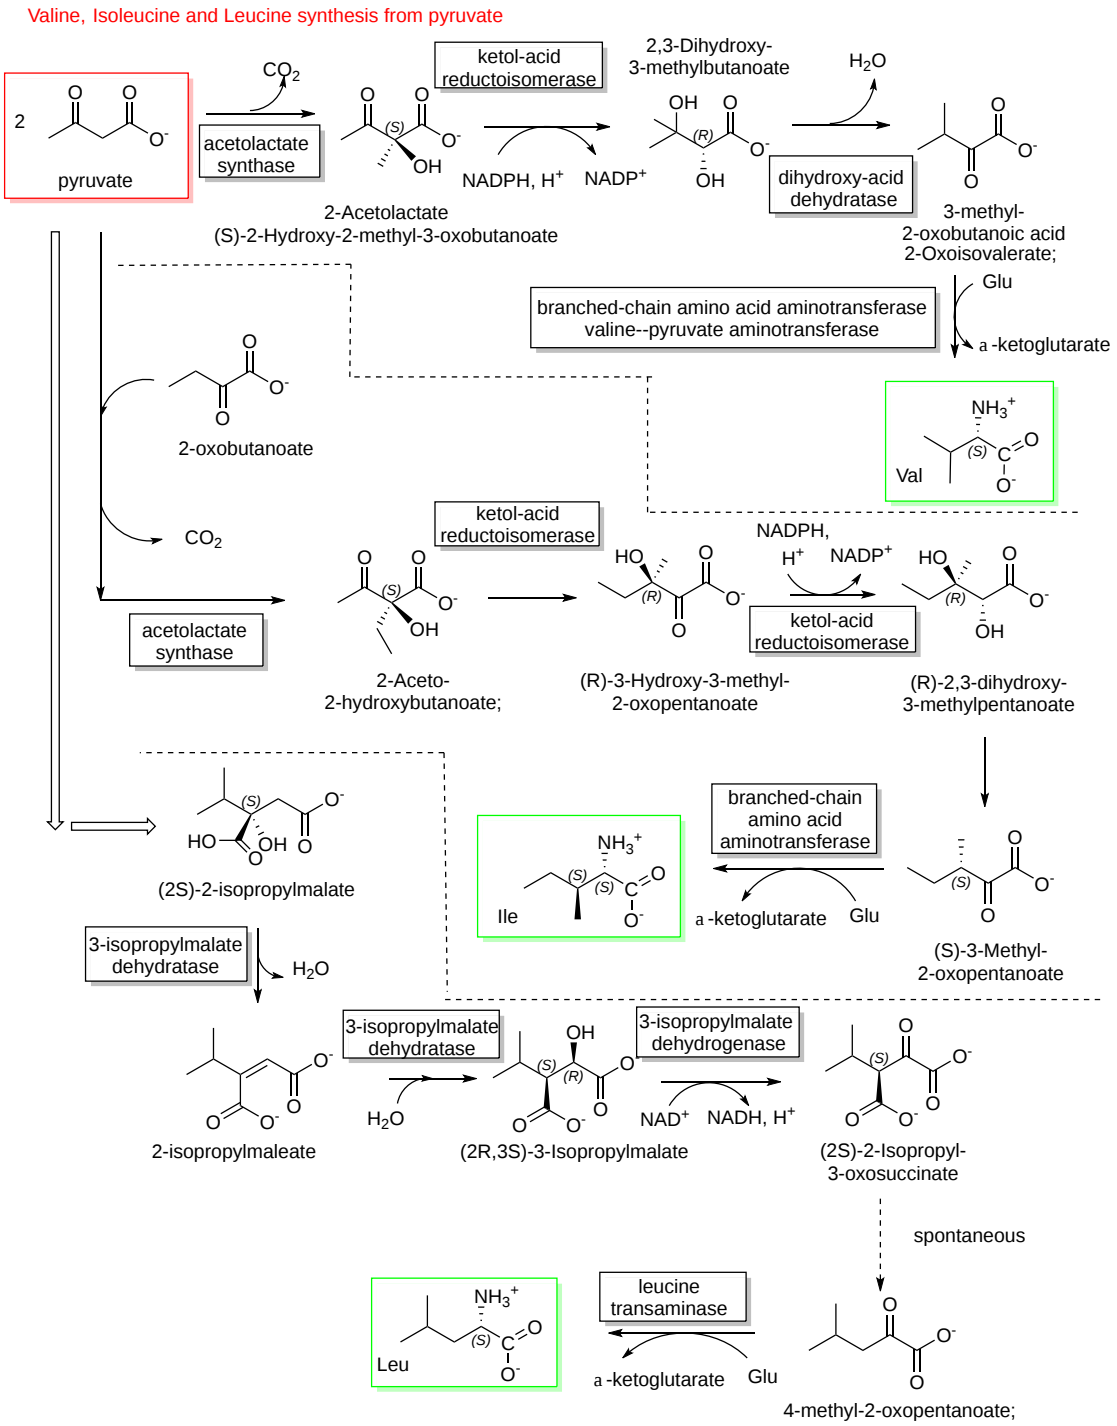

Figure 22.2.7: The synthesis of valine, leucine, and isoleucine from pyruvate

22.2.3: TCA INTERMEDIATES

22.2.3.1: FROM A-KETOGLUATARATE: GLU, GLN, PRO, ARG

Since amino acid metabolism is so complex, it's important to constantly review past learning. Figure 22.2.8 from section 18.2 shows the relationship among Glu, Gln, and keto acids.

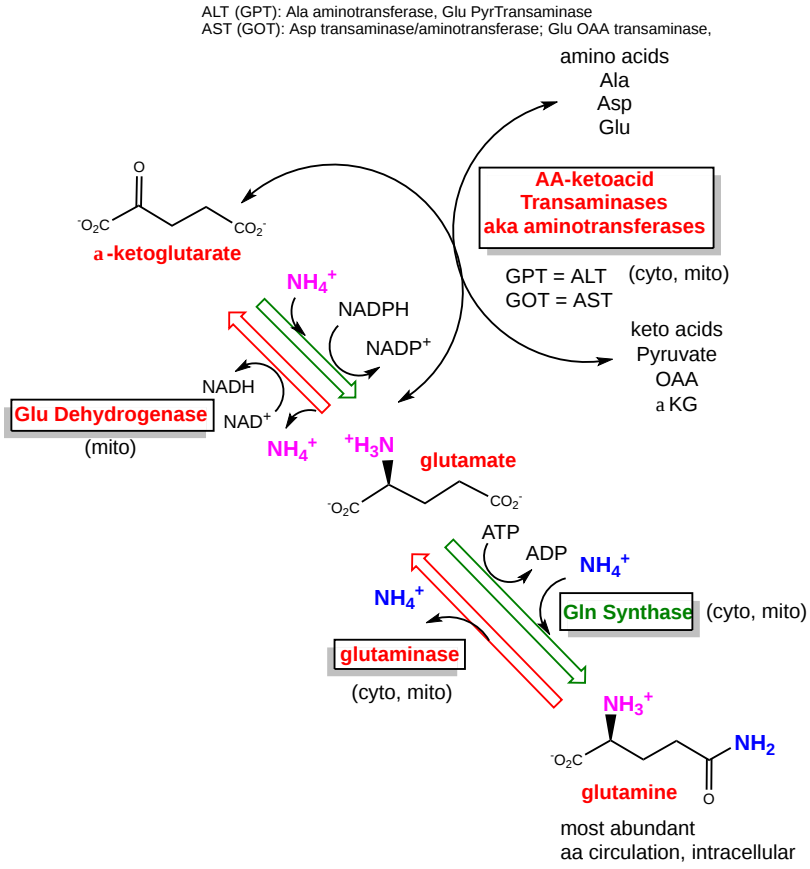

Figure 22.2.8: Glutamate and glutamine synthesis from α-ketoglutarate

As is evident from the figure, glutamic acid can be made directly through the transamination of α-ketoglutarate by an ammonia donor, while glutamine can be made by the action of glutamine synthase on glutamic acid.

Arginine is synthesized in the urea cycle as we have seen before. It can be made from α-ketoglutarate through the following sequential intermediates: N-acetylglutamate, N-acetylglutamate-phosphate, N-acetylglutamate-semialdehyde, N-acetylornithine to N-acetylcitruline. The is deacetylated and enters the urea cycle.

The pathway for conversion of α-ketoglutarate to proline is shown in Figure 22.2.9.

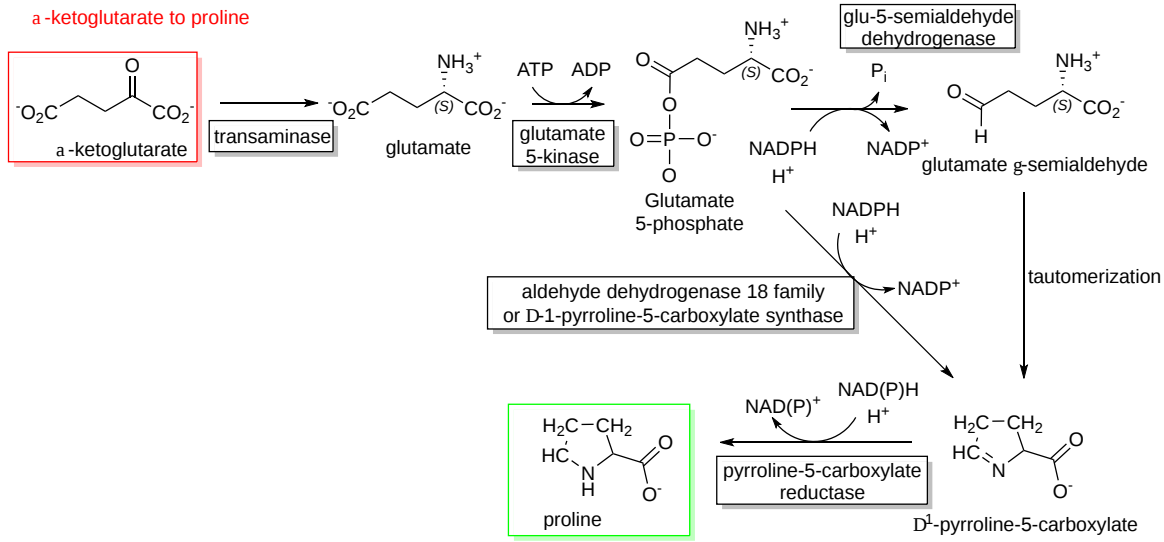

Figure 22.2.9: Conversion of α-ketoglutarate to proline

22.2.3.2: FROM OXALACETATE: ASP, ASN, MET, THR, LYS

22.2.3.2.1: OAA TO ASPARTATIC ACID

This is a simple transamination

22.2.3.2.2: ASPARTIC ACID TO ASPARAGINE

This is catalyzed by the enzyme Asparagine Synthase as shown in the reaction equation below:

$$\text{Aspartate} + \text{Glutamine} + \text{ATP} + H_2O \rightarrow \text{Asparagine} + \text{Glutamic Acids} + \text{AMP} + PP_i$$

22.2.3.2.3: ASPARTIC ACID TO LYSINE

There are two pathways.

- The diaminopimelic acid (DAP) pathway uses aspartate and pyruvate and forms diaminopimelic acid as an intermediate. It's found in bacteria, some fungi, and archaea and in plants.
- The aminoadipic acid (AAA) pathway uses α-ketoglutarate and acetyl-CoA and forms aminoadipic acid as an intermediate. It is used by fungi.,

Here we present just the synthesis of lysine from aspartate and pyruvate using the diaminopimelic acid DAP pathway. The pathway is shown in Figure 22.2.10.

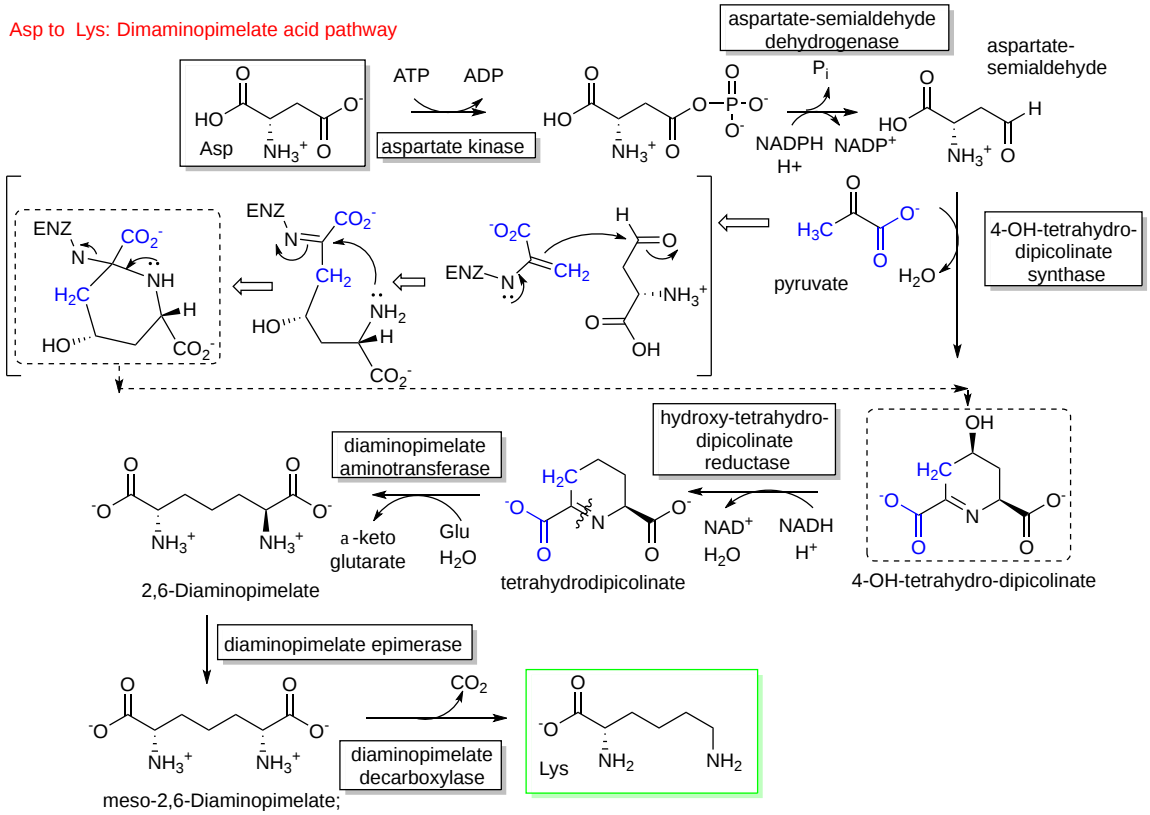

Figure 22.2.10: The synthesis of lysine from aspartic acid in the diaminopimelic acid DAP pathway

.

22.2.3.2.4: ASPARTIC ACID TO THREONINE

The conversion of aspartic acid to threonine is shown in Figure 22.2.11.

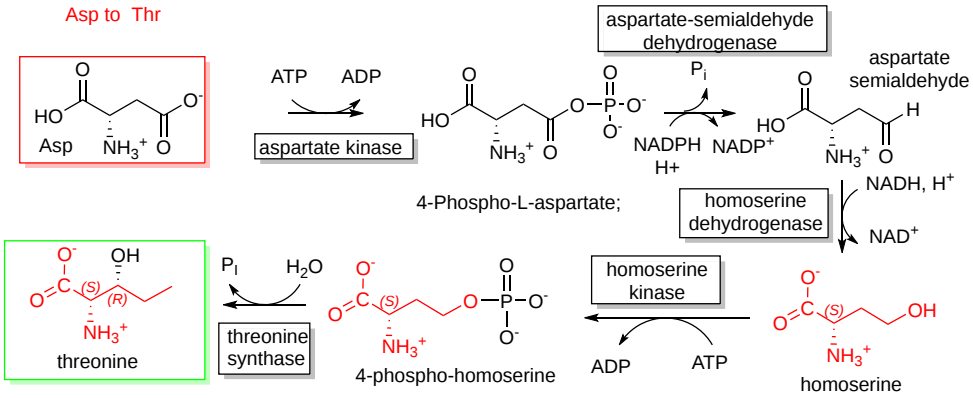

Figure 22.2.11: The conversion of aspartic acid to threonine

22.2.3.2.5: ASPARTIC ACID TO METHIONINE

The conversion of aspartic acid to methionine is shown in Figure 22.2.12.

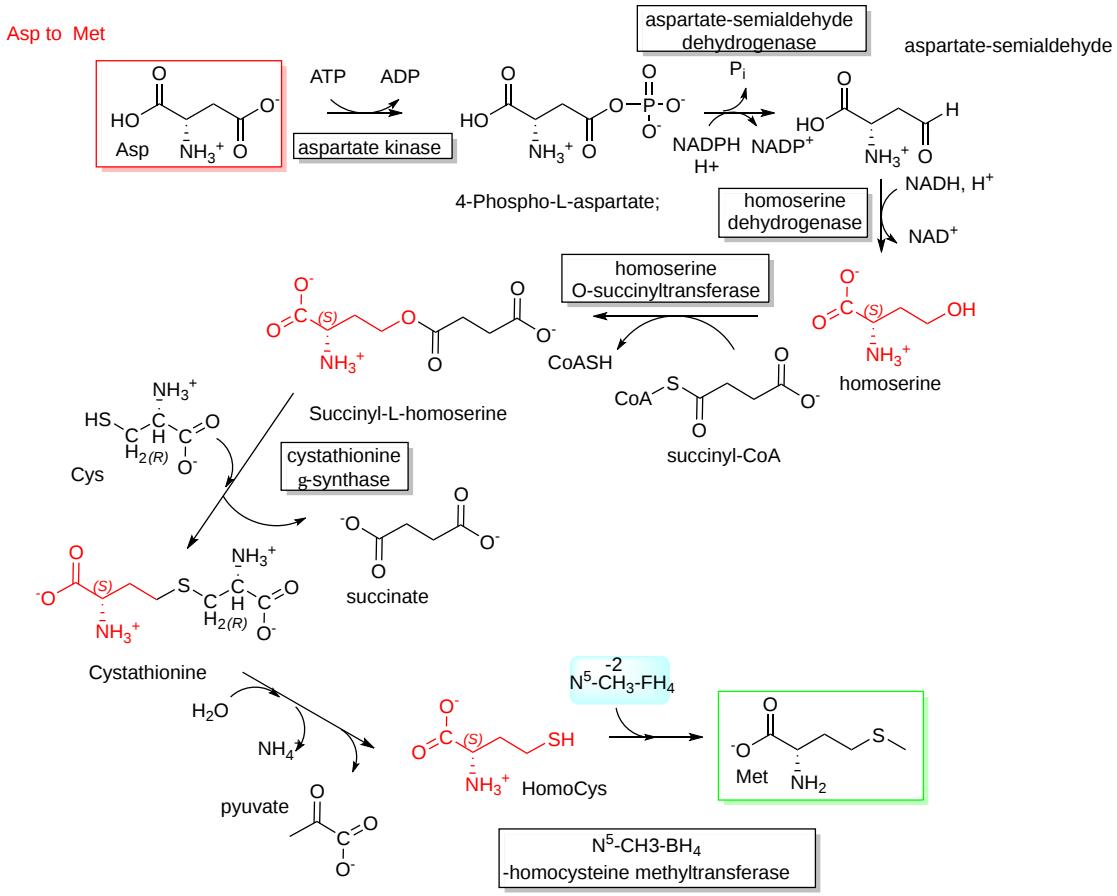

Figure 22.2.12: The conversion of aspartic acid to methionine

22.3: MOLECULES DERIVED FROM AMINO ACIDS

22.3.1: INTRODUCTION

Once made or ingested, amino acids have many metabolic fates. Of course, they are used for the synthesis of proteins. Aspartate and glutamate (and indirectly glutamine) can be converted to oxaloacetate and α-ketoglutarate, respectively, and used in the citric acid cycle for energy production. They can also be used for gluconeogenesis using mitochondrial and cytoplasmic enzymes. Branched-chain amino acids can be converted to acetyl-CoA and used in energy production or fat synthesis. A review summary of the use of amino acids in energy and biosynthetic metabolic pathways is shown in Figure 22.3.1.

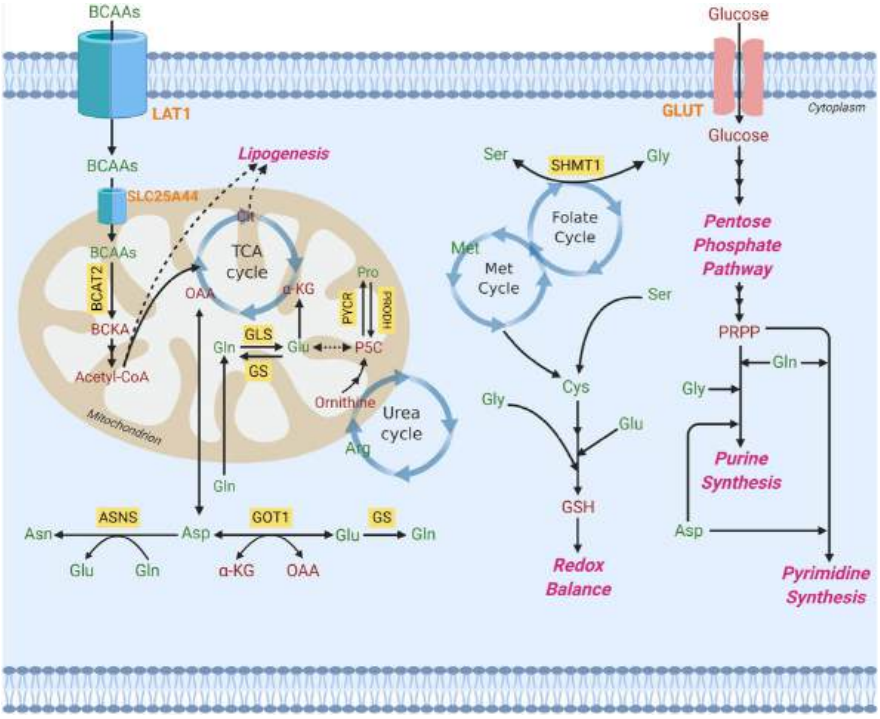

Figure 22.3.1: Review summary of the use of amino acid in energy and biosynthetic metabolic pathways. Lieu, E.L., Nguyen, T., Rhyne, S., *et al.* Amino acids in cancer. *Exp Mol Med* **52,** 15–30 (2020). https://doi.org/10.1038/s12276-020-0375-3. Creative Commons Attribution 4.0 International License, http://creativecommons.org/licenses/by/4.0/.

Amino acids are shown in green and other metabolites are in red. Orange represents transporters. Yellow boxes signify enzymes. Lesser known abbreviations for species include SHMT1 serine hydroxymethyltransferase, cytosolic, BCAT branched-chain amino acid transaminase, mitochondrial, BCAA branched-chain amino acid (valine, leucine, isoleucine), BCKA branched-chain ketoacid, GOT1 aspartate transaminase, cytosolic (AST), GLS glutaminase, GS glutamine synthetase (cytosolic and mitochondrial), ASNS asparagine synthetase, PRODH pyrroline-5-carboxylate dehydrogenase, PYCR pyrroline-5-carboxylate reductase, P5C pyrroline-5-carboxylate, GSH glutathione, PRPP phosphoribosyl pyrophosphate, LAT1 large-neutral amino acid transporter 1, SLC25A44 solute carrier family 25 member 44, GLUT glucose transporter,

Cancer cells from an increased need for fuels and biosynthetic intermediates. Both can come from amino acids as described previously. Glutamine is a key amino acid, especially if glucose is depleted as α-ketoglutarate (α-KG) and subsequently oxaloacetate (OAA generated from it powers the TCA cycle as fumarate, malate, and citrate are significantly increased. Hence it is both anaplerotic and a source of fuel. Similar increases in citrate occur in hypoxia. Aerobic glycolysis (Warburg effect) occurs in cancer cells, which show enhanced glucose uptake and conversion to lactate even in the presence of oxygen. This process can go so quickly that the amount of ATP produced in cancer cells from aerobic glycolysis can be similar to the from oxidative metabolism in the mitochondria, even though it is far less efficient. More information on cancer cell metabolism is found in Chapter 23.

In this chapter, we will discuss the conversion of amino acids to other molecules not directly involved in those metabolic pathways. We will focus on their use for the synthesis of polyamines, heme, and neurotransmitters in this chapter section. We won't discuss detailed mechanisms or structures for the proteins and enzymes involved in these pathways. In the next chapter section (22.4), we will present amino acids as substrates in the synthesis of pyrimidine and purine bases for nucleotides and nucleic acids.

22.3.2: POLYAMINE SYNTHESIS

If a non-quaternary amine has a single positive charge when protonated, a polyamine can have multiple positive charges. Hence they would be expected to bind to almost any negatively charged biomolecule, but especially those with multiple negative charges. These would include the polyanions RNA and DNA as well as proteins and lipid bilayers. They would then have the potential ability to regulate many features of cell life, including DNA replication and transcription, RNA translation, and a multitude of binding interactions. The question arises if these interactions are nonspecific, or specific, in which case they can be considered key regulators of cellular activity. Polyamine response elements have been found that regulate the transcription of genes including c-Myc and c-Jun. Polyamines have been shown tumor growth and aggressiveness.

The main biological polyamines include putrescine, spermine, and spermidine. Another is cadaverine. Given their names, you can surmise that they smell horrible. The synthesis of three polyamines from arginine and SAM is shown in Figure 22.3.2.

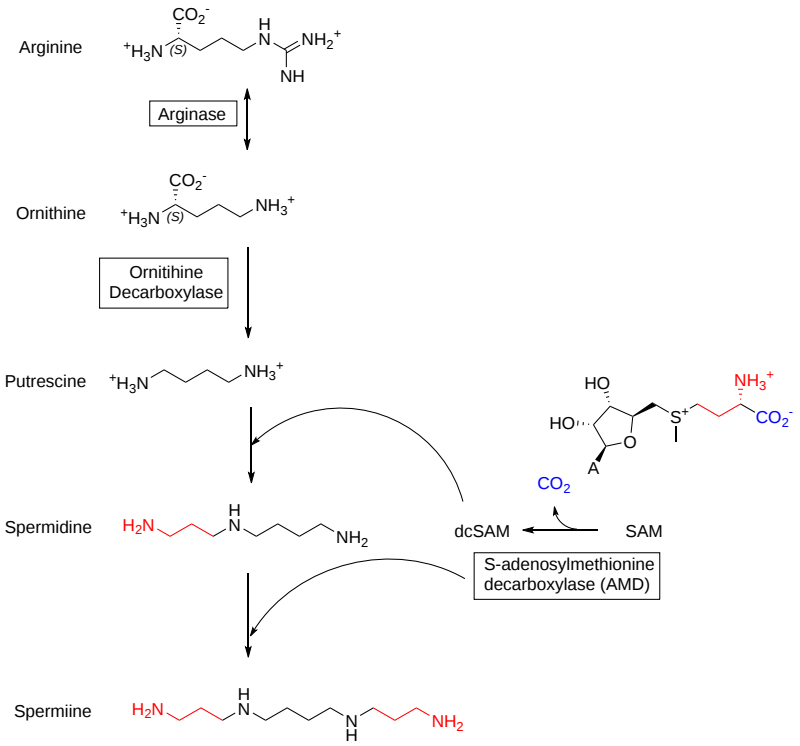

Figure 22.3.2: Polyamine synthesis form arginine and SAM

22.3.3: GLUTATHIONE SYNTHESIS AND REDOX BALANCE

Glutathione, γ-glutamylcysteinylglycine (GSH), is a chief regulator of the oxidation state of a cell. As a disulfide bond can be cleaved and hence reduced by the excess concentration of a thiol (sulfhydryl) like b-mercaptoethanol (which gets oxidized in the process), the free thiol on glutathione can act as a reducing agent in the cell. The production of reactive oxygen species (ROS) in normal but especially tumor cells, which have increased O_2 demand and use, is countered by the generation of an antioxidant defense state. This is characterized in part by increased levels of reductants such as NADPH but especially glutathione. It can react with H_2O_2 through the enzyme GSH peroxidase to form water and the oxidized disulfide form of GSH, GSSG. The GSSG is oxide back to GSH by glutathione reductase (GR) and NADPH. Figure 22.3.3 shows the synthesis of glutathione from glutamate, cysteine, and glycine.

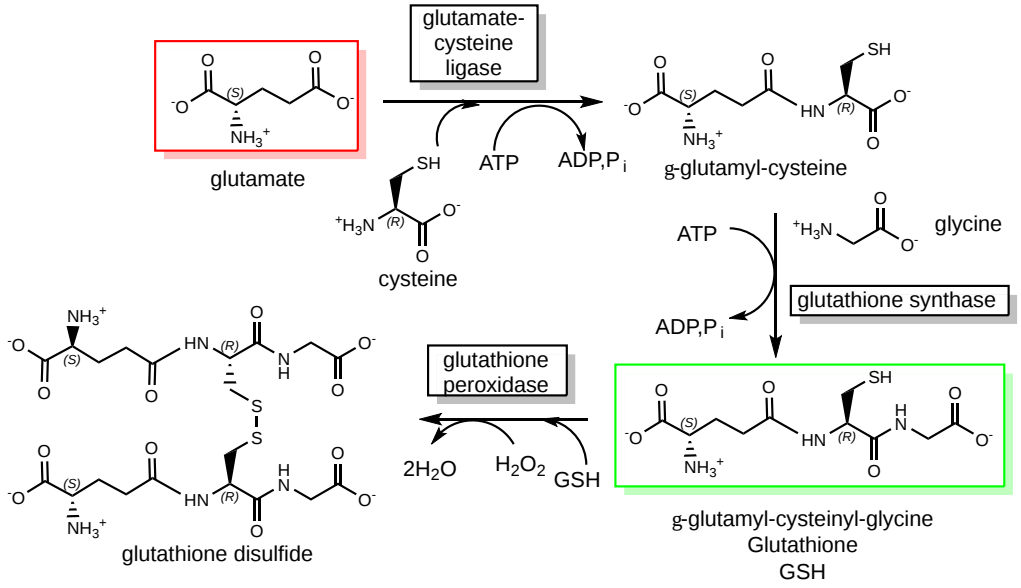

Figure 22.3.3: Synthesis of glutathione

NADPH is generated in the cell by the phosphopentose pathway metabolism of glucose and by malic enzyme. It can also be generated from the Ser-Glycine One Carbon Cycle (SGOT) that we saw in Chapter 18.4, which is shown again in Figure 22.3.4. Under appropriate conditions, this cycle can produce NADPH.

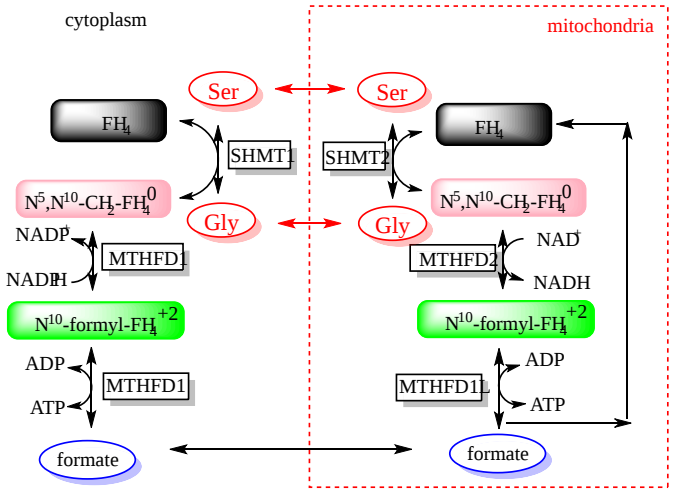

Figure 22.3.4: The Ser-Gly One Carbon (SGOC) Cycle

Serine Hydroxymethyltransferases (SHMTs) 2 is upregulated by HIF1α and helps maintain the NADPH/$NADP^+$ ratio. Given the connection between the SGOC and the methionine cycle through folate, a decrease in serine concentration leads to a decrease in GSH.

22.3.4: HEME BIOSYNTHESIS

This section is derived from Aminat S. Ogun; Neena V. Joy; Menogh Valentine. https://www.ncbi.nlm.nih.gov/books/NBK537329/. Creative Commons Attribution 4.0 International License (http://creativecommons.org/licenses/by/4.0/)

Heme is a macrocyclic tetrapyrrole ring structure containing two nonpolar vinyl groups on one edge and two charge propionates on the other. It is extensively conjugated with 26 π electrons (4n+2 = 4(6)+2) so it is aromatic. The molecule without Fe^{2+} is called protoporphyrin IX and with a centrally-coordinate Fe^{2+}, it is called heme. The structures of both are shown in Figure 22.3.5.

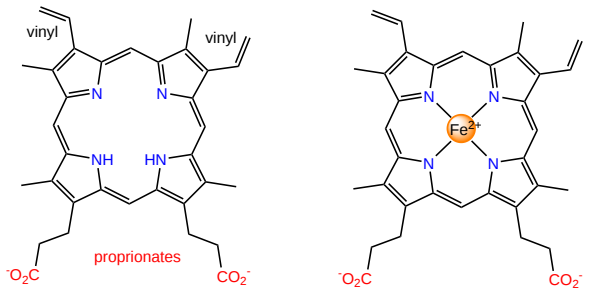

Figure 22.3.5: Structure of protoporphyrin IX and heme

It is found in oxygen-binding proteins and as substrates and cofactors for enzymes involved in electron transport. It is synthesized in the bone marrow and liver. Alternative forms of heme include heme b (in hemoglobin), heme a (cytochrome a), and heme c (cytochrome c).

Its synthesis, as expected given its macrocyclic structure, is complicated. The key enzyme in the pathway for regulation is 5'-Aminolevulinic acid synthase (ALA-S). Liver and bone express ALAS2 while ALAS1 is expressed in all tissues. The synthesis starts in the mitochondria and ends in the cytosol. The overall pathway for heme synthesis is shown in Figure 22.3.6.

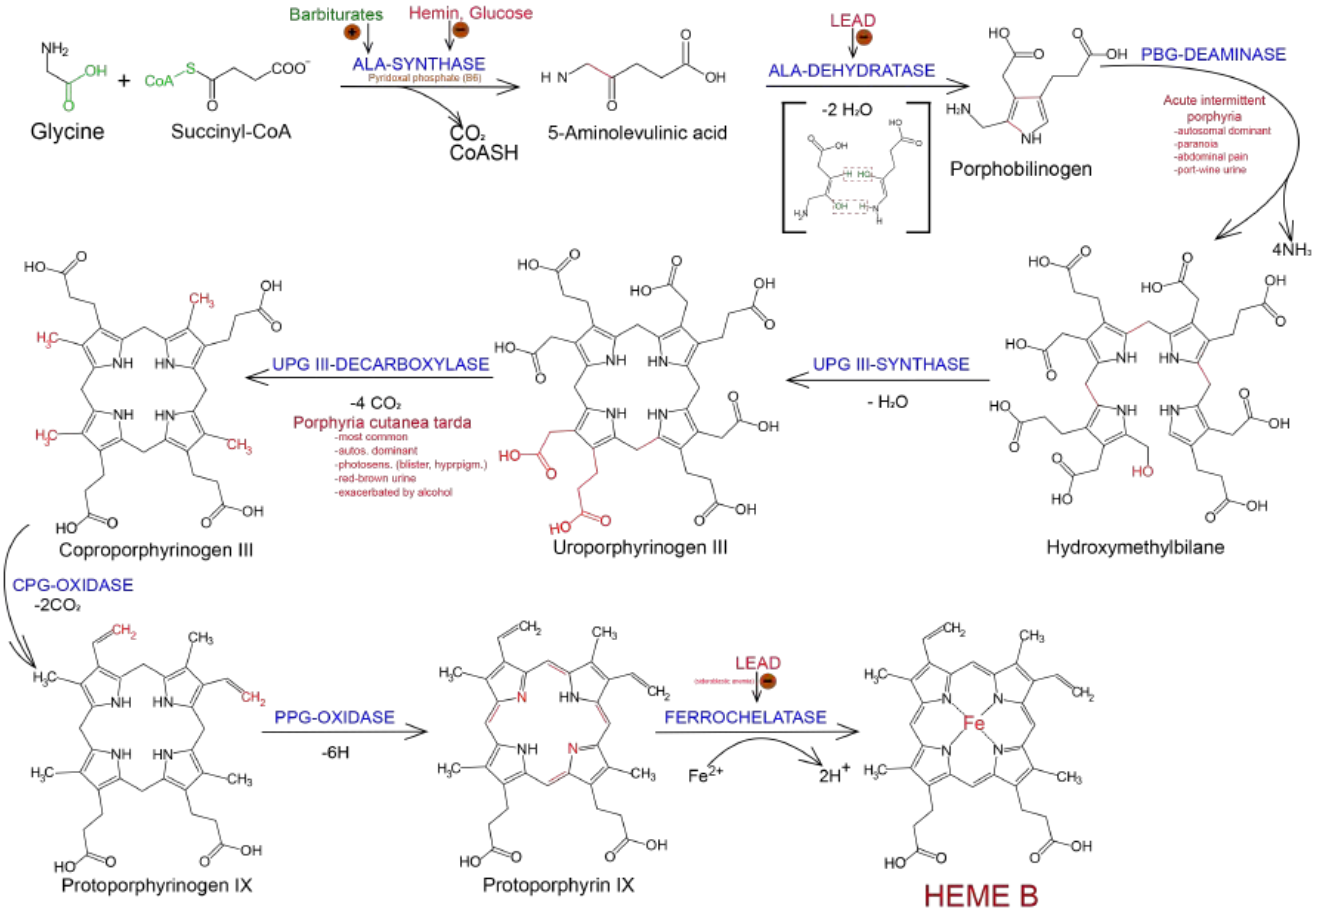

Figure 22.3.6: Heme biosynthetic pathway. Wikimedia Commonsile: Heme-Synthesis-Chemical-Details-Mirror.svg

5'-Aminolevulinic acid synthase (ALA-S), a pyridoxal phosphate-dependent enzyme, catalyzes the rate-limiting step in heme synthesis in the liver and erythroid cells. It is highly regulated There are two forms of ALA Synthase, ALAS1, and ALAS2. All cells express ALAS1 while only the liver and bone marrow expresses ALAS2. The gene for ALAS2 is on the X-chromosome. After the synthesis of ALA in the mitochondria, it moves into the cytoplasm for the remaining steps.

Figure 22.3.7 shows a likely mechanism for the first committed step, the production of ALA. This enzyme is used in the synthesis of all tetrapyrroles, including heme, chlorophyll, and cobalamin.

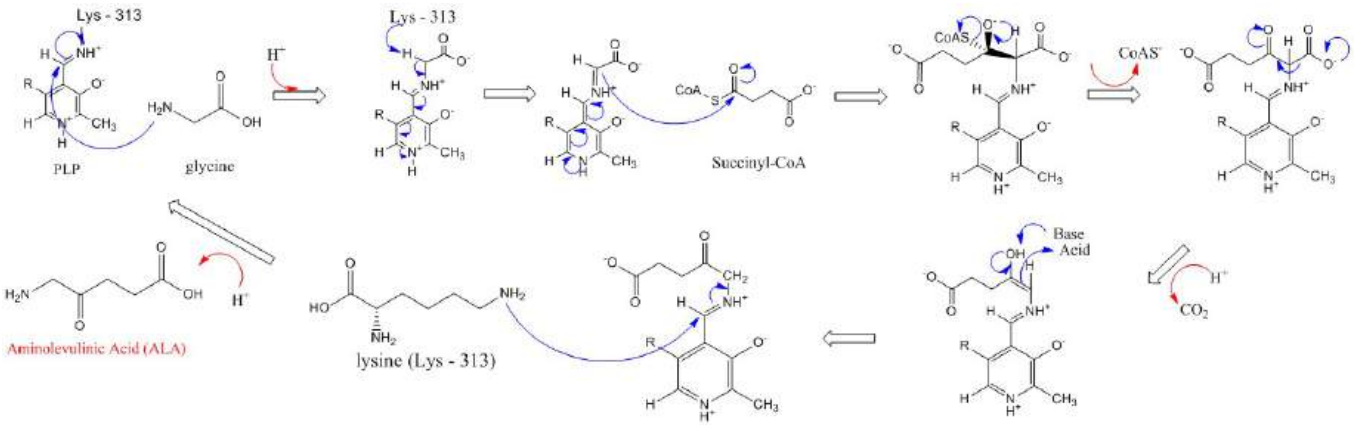

Figure 22.3.7: Mechanism for 5'-Aminolevulinic acid synthesis by ALAS (Wikipedia. https://en.Wikipedia.org/wiki/Aminol..._acid_synthase)

The pathway shown in Figure 6 above is called the C4 pathway and is found in mammals, fungi, and purple nonsulfur bacteria. A C5 pathway is found in most bacteria, all archaea, and plants. The biosynthetic pathway for heme synthesis in E. Coli is shown in Figure 22.3.8.

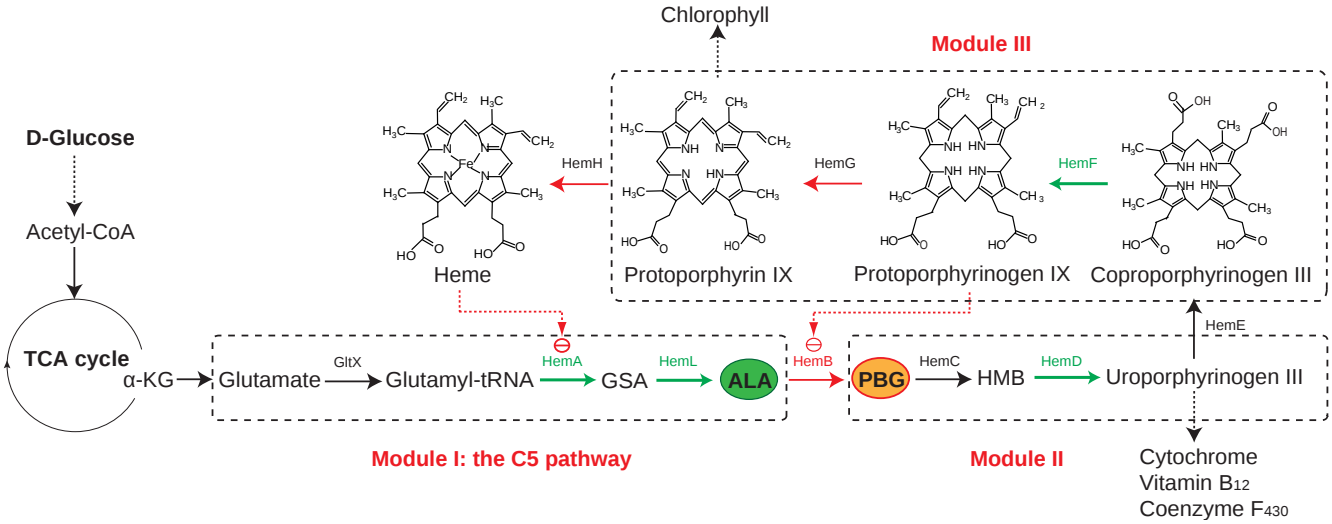

Figure 22.3.8: Heme pathway in *E. coli*. Zhang, J., Kang, Z., Chen, J. *et al.* Optimization of the heme biosynthesis pathway for the production of 5-aminolevulinic acid in *Escherichia coli*. *Sci Rep* **5,** 8584 (2015). https://doi.org/10.1038/srep08584. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/

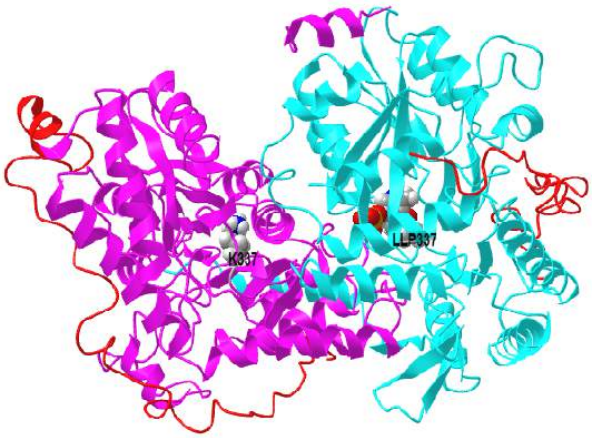
The pathway is divided into three modules (module I, module II, and module III in the dotted box). The arrows in green and red represent the enzymes that are positive and negative to ALA accumulation, respectively. Dotted red arrows represent the feedback inhibition. α-KG: α-ketoglutarate, GSA: glutamate-1-semialdehyde, ALA: 5-aminolevulinic acid, PBG: porphobilinogen, HMB: hydroxymethylbilane, GltX: glutamyl-tRNA synthetase, HemA: glutamyl-tRNA reductase, HemL: glutamate-1-semialdehyde aminotransferase, HemB: 5-aminolevulinic acid dehydratase, HemC: porphobilinogen deaminase, HemD: uroporphyrinogen III synthase, HemE: uroporphyrinogen decarboxylase, HemF: coproporphyrinogen III oxidase, HemG: protoporphyrin oxidase, HemH: ferrochelatase.

In immature red blood cells (reticulocytes), heme increase globin protein synthesis. The hormone erythropoietin increases heme synthesis. In the liver, heme is part of cytochrome P450s. Increased concentration of drugs causes increases in ALAS1 to produce the cytochrome P450s to metabolize them. Also, low heme concentration increases ALAS1 transcription. Mutations in ALAS2 can lead to X-linked sideroblastic anemia from decreased heme production even as Fe^{2+} continues to enter the cell.

Yeast ALAS is a homodimer with PLP covalently attached through a Schiff base link to lysine 337 of just one of the monomers. The structures of a noncovalent complex of PLP with ALAS (pdb 5TXR) and the covalently bound one (5TXT) show large changes in the protein conformation. PLP when covalently attached reorders the active. A C-terminal extension not found in bacteria wraps around the dimer and binds near the active site and is important for activity. Mutations in the tail can result in human diseases.

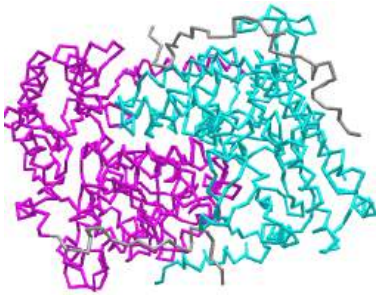
Figure 22.3.9 shows an interactive iCn3D model of the 5-aminolevulinic acid synthase with covalently attached PLP (5TXT).



NCBI iCn3D Figure 22.3.9: 5-aminolevulinic acid synthase with covalently attached PLP (5TXT). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?fTBbWuS3HPTP8uRm9

Lysine 337 (spacefill, CPK colors, labeled) in the A chain (magenta, no bound PLP) is shown. Lys 337 in the B chain (cyan) is covalently linked to PLP. The side chain of lysine 337 covalently attached to PLP is shown in spacefill, CPK colors, and labeled. The C-terminal extension (493–548) is shown as a red backbone chain. The very distal end of the extension is disordered and missing in the B chain (cyan).

Figure 22.3.10 shows an interactive iCn3D model of aligned 5-aminolevulinic acid synthase with free PLP (not covalently attached, 5TXR) and with covalently attached PLP (5TXT).



NCBI iCn3D Figure 22.3.11: Alignment of 5-aminolevulinic acid synthase with free PLP (5TXR) and with and with covalently attached PLP (5TXT). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...aqN4Qpi2pSLkD7

The 5TXT structure contains two molecules of a stabilizing molecule shown in stick form, which you can ignore. The A chain is shown in magenta and the B chain is in cyan. Press "a" to toggle back and forth between the structures. The C-terminal extension is missing from the figure.

Figure 22.3.11 shows another view of heme synthesis which emphasizes the role of mitochondrial and cytoplasmic enzymes.

22.3.5: NEUROTRANSMITTERS

The section below is modified from Manorama Patri. **Synaptic Transmission and Amino Acid Neurotransmitters.** DOI: 10.5772/intechopen.82121. https://www.intechopen.com/books/neu...rotransmitters. Creative Commons Attribution 3.0 License,

There are three major categories of amino acids and their derivatives act as neurotransmitters are:

1. Amino acids: The neurotransmitters of this group are involved in fast synaptic transmission and are inhibitory and excitatory in action (primarily glutamic acid, GABA, aspartic acid, and glycine).
2. Amines: Amines are modified amino acids such as biogenic amines, e.g., catecholamines. The neurotransmitters of this group involve in slow synaptic transmission and are inhibitory and excitatory in action (noradrenaline, adrenaline, dopamine, serotonin, and histamine).
3. Others: The ones which do not fit in any of these categories (acetylcholine and nitric oxide). Amino acids are among the most abundant of all neurotransmitters present within the central nervous system (CNS).

Amino acid transmitters provide the majority of excitatory and inhibitory neurotransmission in the nervous system. Amino acids used for synaptic transmission are compartmentalized (e.g., glutamate, compartmentalized from metabolic glutamate used for protein synthesis by packaging the transmitter into synaptic vesicles for subsequent Ca^{2+}-dependent release). Amino acid neurotransmitters are all products of intermediary metabolism except GABA. Unlike all the other amino acid neurotransmitters, GABA is not used in protein synthesis and is produced by an enzyme (glutamic acid decarboxylase; GAD) uniquely located in neurons.

Here is some more specific information:

- Glutamate: Glutamate is used at the great majority of fast excitatory synapses in the brain and spinal cord. Glutamate binds to glutamate receptors of which there are many subtypes based on other molecules (some amino acid derivatives) that can bind to them. These other molecules include N-methyl-D-aspartate (NMDA), α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) kainate, and quisqualate.
- Aspartate: Aspartate is the most abundant excitatory neurotransmitter in the CNS. Like glycine, aspartate is primarily localized to the ventral spinal cord. Note that the two major excitatory neurotransmitters both have carboxylic acid side chains.
- Gamma-aminobutyric acid (GABA): GABA, which is not one of the canonical amino acids used in protein biosynthesis, is the most ubiquitous inhibitory neurotransmitter in the brain.
- Glycine: lycine receptors are ligand-gated ion channels that increase Cl^- influx and hence are generally inhibitory. Hydroxymethyl transferase converts the amino acid serine to glycine. Glycine has been found to play a role in the functional modulation of NMDA receptors

The pathways for the synthesis of amino acid-derived bioactive amines and neurotransmitters are shown in Figure 22.3.12.

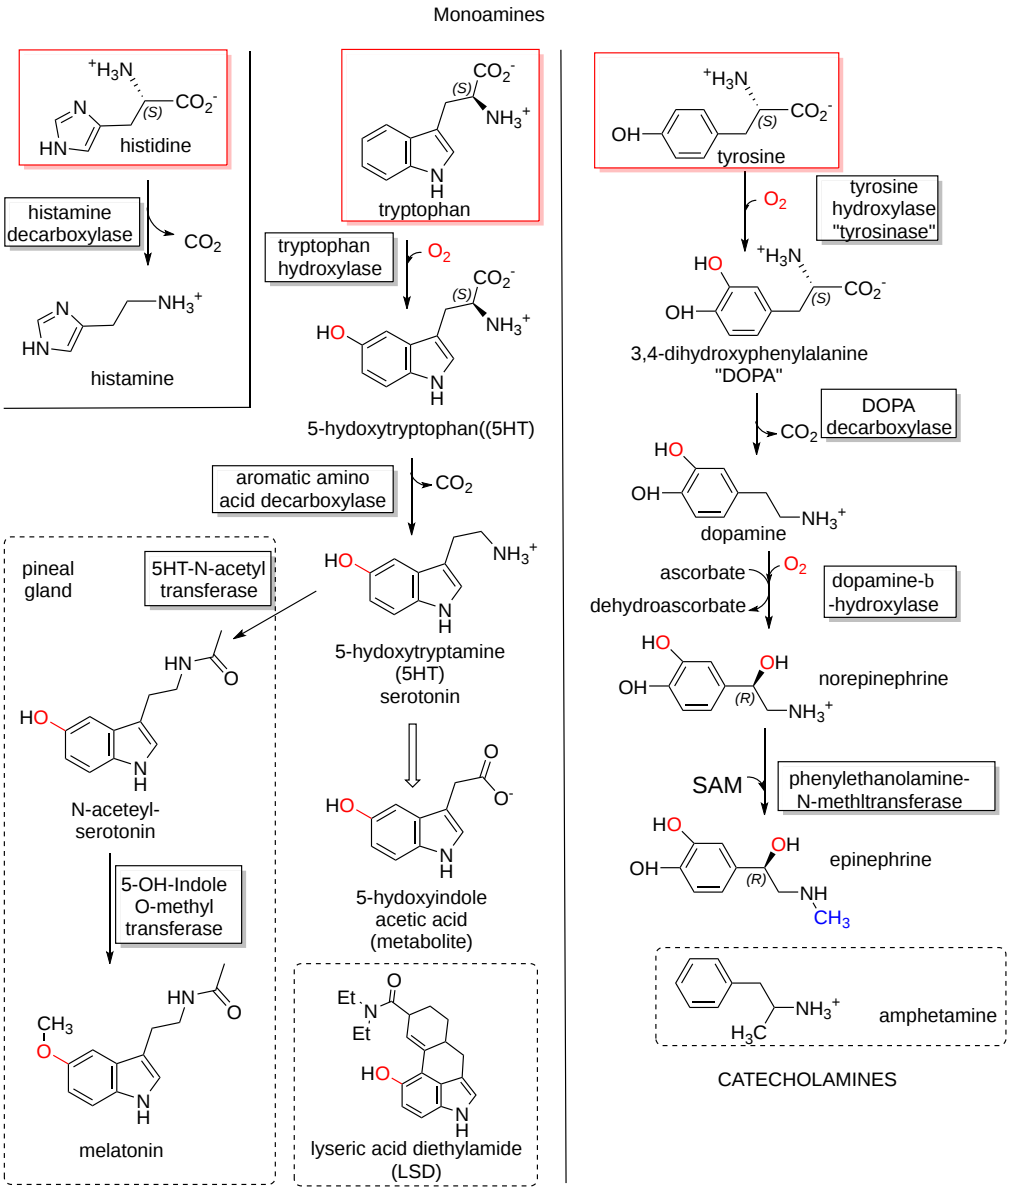

Figure 22.3.12: Pathways for the synthesis of amino acid-derived bioactive amines and neurotransmitters

Note the structural similarity of the psychotropic and hallucinogenic drug LSD to serotonin (5HT), amphetamines to norepinephrine and epinephrine, and melatonin (a substance some take as a sleeping aid and which forms in the dark at night in brains. The name **catecholamines** derive from the common name of the 1,2-dihydroxybenzene group (catechol).

The first and rate-limiting step in catecholamine synthesis is catalyzed by **tyrosine hydroxylase (TH).** It has no heme but it has an Fe^{2+} and tetrahydrobiopterin as a cofactor used in the synthesis of dihydroxyphenylalanine (DOPA). Tyrosine hydroxylase is rate-limiting for the synthesis of all three transmitters.

The enzyme is inhibited by catecholamines including dopamine, a downstream product, and is activated by phosphorylation on serine 40. The structures of TH in the absence of dopamine and the pSer40 state are known. The protein is a tetramer with a regulatory domain (dimer) and catalytic domain (also a dimer) separated by 15 Å.

The mammalian TH is a member of the aromatic amino acid hydroxylases (AAAHs) which are mainly found as homotetramers. Each subunit has 3 domains:

- The N-terminal **regulatory domain (RD)** that has an unstructured variable-length section followed by an ACT (aspartate kinase-chorismate mutase-TyrA) domain. The N-terminal tail contains serine 40 which on phosphorylation relieves the inhibition when dopamine is bound to the catalytic domain.
- a central **catalytic domain (CD)** that binds Fe^{2+}, aromatic amino acid substrates, and the tetrahydrobiopterin cofactor
- C-terminal oligomerization domain (OD) which leads to dimer and tetramer formation.

Figure 22.3.13 shows a potential model that illustrates dopamine (DA)-mediated feedback inhibition and its regulation by serine 40 phosphorylation through the interaction of the N-terminal tail of the regulatory domain (RD) with the catalytic domain. All forms containing bound dopamine (yellow star) are inactive.

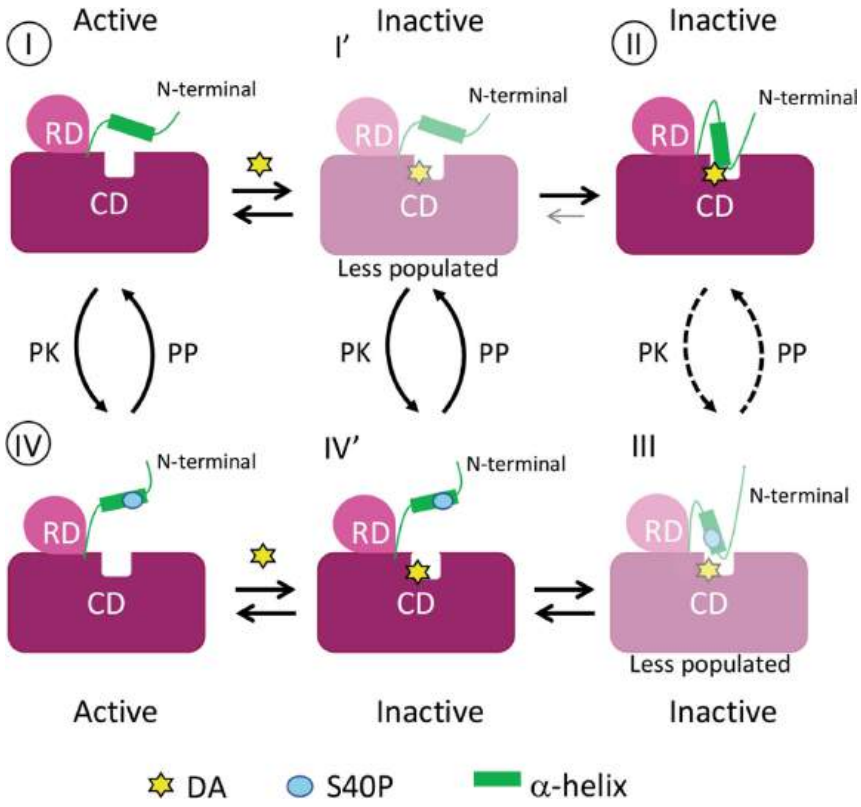

Figure 22.3.13: Cartoon model of DA-mediated feedback inhibition and its regulation by S40 phosphorylation. Bueno-Carrasco, M.T., Cuéllar, J., Flydal, M.I. *et al.* Structural mechanism for tyrosine hydroxylase inhibition by dopamine and reactivation by Ser40 phosphorylation. *Nat Commun* **13,** 74 (2022). https://doi.org/10.1038/s41467-021-27657-y. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/.

In the active, apo, and non-phospho states, the 39−58 α-helix of the N-terminal regulatory domain of TH is detached from the main structure (I, apo-TH). The feedback inhibitor DA binds to the TH active site, most likely in the open conformation (I′, TH(DA)). DA-binding favors the interaction of the N-terminal α-helix with the same binding site, which blocks DA exit and contributes to the high-affinity binding and strong inhibition of TH activity (II, TH(DA)). Protein Kinase (PK) phosphorylation of S40 in TH(DA), leads to state III (THS40p(DA)), prompting the detachment of the α-helix from the TH active site (IV′), which opens up for DA-dissociation and activation (IV, THS40p). PKs and protein phosphatase(s) (PP) control the transition between THS40p and unphosphorylated TH for both DA bound (I′ ↔ IV′ and II ↔ III) and apo-TH (I ↔ IV). States I′ and III are expected to be only transiently populated during DA binding as states II and IV' will be more stable. Hence states I′ and III states are faded. S40 is also expected to be less accessible in state II than in state I, which is indicated by stippled lines for phosphorylation of TH in state II. The case for dephosphorylation is not known, but it could be expected that state III is a poorer substrate for PP than the open states IV′ and IV. The dephosphorylation reaction III → II is therefore also stippled. The states where we provide structural details in this work (I, II, and IV) are marked with circles.

Figure 22.3.14 shows a model of the TH active site changes on phosphorylation of serine 40 using structural and molecular dynamics approaches that led to the cartoon model above.

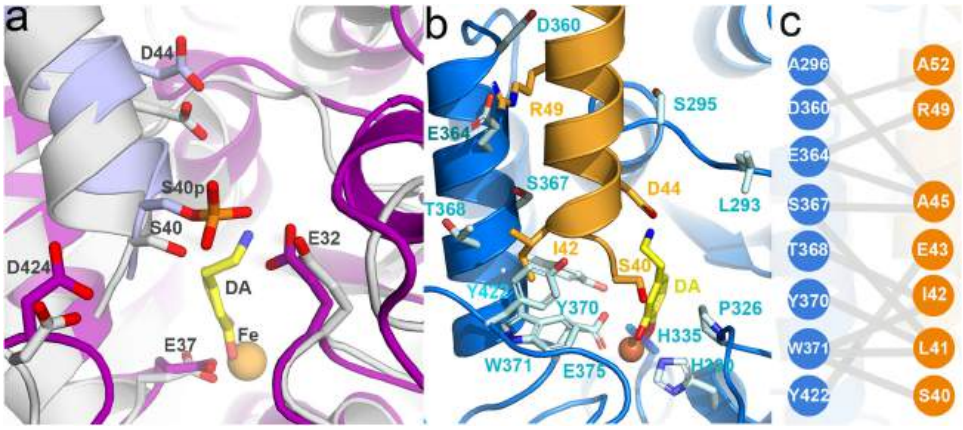

Figure 22.3.14: **Modeling of the TH active site.**

Panel (a) shows models demonstrating the effect of serine 40 phosphorylation on the interaction of the N-terminal α-helix with bound dopamine (DA). Representative conformations from the last 50 ns of a 500 ns MD simulations for TH(DA) (grey ribbon) and pS40-TH(DA) (light blue ribbon) are shown. The resulting structures show a slight shift of the N-terminal α-helix upon phosphorylation, most probably due to electrostatic repulsion between the phosphate and E325, E375, and D424.

Panel (b) shows a detailed view of the atomic model of the TH(DA) active site. (left) The N-terminal α-helix (orange), establishes connections with the adjacent helix D360-E375 and with residues of the 290–297 and 420–429 loops (blue, right).

Pane (c) shows a cartoon depicting the interactions established between residues of the N-terminal α-helix that enters the active site, and residues of adjacent regions.

Figure \(\PageIndex{15}\) below shows an interactive iCn3D model of the full-length tyrosine hydroxylase in complex with dopamine (residues 40-497) in which the regulatory domain (residues 40-165) has been included only with the backbone atoms (6zvp)

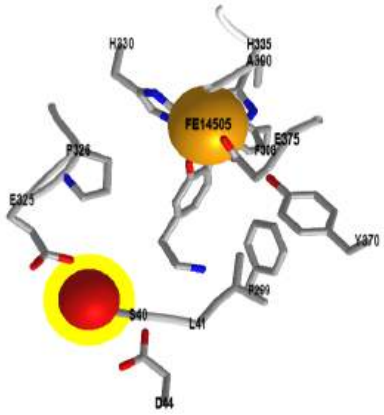
Finally, Figure 22.3.16 shows an interactive iCn3D model of the active site of tyrosine hydroxylase in complex with dopamine (6zvp)



NCBI iCn3D Figure 22.3.16: Active site of tyrosine hydroxylase dopamine complex (6zvp). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?sx5obQnzojmKXuLS9

The side chains binding the active site Fe^{2+} and the interaction of Fe^{2+} with dopamine (LDP) are shown in sticks and labeled. The oxygen of serine 40 is shown as a red sphere. Dopamine is the molecule containing the 1,2-dihydroxybenzene.

Figure 22.3.17 shows a final summary presentation of the conversion of phenylalanine, tyrosine, and tryptophan to neurotransmitters.

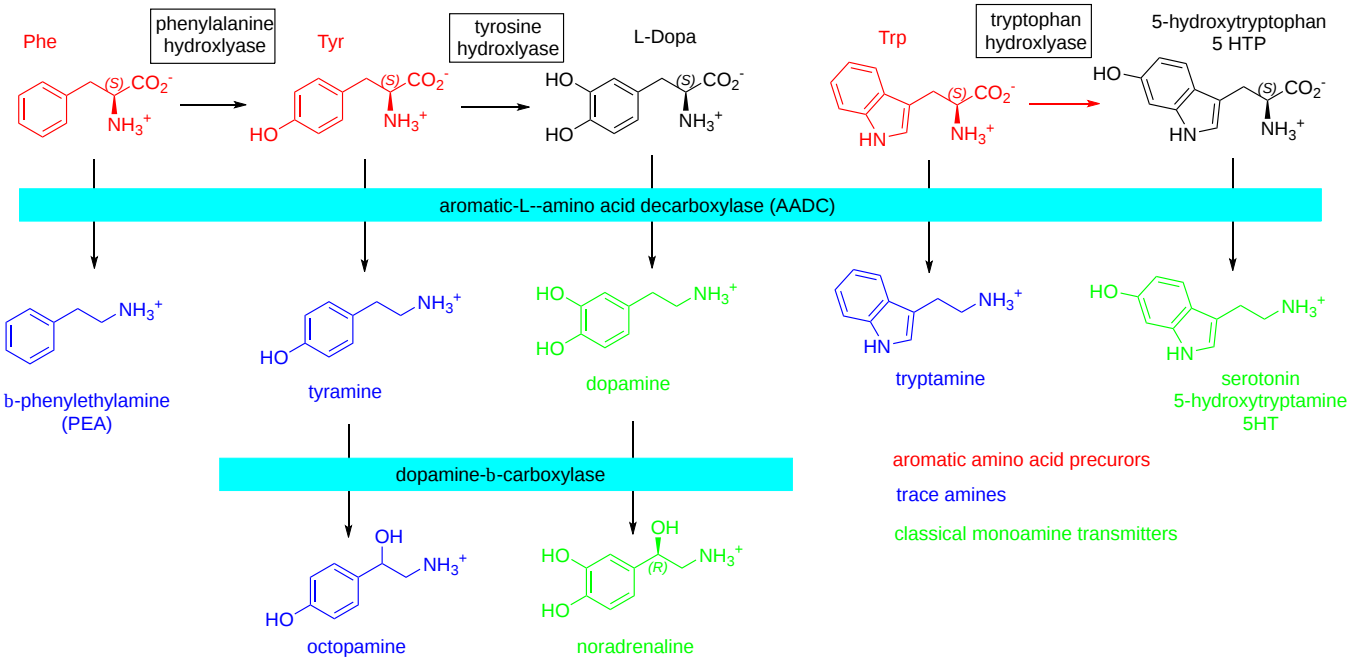


Figure 22.3.17: Comparison of monoamine synthesis pathways. Adapted from Hochman, Shawn. (2015). Neural Regeneration Research. 10. 10.4103/1673-5374.169625. Creative Commons Attribution-NonCommercial-ShareAlike 4.0 International

22.4: BIOSYNTHESIS AND DEGRADATION OF NUCLEOTIDES

22.4.1: INTRODUCTION

We conclude our exploration of metabolic pathways with the biosynthesis and breakdown of nucleotides, the monomers that comprise nucleic acids. We can't also forget the important role of ATP as the universal carrier of biological free energy, as well as the nucleotides involved in signal transduction (GTP in heterotrimeric G proteins, small G proteins, and ATP as substrate in protein phosphorylations by kinases). As with the other later sections on metabolism, we won't focus much on detailed reaction mechanisms or enzyme structures, with one exception, the enzyme that converts nucleotides to deoxynucleotides.

Nucleotide synthesis is often included in chapters on amino acid metabolism as almost every atom in the purine and pyrimidine ring derives from them as shown in Figure 22.4.1.

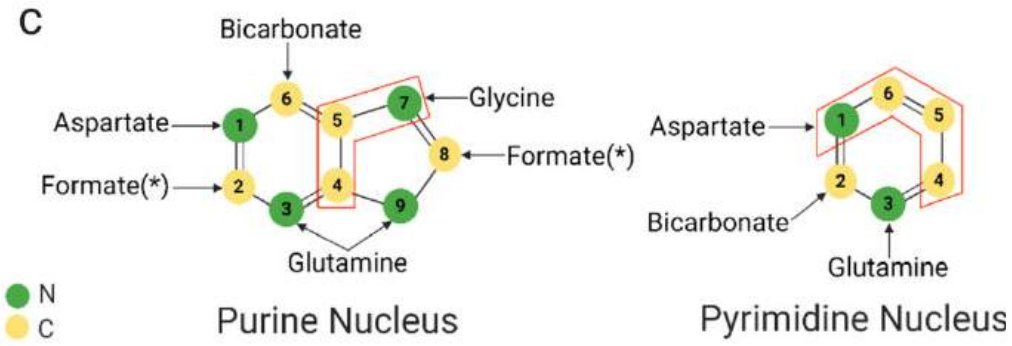

Figure 22.4.1: Source of atoms in nucleotide bases. Lieu, E.L., Nguyen, T., Rhyne, S., *et al.* Amino acids in cancer. *Exp Mol Med* **52,** 15–30 (2020). https://doi.org/10.1038/s12276-020-0375-3. Creative Commons Attribution 4.0 International License, http://creativecommons.org/licenses/by/4.0/.

For purines, glutamine and aspartate provide the nitrogen for the nucleotide's rings. They also provide the NH_3s for the ring substituents (glutamine for adenine and aspartate for guanine). Glycine and formate provide the carbon atoms for the rings. The one carbon molecule formate, which derives from glycine, is also added to purine rings. Glycine provides a one-carbon unit indirectly through the main carrier of activated one-carbon units, 5,10-meTHF, which is converted to formate through 10-formyl THF.

Pyrimidines are much smaller and their synthetic pathway reflects that. Instead of being synthesized as nucleobases as in the case of purines, they are made as ribonucleotides as they are linked to phosphoribosyl pyrophosphate (PRPP). Glutamine and aspartate again provide the ring C and N atoms. The one-carbon unit derives from serine-to-glycine conversion. A methyl group from the activated 1C donor, 5,10-meTHF, is added to dUMP to make dTMP.

22.4.2: PURINE SYNTHESIS

The material below derives from De Vitto, H.; Arachchige, D.B.; Richardson, B.C.; French, J.B. The Intersection of Purine and Mitochondrial Metabolism in Cancer. Cells 2021, 10, 2603. https://doi.org/10.3390/cells10102603. **Creative Commons Attribution License**

Mammals have two pathways for purine synthesis, a de novo pathway and a salvage pathway to recycle nucleotide bases. The salvage pathway is typically sufficient as purine bases come from nucleic acid breakdown. The resulting free bases (adenine, guanine, and hypoxanthine are connected to **phosphoribosyl pyrophosphate (PRPP)** to form nucleoside monophosphates (NMP) using either **adenine phosphoribosyltransferase (*APRT*)** to form AMP or hypoxanthine-guanine phosphoribosyltransferase (*HGRT*) to form IMP and GMP. PRPP is a substrate in both the salvage and de novo pathways. The overall de novo and salvage pathways for purine synthesis are described in detail in Figure 22.4.2.

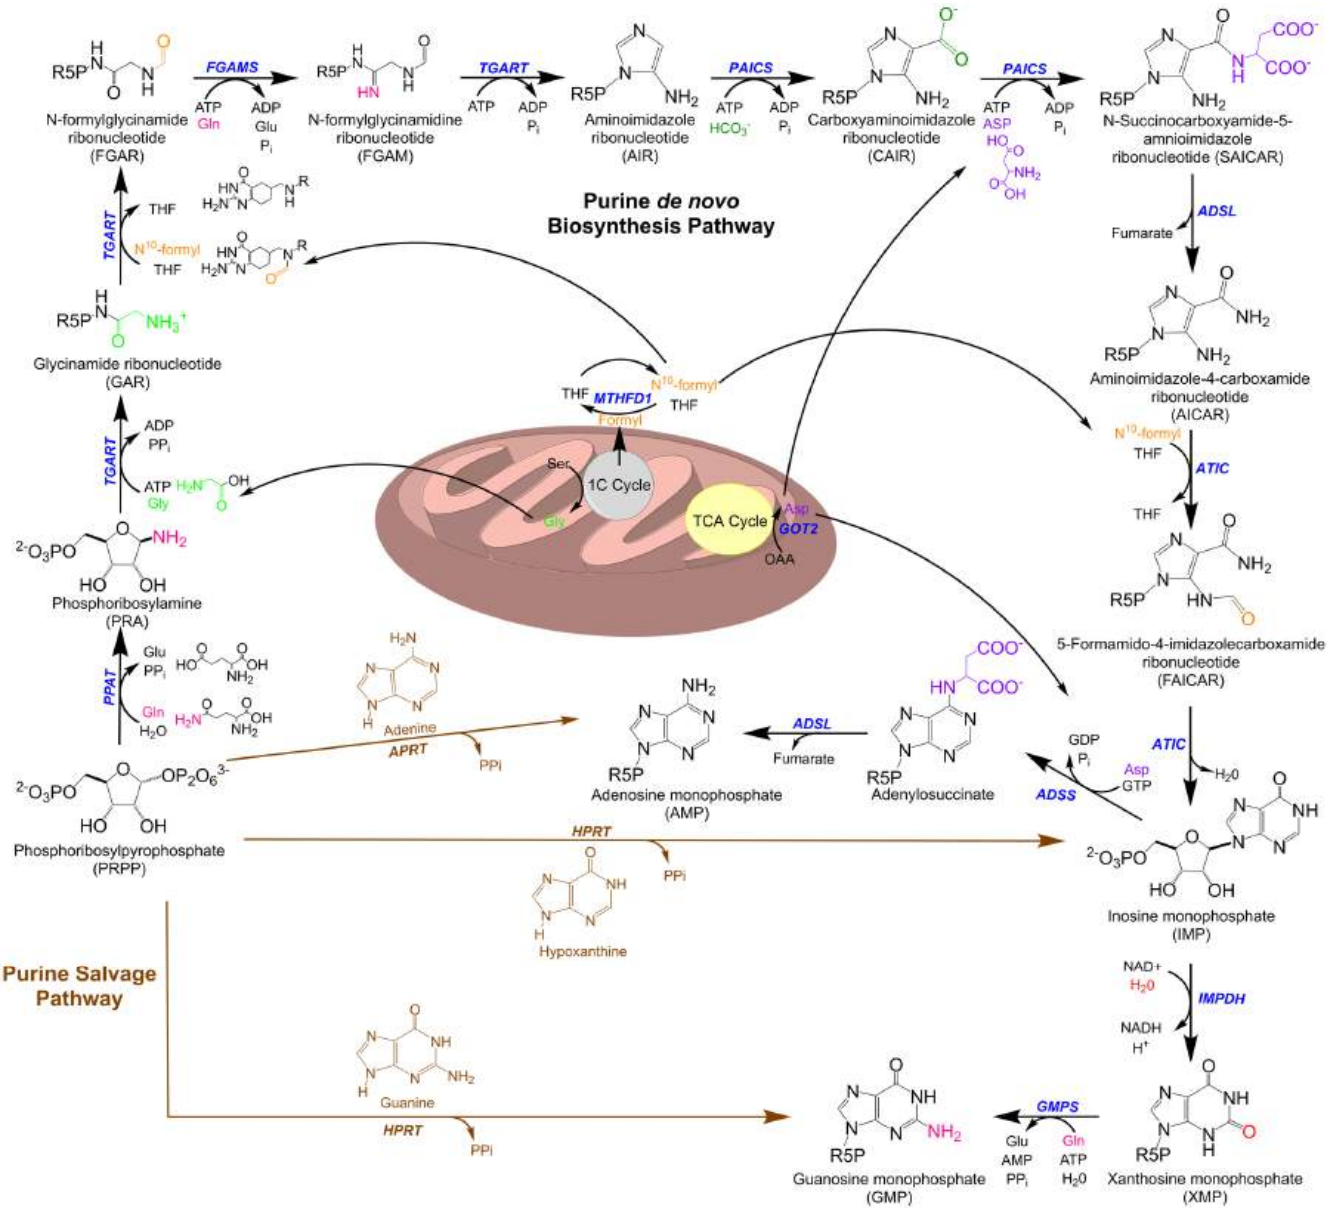

Figure 22.4.2: Purine metabolic pathways. De Vitto, H.; Arachchige, D.B.; Richardson, B.C.; French, J.B. The Intersection of Purine and Mitochondrial Metabolism in Cancer. Cells 2021, 10, 2603. https://doi.org/10.3390/cells10102603. **Creative Commons Attribution License**

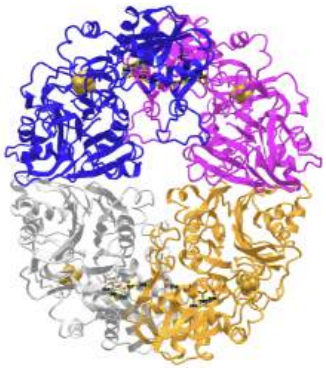
The conserved de novo biosynthesis pathway to generate IMP consists of 10 chemical steps catalyzed by 6 gene products in humans. These include the trifunctional enzyme *TGART*, composed of GAR synthetase (GARS), GAR transformylase (GARTfase), and AIR synthetase (AIRS) domains; the bifunctional enzymes *PAICS*, composed of CAIR synthetase/AIR carboxylase (CAIRS) and SAICAR synthetase (SAICARS), and *ATIC*, composed of AICAR transformylase (AICART) and IMP cyclohydrolase (*IMPCH*); and three monofunctional enzymes, phosphoribosyl amidotransferase (*PPAT*), formyl glycin amidine ribonucleotide synthetase (*FGAMS*), and adenylosuccinate lyase (*ADSL*). Downstream IMP is converted to (1) GMP through stepwise reactions of IMP dehydrogenase (*IMPDH*) followed by GMP synthetase (*GMPS*) and (2) AMP via adenylosuccinate synthetase (*ADSS*) followed by *ADSL*. The salvage pathway requires PRPP to generate IMP and GMP through one-step reactions mediated by hypoxanthine phosphoribosyltransferase (*HPRT*) utilizing hypoxanthine and guanine bases. AMP is generated by adenine phosphoribosyltransferase (*APRT*) utilizing adenine base and PRPP as substrates. Mitochondria supply precursors for purine de novo biosynthesis including glycine, N^{10}-formyl THF, and aspartic acid through their one-carbon cycle (1C cycle) and tricarboxylic acid cycle (TCA).

The de novo pathway kicks in when there is high demand for purines. Six enzymes are required for the 10-step pathway. Three of these are multifunctional enzymes catalyzing multiple steps in the pathway, comprising the two bifunctional enzymes phosphoribosylaminoimidazole carboxylase (*PAICS)* and AICAR transformylase/inosine monophosphate cyclohydrolase (*ATIC)* and the trifunctional enzyme glycinamide

ribonucleotide transformylase (*TGART*). When active, the pathway is limited both by substrate availability and by the reaction rate of its initial step, the conversion of PRPP to phosphoribosylamine (PRA) by **phosphoribosylpyrophosphate amidotransferase (*PPAT*)**. The final product of the de novo biosynthesis pathway, IMP is a substrate for the production of both AMP and GMP. 6 ATP are used to make 1 IMP from PRPP. None are required in the salvage pathway.

PPAT is also called Glutamine phosphoribosylpyrophosphate amidotransferase or amidophosphoribosyltransferase. It catalyzes the rate limiting step, is tightly regulated. *PPAT* possesses two nucleotide-binding sites near the active site, allowing for feedback control by downstream purine nucleotides via allosteric inhibition.

Figure 22.4.3 shows an interactive iCn3D model of the Glutamine Phosphoribosylpyrophosphate Amidotransferase from Arabidopsis thaliana (6LBP)



NCBI iCn3D Figure 22.4.3: Glutamine Phosphoribosylpyrophosphate Amidotransferase from Arabidopsis thaliana (6LBP). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...uWnf1bTq1odk88

The plant enzyme is a homotetramer, which each subunit having a Fe_4S_4 center (spacefill). The active site residues in each subunit (DDS 432-444 and DS 369-370) are shown as colored sticks and labeled.

Regulation of IMP production also occurs through enzyme phosphorylation. For example, Thr 397 on PPAT is phosphorylated by protein kinase B (PKB). PRPP concentrations also affects the rate. Another regulation of the flux through the de novo pathway is through the condensation of the enzymes into the purinosome, which contains *PPAT*, *TGART*, formylglycinamidine ribonucleotide synthetase (*FGAMS*), *PAICS*, adenylosuccinate lyase (*ADSL*), and *ATIC*. The purinosome also interacts with the mitochondria which would allow high local concentrations of ATP.

A cartoon view of the purinosome is shown in Figure 22.4.4.

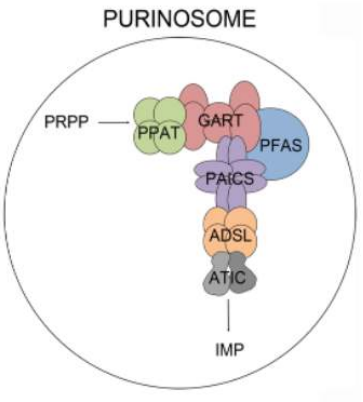


Figure 22.4.4: Cartoon showing the purinosome. Baresova et al (2018) PLoS ONE 13(7): e0201432. https://doi.org/10.1371/journal.pone.0201432. Creative Commons Attribution License,

Figure 22.4.5 shows another view of de novo IMP synthesis in which the origin of each atom in the purine ring is shown in color.

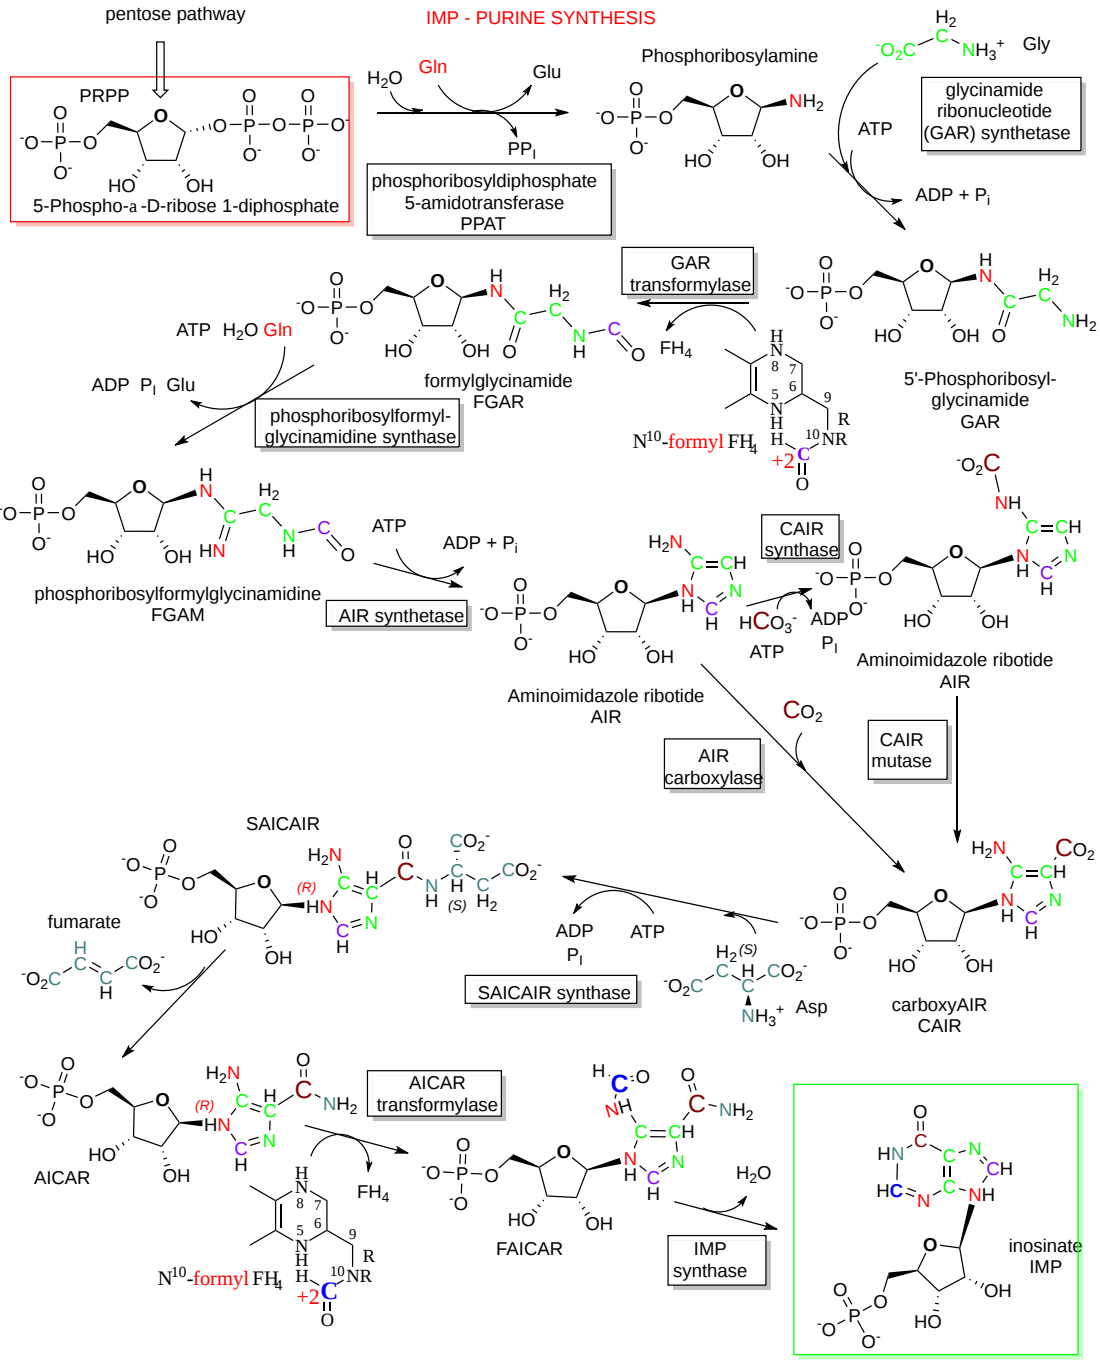

Figure 22.4.5: De novo IMP synthesis showing the origin of atoms in IMP.

Figure 22.4.6 shows an expanded view of the conversion of IMP to GTP and ATP.

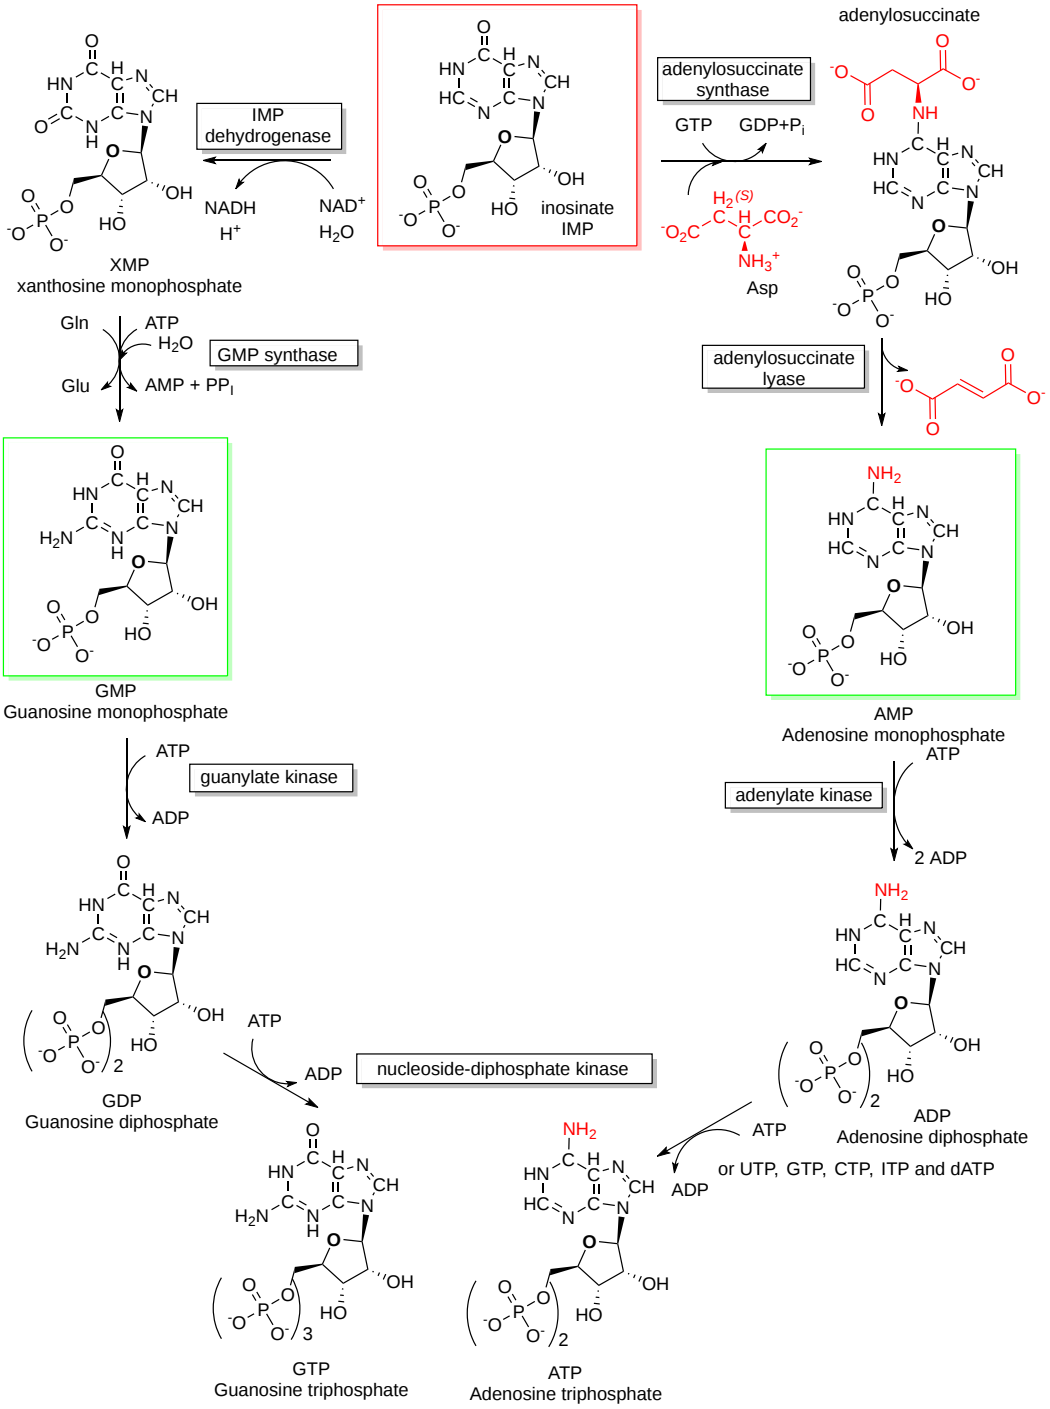

Figure 22.4.6: Conversion of IMP to GTP and ATP

22.4.3: PYRIMIDINE SYNTHESIS

As mentioned in the introduction, pyrimidines have a much simpler biosynthetic pathway. Instead of being synthesized as nucleobases as in the case for purines, they are made as ribonucleotides as they are linked to phosphoribosyl pyrophosphate (PRPP). Glutamine and aspartate again provide the ring C and N atoms. The one-carbon unit derives from serine-to-glycine conversion. A methyl group from the activated 1C donor, 5,10-meTHF, is added to dUMP to make dTMP.

The first step in the pathway for pyrimidine synthesis is the condensation of aspartate and carbamoyl phosphate. We have seen the synthesis of carbamoyl phosphate in the urea cycle by the enzyme carbamoylphosphate synthase I (CPSI) in Chapter 18.3 but present the reaction again in Figure 22.4.7.

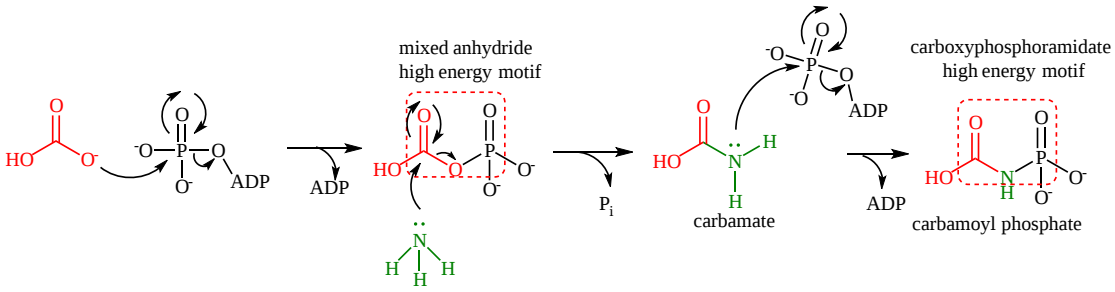

Figure 22.4.7: Synthesis of carbamoyl phosphate

A different cytosolic version of the enzyme, CPS II, is used to synthesize both arginine and pyrimidine nucleotides. It uses glutamine as a donor of NH_3.

The pathway for the synthesis of UTP and CTP are shown in Figure 22.4.7. It does not explicitly show the synthesis of carbamoylphosphate, which is an intergyral part of the pathway and one of the rate-limiting steps in pyrimidine synthesis.

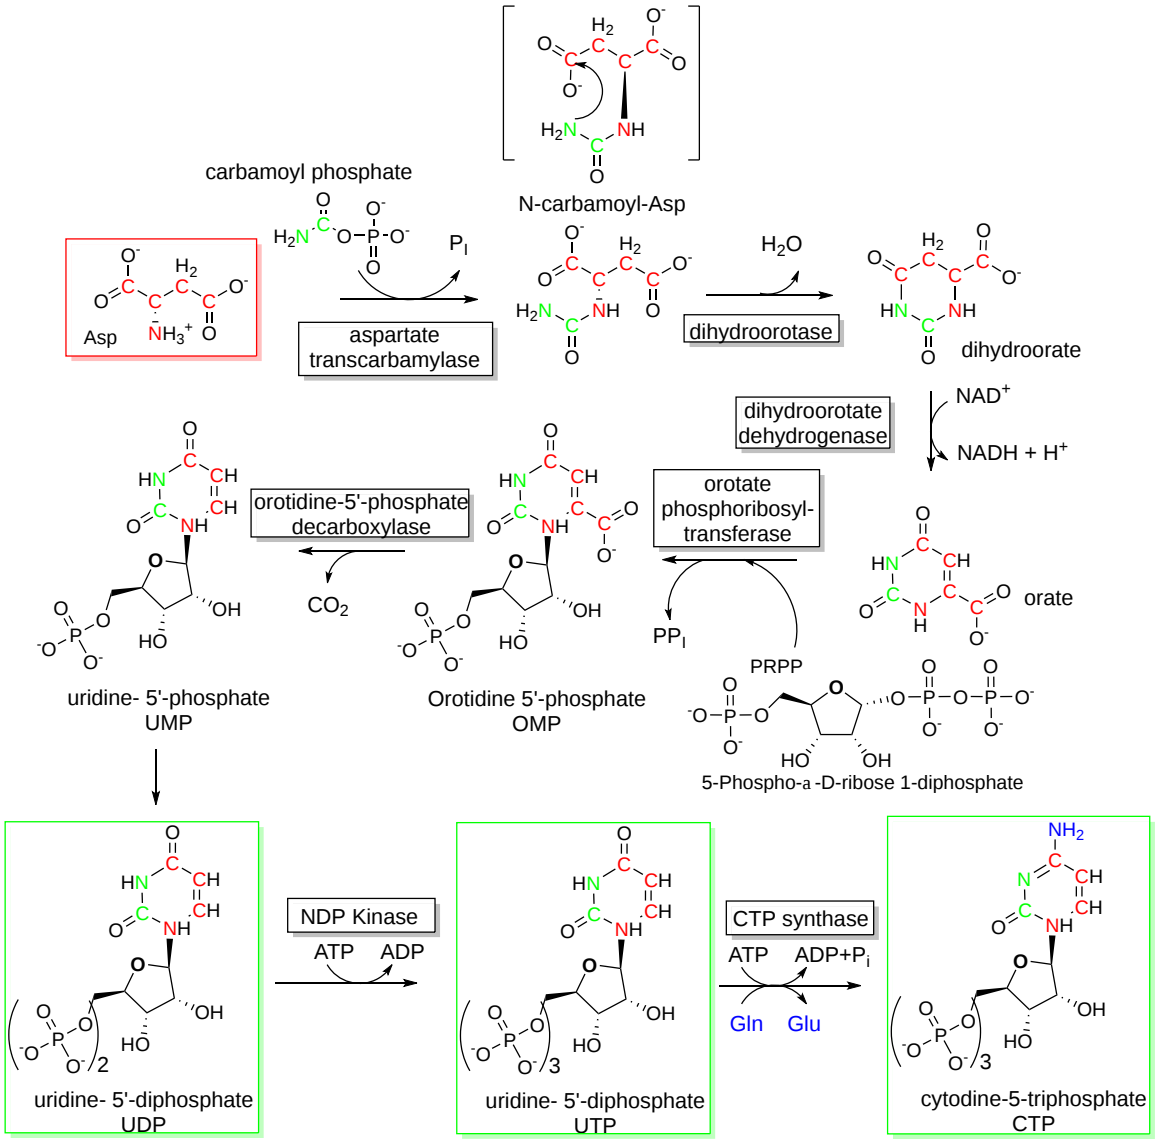

Figure 22.4.8: De novo synthesis of UDP, UTP and CTP

UDP and CDP can be converted to dCDP and dUDP, then on to dCPT and dUTP, and to dTMP as shown in Figure 22.4.9.

Deoxythymidine-5'-monophosphate Synthesis

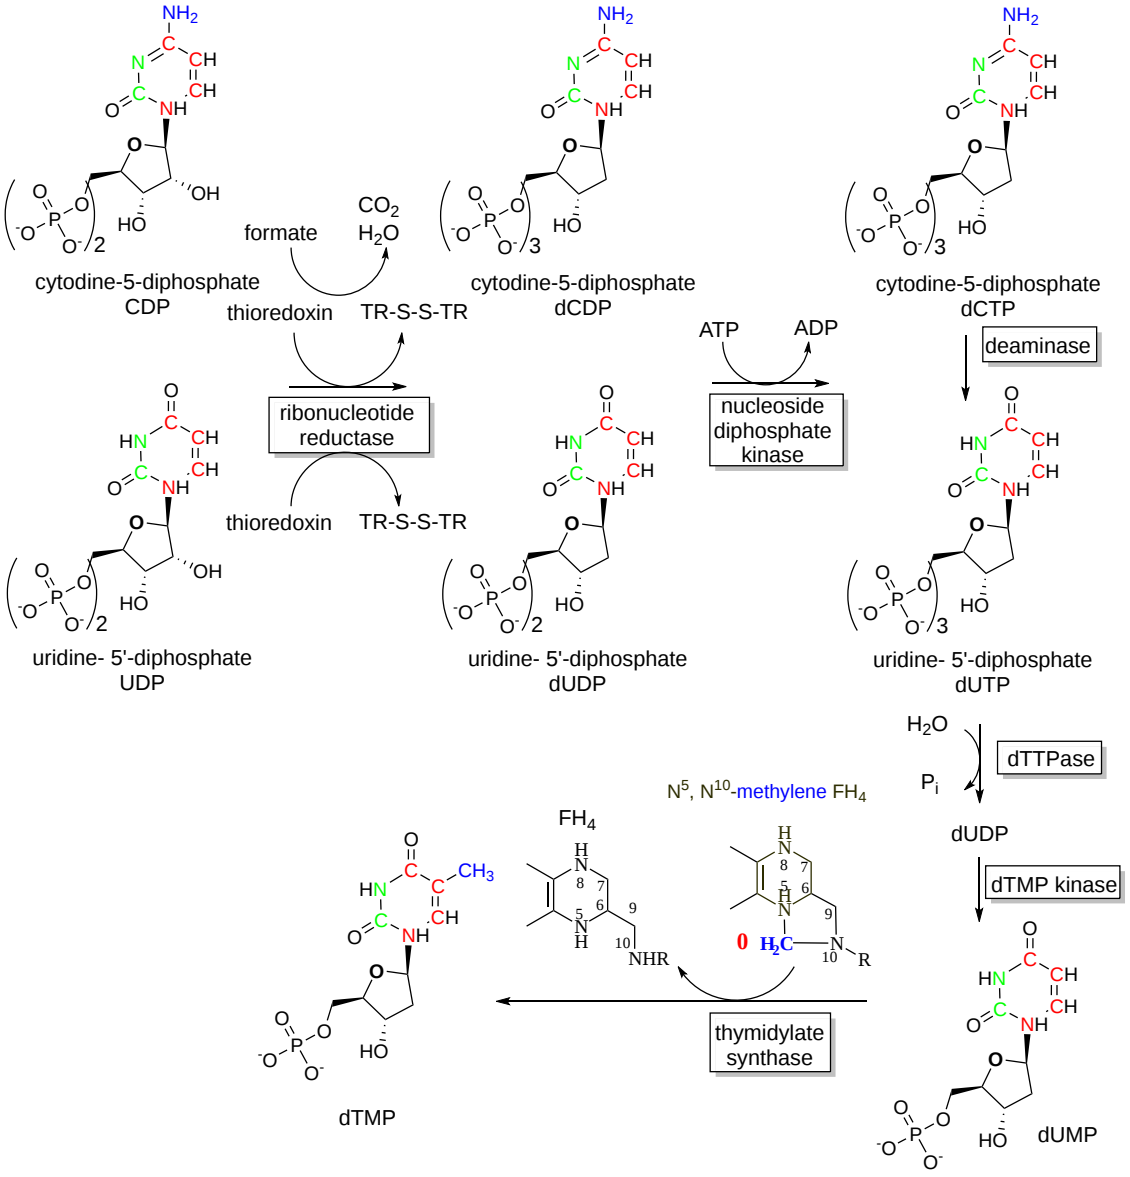

Figure 22.4.9: Synthesis of dTMP

Some of the material below derives from Li et al. *Int. J. Mol. Sci.* **2021**, *22*(19), 10253; **https://doi.org/10.3390/ijms221910253.** Creative Commons Attribution (CC BY) license (**https://creativecommons.org/licenses/by/4.0/**)

In purine synthesis, we saw multifunctional enzymes that catalyze several steps, as well as the assembly of the enzymes in the de novo pathway into the purinosome. In an analogous fashion, three different enzyme activities that catalyze the first three combined rate limiting steps of pyrimidine synthesis, **C**arbamoyl-phosphate synthetase, **A**spartate transcarbamoylase, and **D**ihydroorotase are found in a single, multifunction protein referred to as **CAD**. Its structure is a hexamer of a 243K monomer. It has 4 domains that include

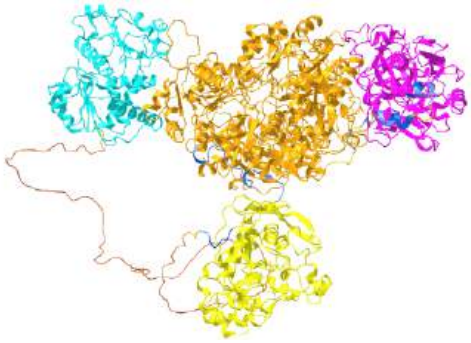
- glutamine amidotransferase (GATase) which "moves" HCO_3^-, glutamine, and ATP to the CPSIIase domain
- carbamoylphosphate synthetase II (CPSIIase): This has two parts, CPSaseA, and CPSase B. They combine functionally with GATase to form a glutamine-dependent carbamoylphosphate synthase (CPSase)
- aspartate transcarbamylase (ATCase) acts as a homotrimer
- dihydroorotase (DHOase) catalyzes the reversible cyclization reaction.

The CAD protein is a 'fusion' protein encoding these four enzymatic activities of the pyrimidine pathway. Figure 22.4.10 shows the domain structure of the CAD protein.

Figure 22.4.10: Domain structure of CAD

The red represents glutamine amidotransferase and the blue the carbamoyl phosphate synthase ATP binding domain. More specifically, the following amino acid stretches comprise the different domains: GATase (2-365), CPSase A (395-933), CPSlase B (934-1455), DHOase (1456-1788), and ATCase (1918-2225)

Figure 22.4.11 shows an interactive iCn3D model of the AlphaFold predicted model of the CAD protein (P27708)



NCBI iCn3D Figure 22.4.11: AlphaFold predicted model of the CAD protein (P27708). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...5V2XUmfsz1qjZ6

The GATase domain is magenta, the CPSase domains orange, the DHOase domain yellow, and the ATCase domain cyan. The structure of the disordered loops could not be modeled.

22.4.4: RIBONUCLEOTIDE REDUCTASES (RNRS)

Ribonucleotide reductases (RNRs), also called **ribonucleoside-diphosphate reductase,** catalyze the oxidation of the C2'-OH on the ribose ring to C2'-H through a free radical mechanism for the oxidation of for all NDPs including ADP, GDP, CDP and UDP (which converts to dUDP and in a different reaction to dTDP). The reaction is as follows:

[thioredoxin]-dithiol + ribonucleoside 5'-diphosphate ↔ [thioredoxin]-disulfide + 2'-deoxyribonucleoside 5'-diphosphate + H_2O

To refresh your mind, thioredoxin is a small protein (12K) that is part of a complex with thioredoxin reductase and thioredoxin-interacting protein. It has two key sulfhydryls at the active site which act as reducing agents as they get converted to a disulfide as shown in Figure 22.4.12.

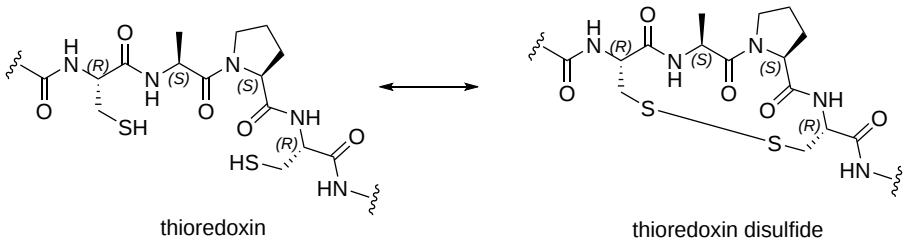


Figure 22.4.12: Reduced thioredoxin and its oxidized form

This single enzyme is so critical to cellular life that we will examine it more closely.

There are several classes of these enzymes (Ia-Ie, II, and III). The class I enzymes generally use a di-transition metal complex as a cofactor while class II uses adenosylcobalamin. We will focus on class I enzymes, which have two subunits, called α and β or M1 and M2, respectively. The NDP binds in an α/M1 subunit active site which is developed only in the dimer. The β/M2 subunit is often referred to as the radical-generating subunit as it contains the transition metal complex that generates a free tyrosyl radical cation critical to the reaction.

Almost all class I ribonucleotide reductases (RNRs) use transition metal ions located in the β/M2 subunit in the catalytic cycle for the dehydroxylation of the 2' OH on the ribose ring of the nucleotide. The metal ion complex a β/M2 subunit tyrosine to a tyrosine free radical cation which oxidizes an active site cysteine in the α/M1 subunit to form a thiol radical cation ($Cys•^+$), called a thiyl radical. This abstracts a

H• from the 3'C on the ribose of the substrate, forming a 3'C radical cation. This facilitates a dehydration reaction which leads to the dehydroxylation of the 2' OH, regenerating the thiyl radical. Reducing equivalents to restore the catalytic function of the enzyme come from the oxidation of a thioredoxin disulfide bound in the other subunit of the protein or a formate.

Given the importance of these enzymes, they must be highly regulated. There are two regulatory sites:

- a specificity site: determines nucleotide (NDP) specificity
- an activity site: regulates catalytic activity

The specificity and activity sites are in the α/M1 subunit where allosteric regulators dNTPs and ATP bind to different sites. When ATP is bound, the enzyme uses CDP and UDP as substrates. When dGTP is bound, ADP is the preferred substrate. Finally, when dTTP is bound, GDP is the preferred substrate. The enzyme is inhibited by dATP binding to the actual active site.

Figure 22.4.13s shows an abbreviated mechanism and cartoon showing the activities of the two subunits.

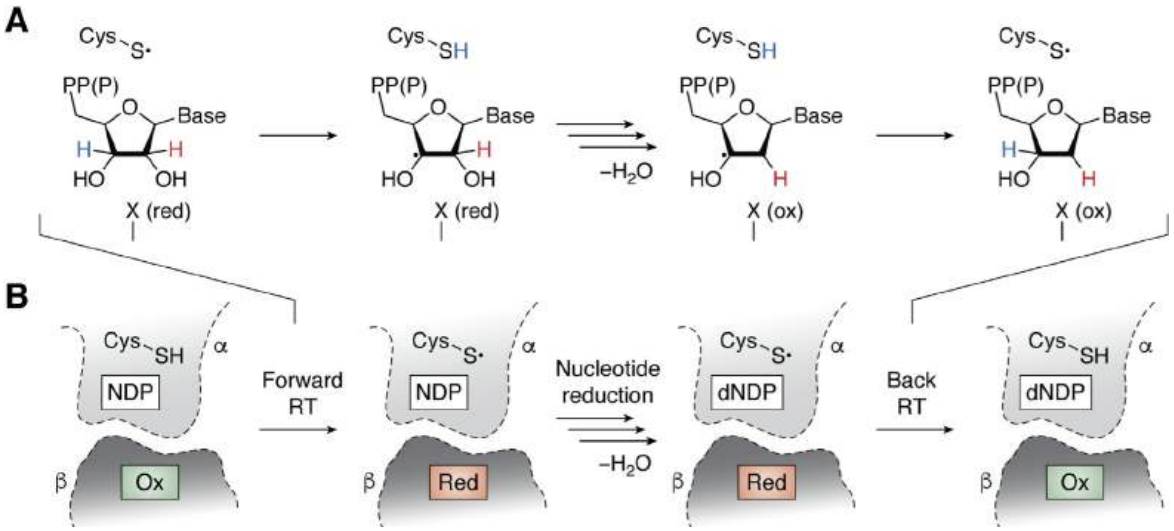

Figure 22.4.13: Abbreviated mechanism and a cartoon showing the activities of the two subunits. in class I RNR. *A*, universal mechanism for nucleotide reduction in RNRs. *B*, diagram of the steps involved in radical translocation in class I RNRs. Ruskoski and. Boal. J. Biol. Chem. (2021) 297(4) 101137. DOI:https://doi.org/10.1016/j.jbc.2021.101137. CC-BY license (http://creativecommons.org/licenses/by/4.0/)

Radical formation starts at tyrosine 122 in the metal center site in the β/M2 subunit. Electron transfer then occurs across the two subunits from a very distant active site Cys 439 in the α subunit. which enables the formation of the thiyl radical cation ($Cys^{\bullet+}$).

The structure of an E. Coli Type IA enzyme with bound ligands has been determined after much effort that involved trapping of a long-life intermediate. It required replacement of Tyr 122 in both β chains with 2,3,5-trifluorotyrosine, which allowed the structure to be determined by cyro-EM. Tyr 122 in the β chain forms starts the process of electron transfer as it becomes the Tyr $122^{\cdot+}$ radical cation.

A detailed mechanisms showing both electron transfer to $Y122^{\cdot+}$ and accompanying proton transfer is shown in Figure 22.4.14.

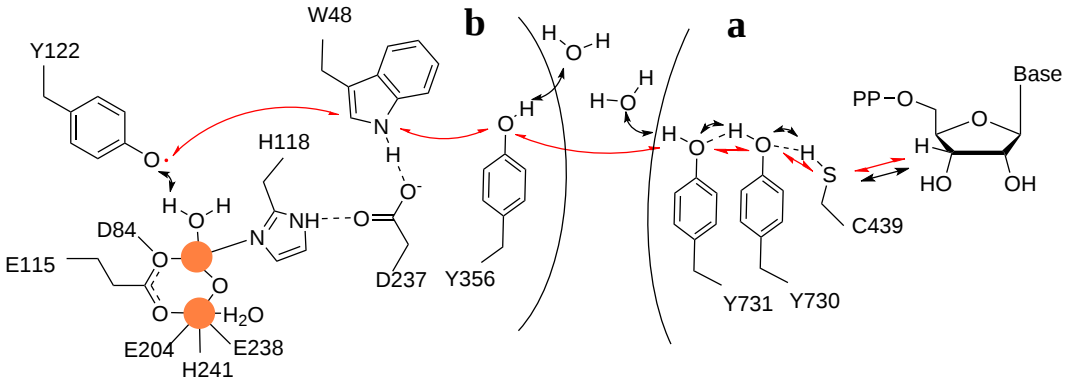

Figure 22.4.14: Pathway of electron and proton transfers for the formation of the thiyl radical cation ($Cys^{\bullet+}$). after Kang et al. Science (2020). DOI: 10.1126/science.aba6794)

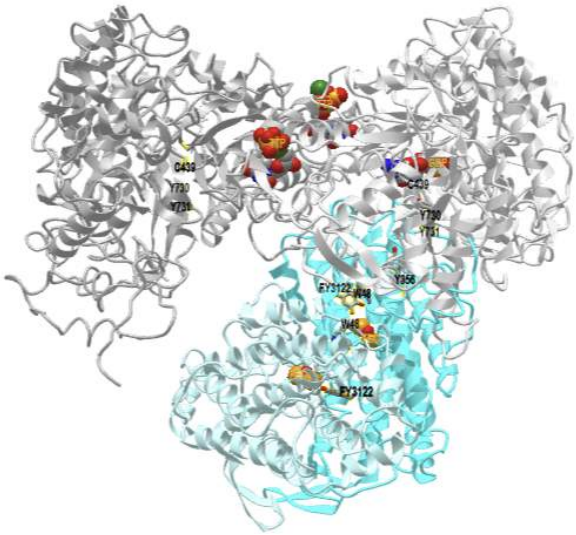
The path for electron flow from the sulfur of C439 in the β subuit to regenerate Y122 is shown. That electron transfer occurs over a very long distance of 35 Å as it hops from the original sulfur donor to the acceptor.

Figure 22.4.15 shows an interactive iCn3D model of the holocomplex of E. coli class Ia ribonucleotide reductase with GDP and TTP (6W4X).



NCBI iCn3D Figure 22.4.15: Holocomplex of E. coli class Ia ribonucleotide reductase with GDP and TTP (6W4X). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...71ubUDRovXURG8

The structure is a tetramer of two α chains (different shades of gray) and two β chains (different shades of cyan). The GDP and TTP in the α subunit and the Fe cluster in the β subunit are shown in CPK spacefill and labeled. The key side chains in the α and β chains that participate in electron transfer over the 35 Å distance are shown in CPK-colored sticks and labeled. The Fe^{2+} ions are in the form of a μ-oxo-diron complex (2 Fe ions coordinated by 1 oxide).

Figure 22.4.16 shows specificity and catalytic sites of the biologically active tetramer form for Class 1 RNR as well as the transition metal cofactors (Fe, Mn, or both) in various Class 1 RNRs.

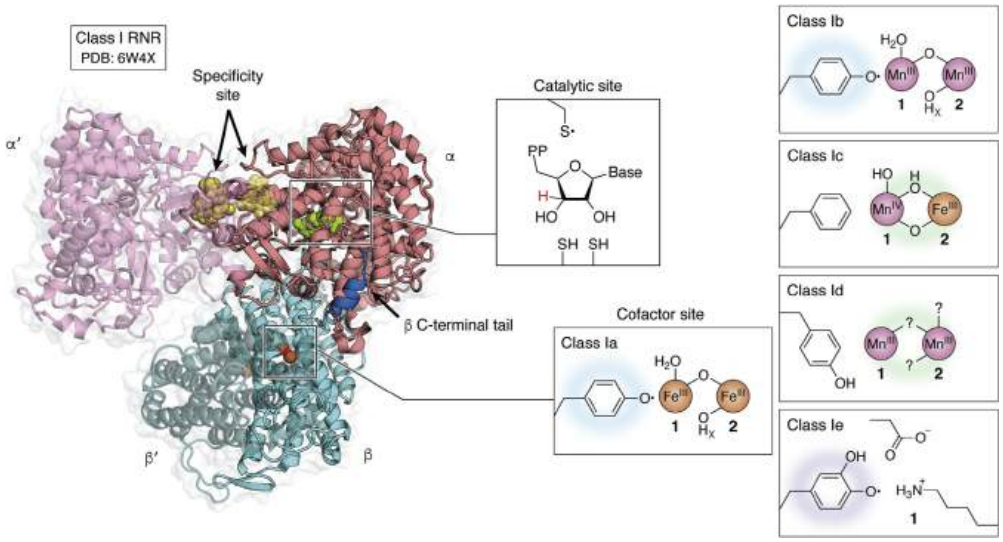


Figure 22.4.16: Quaternary structure of the active holoenzyme complex in class I RNR (PDB accession code 6W4X). *Insets* show the location of the active site in the catalytic α subunit (*middle top*) and the metallo- or radical cofactor (*middle bottom* and *far right*) in the β subunit

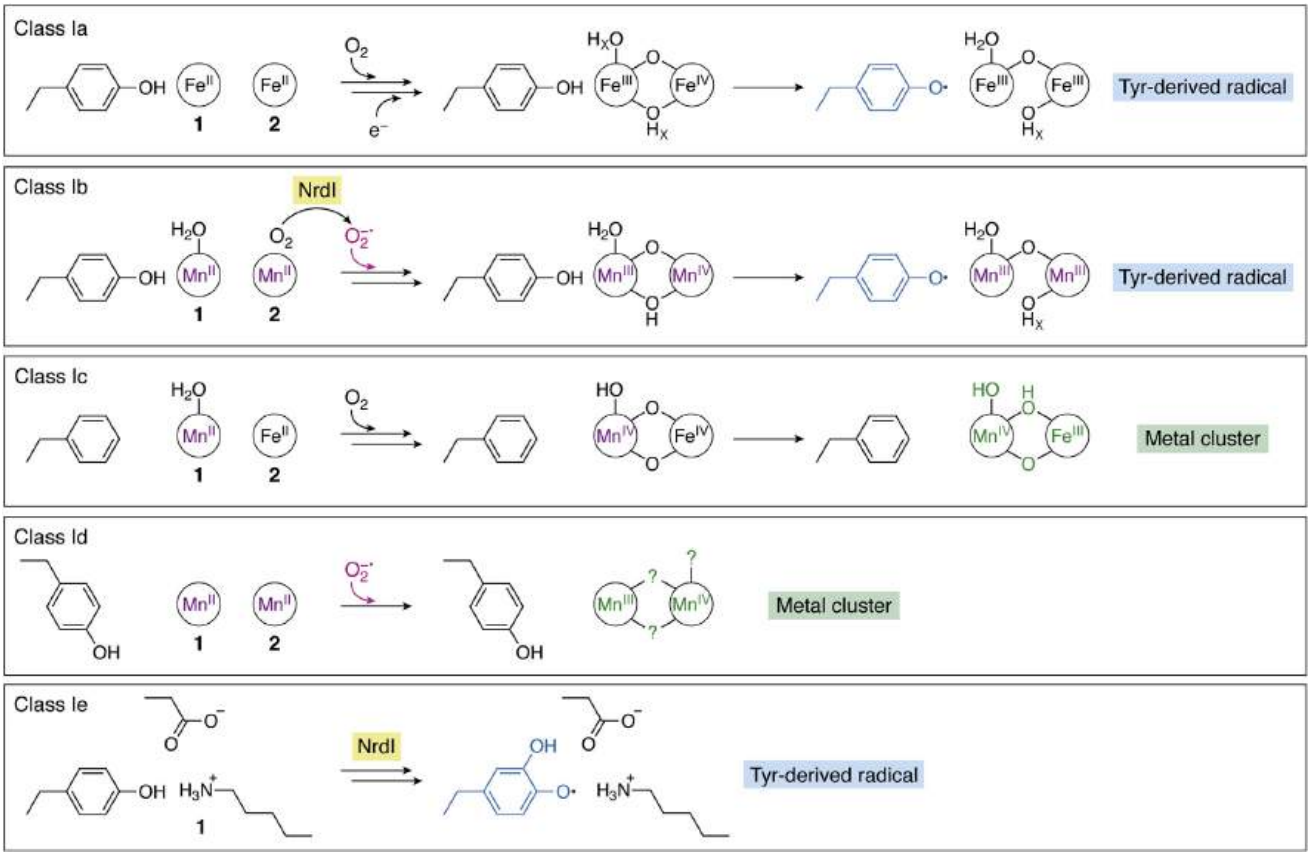
The tyrosyl free radical forms on binding of dioxygen to the transition metal ion center electron and subsequent loss of an electron from tyrosine, as shown in Figure 22.4.17:

Figure 22.4.17: Cofactor assembly mechanisms for class I RNRs. Manganese-dependent enzymes are highlighted in *purple*. Superoxide-dependent RNRs are highlighted in *hot pink*. Subclasses that require a NrdI activase are indicated with a *yellow box*. Metal-centered Cys oxidants shown in *green* and Tyr-derived radical Cys oxidants shown in *blue*.

The mechanisms of cofactor actions are not fully understood. O_2 initially adds to the Fe^{2+}/Fe^{2+} cluster which forms a peroxo-Fe^{3+}/Fe^{3+}



intermediate.

Structural features of the active site for different class I RNRs along with redox-active transition metal ions are shown in Figure 22.4.18.

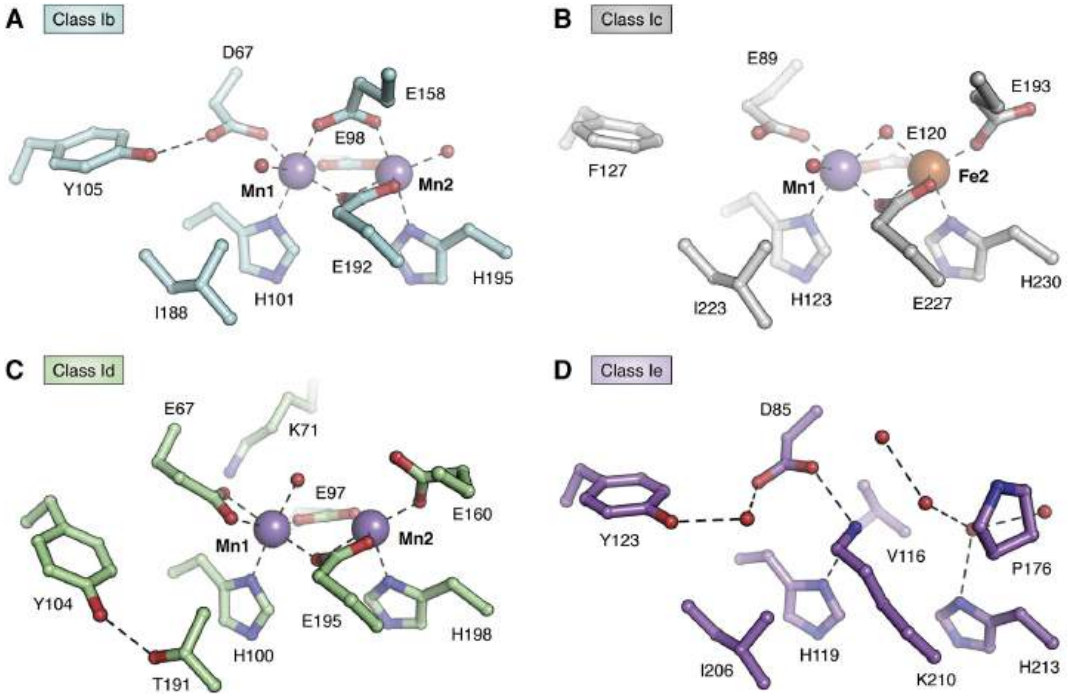


Figure 22.4.18: Comparison of metal-binding sites in class I RNRs

The PDB codes for each structure are as follows: A, (3N3A), B, 4M1I), C, (6CWP), and D (6EBO). Water molecules are shown as *red spheres*.

Now let's look at the regulation of class IA RNRs in more detail. Let's consider perhaps the most important allosteric regulators which bind 15 Å from the active site which affect RNR enzymatic activity:

- dATP: inhibits RNRs when it binds to the α subunit
- ATP: reverses the inhibition by dATP

dATP/ATP also affects RNR enzyme specificity as they tilt the preference of RNR towards pyrimidine substrates, where TTP and dGTP promote purine substrate binding. These same rules apply to human and E. coli RNRs, with the locations of the active sites also being the same.

The allosteric regulators appear to affect the quaternary structure of the enzyme.

In E. Coli, the binding of dADP converts the structure of the enzyme from an active $\alpha_2\beta_2$ form to an inhibited $\alpha_4\beta_4$ ring structure. When dATP is bound, a "**cone**" domain in α forms interactions with the β subunit, leading to the formation of a dimer of the $\alpha_2\beta_2$ tetramer. ATP reverses this effect by displacing dATP and pushing the equilibrium towards the active $\alpha_2\beta_2$ form. This is shown in Panel A of Figure 22.4.19.

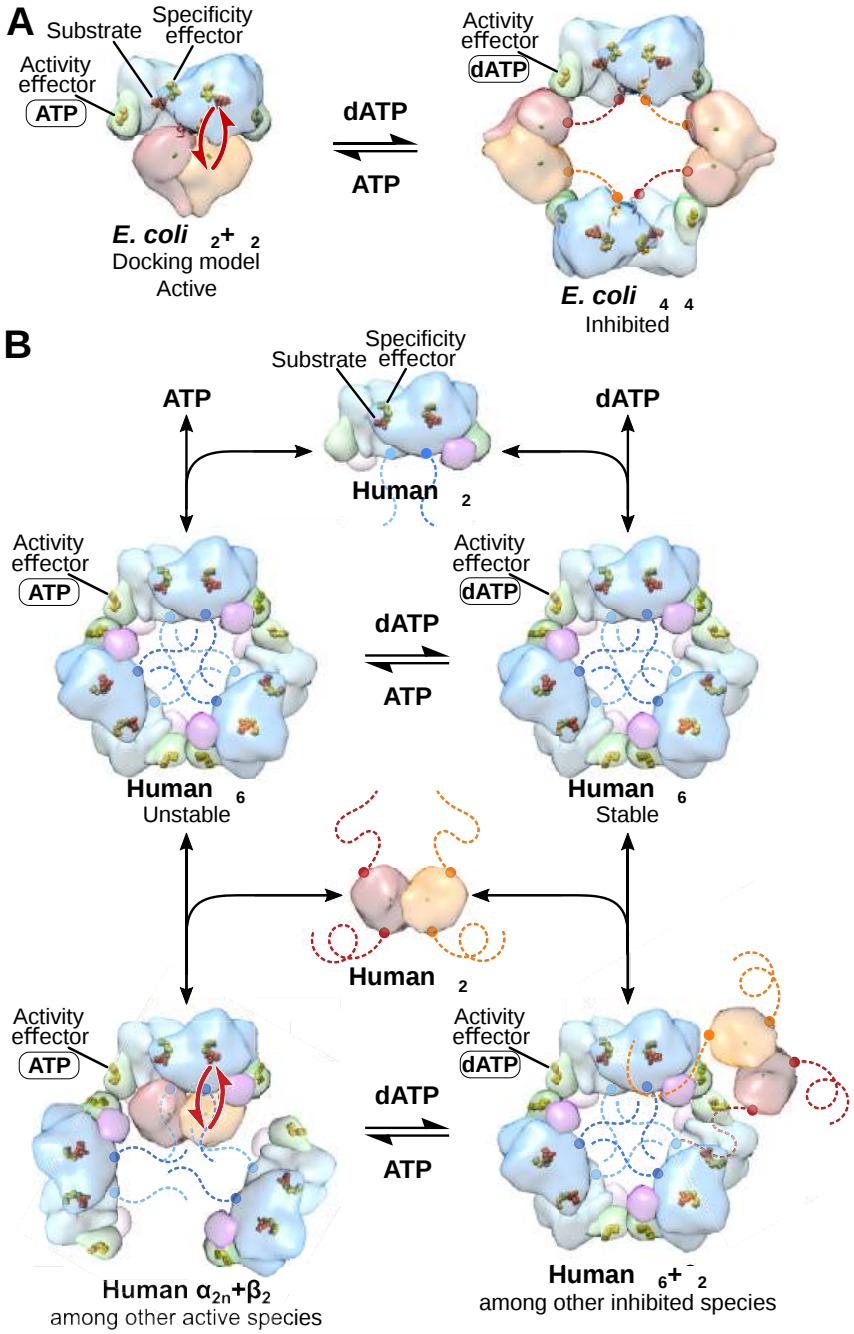

Figure 22.4.19: **Comparison of mechanisms of allosteric regulation of activity for *E. coli* and human RNRs.** Brignole et al. 3.3-Å resolution cryo-EM structure of human ribonucleotide reductase with substrate and allosteric regulators bound eLife 7:e31502. https://doi.org/10.7554/eLife.31502. Attribution 4.0 International (CC BY 4.0).

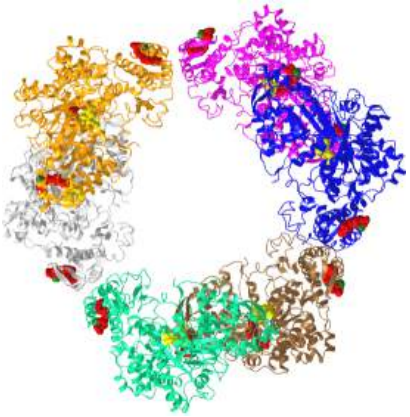
Panel B above illustrates the regulation of the human enzyme, which appears to be quite different. In the absence of either dATP or ATP, RNRs exist just as α_2 dimers. On binding either dATP or ATP, the α_2 dimer is converted to an α_6 (a trimer of dimers) structure. Both are inactive in the absence of β subunits (which provide the metal cofactor site)

- When β_2 is added to the dATP bound α_6 hexamer, the hexamer becomes stabilized, but the resulting complex is inhibited.
- When β_2 is added to the ATP bound α_6 hexamer, the hexamer becomes destabilized and into smaller structures which are active.

Hence the ratio of cellular dATP/ATP changes the aggregation state of the RNR and hence its activity in both E. Coli and humans.

Figure 22.4.20 shows an interactive iCn3D model of the Human ribonucleotide reductase large subunit (alpha) with dATP and CDP (6AUI).



NCBI iCn3D Figure 22.4.20: Human ribonucleotide reductase large subunit (alpha) with dATP and CDP (6AUI). (Copyright; author via source). Click the image for a popup or use this external link:https://structure.ncbi.nlm.nih.gov/i...w1sFwwYSAD4nG6

Each of the α subunits in the hexamer is shown in a different color. dATPs (allosteric inhibitors) are shown in spacefill, red. CDPs (substrates) are shown in spacefill yellow.

The hole in the middle of the structure prevents β_2 from binding in a catalytically productive fashion, so the structure is inactive.

A specific loop, loop 2, assists in the determination of RNRs specificity. It is between the base of dATP and the base of the substrate CDP. The backbone of the loop interacts with the adenine base and orients Gln 288 in the active site to interact with the cytosine of the substrate CDP. In both systems, backbone atoms of this loop ‘read out’ the adenine base and position Gln288 into the active site to recognize the cytosine of CDP. Figure 22.4.20 gives further details on the origin of substrate specificity.

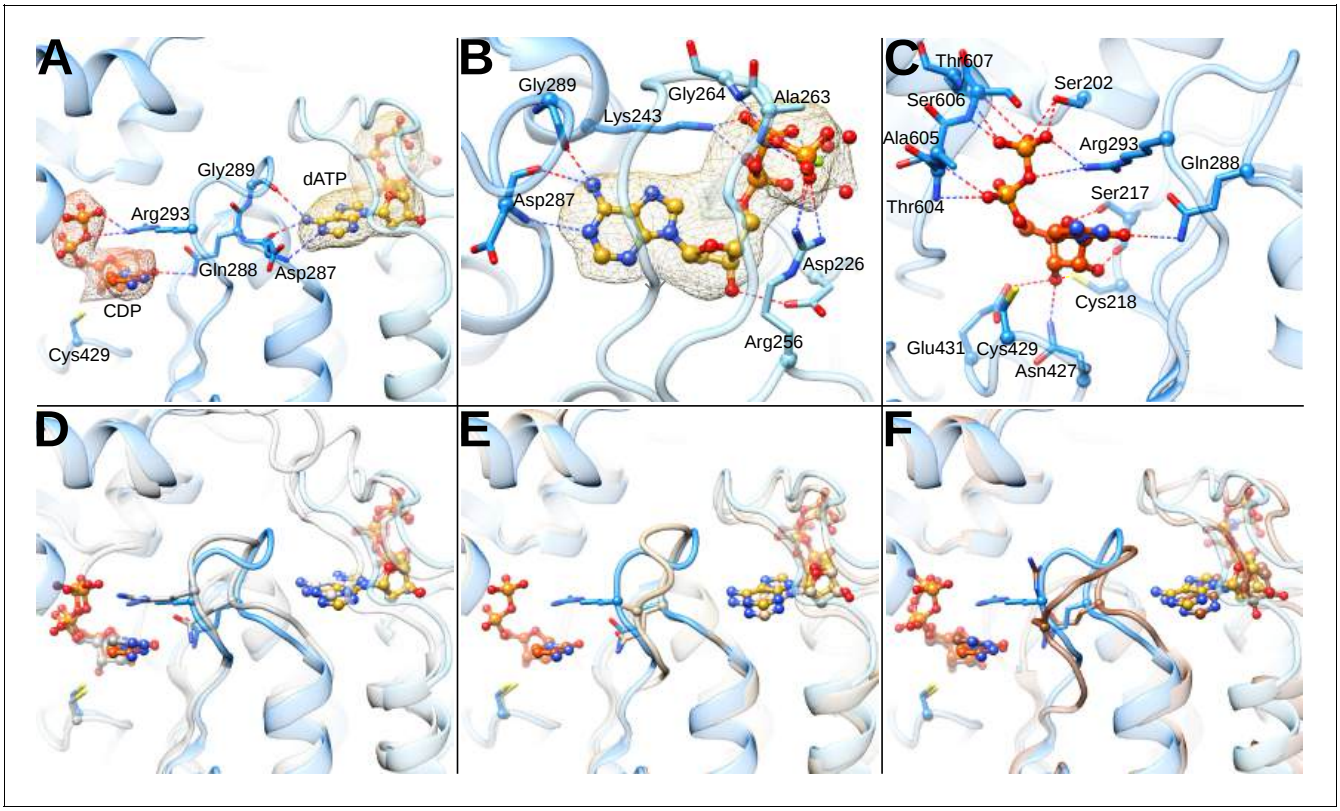


Figure 22.4.21: Determinants of substrate specificity are conserved from *E. coli* to humans**.**

Panel (**A**) shows residues of human α (blue) interacting with CDP (carbons in orange) in the active site and dATP (carbons in yellow) in the specificity site. Density for CDP in orange mesh and for dATP in the yellow mesh.

Panel (**B**) zooms in on dATP in the specificity site. Water molecules and oxygen atoms are in red, nitrogen in blue, magnesium in green, and phosphate in gold.

Panel (**C**) zooms in on CDP in the active site.

Panel (**D**) shows an overlay of human α from the α_6 EM structure in blue with *E. coli* α from the $\alpha_4\beta_4$-CDP-dATP cocrystal structure in gray (PDB: 5CNS) shows a nearly identical loop 2 conformation positioning Gln288 and Arg293 (Gln294 and Arg298 in *E. coli*).

Panel (**E**) shows an overlay of human α from the α_6 EM structure in blue with the crystal structure of human α with N- and C-termini truncated (residues 77–742) cocrystallized with dATP in tan (PDB: 2WGH) shows similar positioning of dATP but an altered conformation of loop 2 in the absence of bound CDP. The CDP shown is from the α_6 EM structure.

Panel (**F**) shows an overlay of human α from the α_6 EM structure in blue with equivalent residues of yeast α structure with CDP and AMPPNP in brown (PDB: 2CVU) and shows a conformation of loop 2 that is distinct from that seen in structures of *E. coli* and human α

22.4.4.1: TRANSCRIPTIONAL REGULATION OF RNRS

Given the importance of this key enzyme, it should come as no surprise that its levels are regulated at the transcription level. As the activity of RNR is determined by its polymeric quaternary state, the transcriptional activation of the genes for RNRs is controlled in bacteria by quaternary states of the RNR-specific transcriptional repressor NrdR. The transcription factors bind to a specific DNA sequence called an NrdR box, which precedes the start site of transcription for RNR, where RNA polymerase binds.

The NrdR protein acts to repress the synthesis of RNR genes. Its aggregation state is controlled by dATP/ATP ratios. When dATP is high, the NrdR binds to DNA and represses the synthesis of the RNR gene. In contrast when ATP is high, the protein does not bind to DNA and hence it can not repress transcription. The association /dissociation of the repressor is controlled by the aggregation state of NrdR. When abundant, NrdR exists as a 12-mer complex with two molecules of ATP bound per monomer. This ATP-bound 12-mer can't bind DNA, so transcription of the gene for RNR is not repressed. As dATP increases, one ATP is displaced so each monomer has 1 dATP and 1 ATP bound. This causes the NrdR to covet to an 8-mer. A 4-mer (tetrameric) version of this protein binds to the NrdR box sequence at the start of the RNR gene, repressing its synthesis.

Figure 22.4.22 shows the **dodecameric, octameric, and tetrameric structures of NrdR and their functions.**

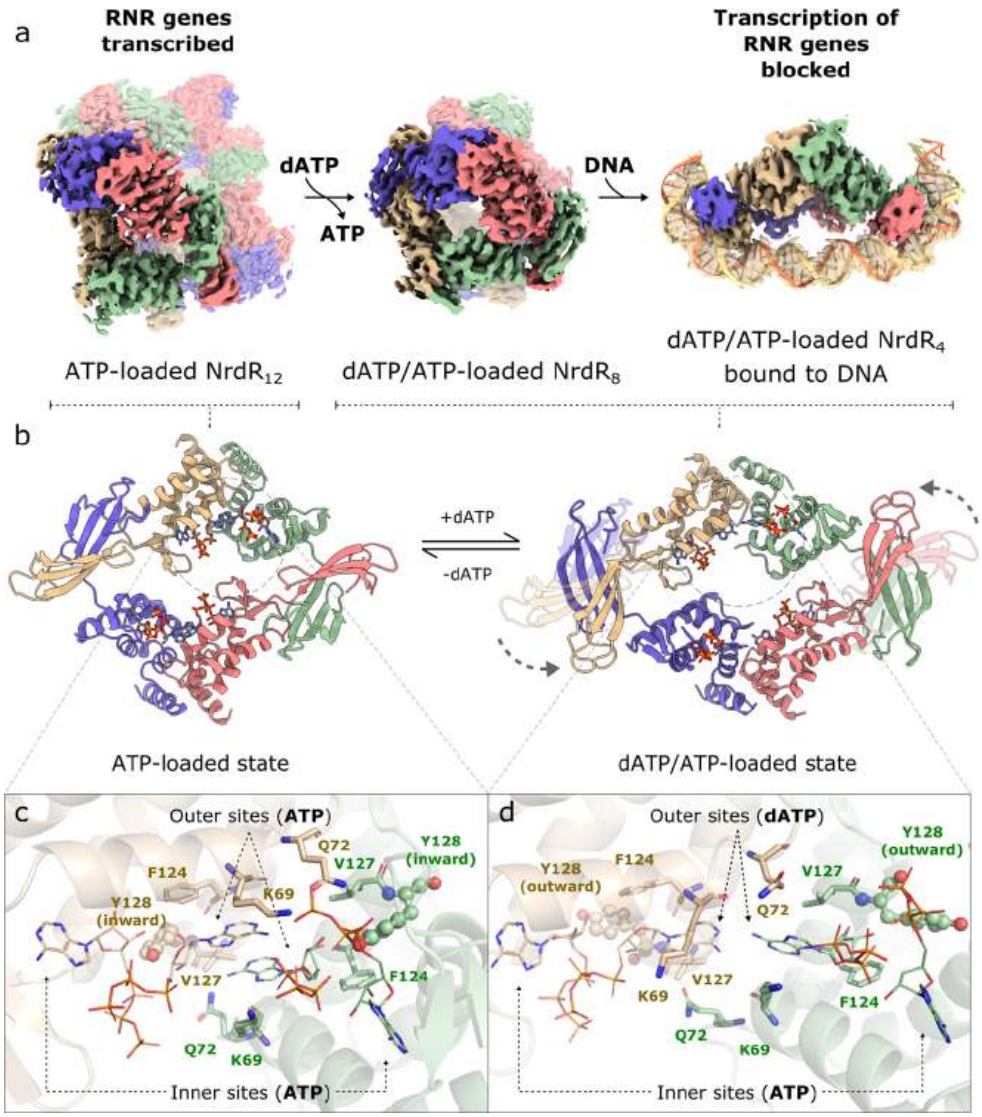

Figure 22.4.22: **Mechanism of NrdR function involving dodecameric, octameric, and tetrameric structures.** Rozman Grinberg, I., Martínez-Carranza, M., Bimai, O. *et al.* A nucleotide-sensing oligomerization mechanism that controls NrdR-dependent transcription of ribonucleotide reductases. *Nat Commun* **13,** 2700 (2022). https://doi.org/10.1038/s41467-022-30328-1. CHAPTER OVERVIEW

23: Chromosome Structure

23.1: Gene Mapping and Chromosomal Karyotypes

23.2: DNA Transposable Elements

23.3: Chromosome Packaging

23.1: Gene Mapping and Chromosomal Karyotypes

23.1.1: Introduction

Genes provide instructions to build living organisms and each specific gene maps to the same chromosome in every cell. This physical gene location within the organism's chromosomes is called the gene loci. If two genes are found on the same chromosome, especially when they are near one another, they are said to be linked.

Genetic linkage is the tendency of DNA sequences that are close together on a chromosome to be inherited together during the meiosis phase of sexual reproduction. Two genetic markers that are physically near to each other are unlikely to be separated into different chromatids during chromosomal crossover and are therefore said to be more *linked* than markers that are far apart. In other words, the nearer two genes are on a chromosome, the lower the chance of recombination between them, and the more likely they are to be inherited together. Markers on different chromosomes are perfectly *unlinked*.

Genetic linkage is the most prominent exception to Gregor Mendel's Law of Independent Assortment. The first experiment to demonstrate linkage was carried out in 1905. At the time, the reason why certain traits tend to be inherited together was unknown. Later work revealed that genes are physical structures related by physical distance.

The typical unit of genetic linkage is the centimorgan (cM). A distance of 1 cM between two markers means that the markers are separated into different gametes on average once per 100 meiotic products, thus once per 50 meioses. A **linkage map** (also known as a **genetic map**) is a table for a species or experimental population that shows the position of its known genes or genetic markers relative to each other in terms of recombination frequency, rather than a specific physical distance along each chromosome. Linkage maps were first developed by Alfred Sturtevant, a student of Thomas Hunt Morgan. Figure 23.1.1 shows a gene linkage map with the relative positions of allelic characteristics on the second Drosophila chromosome.

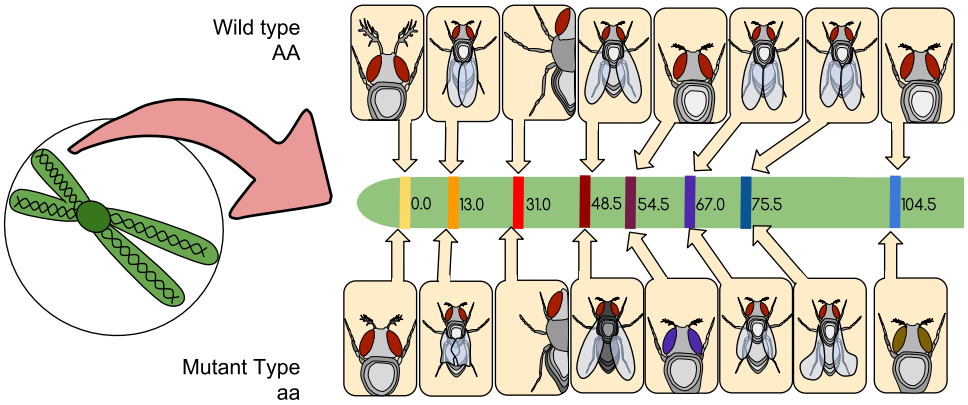

Figure 23.1.1: Gene linkage map showing the relative positions of allelic characteristics on the second Drosophila chromosome. The alleles on the chromosome form a linkage group due to their tendency to form together into gametes. The distance between the genes (map units) is equal to the percentage of crossing-over events that occurs between different alleles. This diagram is also based on the findings of Thomas Hunt Morgan in his Drosophila cross. (CC BY-SA 4.0 International; Twaanders17 via Wikipedia

A linkage map is a map based on the frequencies of recombination between markers during the crossover of homologous chromosomes. The greater the frequency of recombination (segregation) between two genetic markers, the further apart they are assumed to be. Conversely, the lower the frequency of recombination between the markers, the smaller the physical distance between them. Historically, the markers originally used were detectable phenotypes (enzyme production, eye color) derived from coding DNA sequences; eventually, confirmed or assumed noncoding DNA sequences such as microsatellites or those generating restriction fragment length polymorphisms (RFLPs) have been used.

Linkage maps help researchers to locate other markers, such as other genes by testing for genetic linkage of the already known markers. In the early stages of developing a linkage map, the data are used to assemble **linkage groups**, a set of genes that are known to be linked. As knowledge advances, more markers can be added to a group, until the group covers an entire chromosome. For well-studied organisms, the linkage groups correspond one-to-one with the chromosomes.

Traditional studies used to physically map genes onto specific chromosomes were painstaking and involved using restriction enzymes to fragment the genome of an organism and then clone the fragments into YACs or BACs creating a DNA library. The library could then be screened with specific genetic probes to determine which fragment contained a gene of interest. The

fragments would then need to be sequenced and reassembled using overlapping patterns. Today, the sequencing of entire genomes from nearly any organism is possible and relatively easy in comparison. Thus, a traditional genetic map can more readily be overlayed on the physical chromosomal map of an organism as shown in Figure 23.1.2 This was one of the overarching goals of the human genome project.

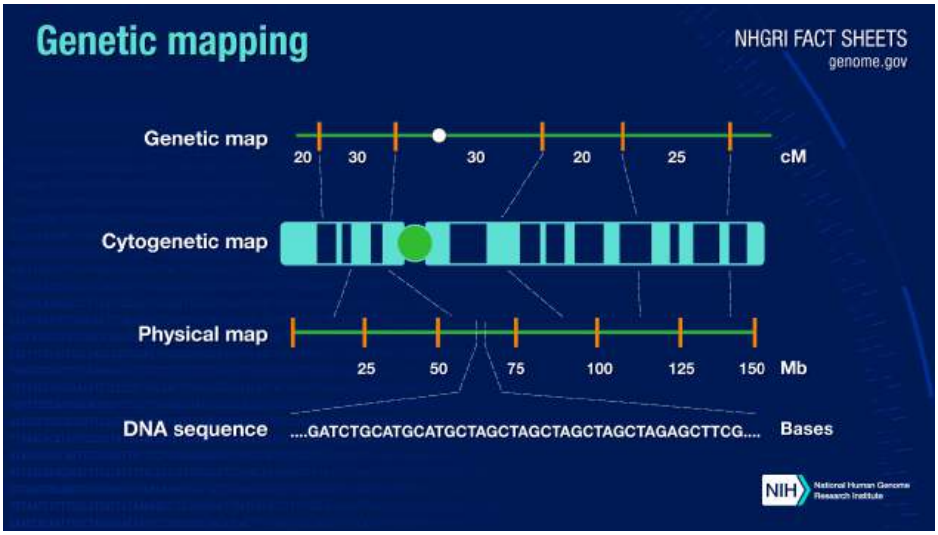

Figure 23.1.2: Traditional genetic map overlayed on the physical chromosomal map of an organism. The National Institutes of Health

23.1.2: Karyotypes

The entire chromosome set of a species is known as a **karyotype**, which can be thought of as a global map of the nuclear genome. **Karyotyping** is the process by which the condensed chromosomes of an organism are stained and photographed using light microscopy. Karyotyping can be used to determine the chromosome complement of an individual, including the number of chromosomes and any abnormalities.

Karyotypes describe the chromosome count of an organism and what these chromosomes look like under a light microscope. Attention is paid to their length, the position of the centromeres, banding pattern, any differences between the sex chromosomes, and any other physical characteristics. The preparation and study of karyotypes are part of the larger field of **cytogenetics**. The field of **cytogenetics** involves the study of inheritance in relation to the structure and function of chromosomes. Thus, karyotyping is a fundamental process within this field.

The study of whole sets of chromosomes is sometimes known as **karyology**. The chromosomes are depicted (by rearranging a photomicrograph) in a standard format known as a *karyogram* or *idiogram*: in pairs, ordered by size and position of centromere for chromosomes of the same size, as shown in Figure 23.1.3

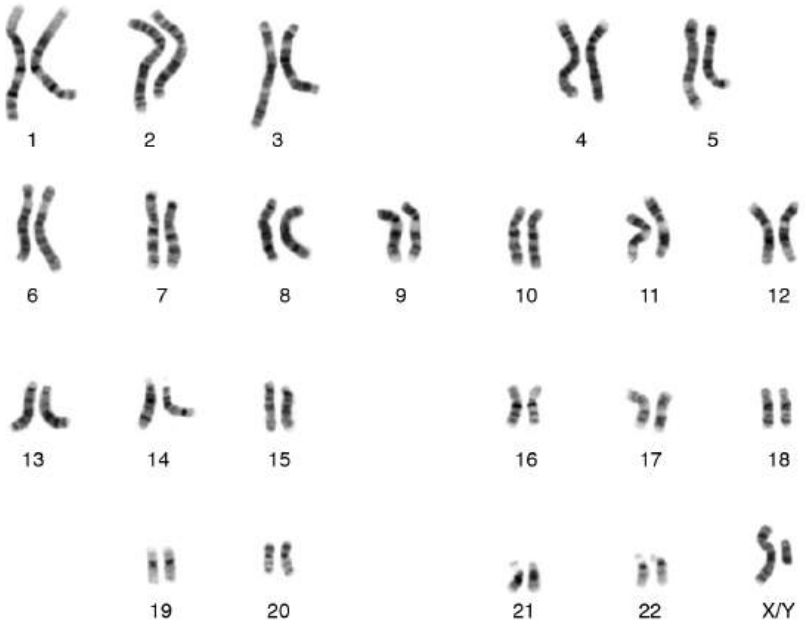

Figure 23.1.3: Human Karyogram. The National Cancer Institute

The basic number of chromosomes in the somatic cells of an individual or a species is called the **somatic number** and is designated ***2n*.** In the germ line (the sex cells) the chromosome number is ***n*** (humans: n = 23). Thus, in humans 2n = 46. In normal **diploid** organisms, autosomal chromosomes are present in two copies. There may, or may not, be sex chromosomes. **Polyploid** cells have multiple copies of chromosomes and **haploid** cells, usually, gametes, have single copies. Karyotypes can be used for many purposes; such as to study chromosomal aberrations, cellular function, taxonomic relationships, medicine and to gather information about past evolutionary events (***karyosystematics***).

During the chromosomal staining processes used to produce a karyotype, the staining intensity along the chromosome can vary due to localized sequence and structural differences. These banding patterns are an inherent characteristic of a chromosome and can be utilized as a diagnostic tool. Typically, karyotypes are prepared from cells that are actively undergoing mitosis. The mitotic progression is blocked in prometaphase or metaphase when chromosomes exist in their most condensed state. The cells are lysed, but the nuclei are retained intact and are subsequently treated with a chemical fixing agent. Once fixed, a number of different types of stains can be used to visualize the chromosomes.

One of the first types of chromosomal staining procedures developed was known as Q-banding, which was developed in 1970 by Torbjorn Caspersson. This technique uses the DNA-alkylating dye, quinacrine, which forms a covalent link with the DNA. Researchers noted that the staining patterns resulting from this technique were consistent and repeatable, demonstrating that banding patterns can be used to identify and characterize individual chromosomes. Giemsa dye, as shown in Figure 24.3, is more commonly used today, as it can be used with bright field microscopy and produces high detail banding patterns. A specific technique, called G-banding uses Giemsa staining following the treatment of mitotic chromosomes with the protease, trypsin. Pre-treating the sample with trypsin before staining causes the partial breakdown of chromosomal proteins leading to chromosomal relaxation. This allows more thorough staining of the chromosomes when treated with Giemsa dye. When the chromosomal region is more tightly packed into heterochromatin, it tends to stain more darkly with the Giemsa dye, than the more lightly packaged euchromatic regions. Heterochromatic regions tend to have higher A-T content and don't contain as many gene regions as euchromatic regions. Euchromatic regions stain more lightly with G-banding. Other types of staining with Giemsa, include R-banding or Reverse-banding, which involves heating the DNA before staining. This is thought to cause the melting of A-T-rich regions, reducing the Giemsa staining, when compared to G-C-rich, gene-containing regions of the chromosomes.

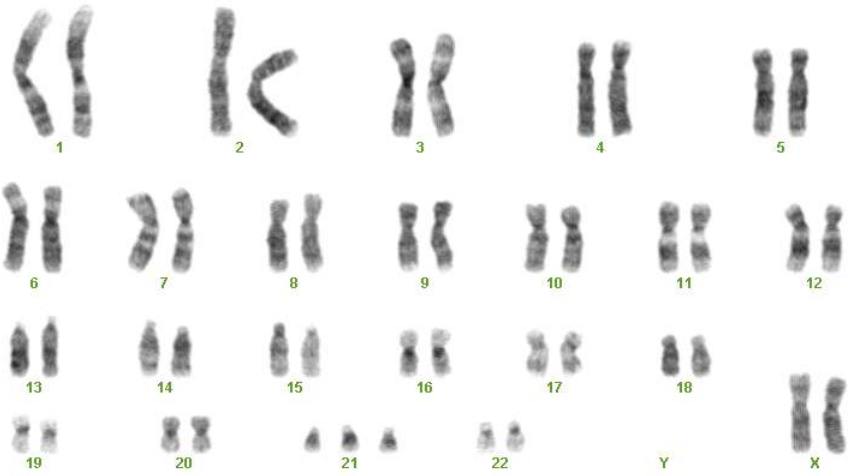

Figure 23.1.4: Female Down Syndrome Karyotype Demonstrating Trisomy 21. (Karyotype prepared by Fatma Soylemez). Image from: Soylemez, F. (2014) Chapter in Health Problems in Down Syndrome.

When visualizing a karyotype, the chromosomal images are aligned so that heterologous chromosomes are paired together and positioned such that the p-arm (short arm) is on top and the q-arm (long arm) points downward. Karyotypes can be used to quickly identify gross chromatic abnormalities that are larger than a few megabases in difference. This includes abnormalities such as ***aneuploidy*** (the addition or absence of an entire chromosome), or ***translocations*** (the transfer of part of a chromosome to a neighboring chromosome), as shown in Figure 23.1.4 and Figure 23.1.5.

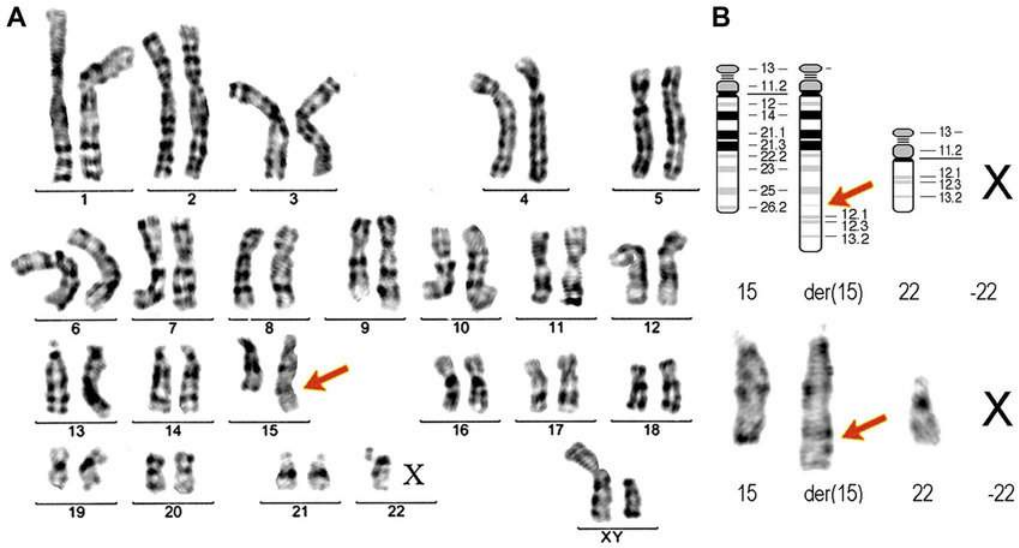

Figure 23.1.5: Karyotype of a Translocation (A) G-banding karyotype of a patient with t(15;22) translocation. Chromosome 22 monosomy with an unbalanced translocation is observed. The red arrows indicate the abnormal chromosomes. X indicated total monosomy. Original magnification, x110. (B) Ideogram and partial G-banding karyotype showing a more defined image of the translocation of the q-arm of chromosome 22 to chromosome 15. Image from: Gug, C., et al (2018) Exp & Ther Med 16(4) 6609

The telomeric regions of chromosomes can also be identified using fluorescent staining techniques, as shown in Figure 23.1.6. The structure of telomeric chromosomal regions is described in section 24.3.

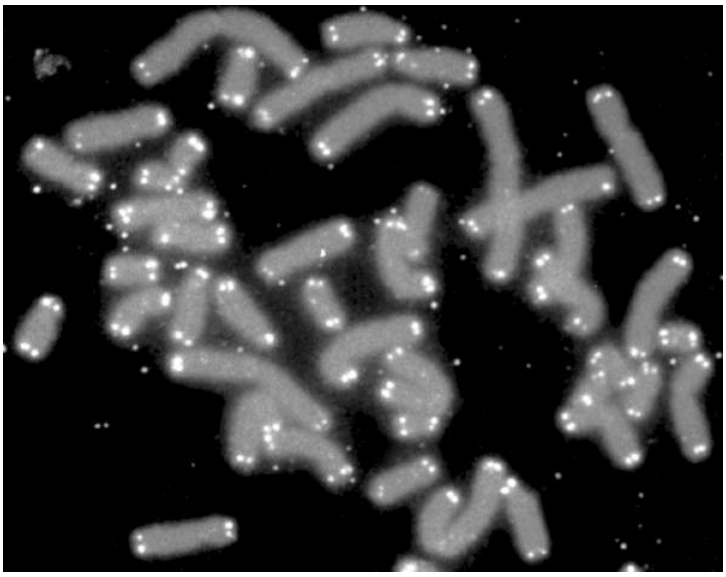

Figure 23.1.6: Telomere Staining. Image from: U.S. Department of Energy Human Genome Program

More recently, techniques such as chromosome painting, use fluorescently labeled probes to hybridize with specific chromosomes or even specific gene regions of a chromosome. Karyotypes originating from this technique are called spectral karyotypes. This technique can be especially useful in identifying translocations that have occurred in human cells, as shown in Figure 23.1.7.

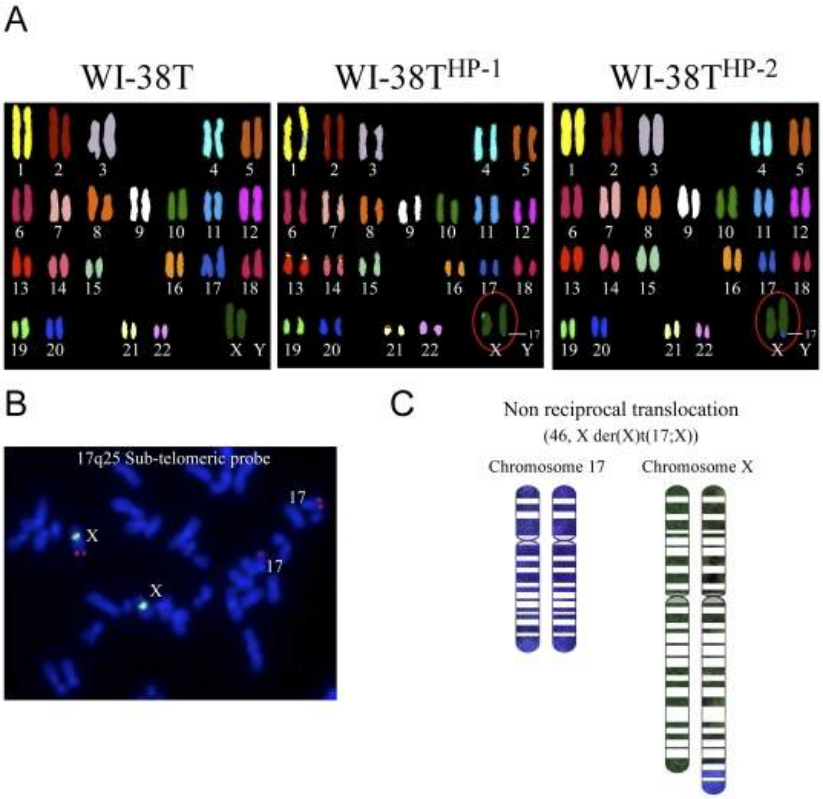

Figure 23.1.7: Spectral karyotyping (SKY) analysis of a fibroblast cell line derived from lung tissue (WI-38T) Different strains of WI-38T were developed and two showed high proliferation rates typical of the premalignant state. (A) shows SKY analysis for WI-38T and the two high proliferation strains. Both high proliferation strains show translocations of chromosome 17 to the X chromosome. (B) shows specific staining of WI-38T(HP-1) for the 17q25 region of chromosome 17 (pink) which is visible on both copies of chromosome 17 and also on one of the X chromosomes, indicating the translocation. (C) shows a graphic image of the translocation. Image from: Buganim, Y., et al (2010) PLoS ONE 5(3) e9657

23.2: DNA Transposable Elements

23.2.1: Introduction

Eukaryotic genomes contain an abundance of repeated DNA, and some repeated sequences are mobile. **Transposable elements** (TEs) are defined as DNA sequences that can move from one location to another in the genome. TEs have been identified in all organisms, prokaryotic and eukaryotic, and can occupy a high proportion of a species' genome. For example, transposable elements comprise approximately 10% of several fish species, 12 % of the *C. elegans* genome, 37% of the mouse genome, 45% of the human genome, and up to >80% of the genome of some plants like maize. From bacteria to humans, transposable elements have accumulated over time and continue to shape genomes through their mobilization.

TEs were discovered by Barbara McClintock during experiments conducted in 1944 on maize. Since they appeared to influence phenotypic traits, she named them **controlling elements**. However, her discovery was met with less than enthusiastic reception by the genetic community. Her presentation at the 1951 Cold Spring Harbor Symposium was not understood and at least not very well received. She had no better luck with her follow-up publications and after several years of frustration decided not to publish on the subject for the next two decades. Not for the first time in the history of science, an unappreciated discovery was brought back to life after some other discovery has been made. In this case, it was the discovery of insertion sequences (IS) in bacteria by Szybalski group in the early 1970s. In the original paper, they wrote: "Genetic elements were found in higher organisms which appear to be readily transposed from one to another site in the genome. Such elements, identifiable by their controlling functions, were described by McClintock in maize. It is possible that they might be somehow analogous to the presently studied IS insertions". The importance of McClintock's original work was eventually appreciated by the genetic community with numerous awards, including 14 honorary doctoral degrees and a Nobel Prize in 1983 "for her discovery of mobile genetic elements". Her picture is shown in Figure 23.2.1.

This photo was taken when McClintock received the American Association of University Women Achievement Award in 1947 for her work on cytogenetics. She received the Nobel Prize in Physiology or Medicine in 1983 for her discovery of mobile genetic elements. Image from: Smithsonian Institution

The mobilization of TEs is termed **transposition or retrotransposition**, depending on the nature of the intermediate used for mobilization. There are several ways in which the activity of TEs can positively and negatively impact a genome; for example, TE mobilization can promote gene inactivation, modulate gene expression or induce illegitimate recombination. Thus, TEs have played a significant role in genome evolution. For example, DNA transposons can inactivate or alter the expression of genes by insertion within introns, exons, or regulatory regions. In addition, TEs can participate in the reorganization of a genome by the mobilization of non-transposon DNA or by acting as recombination substrates. This recombination would occur by homology between two sequences of a transposon located in the same or different chromosomes, which could be the origin of several types of chromosome alterations. Indeed, TEs can participate in the loss of genomic DNA by internal deletions or other mechanisms.

The reduction in fitness suffered by the host due to transposition ultimately affects the transposon, since host survival is critical to the perpetuation of the transposon. Therefore, strategies have been developed by host and transposable elements to minimize the

deleterious impact of transposition, and to reach equilibrium. For example, some transposons tend to insert in nonessential regions in the genome, such as heterochromatic regions, where insertions will likely have a minimal deleterious impact. In addition, they might be active in the germ line or embryonic stage, where most deleterious mutations can be selected against during fecundation or development, allowing only non-deleterious or mildly deleterious insertions to pass to successive generations. New insertions may also occur within an existing genomic insertion to generate an inactive transposon or can undergo self-regulation by **overproduction-inhibition**. On the other hand, host organisms have developed different mechanisms of defense against high rates of transposon activity, including DNA-methylation to reduce TE expression, several RNA interference-mediated mechanisms, mainly in the germ line, or through the inactivation of transposon activity by the action of specific proteins.

In some cases, transposable elements have been “domesticated” by the host to perform a specific function in the cell. A well-known example is RAG proteins, which participate in V(D)J recombination during antibody class switching, and exhibit a high similarity to DNA transposons, from which these proteins appear to be derived. Another example is the centromeric protein CENP-B, which seems to have originated from the pogo-like transposon. The analogous human mariner *Himar1* element has been incorporated into the SETMAR gene, which consists of the histone H3 methylase gene and the Himar1 transposase domain. This gene is involved in the non-homologous end-joining pathway of DNA repair and has been shown to confer resistance to ionizing radiation. From a genome-wide view, it has been estimated that ~25% of human promoter regions and ~4% of human exons contain sequences derived from TEs. Thus, we are likely underestimating the rate of domestication events in mammalian genomes.

The first TE classification system was proposed by Finnegan in 1989 and distinguished two classes of TEs characterized by their transposition intermediate: RNA (class I or retrotransposons) or DNA (class II or DNA transposons). The transposition mechanism of class I is commonly called “copy and paste” and that of class II, “cut and paste.” In 2007 Wicker et al. proposed a hierarchical classification based on TEs structural characteristics and mode of replication, as shown in Figure 23.2.2

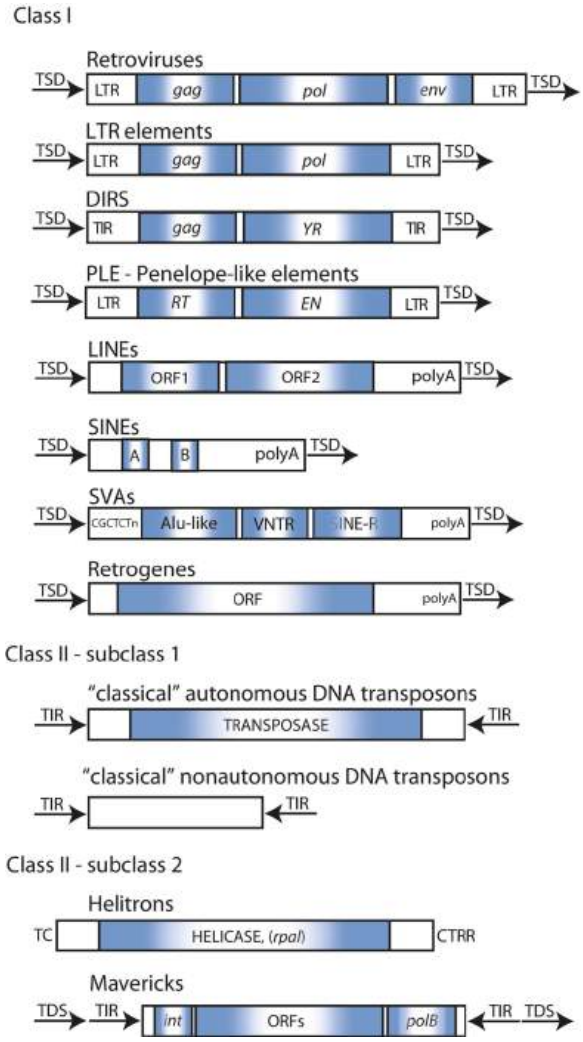

Figure 23.2.2: Structures of eukaryotic mobile elements. See text for detailed discussion Image from Makalowski, W, et. al. (2019)

23.2.2: Class I: Mobile Elements

As mentioned above, class I TEs transpose through an RNA intermediary. The RNA intermediate is transcribed from genomic DNA and then reverse-transcribed into DNA by a TE-encoded reverse transcriptase (RT), followed by reintegration into a genome. Each replication cycle produces one new copy, and as a result, class I elements are the major contributors to the repetitive fraction in large genomes. Retrotransposons are divided into five orders: LTR retrotransposons, DIRS-like elements, Penelope-like elements (PLEs), LINEs (*l*ong *in*terspersed *e*lements), and SINEs (*s*hort *in*terspersed *e*lements). This scheme is based on the mechanistic features, organization, and reverse transcriptase phylogeny of these retroelements. Accidentally, the retrotranscriptase coded by an autonomous TE can reverse-transcribe another RNA present in the cell, e.g., mRNA, and produce a retrocopy of it, which in most cases results in a pseudogene.

The LTR retrotransposons are characterized by the presence of *l*ong *t*erminal *r*epeats (LTRs) ranging from several hundred to several thousand base pairs. Both exogenous retroviruses and LTR retrotransposons contain a *gag* gene that encodes a viral particle coat and a *pol* gene that encodes a reverse transcriptase, ribonuclease H, and an integrase, which provide the enzymatic machinery for reverse transcription and integration into the host genome. Reverse transcription occurs within the viral or viral-like particle (GAG) in the cytoplasm, and it is a multi-step process. Unlike LTR retrotransposons, exogenous retroviruses contain an *env* gene, which encodes an envelope that facilitates their migration to other cells. Some LTR retrotransposons may contain remnants of an *env* gene, but their insertion capabilities are limited to the originating genome. This would rather suggest that they originated in exogenous retroviruses by losing the *env* gene. However, there is evidence that suggests the contrary, given that LTR retrotransposons can acquire the *env* gene and become infectious entities. Presently, most of the LTR sequences (85%) in the human genome are found only as isolated LTRs, with the internal sequence being lost most likely due to homologous recombination between flanking LTRs. Interestingly, LTR retrotransposons target their reinsertion to specific genomic sites, often around genes, with putative important functional implications for a host gene. It is estimated that 450,000 LTR copies make up about 8% of our genome. LTR retrotransposons inhabiting large genomes, such as maize, wheat, or barley, can contain thousands of families. However, despite the diversity, very few families comprise most of the repetitive fraction in these large genomes. Notable examples are Angela (wheat), BARE1 (barley), Opie (maize), and Retrosor6 (sorghum).

The DIRS order clusters structurally diverged groups of transposons that possess a tyrosine recombinase (YR) gene instead of an integrase (INT) and do not form target site duplications (TSDs). Their termini resemble either split direct repeats (SDR) or inverted repeats. Such features indicate a different integration mechanism than that of other class I mobile elements. DIRS were discovered in the slime mold (*Dictyostelium discoideum*) genome in the early 1980s, and they are resent in all major phylogenetic lineages including vertebrates. It has been shown that they are also common in hydrothermal vent organisms.

Another order, termed *Penelope*-like elements (PLE), has wide, though patchy distribution from amoebae and fungi to vertebrates with copy numbers up to thousands per genome. Interestingly, no PLE sequences have been found in mammalian genomes, and apparently, they were lost from the genome of *C. elegans*. Although PLEs with an intact ORF have been found in several genomes, including *Ciona* and *Danio*, the only transcriptionally active representative, *Penelope*, is known from *Drosophila virilis*. It causes the hybrid dysgenesis syndrome characterized by the simultaneous mobilization of several unrelated TE families in the progeny of dysgenic crosses. It seems that *Penelope* invaded *D. virilis* quite recently, and its invasive potential was demonstrated in *D. melanogaster*. PLEs harbor a single ORF that codes for a protein containing reverse transcriptase (RT) and endonuclease (EN) domains. The PLE RT domain more closely resembles telomerase than the RT from LTRs or LINEs. The EN domain is related to GIY-YIG intron-encoded endonucleases. Some PLE members also have LTR-like sequences, which can be in a direct or an inverse orientation, and have a functional intron.

LINEs do not have LTRs; however, they have a poly-A tail at the 3′ ends and are flanked by the TSDs. They comprise about 21% of the human genome and among them L1 with about 850,000 copies is the most abundant and best-described LINE family. L1 is the only LINE retroposon still active in the human genome. In the human genome, there are two other LINE-like repeats, L2 and L3, distantly related to L1. A contrasting situation has been noticed in the malaria mosquito *Anopheles gambiae*, where around 100 divergent LINE families compose only 3% of its genome. LINEs in plants, e.g., Cin4 in maize and Ta11 in *Arabidopsis thaliana*, seem rare as compared with LTR retrotransposons. A full copy of mammalian L1 is about 6 kb long and contains a PolII promoter and two ORFs. The ORF1 codes for a non-sequence-specific RNA binding protein that contains zinc finger, leucine zipper, and coiled-coil motifs. The ORF1p functions as a chaperone for the L1 mRNA. The second ORF encodes an endonuclease, which makes a single-stranded nick in the genomic DNA, and a reverse transcriptase, which uses the nicked DNA to prime reverse transcription of LINE RNA from the 3′ end. Reverse transcription is often unfinished, leaving behind fragmented copies of LINE elements; hence most of the L1-derived repeats are short, with an average size of 900 bp. LINEs are part of the CR1 clade, which

has members in various metazoan species, including fruit flies, mosquito, zebrafish, pufferfish, turtles, and chicken. Because they encode their own retrotransposition machinery, LINE elements are regarded as autonomous retrotransposons.

SINEs evolved from RNA genes, such as 7SL and tRNA genes. By definition, they are short, up to 1000 base pairs long. They do not encode their own retrotranscription machinery and are considered nonautonomous elements and in most cases are mobilized by the L1 machinery. The outstanding member of this class from the human genome is the Alu repeat, which contains a cleavage site for the *Alu*I restriction enzyme that gave its name. With over a million copies in the human genome, Alu is probably the most successful transposon in the history of life. Primate-specific Alu and its rodent relative B1 have limited phylogenetic distribution suggesting their relatively recent origins. The mammalian-wide interspersed repeats (MIRs), by contrast, spread before eutherian radiation, and their copies can be found in different mammalian groups including marsupials and monotremes. SVA elements are unique primate elements due to their composite structure. They are named after their main components: SINE, VNTR (a variable number of tandem repeats), and Alu. Usually, they contain the hallmarks of the retroposition, i.e., they are flanked by TSDs and terminated by a poly(A) tail. It seems that SVA elements are nonautonomous retrotransposons mobilized by L1 machinery, and they are thought to be transcribed by RNA polymerase II. SVAs are transpositionally active and are responsible for some human diseases. They originated less than 25 million years ago, and they form the youngest retrotransposon family with about 3000 copies in the human genome.

Retro(pseudo)genes are a special group of retroposed sequences, which are products of reverse transcription of a spliced (mature) mRNA. Hence, their characteristic features are an absence of promoter sequence and introns, the presence of flanking direct repeats, and a 3′-end polyadenosine tract. Processed pseudogenes, as sometimes retropseudogenes are called, have been generated in vitro at a low frequency in the human HeLa cells via mRNA from a reporter gene. The source of the reverse transcription machinery in humans and other vertebrates seems to be active L1 elements. However, not all retroposed messages have to end up as pseudogenes. About 20% of mammalian protein-encoding genes lack introns in their ORFs. It is conceivable that many genes lacking introns arose by retroposition. Some genes are known to be retroposed more often than others. For instance, in the human genome, there are over 2000 retropseudogenes of ribosomal proteins. A genome-wide study showed that the human genome harbors about 20,000 pseudogenes, 72% of which most likely arose through retroposition. Interestingly, the vast majority (92%) of them are quite recent transpositions that occurred after primate/rodent divergence. Some of the retroposed genes may undergo quite complicated evolutionary paths. An example could be the RNF13B retrogene, which replaced its own parental gene in the mammalian genomes. This retrocopy was duplicated in primates, and the evolution of this primate-specific copy was accompanied by the exaptation of two TEs, Alu and L1, and intron gain via changing a part of the coding sequence into an intron leading to the origin of a functional, primate-specific retrogene with two splicing variants.

23.2.3: Class II: Mobile Elements

Class II elements move by a conservative cut-and-paste mechanism; the excision of the donor element is followed by its reinsertion elsewhere in the genome. DNA transposons are abundant in bacteria, where they are called insertion sequences, but are also present in all phyla. Two subclasses of DNA transposons have been distinguished, based on the number of DNA strands that are cut during transposition.

Classical “cut-and-paste” transposons belong to subclass I, and they are classified as the TIR order. They are characterized by terminal inverted repeats (TIR) and encode a transposase that binds near the inverted repeats and mediates mobility. This process is not usually a replicative one, unless the gap caused by excision is repaired using the sister chromatid. When inserted at a new location, the transposon is flanked by small gaps, which, when filled by host enzymes, cause duplication of the sequence at the target site. The length of these TSDs is characteristic of particular transposons. Nine superfamilies belong to the TIR order, including *Tc1-Mariner*, *Merlin*, *Mutator*, and *PiggyBac*. The second-order Crypton consists of a single superfamily of the same name. Originally thought to be limited to fungi, now it is clear that they have a wide distribution, including animals and heterokonts. A heterogeneous, small, nonautonomous group of elements MITEs also belong to the TIR order, which in some genomes amplified to thousands of copies, e.g., *Stowaway* in the rice genome, *Tourist* in most bamboo genomes, or *Galluhop* in the chicken genome.

Subclass II includes two orders of TEs that, just as those from subclass I, do not form RNA intermediates. However, unlike “classical” DNA transposons, they replicate without double-strand cleavage. Helitrons replicate using a rolling-circle mechanism, and their insertion does not result in the target site duplication. They encode tyrosine recombinase along with some other proteins. Helitrons were first described in plants, but they are also present in other phyla, including fungi and mammals. Mavericks are large transposons that have been found in different eukaryotic lineages excluding plants. They encode various numbers of proteins that

include DNA polymerase B and an integrase. Kapitonov and Jurka suggested that their life cycle includes a single-strand excision, followed by extrachromosomal replication and reintegration to a new location.

23.2.4: TEs are not randomly distributed in the genome

As seen in the previous section, TEs are highly diverse and in principle, every TE sequence in a genome can be affiliated to a (sub)family, superfamily, subclass, and class. This is summarized in Figure 23.2.3 However, much like the taxonomy of species, the classification of TEs is in constant flux, perpetually subject to revision due to the discovery of completely novel TE types, the introduction of new levels of granularity in the classification, and the ongoing development of methods and criteria to detect and classify TEs.

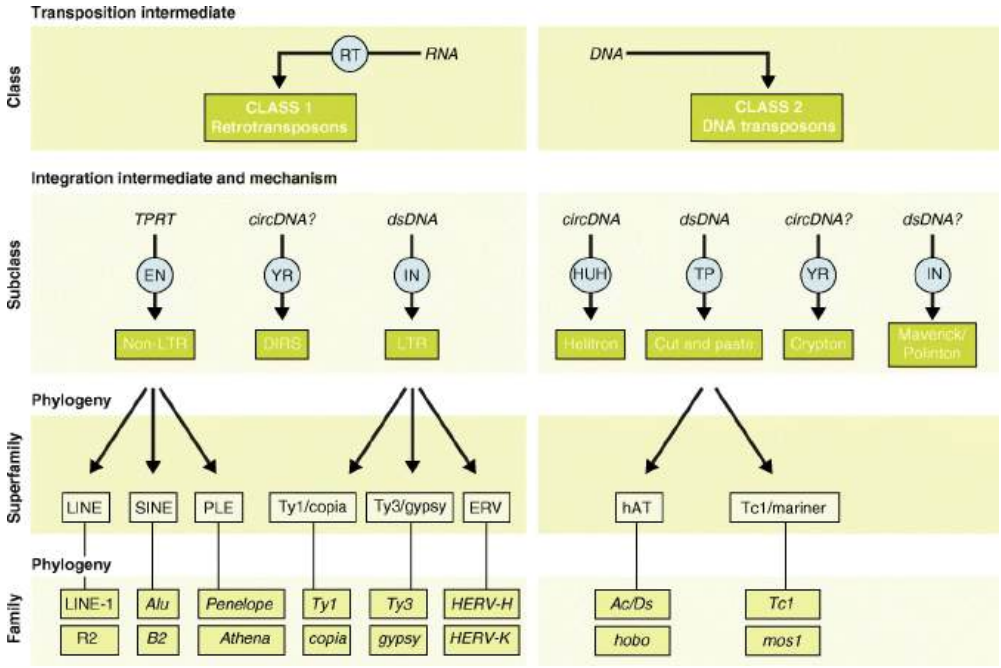

Figure 23.2.3: Classification of Eukaryotic Transposable Elements. This schematic shows the key features and relationships between TE classes, subclasses, superfamilies, and families. Blue circles represent TE-encoded enzymes. circDNA circular DNA intermediate, DIRS Dictyostelium repetitive sequence, dsDNA linear double-stranded DNA intermediate, EN endonuclease, IN integrase, PLEs Penelope-like elements, HUH, Rep/Helicase protein with HUH endonuclease activity, RT reverse transcriptase, TP transposase, TPRT target primed reverse transcription, YR tyrosine recombinase. Image from: Bourque, G., et. al. (2018) Genetic Biology 19:199

The genome may be viewed as an ecosystem inhabited by diverse communities of TEs, which seek to propagate and multiply through sophisticated interactions with each other and with other components of the cell. These interactions encompass processes familiar to ecologists, such as parasitism, cooperation, and competition. Thus, it is perhaps not surprising that TEs are rarely, if ever, randomly distributed in the genome, as shown in Figure 23.2.4 TEs exhibit various levels of preference for insertion within certain features or compartments of the genome. These are often guided by opposite selective forces, a balancing act of facilitating future propagation while mitigating deleterious effects on host cell function. At the most extreme end of the site-selection spectrum, many elements have evolved mechanisms to target specific loci where their insertions are less detrimental to the host but favorable for their propagation. For instance, several retrotransposons in species as diverse as slime mold and budding and fission yeast have evolved independently, but convergently, the capacity to target the upstream regions of genes transcribed by RNA polymerase III, where they do not appear to affect host gene expression but retain the ability to be transcribed themselves.

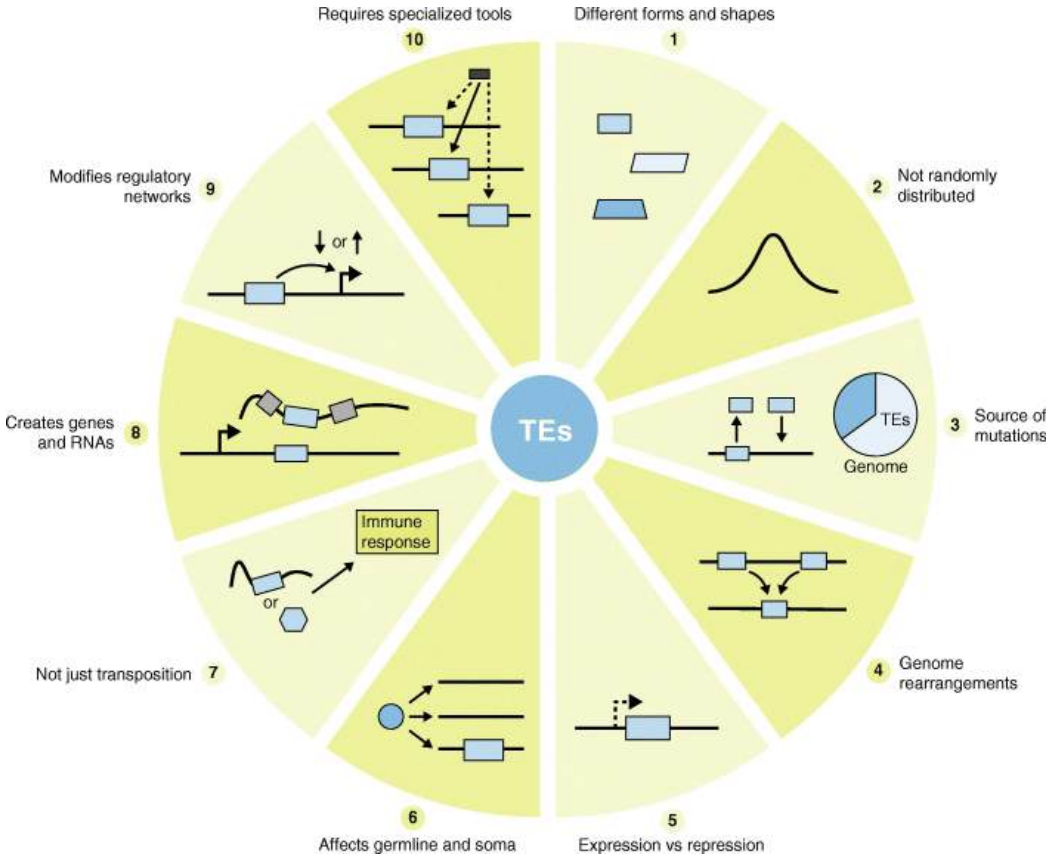

Figure 23.2.4: Ten things you should know about transposable elements (TEs). Examples of how TEs can impact genomes in direct and indirect ways. Blue boxes represent TEs, gray boxes represent canonical exons, and the black box represents a sequencing read. Right-angled arrows represent gene sor TE promoters. Image from: Bourque, G., et. al. (2018) Genetic Biology 19:199

23.2.5: TEs are an extensive source of mutations and genetic polymorphisms

TEs occupy a substantial portion of the genome of a species, including a large fraction of the DNA unique to that species. In maize, where Barbara McClintock did her seminal work, an astonishing 60 to 70% of the genome is comprised of LTR retrotransposons, many of which are unique to this species or its close wild relatives, but the less prevalent DNA transposons are currently the most active and mutagenic (Fig. 24.2.4). Similarly, the vast majority of TE insertions in *Drosophila melanogaster* are absent at the orthologous site in its closest relative *D. simulans* (and vice versa), and most are not fixed in the population. Many TE families are still actively transposing and the process is highly mutagenic; more than half of all known phenotypic mutants of *D. melanogaster* isolated in the laboratory are caused by spontaneous insertions of a wide variety of TEs. Transposition events are also common and mutagenic in laboratory mice, where the ongoing activity of several families of LTR elements are responsible for 10–15% of all inherited mutant phenotypes. This contribution of TEs to genetic diversity may be underestimated, as TEs can be more active when organisms are under stress, such as in their natural environment.

Because TE insertions rarely provide an immediate fitness advantage to their host, those reaching fixation in the population do so largely by genetic drift and are subsequently eroded by point mutations that accumulate neutrally. Over time, these mutations result in TEs that can no longer encode transposition enzymes and produce new integration events. For instance, our (haploid) genome contains ~ 500,000 L1 copies, but more than 99.9% of these L1 copies are fixed and no longer mobile due to various forms of mutations and truncations. It is estimated that each person carries a set of ~ 100 active L1 elements, and most of these are young insertions still segregating within the human population. Thus, as for any other organism, the ‘reference’ human genome sequence does not represent a comprehensive inventory of TEs in humans. Thousands of ‘non-reference’, unfixed TE insertions have been cataloged through whole genome sequencing and other targeted approaches. On average, any two human haploid genomes differ by approximately a thousand TE insertions, primarily from the L1 or Alu families. The number of TE insertion polymorphisms in a species with much higher TE activity such as maize dwarfs the number in humans.

If TEs bring no immediate benefit to their host and are largely decaying neutrally once inserted, how do they persist in evolution? One key to this conundrum is the ability of TEs not only to propagate vertically but also horizontally between individuals and

species. There is now a large body of evidence supporting the idea that horizontal transposon transfer is a common phenomenon that affects virtually every major type of TE and all branches of the tree of life. While the cellular mechanisms underlying horizontal transposon transfer remain murky, it is increasingly apparent that the intrinsic mobility of TEs and ecological interactions between their host species, including those with pathogens and parasites, facilitate the transmission of elements between widely diverged taxa.

TEs are associated with genome rearrangements and unique chromosome feature

Transposition represents a potent mechanism of genome expansion that over time is counteracted by the removal of DNA via deletion. The balance between the two processes is a major driver in the evolution of genome size in eukaryotes. Several studies have demonstrated the impact and range of this shuffling and cycling of genomic content on the evolution of plant and animal genomes. Because the insertion and removal of TEs are often imprecise, these processes can indirectly affect surrounding host sequences. Some of these events occur at high enough frequency to result in vast amounts of duplication and reshuffling of host sequences, including genes and regulatory sequences. For example, a single group of DNA transposons (MULEs) has been responsible for the capture and reshuffling of ~ 1,000 gene fragments in the rice genome. Such studies have led to the conclusion that the rate at which TEs transpose, which is in part under host control, is an important driver of genome evolution.

In addition to rearrangements induced as a byproduct of transposition, TEs can promote genomic structural variation long after they have lost the capacity to mobilize. In particular, recombination events can occur between the highly homologous regions dispersed by related TEs at distant genomic positions and result in large-scale deletions, duplications, and inversions (Fig. 24.2.4). TEs also provide regions of microhomology that predispose to template switching during repair of replication errors leading to another source of structural variants. These non-transposition-based mechanisms for TE-induced or TE-enabled structural variation have contributed substantially to genome evolution. These processes can also make the identification of actively transposing elements more difficult in population studies that infer the existence of active elements through the detection of non-reference insertions.

TEs also contribute to specialized chromosome features. An intriguing example is in *Drosophila*, where LINE-like retrotransposons form and maintain the telomeres in replacement of the telomerase enzyme which has been lost during dipteran evolution. This domestication event could be viewed as a replay of what might have happened much earlier in eukaryotic evolution to solve the ‘end problem’ created by the linearization of chromosomes. Indeed, the reverse transcriptase component of telomerase is thought to have originated from an ancient lineage of retroelements. TE sequences and domesticated transposase genes also play structural roles at centromeres.

There is an intricate balance between TE expression and repression

To persist in evolution, TEs must strike a delicate balance between expression and repression (Fig. 24.2.4). Expression should be sufficient to promote amplification, but not so vigorous as to lead to a fitness disadvantage for the host that would offset the benefit to the TE of increased copy numbers. This balancing act may explain why TE-encoded enzymes are naturally suboptimal for transposition and why some TEs have evolved self-regulatory mechanisms controlling their own copy numbers. A variety of host factors are also employed to control TE expression, which includes a variety of small RNA, chromatin, and DNA modification pathways, as well as sequence-specific repressors such as the recently profiled KRAB zinc-finger proteins. However, many of these silencing mechanisms must be at least partially released to permit the developmental regulation of host gene expression programs, particularly during early embryonic development. For example, genome-wide loss of DNA methylation is necessary to reset imprinted genes in primordial germ cells. This affords TEs an opportunity, as reduced DNA methylation often promotes TE expression. Robust expression of a TE in the germ lineage (but not necessarily in the gametes themselves) is often its own downfall. In one example of a clever trick employed by the host, TE repression is relieved in a companion cell derived from the same meiotic product as flowering plant sperm. However, this companion cell does not contribute genetic material to the next generation. Thus, although TEs transpose in a meiotic product, the events are not inherited. Instead, TE activity in the companion cell may further dampen TE activity in sperm via the import of TE-derived small RNAs.

Another important consequence of the intrinsic expression/repression balance is that the effects of TEs on a host can vary considerably among tissue types and stages of an organism’s life cycle. From the TE’s perspective, an ideal scenario is to be expressed and active in the germline, but not in the soma, where expression would gain the TE no advantage, only disadvantages. This is indeed observed among many species, with ciliates representing an extreme example of this division—TEs are actively deleted from the somatic macronucleus but retained in the micronucleus, or germline. Another example is the P-elements in *Drosophila*, which are differentially spliced in the germline versus soma. Many organisms, including plants, do not differentiate germ lineage cells early in development; rather, they are specified from somatic cells shortly before meiosis commences. Thus, TEs

that transpose in somatic cells in plants have the potential to be inherited, which suggests that the interest of TEs and hosts are in conflict across many more cells and tissues than in animals with a segregated germline.

TEs are insertional mutagens in both germline and soma

Like other species, humans contend with a contingent of currently active TEs where the intrinsic balance between expression and repression is still at play. For us, this includes L1 and other mobile elements that depend on L1-encoded proteins for retrotransposition. These elements are responsible for new germline insertions that can cause genetic disease. More than 120 independent TE insertions have been associated with human disease. The rate of de novo germline transposition in humans is approximately one in 21 births for *Alu* and one in 95 births for L1.

Historically, little attention has been given to transposition in somatic cells and its consequences, because somatic transposition may be viewed as an evolutionary dead-end for the TE with no long-term consequences for the host species. Yet, there is abundant evidence that TEs are active in somatic cells in many organisms (Fig. 24.2.4). In humans, L1 expression and transposition have been detected in a variety of somatic contexts, including early embryos and certain stem cells. There is also a great deal of interest in mobile element expression and activity in the mammalian brain, where L1 transposition has been proposed to diversify neuronal cell populations. One challenge for assessing somatic activity has rested with the development of reliable single-cell insertion site mapping strategies.

Somatic activity has also been observed in human cancers, where tumors can acquire hundreds of new L1 insertions. Just like for human polymorphisms, somatic activity in human cancers is caused by small numbers of so-called ‘hot’ L1 loci. The activities of these master copies vary depending on the individual, tumor type, and timeframe in the clonal evolution of the tumor. Some of these de novo L1 insertions disrupt critical tumor suppressors and oncogenes and thus drive cancer formation, although the vast majority appear to be ‘passenger’ mutations. Host cells have evolved several mechanisms to keep TEs in check. However, as the force of natural selection begins to diminish with age and completely drops in post-reproductive life, TEs may become more active.

TEs can be damaging in ways that do not involve transposition

TEs are best known for their mobility, and their ability to transpose to new locations. While the breakage and insertion of DNA associated with transposition represent an obvious source of cell damage, this is not the only or perhaps even the most common mechanism by which TEs can be harmful to their host. Reactivated transposons harm the host in multiple ways. First, de-repression of transposon loci, including their own transcription, may interfere with transcription or processing of host mRNAs through a myriad of mechanisms. Genome-wide transcriptional de-repression of TEs has been documented during replicative senescence of human cells and several mouse tissues, including the liver, muscle, and brain. De-repression of LTR and L1 promoters can also cause oncogene activation in cancer. Second, TE-encoded proteins such as the endonuclease activity of L1 ORF2p can induce DNA breaks and genomic instability. Third, accumulation of RNA transcripts and extrachromosomal DNA copies derived from TEs may trigger an innate immune response leading to autoimmune diseases and sterile inflammation (Fig. 24.2.4). Activation of interferon response is now a well-documented property of transcripts derived from endogenous retroviruses and may give immunotherapies a boost in identifying and attacking cancer cells. The relative contribution of all the above mechanisms in organismal pathologies remains to be determined.

Following transcription (and sometimes splicing) of TEs, the next step in the process involves the translation of the encoded proteins and, for retroelements, reverse transcription of the TEs into cDNA substrates suitable for transposition. Once engaged by a TE-encoded reverse transcriptase protein, the resulting cytosolic DNAs and RNA:DNA hybrids can alert inflammatory pathways. An example of this is seen in patients with Aicardi–Goutières syndrome, where the accumulation of TE-derived cytosolic DNA is due to mutations in pathways that normally block TE processing or degrade TE-derived DNA. Although not all TEs encode functional proteins, some do, including a few endogenous retroviruses capable of producing Gag, Pol, or envelope (Env) proteins. Overexpression of these Env proteins can be cytotoxic and has been linked to at least two neurodegenerative diseases, multiple sclerosis, and amytrophic lateral sclerosis. Small accessory proteins produced by the youngest human endogenous retrovirus (HERV) group, HERV-K (HML-2), may play a role in some cancers but the evidence remains circumstantial.

Key coding and non-coding RNAs are derived from TEs

Although usually detrimental, there is growing evidence that TE insertions can provide the raw material for the emergence of protein-coding genes and non-coding RNAs, which can take on important and, in some cases essential, cellular function (Fig. 24.2.4). The process of TE gene ‘domestication’ or exaptation over evolutionary time contributes to both deeply conserved functions and more recent, species-specific traits. Most often, the ancestral or a somewhat modified role of a TE-encoded gene is harnessed by the host and conserved, while the rest of the TE sequence, and hence its ability to autonomously transpose, has been

lost. Spectacular examples of deeply conserved TE-derived genes are *Rag1* and *Rag2*, that catalyze V(D)J somatic recombination in the vertebrate immune system. Both genes, and probably the DNA signals they recognize, were derived from an ancestral DNA transposon around 500 million years ago. Indeed, DNA transposases have been co-opted multiple times to form new cellular genes.

The *gag* and *env* genes of LTR retrotransposons or endogenous retroviruses (ERVs) have also been domesticated numerous times to perform functions in placental development, contribute to host defense against exogenous retroviruses, act in brain development, and play other diverse roles. One of the most intriguing examples of TE domestication is the repeated, independent capture of ERV *env* genes, termed *syncytins*, which appear to function in placentation by facilitating cell–cell fusion and syncytiotrophoblast formation. Notably, one or more *syncytin* genes have been found in virtually every placental mammalian lineage where they have been sought, strongly suggesting that ERVs have played essential roles in the evolution and extreme phenotypic variability of the mammalian placenta. Another example of a viral-like activity re-purposed for host cell function is provided by the neuronal *Arc* gene, which arose from the *gag* gene from a LTR retrotransposon domesticated in the common ancestor of tetrapod vertebrates. Genetic and biochemical studies of murine Arc show that it is involved in memory and synaptic plasticity and has preserved most of the ancestral activities of Gag, including the packaging and intercellular trafficking of its own RNA. Remarkably, flies appear to have independently evolved a similar system of trans-synaptic RNA delivery involving a *gag*-like protein derived from a similar yet distinct lineage of LTR retrotransposons. Thus, the biochemical activities of TE-derived proteins have been repeatedly co-opted during evolution to foster the emergence of convergent cellular innovations in different organisms.

TEs can donate their own genes to the host, but they can also add exons and rearrange and duplicate existing host genes. In humans, intronic *Alu* elements are particularly prone to be captured as alternative exons through cryptic splice sites residing within their sequences. L1 and SVA (SINE/VNTR/Alu) elements also contribute to exon shuffling through transduction events of adjacent host sequences during their mobilization. The reverse transcriptase activity of retroelements is also responsible for the trans-duplication of cellular mRNAs to create ‘processed’ retrogenes in a wide range of organisms. The L1 enzymatic machinery is thought to be involved in the generation of tens of thousands of retrogene copies in mammalian genomes, many of which remain transcribed and some of which have acquired new cellular functions. This is a process still actively shaping our genomes; it has been estimated that 1 in every 6000 humans carries a novel retrogene insertion.

TEs also make substantial contributions to the non-protein coding functions of the cell. They are major components of thousands of long non-coding RNAs in human and mouse genomes, often transcriptionally driven by retroviral LTRs. Some of these TE-driven lncRNAs appear to play important roles in the maintenance of stem cell pluripotency and other developmental processes. Many studies have demonstrated that TE sequences embedded within lncRNAs and mRNAs can directly modulate RNA stability, processing, or localization with important regulatory consequences. Furthermore, TE-derived microRNAs and other small RNAs processed from TEs can also adopt regulatory roles serving host cell functions. The myriad of mechanisms by which TEs contribute to coding and non-coding RNAs illustrate the multi-faceted interactions between these elements and their host.

TEs contribute cis-regulatory DNA elements and modify transcriptional networks

Cis-regulatory networks coordinate the transcription of multiple genes that function in concert to orchestrate entire pathways and complex biological processes. In line with Barbara McClintock’s insightful predictions, there is now mounting evidence that TEs have been a rich source of material for the modulation of eukaryotic gene expression (Fig. 24.2.4). Indeed, TEs can disperse vast amounts of promoters and enhancers, transcription factor binding sites, insulator sequences, and repressive elements. The varying coat colors of agouti mice provide a striking example of a host gene controlling coat color whose expression can be altered by the methylation levels of a TE upstream of its promoter. In the oil palm, the methylation level of a TE that sits within a gene important for flowering ultimately controls whether or not the plants bear oil-rich fruit.

As TE families typically populate a genome as a multitude of related copies, it has long been postulated that they have the potential to donate the same cis-regulatory module to ‘wire’ batteries of genes dispersed throughout the genome. An increasing number of studies support this model and suggest that TEs have provided the building blocks for the assembly and remodeling of cis-regulatory networks during evolution, including pathways underlying processes as diverse as pregnancy, stem cell pluripotency, neocortex development, innate immunity in mammals, or the response to abiotic stress in maize. Indeed, TE sequences harbor all the necessary features of a ‘classical’ gene regulatory network. They are bound by diverse sets of transcription factors that integrate multiple inputs (activation/repression), respond to signals in both *cis* and *trans*, and are capable of co-ordinately regulating gene expression. In this context, TEs are highly suitable agents to modify biological processes by creating novel cis-regulatory circuits and fine-tuning pre-existing networks.

Outlook

As potent insertional mutagens, TEs can have both positive and negative effects on host fitness, but it is likely that the majority of TE copies in any given species—and especially those such as humans with small effective population size—have reached fixation through genetic drift alone and are now largely neutral to their host. When can we say that TEs have been co-opted for cellular function? The publication of the initial ENCODE paper, which asserted 'function for 80% of the genome', was the subject of much debate and controversy. Technically speaking, ENCODE assigned only 'biochemical' activity to this large fraction of the genome. Yet critics objected to the grand proclamations in the popular press (The Washington Post Headline: "Junk DNA concept debunked by new analysis of the human genome") and to the ENCODE consortium's failure to prevent this misinterpretation. To these critics, ignoring evolutionary definitions of function was a major misstep.

This debate can be easily extended to include TEs. TEs make up the vast majority of what is often referred to as 'junk DNA'. Today, the term is mostly used (and abused) by the media, but it has deep roots in evolutionary biology. Regardless of the semantics, what evidence is needed to assign a TE with a function? Many TEs encode a wide range of biochemical activities that normally benefit their own propagation. For example, TEs often contain promoter or enhancer elements that highjack cellular RNA polymerases for transcription and autonomous elements encode proteins with various biochemical and enzymatic activities, all of which are necessary for the transposon to replicate. Do these activities make them functional?

The vast differences in TEs between species make standard approaches to establishing their regulatory roles particularly challenging. For example, intriguing studies on the impact of HERVs, in particular HERV-H, in stem cells and pluripotency must be interpreted using novel paradigms that do not invoke deep evolutionary conservation to imply function, as these particular ERVs are absent outside of great apes. Evolutionary constraints can be measured at shorter time scales, including the population level, but this remains a statistically challenging task, especially for non-coding sequences. Natural loss-of-function alleles may exist in the human population and their effect on fitness can be studied if their impact is apparent, but these are quite rare and do not allow systematic studies. It is possible to engineer genetic knockouts of a particular human TE locus to test its regulatory role but those are restricted to in-vitro systems, especially when the orthologous TE does not exist in the model species. In this context, studying the impact of TEs in model species with powerful genome engineering tools and vast collections of mutants and other genetic resources, such as plants, fungi, and insects, will also continue to be extremely valuable.

Finally, a growing consensus is urging more rigor when assigning cellular function to TEs, particularly for the fitness benefit of the host. Indeed, a TE displaying biochemical activity (such as those bound by transcription factors or lying within open chromatin regions) cannot be equated to a TE that shows evidence of purifying selection at the sequence level or, when genetically-altered, result in a deleterious or dysfunctional phenotype. Recent advances in editing and manipulating the genome and the epigenome en masse yet with precision, including repetitive elements, offer the promise for a systematic assessment of the functional significance of TEs.

23.3: Chromosome Packaging

Some of the material in this chapter section comes from Chapter 8.4, Chromosomes and Chromatin, as it was important to describe it earlier in the structure/function unit. In addition, some biochemistry courses might not get to the material in a late chapter in a text. Repetition of some of the material is easier in an online textbook as well.

23.3.1: Introduction

Recall from Chapter 8, that within eukaryotic cells, DNA is organized into long linear structures called ***chromosomes***, as shown in Figure 23.3.1. A ***chromosome*** is a deoxyribonucleic acid (DNA) molecule with part or all of the genetic material (genome) of an organism. Most eukaryotic chromosomes include packaging proteins which, aided by chaperone proteins, bind to and condense the DNA molecule to prevent it from becoming an unmanageable tangle. Before typical cell division, these chromosomes are duplicated in the process of DNA replication, providing a complete set of chromosomes for each daughter cell. The replicated arms of a chromosome are called ***chromatids***. Before being separated into the daughter cells during mitosis, replicated chromatids are held together by a chromosomal structure called the ***centromere***.

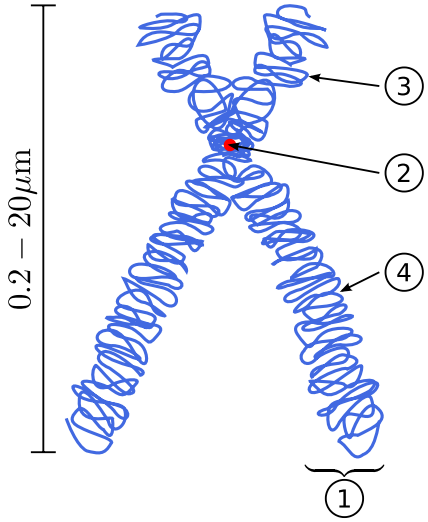

Figure 23.3.1: Diagram of Replicated and Condensed Eukaryotic Chromosome. (1) Chromatid – one of the two identical parts of the chromosome after the S phase. (2) Centromere – the point where the two chromatids are joined together. (3) Short arm is termed *p*; the Long arm is termed q. Image by: Magnus Manske, Dietzel65, and Tryphon

Eukaryotic organisms (animals, plants, fungi, and protists) store most of their DNA inside the cell nucleus as linear nuclear DNA, and some in the mitochondria as circular mitochondrial DNA or in chloroplasts as circular chloroplast DNA. In contrast, prokaryotes (bacteria and archaea) do not have organelle structures and thus, store their DNA only in a region of the cytoplasm known as the ***nucleoid region***. Prokaryotic chromosomes consist of ***double–stranded circular DNA***.

The genome of a cell is often significantly larger than the cell itself. For example, if the DNA from a human cell containing 46 chromosomes were stretched out in a line, it would extend more than 6 feet (2 meters)! How is it possible that the genetic information not only fits into the cell but fits into the cell nucleus? Eukaryota solves this problem by a combination of supercoiling and packaging DNA around the ***histone family of proteins*** (described below). Prokaryotes do not contain histones (with a few exceptions). Prokaryotes tend to compress their DNA using ***nucleoid-associated-proteins (NAPs)*** and ***supercoiling*** (Figure 24.3.2).

23.3.2: Supercoiling

DNA supercoiling refers to the over- or under-winding of a DNA strand, and is an expression of the strain on that strand, as shown in Figure 23.3.2 Supercoiling is important in many biological processes, such as compacting DNA, and regulating access to the genetic code. DNA supercoiling strongly affects DNA metabolism and possibly gene expression. Additionally, certain enzymes such as ***topoisomerases*** can change DNA topology to facilitate functions such as DNA replication or transcription.

In a “relaxed” double-helical segment of B-DNA, the two strands twist around the helical axis once every 10.4–10.5 base pairs of sequence. Adding or subtracting twists, as some enzymes can do, impose strain. If a DNA segment under twist strain were closed into a circle by joining its two ends and then allowed to move freely, the circular DNA would contort into a new shape, such as a

simple figure-eight (Figure 23.3.2). Such a contortion is a ***supercoil***. The noun form "supercoil" is often used in the context of DNA topology.

Figure 23.3.2: DNA Supercoiling. The supercoiled structure of linear DNA molecules with constrained ends. The helical nature of the DNA duplex is omitted for clarity. Image by: Richard Wheeler

Positively supercoiled (overwound) DNA is transiently generated during DNA replication and transcription, and, if not promptly relaxed, inhibits (regulates) these processes. The simple figure eight is the simplest supercoil and is the shape a circular DNA assumes to accommodate one too many or one too few helical twists. The two lobes of the figure- eight will appear rotated either clockwise or counterclockwise with respect to one another, depending on whether the helix is over- or underwound. For each additional helical twist being accommodated, the lobes will show one more rotation about their axis. As a general rule, the DNA of most organisms is negatively supercoiled.

Lobal contortions of a circular DNA, such as the rotation of the figure-eight lobes above, are referred to as ***writhe.*** The above example illustrates that twist and writhes are interconvertible. Supercoiling can be represented mathematically by the sum of ***twist*** and ***writhe*** (Figure 23.3.2 The ***twist*** is the number of helical turns in the DNA and the writhe is the number of times the double helix crosses over on itself (these are the supercoils). Extra helical twists are positive and lead to positive supercoiling, while subtractive twisting causes negative supercoiling. Many topoisomerase enzymes sense supercoiling and either generate or dissipate it as they change DNA topology.

In addition to forming supercoiled structures, circular chromosomes from bacteria have been shown to undergo the processes of ***catenation*** and ***knotting*** upon the inhibition of topoisomerase enzymes. ***Catenation*** is the process by which two circular DNA strands are linked together like chain links, whereas ***DNA knotting*** is the interlooping structures occurring within a single circular DNA structure, as shown in Figure 23.3.3 *In vivo*, the action of topoisomerase enzymes is critical to keep knots and catenoids from tangling the DNA structure. Catenanes are effectively **topologically linked circular molecules**

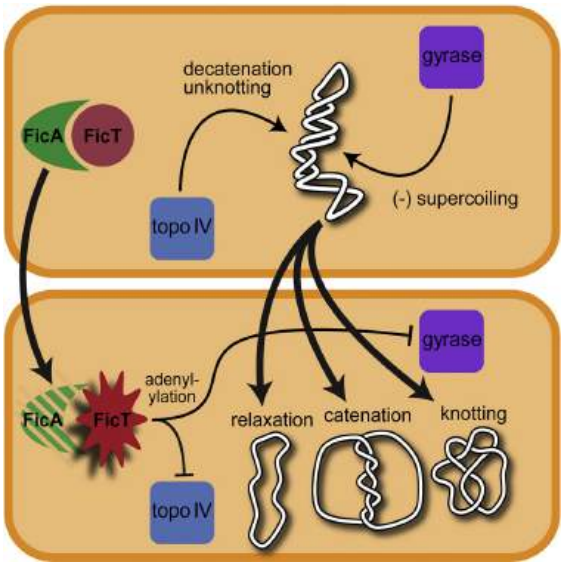

Figure 23.3.3: DNA Catenation and Knotting. The upper structure shows the negatively supercoiled form of bacterial DNA. The inhibition of topoisomerase enzyme activity leads to the relaxation, catenation, and knotting of the chromosomal structure. Image from: Harms, A. et al. (2015) Cell Reports 12(9):1497-1507.

In part, because chromosomes may be very large, segments in the middle may act as if their ends are anchored. As a result, they may be unable to distribute excess twist to the rest of the chromosome or to absorb twist to recover from underwinding—the segments may become *supercoiled*, in other words. In response to supercoiling, they will assume an amount of writhe, just as if their ends were joined.

Supercoiled circular DNA forms two major structures; a ***plectoneme*** or a ***toroid***, or a combination of both (Figure 24.3.2). A negatively supercoiled DNA molecule will produce either a one-start left-handed helix, ***the toroid***, or a two-start right-handed helix with terminal loops, the ***plectoneme. Plectonemes*** are typically more common in nature, and this is the shape most bacterial plasmids will take (Figure 4.10). For larger molecules, it is common for hybrid structures to form – a loop on a toroid can extend into a plectoneme, as shown in Figure 23.3.4 DNA supercoiling is important for DNA packaging within all cells, and seems to also play a role in gene expression.

Figure 23.3.4: Bacterial DNA Supercoiling. Atomic force microscopy (AFM) visualization of torsionally relaxed (A), and negatively supercoiled (B) bacterial plasmids pBR322. (C) Electron microscopy image of the E. coli chromosomal DNA displaying a hybrid toroidal-plectoneme structure. Image A and B from Witz, G. and Stasiak, A. (2009) Nucleic Acids Research 38(7):2119-2133. Image C from Prokaryotic Chromosomes

23.3.3: Topoisomerases

Topoisomerase can change the tension in supercoiled DNA. Think of how you untie a knot. It takes a lot of work sometimes, and if it's too hard, you simply cut the impediment to unknotting. Topoisomerases work by making transient breaks in the DNA before unwinding and religation. There are two main types of topoisomerases, topo I and topo II. It's very hard to describe their activities with just words and static diagrams. View the video below and you will get a great sense of what the enzymes do and how they are different.

With this background, we can now explore each enzyme in more detail. They are both targets of cancer drugs which makes them even more interesting.

Topo I enzyme relaxes DNA by nicking one stand. The dsDNA then rotates around the non-nicked strand. It unwinds new DNA and allows the condensation of chromosomes. When both DNA and RNA polymerase makes new DNA and RNA strands, respectively, they increase the supercoiling of the nucleic acid. Topoisomerases relax them. They also play a role in the regulation of gene expression by affecting gene promoters where RNA polymerase binds, with negative supercoiling enhancing transcription and positive supercoiling inhibiting it.

Figure 23.3.5 shows the topology of DNA and an overview of the mechanisms of Topo I and II. : DNA topology and DNA topoisomerase mechanism

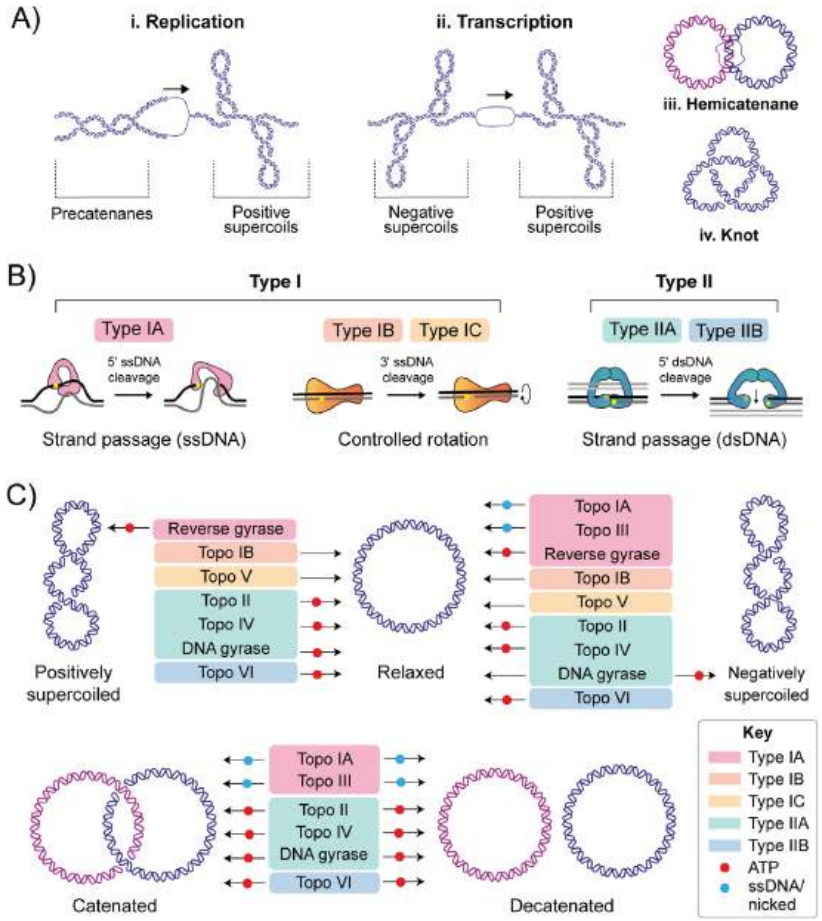

Figure 23.3.5: DNA topology and DNA topoisomerase mechanisms. Shannon J. McKie, Keir C. Neuman, and Anthony Maxwell. Bioessays (2021). https://doi.org/10.1002/bies.202000286. Attribution 4.0 International (CC BY 4.0)

(A) Topological consequences of DNA metabolism. i) During DNA replication, strand separation leads to positive supercoiling ahead of the advancing protein machinery, and precatenane formation behind. Precatenanes form as the newly-synthesized duplexes wrap around one another, and, if not removed before completion of replication, catenated DNA molecules are formed. ii) During transcription, strand separation leads to positive supercoiling ahead of the advancing protein machinery, and negative supercoil formation behind. iii) Hemicatenanes are a possible end result of replication, in which the parental strands of the replicated duplexes remain base-paired. iv: DNA knotting can also occur as a result of DNA replication in which a DNA molecule is intramolecularly linked.

(B) Summary of topo categories and mechanism. The topos are categorized based on whether they catalyze single- (type I) or double-stranded (type II) DNA breaks. The type I topos are further subdivided to type IA, IB, and IC. Type IA form a transient covalent bond to the 5′ DNA phosphate and function via a strand passage mechanism. Type IB and IC form a transient covalent bond to the 3′ DNA phosphate and function via a controlled-rotation mechanism. Type II topos are further subdivided into type IIA and IIB. Both form a transient covalent bond to the 5′ DNA phosphate of both strands of the duplex and function via a strand-passage mechanism.

(C) Summary of the topological manipulations performed by DNA topoisomerases, namely relaxation of positive and negative supercoils and decatenation. Type IA topos are color-coded pink, type IB are orange, type IC are yellow, type IIA are green, and type IIB are blue. The requirement of ATP or ssDNA for activity is denoted using a red or blue circle, respectively

Topoisomerase I (Topo I):

Class I topoisomerases wrap around the DNA and cut one strand. Keeping that spot in place, the helix can spin to reduce strain caused by either over- or underwinding. After these geometric contortions, the single-stranded DNA nick is repaired and the tension is relieved. Type IA topoisomerase from E. Coli is shown in Figure 23.3.6

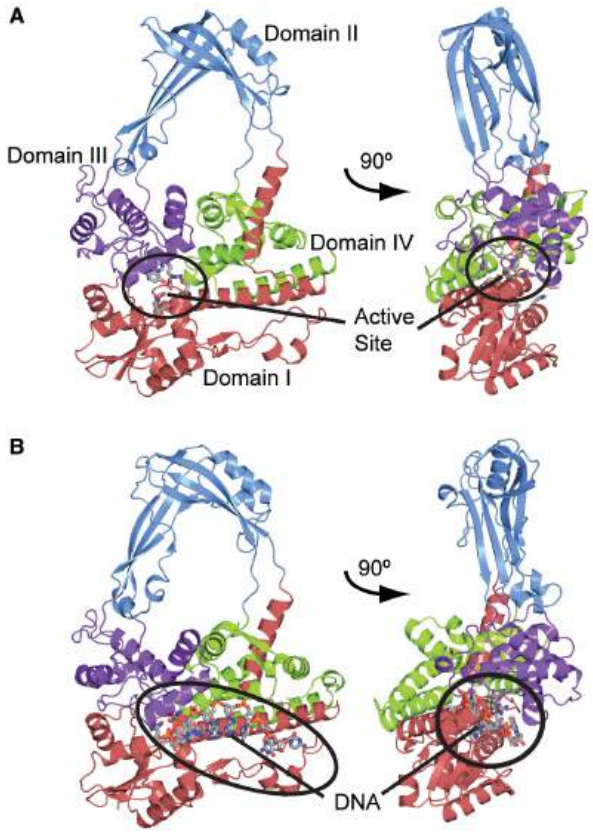

Figure 23.3.6 Structure of a type IA topoisomerase. E. coli topoisomerase III is shown to illustrate the overall structure of a type IA topoisomerase and the typical toroidal fold observed in all members of this type.

(A) Diagram showing the structure of the apo-enzyme [PDB 1D6M(7)]. In the absence of DNA, the active site, found at the intersection of domains I and III (encircled), is buried.

(B) Diagram showing the structure of a complex with single-stranded DNA [PDB 1I7D (23)]. Note the movement of domains that occurs to accommodate DNA. In both diagrams, the four major domains of the protein are colored red, blue, purple, and green for domains I, II, III, and IV, respectively. The single-stranded DNA binding groove, shown circled in black, extends from domain IV to the active site. The active site residues as well as the single-stranded DNA in the complex are shown in a ball and stick representation. Dasgupta T, Ferdous S, Tse-Dinh YC. Mechanism of Type IA Topoisomerases. Molecules. 2020 Oct 17;25(20):4769. doi: 10.3390/molecules25204769. PMID: 33080770; PMCID: PMC7587558. Creative Commons Attribution (CC BY) license (http://creativecommons.org/licenses/by/4.0/).

A simplified cartoon mechanism for Topo I is shown in Figure 23.3.7.

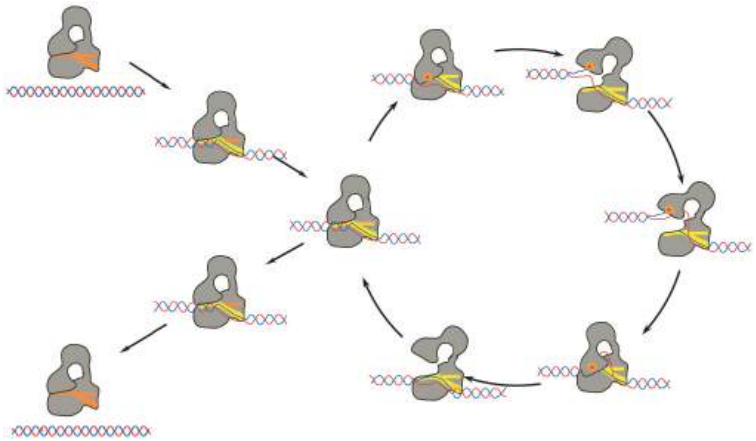

Figure 23.3.7: Diagram showing the proposed mechanism of DNA relaxation by type IA topoisomerases. The mechanism involves several transient
conformational intermediates both of the protein and the DNA. The sequence of the steps and the intermediates are hypothetical and more states are likely to be involved in the cycle. Processivity by the enzyme requires that after one relaxation event, the protein continues to another relaxation cycle without releasing the DNA. In the diagram,
the protein is shown in grey, and the DNA in red/blue. The orange dot represents the presence of the covalent protein/DNA complex. The single-stranded DNA binding groove is shown in red or yellow. Dasgupta, T et al. ibid.

A more detailed view of the domain structure and mechanism for Topo I is shown in Figure 23.3.8

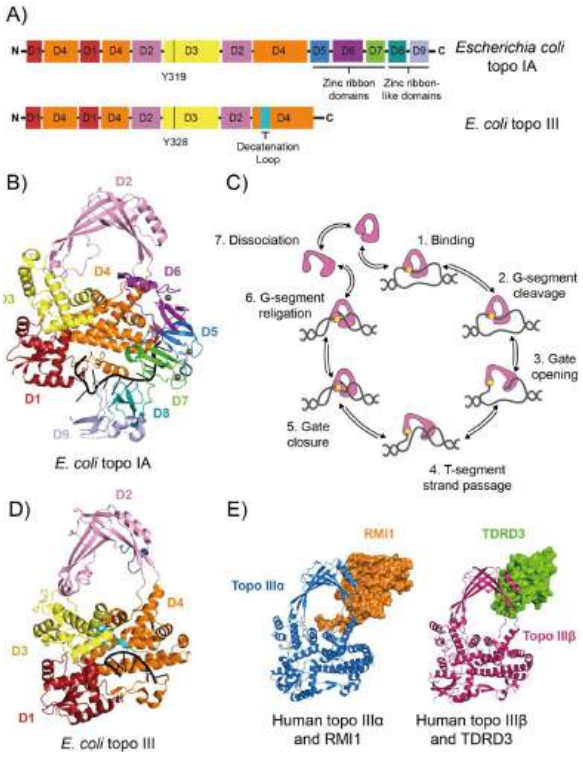

Figure 23.3.8: Type IA DNA topoisomerases. Dasgupta, T et al. ibid.

(A) Protein domain organization of *Escherichia coli* DNA topoisomerase IA (topo IA) and DNA topoisomerase III (topo III). Black vertical lines represent the active site tyrosines.

(B) Crystal structure of *E. coli* topo I bound to ssDNA (PDB: 4RUL).[20]

(C) Strand-passage mechanism for type IA topos. (1) topo binds the G-segment ssDNA region, (2) the G-segment is cleaved. (3) The topo DNA gate is opened, (4) which allows T-segment transfer through the cleaved G-strand. (5) The DNA gate is closed, (6) and the G-strand is re-ligated, changing the linking number by 1. (7) The topo can then go through another round of relaxation or dissociate from the DNA. Type IA topo (domains 1–4) is in pink, the active site tyrosine is yellow and the DNA is grey.

(D) Crystal structure of *E. coli* topo III bound to ssDNA (PDB: 2O54).[26]

(E) Crystal structures of human topo IIIα (blue) bound to RMI1(orange) (PDB: 4CGY),[39] and human topo IIIβ (magenta) bound to TDRD3 (green) (PDB: 5GVE).[60] For panels A, B, and C, the topo I and III domains are color-coded as follows: D1 is red, D2 is pink, D3 is yellow, D4 is orange, D5 is marine blue, D6 is purple, D7 is green, D8 is teal, and D9 is light blue

Figure 23.3.9 shows an interactive iCn3D model of E.Coli topoisomerase I in complex with ssDNA (4RUL).

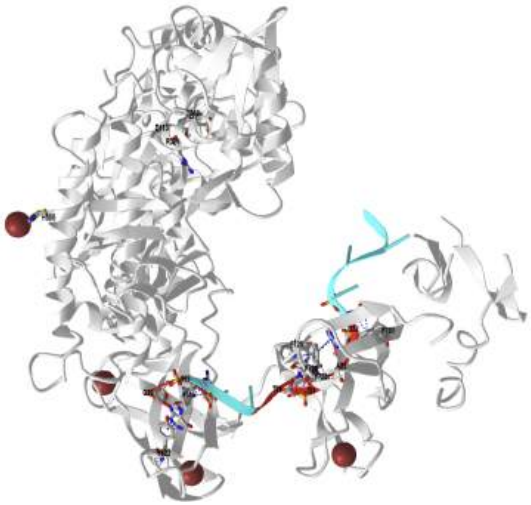

Figure 23.3.9: E.Coli topoisomerase I in complex with ssDNA (4RUL). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...JxcFvds2e8p2WA

The topoisomerase is shown in gray and the single-stranded DNA is in cyan. 4 Zn^{2+} ions are shown. Three form Zn-finger motifs. Two of these are shown near the protein binding site for DNA. A fourth Zn is bound to a single His 566 in the structure. The active site amino acids of the enzyme, which includes residues D111, D113, Y319, and R321 from D1 and D3, are shown and labeled. Also shown are active site residues, E115, F139 and Y312. There are 4 Cys-Zn ribbon domains. The ones that interact with the ssDNA involve π-stacking, some of which are illustrated in the iCn3D model.

Class II topoisomerases (Topo II)

A series of enzymes are included in this class including DNA gyrase and Topo (IV) from prokaryotes and Topo II from eukaryotes. In eukaryotes, they help sister chromosomes separate if they get tangled during cell division. This enzyme works by: this enzyme makes a double-stranded cut, moves on the helix through the cut, and reseals the cut.

- binding the gate segment (G -segment) ds-DNA at a DNA gate where a double-stranded break is made
- binding the transport segment (T-segment) ds-DNA at the N-gate where the nucleotide ATP binds
- The T-segment DNA moves through the break in the G-segment and released the C-gate
- The G- and T-segments are reconnected.

After this, the N gate reopens to allow the process to occur again.

The domain structure of Topo IIs and the general mechanism of action are shown in Figure 23.3.10

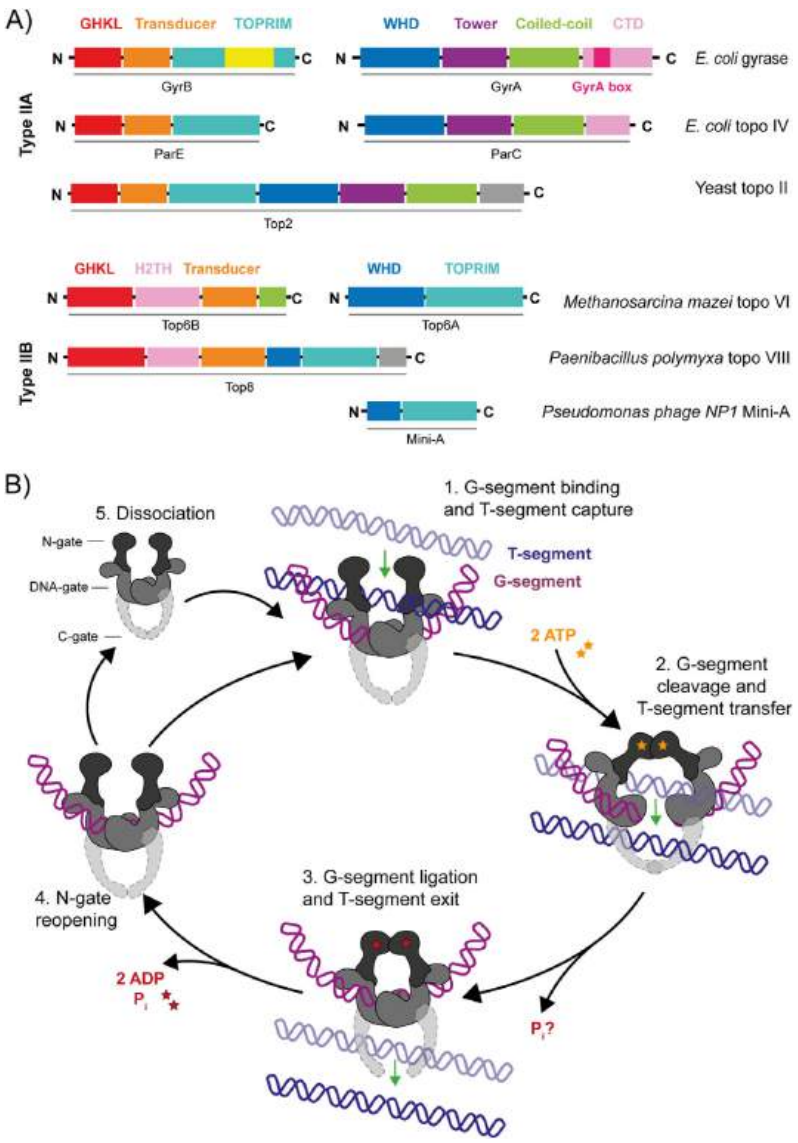

Figure 23.3.10 Type II DNA topoisomerases: domain organization and mechanism.

(A) Protein domain organization for the type IIA topos: *E. coli* DNA gyrase, *E. coli* DNA topoisomerase IV (topo IV), yeast DNA topoisomerase II (topo II), *Methanosarcina mazei* DNA topoisomerase VI (topo VI), *Paenibacillus polymyxa* DNA topoisomerase VIII (plasmid-borne), and *Pseudomonas phage NP1* Mini-A.

(B) type II topo strand passage mechanism. (1) G-segment is bound at the DNA gate and the T-segment is captured. (2) ATP binding stimulates dimerization of the N-gate, the G-segment is cleaved and the T-segment is passed through the break. (3) The G-segment is re-ligated and T-segment exits through the C-gate. For type IIB topos, there is no C-gate so once the T-segment passes through the G-segment, it is released from the enzyme. (4) Dissociation of ADP and P_i allows N-gate opening, a scenario where the enzyme either remains bound to the G-segment, ready to capture a consecutive T-segment, or (5) dissociates from the G-segment.

Figure 23.3.11shows an interactive iCn3D model of Yeast Topoisomerase II-DNA-AMPPNP complex (4GFH) .

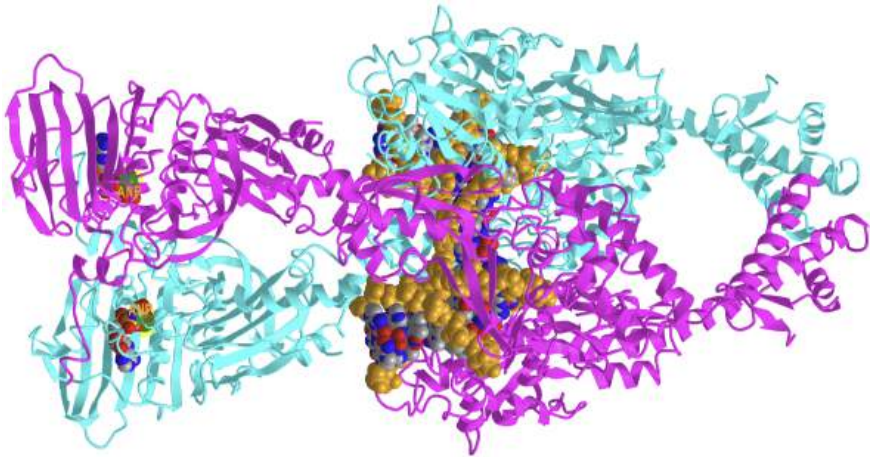

Figure 23.3.11: Yeast Topoisomerase II-DNA-AMPPNP complex (4GFH). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...b5EHLfMwde5Dw8

The two protein chains in the homodimer are shown in magenta and cyan. The double-stranded DNA is shown with a brown backbone and CPK-colored spheres. ANP (AMPPNP), a nonhydrolyzable ATP analog, and Mg^{2+} ions are shown in spacefill and labeled.

The ATP binding and ATPase domain of one of the monomers (cyan for example) is adjacent to the nuclease-cutting domain of the other monomer (magenta). This requires some conformational gymnastics as the ATP binding and cleavage domain move around each other to allow the DNA strand to pass in the right direction and to reset the enzyme.

Note the circular nature of chloroplast and mitochondrial DNA, suggesting a bacterial origin for both of these organelle structures. Sequence alignments further lend support for the ***endosymbiotic theory,*** which proposes that bacteria were engulfed by early eukaryotic organisms and subsequently became symbiotic to their eukaryotic counterpart, rather than being digested.

A reminder about mitochondrial DNA

In the cells of extant organisms, the vast majority of the proteins present in the mitochondria (numbering approximately 1500 different types in mammals) are coded for by nuclear DNA. However, sequencing of the human mitochondrial genome has revealed 16,569 base pairs encoding 13 proteins (Figure 24.3.5). Many of the mitochondrially produced proteins are required for electron transport during the production of ATP, as shown in Figure 23.3.12

Figure 23.3.12: Mitochondrial Genome. Mitochondria are organelle structures containing a double membrane, thought to have originated as an independent prokaryotic organism that was originally engulfed by a eukaryotic organism, where it became a symbiotic counterpart. Mitochondria contain circular chromosomal DNA that shares high sequence similarity with alpha protobacteria. The human mitochondrial genome contains 16,569 base pairs encoding 13 proteins and ribosomal RNA (rRNA) components. Images adapted from: The National Human Genome Research Institute and Shanel, Knopfkind, and JHC.

23.3.4: Histones and DNA packing

Within eukaryotic chromosomes, chromatin proteins, known as ***histones***, compact and organize DNA. These compacting structures guide the interactions between DNA and other proteins, helping control which parts of the DNA are transcribed.

Histones are highly alkaline proteins found in eukaryotic cell nuclei that package and order the DNA into structural units called nucleosomes. They are the chief protein components of chromatin, acting as spools around which DNA winds, and playing a role in gene regulation. Without histones, the unwound DNA in chromosomes would be very long (a length-to-width ratio of more than 10 million to 1 in human DNA). For example, each human diploid cell (containing 23 pairs of chromosomes) has about 1.8 meters of DNA; wound on the histones, the diploid cell has about 90 micrometers (0.09 mm) of chromatin.

Five major families of histones exist: H1/H5, H2A, H2B, H3, and H4. Histones H2A, H2B, H3, and H4 are known as the core histones, while histones H1/H5 are known as the linker histones.

The core histones all exist as dimers, which are similar in that they all possess the histone fold domain: three alpha helices linked by two loops. It is this helical structure that allows for interaction between distinct dimers, particularly in a head-tail fashion (also called the handshake motif). The resulting four distinct dimers then come together to form one octameric nucleosome core, approximately 63 Angstroms in diameter. Around 146 base pairs (bp) of DNA wrap around this core particle 1.65 times in a left-handed super-helical turn to give a particle of around 100 Angstroms across, called a nucleosome, as shown in Figure 23.3.13

Figure 23.3.13: Nucleosome Core Structure. Histones H2A and H2B dimerize, and Histones H3 and H4 dimerize. Two dimers of each join to form a histone core octamer. The DNA double helix winds 1.65 times around the octamer core forming the nucleosome structure. Image adapted from: Nucleosome Structure

The linker histone H1 binds the ***nucleosome*** at the entry and exit sites of the DNA, thus locking the DNA into place and allowing the formation of a higher order structure, as shown in Figure 23.3.14 The most basic such formation is the 10 nm fiber or beads on a string conformation. This involves the wrapping of DNA around nucleosomes with approximately 50 base pairs of DNA separating each pair of nucleosomes (also referred to as linker DNA).

Figure 23.3.14: Overall Nucleosome Structure. (A) Side view diagram of the nucleosome structure with the histone octamer shown in blue, the DNA double helix in red, and the histone H1 linker in green. (B) Shows a top-view rendering of the histone octamer with the associated DNA helix. Note that the Histone tails from H3 and H2B protrude from the DNA. Image A from: Darekk2 Image B from EMW

The nucleosome contains over 120 direct protein-DNA interactions and several hundred water-mediated ones. Direct protein – DNA interactions are not spread evenly about the octamer surface but rather located at discrete sites. These are due to the formation of two types of DNA binding sites within the octamer; the α1α1 site, which uses the α1 helix from two adjacent histones, and the L1L2 site formed by the L1 and L2 loops. Salt links and hydrogen bonding between both side-chain basic and hydroxyl groups and main-chain amides with the DNA backbone phosphates form the bulk of interactions with the DNA. This is important, given that the ubiquitous distribution of nucleosomes along genomes requires it to be a non-sequence-specific DNA-binding factor. Although nucleosomes tend to prefer some DNA sequences over others, they are capable of binding practically to any sequence, which is thought to be due to the flexibility in the formation of these water-mediated interactions. In addition, non-polar interactions are made between protein side-chains and the deoxyribose groups, and an arginine side-chain intercalates into the DNA minor groove at all 14 sites where it faces the octamer surface. The distribution and strength of DNA-binding sites about the octamer surface distort the DNA within the nucleosome core. The DNA is non-uniformly bent and also contains twist defects. The twist of free B-form DNA in solution is 10.5 bp per turn. However, the overall twist of nucleosomal DNA is only 10.2 bp per turn, varying from a value of 9.4 to 10.9 bp per turn.

The histone tail extensions constitute up to 30% by mass of the histones but are not visible in the crystal structures of nucleosomes due to their high intrinsic flexibility, and have been thought to be largely unstructured (Figure 4.14). The N-terminal tails of histones H3 and H2B pass through a channel formed by the minor grooves of the two DNA strands, protruding from the DNA every 20 bp. The N-terminal tail of histone H4, on the other hand, has a region of highly basic amino acids (16-25), which, in the crystal structure, forms an interaction with the highly acidic surface region of a H2A-H2B dimer of another nucleosome, being potentially relevant for the higher-order structure of nucleosomes. This interaction is thought to occur under physiological conditions also, and suggests that acetylation of the H4 tail distorts the higher-order structure of chromatin.

Figure 23.3.15shows an interactive iCn3D model of the human nucleosome (3afa). One member of each pair of histones is shown in cartoon rendering, while the other member of the pair is shown in the same color but in spacefill rendering. The structure of a human nucleosome (3afa) is shown below (H2A is shown in cyan, H2B in blue, H3 in magenta, and H4 in purple). Each strand of DNA is shown in a different shade of gray.

The formation of the DNA double helix represents the first-order packaging of the chromosome structure. The formation of nucleosomes represents the second level of packaging for eukaryotic chromosomes. *In vitro* data suggests that nucleosomes are then arranged into either a solenoid structure which consists of 6 nucleosomes linked together by the Histone H1 linker proteins or a zigzag structure that is similar to the solenoid construct, as shown in Figure 23.3.16 Both the solenoid and zigzag structures are approximately 30 nm in diameter. The solenoid and zigzag structures reported from *in vitro* data have not yet been confirmed to occur *in vivo.*

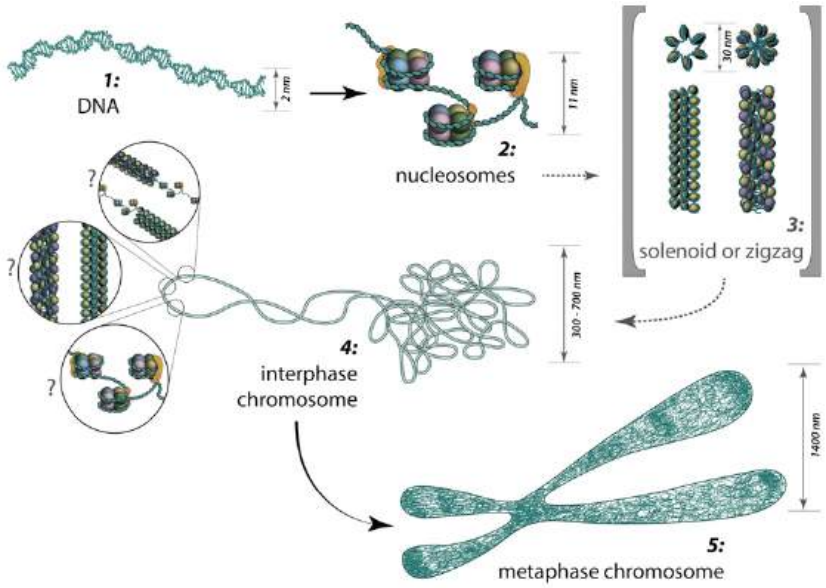

Figure 23.3.16: Chromosome Structure. (1) DNA double helix is approximately 2 nm in diameter. (2) The nucleosome core structure is approximately 11 nm in diameter. (3) The solenoid/zigzag structure is approximately 30 nm in diameter and is proposed to form chromosome loops (4) during cellular interphase and more condensed chromosome territories (5) during mitosis. Image by: MBInfo

During interphase, each chromosome occupies a spatially limited, roughly elliptical domain which is known as a chromosome territory (CT). Each chromosome territory is comprised of higher-order chromatin units of ~1 Mb each. These units are likely built up from smaller loop domains that contain the solenoid/zigzag structural motifs. On the other hand, 1Mb domains can themselves serve as smaller units in higher-order chromatin structures.

Chromosome territories are known to be arranged radially around the nucleus. This arrangement is both cell and tissue-type specific and is also evolutionarily conserved. The radial organization of chromosome territories was shown to correlate with their gene density and size. In this case, the gene-rich chromosomes occupy interior positions, whereas larger, gene-poor chromosomes, tend to be located around the periphery. Chromosome territories are also dynamic structures, with genes able to relocate from the periphery towards the interior once they have been ‘switched on’. In other cases, genes may move in the opposite direction, or simply maintain their position. The eviction of genes from their chromosome territories into the interchromatin compartment or a neighboring chromosome territory is often accompanied by the formation of large decondensed chromatin loops.

23.3.5: Models describing chromosome territory arrangement

With the development of high-throughput biochemical techniques, such as 3C (chromosome conformation capture) and 4C (chromosome conformation capture-on-chip and circular chromosome conformation capture), numerous spatial interactions between neighboring chromatin territories have been described, as shown in Figure 23.3.17. These descriptions have been supplemented with the construction of spatial proximity maps for the entire genome (e.g., for a human lymphoblastoid cell line). Together, these observations and physical simulations have led to the proposal of various models that aim to define the structural organization of chromosome territories:

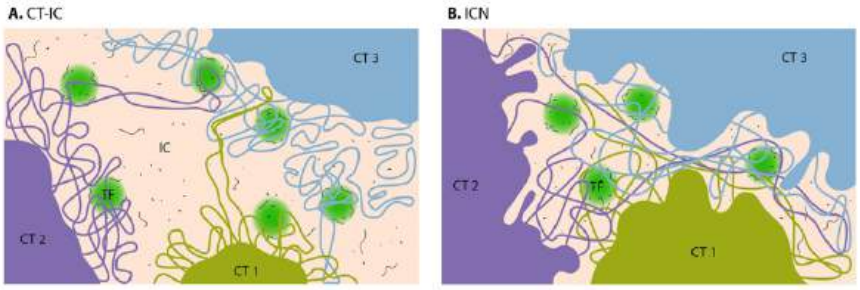

Figure 23.3.17: Computer Models of Chromosome Territory (CT) Structure. In the CT-IC model, the space between discrete CTs can be visualized in light and electron microscope and is called the interchromatin compartment (IC). Transcription factories (TF, green color) are localized predominantly in perichromatin region. In the ICN model, the interchromatin compartment is not apparent. Instead, the space between CTs is occupied by intermingling decondensed chromatin loops, which often share the same transcription factories. Image by: MBInfo

1. The chromosome territory-interchromatin compartment (CT-IC) model describes two principal compartments: chromosome territories (CTs) and an interchromatin compartment (IC). In this model, chromosome territories build up an interconnected chromatin network that is associated with an adjacent 3D space called the interchromatin compartment. The latter can be observed using both light and electron microscopy.

Within a single chromosome territory, the interphase chromosome is divided into defined regions based on the level of chromosome condensation. Here, the inner part of the interphase chromosome is comprised of more condensed chromatin domains or higher-order chromatin fibers, while a thin (<200 nm) layer of more decondensed chromatin, known as the perichromatin region, can be found around the chromosomal periphery. Functionally, the perichromatin region represents the major transcriptional compartment and is also the region where most co-transcriptional RNA splicing takes place. DNA replication and DNA repair are also predominately carried out within the perichromatin region. Finally, nascent RNA transcripts, referred to as perichromatin fibrils, are also generated in the perichromatin region. Perichromatin fibrils are then subjected to the splicing events by the factors, provided by the interchromatin compartment.

The lattice model, proposed by Dehgani et al. is based on reports that transcription also occurs within the inner, more condensed chromosome territories and not only at the interface between the interchromatin compartment and the perichromatin region. Using ESI (electron spectroscopic imaging), Dehgani et al. showed that chromatin was organized as an array of deoxyribonucleoprotein fibers of 10–30 nm in diameter. In this study, the interchromatin compartments, which are described in the CT-IC model as large channels between chromosome territories, were not apparent. Instead, chromatin fibers created a loose meshwork of chromatin throughout the nucleus that intermingled at the periphery of chromosome territories. Thus, inter- and intra-chromosomal spaces within this meshwork are essentially contiguous and together form the intra-nuclear space.

2. The interchromatin network (ICN) model predicts that intermingling chromatin fibers/loops can make both cis- (within the same chromosome) and trans- (between different chromosomes) contacts. This intermingling is uniform and makes a distinction between the chromosome territory and interchromatin compartment functionally meaningless. The advantage of the ICN model is that it permits high chromatin dynamics and diffusion-like movements. The authors propose that ongoing transcription influences the degree of intermingling between specific chromosomes by stabilizing associations between particular loci. Such interactions are likely to depend on the transcriptional activity of the loci and are therefore cell-type specific.

The cell type-specific organization of chromosome territories has been studied by measuring the volume and frequency of intermingling between heterologous chromosomes. By using 3C (chromosome conformation capture) and FISH (fluorescence in situ hybridization) to map the regions of chromosome intermingling, it was revealed that these regions contain a higher density of active genes and are enriched with markers of transcriptional activation and repression, such as activated RNAPII. By comparing the positions of the CTs in undifferentiated mouse embryonic stem (ES) cells, ES cells in early stages of differentiation, and terminally differentiated NIH3T3 cells, it was shown that fully differentiated cells had a higher enrichment of RNAPII, compared to undifferentiated or less-differentiated cells. The findings support the notion that the intermingling regions have functional significance in the nucleus and provide a basis for understanding how the radial and relative positions of chromosomal territories evolve during the process of differentiation, explaining their organization in a cell type-dependent manner.

3. The Fraser and Bickmore model emphasizes the functional importance of giant chromatin loops, which originate from chromosome territories and expand across the nuclear space to share transcription factories. In this case, both *cis*- and *trans*- oops of decondensed chromatin can be co-expressed and co-regulated by the same transcription factory.

4. The Chromatin polymer models assume a broad range of chromatin loop sizes and predict the observed distances between genomic loci and chromosome territories, as well as the probabilities of contacts being formed between given loci. These models apply physics-based approaches that highlight the importance of entropy for understanding nuclear organization. By proposing the existence of conformational chromatin ensembles with structures based on three possible homopolymer states, these models also provide alternative structures to the traditional 30 nm chromatin fiber, which has been brought into question following recent studies.

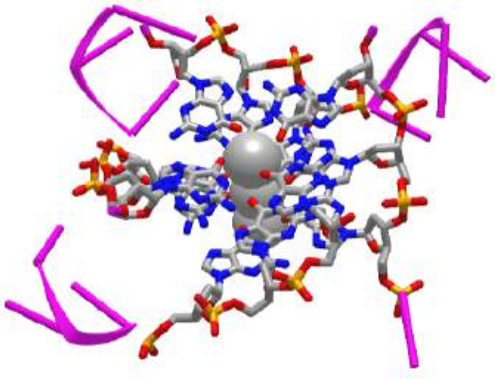
With a lack of experimental evidence to support these described models, it must be remembered that they serve only to hypothesize the structural and chemical properties of intermediate chromatin structures and to highlight unanswered questions. For example, the mechanisms that exist to control the rate and the extent of chromatin movement remain to be defined

23.3.6: Telomere Structures

At the ends of the linear chromosomes are specialized regions of DNA called telomeres, shown in Figure 23.3.18 The main function of these regions is to allow the cell to replicate chromosome ends using the enzyme telomerase, as the enzymes that normally replicate DNA cannot copy the extreme 3′ ends of chromosomes. These specialized chromosome caps also help protect the DNA ends, and stop the DNA repair systems in the cell from treating them as damage to be corrected. In human cells, telomeres are usually lengths of single-stranded DNA containing several thousand repeats of a simple TTAGGG sequence.

Figure 23.3.18: Telomere Structure. (A) Telomeres are located at the end of chromosomes, where they help protect against the loss of DNA during replication. (B) DNA quadruplex formed by telomere repeats. The looped conformation of the DNA backbone is very different from the typical DNA helix. The green spheres in the center represent potassium ions. Image (A) by MBInfo and Image (B) by: Thomas Splettstoesser

In human cells, telomeres contain 300-8000 repeats of a simple **TTAGGG** sequence. The repetitive **TTAGGG** sequences in telomeric DNA can form unique higher-order structures called **quadruplexes**. Figure 23.3.19shows an interactive iCn3D model of parallel quadruplexes from human telomeric DNA (1KF1). The structure contains a single DNA strand **(**5'-AGGGTTAGGGTTAGGGTTAGGG-3') which contains four TTAGGG repeats.



NCBI iCn3D Figure 23.3.19 A buried phenylalanine in low molecular weight protein tyrosyl phosphatase (1xww) (Copyright; author via source).
Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...y5joFHDgWJQsQ6

Rotate the model to see 3 parallel layers of quadruplexes. In each layer, **4** noncontiguous guanine bases interact with a K^+ ion. Hover over the guanine bases in one layer and you will find that one layer consists of guanines 4, 10, 16, and 22, which derive from the last G in each of the repeats in the sequence of the oligomer used (5'-AGGGTTAGGGTTAGGGTTAGGG-3'). These quadruplexes certainly serve as recognition and the binding site for telomerase proteins. The guanine-rich telomere sequences which can form quadruplex may also function to stabilize chromosome ends

During DNA replication, the double-stranded DNA is unwound and DNA polymerase synthesizes new strands. However, as DNA polymerase moves in a unidirectional manner (from 5' to 3'), only the leading strand can be replicated continuously. In the case of the lagging strand, DNA replication is discontinuous. In humans, small RNA primers attach to the lagging strand DNA, and the DNA is synthesized in small stretches of about 100-200 nucleotides, which are termed Okazaki fragments. The RNA primers are removed, and replaced with DNA and the Okazaki fragments are ligated together. At the end of the lagging strand, it is impossible to attach an RNA primer, meaning that there will be a small amount of DNA lost each time the cell divides. This 'end replication problem' has serious consequences for the cell as it means the DNA sequence cannot be replicated correctly, with the loss of genetic information.

To prevent this, telomeres are repeated hundreds to thousands of times at the end of the chromosomes. Each time cell division occurs, a small section of telomeric sequences is lost to the end replication problem, thereby protecting the genetic information. At some point, the telomeres become critically short. This attrition leads to cell senescence, where the cell is unable to divide, or apoptotic cell death. Telomeres are the basis for the Hayflick limit, the number of times a cell can divide before reaching senescence.

Telomeres can be restored by the enzyme telomerase, which extends telomeres length (Figure 24.3.10). Telomerase activity is found in cells that undergo regular division, such as stem cells and lymphocyte cells of the immune system. Telomeres can also be extended through the Alternative Lengthening of Telomeres (ALT) pathway. In this case, rather than being extended, telomeres are switched between chromosomes by homologous recombination. As a result of the telomere swap, one set of daughter cells will have shorter telomeres, and the other set will have longer telomeres.

A downside to telomere extension is the potential for uncontrolled cell division and cancer. Abnormally high telomerase activity has been found in the majority of cancer cells, and non-telomerase tumors often exhibit ALT pathway activation. As well as the potential for losing genetic information, cells with short telomeres are at high risk for improper chromosome recombination, which can lead to genetic instability and aneuploidy (an abnormal number of chromosomes).

These guanine-rich telomere sequences may also stabilize chromosome ends by forming structures of stacked sets of four-base units, rather than the usual base pairs found in other DNA molecules (Figure 24.3.10). Here, four guanine bases form a flat plate and these flat four-base units then stack on top of each other, to form a stable G-quadruplex structure. These structures are stabilized by hydrogen bonding between the edges of the bases and the chelation of a metal ion in the center of each four-base unit. Other structures can also be formed, with the central set of four bases coming from either a single strand folded around the bases or several different parallel strands, each contributing one base to the central structure.

In addition to these stacked structures, telomeres also form large loop structures called telomere loops or T-loops. Here, the single-stranded DNA curls around in a long circle stabilized by telomere-binding proteins. At the very end of the T-loop, the single-stranded telomere DNA is held onto a region of double-stranded DNA by the telomere strand disrupting the double-helical DNA and base pairing to one of the two strands. This triple-stranded structure is called a displacement loop or D-loop.

CHAPTER OVERVIEW

24: DNA Metabolism

24.1: DNA Replication

24.2: DNA Mutations, Damage, and Repair

24.3: DNA Recombination

24.1: DNA Replication

24.1.1: Introduction

The elucidation of the structure of the double helix by James Watson and Francis Crick in 1953 provided a hint as to how DNA is copied during the process of ***DNA replication***. Separating the strands of the double helix would provide two templates for the synthesis of new complementary strands, but exactly how new DNA molecules were constructed was still unclear. In one model, ***semiconservative replication***, the two strands of the double helix separate during DNA replication, and each strand serves as a template from which the new complementary strand is copied. After replication in this model, each double-stranded DNA includes one parental or "old" strand and one daughter or "new" strand. There were two competing models also suggested: ***conservative*** and ***dispersive***, which are shown in Figure 24.1.1.

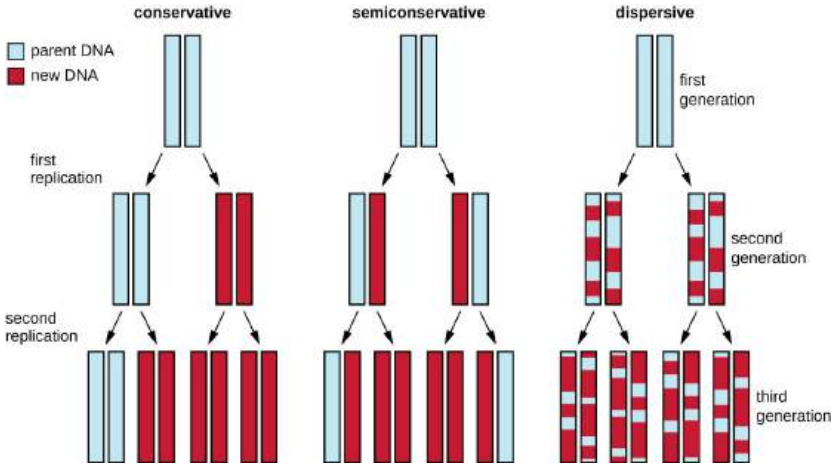

Figure 24.1.1: Three Models of DNA replication. In the ***conservative model,*** parental DNA strands (blue) remained associated in one DNA molecule while new daughter strands (red) remained associated in newly formed DNA molecules. In the ***semiconservative model,*** parental strands separated and directed the synthesis of a daughter strand, with each resulting DNA molecule being a hybrid of a parental strand and a daughter strand. In the ***dispersive model***, all resulting DNA strands have regions of double-stranded parental DNA and regions of double-stranded daughter DNA. Figure by Parker, N., et.al. (2019) Openstax

Matthew Meselson and Franklin Stahl devised an experiment in 1958 to test which of these models correctly represents DNA replication, as shown in Figure 24.1.2 They grew the bacterium, *Escherichia coli* for several generations in a medium containing a "heavy" isotope of nitrogen (^{15}N) that was incorporated into nitrogenous bases and, eventually, into the DNA. This labeled the parental DNA. The *E. coli* culture was then shifted into a medium containing ^{14}N and allowed to grow for one generation. The cells were harvested and the DNA was isolated. The DNA was separated by ultracentrifugation, during which the DNA formed bands according to its density. DNA grown in ^{15}N would be expected to form a band at a higher density position than that grown in ^{14}N. Meselson and Stahl noted that after one generation of growth in ^{14}N, the single band observed was intermediate in position in between DNA of cells grown exclusively in ^{15}N or ^{14}N. This suggested either a semiconservative or dispersive mode of replication. Some cells were allowed to grow for one more generation in ^{14}N and spun again. The DNA harvested from cells grown for two generations in ^{14}N formed two bands: one DNA band was at the intermediate position between ^{15}N and ^{14}N, and the other corresponded to the band of ^{14}N DNA.

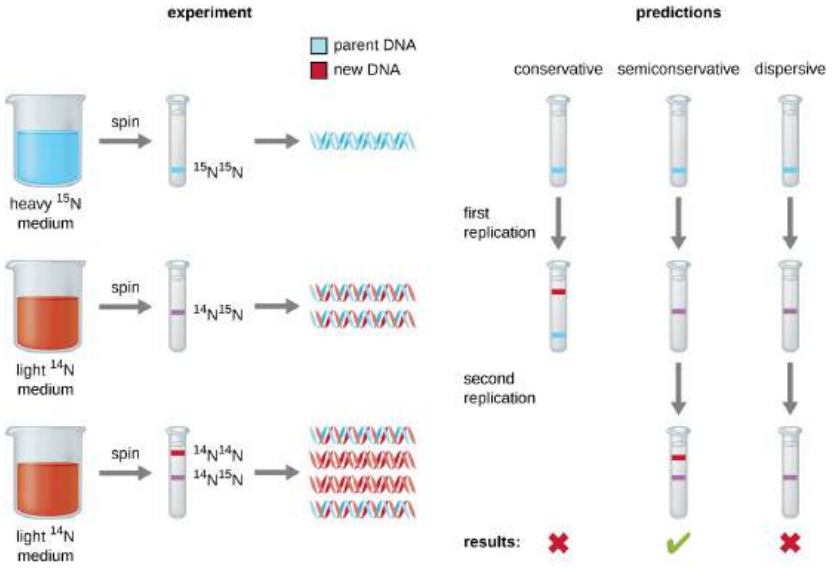

Figure 24.1.2: Meselson and Stahl experimented with *E. coli* grown first in heavy nitrogen (^{15}N) then in ^{14}N. DNA grown in ^{15}N (blue band) was heavier than DNA grown in ^{14}N (red band), and sedimented to a lower level on ultracentrifugation. After one round of replication, the DNA sedimented halfway between the ^{15}N and ^{14}N levels (purple band), ruling out the conservative model of replication. After a second round of replication, the dispersive model of replication was ruled out. These data supported the semiconservative replication model. Figure by Parker, N., et.al. (2019) *Openstax*

These results could only be explained if DNA replicates in a semiconservative manner. Therefore, the other two models were ruled out. As a result of this experiment, we now know that during DNA replication, each of the two strands that make up the double helix serves as a template from which new strands are copied. The new strand will be complementary to the parental or “old” strand. The resulting DNA molecules have the same sequence and are divided equally into the two daughter cells.

Think about It: What would have been the conclusion of the Meselson-Stahl experiment if, after the first generation, they had found two bands of DNA?

To synthesize double-stranded DNA, the parental strands must separate so DNA polymerases can copy both strands. As all DNA polymerases synthesize new DNA in a 5' to 3' direction from a 3' to 5' template, different mechanisms are used to faithfully synthesize both parental strands. The general mechanism is shown in Figure 24.1.3

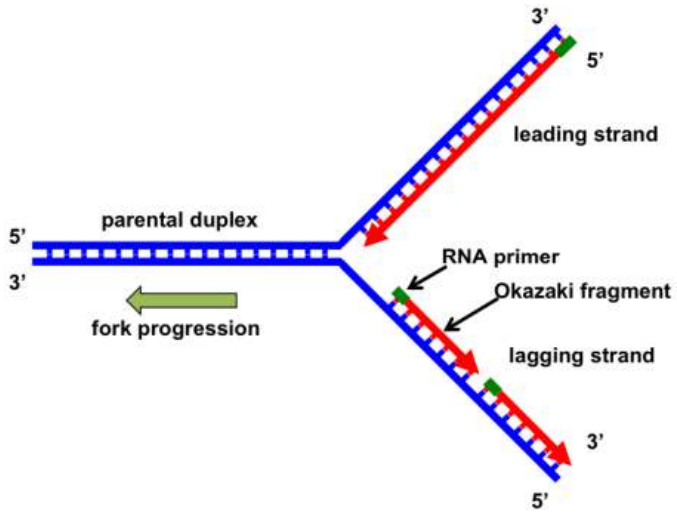

Figure 24.1.3 The replication fork. Leading-strand synthesis proceeds continuously in the 5' to 3' direction. Lagging-strand synthesis also occurs in the 5' to 3' direction, but in a discontinuous manner. An RNA/DNA primer (labeled in green) initiates leading-strand synthesis and every Okazaki fragment on the lagging strand.

Small RNA primers are needed for the new strands. Short (1000-2000 NT) DNA (Okazaki) fragments are made on the 3'-5' parental strand. Ultimately the RNA primers are degraded and filled, and the Okazaki fragments ligated. We will discuss replication in detail

for E. Coli, a model prokaryote, followed by replication in eukaryotes.

Figure 24.1.4 shows a general overview of a DNA "replication fork" from where DNA strand synthesis proceeds..

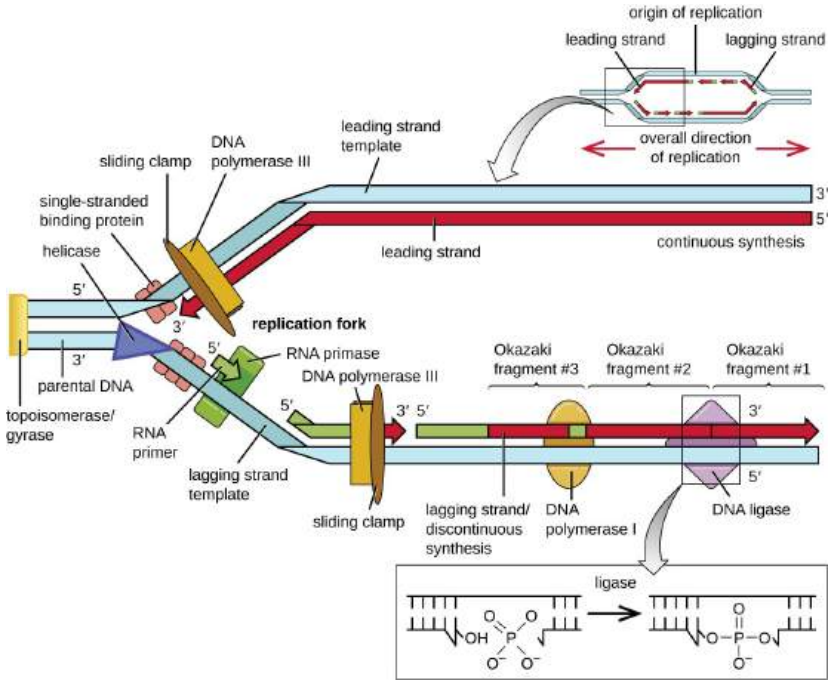

Figure 24.1.4: General Overview of a DNA Replication Fork. At the origin of replication, topoisomerase II relaxes the supercoiled chromosome. Two replication forks are formed by the opening of the double-stranded DNA at the origin, and helicase separates the DNA strands, which are coated by single-stranded binding proteins to keep the strands separated. DNA replication occurs in both directions. An RNA primer complementary to the parental strand is synthesized by RNA primase and is elongated by DNA polymerase III through the addition of nucleotides to the 3′-OH end. On the leading strand, DNA is synthesized continuously, whereas on the lagging strand, DNA is synthesized in short stretches called Okazaki fragments. RNA primers within the lagging strand are removed by the exonuclease activity of DNA polymerase I, and the Okazaki fragments are joined by DNA ligase. Figure by Parker, N., et.al. (2019) Openstax

24.1.2: DNA Replication in E. Coli

DNA replication has been well studied in bacteria primarily because of the small size of the genome and the mutants that are available. *E. coli* has 4.6 million base pairs (Mbp) in a single circular chromosome and all of it is replicated in approximately 42 minutes, starting from a single ***origin of replication*** and proceeding around the circle bidirectionally (i.e., in both directions), as shown in Figure 24.1.5. This means that approximately 1000 nucleotides are added per second. The process is quite rapid and occurs with few errors. *E. coli* has a single ***origin of replication***, called *oriC*, on its one chromosome. The origin of replication is approximately 245 base pairs long and is rich in adenine-thymine (AT) sequences.

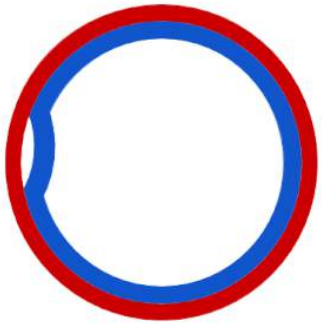

Figure 24.1.5: Prokaryotic DNA Replication. Replication of DNA in prokaryotes begins at a single origin of replication, shown in the figure to the left, and proceeds in a bidirectional manner around the circular chromosome until replication is complete. The bidirectional nature of replication creates two replication forks that are actively mediating the replication process. The right-hand figure shows a dynamic model of this process. The red and blue dots represent the incorporation of daughter strand nucleotides during the process of replication. Figures from: Daniel Yuen at David Tribe Derivatives and Catherinea228

24.1.2.1: Replication Overview - E. Coli

The open regions of DNA that are actively undergoing replication are called **replication forks**. All the proteins involved in DNA replication aggregate at the ***replication forks*** to form a replication complex called a **replisome.** The initial assembly of the complex that initiates primer synthesis is called the **primosome**. Table 24.1.1 below show the components that assemble at the replication fork to form the E. Coli replisome.

E. coli Gene	Enzyme/Protein Function	Description
dnaA	Initiator Protein	Melts DNA at oriC, exposing two template ssDNA strands
dnaB	Helicase	Unwinds the DNA helix at the front end of each replication fork during replication
dnaC	Helicase Loader	Loads the DnaB Helicase onto the ssDNA template strands
dnaG	Primase	Synthesizes RNA primers used to initiate DNA synthesis
dnaE	α-Catalytic Subunit of DNA Polymerase III	Catalytic subunit of the main replicative polymerase during DNA replication
dnaQ	ε-Editing Subunit of DNA Polymerase III	Editing subunit of the main replicative polymerase during DNA replication
dnaN	β-clamp subunit of DNA Polymerase III	Clamping subunit of the main replicative polymerase during DNA replication
polA	DNA Polymerase I	Processes Okazaki fragments and also fills in gaps during DNA repair processes
polB	DNA Polymerase II	Proofreading and editing, especially on lagging strand synthesis and some involvement in DNA repair
ssb	Single Stranded Binding Proteins (SSB)	Bind with single-stranded regions of DNA in the replication fork and prevent the strands from rejoining
A dimer encoded by *gyrA* and *gyrB*	DNA Gyrase	Type II Topoisomerase involved in releiving positive supercoiling tension caused by the action of Helicase
A dimer encoded by *parC* and *parE*	Topoisomerase IV	Type II Topoisomerase involved in decatenation of daughter chromosomes during DNA replication
ligA	DNA Ligase	Fixes nicks in the DNA backbone during DNA replication, DNA damage, and DNA repair processes
Note: Only the genes involved in the formation of the catalytic domain of DNA polymerase III are listed		

Table 24.1.1: **Enzymes involved in DNA Replication in the prokaryote, E. coli**

In *E. coli*, DNA replication is initiated at the single origin of replication, *oriC.* Binding of the initiator protein, **DnaA**, locally unfolds the DNA to form two template ssDNA, which bind **DnaB helicase.** A DnaB hexamer adds to each strand in a process promoted by **DnaC**, a helicase loader. The **single-stranded DNA binding protein B (SSPB)**binds to and protects the rest of the ssDNA, preventing further binding by DnaB. The **primase, DnaG**, is recruited to the site by the DnaB hexamer and synthesizes the RNA primers. DnaB also recruits DNA polymer III holoenzyme (PolIII HE) which binds through a β clamp. All of the bound proteins collectively form the replisome. An overview of E. Coli **replisome** is shown in Figure 24.1.6

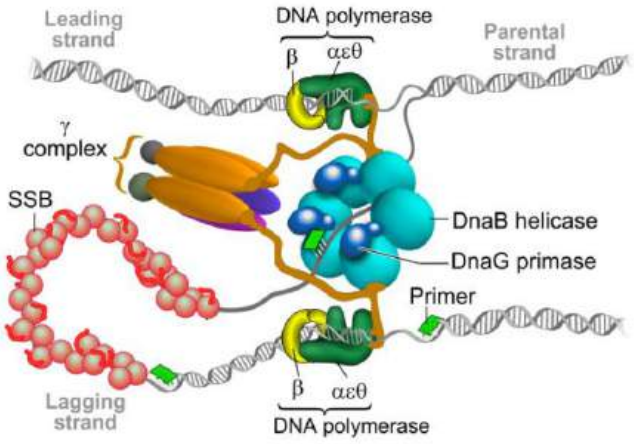

Figure 24.1.6: The bacterial replisome. Ilic, S.; Cohen, S.; Singh, M.; Tam, B.; Dayan, A.; Akabayov, B. DnaG Primase—A Target for the Development of Novel Antibacterial Agents. *Antibiotics* **2018**, *7*, 72. https://doi.org/10.3390/antibiotics7030072 Creative Commons Attribution (CC BY) license (**http://creativecommons.org/licenses/by/4.0/**)

Once assembled, replisomes move in opposite directions from the single oriC in the E. Coli chromosome. They meet at the opposite ends at a **termination site (ter)** to which ***Tus*** proteins are bound that create 'replication fork traps'. After completion of DNA replication, the newly synthesized genomes are separated and segregated to daughter cells.

An alternative term, the **primosomes**, is used to describe a subcomplex of the replisome which starts replication of the E. Coli chromosome, as well as some phages and plasmids. It contains 6 proteins including helicases and primases, and catalyzes the movement of the replication form by unwinding and primer synthesis. The motor protein **helicases**, use ATP to move along the ds-DNA backbone, unraveling it as it proceeds. The human genome has genes for 64 RNA and 31 DNA helicases (about 1% of eukaryotic genes).

24.1.2.2: Primase and Polymerase activities

The synthesis of both RNA strands by the DnaG primase, and DNA strands by DNA polymerase III holoenzyme (pol III) occurs at each start site for an Okazaki fragment. Both enzymes bind to the conserved carboxy-terminal tail of the single-stranded DNA-binding protein (SSB). It turns out that they can both be bound simultaneously.

The primase (DnaG) has three domains:

- N-terminus that binds the template
- RNA polymerase domain
- C-terminus that binds helicase and the C-terminus of SSB.

Primase is displaced by polIII after about 10 nucleotides have been added to the RNA primer so DNA synthesis can now occur at the 3' end of the primer.

Figure 24.1.7 shows how the primase to polymerase switch is made.

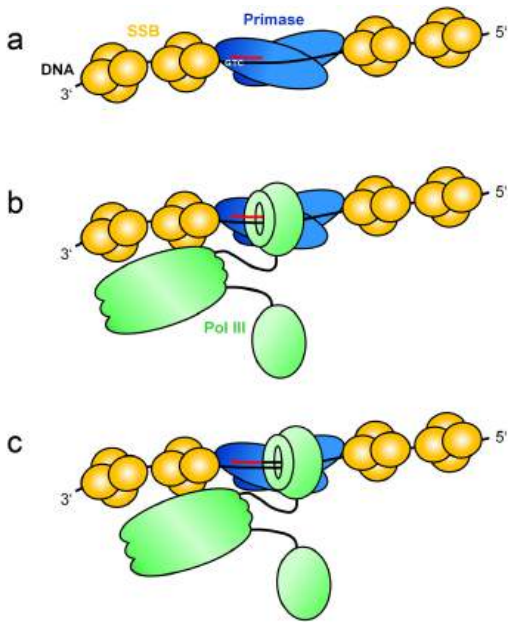

Figure 24.1.7: Schematic representation of the primase-to-polymerase switch during DNA replication in *E. coli*. Bogutzki, A., Naue, N., Litz, L. *et al. Sci Rep* **9,** 14460 (2019). https://doi.org/10.1038/s41598-019-51031-0. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/

Panel (**a**): Two primase molecules cooperate in the synthesis of the RNA primer (red).

Panel (**b**): For elongation of the primer, pol III enters the complex, whereupon primase and pol III are concurrently bound to the primed site, possibly via interactions with the C-termini of an adjacent SSB tetramer.

Panel (**c**): During pol III-mediated elongation of the primer by several nucleotides, both enzymes stay bound to the template. Only after the primer has been elongated by more than 10 nucleotides, one of the primases is released in the G4ori system. It is presumably the displacement of SSB by pol III that causes the consequent dissociation of primase. Whereas in the G4ori system, the two primases are positioned by hairpin structures that prevent SSB from binding to this part of the origin. At the *E. coli* replication fork, primases are brought into contact via their interaction with the replicative helicase DnaB.

What happens if the replication fork does not move to the termination site? If the DNA is damaged or if the replisome falls off of the chromosome, it can rebind and restart using **Pri** proteins. PriA is a DNA helicase that can bind to replication forks through DNA motifs and through interactions with SSBs. Other proteins involved include PriB, PriC, DnaT, DnaC, DnaB helicase, and DnaG primase as illustrated in Figure 24.1.8

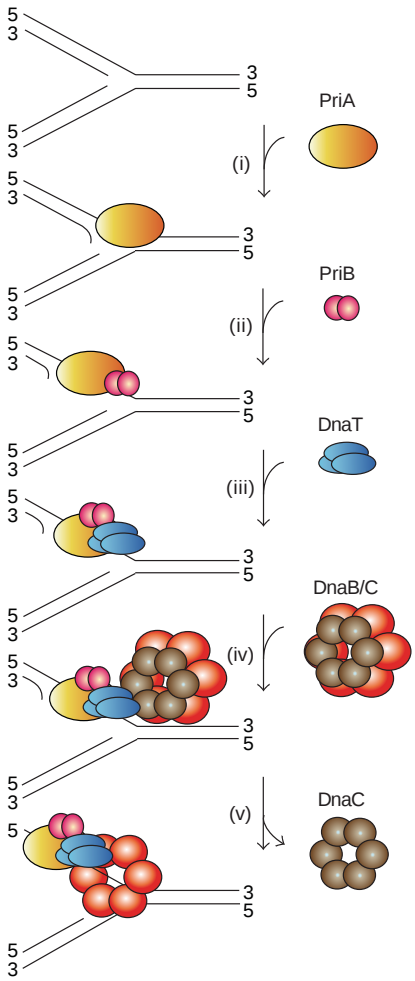

Figure 24.1.8 Primosome restart assembly. The proposed assembly mechanism is as follows. (i) PriA recognizes and binds to a replication fork, (ii) PriB joins PriA to form a PriA-PriB-DNA ternary complex, (iii) DnaT participates in this nucleocomplex to form a triprotein complex, in which PriB is released from ssDNA due to recruitment of DnaT, (iv) the PriA-PriB-DnaT-DNA quaternary complex loads the DnaB/C complex, and (v) DnaB is loaded on the lagging strand template. Yen-Hua Huang and **Cheng-Yang Huang.** BioMed Research International (2014). https://doi.org/10.1155/2014/195162. Huang and Cheng-Yang Huang. The primosome and replisome are complicated in structure and in their functional activity. Words go only so far in painting an image of how it works. To help we show a few different images of the replisome of E. Coli below.

The first is shown in Figure 24.1.9

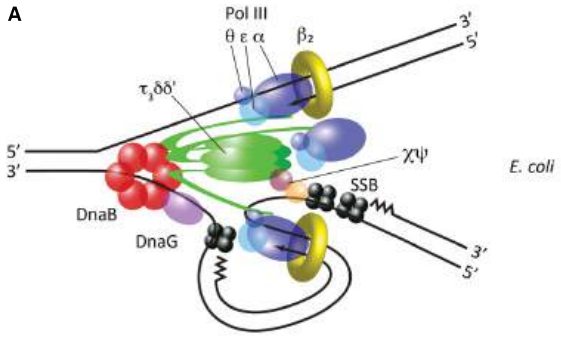

Figure 24.1.9: **Replisome architecture in bacteria. (A)** Architecture of the *E. coli* replisome, derived from *in vitro* studies and direct observation *in vivo*. Beattie TR, Reyes-Lamothe R. A. Front Microbiol. 2015 doi: 10.3389/fmicb.2015.00562. Creative Commons Attribution License (CC BY)

In this diagram, the leading strand is shown in the upper right end of the diagram. The central bottom loop shows the lagging strand. The $\tau_3\delta\delta'\psi\chi$ is the clamp loader and the DnaB (red) is hexameric. The ssDNA in the lagging strand loop is bound by ssDNA binding proteins (SSB).

Figure 24.1.10shows the rebind primosome which is mostly similar to the regular one.

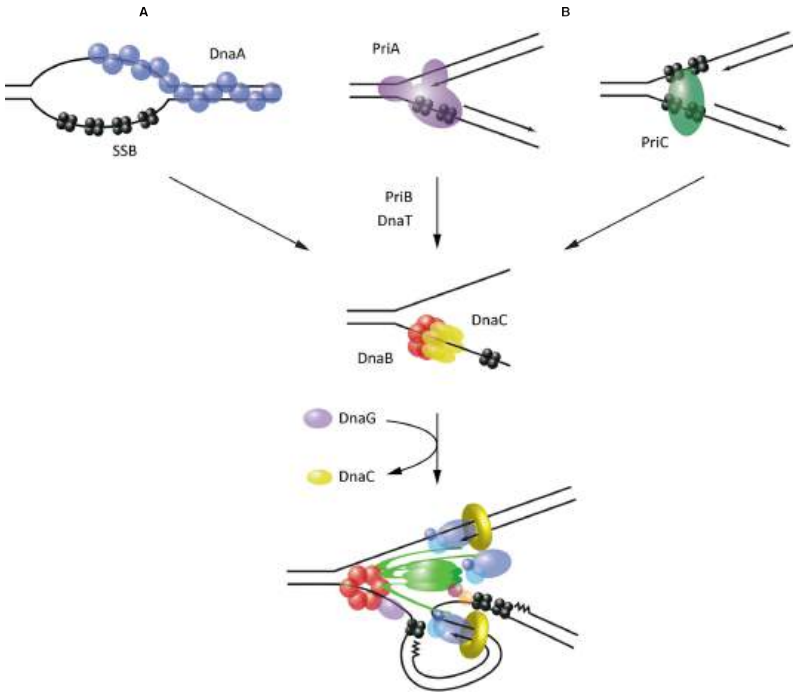

Figure 24.1.10 **Mechanisms of helicase loading leading to replisome assembly in *E. coli*. (A)**Recognition and melting of the *oriC* locus during initiation by DnaA. **(B)**Recognition of abandoned fork structures during replisome reloading by PriA and PriC. All pathways converge on the loading of the replicative helicase DnaB, which acts as an assembly platform for the remaining replisome components.

Finally, Figure 24.1.11shows models of DNA polymerase for lagging strand synthesis.

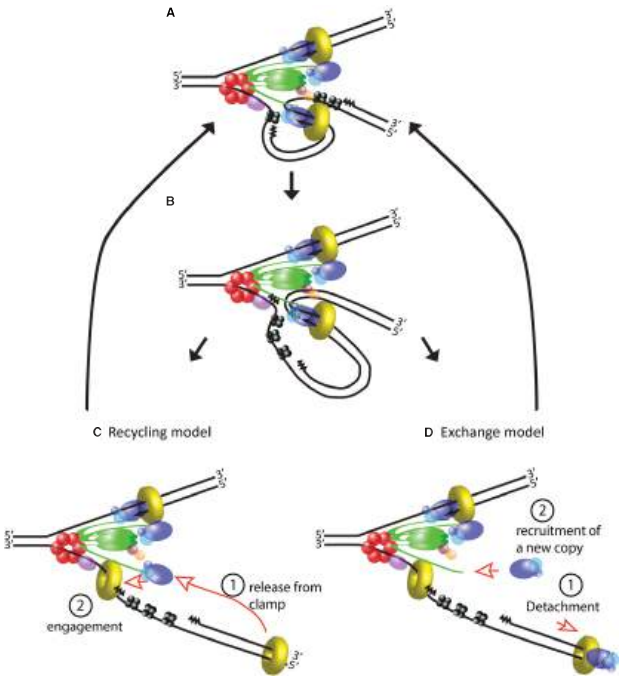

Figure 24.1.11: **Usage of DNA polymerase during lagging strand synthesis. (A)**S chematic of the *E. coli* replisome during the elongation step of an Okazaki fragment. **(B)**Lagging strand polymerase meets the RNA primer of the previous Okazaki fragment and stops synthesis. **(C)** Current model of events following completion of an Okazaki fragment. DNA polymerase is released from the β clamp (step 1) and the same molecule rebinds to a new β clamp to start the next Okazaki fragment (step 2). **(D)**An alternative model based on evidence from T4 and T7 replisomes. After completing the Okazaki fragment, the DNA polymerase detaches from the rest of the replisome (step 1). A new molecule of DNA polymerase is recruited to the replisome (step 2) and engages in the synthesis of a new Okazaki fragment. In this tentative model, a local pool of "spare" polymerases may facilitate their exchange and additional components may exchange along with the polymerase (not depicted)

24.1.3: E. Coli DNA Polymerases

E. Coli has 5 DNA polymerases. **DNA polymerase I** aids in lagging strand synthesis as it removes the RNA primers and incorporates DNA in its place. **DNA polymerase II,** may play an editing role following lagging strand synthesis by DNA polymerase I. DNA polymerases I and II also play a role in DNA repair, as do **DNA polymerases IV and V**.

DNA polymerases are shaped like a right hand in overall shape with three domains named palm, fingers, and thumb. The bottom of the cleft formed by the three domains forms the polymerase active site in the Palm domain, The monomeric nucleotides to be added bind through the finger domain, while the thumb domains facilitates the dissociation of the newly synthesized DNA. These features are illustrated for a polymerase that requires host thioredoxin for a bacteriophage T7 DNA polymerase in Figure 24.1.12

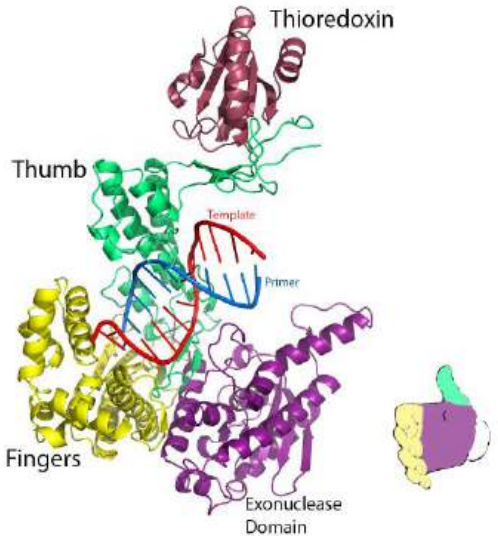

Figure 24.1.12 Structure of T7 DNA replication complex. Melum 103 - Own work, CC BY-SA 4.0, https://commons.wikimedia.org/w/inde...curid=38408627

24.1.3.1: DNA Polymerase III

Pol III is a fascinating enzyme. It consists of an αεθ core with both 5'-3' polymerase and 3′−5′ proofreading activities, a β_2 ring-shaped "sliding clamp" that keeps the enzyme on the DNA track (processive) without iteratively jumping off and rebinding (distributive), and a $(\tau/\gamma)_3\delta\delta'\psi\chi$ clamp loader. The SSB protein has a conserved amphiphilic C-terminus that binds both DnaG (primase) and the χ subunit of the clamp loader. A

After primer addition by DnaG, the $\beta_2$clamp of polIII is brought to the end of the primer terminus by the clamp loader, after which α and ε subunits bind the clamp. The holoenzyme can add ∼1000 Nt/s and over 150 kb without falling off. Hence it is a very processive enzyme.

Figure 24.1.13 shows an interactive iCn3D model of the the E. coli replicative DNA polymerase III (alpha, $beta_2$, epsilon, tau complex) bound to DNA (5FKV)

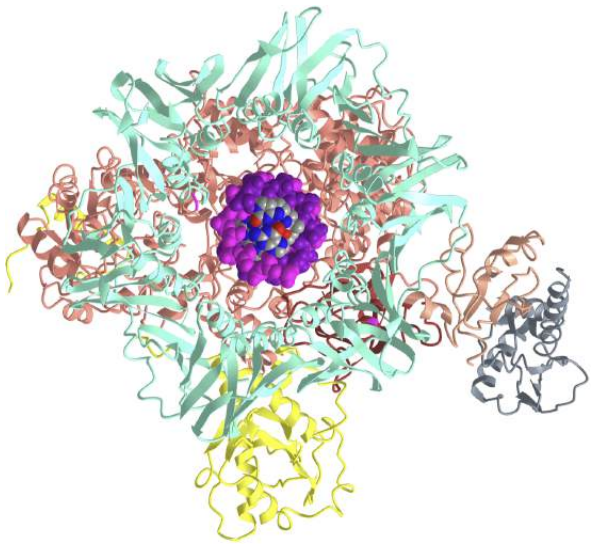

Figure 24.1.13: E. coli replicative DNA polymerase III (alpha, $beta_2$, epsilon, tau complex) bound to DNA (5FKV). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...vf4pCugQms7tw8

- β_2 in aquamarine
- τ_C in slate gray
- DNA in spacefill, backbone magenta and purple, bases in CPK colors

Overall, there are significant conformational changes in the DNA Polymerase III complex upon binding to the DNA that cause the tail of the polymerase to move from interacting with the clamp in the DNA-bound state to a position 35 Å away from the clamp in the DNA-free state. It has been hypothesized that this large conformational change may help the polymerase act as a switch to facilitate the lagging strand synthesis. On the lagging strand, the polymerase repositions to a newly primed site every ∼1000 bp. To do so, the polymerase needs to release both clamp and DNA. The switch-like movement of the polymerase tail may play a part in the release and consequent repositioning of the polymerase at the end of the Okazaki fragment.

Video 25.1.1: **DNA Binding Induces Large Conformational Changes in the DNA Polymerase III Complex**(click link to view). The video shows the linear morphing of the DNA-free to the DNA-bound state showing the large conformation change between the two states. The green subunit is the β-clamp, The α-subunit is shown in orange with the active-site residues in magenta, the α-C-terminal domain (α-CTD shown in brown, the ε-subunit in yellow, and the τ-tail shown in blue. Video from: Fernandez-Liero, R., et al. (2015) eLife 4:e11134

The complex can also proofread the newly synthesized DNA. This requires some conformational changes in the polIII complex, including a rotation/tilt of the dsDNA against the β_2 ring-shaped "sliding clamp". The thumb domain moves between the two DNA strands containing a mismatch and produced a distorted DNA. The epsilon subunit, a nuclease, can reach the mismatched nucleotide and clip it off.

Figure 24.1.14shows an interactive iCn3D model of the E. coli replicative DNA polymerase III-clamp-exonuclease-theta complex bound to DNA in the editing mode (5M1S)

24.1.3.2: DNA Polymerase I

DNA polymerase I, as does polIII, has a 5' to 3' polymerase activity. Also, both have a 3' to 5' exonuclease activity for proofreading as well as a 5'-3' exonuclease to remove RNA primers. It contains three domains, a 5'-3' exonuclease followed by a 3'-5' exonuclease, then the polymerase domain. Selective proteolysis between the first two domains produces the **Klenow fragment.** In contrast, the 5'-3' exonuclease of polIII is in the separate epsilon subunit.

Figure 24.1.15shows an interactive iCn3D model of the predicted AlphaFold structure of E. Coli DNA Polymerase I (P00582)

- 5' to 3' exonuclease, 1-323, magenta
- 3' to 5' exonuclease, 324-517, orange
- 5' to 3' polymerase, 521-928, cyan
- Val700-Arg713, Motif A, yellow
- Klenow fragment: 324-928

Key aspartate and glutamates involved in the polymerase active site are shown in sicks and labeled. Motif A is conserved in prokaryotic DNA polymerases. Essential roles of motif A in catalysis include interaction with the incoming dNTP and coordination with two divalent metal ions that are required for the polymerization reaction. Note the distance between the 3' to 5' exonuclease and the 5'-3' polymerase.

24.1.4: Other enzyme activities

24.1.4.1: DNA Ligase

DNA Ligase enzymes seal the breaks in the backbone of DNA that are caused during DNA replication, DNA damage, or during the DNA repair process. The biochemical activity of DNA ligases results in the sealing of breaks between 5′-phosphate and 3′-hydroxyl termini within a strand of DNA. DNA ligases have been differentiated as being ATP-dependent or NAD^+-dependent depending on the co-factor (or co-substrate) that is used during their reaction. Typically, more than one type of DNA ligase is found within an organism.

Figure 24.1.16shows the structure of *E. coli* LigA in complex with nicked adenylated DNA from PDB 2OWO, visualized by UCSF Chimera. The various domains are indicated by different colors and relate to Pfam domains indicated.

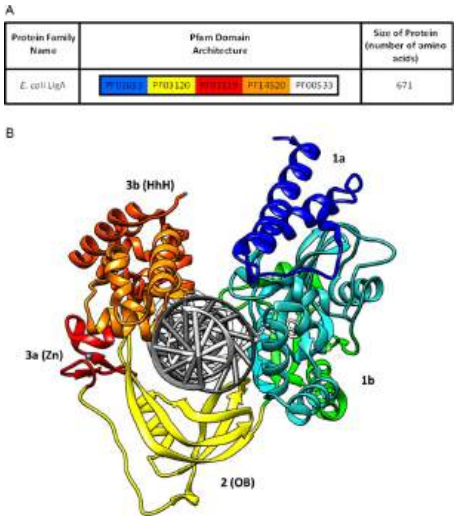

Figure 24.1.16 Structure of DNA ligase. Pergolizzi, G., Wagner, G.K, and Bowater, R.P. (2016) Biosci Rep 36(5) e00391

DNA ligase enzyme is covalently modified by the addition of the AMP moiety to a Lysine residue on the enzyme. The AMP derives from the ATP or NADH cofactor. The downstream 5'-phosphate at the site of the DNA nick is able to mediate a nucleophilic attack on the AMP-enzyme complex, causing the AMP to transfer to the 5'-phosphate position of the DNA. The AMP serves as a good leaving group for the nucleophilic attack of the upstream 3'-OH with the 5'-phosphate to seal the DNA backbone, and release the AMP. DNA ligase can use either adenosine triphosphate (ATP) or nicotinamide adenine dinucleotide (NAD^+) as a cofactor. Figure 24.1.17shows a mechanism of the ligation reaction, which is powered by ATP hydrolysis.

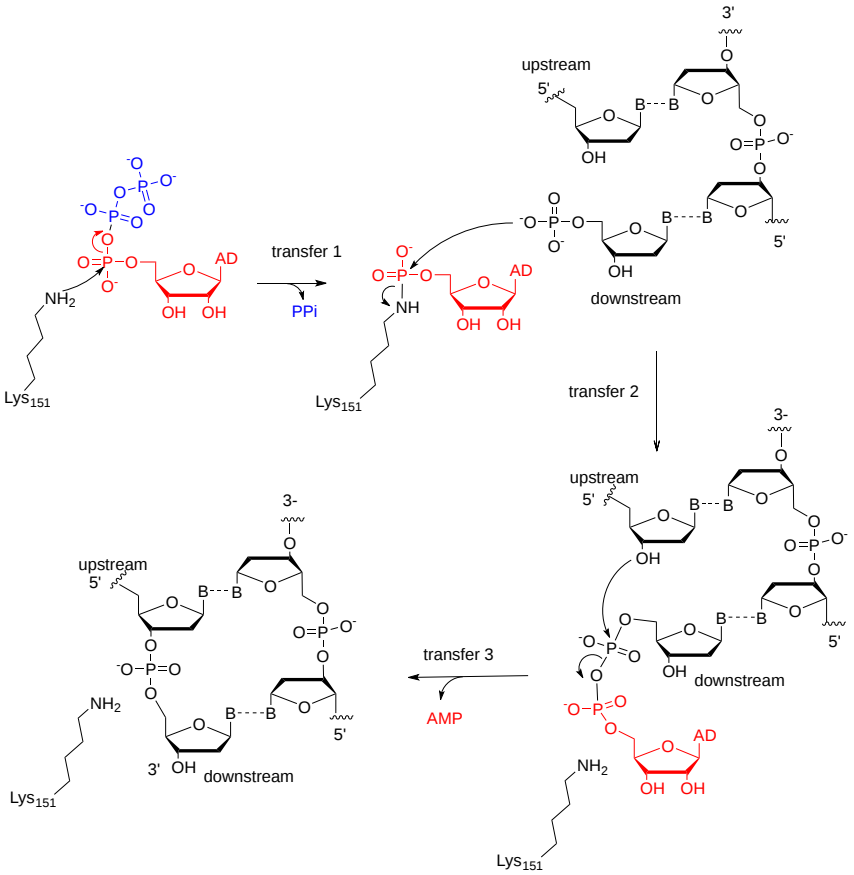

Figure 24.1.17: DNA Ligase Reaction. After Showalter, A. (2002). .

Figure 24.1.18shows an interactive iCn3D model of Human DNA Ligase I bound to 5'-adenylated, nicked DNA (1X9N)

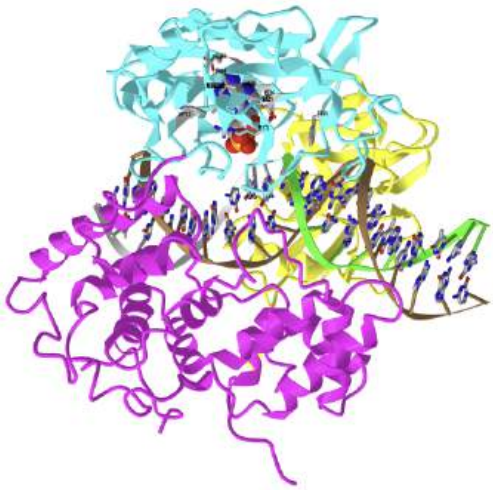

Figure 24.1.18: Human DNA Ligase I bound to 5'-adenylated, nicked DNA (1X9N). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...VNgobsRuLTsXZA

The protein has three domains:

- DNA binding domain (DBD), shown in magenta. In contrast to most DNA binding proteins, Ligase I binds to the *minor* grove around the area of DNA damage.
- Adenylation domain (AdD), shown in cyan, has covalently attached cofactor AMP and key catalytic residues shown as sticks and labeled. It ligates the broken DNA and forms a phosphodiester bond.
- The OB-fold domain (OBD), shown in yellow, facilitates catalysis as it binds and unwinds over the short region.

The DNA strands are as follows:

- ss DNA terminated with dideoxy is shown in green
- ss template DNA is shown in brown
- ss 5'-phosphorylated DNA is shown in gray

The AdD and OBD domains are similar in structure to other covalent nucleotidyltransferases involved in DNA and RNA ligation and capping of messenger RNA. Glu 566, Glu 621, and Arg 573 interact with AMP and probably help determine the specificity of the AMP cofactor (over GTP). Divalent cations are required for catalysis but are not present in the above structure. A E566K mutation leads to severe immunodeficiency. Lys 568 forms the covalent AMP adduct. The dideoxynucleoside in the structure is not optimally positioned for reaction with 5'P of AppDNA. Glu 720 and Glu 621 are highly conserved and presumably involved in metal ion binding.

Zoom into the structure to observe the changes at the 3' end of the dideoxy DNA and 5' end of the phosphorylated DNA. These nucleotides are given the abbreviation X in iCn3D as they are modified.

24.1.4.2: Topoisomerases

We just studied these in a previous section but here is a review for this section. The unwinding of the double-stranded helix at the replication fork generates winding tension in the DNA in the form of positive supercoils upstream of the replication fork. Enzymes called **topoisomerases** counteract this by introducing negative supercoils into the DNA in order to relieve this stress in the helical molecule during replication. There are four known topoisomerase enzymes found in *E. coli* that fall into two major classes, Type I Topoisomerases and Type II Topoisomerases, as shown in Figure 24.1.19 Topoisomerase I and III are Type I topoisomerases, whereas DNA gyrase and Topoisomerase IV are Type II topoisomerases.

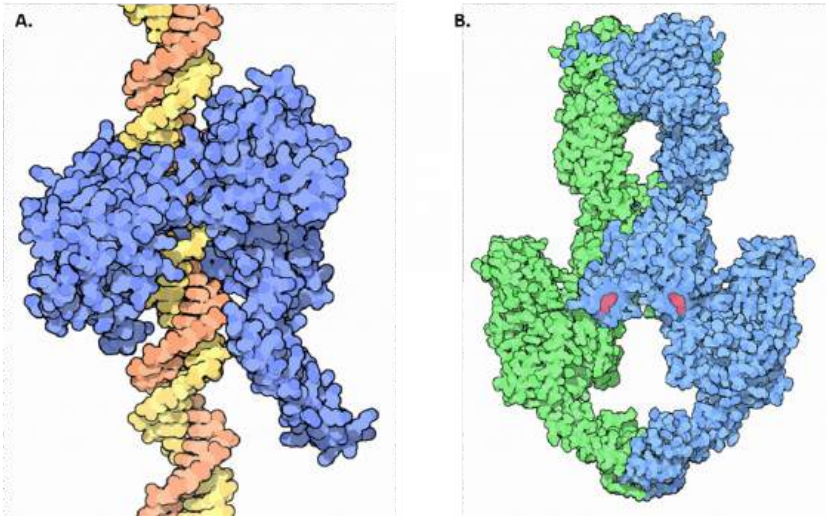

Figure 24.1.19: Structures of Type I and Type II Topoisomerase. (A) Crystal structure of a Type I Topoisomerase, shown in blue, bound to DNA, shown in orange and yellow. (B) Crystal structure of a Type II Topoisomerase. Topoisomerase II forms a tetrameric structure, shown in green and blue. ATP cofactors (pink) are shown bound to the enzyme.

Goodsell, D.S. (2015) RCSD PDB-101 Molecule of the Month

Type I Topoisimerase

Type I Topoisomerases relieve tension caused during the winding and unwinding of DNA. One way that they can do this is by making a cut or nick in one strand of the DNA double helix as shown in Figure 24.1.19 The 5'-phosphoryl side of the nicked DNA strand remains covalently bound to the enzyme at a tyrosine residue, while the 3'-end is held noncovalently by the enzyme. The Type I topoisomerases rotate or spin the 3'-end of the DNA around the intact DNA strand. This releases the overwinding in the DNA and effectively releases tension. The enzyme completes the reaction by resealing the phosphodiester backbone or ***ligating*** the broken strand back together. Overall, only one strand of the DNA is broken during the reaction mechanism and there is ***NO*** requirement of ATP during the reaction. The *E. coli* Topo I enzyme can only remove negative DNA supercoils, but not positive ones. Thus, this enzyme is not involved in relieving the positive supercoiling caused by the DNA helicase during replication. This is in contrast to eukaryotic Topo I that can relieve both positive and negative supercoiling. Although *E. coli* Topoisomerase I is not directly involved in relieving the tension caused by DNA replication, it is essential for *E. coli* viability. It is thought to help balance the actions of the Type II topoisomerases and help maintain optimal supercoiling density within the chromosomal DNA. Thus, Topo I is thought to help maintain the homeostatic balance of chromosome supercoiling within *E. coli.* Topo III, which is also a Type I Topoisomerase, appears to play a role in the decatenation of the daughter chromosomes during DNA replication, but does not play a role in the relaxation of supercoiling.

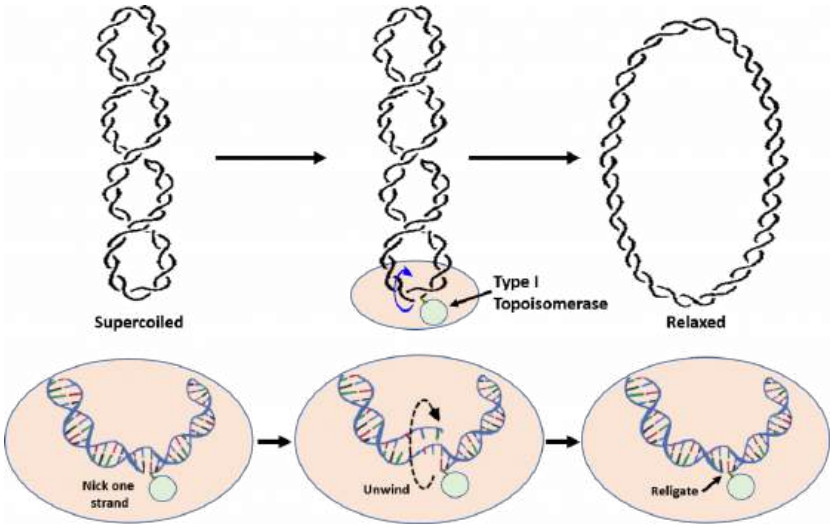

Figure 24.1.19: Reaction of Type I Topoisomerases. During the reaction, Type I Topoisomerases nick one strand of the DNA. One end of the nicked DNA is covalently attached to the enzyme, shown in light green in the lower diagrams. The other end is held non-covalently and rotated around the double helix to unwind the supercoiling and relax the DNA. Once supercoiling tension is released, the backbone is resealed and the Topoisomerase I enzyme is released. emixed from: Notahelix and JoKalliauer, and the National Human Genome Research Institute

Type II Topoisomerases have multiple functions within the cell. They can increase or decrease winding tension within the DNA or they can unknot or decatanate DNA that has become tangled with another strand as shown in Figure 24.1.20 It does so by a more dangerous method than their Type I counterparts, by breaking both strands of the DNA during their reaction mechanism. The enzyme is covalently attached to both broken sides while the other DNA helix is passed through the break. The double-stranded break is then resealed.

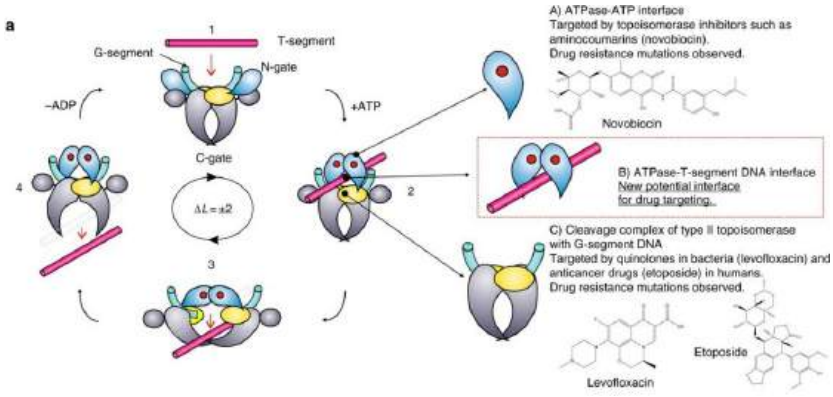

Figure 24.1.20: Reaction of Type II Topoisomerases. Figure modified fromLaponogov, I., et al. (2018) *Nature Communications* 9:2579. .

The proposed type II topoisomerase reaction cycle is exemplified by topoisomerase IV. Topoisomerase IV subunits are denoted in grey, cyan, and yellow. The gate or G-DNA is in green and the transported or T-DNA is in mauve. ATP bound to the ATPase domains is denoted by a red dot. In step 1, the G-DNA binds with the enzyme. ATP and the T-DNA segment associated with the enzyme in step 2. In step 3, the G-DNA is cleaved and the T-DNA is passed through the break. Drug-targetable domains within the type II topoisomerase complex are highlighted in subsections A, B, and C with examples on the right-hand side of the figure.

Type II Topoisomerase - D

DNA gyrase is the type II topoisomerase enzyme that is primarily involved in relieving positive supercoiling tension that results due to the helicase unwinding at the replication fork. Type II Topoisomerases, especially Topo IV, also address a key mechanistic challenge that faces the bacterial replisome during the termination of DNA replication. The circular nature of the bacterial chromosome dictates that a pair of replisomes that initiate from a single origin of replication will eventually converge on each other in a head-to-head orientation. Positive supercoiling accumulates between the the two replisomes as they converge, but the activity of DNA gyrase, which normally removes positive supercoils, becomes limited by the decreasing amount of template DNA available. Instead, supercoils may diffuse behind the replisomes, forming precatenanes between newly replicated DNA; in *E.coli* these must be resolved by Topo IV for chromosome segregation to occur.

24.1.5: Termination of Replication

If starting replication is critically important and obviously highly controlled as illustrated above, then termination of replication must be equally critical, otherwise genome instability would arise. There is one discrete origin of replication in E. Coli, oriC, with a defined sequence. In contrast, there are 10, 23 base-pair, nonpalindromic **termination sites (Ter)**of slightly different sequences. These bind the **termination protein, Tus**. The affinity of Tus for the Ter site depends on the Ter sequence and, in general,is tight with a K_D in the picomolar range. There are two types of Ter-Tus complexes, one an **open**"**permissive**" conformation that allows replication to continue, and a **locked**, "nonpermissive" form that stops it. In the nonpermissive conformation, a key and conserved cytosine on the leading strand at a conserved GC base pair is flipped out into a cytosine binding pocket, which you can think of as a "stop sign" for replication.

If you think of the E. Coli circular chromosome as a clock with the oriC at 12 o'clock, there are 5 Ter sequences as the replication fork move counter-clockwise at about 7 o'clock and another 5 as the fork move clockwise at around 5 o'clock. The sequences run in opposite polarity to prevent the left-side replication fork from entering the right-hand side as it moves around the chromosome and vice versa. The replisome displaces the Tus proteins at the permissive Ter sites but stops at the nonpermissive site, where DnaB helicase unwinds the DNA, flipping out the cytosine as the locked conformation forms. These processes are illustrated in Figure 24.1.21

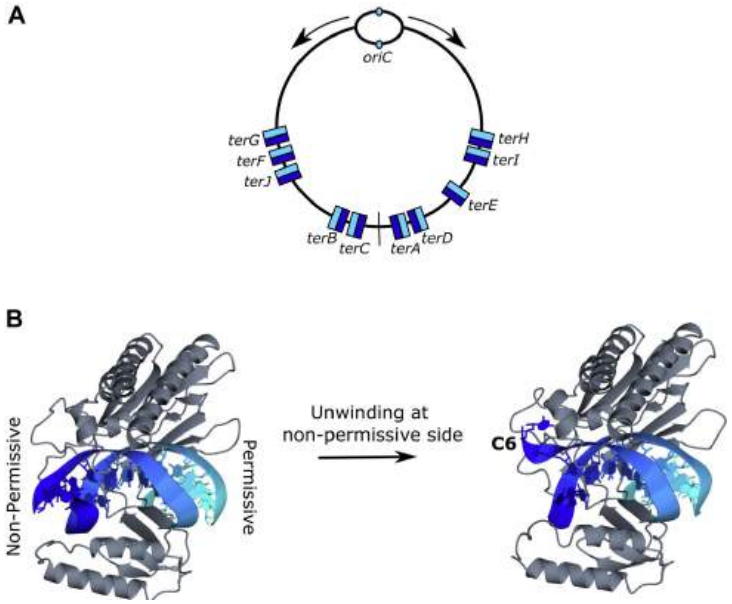

Figure 24.1.21: DNA replication and Tus-*ter* termination trap in *E. coli*. Katie H. Jameson et al., JBC, 297, (2021). DOI:https://doi.org/10.1016/j.jbc.2021.101409. Creative Commons Attribution (CC BY 4.0)

Panel A, *E. coli* contains a single circular chromosome, which replicates bidirectionally from a single origin (*small oval*). The direction of replisome travel from the origin is depicted by *arrows*. Chromosomal midpoint indicated by a *straight line*. The location of the *ter* sites on the *E. coli* chromosome is shown relative to *oriC*. Permissive orientation is displayed in *light blue*, nonpermissive orientation is displayed in *dark blue*.

Panel B, the structure of Tus-*ter* (PDB ID: 2I06) illustrating the nonpermissive and permissive faces (*left*) and the “locked” conformation formed by DNA unwinding at the nonpermissive face (*right*). The cytosine base at position 6 of *ter* (C6), which flips into a specific binding site on the nonpermissive face of Tus to form the “lock,” is indicated.

Replication can proceed at the Ter site if the replisome is moving from the light blue to dark blue sequences of the TER site. The TER site hence exhibits polarity.

Video 9.2 Overview of the DNA Replication Process

Video from: Yourgenome, animated by Polymime Animation Company, Ltd

24.1.6: DNA Replication of Extrachromosomal Elements: Plasmids and Viruses

To copy their nucleic acids, plasmids and viruses frequently use variations on the pattern of DNA replication described for prokaryote genomes. We will focus here on one style known as the ***rolling circle method.***

Whereas many bacterial ***plasmids*** replicate by a process similar to that used to copy the bacterial chromosome, other plasmids, several ***bacteriophages***, and some ***viruses*** of eukaryotes use ***rolling circle*** replication as shown in Figure 24.1.24

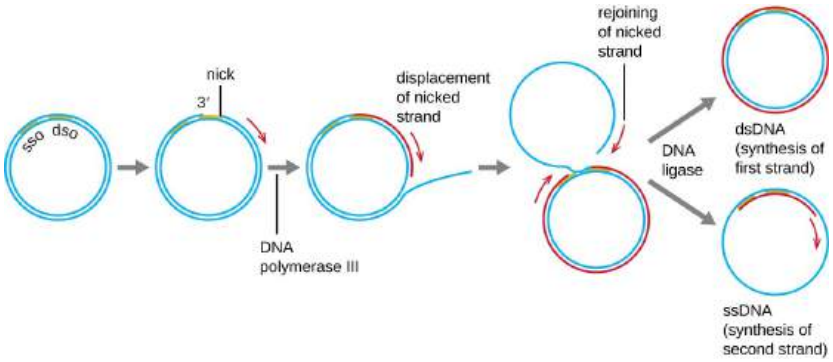

Figure 24.1.24 **Rolling Circle Replication.** The process of rolling circle replication is initiated by a single stranded nick in the DNA. Within prokaryotes, DNA polymerase III is utilized to generate the daughter strand. DNA ligase rejoins nicks in the backbone and enables the initiation of DNA synthesis of the second daughter strand. Figure by Parker, N., et.al. (2019) *Openstax*.

The circular nature of plasmids and the circularization of some viral genomes on infection make this possible. Rolling circle replication begins with the enzymatic nicking of one strand of the double-stranded circular molecule at the ***double-stranded origin (dso) site***. In bacteria, DNA polymerase III binds to the 3′-OH group of the nicked strand and begins to unidirectionally replicate the DNA using the un-nicked strand as a template, displacing the nicked strand as it does so. Completion of DNA replication at the site of the original nick results in the full displacement of the nicked strand, which may then recircularize into a single-stranded DNA molecule. RNA primase then synthesizes a primer to initiate DNA replication at the ***single-stranded origin (sso) site*** of the single-stranded DNA (ssDNA) molecule, resulting in a double-stranded DNA (dsDNA) molecule identical to the other circular DNA molecule.

24.1.7: DNA Replication in Eukaryotes

24.1.7.1: The Cell Cycle

The ***cell cycle*** is an ordered series of events involving cell growth and cell division that produces two new daughter cells. Cells on the path to cell division proceed through a series of precisely timed and carefully regulated stages of growth, DNA replication, and division that produce two genetically identical cells. The cell cycle has two major phases, ***interphase,*** and the ***mitotic phase***, as shown

in Figure 24.1.25 During interphase, the cell grows and DNA is replicated. During the mitotic phase, the replicated DNA and cytoplasmic contents are separated and the cell divides. Watch this video about the cell cycle: http://openstax.org/l/biocellcyc

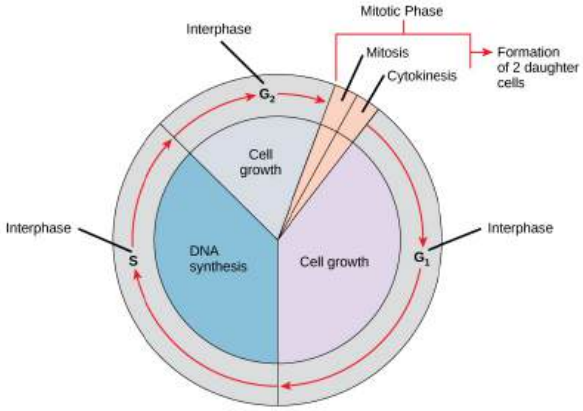

Figure 24.1.25 **Diagram of the Cell Cycle.** Fowler, S., et.al. (2013) *Openstax*

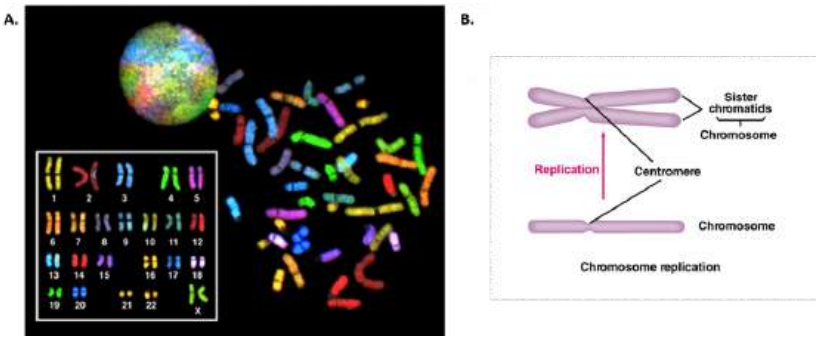
A cell moves through a series of phases in an orderly manner. During interphase, G_1 involves cell growth and protein synthesis, the S phase involves DNA replication and the replication of the centrosome, and G_2 involves further growth and protein synthesis. The mitotic phase follows interphase. Mitosis is nuclear division during which duplicated chromosomes are segregated and distributed into daughter nuclei. Usually, the cell will divide after mitosis in a process called cytokinesis in which the cytoplasm is divided and two daughter cells are formed.

During interphase, the cell undergoes normal processes while also preparing for cell division. For a cell to move from interphase to the mitotic phase, many internal and external conditions must be met. The three stages of interphase are called G_1, S, and G_2. The first stage of interphase is called the G_1 phase, or first gap, because little change is visible. However, during the G_1 stage, the cell is quite active at the biochemical level. The cell is accumulating the building blocks of chromosomal DNA and the associated proteins, as well as accumulating enough energy reserves to complete the task of replicating each chromosome in the nucleus. Throughout interphase, nuclear DNA remains in a semi-condensed chromatin configuration. In the S phase (synthesis phase), DNA replication results in the formation of two identical copies of each chromosome—***sister chromatids***—that are firmly attached at the centromere region,as shown in Figure 24.1.26 At this stage, each chromosome is made of ***two sister chromatids*** and is a duplicated chromosome. The centrosome is duplicated during the S phase. The two centrosomes will give rise to ***the mitotic spindle,*** the apparatus that orchestrates the movement of chromosomes during mitosis. In mammals, the centrosome consists of a pair of rod-like ***centrioles*** at right angles to each other. Centrioles help organize cell division. Centrioles are not present in the centrosomes of many eukaryotic species, such as plants and most fungi.



24.1.7.0.1:

Figure 24.1.26 **Human Chromosome Structure.** Figure A from: The National Human Genome Research Institute, and Figure B from: The School of Biomedical Sciences Wiki

(A) Shows a spectral karyogram of a normal human female. Humans have a total of 23 pairs of chromosomes for a total of 46. Each pair of chromosomes are referred to as ***homologous chromosomes*** as they contain copies of the same gene regions. Each of the homologous pairs of chromosomes is stained the same color. Chromosomes are shown in their condensed, unreplicated state. (B) Shows a schematic diagram of a single chromosome before (lower diagram) and after (upper diagram) replication. Upon replication, the identical copies of the chromosome are called ***sister chromatids*** and are linked together at the ***centromere*** structure.

Figure A from: The National Human Genome Research Institute, and Figure B from: The School of Biomedical Sciences Wiki

In the G_2 phase, or second gap, the cell replenishes its energy stores and synthesizes the proteins necessary for chromosome manipulation. Some cell organelles are duplicated, and the cytoskeleton is dismantled to provide resources for the mitotic spindle. There may be additional cell growth during G_2. The final preparations for the mitotic phase must be completed before the cell is able to enter the first stage of mitosis. To make two daughter cells, the contents of the nucleus and the cytoplasm must be divided. The mitotic phase is a multistep process during which the duplicated chromosomes are aligned, separated, and moved to opposite poles of the cell, and then the cell is divided into two new identical daughter cells. The first portion of the mitotic phase, ***mitosis,*** is composed of five stages, which accomplish nuclear division. The second portion of the mitotic phase, called ***cytokinesis***, is the physical separation of the cytoplasmic components into two daughter cells.

If cells are not traversing through one of the phases of interphase or mitosis, they are said to be in G_0 or a resting state. If cells enter G_0 permanently, they are said to have entered a stage of ***replicative senescence*** and will no longer be maintained for long-term viability within the organism.

The progression of cells through the cell cycle requires the coordinated actions of specific protein kinases, known as ***cyclin-dependent kinases***. Cyclin-dependent kinases are usually abbreviated as CDK or CDC proteins. CDK/CDC proteins require the binding of a regulatory cyclin protein to become activated, as shown in Figure 24.1.27. The major cyclin proteins that drive the cell cycle in the forward direction, are expressed only at discrete times during the cell cycle. When activated by a cyclin counterpart, CDK/CDC enzymes phosphorylate downstream targets involved with cell cycle progression. For example, the primary cyclin-CDK complex involved in the initiation of DNA replication during S-phase is the CyclinE-CDK2 complex. CDK2 is activated by the expression and binding of Cyclin E during late G1 phase. This causes CDK2 to phosphorylate downstream targets, including the retinoblastoma tumor suppressor protein, pRb. pRB normally binds and inhibits the activity of transcription factors from the E2F family. Following the release of E2F transcription factors from pRb, E2Fs activate the transcription of genes involved in DNA replication and the progression of cells into S-phase.

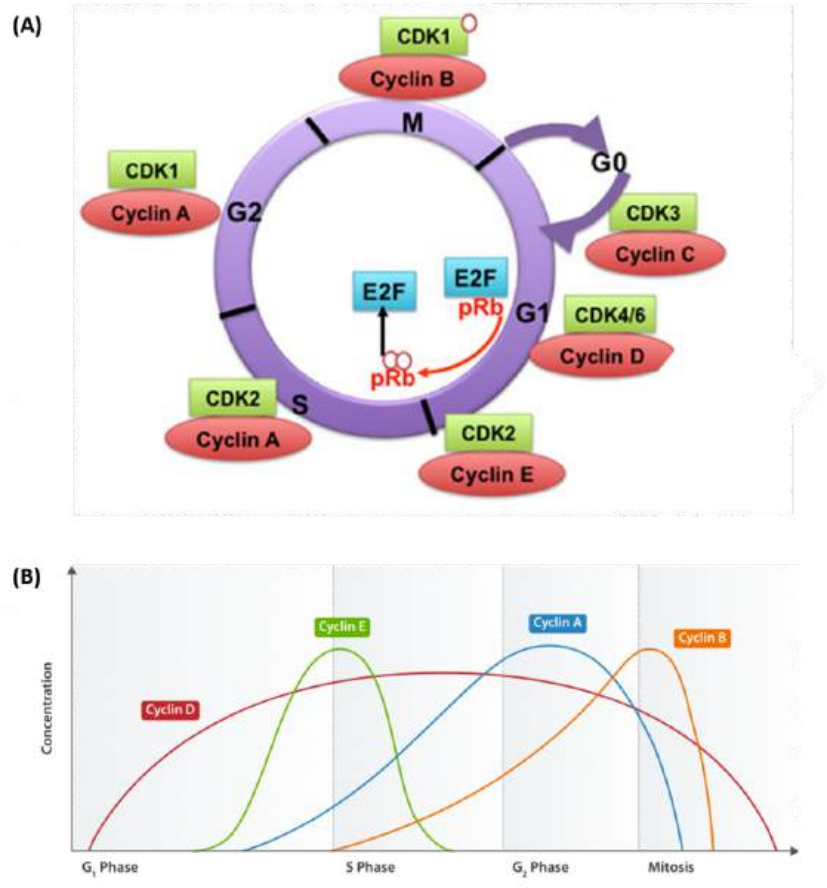


Figure 24.1.26: Cyclin Dependent Kinases (CDKs) and their Cyclin Regulatory Subunits. Figure A from: Aleem, E., and Arceci, R.J. (2015) *Front. Cell and Dev* 3 (16) and Figure B from: Cyclinexpression_waehrend-Zellzyklus

Panel (A) shows CDK-cyclin complexes with direct functions in regulating the cell cycle are shown. CDK3/cyclin C drives cell cycle entry from G_0. CDK4/6/cyclin D complexes initiate phosphorylation of the retinoblastoma protein (pRb) and promote the activation of CDK2/cyclin E complex. In late G1, CDK2/cyclin E complex completes phosphorylation and inactivation of pRb, which releases the E2F transcription factors and G1/S transition takes place. DNA replication takes place in S phase. CDK2/cyclin A complex regulates progression through S phase and CDK1/cyclin A complex through G2 phase in preparation for mitosis (M). Mitosis is initiated by CDK1/cyclin B complex.

Panel (B) Shows the cyclical nature of cyclin expression during cell cycle progression. Cyclin abundance is regulated by transcriptional expression and rapid protein degradation. Thus, their biological activity is targeted at very specific time points during the cell cycle progression.

24.1.7.1: Replication Initiation

Origin organization, specification, and activation in eukaryotes are more complex than in bacterial or archaeal kingdoms and significantly deviate from the paradigm established for prokaryotic replication initiation. The large genome sizes of eukaryotic cells, which range from 12 Mbp in *S. cerevisiae t*o 3 Gbp in humans, necessitates that DNA replication starts at several hundred (in budding yeast) to tens of thousands (in humans) origins to complete DNA replication of all chromosomes during each cell cycle, as shown in Figure 24.1.27.

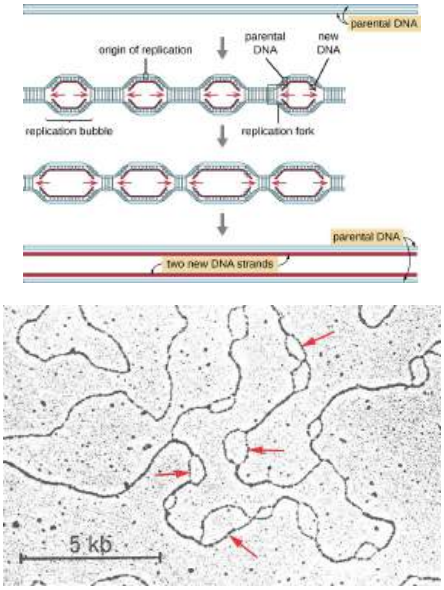

Figure 24.1.27: **Eukaryotic chromosomes are typically linear, and each contains multiple origins of replication**. The top figure is a graphic representation of the eukaryotic origins of replication, while the bottom image is a Cryo-electron micrograph image. The figure on the top is from *Parker, N. et al.* and the figure on the bottom is from *Fritensky, B. and Brien, N*

With the exception of *S.cerevisiae* and related *Saccharomycotina* species, eukaryotic origins do not contain consensus DNA sequence elements but their location is influenced by contextual cues such as local DNA topology, DNA structural features, and chromatin environment. Nonetheless, eukaryotic origin function still relies on a conserved initiator protein complex to load replicative helicases onto DNA during the late M and G1 phases of the cell cycle, a step known as ***origin licensing***. In contrast to their bacterial counterparts, replicative helicases in eukaryotes are loaded onto origin duplex DNA in an inactive, double-hexameric form and only a subset of them (10–20% in mammalian cells) is activated during any given S phase, events that are referred to as ***origin firing***. The location of active eukaryotic origins is therefore determined on at least two different levels, origin licensing to mark all potential origins, and origin firing to select a subset that permits assembly of the replication machinery and initiation of DNA synthesis. The extra licensed origins serve as backup and are activated only upon slowing or stalling of nearby replication forks, ensuring that DNA replication can be completed when cells encounter replication stress. Together, the excess of licensed origins and the tight cell cycle control of origin licensing and firing embody two important strategies to prevent under- and overreplication and to maintain the integrity of eukaryotic genomes.

24.1.7.2: Human Primosome

In humans,, the primosome contains primase and DNA polymerase α (Polα), and makes RNA-DNA primers to which deoxynucleotides are added by polymerases δ and ϵ. Hence there are two catalytic sites for addition or ribo- and deoxyribonucleotides. The structure of the human primosome and the C-terminal domain of the primase large subunit ($p58_C$) with bound DNA/RNA duplex is presented below. $p58_C$ coordinates the catalytic activities.

As with other polymerases, primase synthesis of RNA primers has the following steps:

- initiation (rate limiting): primase binds to DNA and makes a dinucleotide RNA;
- elongation, which is not as fast as DNA replication since it is less processive, adding only around 10 nucleotides. These short fragments are moved to Polα where deoxynucleotides are added with inactivation of the primase
- termination.

The structures of the enzymes are as follows:

Human Polα consists of a :

- large catalytic subunit (p180) with a C-terminal $p180_C$ domain with two Zn^{2+} binding modules.
- smaller accessory subunit (p70) with an N-terminal ($p70_N$), a phosphodiesterase, and oligonucleotide/oligosaccharide-binding (OB) domains.

Human primase consist of

- catalytic (p49)
- regulatory (p58) subunits with two domains, the N-terminal ($p58_N$), which interacts with p49 and which connects primase and Polα, and a C-terminal ($p58_C$) which contains an iron-sulfur cluster involved in substrate binding and primase activity.

The structures are shown in Figure 24.1.28

Figure 24.1.28 Structure of the human primosome hetero-tetramer complex. Baranovskiy et al. JBC, 291, 10006-10020 (2016). DOI: https://doi.org/10.1074/jbc.M116.717405. Creative Commons Attribution (CC BY 4.0)

Panel A shows a schematic representation of the domain organization. The flexibly tethered domains are shown as separate parts. $p58_C$ coordinates the iron-sulfur cluster. *Exo** is an exonuclease domain with no associated activity due to the evolutionary substitution of the catalytic amino acid residues; *PDE*, phosphodiesterase.

Pane B shows the crystal structure of the primosome. Subunits are shown as schematics and colored as in *A*. The α-carbons of catalytic aspartates are shown as *purple spheres*.

Figure 24.1.29shows an interactive iCn3D model of the Human primosome without nucleic acids (5EXR)

The ss-DNA is shown with a cyan backbone while the RNA primer backbone is shown in magenta. dCTP is shown in spacefill.

24.1.7.3: Eukaryotic DNA polymerases

Similar to DNA replication in prokaryotes, DNA replication in eukaryotes occurs in opposite directions between the two new strands at the replication fork. Within eukaryotes, two replicative polymerases synthesize DNA in opposing orientations, as shown in Figure 24.1.32 ***Polymerase ε (epsilon)*** synthesizes DNA in a continuous fashion, as it is "pointed" in the same direction as DNA unwinding. Similar to bacterial replication, this strand is known as the ***leading strand.*** In contrast, ***polymerase δ (delta)*** synthesizes DNA on the opposite template strand in a fragmented, or discontinuous, manner and this strand is termed the ***lagging strand***. The discontinuous stretches of DNA replication products on the lagging strand are known as Okazaki fragments and are about 100 to 200 bases in length at eukaryotic replication forks. Owing to the "lagging" nature, the lagging strand generally contains a longer stretch of ssDNA that is coated by single-stranded binding proteins, which stabilizes ssDNA templates by preventing secondary structure formation or other transactions at the exposed ssDNA. In eukaryotes, ssDNA stabilization is maintained by the heterotrimeric complex known as ***replication protein A (RPA)*** (Figure 9.19). Each Okazaki fragment is preceded by an RNA primer, which is displaced by the procession of the next Okazaki fragment during synthesis. In eukaryotic cells, a small amount of the DNA segment immediately upstream of the RNA primer is also displaced, creating a flap structure. This flap is then cleaved by endonucleases (such as Fen1, discussed later). At the replication fork, the gap in DNA after removal of the flap is sealed by ***DNA ligase I***. Owing to the relatively short nature of the eukaryotic Okazaki fragment, DNA replication synthesis occurring discontinuously on the lagging strand is less efficient and more time consuming than leading-strand synthesis.

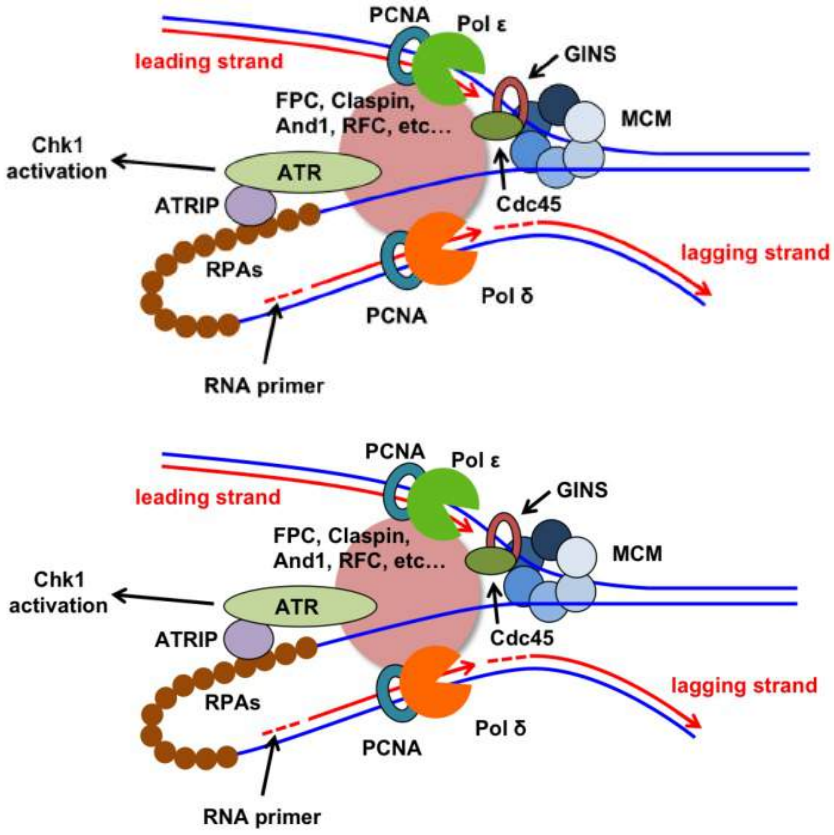

Figure 24.1.32: The Eukaryotic Replisome Complex Coordinates DNA Replication. *Lemanm A.R. and Noguchi, E. (2013) Genes 4(1):1-32*.

Replication on the leading and lagging strands is performed by Pol ε and Pol δ, respectively. Many replisome factors (including the FPC [fork protection complex], Claspin, And1, and RFC [the replication factor C clamp loader]) are charged with regulating polymerase functions and coordinating DNA synthesis with the unwinding of the template strand by Cdc45-MCM [mini-chromosome maintenance]-GINS [go-ichi-ni-san]. The replisome also associates with checkpoint proteins as DNA replication and genome integrity surveillance mechanisms.

Figure 24.1.33shows an interactive iCn3D model of the Core human replisome (7PFO). (long load time)

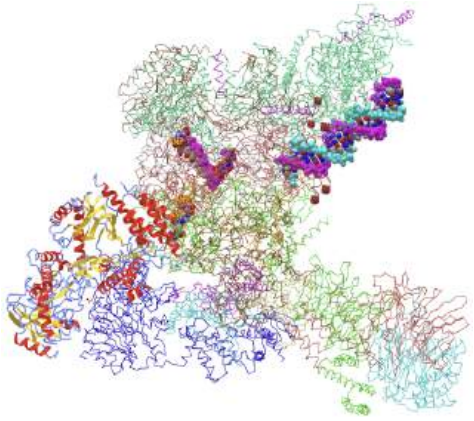

Figure 24.1.33: Core human replisome (7PFO). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...XQQijVnottcwa7 (long load time)

The leading DNA strand backbone is shown in spacefill magenta while the lagging strand backbone is shown in cyan. The DNA bases are shown as CPK spheres. The ATP analog, phosphaminophosphonic acid-adenlate ester, is shown in spacefill with CPK colors and

labeled. The C-alpha traces of the different protein subunits are all shown in different colored alpha-C traces, except the DNA polymerase epsilon catalytic subunit A which is shown in cartoon form and colored by secondary structure. (long load time)

At the eukaryotic replication fork, three distinct replicative polymerase complexes contribute to canonical DNA replication: α, δ, and ε. These three polymerases are essential for the viability of the cell. Because DNA polymerases require a primer on which to begin DNA synthesis, first, polymerase α (Pol α) acts as a replicative primase. Pol α is associated with an RNA primase and this complex accomplishes the priming task by synthesizing a primer that contains a short ~10-nucleotide RNA stretch followed by 10 to 20 DNA bases. Importantly, this priming action occurs at replication initiation at origins to begin leading-strand synthesis and also at the 5' end of each Okazaki fragment on the lagging strand.

However, Pol α is not able to continue DNA replication. From *in vitro* studies, it was observed that DNA replication must be "handed off" to another polymerase to continue synthesis. The polymerase switching requires clamp loaders. Initially, it was thought that Pol δ performed leading-strand replication and that Pol α completed each Okazaki fragment on the lagging strand. Using mutator polymerase variants and mapping nucleotide misincorporation events, Kunkel and colleagues found that Pol ε and Pol δ mutations lead to mismatched nucleotide incorporation only on the leading and lagging strands, respectively. Thus, normal DNA replication requires the coordinated actions of three DNA polymerases: Pol α for priming synthesis, Pol ε for leading-strand replication, and Pol δ for generating Okazaki fragments during lagging-strand synthesis.

In eukaryotes, DNA polymerases are grouped into seven families (A, B, C, D, X, Y, and RT). Crystal structures of the three nuclear replicative DNA polymerases demonstrate that they belong to the B family (Figure 25.1.17). All three replicative DNA polymerases are multi-subunit enzymes as shown in Table 24.1.2below.

Table 25.1.2 Subunits of the Major Eukaryotic Replicative DNA Polymerases

Polymerase	**Species**		**Function**
Polymerase α	***H. sapiens***	***S. cerevisiae***	
Catalytic or A-subunit	POLA1 (p180)	POL1	Catalytic subunit; polymerase activity; inactivated exonuclease
B-subunit	POLA2 (p70)	POL12	Regulatory subunit
Primase small subunit	PRIM1 (p49)	PRI1	Primase
Primase large subunit	PRIM2 (p58)	PRI2	Primase
Polymerase δ	***H. sapiens***	***S. cerevisiae***	
Catalytic or A-subunit	POLD1 (p125)	POL3	Catalytic subunit; has both polymerase and exonuclease activity
B-subunit	POLD2 (p50)	POL31	Accessory subunit
C-subunit	POLD3 (p66 or p68)	POL32	Accessory subunit
D-subunit	POLD4 (p12)	–	Accessory subunit
Polymerase ε	***H. sapiens***	***S. cerevisiae***	
Catalytic or A-subunit	POLE or POLE1	POL2	Catalytic subunit; has both polymerase and exonuclease activity
B-subunit	POLE2	DPB2	Accessory subunit
C-subunit	POLE3 (p17; CHRAC17)	DPB3	Accessory subunit
D-subunit	POLE4 (p12)	DPB4	Accessory subunit

Table 24.1.2 Subunits of the Major Eukaryotic Replicative DNA Polymerases. *Doublié, S. and Zahn, K.E. (2014) Front. Microbiol 5:444*

All B family polymerases are composed of five subdomains, the fingers, thumb, and palm which constitute the core of the enzyme, as well as an exonuclease domain and an N-terminal domain (NTD). The palm, a highly conserved fold composed of four antiparallel β

strands and two helices, harbors two strictly conserved catalytic aspartates, located in motif A, **D**XXLYPS and motif C, DT**D**S , as shown in Figure 24.1.34

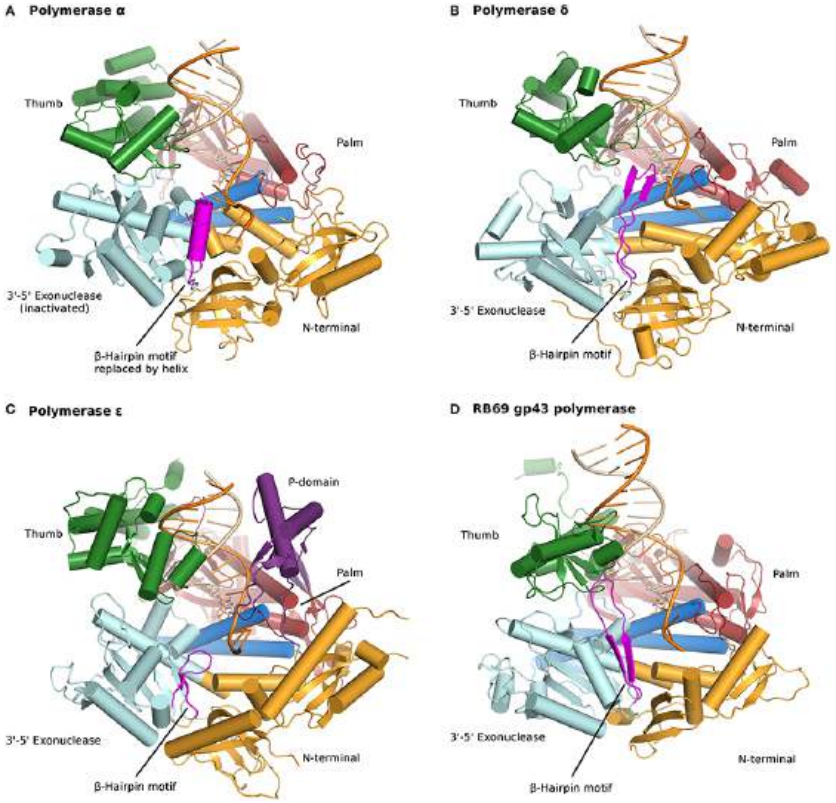

Figure 24.1.34: Structure of polymerases. *Doublié, S. and Zahn, K.E. (2014) Front. Microbiol 5:444*

This fold is shared by a very large group of enzymes, including DNA and RNA polymerases, reverse transcriptases, CRISPR polymerase, and even reverse (3′–5′) transferases. In contrast, the thumb and the fingers subdomains exhibit substantially more structural diversity. The fingers undergo a conformational change upon binding DNA and the correct incoming nucleotide. This movement allows residues in the finger subdomain to come in contact with the nucleotide in the nascent base pair. The thumb holds the DNA duplex during replication and plays a part in processivity. The exonuclease domain carries a 3′–5′ proofreading activity, which removes misincorporated nucleotides. The NTD seems to be devoid of catalytic activity. In pol δ the NTD comprises three motifs, one has a topology resembling an OB fold, one a single-stranded DNA binding motif, and the another has a RNA-binding motif (RNA Recognition Motif or RRM). The NTD likely plays a role in polymerase stability and fidelity through its interactions with other domains.

DNA polymerases require additional factors to support DNA replication *in vivo*. DNA polymerases have a semi-closed hand structure, which allows them to load onto DNA and translocate. This structure permits DNA polymerase to hold the single-stranded template, incorporate dNTPs at the active site, and release the newly formed double strand. However, the conformation of DNA polymerases does not allow for their stable interaction with the template DNA. To strengthen the interaction between template and polymerase, DNA sliding clamps have evolved, promoting the processivity of replicative polymerases. In eukaryotes, this sliding clamp is a homotrimer known as ***proliferating cell nuclear antigen (PCNA),*** which forms a ring structure. The PCNA ring has polarity with a surface that interacts with DNA polymerases and tethers them securely to DNA. PCNA-dependent stabilization of DNA polymerases has a significant effect on DNA replication because it enhances polymerase processivity up to 1,000-fold (Figure 25.1.19).

The ***DNA helicases (MCM proteins)*** and polymerases must also remain in close contact at the replication fork (Figure 25.1.19). If unwinding occurs too far in advance of synthesis, large tracts of ssDNA are exposed. This can activate DNA damage signaling or induce aberrant DNA repair processes. To thwart these problems, the eukaryotic replisome contains specialized proteins that are designed to regulate the helicase activity ahead of the replication fork. These proteins also provide docking sites for physical interaction between helicases and polymerases, thereby ensuring that duplex unwinding is coupled with DNA synthesis.

24.1.7.4: Control of Origin Firing

Origin usage in eukaryotes can be dynamic, with origin firing at different sites depending on cell type and developmental stage. Nevertheless, the mechanism of replisome assembly and origin firing is highly conserved. During late mitosis and G_1 phase, cell cycle proteins, such as Cdc6, associate with *Ori* sites throughout the genome and recruit the helicase enzymes, ***MCMs 2-7*** as shown in Figure 24.1.35 At this time, double hexamers of the MCM2-7 complex are loaded at replication origins. This generates a ***pre-replication complex (pre-RC)***. Origins with an associated pre-RC are considered licensed for replication. Licensed replication origins can then be "fired," when replication actually initiates at the *Ori*. Origin firing is brought about by multiple phosphorylation events carried out by the cyclin E-CDK2 complex at the onset of S phase and by other ***cyclin-dependent kinases (CDKs)*** prior to individual origin firing (Figure 24.1.35). ***Cyclin-dependent kinases (CDKs)*** are the families of protein kinases first discovered for their role in regulating the cell cycle. They are also involved in regulating transcription, mRNA processing, and the differentiation of nerve cells. CDKs are activated through the binding of an associated cyclin regulatory protein. Without a cyclin, CDKs exhibit little kinase activity. Following the phosphorylation of the pre-RC, origin melting occurs and DNA unwinding by the helicase generates ssDNA, exposing a template for replication (Figure 24.1.35). The replisome then begins to form with the localization of replisome factors such as Cdc45. DNA synthesis begins on the melted template, and the replication machinery translocates away from the origin in a bidirectional manner.

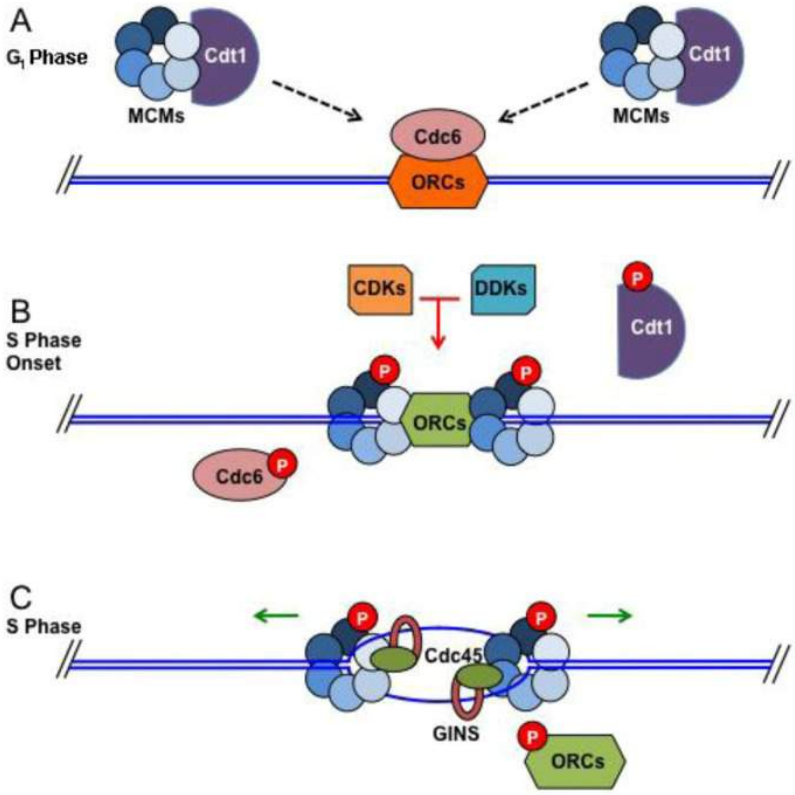

Figure 24.1.35: MCM2-7 loads onto DNA at replication origins during G1 and unwinds DNA ahead of replicative polymerases. Figure from: *Lemanm A.R. and Noguchi, E. (2013) Genes 4(1):1-32*

Pane (**A**) shows the combined activities of Cdc6 and Cdt1 bring MCM complexes (shown as blue circles of varying shades) to replication origins.

Panel (**B**) shows CDK/DDK-dependent phosphorylation of pre-RC components leads to replisome assembly and origin firing. Cdc6 and Cdt1 are no longer required and are removed from the nucleus or degraded

Panel (**C**) shows MCMs and associated proteins (GINS and Cdc45 are shown) unwinding DNA to expose template DNA. At this point, replisome assembly can be completed and replication initiated. "P" indicates phosphorylation.

24.1.7.5: Replication through Nucleosomes

Eukaryotic genomes are substantially more complicated than the smaller and unadorned prokaryotic genomes. Eukaryotic cells have multiple noncontiguous chromosomes, each of which must be compacted to allow packaging within the confined space of a nucleus. As seen in chapter 4, chromosomes are packaged by wrapping ~147 nucleotides (at intervals averaging 200 nucleotides) around an

octamer of histone proteins, forming the ***nucleosome***. The histone octamer includes two copies each of histone H2A, H2B, H3, and H4. In chapter 8, it was highlighted that histone proteins are subject to a variety of post-translational modifications, including phosphorylation, acetylation, methylation, and ubiquitination that represent vital epigenetic marks. The tight association of histone proteins with DNA in nucleosomes suggests that eukaryotic cells possess proteins that are designed to remodel histones ahead of the replication fork, in order to allow smooth progression of the replisome. It is also essential to reassemble histones behind the fork to reestablish the nucleosome conformation. Furthermore, it is important to transmit the epigenetic information found on the parental nucleosomes to the daughter nucleosomes, in order to preserve the same chromatin state. In other words, the same histone modifications should be present on the daughter nucleosomes as on the parental nucleosomes. This must all be done while doubling the amount of chromatin, which requires the incorporation of newly synthesized histone proteins. This process is accomplished by ***histone chaperones*** and ***histone remodelers***, which are discussed below and shown in Figure 24.1.36

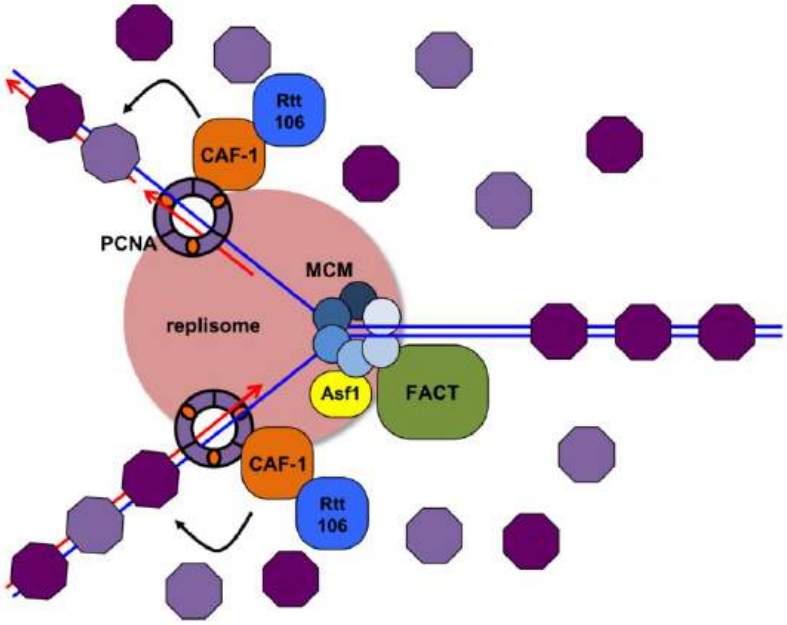

Figure 24.1.36: Nucleosome displacement and deposition during DNA replication. *Lemanm A.R. and Noguchi, E. (2013) Genes 4(1):1-32*

Histones are removed from chromatin ahead of the replication fork. FACT may facilitate this process. Asf1 recruits histone H3-H4 dimers to the replication fork. CAF-1 and Rtt106 load newly synthesized (light purple) histones to establish chromatin behind the fork. Previously loaded histones (dark purple) are also deposited on both daughter DNA strands. The histone chaperones involved in these processes are associated with replisome proteins: CAF-1/Rtt106 with PCNA and FACT/Asf1 with MCMs.

Several histone chaperones are known to be involved in replication-coupled nucleosome assembly, including the ***FACT complex***. The ***FACT complex*** components were originally identified as proteins that greatly stimulate transcription by RNA polymerase II. In budding yeast, FACT was found to interact with DNA Pol α-primase complex, and the FACT subunits were found to interact genetically with replication factors. More recently, studies showed that FACT facilitates DNA replication *in vivo* and is associated with the replisome in budding yeast and human cells. The FACT complex is a heterodimer that does not hydrolyze ATP, but facilitates the “loosening” of histones in nucleosomes

24.1.7.6: Replication Fork Barriers and the Termination of Replication

In prokaryotes, such as the *E. coli*, bidirectional replication initiates at a single replication origin on the circular chromosome and terminates at a site approximately opposed from the origin. This replication terminator region contains DNA sequences known as *Ter* sites, polar replication terminators that are bound by the Tus protein. The *Ter*-Tus complex counteracts helicase activity, resulting in replication termination. In this way, prokaryotic replication forks pause and terminate in a predictable manner during each round of DNA replication.

In eukaryotes, the situation differs. Replication termination typically occurs by the collision of two replication forks anywhere between two active replication origins. The location of the collision can vary based on the replication rate of each of the forks and the timing of origin firing. Often, if a replication fork is stalled or collapsed at a specific site, replication of the site can be rescued when a replisome traveling in the opposite direction completes copying the region. However, there are numerous programmed ***replication***

fork barriers (RFBs) and replication “challenges” throughout the genome. To efficiently terminate or pause replication forks, some fork barriers are bound by RFB proteins in a manner analogous to *E. coli* Tus. In these circumstances, the replisome and the RFB proteins must specifically interact to stop replication fork progression.

24.1.8: Telomeres and Replicative Senescence

24.1.8.1: The End Replication Problem

We have discussed the structure of telomers in the previous section. Let's look now at their activity/function. In humans, ***telomeres*** consist of hundreds to thousands of repetitive sequences of TTAGGG at chromosomal ends for maintaining genomic integrity. Because the DNA replication is asymmetric along double strands, RNA primer sequence at the 3′-hydroxyl end cannot be replaced by DNA polymerase I, as there is no 3'-OH primer group present for the polymerase to extend the DNA chain. This causes the loss of 30–200 nucleotides with each DNA replication and cell division and is known as ***the end replication problem***. ***Telomeres*** provide a repetitive noncoding sequence of DNA at their 3′ en, to prevent the loss of critical genetically encoded information during replication. Moreover, telomeres are coated with a complex of six capping proteins, also known as ***shelterin proteins***, which are packed into a compact ***T-loop structure*** that hides the ends of the chromosomes. This prevents the DNA repair machinery from mistaking chromosomal ends for double-stranded DNA breaks, as shown in Figure 24.1.37. Therefore, telomeres have been proposed as a ***mitotic clock*** that measures how many times a cell has divided and in essence, gives a cell a defined lifetime.

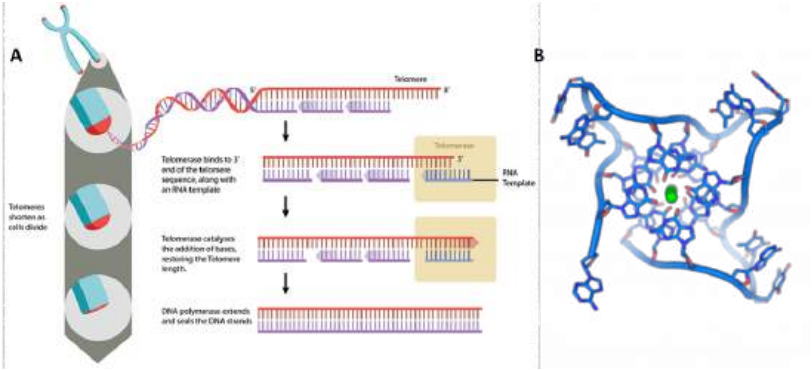

Figure 24.1.37: Telomere Structure. *Image (A) by: MBInfo and Image (B) by:Thomas Splettstoesser*

Pane (A): shows telomeres located at the end of chromosomes, where they help protect against the loss of DNA during replication.

Panel (B) shows DNA quadruplex formed by telomere repeats. The looped conformation of the DNA backbone is very different from the typical DNA helix, this is known as ***T-loop formation***. The green spheres in the center represent potassium ions.

The human ***telomerase enzyme*** is responsible for maintaining and elongating telomeres and consists of an ***RNA component (TERC)*** and a ***reverse transcriptase (TERT)***, that serves as the catalytic component, as shown in Figure 24.1.38 The ***TERT*** uses the ***TERC*** as a template to synthesize new telomeric DNA repeats at a single-stranded overhang to maintain telomere length (Figure 25.1.26). Some cells such as germ cells, stem cells, hematopoietic progenitor cells, activated lymphocytes, and most cancer cells constitutively express telomerase and maintain telomerase activity to overcome telomere shortening and cellular senescence. However, most other somatic cells generally have a low or undetectable level of telomerase activity and concomitantly limited longevity. Interestingly, overall telomerase activity decreases with age, but increases markedly in response to injury, suggesting a role for telomerase in cellular regeneration during wound healing. The telomere length and integrity are regulated through the interplay between the ***telomerase*** and ***shelterin proteins.***

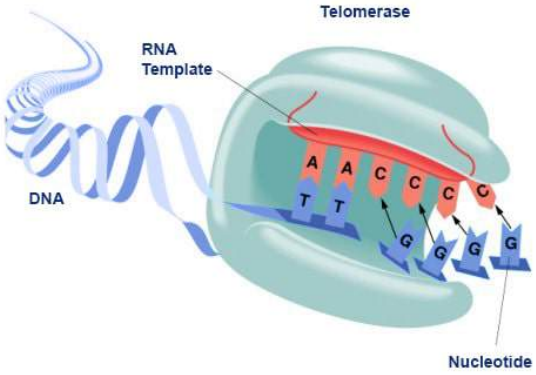

Figure 24.1.37: Conceptual Model of Telomerase Activity. Abbexa Ltd.

The active site of the telomerase enzyme contains the RNA template, TERC (shown in red) and aligns with the last few telomeric bases at the end of the chromosome (shown in blue). This creates a single-stranded overhang that can be used as a template by the TERT reverse transcriptase to extend the telomere sequence.

In vivo, shortened telomeres and damaged telomeres generally caused by reactive oxygen species (ROS) are usually assumed to be the main markers of cellular aging and are thought to be the main cause of ***replicative senescence***. *In vitro*, telomeres lose approximately 50–200 bp at each division due to the end-replication problem. Approximately 100 mitoses are thought to be sufficient to reach the ***Hayflick limit***, or the maximum number of mitotic events allowed prior to entering replicative senescence. Cells in continual renewal, such as blood cells, compensate for telomere erosion by expressing telomerase, the only enzyme able to polymerize telomeric sequences *de novo* at the extremity of telomeres. Knocking out telomerase components, such as the catalytic subunit (TERT) or the RNA template (TERC), induces several features of aging in mice. In humans, germline mutations in telomerase subunits are responsible for progeroïd syndromes, such as Dyskeratosis congenita, a rare genetic form of bone marrow failure. Furthermore, healthy lifespan in humans is positively correlated with longer telomere length and patients suffering from age-related diseases and premature aging have shorter telomeres compared with healthy individuals. An accumulation of unrepaired damage within telomeric regions has also been shown to accumulate in aging mice and non-human primates, suggesting that damage of telomeres with age may also be contributing to age-driven disease states and reduced health span.

Thus, one could argue that the activation and expression of telomerase may be a way of reducing age-related diseases and increasing overall longevity. However, the constitutive expression of telomerase, unfortunately, is a characteristic of almost all cancer cells. It is therefore, no surprise that transgenic animals over-expressing the catalytic subunit of telomerase (mTERT), develop cancers earlier in life. However, over-expression of telomerase in mice that are highly resistant to cancers has shown large increases in median lifespan and significantly reduced age-associated disorders. Since humans are not highly resistant to cancer, this is not a feasible option for humans. However, additional studies in mice, where constitutive expression of telomerase is only introduced into a small percentage of host cells using adenovirus gene therapy techniques has yielded more promising results. Adenoviruses are a group of viruses that form an icosahedral protein capsid that houses a linear double-stranded DNA genome. Infections in humans typically cause symptoms of the common cold and are usually mild in nature. These are a good target for gene therapy, as the DNA that they carry can be mutated, so that they are deficient in their ability to replicate once they have infected the host. They can also be transformed to carry a gene of interest into the host, where that gene can then integrate into the host genome. Experiments in mice that were infected with an adenovirus carrying the mTERT gene showed that mTERT was delivered to a wide range of tissues within the body, and increased telomere length within those tissues. Furthermore, the mTERT expressing mice were healthier than their litter mates and displayed a reduction in disabling conditions associated with physiological aging such as osteoporosis and insulin resistance, as shown in Figure 24.1.38 Cognitive skills and metabolic functions were also improved. Noticeably, mice treated with gene therapy did not have increased incidence in cancer rates, suggesting that in at least for the short-lived mouse species, gene therapy approach to increased telomerase activity is safe. Within these animals, the median lifespan was increased by 24% when animals were treated at 1 year of age, and by 13% if treated at 2 years of age.

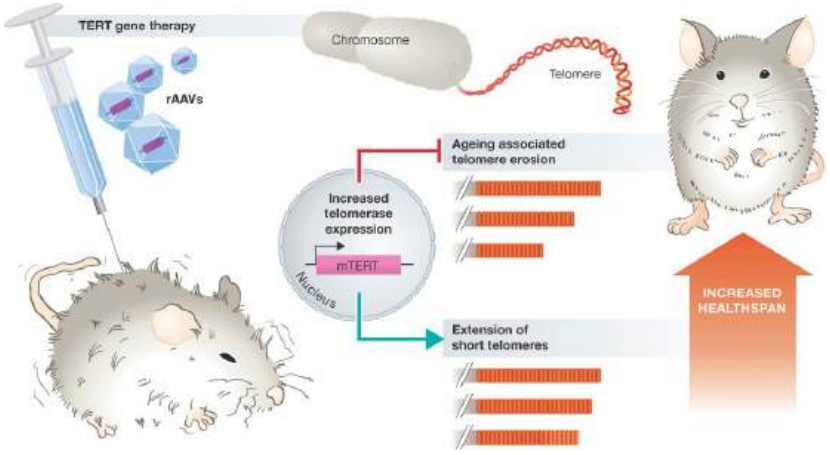

Figure 24.1.38: Promoting healthspan in Mice using a Telomerase Gene Therapy. Delivery of the catalytic subunit of telomerase (TERT) using a modified adenovirus vector (rAAV) suppresses aging-associated telomere erosion and extends short telomeres in a variety of tissues. Consequently, animals display improved healthspans and extended lifespans. Boccardi, V. and Herbig, U. (2012) EMBO Mol Med 4:685-687.

24.1.8.2: Replication and Repair of Telomere Sequences

In addition to the end replication problem, telomeric DNA (telDNA) replication and repair is a real challenge due to the different structural features of telomeres. First, the nucleotide sequence itself consists of a hexanucleotide motif (TTAGGG) repeated over kilobases, with the 5′-3′ strand named the “G-strand” due to its high content in guanine. During the progression of the replication fork, the lagging strand, corresponding to the G-strand, forms G-quadruplex (G4) structures, which have to be resolved to allow fork progression and to complete replication, as shown in Figure 24.1.39 Secondly, R-loops corresponding to highly stable RNA:DNA hybrids, involving the long non-coding telomeric transcript TERRA (telomeric repeat-containing RNA) also have to be dissociated. Thirdly, the extremity of telomeres adopts a specific loop structure, the T-loop, which has to be unraveled. This is the loop that hides the double-stranded end from the DNA damage sensors, and is locked by the hybridization of the 3′ single strand overhang extremity with the above 3′-5′ strand, thereby displacing the corresponding 5′-3′ strand to form a D-loop (displacement loop) structure (Figure 24.1.38). Lastly, replication also has to deal with barriers encountered elsewhere in the genome, such as torsions and a condensed heterochromatic environment.

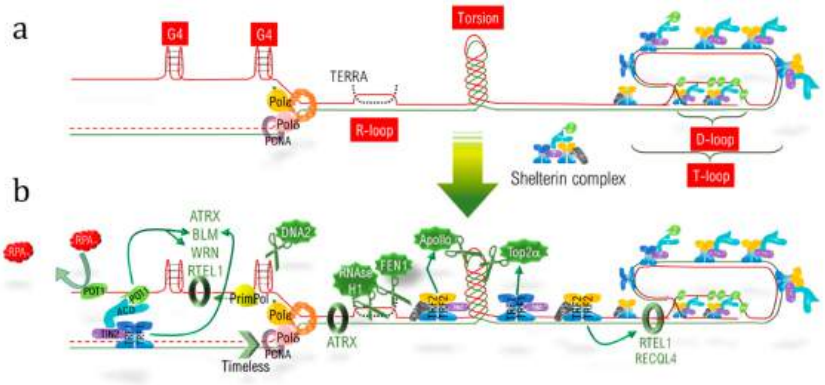

Figure 24.1.39: Obstacles and solutions to replicate telomeres. Billiard, P. and Poncet, D.A. (2019) Int J. Mol. Sci. 20(19) 4959

Panel (a) shows the Telomeric sequence, with the G-strand in a solid red line and the C-strand in a solid green line, is depicted. The terminal D-loop structuring the much larger T-loop is stabilized by the shelterin complex. The replisome (PCNA, pol ε, etc) polymerizes a new G-strand (depicted in a dotted red line) and frees the parental G-strand, enabling the formation of G4 secondary structure. R-loops corresponding to TERRA hybridization (in dotted black lines) with the 3'-5' strand and torsions due to the fork progression are also shown.

Panel (b) shows replication helpers, such as helicases, either helping in G4 unwinding or in D-loop unlocking are depicted. The DNAses (Top2a, DNA2) and RNAses (RNAse H1 and FEN1) help in resolving torsions and RNA:DNA heteroduplexes, while Timeless stimulates the replisome and POT1 competes with RPA1 for binding of the single-strand and helps in G4 dissolution. The shelterin components, POT1, TRF1, and TRF2 help in loading the helper proteins (fine green arrows)

Since telomeres face a host of obstacles to completing the replication process, as discussed in Figure 25.1.28, the cell possesses a set of specialized machinery to fully achieve their replication, such as the RTEL1, TRF1, and TRF2 proteins, DNAses, RNAsses, and Timeless. The recruitment of these factors is orchestrated by the shelterin complex.

At the molecular level, the GGG telomeric repeats are particularly sensitive to ROS, which produce stretches of 8-oxoguanine that are especially difficult to repair. Coupled with inefficient telomere repair, these ROS-induced lesions produce single and double-strand breaks, and/or generate replicative stress, ultimately resulting in telomere shortening. The presence of unrepaired single or tandem 8-oxoguanine drastically inhibits the binding of TRF1 and TRF2, and impairs the recruitment of telomerase, especially when ROS damage is localized in the 3′ overhang. This type of damage contributes to telomere deprotection and shortening. Strikingly, ROS (and other metabolic stresses) also induce the relocation of TERT to mitochondria, as observed (i) in primary neurons after oxidative stress; (ii) in neurons exposed to the tau protein; (iii) in Purkinje neurons subjected to excitotoxicity; and (iv) in cancer cell lines treated with a G4 ligand. Mitochondrial TERT increases the inner membrane potential, as well as the mtDNA copy number, and decreases ROS production with a protective effect on mtDNA. Mitochondria are also critical sensors of cellular damage and contribute to the processes of autophagy and apoptosis (programmed cell death). The relocalization of TERT following chromosomal damage in the nucleus, may indicate one mechanism the mitochondria utilizes to monitor cellular stress and damage.

24.1.9: Replication of Mitochondrial DNA

Mammalian mitochondria contain multiple copies of a circular, double-stranded DNA genome approximately 16.6 kb in length, as shown in Figure 24.1.40 The two strands of mtDNA differ in their base composition, with one being rich in guanines, making it possible to separate a heavy (H) and a light (L) strand by density centrifugation. The mtDNA contains one longer ***noncoding region (NCR)*** also referred to as the control region. In the NCR, there are promoters for polycistronic transcription, one for each mtDNA strand; the light strand promoter (LSP) and the heavy strand promoter (HSP). The NCR also harbors the origin for H-strand DNA replication (O_H). A second origin for L-strand DNA replication (O_L) is located outside the NCR, within a tRNA cluster.

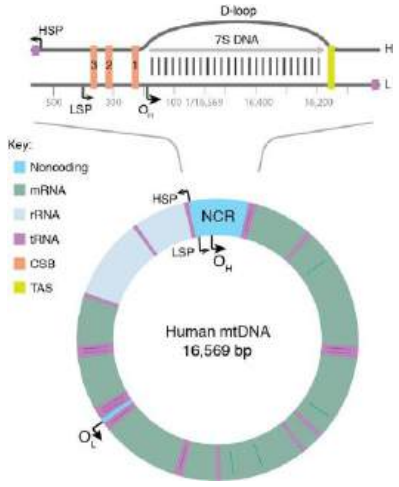

Figure 24.1.40: Map of human mtDNA. Falkenberg, M. (2018) *Essays Biochem* 62(3):287-296

Falkenberg, M. (2018) *Essays Biochem* 62(3):287-296

As shown in Figure 24.1.40 the genome encodes for 13 mRNA (green), 22 tRNA (violet), and 2 rRNA (pale blue) molecules. There is also a major noncoding region (NCR), which is shown enlarged at the top in blue. The major NCR contains the heavy strand promoter (HSP), the light strand promoter (LSP), three conserved sequence boxes (CSB1-3, orange), the H-strand origin of replication (O_H), and the termination-associated sequence (TAS, yellow). The triple-stranded displacement-loop (D-loop) structure is formed by a premature termination of nascent H-strand DNA synthesis at TAS. The short H-strand replication product formed in this manner is termed 7S DNA. A minor NCR, located approximately 11,000 bp downstream of O_H, contains the L-strand origin of replication (O_L).

A dedicated DNA replication machinery is required for its maintenance. Mammalian mtDNA is replicated by proteins distinct from those used for nuclear DNA replication and many are related to replication factors identified in bacteriophages. DNA polymerase γ (POLγ) is the replicative polymerase in mitochondria. In human cells, POLγ is a heterotrimer with one catalytic subunit (POLγA) and two accessory subunits (POLγB). POLγA belongs to the A family of DNA polymerases and contains a 3′–5′ exonuclease domain that acts to proofread the newly synthesized DNA strand. POLγ is a highly accurate DNA polymerase with a frequency of misincorporation lower than 1×10^{-6}. The accessory POLγB subunit enhances interactions with the DNA template and increases both the catalytic activity and the processivity of POLγA. The DNA helicase TWINKLE travels in front of POLγ, unwinding the double-

stranded DNA template. TWINKLE forms a hexamer and requires a fork structure (a single-stranded 5′-DNA loading site and a short 3′-tail) to load and initiate unwinding. Mitochondrial single-stranded DNA-binding protein (mtSSB) binds to the formed ssDNA, protects it against nucleases, and prevents secondary structure formation

The most accepted model of DNA replication in the mitochondria is the ***strand displacement model,*** as shown in Figure 24.1.41 Within this model, DNA synthesis is continuous on both the H- and L-strand. There is a dedicated origin for each strand, O_H and O_L. First, replication is initiated at O_H and DNA synthesis then proceeds to produce a new H-strand. During the initial phase, there is no simultaneous L-strand synthesis and mtSSB covers the displaced, parental H-strand. By binding to single-stranded DNA, mtSSB prevents the mitochondrial RNA polymerase (POLRMT) from initiating random RNA synthesis on the displaced strand. When the replication fork has progressed about two-thirds of the genome, it passes the second origin of replication, O_L. When exposed in its single-stranded conformation, the parental H-strand at O_L folds into a stem–loop structure. The stem efficiently blocks mtSSB from binding and a short stretch of single-stranded DNA in the loop region, therefore remains accessible, allowing POLRMT to initiate RNA synthesis. POLRMT is not processive on single-stranded DNA templates. After adding approximately 25 nucleotides, it is replaced by POLγ and L-strand DNA synthesis is initiated. From this point, H- and L-strand synthesis proceeds continuously until the two strands have reached full circle. Replication of the two strands is linked, since H-strand synthesis is required for the initiation of L-strand synthesis. DNA Ligase III is used to complete the ligation of the newly formed DNA strands.

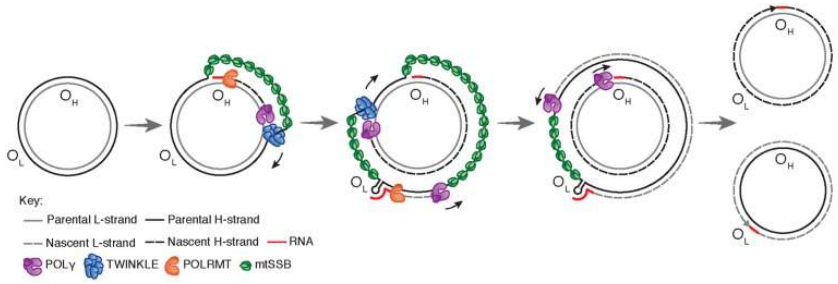

Figure 25.1.24 Replication of the human mitochondrial genome.
Mitochondrial DNA replication is i
nitiated at O
H
and proceeds unidirectionally to produce the full-length nascent H-strand.
mtSSB
binds and protects the exposed, parental H-strand. When the replisome passes O
L
, a stem–loop structure is formed that blocks mtSSB binding, presenting a single-stranded loop-region from which POLRMT can initiate primer synthesis. The transition to L-strand DNA synthesis takes place after about 25 nt, when POLγ replaces POLRMT at the 3′-end of the primer. Synthesis of the two strands proceeds in a continuous manner until two full, double-stranded DNA molecules have been formed.

Figure from:
Falkenberg, M. (2018) *Essays Biochem* 62(3):287-296

During DNA replication, the parental molecule remains intact, which poses a steric problem for the moving replication machinery. Topoisomerases belonging to the type 1 family can relieve torsional strain formed in this way, by allowing one of the strands to pass through the other. In mammalian mitochondria, TOP1MT a type IB enzyme can act as a DNA “swivel”, working together with the mitochondrial replisome. Furthermore, replication of circular DNA often causes the formation of catenanes, or interlocked circles that need to be separated from one another. The type 1A topoisomerase, topoisomerase 3α (Top3α), is required to resolve the hemicatenane structure that can form during mtDNA replication.

Curiously, not all replication events initiated at O_H continue to full circle. Instead, 95% are terminated after about the first 650 nucleotides at a sequence known as the ***termination associated sequences (TAS)*** (Figure 25.1.23). This creates a short DNA fragment known as the 7S DNA, that remains bound to the parental L-strand, while the parental H-strand is displaced (Figure 25.1.23). As a result, a triple-stranded ***displacement loop structure, a D-loop,*** is formed. The functional importance of the D-loop structure is unclear and how replication is terminated at TAS is also not known.

24.1.9.0.1: Mastering the Content

Which of the following is the enzyme that replaces the RNA nucleotides in a primer with DNA nucleotides?

1. DNA polymerase III
2. DNA polymerase I
3. primase

4. helicase

24.2: DNA Mutations, Damage, and Repair

The integrity of the DNA structure for cell viability is underscored by the vast amounts of cellular machinery dedicated to ensuring its accurate replication, repair, and storage. Even still, mutations within the DNA are a fairly common event.

24.2.1: DNA Mutations

Mutations are random changes that occur within the sequence of bases in DNA. They can be large-scale, altering the structure of the chromosomes, or small scale where they only alter a few or even a single base or nucleotide. Mutations can occur for many reasons. For example, DNA mutations can be caused by mistakes made by the DNA polymerase during replication. As noted in chapter 9, DNA polymerases are highly processive enzymes that contain proofreading and editing functions. With these safeguards, their error rates are typically very low and range from one in a million bases to one in a billion bases. Even with such high fidelity, this error rate will lead to between 3 and 3,000 errors within the human genome for each cell undergoing DNA replication. DNA mutations can also result through the replication of DNA that has been damaged by endogenous or exogenous agents. The next section will highlight common types of DNA damage and their effects. If a DNA polymerase encounters a damaged DNA base in the template DNA during replication it may place a random nucleotide base across from the lesion. For example, an adenine-containing nucleotide will often be added across a lesion, regardless of what the correct match should be. This can lead to the formation of ***transition*** or ***transversion*** mutations.

A ***transition*** mutation is a point mutation that changes a purine nucleotide to another purine (A ↔ G) or a pyrimidine nucleotide to another pyrimidine (C ↔ T). ***Transversion*** refers to the substitution of a purine for a pyrimidine or vice versa. Sometimes lesions may cause bases to be skipped during replication or cause extra nucleotides to be inserted into the backbone. DNA polymerases can also slip during the replication of regions of the DNA that have repeated sequences or large stretches repeating a single base. Larger lesions or cross-links in the DNA during replication can lead to more catastrophic DNA damage including DNA strand breaks. Mutations may also occur during the processes of mitosis and meiosis when sister chromatids and/or homologous chromosomes are separated from one another.

In nature, ***mutagenesis,*** or the process of generating DNA mutations, can lead to changes that are harmful, beneficial, or have no effect. Harmful mutations can lead to cancer and various heritable diseases, but beneficial mutations are the driving force of evolution. In 1927, Hermann Muller first demonstrated the effects of mutations with observable changes in chromosomes. He induced mutagenesis by irradiating fruit flies with X-rays.

When a mutation is caused by an environmental factor or a chemical agent, that agent is called a ***mutagen.*** Typical mutagens include chemicals, like those inhaled while smoking, and radiation, such as X-rays, ultraviolet light, and nuclear radiation. Different mutagens have different modes of damaging DNA and are discussed further in the next section. It is important to note that DNA damage, in and of itself, does not necessarily lead to the formation of a mutation in the DNA. There are elaborate DNA repair processes designed to recognize and repair different types of DNA lesions. Fewer than 1 in 1,000 DNA lesions will result in a DNA mutation. The processes of DNA damage recognition and repair are the focus of later sections within this chapter.

24.2.1.1: Types of Mutations

There are a variety of types of mutations. Two major categories of mutations are germline mutations and somatic mutations.

- ***Germline mutations*** occur in gametes, the sex cells, such as eggs and sperm. These mutations are especially significant because they can be transmitted to offspring and every cell in the offspring will have the mutations.
- ***Somatic mutations*** occur in other cells of the body. These mutations may have little effect on the organism because they are confined to just one cell and its daughter cells. Somatic mutations also cannot be passed on to offspring.

Mutations also differ in the way that the genetic material is changed. Mutations may change an entire chromosome or just one or a few nucleotides.

Chromosomal alterations are mutations that change chromosome structure or number. They occur when a section of a chromosome breaks off and rejoins incorrectly or does not rejoin at all. Possible ways these mutations can occur are illustrated in the figure below. Chromosomal alterations are very serious. They often result in the death of the cell or organism in which they occur. If the organism survives, it may be affected in multiple ways. An example of a human chromosomal alteration is the mutation that causes Down Syndrome. It is a duplication mutation that leads to developmental delays and other abnormalities. It occurs when the individual inherits an extra copy of chromosome 21. It is also called trisomy ("three-chromosome") 21. Thus, large-scale mutations in the chromosomal structure include ***(1) Amplifications (including gene duplications)*** where repetition of a

chromosomal segment or presence of an extra piece of a chromosome broken piece of a chromosome may become attached to a homologous or non-homologous chromosome so that some of the genes are present in more than two doses leading to multiple copies of all chromosomal regions, increasing the dosage of the genes located within them, ***(2) Deletions*** of large chromosomal regions, leading to loss of the genes within those regions, and ***(3) Chromosomal Rearrangements*** such as ***translocations*** (which interchange of genetic parts from nonhomologous chromosomes), ***insertions*** (which insert segments of one chromosome into another nonhomologous chromosome), and ***inversions*** (which invert or flip a section of a chromosome into the opposite orientation), as shown in Figure 24.2.1.

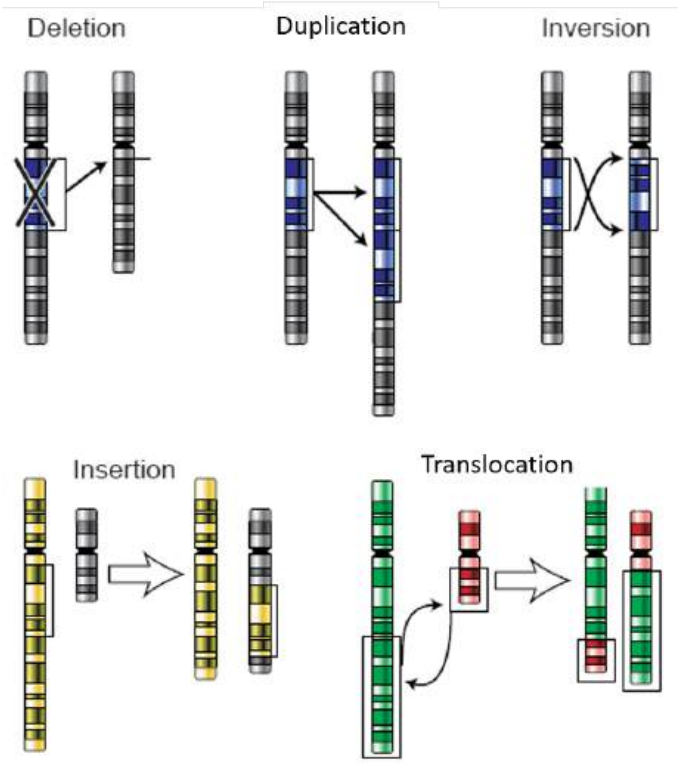

Figure 24.2.1: Chromosomal Alterations. Chromosomal alterations are major changes in the genetic material.*Image modified from Dietzel65*

There are also smaller mutations that can occur that only alter a single nucleotide or a small number of nucleotides within a localized region of the DNA. These are classified according to how the DNA molecule is altered. One type, a ***point mutation***, affects a single base and most commonly occurs when one base is substituted or replaced by another. Mutations also result from the addition of one or more bases, known as an ***insertion***, or the removal of one or more bases, known as a ***deletion***.

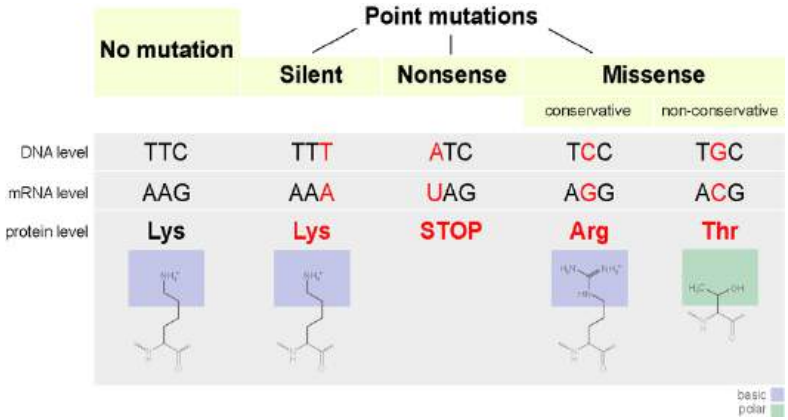

Figure 24.2.2: **The Potential Effects of Point Mutations on Protein Coding Regions.** The image shows various types of point mutations (silent, missense, and nonsense), which may lead to changes in the protein structure. Figure from: Jonsta247

Point mutations (Table 24.2.1 and Figure 24.2.2) may have a wide range of effects on protein function. As a consequence of the degeneracy of the genetic code, a ***point mutation*** will commonly result in the same amino acid being incorporated into the resulting

polypeptide despite the sequence change. This change would not affect the protein's structure and is thus called a ***silent mutation***. A ***missense mutation*** results in a different amino acid being incorporated into the resulting polypeptide. The effect of a missense mutation depends on how chemically different the new amino acid is from the wild-type amino acid. The location of the changed amino acid within the protein also is important. For example, if the changed amino acid is part of the enzyme's active site or greatly affects the shape of the enzyme, then the effect of the missense mutation may be significant. Many missense mutations result in proteins that are still functional, at least to some degree. Sometimes the effects of missense mutations may be only apparent under certain environmental conditions; such missense mutations are called ***conditional mutations***. Rarely, a missense mutation may be beneficial. Under the right environmental conditions, this type of mutation may give the organism that harbors it a selective advantage. Yet another type of point mutation called a ***nonsense mutation***, converts a codon encoding an amino acid (a sense codon) into a stop codon (a nonsense codon). Nonsense mutations result in the synthesis of proteins that are shorter than the wild type and typically not functional.

Table 24.2.1: Types of Point Mutations

Type	Description	Example	Effect
Silent	mutated codon codes for the same amino acid	CAA (glutamine) → CAG (glutamine)	none
Missense	mutated codon codes for a different amino acid	CAA (glutamine) → CCA (proline)	variable
Nonsense	a mutated codon is a premature stop codon	CAA (glutamine) → UAA (stop) usually	serious

Smaller scale ***deletions*** and ***insertions*** also cause various effects. Because codons are triplets of nucleotides, insertions or deletions in groups of three nucleotides may lead to the insertion or deletion of one or more amino acids and may not cause significant effects on the resulting protein's functionality. However, ***frameshift mutations***, caused by insertions or deletions of a number of nucleotides that are not a multiple of three are extremely problematic because a shift in the reading frame results, as shown in Figure 24.2.3. Because ribosomes read the mRNA in triplet codons, frameshift mutations can change every amino acid after the point of the mutation. The new reading frame may also include a stop codon before the end of the coding sequence. Consequently, proteins made from genes containing frameshift mutations are nearly always nonfunctional.

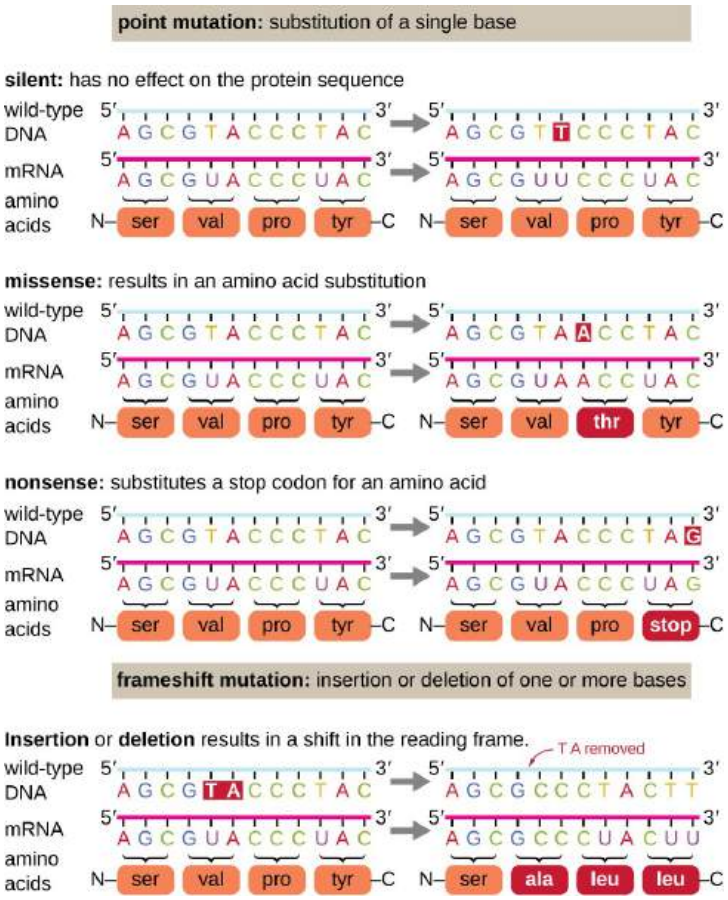

Figure 24.2.3: Summary of Small Scale Mutations on Protein Coding Regions. DNA alterations that lead to changes in the protein sequence encoded by the DNA can include point mutations, DNA insertions, and DNA deletions. Figure from: Parker, et al (2019) Microbiology from Openstax

The majority of mutations have neither negative nor positive effects on the organism in which they occur. These mutations are called neutral mutations. Examples include silent point mutations, which are neutral because they do not change the amino acids in the proteins they encode.

Some mutations have a positive effect on the organism in which they occur. They are referred to as beneficial mutations. If they occur in germline cells (eggs or sperm) these traits can be heritable and passed from one generation to the next. Beneficial mutations generally code for new versions of proteins that help organisms adapt to their environment. If they increase an organism's chances of surviving or reproducing, the mutations are likely to become more common within a population over time. There are several well-known examples of beneficial mutations. Here are just two:

1. Mutations have occurred in bacteria that allow the bacteria to survive in the presence of antibiotic drugs. The mutations have led to the evolution of antibiotic-resistant strains of bacteria.
2. A unique mutation is found in people in a small town in Italy. The mutation protects them from developing atherosclerosis, which is the dangerous buildup of fatty materials in blood vessels. The individual in which the mutation first appeared has even been identified.

Harmful mutations can also occur. Imagine making a random change in a complicated machine such as a car engine. The chance that the random change would improve the functioning of the car is very small. The change is far more likely to result in a car that does not run well or perhaps does not run at all. By the same token, any random change in a gene's DNA is more likely to result in the production of a protein that does not function normally or may not function at all, than in a mutation that improves the function. Such mutations are likely to be harmful. Harmful mutations may cause genetic disorders or cancer.

- A genetic disorder is a disease, syndrome, or other abnormal condition caused by a mutation in one or more genes or by a chromosomal alteration. An example of a genetic disorder is cystic fibrosis. A mutation in a single gene causes the body to produce thick, sticky mucus that clogs the lungs and blocks ducts in digestive organs. Genetic disorders are usually caused by gene mutations that occur within germline cells and are heritable.

- Illnesses caused by mutations that occur within an individual, but are not passed on to their offspring, are mutations that occur in somatic cells. Cancer is a disease caused by an accumulation of mutations within somatic cells. It results in cells that grow out of control and form abnormal masses of cells called tumors. It is generally caused by mutations in genes that regulate the cell cycle, DNA repair, angiogenesis, and other genes that favor cell growth and survival. Because of the mutations, cells with the mutated DNA have evolved to divide without restrictions, hide from the immune system, and develop drug resistance.

24.2.2: Types of DNA Damage

DNA damage, due to environmental factors and normal metabolic processes inside the cell, occurs at a rate of 1,000 to 1,000,000 molecular lesions per cell per day. While this constitutes only 0.000165% of the human genome's approximately 6 billion bases (3 billion base pairs), if left unrepaired can cause mutations in critical genes (such as tumor suppressor genes) can impede a cell's ability to carry out their function and appreciably increase the likelihood of tumor formation and disease states such as cancer.

The vast majority of DNA damage affects the primary structure of the double helix; that is, the bases themselves are chemically modified. These modifications can, in turn, disrupt the molecules' regular helical structure by introducing non-native chemical bonds or bulky adducts that do not fit in the standard double helix. Unlike proteins and RNA, DNA usually lacks tertiary structure, and therefore damage or disturbance does not occur at that level. DNA is, however, supercoiled and wound around "packaging" proteins called histones (in eukaryotes), and both superstructures are vulnerable to the effects of DNA damage.

Several types of DNA damage can occur due either to normal cellular processes or due to the environmental exposure of cells to DNA-damaging agents. DNA bases can be damaged by: (1) oxidative processes, (2) alkylation of bases, (3) base loss caused by the hydrolysis of bases, (4) bulky adduct formation, (5) DNA crosslinking, and (6) DNA strand breaks, including single and double-stranded breaks. An overview of these types of damage is described below.

24.2.2.1: Oxidative Damage

Reactive oxygen species (ROS) can cause significant cellular stress and damage including oxidative DNA damage. Hydroxyl radicals ($^{\bullet}OH$) are one of the most reactive and electrophilic of the ROS and can be produced by ultraviolet and ionizing radiations or from other radicals arising from enzymatic reactions. The $^{\bullet}OH$ can cause the formation of 8-oxo-7,8-dihydroguanine (8-oxoG) from guanine residues, among other oxidative products, as shown in Figure 24.2.4 Guanine is the most easily oxidized of the nucleic acid bases because it has the lowest ionization potential among the DNA bases. The 8-oxo-dG is one of the most abundant DNA lesions, and it is considered as a biomarker of oxidative stress. It has been estimated that up to 100,000 8-oxo-dG lesions can occur daily in DNA per cell. The reduction potential of 8-oxo-dG is even lower (0.74 V vs. NHE) than that of guanosine (1.29 V vs NHE). Therefore, it can be further oxidized creating a variety of secondary oxidation products.

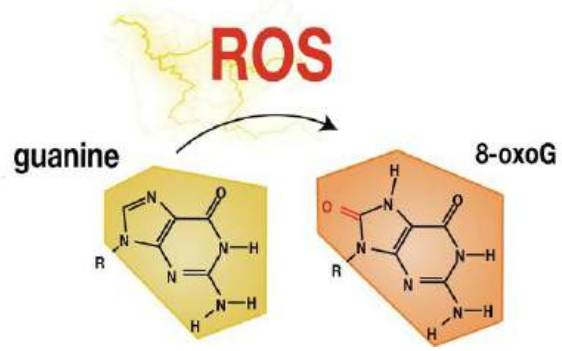

Figure 24.2.4: Reactive Oxygen Species and DNA Damage. Under conditions of oxidative stress, 8-oxoG is the result of reactive oxygen species (ROS) modifying guanine. Figure from: Poetsch, A.R. (2020) Comp & Struct Biotech J. 18:207-219.

As mentioned previously, increased levels of 8-oxo-dG in tissue can serve as a biomarker of oxidative stress. Furthermore, increased levels of 8-oxo-dG are frequently found associated with carcinogenesis and other disease states, as shown in Figure 24.2.5. During the replication of DNA that contains 8-oxo-dG, adenine is most often incorporated across from the lesion. Following replication, the 8-oxo-dG is excised during the repair process and thymine is incorporated in its place. Thus, 8-oxo-dG mutations typically result in a G to T transversion.

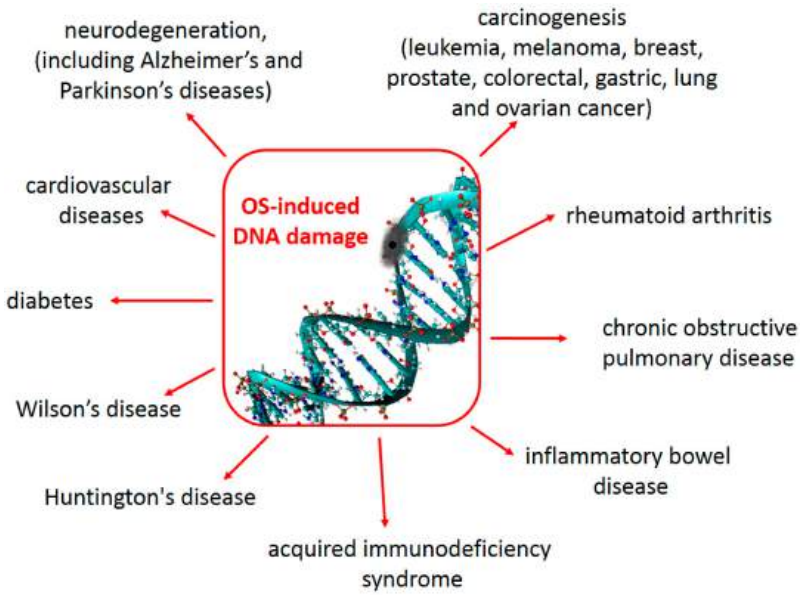

Figure 24.2.5: Oxidative Stress and Human Health. DNA damage caused by oxidative stress has been associated with many human disease states. Figure from: Galano, A., Tan, D-X., and Reiter, R.J. (2018) Molecules 23(3)530

24.2.2.2: Alkylation of Bases

Alkylating agents are widespread in the environment and are also produced endogenously, as by-products of cellular metabolism. They introduce lesions into DNA or RNA bases that can be cytotoxic, mutagenic, or neutral to the cell. Figure 24.2.6 depicts the major reactive sites on the DNA bases that are susceptible to alkylation. Cytotoxic lesions block replication, interrupt transcription, or signal the activation of apoptosis, whereas mutagenic ones are miscoding and cause mutations in newly synthesized DNA. The most common type of alkylation is methylation with the major products including N7-methylguanine (7meG), N3-methyladenine (3meA), and O6-methylguanine (O6meG). Smaller amounts of methylation also occurs on other DNA bases, and include the formation of N1-methyladenine (1meA), N3-methylcytosine (3meC), O4-methylthymine (O4meT), and methyl phosphotriesters (MPT).

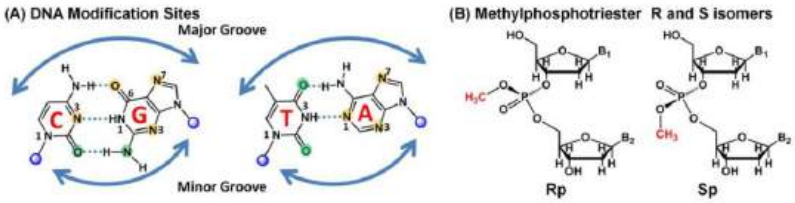

Figure 24.2.6: Major Sites of Alkylation in DNA. The diagram shows DNA Watson-Crick base pairs with principal damage sites modified by small alkylating agents (methyl and ethyl). (A) Sites of base modification by SN1 and SN2 alkylating agents. The orange indicates major damage sites and the green minor damage sites. (B) Phosphotriester formation is indicated by the presence of methyl groups, along with the Rp and Sp isomers. Figure from: Ahmad, A., Nay, S.L. and O'Conner, T.R. (2015) Chapter 4 Direct Reversal Repair in Mammalian Cells

Alkylating agents can cause damage to all exocyclic nitrogens and oxygens in DNA and RNA, as well as at ring nitrogens (Figure 25.2.6A). However, the percentage of each base site modified depends on the alkylating agent, the position in DNA or RNA, and whether nucleic acids are single- or double-stranded. Interestingly, O-alkylations are more mutagenic and harmful than N-alkylations, which may be more cytotoxic, but not as mutagenic.

As we will explore in Chapter 13, methylation of DNA also serves as an important mechanism regulating gene expression.

24.2.2.3: Base Loss

An ***AP site (apurinic/apyrimidinic site)***, also known as an ***abasic site***, is a location in DNA (also in RNA but much less likely) that has neither a purine nor a pyrimidine base, either spontaneously or due to DNA damage, as shown in Figure 24.2.7. It has been estimated that under physiological conditions 10,000 apurinic sites and 500 apyrimidinic may be generated in a cell daily.

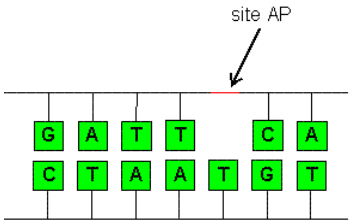

Figure 24.2.7: Abasic Sites. Apurinic and Apyrimidimic (AP) sites occur due to unstable hydrolysis. Figure from Mayhew

AP sites can be formed by spontaneous depurination, but also occur as intermediates in base excision repair, the repair process described in section 25.2.5. If left unrepaired, AP sites can lead to mutation during semiconservative replication. They can cause replication fork stalling and are often bypassed by ***translesion synthesis***, which is discussed in greater detail in section 12.8. In *E. coli*, adenine is preferentially inserted across from AP sites, known as the "A rule". The situation is more complex in higher eukaryotes, with different nucleotides showing a preference depending on the organism and environmental conditions.

24.2.2.4: Bulky Adduct Formation

Some chemicals are biologically reactive and will form covalent linkages with biological molecules such as DNA and proteins creating large ***bulky adducts***, or appendages, that branch off from the main molecule. We will use the mutagen/carcinogen, **benzo[*a*]pyrene,** as an example for this process.

Benzo[*a*]pyrene is a polycyclic aromatic hydrocarbon that forms during the incomplete combustion of organic matter at temperatures between 300°C (572°F) and 600°C (1,112°F). The ubiquitous compound can be found in coal tar, tobacco smoke, and many foods, especially grilled meats. Benzo[*a*]pyrene is a ***procarcinogen*** that needs to be biologically activated by metabolism before it forms a reactive metabolite, as in Figure 24.2.8 Normally, when the body is exposed to foreign molecules, it will start a metabolic process that makes the molecule more hydrophilic and easier to remove as a waste product. Unfortunately, in the case of benzo[*a*]pyrene, the resulting metabolite is a highly reactive epoxide that forms a bulky adduct preferentially with guanine residues in DNA. If left unrepaired, during DNA replication an adenine will usually be placed across from the lesion in the daughter molecule. Subsequent repair of the adduct will result in the replacement of the damaged guanine base with thymine, causing a G --> T transversion mutation.

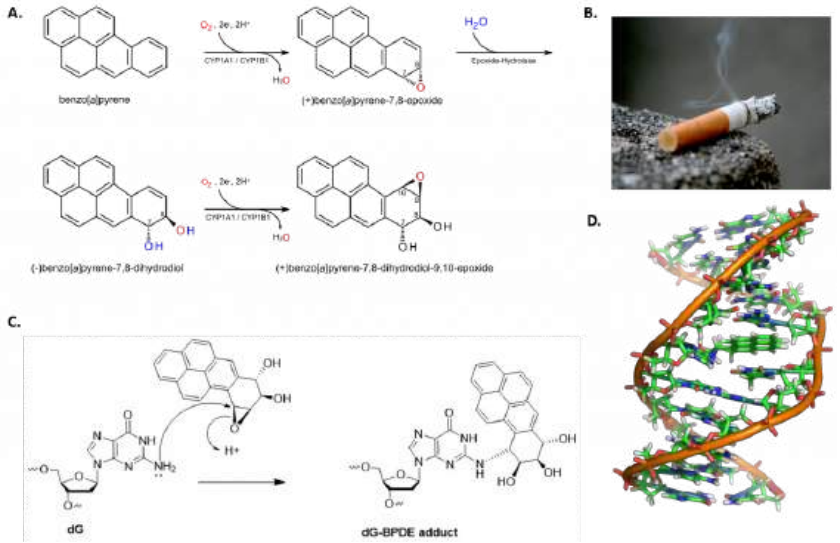

Figure 24.2.8: Benzo[*a*]pyrene Activation and Adduct Formation. (A) Benzo[*a*]pyrene is biologically activated to a dihydrodial epoxide during normal metabolic processes. (B) Cigarette smoke is a source of benzo[*a*]pyrene. (C) The activated (+)benzo[*a*]pyrene-7,8-dihydrodiol-9,10-epoxide can form a DNA adduct with guanine residues. (D) The benzo[*a*]pyrene adduct forms a bulky lesion that distorts the DNA backbone. Figures from: (A) Eleska, (B) Elizabeth Aguilera (C) DI93biochemist, and (D) Zephryis

24.2.2.5: DNA Crosslinking

Crosslinking of DNA occurs when various exogenous or endogenous agents react with two nucleotides of DNA, forming a covalent linkage between them. This crosslink can occur within the same strand ***(intrastrand)*** or between opposite strands of

double-stranded DNA ***(interstrand)***, as shown in Figure 24.2.9. These adducts interfere with cellular metabolism, such as DNA replication and transcription, triggering cell death.

Figure 24.2.9: f Intrastrand and Interstrand DNA Crosslinks. Lopez and Martinez, Cell. Mol. Life Sci. (2016) 73:3097–3114 DOI 10.1007/s00018-016-2218-x. Creative Commons Attribution 4.0 International License (http://creativecommons.org/licenses/by/4.0/),

UV light can cause molecular crosslinks to form between two pyrimidine residues, commonly two thymine residues, that are positioned consecutively within a strand of DNA, as shown in Figure 24.2.10 Two common UV products are cyclobutane pyrimidine dimers (CPDs) and 6–4 photoproducts. These premutagenic lesions alter the structure and possibly the base pairing. Up to 50–100 such reactions per second might occur in a skin cell during exposure to sunlight, but are usually corrected within seconds by photolyase reactivation or nucleotide excision repair. Uncorrected lesions can inhibit polymerases, cause misreading during transcription or replication, or lead to the arrest of replication. Pyrimidine dimers are the primary cause of melanomas in humans.

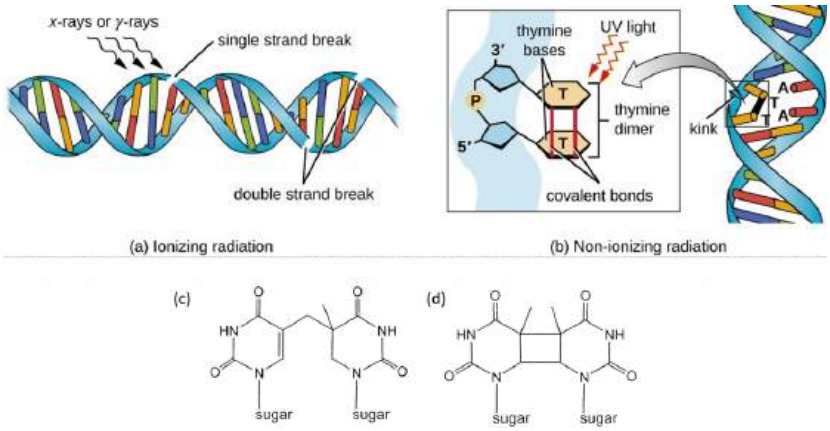

Figure 24.2.10: **Double-Stranded DNA breaks and Thymine Dimer Formation** (a) Ionizing radiation, such as X-rays and γ-rays contain enough energy to cause single and double-stranded breaks in the DNA backbone. (b) Energy from non-ionizing radiation such as UV light is directly absorbed by the DNA causing thymine residues that are adjacent within a single DNA strand to become cross-linked. (c) a 6,4-dimer that forms a single covalent bond and (d) thymine-thymine cyclobutane dimer that forms two covalent bonds between the thymine residues. Figures from: (a and b) Parker, et al (2019) Microbiology from Openstax and (c and d) Smokefoot

24.2.2.6: DNA Strand Breaks

Ionizing radiation such as that created by radioactive decay or in cosmic rays causes breaks in DNA strands (see Figure above). Low-level ionizing radiation may induce irreparable DNA damage (leading to replication and transcription errors needed for neoplasia or may trigger viral interactions) leading to premature aging and cancer. Chemical agents that form crosslinks within the DNA, especially interstrand crosslinks, can also lead to DNA strand breaks if the damaged DNA undergoes DNA replication. Crosslinked DNA can cause topoisomerase enzymes to stall in the transition state when the DNA backbone is cleaved. Instead of relieving supercoiling and resealing the backbone, the stalled topoisomerase remains covalently linked to the DNA in a process called ***abortive catalysis***. This leads to the formation of a single-stranded break in the case of Top1 enzymes or double-stranded breaks in the case of Top2 enzymes. DNA double-strand breaks due to topoisomerase stalling can also occur during the transcription of DNA, as shown in Figure 24.2.11 Abortive ***catalysis*** and the formation of DNA strand breaks during transcriptional events may serve as a damage sensor within the cell and help to instigate DNA damage response signaling pathways that initiate DNA repair processes.

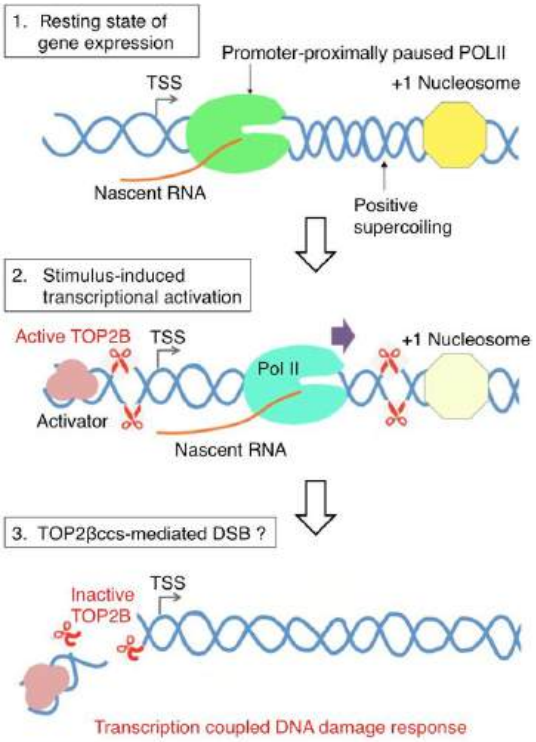

Figure 24.2.11: Model of Topoisomerase IIB (**TOP2B)-mediated DNA Double Strand Breaks During Transcription.** Morimoto, S., et al (2019) Genes 10:868

Panel (1) shows that in the uninduced state of transcription, Pol II is paused between +25 and +100 from the transcription start site. The pausing is attributed to different elements including pausing-stabilizing transcription factors, the +1 nucleosome, and DNA structure and torsion. Positive supercoiling ahead of Pol II may require the function of TOP2B.

Panel (2) shows transcription activation induced by various stimuli activates TOP2B to resolve DNA torsion in the promoter and gene body.

Panel (3) shows that in this process, double-strand breaks could be formed from abortive catalysis of TOP2B, which occurs frequently in some genes. This may be responsible for DNA damage response signaling that has been observed in a number of stimulus-inducible genes in humans. Figure from:

24.2.3: Cellular Stress and DNA Damage Response

Genetic damage produced by either exogenous or endogenous mechanisms represents an ongoing threat to the cell. To preserve genome integrity, eukaryotic cells have evolved repair mechanisms specific for different types of DNA Damage. However, regardless of the type of damage a sophisticated surveillance mechanism, that elicits ***DNA damage checkpoints***, detects and signals its presence to the DNA repair machinery. ***DNA damage checkpoints*** have been functionally conserved throughout eukaryotic evolution, with most of the relevant players in the checkpoint response highly conserved from yeast to humans. Checkpoints are induced to delay cell cycle progression and to allow cells time to repair damaged DNA before DNA replication, as shown in Figure 24.2.12 Once the damaged DNA is repaired, the checkpoint machinery triggers signals that will resume cell cycle progression. Within cells, multiple pathways contribute to DNA repair, but independent of the specific repair pathway involved, three phases of checkpoint activation are traditionally identified: (1) Sensing of damage, (2) Activating the signaling cascade, and (3) Switching on downstream effectors. The sensor phase recognizes the damage and activates the signal transduction phase to block cell cycle progression and select the appropriate repair pathway.

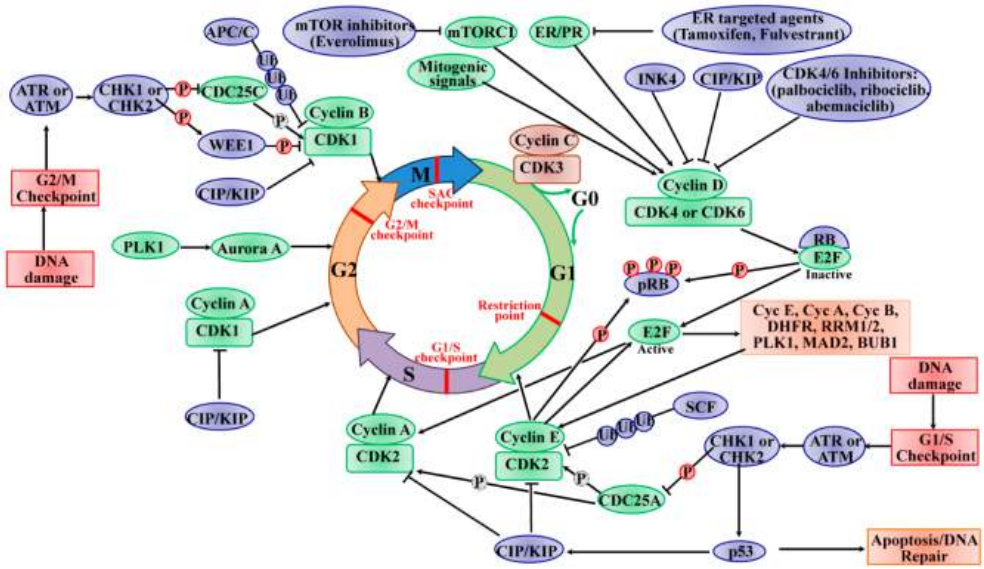

Figure 24.2.12: Cell Fates Following DNA Damage. Cell cycle checkpoints are induced by DNA damage, shown in red. Cyclin-Dependent Kinase Inhibitors (CIP/KIP), shown in purple, block cell cycle progression in all phases of the cell cycle (G1, S, G2, or M) following DNA damage by inhibiting cyclin-dependent kinase complexes (shown in green). Signaling cascades activated in response to DNA damage also elicit DNA repair pathways, or if the DNA damage is severe, programmed cell death (Apoptosis) will be activated. Image from: Ding, L., et al. (2020) Int. J. Mol. Sci. 21(6):1960

In addition to blocking cell cycle progression, DNA damage sensors also activate DNA repair mechanisms that are specific for the type of damage present. For example, single-stranded DNA breaks are repaired primarily by Base Excision Repair, bulky DNA adducts, and crosslinks are repaired by Nucleotide Excision Repair, and smaller nucleotide mutations, such as alkylation are repaired by Mismatch Repair. Cells also have two major mechanisms for repairing Double-Strand-Breaks (DSBs). They include Non-Homologous End-Joining (NHEJ) and Homologous Recombination (HR). If damage is too extensive to be repaired, apoptotic pathways will be elicited. In the following sections, details about the major DNA repair pathways will be given.

In multicellular organisms, the response to DNA damage can result in two major physiological consequences: (1) Cells can undergo cell cycle arrest, repair the damage, and re-enter the cell cycle, or (2) cells can be targeted for cell death (apoptosis) and removed from the population. The cell cycle process is highly conserved and precisely controlled to govern the genome duplication and separation into the daughter cells. The cell cycle consists of four distinct and ordered phases, termed G0/G1 (gap 1), S (DNA synthesis), G2 (gap 2), and M (mitosis). Multiple checkpoints exist within each stage of the cell cycle to ensure the faithful replication of DNA in the S phase and the precise separation of the chromosomes into daughter cells. The G1 and G2 phases are critical regulatory checkpoints, whereby the restriction point between the G1 and S phase determines whether the cells enter the S phase or exit the cell cycle to halt at the G0 phase. The cell cycle progression requires the activity of cyclin-dependent kinases (CDKs), a group of serine/threonine kinases. CDKs are activated when they form complexes with cyclin regulatory proteins that are expressed specifically at different stages of the cell cycle. Cyclins bind to and stabilize CDKs in their active conformation. The formation of cyclin/CDKs controls the cell-cycle progression via phosphorylation of the target genes, such as tumor suppressor protein retinoblastoma (Rb).

During DNA damage, the cell cycle is arrested or blocked by the action of cyclin-dependent kinase inhibitors. As noted in Figure 12.12, this is a complicated signal transduction cascade that has many downstream effects. A primary function of cell cycle arrest is that CDK inhibition allows time for DNA repair before cell-cycle progression into the S-phase or mitosis. As shown in Figure 25.2.12, two major cell-cycle checkpoints respond to DNA damage; they occur pre- and post-DNA synthesis in the G1 and G2 phases, respectively, and impinge on the activity of specific CDK complexes. The checkpoint kinases phosphatidylinositol 3-kinase (PI3K)-like protein kinases (PI3KKs) ataxia telangiectasia and Rad3-related (ATR) or ataxia telangiectasia mutated (ATM) protein, and the transducer checkpoint kinases CHK1 (encoded by the CHEK1 gene) and CHK2 (encoded by the CHEK2 gene) are key regulators of DNA damage signaling. The DNA damage signaling is detected by ATM/ATR, which then phosphorylates and activates CHK2/CHK1, respectively. The activated CHK2 is involved in the activation of p53, leading to p53-dependent early phase G1 arrest to allow time for DNA repair. The activation of p53 induces the expression of the Cyclin-Dependent Kinase Inhibitor (CKI) $p21^{CIP1}$ gene, leading to the inhibition of cyclin E/CDK2 complexes and subsequent upregulation of DNA repair machinery.

If the DNA repair cannot be completed successfully or the cells cannot program to respond to the stresses of viable cell-cycle arrest, the cells face the fate of apoptosis induced by p53. The activated CHK1 mediates temporary S phase arrest through phosphorylation to inactivate CDC25A, causing ubiquitination and proteolysis. Moreover, the activated CHK1 phosphorylates and inactivates CDC25C, leading to cell-cycle arrest in the G2 phase. The active CHK1 also directly stimulates the phosphorylation of WEE1, resulting in enhancing the inhibitory Tyr15 phosphorylation of CDK2 and CDK1 and subsequent cell-cycle blocking in the G2 phase. The activity of WEE1 can also be stimulated by the low levels of CDK activity in the G2 cell-cycle phase. The SAC, also known as the mitotic checkpoint, functions as the monitor of the correct attachment of the chromosomes to the mitotic spindle in metaphase, which is regulated by the TTK protein kinase (TTK, also known as monopolar spindle 1 (MPS1)). The activation of SAC transiently induces cell-cycle arrest by inhibiting the activation of APC/C. To establish and maintain the mitotic checkpoint, the TTK recruits many checkpoint proteins to kinetochores during mitosis via phosphorylating its substrates to ensure adequate chromosome segregation and genomic integrity. In this way, the genomic instability from chromosome segregation defects is protected by SAC. Once the SAC is passed, the APC/C E3 ligase complex stimulates and tags cyclin B and securin for ubiquitin-mediated degradation, leading to the initiation of mitosis. In a word, the checkpoints offer a failsafe mechanism to ensure the genomic integrity from the parental cell to the daughter cell. The signal transduction cascade of checkpoint activation eventually converges to CDK inhibition, which indicates the CDK function as a key driver of cell-cycle progression.

24.2.3.1: Mismatch Repair

DNA **mismatch repair (MMR)** is a highly conserved DNA repair system that greatly contributes to maintaining genome stability through the correction of mismatched base pairs and small modifications of DNA bases, such as alkylation. The major source of mismatched base pairs is replication error, although it can arise also from other biological processes. Thus, the MMR machinery must have a mechanism for determining which strand of the DNA is the template strand and which strand has been newly synthesized. In *E. coli*, methylation of the DNA is a common post-replicative modification that occurs. Thus, in newly synthesized DNA, the unmethylated strand is recognized as the new strand, and the methylated strand is used as the template to repair mismatches. In *E.coli*, MMR increases the accuracy of DNA replication by 20–400-fold. Mutations and epigenetic silencing in MMR genes have been implicated in up to 90% of human hereditary nonpolyposis colon cancers, indicating the significance of this repair system in maintaining genomic stability. Post-replicative MMR is performed by the long-patch MMR mechanism in which multiple proteins are involved and a relatively long tract of the oligonucleotide is excised during the repair reaction. In contrast, particular kinds of mismatched base pairs are repaired through very short-patch MMR in which a short oligonucleotide tract is excised to remove the lesion. Table$24.2.2$below shows mismatch repair enzymes in bacteria, yeast, and humans.

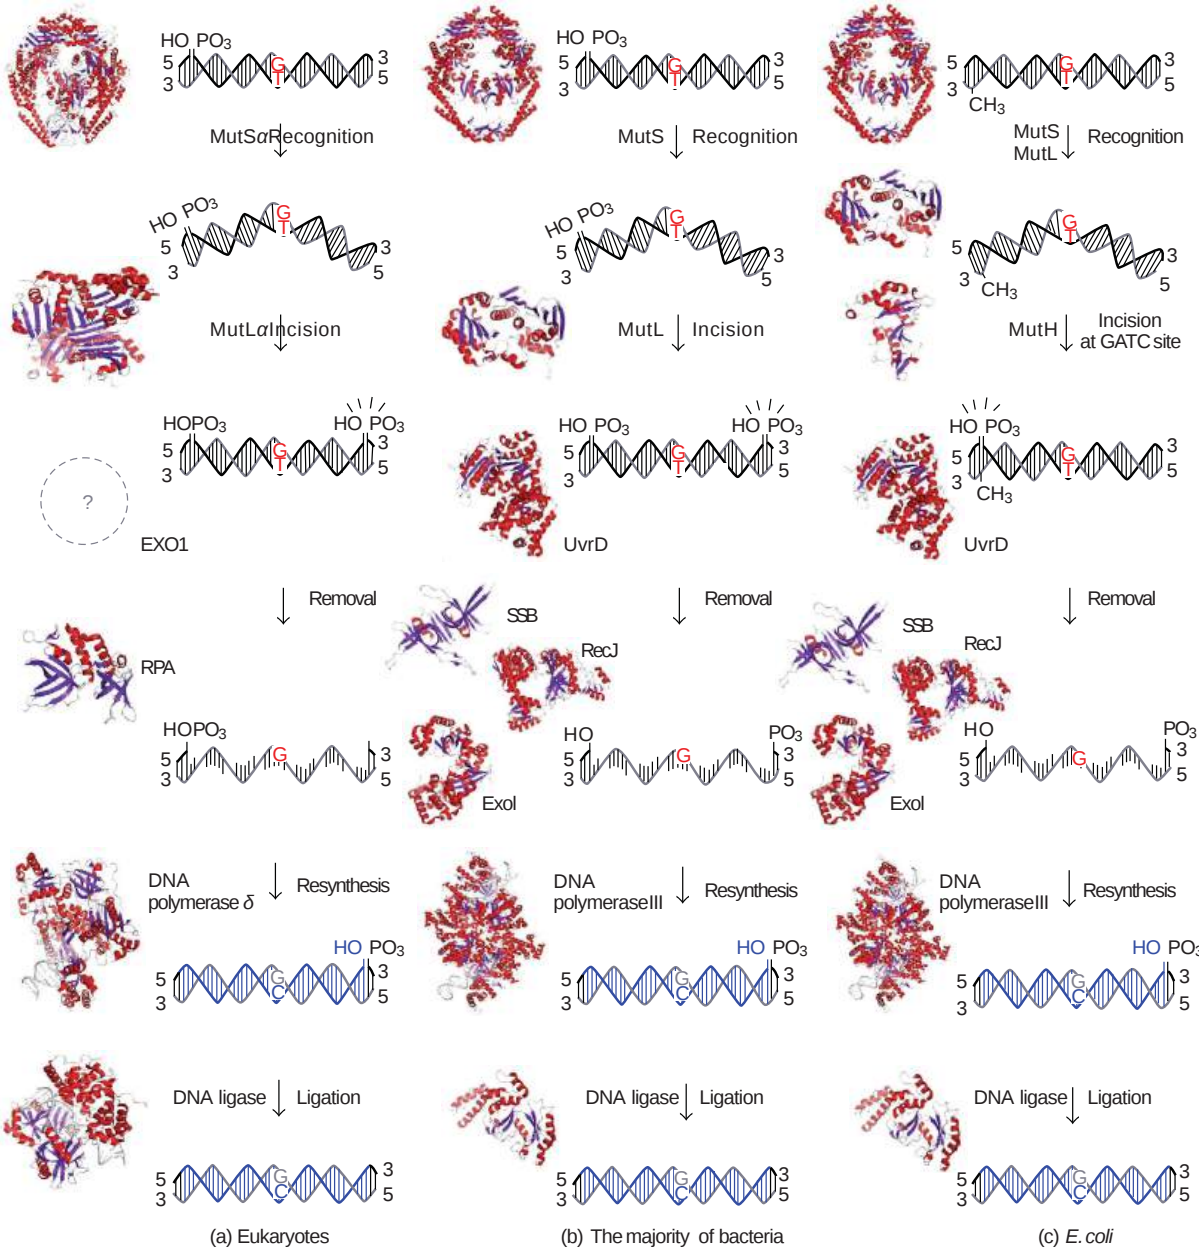
Repair synthesis	DNA polymerase III	DNA polymerase III	DNA polymerase δ	DNA polymerase δ

[*1] The involvement of bacterial clamp and clamp-loader in the strand incision reaction has not yet been confirmed. [*2] It is demonstrated that the endonuclease motif in MLH3 is responsible for in vivo MMR; however, the endonuclease activity of MutL γ has not yet been confirmed biochemically. [*3] In yeast and human, EXO1 has the 5' -flap endonuclease activity in addition to 5' - 3' exonuclease activity.

Table24.2.2: Mismatch repair enzymes in bacteria, yeast, and human

MMR in eukaryotes and most bacteria directs the repair to the error-containing strand of the mismatched duplex by recognizing the strand discontinuities. On the other hand, E. coli MMR reads the absence of methylation as a strand discrimination signal. The **MutS** protein recognizes mismatches, In both MMR systems, strand discrimination is conducted by **nicking endonucleases. MutL** homologs from eukaryotes and most bacteria incise the discontinuous strand to introduce the entry or termination point for the excision reaction. In E. coli, **MutH** nicks the unmethylated strand of the duplex to generate the entry point of excision. Figure 24.2.13shows different MMR pathway models.



24.2.4:

Figure 24.2.13 A schematic representation of MMR pathway models. Fukui, K. (2010) J. Nuc. Acids 260512. Creative Commons Attribution License

Vertical panel (a): Eukaryotic MMR. A DNA mismatch is generated by the misincorporation of a base during DNA replication. MutSα recognizes base-base mismatches and MutLα nicks the 3-or5-side of the mismatched base on the discontinuous strand. The resulting DNA segment is excised by the EXO1 exonuclease, in cooperation with the single-stranded DNA-binding protein RPA. The DNA strand is resynthesized by DNA polymerase δ and DNA ligase 1.

Vertical panel (b): MMR in mutH-less bacteria. Mismatched bases are recognized by MutS. After the incision of the discontinuous strand by MutL, the error-containing DNA strand is removed by the cooperative functions of DNA helicases, such as UvrD, the exonucleases RecJ and ExoI, and the single-stranded DNA-binding protein SSB. DNA polymerase III and DNA ligase fill the gap to complete the repair.

Vertical panel (c): E. coli MMR. MutS recognizes mismatched bases, and MutL interacts with and stabilizes the complex. Then, MutH endonuclease is activated to incise the unmethylated GATC site to create an entry point for the excision reaction. DNA

helicase, a single-stranded DNA-binding protein, and several exonucleases are involved in the excision reaction. PDB IDs of crystal structures in this figure are 2O8B (human MutSα), 1H7S (human MutLα), 1L1O (human RPA), 3IAY (human DNA polymerase δ), 1X9N (human DNA ligase 1), 1E3M (bacterial MutS), 1B63 (bacterial MutL), 2AZO (E. coli MutH), 2ISI (bacterial UvrD), 2ZXO (bacterial RecJ), 3C95 (bacterial ExoI), 2CWA (bacterial SSB), 2HQA (bacterial DNA polymerase III), and 2OWO (bacterial DNA ligase).

Figure 24.2.14shows an interactive iCn3D model of the E. Coli DNA Mismatch Repair Protein Muts Binding to a G-T Mismatch (1E3M).

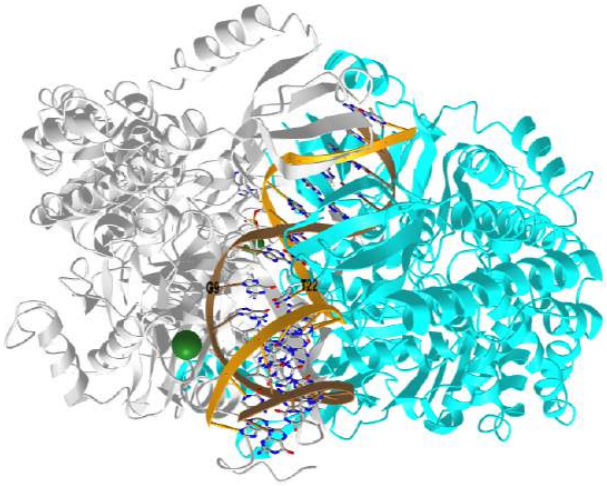


Figure 24.2.14: E. Coli DNA Mismatch Repair Protein MutS Binding to a G-T Mismatch (1E3M). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?YHB4ptjaS1mt7gp3A

The MutS monomers are colored gray and cyan. The mismatched G9-T22 base pair is labeled. ADP is shown in spacefill. Phe 36 from the gray monomer is shown in magenta.

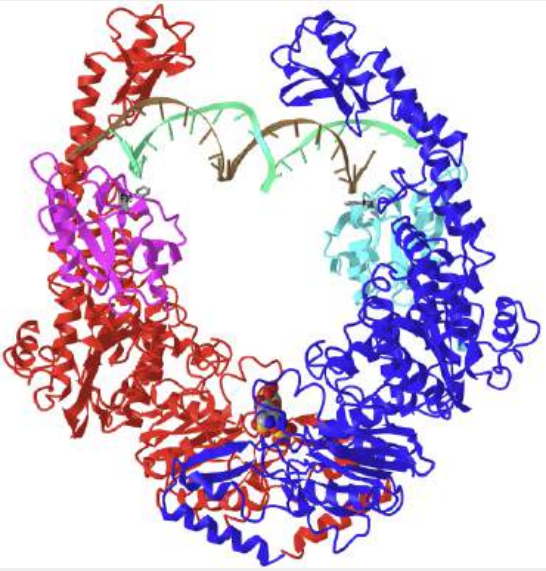
The conformation of the monomers is different, so the dimer displays pseudo symmetry. Both subunits contribute to DNA binding, but only one (gray) binds both ADP and the actual mismatched GT base pair, the llatterthrough minor grove interactions, which kinks the DNA. General major grove interaction clamps the DNA. Note how far away the ADP binds. Phenylalanine 36 in the gray subunit (which binds the mismatch) inserts adjacent to the mismatch.

ATP is bound and hydrolyzed to ADP by the MutS protein on binding the mismatch. Next, a dimer of MutL binds in a process that also requires ATP. MutH, a nuclease, also binds to MutL. The bound DNA is scanned until a "signal" is detected. In E. Coli, the signal is a GATC sequence that is methylated on just one strand and nicked by the MutH on the unmethylated GATC. Helicase II binds and unwinds the DNA in the region of the mismatch. Exonucleases (3' to 5' or 5' to 3') remove the sequence on the mismatched. PolII and DNA ligase then repair the DNA.

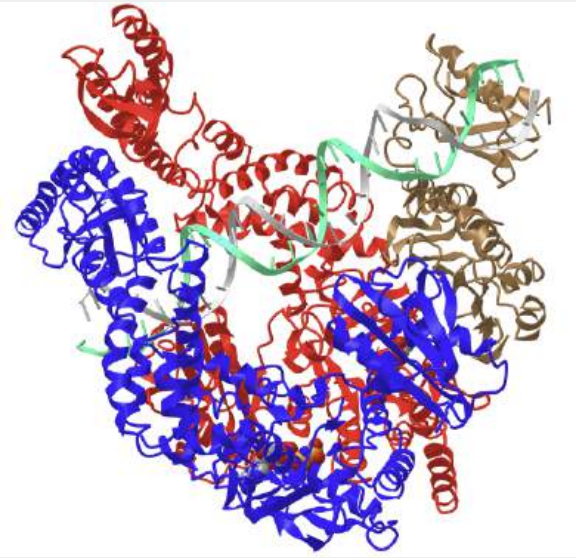
MutS is yet another fascinating enzyme as it must scan millions of DNA bases without initiating repair until it localizes a mismatch. A series of sequential conformation changes that lead to specific recognition of the mismatch must occur.

Fernandez-Leiro et al have determined the structure of MutS in a variety of stages along the repair pathway. Figure 24.2.15 shows interactive iCn3D models of the E. Coli MutS scanning form (EMD-11791, PDB 7AI5) and the more progressed MutS:MutL kink clamped form (EMD-11795, PDB 7AIC)

E. Coli MutS scanning form (EMD-11791, PDB 7AI5)	E. Coli MutS with MutL in kink clamped form (EMD-11795, PDB 7AIC)



Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...pdHkXxzXsZnqu6



Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...hQ6PeKbQeCw916

Figure 24.2.15: E. Coli MutS scanning form (EMD-11791, PDB 7AI5) (left) and the more progressed MutS:MutL kink clamped form (EMD-11795, PDB 7AIC) (right)

In the scanning form, the 2 monomers have been color coded as follows: monomer 1, N-terminal the interacts with DNA magenta, with the rest of the protein in red; monomer 2, the N-terminal part reacts with the DNA cyan, and the rest of the chain blue. In the kink-clamped state (right) the N-terminal magenta and N-terminal cyan sections were not present in the resolved structure. ATP is shown in spacefill.

These structures suggest that during scanning by the homoduplex of normal DNA, the conformational change necessary for MutS to morph to the kink-clamped state can not occur due to a steric block. Kinking of the DNA at the mismatch removes the steric block.

 Video 1: Molecular mechanism of DNA mismatch repair initiation. Front and side views of MutS passing through the first four stages of the repair cascade: DNA scanning, mismatch recognition, intermediate state, and MutL recruitment. The movements show a computational morphing between the four cryo-EM structures. MutS monomer A is shown in a pale-green color, monomer B in pale blue, DNA in dark gray, and $MutL^{LN40}$ in yellow.

 Video 2: Mismatch repair licensing at a mismatch. Top and side views of MutS as it transforms from the DNA-scanning state to the mismatch-bound state. The initial part of the movie represents the movement of monomer B relative to monomer A during the scanning state, as derived from the principal component analysis of the multibody refinement. Note that the MutS dimer explores multiple conformations, attempting to distort the DNA, without crossing over the opposite monomer. When a mismatch is present in the DNA, it allows MutS to deform and kink the DNA and the two MutS monomers to cross over in a clockwise manner. Movements show a computational morphing between the different states. MutS monomer A is shown in a pale-green color, monomer B in pale blue, and DNA in gray. The DNA mismatch is highlighted in pink

 Video 3: Multiple conformational changes of mismatch and connector domains tracking DNA. Front and side views of MutS as it goes from the mismatch-bound state to the $MutL^{LN40}$-bound clamp state via the intermediate state. MutS monomer A is shown in a pale green color, monomer B in pale blue, and DNA in dark gray. DNA mismatch is highlighted in pink. The mismatch domain is shown in dark green and the connector domain in light green. The ends of a central helix in the connector domain are colored in red and blue for clarity. Movements show a computational morphing between the different states.

24.2.5: Base Excision Repair

Most oxidized bases are removed from DNA by enzymes operating within the Base Excision Repair (BER) pathway. Single-stranded DNA breaks can also be repaired through this process. Removal of oxidized bases in DNA is fairly rapid. For example, 8-oxo-dG was increased 10-fold in the livers of mice subjected to ionizing radiation, but the excess 8-oxo-dG was removed with a half-life of 11 minutes. 8-oxoG is excised by 8-oxoguanine DNA glycosylase (OGG1) leaving an apurinic site (AP site), as shown in Figure 24.2.16. AP sites are then processed further into single-strand breaks via backbone incision of AP-endonuclease 1 (APE1). In long patch base excision repair, the base and some additional nucleotides are replaced dependent on the activity of polymerase delta (Polδ) and epsilon (Polε) together with proliferating cell nuclear antigen (PCNA). The old strand is removed by Flap-endonuclease 1 (FEN1), before ligase I (LigI) ligates the backbone back together. Short patch base excision repair constitutes of polymerase beta (Polβ) replacing the single missing base, ligase III (LigIII) ligating the DNA backbone back together, and X-ray repair cross-complementing protein 1 (XRCC1) aiding the process and serving as a scaffold for additional factors.

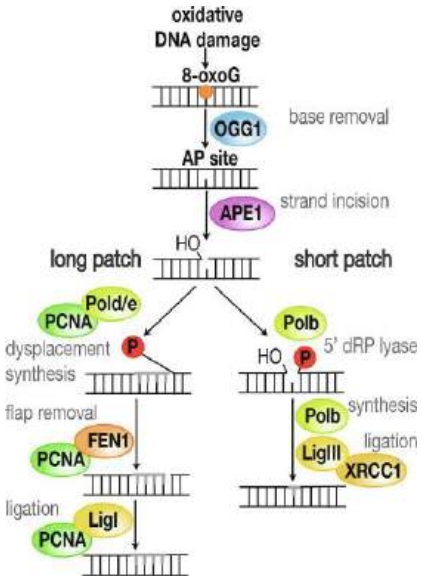

Figure (\PageIndex{16}\): Base Excision Repair. Poetsch, A.R. (2020) Comp & Struct Biotech J. 18:207-219.

Base excision repair (BER) of 8-oxo-7,8-dihydroguanine (8-oxoG). Oxidative DNA damage is repaired via several repair intermediates by base excision repair (BER). Through the emoval of the oxidized base, a reactive apurinic site (AP site) is formed. Incision of the strand creates a single-strand break, and the damaged site is then repaired through either short or long patch BER.

24.2.5.1: 25.2.6 Nucleotide Excision Repair

Bulky DNA adducts and DNA crosslinks, such as those caused by UV light are repaired using Nucleotide Excision Repair (NER) pathways. In higher eukaryotic cells, NER excises 24-32 nucleotide DNA fragments containing the damaged lesion with extreme accuracy. Reparative synthesis using the undamaged strand as a template, followed by ligation of the single-strand break that emerged as a result of the damage, is the final stage of DNA repair. The process involves the coordinated action of approximately 30 proteins that successively form complexes with variable compositions on the DNA. NER consists of two pathways distinct in terms of initial damage recognition. ***Global genome nucleotide excision repair (GG-NER)*** detects and eliminates bulky damages in the entire genome, including the untranscribed regions and silent chromatin, while ***transcription-coupled nucleotide excision repair (TC -NER)*** operates when damage to a transcribed DNA strand limits transcription activity. TC-NER is activated by the stalling of RNA polymerase II at the damaged sites of a transcribed strand, while GG-NER is controlled by the protein, XPC, a specialized protein factor that reveals the damage. A schematic GG-NER process is presented in Figure (\PageIndex{17}\) below.

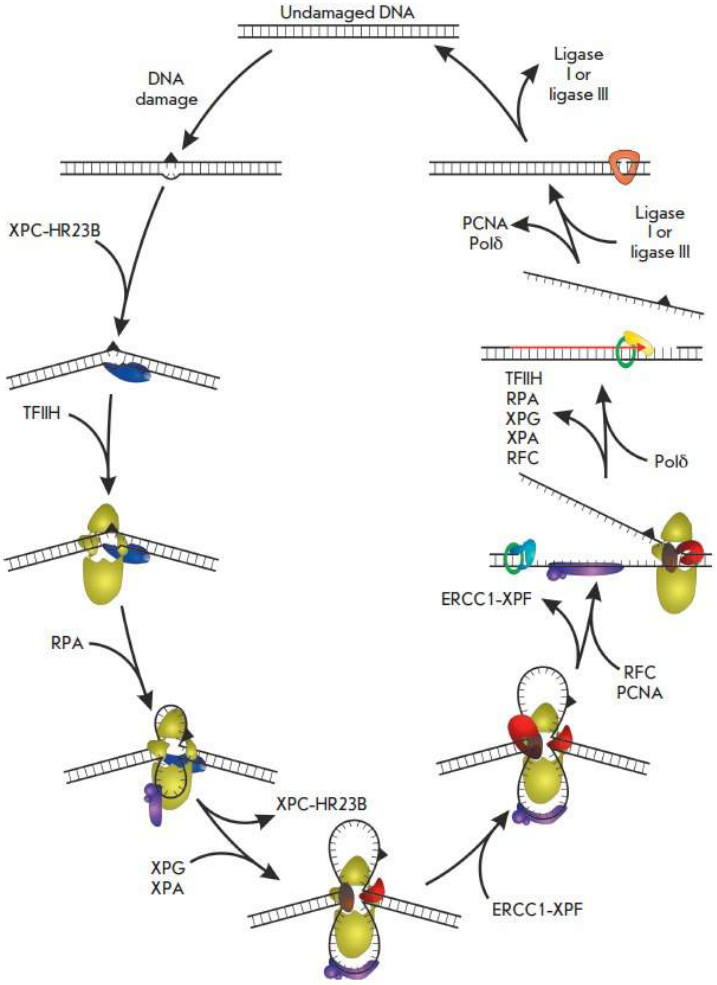

Figure (\PageIndex{17}\): Schematic of Global Genome Nucleotide Excision Repair. Figure from: Petruseva, I.O., et al (2014) 6(1):23-34.

Genetic mutations in NER pathway genes can result in UV-sensitive and high-carcinogenic pathologies, such as xeroderma pigmentosum (XP), Cockayne syndrome (CS), and trichothiodystrophy (TTD), as well as some neurodegenerative manifestations.

Xeroderma pigmentosum has provided the names of some of the genes involved in NER. Mutation of XP genes and loss of proper NER function causes the symptoms associated with the disease. People with XP have an impaired ability to repair bulky DNA adducts and crosslinks, such as thymine dimers that are caused by UV-light exposure. People suffering from XP have extreme photosensitivity, skin atrophy, hyperpigmentation, and a high rate of sunlight-induced skin cancer. The risk of internal tumors in XP patients is also 1,000-fold higher. Moreover, the disease is often associated with neurologic disorders. Currently, there is no effective treatment for this disorder.

The detection of bulky DNA lesions during NER is particularly challenging for a cell, which can be solved only through highly sensitive recognition that requires multiple protein components. In contrast to BER, where a damaged base is simultaneously recognized and eliminated by a single specialized glycosylase, specialized groups of proteins are responsible for the recognition of the lesion and the excision of the lesion in NER. In eukaryotic NER, universal sensor proteins perform the initial recognition of the total range of bulky damages. In the case of TC-NER, it occurs when the transcribing RNA polymerase II is stalled by damage; in GG-NER, these are complexes of the XPC factor and DDB1-DDB2 heterodimer (XPE factor) enhancing the repair of UV damage. In general, NER recognition of damage is a multistep process involving several proteins that form near damaged complexes of variable compositions. The process is completed by the formation of a preincision complex ready to eliminate a damaged DNA fragment by specialized NER endonucleases.

In a eukaryotic cell after stable XPC/DNA complex formation during the initial recognition of the damage, NER is performed by a ***repairasome***, which is a complex of variable composition and architecture consisting of a large number of subunits. Individual

subunits of the complex have no sufficient affinity and selectivity to the substrate (DNA containing bulky damage). The situation changes when specific protein complexes are established at the damage site. A total of 18 polypeptides must be accurately positioned within two or three DNA turns when a stable structure ready for damage removal is formed and excision starts. The structure of NER-associated proteins provides the possibility of contact with the DNA substrate and of dynamic specific protein-protein interactions. The changes in interactions performed by the same protein are one of the mechanisms that regulate the repair process and fine-tune the complexes, providing high-precision nucleotide excision repair.

24.2.5.2: 25.2.7 Repair of Double-Stranded DNA Breaks

Cells have evolved two main pathways to repair double-strand breaks within the DNA: ***the non-homologous end-joining (NHEJ) pathway***, which ensures direct resealing of DNA ends; and ***the homologous recombination (HR) pathway*** that relies on the presence of homologous DNA sequences for DSB repair, as shown in Figure (\PageIndex{18}\) below.

NHEJ repair is the simplest and most widely utilized mechanism to repair DSB that occur in DNA. Repair by NHEJ involves direct resealing of the two broken ends independently of sequence homology. Although being active throughout the cell cycle, NHEJ is relatively more important during the G1 phase. Proteins required for NHEJ include but are not restricted to, the highly conserved Ku70/Ku80 heterodimeric complex, DNA-dependent protein kinase catalytic subunit (DNA-PKcs), and DNA Ligase IV (LIG4) in complex with XRCC4. By directly binding DNA ends, Ku70/Ku80 ensures protection against exonucleases and, as such, acts as an inhibitor of HR. Very short sequence homologies are likely to help DNA end alignment before NHEJ-dependent repair, however, they are not strictly required. NHEJ protects genetic integrity by rejoining broken strands of DNA that may otherwise be lost during DNA replication and cell regeneration. However, during the process of NHEJ, insertions or deletions within the joined regions may occur (Fig 25.2.17).

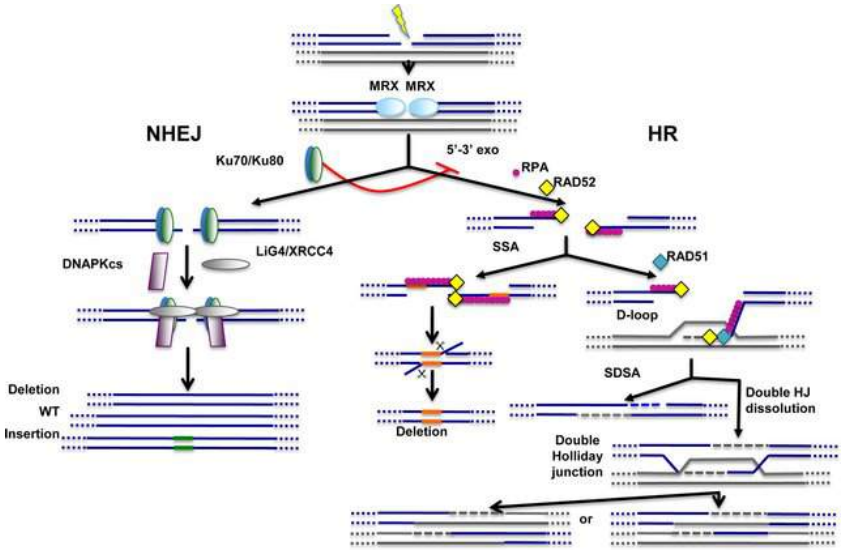

Figure (\PageIndex{18}\): Main Pathways of DNA Double-Stranded Break Repair. Diccotignies, A. (2013) Frontiers in Genetics 4(48):48

Non-homologous end-joining (NHEJ) and homologous recombination (HR) pathways act competitively to repair DNA double-strand breaks (DSBs). Key players of NHEJ and HR are depicted. The MRE11/RAD50/XRS2 (MRX) complex is recruited very early at DNA ends and appears to play important roles for both NHEJ and HR. Ku70/Ku80 heterodimer is required for NHEJ and, through inhibition of DNA end resection (5′–3′ exo), acts as a repressor of HR. The fidelity of NHEJ-dependent DSB repair is low and, most of the time, associated with nucleotide deletions and/or insertions at repair junctions. The common early step of HR-dependent mechanisms is the formation of ssDNA which is then coated by replication protein A (RPA). Single-strand annealing (SSA) mechanism requires the presence of direct repeats (shown in orange) on both sides of the break. SSA does not imply any strand invasion process and is therefore not dependent on RAD51 protein. Strand invasion and D-loop formation are however common steps of synthesis-dependent strand annealing (SDSA) and double Holliday junction (HJ) dissolution mechanisms. In the latter case, double Holliday junctions are resolved with or without crossing over.

In contrast to NHEJ, homologous recombination (HR) requires a homologous DNA sequence to serve as a template for DNA-synthesis-dependent repair and involves extensive DNA-end processing. As expected, HR is extremely accurate, as it leads to precise repair of the damaged locus using DNA sequences homologous to the broken ends. HR predominantly uses the sister

chromatid as a template for DSB repair, rather than the homologous chromosome. Correspondingly, HR is largely inhibited while cells are in the G1 phase of the cell cycle when the sister chromatid has not yet been replicated, as shown in panel (A) of Figure (\PageIndex{19}\) below. HR repair mechanisms play a bigger role in DSB repair that occurs after S-phase DNA replication (S-phase, G2, and M).

Repair through HR is not defined by a unique mechanism but operates through various mechanistically distinct DSB repair processes, including synthesis-dependent strand annealing (SDSA), double Holliday junction resolution, and single-strand annealing (SSA). The common step for HR-dependent DSB repair mechanisms is the initial formation of single-stranded DNA (ssDNA) for pairing with homologous DNA template sequences. For this to occur, the 5' DNA strand at the DSB is processed by multiple nucleases and accessory proteins to create a 3' ssDNA section that can be used as a template for recombination (see Figure 18 above).

Panel B of Figure (\PageIndex{19}\) below provides a more detailed look at the HR process. During the highly regulated process of HR, three main phases can be distinguished. Firstly, 3′-single-stranded DNA (ssDNA) ends are generated by nucleolytic degradation of the 5′-strands. This first step is catalyzed by endonucleases, including the MRN complex (consisting of Mre11, Rad50, and Nbs1). In the second step, the ssDNA-ends are coated by replication protein A (RPA) filaments. In the third step, RPA is replaced by Rad51 in a BRCA1- and BRCA2-dependent process, to ultimately perform the recombinase reaction using a homologous DNA template.

Importantly, HR is not only employed to repair DNA lesions induced by DNA-damaging agents but is also essential for proper chromosome segregation during meiosis. The relevance of HR in these physiological processes is illustrated by its strict requirement during development. Mice lacking key HR genes, such as *Brca1*, *Brca2*, or *Rad51*, display extensive genetic alterations which lead to early embryonic lethality. Whereas homozygous inactivation of HR genes is usually embryonic lethal, heterozygous inactivation of,*BRCA1* and *BRCA2*, does not interfere with cellular viability but rather predisposes individuals to cancer, including breast and ovarian cancer. The tumors that develop in individuals with heterozygous *BRCA1/2* mutations invariably lose their second *BRCA1/2* allele, indicating that in certain cancers, the absence of BRCA1/2 is compatible with cellular proliferation. How exactly such tumors cope with their HR defect is currently not fully understood.

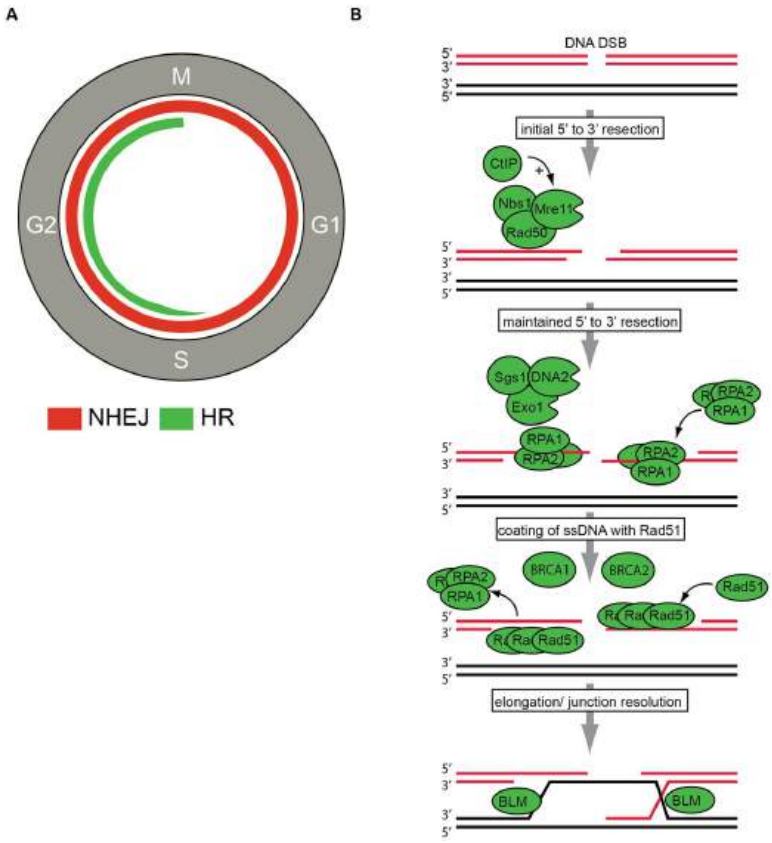

Figure (\PageIndex{19}\): **DNA double-strand break (DSBs) repair.** Krajewska, M., Fehrmann, R.S.N., de Vries, E.G.E., and van Vugt, A.A.T.M. (2015) Front. Genet. 6:96

Panel (A) shows the DNA DSBs repair pathways in the context of cell cycle regulation. Non-homologous end joining (NHEJ) can be performed throughout the cell cycle and is indicated with the red line. Homologous recombination (HR) can only be employed in S/G2 phases of the cell cycle and is indicated in green.

Pane (B) shows the key steps in the HR repair pathway are indicated. After DSB recognition, 5′–3′ end resection is initiated by the MRN (Mre11, Rad50, Nbs1) complex and CtIP. Subsequently, further resection by the Exo1, DNA2, and Sgs1 proteins is conducted to ensure 'maintained' resection. Then, resected DNA ends are bound by replication protein A (RPA). The actual recombination step within HR repair, termed strand exchange, is executed by the recombinase Rad51. Rad51 replaces RPA to eventually assemble helical nucleoprotein filaments called '*presynaptic filaments.*' This process is facilitated by other HR components, including BRCA1 and BRCA2. The final step of junction resolution is executed by helicases including Bloom syndrome, the RecQ helicase-like (BLM) helicase.

24.2.5.3: Error-Prone Bypass and Translesion Synthesis

If DNA is not repaired before DNA replication, the cell must employ another strategy to replicate the DNA, even in the presence of a DNA lesion. This is important to avoid causing double-stranded DNA breaks that can occur when a replisome stalls at the replication fork. Under these circumstances, another strategy that cells use to respond to DNA damage is to bypass lesions found during DNA replication and continue with the replicative process. DNA damage bypass can occur by recombination mechanisms or through a novel mechanism called ***translesion synthesis***. ***Translesion synthesis*** employs an alternate DNA polymerase that can substitute for a DNA polymerase that has stalled at the replication fork due to DNA damage. Specialized DNA polymerases, that are active in regions with DNA damage, have active sites that can accommodate fluctuations in DNA topography that enable them to bypass the lesions and continue with the replicative process.

The evolution of DNA polymerases that can tolerate the presence of distorted DNA lesions and continue with the replicative process can be seen at all levels of life, from prokaryotic, single-celled organisms through eukaryotic multicellular organisms, including humans. In fact, within vertebrates, there has been a large expansion of DNA polymerases that play a role in DNA

damage bypass mechanisms and highlight the importance of these processes in damage tolerance and cell survival, as shown in Table (\PageIndex{3}\) below.

Translesion DNA Polymerases		
E. coli	*S. cervisiae*	*H. sapiens*
DNA pol IV	REV1	REV1
DNA pol V	DNA polζ	DNA polζ
	DNA polη	DNA polη
		DNA polι
		DNA polκ
		DNA polμ
		DNA polλ
		DNA polθ
		DNA polυ
		DNA polσ

Table (\PageIndex{3}\): **DNA Polymerases involved in Error-Prone Bypass**

The activity of error-prone DNA polymerases is tightly regulated to avoid the rampant introduction of mutations within the DNA sequence. One of the main mechanisms that is employed within a replisome that is stalled at the replication fork due to DNA damage, involves the monoubiquitination of PCNA. Recall from Chapter 9, that PCNA is the sliding clamp that enables the DNA polymerase to bind tightly enough with the DNA during replication to mediate efficient DNA synthesis. Monoubiquitination of PCNA enables the recruitment of a translesion DNA polymerases and the bypass of the damaged lesions during DNA synthesis.

During translesion synthesis, the polymerase must insert a dNTP opposite of the lesion. None of the dNTP bases will likely be able to form stable hydrogen bond interactions with the damaged lesion. Thus, the nucleotide that causes the least distortion or repulsion will usually be added across from the lesion. This can cause transition or transversion mutations to occur at the lesion location. Alternatively, translesion polymerases can be prone to slippage, and either causes an insertion or deletion mutation in the vicinity of the DNA lesion. These slippages can lead to frameshift mutations if they occur within gene coding regions. Thus, over a lifetime, translesion synthesis in multicellular organisms can lead to an accumulation of mutations within somatic cells and cause the formation of tumors and the disease of cancer.

Evolution by natural selection is also possible due to random mutations that occur within germ cells. Occasionally, germline mutations may lead to a beneficial mutation that enhances the survival of an individual within a population. If this gene proves to enhance the survival of the population, it will be selected over time within the population and cause the evolution of that species. An example of a beneficial mutation is the case of a population of people that show resistance to HIV infection. Since the first case of infection with human immunodeficiency virus (HIV) was reported in 1981, nearly 40 million people have died from HIV infection, the virus that causes acquired immune deficiency syndrome (AIDS). The virus targets helper T cells that play a key role in bridging the innate and adaptive immune response, infecting and killing cells normally involved in the body's response to infection. There is no cure for HIV infection, but many drugs have been developed to slow or block the progression of the virus. Although individuals around the world may be infected, the highest prevalence among people 15–49 years old is in sub-Saharan Africa, where nearly one person in 20 is infected, accounting for greater than 70% of the infections worldwide, as shown in Figure (\PageIndex{20}\) below. Unfortunately, this is also a part of the world where prevention strategies and drugs to treat the infection are the most lacking.

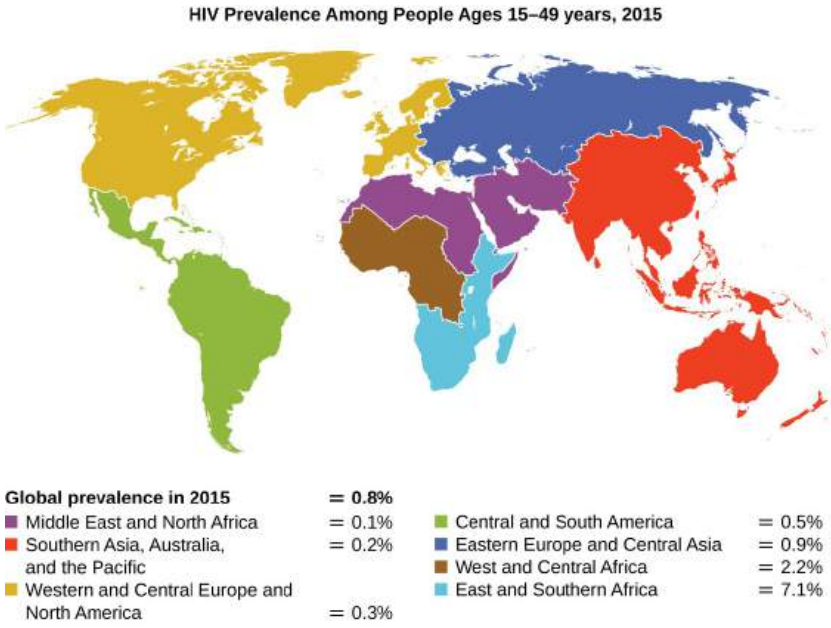

Figure (\PageIndex{20}\): HIV is highly prevalent in sub-Saharan Africa, but its prevalence is quite low in some other parts of the world. Figure from: Parker, et al (2019) Microbiology from Openstax

In recent years, scientific interest has been piqued by the discovery of a few individuals from northern Europe who are resistant to HIV infection. In 1998, American geneticist Stephen J. O'Brien at the National Institutes of Health (NIH) and colleagues published the results of their genetic analysis of more than 4,000 individuals. These indicated that many individuals of Eurasian descent (up to 14% in some ethnic groups) have a deletion mutation, called CCR5-delta 32, in the gene encoding CCR5. CCR5 is a coreceptor found on the surface of T-cells that is necessary for many strains of the virus to enter the host cell. The mutation leads to the production of a receptor to which HIV cannot effectively bind and thus blocks viral entry. People homozygous for this mutation have greatly reduced susceptibility to HIV infection, and those who are heterozygous have some protection from infection as well.

It is not clear why people of northern European descent, specifically, carry this mutation, but its prevalence seems to be highest in northern Europe and steadily decreases in populations as one moves south. Research indicates that the mutation has been present since before HIV appeared and may have been selected for in European populations as a result of exposure to the plague or smallpox. This mutation may protect individuals from the plague (caused by the bacterium *Yersinia pestis*) and smallpox (caused by the variola virus) because this receptor may also be involved in these diseases. The age of this mutation is a matter of debate, but estimates suggest it appeared between 1875 years to 225 years ago, and may have been spread from Northern Europe through Viking invasions.

This exciting finding has led to new avenues in HIV research, including looking for drugs to block CCR5 binding to HIV in individuals who lack the mutation. Although DNA testing to determine which individuals carry the CCR5-delta 32 mutation is possible, there are documented cases of individuals homozygous for the mutation contracting HIV. For this reason, DNA testing for the mutation is not widely recommended by public health officials so as not to encourage risky behavior in those who carry the mutation. Nevertheless, inhibiting the binding of HIV to CCR5 continues to be a valid strategy for the development of drug therapies for those infected with HIV.

24.2.6: Practice Problems

24.2.6.1: Multiple Choice

Which of the following is a change in the sequence that leads to the formation of a stop codon?

1. missense mutation
2. nonsense mutation
3. silent mutation
4. deletion mutation

[reveal-answer q="745512"]Show Answer[/reveal-answer]
[hidden-answer a="745512"]Answer b. A nonsense mutation is a change in the sequence that leads to formation of a stop codon.

[/hidden-answer]

The formation of pyrimidine dimers results from which of the following?

1. spontaneous errors by DNA polymerase
2. exposure to gamma radiation
3. exposure to ultraviolet radiation
4. exposure to intercalating agents

[reveal-answer q="709151"]Show Answer[/reveal-answer]
[hidden-answer a="709151"]Answer c. The formation of pyrimidine dimers results from exposure to ultraviolet radiation.[/hidden-answer]

Which of the following is an example of a frameshift mutation?

1. a deletion of a codon
2. missense mutation
3. silent mutation
4. deletion of one nucleotide

[reveal-answer q="688366"]Show Answer[/reveal-answer]
[hidden-answer a="688366"]Answer a. The deletion of one nucleotide is an example of a frameshift mutation.[/hidden-answer]

Which of the following is the type of DNA repair in which thymine dimers are directly broken down by the enzyme photolyase?

1. direct repair
2. nucleotide excision repair
3. mismatch repair
4. proofreading

[reveal-answer q="755583"]Show Answer[/reveal-answer]
[hidden-answer a="755583"]Answer a. In a direct repair, thymine dimers are directly broken down by the enzyme photolyase. [/hidden-answer]

Which of the following regarding the Ames test is true?

1. It is used to identify newly formed auxotrophic mutants.
2. It is used to identify mutants with restored biosynthetic activity.
3. It is used to identify spontaneous mutants.
4. It is used to identify mutants lacking photoreactivation activity.

[reveal-answer q="770537"]Show Answer[/reveal-answer]
[hidden-answer a="770537"]Answer b. It is used to identify mutants with restored biosynthetic activity.[/hidden-answer]

24.2.6.4: Fill in the Blank

A chemical mutagen that is structurally similar to a nucleotide but has different base-pairing rules is called a _____.

[reveal-answer q="702924"]Show Answer[/reveal-answer]
[hidden-answer a="702924"]A chemical mutagen that is structurally similar to a nucleotide but has different base-pairing rules is called a **nucleoside analog**.[/hidden-answer]

The enzyme used in light repair to split thymine dimers is called _____.

[reveal-answer q="939657"]Show Answer[/reveal-answer]
[hidden-answer a="939657"]The enzyme used in light repair to split thymine dimers is called **photolyase**.[/hidden-answer]

The phenotype of an organism that is most commonly observed in nature is called the _____.

[reveal-answer q="640686"]Show Answer[/reveal-answer]
[hidden-answer a="640686"]The phenotype of an organism that is most commonly observed in nature is called the **wild type**. [/hidden-answer]

24.2.6.5: True/False

Carcinogens are typically mutagenic.

[hidden-answer a="166576"]True[/hidden-answer]

24.2.6.6: Think about It

Why is it more likely that insertions or deletions will be more detrimental to a cell than point mutations?

24.2.6.7: Critical Thinking

Below are several DNA sequences that are mutated compared with the wild-type sequence: 3′-T A C T G A C T G A C G A T C-5′. Envision that each is a section of a DNA molecule that has separated in preparation for transcription, so you are only seeing the template strand. Construct the complementary DNA sequences (indicating 5′ and 3′ ends) for each mutated DNA sequence, then transcribe (indicating 5′ and 3′ ends) the template strands, and translate the mRNA molecules using the genetic code, recording the resulting amino acid sequence (indicating the N and C termini). What type of mutation is each?

Mutated DNA Template Strand #1: 3′-T A C T G T C T G A C G A T C-5′	
Complementary DNA sequence:	[practice-area rows="1"][/practice-area]
mRNA sequence transcribed from template:	[practice-area rows="1"][/practice-area]
Amino acid sequence of peptide:	[practice-area rows="1"][/practice-area]
Type of mutation:	[practice-area rows="1"][/practice-area]

Mutated DNA Template Strand #2: 3′-T A C G G A C T G A C G A T C-5′	
Complementary DNA sequence:	[practice-area rows="1"][/practice-area]
mRNA sequence transcribed from template:	[practice-area rows="1"][/practice-area]
Amino acid sequence of peptide:	[practice-area rows="1"][/practice-area]
Type of mutation:	[practice-area rows="1"][/practice-area]

Mutated DNA Template Strand #3: 3′-T A C T G A C T G A C T A T C-5′	
Complementary DNA sequence:	[practice-area rows="1"][/practice-area]
mRNA sequence transcribed from template:	[practice-area rows="1"][/practice-area]
Amino acid sequence of peptide:	[practice-area rows="1"][/practice-area]
Type of mutation:	[practice-area rows="1"][/practice-area]

Mutated DNA Template Strand #4: 3′-T A C G A C T G A C T A T C-5′	
Complementary DNA sequence:	[practice-area rows="1"][/practice-area]
mRNA sequence transcribed from template:	[practice-area rows="1"][/practice-area]
Amino acid sequence of peptide:	[practice-area rows="1"][/practice-area]
Type of mutation:	[practice-area rows="1"][/practice-area]

24.3: DNA Recombination

Search Fundamentals of Biochemistry

24.3.1: Homologous Recombination

Homologous recombination is a type of genetic recombination in which genetic information is exchanged between two similar or identical molecules of double-stranded or single-stranded nucleic acids (usually DNA as in cellular organisms but may be also RNA in viruses). As noted in section 25.2, This process is widely used by cells to accurately repair harmful breaks that occur on both strands of DNA, known as **double-strand breaks (DSB)**, in a process called **homologous recombinational repair (HRR)**. Homologous recombination also produces new combinations of DNA sequences during **meiosis**, the process by which eukaryotes make gamete cells, like sperm and egg cells in animals. These new combinations of DNA represent genetic variation in offspring, which in turn enables populations to adapt during evolution. Homologous recombination is also used in horizontal gene transfer to exchange genetic material between different strains and species of bacteria and viruses.

Although homologous recombination varies widely among different organisms and cell types, for double-stranded DNA (dsDNA) most forms involve the same basic steps. After a double-strand break occurs, sections of DNA around the 5' ends of the break are cut away in a process called *resection*. In the *strand invasion* step that follows, an overhanging 3' end of the broken DNA molecule then "invades" a similar or identical DNA molecule that is not broken. After strand invasion, the further sequence of events may follow either of two main pathways discussed below (see Models); the DSBR (double-strand break repair) pathway or the SDSA (synthesis-dependent strand annealing) pathway. Homologous recombination that occurs during DNA repair tends to result in non-crossover products, in effect restoring the damaged DNA molecule as it existed before the double-strand break.

There are several different ways to repair DSB as illustrated in Figure 24.3.1. The broken (or **resected**) DNA with a double-stranded break must find and come together (synapse), invade (or intertwine) with the DNA of a donor, that is homologous to it. The repair can then ensue. In somatic cells that undergo mitosis and not meiosis, the preferred donor is the sister chromatid (the copy of one chromosome made during cell division) and not the homologous chromosome (from the diploid cell). Variants include **synthesis-dependent strand annealing pathway (SDSA)**. Other variants include **nonhomologous end-joining (NHEJ), microhomology-mediated end-joining (MMEJ),** and **double Holiday junction (dHJ).**

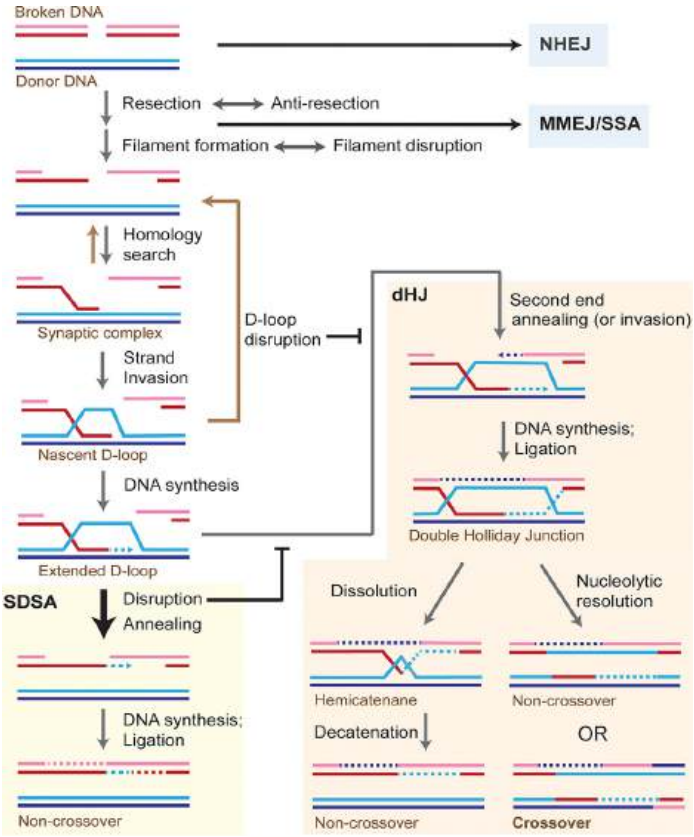

Figure 24.3.1: Model for the repair of DNA double-strand breaks by homologous recombination in somatic cells. Wright et al. J. Biol. Chem. (2018) 293(27) 10524 –10535. Creative Commons Attribution (CC BY 4.0)

When a DNA double-strand break (*DSB*) occurs in a DNA molecule, a repair can proceed by multiple pathways largely controlled by end resection. NHEJ is capable of repairing unresected or minimally resected DSBs in a template-independent fashion. MMEJ and single-strand annealing (SSA) rely on different extents of homology between the two DSB ends for repair independent of a donor molecule. Homologous recombination proceeds as shown in the figure using a homologous donor DNA. Most of the extended D-loops in somatic cells are disrupted and subsequently repaired by SDSA. The result of the repair by SDSA is always a noncrossover outcome, thus avoiding the loss of heterozygosity produced by somatic crossovers. SDSA occurs by disruption of the extended D-loop and annealing the newly synthesized DNA with the second end of the broken molecule. Alternatively, the newly synthesized strand may invade the second end. The extended D-loop can also undergo second-end capture or invasion to form a double Holliday junction (*dHJ*). This may either lead to a crossover or a noncrossover outcome. Invasion by the second break end makes dHJ formation and hence crossover outcome more likely for another model for crossover generation. dHJs can be dissolved into noncrossovers by the concerted action of the Sgs1–Top3–Rmi1 complex to migrate the two junctions toward each other and then decatenate the strands of the hemicatenane by the Top3 topoisomerase activity. Each *colored line* indicates a strand of DNA, and *dotted lines* represent DNA synthesis.

In the process of homologous recombination, a key intermediate is the **Holiday junction,** named after Robin Holiday who discovered it. It consists of branched nucleic acid with four double-stranded arms joined. A holiday junction is seen as the crossing of **red** and **blue** strands in the middle of Figure 1 labeled Nascent D-loop. Also, one is seen in the Extended D-loop just below it. A double Holiday junction is seen in the middle of the right-hand section. Two views of Holiday junctions are shown in Figure 24.3.2

Figure 24.3.2 Two views of holiday junctions. The left-hand panel shows the primary and secondary sequences and some tertiary (3D) aspects of base-stacking conformational isomers of the Holliday junction. The bases nearest to the junction point determine which stacked isomer dominates.

Figure 24.3.3 shows an interactive iCn3D model of the structure of the Holliday junction intermediate in Cre-loxP site-specific recombination (3CRX).

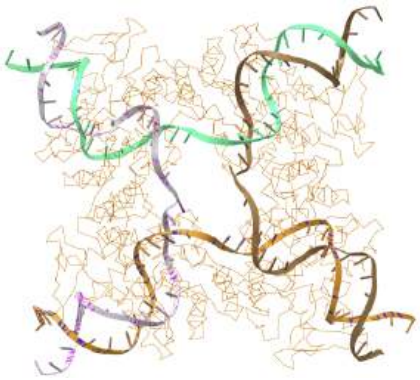

Figure 24.3.3: Structure of the Holliday junction intermediate in Cre-loxP site-specific recombination (3CRX). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...CQeGXUXiQa4AY8

The alpha carbon backbone of the four Cre recombinase monomers in the tetramer is shown in red. The DNA is nearly planar with a twofold-symmetric DNA intermediate that is similar to a square and stacked Holiday junction for the DNA in the unbound state.

Homologous recombination is conserved across all three domains of life as well as DNA and RNA viruses, suggesting that it is a nearly universal biological mechanism. The discovery of genes for homologous recombination in protists—a diverse group of eukaryotic microorganisms—has been interpreted as evidence that meiosis emerged early in the evolution of eukaryotes. Since their dysfunction has been strongly associated with increased susceptibility to several types of cancer, the proteins that facilitate homologous recombination are topics of active research. Homologous recombination is also used in gene targeting, a technique for introducing genetic changes into target organisms. For their development of this technique, Mario Capecchi, Martin Evans, and Oliver Smithies were awarded the 2007 Nobel Prize for Physiology or Medicine; Capecchi[3] and Smithies[4] independently discovered applications to mouse embryonic stem cells, however, the highly conserved mechanisms underlying the DSB repair model, including uniform homologous integration of transformed DNA (gene therapy), were first shown in plasmid experiments by Orr-Weaver, Szostack, and Rothstein.

Before the beginning of meiosis, the replication of the DNA is required to form sister chromatids, as shown in Step 1 in Figure 24.3.4 Once replicated, the DNA will condense and begin the process of meiosis. As the cells enter metaphase of meiosis, heterologous chromosomes are paired together (Step 2). When the homologous chromosomes are paired, they can under genetic mixing or DNA recombination form new chromosomal arrangements that are unique from the parental chromosomes (Step 3). Once the process of recombination is finished, the heterologous chromosomes are separated into two different daughter cells (Step 4). This is called ***Meiosis I***. At this stage the chromosomes have been reduced from the diploid to the haploid state, however, each chromosome set is still paired with its sister chromatid and needs to undergo a second round of cell division to produce the final set of four gametes (Step 5). This is called ***Meiosis II*** and results in the formation of four haploid gametes that are genetically unique.

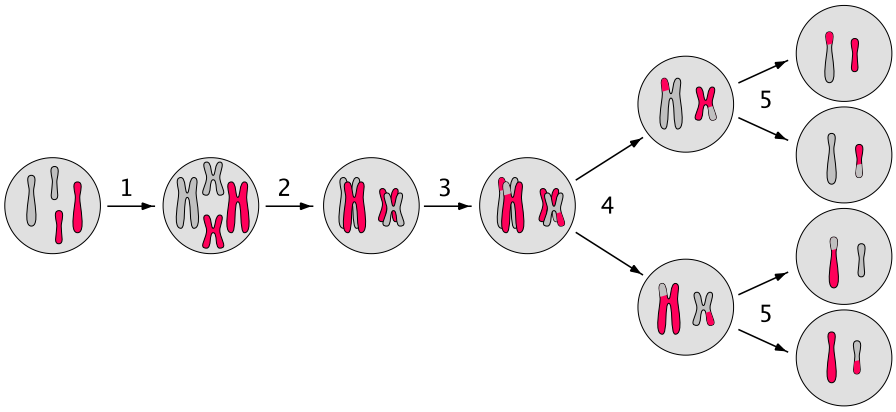

Figure 24.3.4: The Process of Meiosis. Peter Coxhead

During the process of ***meiosis,*** cell division is used to create the gametes or reproductive cells of an organism (the egg and the sperm cells). Meiosis results in the reduction of the genome from the 2n or diploid state to the 1n or haploid state. As you can see in Figure 25.3.1, the process of meiotic division results in the generation of four genetically unique haploid cells and involves the pairing of heterologous chromosomes during metaphase of meiosis. In humans, the meiotic process results in four viable sperm cells in the male and a single viable egg in the female. The other three cells produced in the female during the meiotic division are termed polar bodies and are very small and do not contain enough cytoplasmic components to survive. They get reabsorbed into the body. In either case, the resulting egg or sperm cell each carries a single copy of the genome and is in the haploid state.

It is during the process of meiosis that homologous recombination occurs in a controlled manner to introduce genetic variation into the resulting gametes. As a result, each egg and sperm cell has a unique genetic makeup that is a mixture of both parental copies of the genome.

Proper segregation during meiosis requires that homologs be connected by the combination of crossovers and sister chromatid cohesion. To generate crossovers, numerous double-strand breaks (DSBs) are introduced throughout the genome by the conserved Spo11 endonuclease. DSB formation and its repair are then highly regulated to ensure that homologous chromosomes contain at least one crossover and that no DSBs remain before meiosis I segregation. The synaptonemal complex (SC) is a meiosis-specific structure formed between homologous chromosomes during prophase that promotes DSB formation and biases the repair of DSBs to homologous chromosomes rather than back to the sister chromatids, ensuring that genetic recombination occurs. ***Synapsis,*** the pairing of homologous chromosomes, occurs when a particular recombination pathway is successful in establishing stable interhomolog connections.

24.3.2: Formation of the Synaptonemal Complex

In the 1950s, electron microscopists discovered an evolutionarily conserved, meiosis-specific structure formed between homologous chromosomes, unique to prophase I, called the SC, as shown in Figure 24.3.5. The SC physically connects homologs during prophase I and is removed before metaphase I, when homologs are connected instead by the combination of crossovers and sister chromatid cohesion. What is the function of the SC? Decades of research have shown that this elaborate chromosomal structure is critical for the regulation of recombination, the process by which crossovers are generated.

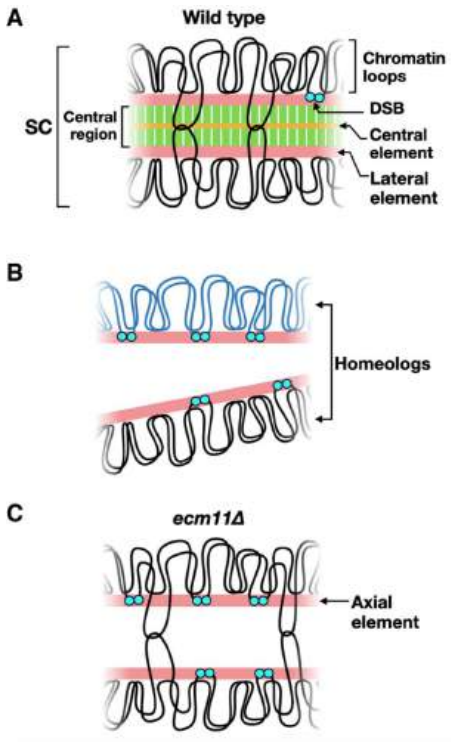

Figure 24.3.5: The relationship of DSB formation to synapsis in different situations. Hollingsworth, N.M. (2020) Genes and Dev 34:1562-1564.

Panel (*A*) shows the synaptonemal complex. When chromosomes form synapses, recombination intermediates contain double Holliday junctions (shown by intersecting loops). When cells exit the ***pachytene stage,*** the stage of meiotic prophase when chromosomes fully synapse, Holliday junctions are resolved to form crossovers, and the SC is disassembled. DSB formation is greatly reduced by synapsis but is not completely abolished until cells exit ***pachynema***.

Panel (*B*) shows the sequence diversity between homologous chromosomes largely inhibits recombination and synapsis, resulting in persistent DSB formation.

Panel (*C*) shows that in the absence of the central element, the transverse filament is not assembled, resulting in chromosomes that lack the central region. Recombination intermediates containing double Holliday junctions are still formed, but DSB formation is not down-regulated. Image from:

SC formation begins with the condensation of sister chromatids along meiosis-specific protein cores to make axial elements. Axial elements from homologous chromosomes are “zippered” together by the insertion of the central region. (Note that after synapsis, axial elements are called lateral elements (Panel A above). The central region is comprised of (1) transverse filaments located perpendicular to the lateral elements, and (2) the central element, which runs parallel to the lateral elements midway through the central region.

Assembly of the SC is initiated in the early stage of meiotic prophase I, which is commonly divided into five substages (leptotene, zygotene, pachytene, diplotene, and diakinesis). For proper assembly of the SC followed by the correct pairing of the homologous chromosome, lateral elements (LEs), which are composed of two main proteins (SYCP2 and SYCP3) should be formed along each chromosome at the initial stage, during leptotene. Later the two LEs associate with the linker part, known as the transverse filaments (TFs). TFs are primarily composed of the protein SYCP1. The central element (CE), which is composed of SYCE1, SYCE2, SYCE3, and TEX12, then connects to the LEs through the TFs, as shown in Figure 24.3.6

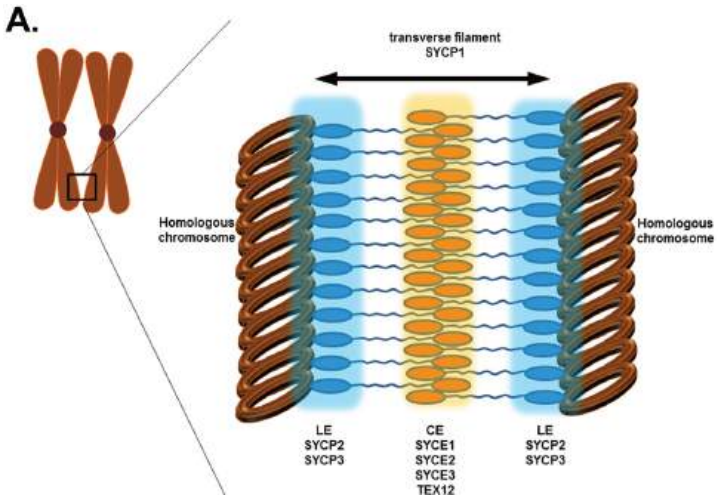

Figure 24.3.6: Organization of the Synaptonemal Complex. Image from: Seo, E.K., et al. (2016) PLOS one: DOI 10.1371

The lateral elements complete their pairing during the zygotene stage leading to the formation of the tripartite SC structure seen during the pachytene stage of the first meiotic prophase as shown in Figure 24.3.7 and Figure 24.3.8. This occurs in both males and females during gametogenesis.

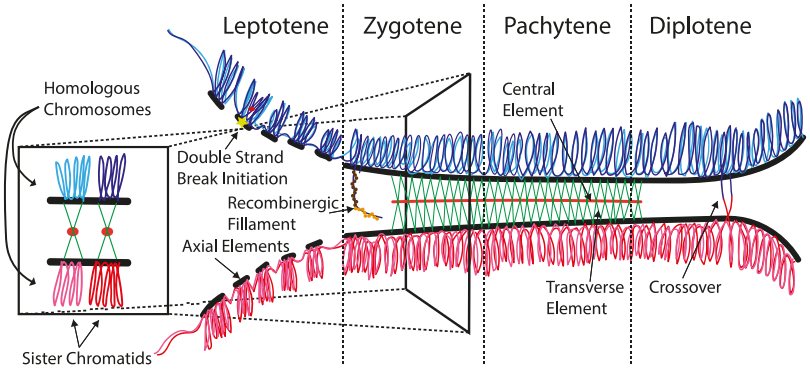

Figure 24.3.7: Schematic of the Synaptonemal Complex at Different Stages During Prophase I. Image from: Daniel Wells

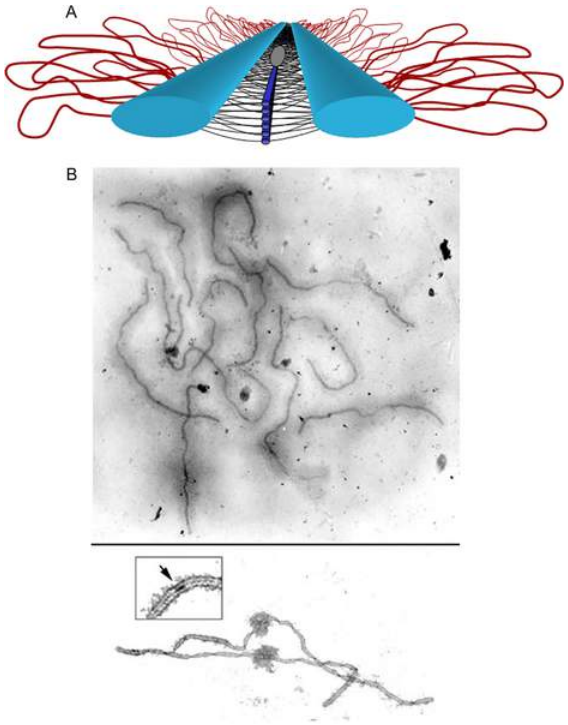

Figure 24.3.8: **The Synaptonemal Complex.** The Public Library of Science

Panel (A) shows a model of the SC. Lateral elements (light blue rods) of homologous chromosomes align and synapse together via a meshwork of transverse filaments (black lines) and longitudinal filaments (dark blue rods). The longitudinal filaments are collectively referred to as the “central element” of the SC. Ellipsoidal structures called recombination nodules (gray ellipsoid) are constructed on the central region of the SC. As their name implies, recombination nodules are believed to be involved in facilitating meiotic recombination (crossing over). The chromatin (red loops) of each homolog is attached to its corresponding lateral element. Because there are two “sister chromatids” in each homolog, two loops are shown extending laterally from each point along a lateral element.

Panel (B) Top shows a set of tomato SCs. Chromatin “sheaths” are visible around each SC showing two tomato SCs. The chromatin has been stripped from the SCs, allowing the details of the SC to be observed. Each SC has a kinetochore (“ball-like” structure) at its centromere. Recombination nodules, ellipsoidal structures found on the central regions of SCs, mark the sites of crossover events (see inset).

Zygotene is the sub-stage where synapsis between homologous chromosomes begins. It is also known as zygonema. This synapse can form up and down the chromosomes allowing numerous points of contact called 'synaptonemal complex', this can be compared to a zipper structure, due to the coils of chromatin. The SC facilitates synapsis by holding the aligned chromosomes together. After the homologous pairs synapse they are either called tetrads or bivalents. Bivalent is more commonly used at an advanced level as it is a better choice due to similar names for similar states (a single homolog is a 'univalent', and three homologs are a 'trivalent').

Once the synapse is formed it is called a bivalent (where a chromatid of one pair is synapsed/attached to the chromatid in a homologous chromosome and crossing over can occur. Subsequently, the synapses snap completing the crossing over of the genetic information. As a result, the variation in genetic material has increased significantly, because up and down the chromosome there has been an exchange of the mother and father's genetic material. The two sister chromatids separate from each other, but the homologous chromosomes remain attached. This makes the complex look much thicker. The SC is complete, allowing chiasma to form. This is what allows the crossing over alleles to occur as this is a process that only happens over a small region of the chromosomes.

The chiasma is a structure that forms between a pair of homologous chromosomes by crossover recombination and physically links the homologous chromosomes during meiosis as shown in Figure 24.3.9. Chiasmata are essential for the attachment of the homologous chromosomes to opposite spindle poles (bipolar attachment) and their subsequent segregation to the opposite poles during meiosis I.

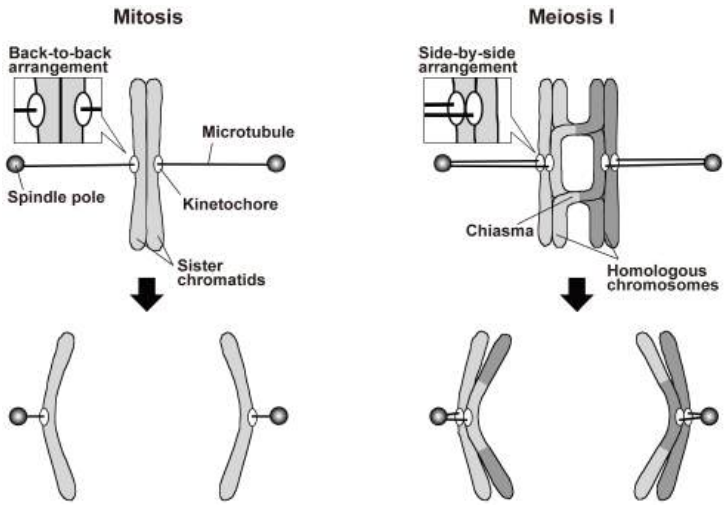

Figure 24.3.9: Chiasmata Promote Monopolar Attachment of Sister Chromatids and Their Co-Segregations Towards the Proper Pole during Meiosis I. Image from Hirose, Y., et al (2011) PLoS Genet. 7(3):e1001329

24.3.3: Mechanism of Homologous Recombination

Meiotic recombination is a tightly regulated process that is triggered by the programmed induction of DNA double-strand breaks (DSBs). Once formed, the ends of the DSBs are nucleolytically processed to generate 3′ single-stranded DNA (ssDNA) tails. Meiotic recombination factors then engage these ssDNA tails to form a nucleoprotein ensemble capable of locating DNA homology in the chromosome homolog and mediating invasion of the homolog to form a DNA joint called a displacement loop or D-loop. The 3′ end of the invading strand is extended by DNA synthesis, followed by the pairing of the non-invading 3′ single-stranded tail with the displaced ssDNA strand in the enlarged D-loop (second-end capture). After DNA synthesis and DNA ligation, a double Holliday Junction (dHJ) intermediate is formed. Resolution of the dHJ intermediate can result in crossover recombinants that harbor a reciprocal exchange of the arms of the homologous chromosomes.

Genetic studies have revealed that meiotic DSBs arise via the action of a protein ensemble that harbors the Spo11 protein, which bears homologous to archaeal Topo VIA, the catalytic subunit of a type II topoisomerase. Indeed, studies in *S. cerevisiae*, *S. pombe*, and *M. musculus* have shown that Spo11 becomes covalently conjugated to the 5′ ends of DNA through a tyrosine residue proposed to be the catalytic center of topoisomerase function. Thus, mutations in the putative catalytic tyrosine residue of Spo11 engender the same phenotype as *spo11* deletion in *S. cerevisiae*, *S. pombe*, *A. thaliana*, and *M. musculus*. All these observations suggest that Spo11 is directly involved in catalyzing DSB formation to trigger meiotic recombination. Figure 24.3.10provides an overview of this process.

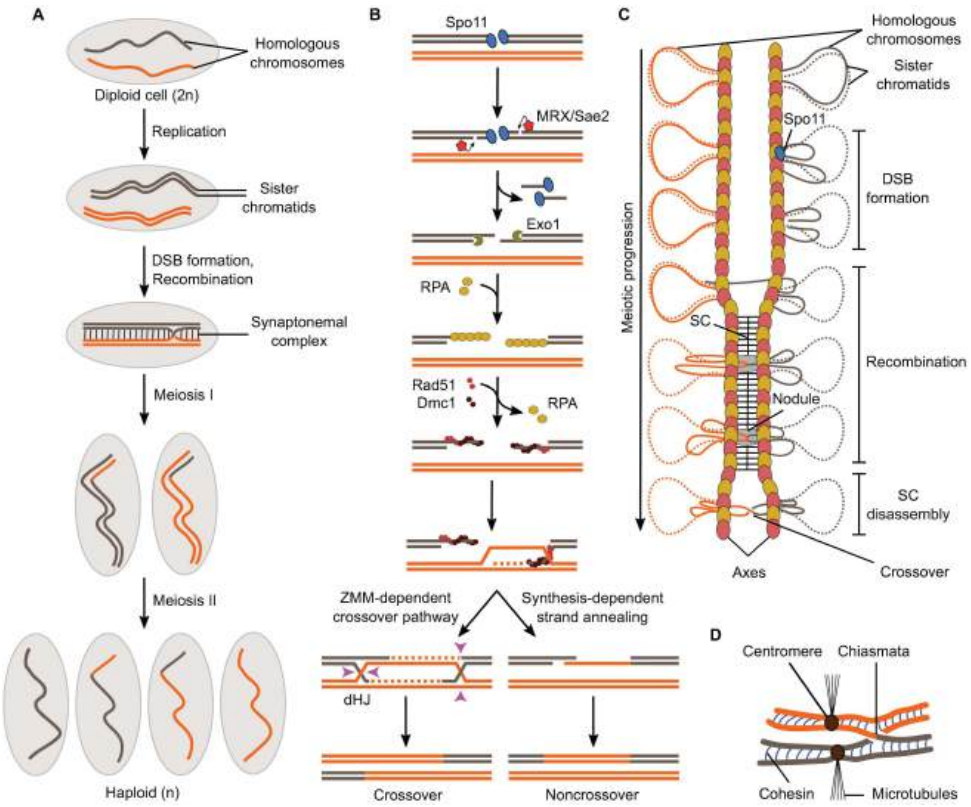

Figure 24.3.10: Overview of meiosis and meiotic recombination.Yadav, V.K. and Bouuaert, C.C. (2021) Front. Cell Dev. Biol 9:642737

Panel (A) shows a schematic of the formation of haploid gametes from a diploid cell with a single pair of homologous chromosomes. DSB formation and recombination promote homolog pairing and lead to the exchange of chromosomal fragments (crossovers) in the context of synapsed chromosomes.

Panel (B) shows meiotic recombination is initiated by Spo11-mediated DSB formation and leads to the formation of crossovers via a ZMM-dependent double Holliday Junction (dHJ) resolution pathway or non-crossovers by synthesis-dependent strand annealing.

Panel (C) shows the relationships between meiotic recombination and higher-order chromosome structure. DSB formation happens in the context of the loop-axis structure. As recombination progresses, the SC polymerizes between the axes and is disassembled before chromosome segregation. Axis proteins Red1 (red ovals) and Hop1 (yellow ovals) are shown.

Panel (D)shows that in metaphase I, homologs are held together through chiasmata and sister chromatid cohesion. Image from:

Following break formation, Spo11 remains covalently attached to the 5′-strands at both DNA ends and is released by an endonucleolytic cleavage reaction mediated by MRX (Mre11, Rad50, and Xrs2) and Sae2, which liberates Spo11 attached to a short oligonucleotide (Fig. 25.3.7B). The 5′-strands are further resected by 5′-3′ exonucleases to produce long single-stranded tails, which are coated with the ssDNA-binding protein, RPA. RPA is then replaced by recombinases Rad51 and Dmc1 that form a nucleoprotein filament and search for sequence similarity preferentially located on the homologous chromosome, producing D-loop structures. Following DNA synthesis using the homolog as a repair template, the recombination structures experience one of two main outcomes (Fig. 25.3.7B). The invading strand can be ejected from the donor by the action of helicases, which provides an opportunity for the DNA ends to re-anneal. This process is referred to as synthesis-dependent strand annealing (SDSA) and produces non-crossovers, that is, products not associated with reciprocal exchanges of chromosome fragments, but with the local transfer of genetic information from the repair template to the broken molecule (gene conversion). Alternatively, recombination structures are stabilized by the “ZMM” family of proteins and channeled through a pathway that produces mostly crossovers. Here, both ends of the break engage the donor to form a double Holliday Junction intermediate, which is resolved through a crossover-specific pathway that involves MutLγ and Exo1.

Every aspect of meiotic recombination is tied to the structural organization of the chromosomes (Fig. 25.3.7C). Early in the meiotic prophase, chromosomes organize as a series of DNA loops that are anchored along a nucleoprotein axis. DSB formation happens in the context of this loop-axis structure. As recombination progresses, polymerization of a proteinaceous structure called the

synaptonemal complex (SC) initiates between the two axes and elongates along their entire length. Recombination proceeds within the SC, inside a nodule embedded between the axes. After recombination is completed, the SC disassembles and crossovers, now cytologically visible as chiasmata, provide physical connections between the homologs until their segregation at anaphase (Fig. 25.3.7D).

CHAPTER OVERVIEW

25: RNA Metabolism

25.1: DNA-Dependent Synthesis of RNA
25.2: RNA Processing
25.3: RNA-Dependent Synthesis of RNA and DNA
25.4: 26.4 References

25.1: DNA-Dependent Synthesis of RNA

25.1.1: Types of RNA

Structurally speaking, ***ribonucleic acid (RNA)***, is quite similar to DNA. However, whereas DNA molecules are typically long and double-stranded, RNA molecules are much shorter and are typically single-stranded. A ribonucleotide within the RNA chain contains ribose (the pentose sugar), one of the four nitrogenous bases (A, U, G, and C), and a phosphate group. The subtle structural difference between the sugars gives DNA added stability, making DNA more suitable for the storage of genetic information, whereas the relative instability of RNA makes it more suitable for its more short-term functions. The RNA-specific pyrimidine ***uracil*** forms a complementary base pair with adenine and is used instead of the thymine that is found in DNA. Even though RNA is single-stranded, most types of RNA molecules show extensive intramolecular base pairing between complementary sequences within the RNA strand, creating a predictable three-dimensional structure essential for their function, as shown in Figure 25.1.1and Figure 25.1.2

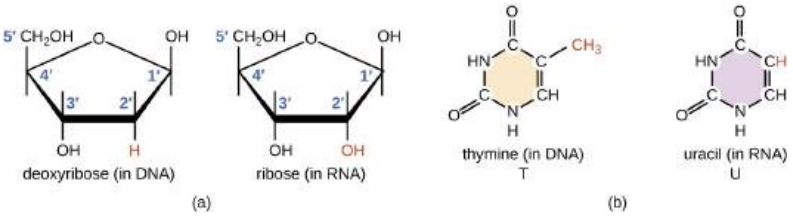

Figure 25.1.1: **RNA Structural Elements** (a) Ribonucleotides contain the pentose sugar ribose instead of the deoxyribose found in deoxyribonucleotides. (b) RNA contains the pyrimidine uracil in place of thymine found in DNA. Figure from: Parker, et al (2019) Microbiology from Openstax

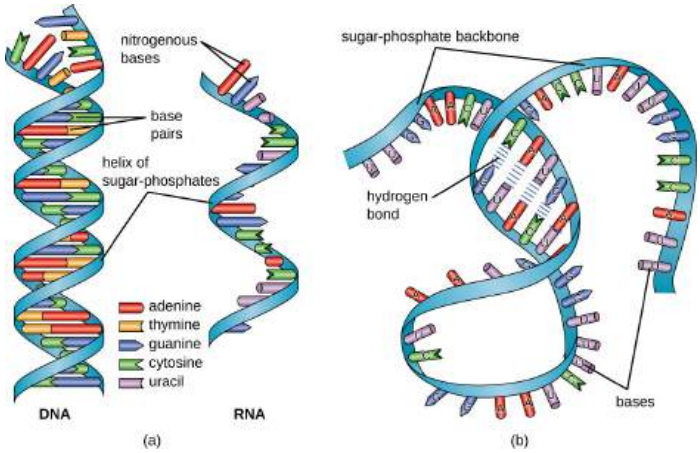

Figure 25.1.2: Parker, et al (2019) Microbiology from Openstax

RNA can largely be divided into two types, one that carries the code for making proteins or coding RNA, which is also called messenger RNA (mRNA), and non-coding RNA (ncRNA). The ncRNA can be subdivided into several different types, depending either on the length of the RNA or on the function. Size classification begins with ***the short ncRNAs*** (~20–30 nt), which include microRNAs (miRs), and small interfering (siRNAs); ***the small ncRNAs*** up to 200 nt, which include transfer RNA (tRNA), small nuclear RNA (snRNA), and small nucleolar RNA (snoRNA); and ***long ncRNAs*** (> 200 nt), which include ribosomal RNA (rRNA), enhancer RNA (eRNA) and long intergenic ncRNAs (lincRNAs), among others.

Cells access the information stored in DNA by creating RNA, through the process of ***transcription***, which then directs the synthesis of proteins through the process of ***translation***. The three main types of RNA directly involved in protein synthesis are messenger RNA (mRNA), ribosomal RNA (rRNA), and transfer RNA (tRNA). The mRNA carries the message from the DNA, which controls all of the cellular activities in a cell. If a cell requires a certain protein to be synthesized, the gene for this product is “turned on” and the mRNA is synthesized through the process of ***transcription***. The mRNA then interacts with ribosomes and other cellular machinery to direct the synthesis of the protein it encodes during the process of ***translation***. mRNA is relatively unstable and short-lived in the cell, especially in prokaryotic cells, ensuring that proteins are only made when needed.

rRNA and tRNA are stable types of RNA. In prokaryotes and eukaryotes, tRNA and rRNA are encoded by the DNA, where they are transcribed into long RNA molecules that are subsequently cut to release smaller fragments containing the individual mature

RNA species. In eukaryotes, synthesis, cutting, and assembly of rRNA into ribosomes takes place in the nucleolus region of the nucleus, but these activities occur in the cytoplasm of prokaryotes. Within the nucleolus region, ribosome assembly requires the activity of numerous snoRNAs.

Ribosomes are composed of rRNA and protein. As its name suggests, rRNA is a major constituent of ribosomes, composing up to about 60% of the ribosome by mass and providing the location where the mRNA binds. The rRNA ensures the proper alignment of the mRNA, tRNA, and the ribosomes; the rRNA of the ribosome also has an enzymatic activity (peptidyl transferase) and catalyzes the formation of the peptide bonds between two aligned amino acids during protein synthesis (Figure 26.1.3). Although rRNA had long been thought to serve primarily a structural role, its catalytic role within the ribosome was shown in 2000. Scientists in the laboratories of Thomas **Steitz** (1940–) and Peter **Moore** (1939–) at Yale University were able to crystallize the ribosome structure from *Haloarcula marismortui*, a halophilic archaeon isolated from the Dead Sea. Because of the importance of this work, Steitz shared the 2009 Nobel Prize in Chemistry with other scientists who made significant contributions to the understanding of ribosome structure. The structure and function of ribosomes will be discussed in further detail in Chapter 27.

Transfer RNA (tRNA) is the third prominent type of RNA involved in protein translation. tRNAs are usually only 70–90 nucleotides long. They carry the correct amino acid to the site of protein synthesis in the ribosome. It is the base pairing between the tRNA and mRNA that allows for the correct amino acid to be inserted in the polypeptide chain being synthesized, as shown in Figure 25.1.3 Any mutations in the tRNA or rRNA can result in global problems for the cell because both are necessary for proper protein synthesis.

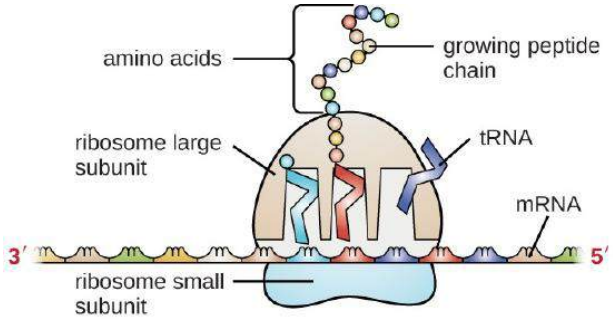

Figure 25.1.3: A generalized illustration of how mRNA and tRNA are used in protein synthesis within a cell. Figure from: Parker, et al (2019) Microbiology from Openstax

As described previously, some RNA molecules have enzymatic properties and serve as ribozymes. Within this chapter, the activity of snRNAs during the process of intron removal from mRNA sequences function as ribozymes and will be described. Furthermore, a detailed description of the enzymatic features of the ribosome structure will be provided in Chapter 27.

Other small ncRNAs and lncRNA molecules play a role in the regulation of transcriptional and translational processes. For example, the post-transcriptional expression levels of many genes can be controlled by RNA interference, in which miRNAs, specific short RNA molecules, pair with mRNA regions and target them for degradation, as shown in Figure 25.1.4 This process is aided by protein chaperones called argonautes. This antisense-based process involves steps that first process the miRNA so that it can base-pair with a region of its target mRNAs. Once the base pairing occurs, other proteins direct the mRNA to be destroyed by nucleases. Fire and Mello were awarded the 2006 Nobel Prize in Physiology or Medicine for this discovery.

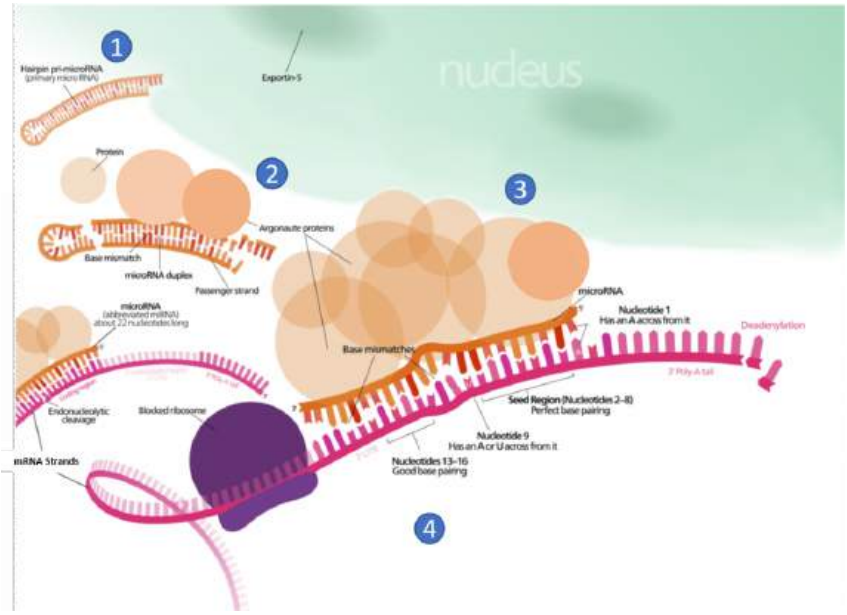

Figure 25.1.4: Role of Micro RNA (miRNA) in the Inhibition of Eukaryotic mRNA Translation. (1) A protein called Exportin-5 transports a hairpin primary micro RNA (pri-miRNA) out of the nucleus and into the cytoplasm. (2) An enzyme called Dicer (not shown), trims the pri-miRNA and removes the hairpin loop. A group of proteins, known as Argonautes, form a miRNA/protein complex. (3) miRNA/protein complex hydrogen bonds with mRNA based on complimentary sequence homology, and blocks translation. (4,5) The miRNA/protein complex binding speeds up the breakdown of the polyA tail of the mRNA, causing the mRNA to be degraded sooner. Figure modified from: Wikimedia Commons

At steady state, the vast majority of human cellular RNA consists of rRNA (~90% of total RNA for most cells) as shown in Figure 25.1.5. Although there is less tRNA by mass, their small size results in their molar level being higher than rRNA (Figure 26.1.5). Other abundant RNAs, such as mRNA, snRNA, and snoRNAs are present in aggregate at levels that are about 1–2 orders of magnitude lower than rRNA and tRNA (Figure 26.1.5). Certain small RNAs, such as miRNA and piRNAs can be present at very high levels; however, this appears to be cell type dependent. lncRNAs are present at levels that are two orders of magnitude less than total mRNA. Although the estimated number of different types of human lncRNAs may have a very restricted expression pattern and thus, accumulate to higher levels within specific cell types. For example, sequencing of mammalian transcriptomes has revealed more than 100,000 different lncRNA molecules can be produced, compared with the approximate 20,000 protein-coding genes. The diversity and functions of the transcriptome within biological processes are currently a highly active area of research.

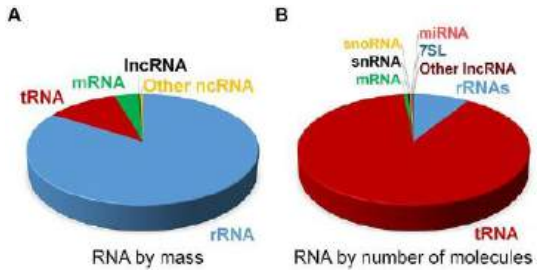

Figure 25.1.5: Estimate of RNA levels in a typical mammalian cell. The proportion of the various classes of RNA in mammalian somatic cells by total mass (A) and by the absolute number of molecules (B). The total number of RNA molecules is estimated at roughly 10^7 per cell. Other ncRNAs in (A) include snRNA, snoRNA, and miRNA. Note that due to their relatively large sizes, rRNA, mRNA, and lncRNA make up a larger proportion of the mass as compared to the overall number of molecules. Figure from: Palazzo, A. and Lee, E.S. (2015) Frontiers in Genetics 6:2

25.1.2: RNA Polymerases

This chapter will focus on the synthesis of RNA by DNA-dependent RNA Polymerase Enzymes (RNAPs). These enzymes are required to carry out the process of transcription and are found in all cells ranging from bacteria to humans. All RNAPs are multi-subunit assemblies, with bacteria having five core subunits, $\alpha_2\beta\beta'\omega$, that have **homologs** in archaeal and eukaryotic RNAPs. Bacterial RNAPs are the simplest form of RNA polymerases and provide an excellent system to study how they control transcription.

25.1.2.1: Prokaryotic RNA Polymerase Enzymes

The RNAP catalytic core within bacteria contains five major subunits ($\alpha_2\beta\beta'\omega$) (see Figure \(\PageIndex{7}\)) below. To position this catalytic core onto the correct promoter requires the association of a sixth subunit called the **sigma factor (σ)**. Within bacteria, there are multiple different sigma factors that can associate with the catalytic core of RNAP that help to direct the catalytic core to the correct DNA locations, where RNAP can then initiate transcription. For example, within *E. coli* σ^{70} is the housekeeping sigma factor that is responsible for transcribing most genes in growing cells. It keeps essential genes and pathways operating. Other sigma factors are activated during certain environmental situations, such as σ^{38} which is activated during starvation or when cells reach the stationary phase. When the sigma subunit associates with the RNAP catalytic core, the RNAP has then formed the holoenzyme. When bound to DNA, the holoenzyme conformation of RNAP can initiate transcription.

Transcription takes place in several stages. To start with, the RNA polymerase holoenzyme locates and binds to promoter DNA. At this stage the RNAP holoenzyme is it the closed conformation (RP_c), as shown in Figure 25.1.6. Initial specific binding to the promoter by sigma factors of the holoenzyme sets in motion conformational changes in which the RNAP molecular machine bends and wraps the DNA with mobile regions of RNAP playing key roles, as shown in Figure 25.1.6. Next, RNAP separates the two strands of DNA and exposes a portion of the template strand. At this point, the DNA and the holoenzyme are said to be in an 'open promoter complex' (RP_o), and the section of promoter DNA that is within it is known as a '**transcription bubble**'. Intermediates($I_{1\text{-}3}$) between RP_c and RP_o occur.

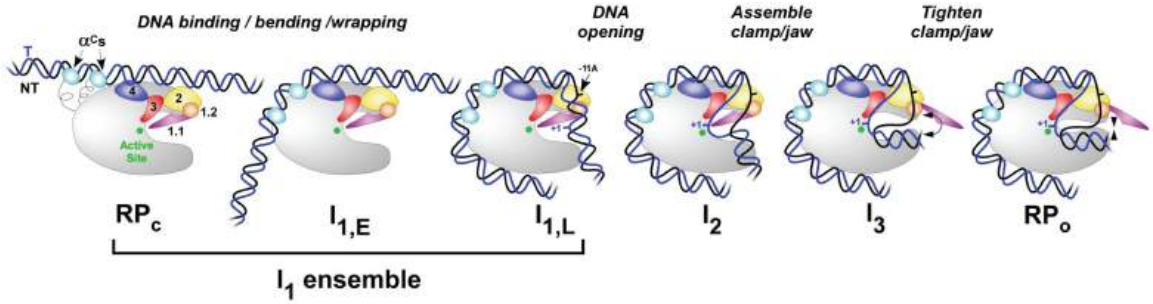

Figure 25.1.6: **Schematic Representation of *E.coli* Transcriptional Initiation.** Closed complexes like RPC, I1,E (early), or I1,L (late) can be significant members of the rapidly equilibrating I1 ensemble. RPo signifies the end of the initiation stage and entry into the elongation phase of RNA synthesis. The α domains are shown in light blue; σ domains are indicated by numbers 1.1, 1.2, 2, 3, and 4. Figure from: Ruff, E.F., et. al. (2015) Biomolecules 5(2):1035-1062.

In bacterial systems, the sigma factor locates the transcriptional start site using key DNA sequence elements located at -35 nucleotides and -10 nucleotides from the transcriptional initiation site, as shown in Panel A of Figure 25.1.7. This region is called the Pribnow box. For RNAP from *Thermus aquaticus*, the −35 element interacts exclusively with σ_4. The duplex DNA just upstream of the −10 element (−17 to −13) interacts with β′, σ_2, and σ_3 (Panel B). Flipping of the A_{-11}(nt) base from the duplex DNA into its recognition pocket in σ_2 is thought to be the key event in the initiation of promoter melting and the formation of the transcription bubble (Panel C). Once the transcription bubble has formed and transcription initiates, the sigma subunits dissociate from the complex and the RNAP catalytic subunit continues elongation on its own.

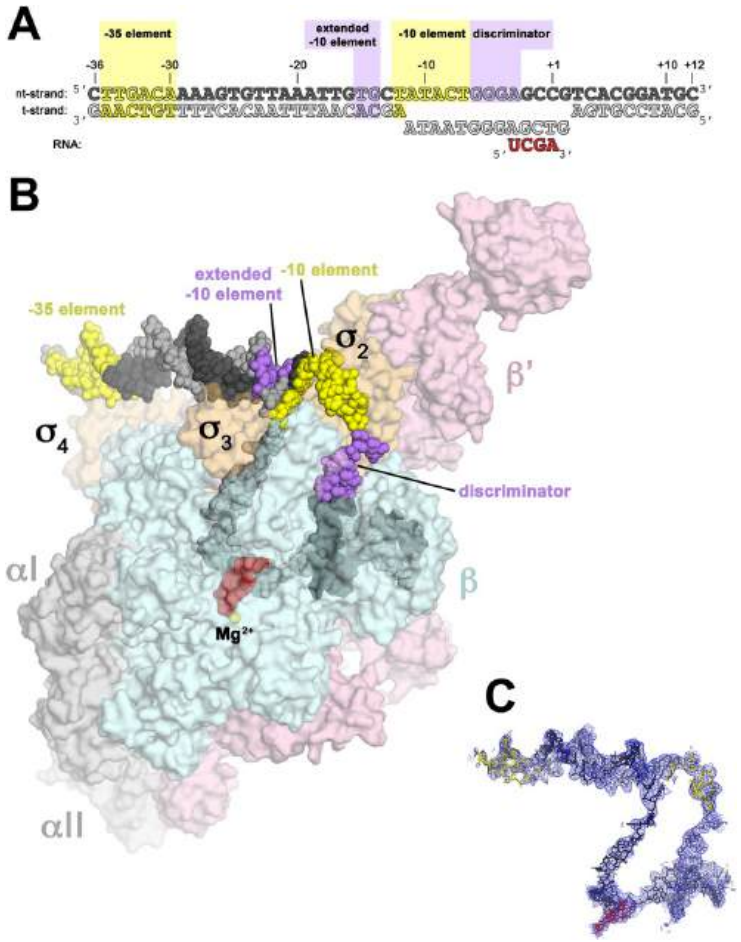

Figure 25.1.7: Structure of the RNAP Holoenzyme in *Thermus aquaticus.* (Figure modified from: Bae, B., et.al. (2015) eLife 4:e08504

Panel (A) shows oligonucleotides used for the crystallization of the RNAP holoenzyme in the open conformation. The numbers above denote the DNA position with respect to the transcription start site (+1). The −35 and −10 (Pribnow box) elements are shaded yellow, and the extended −10 and discriminator elements are purple. The nontemplate-strand DNA (top strand) is colored dark grey; template-strand DNA (bottom strand), light grey; RNA transcript, red.

Panel (**B**) shows the overall structure of RNAP holoenzyme in the open conformation bound with the DNA nucleotides. The nucleic acids are shown as CPK spheres and color-coded as in diagram A. Within RNAP, the αI, αII, ω, are shown in grey; β in light cyan; β′ in light pink; $\Delta 1.1\sigma^A$ in light orange. The *Taq* $E\Delta 1.1\sigma^A$ (Taq derives from *Thermus aquaticus*) is shown as a molecular surface and the forward portion of the RNAP holoenzyme is transparent to reveal the RNAP active site Mg^{2+} (yellow sphere) and the nucleic acids held inside the RNAP active site channel.

Panel (**C**) Electron density and model for RNAP holoenzyme nucleic acids in the open conformation. Color coding matches diagram A.

Figure 25.1.8 shows an interactive iCn3D model of the T. aquaticus transcription initiation complex containing bubble promoter and RNA (4XLN).

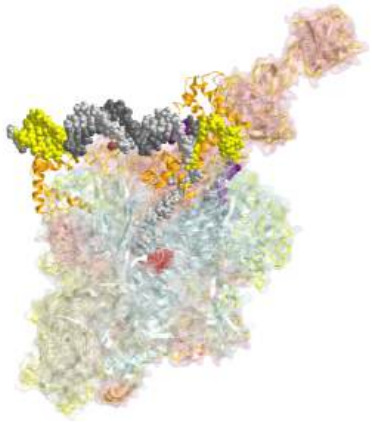

Figure 25.1.8: T. aquaticus transcription initiation complex containing bubble promoter and RNA (4XLN). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...pSXsY6HdMDdELA (long load time but worth the wait)

It is colored coded in fashion similar to that shown in Figure 25.1.7.

The rendering of the DNA is as follows:

- The non-template (nt-strand) DNA is colored dark grey; spheres
- template (t-strand) DNA, light grey; spheres
- Pribnow box yellow
- discriminator purple

The proteins are shown as surfaces with transparent secondary structures underneath. The color is as follows:

- (αI, αII, ω, light yellow;
- β, light cyan;
- β′, light pink;
- Taq EΔ1.1σ^{A}, light orange),

The RNA polymerase active site is located at the Mg^{2+} (black sphere) binding site. The nucleic acids are inside the RNAP active site channel.

25.1.2.2: Eukaryotic RNA Polymerase Enzymes

In eukaryotic cells, three RNAPs (I, II, and III) share the task of transcription, the first step in gene expression. RNA Polymerase I (Pol I) is responsible for the synthesis of the majority of rRNA transcripts, whereas RNA Polymerase III (Pol III) produces short, structured RNAs such as tRNAs and 5S rRNA. RNA Polymerase II (Pol II) produces all mRNAs and most regulatory and untranslated RNAs.

The three eukaryotic RNA polymerases contain homologs to the five core subunits found in prokaryotic RNAPs. In addition, the eukaryotic Pol I, Pol II and Pol III have five additional subunits forming a catalytic core that contains 10 subunits, as shown in Figure 25.1.9. The core has a characteristic crab-claw shape, which encloses a central cleft that harbors the DNA, and has two channels, one for the substrate NTPs and the other for the RNA product. Two ‘pinchers’, called the ‘clamp’ and ‘jaw’ stabilize the DNA at the downstream end and allow the opening and closing of the cleft. For transcription to occur, the enzyme has to maintain a

transcription bubble with separated DNA strands, facilitate the addition of nucleotides, translocate along the template, stabilize the DNA:RNA hybrid, and finally allow the DNA strands to reanneal. This is achieved by a number of conserved elements in the active site, which include the fork loop(s), rudder, wall, trigger loop, and bridge helix.

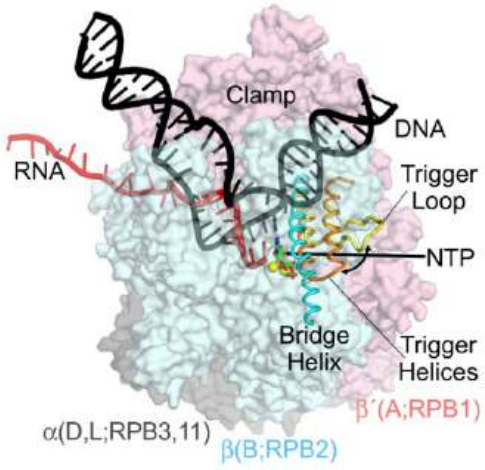

Figure 25.1.9: Structural Diagram of RNA Polymerase from *Thermus thermophilus* (PDB205j) with archaea adn eukaryotic homologs. Hein, P.P. and Landick, R. (2010) BMC Biology 8:141

DNA (black) is melting into a transcription bubble that allows template-strand pairing with RNA (red) in a 9-10 base pair RNA-DNA hybrid. The bridge helix (cyan) and trigger loop/helices (yellow/orange) lie on the downstream side of the active site. The presumed path of the NTP entry is indicated by the straight arrow. Interconversion of the trigger loop and trigger helices is indicated by the curved arrow. The RNA polymerase subunits are shown as semi-transparent surfaces with the identities of orthologous subunits in bacteria (α, β, and β', gray, blue, and pink, respectively), archaea (D, L, B, and A), and eukaryotic RNA polymerase II (RPB3, 11, RPB2, RPB1) indicated. The active site Mg^{2+} ions are shown as yellow spheres, and α,β-methylene-ATP in green and red.

Table 25.1.1 shows RNA polymerase (RNA pol) subunit composition in bacteria, archaea, and, yeast and plants (both eukaryotes).

Table 25.1.1: RNA polymerase (RNA pol) subunit composition. Abel, C., Verónica, M., I., G. A. , & Francisco, N. (2017). Subunits Common to RNA Polymerases. In (Ed.), The Yeast Role in Medical Applications. IntechOpen. https://doi.org/10.5772/intechopen.70936. Creative Commons Attribution 3.0 License

Schematic representations of the structure of the eukaryotic RNA pols I, II and III are shown in Figure 25.1.10

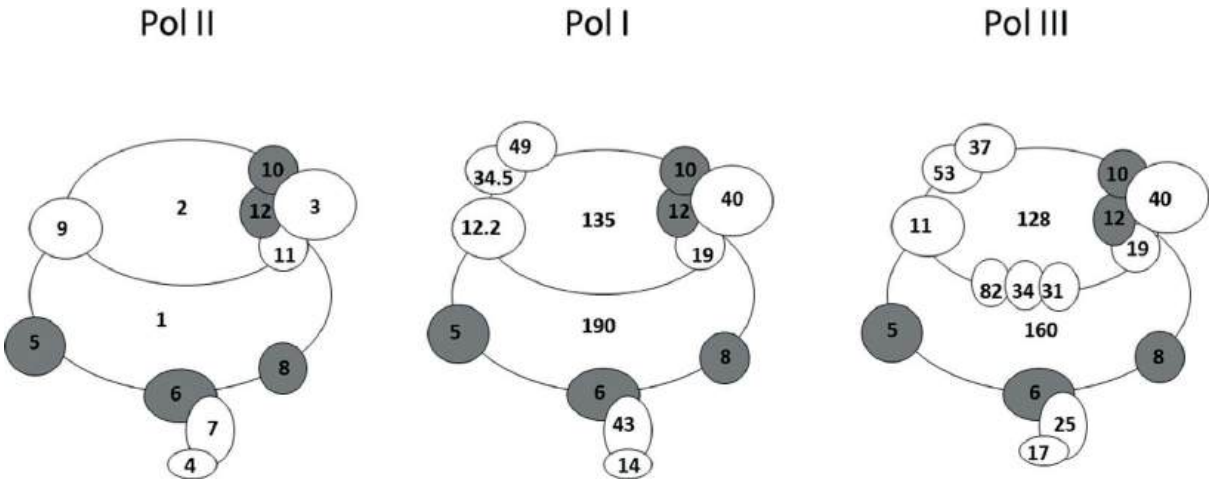

Figure 25.1.10 Schematic representation of the structure of the RNA pols I, II and III. Each RNA pol common subunit is indicated in grey. The numbers correspond to each subunit are indicated in Subunits Common to RNA Polymerases. Abel et al, ibid.

RNA polymerases must bind to DNA, and to host of **transcription factors (TF)** necessary for specific and regulatable transcription. (Note: RNAP is not considered a transcription factor.) The comparative structures of RNAP I-III are shown in Figure 25.1.11 The "stalk" is a structural feature found in eukaryotes but not in prokaryotes. The figure focuses mostly on a comparison of RNAP I and RNAP III.

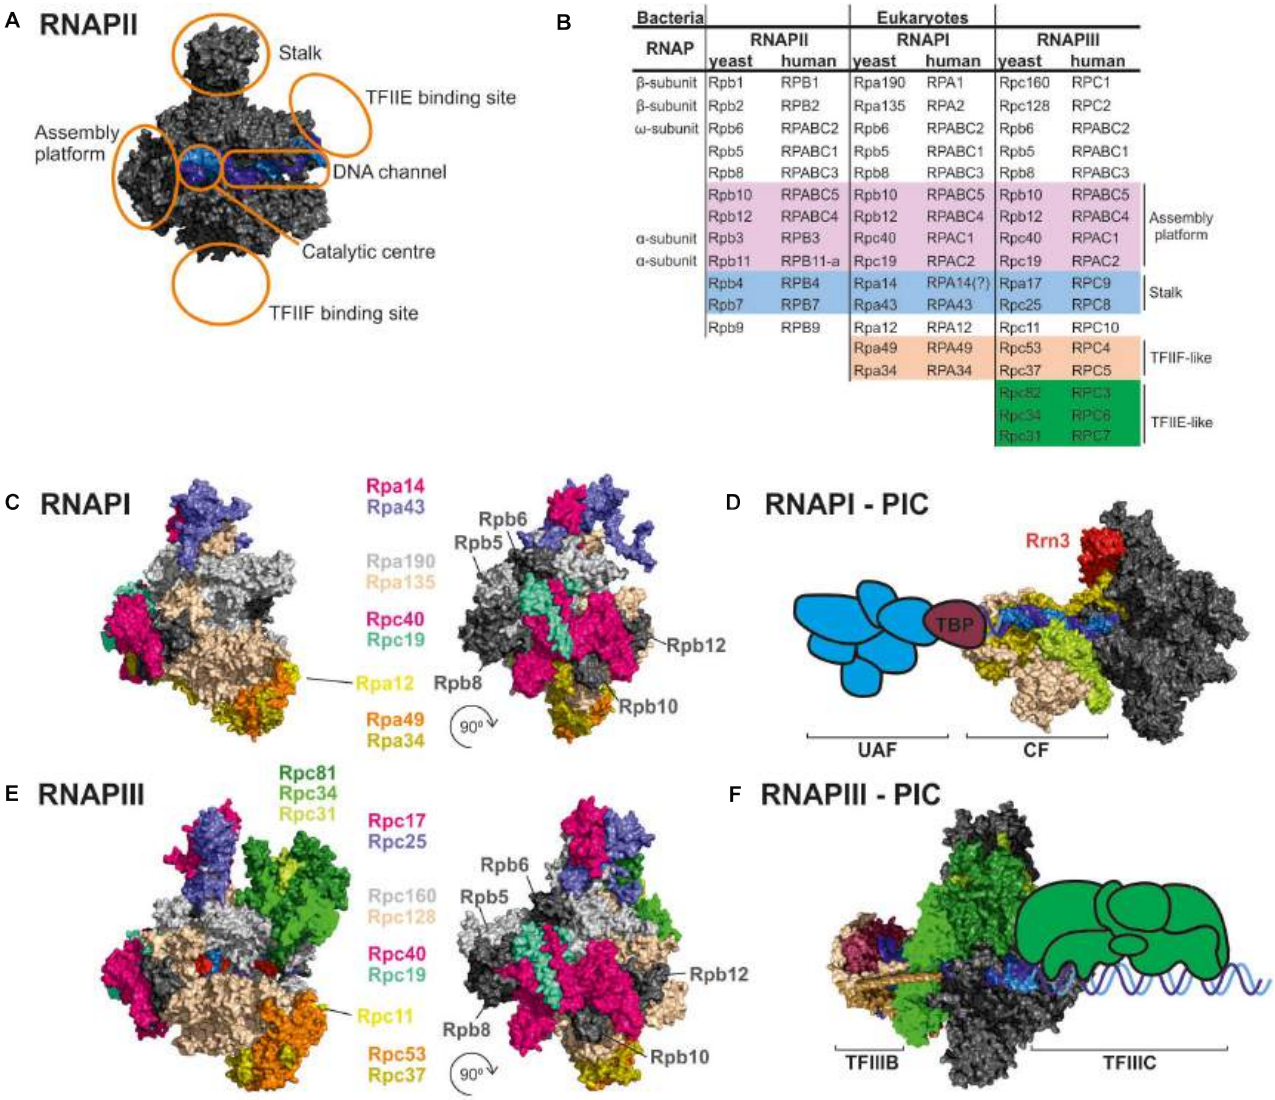

Figure 25.1.11: Comparison of RNAPI, II and III structures and transcription factors. Turowski TW and Boguta M (2021) Specific Features of RNA Polymerases I and III: Structure and Assembly. Front. Mol. Biosci. 8:680090. doi: 10.3389/fmolb.2021.680090. Creative Commons Attribution License (CC BY).

Panel (A) shows the general architecture of RNAPII, consisting of the catalytic core and stalk. RNAPII core consists of a DNA binding channel, catalytic center, and assembly platform. RNAPII binds multiple transcription factors (TFs). Some TFs are homologous to additional subunits of specialized RNAPs (i.e., TFIIF).

Panel (B) shows the subunit composition of eukaryotic RNAPs. Human nomenclature is shown for comparison. Please note that the C-terminal region of Rpa49 subunit harbors a “tandem winged helix” which is predicted in TFIIE and that human RNAPIII RPC7 subunit is coded by two isoforms α and β. The question mark indicates the name is unconfirmed.

Panel (C) shows the subunit composition of yeast RNAPI.

Panel (D) shows a Model of the RNAPI pre-initiation complex, showing an early intermediate with visible Rrn3 and core factor (CF). TATA-binding protein (TBP) and upstream-associated factor (UAF) are added schematically.

Panel (E) shows the subunit composition of yeast RNAPIII.

Panle (F) shows atomic model of RNAPIII pre-initiation complex with TFIIIB. The Rpc82/34/31 heterotrimer is involved in initiation and marked in green as in E. TFIIIC is added schematically. PDB: 5C4X, 5FJ8, 4C3J, 6EU0, and 6TPS

The stalks have two proteins that are not as homologous as the core subunits. These are highlighted in blue in Panel B of Figure 25.1.11 RNAP I and III have additional subunits compared to RNAP II. Overall RNAP I-III have 14, 12, and 17 subunits, respectively. RNAP I and III appear to have integrated transcription-like factors into their core enzyme. In contrast, RNAP II (which transcribes DNA to form messenger RNA), binds to discrete and separate transcription factors to form a **preinitiation complex (PIC)**which we will discuss below.

25.1.3: Transcription Factors and the Preinitiation Complex (PIC)

Unlike prokaryotic systems which can initiate the recruitment of RNAP holoenzymes directly onto the DNA promoter regions and mediate the conversion of RNAP to the open conformation, eukaryotic RNA polymerases require a host of additional general transcription factors (GTFs), to enable this process. Here we will focus on the activation of RNA Polymerase II as an example of the complexity of eukaryotic transcription initiation.

Class II gene transcription in eukaryotes is a tightly regulated, essential process controlled by a highly complex multicomponent machinery. A plethora of proteins, more than a hundred in humans, are organized in very large multiprotein assemblies that include a core of General Transcription Factors (GTFs). The GTFs include the factors TFIIA, TFIIB, TFIID, TFIIE, TFIIF, TFIIH, RNA polymerase (RNA pol II), as well as a large number of diverse complexes that act as co-activators, co-repressors, chromatin modifiers, and remodelers, as shown in Figure 25.1.12 Class II gene transcription is regulated at various levels: while assembling on chromatin, before and during transcription initiation, throughout elongation and mRNA processing, and termination. A host of activators and repressors has been reported to regulate transcription, including a central multisubunit complex called the ***Mediator*** that helps in the recruitment of GTFs and the activation of RNA Pol II. Here we will focus on the formation of the GTFs that make up the core ***preinitiation complex (PIC)*** during transcriptional activation.

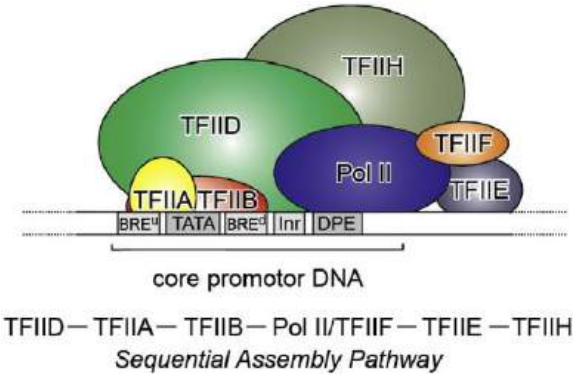

Figure 25.1.12: Transcription Preinitiation Complex (PIC). Gupta, K., et.al. (2016) J Mol Bio 428(12):2581-91.

Class II gene transcription in humans is brought about by over a hundred polypeptides assembling on the core promoter of protein-encoding genes, which then give rise to mRNA. A PIC on a core promoter is shown in a schematic representation. PIC contains, in addition to promoter DNA, the GTFs (TFIIA, B, D, E, F, and H), and RNA Pol II. PIC assembly is thought to occur in a highly regulated, stepwise fashion, as indicated. TFIID is among the first GTFs to bind the core promoter via its TATA-box Binding Protein (TBP) subunit. Nucleosomes at transcription start sites contribute to PIC assembly, mediated by signaling through epigenetic marks on histone tails. The Mediator (not shown) is a further central multiprotein complex identified as a global transcriptional regulator. TATA = TATA-box DNA; BRE^u = B recognition element upstream; BRE^d = B recognition element downstream; Inr = Initiator; DPE = Down-stream promoter element. Figure from:

Transcription of RNA pol II-dependent genes is triggered by the regulated assembly of the **Preinitiation Complex (PIC)**. PIC formation starts with the binding of TFIID to the core promoter. TFIID is a large megadalton-sized multiprotein complex with around 20 subunits made up of 14 different polypeptides: the TATA-box binding protein (TBP) and the **TBP-associated factors (TAFs)** (numbered 1–13), as shown in Figure 25.1.13 Some of the TAF subunits are present in two copies. A key feature in TAFs is the **histone fold domain (HFD),** which is present in 9 out of 13 TAFs in TFIID. The HFD is a strong protein–protein interaction motif that mediates specific dimerization. The HFD-containing TAFs are organized in discrete heterodimers, with the exception of TAF10, which is capable of forming dimers with two different TFIID components, TAF3 and TAF8. HFDs and several other structural features of TBP and the TAFs are well conserved between species.

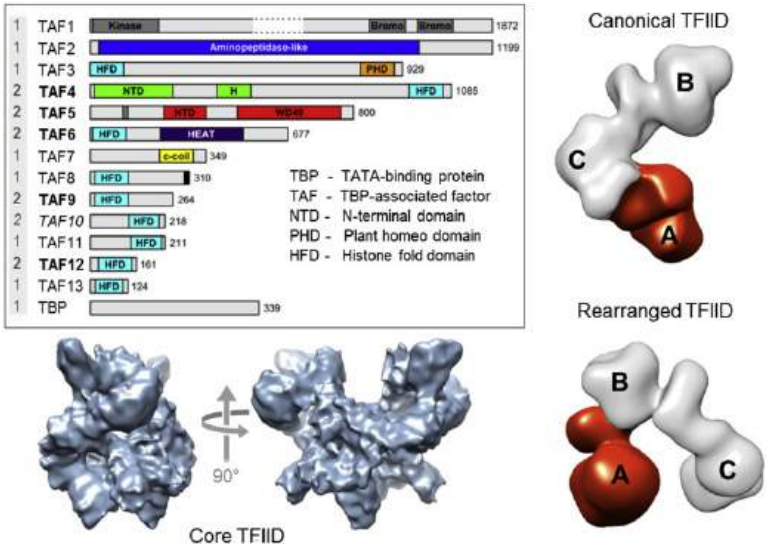

Figure 25.1.12: Human TFIID. Gupta, K., et.al. (2016) J Mol Bio 428(12):2581-91.

TFIID is a large megadalton-sized multiprotein complex comprising about 20 subunits made up of 14 different polypeptides. The constituent proteins of TFIID, TBP and the TAFs, are shown in a schematic representation depicted as bars (inset, left). Structured domains are marked and annotated. The presumed stoichiometry of TAFs and TBP in the TFIID holo-complex is given (far left, gray underlaid). TAF10 (in italics) makes histone fold pair separately with both TAF3 and TAF8. TAFs present in a physiological TFIID core complex extracted from eukaryotic nuclei are labeled in bold. The architecture of the TFIID core complex (EMD-2230) determined by cryo-EM is shown (bottom left) in two views related by a 90° rotation (arrows). The holo–TFIID complex is characterized by remarkable structural plasticity. Two conformations, based on cryo-EM data (EMD-2284 and EMD-2287), are shown on the right, a canonical form (top) and a more recently observed rearranged form (bottom). In the rearranged conformation, lobe A (colored in red) migrates from one extreme end of the TFIID complex (attached to lobe C) all the way to the other extremity (attached to lobe B).

TFIID was shown to adopt an asymmetric, horse-shoe shape with three almost equal-sized lobes (A, B, and C), exhibiting a considerable degree of conformational flexibility with at least two distinct conformations (open and closed), as shown in Figure 25.1.12 The TBP component of TFIID binds with a specific DNA sequence called the TATA box. This DNA sequence is found around 30 base pairs upstream of the transcription start site in many eukaryotic gene promoters. When TBP binds to a TATA box within the DNA, it distorts the DNA by inserting amino acid side chains between base pairs, partially unwinding the helix, and doubly kinking it. The distortion is accomplished through a great amount of surface contact between the protein and DNA. TBP binds with the negatively charged phosphates in the DNA backbone through positively charged lysine and arginine amino acid residues. The sharp bend in the DNA is produced through the projection of four bulky phenylalanine residues into the minor groove. As the DNA bends, its contact with TBP increases, thus enhancing the DNA-protein interaction. The strain imposed on the DNA through this interaction initiates the melting, or separation, of the strands. Because this region of DNA is rich in adenine and thymine residues, which base-pair through only two hydrogen bonds, the DNA strands are more easily separated.

The role of TAFs is complicated. Take for example TAF11 and TAF13. These act as competitive inhibitors of TBP to the TATA (Pribnow) box as well as TAF1 which somewhat mimics the structural features of the Pribnow box. TAF11/TAF13 binds to the DNA surface where TBP binds. suggesting a novel regulation of TFIID. These interactions are illustrated in Figure 25.1.14

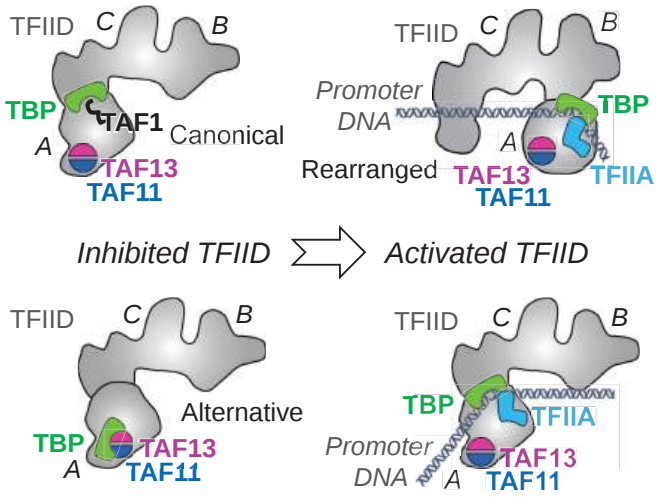

Figure 25.1.14 Novel TFIID regulatory state comprising TAF11/TAF13/TBP. Kapil Gupta,et al. (2017) Architecture of TAF11/TAF13/TBP complex suggests novel regulation properties of general transcription factor TFIID eLife 6:e30395. https://doi.org/10.7554/eLife.30395. Creative Commons Attribution License

Given its role in transcribing the DNA for thousands of messenger RNAs, let's focus on the preinitation complex for RNAP II. Structures are known for the closed and open promoters. A key component is TFH (see Figure 25.1.12). TFIIH opens the DNA for transcription. As if we need to complicate the structure of the preinitiation complex even more, it turns out the TFIIH is not a single dark green cartoon as shown in Figure 12, but a rather large complex itself. Its structure is shown in Figure 25.1.15

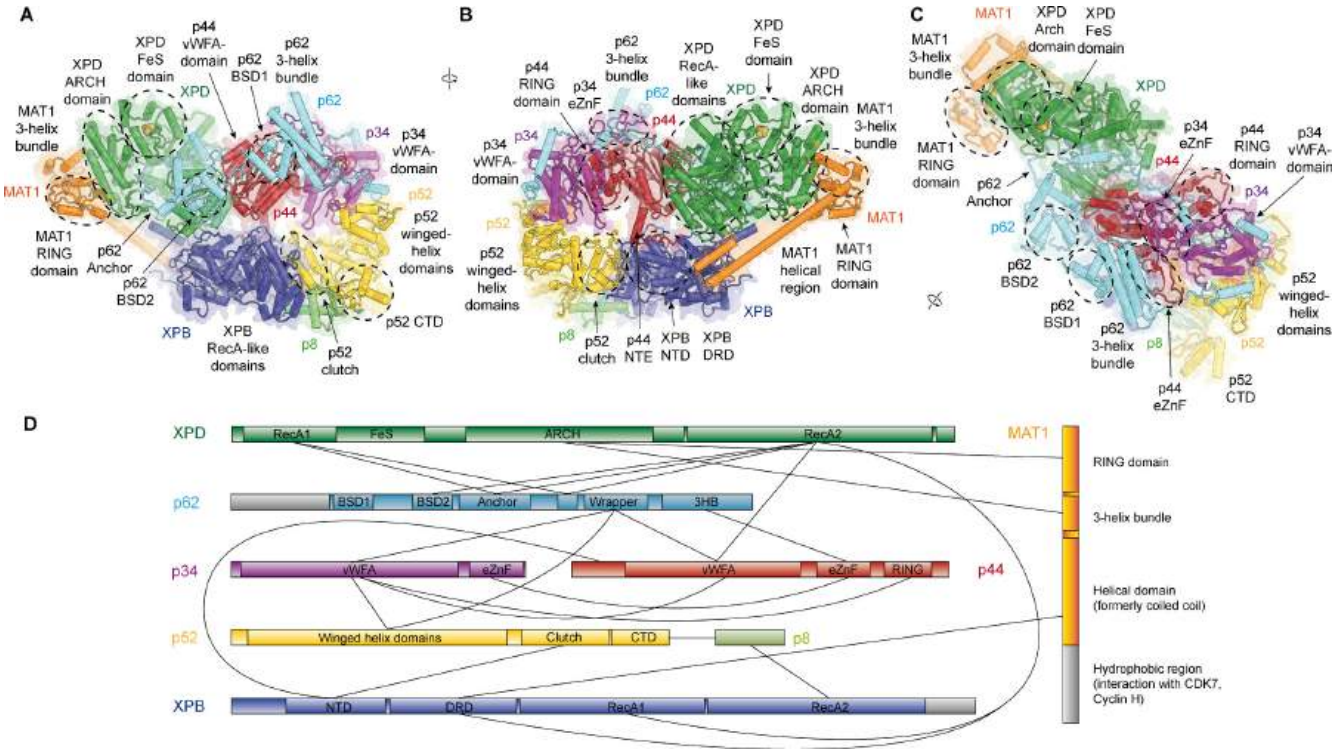

Figure 25.1.15 Structure of the TFIIH core complex. Greber et al. (2019). The complete structure of the human TFIIH core complex. *eLife* **8**:e44771. https://doi.org/10.7554/eLife.44771. Creative Commons Attribution License

Panes (**A, B, C**) shows three views of the structure of the TFIIH core complex and MAT1. Subunits are color-coded and labeled (in color); individual domains are labeled (in black) and circled if needed for clarity.

Panel (**D**) shows the domain-level protein-protein interaction network between the components of the TFIIH core complex and MAT1 derived from the interactions observed in our structure. Proteins are shown with the same colors as in A and major unmodeled regions are shown in grey. Abbreviations: CTD: C-terminal domain; DRD: DNA damage recognition domain; FeS: iron sulfur cluster domain; NTD: N-terminal domain; vWFA: von Willebrand Factor A.

The largest subunits are DNA-dependent helicases/translocases/ATPases XPB and XPD, which are bridged by MAT1. It appears that XPB starts and propagates a twist in the DNA which propagates ot open the DNA 30 BP downstream of the TATA box. This mostly likely is followed by the dissociation of TFIIH and a stoppage in DNA twisting, which allows RNA transcription to start.

Figure 25.1.16 shows an interactive iCn3D model of the human/mouse/mastadenovirus C RNA polymerase II core pre-initiation complex with open promoter DNA (7NVU).

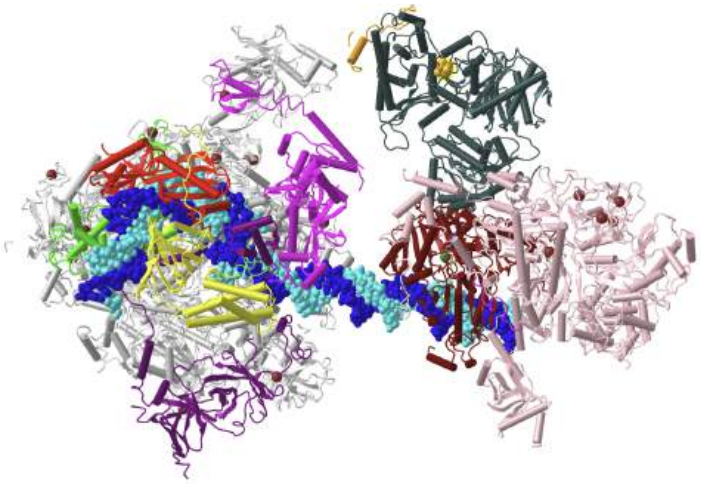

Figure 25.1.16: Human/mouse/a mastadenovirus C RNA polymerase II core pre-initiation complex with open promoter DNA (7NVU). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...Bc8itsYA7qctWA (long load time but worth the wait)

The following color schemes are used:

- MAT1 - orange
- TF2A - yellow
- TF2B - green
- TF2E - magenta
- TF2F- purple
- ATP-dependent translocase (helicase) subunit XPD - dark slate gray
- TBP (TATA box binding protein) - red
- TF2H - Pink
- 2H-XPB helicase - maroon
- NT-DNA - cyan
- template (T)-DNA - blue (Note: part of it is shown in a yellow cartoon in the interactive model)
- the SF_4 cofactor is shown in spacefill with CPK colors

In summary, the binding of TFIID to the core promoter is followed by the recruitment of further GTFs and RNA pol II. Several lines of evidence suggest that this process occurs in a defined, stepwise order and undergoes significant restructuring. First, PIC adopts an inactive state, the “closed” complex, which is incompetent to initiate transcription. In addition to TFIID, TFIIH is also critical for the shift of RNA Pol II from the closed to the open conformation. TFIIH has an ATP-dependent translocase activity within one of its subunits, that opens up about 11 to 15 base pairs around the transcription start site by moving along one DNA strand inducing torsional strain, leading to conformational rearrangements and the positioning of single-stranded DNA to the active site of RNA pol II. In this “open” complex, RNA pol II can enter elongation to transcribe throughout a gene in a highly processive manner without dissociating from the DNA template or losing the nascent RNA.

In most eukaryotes, after synthesizing about 20–100 bases, RNA pol II can pause (***Promoter proximal pause***) and then disconnect from promoter elements and other components of the transcription machinery, giving rise to a fully functional elongation complex

in a process called ***promoter escape***. The promoter-bound components of the PIC, in contrast, remain in place, and thus only TFIIB, TFIIF, and RNA pol II need to be recruited for re-initiation, significantly increasing the transcription rate in subsequent rounds of transcription. ***Promoter escape*** is preceded by an ***abortive transcription*** in many systems, where multiple short RNA products of 3 to 10 bases in length are synthesized.

In addition to promoter elements within the DNA, ***enhancer elements*** are also important for the initiation of transcription. ***Promoters*** are defined as DNA elements that recruit transcription complexes for the synthesis of coding and non-coding RNA. ***Enhancers*** are defined as DNA elements that positively regulate transcription at promoters over long distances in a position- and orientation-independent manner. However, studies have revealed that many enhancers can recruit Pol II and initiate transcription of enhancer RNA (eRNA), thus blurring the functional distinction between enhancers and promoters (Figure 10.13).

Enhancer transcription produces relatively short ncRNA. Furthermore, transcription at enhancers is unstable and often leads to the termination of elongation. In contrast, transcription initiation at most Pol II promoters is stable and produces long mRNAs. Topological studies revealed that enhancers come in close proximity to target gene promoters during transcription activation. According to current gene activation models, the ***Mediator complex*** forms a physical bridge between distant regulatory regions and promoters, thereby promoting looping. Transcription of at least a subset of genes regulated by enhancers occurs in bursts indicating a discontinuous process of transcription complex recruitment, assembly, and/or conversion to elongation-competent forms. The bursting phenomenon suggests that enhancer/promoter contacts may be transient and infrequent, as shown in Figure 25.1.17.

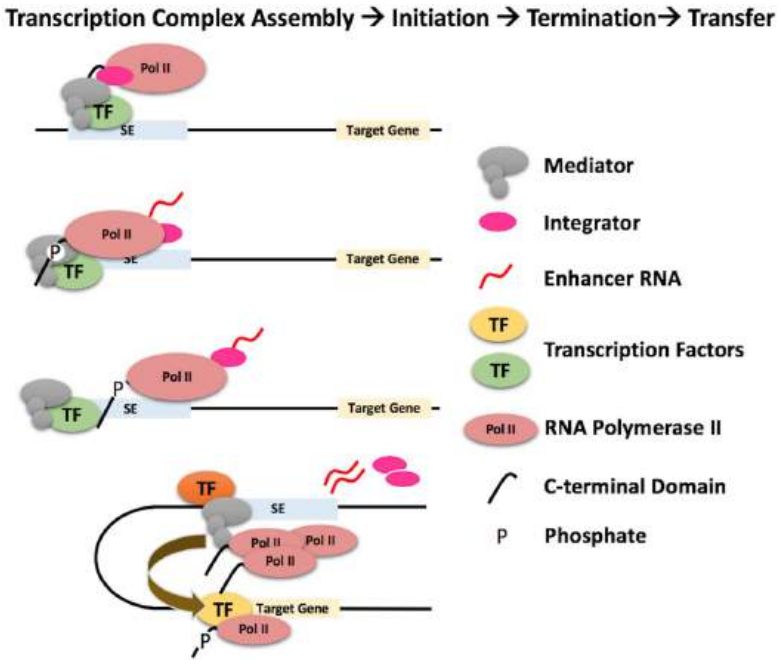

Figure 25.1.17: RNA polymerase II Enhancer Transfer Model. Gurumurthy, A., et.al. (2018) BioEssays 1800164

Depicted are the steps involved in the recruitment of Pol II to SEs, assembly into elongation-competent transcription complexes, transcription initiation, and elongation, abortion and termination, and transfer to target genes. Transcription factors recruit Mediator and other co-regulators to SEs. Mediator recruits Pol II and assembles a fraction into elongation competent transcription complexes. Transcription is initiated by phosphorylation of the CTD. Early abortion and transcription termination conferred by Integrator releases Pol II, which is dephosphorylated and transferred to target gene promoters. Super Enhancer Element (SE).

25.1.4: Transcriptional Elongation and Termination

25.1.4.1: Prokaryotic Transcriptional Elongation

The rate of transcription elongation by *E. coli* RNAP is not uniform. RNA synthesis is characterized by pauses, some of which may be brief and resolved spontaneously, whereas others may lead to the ***transcription elongation complex (TEC)*** backtracking.

Elongation rate and pausing are determined by template sequence and RNA structure (e.g., stem-loops) and involve at least two components of the RNAP catalytic center, the ***bridge helix (BH)*** and ***trigger loop (TL).*** Elongation is proposed to occur in three

steps, as shown in Figure 25.1.18 First, the TL folds in response to NTP binding. Mutational analyses indicate that this conformational change in the TL can be rate-limiting, and reflects the ability of the incoming NTP to bind to TEC. The second step is the incorporation of the NTP and the release of pyrophosphate. The third step involves the translocation of the RNAP down the DNA Template such that the next RNA nucleotide can be added to the nascent transcript.

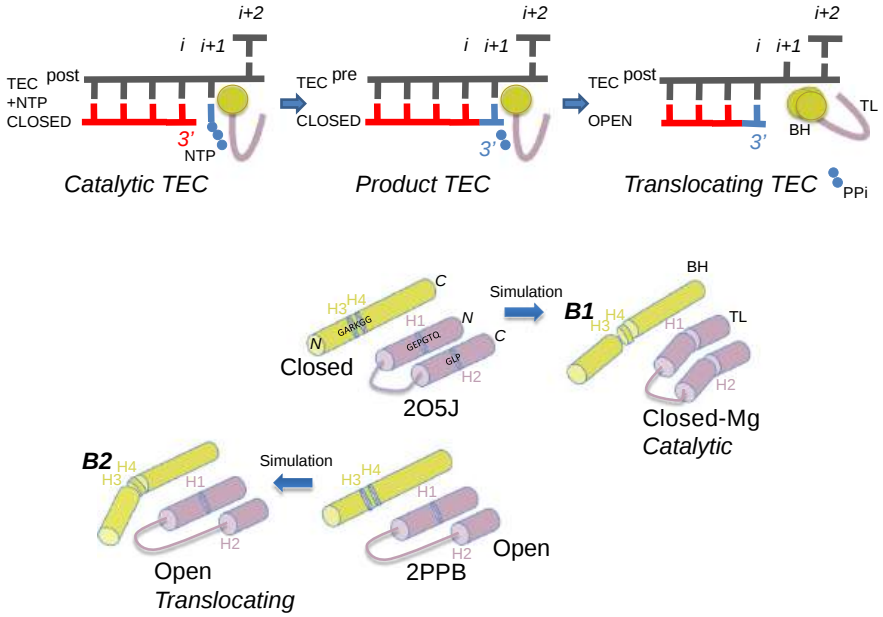

Figure 25.1.18: A model for Transcriptional Elongation. Kireeva, M., et. al. (2012) BMC Biophysics 5(1):11

The trigger loop hinges, bridge helix hinges, and bridge helix bending models are based on molecular dynamics simulations. At the top of the figure, diagrams of the closed TEC, the closed product TEC (after chemistry), and the translocating TEC are shown. DNA is grey; RNA is red; the NTP substrate (or incorporated NMP and pyrophosphate) is blue; the trigger loop (TL) is purple; the bridge helix (BH) is yellow. Interpretations of simulations are shown schematically below. Simulations indicate trigger loop hinges H1 and H2, bridge helix hinges H3 and H4 and bridge helix bend modes B1 (straighter) and B2 (more sharply bent).

Backtracking of TEC may take place after a brief pause in transcription, caused by the thermodynamic properties of nucleic acids sequences surrounding the elongation complex. In addition, misincorporation events render elongation complexes prone to backtracking by at least one bp. In this case, the rescue from backtracking through the cleavage of the 3' end of the erroneous transcript also may be seen as a proofreading reaction. Any backtracking event causes a pause or arrest of transcription elongation, which may limit its overall rate (the average speed of RNAP along the template) or the processivity (the fraction of RNAP molecules reaching the end of the gene).

While the general structure of the elongation complex (the transcription bubble, the RNA-DNA hybrid) remains unchanged during backtracking, the extension of RNA becomes impossible in this conformation. However, such complexes can be resolved by the hydrolytic activity of RNAP, which cleaves the phosphodiester bond in the active center of the backtracked complex, producing a new RNA 3' end in the active center. For single base backups, the hydrolytic reaction is catalyzed by a flexible domain of RNAP located in the secondary channel called the Trigger Loop (TL) and the two metal ions of the active center.

Longer sequences of backtracked TEC can restart when acted upon by GreA/B factors, which restore the 3'-end of the nascent transcript to the active center. GreA and GreB are transcript cleavage factors that act on backtracked elongation complexes. When Gre factors are bound in the secondary channel, Gre factors displace the TL from the active center, as shown in Figure 25.1.19 The displacement switches off the relatively slow TL-dependent intrinsic transcript hydrolysis, and imposes the highly efficient Gre-assisted hydrolysis. This efficiency is thought to be due to the stabilization of the second catalytic Mg^{2+} ion and an attacking water molecule by the Gre factors.

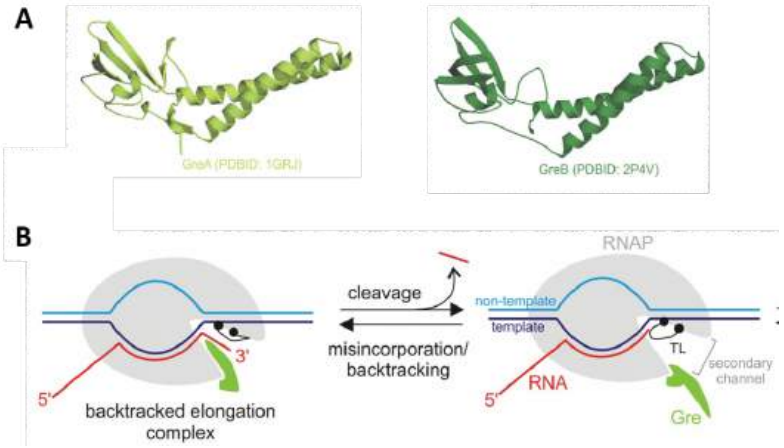

Figure 25.1.19: The Role of Gre Factors in Relieving Transcription Elongation Complex Backtracking. Zenkin, N., and Yuzenkova, Y. (2015) Biomolecules 5(3):1195-1209.

Panel (**A**) shows a ribbon diagram of the GreA and GreB proteins.

Panel (**B**) shows the mode of functioning of Gre factors. The Gre factor is bound to the active elongation complex but does not impose hydrolytic activity on it. Upon backtracking or misincorporation, the Gre factor protrudes its coiled-coil domain through the secondary channel of RNAP (shown in the lefthand diagram), where it substitutes for the catalytic domain Trigger Loop (TL). This substitution switches off the slow TL-dependent phosphodiester bond hydrolysis and, and instead, facilitates highly efficient Gre-dependent hydrolysis. After the resolution of the backtracked complex through RNA cleavage, the elongation complex returns to the active conformation, and the Gre factor gives way to the TL, which can now continue the catalysis of RNA synthesis (shown in the right-hand diagram). The controlled switching between Gre and the TL eliminates possible interference of Gre with the RNA synthesis.

25.1.4.2: Prokaryotic Transcriptional Termination

Transcription termination determines the ends of transcriptional units by disassembling the transcription elongation complex (TEC), thereby releasing RNA polymerases and nascent transcripts from DNA templates. Failure in termination causes transcription readthrough, which yields wasteful and possibly harmful intergenic transcripts. It can also perturb the expression of downstream genes when the unterminated TEC sweeps transcription initiation complexes off their promoters or collides with RNA polymerases that transcribe opposite strands.

Transcriptional termination in prokaryotes can be template-encoded and factor-independent ***(intrinsic termination)***, or require accessory factors, such as **Rho**, Mfd, and DksA. ***Intrinsic termination*** occurs at specific template sequences - an inverted repeat followed by a run of A residues. Termination is driven by the formation of a short stem-loop structure in the nascent RNA chain, as shown in Figure 25.1.20 RNA synthesis arrests and TEC dissociates at the 7th and 8th U of the run. Formation of the stem-loop dissociates the weak rU:dA hybrid. Stem-loop formation is hindered by upstream complementary RNA sequences that compete with the downstream portion of the stem, as well as by RNA: protein interactions in the RNA exit channel. Intrinsic termination depends critically upon timing. Hairpin folding and transcription of the termination point must be coordinated, so that the complete hairpin is formed by the time RNAP transcribes the termination point. The size of the stem, the sequence of the stem, and the length of the loop all affect termination efficiency.

The bridge α-helix in the β' subunit borders the active site and may have roles in both catalysis and translocation. Mutations in the YFI motif (β' 772-YFI-774) affect intrinsic termination as well as pausing, fidelity, and translocation of RNAP. One mutation, F773V, abolishes the activity of the λ tR2 intrinsic terminator, although neighboring mutations have little effect on termination. Modeling suggests that this unique phenotype reflects the ability of F773 to interact with the fork domain in the β subunit.

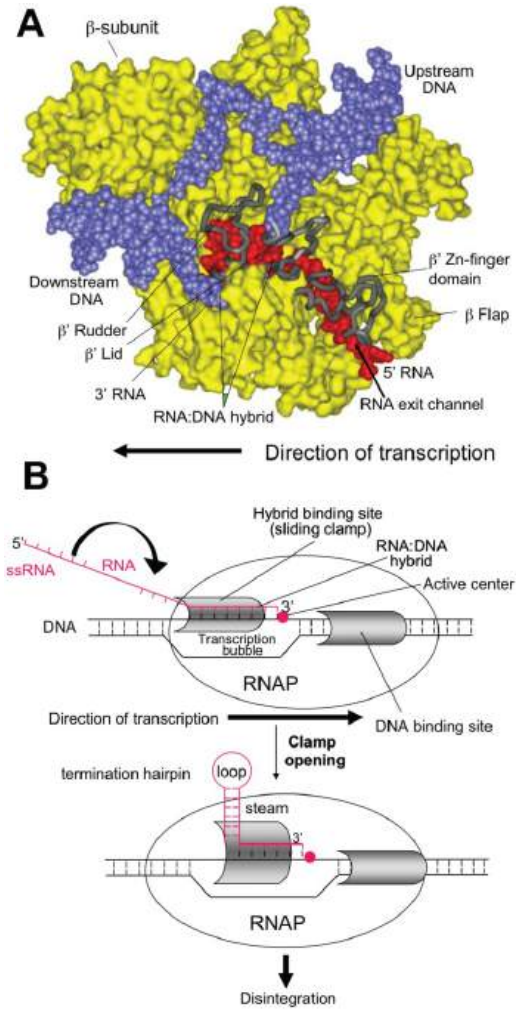

Figure 25.1.20: Model of Intrinsic Termination. Washburn, R.S., and Gottesman, M.E. (2015) Biomolecules 5(2)1063-1078.

Panel (A) shows the open conformation of the RNAP during transcriptional elongation. RNAP is shown in yellow, the DNA template in blue, and the nascent RNA in red. Key elements of the RNAP RNA exit channel are shown in grey and labeled as indicated.

Panel (B) shows the extension of the nascent RNA through the RNAP exit channel and the potential for forming the RNA hairpin structure when enough length has been achieved.

Panel (C) shows the clamp opening and disintegration of the TEC when the RNA hairpin structure is encountered at the transcriptional bubble.

Figure 25.1.21 shows an interactive iCn3D model of the T. thermophilus RNAP polymerase elongation complex with the NTP substrate analog (2O5J). (long load time)

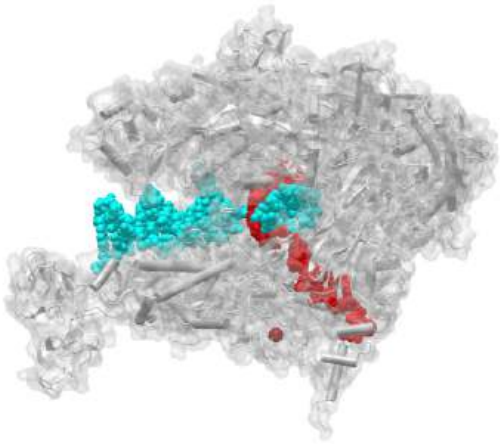

Figure 25.1.21: T. thermophilus RNAP polymerase elongation complex with the NTP substrate analog (2O5J). (Copyright; author via source). Click the image for a popup or use this external link:https://structure.ncbi.nlm.nih.gov/i...g4RAeYA3FiGDLA (long load time)

Transcriptional termination can also be dependent upon accessory factors, such as the **Rho** protein. Transcription termination factor Rho is an essential protein in *E. coli* first identified for its role in transcription termination at Rho-dependent terminators, and is estimated to terminate ~20% of *E. coli* transcripts. The *rho* gene is highly conserved and nearly ubiquitous in bacteria. Rho is an RNA-dependent ATPase with RNA:DNA helicase activity, and consists of a hexamer of six identical monomers arranged in an open circle, as shown in Figure 25.1.22

Rho binds to single-stranded RNA in a complex multi-step pathway that involves two distinct sites on the hexamer. The primary binding site (PBS), distributed on the N-terminal domains around the hexamer (cyan), ensures initial anchoring of Rho to the transcript at a Rut (Rho utilization) site, a∼70 nucleotides (nt) long, cytidine-rich and poorly-structured RNA sequence. Each Rho monomer contains a subsite capable of binding specifically the base residues of a 5′-YC dimer (Y being a pyrimidine). Biochemical and structural data suggest that Rho initially binds to RNA in an open, 'lock-washer' conformation that closes into a planar ring as RNA transfers to the central cavity. There, the ssRNA contacts an asymmetric secondary binding site (SBS) (green), and this step, which presumably is rate-limiting for the overall reaction, leads to motor activation. Upon hydrolysis of ATP, the ssRNA is pulled upon conformational changes of the conserved Q and R loops of the SBS, leading to Rho translocation, and ultimately promoting RNA polymerase (RNAP) dissociation. The molecular mechanism of Rho translocation based on single-molecule fluorescence methods appears to be tethered tracking. The tethered tracking model postulates that Rho maintains its contacts between the PBS and the loading (Rut) site upon translocation (Panel B). This mechanism would allow Rho to maintain its high-affinity interaction with Rut, and implies the growth of an RNA loop between the PBS and the SBS upon translocation.

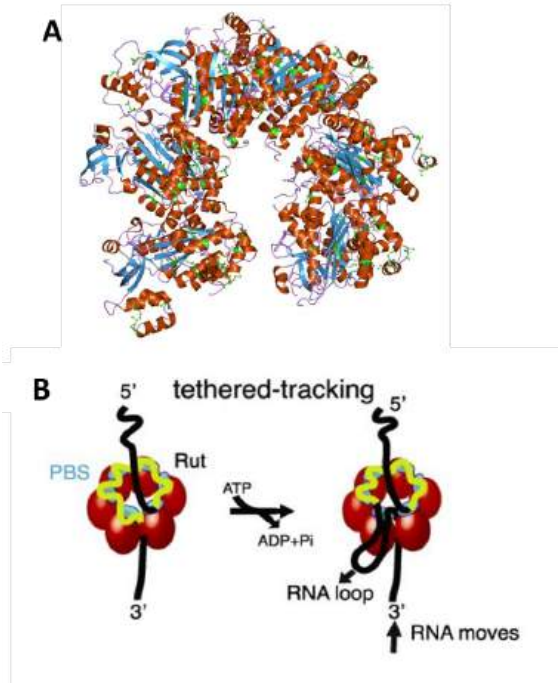

Figure 25.1.22: Schematic of Rho factor structure and mechanisms. (A) Jawahar Swaminathan and (B) Gocheva, V., et. al. (2015) Nuc Acids Res 43(1)10.1093.

Panel (A) shows the molecular structure of the Rho protein (PDB 1pv4)

Panel (B)shows how Rho assembles as a homo-hexameric ring (red spheres or tetragons), with RNA (black/yellow curve) binding to the primary binding sites (PBS, cyan) and the secondary binding sites inside the ring (SBS, green), where ATP-coupled translocation takes place. The Rut-specific binding site is depicted in yellow. The tethered-tracking model proposed that Rho translocates RNA while maintaining interactions between PBS and Rut. This model requires the formation of a loop that would shorten the extension of RNA upon translocation. Figure modified from:

Figure 25.1.23 shows an interactive iCn3D model of the E. Coli Rho transcription termination factor in complex with ssRNA substrate and ANPPNP (1PVO).

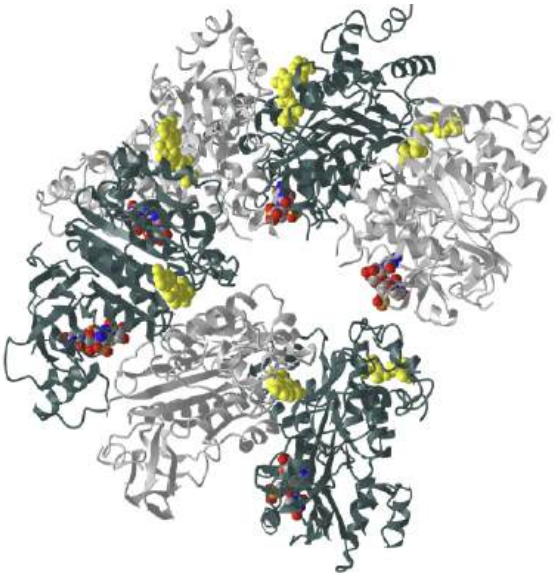

Figure 25.1.23: E. Coli Rho transcription termination factor in complex with ssRNA substrate and ANPPNP (1PVO). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...boj4YBbvevcsEA

The six subunits of the hexamer are shown in alternating slate gray and light gray. The di-ribonucleotides (5'-R(P*UP*C)-3') are shown in spacefill and colored CPK. ANPPNP is shown in spacefill yellow.

Figure 25.1.24shows an interactive iCn3D model of the closed ring structure of the E. Coli Rho transcription termination factor in a complex with nucleic acid in the motor domains (2HT1).

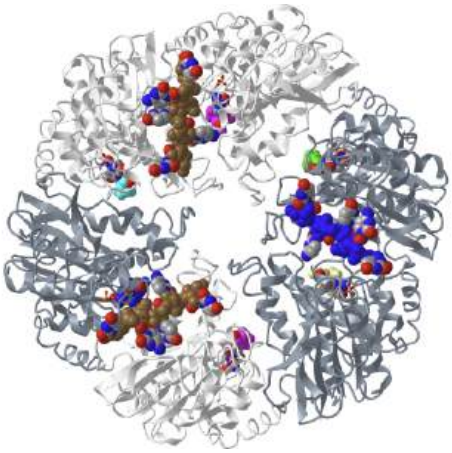

Figure 25.1.24: Closed ring structure of the E. Coli Rho transcription termination factor in complex with nucleic acid in the motor domains (2HT1). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...GVkVhPknbmiYj7

The six subunits of the hexamer are again shown in alternating slate gray and light gray. The ssRNAs are shown in spacefill with the backbones in one color and the bases in CPK colors.

Figure 25.1.25 shows an interactive iCn3D model of the E. coli Rho-dependent Transcription Pre-termination Complex (6XAS) (long load).

Figure 25.1.25: E. coli Rho-dependent Transcription Pre-termination Complex (6XAS). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...kUxfqN2TFPcSL9 (long load)

- The RNA polymerase subunits ($\alpha_2\beta\beta\omega$) are shown in light cyan
- The six subunits of the Rho hexamer are again shown in alternating slate gray and light gray
- NusA is shown in magenta
- Both DNA strands are shown in spacefill with the backbone blue and the bases red
- Only part of the RNA is shown (spacefill, backbone yellow, bases CPK), so it appears discontinuous

25.1.4.3:

25.1.4.4: Eukaryotic Transcriptional Termination

In eukaryotes, termination of protein-coding gene transcription by RNA polymerase II (Pol II) usually requires a functional polyadenylation (pA) signal, typically a variation of the AAUAAA hexamer. Nascent pre-mRNA is cleaved and the 5′ fragment is

polyadenylated at the pA site shortly downstream from the hexamer by cleavage and pA factors (CPFs). Two mechanisms have been suggested for pA-dependent transcription termination. In ***the allosteric model***, the pA signal and/or other termination signals bind with the pA signal downstream region (PDR) and induce reorganization of the Pol II complex. This includes the association or dissociation of endonuclease components such as the CPFs. This causes conformational changes in Pol II and TEC disassembly ensues. In ***the kinetic model,*** also known as ***the "torpedo" model***, cleavage at the pA site separates the pre-mRNA from the TEC, which continues synthesizing a downstream nascent transcript. This new transcript is a substrate of XRN2/Rat1p, a processive 5′-to-3′ exoribonuclease that catches up with, and disassembles, the TEC by an unknown mechanism.

The two pA-dependent models are not mutually exclusive, and unified models have been proposed. Loosely conserved pA signal sequences downstream of protein-coding genes bind to components of the polyadenylation factor (CF1) complex leading to the assembly of the cleavage and polyadenylation machinery. Termination is coupled to cleavage in a manner that has not yet been completely resolved, however, one of the major factors involved in yeast pA termination is the endonuclease, Ysh1. For example, the depletion of Ysh1 blocks TEC dissociation, but does not cause substantial readthrough at the termination site (Fig. 26.1.18 A&B). These results suggest that Ysh1 does not directly cause the pausing that occurs in the allosteric termination pathway, but rather plays a role in the dissociation of the Pol II complex from the DNA template, as shown in Figure 25.1.26 It should be noted that not all pA-dependent termination is dependent on Ysh1 and that other mechanisms of pA-mediated termination still remain to be elucidated.

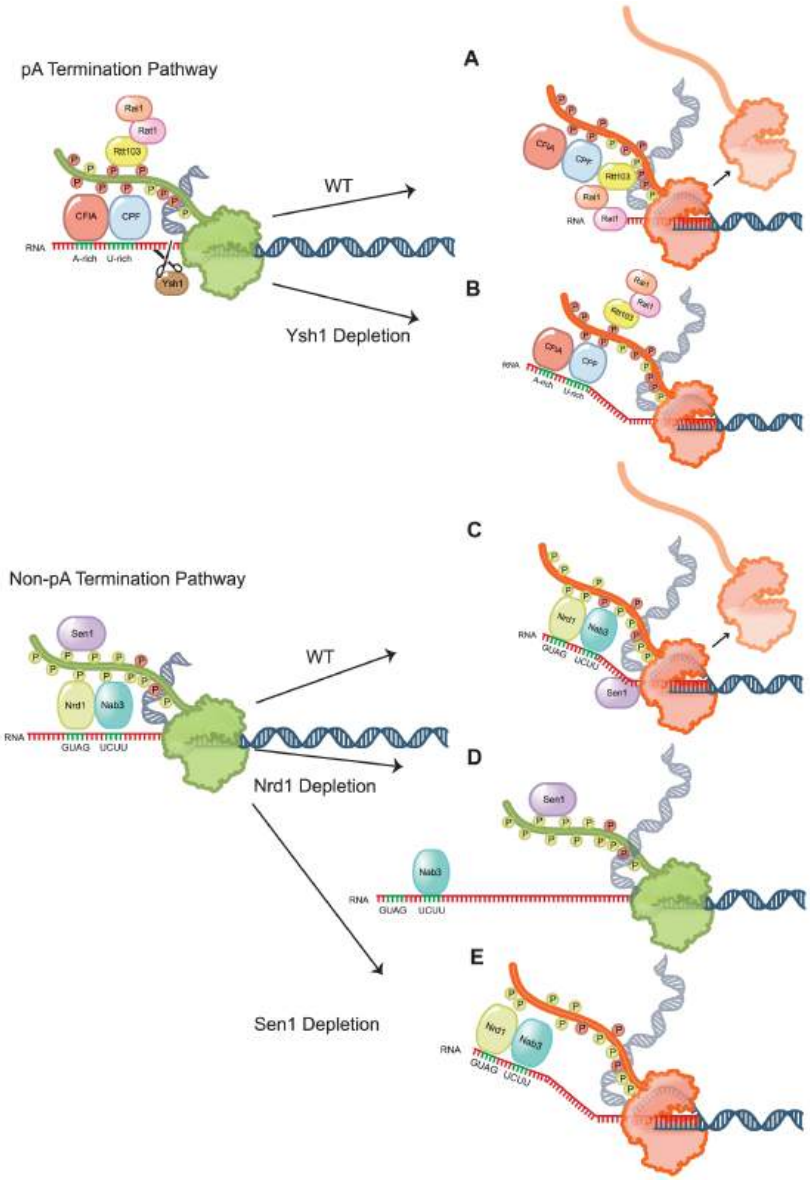

Figure 25.1.26: Schematic representation of Pol II termination after removal of non-pA and pA termination factors. *Schaughency, P., Merran, J., and Corden J.L. (2014) PLOS Genetics 10(10):e1004632*

Panel (A) shows the elongating Pol II (green) terminates pA transcripts (A) after an allosteric change (red) that reduces processivity.

Panel (B) shows the depletion of Ysh1 leads to minimally extended readthrough transcripts but does not block the allosteric change in Pol II.

Panel (C) shows how Nrd1 and Nab3 binding recruits Sen1 for termination of non-pA transcripts.

Panel (D) shows Pol II elongation complex lacking Nrd1 does not recognize termination sequences in the nascent transcript and thus does not facilitate the allosteric transition in Pol II. This leads to a processive readthrough.

Panel(E) shows how Nrd1 and Nab3 recognize terminator sequences allowing the allosteric change in Pol II but depletion of Sen1 blocks the removal of Pol II from the template. *Figure from:*

The mechanisms of termination of Pol II-mediated transcription differ for coding and non-coding transcripts. Coding transcripts and possibly some stable uncharacterized transcripts (SUTs) are nearly always processed at the 3′-end by the cleavage and polyadenylation (pA) machinery and are processed by the pA-dependent termination mechanisms described above. In contrast, ncRNAs are terminated and processed by an alternative pathway that, in yeast, requires the RNA-binding proteins Nrd1 and Nab3, as well as, the RNA helicase Sen1. Nrd1 and Nab3 recognize RNA sequence elements downstream of snoRNAs and CUTs and this

leads to the association of a complex that contains the DNA/RNA helicase Sen1 and the ***nuclear exosome***. The ***nuclear exosome*** is a complex of ribonucleases with 3' to 5' exonuclease and endonuclease activity. It functions to degrade unstable or incorrect RNA transcripts.

Both Nrd1 and Sen1 depletion lead to readthrough transcription of ncRNAs, suggesting their importance in non-pA-dependent transcription termination (Fig 26.1.18 C & D). Furthermore, depletion of Nrd1 also causes the accumulation of longer readthrough ncRNAs, suggesting its role in trafficking ncRNAs to the nuclear exosome following termination.

25.2: RNA Processing

Post-transcriptional modifications of rRNA and tRNA will be topics of Chapter 27 as their structure and function in protein synthesis will be a focal point. Thus, this section will focus on post-transcriptional modifications of mRNA. We'll spend most of our time on eukaryotic RNA processing.

25.2.1: Prokaryotic RNA Processing

First, let's take a brief look at a fascinating feature of transcription in bacterial cells. Bacterial cells do not have extensive post-transcriptional modifications of mRNA primarily because transcription and translation are coupled processes. Bacterial cells lack the physical barrier of a nucleus, which allows transcription and translation machinery to function at the same time, enabling the concurrent translation of an mRNA while it is being transcribed (Fig 26.2.1). As mRNA is synthesized in prokaryotes, a ribosome binding motif called the Shine-Dalgarno sequence, located in the 5' untranslated region of the mRNA emerges early, allowing the ribosome to bind and translation to occur. In addition, the protein N-utilzation Substance, better known as **NusG,** plays a critical role. NusG has three separate domains and the functions of two of them are known. The NusG N-terminal domain (NusG-NTD) can bind to RNAP, whereas the C-terminal domain (NusG-CTD) can combine with the NusE (RpsJ) component of ribosomes. These two functions of NusG enable transcription to be coupled with translation. NusG CTD can also bind to Rho to terminate transcription, as shown in Figure 25.2.1.

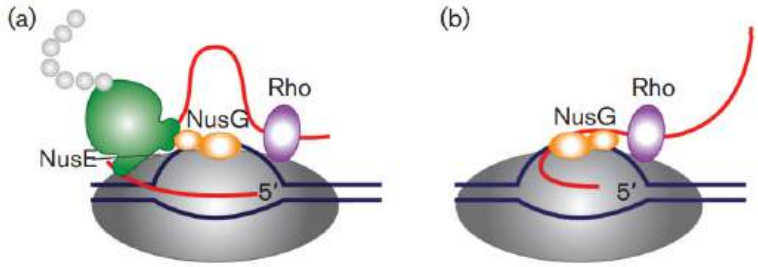

Figure 25.2.1: **The roles of NusG in transcription/translation coupling.** (a) Composition of an active RNAP complex. RNAP is shown in dark grey, DNA in blue and nascent RNA in red. The ribosome is shown in green with the nascent polypeptide chain in light grey; the bulge in the small subunit denotes the location of NusE (RpsJ). NusG is shown in orange: its shape denotes two functional sections. The larger section denotes the N-terminal domain, which binds to RNAP. The smaller section denotes the C-terminal domain, which interacts with NusE in situ. Rho is shown in purple. (b) After the translation is completed, NusG remains bound to RNAP and may also bind to Rho through the C-terminal domain leading to the termination of transcription. *Figure from: Cortes, T., and Cox, R.A. (2015) Microbiology 161:719-728.*

Another protein, NusA, slows RNAP, in contrast to NusG which increases its processivity, as reflected by the length of the RNA made before RNAP falls off.

25.2.2: Eukaryotic RNA Processing

In multicellular organisms, almost every cell contains the same genome, yet complex spatial and temporal diversity is observed in gene transcripts. This is achieved through multiple levels of processing leading from gene to protein, of which RNA processing is an essential stage. Following the transcription of a gene by RNA polymerases to produce a primary mRNA transcript, further processing is required to produce a stable and functional mature RNA product. This involves various processing steps including RNA cleavage at specific sites, intron removal, called ***splicing***, which substantially increases the transcript repertoire, and the addition of a 5'CAP. Another crucial feature of the RNA processing of most genes is the generation of 3′ ends through an initial endonucleolytic cleavage, followed in most cases by the addition of a poly(A) tail, a process termed 3′ end cleavage and polyadenylation (CPA).

25.2.3: Cleavage and 3'-Polyadenylation (CPA)

Polyadenylation is a required step for the correct termination of nearly all mRNA transcripts. Except for replication-dependent histone genes, metazoan protein-encoding mRNAs contain a uniform 3' end consisting of a stretch of adenosines. In addition to determining the correct transcript length at transcription termination, the poly(A) tail helps to ensure the translocation of the

nascent RNA molecule from the nucleus to the cytoplasm, enhances translation efficiency, acts as a signal feature for RNA degradation, and thereby contributes to the production efficiency of a protein.

Cleavage and polyadenylation (CPA) are carried out by the **cleavage/polyadenylation apparatus (CPA)**, a multi-subunit 3′ end processing complex, which involves over 80 proteins, comprised of four core protein subcomplexes, as shown in Figure 25.2.2 These consist of

1. **cleavage and polyadenylation specificity factor (CPSF)**, comprised of proteins CPSF1-4, factor interacting with PAPOLA and CPSF1 (FIP1L1), and WD repeat domain 33 (WDR33) (shown in green below);
2. cleavage stimulation factor (CstF), a trimer of CSTF1-3 (shown in red below;
3. cleavage factor I (CFI), a tetramer of two small nudix hydrolase 21 (NUDT21) subunits, and two large subunits of CPSF7 and/or CPSF6 (shown in orange in Figure 26.2.2 A); Note: Nudix are named for **nu**cleoside **di**phosphates hydroxylases.
4. cleavage factor II (CFII), composed of cleavage factor polyribonucleotide kinase subunit 1 (CLP1) and PCF11 cleavage and polyadenylation factor subunit (PCF11) (shown in yellow in Figure 26.2.2 A). Additional factors include symplekin, the **poly(A) polymerase (PAP)**, and the nuclear poly(A) binding proteins such as poly(A) binding protein nuclear 1 (PABPN1).

CPA is initiated by this complex recognizing specific sequences within the nascent pre-mRNA transcripts termed **polyadenylation signals (PAS)**. The PAS sequence normally consists of either a canonical 6 base sequence, the **AATAAA hexamer,** or a close variant usually differing by a single nucleotide (e.g., ATTAAA, TATAAA). It is located 10 to 35 nucleotides upstream of the cleavage site (CS) usually consisting of a CA dinucleotide. The PAS is also determined by surrounding auxiliary elements, such as upstream U-rich elements (USE), or downstream U-rich and GU-rich elements and G-rich sequences (DSE).

As soon as the nascent RNA molecule emerges from RNA polymerase II (RNA Pol II), the CPSF complex is recruited to the PAS **AATAAA hexamer,** through numerous interactions. Upon successful assembly of this macromolecular machinery, CPSF3 performs the endonucleolytic cleavage followed by a non-templated addition of approximately 50-100 A residues.

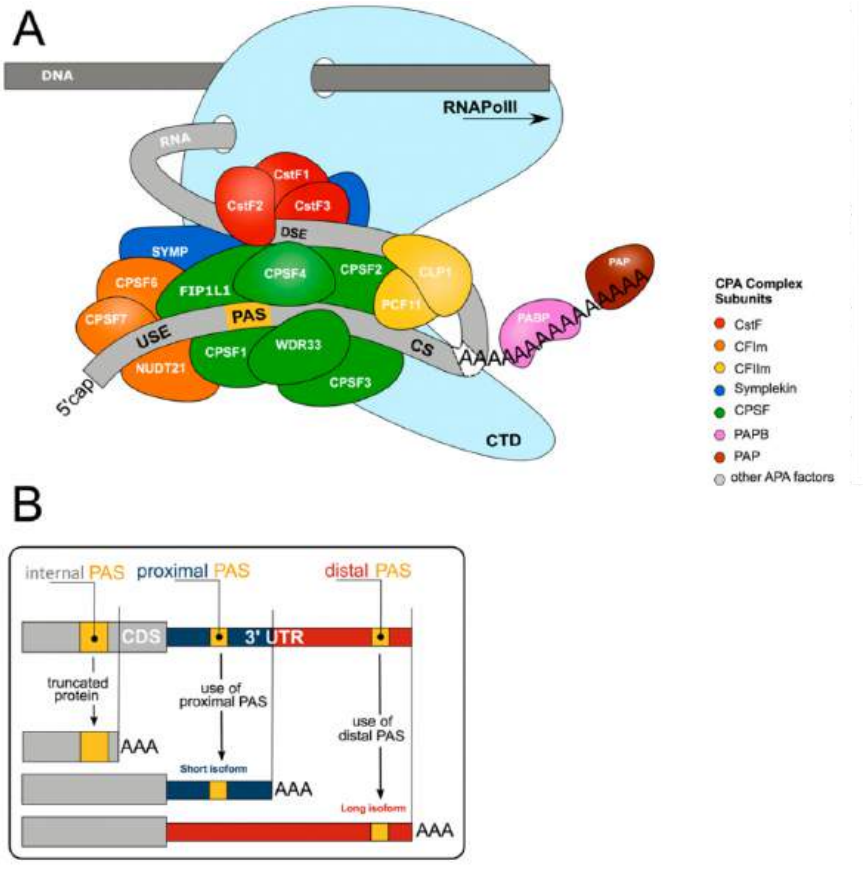

Figure 25.2.2: The human core 3′ end RNA processing machinery and impact on alternative polyadenylation. *Nourse, J., et. al. (2020) Biomolecules 10(6):915*

Panel (**A**) shows the core 3′ end processing machinery consists of complexes composed of multiple trans-acting proteins interacting with RNA via multiple cis-elements (USE = upstream sequence element; PAS = poly(A) signal; CS = cleavage site; DSE = downstream sequence element; CTD = C-terminal domain). Upon co-transcriptional assembly of these complexes, RNA cleavage and polyadenylation occur to form the 3′ end of the nascent RNA molecule.

Panel (**B**) shows more than 70% of all genes harbor more than one polyadenylation signal (PAS). This gives rise to transcript isoforms differing at the mRNA 3′ end. While alternative polyadenylation (APA) in 3′UTR changes the properties of the mRNA (stability, localization, translation), internal PAS usage (in introns or the coding sequence (CDS)) changes the C-termini of the encoded protein, resulting in different functional or regulatory properties.

Alternative polyadenylation (APA) occurs when more than one PAS is present within a pre-mRNA and provides an additional level of complexity in CPA-mediated RNA processing (Figure 26.2.2 B). Early studies revealed a significant portion of genes undergo APA, and with the advent of next-generation RNA sequencing technologies, the large-scale regulation of genes has become apparent, with approximately 70% of the transcriptome exhibiting APA regulation. As APA determines 3′UTR content and thus the regulatory features available to the mRNA, changes in the APA profile of a gene can have enormous impacts on expression.

For those trying to understand the structure and mechanism of the **cleavage/polyadenylation apparatus (CPA),** it is especially frustrating that different names are given to the constituents that comprise it, especially when comparing the proteins from different organisms. Hence it is useful to see multiple representations of the complex. Figure 25.2.3 shows a different cartoon representation of the cleavage and polyadenylation reactions. Note again the number of colored subcomplexes within the CPA as well as the different abbreviations shown for the individual proteins. This cartoon diagram is useful in visualizing the different steps involved.

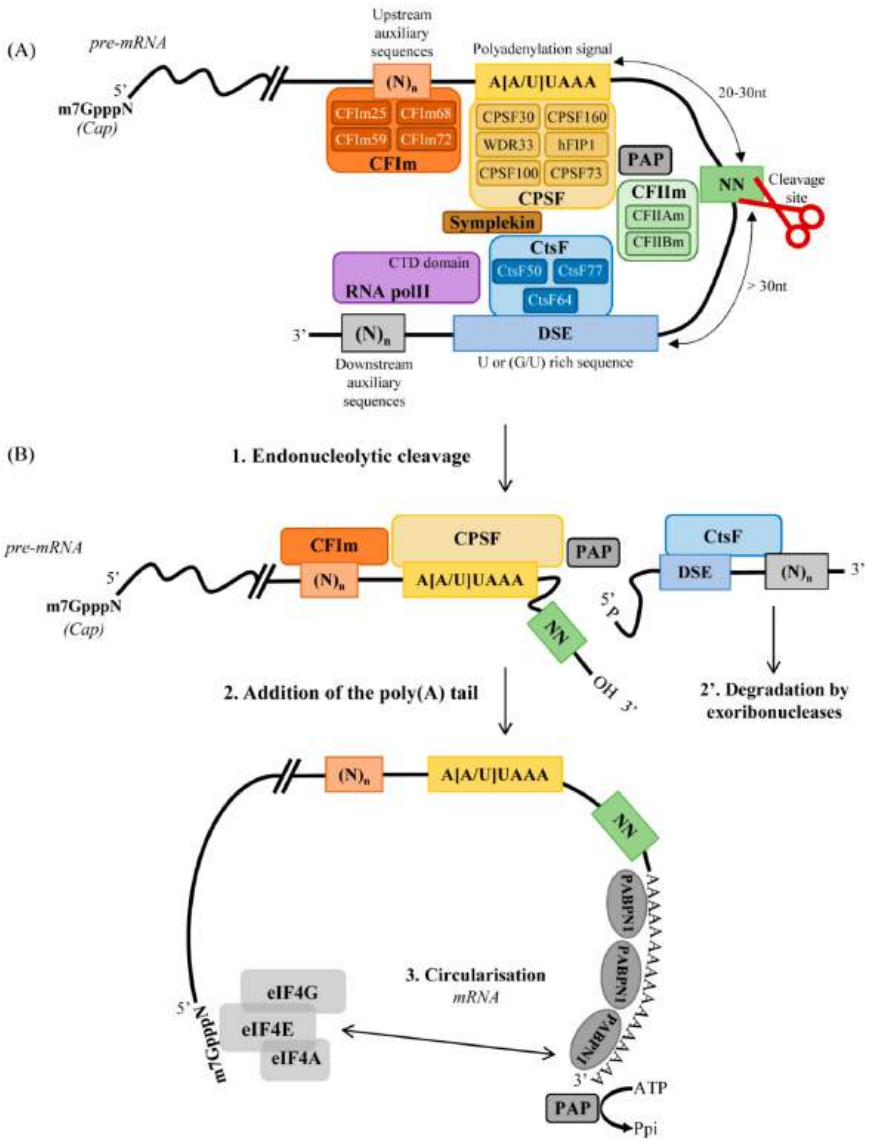

Figure 25.2.3: *Cis*-regulatory sequence elements and protein factors involved in cleavage and polyadenylation. Marsollier, A.-C.; Joubert, R.; Mariot, V.; Dumonceaux, J. Targeting the Polyadenylation Signal of Pre-mRNA: A New Gene Silencing Approach for Facioscapulohumeral Dystrophy. *Int. J. Mol. Sci.* **2018**, *19*, 1347. https://doi.org/10.3390/ijms19051347. **Creative Commons Attribution License**

Panel (**A**) shows that the specificity and efficiency of 3′end processing are determined by the binding of more than 80 RNA-binding proteins to regulatory *cis*-acting RNA sequence elements including the polyadenylation signal (PAS) A[A/U]UAAA; the cleavage site (represented by NN) and the downstream sequence element (DSE). Auxiliary sequences can be found near the polyadenylation signal or the DSE. The core processing complex, which is sufficient for the cleavage and polyadenylation, is composed of approximately 20 proteins, distributed in 8 complexes: the cleavage and polyadenylation specificity factor (CPSF), the cleavage stimulation factor (CstF); the mammalian cleavage factors I (CFIm) and the mammalian cleavage factors II (CFIIm); the single protein poly(A) polymerase (PAP); the single protein poly(A)-binding protein nuclear 1 (PABPN1); the single protein RNA polymerase II large subunit (Pol II); and the symplekin. Subunits of the different factors are indicated.

Panel (**B**) shows how CPSF and CstF are co-transcriptionally recruited to the poly(A) signal and the DSE respectively, causing an endonucleolytic cleavage of the pre-mRNA between the PAS and the DSE at the cleavage site. Two fragments are generated: one fragment with a free 5′phosphate group which is rapidly degraded by exoribonucleases and one fragment with a free 3′hydroxyl group on which 250 adenines will be added by PAP. The newly-synthetized poly(A) tail is covered by PAPBN1, allowing mRNA circularization and stabilization.

Now let's look at the structure of some of the complexes of the **cleavage/polyadenylation apparatus (CPA)**.

In yeast, the 3' processing is carried out by the cleavage and polyadenylation factor (CPF) which is called the CPSF in humans. On endonuclease cleavage, the RNA bound to RNA polymerase II is in two pieces, as shown in the figure above. The main mRNA now has a 3'-OH which is the site of polyadenylation. The minor cleavage fragment has a 5'-phosphate which gets degraded by the exonuclease Rat1, which as it cleaves the minor product helps displaces RNA polymerase II and helps to stop transcription.

In yeast, the CPF has 14 subunits with polymerase, nuclease, and phosphatase subcomplexes or "modules". The polymerase module, as the name implies, has the poly(A) polymerase, Pap1. Table 25.2.1 below shows some components of the polymerase module of both yeast CPF and human CPSF.

yeast Polymerase Module of CPF	Human mammalian polyadenylation specificity factor (mPSF) or CPSF
Cft1	CPSF160
Pfs2	WDR33
Yth1 - RNA binding subunit	CPSF30 - RNA binding subunit
Fip1 - Pap1 binding subunit	FIP1 - Pap1 binding subunit

Table 25.2.1 Some components of the polymerase module of both yeast CPF and human CPSF.

The **nuclease module** has an endonuclease (Ysh1) and a Mpe1 protein, which facilitate the cleavage site selection and polyadenylation. Table 25.2.2 below shows some components of the polymerase module in yeast and humans

yeast	human
endonuclease Ysh1	endonuclease CPSF73
pseudo-nuclease Cft2	pseudo-nuclease CPSF100
multidomain protein Mpe1	multidomain protein RBBP6

Table 25.2.2 Some components of the polymerase module in yeast and humans

Part of the Cft2 called the **yeast polymerase module interacting motif (yPIM)**, as its name implies, interacts with the polymerase module, in part through the interaction of key and conserved aromatic residues in it (F537, Y549, and F558) with a hydrophobic binding site in Cft1 and Pfs1. These interactions are key in activating and regulating the endonuclease and polyadenylation activities and hence controlling the termination of transcription.

Figure 25.2.4 shows an interactive iCn3D model of the yeast cleavage and polyadenylation specificity factor (CPF) polymerase module in complex with Mpe1, the yPIM of Cft2 and the pre-cleaved CYC1 RNA (7ZGR)

Figure 25.2.4: Yeast cleavage and polyadenylation specificity factor (CPF) polymerase module in complex with Mpe1, the yPIM of Cft2 and the pre-cleaved CYC1 RNA (7ZGR). The different parts of the complex are colored as shown below.

- Yth1 (mRNA 3' processing protein): magenta
- CFT1: green
- MPE1: orange
- Polyadenylation subunit 2 (Pfs2): yellow
- cleavage factor 2 protein (CF2P): cyan
- precleaved RNA CYC1: gray spacefill (backbone) with CPK-colored bases

25.2.4: 5'-CAP Formation

In eukaryotes, the 5′ cap, found on the 5′ end of the eventual mRNA molecule, consists of a guanine nucleotide connected to the mRNA via an unusual 5′ to 5′ triphosphate linkage, as shown in Figure 25.2.5. This guanosine is methylated on the 7 position directly after capping *in vivo* by a methyltransferase. It is referred to as the 7-methylguanylate cap, abbreviated m^7G.

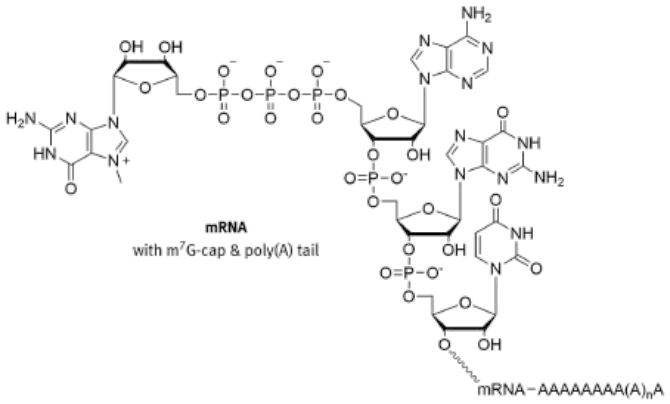

Figure 25.2.5: Structure of the 7-methylguanylate CAP. *Brisbane*

In multicellular eukaryotes and some viruses, further modifications exist, including the methylation of the 2′ hydroxy-groups of the first 2 ribose sugars of the 5′ end of the mRNA. Cap-1 has a methylated 2′-hydroxy group on the first ribose sugar, while cap-2 has methylated 2′-hydroxy groups on the first two ribose sugars. The 5′ cap is chemically similar to the 3′ end of an RNA molecule (the 5′ carbon of the cap ribose is bonded, and the 3′-OH unbonded). This provides significant resistance to 5′ exonucleases.

Small nuclear RNAs (snRNAs) contain unique 5′-caps. Sm-class snRNAs are found with 5′-trimethylguanosine caps, while Lsm-class snRNAs are found with 5′-monomethylphosphate caps. In bacteria, and potentially also in higher organisms, some RNAs are capped with NAD^+, NADH, or 3′-dephospho-coenzyme A. In all organisms, mRNA molecules can be decapped in a process known as messenger ***RNA decapping***.

For capping with 7-methylguanylate, the **capping enzyme complex (CEC)** binds to RNA polymerase II before transcription starts. As soon as the 5′ end of the new transcript emerges from RNA polymerase II, the CEC carries out the capping process (this kind of mechanism ensures capping, as with polyadenylation). The enzymes for capping can only bind to RNA polymerase II that is engaging in mRNA transcription, ensuring the specificity of the m^7G cap almost entirely to mRNA.

The 5′ cap has four main functions:

1. Regulation of nuclear export
2. Prevention of degradation by exonucleases
3. Promotion of translation (see ribosome and translation)
4. Promotion of 5′ proximal intron excision

In addition to the polyA tail, the nuclear export of RNA is regulated by the cap-binding complex (CBC), which binds to 7-methylguanylate-capped RNA, as shown in Figure 25.2.6. The CBC is then recognized by the nuclear pore complex and the mRNA is exported. Once in the cytoplasm after the pioneer round of translation, the CBC is replaced by the translation factors eIF4E and eIF4G of the eIF4F complex. This complex is then recognized by other translation initiation machinery including the ribosome, aiding in translation efficiency.

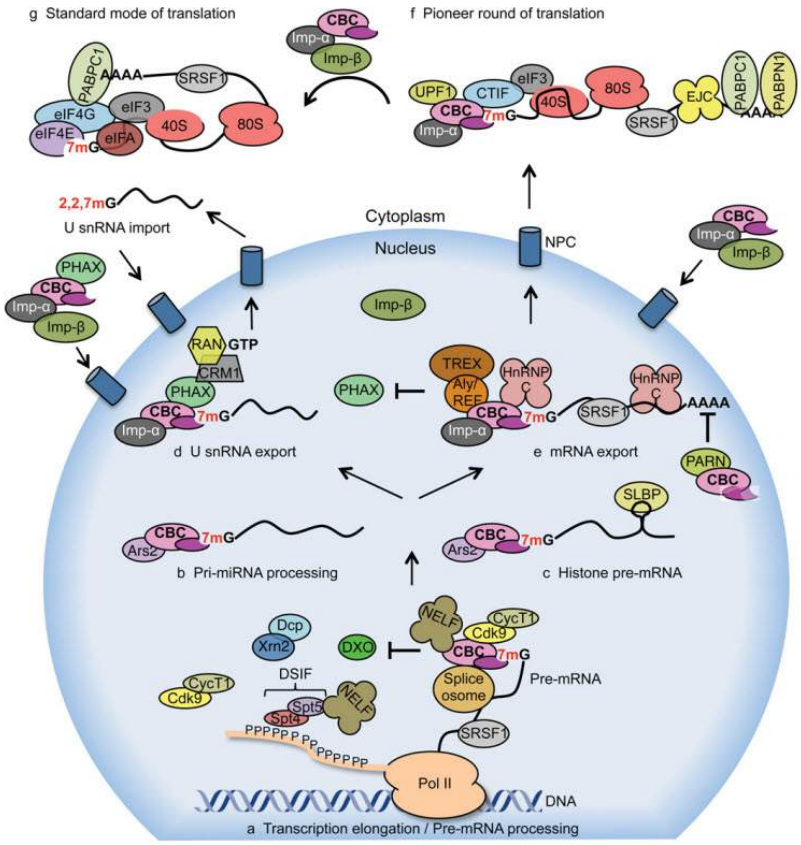

Figure 25.2.6: Importance of the 5-CAP during the lifespan of a mRNA Transcript. *Gonatopoulos-Pournatzis, T. and Crowing V. (2014) Biochemical Journal 457(2):231-42.*

Panel (a) CBC is required for pre-mRNA processing. The co-transcriptional binding of CBC to 7mG prevents the decapping activities of pre-mRNA degradation complexes [DXO (decapping exoribonuclease) and Dcp (decapping mRNA) Xrn2 (5′–3′ exoribonuclease 2)] and promotes pre-mRNA processing. CBC recruits P-TEFb [Cdk9/Cyclin T1 (CycT1)] to transcription initiation sites of specific genes promoting phosphorylation of the RNA pol II CTD at Ser2 residues. This results in the recruitment of splicing factors including SRSF1, which regulates both constitutive and alternative splicing events. Furthermore, CBC interacts with splicing machinery components that result in the spliceosomal assembly. CBC interacts with NELF and promotes pre-mRNA processing of replication-dependent histone transcripts.

Panel (b) CBC forms a complex with Ars2 and promotes miRNA biogenesis by mediating pri-miRNA processing.

Panel (c) CBC/Ars2 promotes pre-mRNA processing of replication-dependent histone transcripts.

Panel (d) CBC promotes the export of U snRNA. CBC interacts with PHAX, which recruits export factors including CRM1 and RAN·GTP.

Panel (e) CBC promotes the export of mRNA. For the export of transcripts over 300 nucleotides, hnRNP C interacts with CBC and inhibits the interaction between CBC and PHAX, allowing the CBC to interact with TREX and the transcript to be translocated to the cytoplasm. CBC interacts with the PARN deadenylase and inhibits its activity, protecting mRNAs from degradation.

Panel (f) CBC mediates the pioneer round of translation. Cbp80 interacts with CTIF, which recruits the 40S ribosomal subunit via eIF3 to the 5′ end of the mRNA for translation initiation. Upon binding of importin-β (Imp-β) to importin-α (Imp-α), mRNA is released from CBC and binds to eIF4E for the initiation of the standard mode of translation. CBC-bound mRNP components not found in eIF4E-bound mRNPs are CTIF, exon junction complex (EJC), and PABPN1.

Panel (g) The standard mode of translation is mediated by eIF4E cap-binding protein. eIF4E is a component of the eIF4F complex which promotes translation initiation.

Capping with 7-methylguanylate prevents 5′ degradation in two ways. First, degradation of the mRNA by 5′ exonucleases is prevented by functionally looking like a 3′ end. Second, the CBC and eIF4E/eIF4G block the access of decapping enzymes to the

cap. This increases the half-life of the mRNA, essential in eukaryotes as the export and translation processes take significant time.

The mechanism that promotes the 5′ proximal intron excision during splicing is not well understood, but the 7-methylguanylate cap appears to loop around and interact with the spliceosome, potentially playing a role in the splicing process.

The decapping of a 7-methylguanylate-capped mRNA is catalyzed by the decapping complex made up of at least Dcp1 and Dcp2, which must compete with eIF4E to bind the cap. Thus the 7-methylguanylate cap is a marker of an actively translating mRNA and is used by cells to regulate mRNA half-lives in response to new stimuli. During the decay process, mRNAs may be sent to P-bodies. P-bodies are granular foci within the cytoplasm that contain high levels of exonuclease activity.

25.2.4.1: **Triphosphatase and guanylyltransferase**

In capping the new mRNA, three different enzymes act sequentially:

- A phosphatase cleaves a terminal phosphate from the 5' end which has 3 phosphates at the start leaving 2 phosphates (the yeast triphosphatase is called Cet1);
- a GMP is added to the remaining diphosphate on the 5'-end to form a triphosphate in a reverse direction as shown in Figure 5 above (in yeast the RNA guanylyltransferase is called Ceg1);
- a methyl group is added to the N7 of the guanine base by a methylase also called a methyl transferase

These three enzymes are localized to a part of RNA polymerase that is highly phosphorylated, positioning them at the correct location for Cap formation. In yeast, the

Figure 25.2.7 shows an interactive iCn3D model of the Saccharomyces cerevisiae Cet1 (the triphosphatase)-Ceg1 (the guanylyltransferase) mRNA Capping Apparatus (3KYH)

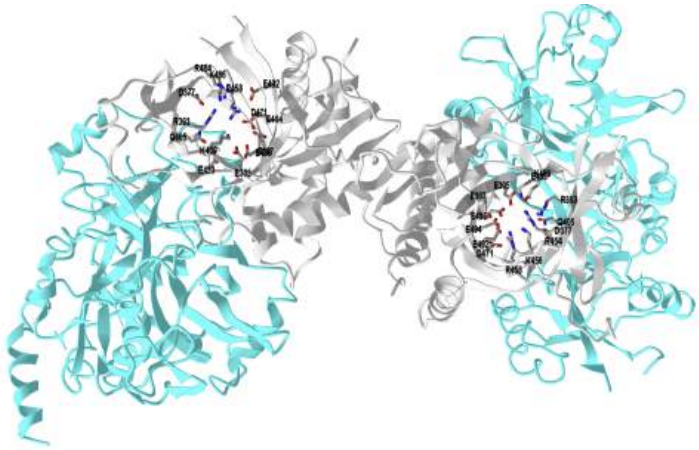

Figure 25.2.7: Saccharomyces cerevisiae Cet1-Ceg1 mRNA Capping Apparatus (3KYH) . (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...UWQ32mQrcF1eN6

The two enzymes exist as a heterotetramer of two homodimers. Two beta (Cet1-triphosphatase) subunits are shown in gray and the two alpha (Ceg1-guanylyltransferase) subunits are shown in cyan. The active site residues are shown in CPK-colored sticks and labeled. The two enzymes interact with yeast RNAP II mostly through Ceg1. Specifically, the Ceg1 oligonucleotide domain interacts with a motif, WAQKW (247-251), on Cet1. A conformational change in a flexible linker after that motif allows capping to ensue.

25.2.4.2: Methyl transferase

The next step is the methyl transfer to the N7 of guanine in the 5' end of the cap. Figure 25.2.8 shows an interactive iCn3D model of the Structure of a bacterial mRNA cap (Guanine-n7) methyltransferase (1RI1)

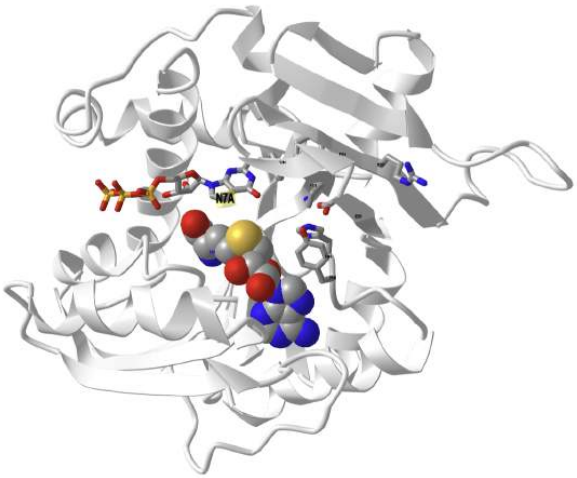

Figure 25.2.8: Structure of a bacterial mRNA cap (Guanine-n7) methyltransferase (1RI1) with bound S-adenoysl-homocysteine. (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...YfaJ6W93zSDaX7

7-Methyl-guanosine-5'-triphosphate-5'-guanosine (GTG) is shown in sticks. The N7 nitrogen of guanine is labeled. S-Adenoslyl-L-homocysteine, the leaving group after methylation by S-adenosyl-L-methionine (SAM), is shown in spacefill. Key amino acid side chains in the active site are labeled (in small letters). The structure is most consistent with an in-line methyl transfer from SAM to the attacking nucleophile, the N7 of guanine. Specificity in most capping methylases occurs through noncovalent interactions (mostly base stacking, with two amino acid aromatic groups (an example of π-π stacking), or one aromatic and one nonpolar side chain. In the bacterial example shown above, the interactions include hydrophobic and hydrogen bonding interactions using Y284, F24, P175, E225, H144, and Y145.

25.2.4.3: Decapping

"What goes up must come down!" If the mRNA is capped during synthesis, there must be an enzyme to decap it. Figure 25.2.9 shows an interactive iCn3D model of the yeast mRNA decapping enzyme Dcp1-Dcp2 complex in the ATP bound closed conformation (2QKM)

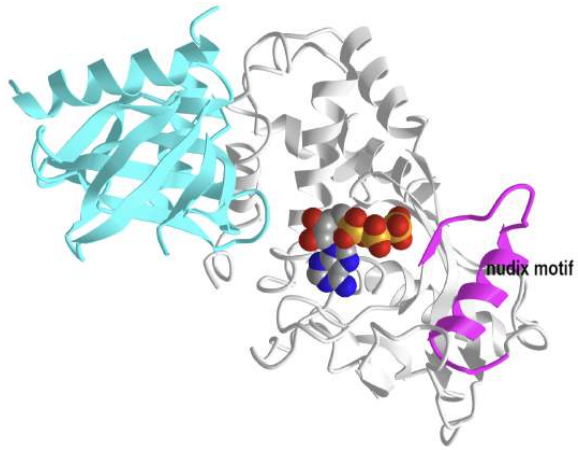

Figure 25.2.9: Yeast mRNA decapping enzyme Dcp1-Dcp2 complex in the ATP bound closed conformation (2QKM). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...hBPokeNeMfcGUA

The rendering is colored as shown below:

- a chain in cyan
- b chain in gray
- nudix motif in magenta
- ATP in spacefill

Dcp2p, as with many other enzymes, has an open (inactive) and closed (active) conformation suggesting that a conformational change between the two states regulates decapping. The ATP binding site demarcates the active site. the Dcp1 protein probably functions to stabilize the closed state.

25.2.5: mRNA Splicing

Eukaryotic genes that encode polypeptides are composed of coding sequences called ***exons*** (*ex*-on signifies that they are *ex*pressed) and intervening sequences called ***introns*** (*int*-ron denotes their *int*ervening role). Transcribed RNA sequences corresponding to introns do not encode regions of the functional polypeptide and are removed from the pre-mRNA during processing. All of the intron-encoded RNA sequences must be completely and precisely removed from a pre-mRNA before protein synthesis so that the exon-encoded RNA sequences are properly joined together to code for a functional polypeptide. If the process errs by even a single nucleotide, the sequences of the rejoined exons would be shifted, and the resulting polypeptide would be nonfunctional. The process of removing intron-encoded RNA sequences and reconnecting those encoded by exons is called ***RNA splicing.*** Intron-encoded RNA sequences are removed from the pre-RNA while it is still in the nucleus. Although they are not translated, introns appear to have various functions, including gene regulation and mRNA transport. On completion of these modifications, the ***mature transcript***, the mRNA that encodes a polypeptide, is transported out of the nucleus, destined for the cytoplasm for translation. Introns can be spliced out differently, resulting in various exons being included or excluded from the final mRNA product. This process is known as ***alternative splicing***. The advantage of alternative splicing is that different types of mRNA transcripts can be generated, all derived from the same DNA sequence. In recent years, it has been shown that some archaea also can splice their pre-mRNA.

The splicing reaction is catalyzed by the ***spliceosome***, a macromolecular complex formed by five small nuclear ribonucleoproteins (snRNPs), termed U1, U2, U4, U5, and U6, and approximately 200 proteins, as shown in Figure 25.2.10 Each of these snRNPs contains snRNAs that can interact with each other through intrastrand hydrogen bonding and hence which help localize the snRNPs to the complexes. The assembly of the spliceosome on pre-mRNA includes the binding of U1 snRNP, U2 snRNP, the pre-formed U4/U6-U5 triple snRNP, and the Prp19 complex. This assembly occurs through the recognition of several sequence elements on the pre-mRNA that define the exon/intron boundaries, which include the 5′ and 3′ splice sites (SS), the associated 3′ sequences for intron excision, the polypyrimidine (Py) tract, and the branch point sequence (BPS). The assembly of the spliceosome during the process is depicted in Figure 25.2.10

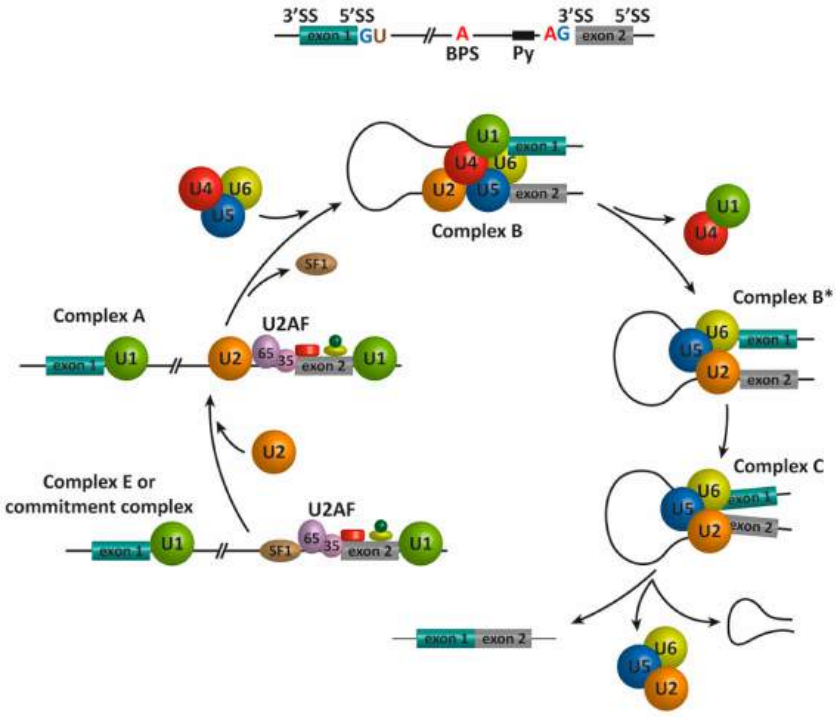

Figure 25.2.10: **Schematic representation of the spliceosome assembly and pre-mRNA splicing.** *Suñé-Pou, M., et. al. (2017) Genes 8(3):87* .

In the first step of the splicing process, the 5′ splice site (GU, 5′ SS) is bound by the U1 snRNP, and the splicing factors SF1/BBP and U2AF cooperatively recognize the branch point sequence (BPS), the polypyrimidine (Py) tract, and the 3′ splice site (AG, 3′ SS) to assemble complex E. The binding of the U2 snRNP to the BPS results in the pre-spliceosomal complex A. Subsequent steps lead to the binding of the U4/U5–U6 tri-snRNP and the formation of complex B. Complex C is assembled after rearrangements that detach the U1 and U4 snRNPs to generate complex B*. Complex C is responsible for the two transesterification reactions at the SS. Additional rearrangements result in the excision of the intron, which is removed as a lariat RNA, and ligation of the exons. The U2, U5, and U6 snRNPs are then released from the complex and recycled for subsequent rounds of splicing

There are different ways that pre-spliceosomes convert to full spliceosomes. The interactions of the small ribonucleoproteins U1 and U2, which bind at the 5' and 3' end of the introns respectively, are key. When multiple introns exist, a few different pathways occur. The interactions can be upstream (cross-introns) and downstream (cross-exons), as shown in Figure 25.2.11.

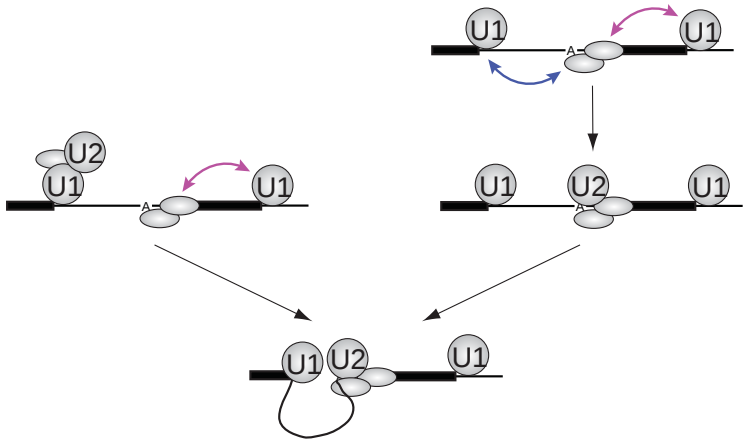

Figure 25.2.11: Implications of synergistic U2 recruitment for the mechanism of exon and intron recognition. Braun et al. (2018) . Synergistic assembly of human pre-spliceosomes across introns and exons. *eLife* **7**:e37751. https://doi.org/10.7554/eLife.37751. Creative Commons Attribution License

The left-hand side of the figure shows how the interaction of U1 and U2 can occur across a single intron, to form the mature version of the spliceosome showing the U1-U2 interaction. The colored arrow shows possible interactions that either speed up or slow down the U1-U2 mature interactions.

The right-hand side shows the formation of an intermediate cross-exon U2-U1 pair in which the exons that flank two introns are first delineated, which then leads to the physical U1-U2 interaction in the mature spliceosome when cross-intron interactions occur.

Now let's move to show the actual structures of two of the spliceosome structures shown in Figure 10 above. Figure 25.2.12shows an interactive iCn3D model of the human fully-assembled precatalytic spliceosome (pre-B complex) (6QX9)

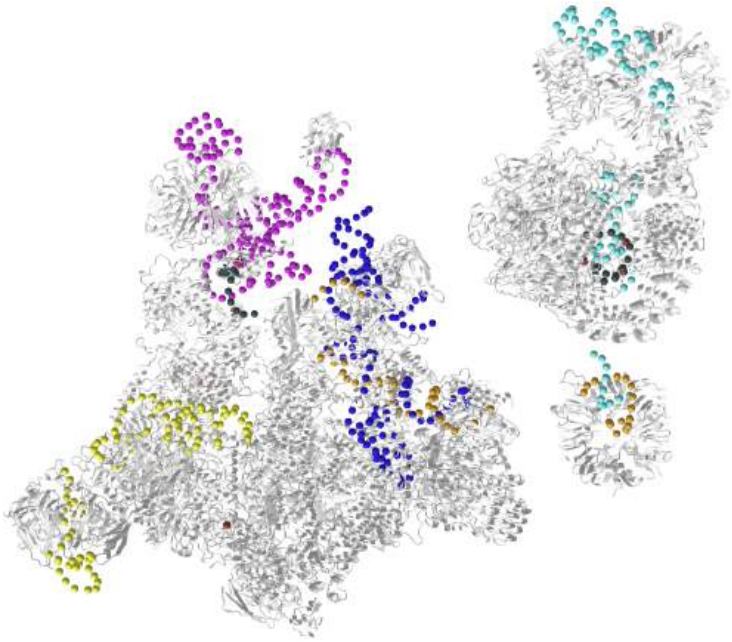

Figure 25.2.12: Human fully-assembled precatalytic spliceosome (pre-B complex) (6QX9). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...zLLvMh82m5u9M8

The full structure of the spliceosome is almost too complicated to understand even if displayed in a molecular model. It's better grasped in a way by the cartoon figure shown previously. To avoid unnecessary visual complexity, the protein subunits in the iCn3D model of the human spliceosome are shown in a gray cartoon, and only the RNA molecules in the U_n small ribonucleoproteins are shown in color, as described below. The resolution is such that each nucleotide in the RNA polymers is shown just as a single-colored sphere not connected to the next nucleotide in the RNA.

- U1 snRNA - magenta
- U6 snRNA - orange
- U5 snRNA - yellow
- U2 snRNA - cyan
- U4 snRNA - blue
- AdML pre-mRNA - black

Since it has U1, U2, U4, U5, and U6, it most closely resembles Complex B (or an immediate precursor pre-B of it) as shown in Figure 10. This form occurs before U1 snRNP dissociates. A helix from the 5'-single-stranded U1 snRNA inserts into a helicase in the complex between two RecA domains which bind ATP and unfold the nucleic acids. This allows the 5' single-stranded RNA to form interactions with an ACAGAGA sequence (mobile loop) in U6. These conformational changes allow the eventual separation of the U4 and U6 snRNA, freeing the snRNA in U6 is form the catalytic site. The B complex itself does not have a functioning active site. After the dissociation of U1 and U4 snRNPs, and the binding of another 20 or so proteins, the active spliceosome is formed.

Now let's look at the final catalytic structure, Complex C, which contains only three of the snRibonucleoproteins, U2, U5, and U6. Figure 25.2.13shows an interactive iCn3D model of the Human C Complex Spliceosome (7A5P)

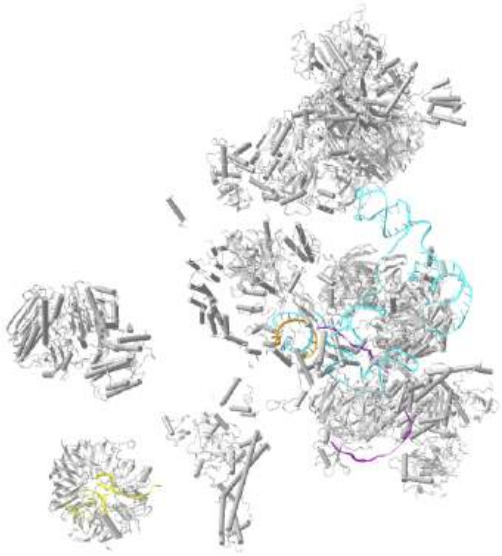

Figure 25.2.13: Human C Complex Spliceosome (7A5P). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...5co1nofAVEnyR6

The color coding is as follows:

- protein - gray
- U6 snRNA - orange
- U5 snRNA - yellow
- U2 snRNA - cyan
- AdML pre-mRNA - magenta

The interactions of the snRNAs are key for structure and catalysis in the spliceosome, and in the figures above the interactions are had to discern. Figure 25.2.14shows the interactions among U2, U5, and U6 snRNA in the human and yeast spliceosomes.

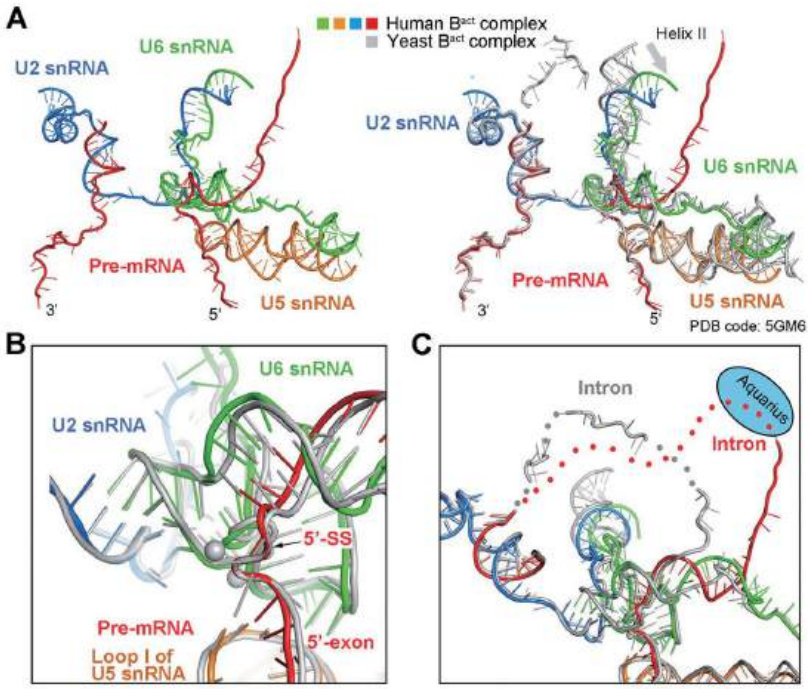

Figure 25.2.14: The RNA elements and the splicing active site of the human mature B^{act} complex. Zhang, X., Yan, C., Zhan, X. *et al.* Structure of the human-activated spliceosome in three conformational states. *Cell Res* **28**, 307–322 (2018). https://doi.org/10.1038/cr.2018.14. Creative Commons Attribution 4.0 Unported License. http://creativecommons.org/licenses/by/4.0/

Panel (A) shows the structure of the RNA elements in the core of the human mature B^{act} complex. The color-coded RNA elements of the human B^{act} complex are shown in the left panel, and their superposition with those of the *S. cerevisiae* B^{act} complex is displayed in the right panel. All yeast RNA elements are colored grey. The helix II of the U2/U6 duplex in the human B^{act} complex is bent relative to that in the yeast complex.

Panel (B) shows a structural overlay of the active site RNA elements between the human and *S. cerevisiae* B^{act} complexes.

Panel (C) shows that the U6/intron duplex in the human B^{act} complex is considerably longer than that in the *S. cerevisiae* B^{act} complex.

In mammals, the first catalytic step of the splicing reaction begins when the U1 snRNP binds the 5′ SS of the intron (defined by the consensus sequence AGGURAGU), and the splicing factors SF1 and U2AF cooperatively recognize the BPS, Py, and 3′ SS to assembled complex E or the commitment complex. Subsequently, U2 snRNP and additional proteins are recruited to the pre-mRNA BPS to form the pre-spliceosome or complex A. The binding of the U4/U6-U5 tri-snRNP forms the pre-catalytic spliceosome or complex B. After RNA-RNA and RNA-protein rearrangements at the heart of the spliceosome, U1 and U4 are released to form the activated complex B or complex B* This complex is responsible for executing the first catalytic step, through which the phosphodiester bond at the 5′ SS of the intron is modified by the 2′-hydroxyl of adenosine of the BPS to form a free 5′ exon and a branched intron, as shown in Figure 25.2.15. The reaction of the 2'-hydroxyl from the branch point adenosine nucleotide is known as a ***transesterification reaction***. During this process, additional rearrangements occur to generate the catalytic spliceosome or complex C (see Figure 10 above), which is responsible for catalyzing the second transesterification reaction leading to intron excision and exon–exon ligation. The resulting intron structure is referred to as a ***lariat structure***. After the second catalytic step, the U2, U5, and U6 snRNPs are released from the post-spliceosomal complex and recycled for additional rounds of splicing.

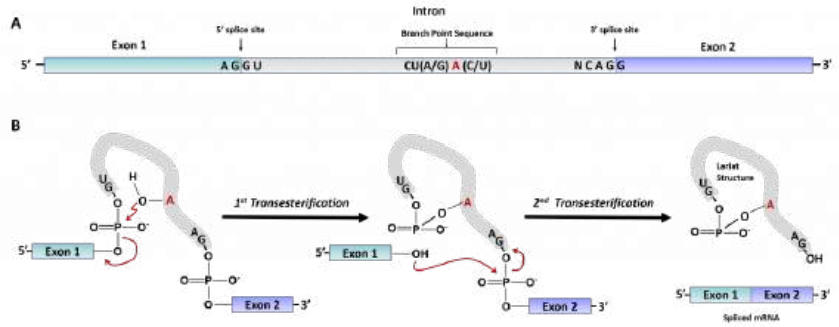

Figure 25.2.15: Transesterification Reactions Involved in mRNA Splicing.

Panel (A) shows a schematic diagram of the pre-mRNA with exons and introns indicated. Key sequences are required for splicing at the 5' and 3' intron locations, and for the recognition and positioning of the branch point Adenosine residue for the first transesterification reaction. (

Panel (B) shows a schematic of the two transesterification reactions required for intron removal. The branch point 2'-OH residue mediates attack on the 5'-phosphate of the intron guanosine residue located at the 5'-splice site. This releases the 3' hydroxyl of Exon 1 which subsequently mediates the attack of the 5' phosphate of the first guanosine residue in Exon 2. The 3' hydroxyl of the intron guanine residue is released forming the Lariat structure and Exon 1 is ligated to Exon 2.

Alternative Splicing (AS) offers an additional mechanism for regulating protein production and function. AS options are determined by the expression of or exposure to *trans* elements present within unique cellular locations and environments. Additional sequence elements within the mRNA, known as ***exonic*** and ***intronic*** splicing silencers or enhancers (ESS, ISS, ESE, and ISE, respectively), participate in the regulation of AS. Specific RNA-binding proteins, including heterogeneous nuclear ribonucleoproteins (hnRNPs) and serine/arginine-rich (SR) proteins, recognize these sequences to positively or negatively regulate AS, as shown in Figure 25.2.16. These regulators, together with an ever-increasing number of additional auxiliary factors, provide the basis for the specificity of this pre-mRNA processing event in different cellular locations within the body.

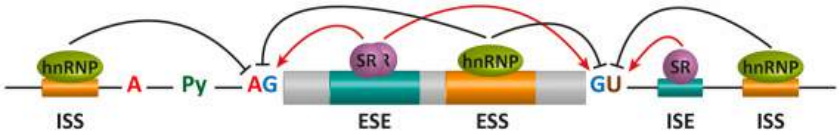

Figure 25.2.16: Alternative splicing (AS) regulation by *cis* mRNA elements and *trans-acting* factors. *Suñé-Pou, M., et. al. (2017) Genes 8(3):87*

The core *cis* sequence elements that define the exon/intron boundaries (5′ and 3′ splice sites (SS), GU-AG, polypyrimidine (Py) tract, and branch point sequence (BPS)) are poorly conserved. Additional enhancer and silencer elements in exons and introns (ESE: exonic splicing enhancers; ESI: exonic splicing silencers; ISE: intronic splicing enhancers; ISI: intronic splicing silencers) contribute to the specificity of AS regulation. *Trans-acting* splicing factors, such as SR family proteins and heterogeneous nuclear ribonucleoprotein particles (hnRNPs), bind to enhancers and silencers and interact with spliceosomal components. In general, SR proteins bound to enhancers facilitate exon definition, and hnRNPs inhibit this process. These *trans-acting* elements are expressed differentially within different locations or under different environmental stimuli to regulate AS.

There are several different types of AS events, which can be classified into four main subgroups. The first type is exon skipping, which is the major AS event in higher eukaryotes. In this type of event, a cassette exon is removed from the pre-mRNA as shown in Figure 25.2.17(panel A). The second and third types are alternative 3′ and 5′ SS selections (panels b and c). These types of AS events occur when the spliceosome recognizes two or more splice sites at one end of an exon. The fourth type is intron retention (panel d), in which an intron remains in the mature mRNA transcript. This AS event is much more common in plants, fungi, and protozoa than in vertebrates. Other events that affect the transcript isoform outcome include mutually exclusive exons (panel e), alternative promoter usage (panel f), and alternative polyadenylation (panel g).

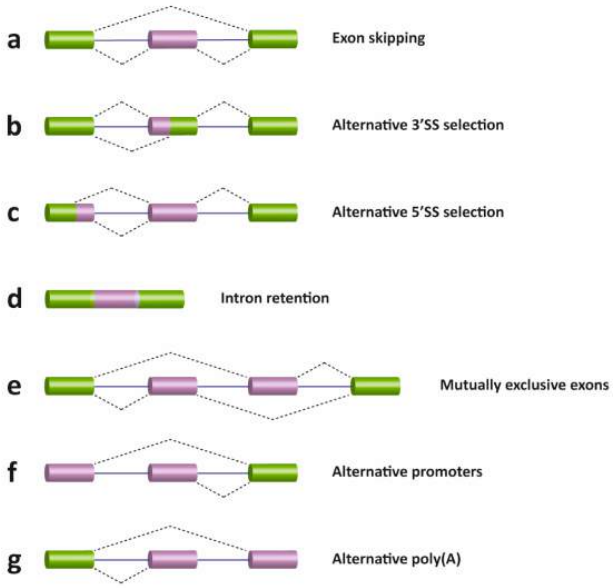

Figure 25.2.17: Schematic representation of different types of alternative transcriptional or splicing events, with exons (boxes) and introns (lines). Constitutive exons are shown in green and alternatively spliced exons are in purple. Dashed lines indicate the AS event. Exon skipping (**a**); alternative 3′ (**b**) and 5′ SS selection (**c**); intron retention (**d**); mutually exclusive exons (**e**); alternative promoter usage (**f**); and alternative polyadenylation (**g**) events are shown. Like alternative splicing (AS), the usage of alternative promoter and polyadenylation sites allows a single gene to encode multiple mRNA transcripts. *Suñé-Pou, M., et. al. (2017) Genes 8(3):87*

Here is a detailed and incredible narrated animation of splicing and the spliceosome.

25.3: RNA-Dependent Synthesis of RNA and DNA

25.3.1: RNA Viruses

Infections with RNA viruses place a constant burden on our healthcare systems and economy. Over the past century, this has been particularly true for infections with the *Human immunodeficiency virus 1* (HIV-1), *Influenza A virus* (IAV), *Rotavirus* (RotaV), *West Nile virus* (WNV), *Dengue virus* (DV), *Measles virus* (MV), and the *Porcine reproductive and respiratory syndrome virus* (PRRSV). But also emergent RNA viruses can have considerable consequences, such as the *Severe acute respiratory syndrome-related coronavirus* (SARS-CoV) in 2003, the *Middle East Respiratory Syndrome coronavirus* (MERS-CoV), and most recently the *Severe acute respiratory syndrome-related coronavirus-2* (SARS-CoV-2) in December of 2019.

Eukaryotes and bacteria can be infected with a wide variety of RNA viruses. On average, these pathogens share little sequence similarity and use different replication and transcription strategies. RNA virus genomes can consist of double-stranded RNA (dsRNA) or single-stranded (ssRNA) as shown in Figure 25.3.1 (Panel a). In turn, the ssRNA viruses can be classified into positive sense (+RNA) and negative sense (−RNA) viruses, depending on the translatability of their genetic material. As summarized for four model RNA pathogens in Panel b, all RNA viruses use dedicated replication and transcription strategies to amplify their genetic material. The common denominator of these strategies is a conserved RNA-dependent polymerase domain. Figure 25.3.1 describes variations of the replication process in the different types of RNA viruses.

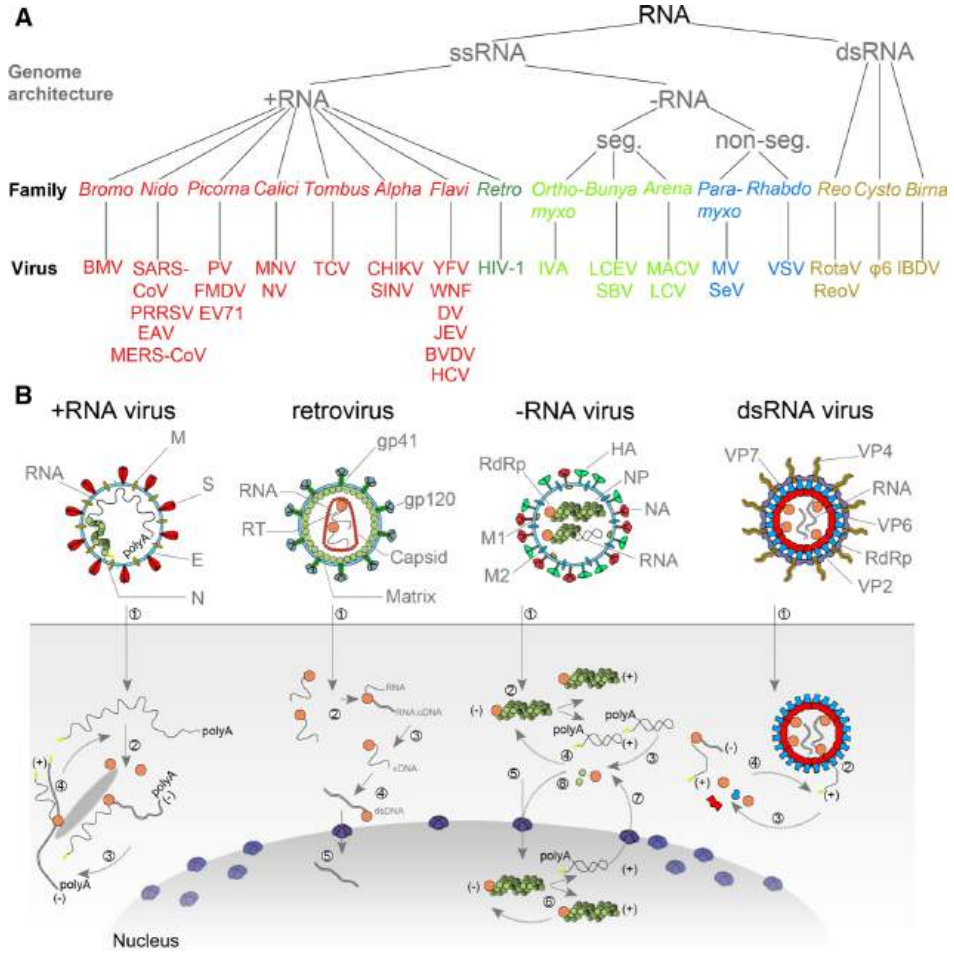

Figure 25.3.1: Taxonomy and Replication Strategies of RNA Viruses. te Velthuis, A.J.W. (2014) *Cell & Mol Life Sci 71:4403-4420*

Panel a shows a simplified taxonomy of the genome architecture of representative RNA viruses.

Panel b (*+RNA virus*)shows infection with a +RNA virus—as exemplified here with a CoV-like virion—releases a single-stranded RNA genome into the cytoplasm (*1*). (*2*) Translation of the 5′-terminal open-reading frame of the genome produces the viral replicase. (*3*) This multi-enzyme complex includes **RNA-dependent RNA polymerase (RdRp)** activity (*orange*) and associates

with intracellular membranes before −RNA synthesis commences. Newly synthesized −RNAs are subsequently used to produce new +RNAs (*4*), which are typically capped (*yellow*) and polyadenylated (polyA). **(*Retrovirus*)** HIV-1 genomes are packaged as ssRNA in virions. When the ssRNA is released (*1*) a cDNA copy is synthesized by the reverse transcriptase enzyme (RT) (*2*). The RNA is next degraded by the intrinsic RNase H activity in the RT (*3*) and the single-stranded cDNA is converted to dsDNA (*4*). The dsDNA is imported into the nucleus (*5*) for integration into the host's genetic material. **(−*RNA virus*)** (*1*) As illustrated here with an IAV-like particle, infection with an −RNA virus releases a viral RNA genome that is associated with a viral polymerase (*orange*) and nucleoprotein (*green*). (*2*) In the case of non-segmented −RNA viruses, these complexes support transcription to produce viral mRNAs or cRNAs. (*3*) Viral mRNAs are next translated and new viral proteins complex with cRNAs to synthesize new vRNAs. (*5*) The vRNA-containing complexes of some segmented −RNA viruses are imported into the nucleus of the host cell, where (*6*) the RdRp produces mRNAs or cRNAs. (*7*) mRNAs are transported to the cytoplasm, while cRNAs are bound by new viral proteins to form cRNPs for −RNA synthesis. **(*dsRNA virus*)** Fully duplexed RNA genomes lack cap and polyA elements. (*1*) The RdRp (*orange*), therefore, transcribes the viral genome inside the capsid of the virion (*blue* and *red*), so viral mRNAs can be (*2*) released into the cytoplasm as illustrated here with a rotavirus-like virion. In the cytoplasm, the mRNA is translated (*3*) or replicated by newly synthesized viral RdRps.

Viral RNA-dependent RNA Polymerases (RdRps) were discovered in the early 1960s from studies on mengovirus and polio viruses when it was observed that these viruses were not sensitive to actinomycin D, a drug that inhibits cellular DNA-directed RNA synthesis. This lack of sensitivity suggested that there is a virus-specific enzyme that could copy RNA from an RNA template and not from a DNA template. RdRps show some structural similarity to telomerase enzymes suggesting a potential ancestral relationship of telomerase with RdRps.

The most famous example of RdRp is of the polio virus. The viral genome is composed of RNA, which enters the cell through receptor-mediated endocytosis. From there, the RNA can act as a template for complementary RNA synthesis, immediately. The complementary strand is then, itself, able to act as a template for the production of new viral genomes that are further packaged and released from the cell ready to infect more host cells. The advantage of this method of replication is that there is no DNA stage; replication is quick and easy. The disadvantage is that there is no 'backup' DNA copy (Fig 26.3.1b; + RNA virus).

Reverse Transcriptase (RT) enzymes, on the other hand, that are common to retroviruses, convert the + RNA strand from the virus into a cDNA copy (Fig 26.3.1b; retroviruses). The RT enzyme then degrades the RNA and the single-stranded cDNA is converted to dsDNA. The dsDNA is then integrated into the host's genome where it can remain in a dormant state. Upon reactivation, + RNA will be manufactured, along with viral proteins used in the assembly of the infectious viral particles.

25.3.2: Structure and Mechanism of RNA Viral Polymerases

The RNA-dependent polymerase domain is a member of the superfamily of template-dependent nucleic acid polymerases and typically <400 amino acids in length. Its sequence is highly variable on average, with some regions showing less than ~10% conservation. Strong amino acid conservation can be observed, however, in regions that are directly involved in nucleotide selection or catalysis, such as the strictly conserved glycine and aspartates in the center of the domain. The prototypic RNA virus RNA polymerase domain harbors seven of such regions or motifs, which are arranged in the order G, F1–3, A, B, C, D, and E from amino- to carboxy-terminus. Each of the seven motifs in the RNA polymerase domain adopts a specific and conserved fold, as shown in Figure 25.3.2

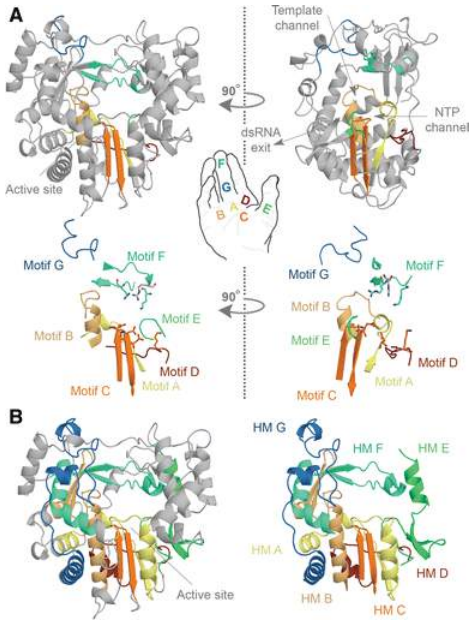

Figure 25.3.2: Conserved structural elements in the RNA virus polymerases. te Velthuis, A.J.W. (2014) *Cell & Mol Life Sci 71:4403-4420.*

Panel a shows the structure of the FMDV RdRp. The motifs A, B, C, D, E, F, and G are color-coded *yellow*, *gold*, *orange*, *red*, *light green*, *aquamarine*, and *blue*. Overall the polymerase structure adopts a shape that resembles a cupped right hand. Herein, motifs A–E lie on the palm, while motifs F and G are part of the fingers. In the side-view of the enzyme, the location of the template and NTP channels is indicated.

Panel b shows conserved structural elements of the FMDV RdRp. Homomorphic A–G were mapped and color-coded *yellow*, *gold*, *orange*, *red*, *light green*, *aquamarine*, and *blue*, respectively. Images A and B are based on PDB accession 2E9R.

Figure 25.3.3 shows an interactive iCn3D model of the Foot-and-mouth disease virus RNA-polymerase in complex with a template- primer RNA, PPi, and UTP (2E9Z)

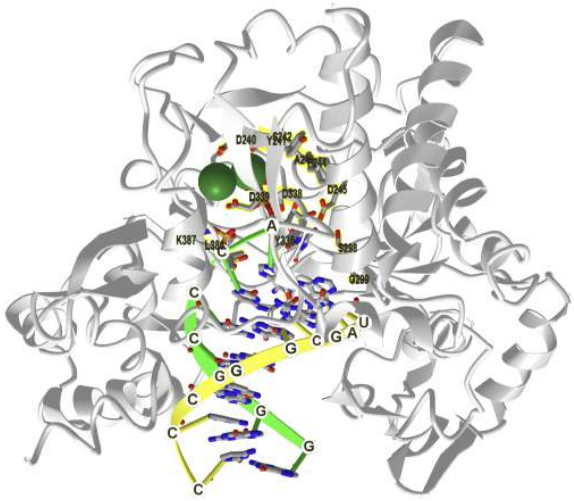

Figure 25.3.3: Foot-and-mouth disease virus RNA-polymerase in complex with a template- primer RNA, PPi and UTP (2E9Z). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...rZJwYWKHqcAd76

Active site region side chains are shown as sticks and labeled. The template stand is shown in yellow and the primer is in green. Note the conserved amino acids Tyr-336, the catalytic Asp-338, and Lys-387 in motifs C and E, respectively. The primer 3'OH forms an H bond with active site Asp 338 (on motif C). In some structures, Asp 338 is bound to a metal ion that interacts with the PPP of the incoming NTP. Two metal ions are involved in catalysis. Tyr 336 interacts with the primer nucleotide while Lys 387 and

Arg 388 interact with the primer backbone. These three residues are highly conserved. The acceptor base of the template strands is adjacent to the NTP binding site. There is no proofreading activity in viral RNA replication.

RNA-dependent RNA polymerases generally have a groove on top of the enzyme where RNA enters. It exits in the front. Nucleotides enter at a rear channel. This is illustrated in Figure 25.3.4 (Panel b). Following the convention for cellular DNA-dependent DNA polymerases (DdDp), the seven motifs and homomorphs are grouped into three subdomains. These subdomains are called fingers, palm, and thumb in reference to the polymerase domain's likeliness to a cupped right hand, as shown in Figure 25.3.4 (Panel A). The finger subdomain loops that interconnect the fingers with the thumb in the RNA-dependent RNA polymerases (RdRps) of +RNA and dsRNA viruses create an overall "closed-hand" conformation that is unique to RNA-dependent RNA polymerases (RdRps) and generally not seen in crystal structures of DNA-dependent DNA polymerases (DdDps) or reverse transcriptases (RTs).

The three subdomains of the RNA-dependent polymerases work together to facilitate the binding of RNA and nucleotides (NTPs). The thumb subdomain contains various residues that are involved in RNA binding and these generally pack into the minor groove of the template RNA. In some polymerases, the thumb also contains sequences that protrude into the template channel to help stabilize the initiating NTPs on the ssRNA template. Crucially, these protrusions are also able to undergo relatively large conformational rearrangements to facilitate the translocation of the template following the first condensation reaction. The other residues of the thumb subdomain contribute to the formation of the NTP tunnel, which sits at an ~110° angle with the template channel as shown in Figure 25.3.4, Panel A. The cavity is lined with positively charged amino acids, though charge interactions are likely not sufficient to guide NTPs into the interior. Indeed, molecular dynamics (MD) simulations have shown that the residues of the NTP channel can also explore a relatively large amount of space, which may allow the RdRp to actively "pump" NTPs down the channel.

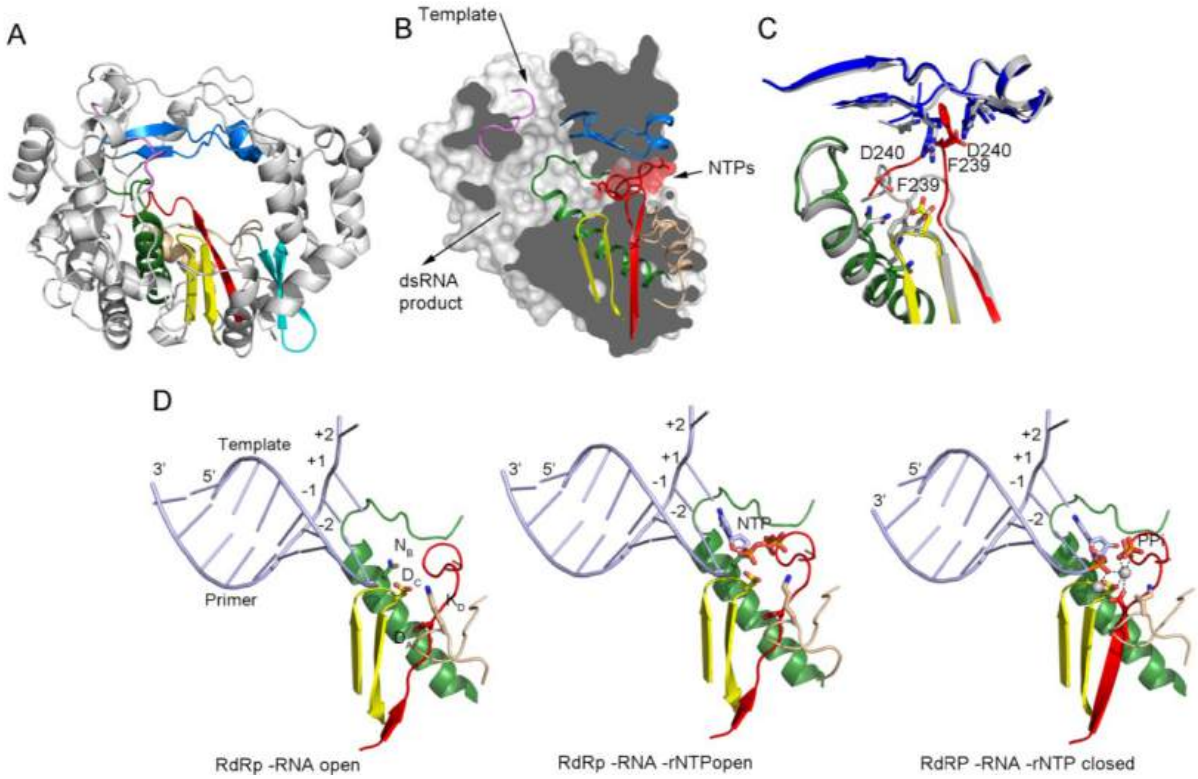

Figure 25.3.4: The Picornavirus (PV) Replication-Elongation Complexes for RNA Dependent RNA Polymerase. Ferrer-Orta, C., et al. (2015) Viruses 7(8):4438-4460

Panel (**A**) shows a ribbon representation of a typical picornaviral RdRP (model from the cardiovirus EMCV $3D^{pol}$, PDB id. 4NZ0). The seven conserved motifs are indicated in different colors: motif A, red; motif B, green; motif C, yellow; motif D, sand; motif E, cyan; motif F, blue; motif G, pink;

Panel (**B**) shows a lateral view of a surface representation of the enzyme (grey) that has been cut to expose the three channels that are the entry and exit sites of the different substrates and reaction products. The structural elements that support motifs A–G are also shown as ribbons. This panel also shows the organization of the palm sub-domain with motif A shown in two alternative

conformations: the standard conformation (PDB id. 4NZ0) found in the apo-form of most crystallized $3D^{pol}$ proteins and the altered conformation found in the tetragonal crystal form of the EMCV enzyme (PDB id. 4NYZ). The alterations affect mainly Asp240, the amino acid in charge of incoming ribonucleotide triphosphate (rNTP) selection, and the neighboring Phe239 that move ~10 Å away from its position in the enzyme catalytic cavity directed towards the entrance of the nucleotide channel, approaching to motif F;

Panel (**C**) shows a close-up of the structural superimposition of the two alternative conformations of the EMCV motif A;

Panel (**D**) shows the PV replication-elongation complexes. Sequential structures illustrating the movement of the different palm residues from a binary PV $3D^{pol}$-RNA open complex (left) to an open $3D^{pol}$-RNA-rNTP ternary complex (middle) where the incoming rNTP is positioned in the active site for catalysis and, a closed ternary complex (right) after nucleotide incorporation and pyrophosphate (PPi) release. The residues D_A (involved in rNTP selection through an interaction with the 2′ hydroxyl group), D_C (the catalytic aspartate of motif C), K_D (the general acid residue of motif D that can coordinate the export of the PPi group), and N_B (a conserved Asn of motif B, interacting with D_A) have been highlighted as sticks. The different structures correspond to the $3D^{pol}$-RNA (PDB id. 3OL6), $3D^{pol}$-RNA-CTP open complex (PDB id. 3OLB) and $3D^{pol}$-RNA-CTP closed complex (PDB id. 3OL7) structures of PV elongation complexes, respectively

The finger subdomain residues mainly pack into the major groove of the RNA template. Furthermore, upon entry of the template, they can unstack the single strand at position +3, as shown in Figure 25.3.5 (Panel A). The non-conserved structural elements of the fingers subdomain play a role in RNA binding as well. In particular, the fingertips of dsRNA and some +RNA virus RdRps allow the polymerase to “hold” the template without extensive conformational changes. The variations and extensions in the fingers subdomain has also been shown to play roles in protein–protein interactions, phosphorylation, oligomerization, and nuclear import. In contrast, the HIV-1 RT lacks such extensions and adopts a more “open-hand” or U-shaped binding cleft. As a consequence, the RT structure must rearrange its subdomains to coordinate the binding of the template, nascent strand, and incoming dNTPs.

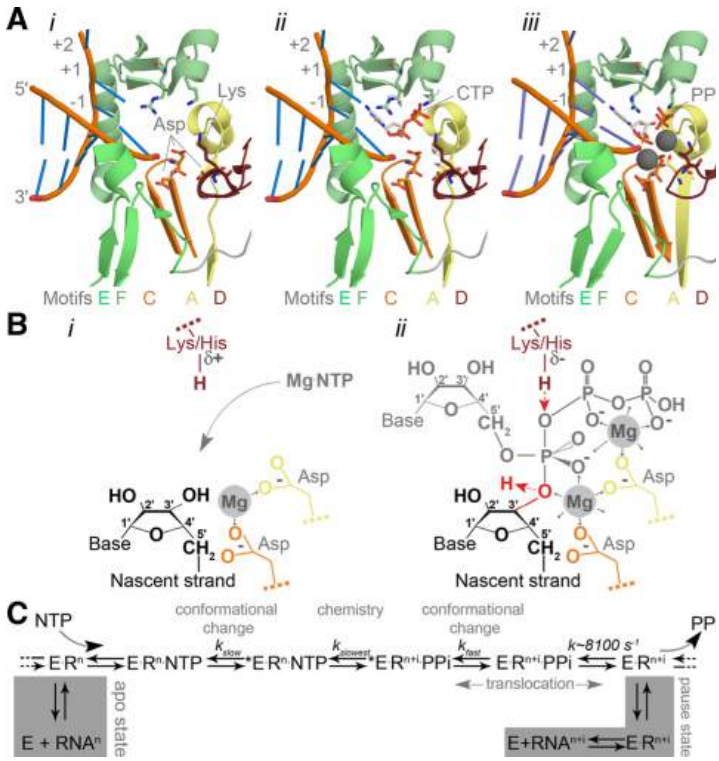

Figure 25.3.5: Catalysis in the RNA virus polymerase active site. te Velthuis, A.J.W. (2014) *Cell & Mol Life Sci 71:4403-4420.*

Panel a shows the structure of the PV active site as it moves from a native state or elongation complex (*i*) to an open complex (*ii*), and a closed complex (*iii*). The closed complex depicted here shows the active site after catalysis. Highlighted are the metal-binding aspartates of motifs A and C, and the lysine of motif D that acts as a general acid. Color coding by motif as in Fig. 26.3.2. Image based on PDB accessions 3Ol6, 3OLB, and 3OL7.

Panel b shows a schematic presentation of the RdRp active site. The aspartates (Asp) of motif A (*yellow*) and C (*orange*) bind divalent metal ions (marked Mg and *shaded grey*), which are used to coordinate the formation of a new phosphodiester bond at the 3′-OH (*red* in panel ii) of the nascent strand (*yellow*). The general acid (*red* Lys/His in panel ii) is positioned near the β-phosphate of the incoming NTP to protonate the PP_i leaving group.

Panel c shows a simplified schematic of the kinetic steps of RNA polymerases. *Asterisk* indicates a closed complex

The NTP and template entry channels meet at the palm subdomain - Figure 25.3.5, Panel A. This is a structure that is comprised of a central, partially formed three-stranded β-sheet, which is also present in RNA-recognition motifs (RRMs). The relative movement of these strands within the RRM is vital to catalysis and dependent on NTP binding. Only when a correct NTP binds can motif A and motif C align and the RRM fold be completed. This catalytically competent conformation of the active site is often referred to as the closed complex (not to be confused with the "closed-hand", which refers to the overall structure of the RdRp) - Figure 25.3.5, Panel d.

The polymerase reaction creates new phosphodiester bonds between NTPs using RNA as a template. The NTP substrates involved in this reaction are coordinated by two metal ions, which are bound by the conserved aspartates of motifs A and C - Figure 25.3.5 - panel a, i. They also position the NTP's triphosphate optimally for attack by the sugar moiety of the nascent strand once its 3′ carbon has lost a proton- Figure 25.3.5, panel b. The N-terminal aspartate of motif C thus uses a metal ion to fix the α-phosphate of the incoming NTP and reduce the pK_a of the nascent RNA's 3′-OH to facilitate the attack - Figure 25.3.5, panel b, ii. The amino-terminal carboxylate of motif A, on the other hand, stabilizes the β- and γ-phosphates with its divalent metal as well as the pentavalent (phosphorane) intermediate that forms during catalysis - Figure 25.3.5, panel b, ii. Structural and biochemical analyses have shown that the formation of this transient structure is dependent on the attack of the NTP's α-phosphate by the 3′-OH, which is often the rate-limiting catalytic step in NTP condensation - Figure 25.3.5, panel b.

Motif D's lysine or histidine assists the N-terminal aspartate of motif A in coordinating the β-phosphate of the incoming NTP, analogous to the trigger loop in DdDps. However, when the positively charged side chain of motif D approaches the β-phosphate, it can protonate the PP_i leaving group as well - Figure 25.3.5, panel b, ii. This second protonation step in the active site is not essential for the polymerase reaction, since catalysis can still take place when motif D's lysine has been mutated to a residue with a different pK_a. The polymerase reaction rate will nevertheless be 50- to 1,000-fold higher when a lysine or histidine is present. Recent data even suggests that motif D can coordinate the export of the PP_i group from the active site once catalysis has taken place, thereby triggering the translocation of the RNA.

Overall, the RNA replication process can be summarized with this four-step mechanism:

1. Nucleoside triphosphate (NTP) binding - initially, the RdRp presents with a vacant active site in which an NTP binds, complementary to the corresponding nucleotide on the template strand. Correct NTP binding causes the RdRp to undergo a conformational change.
2. Active site closure - the conformational change, initiated by the correct NTP binding, results in the restriction of active site access and produces a catalytically competent state.
3. Phosphodiester bond formation - two Mg^{2+} ions are present in the catalytically active state and arrange themselves in such a way around the newly synthesized RNA chain that the substrate NTP can undergo a phosphatidyl transfer and form a phosphodiester bond with the newly synthesized chain. With the use of these Mg^{2+} ions, the active site is no longer catalytically stable, and the RdRp complex changes to an open conformation.
4. Translocation - once the active site is open, the RNA template strand can move by one position through the RdRp protein complex and continue chain elongation by binding a new NTP, unless otherwise specified by the template.

Figure 25.3.6 shows a more detailed representation of the elongation catalytic cycle.

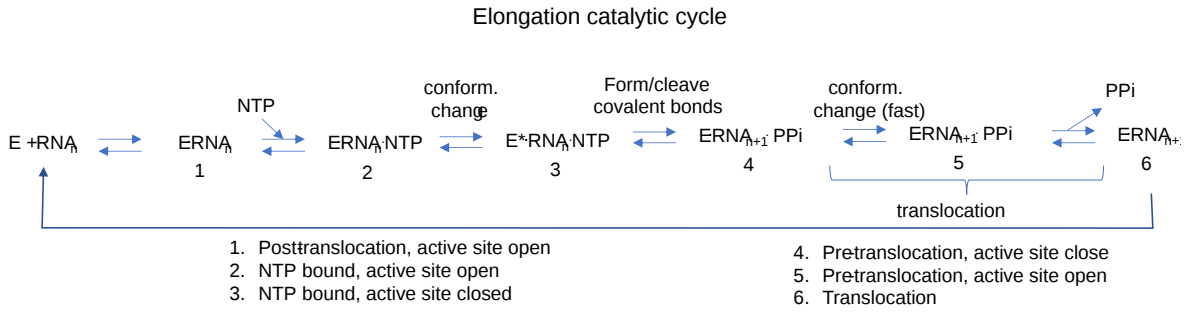

Figure 25.3.6: Elongation catalytic cycle of RNA-dependent RNA polymerases

RNA synthesis can be performed using a primer-independent (*de novo*) or a primer-dependent mechanism that utilizes a viral protein genome-linked (VPg) primer. The *de novo* initiation consists of the addition of a nucleoside triphosphate (NTP) to the 3'-OH of the first initiating NTP. During the following so-called elongation phase, this nucleotidyl transfer reaction is repeated with subsequent NTPs to generate the complementary RNA product. The termination of the nascent RNA chain produced by RdRp is not completely known, however, it has been shown that RdRp termination is sequence-independent.

One feature of RNA-dependent RNA polymerase replication is the immense error rate during transcription. RdRps and RTs are known to have a lack of fidelity on the order of 10^4 nucleotides, which is thought to be a direct result of their insufficient proofreading abilities. This high rate of variation is favored in viral genomes as it allows for the pathogen to overcome defenses developed by hosts trying to avoid infection allowing for evolutionary growth.

Let's look at another RdRp from the poliovirus. The virus has a single-stranded, positive-sense RNA genome, which makes it infectious in itself but much more infectious when replicated. It is translated into a polyprotein which is cleaved into about 12 separate proteins. One protein, 3Dpol, is an RNA-dependent RNA polymerase that transcribes the infecting +RNA strand into a -RNA strand, which then serves as a template for more +RNA strands.

Figure 25.3.7 shows an interactive iCn3D model of the Poliovirus polymerase elongation complex with 2',3'-dideoxy-CTP (3OLB). The model shows the palm, finger, and thumb domains.

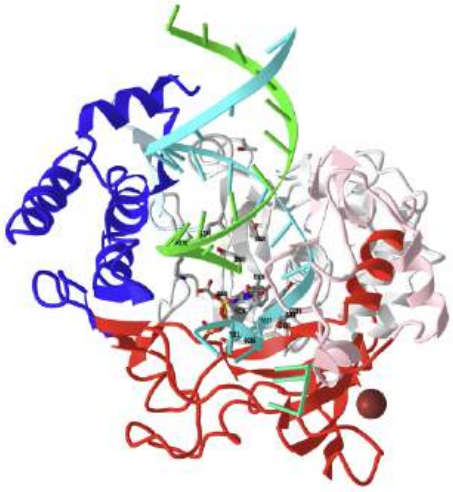

Figure 25.3.7: Poliovirus polymerase elongation complex with 2',3'-dideoxy-CTP (3OLB). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...f5xp9f7B6Qo4SA

Color coding is as follows:

- red: finger domain
- pink: pinky finger part of the finger domain
- blue: thumb domain
- light blue: primer grip at the beginning of the thumb domain
- cyan: RNA template

- green: RNA product
- gray: palm domain

Structural studies suggest that the pinky finger is involved in the initiation, while nucleotide binding and catalysis used the palm domain. The thumb domain appears to affect the translocation step. In most nucleases, the finger binds and positions NTPs in the active site. After catalysis, the reverse motion opens the active site which allows translocation by effectively ratcheting the template by one base pair which is driven by PPi release. These conformational changes can't be made so easily in +RNA stranded viral RdRps.

CHAPTER OVERVIEW

26: Protein Metabolism

26.1: The Genetic Code

26.2: Protein Synthesis

26.3: Translational Regulation and Protein Degradation

26.1: The Genetic Code

26.1.1: Overview of Translation

Within this chapter, we will cover the details of prokaryotic and eukaryotic translation. *Translation* is the process of converting the information housed in mRNA into the protein sequence. Essentially, you are translating the language of nucleotides into the language of amino acids. Recall that prokaryotic and eukaryotic transcription and translation systems differ in large part due to the compartmentalization of larger eukaryotic cells. Due to this compartmentalization, transcription and translation are separated spatially and temporally within the cell. Transcription occurs within the nucleus of eukaryotes and translation occurs within the cytoplasm. Prokaryotes do not have compartmentalization and have, thus, evolved a coupled transcription/translation system where both processes occur simultaneously. Both are illustrated in Figure 26.1.1.

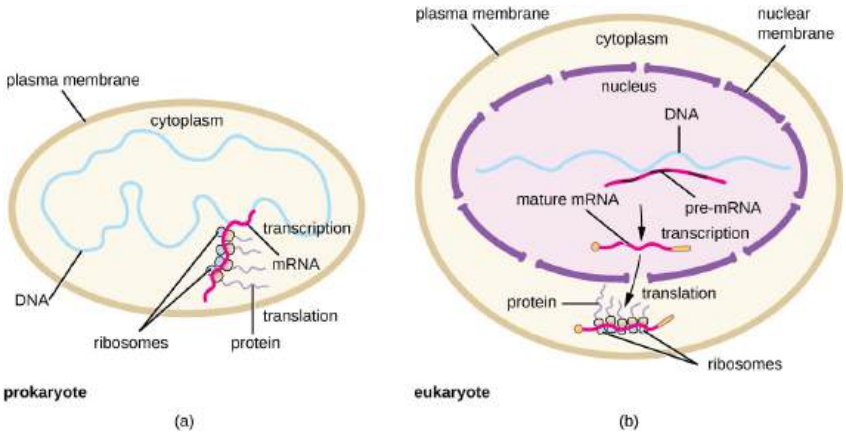

Figure 26.1.1: Cellular Location of Transcription and Translation in Prokaryotes and Eukaryotes. Baccei, A., and Rice, M. Lumen Learning

Panel (a) shows that prokaryotes lack cellular compartmentalization and show coupled transcription-translation processing;

Panel (b) shows that eukaryotes have a high degree of compartmentalization and separate the processes of transcription, which is in the nucleus of the cell, from the processes of translation, which is localized in the cytoplasm.

Recall that peptide formation is a dehydration reaction that combines the carboxylic acid of the upstream amino acid with the amine functional group of the downstream amino acid to form an amide linkage as shown in Figure 26.1.2. Water is the by-product. The ribosome (a large complex of peptides and rRNA molecules) serves as the enzyme that mediates this reaction. It requires a mature mRNA to serve as the template and directionally performs peptide bond synthesis from the N to the C-terminal of the growing peptide/protein. This is known as *N- to C-synthesis*. Note that the overall protonation state shown is very unlikely since under conditions when the carboxyl groups are protonated, so would the amines. This representation makes it easier to highlight the departing water

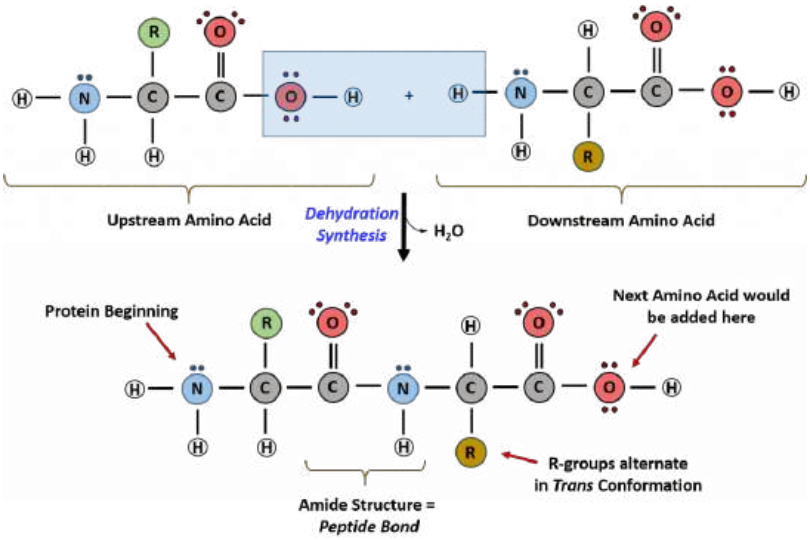

Figure 26.1.2: Formation of the Peptide Bond. The addition of two amino acids to form a peptide requires dehydration synthesis. The carboxylic acid of the upstream amino acid is joined with the amine functional group of the downstream amino acid to form the amide linkage. Within the ribosome, this reaction is highly directional and only occurs in the N to C orientation.

To maintain proper protein function, the error rate of translation is approximately 10^{-4} or 1 error in every 10,000 amino acids encoded. The fidelity of protein synthesis is maintained by the ribosome's ability to match the code from the template mRNA stand with the appropriate amino acid. Template mRNA is read by the ribosome in groups of three nucleotides, called a *codon*, as shown in Figure 26.1.3

Figure 26.1.3: Reading the mRNA Template. modified from: (A) Yikrazuul and (C) Zedalis, J., et al. Openstax

The template is non-overlapping and reads in discrete groups of three. This is known as the *reading frame* of the mRNA, and it is always read from the 5′ to 3′ direction. Thus, for each mRNA, there are three potential reading frames (panel B). Only one reading frame will be the correct one for protein synthesis. The ribosome must recognize and align the correct reading frame of the mRNA such that the correct codon sequences can be read. Small distinct tRNA molecules are tethered with specific amino acids and contain specific anticodons that complement mRNA codon sequences. The tRNA molecules can cycle on and off of the ribosome structure to hybridize with the correct codon sequences and chaperone the correct amino acid for peptide bond formation. The

ribosome then serves as a ribozyme and mediates the peptidyl transferase activity to form the peptide bond. The mRNA is then shifted to reveal the next codon within the sequence and the process is repeated until the entire protein has formed. Panel C shows the codon chart for all of the possible combinations of three nucleotides. 64 possible codon combinations are possible using the 4 nucleotide possibilities, but only 20 amino acids are encoded during protein synthesis. Each codon is specific for a single amino acid. There is *very little ambiguity* within the code.

However, there is *redundancy* within the code; i.e. many amino acids have more than one codon that encodes for that specific amino acid. To account for this redundancy, many tRNA molecules can recognize more than one codon using a single anticodon. This is known as *degeneracy. Degeneracy* usually occurs at the third position of the codon and is known as the *wobble base* position. *Degeneracy* helps to minimize the effects of mutations within the coding sequence, as mutations in the *wobble base* position will often lead to *silent mutation*– ie the mutation will still encode for the same amino acid.

In addition, if comparing the polarity of amino acids encoded by the different codons, neighboring codons typically encode for amino acids with similar polarity, as shown in Figure 26.1.4 This also helps to minimize the effects of mutations, by converting one amino acid within the sequence to one that has similar polarity. This type of mutation is more likely to cause less disturbance to the 3-dimensional structure of the resulting protein and retain biological function.

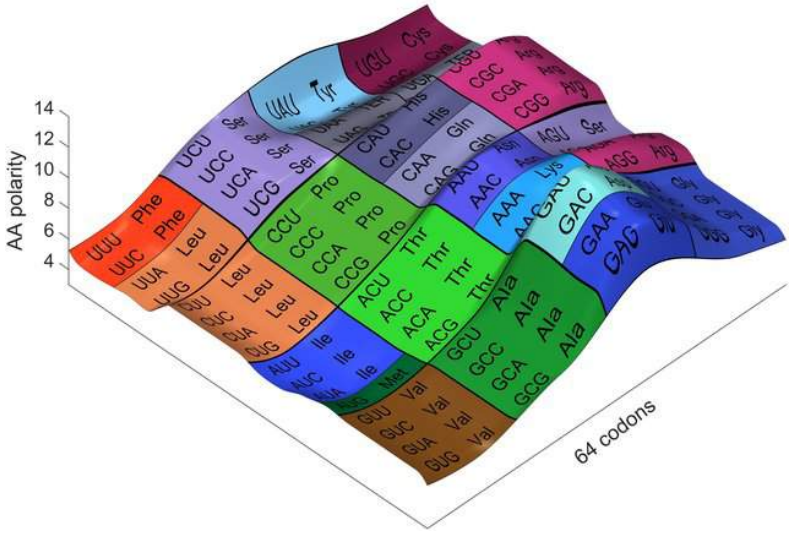

Figure 26.1.4: The Relationship of Codons and the Polarity of the Encoded Amino Acids. A representation of the genetic code, as a function of the measured polarity of each codon. The smoothness of the landscape shows that moving from one AA to its neighbor does not change the polarity too abruptly. Eckmann, J-P., Rougemont, J., and Tlusty, T. (2019) ResearchGate

Degeneracy within the genetic code also allows for differential A/T & G/C concentrations within species. For example, the G/C content of bacteria can range from as low as 30% to as high as 70%. Organisms living at high temperatures or extreme environments often have higher G/C content. This effectively increases the hydrogen bond strength between the strands of the DNA (G/C pairs have 3 H-bonds, whereas A/T pairs only have 2) and causes an increase in the melting temperature of the chromosome. Thus, the DNA is stable at a higher temperature or under more extreme ionic conditions, such as high salt. A more detailed discussion of how a single tRNA can function to recognize more than one codon is the topic of the next section.

The Genetic Code is universal for almost all species alive on the planet, providing support for a single origin of life. Most deviations in the code occur within the mitochondria of eukaryotic species, as shown in Figure 26.1.5

Figure 26.1.5: Variations in the Genetic Code. Universal genetic code (inside the box) and variations in animal mitochondrial genetic code (outside the box). Term = Termination Codon. Figure from: Watanabe, K., and Yokobori, S. (2011) J. Nuc. Acids Article ID: 623095, 12 pages

26.1.2: Transfer RNA (tRNA) Structure

Transfer RNAs (tRNAs) are central players in translation, functioning as adapter molecules between the informational level of nucleic acids and the functional level of proteins. Typically, tRNA molecules are between 76 – 90 nucleotides long and show a highly conserved secondary and tertiary structure. They also show the highest amount of nucleotide modification of all types of RNA with modifications concentrated in two hotspots—the anticodon loop and the tRNA core region, where the D- and T-loop interact with each other, stabilizing the overall structure of the molecule, as shown in Figure 26.1.6 These modifications can cause large rearrangements as well as local fine-tuning in the 3D structure of a tRNA.

The life of a transfer RNA (tRNA) molecule starts with a series of important maturation steps that can vary in their sequential order from case to case. Leader and trailer sequences are removed by a set of endo- and exonucleases, and in several tRNA precursors, splicing reactions excise intronic sequences. Furthermore, in many organisms, the sequence CCA, which represents the site of amino acid attachment, is not encoded but has to be added post-transcriptionally by CCA-adding enzymes. While all primary tRNA transcripts are composed of the four standard RNA bases A, C, G, and U, many of these nucleotides are modified, altering their properties in very different ways. Currently, 93 post-transcriptional modifications are known, and the variety of their functions is at least similarly diverse and not fully understood. The complexity of such modifications ranges from simple methylations at the bases or the ribose to rather complex and large base hypermodifications, whose synthesis often requires a whole cascade of enzymatic reactions. Modifications can alter a tRNA's shape in subtle ways, but can also lead to massive structural rearrangements. In addition, they ensure efficient translation by maintaining the anticodon loop structure and promoting correct codon-anticodon interactions.

After maturation, tRNAs have multiple interaction partners in their life cycle, ranging from aminoacyl-tRNA-synthetases that are responsible for amino acid attachment, to translation factors, ribosomes, and mRNAs. Apart from synthetases, these interaction partners do not specifically act on one individual tRNA transcript or isoacceptor, but on all tRNAs, similar to the above-mentioned CCA-adding enzyme. Thus, despite a high sequence variation, a cell's tRNAs show a well-conserved cloverleaf-like secondary structure that was originally discovered in 1965. The similar structure of all tRNA molecules allows them to bind to common protein synthesis machinery, such as the ribosome and CCA-adding enzymes. The cloverleaf consists of five parts: the acceptor stem (containing the tRNA's 5′- and 3′-ends), the D-arm, the anticodon arm, the variable loop, and the TΨC-arm (T-arm). At the 3′-terminus, the tRNA carries the CCA sequence, required for aminoacylation, tRNA positioning in the ribosome, and translation termination. In a conserved network of tertiary interactions, mostly between D- and T-loop, tRNAs fold into an L-shaped three-dimensional structure, which was first solved by Kim et al. in 1974, as shown in Figure 26.1.6 (Panel B). The anticodon and the amino acid-accepting CCA-ends are separated by the longest possible distance from each other. This conserved structure of a tRNA is essential for its recognition by the ribosome, other RNAs, and proteins and, consequently, for its functionality. For example, the CCA-adding enzyme uses the acceptor domain for substrate recognition, whereas aminoacyl-tRNA-synthetases use several recognition elements like anticodon, acceptor stem, or the discriminator position.

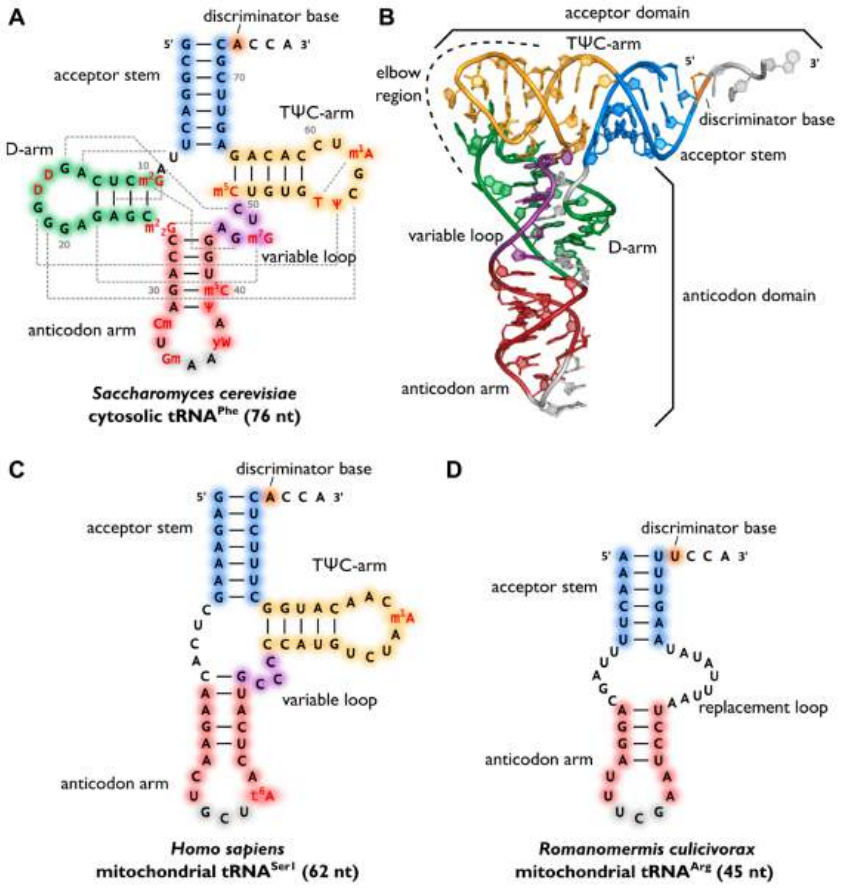

Figure 26.1.6: **Variability of transfer RNA (tRNA) structures.** Lorenz, C., et. al. (2017) Biomolecules 7(2):35

Panel (A) shows the canonical cloverleaf secondary structure of cytosolic $tRNA^{Phe}$ from S. cerevisiae is shown with acceptor stem (blue), D-arm (green), anticodon arm (red), variable loop (purple) and TΨC-arm (yellow). The anticodon is labeled in grey, the discriminator base in orange and post-transcriptional modifications in red. Grey dashed lines indicate tertiary interactions based on structural data and the length of the RNA is indicated in parenthesis;

Panel (B) shows the L-shaped tertiary structure of the cytosolic $tRNA^{Phe}$ from S. cerevisiae. Protein Data Bank entry (PDB): 1EHZ. The acceptor domain is composed of a stacked T-arm and acceptor stem, whereas D- and anticodon arm form the anticodon domain. The region where both domains come together and interact with each other via tertiary base pairing is also called the elbow region;

Panel(C) shows the secondary structure of human mitochondrial $tRNA^{Ser1}$, which lacks the whole D-arm;

Panel (D) shows the secondary structure of the mitochondrial $tRNA^{Arg}$ from the nematode *Romanomermis culicivorax*, which lacks both D- and T-arm. Instead, we find a so-called replacement loop. It represents the shortest tRNA found *in vivo*.

Surprisingly, not all tRNAs fold into the canonical cloverleaf structure. Especially many mitochondrial tRNAs are reduced in length and sometimes completely lack the D- or T-arm as shown in Figure 26.1.6, Panel C. In the mitochondria of nematodes, this situation is carried to an extreme, as tRNAs lacking one or even both arms seem to be the rule (Panel D).

Figure 26.1.7 shows an interactive iCn3D model of the yeast phenylalanine tRNA (1EHZ).

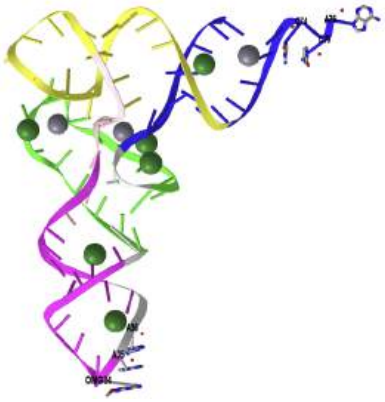

Figure 26.1.7: Yeast phenylalanine tRNA (1EHZ). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...yq7wdue7MNuT56

The coloring, which matches those in Figure 6 above, is shown below:

- Acceptor Stem - blue
- D Arm - green
- Anticodon= magenta
- Variable Loop - pink
- Tω C - yellow

Post-transcriptional enzyme-catalyzed modification of tRNA occurs at many base and sugar positions and influence specific anticodon–codon interactions and regulates translation, its efficiency, and fidelity. This phenomenon of nucleoside modification is most remarkable and results in a rich structural diversity of tRNA of which over 93 modifications have been characterized.

The variety of post-transcriptional modifications can be classified into two groups according to their complexity. The first group comprises the majority of modified bases, which have simple methylations at the ribose or base moiety that are usually introduced by a single enzymatic reaction. Simple modifications can be found at almost every position of the tRNA molecule with a high density in the tRNA core region, where tertiary interactions between D- and T-arm stabilize the three-dimensional fold, as shown in Figure 26.1.8. The second group includes complex modifications, whose synthesis requires the sequential activity of several enzymes. Most often these hypermodified nucleosides are found in the anticodon of tRNAs, where they play a direct role in codon recognition and create what is known as the *wobble base* or *wobble position*.

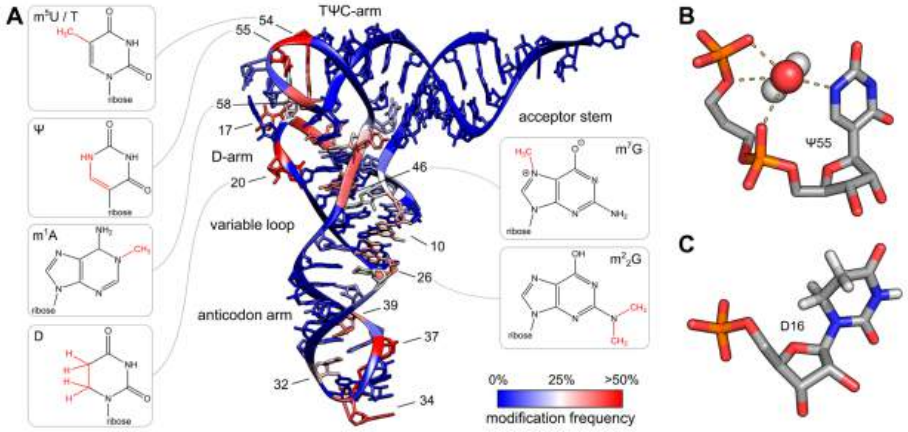

Figure 26.1.8: Post-transcriptional modifications in tRNA. Lorenz, C., et. al. (2017) Biomolecules 7(2):35

Panel (A) shows the colored tRNA structure shows the modification frequency of each base. The modification data were taken from the tRNAmodviz database and plotted on the crystal structure of $tRNA^{Phe}$ from S. cerevisiae. Blue-colored bases are rarely modified; red-colored bases are modification hotspots. tRNAs possess two regions with high modification levels—the anticodon loop (especially positions 34 and 37) and the core or elbow region, where D- and T-loop bases interact with each other and stabilize the tertiary fold. For some important positions, the chemical structure of the most frequent modification at this position is shown;

Panel (B) shows the three-dimensional structure of pseudouridine at position 55 of $tRNA^{Phe}$ from S. cerevisiae. The additional H-bond donor at N1 interacts with the 5′-adjacent phosphates via a coordinated water molecule. The hydrogen bound to N1 was not resolved in the crystal structure. The ribose shows a stabilizing C3′-endo conformation. PDB: 1EHZ-

Panel (C) shows the three-dimensional structure of D16 in the D-arm of $tRNA_i^{Met}$ from Schizosaccharomyces pombe. The C5-C6 bond of dihydrouridine is reduced, which leads to a non-planar structure of the base. The ribose takes the less stable C2′ -endo conformation. PDB: 2MN0.

A *wobble base pair* is a pairing between two nucleotides in RNA molecules that does not follow Watson-Crick base pair rules. The four main *wobble base pairs* are guanine-uracil (G-U), hypoxanthine-uracil (I-U), hypoxanthine-adenine (I-A), and hypoxanthine-cytosine (I-C), as shown in Figure 26.1.9 To maintain the consistency of nucleic acid nomenclature, “I” is used for hypoxanthine because hypoxanthine is the nucleobase of the inosine nucleotide; nomenclature otherwise follows the names of nucleobases and their corresponding nucleosides (e.g., “G” for both guanine and guanosine – as well as for deoxyguanosine). The thermodynamic stability of a wobble base pair is comparable to that of a Watson-Crick base pair. Wobble base pairs are fundamental in RNA secondary structure and are critical for the proper translation of the genetic code.

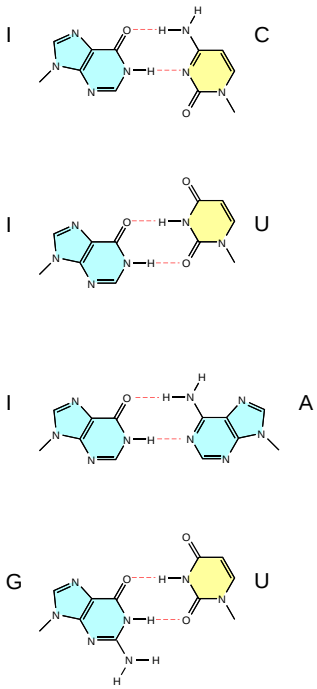

Figure 26.1.9: The Four Main Wobble Base Pairs. The top three diagrams represent the flexibility of the inosine nucleotide to form hydrogen bond interactions with cytosine, uracil, and adenine. tRNA and mRNA wobble base pairing also includes guanine hydrogen binding with uracil. Figure from Fdardel

The *wobble base* position is usually the first position of the anticodon (read in the 5′ – 3′ direction), which aligns with the 3rd position of the mRNA codon. This helps to explain the *degeneracy* found within the genetic code as shown in Figure 3 above and Figure 26.1.10 *Degeneracy* means that a single tRNA can recognize multiple different codons within mRNA.

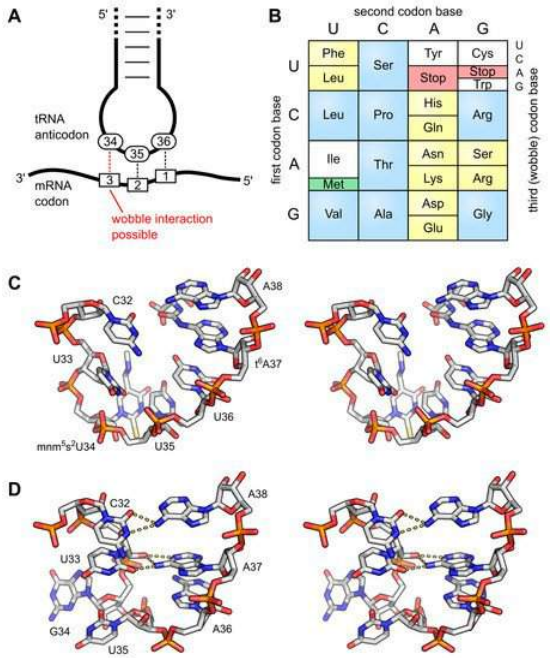

Figure 26.1.10: Anticodon Loop Structure and Codon Degeneracy. Lorenz, C., et. al. (2017) Biomolecules 7(2):35

Panel (A) shows the interaction of the anticodon bases (34–36) of a tRNA with the corresponding bases of the mRNA codons (3, 2, 1). A wobble interaction is possible between codon base 3 and anticodon base 34. The latter is frequently modified and directs the wobble interactions with the third codon base;

Panel (B) shows the standard genetic code is illustrated as a simple decoding table, 2-fold degenerate codon boxes are colored yellow, and 4-fold degenerate boxes are blue. Start and stop codons are colored green and red, respectively;

Panel (C) shows a stereo image of the well-structured anticodon loop of $tRNA^{Lys}$ from E. coli. Modifications mnm^5s^2U34 and t^6A37 prevent wrong base pairing inside the 7-nucleotide loop and promote the formation of the conserved U-turn motif. The stacked anticodon bases are located on the same side of the loop. PDB: 1FL8;

Panel (D) shows a stereo image of a collapsed and unmodified anticodon loop of $tRNA^{Tyr}$ from Bacillus subtilis. Here, bases 32 and 38 as well as 33 and 37 interact with each other and the U-turn motif is missing. The anticodon bases are not ordered and are on opposite sides of the loop. PDB: 2LAC.

A prominent example is $tRNA^{Ile}$ carrying the anticodon UAU. In principle, this anticodon can read codons AUA (for isoleucine) and AUG (for methionine). Yet, it was shown in some instances that $tRNA^{Ile}$ with unmodified UAU anticodon exists, but has a strong preference for its cognate AUA codon, while it rarely misreads AUG. In most organisms, however, $tRNA^{Ile}$ carries the anticodon CUA. To avoid misreading of the methionine codon by this tRNA, C34 (position 1 of the anticodon) is modified to lysidine (k^2C34, with the chemical structure shown in Figure 27.1.10, which restricts codon recognition to only AUA and thereby changes the amino acid identity of the tRNA from methionine to isoleucine. In the archaeal species, *Haloarcula marismortui*, *Methanococcus maripaludis, and Sulfolobus solfataricus*, this $tRNA^{Ile}$ carries a different modification at C34, fulfilling the same purpose of restricting the interaction to AUA codons. Here, the original cytosine is modified at the C2-oxo position, which is replaced by agmatine (decarboxy-arginine), resulting in agmatidine (C+ or agm^2C), as shown in Figure 26.1.11. A complimentary modification is that of N^4-acetylcytosine (ac^4C34, whose chemical structure is shown in Figure 27.1.8) in the elongator-$tRNA^{Met}$ of *E. coli*, which prevents the recognition of the AUA isoleucine codon. In non-plant mitochondria, however, both AUG and AUA codons are read as methionine. Hence, mitochondrial $tRNA^{Met}$ (carrying the anticodon CAU) has to recognize both codon forms. This is achieved by the introduction of 5-formylcytidine (f^5C, Figure 11, at position 34, a modification that pairs with both A and U residues at the corresponding codon position 3.

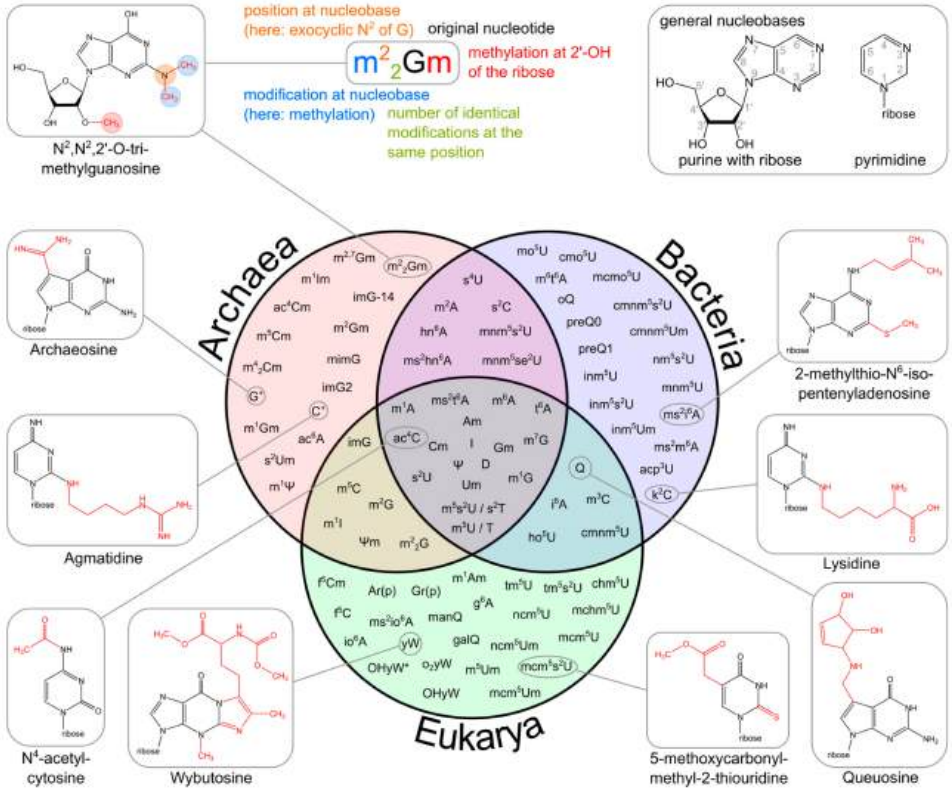

Figure 26.1.11: Variability of tRNA Modifications. Lorenz, C., et. al. (2017) Biomolecules 7(2):35

The upper part of the image illustrates the systematic abbreviation of RNA modifications with N^2,N^2,2′-O-trimethylguanosine ($m^2{}_2Gm$) as an example and also shows the atom numbering in the purine and pyrimidine rings as well as in the ribose. An abbreviation in front of the base letter describes a base modification, whereas letters after the base stand for ribose alterations. Superscripted numbers specify the position at the base and subscripted numbers indicate the frequency of identical modification at

the same position. Abbreviations are as follows: ac—acetyl, acp—aminocarboxypropyl, chm—carboxyhydroxymethyl, cmo—oxyacetic acid, cmnm—carboxymethylaminomethyl, f—formyl, g—glycinyl, gal—galactosyl, hn—hydroxynorvalylcarbamoyl, ho—hydroxy, i—isopentenyl, inm—isopentenylaminomethyl, io—cis-hydroxyisopentenyl, m—methyl, man—mannosyl, mchm—carboxyhydroxymethyl methyl ester, mcm—methoxycarbonylmethyl, mcmo—oxyacetic acid methyl ester, mnm—methylaminomethyl, mo—methoxy, ncm—carbamoylmethyl, nm—aminomethyl, r(p) —5-O-phosphono-b-d-ribofuranosyl, s—thio, se—seleno, t—threonylcarbamoyl, tm—taurinomethyl. The Venn diagram summarizes data collected from the RNA modification database and contains the 93 post-transcriptional modifications that are found in tRNAs. Some examples mentioned throughout the text are shown with their chemical structure.

Organisms vary in the number of tRNA genes in their genome. For example, the nematode worm *C. elegans*, a commonly used model organism in genetics studies, has 29,647 genes in its nuclear genome, of which 620 code for tRNA.The budding yeast *Saccharomyces cerevisiae* has 275 tRNA genes in its genome.

The human genome has approximately 20,848 protein-coding genes, of which there are 497 nuclear genes encoding cytoplasmic tRNA molecules, and 324 tRNA-derived pseudogenes (tRNA genes thought to be no longer functional). Regions in nuclear chromosomes, very similar in sequence to mitochondrial tRNA genes, have also been identified (tRNA-lookalikes). These tRNA-lookalikes are also considered part of the nuclear mitochondrial DNA (genes transferred from the mitochondria to the nucleus).

As with all eukaryotes, there are 22 mitochondrial tRNA genes in humans. Mutations in some of these genes have been associated with severe diseases like the MELAS syndrome.

Cytoplasmic tRNA genes can be grouped into 49 families according to their anticodon features. These genes are found on all chromosomes, except the 22 and the Y chromosomes. High clustering on 6p is observed (140 tRNA genes), as well as on chromosome 1. Currently, it is unclear why there is so much redundancy within the genome to decode 61 of the 64 possible codons (the other three are stop codons used to terminate translation).

26.1.3: Aminoacyl tRNA Synthetases

Aminoacyl-tRNA synthetases (aaRSs) are universally distributed enzymes that catalyze the esterification of a tRNA to its cognate amino acid (i.e., the amino acid corresponding to the anticodon triplet of the tRNA according to the genetic code). The product of this reaction, an aminoacyl-tRNA (aa-tRNA), is delivered by elongation factors to the ribosome to take part in protein synthesis.

Aminoacyl-tRNA synthetases are named after the aminoacyl-tRNA product generated, as such, methionyl-tRNA synthetase (abbreviated as MetRS) charges tRNAMet with methionine. In eukaryotes, an alternative nomenclature is often employed using the one-letter code of the amino acid (MARS), and a number is added to refer to the cytosolic (MARS1) or the mitochondrial (MARS2) variants. A total of 23 aaRSs have been described so far, one for each of the 20 proteinogenic amino acids (except for lysine, for which there are two) plus pyrrolysyl-tRNA synthetase (PylRS) and phosphoseryl-tRNA synthetase (SepRS), enzymes with a more restricted distribution that are only found in some bacterial and archaeal genomes. It is also worth noting that in eukaryotes the protein synthesis machinery of mitochondria and chloroplasts generally utilize their own, bacterial-like sets of synthetases and tRNAs that are distinct from their cytosolic counterparts.

The aminoacyl-tRNA synthetases catalyze a two-step reaction that leads to the esterification of an amino acid to the 3’ end of a tRNA along with the hydrolysis of one molecule of ATP, yielding aminoacyl-tRNA, AMP, and PPi. In the first step, termed amino acid activation, both the amino acid and ATP bind to the catalytic site of the enzyme, triggering a nucleophilic attack of the α-carboxylate oxygen of the amino acid to the α-phosphate group of the ATP, condensing into aminoacyl-adenylate (aa-AMP), which remains bound to the enzyme, and PPi, which is expelled from the active site, as shown in Figure 26.1.12

Figure 26.1.12: The Aminoacylation Reaction**.** In the first step, the amino acid (blue) is activated with ATP (red) in the synthetase active site (not depicted), forming the aminoacyl-AMP and releasing PPi. The amino acid is transferred to the tRNA (green) and AMP is released (depicted in the image transfer to the 3'-OH characteristic of class I aaRS, while in class II transfer happens at the 2'-OH with a 3'-OH attack in the second step). Gomez, M.A.R., and Ibba M. (2020) RNA, doi: 10.1261/rna.071720.119

Although tRNA is usually not required for this first step, certain synthetases do require the tRNA species for productive amino acid activation. In the second part of the reaction, either the 2′- or 3′-hydroxyl group of the terminal adenine nucleotide attacks the carbonyl carbon of the adenylate, forming aminoacyl-tRNA and AMP (Figure 27.1.12 B). While the two-step aminoacylation reaction is universally conserved, the aaRSs that catalyze it show extensive structural, and in some instances functional, diversity.

The 23 known aaRSs can be divided into two major classes based on the architecture of their active sites (Class I and Class II). In class I synthetases, the catalytic domain bears a dinucleotide or Rossman fold (RF) featuring a five-stranded parallel β-sheet connected by α-helices and is usually located at or near the N-terminus of the protein. This RF contains the highly conserved motifs HIGH and KMSKS, separated by a connecting domain termed connective peptide 1 (CP1), as shown in Figure 26.1.13(panel A). Class II active site architecture is organized as seven-stranded β-sheets flanked by α-helices and features three motifs that show a lesser degree of conservation than those in class I (panel B). Both classes also exhibit pronounced differences in their modes of substrate binding. Class I aaRSs bind the minor groove of the tRNA acceptor stem (with the exceptions of TrpRS and TyrRS) and aminoacylate the 2'-OH of the ribose of the terminal adenosine, while class II approach tRNA from the major groove and transfer amino acid to the 3'-OH (except PheRS). The mode of ATP binding is also different between both classes, being bound in an extended configuration in class I, while class II binds a bent configuration with the γ-phosphate folding back over the adenine ring. The kinetics of the aminoacylation reaction can also be used as a distinctive mechanistic signature, as aminoacyl-tRNA release is the rate-limiting step for class I enzymes (except for IleRS and some GluRS) while for class II it is the amino acid activation rate instead.

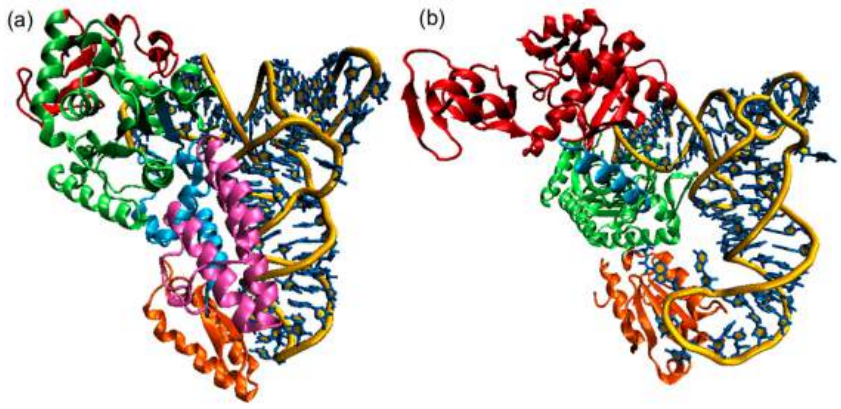

Figure 26.1.13: Structures of Class I and Class II AARSs. Li, R., et. al. (2015) Int J. Mol. Sci. 16(7):15872-15902.

Panel (a) shows the *E. coli*CysRS:tRNA^{Cys} complex. The CP domain (red) and Rossmann fold catalytic domain (green), stem contact fold (cyan), helical bundle domain (magenta), and anticodon binding domain (orange) of CysRS are shown in a ribbon diagram;

Panel (b) A single monomer of the homodimeric *E. coli* ThrRS:tRNA^{Thr} complex. The two N-terminal domains (red), catalytic domain (green), linker (cyan), and anticodon binding domain (orange) of ThrRS are shown in a ribbon diagram. For both structures, the tRNAs are shown in a stick diagram (blue) with a trace of their backbone (yellow).

Figure 26.1.14shows an interactive iCn3D model of the Class I and II aminoacyl-tRNA synthetases

Class I E. Coli Cysteinyl-tRNA synthetase -tRNA(Cys) (1U0B)	class II E. coli threonyl-tRNA synthase - tRNA(Thr) (1QF6)
	(Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...P4oRWxKvJHFDL6	(Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...6aXwfqXGCpD7c6

The color coding is analogous to Figure 26.1.13with the tRNA shown in gray.

For the Class II E. coli threonyl-tRNA synthase - tRNA(Thr), key conserved amino acids in the active site are shown in CPK-colored sticks and labeled. The anticodon in the tRNA is shown in colored sticks as well. Note the large conformational change in the anticodon loop.

The E. coli threonyl-tRNA synthetase is interesting in that it represses the translation of its own mRNA. A Zn^{2+} ion is involved in binding specificity for the amino acid. It is coordinated by H385, H511, and a water molecule (not shown). R363 interacts with the alpha phosphate, while F379 and R520 align on both sides of the adenine rig. D383 interacts with the amine group of the substrate threonine.

To ensure the faithful translation of the genetic message, synthetases must identify and pair particular tRNAs with their cognate amino acid which relies on the proper recognition of both substrates. This can prove extremely challenging for the synthetases as

not only have they to discriminate the correct tRNA isoacceptor amongst a set of other tRNAs very similar in structure and chemical composition but also be able to select the cognate amino acid amidst an extremely large pool of similar amino acids, both proteinogenic and non-proteinogenic. The evolutionary pressure to maintain fidelity has driven aaRSs to develop an elevated specificity for their substrates, both the tRNA and the amino acid.

In addition, some synthetases have evolved editing activities that specifically target and hydrolyze misactivated amino acids and/or misacylated tRNAs. To date, editing activity has been described in 10 out of the 23 aaRSs. In class I synthetases, this activity is located in the highly conserved CP1 domain, although in some enzymes such as MetRS and LysRS the editing activity resides in the catalytic site. In class II synthetases, however, the editing domains are more idiosyncratic. Editing mechanisms can be divided into two categories, *pre- or post-transfer editing*, with regard to the editing taking place before or after the transfer of the amino acid to the tRNA, as shown in Figure 26.1.15

Pre-transfer editing has been described in both class I and class II aaRSs and takes place after aa-AMP synthesis but before the aminoacyl moiety is transferred to the tRNA. Although the tRNA does not participate in the reaction itself, it has been reported that tRNA binding promotes editing activity in some aaRSs and is a requirement in IleRS and LeuRS. Pre-transfer editing can follow two main pathways. The first one is the selective release of the aa-AMP to the cytosol, where the labile phosphoester bond is spontaneously hydrolyzed. The second route involves the enzymatic breakdown of the product and may happen either in the active site or in an independent editing site.

Post-transfer editing takes place after the transfer of the amino acid to the tRNA and involves the hydrolysis of the ester bond, in a domain separated from the active site. The specific mechanism of editing is idiosyncratic to each synthetase but in general, once formed the aa-tRNA triggers a conformational change, and the 3’ terminus containing the aa is translocated from the active site to the editing site, sometimes traversing distances as large as 40 Å. As the core of the tRNA remains bound to the enzyme, this translocation often involves a rearrangement of the 3’ terminus to relocate to the editing site.

Figure 26.1.15: Aminoacyl tRNA Synthetase Editing Pathways**.** Schematic overview of the editing pathways employed by the synthetases. In the figure above, the events are in italics, while the editing paths are in bold. The pathways are divided between pre-transfer and post-transfer pathways. In the *pre-transfer editing*, the activated non-cognate aminoacyl-adenylate may be released from the enzyme and hydrolyze spontaneously or edited within the active site or a specialized active site. During *post-transfer editing*, the aminoacyl-tRNA can be translocated to the editing site or released and cleared by a dedicated trans-editing factor. When a correct cognate has formed, the resulting aminoacyl-tRNA binds the elongation factors and proceeds to translation in the ribosome. Figure from: Gomez, M.A.R., and Ibba M. (2020) RNA, doi: 10.1261/rna.071720.119

26.1.4: Ribosome Structure

The ribosome is a highly conserved molecular machine. In all organisms, it is composed of two unequal subunits, which consist of a distinct set of ribosomal RNA (rRNA) and ribosomal proteins (RPs) that combine to form a large nucleoprotein complex. The ribosome structures in all living organisms harbor three different tRNA binding sites: The A-site, where decoding occurs and the correct aminoacyl-tRNA (aa-tRNA) is selected based on the mRNA codon displayed, the P-site, which carries the peptidyl-tRNA,

and the E-site, which binds exclusively deacetylated tRNAs that are exiting the ribosome. Thus, during translation the tRNA moves from the A-site through the P- and E-site, where it leaves the ribosome, as shown in Figure 26.1.16

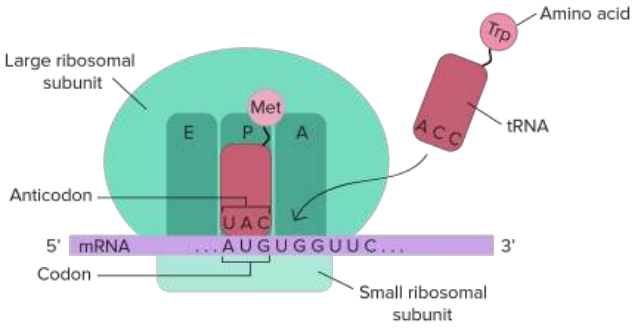

Figure 26.1.16: **Schematic Structure of an Active Ribosome.** The Kahn Academy where it was modified from Openstax College Biology

The mRNA (shown in purple) is assembled between the small subunit and the large subunit of the ribosome (shown in green). tRNA molecules (shown in red) that are loaded with their cognate amino acid (shown in pink) are transitioned through the A-P-E sites of the ribosome during the elongation phase of translation. Movement of the tRNA molecules also shifts the position of the mRNA causing the next three codon bases to line up in the A-site of the ribosome.

The catalytic peptidyl transferase activity occurs when the tRNA molecules are bound in the A- and P-sites, transferring the nascent peptide to the incoming tRNA molecule (Fig. 27.1.15). Ribosomes are ribozymes because the catalytic peptidyl transferase activity that links amino acids together is performed by the rRNA.the complexity of the ribosome structure is reflected in the process of protein synthesis, which can be intersected into three major steps: initiation, elongation, and termination/recycling.

Ribosomes are either free-floating in the cytoplasm or they can be associated with the intracellular membranes that make up the rough endoplasmic reticulum (rER). Proteins translated into the rER will often be transported out of the cell or embedded into the plasma membrane. These processes are illustrated in Figure 26.1.17.

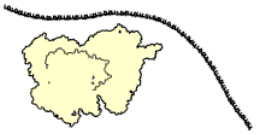

Figure 26.1.17: **A ribosome translating a protein that is secreted into the endoplasmic reticulum.** Figure from: *Bensaccount*

Ribosomes from bacteria, archaea, and eukaryotes in the three-domain system resemble each other to a remarkable degree. They differ in their size, much of the rRNA sequence, and the ratio of protein to RNA. Figure 26.1.18shows the eukaryotic rRNA from the large subunit of the ribosome with highly conserved nucleotide elements (>90% sequence identity) within all of the domains of life, termed universal CNEs or uCNEs indicated. The differences in sequence and structure between eukaryotes and prokaryotes allow some antibiotics to kill bacteria by inhibiting their ribosomes while leaving human ribosomes unaffected.

Figure 26.1.18: **Universally Conserved Nucleotide Elements (uCNEs) in the Large Subunit of the Eukaryotic Ribosome.** rRNA from the yeast large subunit of the ribosome is shown from the crown view (from the subunit interface) with the L1 stalk at the upper left. uCNEs that are ≥90% conserved in sequence in all domains of life are indicated in dark blue. Figure from: Doris, S.M., et. al. (2015) RNA 21:1719-1730

In all species, more than one ribosome may move along a single mRNA chain at one time (as a *polysome*), each "reading" its sequence and producing a corresponding protein molecule. In this way, many proteins can be translated from a single mRNA molecule. Within bacteria, translation is also coupled with transcription, as the two processes are not physically separated from one another. This is illustrated in Figure 26.1.19 In eukaryotic organisms, *polysomes* form during translation. However, transcription and translation are not coupled, as the processes are separated into the nucleus and cytoplasm, respectively.

Figure 26.1.19: Bacterial Transcription and Translation are Coupled. Translation of nascent mRNA in bacteria occurs before the release of the nascent mRNA from the RNA Polymerase and DNA template. Multiple ribosomes assemble on the nascent mRNA and begin the translation of multiple protein products from the newly formed mRNA template. The structure of the ribosomes assembled on the mRNA is referred to as a *polysome*. Figure from: Gonzalezmg1

The mitochondrial ribosomes of eukaryotic cells functionally resemble many features of those in bacteria, reflecting the likely evolutionary origin of mitochondria.

26.1.4.1: Prokaryotic Ribosome Structure

Prokaryotic ribosomes have a mass of about 2500 kDa and a size of 70S (or Svedberg units: A Svedberg unit is a measure of the sedimentation rate in a centrifuge and thus is representative of size). A complete ribosome (70S) can be dissociated into a large subunit (50S) and a small subunit (30S), as shown in Figure 26.1.20 The small subunit is formed by the interactions of 21 different proteins and a 16S RNA molecule, whereas the large subunit contains 34 different proteins and two RNA molecules, a 23S, and a 5S species.

The rate-limiting step in protein synthesis is the formation of the 70S initiation complex which will be discussed in detail in the next section.

Figure 26.1.20: The Small and Large Prokaryotic Ribosomal Subunits*(Left)* Atomic structure of the 30S subunit from *Thermus thermophilus*. Proteins are shown in blue and the single RNA chain is in orange. *(Right)* Atomic structure of the 50S subunit from *Haloarcula marismortui*. Proteins are shown in blue and the two RNA chains are in orange and yellow. The small patch of green in the center of the subunit is the active site where the peptidyl transfer reaction occurs. Figure from: Goodsell, D. (2000) Molecule of the Month

Figure 26.1.21shows an interactive iCn3D model of the E. Coli ribosome (7K00).

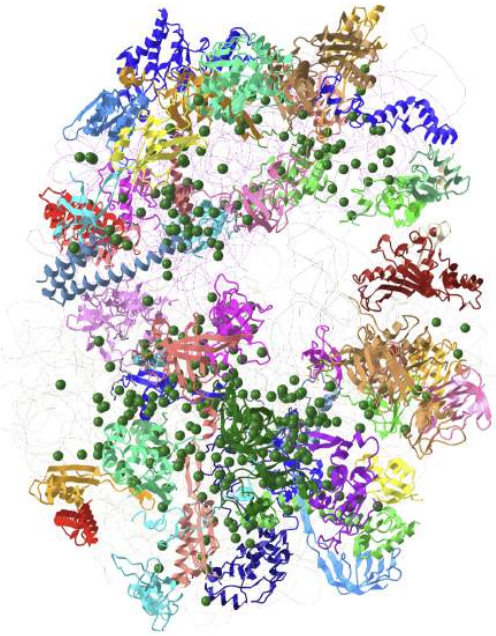

Figure 26.1.21: E. Coli ribosome (7K00). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?51UCkQmuV3BBqeEJ6

The RNA is shown in a faint trace backbone. The proteins are shown as cartoons with different colors. Note the large number of Mg^{2+} ions.

The structure was determined using cryo-EM at high resolution. Some ribosomal proteins have isopeptide bonds (using side chain amine and carboxyl groups) as well as some thioamide backbone replacements for the usual amide links.

26.1.4.2: Eukaryotic Ribosome Structure

Eukaryotic ribosomes are larger than their prokaryotic counterparts at approximately 80S (although there is some modest variation between eukaryotic species). Human cytosolic ribosomes are composed of a large subunit (60S) that contains the 28S, 5.8S, and 5S rRNAs and 47 ribosomal proteins (RPs), and a small subunit (40S) that contains the 18S rRNA and 33 RPs.

The assembly of eukaryotic ribosomal subunits starts in the nucleolus, where RNA polymerase I transcribes the major rRNA precursor (a 45S pre-RNA), from which, after processing and removal of the external and internal transcribed spacers (ETS and ITS), the mature rRNAs are generated, as shown in Figure 26.1.22 The pre-RNA is modified during transcription by small nucleolar ribonucleoproteins (snoRNPs), processed by RNA nucleases, and assembled with numerous RPs. After processing the rRNA precursor, the pre-40S and pre-60S subunits follow separate biogenesis routes. Here we will describe the assembly of the 60S subunit in more detail.

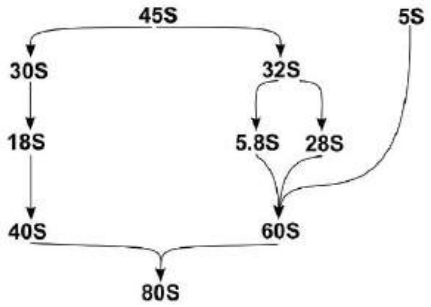

Figure 26.1.22: Schematic Representation of Ribosomal RNA Processing in Eukaryotes. The 45S rRNA transcript is processed by endonucleotide cleavage and splicing to form the 5.8S and 28S components of the large ribosomal subunit and the 18S component of the small ribosomal subunit. The 5S subunit is transcribed independently from the other rRNA components and is incorporated into the large ribosomal subunit. Figure from FeatherPluma

Although the exact assembly of the 60S subunit is not currently known, a model has been postulated that suggests that in the nucleolus, after circularization of rRNA domains, early 60S assembly is carried out sequentially, as shown in Figure 26.1.23 As the transcription of the pre-rRNA proceeds, the rRNA quickly develops a core secondary structure that promotes the interaction of key Assembly Factors (AFs) and RPs before transcriptional termination. Specifically, during this time, the 5.8S portion, ITS2, domains I and II, and partially domain VI are folded in the earliest observed intermediate (state A in Fig. 23). Thus, it appears that the solvent-exposed back side of the large subunit forms like an exoskeleton and construction proceeds by formation of the exit tunnel. This model agrees with a previously suggested model of hierarchical folding based on RP depletion phenotypes. The peptidyl transferase center (PET) is predicted to be one of the later folding steps in the process (state F in Fig. Fig 23) Although the very late-folding peptidyl transferase center is the evolutionarily oldest part of the ribosome, it is likely that folding the solvent side first brings the advantage of providing a stable scaffold for the developing 60S subunit. The folding and assembly of the 40S subunit follow a similar pattern. The two subunits remain unattached until activated in the cytoplasm through the binding of a mRNA transcript with the small subunit. This begins the formation of the initiation complex that will mark the start of the transcriptional process.

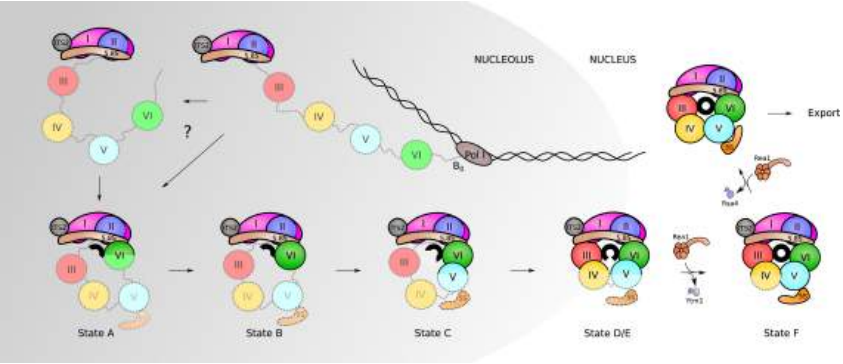

Figure 26.1.23: Assembly Sequence of the Pre-rRNA Domains in the Large Subunit of a Eukaryotic Ribosome. Kater, L., et. al. (2017) Cell 171(7):1599-1610

Assembly of RPs and AFs to the nascent 35S rRNA precursor starts co-transcriptionally. Very early, the pre-rRNA is circularized as domain VI binds to domains I and II and the 5.8S portion of the precursor rRNA. The formation of the PET (displayed here as a black circle) starts with this circularization. Its maturation progresses as rRNA domains fold following this order: VI, V, III, and IV. Full assembly of the PET is only achieved when domain V is completely folded as observed in state F. After that, only a few additional steps need to occur before the particles are exported to the cytoplasm, where they undergo final maturation.

26.2: Protein Synthesis

26.2.1: Prokaryotic Initiation

The small subunit of the ribosome (the 30S) interprets the genetic information by selecting aminoacyl-tRNAs cognate to the mRNA codons in the decoding center. The large subunit (the 50S) carries the catalytic peptidyl transferase center where amino acids are polymerized into a protein. Small and large subunits unite together at the start codon of a gene to form the 70S ribosome and dissociate again at the stop codon upon completing the synthesis of the encoded protein. This process consists of three phases: initiation, elongation, and termination. In this section, we will focus on the initiation of translation.

In bacteria, the initiation phase of protein synthesis involves a limited number of “actors”. Aside from the two ribosomal subunits, key roles are played by the initiator $tRNA^{fmet}$, the translation initiation region (TIR) of the mRNA, and three protein factors – the initiation factors (IFs) IF1, IF2, and IF3 – that ensure speed and accuracy to the overall process. The initiator $tRNA^{fmet}$ contains a methionine residue that has been enzymatically modified to contain an N-terminal formyl group, as shown in Figure 26.2.1. fMet is only used for the initiation of protein synthesis and is thus found only at the N-terminus of the protein. Unmodified methionine is used during the rest translation. Once protein synthesis is completed, the formyl group on methionine may be removed by peptide deformylase, and on occasion, the entire methionine residue can be further removed by the enzyme methionine aminopeptidase.

Figure 26.2.1: Structure of N-formylmethionine.

The TIR sequence within the mRNA contains the start codon and usually an upstream untranslated region that interacts with the small subunit of the ribosome. The bacterial cell produces and expresses a plethora of different mRNAs with different TIR sequences and structures; the efficiency by which these individual transcripts are translated depends not only upon their abundance and stability but also upon the nature of TIR. Thus, unlike the other aforementioned actors that represent constants, the mRNA TIRs represent essentially the only variable in the process of mRNA initiation site selection and can affect translation efficiency.

Although the triplet AUG is by far the most frequent initiation codon found in TIRs, other initiation triplets (i.e., GUG, UUG, AUU, AUC, and AUA) are found in bacteria and the central U is the only universally conserved base of the start codon. Among the aforementioned triplets, those having a 3′-G (i.e., AUG, GUG, and UUG) are recognized equivalently and most efficiently by IF3 during the initiation complex formation.

Another important characteristic of a large number of bacterial mRNA TIRs is the presence of a Shine–Dalgarno (or SD) sequence that is complementary to the 3′ end sequence of 16S rRNA (the anti-SD sequence or aSD). The SD sequence, when present, is usually at an optimal distance of 4–9 nucleotides upstream of the initiation codon, as shown in Figure 26.2.2 While the SD sequence plays an important role in the efficient translation of many mRNA transcripts, it is not essential. Many other mRNA sequences fully lack an SD sequence but are still efficiently transcribed. Thus, the SD sequence is only one example of TIR mechanisms that can play an important role in mRNA binding with the small subunit of the ribosome.

Figure 26.2.2: Shine-Dalgarno Translation Initiation Sequence. Figure modified from *Shakeistone*

Prokaryotic mRNA sequences often share a highly conserved sequence upstream of the start codon known as the Shine-Dalgarno sequence. This consensus sequence is complimentary to the 3′-end of the 16S rRNA sequence in the small subunit of the ribosome.

It is an important feature for the binding and docking of many mRNA molecules with the small ribosomal subunit during transcription initiation.

The three protein initiation factors, IF1, IF2, and IF3, determine the kinetics and fidelity of the overall initiation process. The three IFs are bound, one copy each, to specific sites of the 30S subunit where they assist with the formation of the initiation complex and assembly of the 70S ribosome.

As noted above, the initiator tRNA is first aminoacylated with methionine whose α-NH_2 group is eventually blocked by a specific formyl transferase (TMF) to produce a $tRNA^{fmet}$ molecule. This modification prevents interaction with the elongation factor EF-Tu (which we will see plays an important role in the elongation phase of translation, but not the initiation phase!) Blocking EF-Tu binding ensures instead the recognition and binding of $tRNA^{fmet}$ by initiation factor IF2, effectively docking it with the 30S subunit. Furthermore, $tRNA^{fmet}$ binds with high affinity to the ribosomal P-site, unlike all other aminoacyl-tRNAs that bind to the A-site in a ternary complex with EF-Tu and GTP (details will be presented in the next section). In the P-site, the initiator tRNA must be recognized as correct by the other initiation factors IF3 and IF1.

To form the 30S initiation complex, IF3, and IF2 are the first factors to bind to the 30S subunit forming an unstable 30S-IF3-IF2 complex, as shown in Figure 26.2.3 (panel A). The binding of IF1 causes a conformational change in the 30S subunit stabilizing the complex and allowing the recruitment of the $tRNA^{fmet}$ by IF2. Notably, IF1 binds in the A site of the 30S subunit, where it contacts ribosomal protein S12. Recruitment of the $tRNA^{fmet}$ can also stabilize the mRNA interactions with the 30S subunit through the formation of hydrogen bonds between the codon of the mRNA and the anticodon of the $tRNA^{fmet}$. Note that the binding of mRNA to the 30S subunit is IF-independent and can take place at any time during the 30S assembly process. Two potential routes of mRNA association are shown Figure 26.2.3, panel A, where the mRNA is assembled either prior to or after $tRNA^{fmet}$ recruitment.

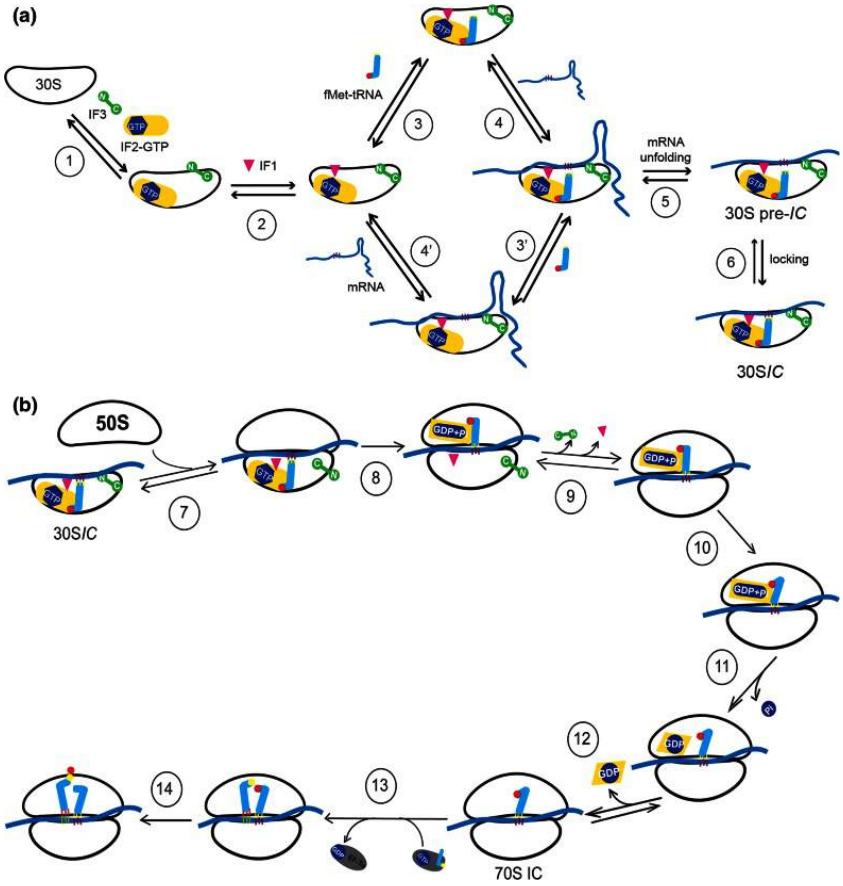

Figure 26.2.3: Initiation of Transcription. Figure from: *Gualerzi, C.O., and Pon, C.L. (2015) Cell Mol Life Sci. 72:4341-4367.*

Step 1: a vacant 30S ribosomal subunit binds IF3 and IF2. *Step 2:* IF1 binds to the 30S subunit in the presence of both IF3 and IF2.

Steps 3 and 3': in the presence of all three factors $tRNA^{fmet}$ is recruited.

Steps 4 and 4':the mRNA is bound with different on and off rates depending on its TIR structure; mRNAs with strong secondary structures are bound more slowly than those having little or no secondary structure.

Step 5: mRNAs containing secondary structures must be unfolded in a process that is facilitated by IF2 bound to GTP and antagonized by IF3.

Step 6: the isomerization of the 30S pre-*IC* allows the P-site codon–anticodon interaction to yield a more stable 30S*IC* from which mRNA and fMet-tRNA are more stably bound.

Step 7: a 30S*IC*, containing IF1, IF2·GTP, IF3 and mRNA whose initiation triplet is P-site decoded by fMet-tRNA, is docked by a 50S subunit.

Step 8: upon contact with the 50S subunit, the GTPase function of IF2 is activated and GTP is rapidly hydrolyzed leaving GDP+Pi bound to IF2.

Step 9: this reversible conformational transition represents the last kinetic checkpoint of translation initiation fidelity by IF3 and IF1, as IF3 and IF1 dissociate from the complex.

Step 10: The first-order isomerization of the IF2-GDP structure causes a shift in the ribosome structure that represents the rate-limiting step in 70S*IC* formation.

Step 11: Pi is dissociated from IF2·GDP.

Step 12: IF2 leaves the ribosome (or moves away from the A-site) clearing the way for EF-Tu binding.

Step 13: the EF-Tu·GTP·aminoacyl-tRNA complex binds to the 70S*IC* and through a number of steps (not represented here) delivers to the ribosomal A-site the aminoacyl-tRNA encoded by the second mRNA codon.

*Step 14:*the $tRNA^{fMet}$ bound in the P-site of the peptidyl transferase center donates its formyl-methionine to the A-site-bound aminoacyl-tRNA to yield the initiation dipeptide fMet-aa. Initiation is then complete and the elongation phase can begin.

Following the recruitment of the mRNA and the $tRNA^{fmet}$ to the 30S initiation complex loaded with the IF2, IF3 and IF1 initiation factors, the 50S subunit is very rapidly docked to yield an initially unstable 70S initiation complex (Fig 27.2.3 b). It should be noted that the IF2 protein is a GTP hydrolase enzyme and, as such, binds with the cofactor GTP prior to the recruitment of the 50S subunit. Contact between the IF2 GTPase activating center with the 50S subunit causes the rapid hydrolysis of GTP to GDP + Pi.

The formation of the 70S complex causes the dissociation of the initiation factors. IF2 is the last factor to be dissociated, leaving the ribosome after having positioned $tRNA^{fMet}$ in the P-site of the 70S initiation complex. It must be placed in the correct orientation to facilitate peptide bond formation. GDP and Pi also dissociate from the complex with the removal of IF2. The elongation factor, EF-G is then free to chaperone the first tRNA into the A-site and the first peptide bond is formed (Step 13 of Fig. 27.2.3 b). This marks the beginning of the elongation phase of protein synthesis.

26.2.2: Eukaryotic Initiation

Eukaryotic translation initiation is more complex than prokaryotic systems and requires the actions of at least 11 eukaryotic initiation factors (eIFs), plus additional auxiliary factors (Table 26.2.1). We will not cover the action of all these eIFs in detail here, but rather focus a few key steps as outlined in Figure 26.2.4

Table 26.2.1: **Comparison of Prokaryotic and Eukaryotic Translation Initiation Factors**

First, the initiator tRNAi is recruited to the small ribosomal subunit (40S) to form a ternary complex with the GTP-bound eukaryotic initiation factor 2 (eIF2). Formation of this 43S pre-initiation complex is strongly enhanced by additional factors, such as eIF3. eIF3 also interacts with the eIF4F complex, which consists of three other initiation factors: eIF4A, eIF4E, and eIF4G. eIF4G is a scaffolding protein that directly associates with both eIF3 and the other two components. eIF4E is the 5′-cap-binding protein. Binding of the mRNA cap by eIF4E is often considered the rate-limiting step of *cap-dependent initiation*, and the concentration of eIF4E is a regulatory nexus of translational control. Certain viruses cleave a portion of eIF4G that binds eIF4E, thus preventing cap-dependent translation to hijack the host machinery in favor of the viral (cap-independent) messages. eIF4A is an ATP-dependent RNA helicase that aids the ribosome by resolving certain secondary structures formed along the mRNA transcript. The poly(A)-binding protein (PABP) also associates with the eIF4F complex via eIF4G, and binds the poly-A tail of most eukaryotic mRNA molecules. This protein has been implicated in playing a role in circularization of the mRNA during translation.The 43S preinitiation complex accompanied by the protein factors moves along the mRNA chain toward its 3′-end, in a process known as ‘scanning’, to reach the start codon (typically AUG). After recognition of the start codon, the large ribosomal subunit (60S) assembles to form the 80S initiation complex, which is ready for elongation. Alternatively, under distinct conditions or on certain transcripts internal initiation can occur in a cap-independent manner at so called *internal ribosome entry sites (IRES).* Eukaroytic translation initiation is shown in Figure 26.2.4

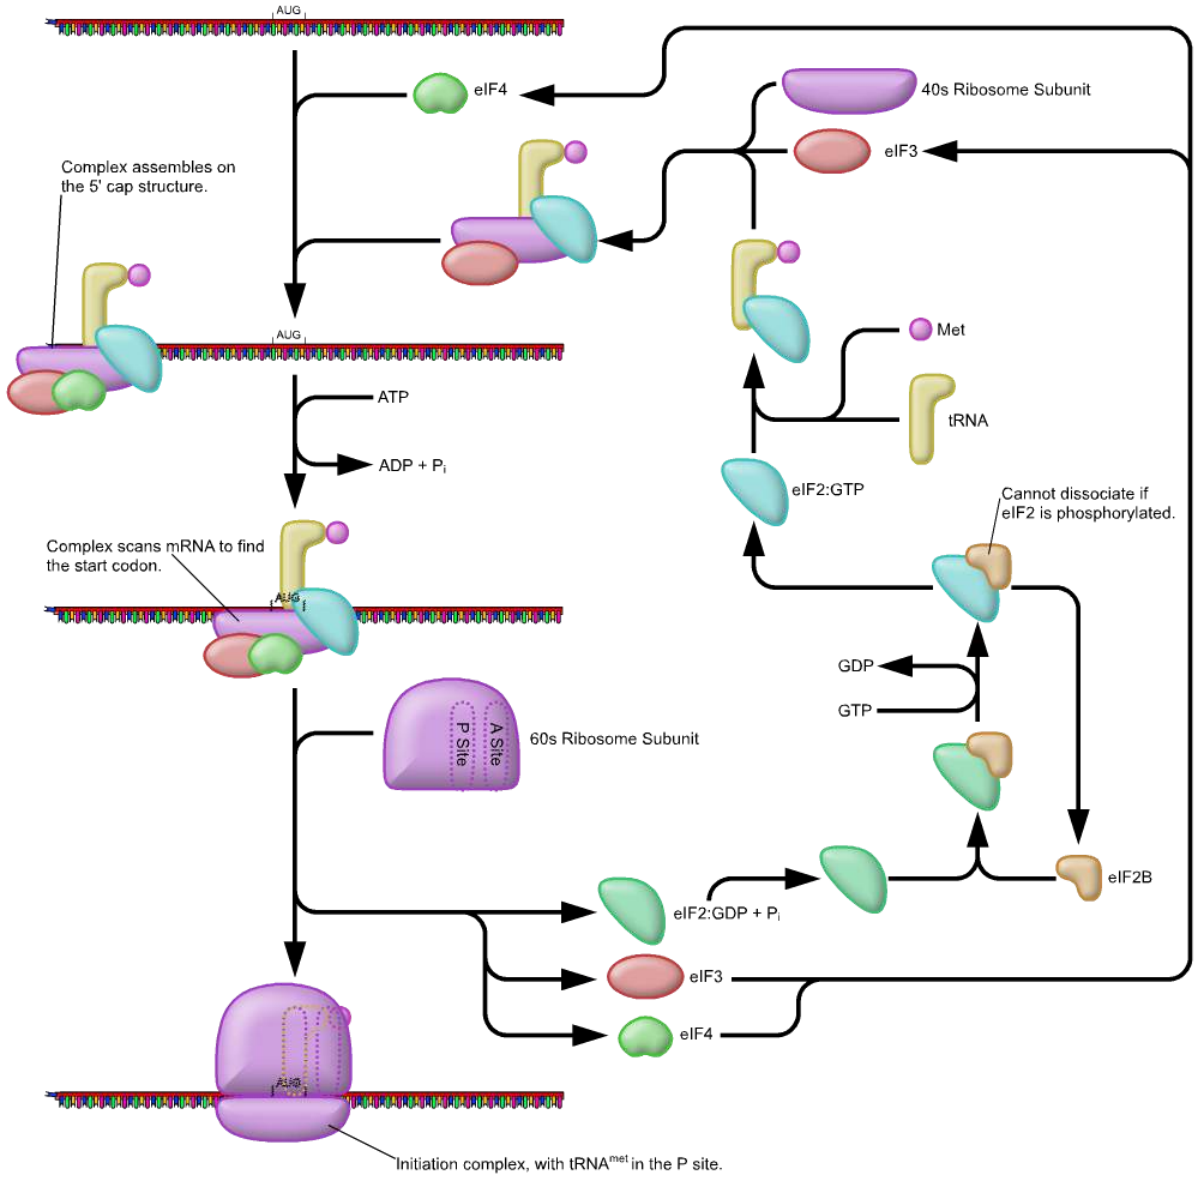

Figure 26.2.4: Eukaryotic Translation Initiation. Figure from: Eukaryotic Translation, Wikiwand

This is a simplified diagram of eukaryotic translation initiation detailing some of the eIFs involved in the process. eIF2 is critical for recruiting the initiation tRNAi to the 40S subunit. eIF3 enhances the activity of eIF2 and also promotes the binding of the 43S pre-initiation complex with the mRNA. eIF3 binds with the mRNA through the interaction of the eIF4 factors and causes the scanning of the pre-initiation complex down the mRNA to locate the start codon (usually AUG). Poly A Binding Proteins (PABPs) bind with the polyA tail sequence of the mRNA and also interact with the eIF4 factors causing the circularization of the mRNA.

As seen in prokaryotic systems with the favored Shine Dalgarno sequence upstream of the start codon within the mRNA sequence, there are also preferred nucleotide sequences within the local vicinity of the start codon in eukaryotic mRNAs, as well. In eukaryotic mRNA, this is known as the **Kozak sequence** (Figure 26.2.5). The sequence was originally defined as 5′-(gcc)gccRccAUGG-3 where:

1. The underlined nucleotides indicate the translation start codon, coding for Methionine.
2. upper-case letters indicate highly conserved bases, *i.e.* the 'AUGG' sequence is constant or rarely, if ever, changes.
3. 'R' indicates that a purine (adenine or guanine) is always observed at this position (with adenine being more frequent according to Kozak rules)
4. a lower-case letter denotes the most common base at a position where the base can nevertheless vary

5. the sequence in parentheses (gcc) is of uncertain significance.

The AUG is the initiation codon encoding a methionine amino acid at the N-terminus of the protein. (Rarely, GUG is used as an initiation codon, but methionine is still the first amino acid as it is the met-tRNA in the initiation complex that binds to the mRNA). Variation within the Kozak sequence alters the “strength” of the translational start site. Kozak sequence strength refers to the favor ability of initiation, affecting how much protein is synthesized from a given mRNA. This is shown in Figure 26.2.5.

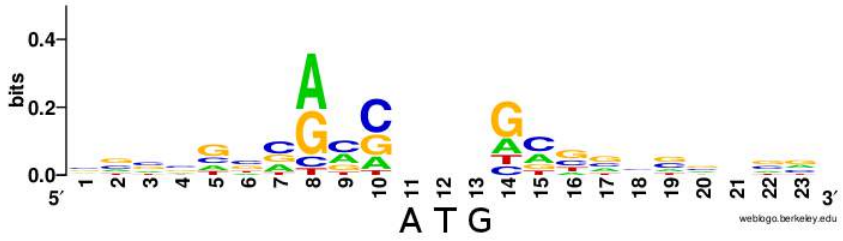

Figure 26.2.5: The Kozak Sequence. The sequence schematic above shows the most conserved bases around the initiation codon from over 10,000 human mRNAs. Larger letters indicate a higher frequency of incorporation. Note the larger size of A and G at the 8 position (−3, Kozak position) and at the G at position 14 which corresponds to (+4) position in the Kozak sequence. Figure from: *Audrey Michel*

26.2.3: The Elongation Phase of Translation

Both prokaryotic and eukaryotic elongation phases of transcription utilize similar elongation factors during the process. Table 26.2.2 provides a summary of their functions.

Table 26.2.2 **Comparison of Prokaryotic and Eukaryotic Translation Elongation Factors**

26.2.4: Prokaryotic Elongation

The prokaryotic elongation phase of transcription requires the activity of three primary elongation factors (EFs), EF-Tu, EF-Ts, and EF-G. During elongation, aminoacyl-tRNAs are delivered to the ribosome in the form of a ternary complex: the tRNA, a translational GTPase (in bacteria: EF-Tu or SelB), and a GTP molecule, as shown in Figure 26.2.6. The tRNA decodes the information on the mRNA by forming hydrogen bonds (H-bonds) between codon and anticodon nucleobases. Remarkably, the free-energy difference between correct (cognate) and incorrect (near-cognate, non-cognate) base pairing alone does not explain the very high fidelity of decoding. Rather, high fidelity is achieved by a two-step decoding process: initial selection leading to GTPase activation and proofreading. In addition to the free-energy difference, kinetic effects contribute to the discrimination. The GTP hydrolysis rate is increased and tRNA rejection rate is decreased by the recognition of the correct codon.

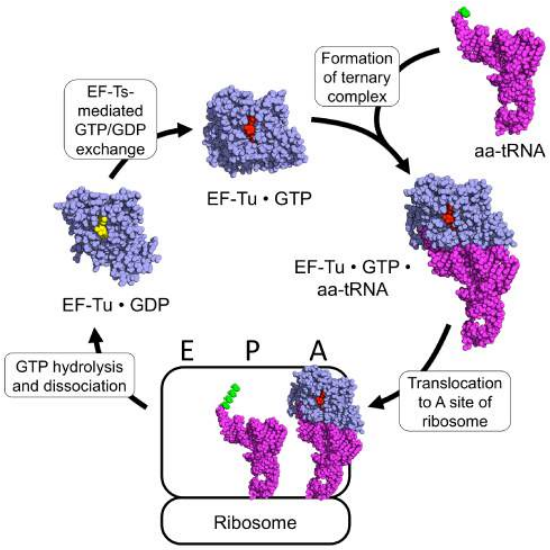

Figure 26.2.6: The EF-Tu tRNA Chaperone Protein. Ef-Tu (shown in blue) is a GTPase enzyme chaperone that when bound to GTP (shown in red), can form a ternary complex with an amino acid-containing tRNA molecule (tRNA shown in purple; amino acid shown in green). The ternary complex translocates to the A-site of the ribosome where the anticodon of the incoming tRNA hybridizes with the codon of the mRNA. An exact match of the codon-anticodon hybridization leads to the hydrolysis of GTP by EF-Tu and its subsequent dissociation from the ribosome (the hydrolysis product GDP is shown in yellow). EF-Tu is unable to release the GDP on its own. It requires an protein-mediated exchange of the GDP for a molecule of GTP using the elongation factor, EF-Ts. Figure from Awchen

Small-subunit nucleotides A1492 and A1493 adopt a flipped-out conformation in the presence of a tRNA and, in this conformation, the tRNA anticodon hydrogen bonds with the codon of the mRNA forming a mini-helix structure as shown in Figure 26.2.7. The flipped out nucleotides A1492, A1493 along with G530 were found to shield the codon–anticodon base pairs from solvent. This shielding of near-cognate base pairs from the solvent is incomplete causing an increase in the free-energy difference between near-cognate and cognate base pairs and more flexibility within the docking region. This reduces the strength of hydrogen bonding between a non-cognate tRNA and causes the inappropriate tRNA to leave the A-site before peptide bond formation can occur. This increases the fidelity and discrimination of tRNA selection, such that only the correct cognate tRNA is incorporated into the A-site.

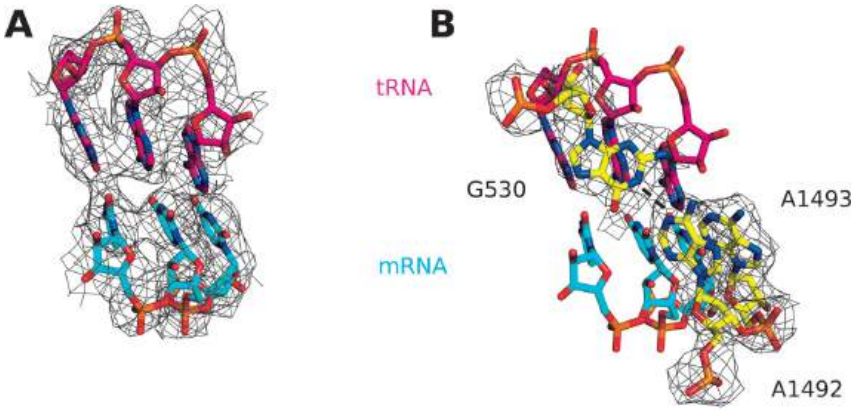

Figure 26.2.7: Cognate Interaction of tRNA and mRNA in *E. coli.* Fislage, M., et. al. (2018) Nuc. Acids Res. 46(11):5861-5874.

Panel (A) shows the interaction of cognate tRNA anticodon (shown in red) with the mRNA codon (shown in blue) when wild type EF-Tu binds and chaperones the tRNA complex to the A-site of the ribosome.Panel (B) is the same figure as shown in (A), with the ribosomal nucleotides A1492 and A1493 depicted in the flipped out conformation.

Interestingly aminoglycosides, a class of antibiotics, bind to the decoding center and lock nucleotides A1492/A1493 in the flipped-out conformation as shown in Figure 26.2.8. In this way aminoglycosides promote the accommodation of near-cognate, thus

wrong, tRNAs into proteins during synthesis causing wide-spread mutagenesis. This is toxic to the bacteria and leads to bacterial cell death.

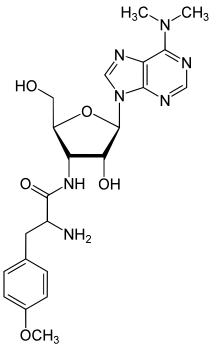

Figure 26.2.8 Structure of the Aminoglycoside Antibiotic, Puromycin. Figure from: *Yikrazuul*

After GTP hydrolysis, the GTPase EF-Tu dissociates from the tRNA. At this point, the EF-Tu is tightly bound with a molecule of GDP and cannot release GDP on its own to be recycled for a second round of tRNA chaperoning. The recharging of EF-Tu is executed by the Elongation Factor Thermo stable (EF-Ts), as shown in Figure 26.2.9. The binding of EF-Ts with EF-Tu-GDP causes a conformational change in EF-Tu that allows the release of GDP. The binding of a new molecule of GTP with the EF-Tu protein causes the dissociation of EF-Ts and fully recharges EF-Tu.

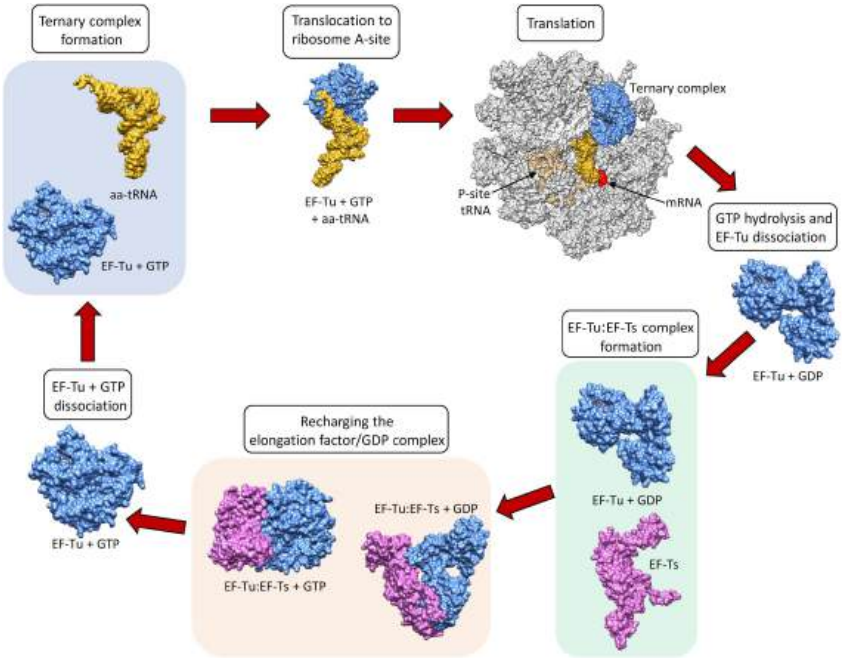

Figure 26.2.9: Recharging of EF-Tu is Mediated by EF-Ts. When EF-Tu is bound with GTP (shown in blue), it can bind an aa-tRNA complex (shown in yellow) causing the translocation of the aa-tRNA to the A-site of the ribosome (shown in grey). The anticodon of the tRNA is positioned in the A-site, such that it can form H-bonds with the codon of the mRNA (shown in red). Binding of the cognate aa-tRNA in the A-site causes GTP hydrolysis by EF-Tu and subsequent dissociation of EF-Tu (GDP) from the ribosome. Following the ribosomal dissociation, EF-Tu(GDP) binds with a molecule of EF-Ts (shown in purple). Binding of EF-Ts causes a conformational change in EF-Tu, such that GDP is released. A molecule of GTP is then incorporated into EF-Tu while it is complexed with EF-Ts. This causes the dissociation of EF-Ts from the complex and the EF-Tu is recharged. *Harvey, K.L, et. al. (2019) Front. Microbiol. 10:2351*

Dissociation of EF-Tu from the ribosome allows the tRNA to move into to the peptidyl transferase center (A-site) on the large subunit. At the core of ribosomal translation is the catalysis of peptide bond formation, as shown in Figure 26.2.10 The current reaction models point to a substrate assisted mechanism. Simulations indicate that the transition state forms due to extensive hydrogen bonding with water molecules and the surrounding rRNA bases and that the C-O bond cleavage takes place after C-N bond formation. Peptide bond formation results in the transition of the amino acid docked on the P-site tRNA to the nascent

growing peptide that is now held on the tRNA in the A-site. Note that this mechanism causes the nascent growing peptide to always grow in the N- to C- direction.

Figure 26.2.10: Proposed Mechanism of Peptide Bond Formation in the Ribosome. *(Left)* tRNA molecules docked in the P- and A-sites are oriented such that the two amino acids move in close proximity. Hydrogen bond formation with the ribosomal rRNA and surrounding water molecules stabilizes the formation of the transition state and enables the amine nitrogen from the A-site amino acid to attack the carbonyl carbon of the P-site amino acid. Formation of the peptide bond occurs prior to the C-O bond breakage forming a transient oxyanion intermediate. *(Right)* The products of the peptidyl transferase reaction include the nascent growing peptide attached to the A-site tRNA and an empty tRNA in the P-site. Figure modified from *Awchen*

Once the peptide bond is formed, the ribosome needs to translocate down the mRNA to make the next mRNA codon available within the A-site. This also requires the shifting of the tRNA molecules, such that the tRNA in the A-site (which is now tethered to the nascent peptide) shifts to the P-site. The P-site tRNA (which is now empty) shifts to the E-site, and if there was an empty tRNA in the E-site, it will shift to exit the ribosome. Shifting the tRNAs and mRNAs within the ribosome core requires the action of the EF-G elongation factor, as shown in Figure 26.2.11

Figure 26.2.11: One Cycle of Elongation. Figure modified from: *Goodsell, D. (2010) Molecule of the Month* (*Left*): During one round of amino acid elongation on a nascent peptide, the EF-Tu protein binds with the cognate aa-tRNA molecule and shuttles it to the A-site of the ribosome. GTP hydrolysis by EF-Tu leads to the hybridization of the anticodon of the tRNA with the codon of the mRNA and causes the dissociation of the EF-Tu (GDP-bound) from the ribosome. *(Center):* Following the dissociation of EF-Tu, the peptide bond is formed leading to the transfer of the nascent peptide from the tRNA in the P-site, to the tRNA in the A-site. (*Right*): Peptide bond formation leads to a conformational change in the ribosome that allows the binding of EF-G (GTP Bound) near the A-site of the ribosome. Rapid hydrolysis of GTP by EF-G causes a large conformational shift in the protein that twists the large subunit of the ribosome and shifts the bound tRNAs from the A- to the P-site; from the P- to the E-site; or from the E-site to exiting the ribosome.

Figure 26.2.12shows an interactive iCn3D model of the eukaryotic 80S ribosome with bound mRNA and tRNAs (6GX3) . (**Very long load time**)

EF-G is a GTP hydrolase protein that binds to the A-site of the ribosome. The EF-G protein has high flexibility that enables it to act as a hinge. Folding of EF-G is dependent on GTP hydrolysis. Thus, when binding to the ribosome, the fast hydrolysis of GTP acts as a power stroke folding the EF-G protein and causing a conformation shift in the ribosome that enables the translocation of the tRNA residues and the mRNA. Translocation of tRNAs is accompanied by large-scale collective motions of the ribosome: relative rotation of ribosomal subunits and L1-stalk motion, as shown in Figure 26.2.13 The L1 stalk, which is a flexible part of the large subunit, is in contact and moves along with the tRNA from the P to the E site. Once in the EF-G-GDP form, the factor quickly dissociates from the ribosome, opening up the A-site for the recruitment of the next aa-tRNA molecule. The elongation cycle will continue to be repeated until a termination codon is reached.

Figure 26.2.13: Large-scale Motion of the Large Subunit of the Ribosome During Translocation. (a) Pre-translocation structure of the ribosome with tRNAs in A and P sites (green, brown). The L1 stalk of the large subunit is shown in purple. (b) Motions accompanying tRNA translocation. Bock, L.V., Kolár, M.H., Grubmüller, H. (2018) Cur. Op. Struc. Bio. 49:27-35.

26.2.5: Eukaryotic Elongation

The elongation phase in eukaryotic translation is very similar to prokaryotic elongation. Essentially, the mRNA is decoded by the ribosome in a process that requires the selection of each aminoacyl-transfer RNA (aa-tRNA), which is dictated by the mRNA codon in the ribosome acceptor (A) site, peptide bond formation and movement of both tRNAs and the mRNA through the ribosome, as shown in Figure 26.2.14 A new amino acid is incorporated into a nascent peptide at a rate of approximately one every sixth of a second. The first step of this process requires guanosine triphosphate (GTP)-bound eukaryotic elongation factor 1A (eEF1α) to recruit an aa-tRNA to the aminoacyl (A) site, which has an anticodon loop cognate to the codon sequence of the mRNA. The anticodon of this sampling tRNA does not initially base-pair with the A-site codon. Instead, the tRNA dynamically remodels to generate a codon-anticodon helix, which stabilizes the binding of the tRNA-eEF1α-GTP complex to the ribosome A site. This helical structure is energetically favorable for cognate or correct pairing, and so discriminates between the non-cognate or unpaired and single mismatched or near-cognate species. This is important for the accuracy of decoding since it provides a mechanism to reject a non-cognate tRNA that carries an inappropriate amino acid. The pairing of the tRNA and codon induces GTP hydrolysis by eEF1α, which is then evicted from the A site. In parallel with this process, the ribosome undergoes a conformational change that stimulates contact between the 3′ end of the aa-tRNA in the A site and the tRNA carrying the polypeptide chain in the peptidyl (P) site. The shift in position of the two tRNAs [A to the P site and P to the exit (E) site] results in ribosome-catalyzed peptide bond formation and the transfer of the polypeptide to the aa-tRNA, thus extending the polypeptide by one amino acid. The second stage of the elongation cycle requires a GTPase, eukaryotic elongation factor 2 (eEF2), which enters the A-site and, through the hydrolysis of GTP, induces a change in the ribosome conformation. This stimulates ribosome translocation to allow the next aa-tRNA to enter the A-site, thus starting a new cycle of elongation.

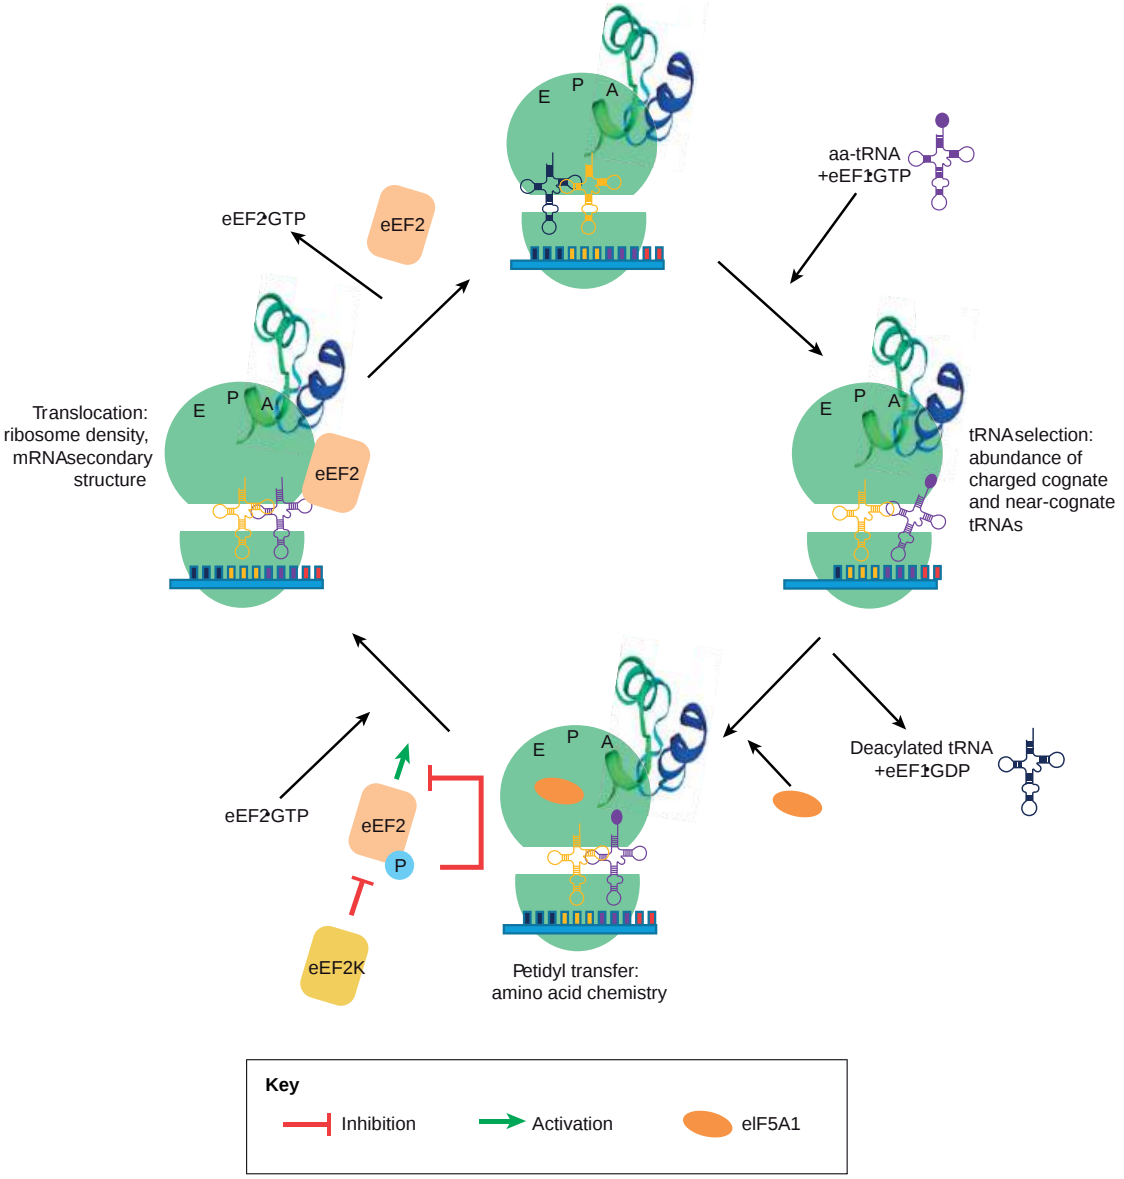

Figure 26.2.14: Eukartyotic Translation Elongation Phase. *Knight, J.R.P., et. al. (2020) Disease Models & Mechanisms 13, dmm043208.*

This schematic represents the four basic steps of eukaryotic translation elongation. The ribosome contains three tRNA-binding sites: the aminoacyl (A), peptidyl (P) and exit (E) sites. In the first step of peptide elongation, the tRNA, which is in a complex with eIF1 and GTP and contains the cognate anticodon to the mRNA coding sequence, enters the A site. Recognition of the tRNA leads to the hydrolysis of GTP and eviction of eEF1 from the A site. In parallel, the deacylated tRNA in the E site is ejected. The A site and the P site tRNAs interact, which allows ribosome-catalyzed peptide bond formation to take place. This involves the transfer of the polypeptide to the aa-tRNA, thus extending the nascent polypeptide by one amino acid. eIF5A allosterically assists in the formation of certain peptide bonds, e.g. proline-proline. eEF2 then enters the A site and, through the hydrolysis of GTP, induces a change in the ribosome conformation and stimulates translocation. The ribosome is then in a correct conformation to accept the next aa-tRNA and commence another cycle of elongation.

26.2.5.1: The Ribosome as a Ribozyme

Protein synthesis from a mRNA template occurs on a ribosome, a nanomachine composed of proteins and ribosomal RNAs (rRNA). Peptide bond formation occurs when another tRNA-amino acid molecule binds to an adjacent codon on mRNA. The tRNA has a cloverleaf tertiary structure with some intrastranded H-bonded secondary structure. The last three nucleotides at the 3' end of the tRNA are CpCpA. The amino acid is esterified to the terminal 3'OH of the terminal A by a protein enzyme, aminoacyl-tRNA synthetase.

Covalent amide bond formation between the second amino acid to the first, forming a dipeptide, occurs at the peptidyl transferase center, located on the larger ribosomal subunit (50S and 60S in bacteria and eukaryotes, respectively). The ribosome ratchets down the mRNA so the dipeptide-tRNA is now at the the P or Peptide site, awaiting a new tRNA-amino acid at the A or Amino site. Figure 26.2.15 below shows a schematic of the ribosome with bound mRNA on the 30S subunit and tRNAs covalently attached to amino acid (or the growing peptide) at the A and P site, respectively.

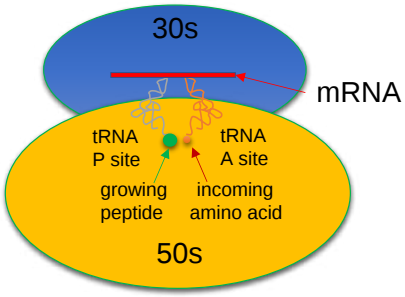

Figure 26.2.15: Ribosome with bound mRNA on the 30S subunit and tRNAs covalently attached to amino acid (or the growing peptide) at the A and P site

A likely mechanism (derived from crystal structures with bound substrates and transition state analogs) for the formation of the amide bond between a growing peptide on the P-site tRNA and the amino acid on the A-site tRNA is shown in Figure 26.2.16 Catalysis does not involve any of the ribosomal proteins (not shown) since none is close enough to the peptidyl transferase center to provide amino acids that could participate in general acid/base catalysis, for example. Hence the rRNA must act as the enzyme (i.e. it is a ribozyme). Initially it was thought that a proximal adenosine with a perturbed pKa could, at physiological pH, be protonated/deprotonated and hence act as a general acid/base in the reaction. However, none was found. The most likely mechanism to stabilize the oxyanion transition state at the electrophilic carbon attack site is precisely located water, which is positioned at the oxyanion hole by H-bonds to uracil 2584 on the rRNA. The cleavage mechanism involves the concerted proton shuffle shown below. In this mechanism, the substrate (Peptide-tRNA) assists its own cleavage in that the 2'OH is in position to initiate the protein shuttle mechanism. (A similar mechanism might occur to facilitate hydrolysis of the fully elongated protein from the P-site tRNA.) Of course all of this requires perfect positioning of the substrates and isn't that what enzymes do best? The main mechanisms for the catalysis of peptide bond formation by the ribosome (as a ribozyme) are intramolecular catalysis and transition state stabilization by the appropriately positioned water molecule.

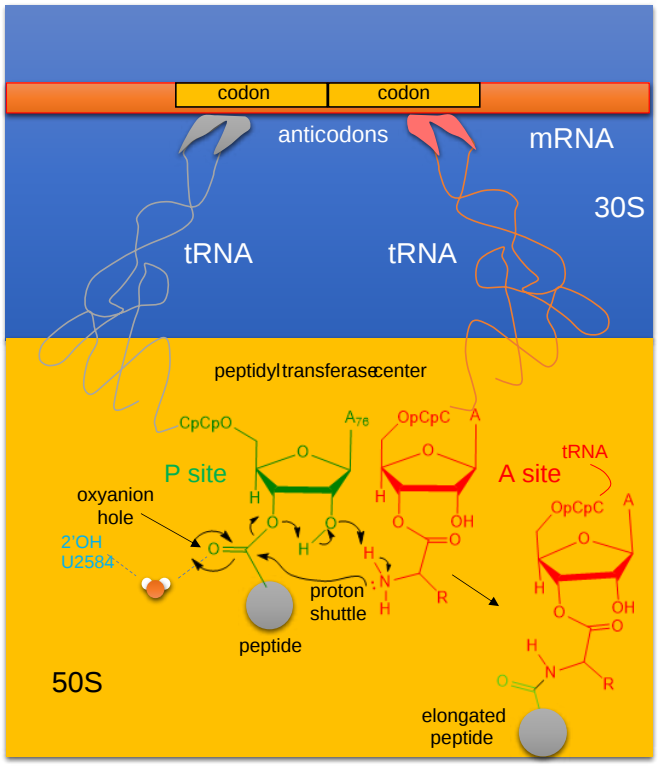

Figure 26.2.16: formation of the amide bond between a growing peptide on the P-site tRNA and the amino acid on the A-site tRNA.

26.2.6: Translation Termination

26.2.6.1: Prokaryotic Termination

Termination of bacterial protein synthesis occurs when a stop codon is presented in the ribosomal A-site and is recognized by a class I release factor, RF1 or RF2. These release factors (RFs) have different but overlapping specificities, where RF1 reads UAA and UAG and RF2 reads UAA and UGA, with strong discrimination against sense codons. The RFs are multi-domain proteins, where binding and stop codon recognition by domain 2 at the decoding site causes the universally conserved GGQ motif of domain 3 to insert into the A-site of the PTC, some 80 Å away from the decoding site. This event triggers hydrolysis of the peptidyl-tRNA bond in the P-site of the PTC, and the nascent peptide chain can then be released via the ribosomal exit tunnel, as shown in Figure 26.2.14 After peptide release, RF1 and RF2 dissociate from the post-termination complex. The dissociation is accelerated by a class II release factor called RF3, which functions as a translational GTPase that binds and hydrolyses GTP in the course of termination.

While RF3 increases the efficiency of peptide hydrolysis, it is not an essential protein for the process. In gene knockout studies, RF3 is dispensable for growth of *Escherichia coli*, and its expression is not conserved in all bacterial lineages. For example, RF3 is not present in the thermophilic model organisms of the *Thermus* and *Thermatoga* genera and in infectious *Chlamydiales* and *Spirochaetae*. This means that both RF1 and RF2 are capable of performing a complete round of termination independently of RF3 or that other GTPases from the elongation or initiation phases of translation can compensate for the action of RF3.

The release factors RF1 and RF2 acquire an open conformation (Figure 26.2.17on the 70S ribosome, which is distinctly different from the closed conformation observed in crystal structures of free RFs. The conformational equilibrium of the free RFs in solution shows that this open conformation is dominating at about 80%.

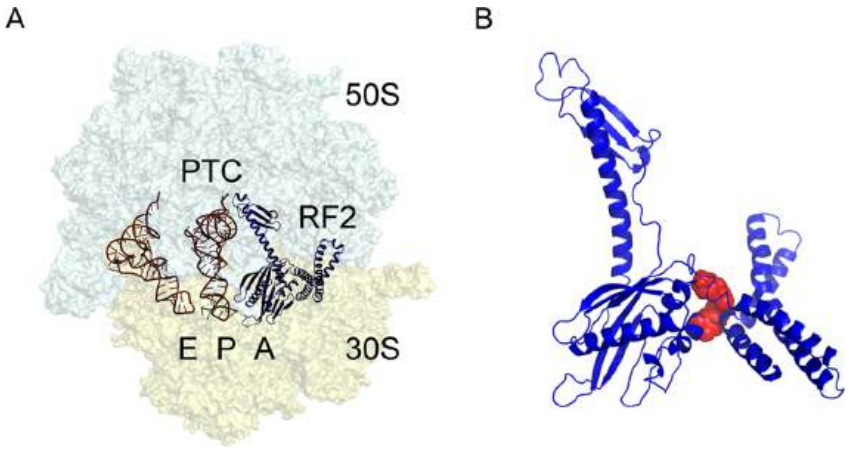

Figure 26.2.17: The bacterial 70S ribosome termination complex with RF2. (A) View of the ribosome termination complex with E- and P-site tRNAs (brown), mRNA (green), and RF2 (dark blue). (B) Close-up view of the hinge region of RF2 between domains 1 and 4 used for virtual screening, where the putative binding region is indicated by a docked ligand (red). *Ge, X., et. al. (2019) Scientific Reports 9:15424.*

During peptide hydrolysis, the RF factors cause rotational and conformational changes within the ribosome that allow the binding of a ribosome recycling factor (RRF) and the EF-G GTPase, which leads to the dissociation of the large subunit from the small subunit and the release of the mRNA, as shown in Figure 26.2.18

Figure 26.2.18: Termination of Translation. quent binding of the ribosome recyclying factor, RRF, and EF-G causes the dissociation of the large and small ribosomal subunits and the release of the mRNA. Figure modified from: *Bock, L.V., Kolár, M.H., Grubmüller, H. (2018) Cur. Op. Struc. Bio. 49:27-35.*

When a stop codon enters the A-site of the ribosome RF1 or RF2 enter the A-site and bind with the mRNA. This leads to the hydrolysis of the protein and release through the exit tunnel. Binding of RF3 and GTP hydrolysis causes the dissociation of the RF factors and conformational change of the ribosome structure. Subse

26.2.7: Eukaryotic Termination

In eukaryotes and archaea, on the other hand, a single omnipotent RF reads all three stop codons. Although the mechanism of translation termination is basically the same, there is neither sequence nor structural homology between the bacterial RFs and the eukaryotic eRF1, apart from the universally conserved GGQ motif which is required for peptide hydrolysis from the tRNA. the eRF3 GTPase coordinates the release of eRF1 following hydrolysis. In Archaea, there is no eRF3 homolog, instead the aEF1A protein mediates this function. The process of eukaryotic ribosomal disassembly and recycling is currently not well understood, but appears to involve an ABC type ATPase called ABCE1. Mitochondria have independent RFs that can recognize standard and non-standard stop codons, and are more homologous with bacterial systems of ribosomal recycling and disassembly.

26.2.8: Summary of Translation

An overall summary of prokaryotic translation is given in Figure 26.2.19

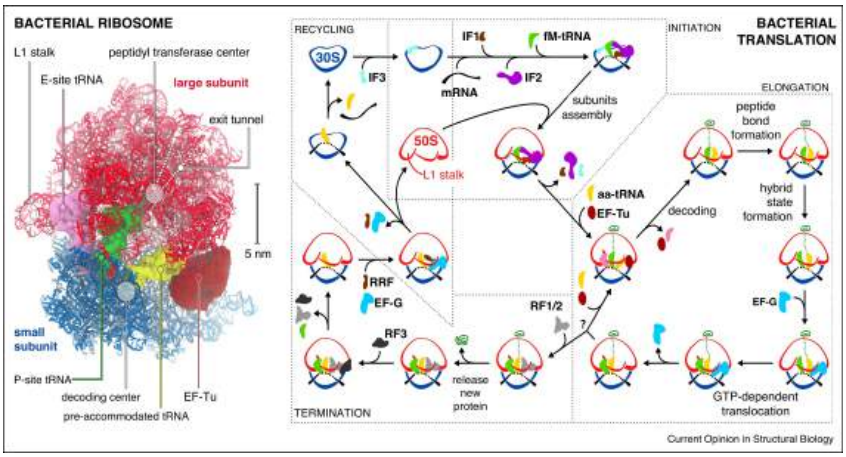

Figure 26.2.19: Summary of Prokaryotic Translation. *Bock, L.V., Kolár, M.H., Grubmüller, H. (2018) Cur. Op. Struc. Bio. 49:27-35.*

Left panel: Structure of the bacterial ribosome in complex with EF-Tu (PDB 5AFI).

Right Panel: Scheme of the bacterial translation cycle. 30S: small subunit; 50S: large subunit; IF1, IF2, IF3: initiation factors; fM-tRNA: N-formylmethionine tRNA; aa-tRNA: aminoacyl tRNA; EF-Tu, EF-G: elongation factors; RF1, RF2, RF3: release factors; RRF: ribosome recycling factor; green trace: nascent protein. The question mark stands for a stop codon recognition.

26.3: Translational Regulation and Protein Degradation

Search Fundamentals of Biochemistry

26.3.1: Regulation of Translation

26.3.1.1: Heterogeneity of Ribosome Structure

Over the years, many studies performed in eukaryotes presented evidence that ribosomes can vary in their protein and rRNA complement between different cell types and developmental states. These observations culminated in the postulation of the *'ribosome filter hypothesis'* by Mauro and Edelman in the year 2002. The authors propose that the ribosome composition functions as a translation determination factor. Depending on the RPs and rRNA sequences represented in the respective ribosome, the complex acts like a filter that selects for specific mRNAs and hence modulates translation, as shown in Figure 26.3.1. RP heterogeneity can arise from differential expression of paralogs/homologs of RP proteins within different cell types or occur due to differential post-translational modifications of RPs, such as phosphorylation. The protein-to-rRNA ratio may also slightly vary within ribosomal composition affecting translation efficiency and selectivity.

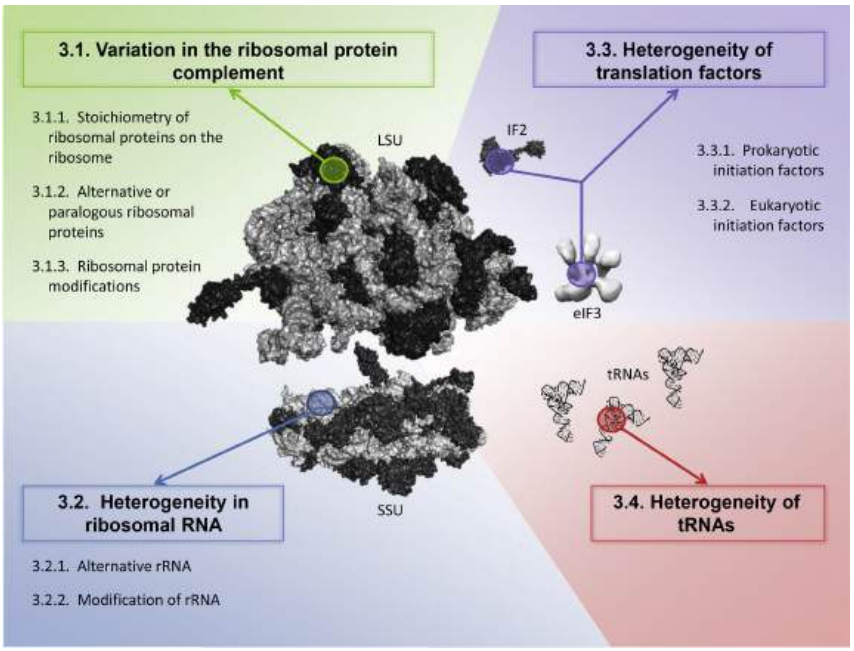

Figure 26.3.1: Components of the translation machinery that have the potential to contribute to functional heterogeneity. Structures were visualized with Polyview 3D software using the following maps: *E. coli* large ribosomal subunit (LSU; pdb accession code: 3d5a, rRNA in light gray, proteins in dark gray); small ribosomal subunit (SSU; pdb accession code: 3d5b); *E. coli* IF2 (pdb accession code: 1g7r); human eIF3 (EMD-2166); yeast $tRNA^{Phe}$ (pdb accession code: 6tna).*Sauert, M., Temmel, H., and Moll, I. (2015) Biochimie 114: 39-47.*

RNA genes are also present in multiple copies throughout the genomes of organisms from all domains of life. For example, the bacteria *Streptomyces coelicolor* harbors six copies of divergent large subunit (LSU) rRNA genes that constitute at least five different LSU rRNA species in a cell. These genes were shown to be differentially transcribed during the morphological development of the organism. Similarly, *B. subtilis* harbors ten *rRNA* operons and their reduction to one copy increased the doubling time as well as the sporulation frequency and the motility of the resulting mutant.

Modification of the rRNA also provides another avenue of ribosomal heterogeneity. Similar to tRNA, rRNA residues can be chemically modified and commonly have 2-OH methylation. The conversion of uridine to pseudouridine is also quite common. In eukaryotes, the modifications are facilitated by snoRNAs and their tissue-specific expression might be a source for ribosome specialization. In light of the increasing evidence, ribosome heterogeneity, though still far from being entirely understood, proves to be an integral mechanism to modulate and fine-tune protein synthesis in response to environmental signals in all organisms.

26.3.1.2: Effects of Sequence and Secondary Structure in mRNA

The amount of protein produced from any given mRNA (i.e., the translational output) is influenced by multiple factors specified by the primary nucleotide sequence. These factors include GC content, codon usage, codon pairs, and secondary structure. For

example, 5'UTR sequences in the mRNA may interact with small miRNAs and lead to RNA interference. miRNA interactions may also target mRNA for degradation(Figure 26.3.2). This process is aided by protein chaperones called argonautes. This antisense-based process involves steps that first process the miRNA so that it can base-pair with a region of its target mRNAs. Once the base pairing occurs, other proteins direct the mRNA to be destroyed by nucleases. Fire and Mello were awarded the 2006 Nobel Prize in Physiology or Medicine for this discovery.

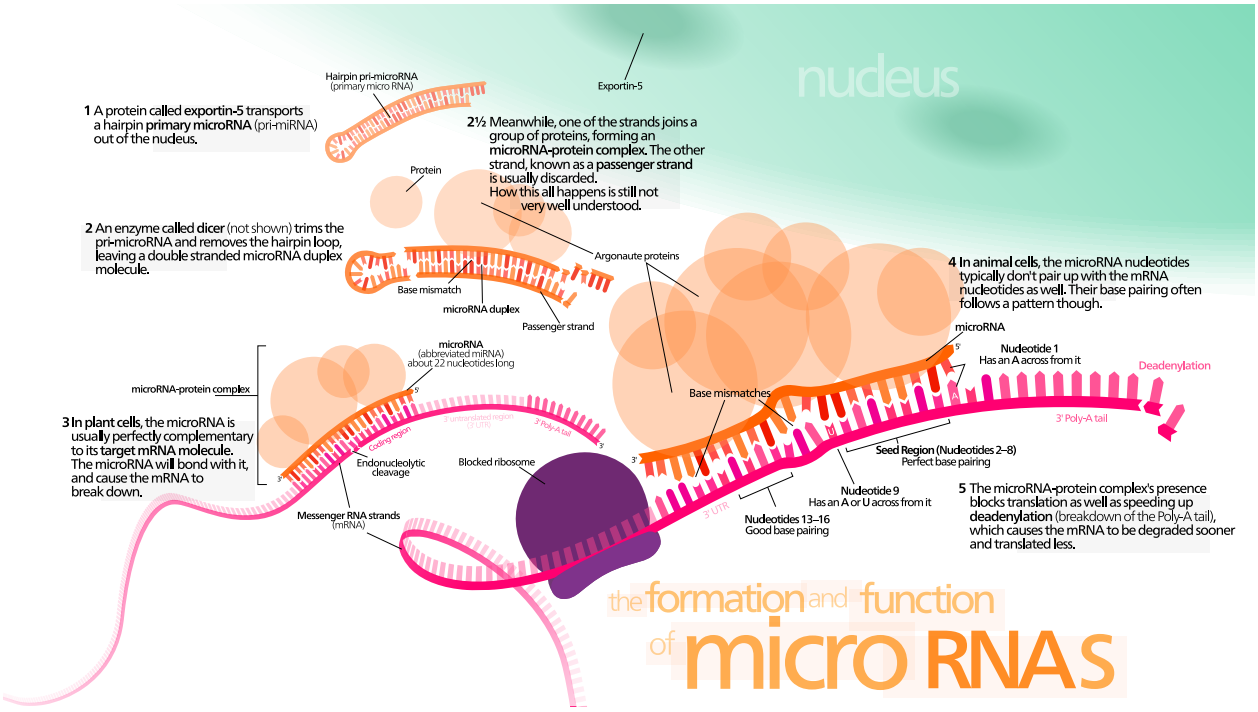

Figure 26.3.2: Role of Micro RNA (miRNA) in the Inhibition of Eukaryotic mRNA Translation. *Wikimedia Commons*

- Step (1) shows how Exportin-5 transports a hairpin primary micro RNA (pri-miRNA) out of the nucleus and into the cytoplasm.
- Step (2) shows how Dicer (not shown) trims the pri-miRNA and removes the hairpin loop. A group of proteins, known as Argonautes, form a miRNA/protein complex.
- Steps (3,4) show how miRNA/protein complex hydrogen bonds with mRNA based on complimentary sequence homology, and blocks translation.
- Step (5) shows the miRNA/protein complex binding speeds up the breakdown of the polyA tail of the mRNA, causing the mRNA to be degraded sooner.

26.3.1.3: Effects of the Nascent Peptide on Ribosome Efficiency

Since the Peptidyl Transferase Center (PTC) is buried within the large subunit, during translation the nascent peptide chain (NC) exits through a 100 Å-long tunnel (Figure 26.3.3). The exit tunnel plays an active role in protein synthesis. Certain peptide sequences specifically interact with tunnel walls and induce ribosome stalling. Furthermore, the exit tunnel is a binding site for a clinically important class of antibiotics known as the macrolides.

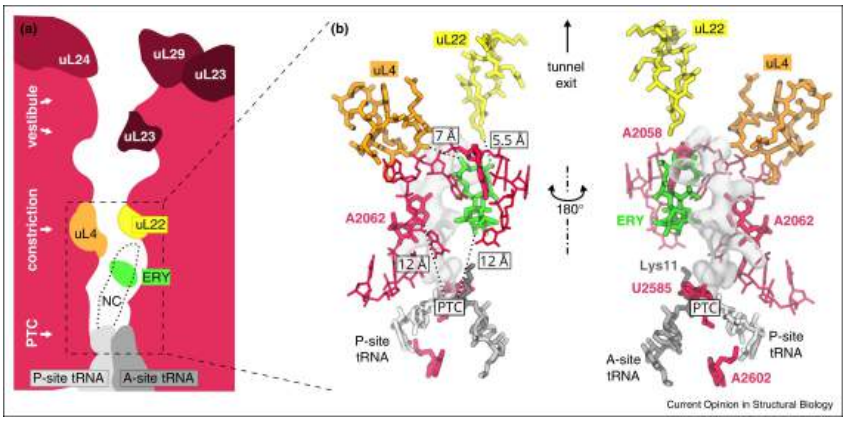

Figure 26.3.3: The Ribosomal Exit Tunnel (a) Scheme of the ribosome exit tunnel with several proteins highlighted. NC, nascent peptide chain; ERY, erythromycin; PTC, peptidyl transferase center. (b) Context of the erythromycin (ERY, in green) binding; figure based on PDB: 5JTE. Several large subunit nucleotides are highlighted in bold red. Two proteins uL4 and uL22 form a constriction site. The nascent peptide is shown as a transparent surface structure. *Bock, L.V., Kolár, M.H., Grubmüller, H. (2018) Cur. Op. Struc. Bio. 49:27-35*

When synthesizing proteins containing proline stretches (i.e. several prolines in a row), ribosomes become stalled. Stalling is alleviated by a specialized elongation factor, EF-P in bacteria. Recently, cryo-EM structures of a ribosome stalled by a proline stretch with and without EF-P were resolved. In simulations of the PTC region, elongation factor P (EF-P) was observed to stabilize the P-site tRNA in a conformation compatible with peptide bond formation, while in the absence of EF-P, the P-site tRNA moved away from the A-site tRNA.

The exit tunnel can accommodate 30–60 AAs, depending on the level of NC compaction. The rate of translation of about 4–22 AA per second in bacteria provides the NC with sufficient time to explore its conformational space and to start folding when still bound to the ribosome-tRNA complex.

26.3.2: Proteasome

The 26S proteasome is the central element of proteostasis regulation in eukaryotic cells. It is required for the degradation of protein factors in multiple cellular pathways and it plays a fundamental role in cell stability. The 26S proteasome has a structural configuration that confines the proteolytic active sites in a location unreachable for native and functional proteins, thus preventing uncontrolled degradation. The proteolytic active sites are found in the interior of a barrel-shaped core particle (CP or 20S). The entrances of the tunnel, placed at the distal ends of the barrel, are commonly occupied by the regulatory particle (RP or 19S), a sophisticated protein assembly that acts as a substrate processing machine. The regulatory particle has the important role of receiving, deubiquitinating, unfolding, and translocating substrates to the CP and it adopts different configurations depending on the activity states they exhibit. This process typically requires ATP hydrolysis. Moreover, conformationally distinct proteasomes may show different subcellular distributions depending on functional requirements in each cell type and environmental situation. Proteasomes are distributed throughout the cell, detected in the cytoplasm and the nucleus, and they can localize to hotspots in distinct intracellular regions or specific sites with high protein metabolism or with specific protein degradation requirements.

The core of the proteasome consists of a symmetrical cylinder-shaped structure composed of four stacked rings, each containing 7 different subunits and is called the 20S proteasome, as shown in Figure 26.3.4 The two outer rings are each composed of seven α-subunits (α1-α7 or PSMA1-7). During proteasome assembly, the α-rings serve as the backbone for the incorporation of β-subunits, followed by the dimerization of two half proteasomes. In mature proteasomes, the α-rings regulate substrate entrance since the α-subunits have hydrophobic loops that close the 20S barrel to prevent the random entry of substrates.

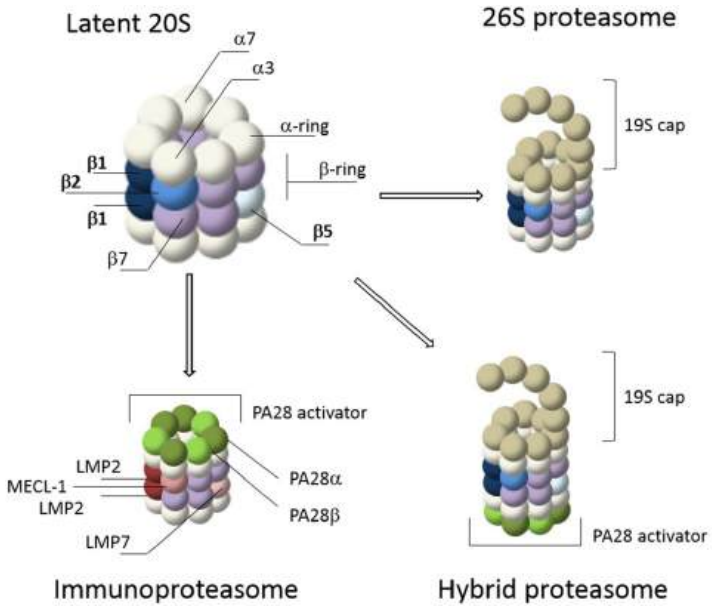

Figure 26.3.4: Sabine et al., Frontiers in Molecular Biosciences, 6 (2019), https://www.frontiersin.org/articles...olb.2019.00056. DOI=10.3389/fmolb.2019.00056. Creative Commons Attribution License (CC BY).

The 20S core of the proteasome consists of 4 stacked rings. The outer rings contain seven α-subunits (white) while the inner rings contain seven β-subunits (purple). The catalytic subunits, β1, β2, and β5, are depicted in shades of blue. Gate opening of the 20S core occurs via capping by proteasome activators such as the 19S cap or PA28. The 19S cap is the most abundant activator and it forms the 26S proteasome together with the 20S core. Different cells have different caps. For example, interferoIFN-γ stimulation induces *de novo* formation of immunoproteasomes, which contains the immune subunits β1i (LMP2), β5i (LMP7), and β2i (MECL-1) (shades of red), as well as proteasome activation by PA28αβ (shades of green). Proteasomes in neural tissue are discussed below.

In general, protein entry can only be established after gate opening by proteasome activators (PAs) such as the 19S cap, after which substrates can enter the interior of the 20S core for degradation. The inner two rings of the 20S barrel consist of the subunits β1-β7 (PSMB1-7). Each β-ring contains 3 catalytic subunits; termed β1, β2, and β5. In mature 20S complexes, the pro-peptides of these catalytic β-subunits are auto-catalytically removed. Upon autocatalytic processing, the N-terminal threonine residues become exposed as the catalytically reactive residues, harboring both the nucleophile (the hydroxyl group) and the catalytic base (the N-terminal amine) involved in peptide bond cleavage. Each catalytic subunit has selectivity toward specific residues. β1 has caspase- or peptidyl-glutamyl peptidase-like activity, preferring cleavage at the C-terminus of acidic residues. β2 has trypsin-like activity and cleaves after basic residues, while β5 has chymotrypsin-like activity and prefers cleavage after hydrophobic residues. Figure 26.3.5 shows an interactive iCn3D model of the Human 20S Proteasome (6RGQ).

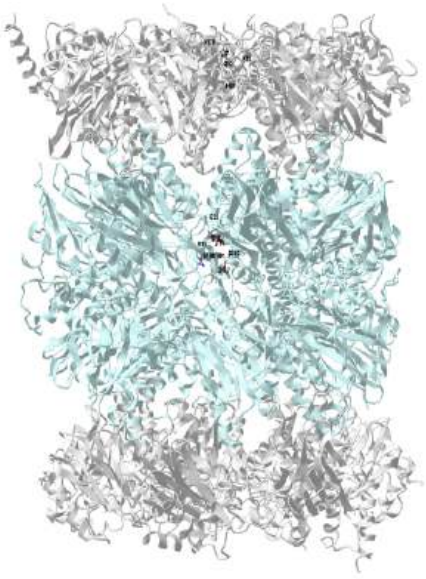

Figure 26.3.5: Human 20S Proteasome (6RGQ). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...9gDp6nj7Co2Ud9

The alpha subunits are shown in light gray and the beta subunits are in light cyan. Active site residue, as defined by databases, are shown for one of the alpha chain (L37, Q53, K55, H68, V170) and one of the beta chains (T1, D17, R19, K33, S130, D167, S170, G171).

A possible generic mechanism for the cleavage of peptide bonds by the beta chain is shown in Figure 26.3.6. The mechanism shows how the newly exposed N-terminal threonine acts as both the nucleophile (the hydroxyl group) and the catalytic base.

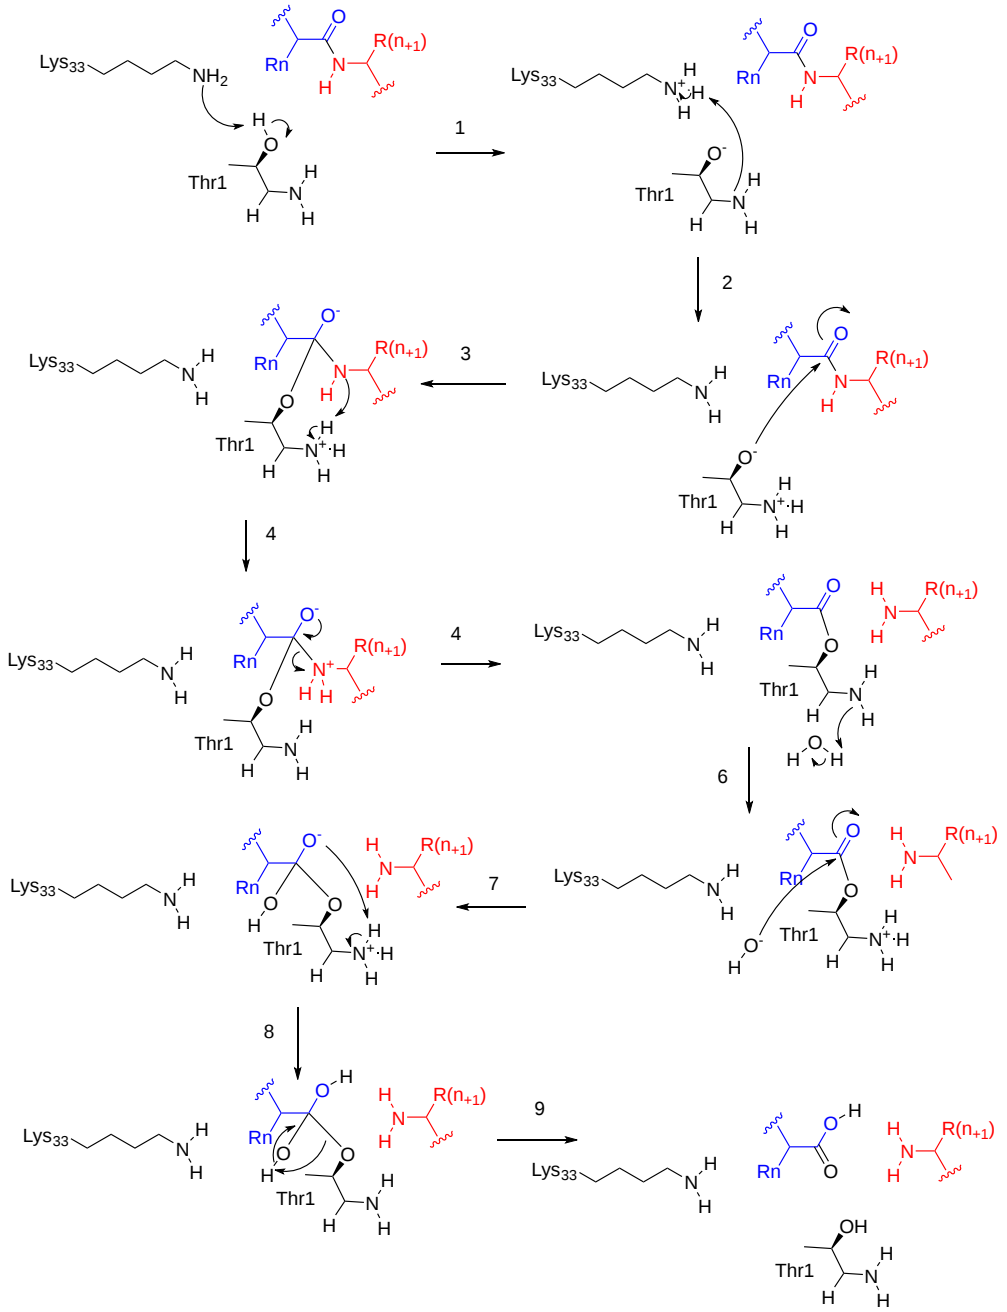

Figure 26.3.6: Possible mechanism for the beta chain proteasome cleavage of proteins. after Arjun Saha, Gabriel Oanca, Dibyendu Mondal, and Arieh Warshel. *The Journal of Physical Chemistry B* **2020***124* (27), 5626-5635. DOI: 10.1021/acs.jpcb.0c04435

Proteins are normally targeted to the proteasome using ubiquitin labels attached covalently to a lysine residue, usually in a chained form that produces a polyubiquitinated protein. The process of protein polyubiquitination is carried out by a highly specialized and diverse enzymatic system, which
includes families of ubiquitin-activating enzymes (E1), ubiquitin-conjugating enzymes (E2), and ubiquitin ligases (E3).

The covalent attachment of ubiquitin to specific target proteins is mainly accomplished by stepwise enzymatic cascade reactions, and ubiquitin is attached to the substrates via the concerted action of ubiquitin-activating enzyme (E1), ubiquitin-conjugating enzyme (E2), and ubiquitin ligase (E3). The attachment of ubiquitin or ubiquitin chains to the substrate is a successive process, as shown in Figure 26.3.7. First, the C-terminal carboxylic acid is activated by adenylation using a molecule of ATP forming an ***adenylate (AMP-) intermediate.*** The ***adenylate*** acts as a good leaving group during the next reaction where an E1-ubiquitin thioester bond is formed between the C-terminal Gly carboxyl group of ubiquitin and the active site Cys of the E1 enzyme. AMP leaves the active site at this point. Note that ATP is used in many reactions to activate carboxylic acid functional groups through the

formation of an adenylate intermediate and that this will be seen as a theme in many different types of reactions throughout this textbook. Once the ubiquitin is docked as a thioester on E1, it can be transferred to a Cys residue of the E2 enzyme to form an E2-ubiquitin thioester-linked intermediate. This enzymatic reaction is known as a ***transesterification***.

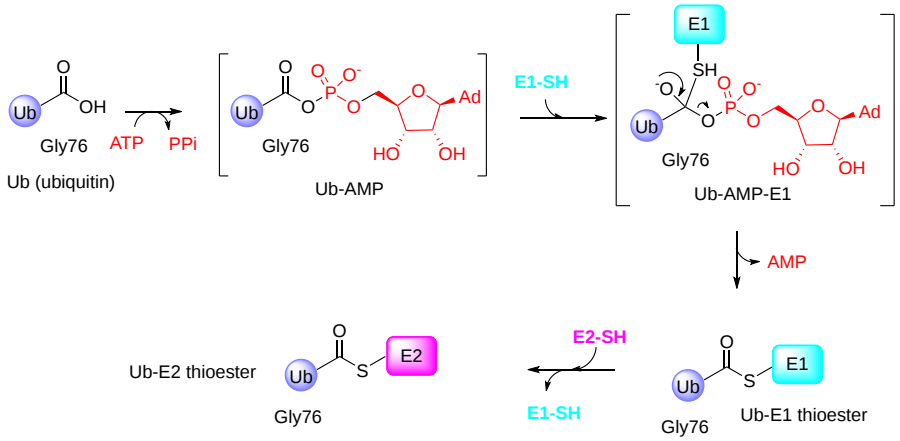

Figure 26.3.7: Enzymatic Activity of the E1 Ubiquitin Activating Enzyme. Conversion of Gly 76 on ubiquitin to E1 and E2 thioesters. After Hann, Z.S., et. al. (2019) *PNAS* 116(31)15475-15484.

Eventually, the E2 transfers the ubiquitin to the substrate protein by E3. Ubiquitin is conjugated to the target protein through an isopeptide bond between its C-terminal glycine (Gly76) and the ε-amino group of a lysine residue. There are three typical ways of linking the ubiquitin with the substrate, as shown in Figure 26.3.8 The first is called mono-ubiquitination, which refers to the modification of one site of a substrate by a single ubiquitin molecule. The second is multi-mono-ubiquitination, which means adding several ubiquitin molecules repetitively to distinct sites (multi-mono-ubiquitination). The third is called polyubiquitination (including linear polyubiquitination and branched polyubiquitination), in which ubiquitin molecules are added to the same site (polyubiquitination, including linear polyubiquitination and branched polyubiquitination) of a substrate. In the second and third ways of linking, the previously attached ubiquitin serves as the “acceptor” of subsequently added ubiquitin. Of course, polyubiquitin chains linked by the same Lys are homogeneous, while those linked at different Lys are heterogeneous or mixed ones.

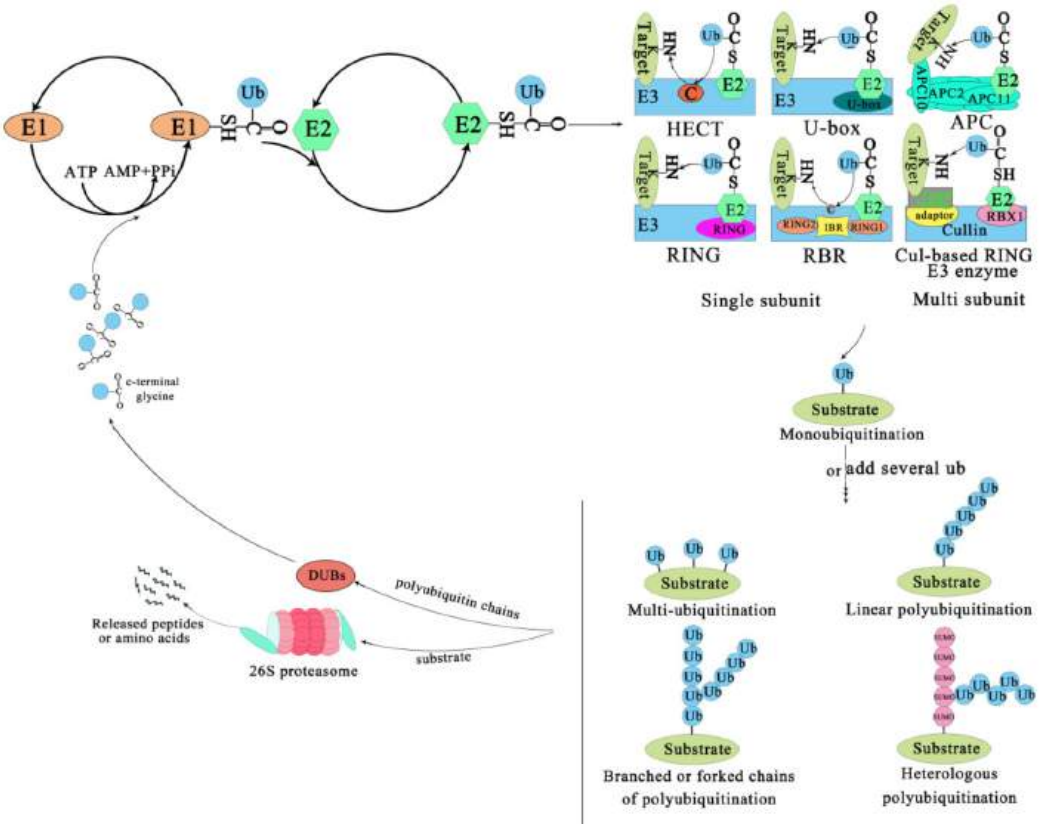

Figure 26.3.8: **The Ubiquitin-Proteasome System.** Liu, W., et.al. (2020) Int J Mol Sci 21(8):2894

The process of ubiquitination from activation to the attachment to the substrate is catalyzed by three major enzymes. The substrates labeled by ubiquitin are degraded by the 26S proteasome or play a non-degradative role in other processes. Abbreviations: APC, Anaphase-promoting complex; DUBs, Deubiquitinating enzymes; E1, Ubiquitin-activating enzyme; E2, Ubiquitin-conjugating

enzyme; E3, Ubiquitin-ligase enzyme; Cul-based, Cullin-RING box1-Ligase; HECT, Homology to E6-AP C Terminus; Ub, Ubiqitin; SUMO, Small ubiquitin-related modifier; RBX1, RING-Box 1; RING, Really interesting new gene; RBR, RING1-IBR(cysteine/histidine-rich region)-RING2.

Subsequently, the substrate complex tagged by the ubiquitin is either degraded by the 26S proteasome or executes nonproteolytic functions, such as the regulation of gene expression, cellular trafficking, or other biological function. In most cases, polyubiquitinated proteins are recognized and degraded by the 26S proteasome, and the ubiquitin or ubiquitin chain is hydrolyzed and freed by deubiquitinating enzymes (DUBs) for reuse in further conjugation cycles after being removed from the substrate protein (Figure 27.3.6).

The family of E3 enzymes is large and diverse. It is estimated that there are 600-700 E3 enzymes in humans, representing approximately 5% of the human genome. Thus, E3 enzymes can be very substrate specific, leading to the specialized degradation of a small subset of proteins within the cell. E2 enzymes are the intersection between E1 and E3 enzymes and help to determine the ubiquitination of specific target proteins by interacting with different types of E3 enzymes.

Figure 26.3.9 shows an interactive iCn3D model of the Yeast proteasome in resting state (C1-a) (6J2X). (long load)

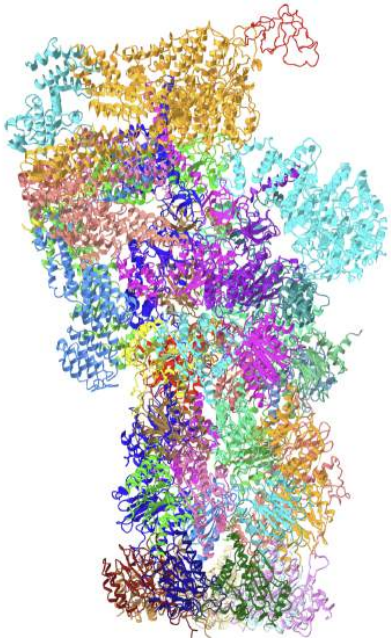

Figure 26.3.9: Yeast proteasome in resting state (C1-a) (6J2X). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?1AmGmkghbZD2zute7

It's too complex to discuss this in much detail. The chains are presented in different colors. You should able to find the alpha and beta chains of the core 20S particle. The regulatory cap proteins comprising the lid are on top of the alpha ring.

CHAPTER OVERVIEW

27: Regulation of Gene Expression

27.1: Regulation of Gene Expression in Bacteria
27.2: Regulation of Gene Expression in Eukaryotes

27.1: Regulation of Gene Expression in Bacteria

27.1.1: Introduction

Each nucleated cell in a multicellular organism contains copies of the same DNA. Similarly, all cells in two pure bacterial cultures inoculated from the same starting colony contain the same DNA, except for changes that arise from spontaneous mutations. If each cell in a multicellular organism has the same DNA, then how is it that cells in different parts of the organism's body exhibit different characteristics? Similarly, how is it that the same bacterial cells within two pure cultures exposed to different environmental conditions can exhibit different phenotypes? In both cases, each genetically identical cell does not turn on, or express, the same set of genes. Only a subset of proteins in a cell at a given time is expressed.

Genomic DNA contains both *structural genes*, which encode products that serve as cellular structures or enzymes, and *regulatory genes*, which encode products that regulate gene expression. The expression of a gene is a highly regulated process. Whereas regulating gene expression in multicellular organisms allows for cellular differentiation, in single-celled organisms like prokaryotes, it primarily ensures that a cell's resources are not wasted making proteins that the cell does not need at that time.

Elucidating the mechanisms controlling gene expression is important to the understanding of human health. Malfunctions in this process in humans lead to the development of cancer and other diseases. Understanding the interaction between the gene expression of a pathogen and that of its human host is important for the understanding of a particular infectious disease. Gene regulation involves a complex web of interactions within a given cell among signals from the cell's environment, signaling molecules within the cell, and the cell's DNA. These interactions lead to the expression of some genes and the suppression of others, depending on circumstances.

Prokaryotes and eukaryotes share some similarities in their mechanisms to regulate gene expression; however, gene expression in eukaryotes is more complicated because of the temporal and spatial separation between the processes of transcription and translation. Thus, although most regulation of gene expression occurs through transcriptional control in prokaryotes, regulation of gene expression in eukaryotes occurs at the transcriptional level and post-transcriptionally (after the primary transcript has been made).

In bacteria and archaea, structural proteins with related functions are usually encoded together within the genome in a block called an *operon* and are transcribed together under the control of a single *promoter,* resulting in the formation of a **polycistronic transcript**, as shown in Figure 27.1.1. In this way, regulation of the transcription of all of the structural genes encoding the enzymes that catalyze the many steps in a single biochemical pathway can be controlled simultaneously, because they will either all be needed at the same time, or none will be needed. For example, in *E. coli*, all of the structural genes that encode enzymes needed to use lactose as an energy source are encoded next to each other in the lactose (or *lac*) operon under the control of a single promoter, the *lac* promoter. French scientists François Jacob (1920–2013) and Jacques Monod at the Pasteur Institute were the first to show the organization of bacterial genes into operons, through their studies on the *lac* operon of *E. coli*. For this work, they won the Nobel Prize in Physiology or Medicine in 1965.

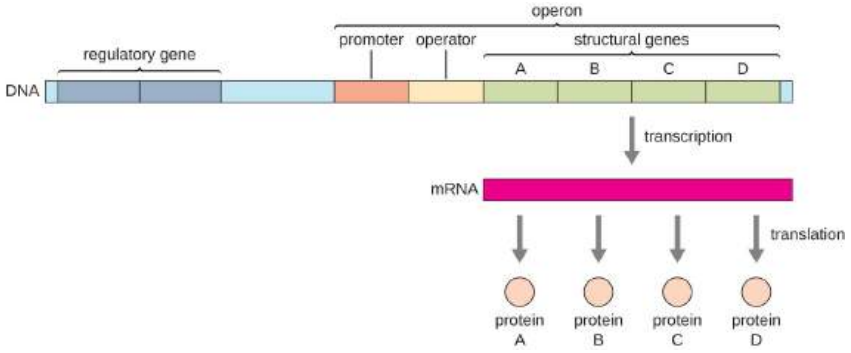

Figure 27.1.1: **Schematic Representation of an Operon.** In prokaryotes, structural genes of related functions are often organized together on the genome and transcribed together under the control of a single promoter. The operon's regulatory region includes both the promoter and the operator. If a repressor binds to the operator, then the structural genes will not be transcribed. Alternatively, activators may bind to the regulatory region, enhancing transcription. *Parker, N., et. al. (2019) Microbiology. Openstax*

Each operon includes DNA sequences that influence its own transcription; these are located in a region called the regulatory region. The regulatory region includes the promoter and the region surrounding the promoter, to which ***transcription factors***, proteins

encoded by regulatory genes, can bind. Transcription factors influence the binding of *RNA polymerase* to the promoter and allow its progression to transcribe structural genes. A ***repressor*** is a transcription factor that suppresses the transcription of a gene in response to an external stimulus by binding to a DNA sequence within the regulatory region called the *operator*, which is located between the RNA polymerase binding site of the promoter and the transcriptional start site of the first structural gene. Repressor binding physically blocks RNA polymerase from transcribing structural genes. Conversely, an *activator* is a transcription factor that increases the transcription of a gene in response to an external stimulus by facilitating RNA polymerase binding to the promoter. An *inducer*, a third type of regulatory molecule, is a small molecule that either activates or represses transcription by interacting with a repressor or an activator.

In prokaryotes, there are examples of operons whose gene products are required rather consistently and whose expression, therefore, is unregulated. Such operons are *constitutively expressed*, meaning they are transcribed and translated continuously to provide the cell with constant intermediate levels of the protein products. Such genes encode enzymes involved in housekeeping functions required for cellular maintenance, including DNA replication, repair, and expression, as well as enzymes involved in core metabolism. In contrast, other prokaryotic operons are expressed only when needed and are regulated by repressors, activators, and inducers.

Prokaryotic operons are commonly controlled by the binding of repressors to operator regions, thereby preventing the transcription of the structural genes. Such operons are classified as either *repressible operons* or inducible operons. Repressible operons, like the tryptophan (*trp*) operon, typically contain genes encoding enzymes required for a biosynthetic pathway. As long as the product of the pathway, like tryptophan, continues to be required by the cell, a repressible operon will continue to be expressed. However, when the product of the biosynthetic pathway begins to accumulate in the cell, removing the need for the cell to continue to make more, the expression of the operon is repressed. Conversely, *inducible operons*, like the *lac* operon of *E. coli*, often contain genes encoding enzymes in a pathway involved in the metabolism of a specific substrate like lactose. These enzymes are only required when that substrate is available, thus expression of the operons is typically induced only in the presence of the substrate.

27.1.2: The trp Operon - A Repressible Operon

E. coli can synthesize tryptophan using enzymes that are encoded by five structural genes located next to each other in the *trp* operon, as shown in Figure 27.1.2 When environmental tryptophan is low, the operon is turned on. This means that transcription is initiated, the genes are expressed, and tryptophan is synthesized. However, if tryptophan is present in the environment, the *trp* operon is turned off. Transcription does not occur and tryptophan is not synthesized.

When tryptophan is not present in the cell, the repressor by itself does not bind to the operator; therefore, the operon is active and tryptophan is synthesized. However, when tryptophan accumulates in the cell, two tryptophan molecules bind to the *trp* repressor molecule, which changes its shape, allowing it to bind to the *trp* operator. This binding of the active form of the *trp* repressor to the operator blocks RNA polymerase from transcribing the structural genes, stopping the expression of the operon. Thus, the actual product of the biosynthetic pathway controlled by the operon regulates the expression of the operon.

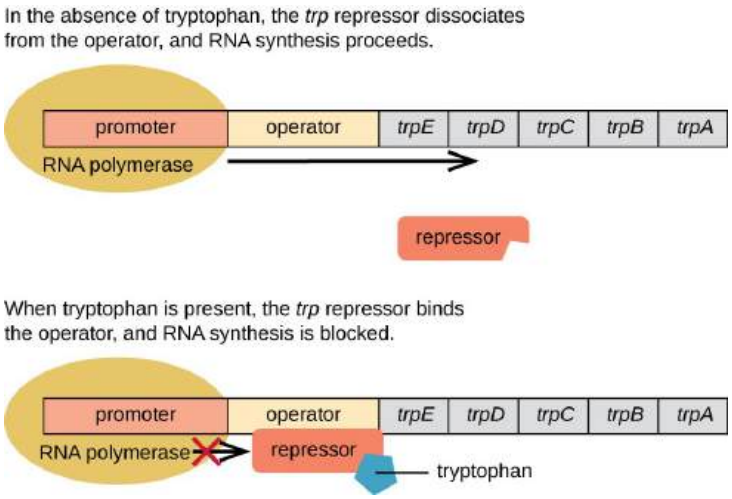

Figure 27.1.2: The Trp Operon. *Parker, N., et. al. (2019) Microbiology. Openstax*

The five structural genes needed to synthesize tryptophan in *E. coli* are located next to each other in the *trp* operon. When tryptophan is absent, the repressor protein does not bind to the operator, and the genes are transcribed. When tryptophan is plentiful, tryptophan binds the repressor protein at the operator sequence. This physically blocks the RNA polymerase from transcribing the tryptophan biosynthesis genes.

Figure 27.1.3 shows an interactive iCn3D model of the E. Coli Trp repressor - operator complex (1TRO).

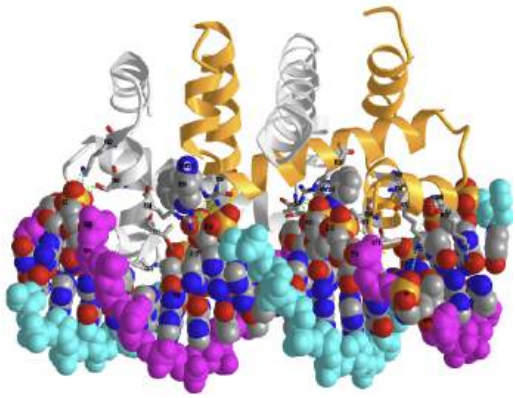

Figure 27.1.3: E. Coli Trp repressor - operator complex (1TRO). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...tjbYwr47gVZjn8

The Trp repressor is shown as a dimer with one subunit gray and the other gold. The backbone of the two DNA strands is shown in spacefill magenta and cyan, except where the bases on the major grove interact with the Trp repressor. The tryptophan in each of the proton monomers is shown in spacefill with CPK colors and labeled. Noncovalent interactions (hydrogen bonds and salt bridges) between the protein and DNA are shown with dotted lines. 6 water-mediated hydrogen bonds to phosphate are not shown. Note that there are few H bonds between the protein and base hydrogen bond donors and acceptors, suggesting that the repressor might bind specifically through geometric interactions with the backbone along with the water-mediated hydrogen bonds.

27.1.3: The Lac Operon: An Inducible Operon

The *lac* operon is an example of an *inducible operon* that is also subject to activation in the absence of glucose. The *lac* operon encodes three structural genes, *lacZ*, *lacY*, and *lacA*, necessary to acquire and process the disaccharide lactose from the environment, as shown in Figure 27.1.4

Figure 27.1.4: Biological Activity of the lac Operon.Figure modified from Esmaeili, A., et. al. (2015) BMC Bioinformatics 16:311

Panel (A) shows a schematic representation of the *lac* operon in *E. coli*. The lac operon has three structural genes, lacZ, lacY, and lacA that encode for β-galactosidase, permease, and galactoside acetyltransferase, respectively. The promoter *(p)* and operator *(o)* sequences that control the expression of the operon are shown. Upstream of the *lac* operon is the *lac* repressor gene, *lacI*, controlled by the *lacI* promoter (*p*).

Panel (B) shows the lac repressor inhibition of the lac operon gene expression in the absence of lactose. The *lac* repressor binds with the operator sequence of the operon and prevents the RNA polymerase enzyme which is bound to the promoter *(p)* from initiating transcription.

Panel (C) shows that in the presence of lactose, some of the lactose is converted into allolactose, which binds and inhibits the activity of the *lac* repressor. The *lac* repressor-allolactose complex cannot bind with the operator region of the operon, freeing the RNA polymerase and causing the initiation of transcription. Expression of the *lac* operon genes enables the breakdown and utilization of lactose as a food source within the organism

The *lacZ* gene encodes the β-galactosidase (β-gal) enzyme responsible for the hydrolysis of lactose into simple sugars glucose and galactose, as shown in Figure 27.1.5. The β-gal enzyme can also mediate the breakdown of the alternate substrate 5-bromo-4-chloro-3-indolyl-β-D-galactopyranoside (Xgal) (panel B). The breakdown product, 5-bromo-4-chloro-3-hydroxyindole – 1, spontaneously dimerizes to form the intensely blue product, 5,5′-dibromo-4,4′-dichloro-indigo – 2. Thus, Xgal has been a valuable research tool, not only in the study of the enzymatic activity of β-gal but also in the development of the commonly used blue-white DNA cloning system that utilizes the β-gal enzyme as a marker in molecular cloning experiments.

Figure 27.1.5: Reactions Controlled by the Expression of the Lac Operon. Andreas Piehler, Yikrazuul, and NUROtikerr Panel (A) shows the expression of the β-galactosidase enzyme enables the breakdown of lactose into simple sugars, glucose, and galactose for *E. coli* to use as a food resource. Panel (B) shows that the β-galactosidase enzyme also mediates the breakdown of the non-native substrate 5-bromo-4-chloro-3-indolyl-β-D-galactopyranoside (Xgal). Breakdown product (1) 5-bromo-4-chloro-3-hydroxyindole quickly dimerizes into the intensely blue product (2) 5,5′-dibromo-4,4′-dichloro-indigo making it a useful tool for molecular biology. Panel (C) shows that β-D-1-thiogalactopyranoside (IPTG) can serve as a non-native inducer of the lac operon. It mimics the structure of lactose and binds with the Lac Repressor.

The lac operon contains two more genes, in addition to *lacZ* (Fig. 4). The *lacY* gene encodes a permease that increases the uptake of lactose into the cell and *lacA* encodes a galactoside acetyltransferase (GAT) enzyme. The exact function of GAT during lactose metabolism has not been conclusively elucidated but acetylation is thought to play a role in the transport of the modified sugars.

For the *lac* operon to be expressed, lactose must be present. This makes sense for the cell because it would be energetically wasteful to create the enzymes to process lactose if lactose was not available.

In the absence of lactose, the *lacI* gene is constitutively expressed, expressing the *lac* repressor protein (Fig. 28.2.3 B). The lac repressor binds with an operator region of the *lac* operon and physically prevents RNA polymerase from transcribing the structural genes (Fig. 28.2.3 B). However, when lactose is present, the lactose inside the cell is converted to allolactose. Allolactose serves as an inducer molecule, binding to the repressor and changing its shape so that it is no longer able to bind to the operator DNA (Fig. 28.2.3 C). Removal of the repressor in the presence of lactose allows RNA polymerase to move through the operator region and begin transcription of the *lac* structural genes. In addition to lactose, laboratory experiments have revealed that the non-natural compound Isopropyl β-D-1-thiogalactopyranoside (IPTG) can also bind with the *lac* repressor and cause the expression of *lac* operon (panel C). Similar to Xgal, this compound has also been used as a research tool for molecular cloning.

Figure 27.1.6 shows an interactive iCn3D model of the lactose operon repressor and its complexes with DNA (1LBG).

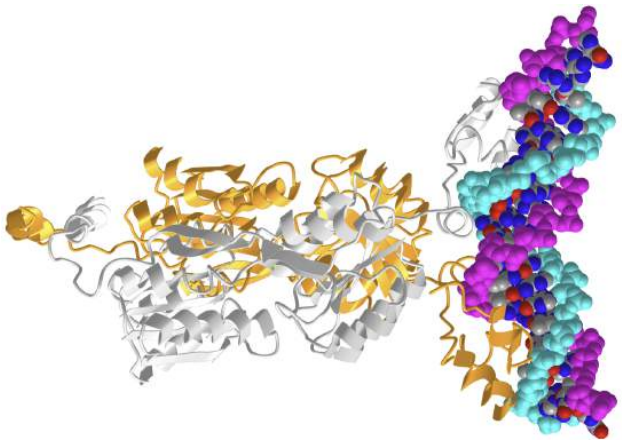

Figure 27.1.6: Lactose operon repressor and its complexes with DNA (1LBG). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...a79MvrAHGpJk99

The resolution of the structure above was insufficient to show the amino acid side chains. Figure 27.1.7 shows an interactive iCn3D model of the NMR solution structure of the dimer of LAC repressor DNA-binding domain complexed to its natural operator O1 (2KEI).

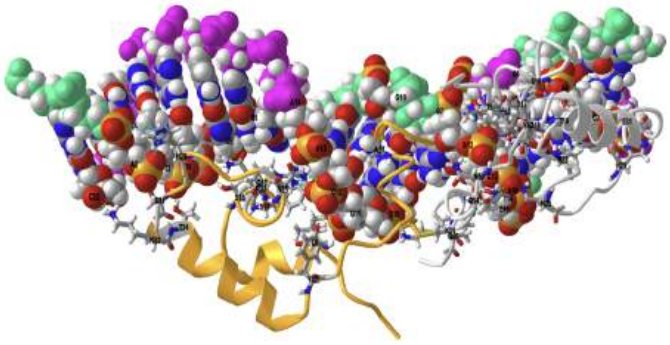

Figure 27.1.7: NMR solution structure of Dimer of LAC repressor DNA-binding domain complexed to its natural operator O1 (2KEI). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...p48VrPFXg6WgD9

Note the presents of white spheres representing hydrogen atoms (these don't appear in crystal structure but do in NMR structures. Color coding is the same as above. Zoom in to see specific interactions between the protein and the exposed DNA base hydrogen bond donors and acceptors. The complex of O1 and O2 shows similar specific and nonspecific contacts, which makes sense given the lambda repressor has similar affinity for those two operator sites. In contrast, one side of the O3 complex shows a loss of protein: DNA interactions, consistent with its lower affinity of its operator O3.

27.1.4: The Lac Operon: Activation by Catabolite Activator Protein

Bacteria typically can use a variety of substrates as carbon sources. However, because glucose is usually preferable to other substrates, bacteria have mechanisms to ensure that alternative substrates are only used when glucose has been depleted. Additionally, bacteria have mechanisms to ensure that the genes encoding enzymes for using alternative substrates are expressed only when the alternative substrate is available. In the 1940s, Jacques Monod was the first to demonstrate a preference for certain substrates over others through his studies of *E. coli*'s growth when cultured in the presence of two different substrates simultaneously. Such studies generated diauxic growth curves, like the one shown in Figure 27.1.8. Although the preferred substrate glucose is used first, *E. coli* grows quickly and the enzymes for lactose metabolism are absent. However, once glucose levels are depleted, growth rates slow, inducing the expression of the enzymes needed for the metabolism of the second substrate, lactose. Notice how the growth rate in lactose is slower, as indicated by the lower steepness of the growth curve.

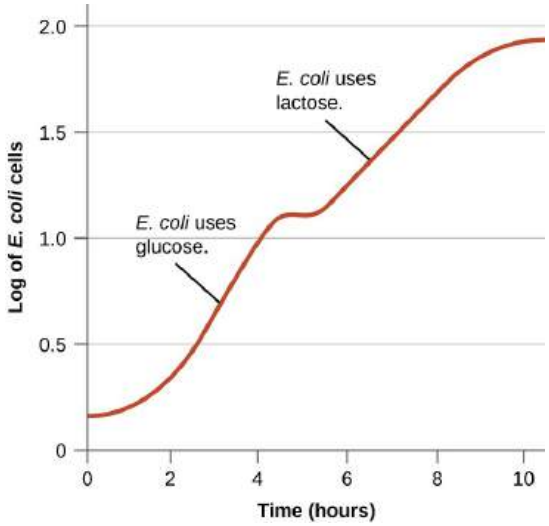

Figure 27.1.8: Utilization of Glucose in *E. Coli.* When grown in the presence of two substrates, *E. coli* uses the preferred substrate (in this case glucose) until it is depleted. Then, enzymes needed for the metabolism of the second substrate are expressed and growth resumes, although at a slower rate. *Parker, N., et. al. (2019) Microbiology. Openstax*

The ability to switch from glucose use to another substrate like lactose is a consequence of the activity of an enzyme called Enzyme IIA (EIIA). When glucose levels drop, cells produce less ATP from catabolism and EIIA becomes phosphorylated. Phosphorylated EIIA activates adenylyl cyclase, an enzyme that converts some of the remaining ATP to cyclic AMP (cAMP), a cyclic derivative of AMP and an important signaling molecule involved in glucose and energy metabolism in *E. coli*, as shown in Figure 27.1.9. As a result, cAMP levels begin to rise in the cell. This is an indicator to the cell, that overall energy levels are low and that ATP is being depleted.

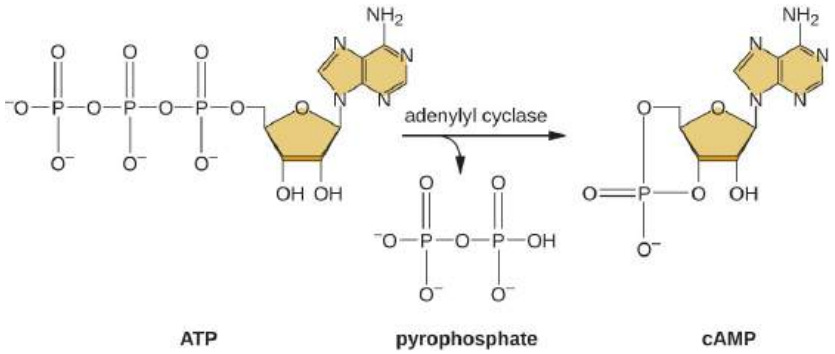

Figure 27.1.9: Conversion of ATP to cAMP. When ATP levels decrease due to the depletion of glucose, some remaining ATP is converted to cAMP by adenylyl cyclase. Thus, increased cAMP levels signal glucose depletion. Figure from: Parker, N., et. al. (2019) Microbiology. Openstax

The *lac* operon also plays a role in this switch from using glucose to using lactose. When glucose is scarce, the accumulating cAMP caused by increased adenylyl cyclase activity binds to catabolite activator protein (CAP), also known as cAMP receptor protein (CRP). The complex binds to the promoter region of the *lac* operon, as shown in Figure 27.1.10. In the regulatory regions of these operons, a CAP binding site is located upstream of the RNA polymerase binding site in the promoter. The binding of the CAP-cAMP complex to this site increases the binding ability of RNA polymerase to the promoter region to initiate the transcription of the structural genes. Thus, in the case of the *lac* operon, for transcription to occur, lactose must be present (removing the lac repressor protein) and glucose levels must be depleted (allowing the binding of an activating protein). When glucose levels are high, there is catabolite repression of operons encoding enzymes for the metabolism of alternative substrates. Because of low cAMP levels under these conditions, there is an insufficient amount of the CAP-cAMP complex to activate the transcription of these operons.

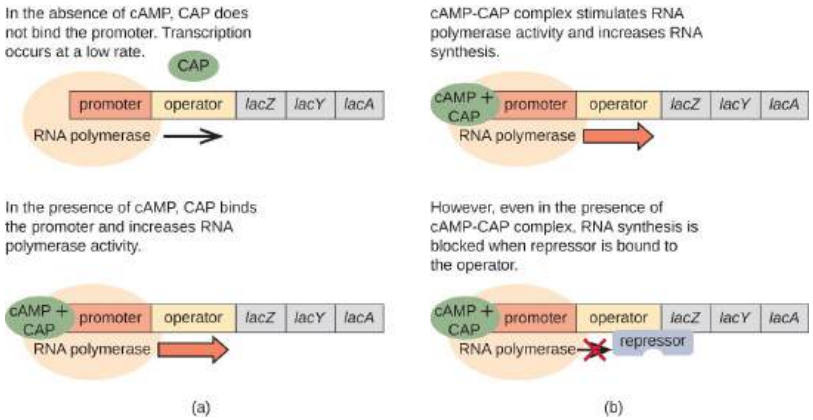

Figure 27.1.10: Effect of CAP on the *Lac* Operon. (a) In the presence of cAMP, CAP binds to the promoters of operons, like the *lac* operon, that encode genes for enzymes for the use of alternate substrates. (b) For the *lac* operon to be expressed, there must be activation by cAMP-CAP as well as the removal of the lac repressor from the operator. Parker, N., et. al. (2019) Microbiology. Openstax

Figure 27.1.11 shows an interactive iCn3D model of the Catabolite activator protein CAP-DNA complex with bound cAMP (2CGP).

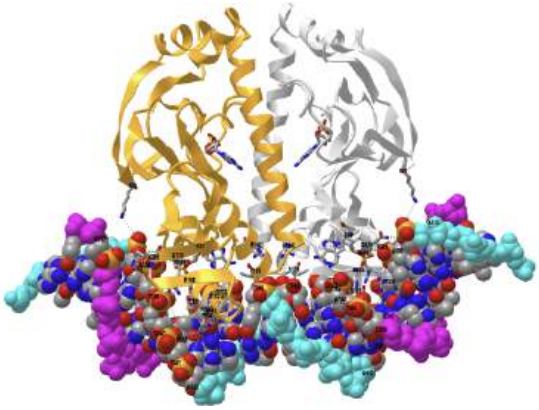

Figure 27.1.11: Catabolite activator protein CAP-DNA complex with bound cAMP (2CGP). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...z6mLhBpPmPMsC6

27.1.5: Global Responses of Prokaryotes

In prokaryotes, several higher levels of gene regulation have the ability to control the transcription of many related operons simultaneously in response to an environmental signal. A group of operons all controlled simultaneously is called a *regulon*.

27.1.5.1: Alarmones

When sensing impending stress, prokaryotes alter the expression of a wide variety of *operons* to respond in coordination. They do this through the production of *alarmones*, which are small intracellular nucleotide derivatives, such as guanosine pentaphosphate (pppGpp), as shown in Figure 27.1.12

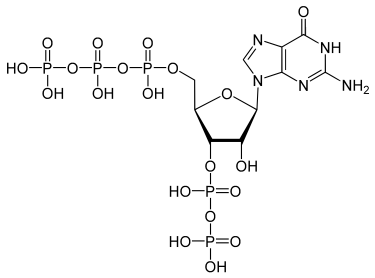

Figure 27.1.12: Structure of Guanosine Pentaphosphate (pppGpp). *Yikrazuul*

Alarmones change which genes are expressed and stimulate the expression of specific stress-response genes. For example, pppGpp signaling is involved in the stringent response in bacteria, causing the inhibition of RNA synthesis when there is a shortage of amino acids present. This causes translation to decrease and the amino acids present are therefore conserved. Furthermore, pppGpp causes the up-regulation of many other genes involved in stress response such as the genes for amino acid uptake (from surrounding media) and biosynthesis.

The use of alarmones to alter gene expression in response to stress appears to be important in pathogenic bacteria, as well. On encountering host defense mechanisms and other harsh conditions during infection, many operons encoding virulence genes are upregulated in response to alarmone signaling. Knowledge of these responses is key to being able to fully understand the infection process of many pathogens and to the development of therapies to counter this process.

27.1.5.2: Quorum Sensing

Quorum sensing (QS) is an intercellular communication mechanism of bacteria used to coordinate the activities of individual cells at the population level in response to surroundings through the production and perception of diffusible signal molecules such as Acyl Homoserine Lactones or small signaling peptides, as shown in Figure 27.1.13 The signal synthase, signal receptor, and signal molecules are three essential elements of the basic QS circuit machinery. Genes encoding signal-generating proteins are also included among the QS target genes. This forms an autoinduction feedback loop to modulate the generation of signal molecules. Several bacterial behaviors including virulence factors expression, secondary metabolites production, biofilm formation, motility, and luminescence are regulated by QS. Through complex regulatory networks, bacteria are capable of expressing corresponding genes according to their population size and of behaving in a coordinated manner.

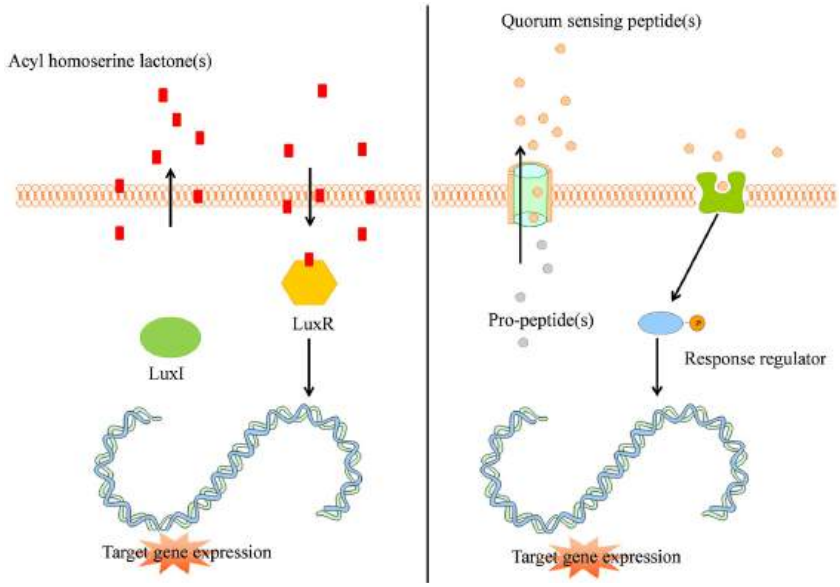

Figure 27.1.13: Examples of Quorum Sensing Pathways. *Verbeke, F., et.al. (2017) Frontiers in Neuroscience 11:183.*

The left panel shows the typical Gram-negative quorum sensing mechanism. Acyl homoserine lactone molecules, synthesized by LuxI, passively pass the bacterial cell membrane and when a sufficient concentration is reached (threshold level) activate the intracellular LuxR which subsequently activates target gene expression in a coordinated way. Note that a single cell is shown for simplicity. However, acyl homoserine lactones will commonly diffuse and target neighboring cells within the colony to mediate a communal or population response within the bacterial colony.

The right panel shows that quorum-sensing peptides are synthesized by the bacterial ribosomes as pro-peptidic proteins and undergo posttranslational modifications during excretion by active transport. The quorum-sensing peptides bind membrane-associated receptors which get autophosphorylated and activate intracellular response regulators via phosphotransfer. These phosphorylated response regulators induce increased target gene expression.

For example, some microbial species, such as *Staphylococcus aureus*, can encase their community within a self-produced matrix of hydrated extracellular polymeric substances that include polysaccharides, proteins, nucleic acids, and lipid molecules. These encasements are known as biofilms. The formation of the *biofilm* on solid surfaces is a step-wise process comprising several stages, as shown in Figure 27.1.14 It starts with the conditioning of the surface through the coating with macromolecules from the aqueous surrounding, which enables the initial reversible adhesion of microorganisms. The next step is the formation of stronger, irreversible attachments to the surface, followed by the proliferation and aggregation of microorganisms into multicellular and multilayered clusters, which actively produce an extracellular matrix. Some cells in the mature biofilms continuously detach and separate from the aggregates, representing a continuous source of planktonic bacteria that can subsequently spread and form new microcolonies.

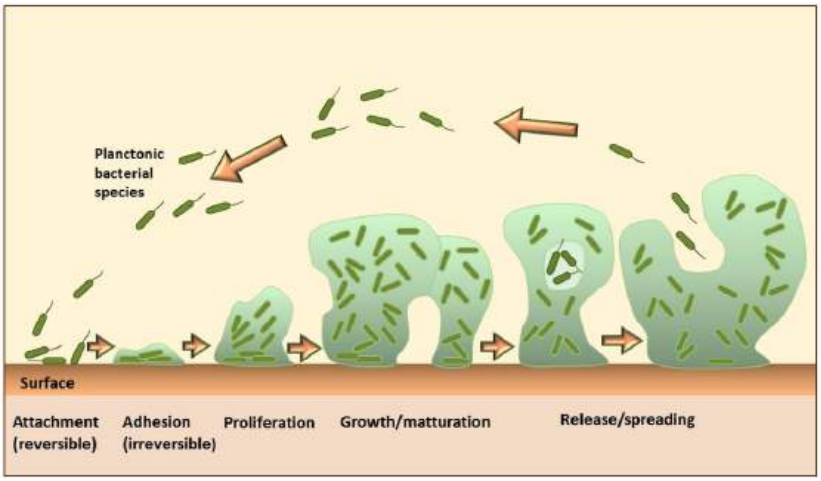

Figure 27.1.14 Schematic drawing of biofilm formation. *Rukavina, Z., and Vanic, Z. (2016) Pharmaceutics 8(2):18.*

Biofilms are a common cause of chronic, nosocomial (originating in a hospital), and medical device-related infections because they can develop either on vital or necrotic tissue as well as on the inert surfaces of different implanted materials. Moreover, biofilms are linked with high-level resistance to antimicrobials, frequent treatment failures, and increased morbidity and mortality. As a consequence, biofilm infections and accompanying diseases have become a major health concern and a serious challenge for both modern medicine and pharmacy. The rough estimation shows that more than 60% of hospital-associated infections are attributable to the biofilms formed on indwelling medical devices, which result in more than one million cases of infected patients annually and more than $1 billion in hospitalization costs per year in the USA.

Biofilm infections share some common characteristics: slow development in one or more hot spots, delayed clinical manifestation, and persistency for months or years, usually with interchanging periods of acute exacerbations and absence of clinical symptoms. Even though they are less aggressive than acute infections, their treatment is challenging to a greater extent. There is upto a 1000-fold decrease in the susceptibility of biofilms to antimicrobial agents and disinfectants as well as resistance to host immune response. Thus, ways to reduce or inhibit biofilm formation are highly sought. The majority of the proposed biofilm-control methods focus on: (i) prevention and minimization of biofilm formation by selection and surface modifications of anti-adhesive materials; (ii) debridement techniques including ultrasound and surgical procedures; (iii) disruption of biofilm QS-signaling system; or (iv) achieving proper drug penetration and delivery to formed biofilms by the use of an electromagnetic field, ultrasound waves, photodynamic activation or specific drug delivery systems.

27.1.5.3: Alternate σ Factors

Since the σ subunit of bacterial RNA polymerase confers specificity as to which promoters should be transcribed, altering the σ factor used is another way for bacteria to quickly and globally change what regulons are transcribed at a given time. The σ factor recognizes sequences within a bacterial promoter, so different σ factors will each recognize slightly different promoter sequences. In this way, when the cell senses specific environmental conditions, it may respond by changing which σ factor it expresses, degrading the old one and producing a new one to transcribe the operons encoding genes whose products will be useful under the new environmental condition. For example, in sporulating bacteria of the genera *Bacillus* and *Clostridium* (which include many pathogens), a group of σ factors controls the expression of the many genes needed for sporulation in response to sporulation-stimulating signals.

27.1.6: Prokaryotic Attenuation and Riboswitches

Although most gene expression is regulated at the level of transcription initiation in prokaryotes, there are also mechanisms to control both the completion of transcription, as well as translation, concurrently. Since their discovery, these mechanisms have been shown to control the completion of transcription and translation of many prokaryotic operons. Because these mechanisms link the regulation of transcription and translation directly, they are specific to prokaryotes, because these processes are physically separated in eukaryotes.

One such regulatory system is attenuation, whereby secondary stem-loop structures formed within the 5’ end of an mRNA being transcribed determine if transcription to complete the synthesis of this mRNA will occur and if this mRNA will be used for translation. Beyond the transcriptional repression mechanism already discussed, attenuation also controls the expression of the *trp*

operon in *E. coli* as shown in Figure 27.1.15 The *trp* operon regulatory region contains a leader sequence called *trpL* between the operator and the first structural gene, which has four stretches of RNA that can base pair with each other in different combinations. When a terminator stem-loop forms, transcription terminates, releasing RNA polymerase from the mRNA. However, when an antiterminator stem-loop forms, this prevents the formation of the terminator stem-loop, so RNA polymerase can transcribe the structural genes.

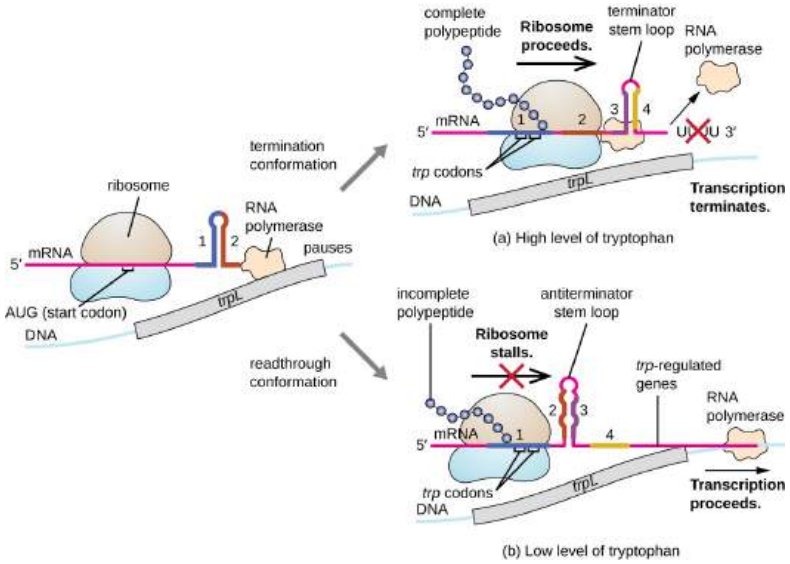

Figure 27.1.15: Attenuation of Transcription and Translation. *Parker, N., et. al. (2019) Microbiology. Openstax*

When tryptophan is plentiful, translation of the short leader peptide encoded by *trpL* proceeds, the terminator loop between regions 3 and 4 forms, and transcription terminates. When tryptophan levels are depleted, translation of the short leader peptide stalls at region 1, allowing regions 2 and 3 to form an antiterminator loop, and RNA polymerase can transcribe the structural genes of the *trp* operon.

A related mechanism of concurrent regulation of transcription and translation in prokaryotes is the use of a riboswitch, a small region of noncoding RNA found within the 5’ end of some prokaryotic mRNA molecules, as shown in Figure 27.1.16 A riboswitch may bind to a small intracellular molecule to stabilize certain secondary structures of the mRNA molecule. The binding of the small molecule determines which stem-loop structure forms, thus influencing the completion of mRNA synthesis and protein synthesis.

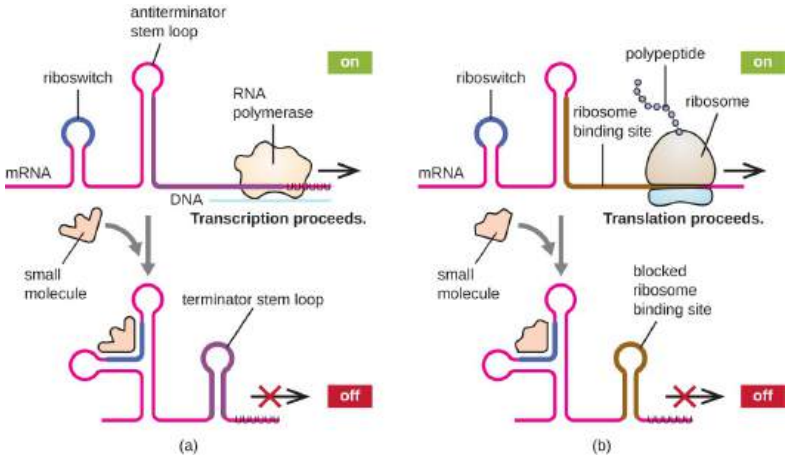

Figure 27.1.16: Riboswitch Form and function. Riboswitches found within prokaryotic mRNA molecules can bind to small intracellular molecules, stabilizing certain RNA structures, and influencing either the completion of the synthesis of the mRNA molecule itself (left) or the protein made using that mRNA (right). *Parker, N., et. al. (2019) Microbiology. Openstax*

Riboswitches found within prokaryotic mRNA molecules can bind to small intracellular molecules, stabilizing certain RNA structures, and influencing either the completion of the synthesis of the mRNA molecule itself (left) or the protein made using that mRNA (right).

Figure 27.1.17shows interactive iCn3D models of a series of bacterial riboswitches. They are described in the legend below.

Guanine-responsive riboswitch bound to metabolite hypoxanthine (4FE5)

A: Guanine-responsive riboswitch bound to metabolite hypoxanthine (4FE5) - Hypothanine, involved in purine metabolism, is shown bound to RNA representing the 5' untranslated region of the xanthine phosphoribosyltransferase (xbt)/ xanthine-specific purine permease (pbux) genes that lead to transcription termination.

B: The M-box in mycobacterial genes regulating Mg^{2+} transport binds divalent cation. They are transcribed under low Mg^{2+} concentrations. Salt bridges (ion-ion interactions) are shown in cyan and pi-cation interactions in red dotted lines

C: Bis-(3'-5')-cyclic dimeric guanosine monophosphate (c-di-GMP) is a second messenger in bacteria and regulates many cellular processes including the formation of biofilms. The riboswitch shown here is from Vibrio cholerae. The U1 small nuclear ribonucleoprotein A is shown in cyan. Figure 27.1.18 shows a cartoon of the actual riboswitch in the 5' untranslated region of target genes

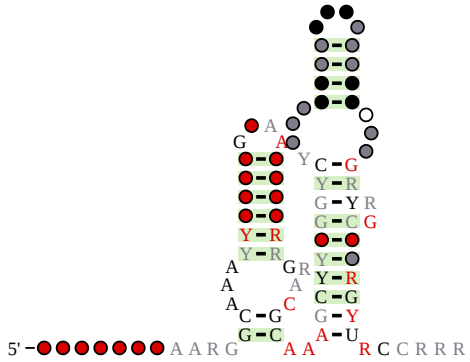

Figure 27.1.18" Consensus secondary structure and sequence conservation of Cyclic di-GMP-I riboswitch

D. This ribozyme is in the 5′ untranslated region of glucosamine-6-phosphate synthase mRNA. The protein enzyme, 2. This protein enzyme catalyzes the conversion of fructose 6-phosphate and glutamine to glucosamine 6-phosphate (GlcN6P) and glutamate. The *glmS* ribozyme in the 5'-untranslated region cleaves itself on binding GlcN6P. This self-cleavage is inhibited by glucose 6-phosphate (Glc6P). Hence high levels of the gene product for the synthase lead to cleavage of its own mRNA. The glmS ribozyme RNA is shown in gray and its substrate RNA in cyan.

27.2: Regulation of Gene Expression in Eukaryotes

As seen in Chapter 26, the initiation of transcription requires the assembly of a multitude of transcription factors (TF) localized at the promoter region. Transcription can also utilize far-reaching interactions of enhancers, that bind at a distant DNA site and loop back around to stabilize the RNA polymerase at the promoter. Control of transcriptional initiation is dependent on TF factor activation, TF binding with specific DNA recognition sequences, and chromatin remodeling.

27.2.1: Transcription Factor (TF) Activation

Many TFs are expressed within cells and held in an inactive conformation until the right environmental stimulus is present within the cell. Cellular signaling pathways can cause post-translational protein modifications leading to TF activation or small molecules may physically bind and allosterically modify the protein structure to mediate activation. Here we will use examples from the cell cycle signaling cascade and steroid hormone receptor pathways to highlight some mechanisms of TF activation. A key element to take away from this section is that transcription factor activation is often highly pleiotropic and has many cellular effects. Depending on the cell type and the environmental conditions, different combinations of downstream target genes may be activated or inactivated. Teasing apart these intricacies and the physiological effects that they have within an organism is a major goal of ongoing research.

27.2.1.1: Cell Cycle Regulation by p53

p53 is one of the most studied proteins in science. To date, over 68,000 papers appear in PubMed containing p53 or TP53 in the title and/or abstract. Originally described as an oncogene (since a mutated, functionally altered form of the protein was first characterized), p53 is now recognized as the most frequently inactivated tumor suppressor in human cancers. It is a transcription factor that controls the expression of genes and miRNAs affecting many important cellular processes including proliferation, DNA repair, programmed cell death (apoptosis), autophagy, metabolism, and cell migration, as shown in Figure 27.2.1. Many of those processes are critical to a variety of human pathologies and conditions extending beyond cancer, including ischemia, neurodegenerative diseases, stem cell renewal, aging, and fertility. Notably, p53 also has non-transcriptional functions, ranging from intrinsic nuclease activity to activation of mitochondrial Bak (Bcl-2 homologous antagonist killer) and caspase-independent apoptosis.

As a transcription factor, p53 responds to various genotoxic insults and cellular stresses (e.g., DNA damage or oncogene activation) by inducing or repressing the expression of over a hundred different genes. p53 transcriptional regulation plays a dominant role in causing the arrest of damaged cells, facilitating their repair and survival, or inducing cell death when DNA is damaged irreparably. p53 can also cause cells to become permanently growth arrested, and there is compelling *in vivo* evidence that these “senescent” cells secrete factors that enhance their clearance by the immune system, leading to tumor regression. Through these mechanisms, p53 helps maintain genomic stability within an organism, justifying its long-held nickname “guardian of the genome”. Other p53 gene targets are involved in inhibiting tumor cell angiogenesis, migration, metastasis, and other important processes (such as metabolic reprogramming) that normally promote tumor formation and progression

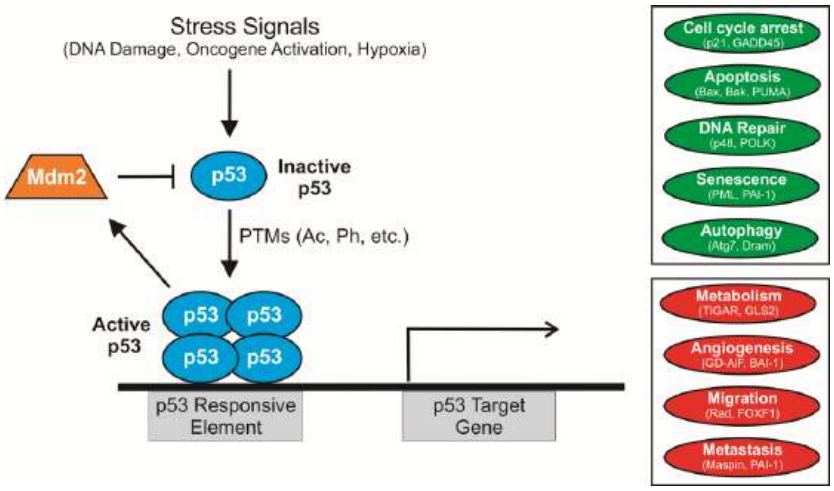

Figure 27.2.1: Cellular stress leads to p53 transcriptional activation of downstream targets. Reed, S.M., and Quelle, D.E. (2015) 7(1):30-69.

Figure 27.2.2 shows an interactive iCn3D model of the human p53 tetramer bound to the natural CDKN1A(p21) p53-response element (3TS8).

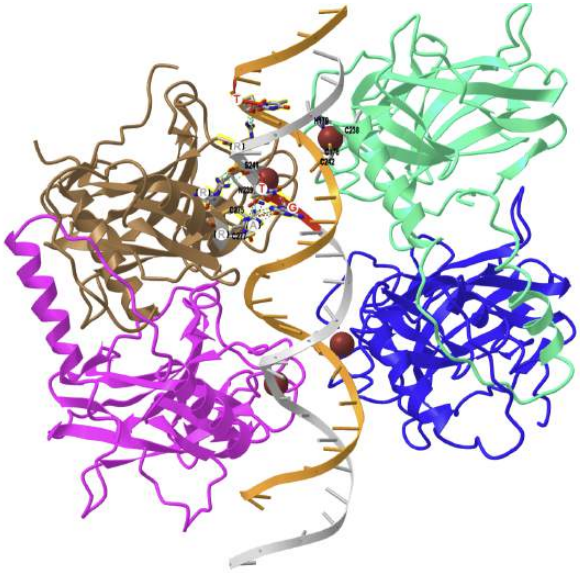

Figure 27.2.2: Human p53 tetramer bound to the natural CDKN1A(p21) p53-response element (3TS8). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...cvfiRBEzfxJuk6

Each monomer of the p53 tetramer is shown in a different color. The noncovalent interactions of the brown monomer with the DNA are shown, with key amino acids and nucleic acid bases shown in CPK-colored sticks. They interact with the Zn^{2+} ions, shown in the light green monomer.

Normally, p53 levels are kept low by its major antagonist, Mdm2, an E3 ubiquitin ligase that is itself a transcriptional target of p53. Stress signals, such as DNA damage, oncogene activation, and hypoxia, promote p53 stability and activity by inducing post-translational modifications (PTMs) and tetramerization of p53. p53 functions as a transcription factor that binds to specific p53 response elements upstream of its target genes. p53 affects many important cellular processes linked to tumor suppression, including the induction (green) of senescence, apoptosis, and DNA repair as well as inhibition (red) of metabolism, angiogenesis, and cell migration. These functions are largely mediated through transcriptional regulation of its targets (examples given).

p53 protein function is regulated post-translationally by coordinated interaction with signaling proteins including protein kinases, acetyltransferases, methyl-transferases, and ubiquitin-like modifying enzymes as shown in Figure 27.2.3 The majority of the sites of covalent modification occur at intrinsically unstructured linear peptide docking motifs that flank the DNA-binding domain of p53 which plays a role in anchoring or in allosterically activating the enzymes that mediate covalent modification of p53. In undamaged cells, the p53 protein has a relatively short half-life and is degraded by a ubiquitin-proteasome-dependent pathway through the action of E3 ubiquitin ligases, such as MDM2 (Fig 28.3.1). Following stress, p53 is phosphorylated at multiple residues, thereby modifying its biochemical functions required for increased activity as a transcription factor. Post-translational modifications help to stabilize the tetramer formation of the protein and enhance the translocation of the protein from the cytoplasm into the nucleus. The tetrameric form of p53 is then functional to bind to DNA in a sequence-specific manner and either activate or repress transcription, depending on the target sequence. Some post-translational modifications, such as acetylation, are DNA-dependent and can play a role in chromatin remodeling and activation of p53 target gene expression.

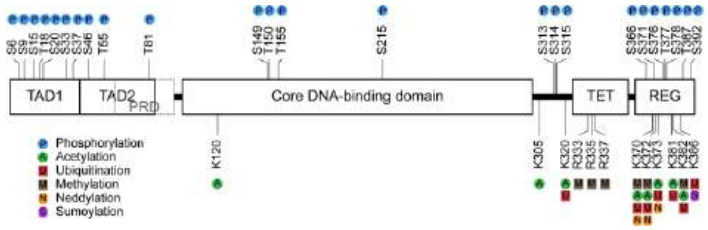

Figure 27.2.3: Sites of Post-Translational Modification on p53. Schematic representation of the 393 amino acid domain structure of human p53 showing the sites of post-translational modification including phosphorylation, acetylation, ubiquitination, methylation, neddylation, and sumoylation. Abbreviations: N-terminal transactivation domain (TAD); proline-rich domain (PRD); tetramerization domain (TET); C-terminal regulatory domain (REG); arginine (R); lysine (K); serine (S); threonine (T). *Maclaine, N.J., and Hupp T.R. (2009) Aging 1(5):490-502*

It should be noted that single-point mutations that modify the ability of the protein to be phosphorylated in one position, typically do not show a decrease in the stabilization or activation of the protein following a damage or stress event. Thus, multiple modifications likely allow for redundancy within this pathway and ensure the activation of the protein following a stress event. Furthermore, the environment within the cell can lead to different p53 phenotypes, such as the activation of growth arrest and DNA repair processes (ie if there is not a lot of damage) or it can lead to the activation of apoptosis or programmed cell death pathways (ie if the damage is too extensive to be repaired).

27.2.1.2: Steroid Hormone Receptors

Steroid hormone receptors (SHRs) belong to the superfamily of *nuclear receptors (NRs)*, which are one of the essential classes of transcriptional factors. NRs play a critical role in all aspects of human development, metabolism. and physiology. Since they generally act as ligand-activated transcription factors, they are an essential component of cell signaling. NRs form an ancient and conserved family that arose early in the metazoan lineage. NR molecular evolution is characterized by major events of gene duplication and gene losses. Phylogenetic analysis revealed a distinct separation of NR ligand binding domains (LBDs) into 4 monophyletic branches, the steroid hormone receptor-like cluster, the thyroid hormone-like receptors cluster, the retinoid X-like and steroidogenic factor-like receptor cluster and the nerve growth factor-like/HNF4 receptor cluster, as shown in Figure 27.2.4

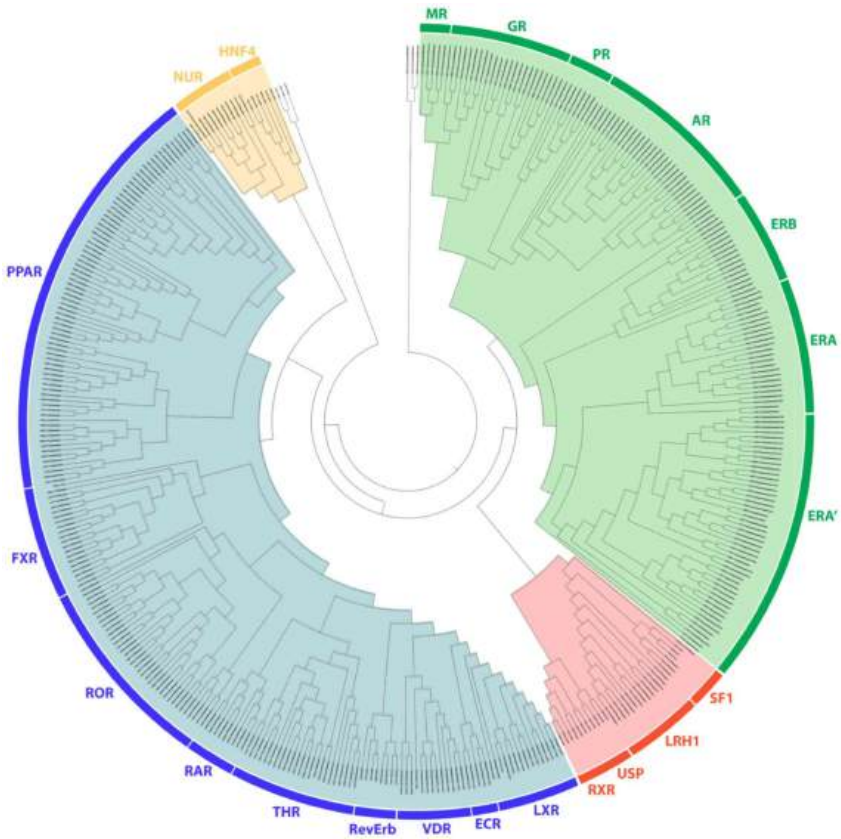

Figure 27.2.4: **Phylogenetic tree of the nuclear receptors' ligand binding domain.** Four distinct monophyletic branches are visible. Those monophyletic branches are divided into subcategories. The phylogenetic trees confidently separate the steroid hormone-like (branch colored green), the retinoid X-like and steroidogenic factor-like receptors cluster (branch colored orange), the thyroid hormone-like receptors cluster (branch colored blue), and the nerve growth factor-like/hepatocyte nuclear factor-4 receptors cluster (branch colored yellow). *Mitsis, T., et. al. (2020) World Acad Sci J 1: 264-274, 2019*

Here we will focus on the Steroid Hormone-Like Receptors branch (SHRs). SHRs plays a key role in many important physiological processes like organ development, metabolite homeostasis, and response to external stimuli. The estrogen receptor comes in two major forms, ERα and ERβ. Other members of this subgroup include the cortisol-binding glucocorticoid receptor (GR), the aldosterone-binding mineralocorticoid receptor (MR), the progesterone receptor (PR), and the dihydrotestosterone (DHT) binding androgen receptor (AR), as shown in Figure \(\PageIndex{5}\ below.

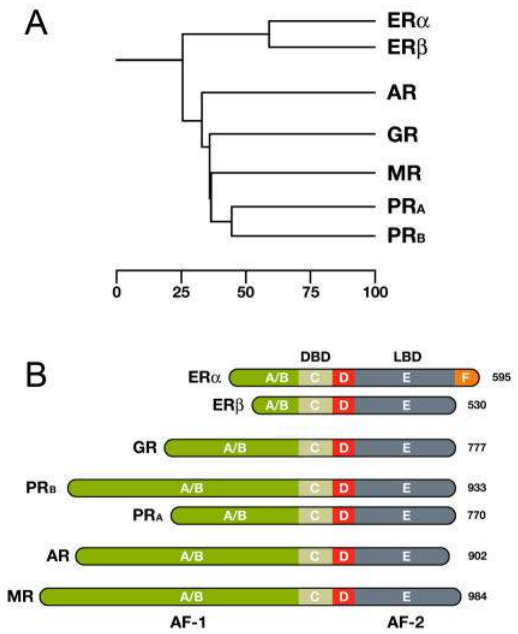

Figure 27.2.5: Overview of Steroid Hormone Receptor Family (SHR). *riekspoor, A., et. al. (2007) Nucl Recept Signal. 5:e003* A. Phylogenetic tree of the Steroid Hormone Receptor (SHR) family showing the evolutionary interrelationships and distance between the various receptors. Based on alignments available at The NucleaRDB [Horn et al., 2001]. B. All steroid receptors are composed of a variable N-terminal domain (A/B) containing the AF-1 transactivation region, a highly conserved DNA Binding Domain (DBD), a flexible hinge region (D), and a C-terminal Ligand Binding Domain (LBD, E) containing the AF-2 transactivation region. The estrogen receptor α is unique in that it contains an additional C-terminal F domain. Numbers represent the length of the receptor in amino acids.

Panel A shows a phylogenetic tree of the Steroid Hormone Receptor (SHR) family showing the evolutionary interrelationships and distance between the various receptors. Based on alignments available at The NucleaRDB [Horn et al., 2001].

Panel B shows that all steroid receptors are composed of a variable N-terminal domain (A/B) containing the AF-1 transactivation region, a highly conserved DNA Binding Domain (DBD), a flexible hinge region (D), and a C-terminal Ligand Binding Domain (LBD, E) containing the AF-2 transactivation region. The estrogen receptor α is unique in that it contains an additional C-terminal F domain. Numbers represent the length of the receptor in amino acids.

The members of the Steroid Hormone Receptor family share a similar, modular architecture, consisting of several independent functional domains (Fig. 5B above). Most conserved is the centrally located DNA binding domain (DBD) containing the characteristic zinc-finger motifs. The DBD is followed by a flexible hinge region and a moderately conserved Ligand Binding Domain (LBD), located at the carboxy-terminal end of the receptor. The estrogen receptor α is unique in that it contains an additional F domain of which the exact function is unclear. The LBD is composed of twelve α-helices (H1-H12) that together fold into a canonical α-helical sandwich. Besides its ligand binding capability, the LBD also plays an important role in nuclear translocation, chaperone binding, receptor dimerization, and coregulator recruitment through its potent ligand-dependent transactivation domain, referred to as AF-2. A second, ligand-independent, transactivation domain is located in the more variable N-terminal part of the receptor, designated as AF-1. To date, no crystal structure of a full-length SHR exists, though structures of the DBD and LBD regions of most SHRs are available. These have helped significantly in understanding the molecular aspects of DNA and ligand binding, but have to some extent also led to biased attention to these parts of the receptor only. For example, many coregulator interaction studies are still performed with the LBD only, while numerous studies have demonstrated that the AF-2 domain often tells only part of the story. With the help of biophysical techniques, however, it is feasible to study the full-length receptor in its native environment.

Most SHRs remain in the cytoplasm of the cell until they are bound with the appropriate steroid as shown in Figure 27.2.6 Steroid binding causes the dimerization of SHRs and localization to the cell nucleus, where the SHRs interact with the DNA at sequence-specific motifs known as Hormone Response Elements (HREs) (Step 5). Many SHRs can also interact with membrane-bound receptors and affect cellular signaling pathways, in addition to the activation of gene expression (step 6).

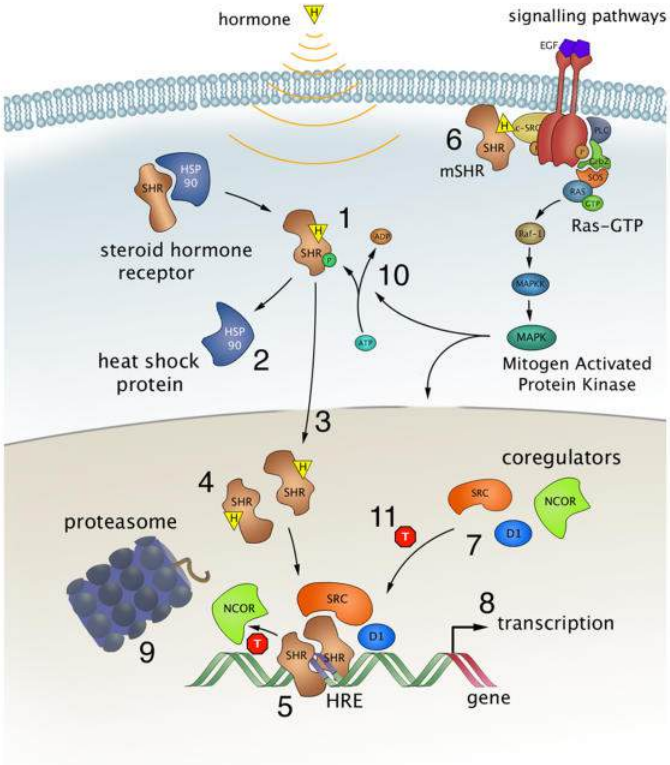

Figure 27.2.6: Steroid Hormone Receptors (SHR) act as hormone-dependent nuclear transcription factors. Upon entering the cell by passive diffusion, the hormone (H) binds the receptor, which is subsequently released from heat shock proteins, and translocates to the nucleus. There, the receptor dimerizes, binds specific sequences in the DNA, called Hormone Responsive Elements or HREs, and recruits a number of coregulators that facilitate gene transcription. *Griekspoor, A., et. al. (2007) Nucl Recept Signal. 5:e003*

Steroid hormones, such as estrogens, reach their target cells via the blood, where they are bound to carrier proteins. Naturally occurring estrogens including estradiol, estrone, estriol, differ primarily in structure on the presence of hydroxyl groups (Fig. 28.3.6). Estradiol is the predominant estrogen during reproductive years both in terms of absolute serum levels as well as in terms of estrogenic activity. During menopause, estrone is the predominant circulating estrogen, and during pregnancy, estriol is the predominant circulating estrogen in terms of serum levels. Another type of estrogen called estetrol (E4) is produced also produced predominantly during pregnancy as shown in Figure 27.2.7. Estrogens function in many physiological processes, including the regulation of the menstrual cycle and reproduction, maintaining bone density, brain function, cholesterol mobilization, and maturation of reproductive organs during development, and they play a role in controlling inflammation.

Figure 27.2.7: Naturally Occurring Estrogens. *Wikipedia (2020) Estrogen.*

Because of their lipophilic nature, it is thought that steroid hormones, such as estrogen, pass the cell membrane by simple diffusion, although some evidence exists that they can also be actively taken up by the endocytosis of carrier protein-bound hormones. For a

long time, it has been assumed that binding of the ligand resulted in a simple on/off switch of the receptor (Fig. 6, step 1). While this is likely the case for typical agonists like estrogen and progesterone, this is not always correct for receptor antagonists, used in drug therapy. These antagonists come in two kinds, so-called partial antagonists (for the estrogen receptors known as SERMs for Selective Estrogen Receptor Modulators) and full antagonists. The partial antagonist can, depending on cell type, act as a SHR agonist or antagonist. In contrast, full antagonists (for ER known as SERDs for Selective Estrogen Receptor Downregulators) always inhibit the receptor, independent of cell type, in part by targeting the receptor for degradation. Binding of either type of antagonist results in major conformational changes within the LBD and in the release from heat shock proteins that thus far had protected the unliganded receptor from unfolding and aggregation (Fig. 6 step 2).

Figure 27.2.8 shows an interactive iCn3D model of the Androgen Receptor DNA-Binding Domain Bound to a Direct Repeat Response Element (1R4I).

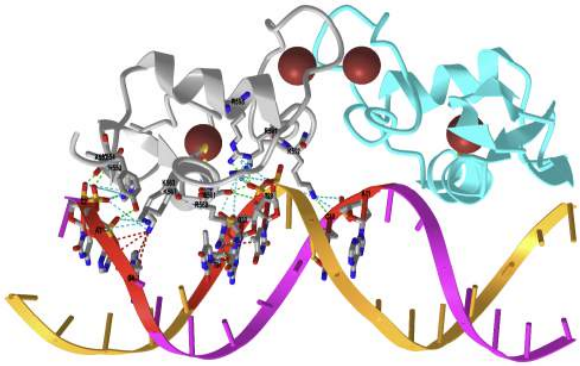

Figure 27.2.8: Androgen Receptor DNA-Binding Domain Bound to a Direct Repeat Response Element (1R4I). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...FKLa7aaZiq6Hz8

27.2.2: Transcription Factor (TF) Recognition and Binding to DNA

TF controls gene expression by binding to their target DNA site to recruit, or block, the transcription machinery onto the promoter region of the gene of interest. Their function relies on the ability to find their target site quickly and selectively. In living cells, TFs are present in nM concentrations and bind the target site with comparable affinity, but they also bind any DNA sequence (nonspecific binding), resulting in millions of low affinity (i.e., $>10^{-6}$ M) competing sites. Nonspecific binding facilitates the search for the target site by three major mechanisms as shown in Figure 27.2.9.

The second scenario is a ‘hopping’ mechanism, in which a TF might hop from one site to another in 3D space by dissociating from its original site and subsequently binding to the new site. This may happen within the same chain and re-association occurs adjacent to the former dissociated site. A third search mechanism is described as ‘intersegmental transfer’. In this scenario, the protein moves between two sites via an intermediate ‘loop’ formed by the DNA and subsequently binds at two different DNA sites. This mechanism applies to TFs with two DNA-binding sites. Proteins with two DNA-binding sites can occasionally bind non-specifically to two locations situated far apart within the DNA strand, that are brought into close contact through the formation of these loops. Such TFs transfer across a point of close contact without dissociating from the DNA.

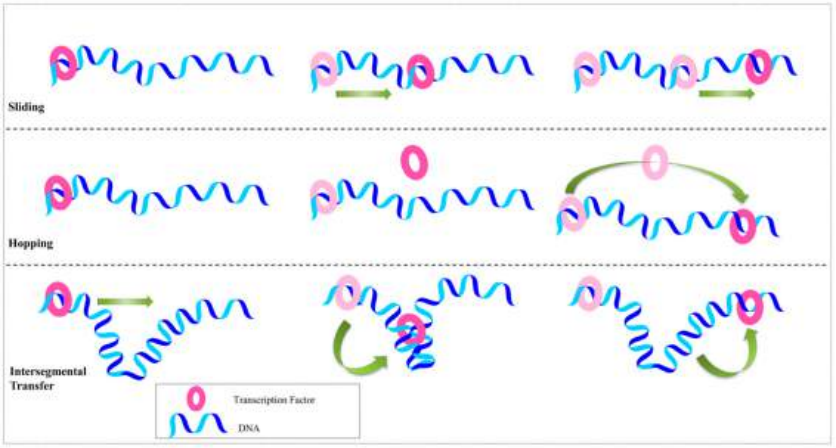

Figure 27.2.9: **Protein-DNA recognition mechanisms.** The main three protein-DNA recognition mechanisms are shown. *Yesudhas, D., et.al. (2017) Genes 8(8):192*

Top: When the transcription factor (pink ring) moves from one site to another by sliding along the DNA and is transferred from one base pair to another without dissociating from the DNA, this mechanism is called sliding.

Center: Hopping occurs when the transcription factor moves on the DNA by dissociating from one site and re-associating with another site.

Bottom: Intersegmental transfer describes the mechanism by which the transcription factor gets transferred through DNA bending or the formation of a DNA loop, resulting in the protein being bound transiently to both sides and subsequently moving from one site to the other.

One of the main scenarios involves a 'sliding' mechanism, in which the protein moves from its initial non-specific site to its actual target site by sliding along the DNA (also known as 1-dimensional (1D) sliding). When the TF starts to move and shift counterions from the phosphate backbone, the same number of counterions binds to the site left free by the protein. The sliding rate is also dependent on the hydrodynamic radius of the protein; the required rotational movement over the DNA backbone is greater for larger proteins, that tend to slide slowly.

Recent Updates: 9/25/23

The sliding model that was proposed by Von Hippel and Berg suggests that DNA-binding protein exists in two interconverting conformations. One is a specific form (O) that can bind to a target DNA sequence, such as an operator in DNA, through specific hydrogen bonds (along with electrostatic interaction) characterized by a low K_D. The other is a nonspecific form (D) that binds mainly with weaker affinity through electrostatic interactions and a high K_D. Nonspecific binding brings the protein to the DNA surface. Dynamic conformational changes from the O to D allow sampling of hydrogen bonds between donor and acceptors in the protein and in the major grove of the protein. The protein can diffuse much more quickly along the DNA to find its target site since the search for the specific target site is now effectively 1D instead of 3D. There is no thermodynamic barrier to sliding since counterions that leave the DNA when bound to the protein rebind behind it as the protein slides. These processes are illustrated in Figure 27.2.10below.

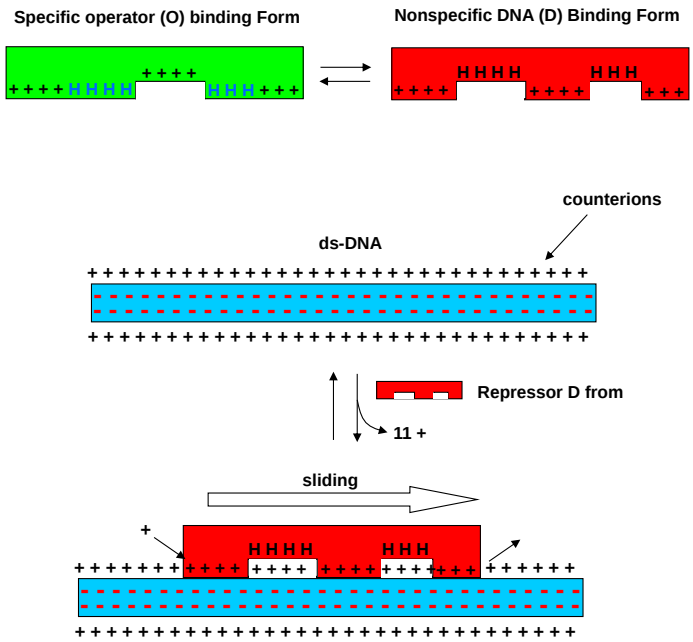

Figure 27.2.10 Two-state model sliding model of DNA protein binding to its specific binding site (operator)

There are a large number of overlapping nonspecific binding sites (let's say each is 6 base pairs in length), which also help drive the nonspecific binding of the protein to the DNA through entropy increases (i.e consider the probability of binding to 1 site on the DNA versus multitudes of overlapping sites). Experiments show that the on-rate for a DNA binding protein for finding its target site increases with increasing length of the DNA molecule the specific site is embedded in. The opposite would be expected given the diffusion rate of large molecules. In fact, the k_{on} was found to be greater than diffusion-controlled limits, which can be explained by the reduced dimensionality of the search for the specific site when the protein is loosely bound through nonspecific electrostatic interactions that enable the 1D search.

Each eukaryotic TF controls tens to hundreds of genes scattered throughout the genome, and expressing each gene needs various TFs simultaneously binding to their sites to form the transcription complex, an extremely rare event in probabilistic terms. As a result, the *in vivo* site occupancy patterns of eukaryotic TFs are more complex than predicted by their *in vitro* site-specific binding profiles and do not strongly correlate with the actual levels of gene expression. An interesting feature highlighted by genome analysis is an accumulation of potential TF binding sites in regions flanking eukaryotic genes. Such clusters of degenerate recognition sites are assumed to be key for transcription control and thus are generally classified as gene regulatory regions (RR). For example, the affinity of the *Drosophila* TF Engrailed to the RRs of its target genes is strongly amplified by long tracts of degenerate consensus repeats that are present in such regions.

Role of Short Tandem Repeats (STRs) in the Genome

As we have mentioned previously, only about 1.5% of the human genome encodes genes for actual proteins. Much of the genome is transcribed at low levels into RNAs, some of which have clearly defined functions (examples include rRNA, mRNAs, and regulatory RNAs). A large part is presumably involved in facilitating the 3D organization of the genome and its dynamic architecture, which determines its replicative and transcriptive access. One poorly understood feature of genomic DNA is **short tandem repeats (STRs)**. These repeats stretch up to 100 nucleotides in length with each repetitive tandem repeat running from just 1 to 6 bases long. They comprise about 6% of the genome (compared to the 1.5% for protein-coding genes), and are found in abundance in chromatin that is transcribed mRNA for proteins. For example, a specific DNA sequence might be GTCACGTGAC while a small STR would be $(CG)_6C(CG)_{11}$

Specifically, STRs surround sites where classic transcription factors (TF) bind. As we described in this and the previous chapter sections, TFs bind through specific DNA binding motifs (like helix-loop-helix or Zn^{2+} fingers) to consensus sequences (such as response elements and enhancers) in the DNA as they function to control transcription. The binding of transcription factors or other proteins to target sequences occurs initially through nonspecific electrostatic interactions, followed by a dimensionally restricted diffusion along the DNA as the protein finds its specific sequence target.

In contrast, the STRs offer little sequence uniqueness for high affinity, low K_D binding sites for specific protein interactions, so the question remains as to how they express function, which their omnipresence suggests they have. Studies by Horton et al (Science 381, 1304 (2023) have shown that classic TFs do indeed bind STRs, albeit at lower affinity (higher K_D) compared to their binding to classic TF-specific sequences. The bind with higher affinity than to nonspecific DNA sequences. Just as nonspecific interactions facilitate TF binding to promoter sites, so do the multiple STRs that straddle the DNA binding element.

If a TF binds its isolated target DNA with a low effective K_D (high affinity) and $-\Delta G^0$ value, a target DNA surrounded by multiple STRs would have an even lower effective K_D (higher affinity) and even more $-\Delta G^0$ value. They do so by increasing the effective on rate (k_{on}) for protein binding. (Remember that $K_D = k_{off}/k_{on}$.) The effective size of the target for the TF becomes greater when it is an “island” in the middle of a STR “sea”. The increased affinity stems in large part from the more favorable entropy of having the TF bind not to just 1 site but effectively to multiple overlapping sites. This also increases the localized concentration of TF near the specific site which drives binding. The k_{off} is not expected to change.

Another effect of the STRs on TF binding is that multiple DNA-binding proteins can bind to the same site through their interactions with STRs at the site, leading to new ways to regulate gene transcription. The group studies just two TFS but sequence analyses suggest that many TF would use a similar mechanism.

27.2.3: Histone Modification and Chromatin Remodeling

Regulation of transcription involves dynamic rearrangements of chromatin structure. Recall that eukaryotic DNA is complexed with histone octamers, which are composed of dimers of the core histones H2A, H2B, H3, and H4. 147 bp of DNA are wrapped 1.65 times around each octamer forming nucleosomes, the basic packaging units of chromatin. Nucleosomes, connected by linker DNA of variable length as “beads on a string”, generate the 11 nm linear structure. The linker histone H1 is positioned at the top of the core histone octamer and enables higher organized compaction of DNA into transcriptionally inactive 30 nm fibers.

To understand the role of chromatin in the regulation of transcription it is important to know where nucleosomes are positioned and how the positioning is achieved. Basically, there are four groups of activities that change chromatin structure during transcription: (1) histone modifications, (2) eviction and repositioning of histones, (3) chromatin remodeling, and (4) histone variant exchange. Histone modifiers introduce post-translational, covalent modifications to histone tails and thereby change the contact between DNA and histones. These modifications govern access to regulatory factors. Histone chaperones aid in the eviction and positioning of histones. A third class of chromatin restructuring factors is ATP-dependent chromatin remodelers. These multi-subunit complexes utilize energy from ATP hydrolysis for various chromatin remodeling activities including nucleosome sliding, nucleosome displacement, and the incorporation and exchange of histone variants.

Post-translational modifications (PTMs) of histone proteins are a primary mechanism that controls chromatin architecture. Over 20 distinct types of histone PTMs have been described, among which the most abundant ones are acetylation and methylation of lysine residues. Histone PTMs can be deposited on and removed from chromatin by different enzymes, known as histone PTM ‘writers’ and ‘erasers’. Histone PTMs exert their regulatory effects via two main mechanisms. First, histone PTMs serve as docking sites for various nuclear proteins—histone PTM ‘readers’—that specifically recognize modified histone residues through their modification-binding domains. Recruitment of these proteins at specific genomic loci promotes key chromatin processes, such as transcriptional regulation and DNA damage repair. Second, some histone PTMs, such as acetylation, directly affect chromatin's higher-order structure and compaction, thereby controlling chromatin accessibility to protein machinery such as those involved in transcription. Chromatin may adopt one of two major states interchangeably. These states are *heterochromatin* and *euchromatin*. *Heterochromatin* is a compact form that is resistant to the binding of various proteins, such as transcriptional machinery. In contrast, *euchromatin* is a relaxed form of chromatin that is open to modifications and transcriptional processes, as shown in Figure 27.2.10 Histone methylation promotes the formation of Heterochromatin whereas, histone acetylation promotes euchromatin.

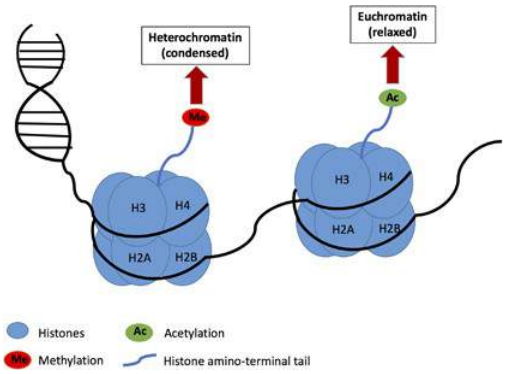

Figure 27.2.11: Schematic drawing of histone methylation and acetylation in relation to chromatin remodeling. *Kim, S., and Kaang, B-K. (2017) Exp & Mol. Med. 49:e281*

The addition of methyl groups to the tails of histone core proteins leads to histone methylation, which in turn leads to the adoption of a condensed state of chromatin called 'heterochromatin.' Heterochromatin blocks transcription machinery from binding to DNA and results in transcriptional repression. The addition of acetyl groups to lysine residues in the N-terminal tails of histones causes histone acetylation, which leads to the adoption of a relaxed state of chromatin called 'euchromatin.' In this state, transcription factors and other proteins can bind to their DNA binding sites and proceed with active transcription.

Chromatin remodeling can also be an ATP-dependent process and involve histone dimer ejection, full nucleosome ejection, nucleosome sliding, and histone variant exchange as shown in Figure 27.2.12 ATP-dependent chromatin remodeling complexes bind to nucleosome cores and the surrounding DNA, and, using energy from ATP hydrolysis, they disrupt the DNA-histone interactions, slide or eject nucleosomes, alter nucleosome structures, and modulate the access of transcription factors to the DNA (Figure 28.3.9). In addition to modulating gene expression, some of the complexes are involved in nucleosome assembly and organization, following transcription at locations in which nucleosomes have been ejected, packing of DNA, following replication, and DNA repair.

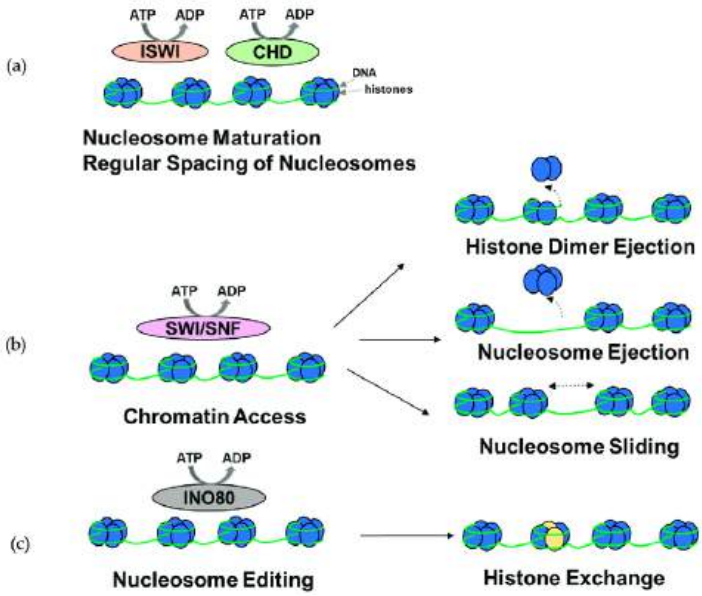

Figure 27.2.12: Overview of the functions of ATP-dependent chromatin remodeling complexes. *Hasan, N., and Ahuja, N. (2019) Cancers 11(12):1859*

Panel (a) shows a subset of ISWI and CHD complexes is involved in nucleosome assembly, maturation, and spacing.

Panel (b) shows SWI/SNF complexes are primarily involved in histone dimer ejection, nucleosome ejection, and nucleosome repositioning through sliding, thus modulating chromatin access.

Panel (c) shows INO80 complexes are involved in histone exchange. It should be noted that the complexes might be involved in other chromatin remodeling functions.

Figure 27.2.13 shows the effects of Histone Variant H3.3 on *C. elegans* Lifespan

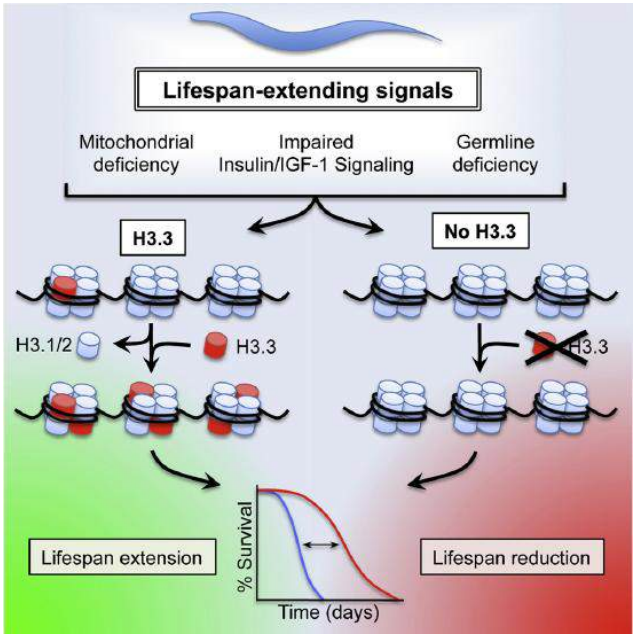

Figure 27.2.13: The Effects of Histone Variant H3.3 on *C. elegans* Lifespan. H3.3 expression increases over time in *C. elegans* during their normal lifespan. In organisms with impaired Inulin/IGF-1 signaling, germline deficiency of H3.3 resulted in significant decreases in lifespan. Piazzesi, A., et. al. (2016) Cell Rep 17(4):987-996.

27.2.4: Protein-DNA Interactions

Proteins use a wide range of DNA-binding structural motifs, such as homeodomain (HD), helix-turn-helix (HTH), and high-mobility group box (HMG) to recognize DNA. HTH is the most common binding motif and can be found in several repressor and activator proteins, as shown in Figure 27.2.14 Despite their structural diversity, these domains participate in a variety of functions that include acting as substrate interaction mediators, enzymes to operate DNA, and transcriptional regulators. Several proteins also contain flexible segments outside the DNA-binding domain to facilitate specific and non-specific interactions. For example, many HD proteins use N-terminal arms and a linker region to interact with DNA. The Encyclopedia of DNA Elements (ENCODE) data suggest that about 99.8% of putative binding motifs of TFs are not bound by their respective TFs in the genome. It is, therefore, clear that the presence of a single binding motif per TF is not adequate for TF binding.

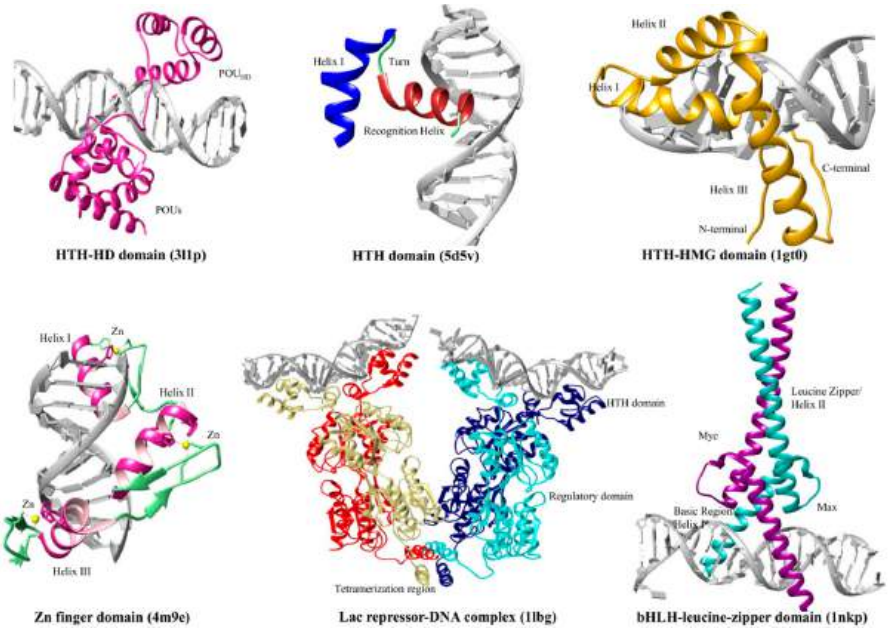

Figure 27.2.14: Representative figures of the transcription factor binding domains. The figure shows the crystal structures of different types of TF domains (3l1p, 4m9e, 5d5v, 1lbg, 1gt0, and 1nkp). The structures were obtained from the Protein Data Bank (PDB) and redrawn using chimera. The respective domains and important regions have been labeled. HTH stands for the helix-turn-helix domain. bHLH stands for the basic helix-loop-helix motif. HD and HMG stand for homeodomain and high-mobility group box domain, respectively. Yesudhas, D., et.al. (2017) Genes 8(8):192

Most of the search mechanistic studies that try to determine how TFs find their binding sites are limited to naked DNA-protein complexes, which do not reflect the actual crowded environment of a cell. Studies with naked DNA and transcription factors have shown that many DNA-binding proteins travel a long distance by 1D diffusion. However, the search process for eukaryotes must occur in the presence of chromatin, which can hinder protein mobility. In this case, the protein must dissociate from the DNA, enter a 3D mode of diffusion state, and continue the target site searching process. The sliding and intersegmental transfer mechanisms can be explained through the example of the *lac* repressor. The *lac* repressor contains 4 identical monomers (a dimer of dimers) for its DNA binding. The binding sequence of these dimers is symmetric or pseudo-symmetric, and each half is identified by these identical monomers. The HTH domain of the *lac* repressor is the DNA-binding domain that facilitates the interaction with its target site on DNA as shown in Figure 27.2.15

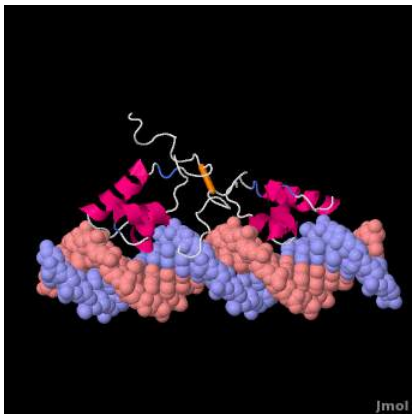

Figure 27.2.15: The Helix-Turn-Helix Motif of the Lac Repressor. Lac repressor binds to DNA non-specifically, enabling it to slide rapidly along the DNA double helix until it encounters the lac operator sequence. The DNA-binding domain employs a helix-turn-helix (HTH) motif (Alpha Helices, Turns). During non-specific binding, the hinge region is disordered. The DNA double helix is depicted as straight in the model when the Lac Repressor binds non-specifically. Upon recognizing the specific operator sequence, the non-specific binding converts to specific binding. During this conversion, the hinge region changes from disordered loops to Alpha Helices, which bind to the minor groove of the DNA. As explained below, this binding stabilizes a kinked ("bent") DNA double helix conformation. *Protopedia – Life in 3D*

As a result of a rapid search (sliding) along the DNA molecule and intersegmental transfer between distant DNA sequences, the lactose repressor finds its target sites faster than the diffusion limit. The section comprised between residues 1–46 of the HTH protein domain, characterized by three α-helices, maintains its secondary structure through specific and non-specific binding. When the repressor binds to a non-specific site, the HTH domain interacts with the DNA backbone and maintains the interaction with its helix region in the major groove juxtaposition. This arrangement facilitates the interaction of the recognition helix with the edges of the DNA bases, enabling the repressor to walk or search for its specific site on the DNA. The C-terminal residues of the DNA-binding domain, residues 47–62, form the hinge region, and are normally disordered during non-specific recognition; however, during specific site recognition, residues 50–58 acquire an α-helix configuration (hinge helix) (Fig. 15 above). The disordered hinge region and the flexibility of the HTH domain allow the protein to move freely along the DNA to search for its target site. In specific binding complexes, the hinge helix of each monomer is located at the symmetrical center of the binding site, thereby causing the hinge helices to interact with each other (intersegmental transfer) to allow better stability. Moreover, DNA bends at the symmetrical center of the specific binding site (37° angle), thereby supporting monomer-monomer interactions.

In addition to the helix-turn-helix structure, the zinc finger motif is also very common, especially in eukaryotic TFs, as shown in Figure 27.2.16 Proteins that contain zinc fingers (zinc finger proteins) are classified into several different structural families. Unlike many other clearly defined supersecondary structures such as Greek keys or β hairpins, there are a number of types of zinc fingers, each with a unique three-dimensional architecture. A particular zinc finger protein's class is determined by this three-dimensional structure, but it can also be recognized based on the primary structure of the protein or the identity of the ligands coordinating the zinc ion. Despite the large variety of these proteins, however, the vast majority typically function as interaction modules that bind DNA, RNA, proteins, or other small, useful molecules. Variations in structures serve primarily to alter the binding specificity of a particular protein. The most common type of zinc finger motif utilizes two Cys and two His residues (CCHH) coordinating the Zn(II) ion to adopt a ββα fold with three hydrophobic residues responsible for the formation of a small hydrophobic core which offers additional stabilization of the zinc finger domain.

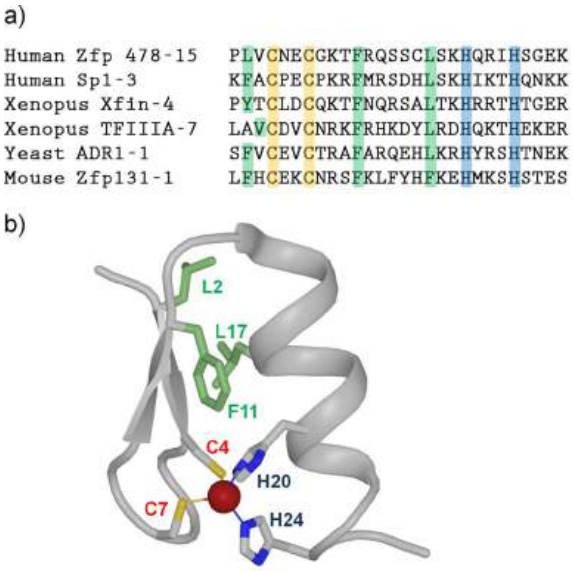

Figure 27.2.16: **Sequence alignments of the CCHH zinc fingers and a representative structure.**Kluska, K., Adamczyk, J., and Krezel, A. (2018) Coord Chem Rev 367:18-64

Panel (a) shows the alignment of the TFIIIA-like zinc finger domains from different organisms. The green color denotes residues that are responsible for the hydrophobic core formation in most CCHH zinc fingers (L17, F11, and L2). Yellow and blue indicate the coordinating Cys and His residues, respectively.

27.2.4.0.1:

Overall, zinc finger motifs display considerable versatility in binding modes, even between members of the same class (e.g., some bind DNA, others protein), suggesting that they are stable scaffolds that have evolved specialized functions. For example, zinc finger-containing proteins function in gene transcription, translation, mRNA trafficking, cytoskeleton organization, epithelial development, cell adhesion, protein folding, chromatin remodeling, and zinc sensing, to name but a few. Zinc-binding motifs are stable structures, and they rarely undergo conformational changes upon binding their target.

The last binding domain that we will consider in detail here is the helix-loop-helix domain found in Leucine zipper-containing proteins. Specifically, bZIPs (Basic-region leucine zippers) are a class of eukaryotic transcription factors. The bZIP domain is 60 to 80 amino acids in length with a highly conserved DNA binding basic region and a more diversified leucine zipper dimerization region. The two regions form α-helical structures that are connected via a looped region. This forms a core helix-loop-helix (HLH) structure within each monomer of the protein. Two monomers then join through the formation of a leucine zipper junction forming a heterodimeric protein structure. The resulting heterodimer can bind with DNA in a sequence-specific manner through the basic α-helices as shown in Figure 27.2.18

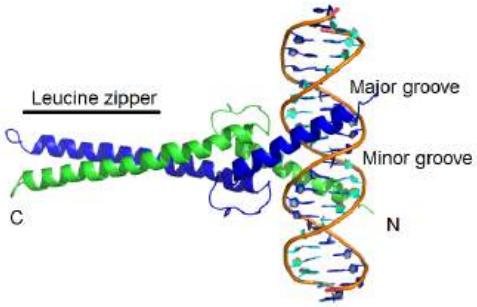

Figure 27.2.18: Leucine Zipper Transcription Factors from the bZIP family. The monomer subunits of a heterodimeric bZIP protein contain a Helix-loop-Helix (HLH) core structure, where one helix forms the leucine zipper with the other monomer, and the basic helices of each monomer interact with the major groove of the target DNA. The helices are held together by a flexible loop region. (One monomer is shown in blue and one monomer is shown in green). Latacca

Specifically, basic residues, such as lysines and arginines, interact in the major groove of the DNA, forming sequence-specific interactions). Most bZIP proteins show a high binding affinity for the ACGT motifs. The bZIP heterodimers exist in a variety of eukaryotes and are more common in organisms with higher evolution complexity.

Figure 27.2.19shows an interactive iCn3D model of the GCN4 basic region leucine zipper binds DNA as a dimer of uninterrupted alpha helices (1YSA).

27.2.5:

27.2.6: Epigenetics and Transgenerational Inheritance

Even though all somatic cells of a multicellular organism have the same genome, different cell types have different transcriptomes (sets of all expressed RNA molecules), different proteomes (sets of all proteins), and, hence, different functions. Cell differentiation during embryonic development requires the activation and repression of specific sets of genes by the action of cell lineage-defining transcription factors. Within a cell lineage, gene activity states are often maintained over several rounds of cell divisions (a phenomenon called “cellular memory” or “cellular inheritance”). Since the rediscovery of epigenetics some 30 years ago (it was originally proposed by Conrad Hal Waddington in the early 1940s), cellular inheritance has been attributed to gene regulatory feedback loops, chromatin modifications (DNA methylation and histone modifications) as well as long-lived non-coding RNA molecules, which collectively are called the *“epigenome”*. Among the different chromatin modifications, DNA methylation and polycomb-mediated silencing are probably the most stable ones and endow genomes with the ability to impose silencing of transcription of specific sequences even in the presence of all of the factors required for their expression.

27.2.7: Defining Transgenerational Epigenetic Inheritance

The metastability of the epigenome explains why development is both plastic and canalized, as originally proposed by Waddington. Although epigenetics deal only with the cellular inheritance of chromatin and gene expression states, it has been proposed that epigenetic features could also be transmitted through the germline and persist in subsequent generations. The widespread interest in ***"transgenerational epigenetic inheritance"*** is nourished by the hope that epigenetic mechanisms might provide a basis for the inheritance of acquired traits. Yes, Lamarck has never been dead and every so often raises his head, this time with the help of epigenetics.

Although acquired traits concerning body or brain functions can be written down in the epigenome of a cell, they cannot easily be transmitted from one generation to the next. For this to occur, these epigenetic changes would have to manifest in the germ cells as well, which in mammals are separated from somatic cells by the so-called Weismann barrier. Further, the chromatin is extensively reshaped during germ cell differentiation as well as during the development of totipotent cells after fertilization, even though some loci appear to escape epigenetic reprogramming in the germline. Long-lived RNA molecules appear to be less affected by these barriers and therefore more likely to carry epigenetic information across generations, although the mechanisms are largely unsolved.

27.2.8: Evidence for Transgenerational Epigenetic Inheritance

In the past 10 years, numerous reports on transgenerational responses to environmental or metabolic factors in mice and rats have been published. The factors include endocrine disruptors, high-fat diet, obesity, diabetes, undernourishment as well as trauma. These studies investigated DNA methylation, sperm RNA, or both. For example, when male mice are made prediabetic by treatment with streptozotocin it affects the DNA methylation patterns in their resulting sperm, as well as the pancreatic islets of F1 and F2 of the resulting offspring. Furthermore, studies have shown that traumatic stress in early life altered behavioral and metabolic processes in the progeny and that injection of sperm RNAs from traumatized males into fertilized wild-type oocytes reproduced the alterations in the resulting offspring.

In humans, epidemiological studies have linked food supply in the grandparental generation to health outcomes in the grandchildren. An indirect study based on DNA methylation and polymorphism analyses has suggested that sporadic imprinting defects in Prader–Willi syndrome are due to the inheritance of a grandmaternal methylation imprint through the male germline. Because of the uniqueness of these human cohorts, these findings still await independent replication. Most cases of segregation of abnormal DNA methylation patterns in families with rare diseases, however, turned out to be caused by an underlying genetic variant. Thus, studies of this nature must rule out the effects of traditional genetic inheritance as being a factor of the observed phenotypes.

Genetic inheritance alone cannot fully explain why we resemble our parents. In addition to genes, we inherited from our parents the environment and culture, which in parts have been constructed by the previous generations as shown in Figure 27.2.20 A specific form of the environment is our mother's womb, to which we were exposed during the first 9 months of our life. The maternal environment can have long-lasting effects on our health. In the Dutch hunger winter, for example, severe undernourishment affected pregnant women, their unborn offspring, and the offspring's fetal germ cells. The increased incidence of cardiovascular and metabolic disease observed in F1 adults is not due to the transmission of epigenetic information through the maternal germline, but a direct consequence of the exposure in utero, a phenomenon called "fetal programming" or—if fetal germ cells and F2 offspring are affected—"intergenerational inheritance".

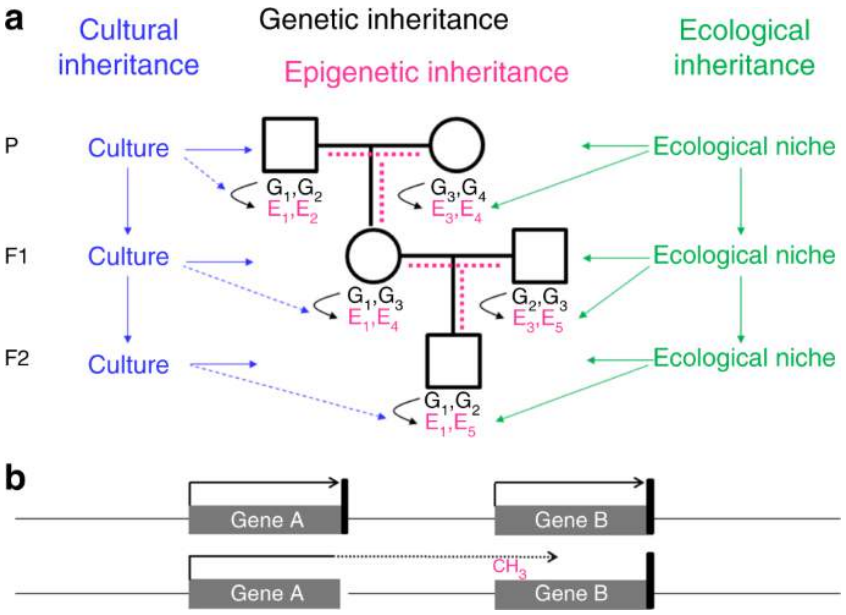

Figure 27.2.20: Transgenerational inheritance systems. *Horsthemke, B. (2018) Nat Comm. 9:2973*

Panel a shows that offspring inherit from their parent's genes (black), the environment (green), and culture (blue). Genes and the environment affect the epigenome (magenta) and the phenotype. Culture also affects the phenotype, but at present, there is no evidence of a direct effect of culture on the epigenome (broken blue lines). It is a matter of debate, how much epigenetic information is inherited through the germline (broken magenta lines). G genetic variant, E epigenetic variant.

Panel b shows that an epimutation (promoter methylation and silencing of gene B in this example) often results from aberrant read-through transcription from a mutant neighboring gene, either in sense orientation as shown here or in antisense orientation. The presence of such a secondary epimutation in several generations of a family mimics transgenerational epigenetic inheritance, although it represents genetic inheritance. Black arrow, transcription; black vertical bar, transcription termination signal; broken arrow, read-through transcription

27.2.9: Roadmap to Proving Transgenerational Epigenetic Inheritance

Here are some steps to show that inheritance is determined by epigenetics and not classical genetics.

- Rule out genetic, ecological, and cultural inheritance. For studies in mice and rats, inbred strains and strictly controlled environments need to be used. When a pregnant female animal is exposed to a specific environmental stimulus, F3 offspring and subsequent generations must be studied to exclude a direct effect of the stimulus on the embryos' somatic cells and germ cells. Even more desirable is the use of *in vitro* fertilization (IVF), embryo transfer, and foster mothers. When a male animal is exposed to an environmental stimulus, F2 offspring must be studied to exclude transient effects on germ cells. To ensure that any phenotype is exclusively transmitted via gametes, IVF must be used, controlling for possible artifacts relating to IVF. In contrast with laboratory animals, it is impossible to rule out ecological and cultural inheritance in humans, but genetic effects should and can be excluded. If an epimutation follows Mendelian inheritance patterns, be cautious: you are more likely looking at a secondary epimutation and genetic inheritance. Study the haplotype background of the epimutation: if in a given family it is always on the same haplotype, you are again most likely dealing with a secondary epimutation. Do whole genome sequencing to search for a genetic variant that might have caused the epimutation and be aware that this variant might be distantly located. Good spots to start looking at are the two neighboring genes, where a mutation might cause transcriptional read-through in sense or antisense orientation into the locus under investigation. Unfortunately, if you don't find anything, you still cannot be 100% sure that a genetic variant does not exist.
- Identify the responsible epigenetic factor in the germ cells. Admittedly, this is easier said than done, especially in female germ cells, which are scarce or unavailable. Be aware that germ cell preparations may be contaminated with somatic cells or somatic DNA. Use swim-up (sperm) or micromanipulation techniques to purify germ cells to the highest purity. Exclude the presence of somatic cells and somatic DNA by molecular testing, for example by methylation analysis of imprinted genes, which are fully methylated or fully unmethylated only in germ cells.

- Demonstrate that the epigenetic factor in the germ cells is responsible for the phenotypic effect in the next generation. If possible, remove the factor from the affected germ cells and demonstrate that the effect is lost. Add the factor to control germ cells and demonstrate that the effect is gained. While RNA molecules can and have been extracted from the sperm of exposed animals and injected into control zygotes, DNA methylation, and histone modifications cannot easily be manipulated (although CRISPR/Cas9-based epigenome editors are being developed and used for this purpose), and all of these experiments can hardly be done in humans. In light of these problems, this might currently be too much to ask for to prove transgenerational epigenetic inheritance in humans, but should, nevertheless, be kept in mind and discussed.

Binding and Noncovalent Interaction Problems

Chapter 1 - Problems

CHAPTER OVERVIEW

Enzyme Kinetics Problems

Topic hierarchy

Carbonic Anydrase Inhibition

WNovak-Beta Jupyter NB - Ex 1: Under Construction

Carbonic Anydrase Inhibition

These questions derive from the Research Literature Module - Carbon Capture Using Carbonic Anhydrase

Question 1

Using the equation below, at what ratio of CO_2/[HCO_3^-] would the rate for the forward reaction (CO_2 sequestration) be cut in half?

$$v_0 = \frac{V_M S}{K_M \left(1 + \frac{I}{Kis}\right) + S} \tag{1}$$

If you need some help, hover over -

Give me a hint!

Answer

$$v_{-I} = \frac{V_M S}{K_M + S} = \frac{(1)(1)}{(1+1)} = 0.5$$

$$v_{+I} = \frac{V_M S}{K_M \left(1 + \frac{[I]}{K_{is}}\right) + S} = \frac{(1)(1)}{1\left(1 + \frac{[I]}{2}\right)} = 0.25 = \frac{1}{1 + \frac{[I]}{2}}$$

$$0.25\left(1 + \frac{[I]}{2}\right) = 1 \tag{2}$$

$$1 + \frac{[I]}{2} = 4$$

$$\frac{[I]}{2} = 3$$

$$[I] = 6$$

Hence it doesn't take much HCO_3^- buildup to inhibit the "capture" of CO_2!

CHAPTER OVERVIEW

Enzyme Mechanisms Questions

Topic hierarchy

Carbonic Anhydrase - Mechanism

Carbonic Anhydrase - Mechanism

These questions derive from the Research Literature Module - Carbon Capture Using Carbonic Anhydrase

Carbonic Anhydrase - Structure and Mechanism 1

An active site Zn^{2+} appears to bind a water molecule and reduce its pK_a such that the bound form is OH^-. This is illustrated in the left panel of Figure 1 below, which depicts the local environment of the bound Zn^{2+} (coordinated by histidine side chains and an OH^-) in the absence (left) and presence (right) of CO_2. Note that the back histidine is difficult to barely visible (but still evident) in both structures. To assist in viewing the structure, the right panel shows an interactive iCn3D model of Zn- human carbonic anhydrase II at pH 7.8 and 0 atm CO (6LUW).

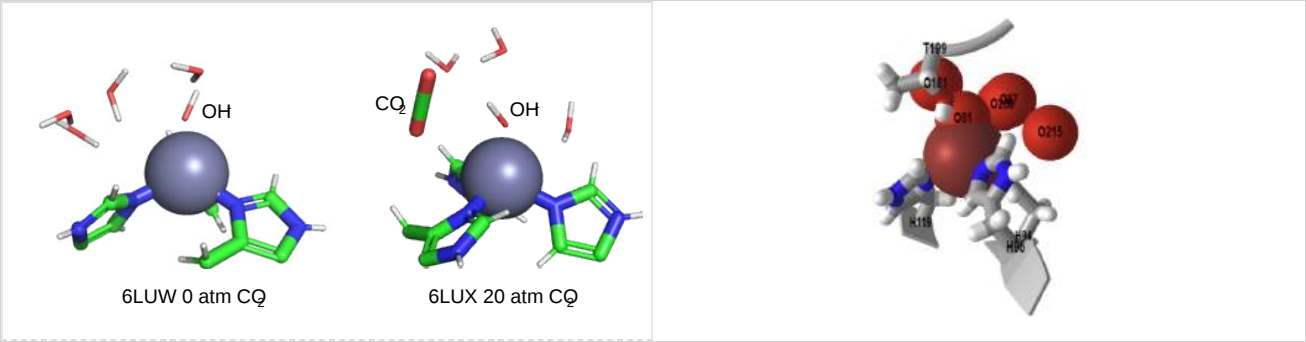

Figure 1: Left panel: Coordination of OH^- to Zn^{2+} in carbonic anhydrase in the absence (left) and presence (right) of substrate CO_2. Right panel: Zn- human carbonic anhydrase II at pH 7.8 and 0 atm CO (6LUW) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...43DYyZFvHJpZn9

? Question \PageIndex1}

What is the coordination geometry of the Zn ion?

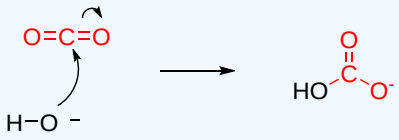
Answer

tetrahedral

? Question 2

Draw a simplified reaction mechanism showing bicarbonate formation from the two reactants, CO_2 and OH^-.

Answer



The enzyme is reversible and in humans is important in CO_2 transport in respiration and maintaining intracellular pH, which is also its key role in most organisms.

CO_2, like the other atmospheric gases O_2 and N_2, are nonpolar and have limited solubility in water. The solubility of these gases in water at 20°C and 1 atm pressure, in g/L and mM, are shown in Table 1 below.

Gas (ref)	solubility (aq) (g/L)	solubility (mM)
CO_2	1.7	38
O_2	0.044	1.3

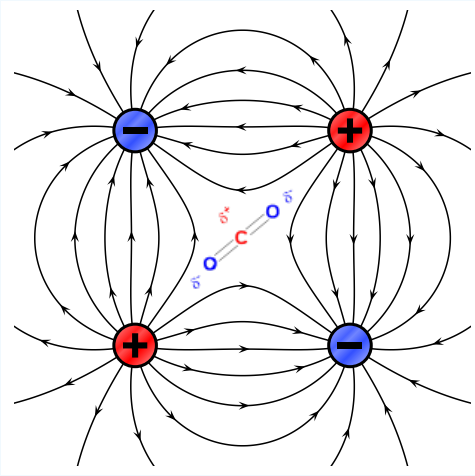
N_2	0.019	0.68

Question 3

Offer reasons that explain the significantly higher (but still low) solubility of CO_2 in water compared to O_2 and N_2.

Answer

CO_2 is considered a nonpolar molecule since it has no net molecular dipole. However, it does have 2 bond dipoles (pointing in opposite directions), so the carbon atom is δ^+ while the Os are δ^-. This probably contributes to its greater solubility than N_2 and O_2 which don't have bond dipoles. CO_2 would not orient itself in a dipole electric field, but it would to some extent in a quadrupole (4 poles) electric field where the positive potentials are oriented north and south and the negative potentials at east and west. CO_2 has a quadrupole moment. In addition, the continued reaction of CO2 and water to form the weak acid carbonic acid would contribute to its higher apparent solubility. It is not clear to the authors if these contributions to solubility are accounted for in the experimental values of solubility.



A quadruple and its associated magnetic field with oriented CO_2. https://commons.wikimedia.org/wiki/F...quadrupole.svg

Question 4

How does the enzyme facilitate the transport of CO_2 in blood? How does it maintain intracellular pH?

Answer

It converts the poorly soluble carbon unit in CO_2 to the strongly soluble bicarbonate anion. HCO_3^-.

A simple explanation for maintaining intracellular pH comes from the chemical equation below.

$CO_2(aq) + H_2O\ (l) \leftrightarrow H_2CO_3\ (aq) + H_2O(l) \leftrightarrow H_3O^+(aq) + HCO_3^-(aq)$.

HCO_3^- is the conjugate base of the weak acid, H_2CO_3 so the system is a classic buffer. For a complete explanation of why the system can act as a buffer at neutral pH even though the pKa of the weak acid is 3.6, see Chapter 2.3 for review.

Let's explore the structure of two different CAs, human carbonic anhydrase II and the carbonic anhydrase from Neisseria gonorrhea.

Human carbonic anhydrase II

The structure of native human carbonic anhydrase II and its catalytic mechanism is shown in Figure 5 below.

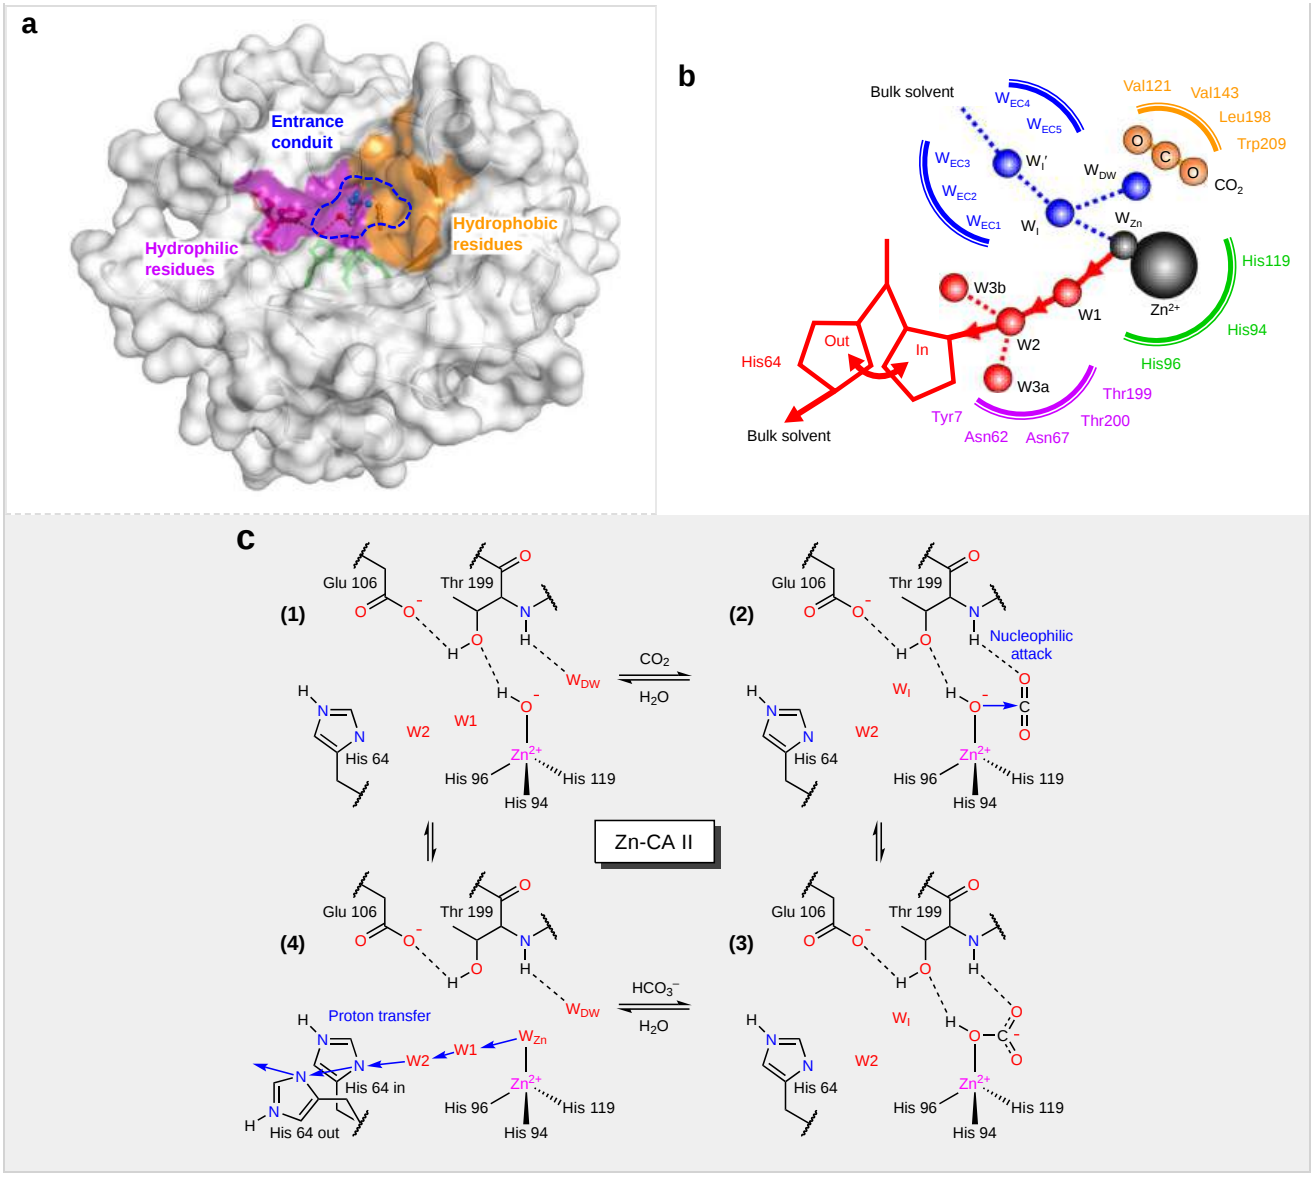


Figure 5: **Structure of native human carbonic anhydrase II (Zn-CA II) and its catalytic mechanism.** Kim, J.K., Lee, C., Lim, S.W. *et al.Nat Commun* **11**, 4557 (2020). https://doi.org/10.1038/s41467-020-18425-5. Creative Commons Attribution 4.0 International License, http://creativecommons.org/licenses/by/4.0/.

Panel a shows the active site consists of the zinc binding site, hydrophobic/hydrophilic regions, and the entrance conduit (EC).

Panel b shows the water networks in the active site that are responsible for the proton transfer (red) and substrate/product/water exchange (blue) during enzyme catalysis.

Panel c shows the forward reaction mechanism of Zn-CA II.

The active site itself lies at the bottom of a deep cavity (15 Å deep) in the protein, which is readily accessible to solvent

An interactive iCn3D model of human carbonic anhydrase II with bound bicarbonate and CO_2 (2VVB) is shown in Figure 6 below.

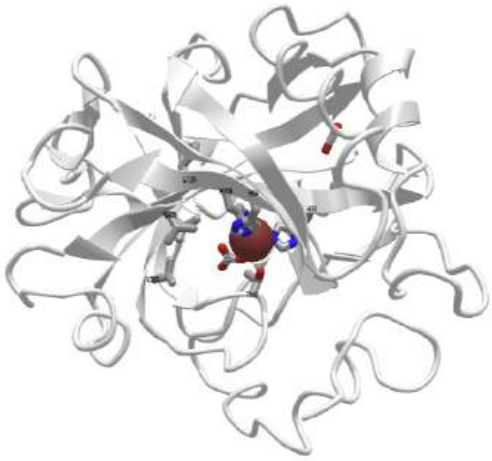

Figure 6: Human carbonic anhydrase II with bound bicarbonate and CO_2 (2VVB) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...ibgmgsm3UWhjX6

The active site residues shown in Figure 6 are labeled and shown as sticks. Bound CO_2 and HCO_3^- are also shown as sticks.

Question 5

This question addresses the Biomolecular Visualization Framework theme(s) Molecular Interactions (MI), Atomic Geometry (AG)

Using iCn3D to show the noncovalent interactions between bicarbonate, Zn, and the protein by using iCn3D. Measure the distance between the hydrogen-bonded atoms in HCO_3^- and Thr 199.

iCn3D instructions

Trackpad and Mouse Controls

•rotate: click and drag (mouse: left click and drag)

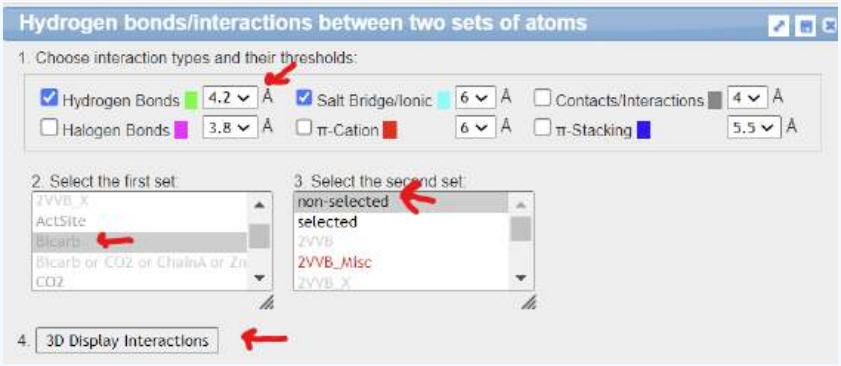
•zoom: pinch and spread (mouse: rotate the scroll wheel)

•translate: two-finger click and drag (mouse: right click and drag)

•Re-center: left click View from the top menu bar, then select “Center Selection”

•Note: ctrl-click on a PC = command-click on Mac; alt-click on PC = option click on Mac

1. Open the external link: https://structure.ncbi.nlm.nih.gov/i...ibgmgsm3UWhjX6
2. From the top menu bar, choose **Analysis**, **Interactions**
3. In the new popup window select the following prompts, then click **4. 3D Display interactions**



4. Close all but the main modeling window.

5. Zoom into the bicarbonate binding site. From the top menu bar, choose **Analysis**, **Distance**, **distance between 2 atoms**, and pick the two atoms (by holding down the Alt key or Option on a Mac) involved in the hydrogen bond between the bicarbonate and the amide

6. Rescale the label size by choosing **Analysis, Label Scale, 0.4**.

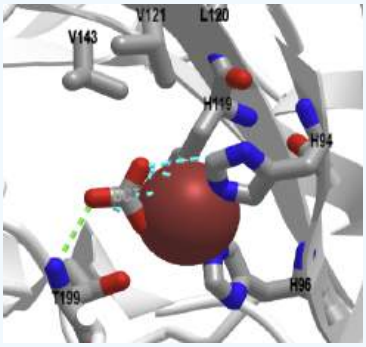
7. From the top menu bar choose **Select, Toggle highlights** to remove yellow and box highligting.

8. Save a PNG file by choosing

9. You can reload the PNG file directly into iCn3D by choosing **File**, **Open File**, i**Cn3D PNG image**

Answer

The blue dotted lines are ion-ion interactions. Note the green hydrogen bond between T199 and the bound bicarbonate. Remember that hydrogen atoms are not shown in PDB files from x-ray structures. The H-bond distance is 3.1 angstroms. For some reason, the H-bond does not show unless the initial constraint distances are moved to 4.2 Angstroms.



? Question 6

What is a likely function of Val, Leu and Trp cluster in CAII (shown in Figures 5 and 6)?

Answer

These side chains are all hydrophobic (as illustrated in gold in Figure 5) and provide a weak binding environment for nonpolar CO_2.

? Question 7

What ligand would likely replace OH^- at low pH values? What would happen to the activity of the enzyme at lower pHs?

Answer

At low pH, ie. at pH values lower than the pKa of the Zn-bound water (which deprotonates to form the OH^- ligand and nucleophile), the ligand and nucleophile would be H_2O. The enzyme would display a lower activity given the weaker nucleophile.

Question 8

From the mechanism shown in Figure 5, does bicarbonate coordinate the Zn^{2+} ion in a monodentate or bidentate manner?

Answer

Monodentate as only 1 coordinate covalent bond forms on an electron pair donation from the bicarbonate to the Zn^{2+}.

Question 9

Write a verbal description of the mechanism of CAII based on Figure 5

Answer

CO_2 binds to the active site through loose association with the cluster of hydrophobic side chains. The Zn^{2+} bound OH^- acting as a nucleophile attacks the central carbon of the CO_2 forming HCO_3^-. The carbonate forms a monodentate interaction with Zn and also a hydrogen bond to Thr 199. The HCO_3^- is then displaced by an incoming water molecule. The other product of the reaction, H^+, moves through a hydrogen bond network of water molecules (W1 and W2) to His 64 and eventually to bulk water. The interactions with substrate and products are weak allowing fast exchange.

Question 10

Why is a proton transfer path needed?

Answer

H^+ is a product of the reaction: CO_2 (g) + H_2O ↔ H_2CO_3 (aq) ↔ HCO_3^- (aq) + H^+ (aq). It must depart to prevent charge build-up, maintain charge balance, and keep the correct electrostatic environment of the active site.

Question 11

Thr 199 plays a key role in the mechanism. State a reason for its importance in the reversible reaction.

Answer

Thr 199 supplies two hydrogen bonds to the bicarbonate. It actually destabilizes bicarbonate bonding with respect to a T199A mutant. In the mutant, carbonate might bind Zn^{2+} in a bidentate fashion, leading to tighter binding and a slower dissociation rate of the product, HCO_3^-.

Question 12

The dissociation constant K_D (or K_{is}) for bicarbonate binding to HCAII is about 77 mM. What kind of inhibitor might it be for the forward reaction?

Answer

Given that it binds in the active site and would prevent binding of the substrate for the forward reaction, CO_2, it is a competitive inhibitor.

Question 13

Using the equation below, at what ratio of $CO_2/[HCO_3^-]$ would the rate for the forward reaction (CO_2 sequestration) be cut in half? Assume the V_M=1, K_M forward reaction is 1, [S] = 1 and K_{is} is 2 (a wide range of values are reported in the Brenda Database.

$$v_0 = \frac{V_M S}{K_M \left(1 + \frac{I}{Kis}\right) + S} \tag{1}$$

If you need some help, hover over -

Give me a hint!

Answer

$$v_{-I} = \frac{V_M S}{K_M + S} = \frac{(1)(1)}{(1+1)} = 0.5$$

$$v_{+I} = \frac{V_M S}{K_M \left(1 + \frac{[I]}{K_{is}}\right) + S} = \frac{(1)(1)}{1\left(1 + \frac{[I]}{2}\right)} = 0.25 = \frac{1}{1 + \frac{[I]}{2}}$$

$$0.25\left(1 + \frac{[I]}{2}\right) = 1 \tag{2}$$

$$1 + \frac{[I]}{2} = 4$$

$$\frac{[I]}{2} = 3$$

$$[I] = 6$$

Hence it doesn't take much HCO_3^- buildup to inhibit the "capture" of CO_2!

Question 14

The rate-limiting step for human CA II is the dissociation of a proton from Zn^{2+}-bound water and not the removal of the resulting proton from the enzyme. What does that imply about the rate of removal of the proton from the enzyme?

Answer

It must be very fast, that is at diffusion-controlled limits through the H-bond channel.

Synthetic mimetics of the active site of CA have been made. These are heteromacrocycles (similar to the heme of hemoglobin) as shown in Figure 9 below.

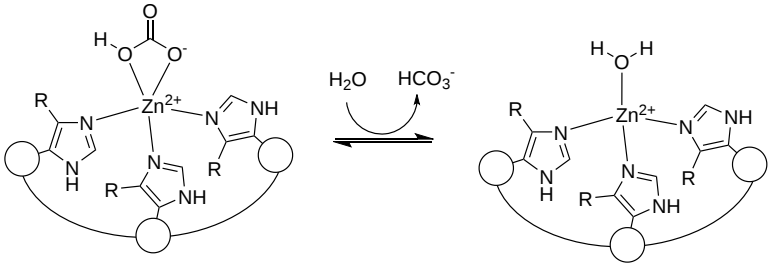


Figure 9:

The macrocycle mimetic has three imidazole groups coordinating zinc.

Question 15

The macrocycle mimetic has three imidazole groups coordinating zinc. Is the bicarbonate coordinated to the Zn^{2+} in a monodentate or bidentate fashion? From the "denticities" of the interactions of bicarbonate and Zn^{2+} for human CAII and the mimetic, which catalyst, CAII or the macrocycle would you expect to have a lower K_D for bicarbonate? How might this affect the rate-limiting step for the mimetic?

Answer

The mimetic is bidentate, is it should bind more tightly to bicarbonate, hindering its dissociation, and hence making "product" inhibition more likely.

Question 16

What is the utility of having both CO_2 and HCO_3^- bind weakly to the enzyme

Answer

Weak binding "permits their rapid exchange. The hydrogen-bonding arrangement in the active site is such that the water or hydroxide ion donates a hydrogen bond to a proximal threonine (Thr199 in hCA II) because the hydroxyl group of this residue is forced to donate its hydrogen in a hydrogen bond to a negatively charged glutamate side chain (Glu106 in hCA II). Site-directed mutations have confirmed this model of the catalytic mechanism. The substrates/products carbon dioxide/bicarbonate are fairly weakly bound against a hydrophobic wall in the active site, which permits their rapid exchange."

CHAPTER OVERVIEW

Global Challenges with Literature-Based Guided Assessments

Topic hierarchy

1. Global Challenges: An Introduction
Carbon Capture Using Carbonic Anhydrase
Trauma and Health

1. Global Challenges: An Introduction

Global Challenges		Topic

Introduction

Instead of presenting a litany of end-of-chapter or end-of-book questions that are not linked in content or concepts, we will present a number of problem-solving assessments linked to research literature that deal with key challenges that face the world today. When the questions are mostly derived from the literature, we'll also call them **Literature-Based Guided Assessments (LGAs)**. Each will focus on a particular biological system (enzyme, pathways, etc) and contain a series of sequential and linked questions on a particular protein, for example, and its function. The problems are summative and hence require an understanding of structure, noncovalent interactions, binding, kinetics, and reaction mechanisms. The modules are guided and have elements of problem-solving and POGIL questions.

Each Module will ultimately focus on the structure and properties of key biomolecules. The modules will:

1. Address ASBMB Core concepts and Learning Objectives (generalized below) through analysis and interpretation of research findings in one or more research publications.

- Energy is required by and transformed in biological systems.
- Macromolecular structure determines function and regulation.
- Information storage and flow are dynamic and interactive.
- Biochemical systems maintain a state of homeostasis, a steady stable state while continually adjusting to conditions, *which requires energy input, organization, and control mechanisms.*
- Evolution plays a pervasive role in shaping the form and function of all biological molecules and organisms.

2. Link to critical problems facing the world (see the Table) which have clearly identified biochemical components. These critical problems include health care disparities, climate change, pandemics, addiction, childhood trauma, food insecurity, biodiversity loss, ecosystem (ocean, soil, forest) health, and misinformation/disinformation. These problems are often linked and not mutually exclusive. Most biochemistry textbooks focus on problems using biomedical examples. Expanding to study key world problems that are not directly biomedical and are underrepresented in textbooks, allows students to apply their acquired knowledge and understanding into different areas.

3. Follow general features found in problem-based learning and in case studies, which provide contextual applications for the detailed learning opportunities found in biochemistry books and courses.

- A broad introduction (text, videos, personal narratives) describing the critical world problem and the relevancy of the selected biochemical system to the problem
- A more detailed description of the selected biochemical system, including links to specific locations in Fundamentals of Biochemistry as well as external resources
- Research literature results (graphs, tables, models, etc), taken from journals that allow derivatives and reuse by appropriate Creative Commons licensing (for example, CC BY 4.0), for interpretation

4. Focus on representative biomacromolecules (protein, nucleic acid, glycan, lipid and combination of them) relevant to the broader problem for which detailed structure/function questions can be explored

5. Explicitly address and link to appropriate BioMolViz framework themes, goals and objectives to the biomolecules key to the LGA.

Relationship of LGAs to BioMolViz and Molecular CaseNet

The completed LGAs will consist of a broad introduction and relevant biochemical research findings woven into a narrative that will include nested questions based on the literature with an ultimate focus on a key biomacromolecule. It will not take the form or

detail of a full case study as found in Molecular CaseNet (headed by Shuchi Dutta and its Steering Committee, which includes Henry Jakubowski, who is also on the Steering Committee of BioMolViz). As the LGAs in Fundamentals of Biochemistry and indeed the whole text, as well as the Molecular CaseNet are free online educational resources (OERs), both communities can freely share resources. Since the LGAs have some attributes of case studies, we hope that contributors to Molecular CaseNet will freely use the LGAs and convert them to more expansive case studies, housed within Molecular CaseNet.

Likewise, the research literature-based questions in the LGAs that focus on biomacromolecule structures will be explicitly linked to the themes, goals and objectives of the BioMolViz literacy framework. However, the specific questions will not be included in the web repository created by BioMolViz. The repository questions have gone through many iterative cycles of construction, revision, external review by expert panels, and validation by actual classroom use. Instead, the questions in Fundamentals of Biochemistry LGAs that target specific biomolecular visualization framework objectives will help to expand knowledge and understanding of biomolecule visual literacy and BioMolViz objectives, which ultimately is the goal of BioMolViz.

A full semester of biochemistry would be necessary to complete a full LGA, as the questions extend from structure, binding, kinetics, mechanism, metabolism, and signal transduction. Yet parts of a complete LGA could be completed after students complete the corresponding chapter in the book. Hence parts of a given LGA will be listed in Volume 5 under the corresponding topic (carbohydrate structure, for example). A link will be provided back to the home LGA from which the questions were derived

Global Challenges as the Bases for Literature-Based Guided Assessments (LGAs)

Here are the world challenges we have selected that we serve as the bases for the LGAs.

World Problems	**Research Literature Modules**
Health Disparities	Type II Diabetes

Carbon Capture Using Carbonic Anhydrase

Global Challenges	Climate Change Carbon Capture Using Carbonic Anhydrase	Literature-Based Guided Assessment (LGA)
		

Key Words, Concepts: protein structure, structure/function relationships, enzyme kinetics, enzyme mechanisms, reaction mechanisms, Western blot analysis, site-directed mutagenesis, biomolecular visualization, computational modeling, graphic analysis

The Problem

Our climate is changing as planetary temperatures rise from increasing amounts of the greenhouse gas carbon dioxide released into the atmosphere (detailed in Chapter 31) on the burning of fossil fuels. The rate of release is unparalleled in geological history. Present levels (415 ppm) have not been seen for at least 3 million years. Human societies and cultures have had the opportunity to develop in relatively stable climatic conditions. Figure 1 below shows the rise in atmospheric CO_2 over the last 1000 years.

Figure 1: CO_2 levels in the atmosphere over the last 1000 years. Our world in data. https://ourworldindata.org/

The steep rise around 1790 coincides with the start of the Industrial Revolution. The rise in atmospheric CO_2 has led to a corresponding rise in the average global temperatures, as illustrated in Figure 2 below.

Figure 2: Average global temperature changes over the last 1000 years. Our world in data. https://ourworldindata.org/

The per capita emissions of CO_2 across the world derive from the use of coal, oil, and gas, as illustrated in Figure 3 below.

Figure 3: Per capita emission of CO_2 from fossil fuel type

If we want to decrease emissions, we also need to know in which economic sectors fossil fuels are used. The main sources of global energy-related CO_2 emissions by sector are shown in Figure 4:

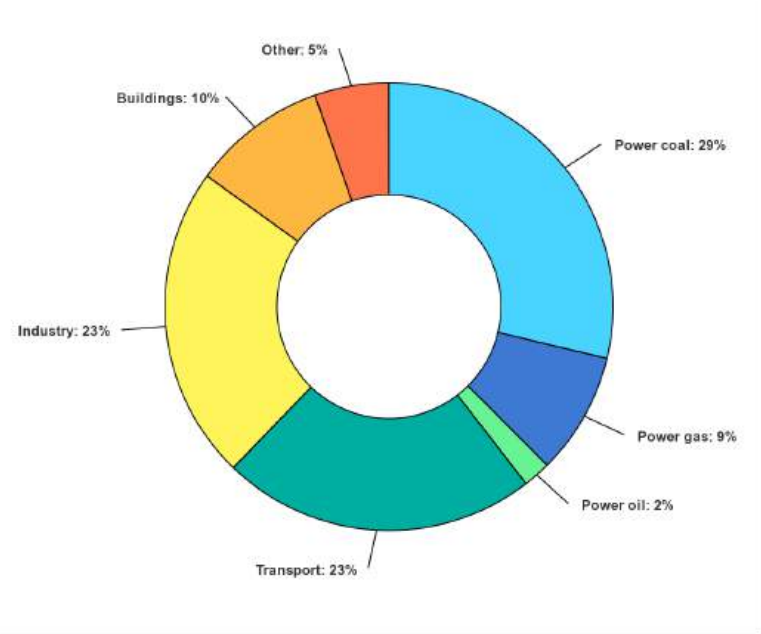

Figure 4: Global energy-related CO_2 emissions by sector. Updated on 10/26/22. https://www.iea.org/data-and-statist...ions-by-sector. IEA. License: CC BY 4.0

Note the use of coal, gas, and oil for energy production (electricity) accounts for 40% of global CO_2 emissions, with transportation (mostly through the use of gasoline and diesel fuel) and industry accounting for about 25% each.

Simple chemistry tells us that there are two ways to decrease the amount of product (in this case CO_2) in a chemical reaction:

- decrease the concentration of reactants (i.e. reduce fossil fuel use)
- remove the product, in this case, CO_2 from the air.

The latter process is called carbon capture or sequestration. It is a daunting process that nature has mastered (through photosynthesis), but it clearly can't keep up with the huge injection of CO_2 in the atmosphere caused by burning fossil fuel.

We simply can't stop using fossil fuels, which would result in huge economic and social unrest. Alternative green fuels (solar, wind, for example) are being rapidly expanded but can't replace fossil fuels for many years. One of the reasons is that fossil fuels are very energy-dense (MJ/kg) compared to other sources of energy. It's also fascinating to look at the energy transitions humans have made over time. Figure 5 below shows the energy transition over a log-time scale (for presentation purposes) as well as the energy densities of individual sources.

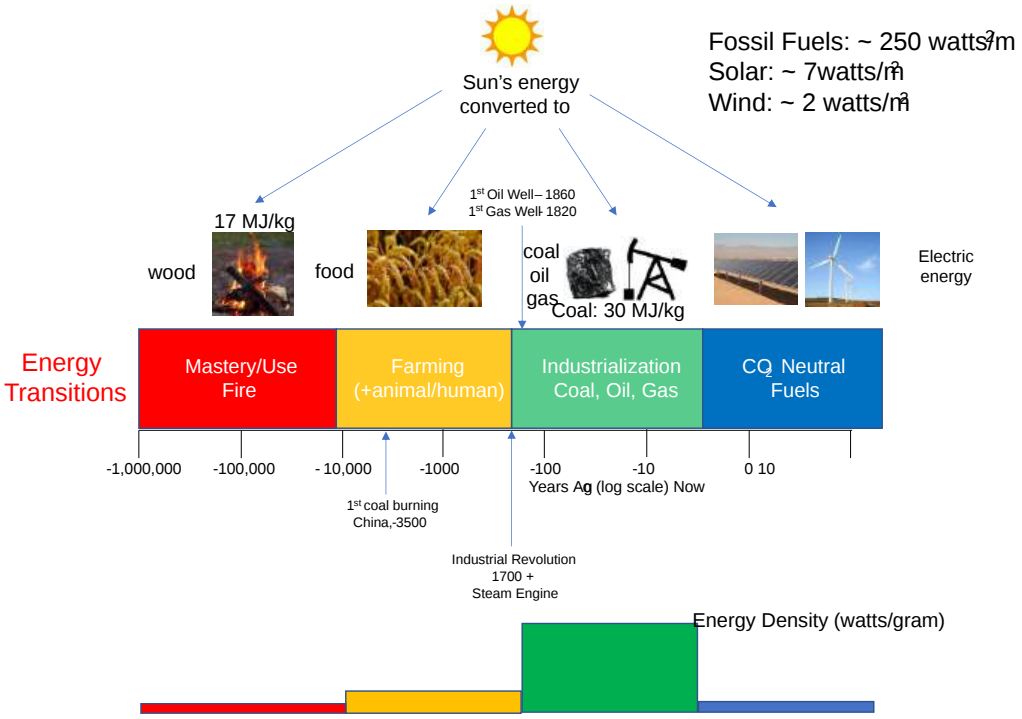

Figure 5: Human-created energy transitions (log time scale) and energy densities of individual sources

New technologies are needed to capture CO_2. We have to move much faster in a new clean energy transition than we have in our entire history. A potentially ideal solution would be to capture CO_2 from power plants before they reach the atmosphere. We will now look at research into an old enzyme, carbonic anhydrase, that is being repurposed for industrial-level carbon capture, carbonic anhydrase.

Carbonic Anhydrase (CA)

We have already encountered this enzyme before (Chapter 6.1). It catalyzes the hydration of CO_2 (g) as shown below.

$$CO_2\,(g) + H_2O \leftrightarrow H_2CO_3\,(aq) \leftrightarrow HCO_3^-\,(aq) + H^+\,(aq)$$

It is among the fastest of all enzymes, with a k_{cat} of 10^6 s^{-1} and a k_{cat}/K_m of 8.3 x 10^7 $M^{-1}s^{-1}$ (reference). It is diffusion controlled in that the rate of diffusion of reactants and products, not the chemical steps, determine the reaction rate. It can convert 10^6 molecules of CO_2(g) to HCO_3^- each second. No wonder scientists and engineers are studying it to capture CO_2. It's a big challenge though to capture CO_2 released on combustion of coal or natural gas in a power plant. Here are two problems that must be overcome:

- The enzyme must be thermostable at elevated temperatures to capture the CO_2 found in high-temperature power plant emissions
- The enzyme is reversible so it will be inhibited by the product HCO_3^-
- The enzyme must be stable to somewhat alkaline conditions (pH of 0.1M $NaHCO_3$ = 8.3)

For carbon capture from fossil fuel emissions, CA is immobilized by surface adsorption, covalent attachment, encapsulation, and entanglement. Immobilized enzymes are typically more thermostable and can be used in flow-through as opposed to solution phase capture. The immobilized enzyme matrix must withstand high temperatures (up to 100°C, and alkaline solvents used to strip the matrix for reuse.

The enzyme is found throughout life and typically has an active site Zn^{2+}. There are 8 families, α, β, γ, δ, ζ η, θ, and ι, with the α family being the most abundant. The α forms are generally active as dimers, but can act as monomers and tetramers.. There are 15 isoforms of the α form in humans and have a prime role in pH regulation. They are found in bacteria, fungi, plants, and algae. β-CAs are found in some types of bacteria, archaea, fungi, some higher plants, and invertebrates. CA in chloroplasts (and mitochondria (algae) are involved in carbon fixation. We will focus our attention on engineering carbonic anhydrase to make them more thermostable, alkali insensitive, and less susceptible to product inhibition by bicarbonate.

Natural enzymes can be isolated and selected for thermal and alkali stability. In addition, new versions selected for these properties can be engineered using directed evolution or site-directed mutagenesis. You wish to increase the thermal stability of a protein using mutagenesis. Essentially you wish to perturb the equilibrium between the folded (native) protein and the unfolded (denatured) protein so as to preferentially stabilized the native state.

? Question 1

Using mutagenesis, what residues might you change in a native protein to make it more stable at higher temperatures?

Answer

? Question 2

What measurements would you make to quantitate the change in thermal stability?

Answer

The actual amino acid composition and more strangely specific dipeptide sequences within a sequence are associated with thermal stability of hyperthermophilic proteins. For example, proteins from two different types of archaea with different optimal growth temperatures show that the one with the higher growth temperature have significantly higher levels of VK, KI, YK, IK, KV, KY, and EV and decreased levels of DA, AD, TD, DD, DT, HD, DH, DR, and DG. Similar experiments have been done in bacterial cells. Using machine learning, the dipeptide sequences K*H, KR, TF, P*M, F**N, V**Y, MW, and WQ were important in themostability where the * denotes a gap in the residues.

Structure and Mechanism

An active site Zn^{2+} appears to bind a water molecule and reduce its pK_a such that the bound form is OH^-. This is illustrated in the left panel of Figure 6 below, which depicts the local environment of the bound Zn^{2+} (coordinated byhistidine side chains and an OH^-) in the absence (left) and presence (right) of CO_2. Note that the back histidine is difficult to barely visible (but still evident) in both structures. To assist in viewing the structure, the right panel shows an interactive iCn3D model of Zn- human carbonic anhydrase II at pH 7.8 and 0 atm CO (6LUW).

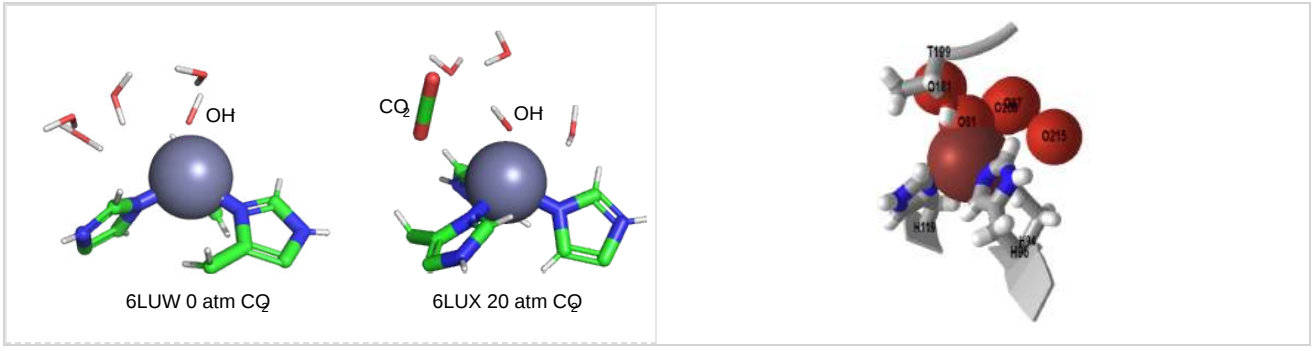

Figure 6: Left panel: Coordination of OH^- to Zn^{2+} in carbonic anhydrase in the absence (left) and presence (right) of substrate CO_2. Right panel: Zn- human carbonic anhydrase II at pH 7.8 and 0 atm CO (6LUW) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...43DYyZFvHJpZn9

? Question 3

What is the coordination geometry of the Zn ion?

Answer

Question 4

Draw a simplified reaction mechanism showing bicarbonate formation from the two reactants, CO_2 and OH^-.

Answer

The enzyme is reversible and in humans is important in CO_2 transport in respiration and maintaining intracellular pH, which is also its key role in most organisms.

CO_2, like the other atmospheric gases O_2 and N_2, are nonpolar and have limited solubility in water. The solubility of these gases in water at 20°C and 1 atm pressure, in g/L and mM, are shown in Table 1 below.

Gas (ref)	solubility (aq) (g/L)	solubility (mM)
CO_2	1.7	38
O_2	0.044	1.3
N_2	0.019	0.68

Question 5

Offer reasons that explain the significantly higher (but still low) solubility of CO_2 in water compared to O_2 and N_2.

Answer

Question 6

How does the enzyme facilitate the transport of CO_2 in blood? How does it maintain intracellular pH?

Answer

We'll explore the structure of two different CAs, human carbonic anhydrase II and the carbonic anhydrase from Neisseria gonorrhea in this guided problem-solving module.

Human carbonic anhydrase II

The structure of native human carbonic anhydrase II and its catalytic mechanism is shown in Figure 7 below.

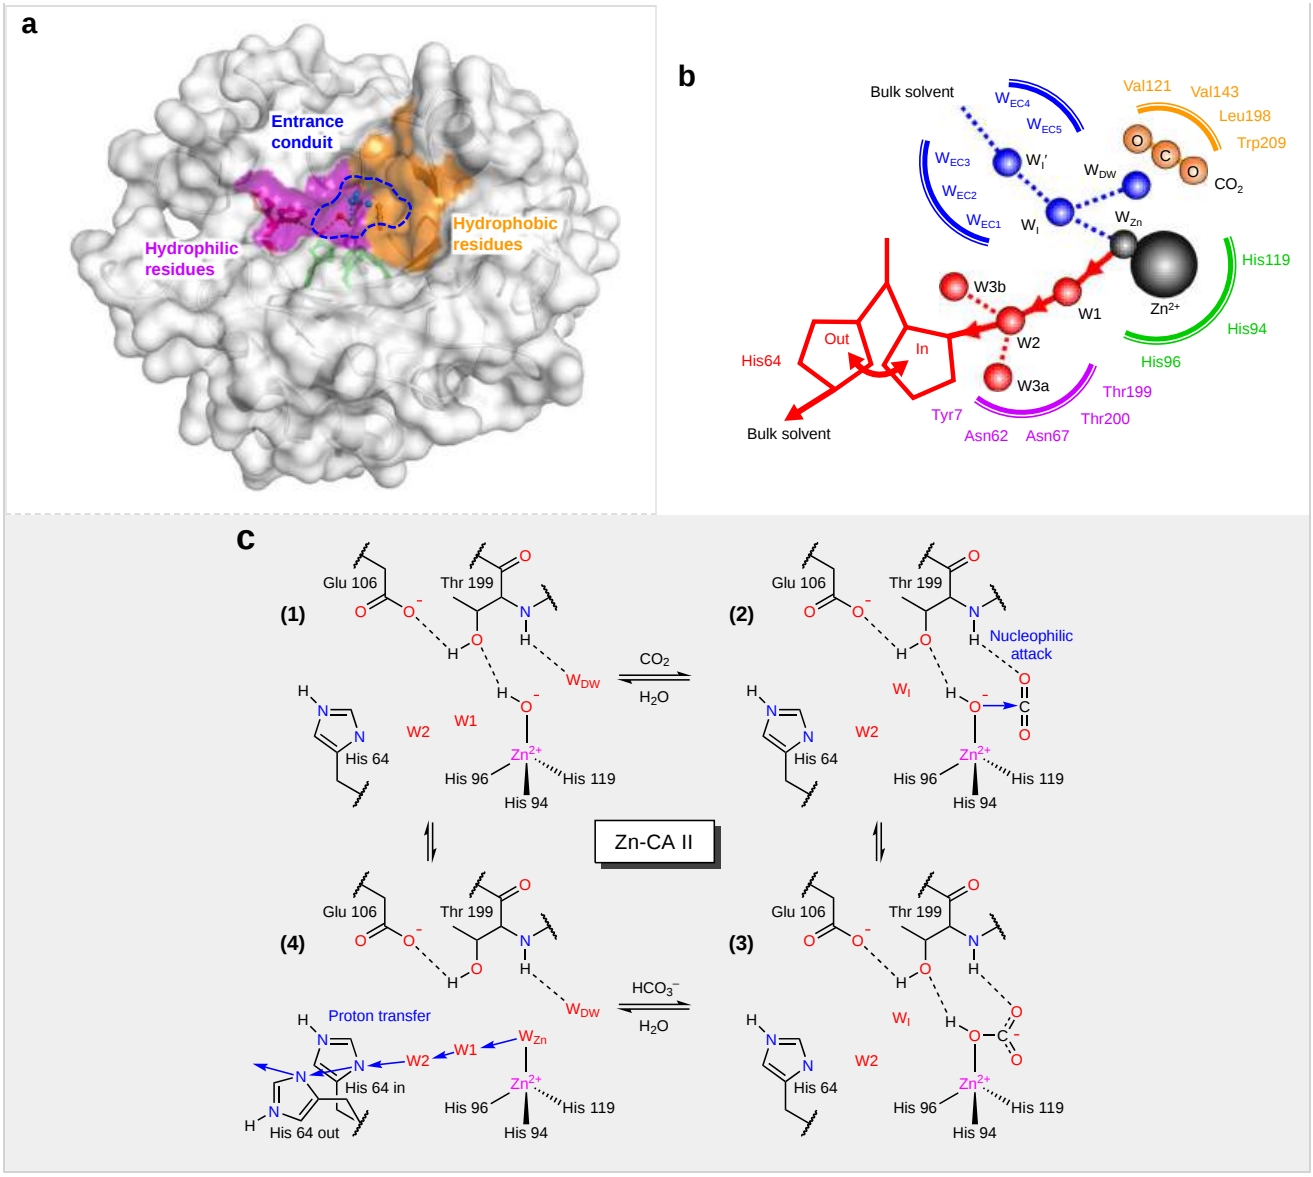

Figure 7: **Structure of native human carbonic anhydrase II (Zn-CA II) and its catalytic mechanism.** Kim, J.K., Lee, C., Lim, S.W. *et al.Nat Commun* **11**, 4557 (2020). https://doi.org/10.1038/s41467-020-18425-5. Creative Commons Attribution 4.0 International License, http://creativecommons.org/licenses/by/4.0/.

Panel a shows the active site consists of the zincbinding site, hydrophobic/hydrophilic regions, and the entrance conduit (EC).

Panel b shows the water networks in the active site that are responsible for the proton transfer (red) and substrate/product/water exchange (blue) during enzyme catalysis.

Panel c shows the forward reaction mechanism of Zn-CA II.

The active site itself lies at the bottom of a deep cavity (15 Å deep) in the protein, which is readily accessible to solvent

An interactive iCn3D model of human carbonic anhydrase II with bound bicarbonate and CO_2 (2VVB) is shown in Figure 8 below.

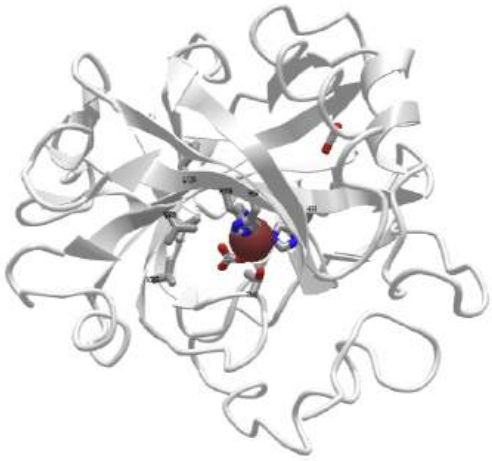

Figure 8: Human carbonic anhydrase II with bound bicarbonate and CO_2 (2VVB) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...ibgmgsm3UWhjX6

The active site residues shown in Figure 8 are labeled and shown as sticks. Bound CO_2 and HCO_3^- are also shown as sticks.

Question 7

This question addresses the Biomolecular Visualization Framework theme(s) Molecular Interactions (MI), Atomic Geometry (AG)

Using iCn3D to show the noncovalent interactions between bicarbonate, Zn, and the protein by using iCn3D. Measure the distance between the hydrogen-bonded atoms in HCO_3^- and Thr 199.

iCn3D instructions

Trackpad and Mouse Controls

•rotate: click and drag (mouse: left click and drag)

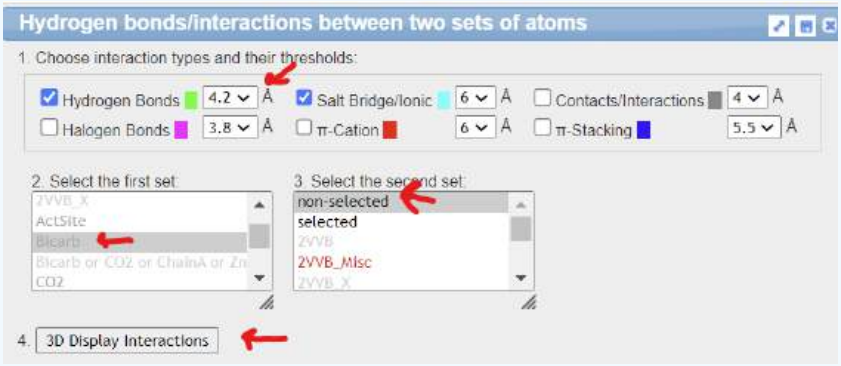
•zoom: pinch and spread (mouse: rotate the scroll wheel)

•translate: two-finger click and drag (mouse: right click and drag)

•Re-center: left click View from the top menu bar, then select “Center Selection”

•Note: ctrl-click on a PC = command-click on Mac; alt-click on PC = option click on Mac

1. Open the external link: https://structure.ncbi.nlm.nih.gov/i...ibgmgsm3UWhjX6
2. From the top menu bar, choose **Analysis**, **Interactions**
3. In the new popup window select the following prompts, then click **4. 3D Display interactions**



4. Close all but the main modeling window.

5. Zoom into the bicarbonate binding site. From the top menu bar, choose **Analysis**, **Distance**, **distance between 2 atoms**, and pick the two atoms (by holding down the Alt key or Option on a Mac) involved in the hydrogen bond between the bicarbonate and the amide

6. Rescale the label size by choosing **Analysis, Label Scale, 0.4**.

7. From the top menu bar choose **Select, Toggle highlights** to remove yellow and box highligting.

8. Save a PNG file by choosing

9. You can reload the PNG file directly into iCn3D by choosing **File**, **Open File**, i**Cn3D PNG image**

Answer

Question 8

What is a likely function of Val, Leu and Trp cluster in CAII (shown in Figures 7 and 8)?

Answer

Question x

What ligand would likely replace OH^- at low pH values? What would happen to the activity of the enzyme at lower pHs?

Answer

Question 9

From the mechanism shown in Figure 7, does bicarbonate coordinate the Zn^{2+} ion in a monodentate or bidentate manner?

Answer

Question 10

Write a verbal description of the mechanism of CAII based on Figure 7

Answer

Question 11

Why is a proton transfer path needed?

Answer

Question 12

Thr 199 plays a key role in the mechanism. State a reason for its importance in the reversible reaction.

Answer

Question 13

The dissociation constant K_D (or K_{is}) for bicarbonate binding to HCAII is about 77 mM. What kind of inhibitor might it be for the forward reaction?

Answer

Question 14

Using the equation below, at what ratio of CO_2/[HCO_3^-] would the rate for the forward reaction (CO_2 sequestration) be cut in half? Assume the V_M=1, K_M forward reaction is 1, [S] = 1 and K_{is} is 2 (a wide range of values are reported in the Brenda Database.

$$v_0 = \frac{V_M S}{K_M \left(1 + \frac{I}{Kis}\right) + S} \quad (1)$$

If you need some help, hover over -

Give me a hint!

Answer

Question 15

The rate-limiting step for human CA II is the dissociation of a proton from Zn^{2+}-bound water and not the removal of the resulting proton from the enzyme. What does that imply about the rate of removal of the proton from the enzyme?

Answer

It must be very fast, that is at diffusion-controlled limits through the H-bond channel.

Synthetic mimetics of the active site of CA have been made. These are heteromacrocycles (similar to the heme of hemoglobin) as shown in Figure 9 below.

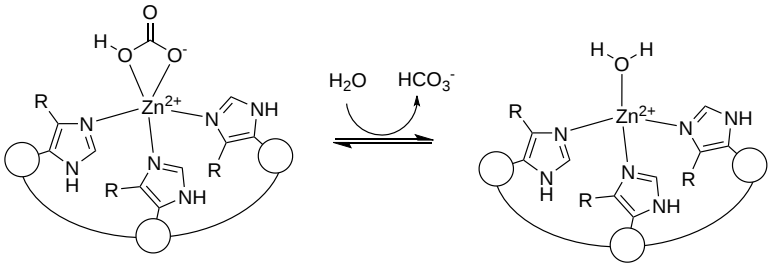


Figure 9:

The macrocycle mimetic has three imidazole groups coordinating zinc.

Question 16

The macrocycle mimetic has three imidazole groups coordinating zinc. Is the bicarbonate coordinated to the Zn^{2+} in a monodentate or bidentate fashion? From the "denticities" of the interactions of bicarbonate and Zn^{2+} for human CAII and the mimetic, which catalyst, CAII or the macrocycle would you expect to have a lower K_D for bicarbonate? How might this affect the rate-limiting step for the mimetic?

Answer

Question 17

What is the utility of having both CO_2 and HCO_3^- bind weakly to the enzyme

Answer

Carbonic anhydrase from Neisseria gonorrhea (*ng*CA)

Data from: Jo, B., Park, T., Park, H. *et al.* Engineering *de novo* disulfide bond in bacterial α-type carbonic anhydrase for thermostable carbon sequestration. *Sci Rep* **6**, 29322 (2016). https://doi.org/10.1038/srep29322. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/

Now that we understand the general chemistry, structure, and reaction mechanism of carbon anhydrase (at least the alpha human CAII form), let's explore efforts to engineer more thermostable variants. One example is the carbonic anhydrase from N. gonorrheas. This CA has been used as a target for mutagenesis to increase thermal stability of the enzyme, through the introduction of new disulfide bonds.

Even though only about 35% of the amino acids are identical, the overall structures are similar. This is illustrated in Figure 10 below.

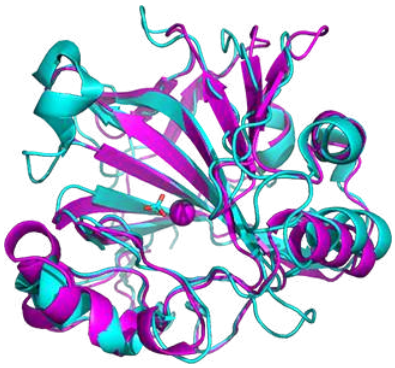

Figure 10: Alignment of the carbonic anhydrase from Neisseria gonorrhea (NG-CA) magenta,1KOQ) and human CA II (cyan, 2VVB)

The active site is mostly conserved compared to human CA II. The Zn^{2+} bound water has a pKa of around 6.5, compared to the value of 7.0 in human CA II. The hydrophobic patch (pocket) is similar, with Phe 93, Leu 153 and Tyr 72 in the NG-CA replacing Phe 95, Phe 176, Phe 70 in human CA II, respectively. The histidine ligands to Zn^{2+} are His92 (94), His94 (96), and His111 (119), where the numbers in parentheses represent Hu CA II. The proton removed from Zn^{2+} bound water is transferred to His 66 (64 in human CA II) and then to His 64.

The single disulfide bond between 181 and C28 is shown in Figure 1 below

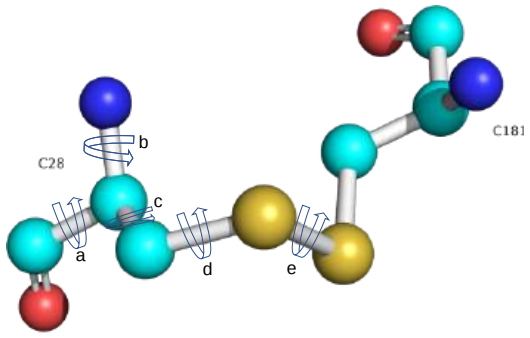

Figure 11: Single disulfide bond between 181 and C28 in wild type Carbonic anhydrase from Neisseria gonorrhea

Question 18

BIOMOLVIZ This question addresses the Biomolecular Visualization Framework theme(s) Atomic Geometry (AG)

Identify the correct torsion angles in Figure *x* above. Verbal definitions of torsional angles in a peptide chain are listed below. The successive atoms after the C_α leading away from the backbone atoms are X_β-X_γ-X_δ-X_ε (in that order). C is the backbone carbonyl C and N is the backbone nitrogen atom.

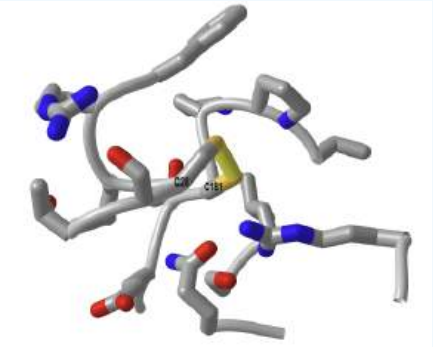
- phi (φ) is the angle of right-handed rotation around N-C_α bond. φ = 0 if the C_α-C bond is cis (eclipsed) to the C-N bond. Values range from -180 to 180 degrees.
- psi (ψ) is the angle of right-handed rotation around C_α -C bond. ψ = 0 if the C-N bond is cis (eclipsed) to the N-C_α bond. Values range from -180 to 180 degrees.
- chi_1 (χ_1) is the rotation around N-C_α-X_β-X_γ
- chi_2 (χ_2) is the rotation around C_α-X_β-X_γ-X_δ
- chi_3 (χ_3) is the rotation around X_β-X_γ-X_δ-X_ε

Answer

Question 19

BIOMOLVIZ This question addresses the Biomolecular Visualization Framework theme(s) Atomic Geometry (AG), Topology and Connectivity (TC)

Figure 12 below shows an interactive iCn3D model of the atoms within 4A of the disulfide bond in Carbonic anhydrase from Neisseria gonorrhea (1KOQ). Rotate the model to determine the approximate chi$_3$ (χ_3) dihedral angle. Hint: site down the S-S bond.



NCBI iCn3D Figure 12: Atoms within 4A of the disulfide bond in Carbonic anhydrase from Neisseria gonorrhea (1KOQ). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...nutjP6EL2PubRA

Answer

We mentioned previously that variants with higher thermal stability are likely to be more rigid and less flexible. Flexibility can be determined through analysis of molecular dynamic simulations and also by examining of the B factor values in PDB file. This number is a measure of the displacement of an atom from a mean The numbers in the last column in the file are called the temperature factors or B-factor. The B-factor describes the mean-square displacement, a measure of the displacement of an atom from an average value. If the atoms are more flexible, the electron density determined in x-ray structures is lower than if the atoms are more fixed, which gives high electron density.

To make stabilizing disulfide bonds, investigators found site chains close enough that when mutated to cysteines could potentially form disulfide bonds. In addition, they search for such residues in surface loops (without alpha and beta structure) which are inherently more flexible. Introducing disulfide bonds into the loop would stabilize it and make it more rigid. Table 2 below shows a description of the double cysteine CA variants in the study.

Variant designation	Position	Wild-type residues	Loop length	Sum of B-factors
T133C/D197C	133, 197	Thr/Asp	63	87.60
P56C/P156C	56, 156	Pro/Pro	99	80.82
N63C/P145C	63, 145	Asn/Pro	81	77.17

Table 2: **Description of the double cysteine CA variants in ngCA**

The locations of the side chair targeted for mutations to cysteine pairs are shown in Figure 13 below.

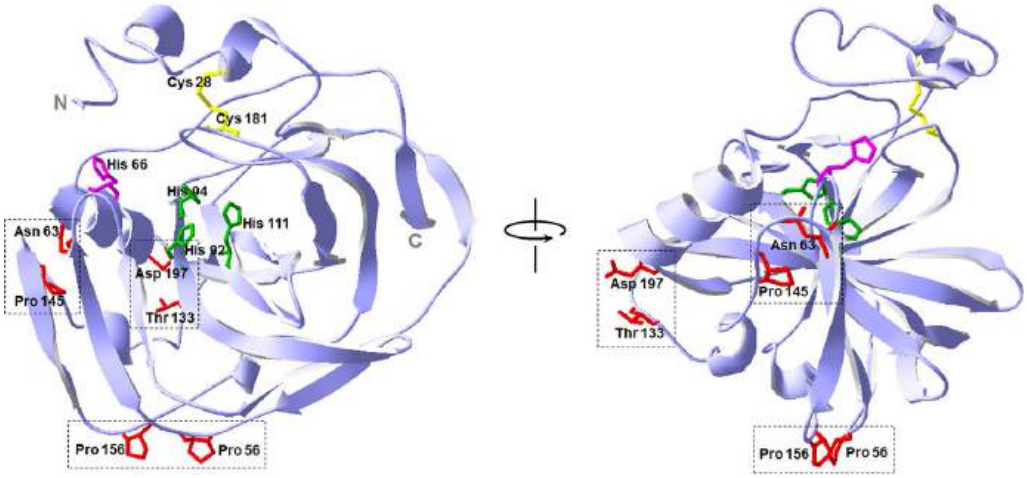


Figure 13**: 3D structure of *ng*CA and location of residue pairs for disulfide engineering**

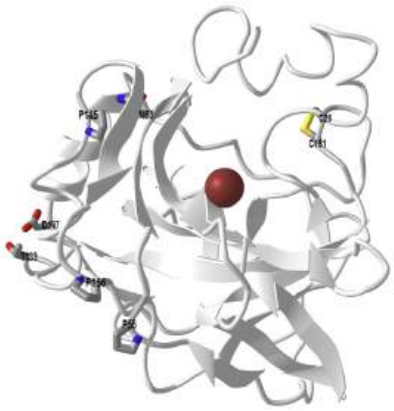
The zinc (not shown)-coordinating histidine residues in the catalytic active site are shown in green. The proton shuttle histidine residue is shown in magenta. The native disulfide bond is colored yellow.

An interactive iCn3D model of carbonic anhydrase from Neisseria gonorrhea (1KOQ) highlighting the 3 pairs of sidechains for mutations is shown in Figure 14 below.



NCBI iCn3D Figure 14: Carbonic anhydrase (Neisseria gonorrhea) with 3 paired side chains for engineered disulfide (1KOQ) (Copyright; author via source).

Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...KRP2tFJ1pV1FF6

The mutations were made and the wild-type proteins and three mutants were subjected to SDS-polyacrylamide gel electrophoresis (SDS-PAGE). The stained gels are shown in Figure 15 below.

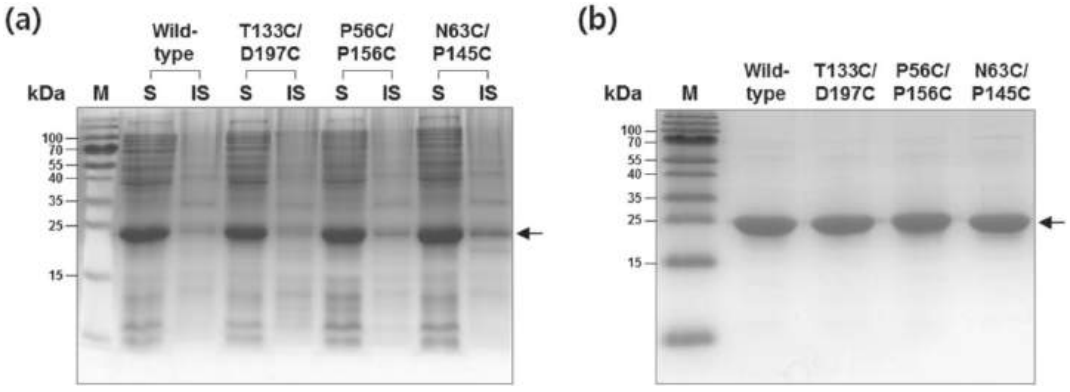


Figure 15: **Expression and purification of disulfide CA variants.**

Panel (**a**) shows the expression of the protein in transformed cells 25 °C after IPTG induction and fractionated into soluble and insoluble fractions. SHuffle strain, an engineered *E. coli* strain that promotes cytoplasmic disulfide bond formation, was used.

Panel (**b**) shows purification results. Each lane was loaded with 4 µg of each purified CA variant. The proteins were visualized with Coomassie blue staining after SDS-PAGE. The arrow indicates the position of the bands corresponding to *ng*CA variants. Lane: M, molecular weight marker; S, soluble fraction; IS, insoluble fraction.

? Question 20

a. Interpret the results of the PAGE gels in Figure 15 above

b. How pure were the proteins based on the PAGE gel result in Panel (b). Can you infer from the gel that the proteins folded correctly?

Answer

The investigators next determined if the expressed and purified wild-type and mutant proteins had the correct number of disulfide bonds. They did this by reacting the proteins in the absence and presence of dithiothreitol with DTNB or 5,5'-dithiobis(2-nitrobenzoic acid), also called Ellman's Reagent. Both structures are shown in Figure 16 below.

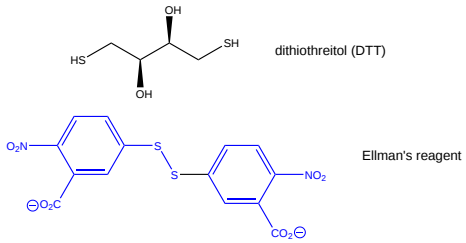

Figure 16: Structures of DTT and DTNB

DTT is a reducing agent that cleaves disulfide.

? Question 21

Draw a mechanism showing the reaction of a disulfide with DTT.

Answer

DTNB reacts with free sulfhydryls to form the 2-nitro-5-thiobenzoic acid anion leaving group that absorbs at 412 nm.

? Question 22

Draw a mechanism showing the reaction of free sulfhydryl (like Cys) with Ellman's reagent

Answer

The results of the reaction of the proteins with Ellmans's agent, in the presence and absence of DTT, are shown in Table 3 below.

CA variant	Free thiol/protein (mol/mol) [a]		Deduced no. S-S bonds
	−DTT	+DTT	
Wild-type	0.06 ± 0.02	1.80 ± 0.14	?
T133C/D197C	0.08 ± 0.02	3.79 ± 0.22	?
P56C/P156C	0.06 ± 0.03	3.89 ± 0.06	?
N63C/P145C	0.08 ± 0.03	3.75 ± 0.05	?

Table 3: Analysis of disulfides in CA using Ellman's reagent. [a]Numbers are represented in mean ± SD.

? Question 23

How many S-S would you deduce from the table are present in the wild-type and mutant enzymes? Did the correct disulfide bonds form? Explain your answers

Answer

Table 4 below shows the catalytic activities of the disulfide CA variants at 25 °C.

CA variant	CO_2 hydration activity			
	Relative esterase activity [a]	$k_{cat} \times 10^{-4}$ (s^{-1})	K_M (mM)	$k_{cat}/K_M \times 10^{-6}$($M^{-1}$ s^{-1})
Wild-type	1.00	1.44	14.2	1.01
T133C/D197C	1.49	1.97	16.7	1.18
P56C/P156C	1.03	1.44	16.9	0.85
N63C/P145C	0.55	0.27	17.3	0.16

Table 4: catalytic activities of the disulfide CA variants at 25 °C [a]The specific activity of the wild-type corresponds to 0.22 U/µmol-enzyme.

? Question 24

Why did the investigators conduct this experiment? Interpret the results

Answer

Now comes the big question: were the investigators able to engineer thermal stability into the carbonic anhydrase? Experimental results to show the thermostability of the disulfide CA mutants are shown in Figure 17 below.

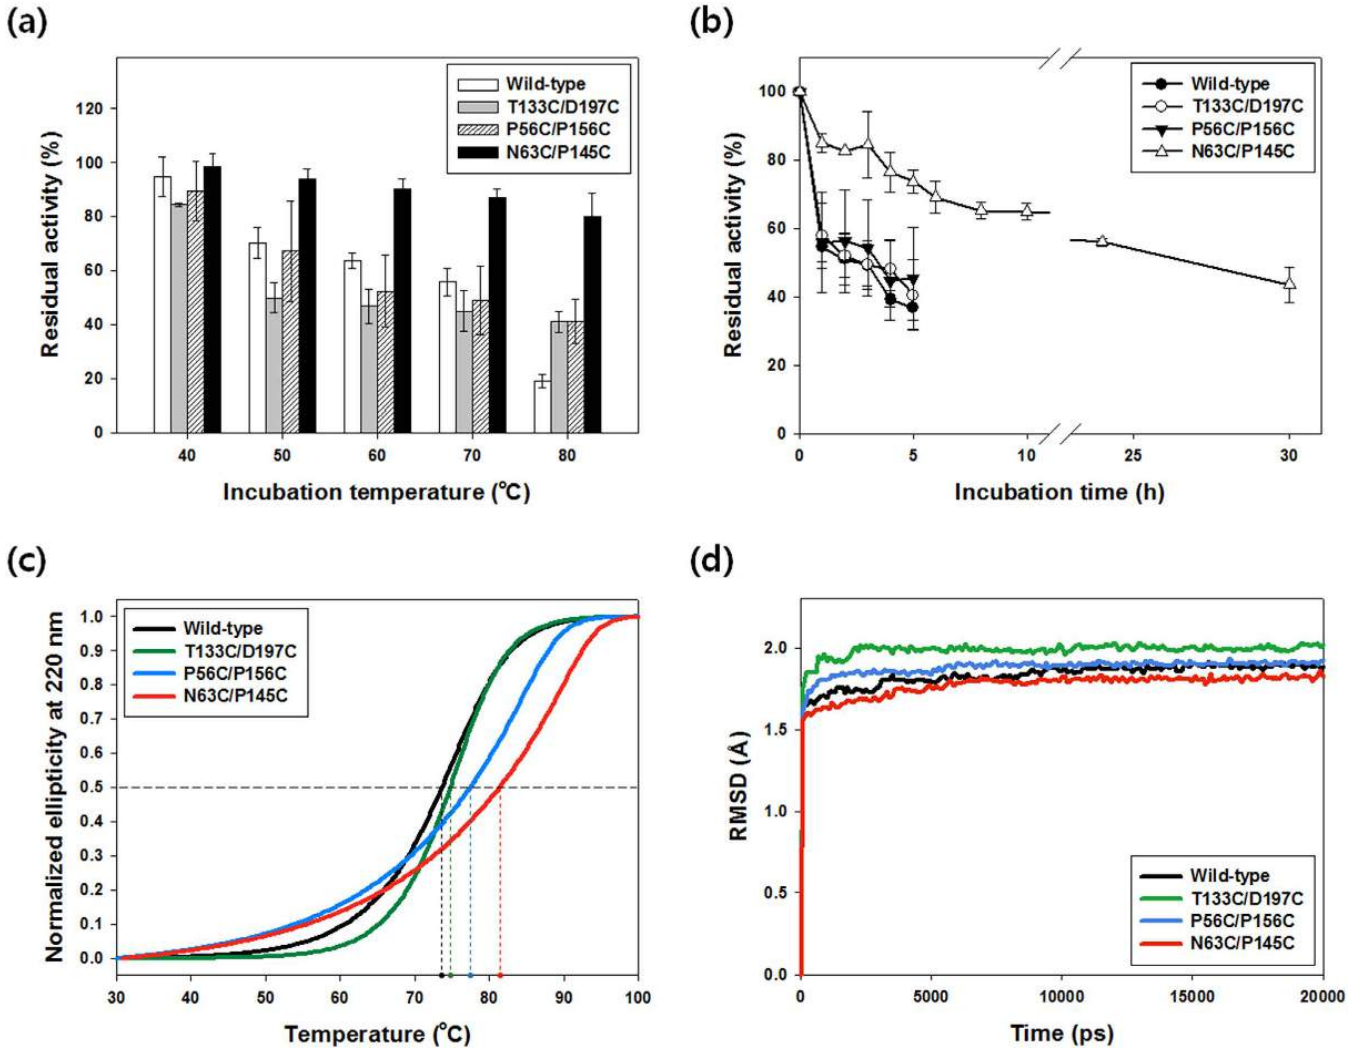

Figure 17: Thermostability of the disulfide CA variants

Panel (**a**) shows short-term kinetic stability. The enzyme solutions (40 µM) were incubated for 30 min at different temperatures, and the residual activities were measured by esterase activity assay. Activities of 100% correspond to untreated samples. Panel (**b**) shows long-term kinetic stability at 70 °C. The half-lives ($t_{1/2}$) of the CA variants were estimated by fitting the experimental data to an exponential decay curve. Each value represents the mean of at least three independent experiments, and the error bars represent the standard deviations.

? Question 25

Analyze the results in Panels (a) an (b). Which protein was most thermostable over the short (30 minute) and long (hours) incubating time at elevated temperatures?

Answer

Panel (c) shows heat-induced denaturation of disulfide CA variants. Temperature-dependent changes of the circular dichroism ellipticity were recorded at 220 nm on CD spectrometer. The denaturation curves were normalized to the fraction of unfolded protein. The horizontal dashed line indicates the point at which the fraction of unfolded protein is 0.5. The vertical dashed lines point to T_M values. Panel (**d**) shows the overall RMSD of disulfide variants from molecular dynamic simulations performed at 400 K for 20 ns.

Question 26

Analyze the results in Panel (c). What do changes in the CD helicity show? Which protein was most thermostable based on T_M values? Is the decrease in enzyme activity in panels (a) and (b) result from the denaturation of the protein?

Answer

Question 27

Analyze the molecular dynamics simulation results in Panel (d)

Answer

You may remember from both introductory chemistry and from Chapter 4.12, that you can calculate the thermodynamic parameters, $\Delta\mathbf{H}^o$ and $\Delta\mathbf{S}^o$ for N ↔D at room temperature from thermal denaturation curves using the van 't Hoff equation.

In this case, K_{eq} values can be calculated from thermal denaturation curves by monitoring change in CD signal at 220 nm, and applying this equation (also from Chapter 3.12).

$$K_{eq} = \frac{[D]_{eq}}{[N]_{eq}} = \frac{f_D}{f_N} = \frac{f_D}{1 - f_D} \tag{2}$$

From this, we can calculate ΔG^0.

$$\Delta G^0 = -R\,T \ln K_{eq} = -R\,T \ln\left[\frac{f_D}{1 - f_D}\right] \tag{3}$$

Knowing K_{eq}, ΔH^0, DS^0 can be calculated as shown below. A semi-log plot of $\ln K_{eq}$ vs 1/T is a straight line with a slope of - $\Delta H^0 R$ and a y-intercept of + $\Delta S^0/R$, where R is the ideal gas constant.

$$\begin{aligned} \Delta G^0 &= \Delta H^0 - T\Delta S^0 = -RT\ln K_{eq} \\ \ln K_{eq} &= -\frac{\Delta H^0 - T\Delta S^0}{RT} \\ \ln K_{eq} &= -\frac{\Delta H^0}{RT} + \frac{\Delta S^0}{R} \end{aligned} \tag{4}$$

The equation below shows that the derivative of equation (8) with respect to 1/T (i.e. the slope of equation 8 plotted as $\ln K_{eq}$ vs 1/T) is indeed $-\Delta H^0/R$. Equation (9) is the van 't Hoff equation, and the calculated value of the enthalpy change is termed the van 't Hoff enthalpy, $\Delta H^0 v_{Hoff}$.

$$\frac{d \ln K_{eq}}{d(1/T)} = -\frac{\Delta H^0}{R} = -\frac{\Delta H^0_{vHoff}}{R} \tag{5}$$

Using this method, the thermodynamic parameters for unfolding of the protein were calculated. The results are shown in Table 4 below.

CA variant	Melting temperature, T_M (°C)	Enthalpy change of unfolding, ΔH (kcal mol^{-1})	Entropy change of unfolding, ΔS (kcal mol^{-1} K^{-1})
Wild-type	73.6	48.8	0.141
T133C/D197C	74.7	52.8	0.153
P56C/P156C	77.4	35.1	0.091
N63C/P145C	81.4	30.0	0.085

Table 4: Thermodynamic parameters for protein unfolding for WT and mutant CAs

? Question 28

Which effects, enthalpy or entropy of unfolding, were associated with the increased thermal stability of the mutants compared to the wild-type protein. Remember were are considering the denaturation reaction, N ↔ D.

Answer

Finally, the enzymatic activity of the wild-type and mutants CAs (using a small ester substrate) were studied as a function of temperature. The relative activity of the wild-type and all 3 disulfide mutants are plotted as a function of temperature in the histogram graphs shown in Figure 18 below.

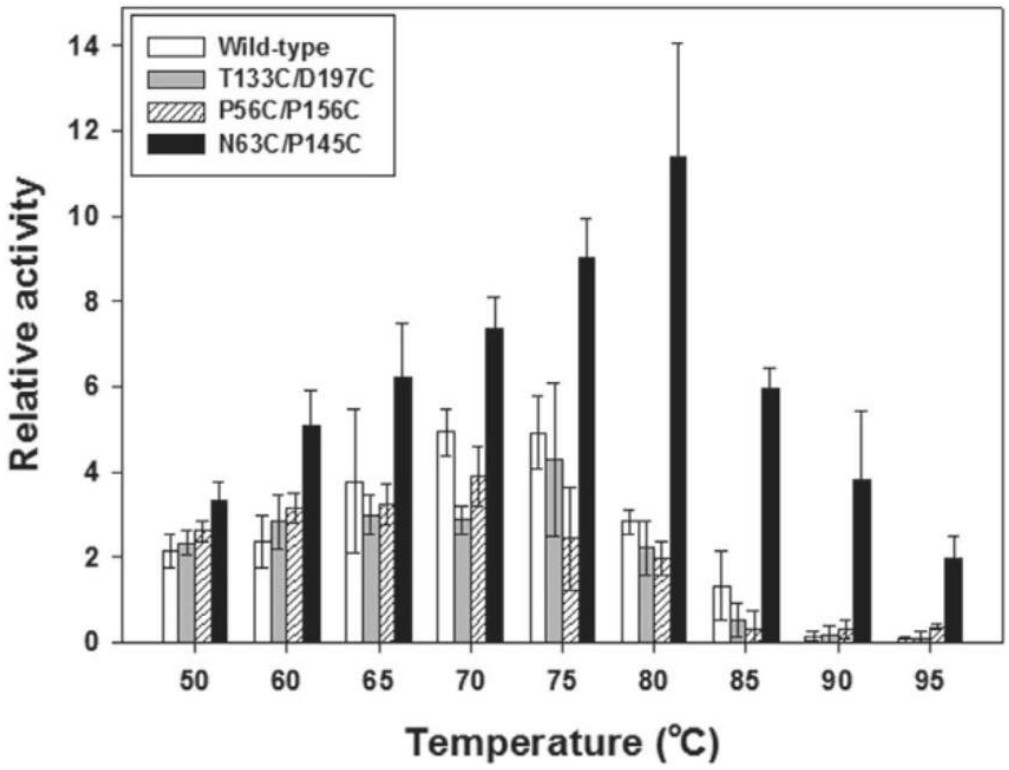

Figure 18: Effect of temperature on the activity of disulfide CA variants.

Esterase activities of disulfide variants were measured at each temperature and normalized to the activity of each enzyme at 25 °C. Each value represents the mean of three independent experiments, and the error bars represent the standard deviations. If you plotted the data as curves, you would get bell-shaped graphs.

? Question 29

Explain why the histogram plots (and line plots if they were drawn) are bell-shaped. Are the results in accordance with the previous results.

Answer

Disulfide engineering

Craig, D.B., Dombkowski, A.A. Disulfide by Design 2.0: a web-based tool for disulfide engineering in proteins. *BMC Bioinformatics* **14**, 346 (2013). https://doi.org/10.1186/1471-2105-14-346. Creative Commons Attribution License (http://creativecommons.org/licenses/by/2.0),

Several computational programs have been developed to determine amino acid pairs that could be mutated to high-temperature stabilizing disulfide bonds. The stabilizing effects appear largest when the disulfide bond is made within the largest (and most flexible) loops (between 25-75 residues). These loops also had the highest residue B-factors.

In selecting pairs to form engineered disulfide, not only proximity (distance) but also geometry (torsion angles) of the resulting disulfide bond are important. We saw this previously in the analysis of the energy of butane rotamers, as illustrated in Figure 19 below.

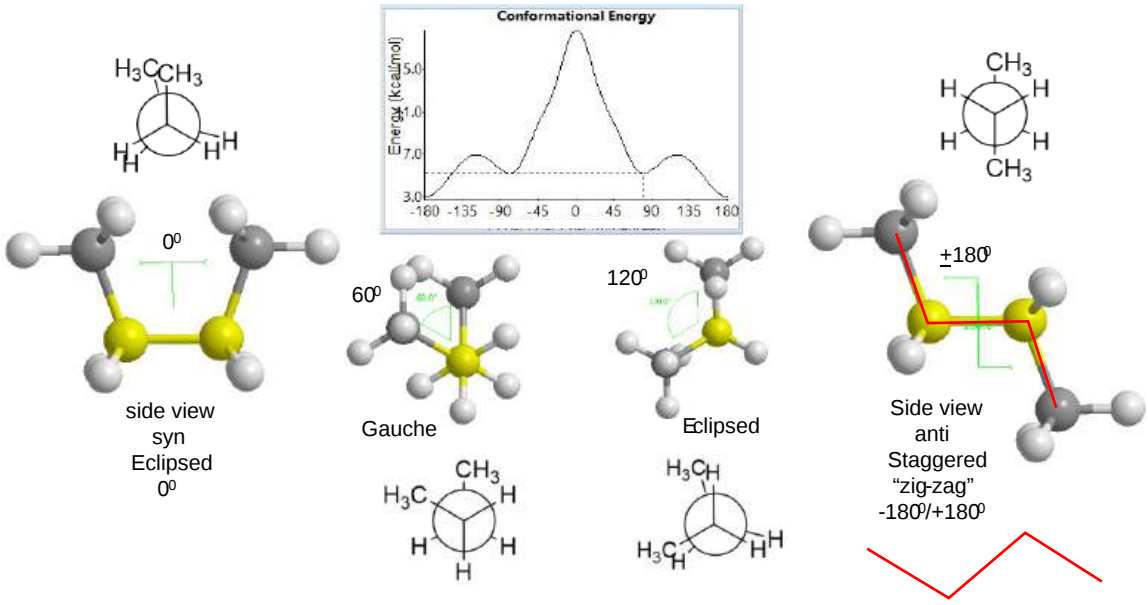

Figure 19: Newman projections for butane

Programs to determine amino acid pairs to mutate for disulfide bond formation test S-S bond torsional stability by determining the torsion angle χ_3 for the S-S bond. Evaluation of a database of many native proteins shows the χ_3 angle are centered in two major peaks at -87 and +97 degrees, as shown in Figure 20 below

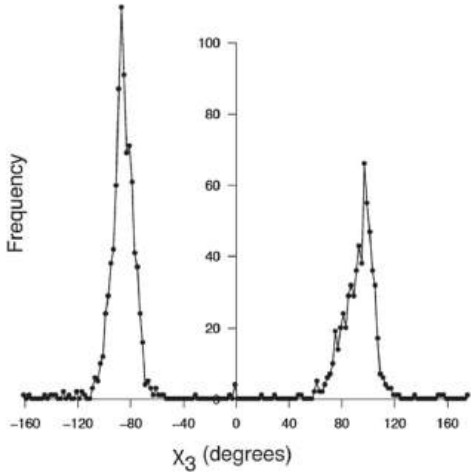

Figure 30: **Distribution of χ_3 torsion angles observed in 1505 native disulfide bonds found in 331 PDB protein structures.** Peaks occur at -87 and +97 degrees. Craig, D.B., Dombkowski, A.A. Disulfide by Design 2.0: a web-based tool for disulfide

? Question 4

Does your calculated value of χ_3 for the native disulfide in carbonic anhydrase from Neisseria gonorrhea follow the observed angles?

Answer

An empirical energy equation was developed to determine the E vs χ_3 dihedral angle for disulfide bonds (Craig, D.B., Dombkowski, A.A., ibid). It is shown below.

$$E(\chi_3) = 4.0\,[1 - \cos(1.957\,[\chi_3 + 87])] \tag{6}$$

A graph of the equation made with Excel is shown in Figure 21 below

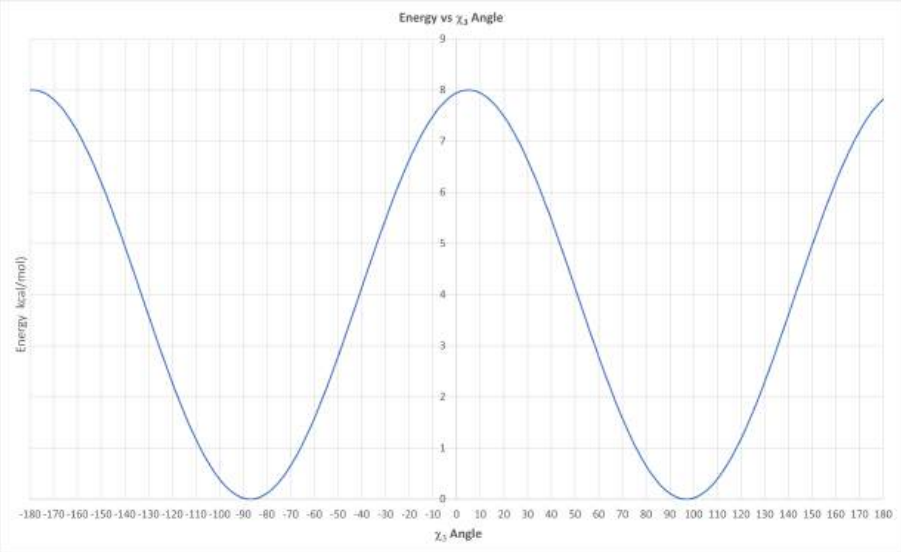

Figure 21: E vs χ_3 dihedral angle for disulfide bonds from empirical equation

Figure 22 shows the distribution of energy values in the 1505 native disulfide bonds using our updated function. The study by Craig and Dombkowski showed that almost all (90%) of disulfides in native proteins in the PDB have an energy < 2.2 kcal/mol, so this metric could be used to determine possible disulfide bond pairs created by mutagenesis.

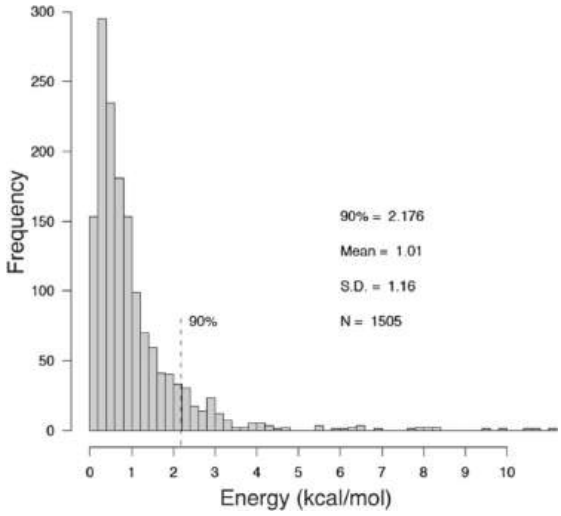

Figure 22: **Distribution of the disulfide bond energy calculated for 1505 native disulfide bonds in our survey set using the DbD2 energy function.** The mean value is 1.0 kcal/mol, and the 90th percentile is 2.2 kcal/mol. (Craig, D.B., Dombkowski, A.A., ibid)

? Question 31

You calculated the approximate value for χ_3 dihedral for the C28-C181 native disulfide bond form in Carbonic anhydrase from Neisseria gonorrhea using iCn3D in Question x above. Determine the approximate energy from the empirical function graph in Figure x above for that χ_3 dihedral. What percent of native disulfide bonds have that particular calculated energy in the 1505 native disulfide surveyed?

Answer

Yet there are other important parameters as well that would affect the energy of the disulfide bond in the protein. Figure 23 below shows a comparison of native residue B-factors in stabilizing and destabilizing engineered disulfide bonds

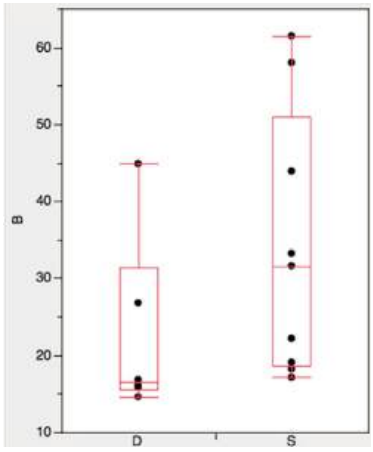

Figure 23: **Comparison of native residue B-factors in stabilizing and destabilizing engineered disulfide bonds.** The native structures associated with engineered disulfides previously reported as stabilizing (S) or destabilizing (D), based on experimental evidence, were analyzed with DbD2. The mean B-factor for residues involved in stabilizing disulfide bonds was 31.6 compared with 16.5 for those involved in destabilizing bonds, $P = 0.066$. (Craig, D.B., Dombkowski, A.A., ibid)

? Question 32

Which proteins were more stabilized by engineered disulfide, those with higher or low B factors.

Answer

Another Paper:

Prediction of disulfide bond engineering sites using a machine learning method

https://www.nature.com/articles/s41598-020-67230-z

Gao, X., Dong, X., Li, X. *et al.* Prediction of disulfide bond engineering sites using a machine learning method. *Sci Rep* **10**, 10330 (2020). https://doi.org/10.1038/s41598-020-67230-z.

The amount of data present in a single PDB file is very large, but it is nothing compared to the collective data in all PDB files. If only we could extract empirical rules from the collective PDB files that govern disulfide bond formation. It turns out we can with machine learning and artificial intelligence that can be used to develop and train predictive algorithms. Machine learning has been used to predict amino acid pairs for cysteine mutations to form engineered disulfide bonds. It recognizes 99% of natural disulfide bonds. residues. It uses these parameters:

- distances between the alpha-carbons and the beta-carbons of the bonded cysteine residues
- three torsion angles around the disulfide bonds (χ^1,χ^{ss},$\chi^{1'}$).

An example of one variable that helps define the stability of disulfide bonds is the distances between the Cα atoms for the disulfide-bonded cysteines, as shown in Figure 24 below.

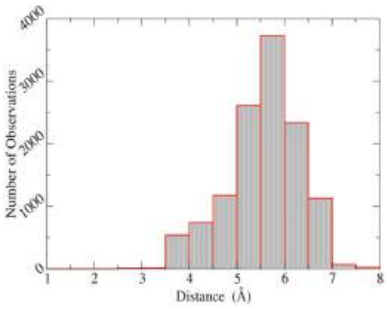

Figure 24: The histogram of distances between Cα atoms of disulfide-bonded cysteines.

The distances range from 3.0 Å and 7.5 Å. Knowing this would constrain the number of choices for paired amino acid side chains for mutagenesis to produce disulfide.

Machine learning can also be used to find other distance constraints to optimize mutagensis experiments. Figure 25 below shows a graph of 10 different distances and their relative importance in determining disulfide bond stability.

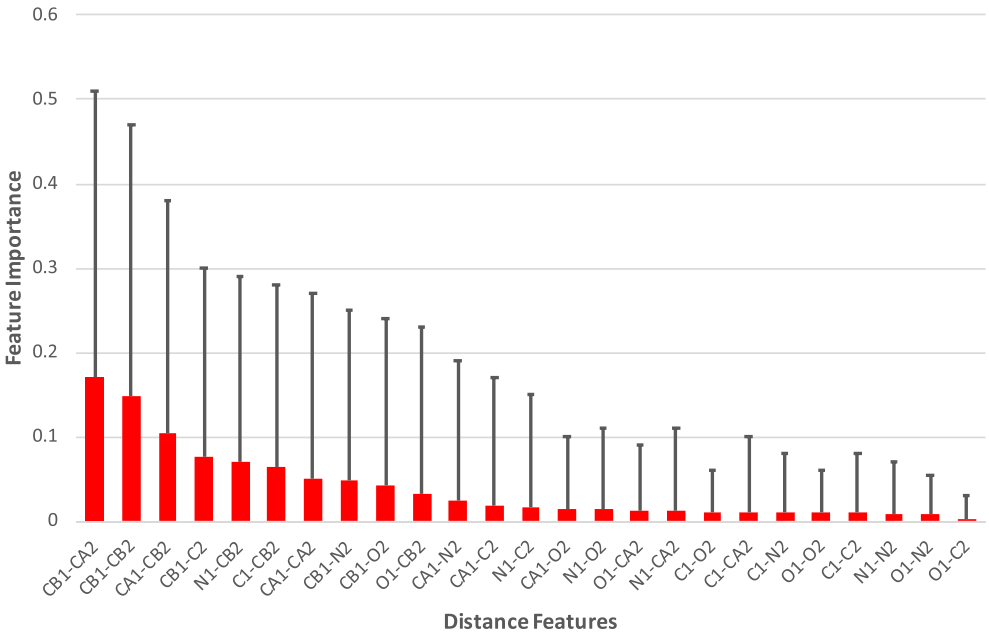

Figure 25: The relevance of the distance features to the classification outcome. Out of the 45 unique distances, 20 distances have negligible influence on the classification performance. The distances between Cβ and main-chain atoms of the pairing residue are important features in disulfide bond classifications.

An interactive iCn3D model of carbonic anhydrase from Neisseria gonorrhea (1KOQ) highlighting two pairs of amino acids identified by machine learning as candidates for mutations to disulfide-bonded cysteines is shown in Figure 26 below.

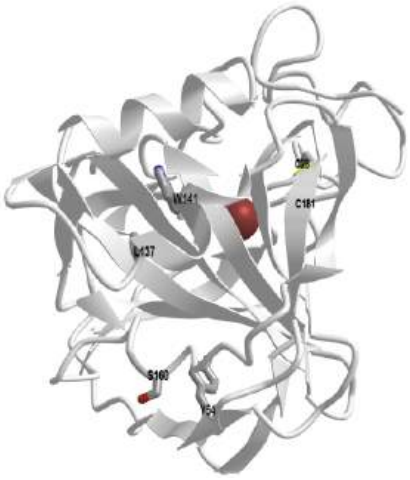

Figure 26: Carbonic anhydrase from Neisseria gonorrhea (1KOQ) highlighting two pairs of amino acids identified by machine learning as candidates for mutations to disulfide-bonded cysteines (Copyright; author via source). ? Question 33

This question addresses the Biomolecular Visualization Framework theme(s) Atomic Geometry (AG), Macromolecular Building Blocks (MB)

Using the data in Figure 25 and measurements made using the iCn3D model above (Figure 25) , determine which pair would be most likely engineered into a disulfide bond. Complete the table below with the distances you made using iCn3D.

iCn3D instructions: Open the external link and follow these instructions

Trackpad and Mouse Controls

•rotate: click and drag (mouse: left click and drag)

•zoom: pinch and spread (mouse: rotate the scroll wheel)

•translate: two-finger click and drag (mouse: right click and drag)

•Re-center: left click View from the top menu bar, then select “Center Selection”

•Note: ctrl-click on a PC = command-click on Mac; alt-click on PC = option click on Mac

Instructions

1. Zoom to clearly see the amino acid pair for distance measures
2. From the top menu bar, choose **Analysis**, **Distance**, distance between 2 atoms
3. Pick the appropriate 2 atoms for measure distance by holding down the Alt key and selecting both
4. Record the distances in the table below.

Mutation Pair	CB1-CA2 (Å)	CB1-CB2 (Å)	CA1-CB2 (Å)
1 (L137) - 2 (W141)			
1 (Y54) - 1 (S160)			

Answer

Global Challenges	Trauma Post Traumatic Stress Disorder and Health	Literature-Based Guided Assessment (LGA)
		

Needed background and learning goals

This LGA is designed for students at the end of a one or two-semester biochemistry class. Any additional background in molecular biology would be helpful. This LGA should help students to:

- describe the complexity and molecular signatures of trauma and PTSD
- analyze transcriptome data and their statistical analyses, a topic not often covered in one-semester biochemistry courses
- create and interpret molecular models to address the structure/function relationships of proteins
- analyze simplified signaling networks and their regulation

This LGA is not only a formative/summative assessment for students, but also is a tutorial on some aspects of signaling and analysis of the transcriptome. Data comes not from just one paper but many.

Introduction

Trauma (and Post Traumatic Stress Disorder (PTSD) arising from it) is a global issue. Many people who have experienced combat, lived in a war zone, witnessed violent events, experienced environmental catastrophes or severe accidents, or who have experienced physical, emotional, or sexual abuse experience some symptoms of PTSD. The young, including small children through young adults (the latter whom society, unfortunately, chooses to send to war) with developing brains are especially susceptible to PTSD. Even one traumatic event may trigger PTSD. From 15-43% of boys and girls have experienced at least one traumatic event. In the U.S., Latinos, African Americans, and Indigenous peoples have higher rates than whites.

Of those boys and girls, 3-15% of girls and 1-6% of boys will likely develop PTSD. Repetitive trauma (such as emotional, sexual, and physical abuse) in children also increases the rates. Girls have a higher rate of PTSD after experiencing trauma. PTSD rates as high as 69-85% have been reported for adults who experienced sexual/physical abuse as children. In those who have experienced war, PTSD has historically been called by different names including soldier's heart, shell shock, and war neurosis. It is not a weakness of character that causes some to get PTSD. Rather it is a a physical, neurological, emotional, and behavioral outcome in some people who have been exposed to events people should never experience.

The Diagnostic and Statistical Manual of Mental Disorders (DSM-5) of the American Psychiatric Association states that PTSD is defined by four symptoms, including re-experiencing (flashbacks), dissociation, avoidance, hyperarousal and hypervigilance, and negative alterations in mood and cognition. Other common features include recurring nightmares and sleep disturbance. Seemingly innocuous clues such as sights and smells can trigger people into flashbacks and other PTSD symptoms. Here are the diagnostic criteria for PTSD from the DSM-5.

Although around 90% of people in the US have had at least one exposure to a traumatizing event, the rate of PTSD in the general population is about 8% but if the trauma results are severe (as in combat veterans and those sexually assaulted), it can rise to 25-35%, or even higher in victims of torture or prolong childhood abuse. Not everyone exposed to such stresses gets diagnosable PTSD. The severity of the trauma, levels, and history of previous stresses, psychological and social support mechanisms, and other traits affect the likelihood of getting PTSD. Genetic factors play a role with 30-40% inheritability reported for women who are

twice as likely to get PTSD and have more severe and persistent symptoms. At a neurobiological level, the mental health effects must involve circuits in the brain that are involved in the learning and extinction of fear. Even mice display sex differences in fear conditioning. Brain areas involved in fear conditioning (prefrontal cortex, amygdala, and the hippocampus) and sex differences in those regions likely play a role in differential susceptibility to PTSD.

As we will see below, PTSD affects all body systems and not just the brain. Abused children typically have poorer general health in later life. In the Adverse Childhood Experiences (ACES) study, Felitti et al. documented that over 50% of 9508 respondents to a question given after a standard health care exam self-reported one episode and 25% more than 1 episode of childhood exposure in these categories: psychological, physical, or sexual abuse; violence against mother; or living with household members who were substance abusers, mentally ill or suicidal, or ever imprisoned. Those who had experienced such episodes in 4 or more categories had 4-12 times the risk for drug abuse, alcoholism, depression, and suicidality. In addition, they smoked at a 2-4 increased rate and had over 50 sexual partners. The study found a strong relationship between childhood exposure to the abuse and dysfunction listed above and the development of adult diseases (heart, lung, and liver diseases as well as cancer) which are among the leading causes of death in adulthood.

Figure 1 shows brain regions implicated in interpersonal violence (IPV), childhood trauma and sexual assault.

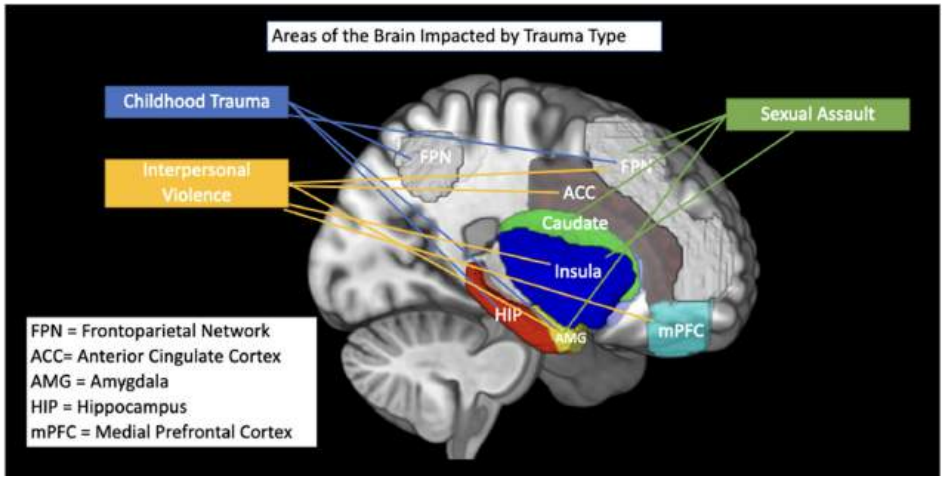

Figure 1: Brain regions implicated in IPV, childhood trauma, and sexual assault. Eder-Moreau Elizabeth et al., Neurobiological Alterations in Females With PTSD: A Systematic Review, Frontiers in Psychiatry, 13, 2022. https://www.frontiersin.org/articles...yt.2022.862476. **Creative Commons Attribution License (CC BY)**.

The general functions of each region are listed below.

- frontoparietal network - the center of cognitive control
- anterior cingulate cortex - cognitive functions as well as emotional expression, control of attention, and regulation of mood
- amygdala - formation of memories (especially emotion-associated ones) and emotion regulation
- hippocampus - involved in the regulation of learning and memory including its consolidation
- medial prefrontal cortex - integrates information from various brain regions and is involved in cognition, emotion, motivation, socialization
- Caudate nucleus - controls movement of the voluntary skeleton and is involved also in learning, memory, emotion and motivation

Brain scans show differences between people with and without a PTSD diagnosis. Changes in the cerebral cortex can be measured using a parameter called fractal dimension (FD) obtained from MRI brain scans. It is determined using multiple attributes that relate to shape complexity. Figure 1 below shows FD values in the brains of PTSD-negative to PTSD-positive first responders from the 9/11 attacks in New York City. PTSD diagnoses were based on interview and their evaluation using the DSM-IV symptom designation (reexperiencing symptoms, avoidance, hyperarousal, and negative life experiences).

Gray indicates no significant differences with statistically significant differences colored from dark blue (P = 0.05) to green/yellow (P ≈ 0.005) to dark red (P ≈ 0.0005).

A review of T and P values

If you compare two sets of data, and you wish to determine if the two means are equal, you can determine P and T values. For a t-test, you define two hypotheses:

- H_0 or the null hypothesis: the population means are equal ($\mu_1 = \mu_{2)}$ (the two population means are equal)
- H_1 alternative hypothesis: the population means are NOT equal ($\mu_1 \neq \mu_2$)

You then perform a t-test which determines the difference in the means compared to the variation in each sample. Effectively it is the difference expressed in standard error units. The higher the T value, the more likely the population means are different and you can reject the null hypothesis. A T value close to zero supports the null hypothesis that the means are the same. The figure below shows t-values ranging from 3-7.5 showing that the scans from PTSD victims are different than control (combat veterans without PTSD).

You can then calculate the p-value that corresponds to the calculated t-value. We mentioned p-values above. A p-value < 0.05 suggests that the null hypothesis is correct and the same means are the same with a high probability (> 95%). The number <0.05 suggests that the risk of concluding that the means are different is less than 5%. The p values represented in the colored regions in the figure above are all <0.5)

Two Sample t-test Calculator

Another technique, **magnetoencephalography (MEG)** has also been used to compare those with PTSD and controls. A flow of ions across a neural membrane produces a magnetic field, just as does the flow of electrons through a wire. If many neurons

(50,000 - 100,000) neurons are active, a magnetic field can be measured in that region. Changes in the summative magnetic field can be measured at the millisecond time scale. Hence MEG provides direct spatial and temporal measures of brain activity. This compares to functional MRI (fMRI) which is more indirect and involves measuring oxgyen levels from blood flow in brain regions where neurons are active when people think about their trauma or view traumatic images. MEG measurement can be measured when subjects are sleeping as well.

Figure 1 below shows differences in magnetoencephalography (MEG) in the resting state of controls (combat veterans without PTSD) and combat victims with PTSD.

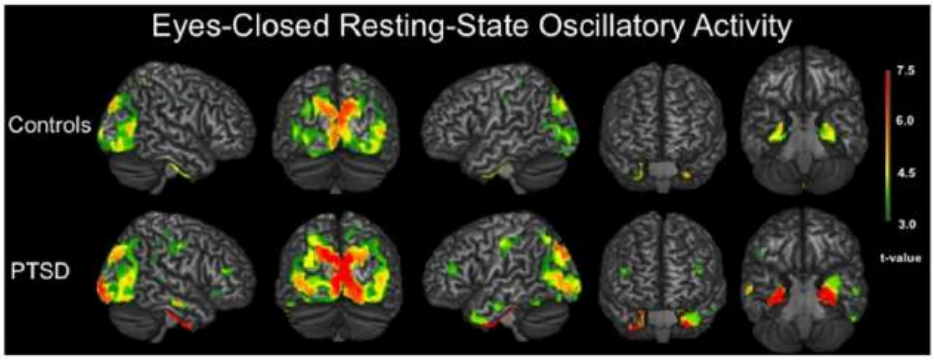

Figure 1: 3D Renditions showing rain regions with significant resting-state neuronal activity in compabte veterans without PTSD (top) and with PTSD (bottom row). Badura-Brack Amy S et al., Resting-State Neurophysiological Abnormalities in Posttraumatic Stress Disorder: A Magnetoencephalography Study. Frontiers in Human Neuroscience. 11, 12-17 (2017). https://www.frontiersin.org/articles...hum.2017.00205. **Creative Commons Attribution License (CC BY)**.

All group-level maps have been thresholded at ($p < 0.001$, corrected); a color scale bar showing respective *t*-values appears on the far right. Brain regions with significant activity in veterans without PTSD included bilateral occipital regions, inferior parietal cortices, postcentral gyri, posterior cingulate, parahippocampal gyri and other medial temporal areas. For veterans with PTSD, bilateral activity was observed in the primary motor and somatosensory cortices (i.e., precentral and postcentral gyri), superior parietal cortices, inferior parietal cortices, occipital regions, dorsolateral prefrontal cortices, inferior temporal sulci, posterior cingulate and bilateral medial temporal structures including parahippocampal gyri, hippocampi and the amygdala.

Figure 1 below shows the results of MEG brain scans documenting brain regions that differ in activity (red stronger in PTSD, blue stronger in control) in combat veterans.

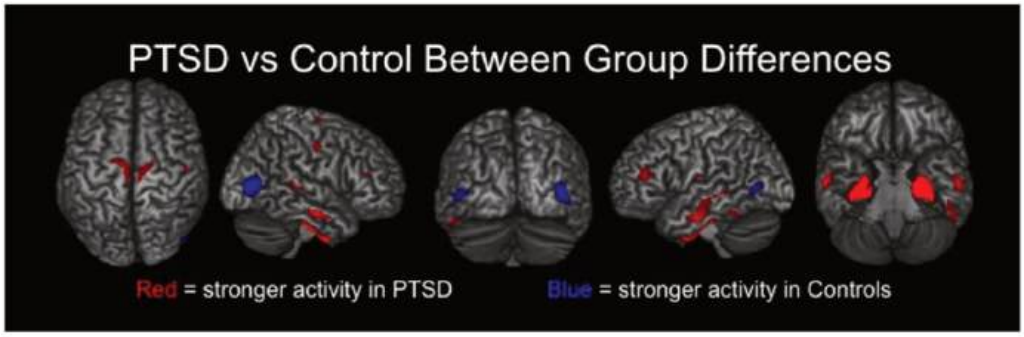

Figure 1: Group differences in resting-state neuronal activity between combat veterans with and without PTSD. Badura-Brack Amy S et al. Ibid.

In the top row, brain areas exhibiting significantly ($p < 0.01$, corrected) stronger activity in veterans with PTSD are shown in red, whereas regions with significantly weaker activity in these patients appear in blue. As shown, veterans with PTSD had stronger resting-state neuronal activity in bilateral medial temporal areas (e.g., amygdalae, parahippocampal), sensorimotor, temporal, and prefrontal regions, along with significantly weaker activity in left and right lateral occipital cortices.

These studies clearly show significant changes in neuronal activity in cohorts with PTSD compared to controls. However, as you will learn below, PTSD leads to widespread systemic changes outside of the nervous system in people with PTSD, with a plethora of biochemical changes and effects. We could focus this section on a specific documented neuronal change to excitatory glutamate

receptors such as the N-methyl-D-aspartate receptor (NMDAR) which is involved in synaptic plasticity critical learning and memory. We'll reserve that for another problem set and instead focus on the systemic changes seen in victims of PTSD to gain a broader understanding of its impact on people.

Effects of trauma on individuals - Soldiers with PTSD

Seid Muhie et al. Signatures of post-traumatic stress disorder in war-zone-exposed veteran and active-duty soldiers. Cell Reports - Medicine. 4, May 16, 2023. DOI:https://doi.org/10.1016/j.xcrm.2023.101045.

Something as complicated as trauma effects on an organism is bound to produce a large number of changes in key metabolites, transcripts, proteins and enzymes. Hence before we focus on one enzyme as an example, let's look at changes in whole systems within traumatized people. Several key studies have focused on active duty and veteran US soldiers with diagnoses of PTSD from their experiences in active combat in Iraq and Afghanistan. There have been large-scale PTSD genome-wide association studies (GWAS). In addition, the study by Muhie et used more defined cohorts and assessment measures:

- The Systems Biology Consortium (SBC) - 340 **veterans** (300 males and 40 females)
- Fort Campbell Cohort (FCC) cohorts - 180 **active-duty** service members (159 males and 21 females); 26 followed 13 month
- All were exposed in PTSD A defined by the military as follows: The person was exposed to: death, threatened death, actual or threatened serious injury, or actual or threatened sexual violence, in the following way(s): Direct exposure. Witnessing the trauma. Learning that the trauma happened to a close relative or close friend.)
- Clinician-Administered PTSD Scale (CAPS)

They analyzed

- whole blood, plasma, serum, buffy-coats (white blood cells)
- 1,305 proteins were assayed in serum samples
- DNA methylation (focusing on *cis*-regulatory sites, probes for DNA within 1,500 bp of the promoter regions)

Changes in gene expression (and other types of -omics data) are often measured using microchips to measure genes, transcripts, and proteins in samples. The processed data is usually color-coded along the visible spectra. This offers a visual impression of whether the expression is increased (red, orange, or pink) or decreased (violet, blue, or green). This visual data can be misleading if changes are expressed on a linear scale. Let's say the expression of a **control (C)** and **sample (S)** are determined and the ratio of S/C is calculated. From a mathematical sense, a linear scale has a potential flaw.

- If the expression of S is doubled with respect to C, then x = S/C =2, a +1 increase in the "signal"
- If the expression of S is halved with respect to C, then x = S/C = 0.5, a -1/2 decrease in the"signal".

We could "normalize" the data and results by using the $\log_{10}(x)$. If expression increased 10 fold, x= S/C=10, and $\log_{10}(10) = +1$. If it decreased 10 fold, then x= S/C=0.1, and $\log_{10}(0.1) = -1$. This gives up and down expression values of equal "visual" weight for the same fold-change in expression.

To better cover changes around the 2-fold increases/decreases (halved) range, $\log_2(x)$ is used instead. This gives a bigger visual change in the calculated expression data, as shown in the table below. A doubling of expression now gives a $\log_2(2) = +1$, the same number as a 10-fold increase gives if expressed as $\log_{10}(10) = +1$

doubling or 2x increase ↑	10-fold increase ↑	halving or 0.5 decrease ↓	10 fold decrease ↓
$\log_2(2) = 1$	$\log_2(10) = 3.3$	$\log_2(0.5) = -1$	$\log_2(0.1) = -3.3$

From the analysis, Muhie et al. found that several major pathways are altered in traumatized soldiers. Figure 1 below shows multi-omics (metabolites, proteins, mRNA, microRNA, and DNA methylation) changes in two major sets of pathways, inflammatory responses/oxidative stress (A, top) and angiogenesis (growth of new blood vessels/epithelial cell dysfunction (B, bottom).

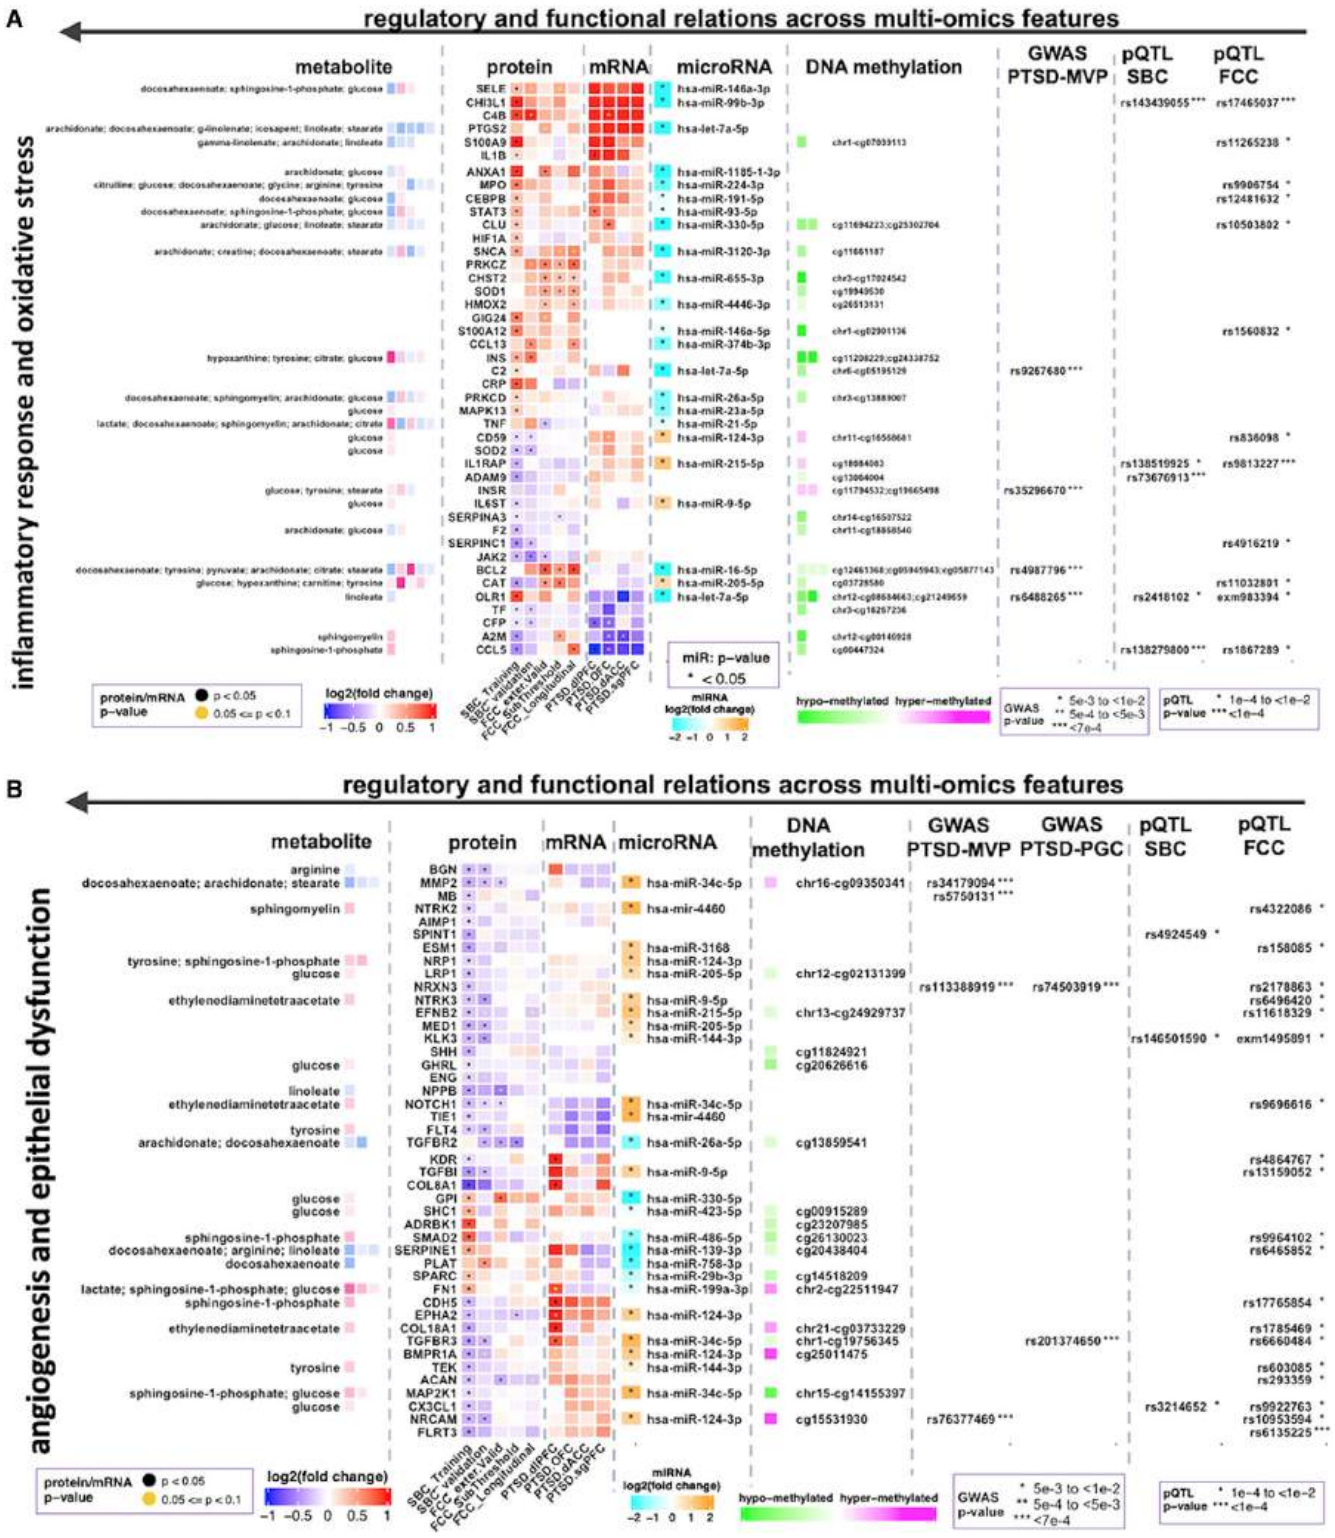

Figure 1: Integrated multi-omics showing regulatory and functional relations (horizontally from right to left) across genetic variants, epigenetic marks, microRNAs, mRNAs proteins, and metabolites. Seid Muhie et al. Signatures of post-traumatic stress disorder in war-zone-exposed veteran and active-duty soldiers. Cell Reports - Medicine. 4, May 16, 2023. DOI:https://doi.org/10.1016/j.xcrm.2023.101045. Creative Commons Attribution (CC BY 4.0).

Panel (A and B) show differentially expressed proteins (DEPs) that were persistent across PTSD cohorts and associated with (A) activated inflammatory response or oxidative stress, (B) impaired angiogenesis, epithelial dysfunction, or cardiovascular

function were integrated with multi-omics datasets and compared across SBC Training (109/109 PTSD+/−), SBC Testing (43/39 PTSD+/−), FCC Validation (47/44 PTSD+/−), FCC Longitudinal (26/26 PTSD+/−), and FCC Subthreshold (68/44 PTSD subclinical/controls) cohorts. Vertical lanes of the protein heatmap correspond to the fold changes of each protein from each group of cohorts (as shown by the labels). SBC: Systems Biology Consortium (veteran cohort), FCC: Fort Campbell (active-duty) Cohort; for brain regions (postmortem mRNA brain data): dlPFC, dorsolateral pre-frontal cortex (PFC); ACC, anterior cingulate cortex (ACC); dACC, dorsal ACC; sgPFC, subgenual PFC; OFC, orbito-frontal cortex

? Exercise 1

Look at the changes in the protein and mRNA for inflammatory response and oxidative stress. Are these expression responses generally increased or decreased?

a. inflammatory response and oxidative stress - proteins

b. inflammatory response and oxidative stress - mRNA

c. angiogenesis and epithelial dysfunction - proteins

d. angiogenesis and epithelial dysfunction - mRNA

Answer

? Exercise 2

What happens to the expression of these genes? What is their function (find it at Uniprot)

a. CDH5

b. SOD2

c. CCL5

Answer

? Exercise 3

Answer these questions on micro-RNA expression.

a. In general compare the expression of mi-RNAs in inflammatory response/oxidative stress and in angiogenesis/epithelial dysfunction

b. Do a web search to find out the role of mi-RNAs 146a (in inflammatory response/oxidative stress).

c. Do a web search to find out the role of mi-RNA 32 (in angiogenesis and epithelial dysfunction).

Answer

The authors state that "Although PTSD has primarily been conceptualized as a brain disease, it is increasingly being recognized as a systemic condition affecting multiple physiological parts and associated with divergent chronic medical conditions. Thus, PTSD

is coming to be seen as a systemic disorder rather than as a purely psychological illness."

Serine/threonine-protein kinase Sgk1 Function

Let's focus on just one enzyme, **serum/glucocorticoid-regulated kinase 1(SGK1)**, also called **serine/threonine-protein kinase**1, that seems to play a significant role in many pathways that are affected by trauma. Let's try to interpret and understand data from several research papers that discuss the role of SGK1 in several signaling pathways. As a Ser/Thr protein kinase, SGK phosphorylates many protein substrates, some of which are protein kinases (to activate/inhibit them), enzymes other than kinases, and transcription factors, as shown in Figure 1 below.

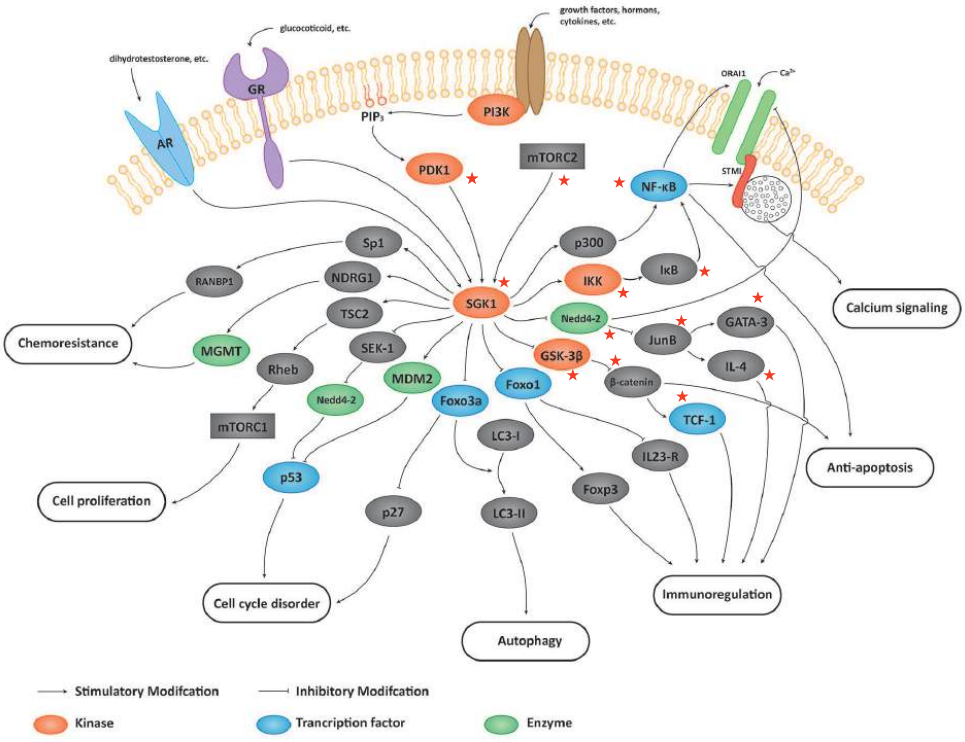

Figure 1: Signaling pathway of SGK1 in oncology. The prospect of serum and glucocorticoid-inducible kinase 1 (SGK1) in cancer therapy: a rising star. Ruizhe Zhu, Gang Yang, Zhe Cao, Kexin Shen, Lianfang Zheng, Jianchun Xiao, Lei You, and Taiping Zhang. Therapeutic Advances in Medical Oncology 2020 10.1177/1758835920940946. Creative Commons Non-Commercial CC BY-NC.

The ones we will discuss below have a red star (★) by them. SGK1 is activated by phosphorylation by two major kinases, PDK1★ and mTORC2★. We will discuss those later when we study the structure/function of the molecule in depth.

1. SGK1 regulates the immune system

The immune system is extremely complicated (for a detailed review see Chapter 5.4). Several major types of immune cells exist:

- Antigen-presenting cells - cells like macrophages, and dendritic and microglial cells in the brain that engulf foreign pathogens or cellular. In addition, virally infected and cancer cells have "tumor" antigens presented on their surfaces for recognition by the immune system.
- B cells - produce antibodies that target foreign extracellular or surface molecules of bacteria (for example).
- T cells - recognize virally-infected or cancer cells by binding to fragments of viral or tumor antigens presented on the cell surface. Two major types are **T Helper** cells that express a protein called CD4. These bind to cells like macrophages that express MHCII protein. Another set of effector T lymphocytes (for example T Cytotoxic, Natural Killer cells) express CD8. These cells express MHCI proteins and kill virus-infected cells and produce antiviral cytokine. Other CD8 cells suppress the immune response.

Signaling among these cells occurs through the release of cytokines from T cells that amplify or dampen immune cell response.

SGK1, downstream of mTORC2 is a regulator of T Helper or T_H cells. There are two major types:

- T_H1: generally produces proinflammatory cytokines (for example interleukin-2 or **IL2**, **interferon-γ**, and tumor necrosis factor β or TNF-β) that are especially involved in immune responses to intracellular pathogens (viruses and bacteria) and in prolonged autoimmune reactions against self (such as in Type I diabetes and MS).
- T_H2: generally produces "antiinflammatory" cytokines such as **IL 4**, **5**, and **13** involved in antibody responses to some extracellular parasites and allergic responses to "persistent" antigens (such as in asthma, dermatitis, etc.) and **IL 10**, which damps down the immune response, in part by turning down expression of T_H1 cytokines.

Each also regulates the other to fine-tune the immune response. They derive from a common precursor T_Hp or T_H0 cell which differentiates into the two"poles" (T cell polarization), T_H1 and T_H2, each with their own phenotype.

To test the role of SGK1 in Tcell activation, the gene was deleted to produce *Sgk1*$^{-/-}$' progeny. Under different "polarizing" sets of conditions, these cells can differentiate from a precursor T_H0 cell into either T_H1 or T_H2 cells. In the absence of polarizing cytokines, T cells from differentiated into TH1 cells.

? Exercise 4

Appropriate factors were added to T_H0 wild-type (WT) or **T-Sgk1**$^{-/-}$ cells to differentiate into the cells shown in the table below. The data is approximate based on graphs in the paper.

Cell Type	**T_H0 WT**	**T_H0 T-Sgk1$^{-/-}$**	**T_H1 WT**	**T_H1 T-Sgk1$^{-/-}$**	**T_H2 WT**	**T_H2 T-Sgk1$^{-/-}$**
IL-4 (ng/mL)	ND	ND	0.20	ND	1.8	0.55

Heikamp, E., Patel, C., Collins, S. *et al.* The AGC kinase SGK1 regulates T_H1 and T_H2 differentiation downstream of the mTORC2 complex. *Nat Immunol* **15**, 457–464 (2014). https://doi.org/10.1038/ni.2867

What conclusions can you draw from these data?

Answer

? Exercise 5

In another set of experiments, the same cell types (stimulated as above) were stained for intracellular **IFN-γ** in CD4+ T cells in the presence of an inhibitor of protein transport across the membrane. The results show that **all the T cells** had substantial IFN-γ expression.

a. Why did they include an inhibitor of protein transport in their experiments.

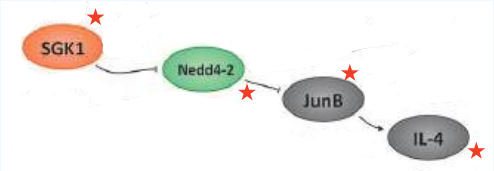
b. How do these results compare to the expression of IL-4 above

c. In a mouse model of asthma, an allergic disease, what might you expect if SGK1 was not present?

Answer

Exercise 6

How does SGK1 affect T_H2 cells and the eventual production of IL-4? It appears to do so through Nedd4 and Jun Bas illustrated in the partial signaling pathway below.



a. Is Nedd4 an enzyme? A kinase? Both?

b. Does SGK1 inhibit or activate Nedd? How specifically?

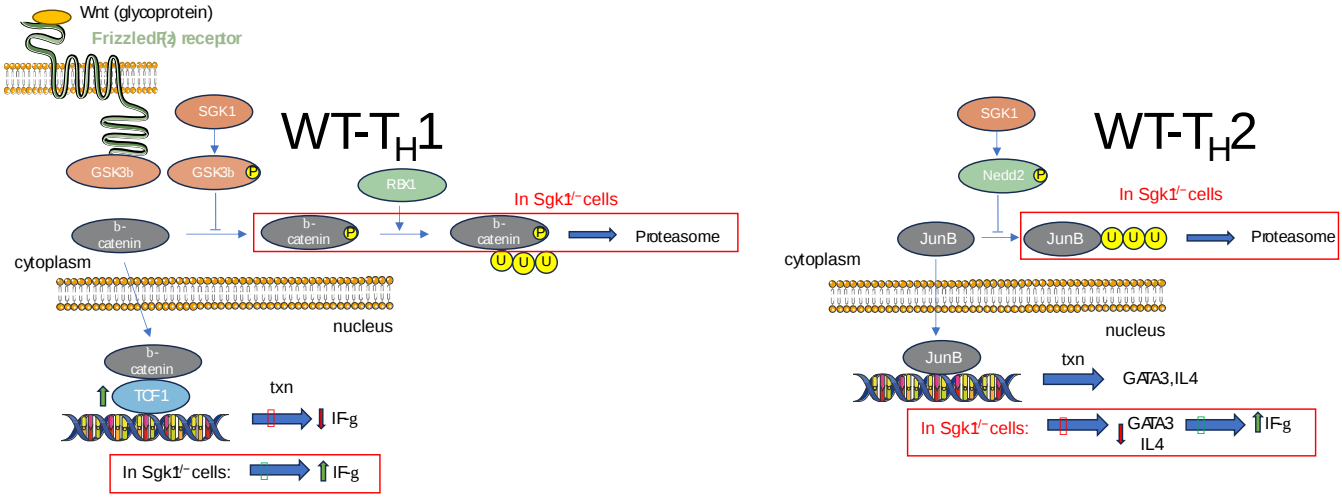
c. Search Uniprot to find out what type of enzyme human Nedd4 is.

d. What is the net effect of SGK1 on Jun B, a transcription factor, and IL-4 concentrations?

e. Jun B is higher in WT T cells cultured to produce T_H2 than in T_H1 cells. Compare Jun B levels in SGK1-deficient T cells under both T_H1- and T_H2-polarizing conditions.

Answer

Here is an expanded pathway showing signaling effects in wildtype and *Sgk1*$^{-/-}$ cells.



Exercise 7

Summarize how the lack of SGK1 causes β-catenin and JunB degradation.

Answer

From these brief questions, it should be clear that the effects of changing the expression of just one protein (SGK1 in this case) are really complicated. SGK1 is involved in:

- the control of protein synthesis and proliferation in endothelial cells (and hence the vasculature)
- major depressive disorders
- development and progression of tumors
- promotion of energy production in detached cells
- skeletal muscle homeostasis
- stress-induced cognitive impairment and PTSD
- symptoms in Parkinson's disease animal models

So let's look at one case of SGK1's involvement in brain function.

---

2. SGK1 affects brain glial cells in neurodegenerative diseases

The protein is widely expressed in the brain with increasing levels for a variety of brain diseases. Its name derives from the fact that its expression increased in rat tumor cells with the addition of serum and glucocorticoids. Parkinson's disease (PD) is associated with the death of dopaminergic neurons (DA). Damaged neurons, extracellular protein aggregates, and microbial agents are removed by microglial cells, which are a specialized type of macrophage in the central nervous system. For instance, they can initiate cell death in damaged cells.

SGK1 is elevated in the midbrain and increased expression leads to death of DA neurons. The increased expression appears to occur in the microglial cell. Hence the inhibition of microglial cell SGK1 would be a useful treatment in PD and other brain neurodegenerative diseases.

The inflammatory activities of microglial arise from the activation of a key transcription factor, NFκB, whose activation leads to the expression of inflammatory cytokines and the inflammasome. NFκB is perhaps the key regulator of the inflammatory response, which as shown above is elevated in PTSD. It is a dimer of two proteins P50/P65 (also called NFkB1/RelA), which binds to promoter regions for inflammatory genes in the nucleus. Cytoplasmic NFkB1 is inactive when bound to an inhibitor, IKB, which keeps it from translocating to the nucleus. Inflammatory signals lead to the phosphorylation of IKB by IkB kinase (or IKK, a dimer of IKKα and IKKβ), leading to the dissociation of IKB and the translocation of the NFκB into the nucleus and subsequent expression of inflammatory cytokines.

SGK1 increases NFκB signaling and the deleterious inflammatory response in glial cells as illustrated in Figure 1 below. For simplicity, both NFκB and IKKβ are shown as monomers

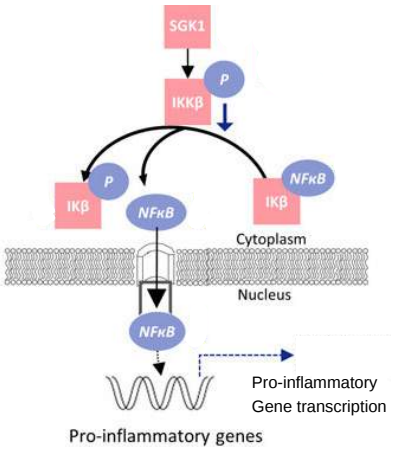


Figure 1: Modified from Kwon et al. **SGK1 inhibition in glia ameliorates pathologies and symptoms in Parkinson disease animal models.** EMBO Molecular Medicine, 2021. https://doi.org/10.15252/emmm.202013076. **Published under the terms of the CC BY 4.0 license**

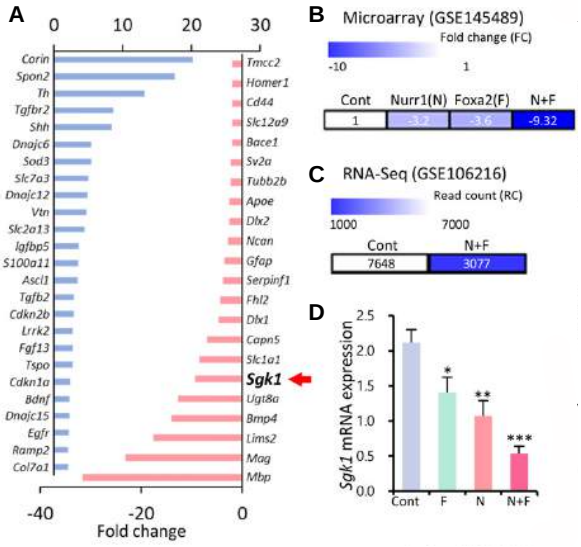
? Exercise 8

From the simplified pathway diagram above, how does SGK1 promote inflammation?

Answer

Hence inflammation can be decreased if SGK1 can be negatively regulated at the transcription or post-transcriptional levels. In glial cells, two other proteins, Nurr1 (N) and Foxa2 (F), are involved in the regulation of SGK1 transcription. To test their effects, glial cells were transduced (genes added) with the N and F genes, and in a mock control without them. The results are shown in the figure below.



Panel A shows that Sgk1 is significantly downregulated (drop in expression, red arrow, red rectangle) in the glial cells transduced with Nurr1 (N) and Foxa2 (F).

Panel B and Panel show fold change (FC) or actual level changes (red count).

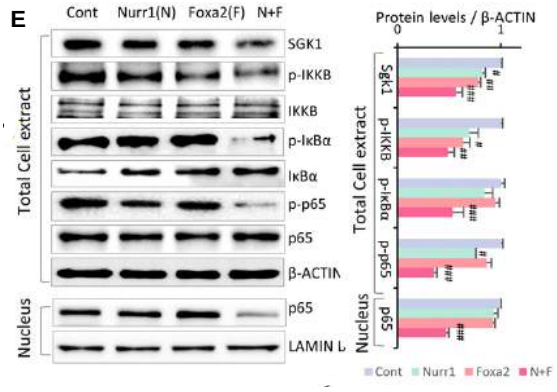
Panel D shows RT-PCR mRNA expression levels.

? Exercise 9

What are the effects of the addition of the gene for N, F, and N+F compared to the sham control?

Answer

Panel E below shows a Western blot of PAGE gels showing protein levels and graphs of the Western blot data showing quantitative values. P65 is one of the subunits of NFKB. β-actin gene is a "housing-keeping" gene whose levels are not expected to change.



Exercise 10

What happens to the concentration of these proteins on the treatment of cells with N+F? The small red letter p indicates that a phospho group is attached as a posttranslational modification. (p65 is the name of that protein and the p indicates no particular phosphorylation state.) Interpret the results.

SGK1	p-IKKB	p-IKBα	p65 (NFKB) total cell	p65 (NFKB) nucleus	β-actin
?	?	?	?	?	?

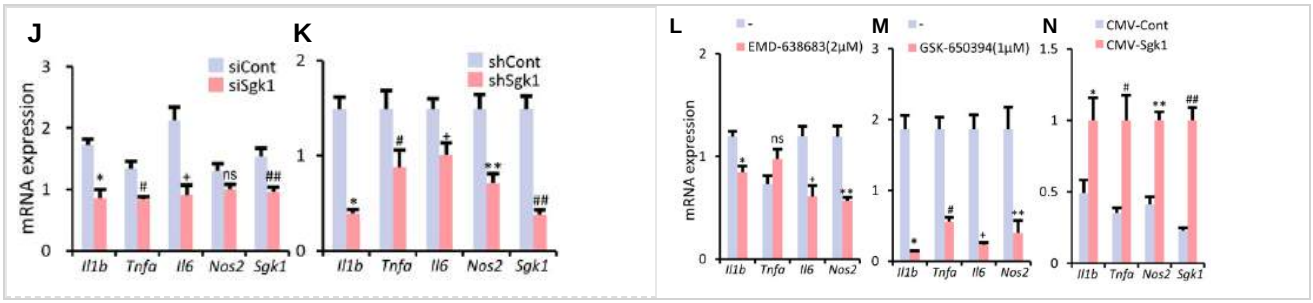
Answer

See the table below.

SGK1	p-IKKB	p-IKBα	p65 (NFKB) total cell	p65 (NFKB) nucleus	β-actin
decreases	decreases	decreased	constant	decreased	constant

The N + F-mediated downregulation of NFκB signaling is attained by inhibiting IκB phosphorylation (E) and thus blocking the release of NFκB from the NFκB-IκB inhibitory complex

What happens to the actual expression of inflammatory cytokines if inhibitory RNA (that block SGK1 translation by binding to SGK1 mRNA) are added to cells or if an "extra" gene is added to overexpress SGK1? The results for inhibition are shown in Panels J-M and for overexpression in N below.



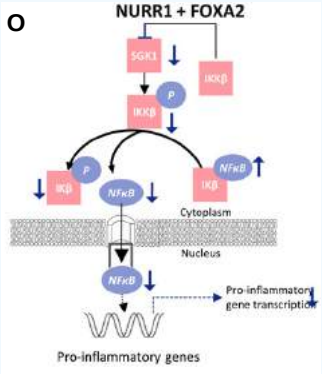
Exercise 11

Interpret the results

Answer

Exercise 12

The figure below summarizes the effect of NURR1, FOXA2 on SGK1-mediated expression of cytokines in glial cells. Summarize these effects in words.



Answer

Structure/Function of SGK1

Structure information is derived from:

Zhao B, Lehr R, Smallwood AM, Ho TF, Maley K, Randall T, Head MS, Koretke KK, Schnackenberg CG. Crystal structure of the kinase domain of serum and glucocorticoid-regulated kinase 1 in complex with AMP PNP. Protein Sci. 2007 Dec;16(12):2761-9. doi: 10.1110/ps.073161707. Epub 2007 Oct 26. Serum and glucocorticoid-regulated kinase 1, SGK 1, a member of the **AGC** kinase family which includes protein kinases A (PKA), G (PKG), and C (PKC), is a serine/threonine kinase. It has 3 domains, an N-terminal PK-like domain, a kinase domain, and a C-terminal hydrophobic domain. Its catalytic domain is around 50% homologous to other members.

The protein is regulated at the transcriptional and also at the post-transcription level, the latter by phosphorylation. Two are required. One occurs at Ser 422 in the C-terminal hydrophobic domain by mTORC2. This allows its recruitment to membrane phosphatidylinositol 3, 4, 5-trisphosphate-dependent kinase (PDK1), which phosphorylates SGK 1 in a second location, Thr 256, located in a conformationally flexible activation loop in the catalytic domain, leading to the formation of a competent active site in the enzyme.

All AGC kinases bind ATP and phosphorylate Ser/Thr side chains on target proteins. Hence the conformations of the catalytic domain of the active protein kinases are similar. Their inactive structures diverge more, which allows them to bind to specific target domains or proteins in a process that provides specificity for the phosphorylation. Such is the case with SGK 1.

Figure 6s shows an interactive iCn3D model of the catalytic domain of inactive serum and glucocorticoid-regulated kinase 1 (SGK 1) in complex with AMP-PNP (2R5T).

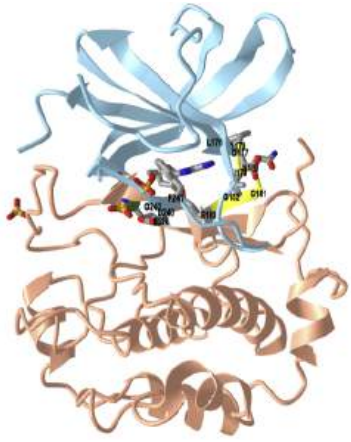

Figure 4: Catalytic Domain of Inactive Serum and Glucocorticoid- Regulated Kinase 1 in Complex with AMP-PNP (2R5T).. (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...695vFs5jzQjH67

As with other AGC kinases, the catalytic domain of SGK1 has an N-terminal (light blue, mostly antiparallel beta strands) lobe and C-terminal (salmon, mostly loops and alpha helices) lobe, with ATP and its substrate analog AMP-PNP binding in the groove between them. Key amino acids involved in catalysis are shown. The ATP binding site consists of residues 104-136 with key catalytic residues at 218-230.

The first phosphorylation occurs at Ser 422 found in the hydrophobic/aromatic motif FLGFSYA. This sequence is conserved in AGC kinases, which have the general consensus sequence FXXFS/TF/Y. This entire motif is not seen in the structure above. The second phosphorylation occurs at Thr 256 (CPK-colored sticks, labeled).

Figure 6 shows another interactive iCn3D model of the inactive SGK 1 and AMP-PNP highlight activation and catalytic features (2R5T).

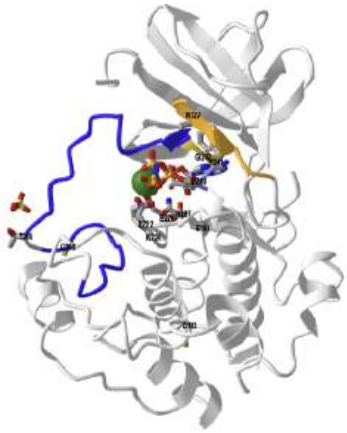

Figure 4: Inactive SGK 1 and AMP-PNP highlighting activation and catalytic features (2R5T). (Copyright; author via source).
Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?MioLpk9FqXoVEbBp8

The activation loop is shown in blue. Activation of the kinase requires phosphorylation of the activation loop Thr 256 (shown in sticks and labeled) by PDK1. (Note that it is next to a SO_4^{2-}, part of ammonium sulfate used in the crystallization process.) Key residues involved in the binding of AMP-PNP in the active site are shown as CPK-colored sticks and labeled.

Catalysis requires binding of substrate, in this case ATP (or in the model above AMP-PNP) and any activating conformational changes that position catalytic residues around the substrate:

- **Glu 146 and Lys 127**: E146 (E91 in PKA), is found in the N-terminal lobe αC-Helix of most AGC kinases. It interacts with a key catalytic residue K127 (K72 in PKA) in the catalytic loop. However, the equivalent αC-Helix is **not** found in the inactive SGK1. Rather it forms a beta-strand. This is perhaps the main feature differentiating inactive SGK1 (along with the activation loop) from other AGC kinases. In AGC kinases, the activation loop is connected to the N-lobe through the αC helix.
- **Lys 72** which stabilizes the β phosphate of ATP.
- **Lys127, Glu183, Asp222, Lys224, Glu226, and Asn227**: These mostly charged side chains interact with the phosphates in the substrate (analog)
- **Asp 240, Phe 241, and Gly 242 (DFG motif)**: This motif is in the activation loop and helps in catalysis by positioning a molecule of ATP bound to magnesium or manganese for phosphoryl transfer which helps the SGK1 to switch between DFG-out (inactive) and DFG-in
- **Cys193** and **Cys258**: These might also affect the activity.

? Exercise 13

Zoom into the iCn3D model and localize E146 and K127. What did you find? Offer an explanation. With what does K127 interact?

Answer

? Exercise 14

Zoom into the iCn3D model and answer the following questions.

a. What is the role of K127 in binding and in catalysis?

b. What is the role of K224?

c. E226:

d. N227

e. E183

f. D222

Answer

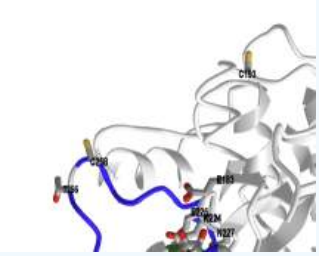
Cys 258 near T256 and it forms a S-S with S193 to form a covalent homodimer :

Exercise 15

Locate Cys 258 and C193 in the iCn3D above. Propose a mechanism in which they might alter activity.

Answer

A disulfide bond between these two Cys on different monomers results in a covalent homodimer. One of the Cys is near the Thr 256 which is phosphorylated by PDK1 to activate SGK 1. This might not occur in the covalent dimer. Also, oxidative modification of Cys 258 might affect the binding site on SGK1 for PDK1 altering its post-translation phosphorylation and the activity of the enzyme.



Exercise 16

One clue to conformational flexibility is to color code the model based on the B-factor.

Use this link and do the following in iCn3D:

- Choose **Analysis, Seq. and Annotations**, and then the Details tab.
- Under Proteins, click 2R5T_A to highlight the protein
- Choose Color, B-Factor, Original

What do the B-factors tell you about the conformational flexibility of the inactive protein?

Answer

Exercise 17

Make an iCn3D model of 2R5T.

- Select these amino acids by choosing **Analysis, Seq and Annotations**, and then the details tab: Ile104, Val112, Ala125, Val160, Leu176, Asp177, Tyr178, Ile179, Leu229, Thr239 (Click/sweep each amino acids to highlight them)
- **Select, save selection**, and give it a name
- **Style, Sidechains, Stick**
- **Color, Atom**
- **Analysis, Label, Per residue and number**
- **Analysis, lab scale, 3.0**
- **Style, background, transparen**t
- **Select, Clear selection** (to remove yellow highlights)

- **Files, Share Link, Lifetime short link,** then copy it and save it in a file documenting your work

What role do these amino acids play in the SGK 1 catalytic domain?

Answer

Investigators studied the phosphorylation and the activity of the protein *in vitro*. The structure reported above and used in the phosphorylation studies contained planned mutations.

? Exercise 18

Investigators make these mutations in the protein. Explain why they did.

a. S74A, S78A, S397A, S401A.

b. S422D mutation.

c. R192A

Answer

The inactive SGK1 structure, with its unique conformation in the αC and activation loop regions, may indicate that αC and the activation loop are important for substrate recognition and binding and thus are two key regulatory elements within the kinase domain. Upon activation, SGK1 will adopt a conformation similar to other active forms of AGC family kinases.

The amino acid sequence of SGK1 provides a plausible explanation for the disordered αC helix. Six successive large hydrophilic residues (KKKEEK, residues 136–141) are located at the beginning of the segment corresponding to αC, while there are only three hydrophilic residues in this region in AKT2 and four in PKA. These large hydrophilic residues are generally quite solvent-exposed and may make the peptide chain more flexible.

? Exercise 19

What happens on the phosphorylation of Thr 256 in the activation loop of SGK1? A comparison with analogous residue, Thr 197) in Protein Kinase A (PKA) would be helpful to know.

- In PKA, Thr 197 becomes phosphorylated and interacts with Arg165 and Lys189 in active PKA
- In SGK 1, Thr 256 becomes phosphorylated and likely interacts with Arg 221 and Lys 245 (the equivalent of Arg 165 and Lys 189 in PKA) in active SGK1.

a. What type of noncovalent interactions occur between pThr197 and Arg 165/Lys 189?

b. Measure the distance between Thr 256 and Arg 221/Lys 245 in this rendered structure of SGK 1 and describe what must happened to these residues in the likely active state of SGK 1.

In the iCn3D model,

- Choose **Analysis, Seq and Annotation**, the Detail tab, and then select Arg 221/Lys 245 with your mouse.
- **Select, Save Selection**, and name it R221K245.
- **Style, Side Chains, Sticks**
- **Color, Atom**

- **Analysis, Label, Per Residue and Number**
- **Analysis, Distance, Between 2 sets**
- Pick the predefined T256 as 1 set, and R221K245 as the second
- Choose Display to see the distance between them in Angstroms.

Bashir A. Akhoon, Neha S. Gandhi, Rakesh Pandey, Computational insights into the active structure of SGK1 and its implication for ligand design, Biochimie,
Volume 165, 2019, Pages 57-66, ISSN 0300-9084, https://doi.org/10.1016/j.biochi.2019.07.007. NO CREATIVE COMMONS PERMISSIONS

Additional Results

1. Transcriptomic studies of four prefrontal cortex subregions from postmortem tissue of people with PTSD show that PTSD has different molecular traits than major depressive disorders. 32 unique genes were identified. A few keys are listed below.

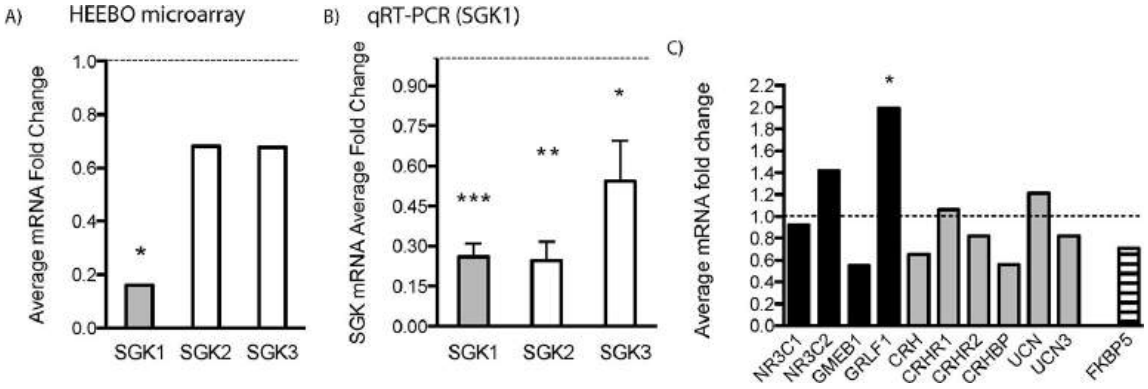
- ELFN1 (downregulated): Synaptic adhesion, allosteric regulator of metabotropic glutamate (excitatory) receptors. It's required for formation of synapses.
- GABA (downregulated): GAD2 encoding glutamic acid decarboxylase-2 required for GABA synthesis, and SLC32A1 which is a vesicular transporter for GABA and glycine. These suggest a downregulation of GABA (an inhibitory neurotransmitter) signaling
- UBA7 (downregulated): ubiquitin-like activating enzyme involved in the expression of inflammatory genes.
- FKBP5 (upregulated): a glucocorticoid receptor chaperone. Key driver on females

---

Licznerski P, Duric V, Banasr M, Alavian KN, Ota KT, Kang HJ, et al. (2015) Decreased SGK1 Expression and Function Contributes to Behavioral Deficits Induced by Traumatic Stress. PLoS Biol 13(10): e1002282. https://doi.org/10.1371/journal.pbio.1002282. Creative Commons CC0 public domain

This group looked at SGK1 expression in the postmortem prefrontal cortex of PTSD subjects (who died with PTSD) and in rat models of PTSD when rats were subjected to stimuli that resulted in symptoms of helplessness (exposure to acute foot shock stress without the possibility of escape) and anhedonia (lose of ability to experience pleasure as measured by decreased preference for a sweetened sucrose solution).

Results of the studies of mRNA levels for SGK1 and two isozymes, SGK 2 and 3 from postmortem samples are shown below.



Panel (A) shows microarray gene expression analysis of postmortem dorsolateral PFC (DLPFC) samples collected from patients with PTSD. The * indicates significant results. The dashed line indicates healthy controls.

Panel (B) shows real-time qPCR was conducted to verify the microarray findings. Data are expressed as a mean fold change ± standard error of the mean (SEM) switch student's *t* test values of $*p < 0.05$, $**p < 0.01$, $***p < 0.001$].

Panel (C) shows expression levels of stress- and glucocorticoid-regulated genes were also examined. Changes are shown as a mean fold change. Asterisk indicates a significant *p*-value ($*p < 0.05$, FDR adjusted). NR3C1, glucocorticoid receptor; NR3C2, mineralocorticoid receptor; GMEB1, glucocorticoid modulatory element binding protein 1; GRLF1, glucocorticoid receptor DNA binding factor 1; CRH, corticotropin-releasing hormone; CRHR1, corticotropin-releasing hormone receptor 1; CRHR2, corticotropin-releasing hormone receptor 2; CRHBP, corticotropin-releasing hormone binding protein; UCN, urocortin; UCN3, stresscopin (urocortin 3); FKBP5, FK506 binding protein 5.

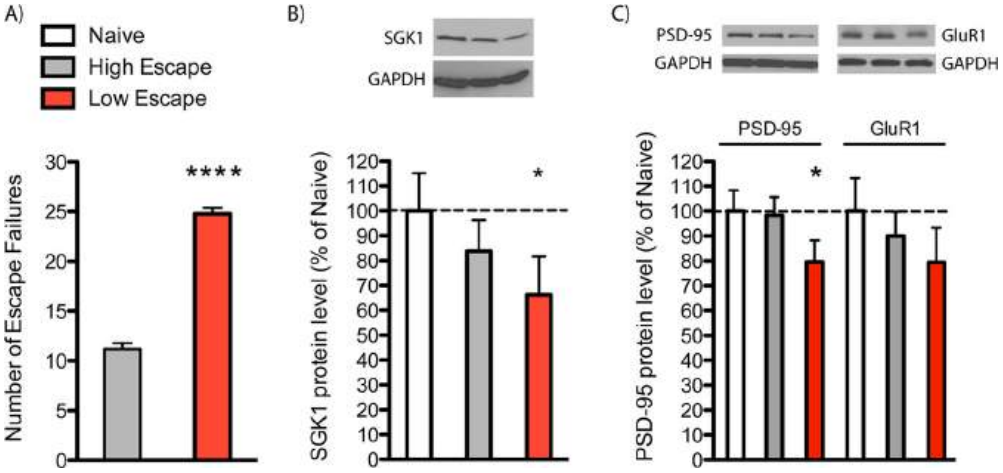
? Exercise 20

Interpret the results.

Answer

Rat brain SGK1 from either low or high escapers from shock (a model for learned helplessness) was run on PAGE gels. The results are shown below.

dfdfd



Panel (A): Rats were exposed to inescapable shock (day 1), tested in active avoidance (AA) (day 4), and then sacrificed (day 8) as indicated. Animals were separated into low- and high-escape groups according to their performance in AA test. Data are the mean ± SEM [t(12) = 14.39, Student's *t* test, ****$p < 0.0001$].

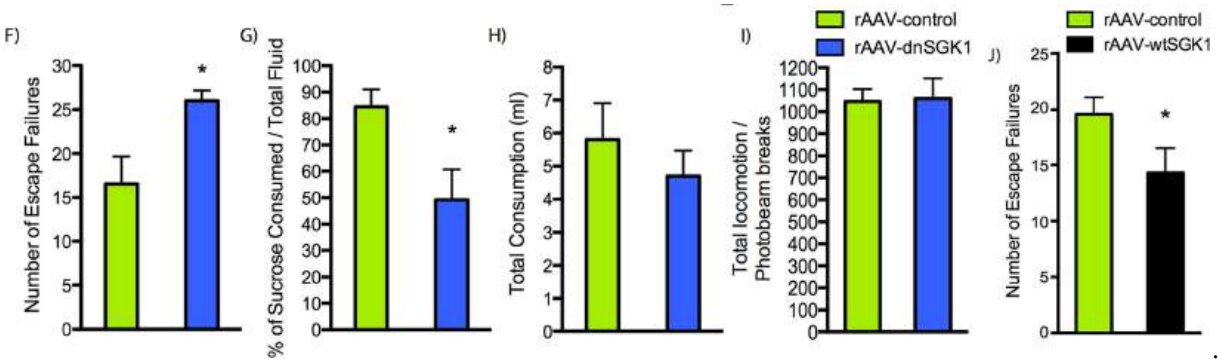
Panel (B): SGK1 and (C) PSD-95 protein levels in dissected PFC are decreased in the low-escape group. Data are mean ± SEM percent change over control group (naive, $n = 5$; high escape, $n = 5$; low escape, $n = 9$).

? Exercise 21

Interpret the results. Why did they run GAPDH (glyceraldehyde-3-phosphate dehydrogenase) on the gels? PSD-95 is the postsynaptic density protein-95 and GluR1 is the glutamate receptor gene product.

Answer

To determine the role of SGK1 in the behavior of live animals, investigators made a dominant negative mutated form of SGK1 (S422A) which was referred to as dnSGK1. The gene was added to an adeno-associated virus (AAV) to express the protein in live animals and then observed their behavior. Some results are shown below.



Effects of rAAV-dnSGK1 infusion into medial PFC on behavior were tested in (F) AA (escape failures), (G) sucrose preference, (H) total fluid consumption, and (I) locomotor activity. Data are shown as mean ± SEM (controls $n = 11$; dnSGK1 $n = 9$). (t(18) = 2.61 for AA and t(18) = 2.795 for SPT, Student's *t* test, *$p < 0.05$]. (J) AA (escape failures) for rAAV-wtSGK1 injected rats (controls $n = 10$; wtSGK1 $n = 10$). (t(18) = 1.933, one-tailed Student's *t* test, *$p < 0.05$.)

? Exercise 22

Answer these questions.

a. What structure/activity changes in SGK1 would you expect in the mutant?

b. Interpret the results

Answer

Now let's return to whole genome/transcriptome studies. To gain new insight, it would be useful to analyze a more specific set of cells to get clues about the effects of PTSD on their biochemistry. The first study mentioned above looked at "omics" analyses of whole blood, plasma, serum, and buffy-coats. A newer approach is to study specific cell types from people with and without PTSD. We've clearly showed that PTSD is a systems disease, but at its heart are neurological effects, so it makes sense to study neurons (not just post-mortem brain tissue or do whole brain scans). Instead of isolating neurons from people, investigators have made glutamineric neurons in culture from stem cells isolated from people so the effects of PTSD can be studied in "petri dishes".

How can you mimic PTSD conditions in culture? One way is to add glucocorticoids (like the drug dexamethasone or hydrocortisone) to the cells from donors with PTSD and as controls, those who don't. We've seen repeatedly in the above examples the effects of changes in SGK1, which as its name implies, is affected by glucocorticoids. Transcriptomic studies to determine changes in gene expression have been done to compare the following sets of cells and PTSD mimics.

1. **Peripheral blood mononuclear cells (PBMCs) from combat veterans with PTSD and controls without PTSD**

This study used **dexamethasone (DEX)** as the cell "stressor". To interpret the graphs you need to know some definitions which are likely unfamiliar to biochemistry students who haven't yet studied large scale omic analyses.

- **FDR** (**False Discovery Rate).** This is the expected # false predictions/ # total predictions, so it's a statistical measure of the likeliness that the results are **not** what is hypothesized (or the null hypothesis). It's like a p-value except for multiple tests. It is the rate at which features that are determined to be significant are in fact **not**. For example, an FDR of 0.05 means that 5% of all features determined to be significant are NOT (so 95 out of 100 are). Hence the lower the FDR, the high likely that the features are significant (in this case that they are associated with PTSD). The table below shows some examples of different FDR values. Often they are expressed as -log FDR(fx) so the larger this value, the more likely an outcome is significant.

FDR (fx)	FDR (% determined significant that aren't)	-log FDR (fx)
0.01	1%	2
0.05	5%	1.3
0.1	10%	1
0.25	25%	0.60

- **DEGS: differentially expressed genes**
- LogFC: differences observed between vehicle and hydrocortisone exposure (for example)

Results from the PBMC studies +/- DEX are shown in the figure below.

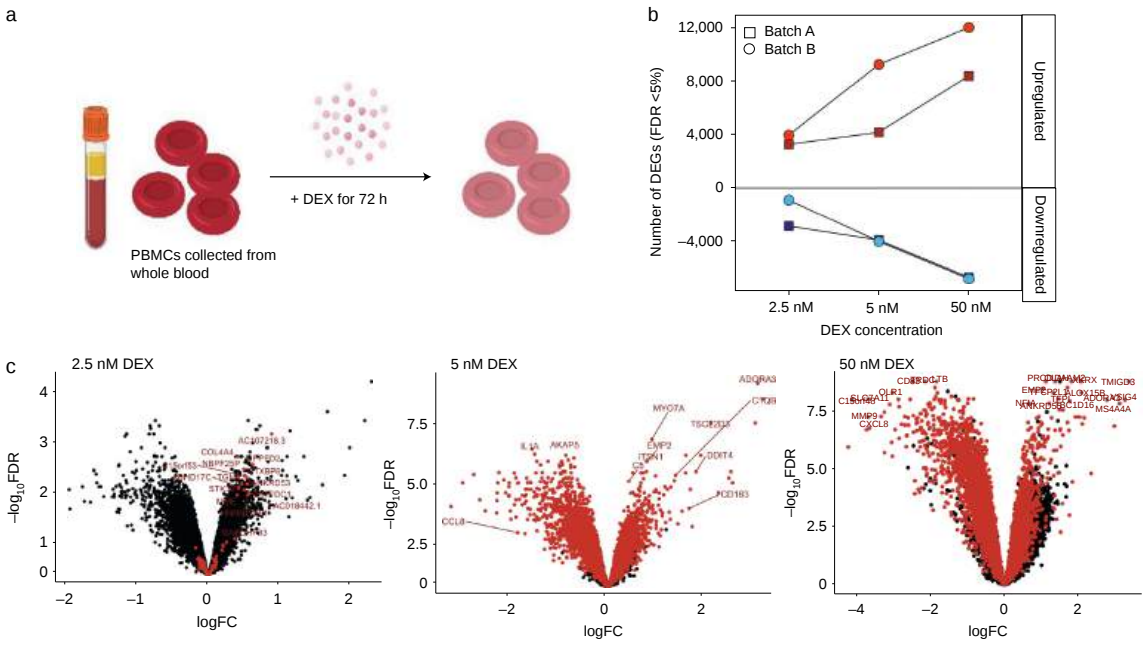


Fig. 1: Transcriptional response to DEX in PBMCs.

Panel a shows how PBMCs from 20 PTSD cases and 20 combat-exposed controls were treated with DEX for 72 h and RNA-seq was performed.

Pane b shows the number of **differentially expressed genes (DEGs)** observed in batch A (this study) and batch B (another published study) are upregulated and downregulated (*y* axis) across three different concentrations of DEX conditioning (*x* axis).

Panel c shows Meta-analysis of expression logFC (differences observed between vehicle and DEX exposure, x axis) was plotted against $-\log_{10}$(FDR) for each gene. Red points indicate significant DEGs in the meta-analysis. (Since the graph in the paper shows logFC and not $\log_{10}$FC, we will assume, as in our previous discussions, that logFC implies $\log_2$FC, which is customary.) Panel c is called a volcano (scatter) plot that shows the statistical significance ($-\log_{10}$FDR or otherwise P value) vs a measure of the magnitude of the change (here logFC)

? Exercise 23

Which part of Figure C, 50 nM DEX shows the genes are most statistically downregulated? Upregulated? Interpret the overall result

Answer

Changes were high in genes for immune signaling (this make sense since most nucleated cells in the blood are immune cells) and also in glucocorticoid sensitivity.

2. Neurons from combat veterans with PTSD and controls that without PTSD

Next investigators did the same experiments using glutaminergic neurons derived from pluripotent stem cells induced with neurogenin 2 (NGN2) to produce NGN2-neurons with glutamate receptors, glutamate transporters, and the neurotransmitter glutamate.

Results from the NGN2 neutrons +/- hydrocortisone (a glucocorticoid) are shown in the figure below.

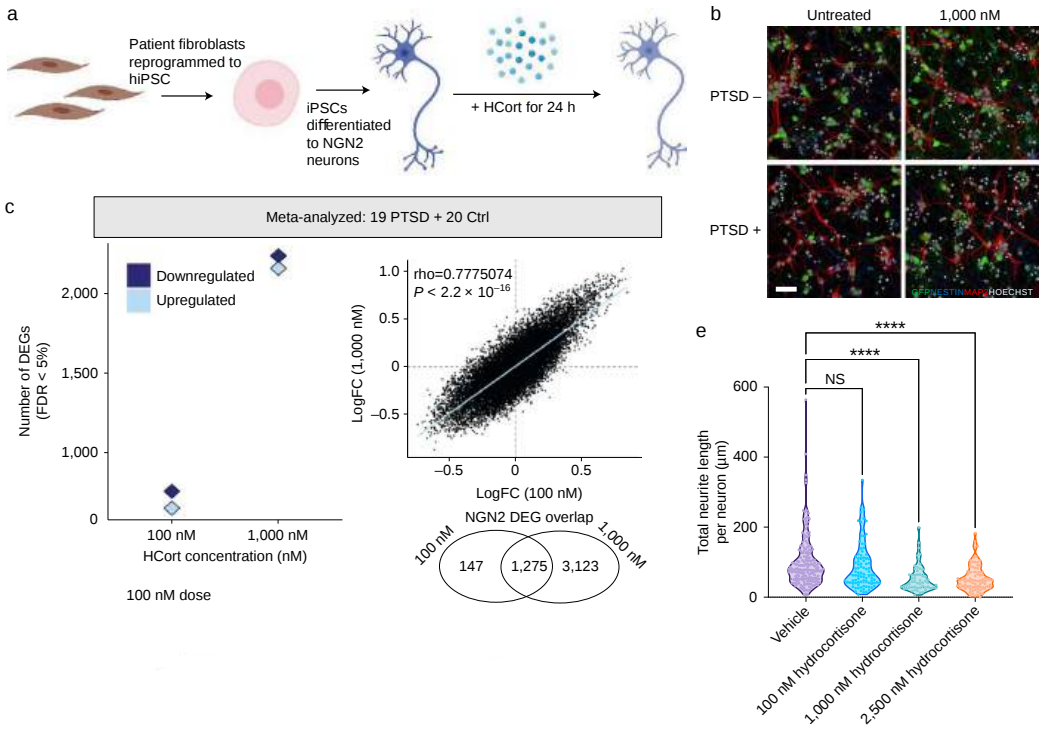

Fig. 2: Gene expression changes to HCort in hiPSC-derived neurons.

Panel a, hiPSC-derived *NGN2*-neurons were treated with HCort for 24 h and RNA-seq performed.

Panel b, *NGN2*-neurons stained for neuronal markers NESTIN and MAP2, nucleic marker HOECHST and green fluorescent protein to confirm neuronal identity and morphology across all conditions.

Panel c, Meta-analyzed DEGs in response to increasing concentrations of HCort shows robust changes in *NGN2*-neurons. A comparative analysis of transcriptome-wide $\log_2$FC in response to different concentrations of HCort in *NGN2*-neurons shows similar responses, indicating a conserved response across all donors to HCort in *NGN2*-neurons.

Panel e, Morphological analysis of neurite outgrowth in day 7 *NGN2*-neurons showing a dose-dependent decrease in neurite outgrowth with HCort exposure.

? Exercise 24

What conclusions can be derived from

- Panel B
- Panel C
- Panel E

Answer

Some genes/pathways that were underexpressed include acetylcholine signaling, ubiquitin ligation, specific cell type development and differentiation. Some that were overexpressed include protein methylation, immune cell function, histone modification, and regulation of gene expression.

3. Direct comparison of gene expression in neurons from active duty/veterans with +/- PTSD

Results from these studies are shown below.

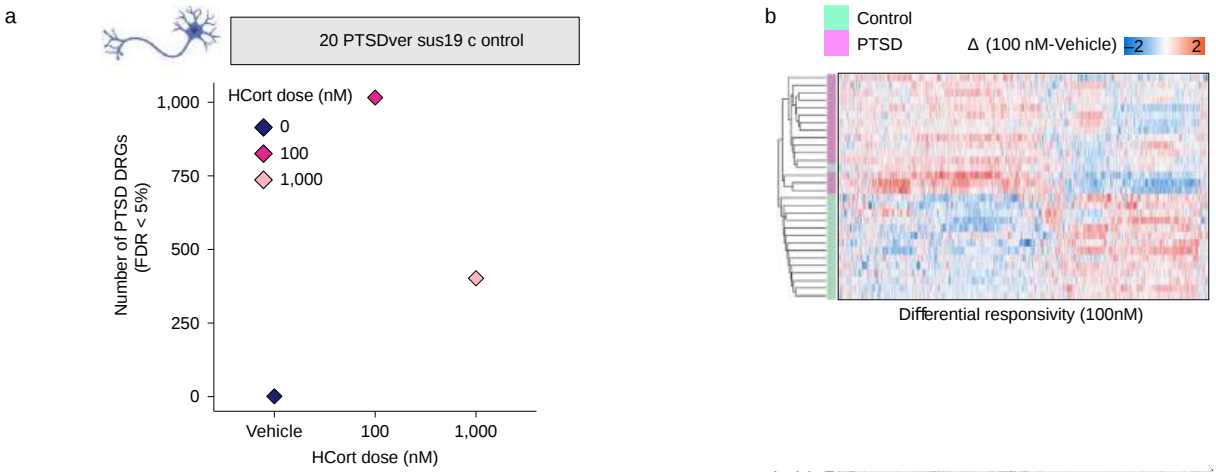

Fig. 4: PTSD(+) specific responses to HCort in *NGN2*-neurons.

Panel a shows genes that differ in their response to HCort in PTSD(+) donors compared with PTSD(–) donors, here termed DRGs, were detected in both the 100 nM and 1,000 nM dose, indicating PTSD diagnosis-specific responses to HCort.

Panel b, Significant *NGN2*-DRGs correctly classify PTSD(+) from PTSD(–) participants using an "unsupervised (machine learning) approach" (does not require selection of input parameters a prior. Just raw data is used).

? Exercise 25

Interpret Panels a and b.

Answer

Here is a summary from the paper:

"Both blood and neuronal glucocorticoid responses were significantly enriched for immune response genes; neuronal glucocorticoid responses were also associated with brain development and neurodevelopmental disorder genes. Although a PTSD diagnosis-specific signature was not detectable at baseline in either cell type, glucocorticoid hypersensitivity in PTSD was observed. These findings are consistent with the glucocorticoid hypersensitivity hypothesis; for example, patients with PTSD have altered blood sensitivity to glucocorticoids[6] and perturbations in glucocorticoid receptor signaling have been shown for PTSD in PM brain tissue[10].

Stress impacts the risk to psychiatric disorders throughout the lifespan—across prenatal development[62,63], childhood[52] and adulthood[52,64,65]. Moreover, the significant and positive relationship between our observed associations in *NGN2*-neurons and previously demonstrated transcriptional PTSD signatures in PM brains suggests that some impacts of glucocorticoid exposure may persist through to adulthood. Notably, glucocorticoid stimulation is not a specific model for PTSD; stress response is comorbid in many psychiatric disorders. HCort-responsive genes therefore likely represent aspects of stress response shared across PTSD and other neuropsychiatric disorders, such as the shared impact on social cognition between PTSD and ASD[66,67]. Combined analysis of context-dependent hiPSC models with cross-lifespan datasets, such as PM brains, may uncover long-term glucocorticoid-dependent PTSD signatures with which to refine hallmarks of PTSD susceptibility following combat exposure."

Epigenetic effects of trauma

The studies - a note of caution

Epigenetic effects of trauma would have the potential to be passed on to offspring and could lead to multigenerational trauma effects. It is very difficult to conduct quality studies to show effects in subsequent generations. Subjects have to be identified and consent to participation in the study. Few studies have been done on the biochemical effects of childhood trauma on victims and intergenerational effects. Perhaps the best studies derive from war victims (soldiers, civilian populations, mostly from WWII) and their descendants. It is also difficult to disentangle possible epigenetic effects from environmental causes such as those that might arise from children brought up by a parent who has or has had PTSD. Studies have also been done after events such as 9/11 and even the Covid pandemic. Animal trauma models have also been explored and even those have ethical concerns.

Epigenetics - short review

Trauma might also be encoded by a myriad of epigenetic changes that may or may not be passed onto offspring. Figure 1 below shows different types of epigenetic changes in trauma victims.

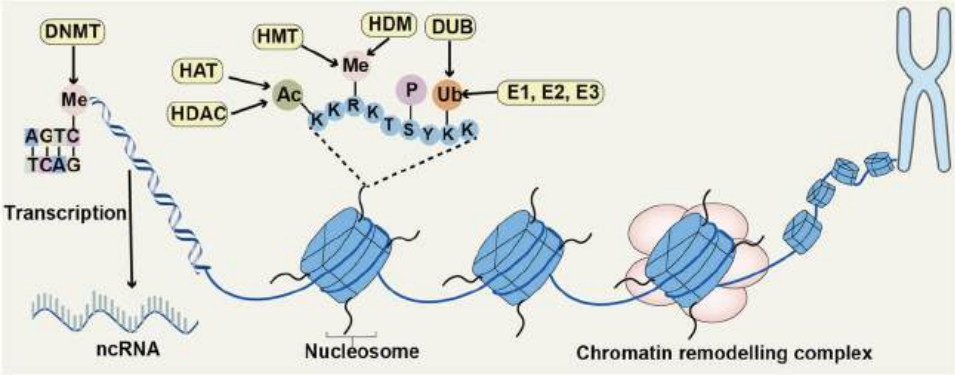

Figure 1: Four different epigenetic regulatory mechanisms. Wu, YL., Lin, ZJ., Li, CC. *et al*. Epigenetic regulation in metabolic diseases: mechanisms and advances in clinical study. *Sig Transduct Target Ther* **8**, 98 (2023). https://doi.org/10.1038/s41392-023-01333-7. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/.

The figure shows 4 kinds of epigenetic changes.

DNA methylation

This occurs on cytosine bases in CpG motifs (island). Methylation is abundant in telomers, centromers, repetitive sequences, and on the inactivated X chromosomes in females. It can affect genome stability and silencing (of expression). 5meC is the most common but other modifications (hydroyxmethy, formyl, and carboxyl) also occur at the 5' position of cytosine bases. The

methylation is catalyzed by several different DNA methyltransferases (DNMTs) using *S*-adenosylmethionine (SAM) as the methyl donor. DNMT1 maintains methylation states while DNMT3A and DNMT3B create new meCs.

Histone modifications

Two copies each of the positively charged histones H2A, H2B, H3, and H4 comprise the nucleosome core around which negatively charged dsDNA wraps. The histones can be post-translationally modified by acetylation, methylation, lactylation, phosphorylation, dopaminylation, and ubiquitination. Acetylation removes the + charge on histones and decreases DNA binding affinity. These modifications also add binding sites for proteins which affect the overall packing of chromatin. Overall, these modifications can change the accessibility of sites on chromatin required for gene transcription and hence they can regulate gene transcription.

Acetylations are catalyzed by histone acetyltransferases (HATs) and reversed by histone deacetylases (HDACs). Most modifications occur on the N-terminal sections of H3 and H4. Proteins with bromodomains act as histone acetylation "readers" and are involved in transcriptional regulation and chromatin remodeling. The N-termini of H3 and H4 are also the site of methylation of lysine or arginine residues, which can produce mono-, di-, or trimethylated lysine residues. Some methylations activate transcription, others inhibit it. The enzymes involved are lysine methyl transferase (KMTs) and lysine demethylases (KDMs), while protein arginine methyltransferases (PRMTs) modify arginines.

Chromatin remodeling

DNA wound around a nucleosome is not accessible to RNA polymerase (about the size of the nucleosome core) for transcription. Even worse for accessibility is condensed chromation. Remodeling of the chromatin, which requires ATP hydrolysis, can open it for transcription by increasing accessibility. Several families of remodelers (SWI/SNF, ISWI, chromodomain helicase DNA binding or CHD and inositol requiring 80 (INO80) can remodel chromatin.

Noncoding RNAs (ncRNAs)

Two types are described below

- endogenous miRNA of about 23 NT length can inhibit gene expression by inhibiting mRNA translation. RNA polymerase II is used in their synthesis and the inhibitor act to inhibit translation through the RNA-induced silencing complex (RISC) and binding to the 3′-untranslated regions (3′-UTRs) of specific mRNAs. The synthesis and hence expression of specific miRNA can hence be regulated by the epigenetic mechanism described above. More directly, but they can also regulate the key enzymes involved in epigenetic modifications including HDACs and DNMTs. diabetes.
- lncRNA are longer than 200 nucleotides and include long intergenic non-coding RNAs (lincRNAs), antisense RNA, and others. They can affect chromatin structure and even enzyme activity through specific binding interactions.

Biomolviz- Constructing iCn3D Models to Target Biomolecular Visualization Skills

It is not only important to visualize pre-rendered models of biomolecules, but it is also important to be able to create them to address key aspects of structure and function. These efforts should be guided by a clear set of learning goals and objectives that target student understanding of structure and function. So it is fortunate that clear learning themes, goals and objectives are articulated in a Biomolecular Visualization Framework created by BioMolViz,

BIOMOLVIZ

Promoting Molecular Visualization Literacy

The BMV framework is used with permission from BioMolViz.Org

AG2.02 Students can describe different conformations of atoms about a bond using visualization tools. (Novice)

AG2.03 Students can distinguish energetically favorable and unfavorable conformations that a structure can adopt. (Amateur)

AG2.04 Students can predict the effect of a given substituent on the structure and function of a macromolecule (e.g., substituent on a carbohydrate/ligand, R groups/rotamers, phosphorylation, methylation of nucleic acids, post-translational modifications). (Expert)

AG3. Students can describe dihedral/torsion angles in biomolecules.

AG3.01 Students can identify a dihedral/torsion angle in a three-dimensional representation of a molecule. (Novice)

AG3.02 Students can identify the planes between which a dihedral/torsion angle exists within a three-dimensional representation of a macromolecule. (Novice)

AG3.03 Students can identify phi, psi, and omega torsion/dihedral angles in a three-dimensional representation of a protein. (Amateur)

Alternate Renderings (AR)		Rendering of a macromolecular structure such as a protein or nucleic acid structure in various ways from the simplest possible way (connections between alpha carbons) to illustration of secondary structure (ribbons) to surface rendering and space filling.

AR1. Students can interpret or create molecular images that convey features such as secondary structure, CPK coloring, and active sites.

AR1.01 Students can manipulate rendered structures to illustrate molecular properties. (Novice)

AR1.02 REMOVED (integrated with SF2.02)

AR1.03 Students can describe or label structural differences among multiple structures. (Amateur, Expert)

AR1.04 Students can infer information from rendering a structure in different ways. (Novice, Amateur, Expert)

AR1.05 Students can create renderings that distinguish secondary structural features. (Novice)

AR1.06 Students can create an information rich rendering of a structure that depicts structural features found in the literature. (Amateur)

AR1.07 Students can create an information rich rendering of a structure containing ligands, covalent modifications, and noncanonical amino acids or nucleotides. (Amateur, Expert)

AR1.08 Students can use molecular visualization to tell a story about a macromolecular structure. (Expert)

AR1.09 REMOVED (integrated with MI1.02)

AR1.10 Students can convert textbook images of small molecules into 3D representations in a molecular visualization program. (Amateur)

AR2. Students can choose the best rendering of a macromolecule to use in a given situation.

AR2.01 Students can recognize that a cartoon rendering is a summary of the detail in a line rendering. (Novice, Amateur)

AR2.02 Students can describe the atoms and their representations in different renderings (e.g., coloring, showing hydrogens/double bonds). (Novice)

AR2.03 Students can identify or create a suitable rendering, or combination of renderings, for a specific purpose (e.g., a surface rendering overlaid with a cartoon to highlight the van der Waals surface alongside secondary structure, or active site sticks shown over a cartoon). (Novice, Amateur)

AR2.04 Students can identify the limitations in various renderings of molecular structures. (Amateur)

AR2.05 Students can understand the level of detail of different molecular representations. (Novice, Amateur, Expert)

AR2.06 Students can transition comfortably between equivalent 2D and 3D renderings of biomolecules. (Novice, Amateur, Expert)

AR2.07 Students can use and interpret color in the context of macromolecules to clarify and/or highlight features (e.g., coloring amino acids differently by property, different molecules uniquely in a complex, protein chains, secondary structure).

(Novice)

Construction and Annotation (CA)		Ability to build macromolecular models, either physical or computerized, and, where possible, add commentary, either written or verbal, to tell a molecular story.

CA1. Students can compose information-rich renderings of macromolecule-ligand interactions.

CA1.01 Students can construct and annotate a model of a macromolecule bound to a ligand. (Amateur)

CA1.02 Students can construct a model of a macromolecule bound to a ligand and identify the types of molecular interactions. (Amateur)

CA1.03 Students can construct a model of a macromolecule bound to a ligand and assess the importance of molecular interactions. (Expert)

CA1.04 Students can produce a model of a macromolecule based on a known structure of a related macromolecule. (Amateur, Expert)

CA2. Students can compose a rendering to predict the cellular location of a protein (e.g., extracellular, membrane associated, or cytoplasmic) based on the properties and orientations of functional groups.

CA2.01 Students can design a rendering that conveys properties such as polarity, charge, secondary structure, etc. to suggest the cellular location of a macromolecule. (Amateur)

CA2.02 Students can create protein images with colored polar/nonpolar residues to determine whether they fold with a hydrophobic core. (Amateur)

CA2.03 Students can create images to display polar/nonpolar residues and propose a role for the protein and/or how it interacts with its environment - and that the predictions would be plausible based on the protein. (Amateur)

CA2.04 Students can make accurate predictions of the location/function of the protein that incorporates additional protein features, such as transmembrane helices, apparent docking surfaces, etc. (Expert)

Ligands and Modifications (LM)		Metals and metal clusters, additions such as glycosylation, phosphorylation, lipid attachment, methylation etc.

LM1. Students can identify ligands and modified building blocks (e.g., hydroxyproline, aminosaccharides, modified nucleobase) within a rendered structure.

LM1.01 Students can use the annotation associated with a pdb file to identify and locate ligands and modified building blocks in a given biomolecule. (Amateur)

LM1.02 Students can visually identify non-protein chemical components in a given rendered structure. (Amateur)

LM1.03 Students can distinguish between nucleic acid and ligands (e.g., metal ions) in a given nucleic acid superstructure. (Amateur)

LM1.04 Students can explain how a ligand in a given rendered structure associates with the biomolecule (e.g., covalent interaction with residue X). (Amateur)

LM1.05 Students can locate/identify ligands and modified building blocks in unannotated structures and describe their role. (Expert)

LM2. Students can describe the impact of a ligand or modified building block on the structure/function of a macromolecule.

LM2.01 Students can look at a given rendered structure and describe how the presence of a specific ligand or modified building block alters the structure of that biomolecule. (Amateur)

LM2.02 Students can explain how the removal of a particular ligand or modified building block would alter the structure of a given biomolecule. (Expert)

LM2.03 Students can use molecular visualization tools to predict how a specified ligand or modified building block contributes to the function of a given protein. (Amateur, Expert)

LM2.04 Students can predict how a ligand or modified building block contributes to the function of a protein for which the structure has been newly solved. (Expert)

Macromolecular Assemblies (MA)		Polypeptides, oligosaccharides, and nucleic acid and lipid superstructures (e.g. protein–nucleic acid complexes, lipid membrane-associated proteins)

MA1. Students can describe various macromolecular assemblies.

MA1.01 Students can identify individual biomolecules in a macromolecular assembly. (Novice, Amateur, Expert)

MA1.02 Students can describe functions of individual biomolecules within a macromolecular assembly. (Novice, Amateur, Expert)

MA1.03 Students recognize the various lipid ultrastructures (e.g., micelles, bicelles, vesicles, and lipid bilayers) in a 3D structure. (Novice)

MA2. Students can compose information-rich renderings of macromolecular assemblies.

MA2.01 Students can render a macromolecular assembly to highlight individual structures. (Amateur)

MA2.02 Students can render a macromolecular assembly to illustrate structural features (e.g., binding interfaces, symmetry, tertiary structure, etc.). (Novice, Amateur, Expert)

Macromolecular Building Blocks (MB)		Recognition of native amino acids, nucleotides, sugars, and other biomonomer units/building blocks. Understanding of their physical and chemical properties, particularly regarding functional groups.

MB1. Students can identify individual building blocks of biological polymers.

MB1.01 Given a rendered structure of a biological polymer, students can identify the ends of a biological polymer. (Novice, Amateur, Expert)

MB1.02 Given a rendered structure, students can divide the polymer into its individual building blocks. (Novice)

MB1.03 Given a rendered structure, students can identify the individual building blocks. (Novice)

MB2. Students can describe the contributions different individual building blocks make in determining the 3-D shape of the polymer.

MB2.01 Students can describe the physical/chemical properties of an individual building block/functional group in a rendered structure of a polymer. (Amateur)

MB2.02 Students can describe the significance of the location of individual building blocks within the 3D structure of a polymer (protein, carbohydrate, or nucleic acid). (Novice, Amateur, Expert)

MB2.03 Students can identify physical/chemical properties of individual building blocks/functional groups in different local environments. (Amateur)

MB2.04 Using a visualized structure, students can identify stereochemistry (e.g., in carbohydrate, lipid, and protein structures). (Amateur)

MB2.05 Students can modify/mutate a building block to change the 3D structure of a polymer (protein, carbohydrate, or nucleic acid). (Amateur, Expert)

Molecular Dynamics (MD)		Animated motion simulating conformational changes involved in ligand binding or catalysis, or other molecular motion/dynamics.

MD1. Students can describe the impact of the dynamic motion of a biomolecule on its function.

MD1.01 Students can recognize that biological molecules have different conformations. (Novice, Amateur)

MD1.02 Students can correlate molecular movement with function. (Novice, Amateur, Expert)

MD2. Students can predict limits to macromolecular movement.

MD2.01 Students can locate potential regions of flexibility and inflexibility in the structure of a biomolecule. (Novice, Amateur)

MD2.02 Students can recognize acceptable/unacceptable movement within a macromolecule by determining whether the movement is within allowable bond angles. (Expert)

MD2.03 Students can recognize acceptable/unacceptable movement within a macromolecule by determining whether the movement results in steric hindrance. (Amateur)

MD2.04 Students can recognize acceptable/unacceptable movement within a macromolecule by considering the atomic packing constraints. (Expert)

Molecular Interactions (MI)		Covalent and noncovalent bonding governing ligand binding and subunit-subunit interactions.

MI1. Students can predict the existence of an interaction using structural and environmental information (e.g. bond lengths, charges, pH, dielectric constant).

MI1.01 Students can distinguish between covalent and noncovalent interactions. (Novice)

MI1.02 Students can identify different noncovalent interactions (e.g., hydrogen bonds, ionic interactions, van der Waals contacts, induced dipole) given a 3D structure. (Amateur)

MI1.03 Students can predict whether a functional group (region) would be a hydrogen bond donor or acceptor. (Amateur)

MI1.04 Students can render the 3D structure of a biomolecule so as to demonstrate the ionic interactions and/or charge distribution of the different non-covalent interactions. (Amateur)

MI1.05 As it relates to a particular rendered structure, students can rank the relative strengths of covalent and noncovalent interactions. (Amateur)

MI2. Students can evaluate the effect of the local environment on various molecular interactions.

MI2.01 Students can identify regions of a biomolecule that are exposed to or shielded from solvent. (Novice)

MI2.02 Students can identify other molecules in the local environment (e.g., solvent, salt ions, metals, detergents, other small molecules) that impact a molecular interaction of interest. (Novice)

MI2.03 Students can predict the impact of other molecules in the local environment (e.g., solvent, salt ions, metals, detergents, other small molecules) on a molecular interaction of interest. (Amateur)

MI2.04 Students can predict the pKa of an ionizable group based on the influence of its local three-dimensional environment. (Amateur)

MI2.05 Students can propose a change to the local environment that would yield a desired change in a molecular interaction. (Expert)

MI2.06 Using molecular visualization tools, students can determine which intermolecular force is most critical to stabilizing a given interaction. (Expert)

Symmetry/ Asymmetry Recognition (SA)		Recognition of symmetry elements within both single chain and multi-chain macromolecules.

SA1. Students can identify symmetric or asymmetric features in rendered molecules.

SA1.01 Students can identify symmetric features in a rendered molecule (shown in fixed orientation). (Novice)

SA1.02 Students can rotate a single macromolecule, multi-chain macromolecules (e.g., homo- or heteromers), complexes of macromolecules, and supramolecular assemblies to identify axes of symmetry. (Amateur)

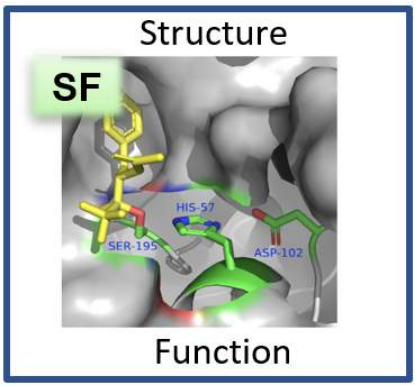
SA1.03 Students can identify symmetric and asymmetric features in rendered molecules after coloring a given rendered molecule to reveal structural features (charge, hydrophobicity, etc.). (Amateur)

SA2. Students can hypothesize the functional significance of symmetry or asymmetry in rendered molecules.

SA2.01 Students can explain the functional significance of rotational axes of symmetry (or asymmetry) in a given rendered molecule. (Novice, Amateur, Expert)

SA2.02 Students can predict functional significance of symmetry (or asymmetry) in a given rendered molecule. (Amateur, Expert)

Structure-Function Relationship (SF)



Active/binding sites, microenvironments, nucleophiles, redox centers, etc. (please also see LM2.03)

SF1. Students can evaluate biomolecular interaction sites using molecular visualization tools.

SF1.01 Students can identify functionally relevant cofactors, ligands or substrates associated with a macromolecule and describe their role (e.g., an active site magnesium ion). (Amateur, Expert)

SF1.02 Students recognize that the size and shape of the ligand must match the size and shape of the binding site. (Novice, Amateur)

SF1.03 Students recognize that the polarity or electrostatic potential of a surface complements that of the ligand or substrate. (Novice, Amateur)

SF1.04 Students recognize that the hydrophobicity of a surface complements that of the ligand or substrate. (Novice, Amateur)

SF1.05 REMOVED (integrated with SF1.03)

SF1.06 Students can use docking software to predict how the surface properties of a macromolecule guide and allow the binding of a ligand or substrate. (Amateur)

SF2. Using molecular visualization, students can predict the function of biomolecules.

SF2.01 Students can recognize structurally related molecules. (Novice)

SF2.02 Students can superimpose structurally related molecules. (Novice, Amateur)

SF2.03 Students can identify functionally relevant features of a macromolecule (e.g., an active site cysteine, a functional loop). (Amateur)

SF2.04 Students can predict molecular function given a binding site. (Amateur, Expert)

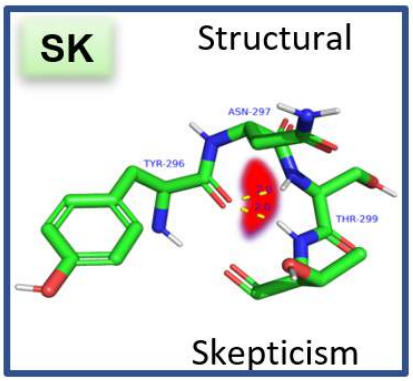
SF3. Using molecular visualization, students can predict the function of an altered macromolecule.

SF3.01 Students can structurally alter a macromolecule. (Novice)

SF3.02 Students can propose structural alterations to test interactions in a macromolecule. (Amateur)

SF3.03 Students can predict the impact of a structural alteration on the function of a macromolecule. (Amateur, Expert)

Structural Model Skepticism (SK)



Recognition of the limitations of models to describe the structure of macromolecules.

SK1. Students can critique the limitations of a structural model of a macromolecule.

SK1.01 Students can explain that the pdb file is a model based on data and that, as a model, it has limitations. (Novice, Amateur)

SK1.02 Students associate resolution with reliability of atom positions. (Amateur)

SK1.03 Students can identify building blocks (for example, amino acid side chains) whose orientation in a biopolymer is uncertain. (Expert)

SK1.04 Students can evaluate the flexibility/disorder of various regions of a macromolecular structure. (Novice, Amateur, Expert)

SK1.05 Students can reconcile inconsistent numbering of individual building blocks among species and structure files. (Novice)

SK1.06 Students can utilize a Ramachandran plot/steric clashes to interpret the validity of a structure. (Amateur, Expert)

SK1.07 Students can describe the limitations of a macromolecule-ligand docking simulation. (Amateur, Expert)

SK2. Students can evaluate the quality of 3D models including features that are open to alternate interpretations based on molecular visualization and PDB flat files.

SK2.01 Students can evaluate a crystal structure for crystal packing effects. (Novice, Amateur, Expert)

SK2.02 Students can resolve differences between the asymmetric unit and the functional biological assembly. (Expert)

SK2.03 Students can differentiate functional ligands (with biological/biochemistry role) from nonfunctional ligands (most solvents, salts, ions, and crystallization agents). (Novice, Amateur, Expert)

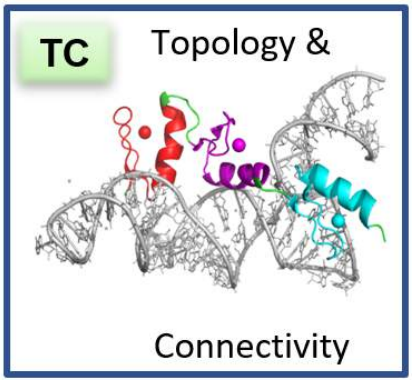
SK3. Students can discuss the value of experimentally altering a biomolecule to facilitate structure determination.

SK3.01 Students can identify non-native structural features. (Amateur)

SK3.02 Students can propose molecular modifications to facilitate structure determination. (Amateur, Expert)

SK3.03 Students can propose a purpose for the introduction of non-native structural features to facilitate structure determination. (Amateur, Expert)

Topology and Connectivity (TC)



Following the chain direction through the molecule, translating between 2D topology mapping and 3D rendering.

TC1. Students can describe or illustrate the linkages between building blocks within a macromolecule.

TC1.01 Students can trace the backbone of a macromolecule in three dimensions. (Novice, Amateur)

TC1.02 Students can use appropriate terms to describe the linkages/bonds/interactions that join individual building blocks together in a macromolecule or macromolecular assembly. (Novice, Amateur)

TC1.03 Given a virtual model of individual building blocks, students can predict the types of linkages/bonds/interactions that are possible or favorable. (Amateur)

TC1.04 Given individual building blocks, students can appropriately connect them to create a biological polymer (e.g., drawing carbohydrate linkages, a small peptide). (Amateur, Expert)

TC2. Students can describe the overall shape and common motifs within a 3D macromolecular structure.

TC2.01 Using molecular visualization software, students can describe the three-dimensional structure of a macromolecule, including overall shape and common structural motifs. (Novice, Amateur, Expert)

TC2.02 Students can identify common domains/motifs within a macromolecule. (Amateur, Expert)

TC2.03 Students can identify connectivity features between domains or subunits in a macromolecular structure. (Amateur)

TC2.04 Students can identify interactions between domains or subunits in a macromolecular structure. (Amateur, Expert)

TC2.05 Students can describe how domains/motifs in a macromolecule work together to achieve a concerted function in the cell. (Amateur, Expert)

TC2.06 Students can identify the levels of protein structure (e.g., parse a tertiary/quaternary structure into a series of secondary structures/motifs) and the ways in which they are connected from a three-dimensional structure. (Novice, Amateur, Expert)

TC3. Students can explain how any given biomolecular interaction site can be made by a variety of topologies.

TC3.01 Students can recognize that the groups that comprise a functional site only require proper arrangement in three-dimensional space rather than a particular order or position in the linear sequence. (Amateur)

TC3.02 Students can recognize similarities and differences in two similar - but not identical - three dimensional structures. (Amateur)

TC3.03 Students can describe dissimilar portions of homologous proteins as arising from genetic insertions/deletions/rearrangements. (Amateur)

BioMolViz Theme: Alternate Renderings (AR)

It is not only important to visualize pre-rendered models of biomolecules, but it is also important to be able to create them to address key aspects of structure and function. These efforts should be guided by a clear set of learning goals and objectives that target student understanding of structure and function. So it is fortunate that clear learning themes, goals and objectives are articulated in a Biomolecular Visualization Framework created by BioMolViz,

BioMolViz Theme: Atomic Geometry (AG)

It is not only important to visualize pre-rendered models of biomolecules, but it is also important to be able to create them to address key aspects of structure and function. These efforts should be guided by a clear set of learning goals and objectives that target student understanding of structure and function. iCn3D Intro Tutorial C: Finding Pockets in Proteins
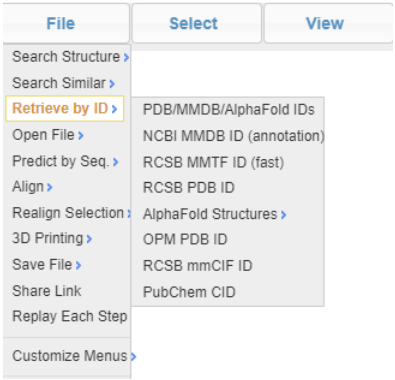
iCn3D Intro Tutorial D: Modeling Psychoactive Drugs in Target Proteins
iCn3D Skill: Alternative Rendering and Saving Files
iCn3D Skill: Displays surface of a protein - Superoxide Dismutase
iCn3D Skill: Aligning two structures
iCn3D Skill: Analysis of Noncovalent Interactions
iCn3D Skill: Creating and Saving Selections
iCn3D Skill: Mutations
iCn3D Skill: Selection through Sequence and Annotations
iCn3D Skill: Showing a Protein-Protein Interface
iCn3D Tutorial: Binding interactions of SARS-Cov-2 Spike receptor domain with ACE2
iCn3D Tutorial: Overlay many ACE2 receptor binding domain analogous to SARS-Co2 RBD using Blast
iCn3D Tutorial: Protein Kinase B (AKT)
iCn3D Tutorial Question: Intermediate Problem - Cyclooxygenase II

iCn3D Basics: File Types

File, Retrieve by ID



MMDB

- MMDB (Molecular Modeling Database) files from the NCBI
- derived from PDB atomic coordinates but with …
- Database information (quaternary struct, molecular interactions, SNPs, conserved domains, clinical variants – i.e related structure info, not just xyz coord

PDB

- xyz coordinates

RCSB MMTF ID (fast)

- Great for very big structures that otherwise too slow in loading; Few modeling options.

AlphaFold Structure

- Computationally determined structures
- Uses Uniprot or RCSB ID.

OPM PDB ID

- Get structures on membrane proteins

Other Membrane Protein Links

•Eukaryotic peripheral membrane proteins (PerMemDB)

•Orientation of proteins in membranes (OPM)

•PDBTM: Protein Data Bank of Transmembrane Proteins

•mpstruct: Membrane Proteins of Known Structure

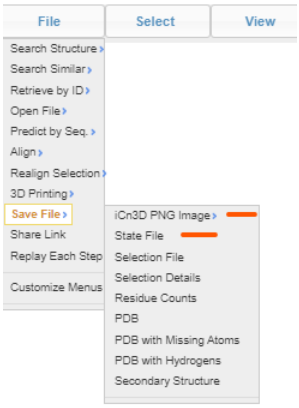
•Membranome: Membrane proteome of single helix membrane proteins

•MemProtMD: A database of membrane proteins embedded in lipid bilayers with lipids obtained in Molecular Dynamics simulation

iCn3D Basics: Saving Files

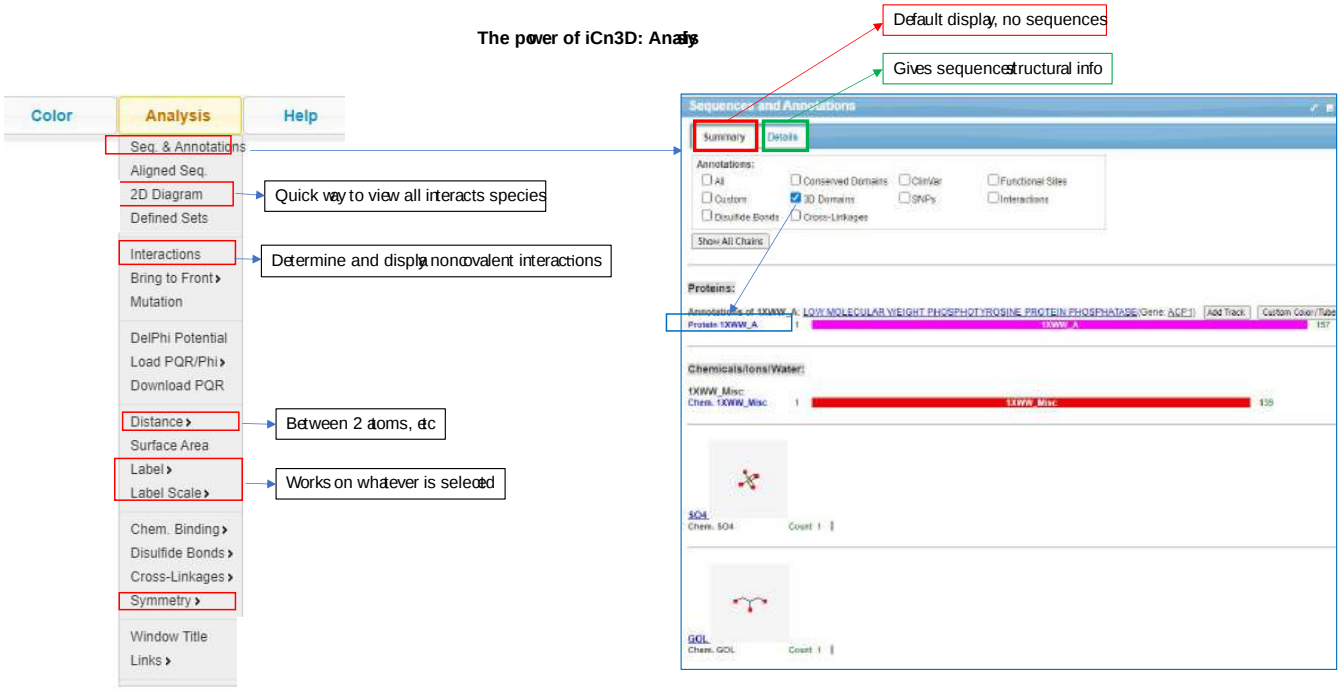
File, Save File

- In a new iCn3D window choose **Open File, iCn3D PNG image** and see the same file you started with.
- Likewise, in a new iCn3D window choose **Open File, State/Script File** and see the same file you started with.
- They can be sent to others to open as well



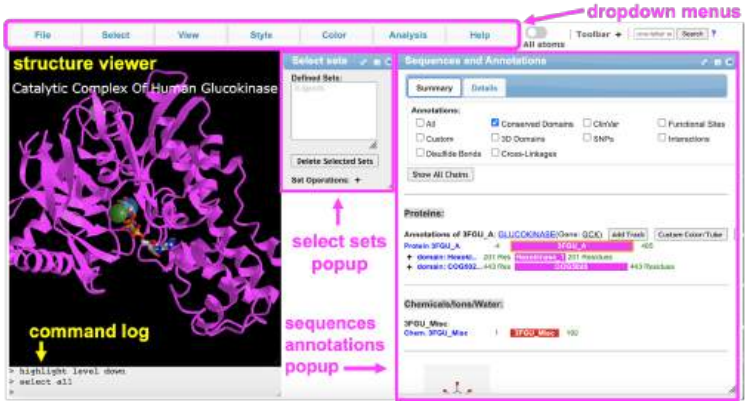
iCn3D Basics: Analysis Menu

Analysis Menu



iCn3D Basics: Mouse Commands

iCn3D modeling screen



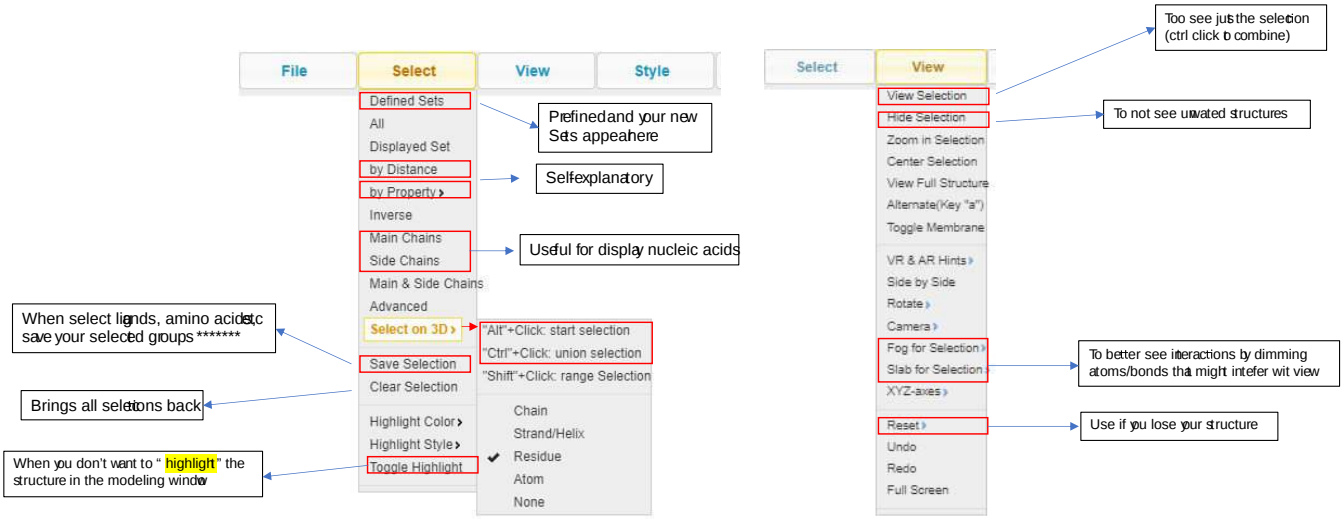
Mouse commands

rotate: click and drag (*mouse*: left click and drag; *keyboard*: j, i, l, and m keys)
zoom: pinch and spread (*mouse*: rotate the scroll wheel; *keyboard*: x and z keys)
translate: two finger click and drag (*mouse*: right click and drag)
Re-center: left click View from the top menu bar, then select "Center Selection"

Note: ctrl click on a PC = command click on Mac
alt click on PC = option click on Mac

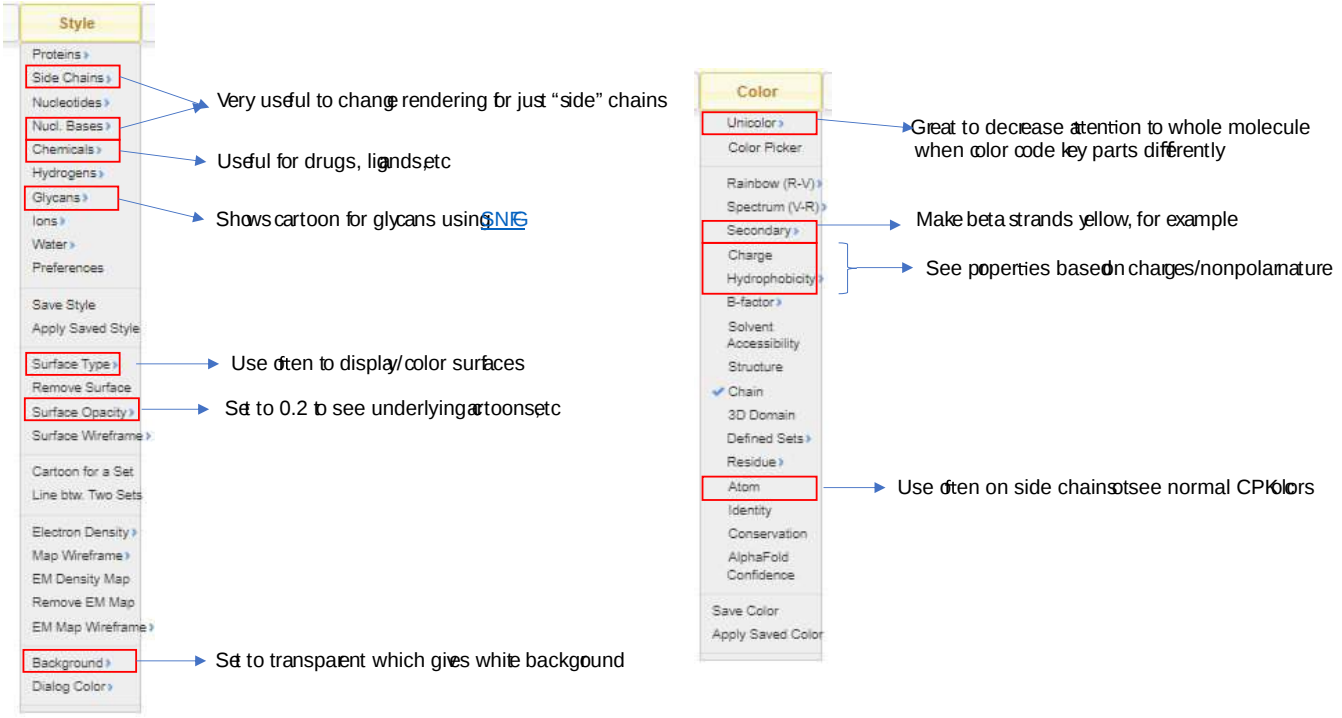
iCn3D Basics: Selecting and Viewing with a mouse

Selecting with the mouse (left) and viewing selection (right)



iCn3D Basics: Style and Color

Style and Color



iCn3D Intro Tutorial A: Modeling a Short Peptide in a Protein

A. Modeling short sections of a protein chain

Pick one of the small protein fragments below for modeling using iCn3D

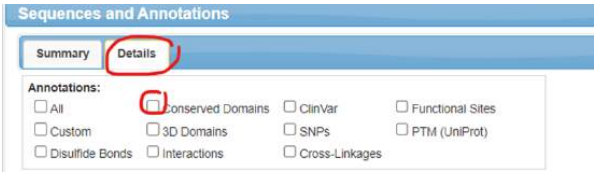
PDB	Description of protein (all small fragments)
2YW8	Crystal structure of human RUN and FYVE domain-containing protein
6EEY	human Scribble PDZ4 R1110G Mutant
2PA1	PDZ domain of human PDLIM2 bound to a C-terminal extension from human beta-tropomyosin
3A03	Hox11L1 homeodomain
3IWL	cisplatin bound to a human copper chaperone (monomer)
5Z2S	DUX4-HD2 domain
6L1C	PHF20L1 Tudor1 Y24L mutant
3D2N	MBNL1 tandem zinc finger 1 and 2 domain
3RD2	NIP45 SUMO-like Domain 2
7NZC	SH3 domain of POSH (Plenty of SH3 Domains protein)
1I2T	HUMAN HYPERPLASTIC DISCS PROTEIN: AN ORTHOLOG OF THE C-TERMINAL DOMAIN OF POLY(A)-BINDING PROTEIN
1NTE	CRYSTAL STRUCTURE ANALYSIS OF THE SECOND PDZ DOMAIN OF SYNTENI
2Y9U	Structural basis of p63a SAM domain mutants involved in AEC syndrome
2FMA	Alzheimer's Amyloid Precursor Protein (APP) Copper Binding Domain in 'small unit cell' form, atomic resolution
4OU0	Crystal Structure of RPA32C
1ZT3	C-terminal domain of Insulin-like Growth Factor Binding Protein-1 isolated from human amniotic fluid
2E3H	Crystal structure of the CLIP-170 CAP-Gly domain 2
1L9L	GRANULYSIN FROM HUMAN CYTOLYTIC T LYMPHOCYTES
5EFM	Beclin 1 Flexible-helical Domian (FHD) (141-171)

2BZX	Atomic model of CrkL-SH3C monomer
1NHL	SNAP-23N Structure
7UW7	Crystal structure of the Human TRIP12 WWE domain (isoform 2) in complex with ADP
4N7F	3rd WW domain of human Nedd4-1
2Q9V	C890S mutant of the 4th PDZ domain of human membrane-associated guanylate kinase
6T9Q	second, C-terminal repeat of the DNA-binding domain of human TImeless
1WVN	domain 3 of human alpha polyC binding protein
3I8Z	human chromobox homolog 4 (CBX4)
2F60	Dihydrolipoamide Dehydrogenase (E3)-Binding Domain of Human E3-Binding Protein
7FGN	FAF1 UBL1
5UM3	V122L mutant of human UBR-box domain from UBR2
2FJZ	Alzheimer's Amyloid Precursor Protein (APP) copper-binding domain (residues 133 to 189) in 'small unit cell' form, metal-free

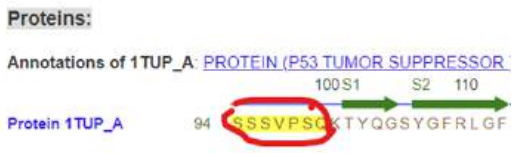
1. Open https://www.ncbi.nlm.nih.gov/Structure/icn3d/full.html
2. Input in your assigned pdb code and select Load Biological Unit

3. Choose **Analysis, Seq and Annotation**

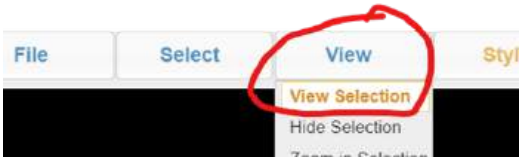
4. Choose Details tab and uncheck conserved domains



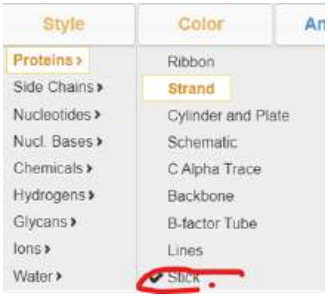
5. With your mouse, select, hold, and sweep between the first 5-10 amino acids (given in single letter code) as illustrated below. When you select them, they will turn yellow.



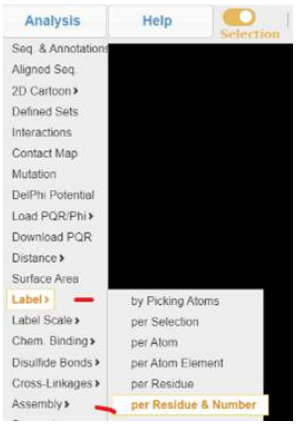
6. Choose **View, View Selection** (to limit view to what you want



7. Choose **Style, Proteins, Sticks** to see all the bonds



8. Change the background from black by choosing from top menu bar **Style, Background, Transparent**



9. Choose, **Analysis, Label, Per residue/#;** then **Analysis, Label Scale, 2**

10. Next, color your model as shown below in different ways as described in the table below. Then take a screen capture of the selection and replace the image in the table cell with your own

Color	Paste snip of renderings as shown below.
Spectrum, Selection to better see each amino acids in selection	Charge Gray if no charges (ignore yellow highlight)	Hydrophobicity (if nonpolar like oil)	Atom (red oxygen, blue nitrogen, yellow Sulfur	
iCn3D Intro Tutorial B: Rendering a Protein

B. Rendering Full Proteins

Pick one of the proteins below that has both alpha helices and beta sheets. You will then change the protein style (rendering) to see the same protein in different ways to illustrate different properties of the proteins.

Monomeric proteins with alpha (helices) and beta (sheets)

1HDO	Human biliverdin IX beta reductase: NADP complex
2HC2	Engineered protein tyrosine phosphatase beta catalytic domain
5ZUN	Crystal structure of human monoacylglycerol lipase in complex with compound 3l
1X3S	Crystal structure of human Rab18 in complex with Gppnhp
4IN0	Crystal Structure of human splicing factor dim2/TXNL4B
1KGD	Crystal Structure of the Guanylate Kinase-like Domain of Human CASK
5KQL	Co-crystal structure of LMW-PTP in complex with 2-oxo-1-phenyl-2-(phenylamino)ethanesulfonic acid
1QGV	HUMAN SPLICEOSOMAL PROTEIN U5-15KD
1MF7	INTEGRIN ALPHA M I DOMAIN
4RQR	Crystal Structure of Human Glutaredoxin with MESNA
4JKA	Open and closed forms of R1865A human PRP8 RNase H-like domain with bound Co ion
5C4M	RhoA GDP with novel switch II conformation
6P0J	Crystal structure of GDP-bound human RalA
4MMM	Human Pdrx5 complex with a ligand BP7
4M6IJ	Crystal structure of human dihydrofolate reductase (DHFR) bound to NADPH
3M9J	Crystal structure of human thioredoxin C69/73S double mutant, reduced form

1. Load ID **4LPK**, Crystal Structure of K-Ras protein with a small molecule, GDP, bound
2. Choose **Color, Secondary, Sheet in Yellow**
3. **Style, Background, White**

4. Choose **Style, Proteins** and display as ribbon, cylinder and plate, C alpha trace, backbone, lines and sphere
5. Paste your results in the table below.

6.

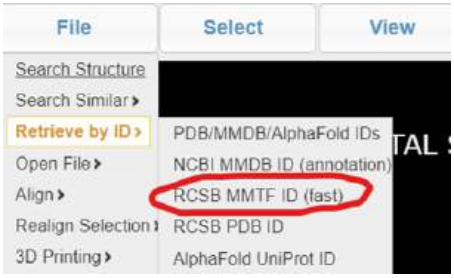
Results (replace image with yours)

PDB ID, description:

ribbon	
Cylinder and plate	
C alpha trace	
backbone	
line	
sphere	

7. Model a protein dimer that has two subunits. Use the pdb code for 1LFD (CRYSTAL STRUCTURE OF THE ACTIVE RAS PROTEIN COMPLEXED WITH THE RAS-INTERACTING DOMAIN OF RALGDS). Paste your favorite image below.

8. Model a huge structure, the human rhinovirus 14 (causes colds, PDB: 4RHV). It so big you have to load it in a different way, as shown below. Paste your favorite image below.



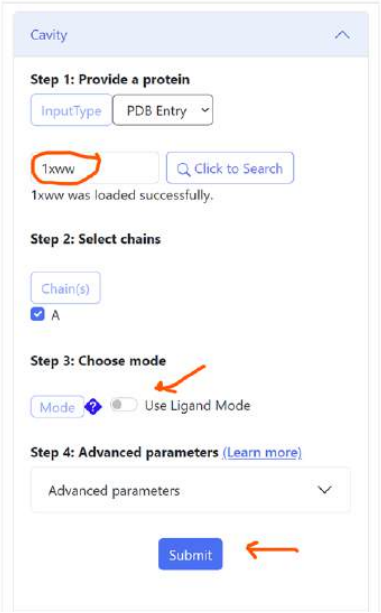
iCn3D Intro Tutorial C: Finding Pockets in Proteins

Small molecules that bind to larger proteins must have shape AND charge complementarity with the binding pocket in the protein. You can put a small molecule into an appropriate-sized pocket in a protein. You can't put a positively charged small molecule into a pocket lined with a positive charge. Let's find the pockets in a small protein, LMWPTP, a phosphatase that cleaves a negatively charged phosphate group (PO_3^{-2}) proteins (pdb 1xww). It also binds the small sulfate ion (SO_4^{-2}) in the same pocket.

Finding Pockets

Let's find the pocket where the ligand could bind using a free program called CavityPlus. 2022

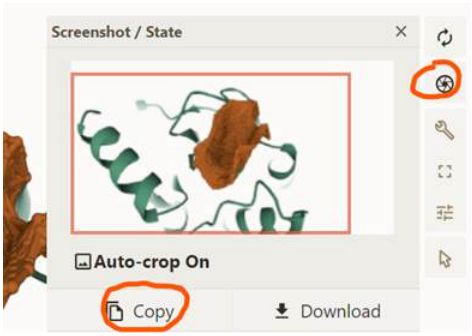
1. Load http://www.pkumdl.cn:8000/cavityplus/computation.php#/ and select **Start Computing**
2. Input 1xww, then select **Click to Search**. Wait until the structure loads to continue.
3. Then simply choose **Submit**. (Make sure that Use Ligand Mode is **not** selected)



bnbnbn

4. After the run, you will see a new window open on the left-hand-side with the protein and the top #1 Cavity highlighted. Site 1 is the presumptive location for the binding of SO_4^{2-}. Use your mouse to rotate the protein to better see the cavity. To see a list of the amino acids lining the binding pocket surface, and the surface area and volume of the cavity, select **…** under **More**. They will appear in the Residue row.

5. Copy and Paste into the table below the list of amino acids comprising the pocket into the table below. Then take a screen snip as shown in the image to the right (Note: if you can unzip the downloaded file, you could select the Download Results link and use other programs to view the results).



Amino acids in pocket	Image snip

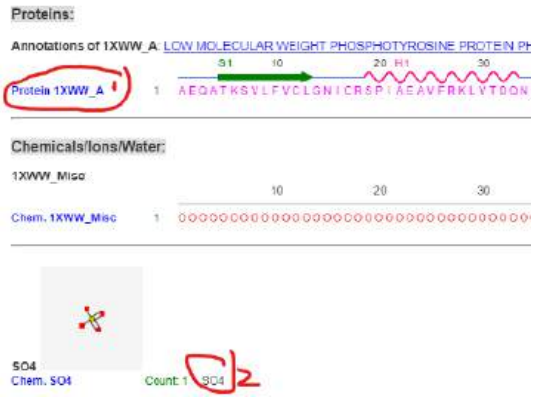
Viewing Small Molecule in a Binding Pocket

Now let's model the phosphate (PO_3^{-2})/sulfate (SO_4^{-2}) binding site in the phosphatase using iCn3D.

1. load 1XWW in iCn3D

2. Render the proteins as follows:

- **Analyses, Sequences and annotation**, Details Tab, uncheck conserved domain
- Click 1XWW_A 1st, then in the top menu bar choose **Select, Save Selection** and name it phosphatase



- **Color, Charge**
- **Style, Surface Opacity, Fast Transparency, 3**
- **Style, surface type, molecular Surface**

3. Next render the SO4 as follows:

- Choose SO4 (2) with the mouse, then **Select, Save Selection** and name it SO4
- **Style, Chemicals, Sphere**

4. Snip and paste an image of the protein with the surface display and the bound SO_4^{-2} in spheres.

5. Optional: To see actual interactions between SO_4^{-2} and the protein

- **Style, Remove surface**
- **Analysis, Interactions**,
- In popup window, choose for 1st set – sulfate; choose for the 2nd set – phosphatase; click 3D Display Interactions; Snip table with types/colors on interactions
- **View Selection; Style, Sidechains, Stick; Color, by Atom**,
- **Analysis, Label, Per Residue and number; Analysis, Label Scale, 2**;
- **Style, background, white**
- Snip an image of the interaction legend and modeled interactions, and paste below.

iCn3D Intro Tutorial D: Modeling Psychoactive Drugs in Target Proteins

Use iCn3D to model the binding of one of the psychoactive/analgesic drug to their receptor (either the 5HT or cannabinoid receptor). Paste the final model in the space shown.

Serotonin (5-hydroxytryptamine) receptors

5-HTreceptors are indirectly involved in the mechanism of action of antidepressant drugs. Most antidepressant drugs like Prozac increase the concentration of 5-HT in the extracellular brain synapse by inhibiting its reuptake into neurons. Prozac doesn't bind to the 5HT receptor but to a membrane protein that removes 5HT from synaptic region.

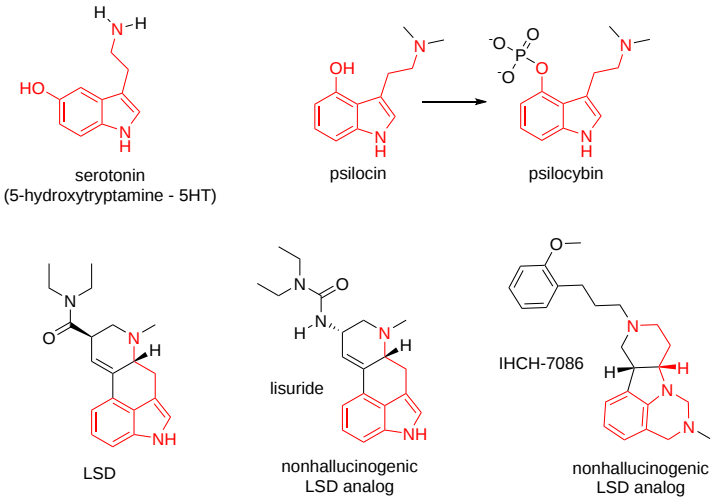
There are 7 types of 5HT receptors and each has different biochemical effects

Different drugs target different 5HT receptors.

Let's focus drugs that target 5-HT_{2A} act as antidepressants, but also lead to hallucination.

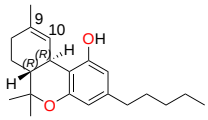
Serotonin (5HT) 2A receptor: These molecules bind to it.

- serotonin (5HT), the physiological agonist, 7WC4 (does not cause hallucinations)
- psilocin, 7WC5 , hallucinogenic, a metabolite of psilocibin)
- LSD, 7WC6, hallucinogenic
- lisuride, 7WC7, non-hallucinogenic
- IHCH-7086, nonhallucinogenic

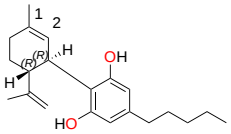


THC and CBD receptors

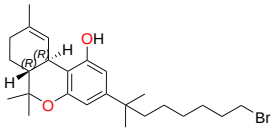
These molecules bind to them.



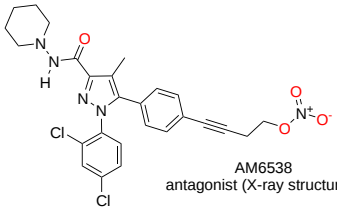
Δ9-tetrahydrocannabinol
THC



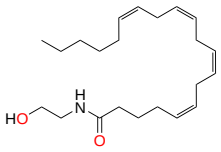
cannabidiol
CBD (AM11542)



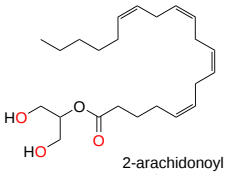
AM11542
agonist



AM6538
antagonist (X-ray structures)



ananamide
endogenous agonist



2-arachidonoyl glycerol
endogenous agonist

- Human CB1 in complex with agonist AM11542 (5XRA)
- class A GPCR Cannabinoid Receptor-Gi Complex Structure with bound agonist (6KPF) - The agonist is AM12033, which is similar to AM11542
- CBD-bound full-length rat TRPV2 in nanodiscs (6U88)

Your model:

PDB ID:

"DRUG"

RECEPTOR:

Rendered Image

---

iCn3D Skill: Alternative Rendering and Saving Files

Structure

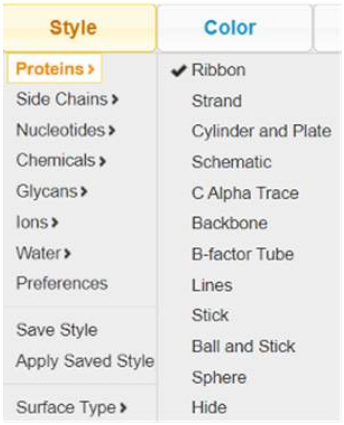
- PDB ID: 1xww
- Protein: Low molecular weight protein tyrosine phosphatase
- Activity: hydrolyzes Tyr-OPO_3^{2-} phosphoester bond
- Description: single chain, bound SO_4^{2-} (competitive inhibitor), bound glycerol (nonspecific stabilizer)

Alternative Rendering

Load Structure and Mouse/Trackpad Controls

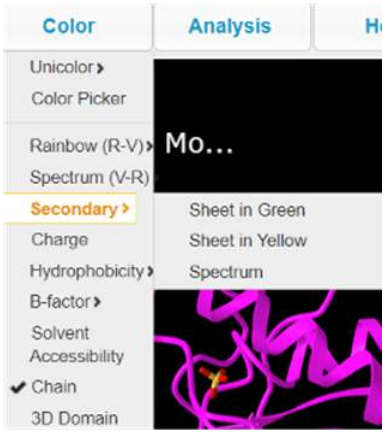
- Open iCn3D - https://www.ncbi.nlm.nih.gov/Structure/icn3d/full.html
- For a simple menu, use the dropdown: File > Customize Menus > Simple Menus.
- In the *Please input MMDB or PDB*, enter 1xww. Press enter or click load biological unit.
- Default render is ribbon (cartoon) with black background and small molecules shown as sticks. Hover over objects with the mouse to reveal their identity.

1. From the top menu bar, choose **Style**, **Protein**, then try some of the available choices:



2. For your favorite protein styles, select **Color** by left-clicking on the top menu, then pick available choices. Try:

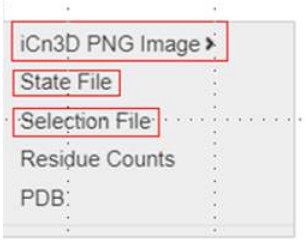
- **Secondary**, **Sheets in Yellow**
- **Charge**
- **Hydrophobicity**



3. Under **Style**, choose **Protein → Ribbon**. Under **Color**, choose **Secondary, Sheets in Yellow** before the next step.
4. To view sidechains, **Style, Side Chains, Stick** (they will remain the same color as secondary structure for now)
5. Color for SO_4^{2-} and bound glycerol will default to CPK coloring (key below)
6. Convert back to cartoon (**Style, Side Chains, Hide**)

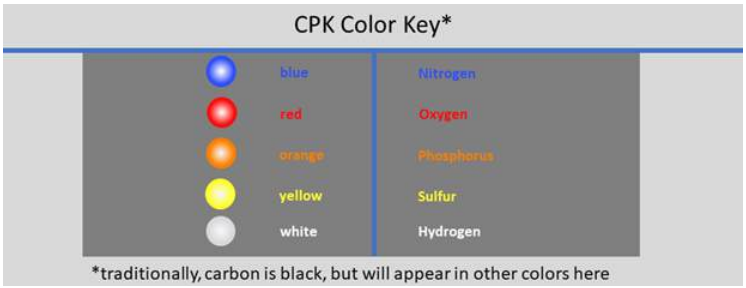
Saving Files

7. Style, Background, Transparent
8. Saving Files: There are several ways to save your work. The first option below saves a PNG image, the second creates a share link
   a. **File, Save Files, iCn3D PNG image, original size**; Give it a name. Can be reloaded in iCn3D with File, Load, iCn3D PNG IMAGE
   b. **File, Share Link, Save Lifelong Short URL**. Copy and paste this link to share your work.



Pre-Rendered Model Link

To check your work (or if you got stuck during any of the steps above) catch up using this link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?CgfEnF27TN7aYQpr6



iCn3D Skill: Displays surface of a protein - Superoxide Dismutase

A. The molecular surface of superoxide dismutase

PDB ID: **2sod**

- Description
- superoxide dismutase
- dimer with 2 Cu^{2+} ions bound in each subunit
- catalyses the reaction of $O_2^- + O_2^- + 2H^+ \rightarrow H_2O_2 + O_2$

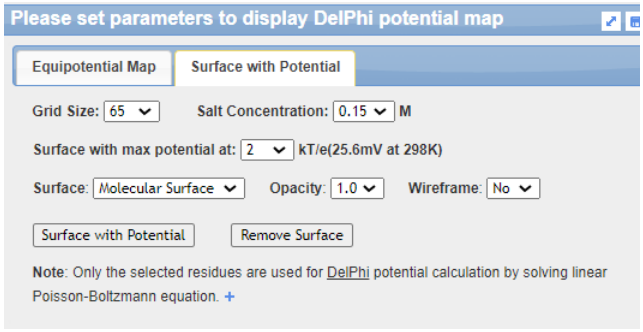
Instructions

1. **File, Retrieve by ID,** MMDB
2. **Style, Surface Opacity, Fast Transparency, 0.2**
3. **Select, Select on 3D, Chain.** Alt Click on one chain
4. **Color, Secondary, Sheets in Yellow**
5. **Style, Surface Type, Molecular** (takes a while to render)
6. Now Alt Click on the other chain
7. **Color, Wimley White Hydrophobicity*** (takes a while to render)
8. **Style, Surface Type, Molecular** (takes a while to render)
9. **Style, Background, White**
10. **File, Share Link, Save short url**

B. The electrostatic surface potential of superoxide dismutase

Background: Superoxide (O_2^-) is a toxic free radical and hence dangerous. To capture it as effectively as possible, the surface distribution of charged side changes is such that a positve electrostatic potential surrounds each active site.

1. **File, Retrieve by ID,** MMDB
2. **Select, Select on 3D, Chain.** Alt Click on one chain, Control-click on the second. Alternatively, choose A**nalysis, Sequence and Annotations, Details Tabs (uncheck conserved domains)**, and click one chain (blue font) and then control-click the second so both are highlighted.
3. In the Details tab of **Analysis, Sequence and Annotations,** sweep both Cu ions (with mouse) to select them, the **Color, Yellow**
4. **Analysis, DelPhi Potential, DelPhi Potential**
5. Choose the **Surface with Potential Map** tab. Chose the options below



6. **Select Surface with Potential.** Look a the blue (positive potential) surround the yellow Zn ions in both active sites.
7. **Style, Surface Type, Molecular** (takes a while to render)
8. **Style, Background, White**
9. **File, Share Link, Save short url**

iCn3D Skill: Aligning two structures

Superimpose and annotate active (phosphorylated) form of cyclin-dependent kinase 2 (1JST) and inactive (1FIN)

Description

1JST (active)

- PHOSPHORYLATED CYCLIN-DEPENDENT KINASE-2 BOUND TO CYCLIN A. Has bound Mn2+ and ATPγS.
- pT160 is on the regulatory T-loop of CDK2. It is mostly buried and neutralized by 3 Arg side chains. Compared to unphosphorylated CDK2–CyclinA, the T-loop moves by as much as 7 Å,
- T loop about 147-163

1FIN (inactive):

- CYCLIN A-CYCLIN-DEPENDENT KINASE 2 COMPLEX. Has a bound ATP as well as Cyclin A (B and D chains)

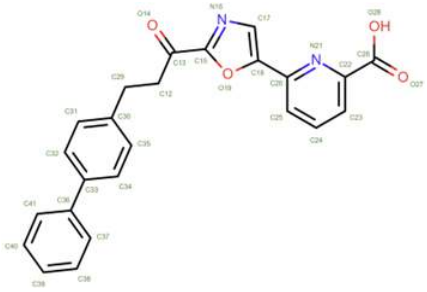
Instructions

1. **File, Align, Structure to Structure**
2. Input **1JST** and 1FIN
3. Choose All Matching Molecules Superimposed
4. In the Select residues in aligned alignment window, click the blue font 1JST-C to select the entire chain. **Color, Green, Dark Green** (green for go = active)
5. Likewise, select 1FIN-A. **Color, Yellow, Yellow** (so we can color the T loop red)
6. Alt Click in the modeling window MN and ctrl Click ATP. **Select, Save Selection, MN_ATP**
7. **Style, Chemicals, Sphere**
8. In long sequences, capture with mouse approx T loop 147-163. **Select, Save Selection**, T loops; Color red
9. In the long sequences, hover over and then click to select in 1JST_C x160 (this is phospho-Thr160) and then in 1FIN_A T160 (i.e. Thr 160). **Select, Save Selection,** Thr160s
10. **Style, Sidechains, Sticks**
11. **Color, Atom**
12. In the Defined Sets, click then ctrl click all of the selections you made: MnATP, Thr160s, align_1FIN_A, and align_1JST_C. Then save as **000All**. Using 000 at the start of the name put the combined selection at the top of the Defined Sets window. This will be important later.
13. Make sure 000All is selected, then **View, View Selection**
14. **Style, Background, White**
15. **File, Share Link, Lifelong Short Link,**
16. Paste the link into a new window, much as a student would. **Analysis, Defined Set**, then click 000All at the top to highlight the superimposed chains. Once all is highlighted, toggle between the two states by clicking the Alternative (Key “a”) menu button directly under the File button.
17. Now try View, Side by Side to see both (**don’t** toggle this form)

iCn3D Skill: Analysis of Noncovalent Interactions

Structure

- PDB ID: 3K83
- Protein: Inhibitor (below, abbreviated F278458) bound to a humanized variant of Fatty Acid Amide Hydrolase (FAH)

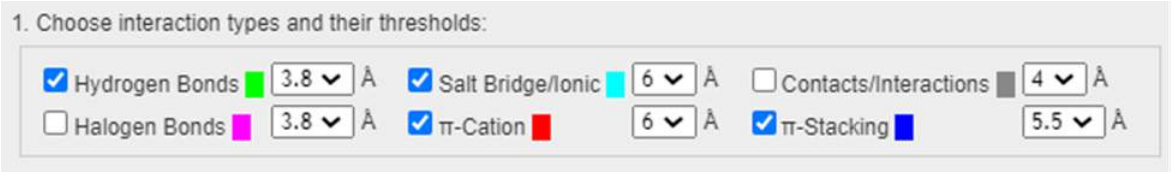


- Activity: FAH Catalyzes the hydrolysis of endogenous amidated lipids like the sleep-inducing lipid oleamide, the endocannabinoid anandamide, and other fatty amides, regulating the signaling functions of these molecules
- Description: The functional unit is a dimer, each with an active site. A chloride binds between the two subunits

In this activity you will see key noncovalent interactions between the inhibitor and (FAH). You will pick one inhibitor and view its noncovalent interactions with one subunit

Modeling Instructions

1. Open a new iCn3D window, 3K83 at: https://www.ncbi.nlm.nih.gov/Structure/icn3d/full.html
2. **Select, Select on 3D** to ensure default is **Residue**; With mouse, zoom and center to Alt-Click the inhibitor (F278458) in the magenta subunit (option-click on a Mac)**.**
3. **Select, Save Selection,** name it **Drug**
4. **Analysis, Interactions.**
5. Under 1. Choose interaction types and their thresholds, Check only the noncovalent interactions shown below. Make sure the Contacts/Interactions is unchecked as it shows all interactions between contacting Van der Waals surfaces including many hydrophobic interactions, so it is quite cluttered.



6. Select the Drug as the first set (under 2. Select the first set); choose 3K83 (under 3. Select the second set)
5. Click on the box: 4. 3D Display Interactions. This will display interacting side chains. Drag the HBonds/Interactions window to the bottom right away from the molecular display. Note the coloring of the dotted lines:

Green - hydrogen bonds

Red - π-cation

Blue - π stacking

6. **Select, Save Selection,** name it **Interactions**
7. **Style, Sidechains, Stick** (so the next step will color side chains)
8. **Color, atom (*Note*:** this drug is covalently bound to Serine241)
9. In defined sets Ctrl click Drug and Interaction to highlight all
10. **View, View Selection** (to only see Drug and Interactions)
11. **Select, Toggle Highlight** (to remove highlights if necessary)

Note: Once you run interactions, iCn3D adds many new additions to the Defined sets window. Explore these to learn different ways to examine the interactions.

Optional (if you'd like to add labels, recolor the background, and obtain the share link as in the previous activity)

12. **Analysis, Label, Per Residue & No**
13. **Analysis, Label Scale,** pick a number that works for you
14. **Style, Background, Transparent**
15. **File, Share Link,** copy short link

Pre-Rendered Model Link

To check your work (or if you got stuck during any of the steps above) view the model using this link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?pDr5EBZmo3TyAbTP6

Note: You can alter interactions on the 3D model, or examine 2D displays of them. Try:

- Click **5. Reset** at the bottom of the HBonds/Interactions window. Add Contacts/ Interactions (mostly nonpolar) by clicking on the box. Choose Drug as the first set. Choose 3K83 as the second set. Then click **4. 3D Display Interactions** to show.
- Next, try **4. 2D Interaction Network**. In the popup that opens, click a colored line in the 2D window to highlight a specific interaction.

If using the Pre-Rendered model: From the top menu, select: **Analysis → Interactions**. In the popup choose **5. Reset**, select 3K83 (full protein) as set 1 and drug as set 2, then **4. 2D Interaction Network**. Click colored lines in the 2D window.

---

iCn3D Skill: Creating and Saving Selections

Structure

- PDB ID: 3UBB
- Protein: Rhomboid intramembrane serine protease GlpG (3UBB) with phosphonofluoridate inhibitor
- Activity: Integral membrane serine protease
- Description: Single chain transmembrane protease from *E. coli* bound to a phosphonofluoridate inhibitor, which is covalently bonded to the catalytic serine. Red and blue dots ("dummy" atoms) indicate extracellular and intracellular membranes, respectively. Uses a catalytic **dyad** composed of serine (S201) and histidine (H254).

Load Structure

1. Open iCn3D - https://www.ncbi.nlm.nih.gov/Structure/icn3d/full.html
2. In the *Please input MMDB or PDB,* enter 3UBB. Press enter or click load biological unit.

Selecting using: 1. The structure viewer window with the Mouse and 2. The sequences and annotations menu (Key Learning Objectives)

This section will show how you can select residues, chains, etc in the Modeling window.

3. **Select, Select on 3D** to ensure default is **Residue**; With cursor, hover over the inhibitor (name 3UB) and Alt Click (option click on Mac) it. A yellow halo will appear around it.
4. **Select, Save Selection**, name it Inhibitor.
5. Now, use the top menu to open the sequences and annotations tab: **Analysis, Seq. and Annotations**
6. In the sequences and annotations window, uncheck "Conserved Domains," and then click the **Details tab**. Click individually on the one letter code for S201 and H254. On selection, they will turn yellow.

(Note: To see the scroll bar in sequences/annotations in a Mac, choose Systems preferences in your operating system [not the iCn3D settings], General, show scroll bars and check always; see iCn3D About notes).

7. **Select, Save Selection,** name CatDyad

Rendering (Optional, can use the highlighted link below instead)

8. **Select**, **defined sets** (Note that "defined sets" brings up a complete list of objects, many selections are pre-built into iCn3D to get you started with a model.)
9. In Selected Sets, click 3UBB_A.
10. **Color, Unicolor, Gray, Light Gray**
11. In Selected Sets, click CatDyad
12. We want to show the side chain of the catalytic dyad, so use the top menu: **Style, SideChains, Sticks**
13. Recolor to CPK coloring: **Color, Atom**
14. **Analysis, Label, Per Residue and Number**
15. **Analysis, Label Scale,** pick number that works for you
16. **Style, Background, Transparent**
17. Remove any active selections (yellow glow) by Select, Toggle highlight

Pre-Rendered Model Link

https://structure.ncbi.nlm.nih.gov/icn3d/share.html?fhT3dwckYg8i5XJj8

The short URL above may be used to catch up for the next section of the tutorial

Selecting sphere within around 5Å of the inhibitor (Key Learning Objective)

Our goal is to find all atoms with 5Å from the inhibitor, this time without showing interactions. In the next step, we will designate 2 sets of objects. Set 1 will be the inhibitor. Set 2 will be nearby residues/bound molecules. In our case, Set 2 will be defined as the protein.

18. **Select, by Distance**
19. For the first set, select inhibitor; for Set 2 click 3UBB
20. For **Set 2. Sphere with a radius to 5 Å**
21. **Click Display; Close the Select by distance window**
22. Now save the highlighted groups 5Å from the inhibitor through **Select, Save Selection,** Name 5AfromInhib
23. **Style, Side chains, Stick**
24. **Color, Atom**
25. Select both the inhibitor and the surrounding residues: In **Defined Sets,** Click Inhibitor, and Ctrl+Click 5AfromInhib (Command+Click on a Mac)
26. Display only the active site for clarity: **View, View Selection**
27. **Analysis, Label, Per Residue & Number**
28. To see water, **Style, Water, Sphere**
29. **File, Share Link,** copy short link

Pre-Rendered Model Link

To check your work (or if you got stuck during any of the steps above) view the model using this link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?sqZf4Zvqn5zWK21d9 This link shows the membrane. Choose **View, Toggle Membrane** to hide it.

---

iCn3D Skill: Mutations

Analysis: Mutation

A simple way to change 1 amino acid to another

PDB ID: **1xww**

Description: human B-form low molecular weight protein tyrosine phosphatase (has single domain) with bound sulfate (SO4) and glycerol (GOL)

Instructions

1. **File, Retrieve by ID,** MMDB
2. **Analysis, Mutation**
3. Input the desired mutation C12S this way (1XWW_A_12_S) where A is the A chain, 12 is the aa # and S is the new mutated amino acid residue Ser. Note that C12 is the wild-type active site nucleophile in phosphatases and changing it to Ser will effectively abolish phosphatase activity. To view you could use 3 different methods. We'll use one.
4. 3D with scap: toggle back and forth between structures using the key “a”
5. **Interaction**: shows the mutation in 3D and change in interactions
6. PDB: shows structure and exports a PDB file within 10 A of the mutation
7. Choose Interactions and say wow!
8. **Color, Atom**
9. **Style, Background, White**
10. Toggle back and forth between the structures with the letter “a”
11. **File, Share Link, Lifelong Short Link**

iCn3D Skill: Selection through Sequence and Annotations

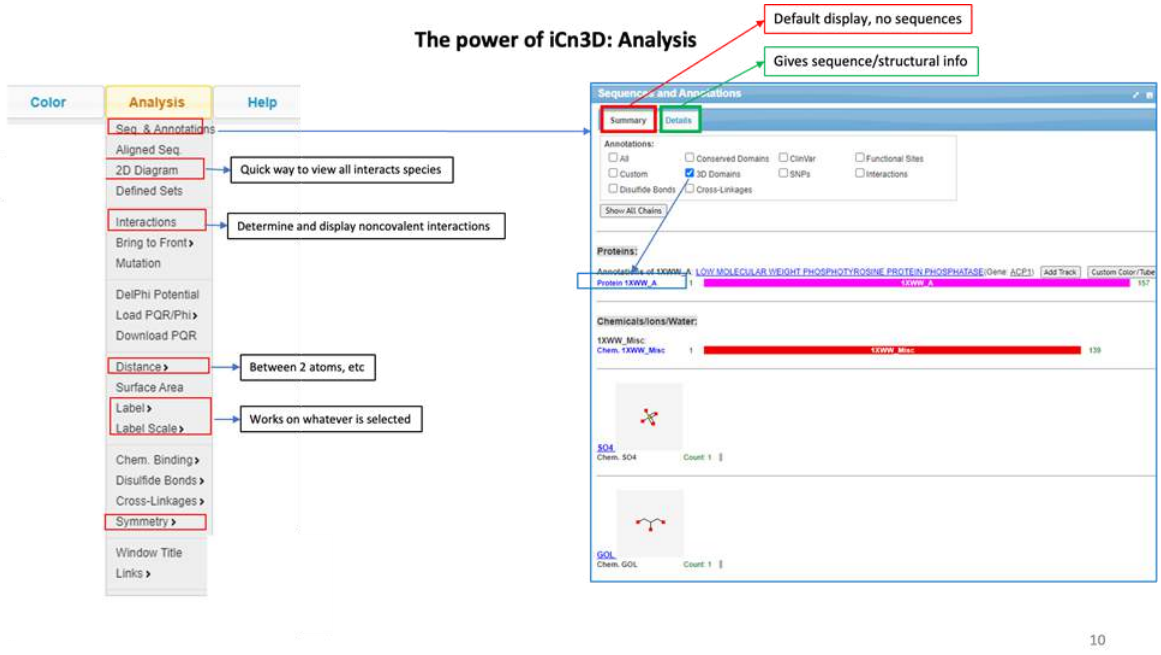
Structure

- MMDB ID: 1xww
- Protein: Low molecular weight protein tyrosine phosphatase
- Activity: hydrolyzes Tyr-OPO_3^{2-} phosphoester bond
- Description: single chain, bound SO_4^{2-} (competitive inhibitor), bound glycerol (nonspecific stabilizer)

Load Structure and Mouse/Trackpad Controls

- Open iCn3D - https://www.ncbi.nlm.nih.gov/Structure/icn3d/full.html
- For a simple menu, use the dropdown: File > Customize Menus > Simple Menus.
- In the *Please input MMDB or PDB*, enter 1xww. Press enter or click load biological unit.
- Default render is ribbon (cartoon) with black background and small molecules shown as sticks. Hover over objects with the mouse to reveal their identity.

Figure: *The Sequences and Annotations Menu*



For this part, we will be using the model from Activity 1. To load the premade model from Part 1, use this link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?CgfEnF27TN7aYQpr6

From the literature, it is known that the active site is a nucleophilic cysteine (C12). It is part of the phosphate-binding loop (P-loop, AA 12-18: sequence CLGNICR). Let's find, select, and render these amino acids.

Modeling Instructions

1. Under **Analysis** (top menu bar), choose **Sequence and Annotations**
2. Choose **Details tab, uncheck Conserved Domains**

Before we continue, look at the built-in choices you have for selection:

Annotations:

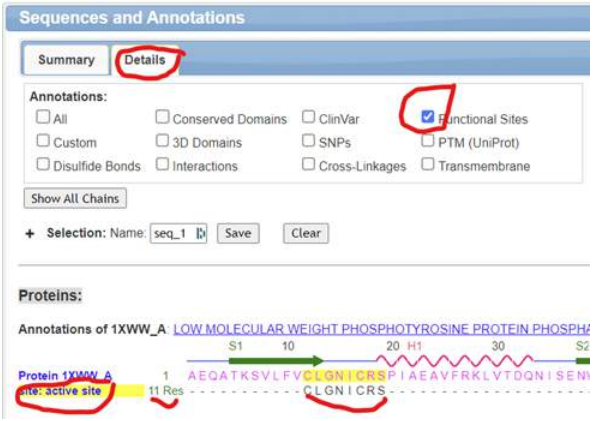
☐ All	☐ Conserved Domains	☐ ClinVar	☐ Functional Sites
☐ Custom	☐ 3D Domains	☐ SNPs	☐ Interactions
☐ Disulfide Bonds	☐ Cross-Linkages		

3. In the Sequences and Annotation window, click Protein 1XWW_A
4. Under **Select** (top menu bar), choose **Toggle Highlights**
5. Hover over C12 in the sequence (in Seq and Annot window), click and hold down the mouse key, and sweep over C12-C18 to select the P loop
6. **Select, Save Selection**, name it: Ploop
7. Within this highlighted selection**, Style, Side Chains, Sticks**
8. **Color, Atom**
9. **Analysis, Label, Per Residue & Number**
10. **Analysis, Label Scale,** pick number that works for you
11. **Analysis, Label, Change Label Color** (globally). Click in the text box and a Color box will pop up, choose from a palette, then **Display**. (Alternatively, pick a hex code**).**
12. In the Sequences and Annotation window, click SO4
13. **Style, Chemicals, Sphere** to change the sulfate to a space filling rendering
14. Files, Share Link, Copy Short URL

Pre-Rendered Model Link

To check your work (or if you got stuck during any of the steps above) catch up using this link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?QhtGuE8pkaJpGs1X9

Note: For some enzymes, iCn3D can automatically display key active site and binding residues. These can be seen as shown by selecting the items indicated in the left figure.



iCn3D Skill: Showing a Protein-Protein Interface

Protein:Protein Interface

PDB ID: 3S9D

- binary complex between interferon alpha 2 (IFNa2) and its recetor IFNAR2
- Cyan: IFN, blue IFN receptor

Instructions

1. **Retrieve by ID,** MMDB
2. **Analysis, Seq. & Annotationsm, Details Tab.**
3. **Select magenta IFN alpha chain:** 3s9d_A
4. **Select, Save Selections** INF
5. Repeat with blue 3s9d-b. Save Select INFR
6. **Select, INF; Select by Distance, within 5A.** Set 1: selected; Set 2: nonselected; **Display**
7. **Select, Save Selection:** 5Ang from IFN
8. **Select 5A from INF: Style, side chains stick, color atom**
9. repeat for INFR
10. **Select Select by Distance, within 5A.** Set 1: IFNR; Set 2: nonselected; Display
11. **Select, Save Selection**: 5Ang from IFNR
12. **Select, Side Chains, sticks; Colore atom**
13. **Select 5A from IFNR: Style, side chain sticks. Color, charge, Style, surface type, vanderWaals**
14. **Analysis, Interactions, Set 1: 5A from INF; Set 2: 5A from INFR**
15. **Select, Save, Selections, Inteactions**
16. **Style, Background, White**
17. **File, Share Link, Lifelong**

iCn3D Tutorial: Binding interactions of SARS-Cov-2 Spike receptor domain with ACE2

A. 1st Way

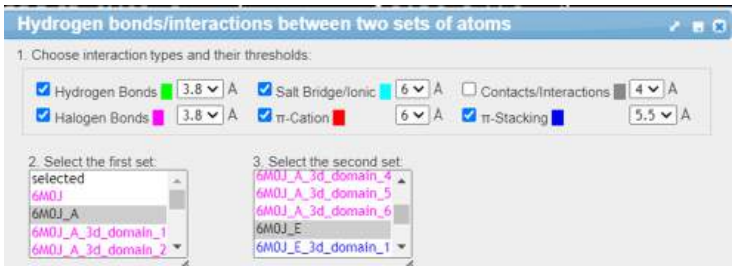
PDB ID: **6M0J**

Description: SARS-CoV-2 spike receptor-binding domain bound with ACE2

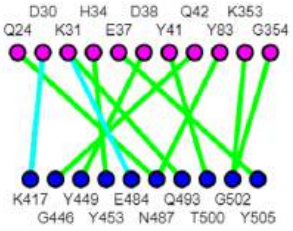
- Angiotensin-converting enzyme 2, chain A, denoted 6M0J_A, pink
- Spike Protein S1, chain B, denoted 6M0J_E, blue

Instructions

1. **File, Retrieve by ID,** MMDB
2. **Seq. & Annotations, Uncheck Conserved Domains**
3. **Analysis, Interactions**, then select the choices in the image below. (Leave out Contact/Interactions to decrease clutter)



4. Click 3D Display Interactions
5. Without closing Interactions window, choose Select, Save Selection, name it BindingInterface
6. Click **2D interaction network** to get the image below



7. In the Selected Sets window, choose BindingInterface.
8. **View, View Selection**
9. **Select, Select Side Chain**
10. **Color, Atom**
11. In the Selected Sets window, choose BindingInterface.
12. **Analysis, Label, Per Residue & Number**
13. **Style, Background, White**
14. **File, Share Link, Lifelong Short Link**

B. 2nd Way

Instructions

1. **File, Retrieve by ID,** MMDB
2. **Seq. & Annotations, Uncheck Conserved Domains, Details Tab**
3. Check **Interactions**

4. From right hand side window sequences: Under 6M0J_A, select the blue label Interact .E, Save as A_with_E
5. Under 6M0J_E, select the blue label Interact .A, Save as E_with_A
6. **Analysis, Interactions.**
7. Choose A_with_E and E_with_A
8. **3D Display Interactions**
9. **Select, Sidechains**
10. **Color, Atom**
11. In H Bonds/ Interactions window, choose Highlight Interactions in Table (can toggle on/off individual interactions),
12. Try the 2D Interaction Map and the Buried Surface Area
13. **Style, Background, White**
14. **File, Share Link, Lifelong Short Link**

---

iCn3D Tutorial: Overlay many ACE2 receptor binding domain analogous to SARS-Co2 RBD using Blast

Use BlastP to align receptor-binding domains

PDB ID: **6M0J**

- SARS-CoV-2 spike receptor-binding domain bound with ACE2
- Angiotensin-converting enzyme 2, chain A, denoted 6M0J_A, pink
- Spike Protein S1, chain B, denoted 6M0J_E, blue

Instructions

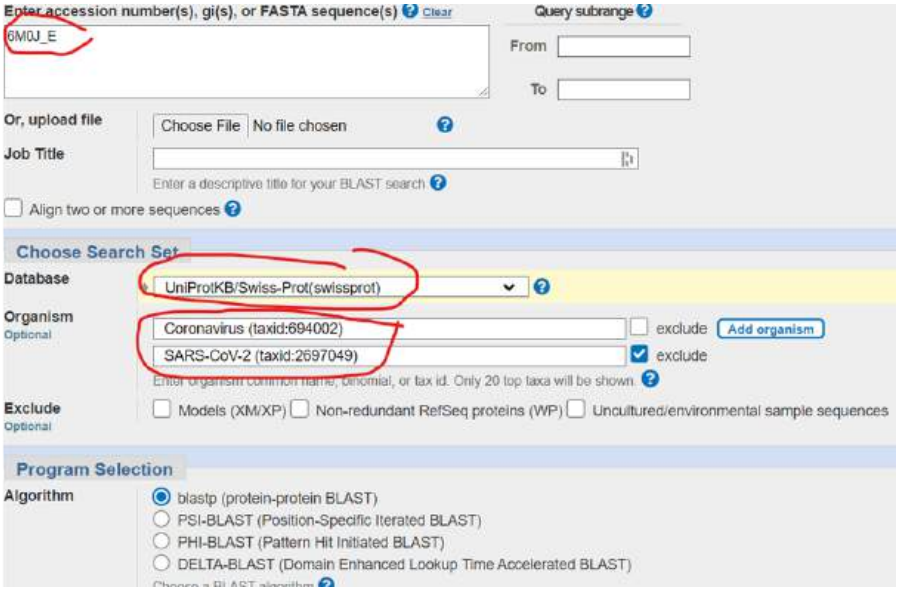
1. **File, Retrieve by ID,** MMDB
2. **Seq. & Annotations.** In Summary tab check Custom and Conserved Domains
3. In Summary tab, click on 6M0J_E
4. **View, View Selection**
5. In Details tab, Add track.
6. Choose the FASTA Alignment Tab in the new window
7. Cut and paste the aligned FASTA sequences file you made using the instructions on the next page or to save time just copy/paste the same FASTA Alignment file below into the iCn3D Fasta window.
8. Enter 319 for the Position of the first residue in Sequences & Annotations window (# is right there); **Check Color sequence by identity**:
9. Choose Add Tracks. The RBD appears color coded with the darkest rd 100% identity and the darkest blue 0% (See F377, K387)
10. **Style, Background, White**
11. **File, Share Link, Lifelong Short Link (this might not work if you choose too many proteins)**

Instructions to use Blast

Use of BlastP for COV-2 ACE2 Receptor Binding Domain (RBD)

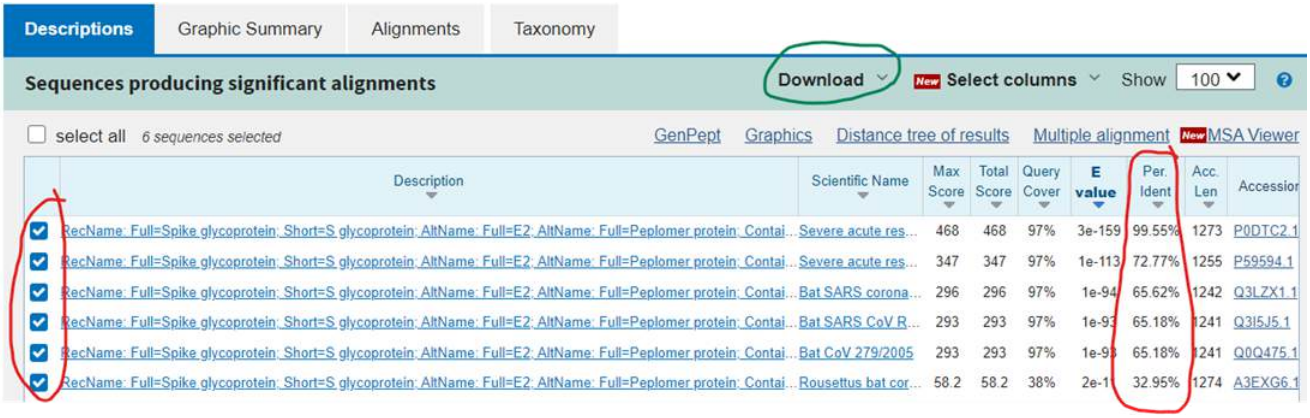
Find sequences homologous to the structure of the RBSthrough BlastP:

Instructions - use this image for help



1. Go to BlastP
2. Enter this Accession number (in this case PDB ID with chain: **6M0J_E** for the RBD
3. Under Choose Search Set

4. **Database:** Choose UniProt
5. **Organism:** input Coronavirus and click it when it appears in the search
6. Add Organism and then input SARS-CoV-2 and click it when it appears in the search; Click Exclude (since we already know the structure of the RBD of CoV-2)
7. Choose Blastp and then BLAST
8. After a few minutes you will get the general output shown below .



9. Check just the ones with percent identity >30% and choose Download, **Fasta Aligned Sequences**
10. **Copy the resulting text file and use in iCn3D** as described in the previous page**.**

---

iCn3D Tutorial: Protein Kinase B (AKT)

Protein Kinase B (AKT)

A more complicated protein with multiple domains and at least two major conformations with different PDB structures: Protein Kinase B (aka AKT)

PDB files:

- 3CQW (active)
- 3O96 (inactive)
- 1UNQ PH domain

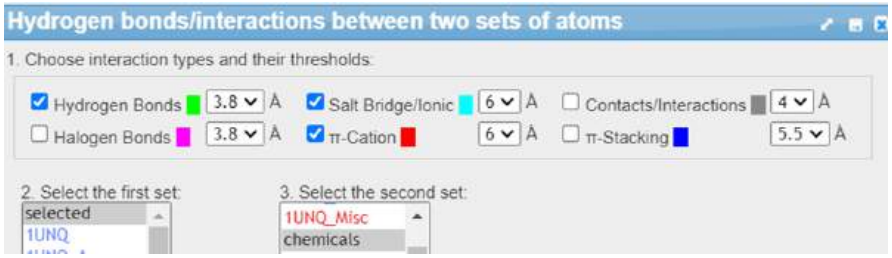
A. Exploration of AKT – Domain Structure

- PDB ID: **1UNQ**
- Description: Pleckstrin Homology Domain Of Protein Kinase B/Akt Bound To Ins(1,3,4,5)-Tetrakisphophate

1. Open new iCn3D
2. **File, Retrieve by ID,** MMDB
3. Alt Click the ligand**. Style, Chemicals, Sphere**
4. **Select, Select on 3D, check Chain,** alt click the protein
5. **Color, Secondary, Sheets in Yellow**

With the protein still selected:

1. **Analysis, Interactions**
2. For the second set choose chemicals
3. Check just the noncovalent interactions shown below



4. Choose 3D Display Interactions. This will display interacting side chains
5. **Selections, Save Selections,** name it Interactions
6. **Style, Sidechains, Stick** (so next step will just color side chains)
7. **Color, atom**
8. In defined sets choose Interactions. **Analysis, Label, Per Residue & No**.
9. **Analysis, Label Scale, 3**
10. **Style, Background, White**
11. **File, Share Link,** copy short link

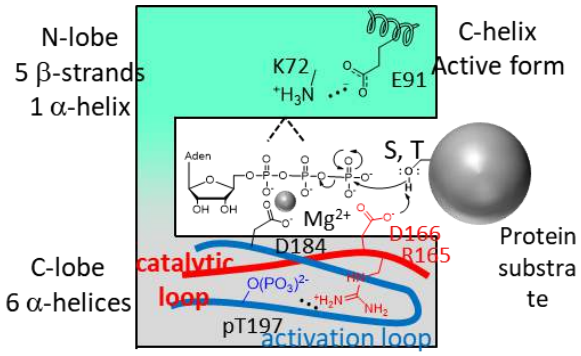
B. Exploration of AKT – Self-defined aa, sequences, Render PH-domain, N-lobe, C-Lobe, Catalytic Loop, Activation Loop

PDB ID: **3O96 (inactive)**

Description:

- Crystal Structure of Human AKT1 with an Allosteric Inhibitor
- RAC-alpha serine/threonine-protein kinase; Chain A
- Allosteric inhibitor IQO

Cartoon structure



Instructions

1. **File, Retrieve by ID,** MMDB
2. **Analysis, Seq. & Annotations, Uncheck Conserved Domains**
3. **Analysis, Defined Sets**. Click 1st domain (PH = top 3O96_A_3d_domain)
4. **Style, Protein, C-Alpha Trace.**
5. **Color , Unicolor, Yellow**
6. **Defined Sets**. Choose 2st domain (N-Lobe). **Color, unicolor, Cyan**
7. Defined Sets. Choose 3st domain (C-Lobe). **Color, unicolor, Grey, Light Gray**
8. **Seq. & Annotations,** Details Tab**,** Uncheck Conserved Domains.
9. Select by hand the catalytic loop (table below) by using the horizontal scroll to find and select 271V-287H. Hover over each amino acids and click to select it or use your mouse to sweep out a rectangle over all the range of amino acids.
10. **Select, Save Selection, CatLoop**
11. **Color, Unicolor, Red**
12. Repeat for **Activation Loop** and save the selection. **Color Unicolor, Blue**
13. **Style, Background, White**
14. **File, Share Link, Lifelong Short Link**

Numbering or generic kinase and AKT

SITE	**Generic** Kinase	**Akt (+108)**
N lobe	K72	K180
N lobe	E91	E199
C lobe, cat loop	R165	R273
C lobe, cat loop	D166	D274
C lobe, act loop	D184	D292
C lobe, act loop	T197	T305 (NO SEQ)
Approx Cat Loop	163-179	271V—287H

Approx Act loop Start DFG (292-294) to APE	184-200	292-319 308Tmiss toAPE end 319

C. Compare 3CQW (active) and 3O96 (inactive) – Superimpose two AKT structures

PDB ID: **3CQW** and **3O96**

Description

3O96 (inactive): Crystal Structure of Human AKT1 with an Allosteric Inhibitor

- RAC-alpha serine/threonine-protein kinase; Chain A
- Allosteric inhibitor IQO

3CQW (active):

- Crystal Structure of Akt-1 complexed with substrate peptide (hence active form) and inhibitor
- Peptide: Glycogen synthase kinase-3 beta peptide

Instructions

1. **File, Align, Structure to Structure**
2. Input **3CQW** and **3O96**
3. Choose All Matching Molecules Superimposed
4. In the top of the right hand alignment window, save the aligned state as presented (al_seq1). Just the aligned sequences will be highlighted.
5. View, View Selection
6. **Style, Background, White**
7. **File, Share Link, Lifelong Short Link**
8. Toggle between the two states by clicking the toggle menu button just underneath the File menu button

iCn3D Tutorial Question: Intermediate Problem - Cyclooxygenase II

Structure

- PDB ID: 4PH9
- Protein: Ibuprofen (IBP) bound to cyclooxygenase-2
- Activity: COX-2 catalyzes the conversion of arachidonic acid(AA) to prostaglandin G2 (PGG2), and is a target of non-steroidal anti-inflammatory drugs (NSAIDs) and COX-2 selective inhibitors (coxibs). Arachidonic acid (AA), not shown in this structure, binds in a "L" shape

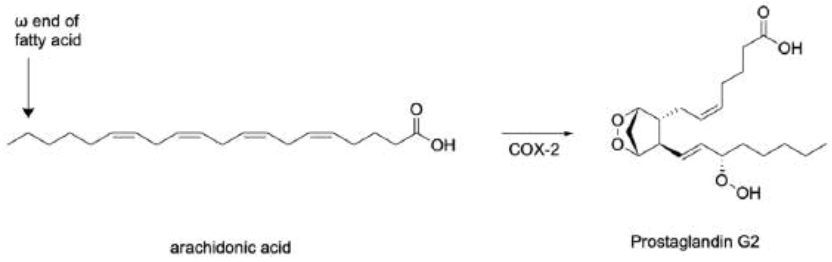
Key amino acids

- Arg-121 and Tyr-356 are close to the carboxylate of AA
- Phe205, Phe209, Val228, Val344, Phe381, and Leu534 form a hydrophobic groove for the ω-end of AA.
- Ser 530, which is above this, gets acetylated by aspirin
- Tyr 385, near C13 in AA, forms a free radical which removes a single electron from C13

For more information on the mechanism of COX-2, scroll down to the end of the chapter section in Fundamentals of Biochemistry.

Description: Biological dimer with heme, ibuprofen (IBP), and many other ligands bound. The initial display is messy! Your task is to clearly render a specific structural feature.

Assessment: The enzyme cyclooxygenase-2 (COX-2) produces arachidonic acid from prostaglandin G2, as shown in the reaction below. Prostaglandin G2 is an important metabolite in inflammation, so inhibition of (COX-2) reduces inflammation.



Potential visualization activities for students:

A. Identify the noncovalent interactions of COX-2 with a heme in 1 subunit
B. Model and describe the noncovalent interactions of COX-2 with ibuprofen
C. Model the interactions at the dimer interface of the protein; identify two amino acids on different subunits that are participating in a [hydrogen bond / ionic interaction]
D. Show the key active site residues of the enzyme

Steps for Discussion and/or Modeling

STEP 1: As a table, or small group at one table, choose one from A-D above.

STEP 2: Load the model 4PH9 at https://www.ncbi.nlm.nih.gov/Structure/icn3d/full.html

With your group, broadly discuss the steps students would need to perform to accomplish the activity you chose in STEP 1. Consider:

- for your course, would it make sense for them to start with the model as it is loaded?
- If you were to pre-render the model and provide them a shared link, which steps would you perform ahead of time? Which steps of modeling are important to their learning

STEP 3: Open the sequences and annotations tab:

- Analysis → Sequences & Annotations
- Uncheck "conserved domains," and then check "functional sites"

STEP 4: Discuss how the built in iCn3D features may help you create a model quickly.

Pre-Rendered Model Links

Voltage-Gated Sodium Channel: LGA - Students 082423

Voltage-Gated Sodium Channel: LGA - Students 082423

Written by Henry Jakubowski, Emily Schmitt Lavin, Arthur Sikora, and Subhasish Chatterjee

Literature-Based Guided Assessment (LGA)		Voltage-Gated Sodium Channel

Introduction

Eukaryotic voltage-gated sodium (Na_V) channels generate and sustain action potentials in nerve and muscle cells by moving Na^+ ions from the outside to the inside of the cell. This increases and makes positive the transmembrane potential of the cell, which at rest is approximately -70 mV (more negative inside). Once activated, the channel undergoes a fast inactivation (1-2 ms), without which the firing of nerves and muscles becomes dysregulated, a potentially lethal effect. Please view the information in Chapter 11.3 on the voltage-gated sodium channel before you do these guided assessment activities.

The questions below are derived from a paper from Jiang et al. on the structure and properties of the **α-scorpion toxin LqhIII** (MW 7,000) bound to rat cardiac sodium channel **Na_V1.5** (MW 227,000) by. (Jiang, D., Tonggu, L., Gamal El-Din, T.M. *et al.* Structural basis for voltage-sensor trapping of the cardiac sodium channel by a deathstalker scorpion toxin. *Nat Commun* **12**, 128 (2021). https://doi.org/10.1038/s41467-020-20078-3. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/)

The **Lqh** toxin is made by **L**eiurus **q**uinquestriatus ***h****ebraeus*. It is found in North Africa, the Middle East, and Western India and is shown below.

htt.://en.wikipedia.org/wiki/Deathstalker.

The study shows how the deathstalker scorpion (LqhIII) toxin inhibits the fast inactivation of cardiac sodium channels (Nav1.5). In other words, you will see how the toxin keeps the channel open longer than it would be open in its absence.

- In the absence of toxin, the sodium channel **Na_V1.5** returns in 1-2 ms to an inactive state when an 'inactivation gate" moves to occlude the open pore.
- The α-scorpion toxin LqhIII inhibits the return of the channel to the inactive state. Since the toxin inhibits the channel's fast inactivation of Na^+ ion flow into the cell, the channel stays open longer.

The toxin leads to the inhibition of the normal fast inhibition (inactivation) of the channel. Hence the channel stays open (activated) longer. This is analogous to the statement that the enemy of my enemy is my friend!

Voltage-Gated Sodium Channel.1: Techniques to study the Na Channel

For the experiments described in the paper, the rat sodium cardiac channel $Na_V1.5$ was purified, its structure determined, and its functional properties (the regulated movement of Na^+ to the inside of the cell - electrophysiology) in human epithelial cells measured. The protein is expressed in rat cardiac cells and is found in the cell membrane of the cell. The iCn3D image below shows the alpha chain of rat cardiac $Na_V1.5$ (6UZ3) embedded in a simple bilayer (DMPC) to model how it might appear in a cardiac cell membrane bilayer.

Answer

.

? Exercise *[Math Processing Error]*

The elution of the complex on a size exclusion column (Panel A) and the analyses for the eluted fractions by SDS-PAGE (Panel B) are shown in the figure below. The α-scorpion toxin LqhIII: rat cardiac sodium channel $Na_V1.5$ complex elutes in the area of the first peak shown in blue.

a. How do molecules separate on size exclusion chromatography?

b. Compare the molecular weights of the first peak to the second complex peak in Panel A.

c. Which band(s) in Panel B likely represent the rat cardiac sodium channel $Na_V1.5$ based on the intensity of the stained band? The toxin LqhIII is the lowest band. (bands at 17.5K and 12.5 are FGF12b and calmodulin, respectively, which were added to stabilize the channel**)**

d. Why do the channel and toxin elute together in the size exclusion column shown in Panel A, but are separate bands in PAGE gel in Panel B?

e. How could you get the complex to separate as two peaks, the free $Na_V1.5$ channel, and the free α-scorpion toxin LqhIII?

f. To get information on the receptor, go to Uniprot and paste in rat cardiac sodium channel $Na_V1.5$ into the search box. Go to Sequence and Isoform in the left panel and find the actual MW. Knowing this, what are the major bands at about 170K and 60K?

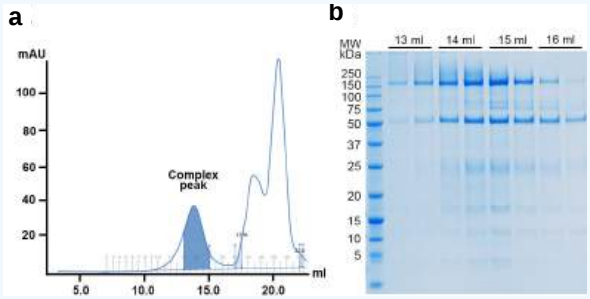

Figure: Purification of the **r**ecombinant NaV1.5C/LqhIII complex. a. Representative size-exclusion chromatography profile of purified **r**Nav1.5C/LqhIII. Peak fractions collected for cryo-EM grid preparation are shown in blue. b. SDS-PAGE of the size exclusion peak fractions stained by Coomassie blue.

Answer

.

CryoEM was used to determine the structure of the sodium channel:toxin complex. Here is a short YouTube video that describes the technique. Also review the appropriate part of Chapter 3.3: Analyses and structural predictions of protein structure.

? Exercise *[Math Processing Error]*

Describe the temperature conditions for protein samples in cryoEM. What is the reported resolution of cryo EM structure? How does this compare to X-ray structures? What are some advantages of using cryoEM over X-ray crystallography and NMR to determine the structure of proteins?

Answer

.

Molecular dynamics was also used to probe the conformational changes in the structure of the complex on the picosecond (10^{-12} s) to nanosecond (10^{-9} s) time scale. For a review of molecular dynamics, see Chapter 3.3: Analyses and structural predictions of protein structure. It can be used to probe dynamic changes in protein structure which cryoEM can't.

? Exercise *[Math Processing Error]*

Answers these multiple choice questions (created by AIPDF through ChatGPT4 -paid version using this prompt: Write 5 question for a biochemistry major about the use of molecular dynamics and the finding in the paper)

1. What was one of the primary uses of molecular dynamics in this research?
   - A) Predicting the behavior of NaV channels without toxins.
   - B) Analyzing hydration and Na^+ permeation through the rNaV1.5C/LqhIII complex.
   - C) Studying the interaction between different toxins.
   - D) Predicting the behavior of potassium channels.

2. In the molecular dynamics simulation analysis, what was aligned to the initial position for each snapshot?
   - A) The α-toxin LqhIII.
   - B) The voltage-sensing domain IV.
   - C) The Cα atoms from pore transmembrane helices.

- D) The fast inactivation gate.

3. Approximately how long were the unrestrained "production" simulations generated?

- A) 10.35 ns.
- B) 5000 steps.
- C) 300 ns.
- D) 2 fs.

4. Based on the molecular dynamics analyses, what was observed about the activation gate structure of the rNaV1.5C/LqhIII complex?

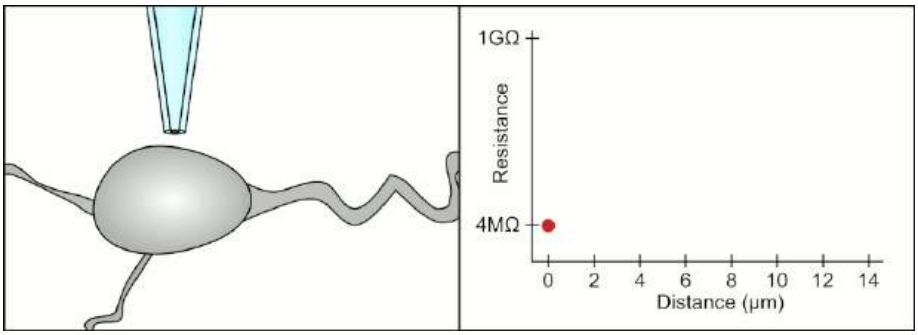
- A) It was fully open for Na^+ conductance.
- B) It was functionally closed for Na^+ conductance.
- C) It was in a metastable state.
- D) It showed no significant change from the rNaV1.5C structure.

Answer

.

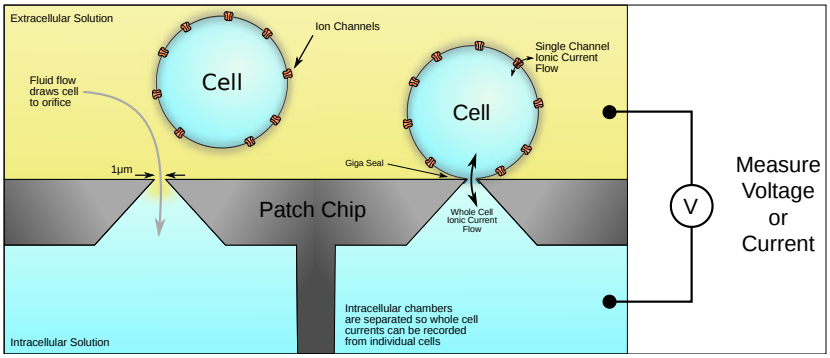
The authors used two types of electrophysiological techniques, patch clamp, and voltage clamp. Here is some brief background.

In a whole-cell patch clamp experiment, a pipet is placed on a cell, and suction is applied until a tight seal, indicated by a sharp rise in electrical resistance (gigaohm level) is made. This is illustrated in the figure below.



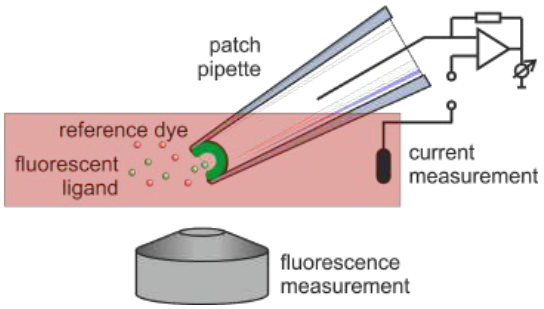
Patch Clamp Resistance. Formation of gigaseal. Holst. https://en.wikipedia.org/wiki/Automa..._Animation.gif. CC BY-SA 3.0

The cell can then be connected to a patch clamp chip in such a way that transmembrane potential or current can be measured on single-channel ion flow. This is illustrated in the figure below.



Holst. Patch Clamp Chip. Batch clamp chip showing a gigaseal, whole-cell recording configuration, and the ion channel and whole cell current. https://en.wikipedia.org/wiki/Automated_patch_clamp#/media/File:Patch_Clamp_Chip.svg. CC BY-SA 3.0

In patch-clamp fluorometry, part of the cell membrane is sucked into the tip with the seal intact. Fluorescent ligands can be applied to one side of the membrane that contains an ion channel and current measurements were made as illustrated in the figure below. Alternatively, as in this paper, side chains in the S4 voltage sensor were labeled with a fluorophore, and changes in fluorescence were observed with changes in membrane potential.



Patch-Clamp Fluorometry. https://www.uniklinikum-jena.de/phys...n/Methods.html

? Exercise *[Math Processing Error]*

Answers these general multiple-choice questions (created by AIPDF through ChatGPT4 -paid version using this prompt: Write five multiple-choice questions about the use of patch clamp techniques to measure sodium currents in cells)

1. What is the primary purpose of the patch-clamp technique in cellular electrophysiology?
   - A) To visualize cell structures.
   - B) To measure the concentration of sodium ions inside cells.
   - C) To record ion currents across cell membranes.
   - D) To stimulate cellular growth.

3. In a typical neuron at resting potential (-70 mV) and in this study (epithelial cells transformed with the rat channel, what is the direction of the sodium current when sodium channels open?
   - A) Inward, into the cell.
   - B) Outward, out of the cell.
   - C) There is no movement of sodium.
   - D) Both inward and outward simultaneously.

4. Which of the following factors can influence the magnitude and direction of sodium currents measured using patch-clamp techniques?
   - A) The concentration of potassium ions outside the cell.
   - B) The voltage across the cell membrane.
   - C) The pH of the cell cytoplasm.
   - D) The size of the cell.

5. Why might a researcher use drugs or toxins during a patch-clamp experiment measuring sodium currents?
   - A) To increase the size of the cell.
   - B) To modulate or block sodium channels and observe the effects.
   - C) To change the color of the cell.
   - D) To stimulate cell division.

Answer

.

? Exercise *[Math Processing Error]*

Answer these general multiple-choice questions about patch-clamp fluorometry. (created by AIPDF through ChatGPT4 -paid version using this prompt: write 5 multiple choice questions of patch clamp fluorometry in which key amino acids in a membrane protein are labeled with a fluorophore)

1. What is the primary advantage of combining patch-clamp with fluorometry in studying membrane proteins?
   - A) It allows simultaneous measurement of electrical activity and conformational changes.
   - B) It increases the fluorescence of all amino acids.
   - C) It enhances the electrical activity of the protein.
   - D) It allows visualization of the entire cell in detail.

2. Why are specific amino acids in a membrane protein labeled with a fluorophore in patch-clamp fluorometry?
   - A) To increase the size of the protein.
   - B) To change the electrical properties of the protein.
   - C) To detect specific conformational changes in the protein during activity.
   - D) To make the protein more soluble in water.

3. Which property of the fluorophore is crucial for patch-clamp fluorometry?
   - A) Its electrical charge.
   - B) Its sensitivity to changes in the local environment or protein conformation.
   - C) Its ability to increase protein activity.
   - D) Its color in visible light.

4. In which scenario would patch-clamp fluorometry be especially useful?
   - A) When studying the overall shape of a cell.
   - B) When investigating the relationship between ion channel gating and conformational changes.
   - C) When trying to increase the fluorescence of a solution.
   - D) When observing the movement of proteins inside the cell.

5. What is a critical consideration when choosing a fluorophore for labeling amino acids in patch-clamp fluorometry?
   - A) The taste of the fluorophore.
   - B) The electrical conductivity of the fluorophore.
   - C) The photostability and brightness of the fluorophore.
   - D) The size of the fluorophore molecule.

Answer

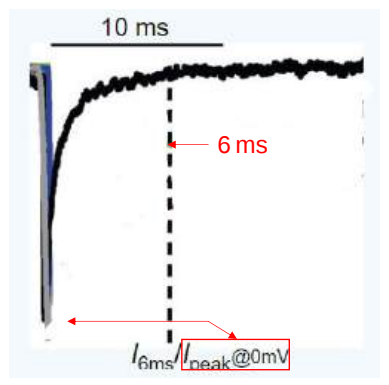
.

Voltage-Gated Sodium Channel.2: Nonstructural Lab Studies of LqhIII Toxin Effects on Rat Sodium Channel $Na_V1.5$ ($rNa_V1.5_C$)

HEK293S GnTI$^-$ (epithelial-like) cells were transformed with the rat cardiac sodium channel $Na_V1.5$ ($rNa_V1.5_C$). The cells were then studied in the absence and presence of the toxin at varying times after toxin addition and at various concentrations of the toxin. The opening and closing of the channel were determined by measuring changes in the Na^+ currents into the cell on channel opening.

? Exercise *[Math Processing Error]*

The resting potential of a cell is around -70 mV (more negative inside). When the transmembrane potential is depolarized by raising the transmembrane potential to around -55 mV or even more positive, the Na^+ channels are activated, and an inward Na^+ current (black line in a modified form of Figure 1a from the paper below) which goes **downward** by convention) through the channel occurs. This is followed by a quick inactivation of the channel and the return to the baseline flow of ions. In the experiment below, the potential was raised from -100 mV (channel closed) to 0 mV (channel open). What is happening to the $Na_V1.5$ Na^+ channel during these 10 ms? What is special about the current at 6 ms (indicated by the dashed vertical line)

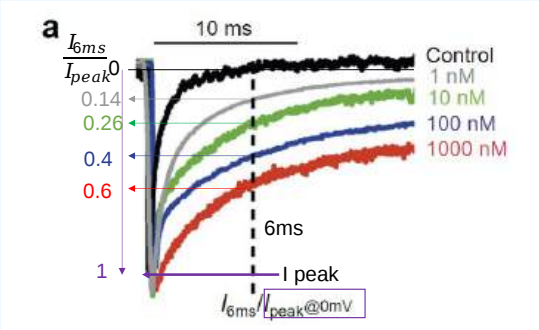


Answer

Initially, the change in voltage opens the $rNa_V1.5_C$ and allows an inward flow of Na^+ ions as evidenced by the vertical drop. As described in the introduction, conformational changes in the $Na_V1.5_C$ (closing of the inactivation loop), follow which closes the channel and stops the current, so the current returns to baseline within about 6 ms. The channel is in the inactive state by around 6 ms.

? Exercise *[Math Processing Error]*

Figure 1a from the paper (modified) below shows a series of lines of different colored (black to red) representing Na^+ currents obtained at 0 (black line) and increasing concentrations (gray through red) of the LqhIII scorpion toxin. Let's assume that the downward I_{peak} =1. The values of I_{6ms}/I_{peak}, calculated from the approximate values shown on the graph, are also shown on the vertical axis Does the toxin alter the immediate response of the cells after the channel was activated? What effect does increasing [toxin] have on the response of the cell? Offer a structural explanation of how the toxin affects the cell by suggesting changes in the toxin-bound structure.



Answer

The toxin at any dose does not substantially affect the initial opening of the channel since the size of the current does not change at first. Then the toxin inhibits the rapid inactivation of the channel within the first 6 ms, leading to a prolonged inward Na^+ current. The inhibition of the inactivation is dose-dependent on the concentration of the toxin. The toxin does not completely block the quick inactivation of the channel as the lines don't return to the black baseline in the time interval measured. This suggests that the toxin binds to the channel and either partially occludes it or prevents the normal conformational change in the $Na_V1.5_C$ that causes a quick deactivation of the channel.

Since Na^+ ions still flow through the channel but at a lower rate than the open state, the toxin-bound channel likely represents a 4th, or partially-opened state of the channel.

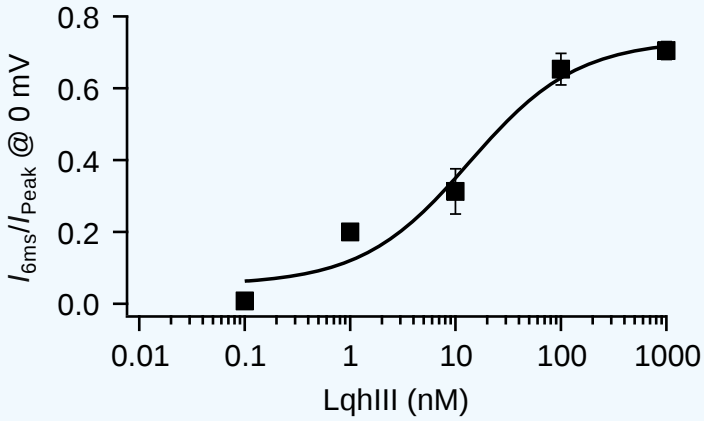
? Exercise *[Math Processing Error]*

Figure 1a (left) from the paper below shows the dependency of the inhibition of the quick inactivation of the channel on the log of the LqhIII concentration. When the transmembrane potential is set to 0 mV (as in this experiment), the channel should open and the current would be maximal. The data points in the graph are close to the ones estimated in the graph from the previous question.

a. In the absence of the toxin, what should the current I be at 6 ms compared to the maximal Na^+ current? That is, what would be the value of I_{6ms}/I_{peak}?

b. Is the channel completely inactivated in the presence of the toxin?

c. At 6 ms, what concentration of toxin (nM) causes 50% inhibition of the maximum effect of the inhibitor on the normal rapid inactivation of the channel?

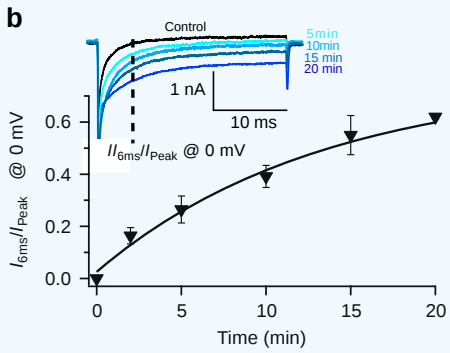


Answer

.

? Exercise *[Math Processing Error]*

In the next experiment, cells were kept at -120 mV at one fixed concentration (100 nM) of toxin. The toxin was left to incubate with the cells for various times up to 20 min. After the incubation time, the transmembrane potential was changed to **0 mV** to activate the channel, and inward Na^+ currents were measured. The results are shown in the top inset graph in Figure 1b from the paper. (Note: It is unclear from the paper if the control was determined at 0 min with 100 nM toxin or no toxin.)



a. Did the length of time cells were pre-incubated with the 100 nM toxin affect Na^+ currents after depolarization of the cells? How did the effects on the cells depend on the preincubation time?

b. Describe and explain these results

Answer

.

Here is another interesting feature of toxin binding. The toxin binds to a site on the resting state of the $Na_V1.5_C$ with high affinity. When the cell becomes depolarized (made more + inside the cell), the affinity for the toxin decreases so it starts to dissociate. The affinity of the toxin for $Na_V1.5_C$ decreases with increasing + transmembrane potential. At very high positive potentials (+100 mV) it appears not to bind.

? Exercise *[Math Processing Error]*

What might account for the decreasing affinity of the bound toxin for the $Na_V1.5_C$ with an increasing transmembrane potential?

Answer

.

? Exercise *[Math Processing Error]*

Time course experiments were conducted on the complex at 100 nM of LqhIII scorpion toxin. A three-pulse protocol can be applied to alter membrane potentials:

- 1^{st}: a pulse from −120 mV to +100 mV for the indicated times then
- 2^{nd}: a 50-ms hyperpolarizing pulse (make membrane potential very negative, perhaps around -100 mV)
- 3^{rd}: a pulse of 50 ms to 0 mV

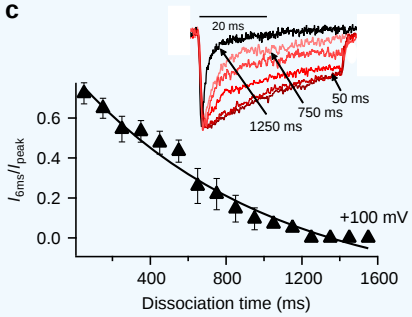
Note that steps 2 and 3 both occur with 0.1 s. What is the purpose of each pulse?

Answer

.

? Exercise *[Math Processing Error]*

Figure 1c from the paper below shows results for a set of 3-pulse designed to allow recovery of the fast inactivation which was blocked by the previous toxin binding. Note that the transmembrane potential for the first pulse was +100 mV



a. Describe what happens to the channel and complex.

b. Explain the results

c. Summarize thermodynamic and kinetic features that make the toxin so effective.

Answer

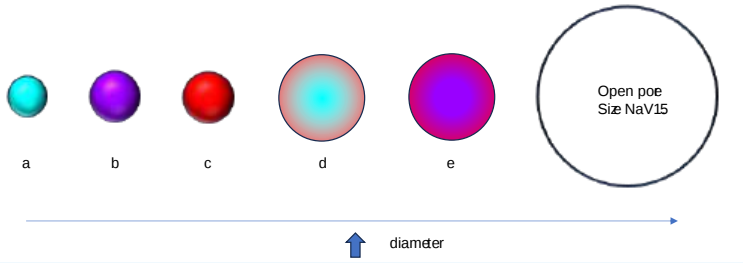
.

Voltage-Gated Sodium Channel.3: Structural Studies of LqhIII Toxin Effects on Rat Sodium Channel $Na_V1.5$ ($rNa_V1.5_C$) - CryoEM

Before we discuss in detail the structure of the sodium channel and its complex with the toxin, let's look at an important attribute of molecules that helps determine their function, the actual size of the species involved.

? Exercise *[Math Processing Error]*

The Na^+ and the K^+ voltage-gated ion channels must have an open pore when the channel protein is active (Na^+ ions move across the channel). Extracellular Na^+ and the K^+ ions don't exist as "naked" ions but they are hydrated by water in an aqueous extracellular environment. The figure below shows the relative sizes of these Group I cations and their hydrated forms, in comparison to the diameter of the open NaV1.5 pore in the channel. Answer the following questions. The red sphere (c) represents the calculated value of the diameter of water assuming its volume when it is bound to a protein is 25 $Å^3$.



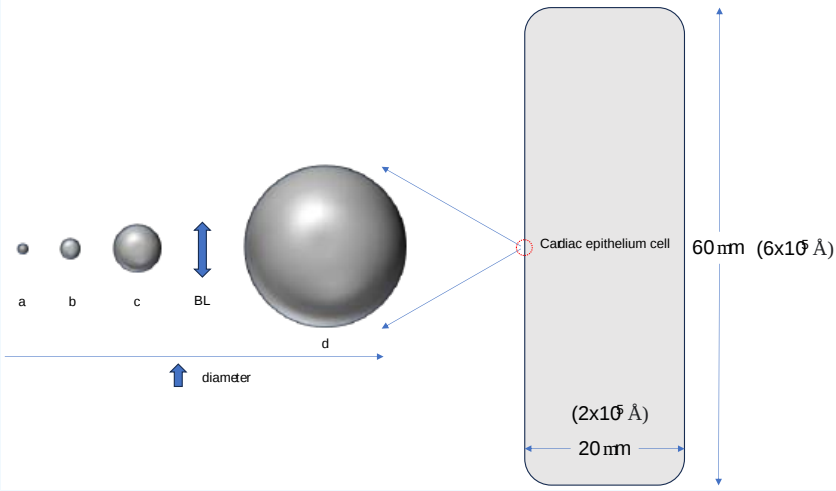
1. Which represents the "naked" (nonhydrated) size of the K^+ ion?
2. Which represents the hydrated Na^+ ion?
3. Based on the pore size alone, which of these species could diffuse through the pore?

Answer

.

Exercise *[Math Processing Error]*

The approximate relative sizes of the hydrated Na^+ ion, pore opening, toxin, and the NaV1.5 protein are shown in the figure below along with the relative width of the bilayer (BL). A cardiac epithelium cell is shown as a rectangle to the right. A red dot  (not visible in the large figure) in the membrane surrounded by the red-dotted circle represents a single NaV1.5 channel.



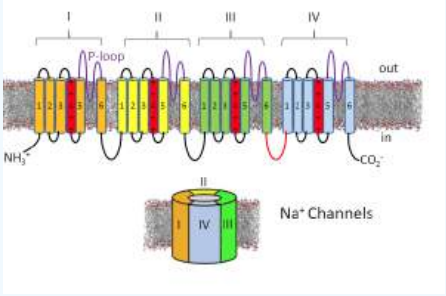
1. Which likely represents the pore?
2. Which represents NaV1.5 channel protein?
3. Which represents the toxin?

Answer

.

Exercise *[Math Processing Error]*

If you hadn't read the paper, where would you consider the most likely location for a toxin to bind to affect the function of Nav1.5? Circle the most likely toxin binding site in the schematic below. Based on the paper, where did it bind? Redraw the toxin in the correct location based on the paper.



Answer

.

? Exercise *[Math Processing Error]*

How is this toxin (LqIII) different in terms of its binding location from other toxins that interfere with the functioning of Nav1.5? What is the effect of the toxin on the channel and the symptoms of this venom?

Answer

.

? Exercise *[Math Processing Error]*

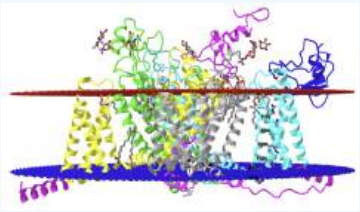
What amino acids should be present in the S4 segment of Nav1.4 and why?

Answer

.

? Exercise *[Math Processing Error]*

The figure below shows an interactive iCn3D model of the rat sodium channel $Na_V1.5$ bound to the LqhIII toxin (7k18).



Rat sodium channel $Na_V1.5$ bound to the LqhIII toxin (7k18). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...jpz8CFQajMKJe7

Domains I-IV are shown in gray, yellow, green, and cyan, respectively. The magenta parts are just extensions/connectors of these domains. The LqhIII toxin is shown in dark blue. The Ile-Phe-Met (IFM) sequence of the inactivation gate that is involved in closing the pore in fast inactivation is shown as black spheres and labeled.

It is important to know that some stretches of amino acids are missing from the structure. These include AAs 1-120 (N-terminus), 298-301, 425-501, 602-608, and 1781-1838.

a. To which domain does the LqhIII toxin bind?

b. Is the binding site close to the pore-forming segments of the domain or the voltage-sensitive segments?

c. Does the layer of red spheres represent the outer (extracellular) or inner (intracellular) leaflet of the membrane?

d. Offer reasons that parts of the protein are missing from the structure.

Answer

.

? Exercise *[Math Processing Error]*

The IFM motif has been shown to be conserved across all voltage-gated sodium channels.

a. What role does it play in these channels and in Nav1.5 and why?

b. The cause of Paroxysomal Extreme Pain Disorder (PEPD), an extremely rare disease with only 15 known affected families, appears to be mutations in the IFM motif which leads to increased sensations of pain. What is a likely effect of the mutations in the IFM motif?

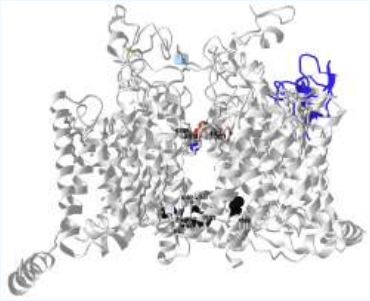
https://en.wikipedia.org/wiki/Paroxy..._pain_disorder

Answer

.

? Exercise *[Math Processing Error]*

The figure below shows a different interactive iCn3D model of the rat sodium channel $Na_V1.5$ bound to the LqhIII toxin (7k18) without a membrane representation for clarity. It shows the selectivity filter DEKA (spacefill, CPK colors), the inactivation gate IFM and the IFM "internal receptor" F1651, L1660, and N1662 (spacefill, CPK colors), and a ring of hydrophobic residues V413, L941, I1471, and I1773 (spacefill, black) that in the closed state completely seal off the cytoplasmic opening in the pore.



Rat sodium channel $Na_V1.5$ bound to the LqhIII toxin without a membrane representation (7k18). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...pPzakHu6Ew6WH9

After viewing the structure from all angles, do you think that the toxin:$Na_V1.5$ complex looks closed, open, or inactivated form? Explain

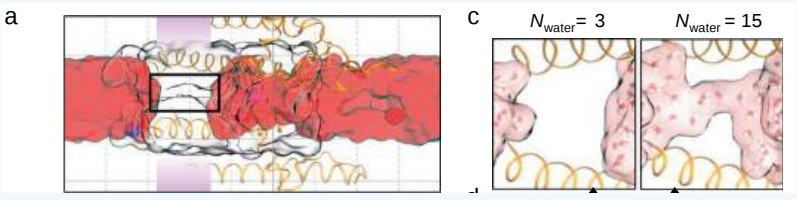
Answer

.

Voltage-Gated Sodium Channel.4: Structural Studies of LqhIII Toxin Effects on Rat Sodium Channel $Na_V1.5$ ($rNa_V1.5_C$) - Molecular Dynamic Simulations

? Exercise *[Math Processing Error]*

Now let's look at some data to see if the pore is really open, partially open, or closed in the toxin:channel complex. One clue is if the structure shows water in the pore as the Na^+ ions must be hydrated to pass through the pore (the opposite case is seen with K^+ channels when K^+ pass through stripped of water). **Molecular dynamic (MD)** simulations were done on the $Na_V1.5$ with and without the toxin to simulate the environment in the channel opening. The results of the MD simulations are shown below in Figures 6 a and c from the paper.



Molecular dynamics analysis of hydration and Na^+ permeation through the $rNa_V1.5_C$/LqhIII complex.

Panel a shows a side view of $rNa_V1.5_C$ (orange ribbons; domains II and IV) from MD simulations highlighting Na^+ ions (blue spheres), the water-occupied volume within a cylinder of radius 8.5 Å (red surface), and the protein-occupied volume within a cylinder of radius 12 Å (colorless surface). The cavity within the pore is outlined with a black rectangle. The region of the intracellular activation gate is shown as a purple band.

Panel c shows molecular representations of the gate containing N_{water} = 3 (left) or 15 (right) water molecules

Based on these studies, do you believe the pore is closed, open, or partially open?

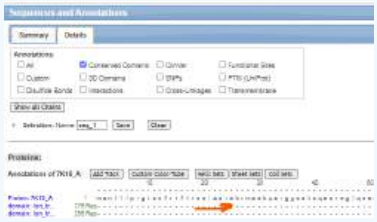
Answer

.

Voltage-Gated Sodium Channel.5: Detailed Structural Analyses of LqhIII Toxin Effects on Rat Sodium Channel $Na_V1.5$ ($rNa_V1.5_C$)

? Exercise *[Math Processing Error]*

From the iCn3D model, write the sequence of the S4 segment that contains the Arg side chains and describe the properties of the amino acids in the sequence. Do this by scrolling along the sequence window in iCn3D (shown below) until you find the labeled Arg shown in the model.



Answer

.

? Exercise *[Math Processing Error]*

Is the helix amphiphilic? That is, are the Arg side chains all on one face of the helix and the nonpolar on the other? To find out, copy and paste the sequence of S4 (above) in this helical wheel predictor and run the program.

Answer

.

✓ Exercise *[Math Processing Error]*

Make a simplified view of the iCn3D model by hiding Domains 1-III to more readily see the contributions of S5 and S6 of Domain IV to the pore.

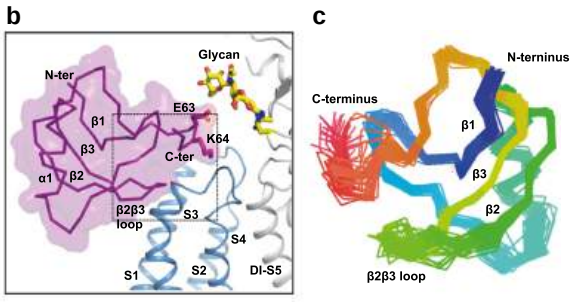
- open iCn3D and load 7K18.
- With your mouse or trackpad, choose **Sequence and Annotation** in the top menu bar
- Choose the Details tab
- Ctrl-Click the two sequences highlighted in yellow below for Domain IV and the toxin.
- Choose **View** from the top menu bar and then **View Selection**
- Choose **Style, Background, Transparent**

Solution

.

Voltage-Gated Sodium Channel.6: **Noncovalent Interactions of LqhIII and Domain IV/VS**

Now let's look at the actual interaction of the toxin with the Domain IV/VS of the channel. A closeup showing the interaction site is shown in Figures 3 b and c from the paper below. Panel C next to it shows the NMR-solution structures of the toxin in the absence of the channel. Each structure determined is represented by a single color line color codes red at the C-terminus to blue at the N-terminus.



Panel b: CryoEM structure of the $rNa_V1.5_C$ Domain IV/VS and LqhIII complex; Panel c: NMR structure of free LqhIII

? Exercise *[Math Processing Error]*

Using this iCn3D model, describe the secondary structure of the bound toxin. How many pairs of cysteine residues are in the LqhIII toxin. Identify which cysteines are involved in the disulfide bonds. What effect do the disulfide bonds have on the beta sheet structure?

Answer

.

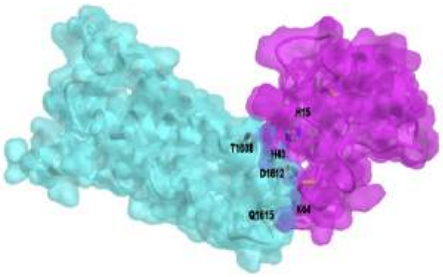
? Exercise *[Math Processing Error]*

What sections of the toxin in panel B make the closest interactions with the Domain IV/VS of the channel? Describe their conformation flexibility in the free toxin.

Answer

.

The figure below shows an interactive iCn3D model of a surface rending of Domain IV of the rat sodium channel $Na_V1.5$ bound to the LqhIII toxin (7k18).



Surface rending of Domain IV of the rat sodium channel $Na_V1.5$ bound to the LqhIII toxin (7k18). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...x5QRPEctT5zsW7.

The molecular surface and underlying secondary structure of the LqhIII toxin are shown in magenta, with key residues H15, H43, and K64 shown as CPK-colored sticks and labeled. Domain IV/VS of the channel is shown in cyan, with key amino acid side chains T1608, D1612, and Q1615 shown as colored and labeled sticks.

? Exercise *[Math Processing Error]*

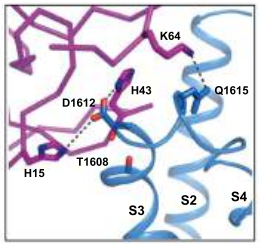
Comment on the shape and possible side chain interactions that contribute to high-affinity binding of the inhibitor to Domain IV/VS.

Answer

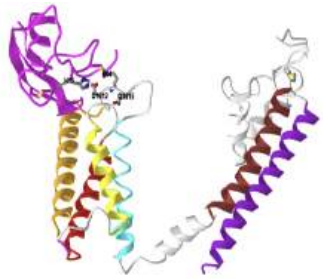
.

Figure 3d from the paper below shows the detailed interactions between LqhIII and *D*IV-VS. Key residues shown in sticks were labeled. Interaction surfaces of the *D*IV-VS (blue) and the LqhIII (purple). Key residues for the interaction are shown in yellow shading and embedded stick

d



The figure below shows an interactive iCn3D model of the rat sodium channel $Na_V1.5$ Domain IV bound to the LqhIII toxin (7k18).



Rat cardiac sodium channel NaV1.5C Domain IV/LqhIII toxin complex (7k18). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?JAjUQAZDZoQ5wiVX9

The toxin is shown in magenta. The segments are colored as follows: S1 is red, S2 is orange, S3 is yellow, S4 is cyan, S5 is brown and S6 is . Key amino acid pairs involved in the binding of the toxin to Domain IV are shown in sticks and labeled.

? Exercise *[Math Processing Error]*

In summary, name and locate the amino acid residues that serve the following roles in the LhqIII toxin: DIV-VS interactions.

1. Which amino acids in the toxin interact with D1612 (the paper describes the interaction as pincers surrounding D1612).
2. The conserved negatively charged residue in the Nav1.5 channel
3. What position is Thr in and what is thought to be its role in the mechanism?

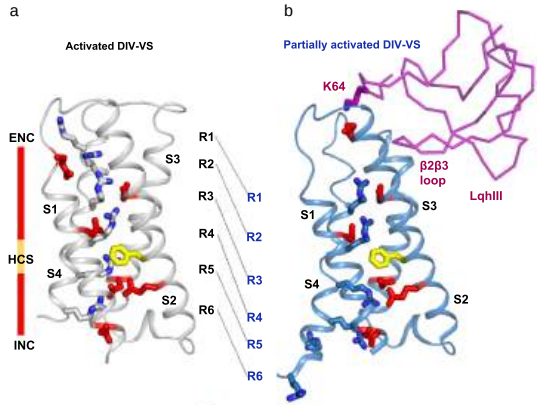
Answer

.

Voltage-Gated Sodium Channel.6.1: Comparison of Activated DomIV-Voltage sensor (VS) with Toxin-bound Partially activated DomIV-VS

Now we'll try to understand Figure 4, Conformational Change of DIV-VS, from the paper and pay special attention to the section of the text, "An intermediate-activated state of DIV-VS trapped by LqhIII" - Let's dissect Figure 4 A and B.

Figure 4a/4b from the paper below shows the c**onformational change of *Domain* IV-Voltage sensor (DIV-VS)** comparing the activated and partially activated state with the bound toxin.



Panel a shows the activated domain IV with key Arg side chains in S4. Panel B shows the partially activated domain IV with the same key Arg side chains in S4. The bound LqhIII is shown as a purple chain. In panels a and b, the:

1. activated Nav1.5 DIV-VS (the voltage sensing domain) is in grey (fig 4a)
2. the intermediate-activated Nav1.5DIV-VS is in blue (Fig 4b)
3. side chains of gating charges of Arg are shown in grey and blue sticks in 4a and in shades of blue sticks in 4b. Side chains in the ENC are shown in red, in the HCS in yellow, and in the INC in red;
4. the shift of each gating charge was indicated by black dashed lines between the structures in panels a and b.

The shift from the cytoplasmic to extracellular parts of the channel is shown in the region between the two panels. The black Rs in the activated DIV-VS(panel A) are further up in the diagram (towards the extracellular region) and further down in the partially activated DIV-VS bound to the toxin.

? Exercise *[Math Processing Error]*

Locate the 6 arginines? (R1-R6) with the blue indicating the N atoms in the positively charged Arg side chain of S4 in Domain IV in one of the iCn3D models above. What do the following abbreviations mean? ENC, HCS, and INC.

Answer

.

? Exercise *[Math Processing Error]*

From Figure 4a to 4b, explain from an electrostatic viewpoint how the movement of the Args towards the extracellular region would promote the movement of Na^+ ions inward. Explain how the movement of Na^+ ions would be diminished in the presence of the toxin.

Answer

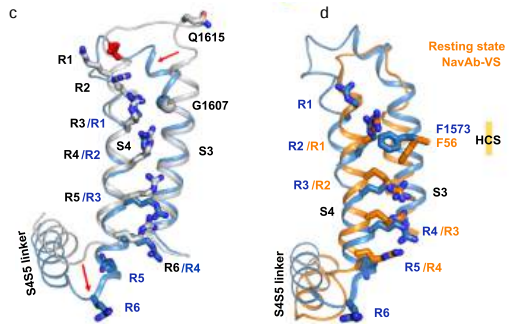
.

Voltage-Gated Sodium Channel.6.2: Comparison of Active and Intermediate-Activated, and Intermediate/Resting state

Now consider Figures 4 C and D from the paper below:

4c: Superposition of NaV1.5 *D*IV-VS between the fully activated state and toxin-bound intermediate-activated state. Red arrows indicate the conformational changes.

4d: Superposition of the intermediate-activated NaV1.5 *D*IV-VS and resting-state NaVAb-VS



? Exercise *[Math Processing Error]*

a. Locate the region in Figure c above that shifts the most from the fully activated to intermediate-activated state of the DIV-VS.

b. Describe the difference shown in Figure d between the intermediate-activated *D*IV-VS structure (blue) upon the resting state Na_VAb-VS structure (orange)

c. What do these differences imply about the conformational states of the apo and toxin-bound channel?

Answer

.

Voltage-Gated Sodium Channel.7: Summary

? Exercise *[Math Processing Error]*

Why might the mode of action be specific for cardiac muscle cells as compared to other toxins that act on sodium channels in skeletal and nerve cells?

Answer

.

After this guided research literature module, you can hopefully better understand the findings in the paper which are summarized in this abstract:

"Voltage-gated sodium (Na_V) channels initiate action potentials in excitable cells, and their function is altered by potent gating-modifier toxins. The α-toxin LqhIII from the deathstalker scorpion inhibits fast inactivation of cardiac $Na_V1.5$ channels with IC_{50} = 11.4 nM. Here we reveal the structure of LqhIII bound to $Na_V1.5$ at 3.3 Å resolution by cryo-EM. LqhIII anchors on top of voltage-sensing domain IV, wedged between the S1-S2 and S3-S4 linkers, which traps the gating charges of the S4 segment in a unique intermediate-activated state stabilized by four ion-pairs. This conformational change is propagated inward to weaken binding of the fast inactivation gate and favor opening the activation gate. However, these changes do not permit Na^+ permeation, revealing why LqhIII slows inactivation of Na_V channels but does not open them. Our results provide important insights into the structural basis for gating-modifier toxin binding, voltage-sensor trapping, and fast inactivation of Na_V channels."

Voltage-Gated Sodium Channel.8: Extensions

1. Interesting sidebar: https://www.sciencedirect.com/science/article/pii/S0021925819308300?via%3Dihub

Chlorotoxin (Cltx) is a 36-amino acid peptide that was originally isolated from *Leiurus quinquestriatus* venom (14) and has been shown to inhibit small conductance Cl− channels in colonic epithelial cells (14, 15). Cltx also inhibits Cl− fluxes across glioma membranes (13, 16). Immunohistochemical studies show that Cltx specifically and selectively binds to glioma cells (17) and radiolabeled Cltx targets tumor cells in mice bearing xenografted glioma tumors. Glioma cell migration and invasion into fetal brain aggregates is significantly reduced by Cltx (13). A recent survey of over 200 tissue biopsies from patients with various malignancies suggests that Cltx binds to the surface of gliomas and other embryologically related tumors of neuroectodermal origin (18) but not to normal brain.

2. Deathstalker scorpion venom also contains chlorotoxin - This is a very interesting story.

https://www.acs.org/molecule-of-the-week/archive/c/chlorotoxin.html#:~:text=Strichartz%20at%20Harvard%20Medical%20School,diagnosing%20and%20treating%20some%20cancers.

Note and remember LqhIII is an alpha toxin

NMDA Receptor - Under Construction

Under Construction

Glutamatergic transmission has been implicated in the pathophysiology of PTSD, particularly in the effects of N-methyl-D-aspartate receptor (NMDAR) signaling on the synaptic plasticity underlying learning and memory [13]. NMDARs comprise two GluN1 subunits and two GluN2 (A-D) or GluN3 (A, B) subunits. In adult forebrain regions, GluN2A and GluN2B are the main subunits forming receptor complexes with GluN1 at excitatory synapses. GluN2B-containing NMDARs play a preferential role in inducing synaptic plasticity, which is critical for the extinction of fear memories [14, 15]. Systemic injection of GluN2B-specific NMDAR antagonists ((RS)-3-(2-carboxypiperazin-4-yl)-propyl-1-phosphonic acid, ifenprodil) can impair the retention of fear extinction learning. GluN2B-containing NMDARs in both the amygdala and medial prefrontal cortex (mPFC) are also involved in reducing fear during extinction, whereas GluN2A-containing NMDARs play a greater role in the initial formation and/or stabilization of learned fear [15]. Rodent studies demonstrate that GluN2B subunit-containing NMDARs play pivotal roles in fear extinction learning.

---

https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4263351/"tetrameric complexes mainly composed of NMDA receptor GluNR1 and GluNR2 subunits with the NR2 subunits modifying the activity of the receptor. "

N-methyl-d-aspartate (NMDA) receptors are Hebbian-like coincidence detectors, requiring binding of glycine and glutamate in combination with the relief of voltage-dependent magnesium block to open an ion conductive pore across the membrane bilayer.

NMDA receptors are Hebbian-like coincidence detectors, requiring the binding of glycine and glutamate to GluN1 and GluN2 subunits[9], respectively, combined with membrane depolarization to relieve magnesium block [10, 11]. Activation of the receptor opens a cation-selective, calcium permeable channel, thus causing further depolarization of the cell membrane and influx of calcium [12]. NMDA receptors are obligatory heterotetrameric assemblies[13, 14], typically composed of two glycine-binding GluN1 subunits and two glutamate-binding GluN2A-D subunits, with the GluN1/GluN2A/GluN2B complex the predominate receptor at hippocampal synapses[15]. Glycine-and d-serine-binding GluN3 subunits are additional subunits, expressed throughout the nervous system but with roles less well defined in comparison to the GluN1/GluN2 assemblies. A hallmark of NMDA receptors, by contrast with AMPA and kainate receptors, is a wide spectrum of allosteric modulation, from nanomolar concentrations of zinc, to the small molecule ifenprodil, polyamines and protons[16] and to voltage-dependent ion channel block by MK-801, ketamine and memantine[17].

The coordinates and structure factors for the structure have been deposited in the Protein Data Bank under accession code 4TLL and 4TLM for Structure 1 and Structure 2, respectively.

These receptors have two GluN1 subunits and two GluN2 (A-D) or GluN3 (A, B) subunits. In the forebrain, GluN2A and B form complex with GluN1 at synapses, with the B subunit playing a role in synaptic plasticity. Synaptic plasticity is necessary to remove "hard-wired" fear circuits. A goal of PTSD therapies is the **extinction** of the previously acquired feared memories through learning. Learning, and more specifically extinction, requires synaptic plasticity.

If one goal of PTSD treatment is the extinction of fear memories, then drugs that target GluN2B are potentially useful. Antagonist (such asd ifenprodil) of GluN2B seem to decrease the ability to extinguish fear retention memories. In other words, the learning and synaptic plasticity need to attenuate the fear memories are inhibited by the antagonist. GluN2B in the NMDAR receptors in the amygdala and medial prefrontal cortex appear to be involved in reducing feat during extinction. IN contact, GluN2A seem to be an important role in forming and stabilizing the learned fear response.

"Glutamatergic transmission has been implicated in the pathophysiology of PTSD, particularly in the effects of N-methyl-D-aspartate receptor (NMDAR) signaling on the synaptic plasticity underlying learning and memory [13]. NMDARs comprise two GluN1 subunits and two GluN2 (A-D) or GluN3 (A, B) subunits. In adult forebrain regions, GluN2A and GluN2B are the main subunits forming receptor complexes with GluN1 at excitatory synapses. GluN2B-containing NMDARs play a preferential role in inducing synaptic plasticity, which is critical for the extinction of fear memories [14, 15]. Systemic injection of GluN2B-specific NMDAR antagonists ((RS)-3-(2-carboxypiperazin-4-yl)-propyl-1-phosphonic acid, ifenprodil) can impair the retention of fear extinction learning. GluN2B-containing NMDARs in both the amygdala and medial prefrontal cortex (mPFC) are also involved in

reducing fear during extinction, whereas GluN2A-containing NMDARs play a greater role in the initial formation and/or stabilization of learned fear [15]. Rodent studies demonstrate that GluN2B subunit-containing NMDARs play pivotal roles in fear extinction learning."

Describe how the NMDA receptor functions, and how it implements the Hebbian model of learning at the synaptic level.

Ras Questions

Introduction Questions

1. Where is Ras located in the cell? What causes Ras to be localized here?
2. How does Ras get activated?
3. What are the three dimensional differences between GDP and GTP bound Ras. Why is the GTP bound form “active?”
4. What does Ras bound to GTP bind to? What are the net effects of this in terms of signal transduction?
5. What reaction does Ras catalyze as an enzyme?
6. What type of reaction is a GAP catalyzing? GEF?
    a. Are they opposite reactions? What is different (enzymatic control)
7. GAP is an acronym for GTPase activating protein. What GTPase is being activated?
8. Would RAS “turn off” without a GAP present? Why is this critical?
9. What molecule (GTP or GDP) would be bound to RAS if there were no GAPs or GEFs present? Why?
10. Why does a GAP increase the enzymatic activity RAS? What does a GAP provide that aids in the chemistry of the reaction?

Phos

https://www.ncbi.nlm.nih.gov/pmc/art...%20Ras%20cycle.

Paper about targeting phosphorylation and cancer therapy: https://www.ncbi.nlm.nih.gov/pmc/articles/PMC8642438/

1. Ras can be phosphorylated at Tyr 32 and Tyr64 by Src kinase, which leads to inhibition of binding to Raf and increased GTP hydrolysis. Provide a rationale for why this post-translational modification plays a role in the overall function of Ras. (Not sure what to ask here- there seems to be a number of kinases involved that do different things as explained in the paper above)
2. There are mutations in Ras, including Gly 12, Gly13, and Gln 61 which impair GTPase activity and GAP-mediated GTP hydrolysis. Predict what changes this would cause in the cell.
3. Think about designing a small molecule drug that affects the Ras signaling pathway and treats cancer. What proteins could you target? For each protein target, should the drug increase or decrease the activity of its target? Explain your answers.

CHAPTER OVERVIEW

Structure/Function - Protein Problems

Topic hierarchy

Disulfide Bonds
LGA: Voltage-Gated Sodium Channel - Students 082423
LGA: Protein Stability - Carbonic Anhydase

Disulfide Bonds

Disulfide engineering

The first set of questions below are based on this reference as noted: Craig, D.B., Dombkowski, A.A. Disulfide by Design 2.0: a web-based tool for disulfide engineering in proteins. *BMC Bioinformatics* **14**, 346 (2013). https://doi.org/10.1186/1471-2105-14-346. Creative Commons Attribution License (http://creativecommons.org/licenses/by/2.0)

Several computational programs have been developed to determine amino acid pairs that could be mutated to high-temperature stabilizing disulfide bonds. The stabilizing effects appear largest when the disulfide bond is made within the largest (and most flexible) loops (between 25-75 residues). These loops also had the highest residue B-factors.

In selecting pairs to form engineered disulfide, not only proximity (distance) but also geometry (torsion angles) of the resulting disulfide bond are important. We saw this previously in the energy analysis of butane rotamers, as illustrated in Figure 1 below.

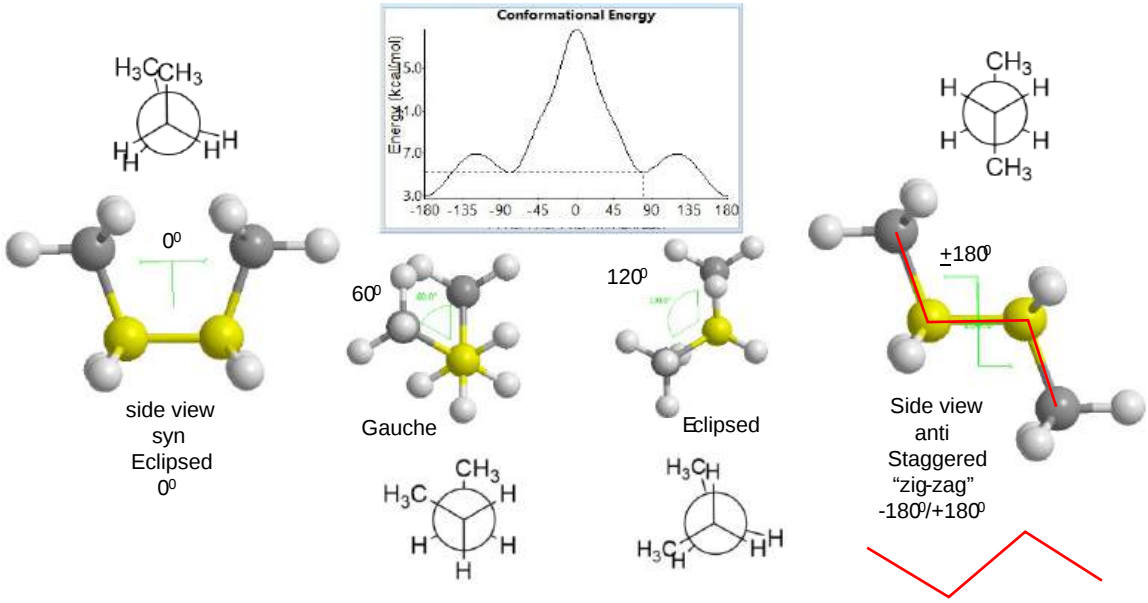

Figure 1: Newman projections for butane

Programs to determine amino acid pairs to mutate for disulfide bond formation test S-S bond torsional stability by determining the torsion angle χ_3 for the S-S bond. Evaluation of a database of many native proteins shows the χ_3 angle are centered in two major peaks at -87 and +97 degrees, as shown in Figure 2 below

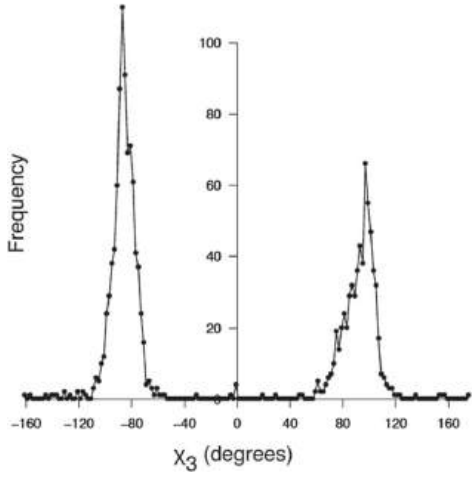

Figure 2: **Distribution of χ_3 torsion angles observed in 1505 native disulfide bonds found in 331 PDB protein structures.** Peaks occur at -87 and +97 degrees. Craig, D.B., Dombkowski, A.A. Disulfide by Design 2.0: a web-based tool for disulfide engineering in proteins. *BMC Bioinformatics* **14**, 346 (2013). https://doi.org/10.1186/1471-2105-14-346. Creative Commons Attribution License (http://creativecommons.org/licenses/by/2.0),

? Question 1

Does your calculated value of χ_3 for the native disulfide in carbonic anhydrase from Neisseria gonorrhea follow the observed angles?

Answer

At about 90^o so yes it does.

An empirical energy equation was developed to determine the E vs χ_3 dihedral angle for disulfide bonds. The equation is shown below (Craig, D.B., Dombkowski, A.A. ibid.).

$$E(\chi_3) = 4.0\,[1 - \cos(1.957\,[\chi_3 + 87])] \tag{1}$$

A graph of the equation made with Excel is shown in Figure 3 below

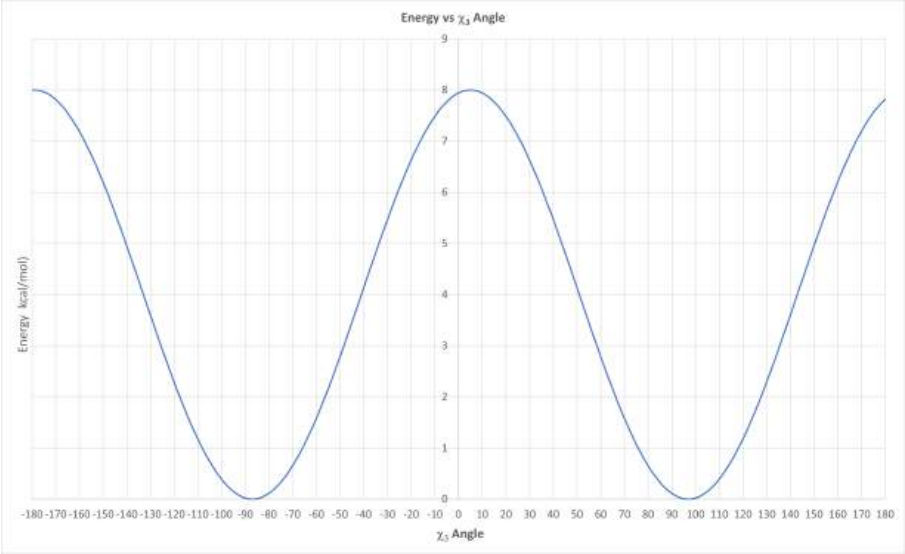

Figure 3: E vs χ_3 dihedral angle for disulfide bonds from empirical equation

Figure 4 below shows the distribution of energy values in the 1505 native disulfide bonds using our updated function. The study by Craig and Dombkowski showed that almost all (90%) of disulfides in native proteins in the PDB have an energy < 2.2 kcal/mol, so this metric could be used to determine possible disulfide bond pairs created by mutagenesis.

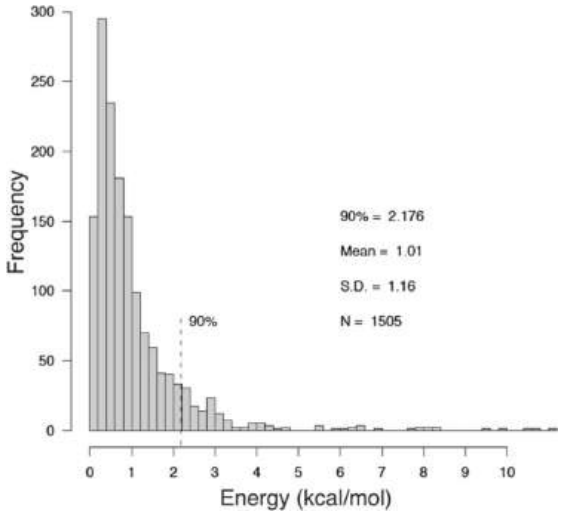

Figure 4: **Distribution of the disulfide bond energy calculated for 1505 native disulfide bonds.** The mean value is 1.0 kcal/mol, and the 90th percentile is 2.2 kcal/mol. Craig, D.B., Dombkowski, A.A. ibid.

? Question 2

You calculated the approximate value for χ_3 dihedral for the C28-C181 native disulfide bond form in Carbonic anhydrase from Neisseria gonorrhea using iCn3D in Question x above. Determine the approximate energy from the empirical function graph in Figure x above for that χ_3 dihedral. What percent of native disulfide bonds have that particular calculated energy in the 1505 native disulfide surveyed?

Answer

The estimated χ_3 dihedral was 90^o. The energy for that χ_3 angle would be approximately $\leq$0.1kcal/mol, which reflects the energies of about 150/1505 or 10% of the disulfides in the database. It is hence in the most stable range of disulfides, based only on the χ_3 dihedral angle.

Yet there are other important parameters as well that would affect the energy of the disulfide bond in the protein. Figure 5 below shows a comparison of native residue B-factors in stabilizing and destabilizing engineered disulfide bonds

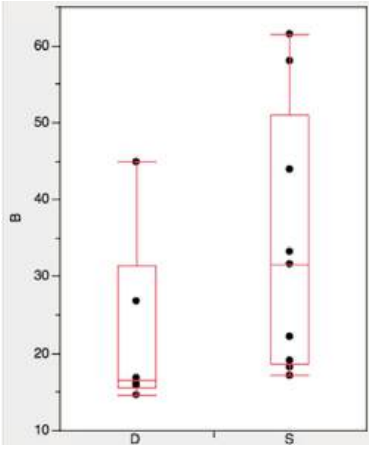

Figure 5: **Comparison of native residue B-factors in stabilizing and destabilizing engineered disulfide bonds.** Analysis of previously reported proteins with stabilizing (S) or destabilizing (D) engineered disulfide bonds. The mean B-factor for residues in proteins with stabilizing disulfide bonds was 31.6 compared with 16.5 for those involved in destabilizing bonds. Craig, D.B., Dombkowski, A.A. ibid.

? Question 3

Which proteins were more stabilized by engineered disulfide, those with higher or low B factors.

Answer

Proteins with engineered disulfides that increase stability have higher B-factors. This makes sense in that proteins with higher B-factors and hence mobility would be predicted to alter conformation and potentially denature more readily.

Prediction of disulfide bond engineering sites using a machine learning method

This set of questions based on this reference: Gao, X., Dong, X., Li, X. *et al.* Prediction of disulfide bond engineering sites using a machine learning method. *Sci Rep* **10**, 10330 (2020). https://doi.org/10.1038/s41598-020-67230-z. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/

The amount of data present in a single PDB file is very large, but it is nothing compared to the collective data in all PDB files. If only we could extract empirical rules from the collective PDB files that govern disulfide bond formation. It turns out we can with machine learning and artificial intelligence that can be used to develop and train predictive algorithms. Machine learning has been used to predict amino acid pairs for cysteine mutations to form engineered disulfide bonds. It recognizes 99% of natural disulfide bonds. residues. It uses these parameters:

- distances between the alpha-carbons and the beta-carbons of the bonded cysteine residues
- three torsion angles around the disulfide bonds (χ^1,χ^{ss},$\chi^{1'}$).

An example of one variable that helps define the stability of disulfide bonds is the distances between the Cα atoms for the disulfide-bonded cysteines, as shown in Figure 6 below.

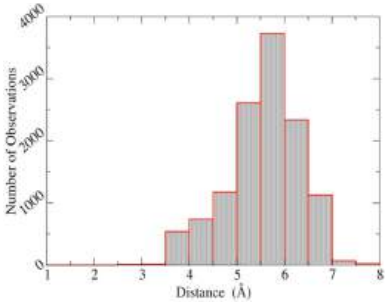

Figure 6: The histogram of distances between Cα atoms of disulfide-bonded cysteines. Gao, X., Dong, X., Li, X. *et al.* Prediction of disulfide bond engineering sites using a machine learning method. *Sci Rep* **10**, 10330 (2020). https://doi.org/10.1038/s41598-020-67230-z. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/

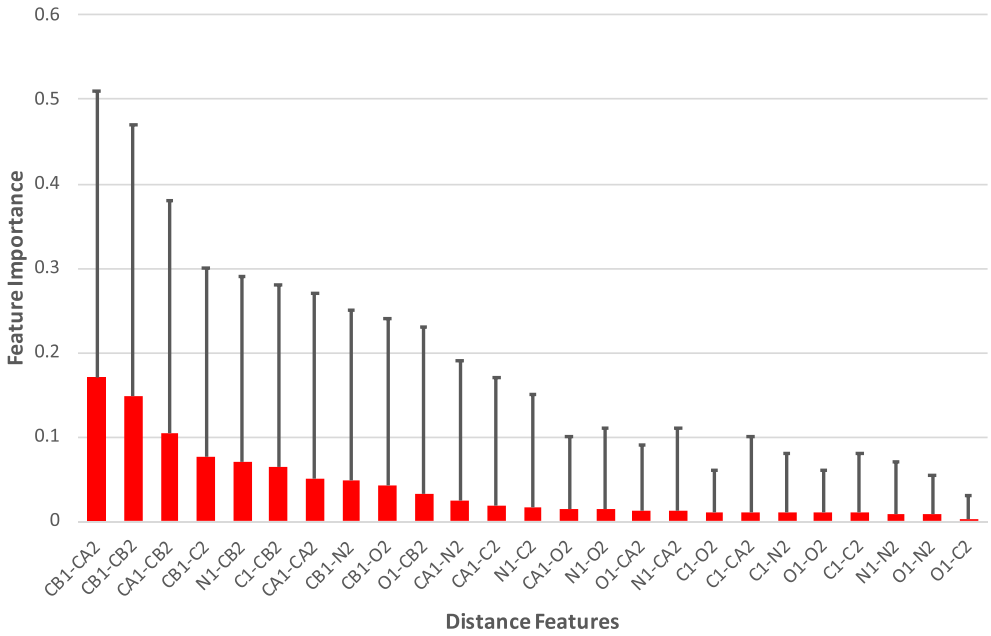
The distances range from 3.0 Å and 7.5 Å. Knowing this would constrain the number of choices for paired amino acid side chains for mutagenesis to produce disulfide.

Machine learning can also be used to find other distance constraints to optimize mutagensis experiments. Figure 7 below shows a graph of 10 different distances and their relative importance in determining disulfide bond stability.



An interactive iCn3D model of carbonic anhydrase from Neisseria gonorrhea (1KOQ) highlighting two pairs of amino acids identified by machine learning as candidates for mutations to disulfide-bonded cysteines is shown in Figure 8 below.

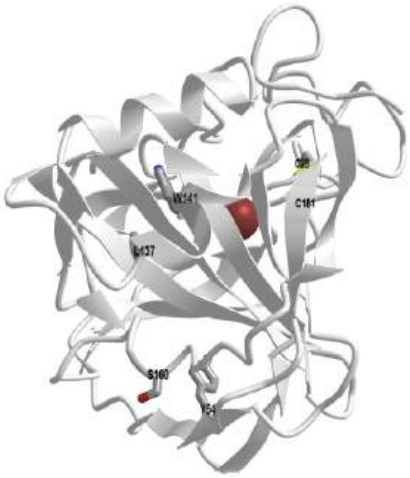


Figure 8: Carbonic anhydrase from Neisseria gonorrhea (1KOQ) highlighting two pairs of amino acids identified by machine learning as candidates for mutations to disulfide-bonded cysteines (Copyright; author via source). Question 4

This question addresses the Biomolecular Visualization Framework theme(s) Atomic Geometry (AG), Macromolecular Building Blocks (MB)

Using the data in Figure 25 and measurements made using the iCn3D model above (Figure 25) , determine which pair would be most likely engineered into a disulfide bond. Complete the table below with the distances you made using iCn3D.

iCn3D instructions: Open the external link and follow these instructions

Trackpad and Mouse Controls

•rotate: click and drag (mouse: left click and drag)

•zoom: pinch and spread (mouse: rotate the scroll wheel)

•translate: two-finger click and drag (mouse: right click and drag)

•Re-center: left click View from the top menu bar, then select “Center Selection”

•Note: ctrl-click on a PC = command-click on Mac; alt-click on PC = option click on Mac

Instructions

1. Zoom to clearly see the amino acid pair for distance measures
2. From the top menu bar, choose **Analysis**, **Distance**, distance between 2 atoms
3. Pick the appropriate 2 atoms for measure distance by holding down the Alt key and selecting both
4. Record the distances in the table below.

Mutation Pair	CB1-CA2 (Å)	CB1-CB2 (Å)	CA1-CB2 (Å)
1 (L137) - 2 (W141)			
1 (Y54) - 1 (S160)			

Answer

Mutation Pair	CB1-CA2 (Å)	CB1-CB2 (Å)	CA1-CB2 (Å)
1 (L137) - 2 (W141)	6	5.2	5.3
1 (Y54) - 1 (S160)	4.1	4.1	5.0

LGA: Voltage-Gated Sodium Channel - Students 082423

Written by Henry Jakubowski, Emily Schmitt Lavin, Arthur Sikora, and Subhasish Chatterjee

LGA.1: Introduction

Eukaryotic voltage-gated sodium (Na_V) channels generate and sustain action potentials in nerve and muscle cells by moving Na^+ ions from the outside to the inside of the cell. This increases and makes positive the transmembrane potential of the cell, which at rest is approximately -70 mV (more negative inside). Once activated, the channel undergoes a fast inactivation (1-2 ms), without which the firing of nerves and muscles becomes dysregulated, a potentially lethal effect. Please view the information in Chapter 11.3 on the voltage-gated sodium channel before you do these guided assessment activities.

The questions below are derived from a paper from Jiang et al. on the structure and properties of the **α-scorpion toxin LqhIII** (MW 7,000) bound to rat cardiac sodium channel **Na_V1.5** (MW 227,000) by. (Jiang, D., Tonggu, L., Gamal El-Din, T.M. *et al*. Structural basis for voltage-sensor trapping of the cardiac sodium channel by a deathstalker scorpion toxin. *Nat Commun* **12**, 128 (2021). https://doi.org/10.1038/s41467-020-20078-3. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/)

The **Lqh** toxin is made by **L**eiurus **q**uinquestriatus ***h****ebraeus*. It is found in North Africa, the Middle East, and Western India and is shown below.

htt.://en.wikipedia.org/wiki/Deathstalker.

The study shows how the deathstalker scorpion (LqhIII) toxin inhibits the fast inactivation of cardiac sodium channels (Nav1.5). In other words, you will see how the toxin keeps the channel open longer than it would be open in its absence.

- In the absence of toxin, the sodium channel **Na_V1.5** returns in 1-2 ms to an inactive state when an 'inactivation gate" moves to occlude the open pore.
- The α-scorpion toxin LqhIII inhibits the return of the channel to the inactive state. Since the toxin inhibits the channel's fast inactivation of Na^+ ion flow into the cell, the channel stays open longer.

The toxin leads to the inhibition of the normal fast inhibition (inactivation) of the channel. Hence the channel stays open (activated) longer. This is analogous to the statement that the enemy of my enemy is my friend!

LGA.2: Techniques to study the Na Channel

For the experiments described in the paper, the rat sodium cardiac channel $Na_V1.5$ was purified, its structure determined, and its functional properties (the regulated movement of Na^+ to the inside of the cell - electrophysiology) in human epithelial cells measured. The protein is expressed in rat cardiac cells and is found in the cell membrane of the cell. The iCn3D image below shows the alpha chain of rat cardiac $Na_V1.5$ (6UZ3) embedded in a simple bilayer (DMPC) to model how it might appear in a cardiac cell membrane bilayer.

Answer

.

? Exercise $LGA.4$

The elution of the complex on a size exclusion column (Panel A) and the analyses for the eluted fractions by SDS-PAGE (Panel B) are shown in the figure below. The α-scorpion toxin LqhIII: rat cardiac sodium channel $Na_V1.5$ complex elutes in the area of the first peak shown in blue.

a. How do molecules separate on size exclusion chromatography?

b. Compare the molecular weights of the first peak to the second complex peak in Panel A.

c. Which band(s) in Panel B likely represent the rat cardiac sodium channel $Na_V1.5$ based on the intensity of the stained band? The toxin LqhIII is the lowest band. (bands at 17.5K and 12.5 are FGF12b and calmodulin, respectively, which were added to stabilize the channel**)**

d. Why do the channel and toxin elute together in the size exclusion column shown in Panel A, but are separate bands in PAGE gel in Panel B?

e. How could you get the complex to separate as two peaks, the free $Na_V1.5$ channel, and the free α-scorpion toxin LqhIII?

f. To get information on the receptor, go to Uniprot and paste in rat cardiac sodium channel $Na_V1.5$ into the search box. Go to Sequence and Isoform in the left panel and find the actual MW. Knowing this, what are the major bands at about 170K and 60K?

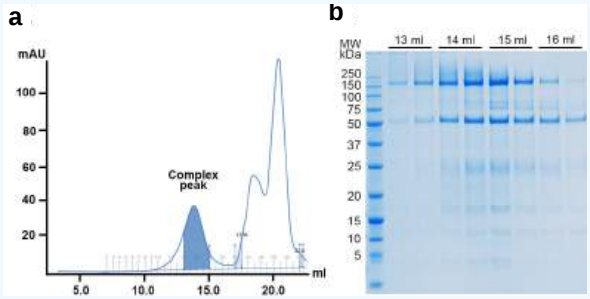

Figure: Purification of the **r**ecombinant NaV1.5C/LqhIII complex. a. Representative size-exclusion chromatography profile of purified **r**Nav1.5C/LqhIII. Peak fractions collected for cryo-EM grid preparation are shown in blue. b. SDS-PAGE of the size exclusion peak fractions stained by Coomassie blue.

Answer

.

CryoEM was used to determine the structure of the sodium channel:toxin complex. Here is a short YouTube video that describes the technique. Also review the appropriate part of Chapter 3.3: Analyses and structural predictions of protein structure.

? Exercise $LGA.5$

Describe the temperature conditions for protein samples in cryoEM. What is the reported resolution of cryo EM structure? How does this compare to X-ray structures? What are some advantages of using cryoEM over X-ray crystallography and NMR to determine the structure of proteins?

Answer

.

Molecular dynamics was also used to probe the conformational changes in the structure of the complex on the picosecond (10^{-12} s) to nanosecond (10^{-9} s) time scale. For a review of molecular dynamics, see Chapter 3.3: Analyses and structural predictions of protein structure. It can be used to probe dynamic changes in protein structure which cryoEM can't.

? Exercise $LGA.6$

Answers these multiple choice questions (created by AIPDF through ChatGPT4 -paid version using this prompt: Write 5 question for a biochemistry major about the use of molecular dynamics and the finding in the paper)

1. What was one of the primary uses of molecular dynamics in this research?
   - A) Predicting the behavior of NaV channels without toxins.
   - B) Analyzing hydration and Na^+ permeation through the rNaV1.5C/LqhIII complex.
   - C) Studying the interaction between different toxins.
   - D) Predicting the behavior of potassium channels.

2. In the molecular dynamics simulation analysis, what was aligned to the initial position for each snapshot?
   - A) The α-toxin LqhIII.
   - B) The voltage-sensing domain IV.
   - C) The Cα atoms from pore transmembrane helices.

- D) The fast inactivation gate.

3. Approximately how long were the unrestrained "production" simulations generated?
   - A) 10.35 ns.
   - B) 5000 steps.
   - C) 300 ns.
   - D) 2 fs.

4. Based on the molecular dynamics analyses, what was observed about the activation gate structure of the rNaV1.5C/LqhIII complex?
   - A) It was fully open for Na^+ conductance.
   - B) It was functionally closed for Na^+ conductance.
   - C) It was in a metastable state.
   - D) It showed no significant change from the rNaV1.5C structure.

Answer

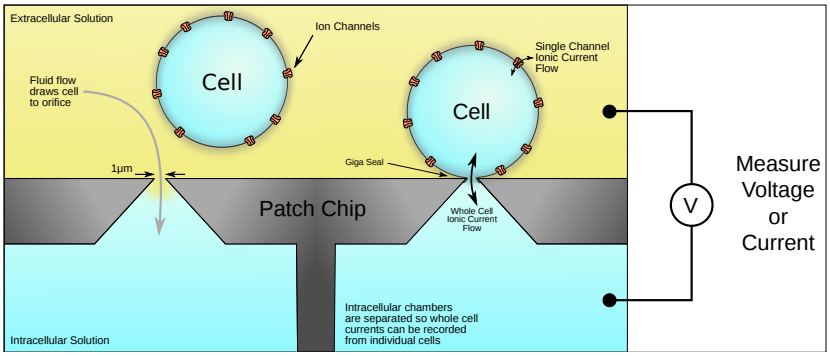
.

The authors used two types of electrophysiological techniques, patch clamp, and voltage clamp. Here is some brief background.

In a whole-cell patch clamp experiment, a pipet is placed on a cell, and suction is applied until a tight seal, indicated by a sharp rise in electrical resistance (gigaohm level) is made. This is illustrated in the figure below.

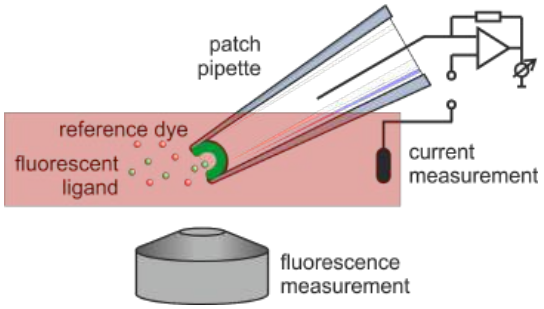
Patch Clamp Resistance. Formation of gigaseal. Holst. https://en.wikipedia.org/wiki/Automa..._Animation.gif. CC BY-SA 3.0

The cell can then be connected to a patch clamp chip in such a way that transmembrane potential or current can be measured on single-channel ion flow. This is illustrated in the figure below.



Holst. Patch Clamp Chip. Batch clamp chip showing a gigaseal, whole-cell recording configuration, and the ion channel and whole cell current. https://en.wikipedia.org/wiki/Automated_patch_clamp#/media/File:Patch_Clamp_Chip.svg. CC BY-SA 3.0

In patch-clamp fluorometry, part of the cell membrane is sucked into the tip with the seal intact. Fluorescent ligands can be applied to one side of the membrane that contains an ion channel and current measurements were made as illustrated in the figure below. Alternatively, as in this paper, side chains in the S4 voltage sensor were labeled with a fluorophore, and changes in fluorescence were observed with changes in membrane potential.



Exercise $LGA.7$

Answers these general multiple-choice questions (created by AIPDF through ChatGPT4 -paid version using this prompt: Write five multiple-choice questions about the use of patch clamp techniques to measure sodium currents in cells)

1. What is the primary purpose of the patch-clamp technique in cellular electrophysiology?
   - A) To visualize cell structures.
   - B) To measure the concentration of sodium ions inside cells.
   - C) To record ion currents across cell membranes.
   - D) To stimulate cellular growth.

3. In a typical neuron at resting potential (-70 mV) and in this study (epithelial cells transformed with the rat channel, what is the direction of the sodium current when sodium channels open?
   - A) Inward, into the cell.
   - B) Outward, out of the cell.
   - C) There is no movement of sodium.
   - D) Both inward and outward simultaneously.

4. Which of the following factors can influence the magnitude and direction of sodium currents measured using patch-clamp techniques?
   - A) The concentration of potassium ions outside the cell.
   - B) The voltage across the cell membrane.
   - C) The pH of the cell cytoplasm.
   - D) The size of the cell.

5. Why might a researcher use drugs or toxins during a patch-clamp experiment measuring sodium currents?
   - A) To increase the size of the cell.
   - B) To modulate or block sodium channels and observe the effects.
   - C) To change the color of the cell.
   - D) To stimulate cell division.

Answer

.

Exercise $LGA.8$

Answer these general multiple-choice questions about patch-clamp fluorometry. (created by AIPDF through ChatGPT4 -paid version using this prompt: write 5 multiple choice questions of patch clamp fluorometry in which key amino acids in a membrane protein are labeled with a fluorophore)

1. What is the primary advantage of combining patch-clamp with fluorometry in studying membrane proteins?
   - A) It allows simultaneous measurement of electrical activity and conformational changes.
   - B) It increases the fluorescence of all amino acids.
   - C) It enhances the electrical activity of the protein.
   - D) It allows visualization of the entire cell in detail.

2. Why are specific amino acids in a membrane protein labeled with a fluorophore in patch-clamp fluorometry?
   - A) To increase the size of the protein.
   - B) To change the electrical properties of the protein.
   - C) To detect specific conformational changes in the protein during activity.
   - D) To make the protein more soluble in water.

3. Which property of the fluorophore is crucial for patch-clamp fluorometry?
   - A) Its electrical charge.
   - B) Its sensitivity to changes in the local environment or protein conformation.
   - C) Its ability to increase protein activity.
   - D) Its color in visible light.

4. In which scenario would patch-clamp fluorometry be especially useful?
   - A) When studying the overall shape of a cell.
   - B) When investigating the relationship between ion channel gating and conformational changes.
   - C) When trying to increase the fluorescence of a solution.
   - D) When observing the movement of proteins inside the cell.

5. What is a critical consideration when choosing a fluorophore for labeling amino acids in patch-clamp fluorometry?
   - A) The taste of the fluorophore.
   - B) The electrical conductivity of the fluorophore.
   - C) The photostability and brightness of the fluorophore.
   - D) The size of the fluorophore molecule.

Answer

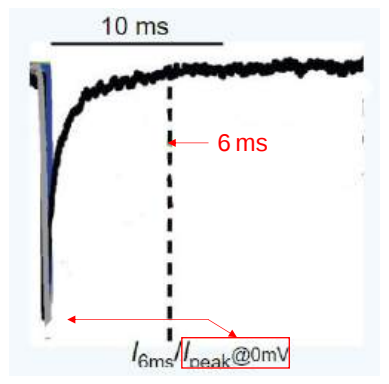
.

LGA.3: Nonstructural Lab Studies of LqhIII Toxin Effects on Rat Sodium Channel $Na_V1.5$ ($rNa_V1.5_C$)

HEK293S GnTI$^-$ (epithelial-like) cells were transformed with the rat cardiac sodium channel $Na_V1.5$ ($rNa_V1.5_C$). The cells were then studied in the absence and presence of the toxin at varying times after toxin addition and at various concentrations of the toxin. The opening and closing of the channel were determined by measuring changes in the Na^+ currents into the cell on channel opening.

? Exercise $LGA.9$

The resting potential of a cell is around -70 mV (more negative inside). When the transmembrane potential is depolarized by raising the transmembrane potential to around -55 mV or even more positive, the Na^+ channels are activated, and an inward Na^+ current (black line in a modified form of Figure 1a from the paper below) which goes **downward** by convention) through the channel occurs. This is followed by a quick inactivation of the channel and the return to the baseline flow of ions. In the experiment below, the potential was raised from -100 mV (channel closed) to 0 mV (channel open). What is happening to the $Na_V1.5$ Na^+ channel during these 10 ms? What is special about the current at 6 ms (indicated by the dashed vertical line)

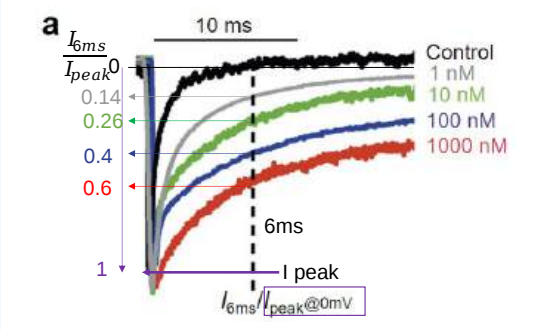


Answer

Initially, the change in voltage opens the $rNa_V1.5_C$ and allows an inward flow of Na^+ ions as evidenced by the vertical drop. As described in the introduction, conformational changes in the $Na_V1.5_C$ (closing of the inactivation loop), follow which closes the channel and stops the current, so the current returns to baseline within about 6 ms. The channel is in the inactive state by around 6 ms.

? Exercise $LGA.10$

Figure 1a from the paper (modified) below shows a series of lines of different colored (black to red) representing Na^+ currents obtained at 0 (black line) and increasing concentrations (gray through red) of the LqhIII scorpion toxin. Let's assume that the downward I_{peak} =1. The values of I_{6ms}/I_{peak}, calculated from the approximate values shown on the graph, are also shown on the vertical axis Does the toxin alter the immediate response of the cells after the channel was activated? What effect does increasing [toxin] have on the response of the cell? Offer a structural explanation of how the toxin affects the cell by suggesting changes in the toxin-bound structure.



Answer

The toxin at any dose does not substantially affect the initial opening of the channel since the size of the current does not change at first. Then the toxin inhibits the rapid inactivation of the channel within the first 6 ms, leading to a prolonged inward Na^+ current. The inhibition of the inactivation is dose-dependent on the concentration of the toxin. The toxin does not completely block the quick inactivation of the channel as the lines don't return to the black baseline in the time interval measured. This suggests that the toxin binds to the channel and either partially occludes it or prevents the normal conformational change in the $Na_V1.5_C$ that causes a quick deactivation of the channel.

Since Na^+ ions still flow through the channel but at a lower rate than the open state, the toxin-bound channel likely represents a 4th, or partially-opened state of the channel.

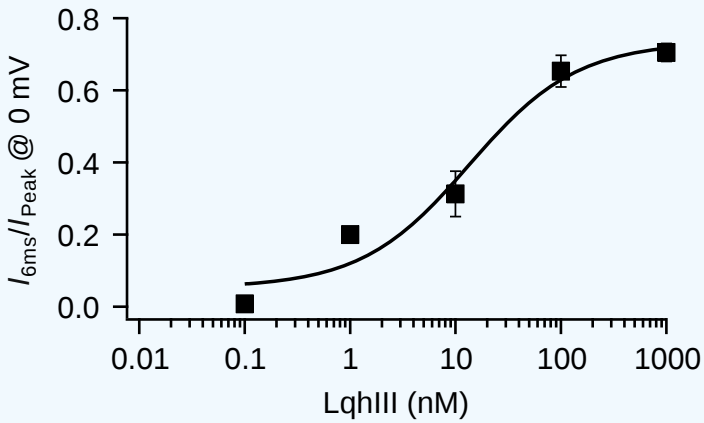
? Exercise $LGA.11$

Figure 1a (left) from the paper below shows the dependency of the inhibition of the quick inactivation of the channel on the log of the LqhIII concentration. When the transmembrane potential is set to 0 mV (as in this experiment), the channel should open and the current would be maximal. The data points in the graph are close to the ones estimated in the graph from the previous question.

a. In the absence of the toxin, what should the current I be at 6 ms compared to the maximal Na^+ current? That is, what would be the value of I_{6ms}/I_{peak}?

b. Is the channel completely inactivated in the presence of the toxin?

c. At 6 ms, what concentration of toxin (nM) causes 50% inhibition of the maximum effect of the inhibitor on the normal rapid inactivation of the channel?

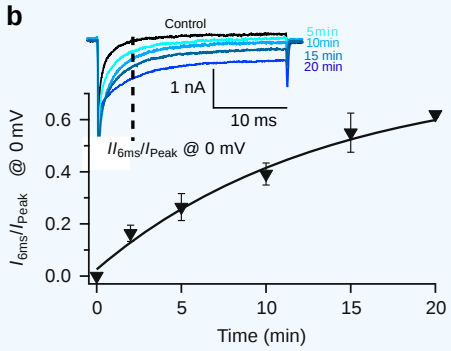


Answer

.

Exercise $LGA.12$

In the next experiment, cells were kept at -120 mV at one fixed concentration (100 nM) of toxin. The toxin was left to incubate with the cells for various times up to 20 min. After the incubation time, the transmembrane potential was changed to **0 mV** to activate the channel, and inward Na^+ currents were measured. The results are shown in the top inset graph in Figure 1b from the paper. (Note: It is unclear from the paper if the control was determined at 0 min with 100 nM toxin or no toxin.)



a. Did the length of time cells were pre-incubated with the 100 nM toxin affect Na^+ currents after depolarization of the cells? How did the effects on the cells depend on the preincubation time?

b. Describe and explain these results

Answer

.

Here is another interesting feature of toxin binding. The toxin binds to a site on the resting state of the $Na_V1.5_C$ with high affinity. When the cell becomes depolarized (made more + inside the cell), the affinity for the toxin decreases so it starts to dissociate. The affinity of the toxin for $Na_V1.5_C$ decreases with increasing + transmembrane potential. At very high positive potentials (+100 mV) it appears not to bind.

Exercise $LGA.13$

What might account for the decreasing affinity of the bound toxin for the $Na_V1.5_C$ with an increasing transmembrane potential?

Answer

.

Exercise $LGA.14$

Time course experiments were conducted on the complex at 100 nM of LqhIII scorpion toxin. A three-pulse protocol can be applied to alter membrane potentials:

- 1^{st}: a pulse from −120 mV to +100 mV for the indicated times then
- 2^{nd}: a 50-ms hyperpolarizing pulse (make membrane potential very negative, perhaps around -100 mV)
- 3^{rd}: a pulse of 50 ms to 0 mV

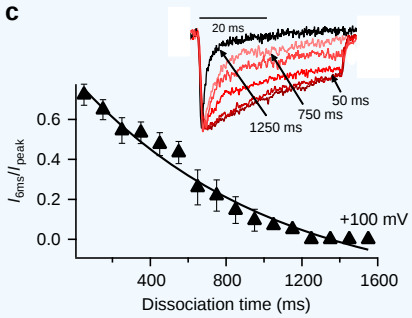
Note that steps 2 and 3 both occur with 0.1 s. What is the purpose of each pulse?

Answer

.

Exercise $LGA.15$

Figure 1c from the paper below shows results for a set of 3-pulse designed to allow recovery of the fast inactivation which was blocked by the previous toxin binding. Note that the transmembrane potential for the first pulse was +100 mV



a. Describe what happens to the channel and complex.

b. Explain the results

c. Summarize thermodynamic and kinetic features that make the toxin so effective.

Answer

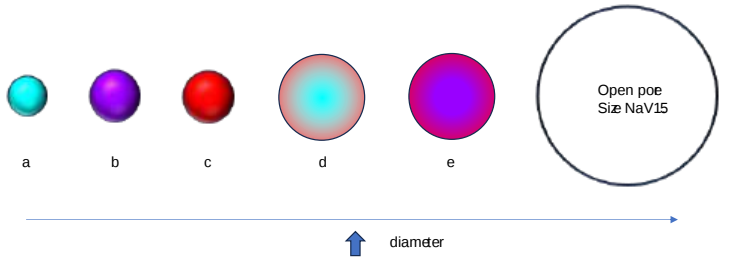
.

LGA.4: Structural Studies of LqhIII Toxin Effects on Rat Sodium Channel $Na_V1.5$ ($rNa_V1.5_C$) - CryoEM

Before we discuss in detail the structure of the sodium channel and its complex with the toxin, let's look at an important attribute of molecules that helps determine their function, the actual size of the species involved.

Exercise $LGA.16$

The Na^+ and the K^+ voltage-gated ion channels must have an open pore when the channel protein is active (Na^+ ions move across the channel). Extracellular Na^+ and the K^+ ions don't exist as "naked" ions but they are hydrated by water in an aqueous extracellular environment. The figure below shows the relative sizes of these Group I cations and their hydrated forms, in comparison to the diameter of the open NaV1.5 pore in the channel. Answer the following questions. The red sphere (c) represents the calculated value of the diameter of water assuming its volume when it is bound to a protein is 25 $Å^3$.



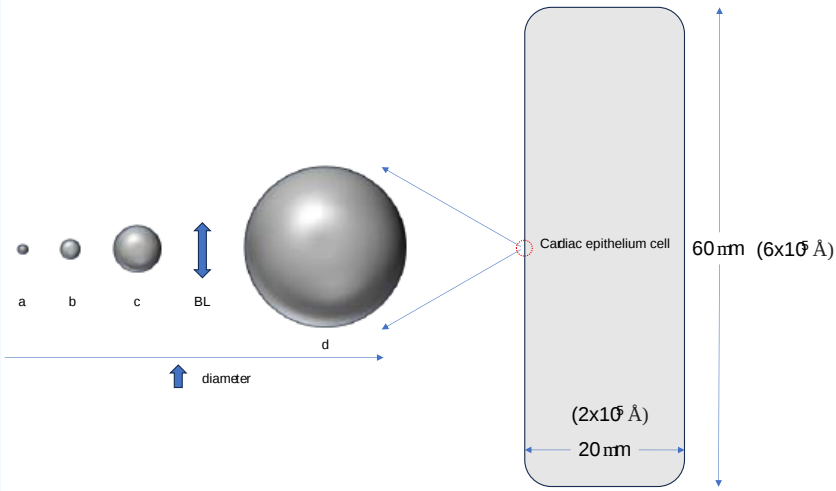
1. Which represents the "naked" (nonhydrated) size of the K^+ ion?
2. Which represents the hydrated Na^+ ion?
3. Based on the pore size alone, which of these species could diffuse through the pore?

Answer

.

Exercise $LGA.17$

The approximate relative sizes of the hydrated Na^+ ion, pore opening, toxin, and the NaV1.5 protein are shown in the figure below along with the relative width of the bilayer (BL). A cardiac epithelium cell is shown as a rectangle to the right. A red dot  (not visible in the large figure) in the membrane surrounded by the red-dotted circle represents a single NaV1.5 channel.



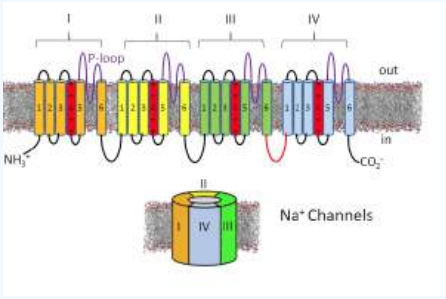
1. Which likely represents the pore?
2. Which represents NaV1.5 channel protein?
3. Which represents the toxin?

Answer

.

Exercise $LGA.18$

If you hadn't read the paper, where would you consider the most likely location for a toxin to bind to affect the function of Nav1.5? Circle the most likely toxin binding site in the schematic below. Based on the paper, where did it bind? Redraw the toxin in the correct location based on the paper.



Answer

.

Exercise $LGA.19$

How is this toxin (LqIII) different in terms of its binding location from other toxins that interfere with the functioning of Nav1.5? What is the effect of the toxin on the channel and the symptoms of this venom?

Answer

.

Exercise $LGA.20$

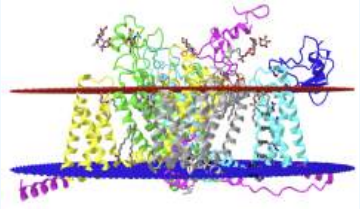
What amino acids should be present in the S4 segment of Nav1.4 and why?

Answer

.

Exercise $LGA.21$

The figure below shows an interactive iCn3D model of the rat sodium channel $Na_V1.5$ bound to the LqhIII toxin (7k18).



Rat sodium channel $Na_V1.5$ bound to the LqhIII toxin (7k18). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...jpz8CFQajMKJe7

Domains I-IV are shown in gray, yellow, green, and cyan, respectively. The magenta parts are just extensions/connectors of these domains. The LqhIII toxin is shown in dark blue. The Ile-Phe-Met (IFM) sequence of the inactivation gate that is involved in closing the pore in fast inactivation is shown as black spheres and labeled.

It is important to know that some stretches of amino acids are missing from the structure. These include AAs 1-120 (N-terminus), 298-301, 425-501, 602-608, and 1781-1838.

a. To which domain does the LqhIII toxin bind?

b. Is the binding site close to the pore-forming segments of the domain or the voltage-sensitive segments?

c. Does the layer of red spheres represent the outer (extracellular) or inner (intracellular) leaflet of the membrane?

d. Offer reasons that parts of the protein are missing from the structure.

Answer

.

Exercise $LGA.22$

The IFM motif has been shown to be conserved across all voltage-gated sodium channels.

a. What role does it play in these channels and in Nav1.5 and why?

b. The cause of Paroxysomal Extreme Pain Disorder (PEPD), an extremely rare disease with only 15 known affected families, appears to be mutations in the IFM motif which leads to increased sensations of pain. What is a likely effect of the mutations in the IFM motif?

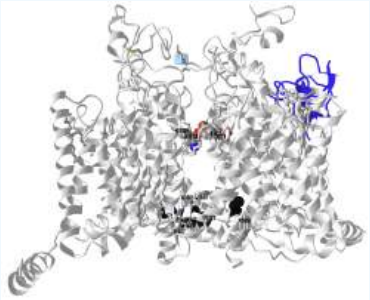
https://en.wikipedia.org/wiki/Paroxy..._pain_disorder

Answer

.

Exercise $LGA.23$

The figure below shows a different interactive iCn3D model of the rat sodium channel $Na_V1.5$ bound to the LqhIII toxin (7k18) without a membrane representation for clarity. It shows the selectivity filter DEKA (spacefill, CPK colors), the inactivation gate IFM and the IFM "internal receptor" F1651, L1660, and N1662 (spacefill, CPK colors), and a ring of hydrophobic residues V413, L941, I1471, and I1773 (spacefill, black) that in the closed state completely seal off the cytoplasmic opening in the pore.



Rat sodium channel $Na_V1.5$ bound to the LqhIII toxin without a membrane representation (7k18). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...pPzakHu6Ew6WH9

After viewing the structure from all angles, do you think that the toxin:$Na_V1.5$ complex looks closed, open, or inactivated form? Explain

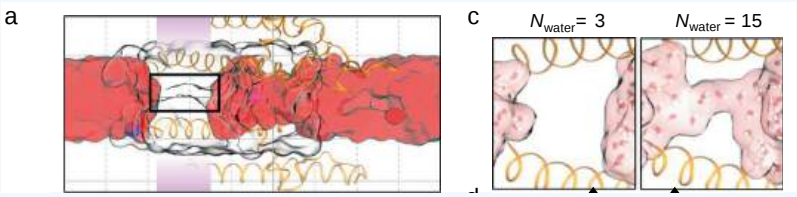
Answer

.

LGA.5: Structural Studies of LqhIII Toxin Effects on Rat Sodium Channel $Na_V1.5$ ($rNa_V1.5_C$) - Molecular Dynamic Simulations

Exercise $LGA.24$

Now let's look at some data to see if the pore is really open, partially open, or closed in the toxin:channel complex. One clue is if the structure shows water in the pore as the Na^+ ions must be hydrated to pass through the pore (the opposite case is seen with K^+ channels when K^+ pass through stripped of water). **Molecular dynamic (MD)** simulations were done on the $Na_V1.5$ with and without the toxin to simulate the environment in the channel opening. The results of the MD simulations are shown below in Figures 6 a and c from the paper.



Molecular dynamics analysis of hydration and Na^+ permeation through the $rNa_V1.5_C$/LqhIII complex.

Panel a shows a side view of $rNa_V1.5_C$ (orange ribbons; domains II and IV) from MD simulations highlighting Na^+ ions (blue spheres), the water-occupied volume within a cylinder of radius 8.5 Å (red surface), and the protein-occupied volume within a cylinder of radius 12 Å (colorless surface). The cavity within the pore is outlined with a black rectangle. The region of the intracellular activation gate is shown as a purple band.

Panel c shows molecular representations of the gate containing N_{water} = 3 (left) or 15 (right) water molecules

Based on these studies, do you believe the pore is closed, open, or partially open?

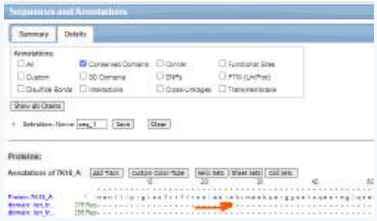
Answer

.

LGA.6: Detailed Structural Analyses of LqhIII Toxin Effects on Rat Sodium Channel $Na_V1.5$ ($rNa_V1.5_C$)

Exercise $LGA.25$

From the iCn3D model, write the sequence of the S4 segment that contains the Arg side chains and describe the properties of the amino acids in the sequence. Do this by scrolling along the sequence window in iCn3D (shown below) until you find the labeled Arg shown in the model.



Answer

.

Exercise $LGA.26$

Is the helix amphiphilic? That is, are the Arg side chains all on one face of the helix and the nonpolar on the other? To find out, copy and paste the sequence of S4 (above) in this helical wheel predictor and run the program.

Answer

.

Exercise $LGA.27$

Make a simplified view of the iCn3D model by hiding Domains 1-III to more readily see the contributions of S5 and S6 of Domain IV to the pore.

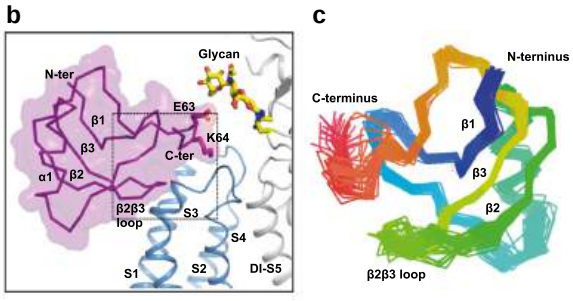
- open iCn3D and load 7K18.
- With your mouse or trackpad, choose **Sequence and Annotation** in the top menu bar
- Choose the Details tab
- Ctrl-Click the two sequences highlighted in yellow below for Domain IV and the toxin.
- Choose **View** from the top menu bar and then **View Selection**
- Choose **Style, Background, Transparent**

Solution

.

LGA.7: Noncovalent Interactions of LqhIII and Domain IV/VS

Now let's look at the actual interaction of the toxin with the Domain IV/VS of the channel. A closeup showing the interaction site is shown in Figures 3 b and c from the paper below. Panel C next to it shows the NMR-solution structures of the toxin in the absence of the channel. Each structure determined is represented by a single color line color codes red at the C-terminus to blue at the N-terminus.



Panel b: CryoEM structure of the rNa$_V$1.5$_C$ Domain IV/VS and LqhIII complex; Panel c: NMR structure of free LqhIII

? Exercise *LGA.28*

Using this iCn3D model, describe the secondary structure of the bound toxin. How many pairs of cysteine residues are in the LqhIII toxin. Identify which cysteines are involved in the disulfide bonds. What effect do the disulfide bonds have on the beta sheet structure?

Answer

.

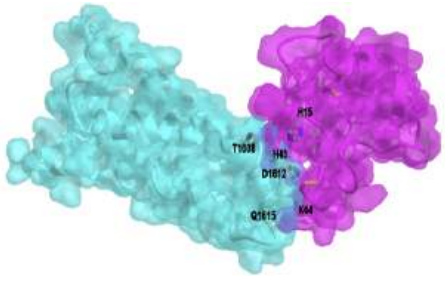
? Exercise *LGA.1*

What sections of the toxin in panel B make the closest interactions with the Domain IV/VS of the channel? Describe their conformation flexibility in the free toxin.

Answer

.

The figure below shows an interactive iCn3D model of a surface rending of Domain IV of the rat sodium channel Na$_V$1.5 bound to the LqhIII toxin (7k18).



Surface rending of Domain IV of the rat sodium channel $Na_V1.5$ bound to the LqhIII toxin (7k18). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...x5QRPEctT5zsW7.

The molecular surface and underlying secondary structure of the LqhIII toxin are shown in magenta, with key residues H15, H43, and K64 shown as CPK-colored sticks and labeled. Domain IV/VS of the channel is shown in cyan, with key amino acid side chains T1608, D1612, and Q1615 shown as colored and labeled sticks.

? Exercise *LGA*.29

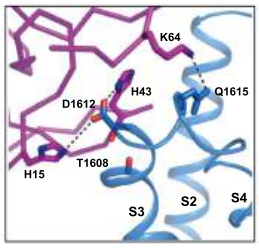
Comment on the shape and possible side chain interactions that contribute to high-affinity binding of the inhibitor to Domain IV/VS.

Answer

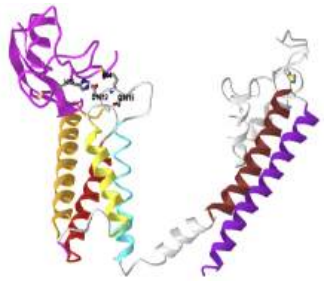
.

Figure 3d from the paper below shows the detailed interactions between LqhIII and *D*IV-VS. Key residues shown in sticks were labeled. Interaction surfaces of the *D*IV-VS (blue) and the LqhIII (purple). Key residues for the interaction are shown in yellow shading and embedded stick

d



The figure below shows an interactive iCn3D model of the rat sodium channel $Na_V1.5$ Domain IV bound to the LqhIII toxin (7k18).



Rat cardiac sodium channel NaV1.5C Domain IV/LqhIII toxin complex (7k18). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?JAjUQAZDZoQ5wiVX9

The toxin is shown in magenta. The segments are colored as follows: S1 is red, S2 is orange, S3 is yellow, S4 is cyan, S5 is brown and S6 is . Key amino acid pairs involved in the binding of the toxin to Domain IV are shown in sticks and labeled.

? Exercise *LGA*.30

In summary, name and locate the amino acid residues that serve the following roles in the LhqIII toxin: DIV-VS interactions.

1. Which amino acids in the toxin interact with D1612 (the paper describes the interaction as pincers surrounding D1612).
2. The conserved negatively charged residue in the Nav1.5 channel
3. What position is Thr in and what is thought to be its role in the mechanism?

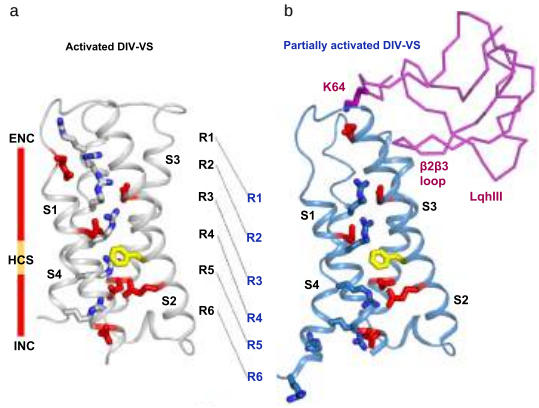
Answer

.

LGA.7.1: Comparison of Activated DomIV-Voltage sensor (VS) with Toxin-bound Partially activated DomIV-VS

Now we'll try to understand Figure 4, Conformational Change of DIV-VS, from the paper and pay special attention to the section of the text, "An intermediate-activated state of DIV-VS trapped by LqhIII" - Let's dissect Figure 4 A and B.

Figure 4a/4b from the paper below shows the c**onformational change of *Domain* IV-Voltage sensor (DIV-VS)** comparing the activated and partially activated state with the bound toxin.



Panel a shows the activated domain IV with key Arg side chains in S4. Panel B shows the partially activated domain IV with the same key Arg side chains in S4. The bound LqhIII is shown as a purple chain. In panels a and b, the:

1. activated Nav1.5 DIV-VS (the voltage sensing domain) is in grey (fig 4a)
2. the intermediate-activated Nav1.5DIV-VS is in blue (Fig 4b)
3. side chains of gating charges of Arg are shown in grey and blue sticks in 4a and in shades of blue sticks in 4b. Side chains in the ENC are shown in red, in the HCS in yellow, and in the INC in red;
4. the shift of each gating charge was indicated by black dashed lines between the structures in panels a and b.

The shift from the cytoplasmic to extracellular parts of the channel is shown in the region between the two panels. The black Rs in the activated DIV-VS(panel A) are further up in the diagram (towards the extracellular region) and further down in the partially activated DIV-VS bound to the toxin.

? Exercise *LGA.31*

Locate the 6 arginines? (R1-R6) with the blue indicating the N atoms in the positively charged Arg side chain of S4 in Domain IV in one of the iCn3D models above. What do the following abbreviations mean? ENC, HCS, and INC.

Answer

.

? Exercise *LGA.29*

From Figure 4a to 4b, explain from an electrostatic viewpoint how the movement of the Args towards the extracellular region would promote the movement of Na^+ ions inward. Explain how the movement of Na^+ ions would be diminished in the presence of the toxin.

Answer

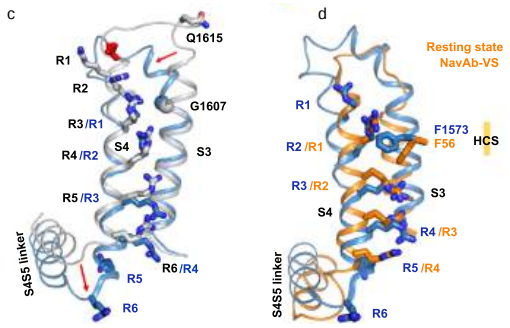
.

LGA.7.2: Comparison of Active and Intermediate-Activated, and Intermediate/Resting state

Now consider Figures 4 C and D from the paper below:

4c: Superposition of NaV1.5 *D*IV-VS between the fully activated state and toxin-bound intermediate-activated state. Red arrows indicate the conformational changes.

4d: Superposition of the intermediate-activated NaV1.5 *D*IV-VS and resting-state NaVAb-VS



? Exercise $LGA.32$

a. Locate the region in Figure c above that shifts the most from the fully activated to intermediate-activated state of the DIV-VS.

b. Describe the difference shown in Figure d between the intermediate-activated *D*IV-VS structure (blue) upon the resting state Na_VAb-VS structure (orange)

c. What do these differences imply about the conformational states of the apo and toxin-bound channel?

Answer

.

LGA.8: Summary

? Exercise $LGA.33$

Why might the mode of action be specific for cardiac muscle cells as compared to other toxins that act on sodium channels in skeletal and nerve cells?

Answer

.

After this guided research literature module, you can hopefully better understand the findings in the paper which are summarized in this abstract:

"Voltage-gated sodium (Na_V) channels initiate action potentials in excitable cells, and their function is altered by potent gating-modifier toxins. The α-toxin LqhIII from the deathstalker scorpion inhibits fast inactivation of cardiac $Na_V1.5$ channels with IC_{50} = 11.4 nM. Here we reveal the structure of LqhIII bound to $Na_V1.5$ at 3.3 Å resolution by cryo-EM. LqhIII anchors on top of voltage-sensing domain IV, wedged between the S1-S2 and S3-S4 linkers, which traps the gating charges of the S4 segment in a unique intermediate-activated state stabilized by four ion-pairs. This conformational change is propagated inward to weaken binding of the fast inactivation gate and favor opening the activation gate. However, these changes do not permit Na^+ permeation, revealing why LqhIII slows inactivation of Na_V channels but does not open them. Our results provide important insights into the structural basis for gating-modifier toxin binding, voltage-sensor trapping, and fast inactivation of Na_V channels."

LGA.9: Extensions

1. Interesting sidebar: https://www.sciencedirect.com/science/article/pii/S0021925819308300?via%3Dihub

Chlorotoxin (Cltx) is a 36-amino acid peptide that was originally isolated from *Leiurus quinquestriatus* venom (14) and has been shown to inhibit small conductance Cl− channels in colonic epithelial cells (14, 15). Cltx also inhibits Cl− fluxes across glioma membranes (13, 16). Immunohistochemical studies show that Cltx specifically and selectively binds to glioma cells (17) and radiolabeled Cltx targets tumor cells in mice bearing xenografted glioma tumors. Glioma cell migration and invasion into fetal brain aggregates is significantly reduced by Cltx (13). A recent survey of over 200 tissue biopsies from patients with various malignancies suggests that Cltx binds to the surface of gliomas and other embryologically related tumors of neuroectodermal origin (18) but not to normal brain.

2. Deathstalker scorpion venom also contains chlorotoxin - This is a very interesting story.

https://www.acs.org/molecule-of-the-week/archive/c/chlorotoxin.html#:~:text=Strichartz%20at%20Harvard%20Medical%20School,diagnosing%20and%20treating%20some%20cancers.

Note and remember LqhIII is an alpha toxin

---

LGA: Protein Stability - Carbonic Anhydrase

Carbonic Anhydrase

Engineered Stability

We have already encountered this enzyme before (Chapter 6.1). It catalyzes the hydration of CO_2 (g) as shown below.

$$CO_2\ (g) + H_2O \leftrightarrow H_2CO_3\ (aq) \leftrightarrow HCO_3^-\ (aq) + H^+\ (aq)$$

It is among the fastest of all enzymes, with a k_{cat} of 10^6 s^{-1} and a k_{cat}/K_m of 8.3 x 10^7 $M^{-1}s^{-1}$ (reference). It is diffusion controlled in that the rate of diffusion of reactants and products, not the chemical steps, determine the reaction rate. It can convert 10^6 molecules of CO_2(g) to HCO_3^- each second. No wonder scientists and engineers are studying it to capture CO_2. It's a big challenge though to capture CO_2 released on combustion of coal or natural gas in a power plant. Here are two problems that must be overcome:

- The enzyme must be thermostable at elevated temperatures to capture the CO_2 found in high-temperature power plant emissions
- The enzyme is reversible so it will be inhibited by the product HCO_3^-
- The enzyme must be stable to somewhat alkaline conditions (pH of 0.1M $NaHCO_3$ = 8.3)

For carbon capture from fossil fuel emissions, CA is immobilized by surface adsorption, covalent attachment, encapsulation, and entanglement. Immobilized enzymes are typically more thermostable and can be used in flow-through as opposed to solution phase capture. The immobilized enzyme matrix must withstand high temperatures (up to 100°C, and alkaline solvents used to strip the matrix for reuse.

The enzyme is found throughout life and typically has an active site Zn^{2+}. There are 8 families, α, β, γ, δ, ζ η, θ, and ι, with the α family being the most abundant. The α forms are generally active as dimers, but can act as monomers and tetramers.. There are 15 isoforms of the α form in humans and have a prime role in pH regulation. They are found in bacteria, fungi, plants, and algae. β-CAs are found in some types of bacteria, archaea, fungi, some higher plants, and invertebrates. CA in chloroplasts (and mitochondria (algae) are involved in carbon fixation. We will focus our attention on engineering carbonic anhydrase to make them more thermostable, alkali insensitive, and less susceptible to product inhibition by bicarbonate.

Natural enzymes can be isolated and selected for thermal and alkali stability. In addition, new versions selected for these properties can be engineered using directed evolution or site-directed mutagenesis. You wish to increase the thermal stability of a protein using mutagenesis. Essentially you wish to perturb the equilibrium between the folded (native) protein and the unfolded (denatured) protein so as to preferentially stabilized the native state.

? Question *LGA.1*

Using mutagenesis, what residues might you change in a native protein to make it more stable at higher temperatures?

Answer

A characteristic of the native state of the protein is its conformational stability compared to the conformational flexibility of the many possible denatured states. In addition, the protein must undergo conformational changes as it unfolds. Hence anything that restricts conformational flexibility might preferentially stabilize the native state. These would include changing single or pairs of side chains to allow the formation of more salt bridges and intrachain disulfide bonds, as well as hydrogen bonds. Loops with greater flexibility, as determined by B-factors in the crystal structure files, or by molecular dynamic simulations, could be changed to contain a disulfide, which would clearly stabilize a flexible loop.

? Question *LGA.2*

What measurements would you make to quantitate the change in thermal stability?

Answer

Measures a signal that changes with increasing temperature. The signal can be enzyme activity, or more easily a spectroscopic signal such as absorbance at 280 nm or fluorescence as a function of temperature. Alternatively, the stability at room temperature could be measured using urea as a perturbant. These are discussed in Chapter 4.12.

The actual amino acid composition and more strangely specific dipeptide sequences within a sequence are associated with thermal stability of hyperthermophilic proteins. For example, proteins from two different types of archaea with different optimal growth temperatures show that the one with the higher growth temperature have significantly higher levels of VK, KI, YK, IK, KV, KY, and EV and decreased levels of DA, AD, TD, DD, DT, HD, DH, DR, and DG. Similar experiments have been done in bacterial cells. Using machine learning, the dipeptide sequences K*H, KR, TF, P*M, F**N, V**Y, MW, and WQ were important in themostability where the * denotes a gap in the residues.

Carbonic anhydrase from Neisseria gonorrhea (*ng*CA)

Data from: Jo, B., Park, T., Park, H. *et al.* Engineering *de novo* disulfide bond in bacterial α-type carbonic anhydrase for thermostable carbon sequestration. *Sci Rep* **6**, 29322 (2016). https://doi.org/10.1038/srep29322. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/

Now that we understand the general chemistry, structure, and reaction mechanism of carbon anhydrase (at least the alpha human CAII form), let's explore efforts to engineer more thermostable variants. One example is the carbonic anhydrase from N. gonorrheas. This CA has been used as a target for mutagenesis to increase thermal stability of the enzyme, through the introduction of new disulfide bonds.

Even though only about 35% of the amino acids are identical, the overall structures are similar. This is illustrated in Figure LGA. 10 below.

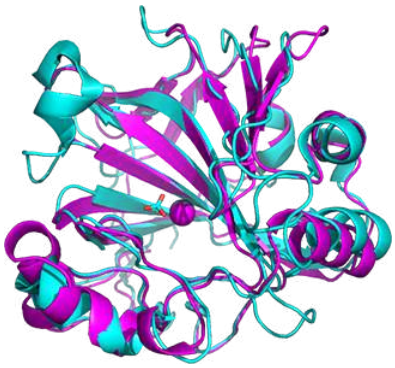

Figure LGA. 10: Alignment of the carbonic anhydrase from Neisseria gonorrhea (NG-CA) magenta,1KOQ) and human CA II (cyan, 2VVB)

The active site is mostly conserved compared to human CA II. The Zn^{2+} bound water has a pKa of around 6.5, compared to the value of 7.0 in human CA II. The hydrophobic patch (pocket) is similar, with Phe 93, Leu 153 and Tyr 72 in the NG-CA replacing Phe 95, Phe 176, Phe 70 in human CA II, respectively. The histidine ligands to Zn^{2+} are His92 (94), His94 (96), and His111 (119), where the numbers in parentheses represent Hu CA II. The proton removed from Zn^{2+} bound water is transferred to His 66 (64 in human CA II) and then to His 64.

The single disulfide bond between 181 and C28 is shown in Figure LGA. 1 below

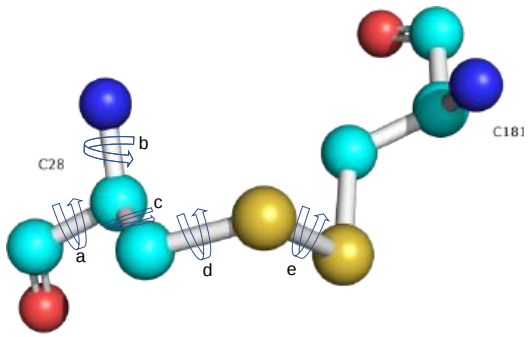

Figure LGA. 11: Single disulfide bond between 181 and C28 in wild type Carbonic anhydrase from Neisseria gonorrhea

Question $LGA.18$

This question addresses the Biomolecular Visualization Framework theme(s) Atomic Geometry (AG)

Identify the correct torsion angles in Figure $LGA.x$ above. Verbal definitions of torsional angles in a peptide chain are listed below. The successive atoms after the C_α leading away from the backbone atoms are X_β-X_γ-X_δ-X_ε (in that order). C is the backbone carbonyl C and N is the backbone nitrogen atom.

- phi (φ) is the angle of right-handed rotation around N-C_α bond. φ = 0 if the C_α-C bond is cis (eclipsed) to the C-N bond. Values range from -180 to 180 degrees.
- psi (ψ) is the angle of right-handed rotation around C_α -C bond. ψ = 0 if the C-N bond is cis (eclipsed) to the N-C_α bond. Values range from -180 to 180 degrees.
- chi_1 (χ_1) is the rotation around N-C_α-X_β-X_γ
- chi_2 (χ_2) is the rotation around C_α-X_β-X_γ-X_δ
- chi_3 (χ_3) is the rotation around X_β-X_γ-X_δ-X_ε

Answer

phi (Φ) = b, psi (Ψ) = a, chi_1 (χ_1) = c, chi_2 (χ_2) = d, and chi_3 (χ_3) = e

Question $LGA.19$

This question addresses the Biomolecular Visualization Framework theme(s) Atomic Geometry (AG), Topology and Connectivity (TC)

Figure $LGA.12$ below shows an interactive iCn3D model of the atoms within 4A of the disulfide bond in Carbonic anhydrase from Neisseria gonorrhea (1KOQ). Rotate the model to determine the approximate chi_3 (χ_3) dihedral angle. Hint: site down the S-S bond.

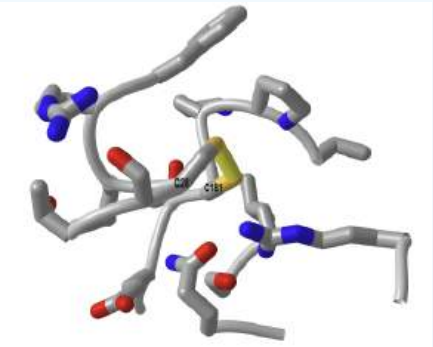

Figure $LGA.12$: Atoms within 4A of the disulfide bond in Carbonic anhydrase from Neisseria gonorrhea (1KOQ). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...nutjP6EL2PubRA

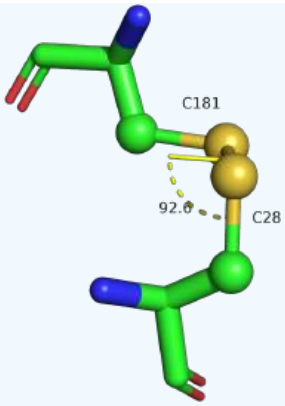
Answer

The visually estimated chi_3 (χ_3) angle for rotation around the S-S bond is $90^{o.}$ Here is the actual angle (image made with Pymol)



We mentioned previously that variants with higher thermal stability are likely to be more rigid and less flexible. Flexibility can be determined through analysis of molecular dynamic simulations and also by examining of the B factor values in PDB file. This number is a measure of the displacement of an atom from a mean The numbers in the last column in the file are called the temperature factors or B-factor. The B-factor describes the mean-square displacement, a measure of the displacement of an atom from an average value. If the atoms are more flexible, the electron density determined in x-ray structures is lower than if the atoms are more fixed, which gives high electron density.

To make stabilizing disulfide bonds, investigators found site chains close enough that when mutated to cysteines could potentially form disulfide bonds. In addition, they search for such residues in surface loops (without alpha and beta structure) which are inherently more flexible. Introducing disulfide bonds into the loop would stabilize it and make it more rigid. Table $LGA.2$ below shows a description of the double cysteine CA variants in the study.

Variant designation	Position	Wild-type residues	Loop length	Sum of B-factors
T133C/D197C	133, 197	Thr/Asp	63	87.60
P56C/P156C	56, 156	Pro/Pro	99	80.82
N63C/P145C	63, 145	Asn/Pro	81	77.17

Table $LGA.2$: **Description of the double cysteine CA variants in ngCA**

The locations of the side chair targeted for mutations to cysteine pairs are shown in Figure $LGA.13$ below.

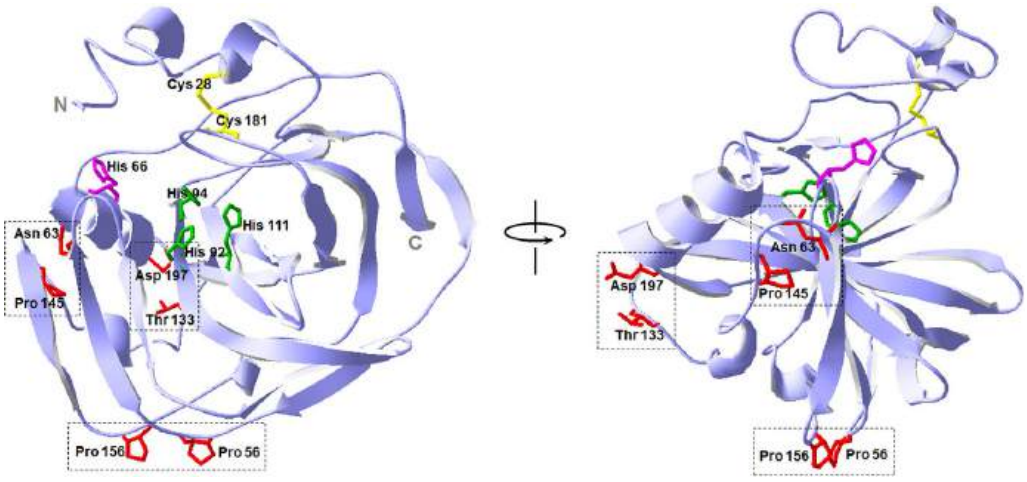


Figure $LGA.13$**: 3D structure of *ng*CA and location of residue pairs for disulfide engineering**

The zinc (not shown)-coordinating histidine residues in the catalytic active site are shown in green. The proton shuttle histidine residue is shown in magenta. The native disulfide bond is colored yellow.

An interactive iCn3D model of carbonic anhydrase from Neisseria gonorrhea (1KOQ) highlighting the 3 pairs of sidechains for mutations is shown in Figure $LGA.14$ below.

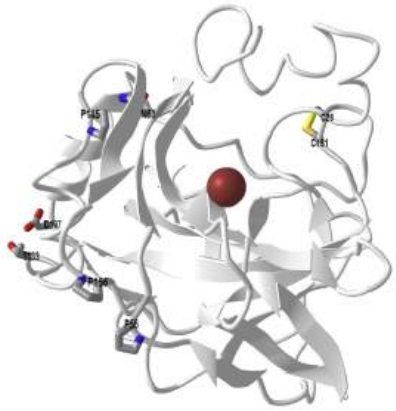

Figure $LGA.14$: Carbonic anhydrase (Neisseria gonorrhea) with 3 paired side chains for engineered disulfide (1KOQ) (Copyright; author via source).

Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...KRP2tFJ1pV1FF6

The mutations were made and the wild-type proteins and three mutants were subjected to SDS-polyacrylamide gel electrophoresis (SDS-PAGE). The stained gels are shown in Figure $LGA.15$ below.

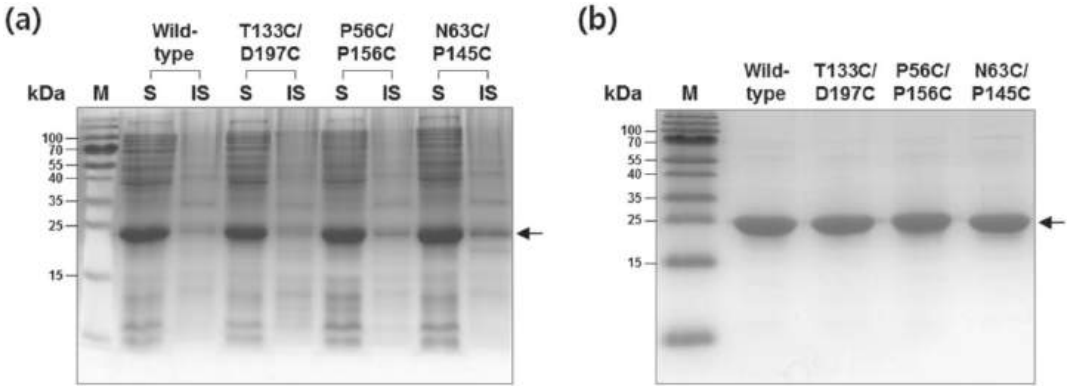

Figure $LGA.15$: **Expression and purification of disulfide CA variants.**

Panel (**a**) shows the expression of the protein in transformed cells 25 °C after IPTG induction and fractionated into soluble and insoluble fractions. SHuffle strain, an engineered *E. coli* strain that promotes cytoplasmic disulfide bond formation, was used.

Panel (**b**) shows purification results. Each lane was loaded with 4 µg of each purified CA variant. The proteins were visualized with Coomassie blue staining after SDS-PAGE. The arrow indicates the position of the bands corresponding to *ng*CA variants. Lane: M, molecular weight marker; S, soluble fraction; IS, insoluble fraction.

? Question $LGA.20$

a. Interpret the results of the PAGE gels in Figure $LGA.15$ above

b. How pure were the proteins based on the PAGE gel result in Panel (b). Can you infer from the gel that the proteins folded correctly?

Answer

a. It appears to show that a small fraction of the wild type and each mutant, especially the N63C/P145C pair, was found in the insoluble fraction. This might result from improper folding of the proteins in E. Coli, leading to hydrophobic side chain surface exposure and aggregation into insoluble "inclusion bodies". This appears to be just a minor issue.

b. All the proteins appear very pure with some very small levels of contamination in the N63C/P145C. The PAGE results show the protein all have the same molecular weight but whether they folded to a native state with activity can not be determined. Nor can it be determined if the disulfide pairs in the mutants were made are if they were, were correctly paired.

The investigators next determined if the expressed and purified wild-type and mutant proteins had the correct number of disulfide bonds. They did this by reacting the proteins in the absence and presence of dithiothreitol with DTNB or 5,5'-dithiobis(2-nitrobenzoic acid), also called Ellman's Reagent. Both structures are shown in Figure $LGA.16$ below.

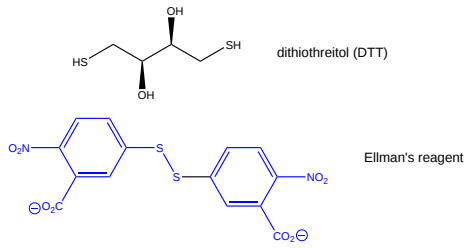

Figure $LGA.16$: Structures of DTT and DTNB

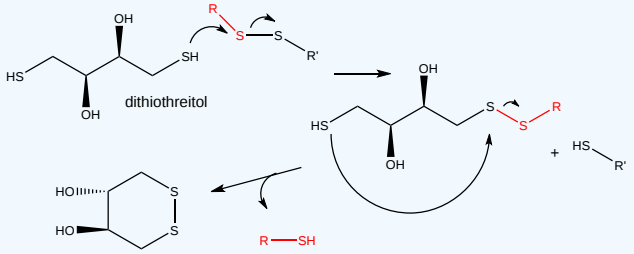
DTT is a reducing agent that cleaves disulfide.

Question $LGA.21$

Draw a mechanism showing the reaction of a disulfide with DTT.

Answer



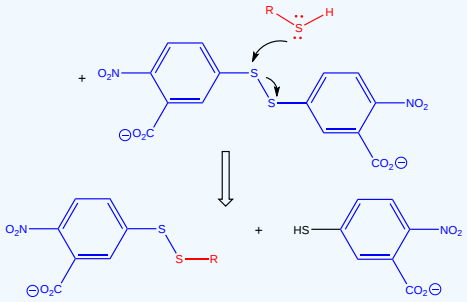
Only surface and not buried free cysteines will be labeled unless the protein is unfolded to expose all the cysteines.

DTNB reacts with free sulfhydryls to form the 2-nitro-5-thiobenzoic acid anion leaving group that absorbs at 412 nm.

Question $LGA.22$

Draw a mechanism showing the reaction of free sulfhydryl (like Cys) with Ellman's reagent

Answer



Only surface and not buried free cysteines will be labeled unless the protein is unfolded to expose all the cysteines.

The results of the reaction of the proteins with Ellmans's agent, in the presence and absence of DTT, are shown in Table $LGA.3$ below.

CA variant	Free thiol/protein (mol/mol) [a]		Deduced no. S-S bonds
	−DTT	**+DTT**	
Wild-type	0.06 ± 0.02	1.80 ± 0.14	?
T133C/D197C	0.08 ± 0.02	3.79 ± 0.22	?
P56C/P156C	0.06 ± 0.03	3.89 ± 0.06	?
N63C/P145C	0.08 ± 0.03	3.75 ± 0.05	?

Table $LGA.3$: Analysis of disulfides in CA using Ellman's reagent. [a]Numbers are represented in mean ± SD.

? Question $LGA.23$

How many S-S would you deduce from the table are present in the wild-type and mutant enzymes? Did the correct disulfide bonds form? Explain your answers

Answer

DTT reduces the disulfide in protein. For each disulfide, two free Cys side chains are made. The molar ratio of CysSH/CA for the wild-type is 1.8 in the presence of DTT. The value is very close to the expected value of 2. For the mutants, the ratio is about 3.8 in the presence of DTT, suggesting 4 free Cys consistent with 2 disulfide bonds.

Table $LGA.4$ below shows the catalytic activities of the disulfide CA variants at 25 °C.

CA variant	CO_2 hydration activity			
	Relative esterase activity [a]	$k_{cat} \times 10^{-4}$ (s^{-1})	K_M (mM)	$k_{cat}/K_M \times 10^{-6}$($M^{-1}$ s^{-1})
Wild-type	1.00	1.44	14.2	1.01
T133C/D197C	1.49	1.97	16.7	1.18
P56C/P156C	1.03	1.44	16.9	0.85
N63C/P145C	0.55	0.27	17.3	0.16

Table $LGA.4$: catalytic activities of the disulfide CA variants at 25 °C [a]The specific activity of the wild-type corresponds to 0.22 U/µmol-enzyme.

? Question $LGA.24$

Why did the investigators conduct this experiment? Interpret the results

Answer

All of the previous results suggest that the mutant proteins were made and had the correct number of double bonds, but the experiments could not tell if the bond pairs were correct. For example, did the T133C/D197C contain a native (C28-C181) and mutant (C133-C197) bond and not another combination? Activity is an excellent predictor of structure. All but one mutant retained nominal activity, as evidenced by a comparison of the rat constants. The N63C/P145C had a 6x lower k_{cat}, but even then it is close to diffusion-controlled.

Now comes the big question: were the investigators able to engineer thermal stability into the carbonic anhydrase? Experimental results to show the thermostability of the disulfide CA mutants are shown in Figure $LGA.17$ below.

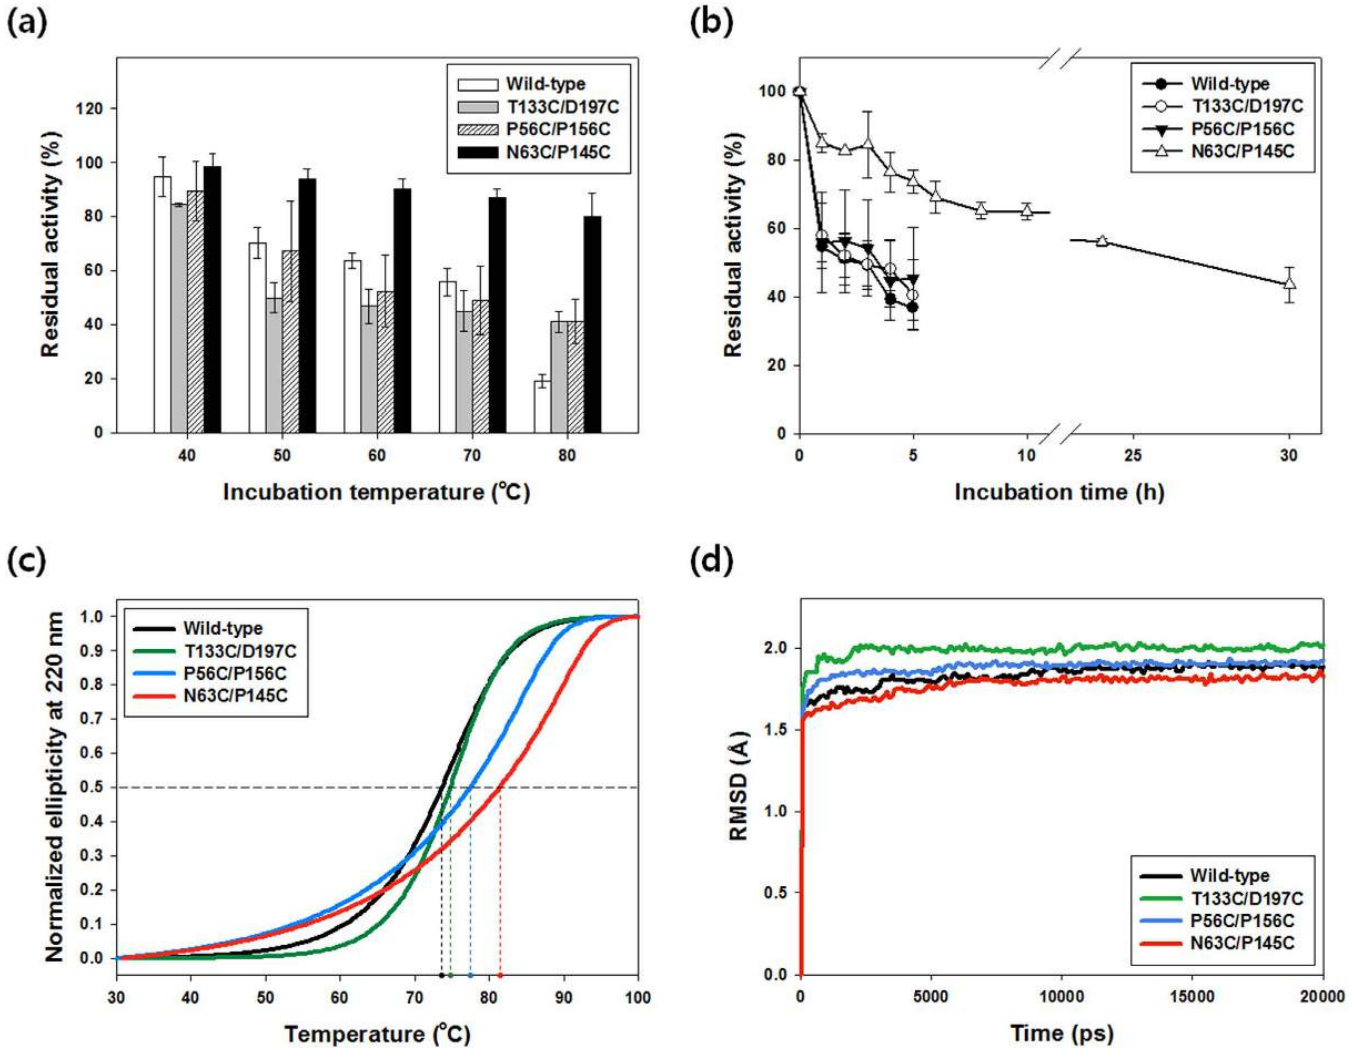


Figure $LGA.17$: Thermostability of the disulfide CA variants

Panel (**a**) shows short-term kinetic stability. The enzyme solutions (40 µM) were incubated for 30 min at different temperatures, and the residual activities were measured by esterase activity assay. Activities of 100% correspond to untreated samples. Panel (**b**) shows long-term kinetic stability at 70 °C. The half-lives ($t_{1/2}$) of the CA variants were estimated by fitting the experimental data to an exponential decay curve. Each value represents the mean of at least three independent experiments, and the error bars represent the standard deviations.

? Question $LGA.25$

Analyze the results in Panels (a) an (b). Which protein was most thermostable over the short (30 minute) and long (hours) incubating time at elevated temperatures?

Answer

At 80 °C, all the mutants showed increases thermostability to short term (30 minute) heating, but one, N63C/P145C was exceptionally thermostable. Longer time courses for heating at 70°C showed that the N63C/P145C was again far more stable over time. Its $t_{1/2}$ was 31.4 h, compared to the values between 4-6 h for the others.

Panel (c) shows heat-induced denaturation of disulfide CA variants. Temperature-dependent changes of the circular dichroism ellipticity were recorded at 220 nm on CD spectrometer. The denaturation curves were normalized to the fraction of unfolded protein. The horizontal dashed line indicates the point at which the fraction of unfolded protein is 0.5. The vertical dashed lines

point to T_M values. Panel (**d**) shows the overall RMSD of disulfide variants from molecular dynamic simulations performed at 400 K for 20 ns.

Question $LGA.26$

Analyze the results in Panel (c). What do changes in the CD helicity show? Which protein was most thermostable based on T_M values? Is the decrease in enzyme activity in panels (a) and (b) result from the denaturation of the protein?

Answer

CD measurements can give a measure of the retention of secondary structure (alpha helices and beta structure) on denaturation. The CD spectrum for different secondary structures is shown below (From Chapter 3.5).

The curves were normalized to fit on a 0-1 scale on the y axis, which then gives a measure of percent denaturation. The temperature half-way up is the T_M, or "melting temperature, at which an equilibrium mixture would contain half native and half denatured protein (true for a small protein with no intermediates). The T_M values were for the wild-type, T133C/D197C, P56C/P156C, and N63C/P145C mutants 73.6 °C 74.7 °C, 77.4 °C, and 81.4 °C. These parallel the $t_{1/2}$ values for enzyme activities, and support the idea that denaturation led to inactivation of the enzyme.

Question $LGA.27$

Analyze the molecular dynamics simulation results in Panel (d)

Answer

The molecular dynamic simulations for all the proteins soon reach equilibrium values as indicated in the plateaus of average room mean square deviation of the protein backbone. The overall molecular root-mean-square deviation (RMSD) of N63C/P145C was the lowest, indicating that it was most rigid. This is in accord with the idea that increased flexibility destabilizes a protein and engineering a disulfide into makes it more rigid and hence more stable to temperature increases. The results are in accordance with the other experiments that show the N63C/P145C was the most thermostable.

" In addition, T133C/D197C showed the highest values in both the overall and the residual RMSD (Fig 3D). This may explain and correlate with the increased activity of T133C/D197C (Ta) and the increased ΔS of unfolding"

You may remember from both introductory chemistry and from Chapter 4.12, that you can calculate the thermodynamic parameters, $\Delta \mathbf{H}^o$ and $\Delta \mathbf{S}^o$ for N ↔D at room temperature from thermal denaturation curves using the van 't Hoff equation.

In this case, K_{eq} values can be calculated from thermal denaturation curves by monitoring change in CD signal at 220 nm, and applying this equation (also from Chapter 3.12).

$$K_{eq} = \frac{[D]_{eq}}{[N]_{eq}} = \frac{f_D}{f_N} = \frac{f_D}{1 - f_D} \tag{LGA.1}$$

From this, we can calculate ΔG^0.

$$\Delta G^0 = -R\,T \ln K_{eq} = -R\,T \ln\left[\frac{f_D}{1-f_D}\right] \tag{LGA.2}$$

Knowing K_{eq}, ΔH^0, DS^0 can be calculated as shown below. A semi-log plot of $\ln K_{eq}$ vs 1/T is a straight line with a slope of - $\Delta H^0 R$ and a y-intercept of + $\Delta S^0/R$, where R is the ideal gas constant.

$$\begin{aligned} \Delta G^0 = \Delta H^0 - T\Delta S^0 = -RT\ln K_{eq} \\ \ln K_{eq} = -\frac{\Delta H^0 - T\Delta S^0}{RT} \\ \ln K_{eq} = -\frac{\Delta H^0}{RT} + \frac{\Delta S^0}{R} \end{aligned} \tag{LGA.3}$$

The equation below shows that the derivative of equation (8) with respect to 1/T (i.e. the slope of equation 8 plotted as $\ln K_{eq}$ vs 1/T) is indeed $-\Delta H^0/R$. Equation (9) is the van 't Hoff equation, and the calculated value of the enthalpy change is termed the van 't Hoff enthalpy, $\Delta H^0 v_{Hoff}$.

$$\frac{d\ln K_{eq}}{d(1/T)} = -\frac{\Delta H^0}{R} = -\frac{\Delta H^0_{vHoff}}{R} \tag{LGA.4}$$

Using this method, the thermodynamic parameters for unfolding of the protein were calculated. The results are shown in Table $LGA.4$ below.

CA variant	Melting temperature, T_M (°C)	Enthalpy change of unfolding, ΔH (kcal mol^{-1})	Entropy change of unfolding, ΔS (kcal mol^{-1} K^{-1})
Wild-type	73.6	48.8	0.141
T133C/D197C	74.7	52.8	0.153
P56C/P156C	77.4	35.1	0.091
N63C/P145C	81.4	30.0	0.085

Table $LGA.4$: Thermodynamic parameters for protein unfolding for WT and mutant CAs

? Question $LGA.28$

Which effects, enthalpy or entropy of unfolding, were associated with the increased thermal stability of the mutants compared to the wild-type protein. Remember were are considering the denaturation reaction, N ↔ D.

Answer

For the reaction N ↔ D, the ΔH^0 values were all positive, indicating the enthalpy changes favored the native state, not the denatured state.

In contrast, the other two mutants were enthalpically destabilized compared to the wild-type as their ΔH^0 were less positive so compared to the wild-type. The prime stabilizer of the native state was the lower entropy (hence a less negative and favored $-T\Delta S^0$ for the denaturation reaction. This makes sense in these mutants are more rigid and would experience less loss of "conformational entropy).

P56C/P156C and N63C/P145C exhibited lower ΔH (destabilizing) and ΔS (stabilizing), showing that the decreased entropic change of unfolding (i.e., the loss of conformational entropy of the unfolded state) by the disulfide bridge was the primary factor for the thermostabilization. These results are not surprising because design strategies aiming 'entropic stabilization' such as disulfide engineering do not always result in engineered proteins ideally with lower ΔS and unchanged ΔH.

These results are in accord with the observation that N63C/P145C was the most thermostable variant and that T133C/D197C showed the highest values in both the overall and the residual RMSD (Fig. 3d). This may explain and correlate with the increased activity of T133C/D197C and the increased ΔS of unfolding.

Finally, the enzymatic activity of the wild-type and mutants CAs (using a small ester substrate) were studied as a function of temperature. The relative activity of the wild-type and all 3 disulfide mutants are plotted as a function of temperature in the histogram graphs shown in Figure $LGA.18$ below.

Figure $LGA.18$: Effect of temperature on the activity of disulfide CA variants.

Esterase activities of disulfide variants were measured at each temperature and normalized to the activity of each enzyme at 25 °C. Each value represents the mean of three independent experiments, and the error bars represent the standard deviations. If you plotted the data as curves, you would get bell-shaped graphs.

? Question $LGA.29$

Explain why the histogram plots (and line plots if they were drawn) are bell-shaped. Are the results in accordance with the previous results.

Answer

Yes. Most chemical reaction show an increase in rate with increasing temperatures until competing reactions take precedence. For an enzyme-catalyzed reaction, that competing reaction is denaturation, which decreases the rate.

Yes the graphs are in accord with the previous results. The N63C/P145C certainly stands out as the best mutant. The authors write that "considering the shifted optimal temperature and the thermoactivation as well as the enhanced thermostability, the disulfide engineered α-type CA with Cys^{63}-Cys^{145} can be a promising biocatalyst for efficient CO_2 sequestration performed under high temperature conditions."

28.1: General Features of Signal Transduction

28.1.1: Introduction to Cell Signaling

Cell signaling is at the heart of biology. A cell must know how to respond to chemical signals in its environment. These signals control every aspect of cell life and interactions. A cell must sense when to grow, divide and die. It must sense the presence of foreign and toxic molecules. It must defend itself. The membrane represents the divide between the outside and inside world. Signals must cross that divide and this most often happens without the signaling molecule entering the cell. Just the signal itself is transduced across the membrane. And it doesn't stop there. Internal signaling, also across internal membranes of organelles in eukaryotes, propagates spatially and temporally across the cytoplasm in all cells (prokaryotes, Archaea, and eukaryotes). It's impossible to describe the myriad of processes that occur in cell signaling in a single chapter, but we will do our best to present the common features used across cells.

In addition, signals in complex organisms must be integrated within tissues and organs, between organs (brain and liver for example), and within the entire organisms. Mathematical modeling is critical in understanding the complexity of these interconnected interactions. Consider the flee, fight, or freeze responses. What if you were walking down the street and suddenly saw a tiger approaching you? Most would flee. In that process, the neural, muscular, and metabolic systems must be integrated. The resting state is followed by the activation of the flight/flee response, the maintenance of the fleeing state, and then the return to the resting state. An alternative is the freeze response, which in some situations would be adaptive.

Perhaps the most complex signaling occurs in the great communication networks in the neural and immune systems. Think of it. You can experience a traumatic or emotionally-charged event once and remember it forever. Ordinary events leave less permanent traces. The biochemical changes accompanying long and short-term memory are fascinating

Let's consider general principles for signal transduction across membranes of any cell that must respond to its environment. Typically the agent that signals a cell to respond is a molecular signal. Signaling can also be mediated by pressure (for touch and hearing) or light for vision. The chemical signal binds either to a cell surface receptor or to a cytoplasmic receptor if the signaling agent is hydrophobic and can transit the membrane bilayer.

28.1.2: The logic of signaling

To a first approximation, you could consider a cell as a black box, as shown in Figure 28.1.1, with input (an external molecule for example) and resulting output signals within a cell, such as activation of gene transcription, trafficking of molecules within the cell, chemical reactions, or even export of molecules from the cell. There could be one or more signals, and one or more outputs. The inputs might arrive gradually and reach a threshold before triggering an output, or the input might be abrupt leading to an immediate output. This Figure 28.1.1:

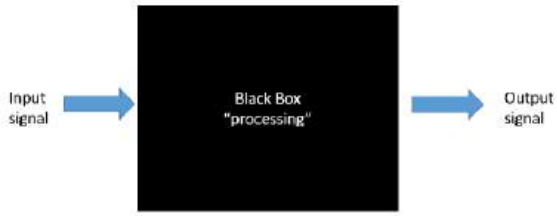

Figure 28.1.1: A cell as a black box processing unit.

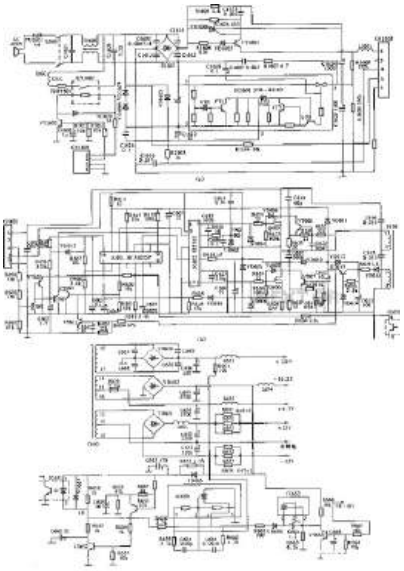
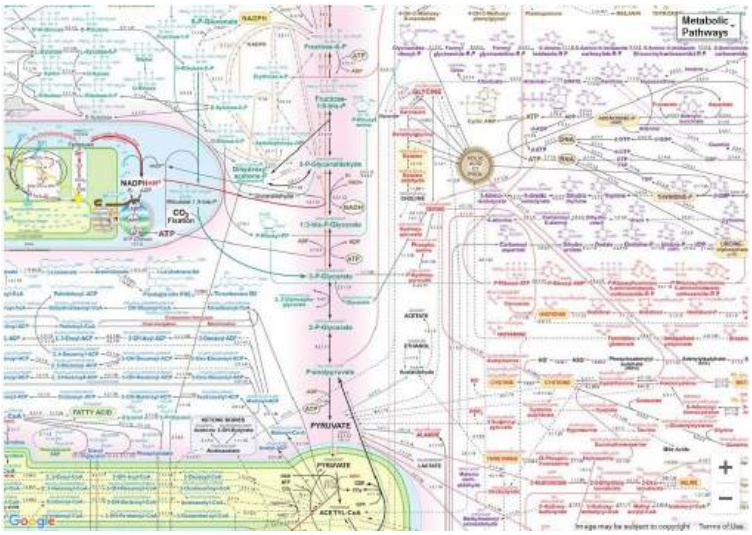
Note the use of terminology taken from the world of electronics. Figure 28.1.2 shows the similarity in the complexity of an electronic wiring diagram (left) to the interconnected metabolic pathways of a cell (right).



Electronic wiring diagram



Metabolic pathway map

Figure 28.1.2: Comparison of an electronic wiring diagram and a metabolic pathway map. https://www.sigmaaldrich.com/US/en/t...c-pathways-map

The analogy is much greater than you might think. Cell signaling researchers have adopted the language and symbols of electronics as they consider how two inputs could lead to different output signals. Figure 28.1.3 shows a truth table with different Boolean operator logic gates and symbols used by electrical engineers that also apply to signals to cells and their outputs. Two input signals, A and B, arrive at different logic gates named AND, NOR, OR, XOR AND, and NAND. 0 indicates no signal (either input or output) while 1 indicates a signal (either input or output).

INPUT AND OUTPUT		INPUT NOR OUTPUT		INPUT OR OUTPUT		INPUT XOR OUTPUT		INPUT NAND OUTPUT	
IN	OUT	IN	OUT	IN	OUT	IN	OUT	IN	OUT
A B		A B		A B		A B		A B	
0 0	0	0 0	1	0 0	0	0 0	0	0 0	0
1 0	0	1 0	0	1 0	1	1 0	1	1 0	1
0 1	0	0 1	0	0 1	1	0 1	1	0 1	1
1 1	1	1 1	0	1 1	1	1 1	0	1 1	0

Figure 28.1.3: Boolean operator logic gates

Each of these logic gates leads to different outputs:

- **AND** gates require both A and B input signals for an output;
- **OR** gates require either A or B or both for an output signal;
- **NOR** gates require neither A or B for an output signal;
- **NAND** gates normally have an output signal unless both inputs A and B are present;
- **XOR** (Exclusionary OR) gates give a signal if the two inputs A and B differ.

An example of an analogous biological AND gate is N-WASP protein [a homolog to the Wiskott-Aldrich syndrome protein (WASP)]. This protein regulates actin polymerization and binds multiple signals. Stimulation with two proteins, Cdc42 and phosphatidylinositol (4,5)-bisphosphate (PIP2), activates polymerization.

Researchers are designing protein logic gates by creating a series of heterodimeric proteins. Consider the following heterodimers: A:A', B:B', and C:C', where the second member in each pair is different from the first and bound reversibly through noncovalent interactions (indicated by the colon :) Other versions could exist, such as A:C'. An AND gate for the formation of an A:C' dimer would be made by making the covalent, single molecules A'-B and B'-C. The A:C' dimer could form only in the presence of both A'-B and B'-C. This is illustrated in Figure 28.1.4

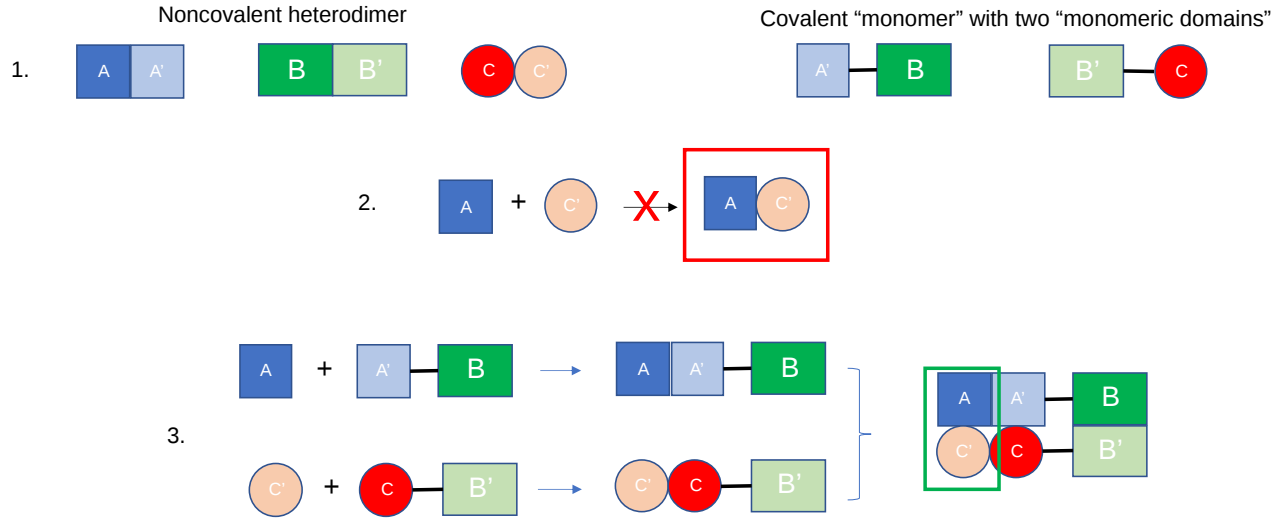


Figure 28.1.4: Designing heterodimeric protein logic gates

Signals and their responses must occur at the right time under the right conditions and for the right duration. Under opposing sets of conditions (for example well feed and starving), opposing signaling pathways, mediated by different signaling molecules, must be mutually integrated and regulated so one is turned on and one shut off. Methods must be in place to terminate signal effects.

Given the complexity of signaling pathways, it's hard to know how to present the material in a single chapter. Binding initiates and mediates almost all biological events. That binding must also be specific to avoid off-target effects. If you were to predict what biomolecule could confer specificity in the binding of a signal and allow changes from the unbound to bound state, you would certainly pick proteins. Protein:ligand binding is key to understanding biosignaling. Other types of biomolecules such as lipids and nucleic acid are involved and are of clear importance, but they are typically involved downstream from the initial protein:signal binding event. Hence we will focus mostly on signaling proteins and conformational/activity changes that occur on signal binding.

To simplify protein involvement in signaling, we can assume signaling proteins have an active and inactive state. The states are interconvertible (reversible). Let's assume the signaling protein is an enzyme. The activity of the enzyme depends on many factors as described in Figure (\PageIndex{5}\) below. The green color represents the active enzyme, while red indicated inactive.

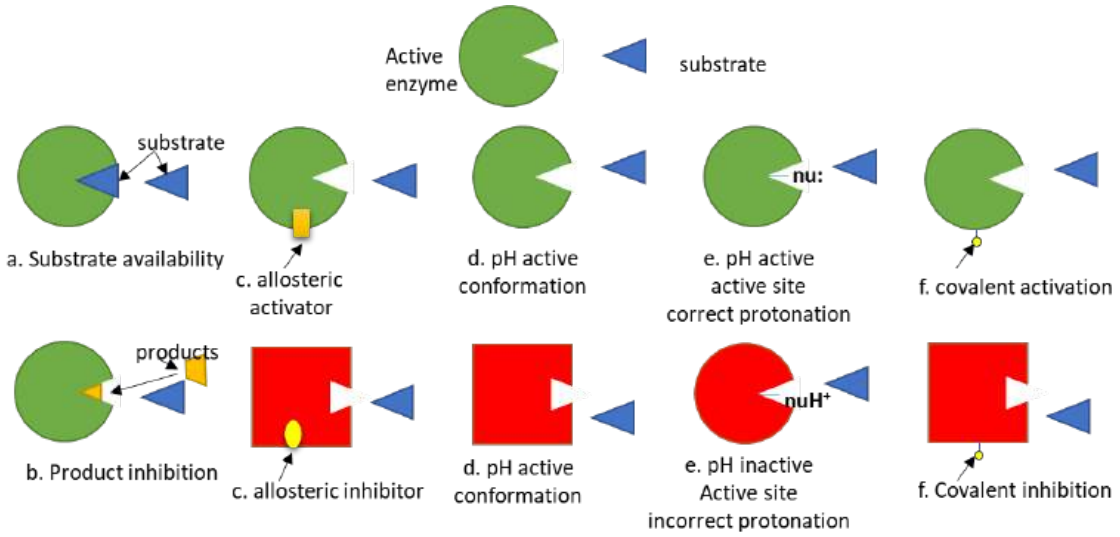

Figure 28.1.5: Ways to change the activity of an enzyme

Of course, proteins that are not enzymes (for example transcription factors) can be regulated similarly.

In addition, the amount (and localization as well) of a signaling protein can regulate the activity of the protein, as illustrated in Figure (\PageIndex{6}\) below.

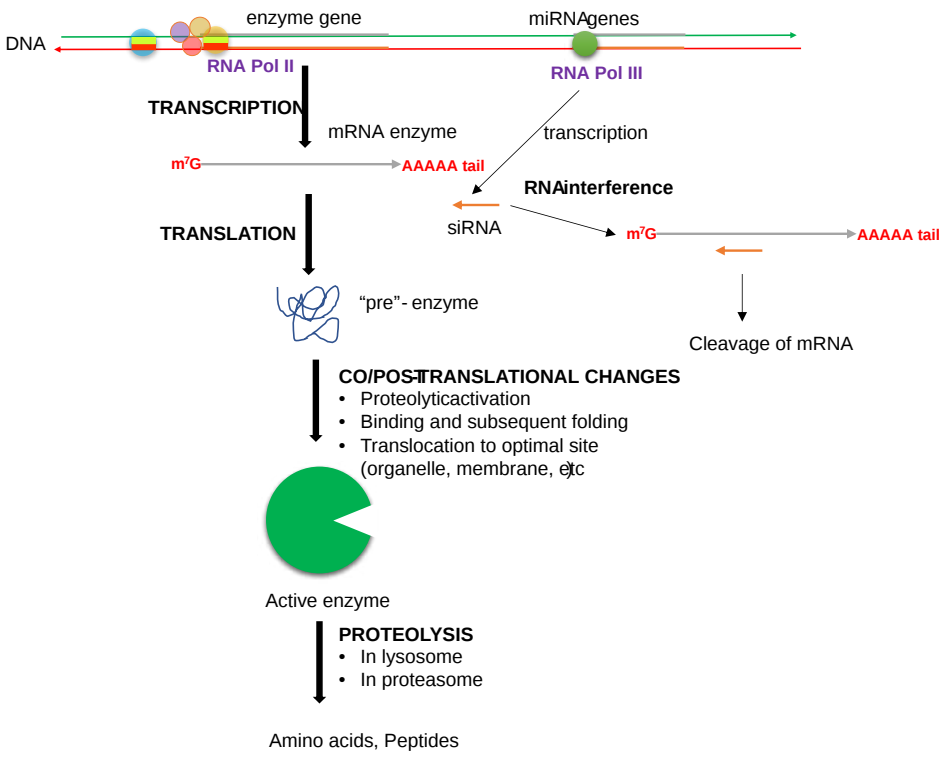

Figure 28.1.6: Ways to change the amount of an enzyme

Each signaling protein can be considered to be a node in a larger pathway consisting of interconnected nodes. This chapter on cell signaling hence can be viewed as a capstone to Unit 1, which explores the structure and function of biomolecules and as a prelude to the study of whole metabolic pathways.

28.1.3: Second Messengers and Signal Translocation

The chemical species that trigger signaling typically binds to a target protein transmembrane receptor on the surface of a cell but does not itself enter the cell. Just the signal enters the cell. If you were to hypothesize how that might happen, you would predict two mechanisms:

- an integral transmembrane receptor undergoes a conformational change on binding that propagates to its cytoplasmic domain, which can then interact either with other cytoplasmic proteins or cytoplasmic domains of other membrane proteins, transmitting the symbol into the cytoplasm;
- the bound conformation of the receptor has enzyme activity and can catalyze chemical reactions on the luminal side of the membrane. This could include the chemical modification of proteins or the synthesis of new small molecules from cell metabolites. These new small molecules are called **second messengers.** They could be formed in the membrane bilayer or the cytoplasm.

There are several diverse types of second messengers. Two common ones are cyclic derivatives of small nucleotides, including cyclic AMP (cAMP) derived from ATP and cyclic GMP (cGMP) derived from GTP. Ca^{2+} ions are usually found in low concentrations in the cytoplasm as they are pumped into internal organelles such as the endoplasmic reticulum and mitochondrion. Signaling processes can release Ca^{2+} ions in waves within the cell. Membrane lipids are also processed to form second messengers. Membrane phospholipids can be cleaved by cell signaling-activated lipases to form free arachidonic acid, sphingosine, diacylglycerol, and inositol-trisphosphate, which can act as second messengers. Redox signaling in the cell can also occur through hydroperoxides acting as second messengers.

What if the response of the cell requires gene transcription? Somehow the signal has to translocate from the cell membrane through the cytoplasm through the nuclear membrane into the nucleus. Hence a series of translocations of multiple downstream signaling events must occur.

We have already seen how newly synthesized proteins have signal sequences that target them to specific cellular locations like the cell membrane, mitochondria, nucleus (nuclear localization sequences - NLS and the small GTP binding protein RAN), or for export. Proteins involved in signaling also can move throughout the cell as part of the signaling process. Likewise, we have seen how cytoplasmic proteins can be targeted to membranes by attachment of fatty acids or isoprenoids.

28.1.4: Post-translational modification of signaling proteins

Nature has chosen the post-translational modifications (PTM) of proteins as a ubiquitous way to alter the signaling states of proteins. As we have seen previously, PTMs can alter protein conformation. They can also present new binding interfaces that allow interaction with other signaling proteins. The main (but not the only) PTM used for signaling is the reversible phosphorylation of the OH-containing amino acid side chains (Tyr, Ser, and Thr) as well as histidine (mostly in prokaryotes), so we will focus on them. Enzymes that catalyse the phosphorylation of proteins are called **protein kinases.** Reversibility is important since if phosphorylation of a target protein is associated with a specific signaling change (either activation or inhibition), then dephosphorylation can easily reverse the signaling event. Enzymes that dephosphorylate phosphoproteins are called **protein phosphatases**. Figure 28.1.7shows the generic reaction of protein kinases and phosphatases.

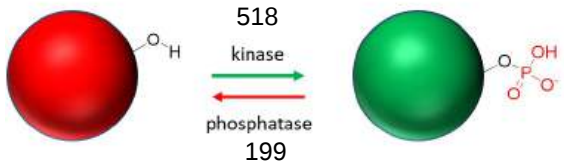

Figure 28.1.7: Kinases and phosphatases

There appear to be 518 protein kinases and 199 protein phosphatases encoded in the human genome. Why so many? If just one protein kinase existed, one mutation in it would be disastrous. In addition, the large number of kinases and phosphatase allows for great control in the specificity of these enzymes for their target protein substrates.

Kinases

Kinases are a class of enzymes that use ATP to phosphorylate molecules within the cell.

The names given to **kinases** show the substrate which is phosphorylated by the enzyme. For example:

- hexokinase - an enzyme that uses ATP to phosphorylate hexoses.
- protein kinase - enzymes that use ATP to phosphorylate proteins within the cell. (Note: Hexokinase is a protein, but is not a protein kinase).
- phosphorylase kinase: an enzyme that uses ATP to phosphorylate the protein phosphorylase within the cell

If a protein is phosphorylated by a kinase, the phosphate group must eventually be removed by a **phosphatase** through hydrolysis. If it wasn't, the phosphorylated protein would be in a constant state of either being activated or inhibited. Kinases and phosphatases regulate all aspects of cellular function. About 1-2% of the entire genome encodes kinases and phosphatases.

Kinases can be classified in many ways. One is substrate specificity: Eukaryotes have different kinases that phosphorylate serine/threonine or tyrosine side chains. Prokaryotes also have His and Asp kinases, but these are unrelated structurally to the eukaryotic kinases. There are 11 structurally different families of eukaryotic kinases, which all fold to a similar active site with an activation loop and catalytic loop between which substrates (ATP and the OH-containing side chain) bind. Simple, single-cell eukaryotic cells (like yeast) have predominantly cytoplasmic Ser/Thr kinases, while more complex eukaryotic cells (like human cells) have many Tyr kinases. These include the membrane-receptor Tyr kinases and the cytoplasmic Src kinases.

Manning et al. have analyzed the entire human genome (DNA and transcripts) and have identified 518 different protein kinases, which cluster into 7 main families as shown in Table 28.1.1: below. Family membership was determined by sequence comparisons of catalytic domains. The entire repertoire of kinases in the genome is called the **kinome**. Alterations in 218 of these appear to be associated with human diseases.

Name	Description
AGC	Contain PKA, PKG, and PKC families
CAMK	Ca2+/CAM-dependent PK
CKI	Casein kinase 1
CMGC	Contain CDK, MAPK,GSK3, CLK families
STE	homologs of yeast sterile 7, 11, 20 kinases; MAP Kinase
PTK	Protein tyrosine kinase
PTKL	Protein tyrosine kinase-like
RGC	Receptor guanylate kinase

Table 28.1.1: The human kinome

Phosphatases

There are three main families of phosphatases, the phospho-Tyr phosphatases (PTP), the phospho-Ser/Thr phosphatases, and those that cleave both. Of all phosphorylation sites, most (86%) are on Ser, 12% involve Thr, and about 2% on Tyr. They can also be categorized by their molecular sizes, inhibitors, divalent cation requirements, etc. In contrast to kinases which differ in the structure of their catalytic domains, many phosphatases (PPs below) gain specificity by binding protein cofactors which facilitate translocation and binding to specific phosphoproteins. The active phosphatase hence often consists of a complex of the phosphatase catalytic subunit and a regulatory subunit. Regulatory subunits for Tyr phosphatases may contain a SH2 domain allowing binding of the binary complex to autophosphorylated membrane receptor Tyr kinases.

Given this background, we can now start to explore signal transduction in a methodical way. There are two major ways to organize our discussions:

- start from the binding of the molecular signal at the cell membrane and trace the signaling events inward into the cell, potentially all the way to the nucleus and gene expression
- describe recurring motifs found in most pathways.

We will use a combination of both, but it makes sense to start with the signaling proteins at the cell membrane. Next, we will focus on second messengers. We'll follow that with detailed explorations of kinases and phosphatases and specific signaling pathways.

28.2: At the cell membrane- receptors and receptor enzymes

28.2.1: Introduction

We are going to start a more detailed description of cell signaling where it begins, at the cell membrane, and move inward, toward intracellular organs, where we will end at the nucleus and changes in gene expression mediated by the signal. Of course, this end is somewhat arbitrary as the signal could propagate from the nucleus back to the membrane where newly synthesized membrane protein might be inserted or even exported, as in the case of secreted antibodies. It is difficult enough to keep track of all the molecular players, let alone add onto that their initial location in the cell and their final location if they translocate. Signaling can also be more daunting for those with a more chemistry focus, who find the details of cellular structure and trafficking a bit daunting. Figure 28.2.1 shows a truncated view of the cell membrane, membrane proteins, and some of the organelles that we will visit throughout this chapter. To stay localized we will repeat the figure or variants of it several times in this section.

28.2.2: Receptors at Cell Membrane

Let's start at the location where signaling almost invariable begins, in the cell membrane, where signals (hormones, neurotransmitters, nutrients, other cells) bind to cell surface transmembrane proteins shown in the red box in Figure 28.2.2

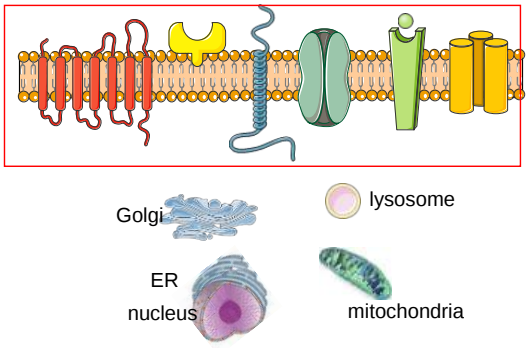

Figure 28.2.2: Signaling events at the cell membrane

We have already discussed integral and peripheral membrane proteins in Chapter 11. When occupied by a ligand signal, the signaling event mediated by a transmembrane receptor might be a change in the membrane protein conformation, which propagates to its intracellular domain. Alternatively, the receptor might change its conformation and become a ligand-gated kinase (or possibly a phosphatase) or a ligand-gated channel or pore. We will discuss signal-gated ion channels in Chapter 28.9 - Neural Signaling.

Ultimately, intracellular enzymes are activated in cells in response to the external molecular signal. This provides amplification of the initial signal since a single activated enzyme undergoes multiple rounds of catalysis before it would become inactivated. If the multiple products (a second messenger or phosphorylated proteins for example) that are formed activate multiple addition enzymes, the signal is further amplified.

28.2.3: Receptors with no kinase or transport activity - G Protein-Coupled Receptors (GPCRs)

One major type of signaling receptor is the **G-protein coupled receptor (GPCR)**. Over **800** GPCRs are encoded in the human genome which represents almost 4-5% of the number of protein-coding genes. The proteins below to five major families: rhodopsin, secretin, glutamate, adhesion, and frizzled/taste2. They don't express enzymatic activity but on binding, they can activate enzymes inside the cell by interacting through their cytoplasmic domains with **G proteins** (GTP binding proteins) in the cytoplasm. GPCRs have been called serpentine receptors as their single amino acid chain proteins have 7 transmembrane-spanning α- helices. All of the GPCRs have similar yet slightly different structures, allowing them to interact with specific ligands. Many of the GPCRs bind to unknown ligands and hence are called **orphan receptors**. We will explore a few GPCRs in more detail below.

28.2.3.1: GPCRs that modulate the membrane enzyme adenylyl cyclase:

β-adrenergic receptor

The β-adrenergic receptor is a prototypical GPCR. Found in muscle, liver, and fat cells, it binds epinephrine and adrenaline, which leads to energy mobilization and muscle activation (i.e. flight or fight response). The mechanism of activation of a GPCR is illustrated using the beta-adrenergic receptor as an example. The unoccupied adrenergic receptor is associated with a **heterotrimeric G protein**, which contains an α, β, and γ subunits. GDP is usually bound to the α subunit. Figure 28.2.3 shows a cartoon of the GPCR interacting with the heterotrimeric G protein.

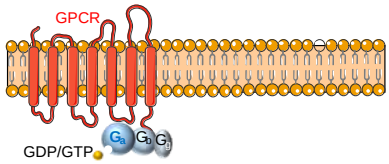

Figure 28.2.3: GPCR-Heterotrimeric complex in the bilayer

When the hormone is bound to the receptor, a conformation change is propagated to the cytoplasmic domain of the GPCR altering its interaction with $G_{\alpha\beta\gamma}$. This causes a conformational change in the G_α subunit, which leads to an exchange of bound GDP with GTP in the G_α subunit, promoting the dissociation of the G_α-GTP from $G_{\beta\gamma}$. G_α-GTP then binds to and activates an adjacent membrane enzyme called **adenylate cyclase**, which produces a second messenger by converting ATP to **cyclic AMP (cAMP)**. Figure 28.2.4 shows steps in the generic GPCR activation cycle.

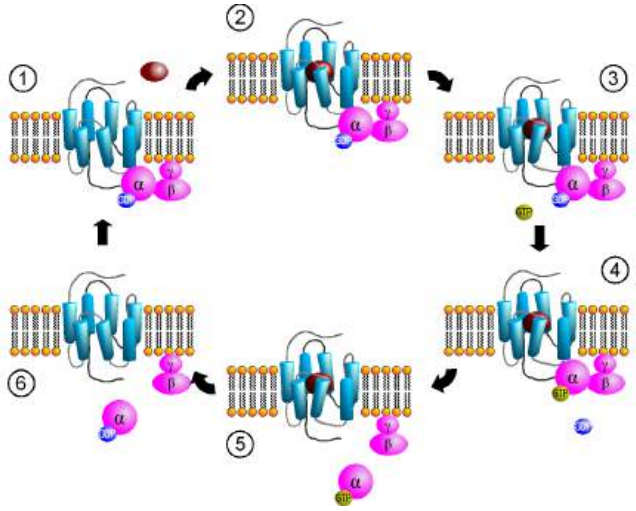

Figure 28.2.4: Activation cycle of G-proteins by G-protein-coupled receptors. https://commons.wikimedia.org/wiki/F...PCR-Zyklus.png Creative Commons Attribution-Share Alike 3.0 Unported

The primary message binds to the GPCR (1 leading to state 2. The cytoplasmic domain conformational changes allow GTP exchange in the G_α subunit as state 3 goes to 4. In 5 the G_α-GTP complex dissociates from $G_{\beta\gamma}$, which remains in the membrane. The G_α-GTP subunit is held and localized to the membrane (not evident in the above figure) through a lipid anchor attached through a post-translational modification.

Remember, the GPCR has no ligand-gated enzymatic activity. Yet it indirectly leads to the activation of a membrane enzyme, adenylate cyclase, when the dissociated G_α-GTP binds to the cyclase. As long as GTP remains bound to the G_α subunit, it will continue to modulate the activity of adenylate cyclase. A built-in regulatory mechanism does exist in the protein since the G_α subunit has **GTPase** activity. The GTP will eventually hydrolyze, and the GDP-G_α subunit will lose affinity for its bound partner (adenylate cyclase), and return to the heterotrimeric G protein associated with the unbound receptor. GPCRs bind the signaling ligand (primary message) in a binding cavity localized at the extracellular face and between four of the transmembrane helices.

The activity and structure of GPCRs have been studied using natural ligands (hormones and neurotransmitters), as well as agonists, partial agonists, inverse agonists, and antagonists. As discussed previously, agonists bind to the natural ligand binding site and elicit the same or a partial response (partial agonist). Inverse agonists bind and lower the response of a constitutively active receptor, and antagonists bind and prevent the normal response of an agonist. About 35% of pharmaceutical drugs target GPCRs, but target only about 15% of the ~800 human GPCRs. The orphan GPCRs are increasingly targets for drug development. Most hormones and neurotransmitters work through GPCRs. In addition, our primary senses of vision, smell (olfaction), and taste (gustation) work through GPCRs.

Figure 28.2.5 shows the structure of the beta 2-andrenergic:Gs complex with bound agonist. No membrane is shown.

Figure 28.2.5: Structure of the beta-andrenergic:Gs complex with bound agonist.

The GPCR is shown in cyan. The 7 transmembrane helices should be obvious. The ligand is bound between them. The G_α subunit is shown in magenta, the G_β in dark blue, and the G_γ in orange/brown. The gray subunit is a Camelid antibody VHH fragment (a single-chain nanoantibody used to stabilize the conformation for crystallization.)

The biggest conformational change that occurs when the GPCR binds an agonist is an outward movement (14 Å) at the intracellular domain of transmembrane segment 6 (TM6) and an extension of the TM5 helix. This leads to a movement of the G_α's alpha-helical domain, enabling GTP exchange for GTP. Of course, multiple reactions determine the fraction of the G_α in the active GTP-bound state. These would include the relative cellular concentrations of free cytoplasmic GDP and GTP, their K_D values for the G_α, the rate constant for the hydrolysis of bound GTP, and the rate constants for the GDP ↔ GTP exchange.

Figure 28.2.6 shows an interactive iCn3D model of the **Crystal structure of the beta2 adrenergic receptor-Gs protein complex 3SN6**

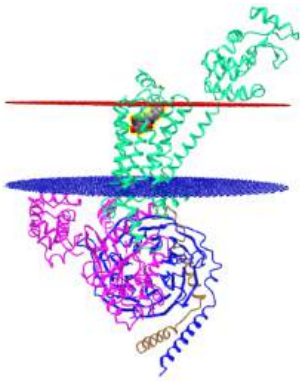

Figure 28.2.6: **β-2 adrenergic receptor-Gs protein complex 3SN6** (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...8R4zKZCfKZy248

The GPCR is shown in green, the G_α in magenta, Gβ in blue, and the Gγ in brown. An agonist (spacefill) is shown in CPK colors near the outer leaflet.

Some bacterial toxins work by inactivating the GTPase activity of the G_α subunit, keeping it in the "stuck" position. For example, cholera toxin, an enzyme released by Vibrio cholera, catalyzes the ADP ribosylation of an Arg in the G_α subunit by transferring everything but the nicotinamide from NAD^+ to the Arg residue.

Since the G_α subunit stimulated the activity of adenylyl cyclases, it is often named a stimulatory G_α protein or $G_{s\alpha}$. Figure 28.2.7 shows an interactive iCn3D model of the adenylyl cyclase activator $G_{s\alpha}$ with GTP-γ-S (1azt)

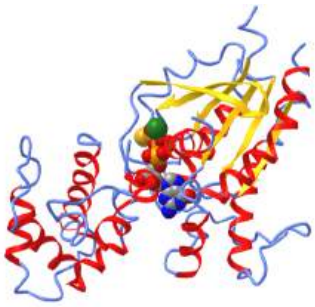

Figure 28.2.7: adenylyl cyclase activator $G_{s\alpha}$ with GTP-γ-S (1azt) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...T7MBqYnaxAH3SA

Now we can explore how the occupied GPCR, which again has no enzymatic activity, activates the enzyme adenylyl cyclase. Figure 28.2.8 shows a cartoon of the $G_{s\alpha}$ subunit bound to adenylyl cyclase as the $G_{\beta\gamma}$ heterodimer remains associated with the membrane

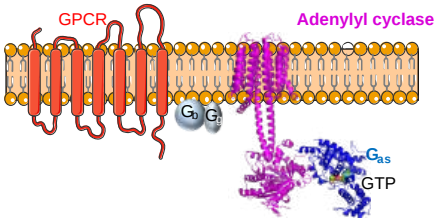

Figure 28.2.8:

Adenylate cyclase converts ATP into the second messenger **cyclic AMP** (cAMP) as shown in Figure 28.2.9. The figure also shows how cAMP is broken down into AMP by the enzyme **cAMP-specific 3',5'-cyclic phosphodiesterase (PDE).** The latter step is necessary to control the lifetime of the second messenger cAMP.

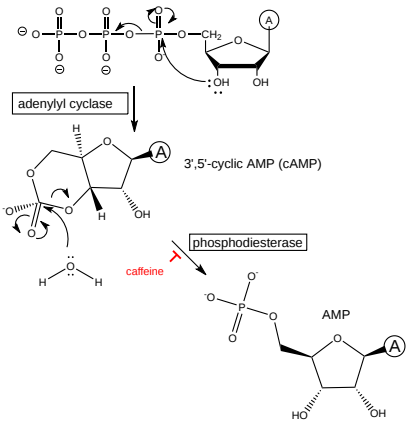

Figure 28.2.9: Formation of cAMP by adenylyl cyclase and its degradation by phosphodiesterase

Why cAMP?

You might ask why cAMP and not just AMP is nature's choice for GPCR signaling. AMP is a very important metabolic species. High concentrations of it signal an energy-depleted state. AMP is used in another signaling process to mobilize a response to adjust the energy state of a cell using a protein called AMP-Protein Kinase, which we will describe later. Many enzymes are also allosterically regulated by AMP.

Figure 28.2.10shows an interactive iCn3D model of the membrane adenylyl cyclase bound to an activated stimulatory $G_{s\alpha}$ protein 6R3Q determined by cryo-EM.

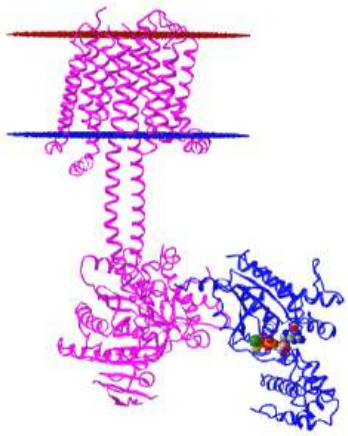

Figure 28.2.10: membrane adenylyl cyclase bound to an activated stimulatory G protein 6R3Q (Copyright; author via source). Click the image for a popup or use this external link:https://structure.ncbi.nlm.nih.gov/i...foXY38deJSMDC6

The carboxyl-terminal cytoplasmic domain has the catalytic and allosteric sites.

Cannabinoid Receptors

In contrast to the beta-adrenergic receptor which mediates activation of adenylate cyclase through $G_{s\alpha}$, some G_{α} subunits inhibit adenylate cyclase when bound. These G_{α} subunits are called $G_{i/o\alpha}$ in contrast to the stimulatory subunits, $G_{s\alpha}$. Also, G_{α} subunits interact with many proteins other than adenylate cyclase. Examples include cannabinoid receptors.

Cannabinoid receptors are named after the exogenous and psychoactive drug Δ^9-tetrahydrocannabinol (**THC**) that binds to the receptor. THC is the major phytocannabinoid (from plants) found in the Cannabis sativa plant and the marijuana-derived from it. The other main cannabinoid in the plant is cannabidiol (**CBD).** Phytocannabinoids bind to two types of human cannabinoid (CB) receptors, CB1 and CB2. They have 44% amino acid and 68% homologies in the entire protein and the transmembrane domain, respectively.

The phytocannabinoids exert their effect through binding to human CB1 and CB2, whose endogenous ligands are two fatty acids derivatives called anandamide (**AEA**) and 2-arachidonoyl glycerol (**2-AG**). The structure of THC, CBD, and the two major

endogenous ligands are shown in Figure 28.2.11

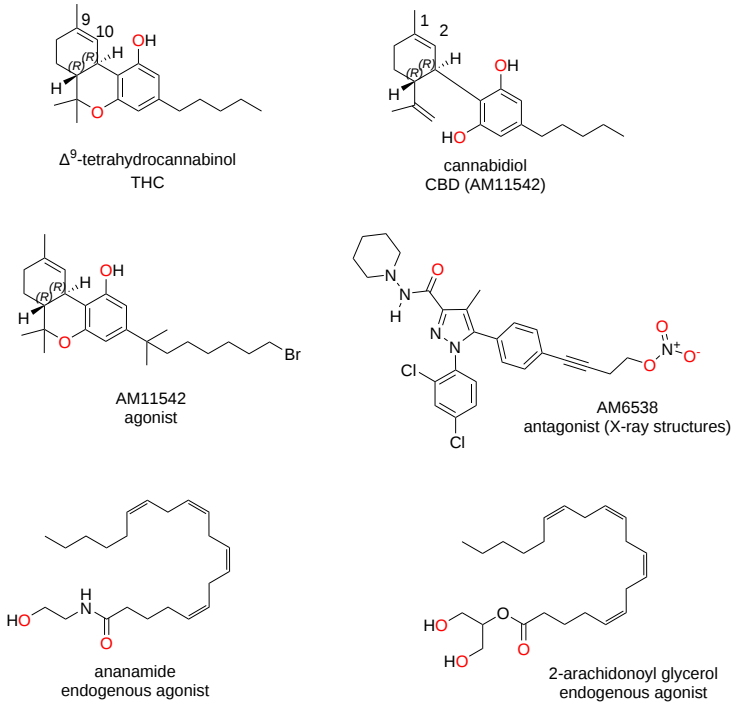

Figure 28.2.11: Structure of agonist and antagonist for cannabinoid receptors

The cannabinoids from Cannabis sativa have a monoterpene isoprenyl group (C10) and a pentyl side chain (C5). The ligands are largely hydrophobic and probably access their binding site in the receptor mainly by lateral movement in the membrane. The receptors differ most in the N-terminal extracellular loop which is also involved in ligand binding.

Figure 28.2.12 shows an interactive iCn3D model of the class A GPCR Cannabinoid Receptor-Gi Complex Structure with bound agonist (6KPF)

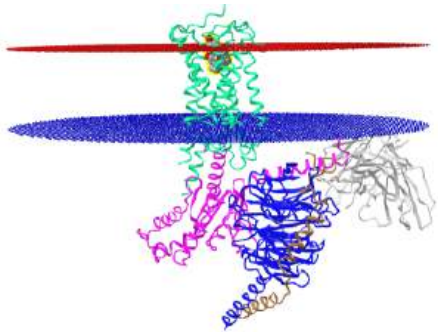

Figure 28.2.12: Class A GPCR Cannabinoid Receptor-GiComplex Structures (6KPF) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...B16mYTKPMhXmg8

The gray protein is a nanobody used to stabilize the protein during crystallization. The agonist is AM12033, which is similar to AM11542 in the figure above, but with a -C≡N terminus instead of a bromide.

THC and CBD

Cannabis sativa contains the psychoactive drug, Δ^9-tetrahydrocannabinol (**THC**), which is a partial agonist for CB1 (binds with reported K_i values of 10 or 53 nm)and CB2 (K_i = 40 nm). Its psychoactive effects on mental activity as well as pain and appetite are well known. In contrast, cannabidiol (**CBD)** is the main, non-psychoactive cannabinoid. It has a much lower affinity for the recombinant CB1 (K_i = 1.5 **μM**) and CB2 (K_i = 3.7 **μM**). It appears to be a partial antagonist for CB1 and a

weak inverse agonist for CB2. It has also been shown that CBD is a negative allosteric modulator of the agonistic effects of THC and 2AG. The actual psychotropic effects of combining THC and CBD are complicated and not understood well.

Figure 28.2.13shows an interactive iCn3D model of human CB1 in complex with agonist AM11542 (5XRA)

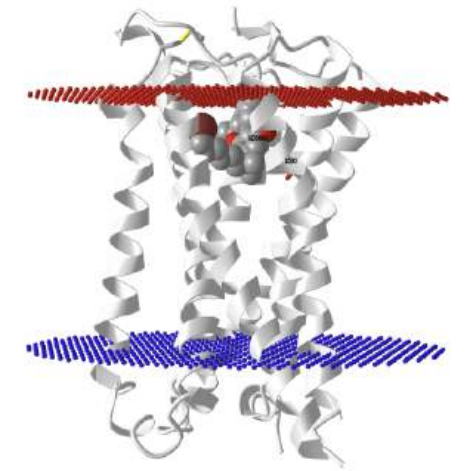

Figure 28.2.13: Human CB1 in complex with agonist AM11542 (5XRA). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...wDv9fXNPaMhwm9

The complex shows a significant conformational change in the structure compared to the receptor bound to an antagonist. This includes a large reduction (50%) in the volume of the binding pocket and an increase in the surface area of the receptor that would bind to G proteins.

How much of a receptor is bound with a cannabinoid depends on the concentration of the cannabinoid ligand and the K_i for the drug. The amount of THC and CBD depends on the genetics of the plant, which has been engineered to greatly decrease THC production (in the hemp plant used for nonpharmacological commercial properties) or increase either THC or CBD production at the expense of the other.

The synthesis of THC and CBD proceeds through a common precursor, CBGA (cannabigerol acid). Two key flavoproteins, Δ^9-tetrahydrocannabinolic acid synthase (THCAS) and cannabidiolic acid synthase (CBDAS) convert this common precursor CBGA into two new precursors, Δ^9-THCA and CBDA, respectively. This final synthetic step involves an oxidative cyclization reaction using O_2 and produces H_2O_2. Spontaneous, non-catalyzed decarboxylation and rearrangements of Δ^9-THCA and CBDA lead to the final products, THC and CBD. This last process occurs on exposure to heat, which occurs in smoking and baking, and at a slower rate during storage.

Commercially used preparations of THC and CBD for medicinal purposes vary widely in concentrations. THC concentration ranges for pain management (<5-10%) are much lower than those for psychotropic effects (<15%), with values of 21% or often found in "recreational" cannabis. High-potency THC strains can contain up to 25-30% THC by dry weight. For strands modified for CBD production, the maximal amount is about 25%. Even though CBD appears to be a partial antagonist for CB1, it appears that the ratio of THC:CBD is important in modulating the "high" or intoxicating state of THC. A ratio of THC:CBD of just over 1:1 leads to synergism or enhancement of the acute effects of THC whereas ratios of THC:CBD of 1:2 to 1:6 seem to have the least intoxicating effects. However, CBD decreases psychotic symptoms of THC and also decreases memory changes associated with THC. CBD also is an allosteric modulator of the μ-opioid receptor.

At present, there are no structures of CBD bound to its cannabinoid receptors. Figure 28.2.14 shows an interactive iCn3D model of the CBD-bound full-length rat transient receptor potential vanilloid 2 (TRPV2) in nanodiscs (6U88)

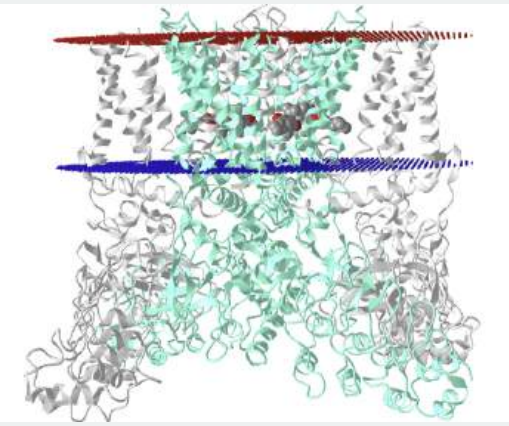

Figure 28.2.14: CBD-bound full-length rat TRPV2 in nanodiscs (6U88)**.** (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...BJcXBriq49LtQA

This receptor is a calcium-permeable non-selective cation channel that is activated at high temperatures (50^0C) but not vanilloids like capsaicin. Hence it acts as a "noxious high temperature" receptor.

Now let's make it even more complicated. There are more than 20 different G_α-like proteins known in 4 major families.

- G_s and G_i regulate adenylyl cyclase
- G_q activates phospholipase Cβ (described below). There are 4 members given these strange names: G_q, G_{11}, G_{14}, and $G_{15/16}$
- $G_{12/13}$ activate small GTPase protein (described in Chapter 28.5)

The G_α protein involved in light sensation is named transducin, while those involved in odorant detection and taste are called $G_{olfactory}$ and $G_{gustatory}$, respectively.

As we add more variants of each signaling component, the origin of the complexity of signaling systems becomes evident. For example, the neurotransmitter serotonin binds to its receptor, a GPCR, and instead of gating the protein open to ion flow (as with other ligand-gated ion channels in the activation of neurons as we will see in Chapter 28.9), it interacts with two different alpha subunits, G_s, which leads to activation of adenylyl cyclase, and G_{12}, which interacts with other small GTP binding proteins called GEFs (we will also see these later).

28.2.3.2: GPCRs modulate the activity of the membrane enzyme phospholipase C.

These receptors use the same mechanism for activation of the membrane enzyme adenylyl cyclase. When the primary signal is bound to the GPCR, a conformation change is propagated to the cytoplasmic domain of the GPCR, altering its interaction with $G_{\alpha\beta\gamma}$ in which the alpha subunit is a member of the $G_{\alpha(q)}$ family. This causes a conformational change in the G_α subunit which leads to an exchange of bound GDP with GTP in the G_α subunit, promoting the dissociation of the G_α-GTP. G_α-GTP then binds to and activates an adjacent membrane enzyme, **phospholipase C (PLC)**, which cleaves membrane phospholipids to produce two, second messengers, **diacylglycerol** and **inositol 1,4,5-trisphosphate (IP_3)**. Their structures are shown in Figure 28.2.15

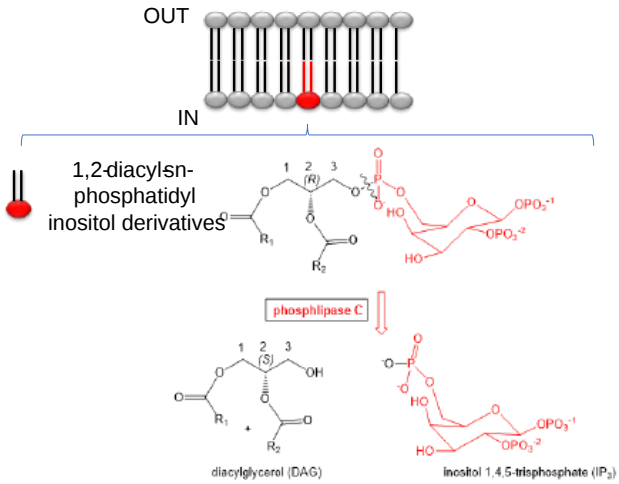

Figure 28.2.15:Activation of phospholipase C

There appear to be 13 kinds of mammalian phospholipase Cs divided into six isotypes (β, γ, δ, ε, ζ, η). Phospholipase C is also named 1-phosphatidylinositol 4,5-bisphosphate phosphodiesterase.

Figure 28.2.16shows an interactive iCn3D model of the $G_{\alpha(q)}$-phospholipase C-β 3 structure (4GNK). The magenta structure is the $G_{\alpha(q)}$ protein with bound GDP in spacefill. The cyan structure is the **Pleckstrin Homology (PH)** domain of the protein. This domain targets proteins to inositol phospholipids in the membrane but appears not to have this function in this protein.

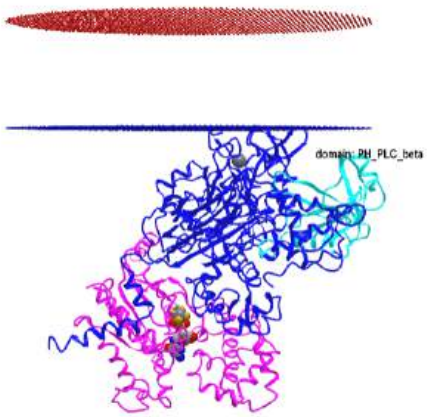

Figure 28.2.16: $G_{\alpha(q)}$-phospholipase C-β-3 structure (4GNK) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?5kiejFu8KgzXsiP9A

Note that in contrast to adenylyl cyclase, PLC is a peripheral, not an integral membrane protein. It is found in the cytoplasm as well as associated with the inner leaflet of the cell membrane where its main activities, regulating and cleaving PIP_2, occur. PLC localizes to lipid rafts enriched in PIP_2. Figure 28.2.17shows the domain structure of phospholipase C β3

Figure 28.2.17 Domain structure of phospholipase C β3

The N-terminal PH_14 represents the **Pleckstrin Homology (PH)** domain, which is among the top 15 of all domains in the human genome. All PLCs except PLCζ have this domain. Note that in another example of complexity, PLC-β binding to the inner leaflet does **not** require PIP2. The iCn3D model above indeed shows binding to the membrane seems to depend on adjacent structures and not the PH domain (cyan) specifically.

Tabel 28.2.1below characteristics of common signals that signal through GPCRs.

signal	vasopressin	epinephrine	light	odorant	odorant	sweet tastant

Tabel 28.2.1: Characteristics of common signals that work through GPCRs.

Changeux and Edelstein reviewed the MHC model 40 years after its conception and support its application to signal transduction processes. They include in signaling molecules not only hemoglobin, but regulatory enzymes (aspartate transcarbamylase, phosphofructokinase, LDH, glycogen phosphorylase), membrane receptors (acetylcholine receptor, rhodopsin), and nuclear receptors (lac repressor, steroid hormone receptors). In all these signaling proteins, residue distant from the "active" site participates in binding to allosteric ligands. Often the allosteric site is on a separate domain that can be cleaved from the protein and still maintain allosteric ligand binding properties. The proteins also consist of multiple subunits easily related by distinct symmetry axes. Allosteric ligands often bind in cavities in subunit interfaces along symmetry axes. In general, crystal structure analyses show that low-affinity T and high-affinity R forms of the signaling proteins exist but are accompanied by minor tertiary structure changes in individual subunits (i.e. perfect symmetry in all subunits is not preserved on the binding of allosteric ligand). For neurotransmitter membrane receptors, these two states can be correlated with an open and closed state (for ion flux), and open conformations of these proteins can often be found in mutant forms. However, for many ligand-gated ion channels and G-protein coupled receptors (serpentine), kinetic analyses show more complicated forms than can be represented by a simple two-state (R and T) model. High-resolution microscopy shows evidence for nonsymmetrical quaternary structural changes. These changes can be observed in the absence of ligand, which gives support to the MWC concept that allosteric ligands select certain conformational states, leading to equilibrium shifts in the unliganded receptor to the more high-affinity state. More refined methods of structural analysis will presumably show more evidence of subtle tertiary changes in the proteins that are preludes to quaternary structural changes. Yet the simplicity of the MWC model for explaining many features of signaling proteins remains.

28.2.4: Receptors with signal-gated kinase activity - **Receptor Tyrosine Kinases (RTK)**

Why bother binding a primary message to a GPCR and going through multiple steps before the activation of a membrane enzyme like adenylate cyclase? Wouldn't it be easier and more efficient to have the membrane receptor a ligand-activated enzyme? Such is the case with special membrane receptors called **Receptor Tyrosine Kinases (RTKs)**. There are about 90 tyrosine kinases in the human genome of which 58 are RTKs. Figure 28.2.18shows the family domain structure of the RTKs.

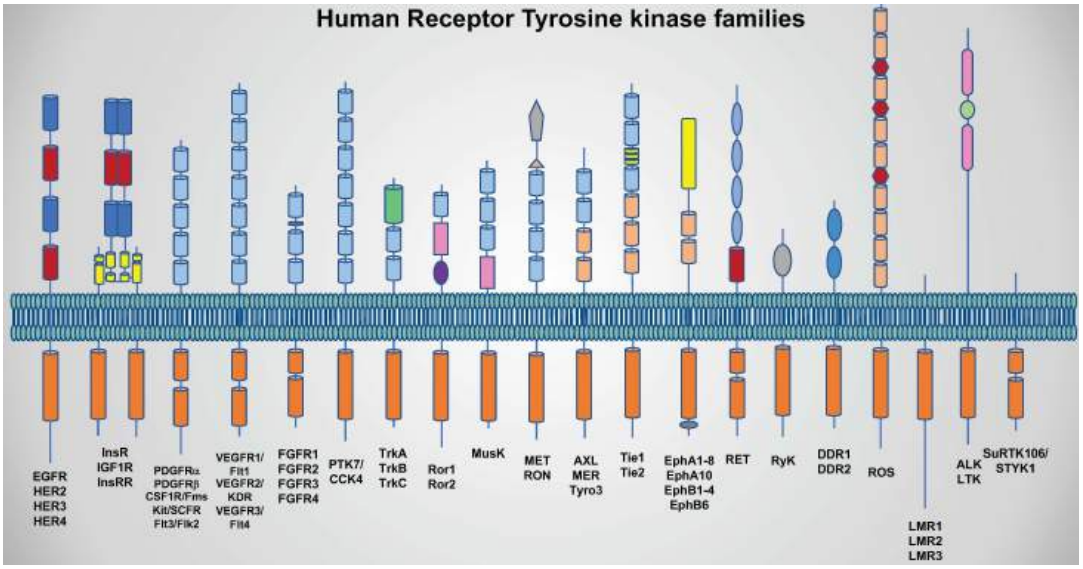

Figure 28.2.18: Family domain structure of the RTKs. Yamaoka, T.; Kusumoto, S.; Ando, K.; Ohba, M.; Ohmori, T. Receptor Tyrosine Kinase-Targeted Cancer Therapy. *Int. J. Mol. Sci.* **2018**, *19*, 3491. https://doi.org/10.3390/ijms19113491. **Creative Commons Attribution License**

Note that the insulin receptor (InsR) is a dimer of two monomeric insulin receptor chains. Figure 28.2.19s shows in more detail the domain structure of the epidermal growth factor receptor (EGFR).

Figure 28.2.19: Domain structure of the EGFR domain.

The domain (red/brown) immediately after the blue domain is the transmembrane domain. Furin is a cellular endoprotease. The green represents L domains which comprise the ligand binding site. Each L domain consists of a single-stranded right-hand beta-helix.

Here is the cascade of events for signaling through EGFR: The transmembrane has ligand-dependent tyrosine kinase activity. Binding of the hormone EGF causes receptor dimerization bringing the intracellular kinase domains (yellow PK_Try_Ser_Thr) together activating them. When active, they can phosphorylate each other (autophosphorylation) or other proteins. When the receptor is autophosphorylated, other proteins can bind to the cytoplasmic domain of the receptor Tyr kinase where they are phosphorylated. The target substrates phosphorylated by the receptor Tyr kinases are proteins with a common 100 amino acid domain called **SH** for **src homology**, based on structural homology to another cytoplasmic protein, **Src**. Src is an intracellular Tyr kinase activated when it binds through 2 SH domains to an autophosphorylated receptor Tyr kinase. Specifically, the SH2 domain has been shown to bind tyrosine-phosphorylated peptides. These domains target proteins to the autophosphorylated receptor Tyr kinase. Many proteins involved in signal transduction have SH2 domains. Some of these proteins also have catalytic domains with kinase activity. Others have phosphatase, transcription factor. or scaffolding domains.

Figure 28.2.20 shows the hormone-depended dimerization of RTKs, their autophosphorylation, and the recruitment of proteins with SH2 domains.

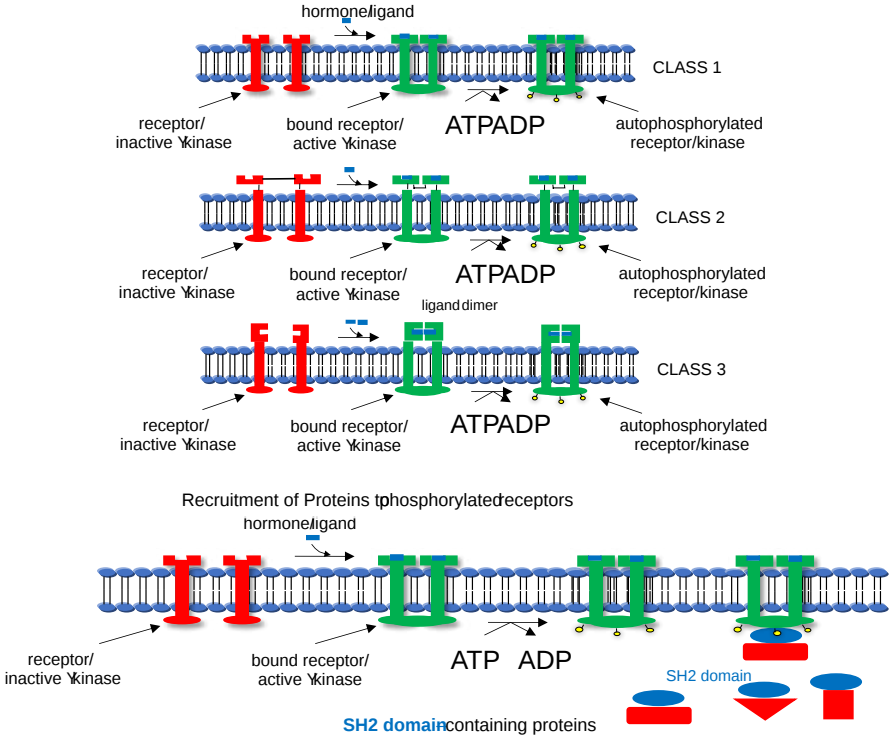

Figure 28.2.20: Activation of receptor tyrosine kinases (RTKs)

It is easier to envision how a GPCR is activated by binding its target hormone than for RTKs. GPCRs are single-chain proteins that pass through the membrane using 7-transmembrane helices. RTKs have a single transmembrane helix. The dimeric form of the RTK has some additional flexibility in the short region between the extracellular and transmembrane domains, allowing for the conformational changes necessary for the activation of the intracellular kinase domains.

The crystal structure of the full EGFR is not known given the difficulties in crystallizing membrane proteins that span the membrane with a single alpha helix. However, separate structures of the dimeric extracellular domain and the intracellular kinase domains are known.

Figure 28.2.21 shows an interactive iCn3D model of the dimeric extracellular and transmembrane domains of the epidermal growth factor receptor (3NJP).

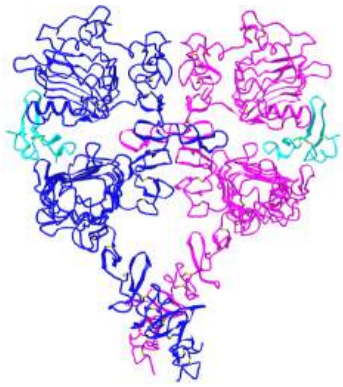

Figure 28.2.21: Dimeric extracellular and transmembrane domains of the epidermal growth factor receptor (3NJP) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...iw1V4T8rsfxDZ7

The two EGFR are shown in blue and magenta. The two bound EGFs are shown in cyan.

Figure 28.2.22shows an interactive iCn3D model of a dimer of the intracellular dimeric EGFR kinase domains in complex with an ATP analog-peptide conjugate (2GS6)

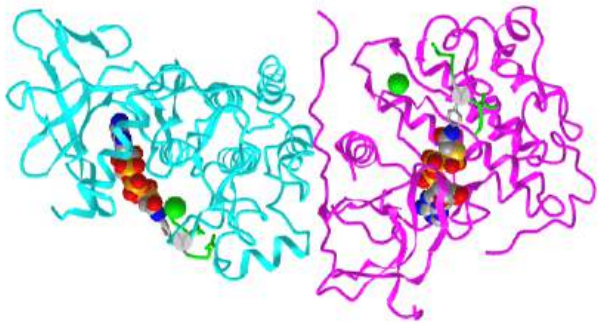

Figure 28.2.22: Dimeric intracellular EGFR kinase domains in complex with an ATP analog-peptide conjugate (2GS6) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...iw1V4T8rsfxDZ7

The two EGFR kinase domains are shown in cyan and magenta. The ATP analogs in each domain (spacefill) are thiophosphoric acid O-((adenosyl-phospho)phospho_-S-acetamidyldiester. The peptide substrates (green stick) are 13mers with a tyrosine (sticks, labeled Y, minus the OHs) connected to the ATP analog.

We've introduced the essential cell membrane players in signal transduction.

- GPCRs which are not enzymes but which activate the bound heterotrimer G prortein G_α subunit, which then can activate or inhibit the integral membrane protein adenylate cylase or activate the membrane-bound enyzme protein kinase C. These enzymes produce second messengers cAMP (adenylate cyclase) and diacylglycerol (DAG)and IP_3 (phospholipase C)
- Receptor tyrosine kinases, ligand-activated receptor kinases, which can,on ligand-induced dimerization, autophosphorylate themselves or other target protein in the cell.

In the next chapter section we will explore the next downstream effects in signaling, mediated by the second messengers cAMP, DAG and IP_3 and the substrates phosphorylated by the ligand-active receptor tyrosine kinases.

28.3: The Next step - The Kinome and Activation of Kinases at the Cell Membrane

In the last section, we studied how the cell surface GPCRs indirectly activate membrane-bound enzymes adenylyl cyclase and phospholipase C (the GPCRs) and how RTKs become active enzymes (kinases) themselves on ligand-induced dimerization. We will now explore what happens next in signaling by examining the products of these activated enzymes and how they continue the signaling process. The products of adenylyl cyclase (cAMP) and phospholipase C (diacylglycerol - DAG - and IP_3) are second messengers. These activate key protein kinases in the cell. The products of the activated RTKs are phosphoproteins (including itself) that are phosphorylated on tyrosines by the RTK. Target proteins bind to the autophosphorylated RTKs through SH2 domains on the target protein. First, we will explore protein kinases and their mechanism in general.

28.3.1: The Kinome

There are 518 different protein kinases (about 1.7% of the human genome) and as a group, they are the key players in most eukaryotic signaling pathways. Collectively they are called the **kinome**. They help regulate every aspect of cell life including metabolism, cell growth, differentiation, and division, as well as programmed cell death. In humans, most (388) are Ser/Thr kinases. 90 are Tyr kinases and 40 are classified as atypical. In this section, we will focus on the **AGC** kinases (60 in total) which include Protein Kinase **A** (PK**A**), Protein Kinase **C** (PK**C**), and also Protein Kinase B (PKB, better known as **AKT**. We'll wait for another section to explore Protein Kinase **G** (PK**G**) which is activated by **cGMP**, not AMP. We'll also study the receptor Tyr kinases (RTKs)

Luckily kinases can be grouped into families based on structure and mechanism. The ones directly activated by the second messengers cAMP (Protein Kinase A) and DAG (Protein Kinase C) are members of one family of kinases the AGC Protein Kinase family. The clustered families of protein kinases are shown in Figure 28.3.1.

28.3.2:

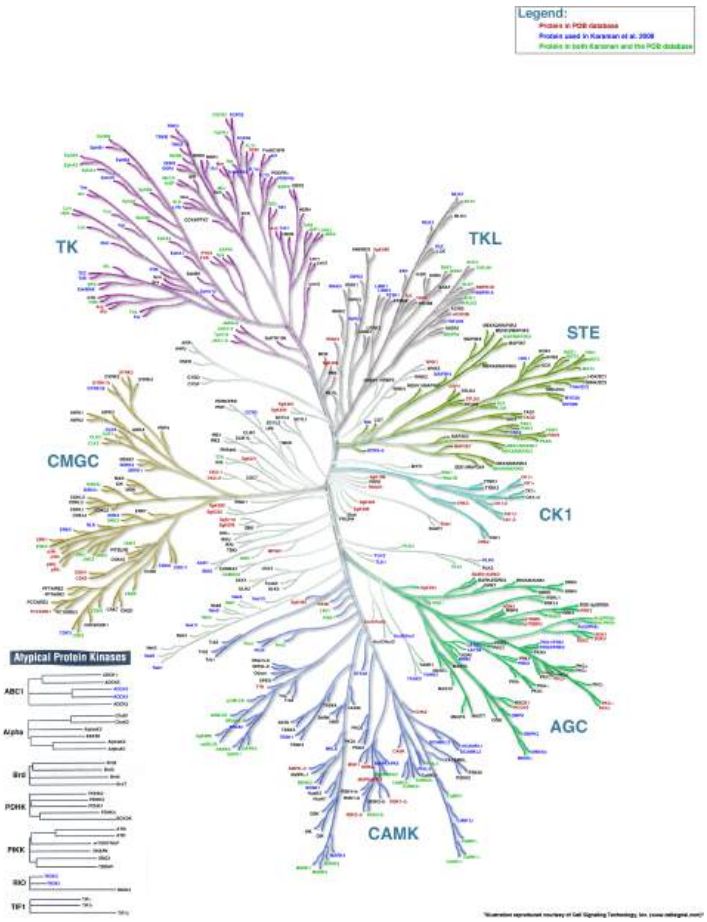

Figure 28.3.1: The family of protein kinases. https://peerj.com/articles/126/. Illustration reproduced courtesy of Cell Signaling Technology, Inc. (www.cellsignal.com)

Luckily, most of the kinases, which catalyze the phosphorylation of the OH-containing side chains (Tyr, Ser, and Thr) of proteins have similar catalytic sites. Given that phosphorylation of proteins often acts as an on/off switch for protein activity and function, it makes great sense that the catalytic site of protein kinases is not available for substrate binding and/or catalysis in the off state. Protein kinases have **catalytic** and **activation loops** and conformation changes on activation of protein kinases usually involve movement of the activation loop and rearrangement of the catalytic residues. These conformational changes are often initiated by phosphorylation by another upstream active protein kinase of key groups in the activation loop! Figure 28.3.2 shows another representation of the different families of protein kinase and their common structural features.

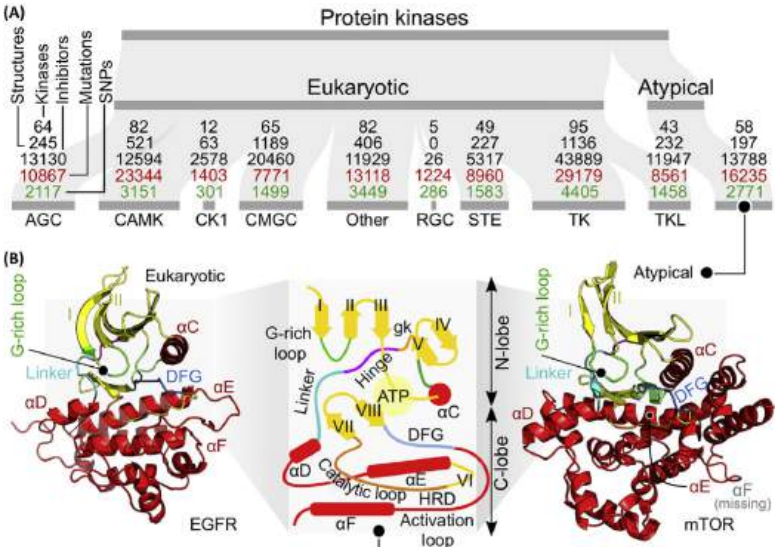

Figure 28.3.2: Family organization and common structural features of protein kinases. Trends in Pharmacological Sciences, November 2019, Vol. 40, No. 11 https://doi.org/10.1016/j.tips.2019.09.002"https://doi.org/10.1016/j.tips.2019.09.002. Creative Commons Attribution (CC BY 4.0)

Pane (A) shows the nine eukaryotic and one atypical protein kinase groups with their numbers of kinases, structures, and inhibitors (shown in black) as well as mutations (in red) and SNPs (in green). Here, the atypical protein kinases are defined as all non-eukaryotic protein kinases including also the nonprotein kinase-like kinases. The middle of Panel (B) shows the activation and catalytic loops and other common features found in the active sites of protein kinases. The left and right parts of Panel (B) show two different kinases. The protein kinase domain of epidermal growth factor receptor (EGFR) is shown on the left and the Ser/Thr protein kinase domain of **mTOR** (**m**ammalian or mechanistic **T**arget **O**f **R**apamycin), a protein we will explore in a separate section, is shown on the right.

28.3.3: AGC Kinases

These **serine/threonine kinases** are activated by the second messengers c**A**MP (**A** Kinase), c**G**MP (**G** kinase, which we will see later), and by diacylglycerol (DAG) formed by activation of phospholipase **C**. Figure 28.3.3 shows the generic structure of active kinase domains (including tyrosine kinases)

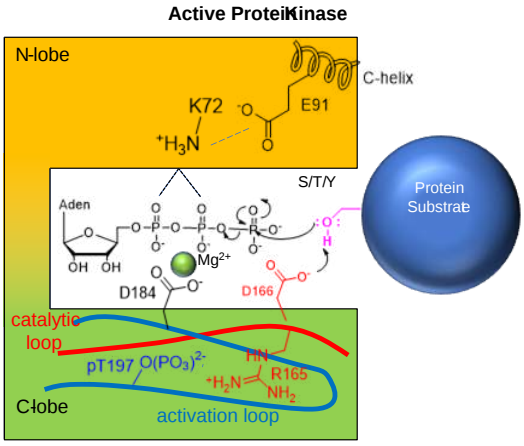

Figure 28.3.3: Generic structure of the active form of ACG kinases (Adapted from the superlative text, Cell Signaling by Lim, Mayer, and Pawson)

A generic kinase has an N-terminal and C-terminal lobe between which the substrates ATP and the target protein containing the key serine, threonine, or tyrosine side chain bind. In the active conformation, Glu 91 (E91) in the αC-helix in the N-lobe forms a salt-bridge (ion-ion interaction) with Lys72 to position it so it can stabilize the binding of the ATP through ion-dipole and H-bond interactions. In the active state, Thr 197 (T197) in the activation loop has been phosphorylated (represented by pT197) by an upstream kinase allowing a less flexible conformation of the loop. This facilitates optimal repositioning of active site side chains in the catalytic loop allowing substrate access and catalysis. Asp 166 (D166) in the catalytic loop acts as a general base in abstracting a proton from the target Ser, Thr or Tyr. Arginine 165 (R165) in the catalytic loop forms a salt bridge to phosphotyrosine 197 (pT197), stabilizing the catalysis-competent conformation of the activation loop. Aspartic acid 184 (D184) plays a key role in stabilizing the Mg^{2+} that itself stabilized the negative charges on the phosphates of ATP and in the developing transition state.

Most kinases are also classified as RD kinases since they have a key arginine (R)- aspartic acid (D) sequence in the catalytic loop. The normal protein substrate for an AGC kinase would be a protein with a Ser or Thr projecting into the active site for phosphorylation by bound ATP. The normal sequence for phosphorylation in protein targets of PKA is Arg-Arg-X-Ser/Thr-X (or more fully as XR(R/K)X(S/T)B where B is a hydrophobic amino acid). Again we will focus on three AGC kinases here, PKA, PKC, and AKT (PKB), and defer our discussion of PKG to another section.

28.3.4: cAMP-dependent Protein Kinase A - PKA

Before we study PKA, the formation of the second messenger cAMP is presented in review in Figure 28.3.4

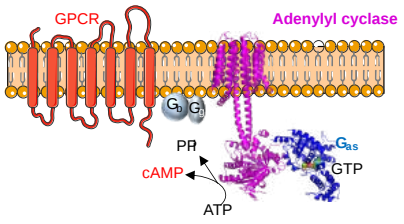

Figure 28.3.4: Synthesis of cAMP on activation of GPCRs and adenylyl cyclase

PKA contains a kinase domain with short N- and C-terminal extensions, making it a prototypical and simple model for study. In the absence of the second messenger cAMP, this prototypic AGC kinase exists as a holo-heterotetramer (or dimer of a heterodimer). It contains two catalytic kinase subunits (C) and two regulatory subunits (R). cAMP produced upon GPCRs activation of adenylyl cyclase binds to the regulatory subunits, causing them to dissociate from the heterotetramer, freeing the catalytic subunits for activity. This is illustrated in Figure 28.3.5

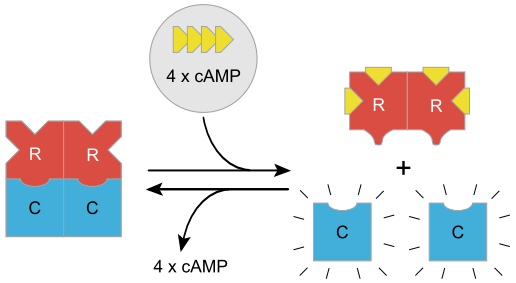

Figure 28.3.5: Activation of Protein kinase A by the second messenger cAMP

The cAMP serves as an allosteric activator of protein kinase A.

Figure 28.3.6 shows the actual structures of the protein kinase A **RIIb tetrameric holoenzyme (3TNP)**

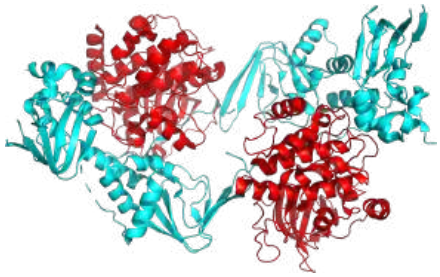

Figure 28.3.6: **Protein Kinase A RIIb tetrameric holoenzyme (3TNP)**

The inhibited catalytic subunits are shown in red and the two regulatory subunits are shown in cyan.

Figure 28.3.7 shows only one catalytic subunit of protein kinase A as it goes from the more closed inactive holoenzyme (tetramer, 3tnp) containing the regulatory subunits (not shown), to the more open apo-form (monomer, 1J3HA), without the regulatory subunit. The conformational change opens the free catalytic subunit to the substrate (protein and ATP) binding.

Figure 28.3.7: Conformational change on the conversion of the catalytic subunit of protein kinase A from the more closed inactive holoenzyme (tetramer, 3tnp) containing the regulatory subunits to the more open apo-form (monomer, 1J3HA) without the regulatory subunit

Side chains required for MgATP binding and phosphoryl transfer are pre-formed in the apo form but some changes still occur on the binding of substrate.

Figure 28.3.8 shows an interactive iCn3D model of the mouse catalytic subunit of cAMP-dependent protein kinase complexed with MnATP and a peptide inhibitor (1ATP)

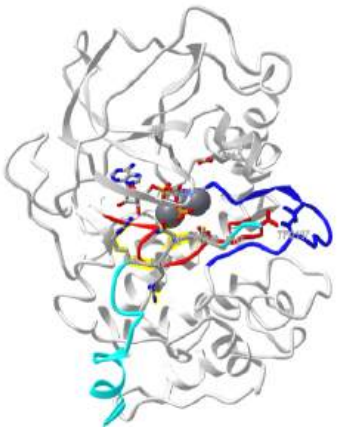

Figure 28.3.8: Catalytic subunit of cAMP-dependent protein kinase complexed with MnATP and a peptide inhibitor (1ATP) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...B8Xyks9kMdbZN9

Zoom into the model to see each of the labeled residues. All of the features shown in Figure 28.3.3 are displayed in this model. The activation loop is shown in dark blue and the catalytic loop is shown in red. The peptide inhibitor is shown in cyan. The normal

target motif for phosphorylation by Protein Kinase A (Arg-Arg-X-Ser/Thr-X) has been replaced in this model by Arg-Arg-X-Ala-X. Why does this make the peptide an inhibitor instead of a substrate?

Many primary signals activate adenylate cyclase through GPCR and produce cAMP as a second messenger. These include corticotrophin, dopamine, epinephrine (β-adrenergic), follicle-stimulating hormone, glucagon, many odorants, prostaglandins E1and E2, and many tastants. All of these would activate protein kinase A. Some enzymes regulated by cAMP-dependent phosphorylation by PKA are shown in Table 28.3.1 below

Enzyme	Pathway
Glycogen Synthase	Glycogen synthesis
Phosphorylase Kinase	Glycogen breakdown
Pyruvate Kinase	Glycolysis
Pyruvate Dehydrogenase	Pyruvate to acetyl-CoA
Hormone-sensitive Lipase	Triacylglycerol breakdown
Tyrosine Hydroxylase	Synthesis of DOPA, dopamine, norepinephrine
Histone H1	Nucleosome formation with DNA
Histone H2B	Nucleosome formation with DNA
Protein phosphatase 1 Inhibitor 1	Regulation of protein dephosphorylation
CREB	cAMP regulation of gene expression
PKA consensus sequence	XR(R/K)X(S/T)B (B = hydrophobic amino acid)

Table 28.3.1: Proteins phosphorylated by Protein Kinase A.

An example of how epinephrine (a flight/fight hormone) can lead to the breakdown of glycogen (your main carbohydrate reserves in muscle and liver) is shown in Figure 28.3.9

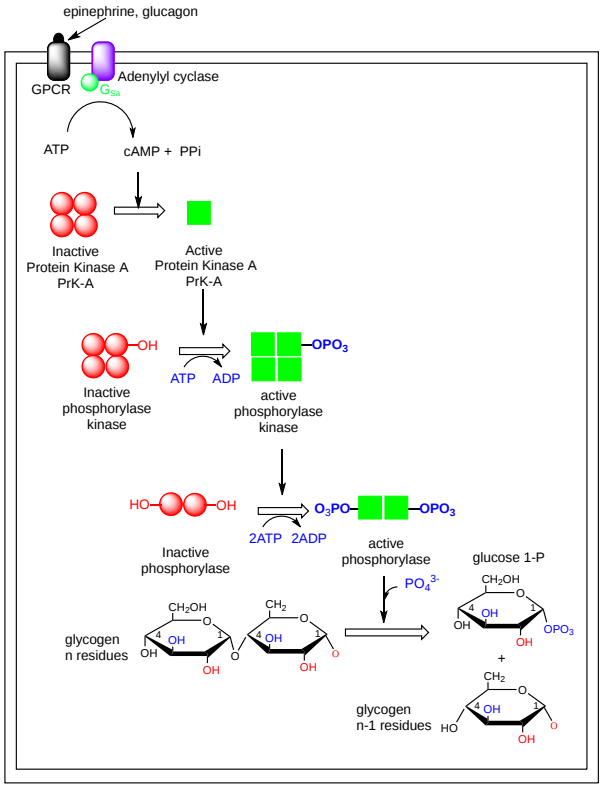

Figure 28.3.9: Cascade activation of glycogen phosphorylase through GPCR and cAMP signaling.

A cascade of events starts with the binding of the hormone to its receptor, followed by the activation of adenylate cyclase and the formation of the second messenger cAMP. This activates PKA, which phosphorylates and activates the enzyme **phosphorylase kinase**. Following the naming convention we discussed earlier, **phosphorylase kinase** is a protein kinase whose target enzyme is another enzyme called glycogen phosphorylase, which is NOT a kinase. When active, glycogen phosphorylase uses inorganic phosphate (P_i) as a nucleophile in a phosphorolysis reaction to cleave glucose from the end of glycogen polymers forming glucose-1-phosphate. This is the first step in the mobilization of glycogen as an energy reserve. No wonder it is so tightly regulated by this complicated signaling pathway.

28.3.5: The second messengers DAG and IP_3 and their activation of Protein Kinase C

The activation of protein kinase C (PKC, a Ser/Thr kinase member of the ACG protein kinase family) is very similar to that of protein kinase A. To start, an extracellular signal molecule binds to a GPCR receptor (again with no intrinsic enzyme activity), causing a conformational change in the receptor that propagates through the membrane to its intracellular domain. That then activates the exchange of GTP for GDP in the alpha subunit of the bound heterotrimeric G protein, which contains the special $G_{\alpha q}$ subunit. The $G_{\alpha q}$ subunit dissociates and binds to the membrane protein enzyme **phospholipase C** (not adenylyl cyclase). Once activated, it cleaves the phospho-head group from the membrane phosphatidyl inositol - 4,5-bisphosphate (PIP2) into two, second messengers - diacylglycerol and inositol trisphosphate (IP_3). These products are shown in Figure 28.3.10

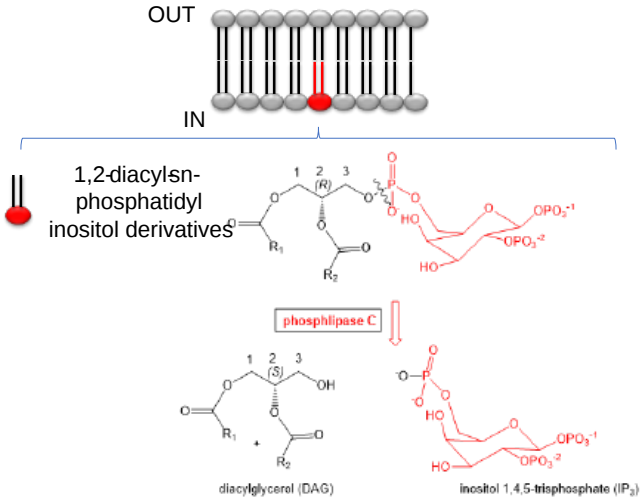

Figure 28.3.10: Cleavage of phosphatidyl inositol - 4,5-bisphosphate (PIP2) into two, second messengers - diacylglycerol and inositol trisphosphate (IP_3)

The formation of the second messengers IP_3 and DAG is presented n Figure 28.3.11 Note that phospholipase C is a peripheral membrane protein bound to the inner leaflet of the cell membrane.

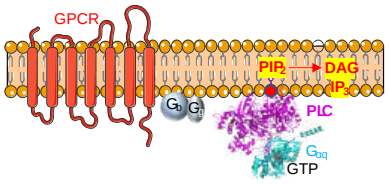

Figure 28.3.11: Synthesis of DAG and IP_3 from PIP_2 by phospholipase C

Diacylglycerol binds to and activates protein kinase C (PKC). The IP_3 binds to ligand-gated receptor/Ca^{2+} channels on internal membranes, leading to an influx of calcium ions into the cytoplasm. The released calcium ions also activate PKC. These steps are illustrated in Figure 28.3.12 in more detail below. The activation of the peripheral membrane phospholipase C (PLC) is very similar to that of the integral membrane protein adenylyl cyclase, both of which produce second messengers.

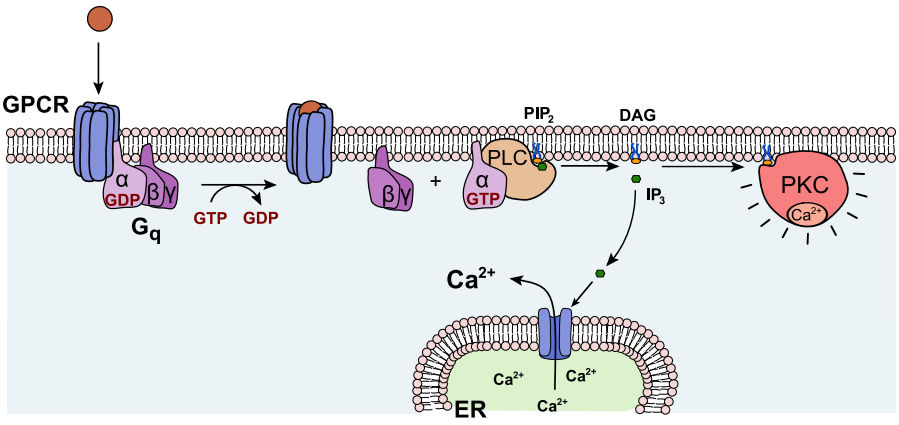

Figure 28.3.12 GPCR activation of phospholipase C, generation of second messengers IP_3, DAG, and Ca^{2+} ions, and downstream activation of Protein Kinase C

You might also expect the regulation of the activation of protein kinase C (PKC) activity to be similar to the regulation of the activation of protein kinase A (PKA). It is, but with a major difference. In contrast to the structure of PKA, which cycles between an inactive R_2C_2 (R is the regulatory and C the catalytic subunit) and an active separated form, PKC is a single chain that has a regulatory, domain, and catalytic domain as shown in Figure 28.3.13 Variants of PKC are also shown.

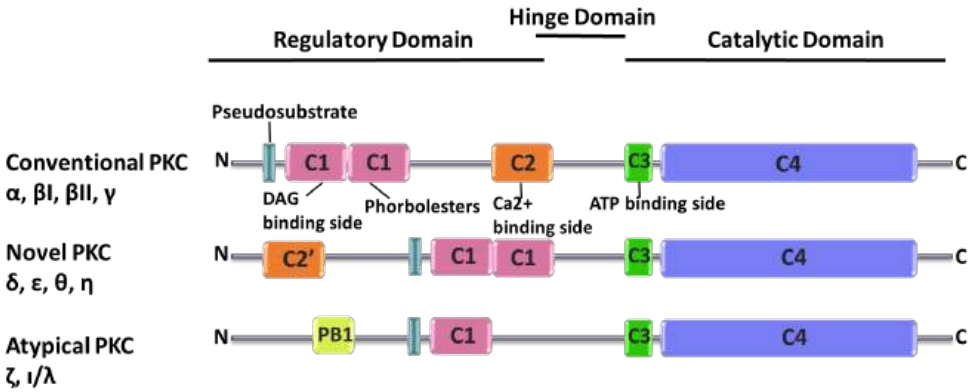

Figure 28.3.13: Domain structure of conventional, novel, and atypical protein kinase Cs. *Kaleli et al. Cells* **2020**, *9*(3), 553; https://doi.org/10.3390/cells9030553https://www.mdpi.com/651098Creative Commons Attribution (CC BY) license (http://creativecommons.org/licenses/by/4.0/).

Protein kinase **C** was named "**C**" because of its activation by **C**a^{2+} ions, but you could also remember it because it requires the upstream activation of phospholipase **C**.

There are more than 500 PKCs divided into 15 subgroups and their downstream functions lead to gene expression. They all have 4 common domains, C1-C4. C1 and C2 are the functional regulatory domain and C3 and C4 are in the overall catalytic domain. They have the following activities.

- C1 binds diacylglycerol (DAG) and phorbol esters (commonly known activators or PKC)
- C2 binds Ca^{2+}, another second messenger, which activates the protein; Novel PKCs use DAG and phosphatidyl ethanolamine but not Ca^{2+} to activate the protein, while atypical ones use only DAG.
- C3 binds ATP
- C4 binds target proteins for phosphorylation.

The structure of the phorbol 12-myristate 13-acetate, which activates PKC, is shown in Figure 28.3.14

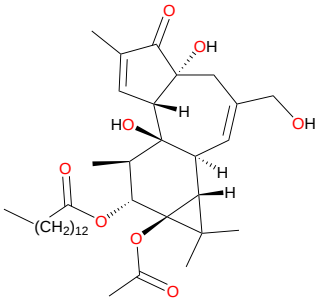

Figure 28.3.14: Phorbol 12-myristate 13-acetate

In a novel way to keep the protein inactive, it contains a small peptide sequence (a pseudosubstrate) that mimics the amino acids around the target phosphorylation site (with the target Ser/Thr). This binds in the active site in the inactive form of PKC like a competitive inhibitor and prevents PKC activity.

PKCα is found in the cytoplasm, cell membrane, nucleus, and mitochondria. Its activation by DAG suggests it becomes localized to membrane surfaces. The protein is conformationally very flexible (note the hinge domain in Figure 28.3.13) so it has been difficult to get detailed structures.

Figure 28.3.15 shows an interactive iCn3D model of the PKC (alpha)-C2 domain complexed with Ca^{2+} and PtdIns(4,5)P2 (IP3) (PDBID 3GPE). The hydrogen bonds and ion-ion interaction between the C2 domain and IP3 are detailed and labeled.

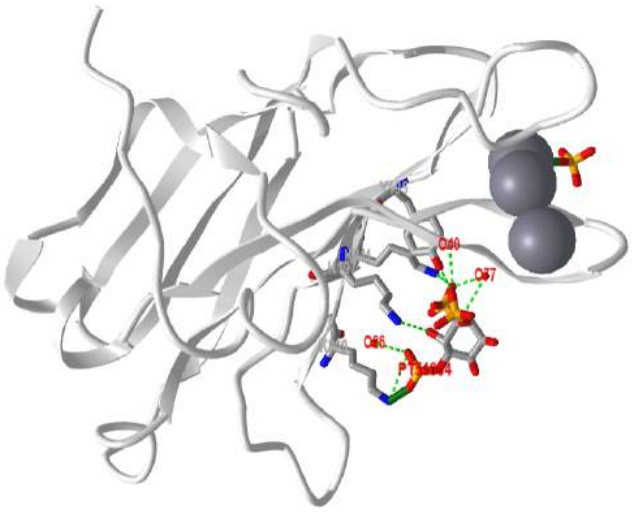

Figure 28.3.15: PKC (alpha)-C2 domain complexed with Ca^{2+} and PtdIns(4,5)P2 (IP3) (3GPE) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...gX24dYC1NhSXi7

Protein kinase C is targeted to the membrane (as shown in Figure 28.3.12), but it lacks the Pleckstrin Homology (PH) which most phospholipase Cs use to interact with PIP_2 in the membrane.

Before activation of PKC by DAG and Ca^{2+}, it must be phosphorylated sequentially. Before these phosphorylations, PKC loosely binds to the membrane with the activation loop open to phosphorylation by kinases. These are the subsequent steps:

1. phosphorylation of Thr500 (PKC βII)) in the activation loop of PKC by an upstream kinase PDK1 (a kinase which also phosphorylates other AGC kinases such as AKT discussed below). This kinase can bind to the exposed activation loop
2. autophosphorylation at the C-terminus of PKC, which leads to conformational positioning of side chains needed for catalysis and substrate binding, and access to the substrate binding site

PKC engages in a very dynamic cycle. It starts as the inactive cytoplasmic form that is autoinhibited by its pseudosubstrate sequence. It then moves to the membrane where the autoinhibition is relieved. All of this requires flexibility which makes it difficult to determine its structure. Figure 28.3.16 shows how the inactive cytoplasmic form of PKC becomes activated at the cell membrane.

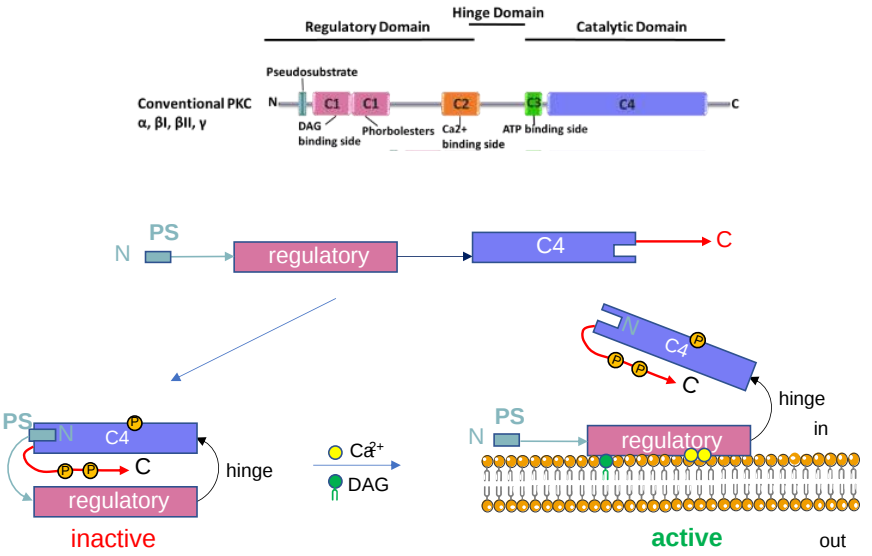

Figure 28.3.16: Conversion of the cytoplasmic inactive PKC to its membrane-bound active form (after Tatyana I. Igumenova. https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4979571/)

The regulatory domain, which contains the C1 (DAG binding) and C2 (Ca^{2+}) domains binds to the membrane freeing and activating the kinase domain on the release of the bound internal pseudosubstrate.

Figure 28.3.17 the optimal consensus sequence flanking both sides of the phosphorylation site in target proteins (based on model peptides) and the sequence of the internal pseudosubstrate motif for several PKCs.

Figure 28.3.17: Optimal consensus substrate and actual internal pseudosubstrate sequences for PKC. Nishikawa et al. JBC. 272, 952–960, 1997. https://creativecommons.org/licenses/by/4.0/

Boxed amino acids show structural similarity between the target and internal pseudosubstrate. Position 0 indicates the serine that is phosphorylated in the target. Note that it is replaced with alanine in the pseudosubstrate. Also, note the abundance of positively charged side chains.

Figure 28.3.16 also shows that phosphorylation of key side chains facilitates the activation of the enzyme. The upstream kinase **3-phosphoinositide-dependent protein kinase 1 (PDPK1 or PDK1**) phosphorylates the key Ser/Thr in the activation loop as we discussed above. PDK1 is a "master" Ser/Thr kinase which phosphorylates and activates many proteins, including PKA, PKC, and protein kinase B (which we will explore below).

Figure 28.3.18 shows an interactive iCn3D model of the Protein Kinase C beta II (3PFQ)

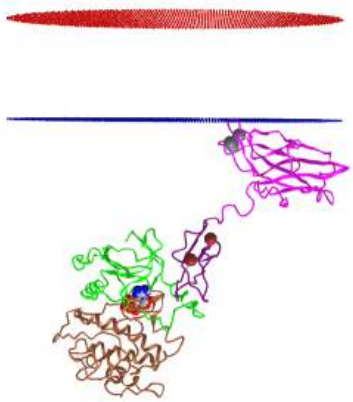

Figure 28.3.18: Protein Kinase C beta II (3PFQ) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...ym5qJhtdWsdN96

The C2 domain (magenta)has two bound Ca^{2+} ions (gray spheres) and interacts with the bottom leaflet of the cell membrane. The C1 domain (purple) has two bound Zn^{2+} ions. The N lobe of the kinase domain is shown in green and the C lobe is shown in brown. A nonhydrolyzable ATP analog, AMPPNP (ANP), is shown in spacefill between the N and C lobes. There is an additional NFD helix preceding the C-terminal tail which can adopt two positions, one which confers low activity and the other high PKC activity. The Phe629 in this region is out of the active site in the low activity form and in it and interacting with the adenine of ATP in the high activity form.

Some signals that activate phospholipase C and make IP3 and diacylglycerol include acetylcholine (a different class than the type located at the neuromuscular junction that we discussed in the last chapter section), angiotensin II, glutamate, histamine, oxytocin, platelet-derived growth factor, vasopressin, gonadotropin-releasing hormone, and thyrotropin-releasing hormone.

In the inactive form of PKC, the arginine-rich basic autoinhibitory pseudosubstrate interacts with acidic side chains in the substrate binding site.An acidic patch in the substrate-binding site (Figure 6.2). When PKC is activated by phosphorylation of the regulatory domain, it phosphorylates arginine-rich sites in protein substrates. This also releases pseudosubstrates from some target inactive protein kinases, which allows them to become active kinases in turn. PKC physiological substrates include receptors, cytoskeleton proteins, protein kinases, proteases, and nuclear proteins

The Ca^{2+} ions also act as second messengers. The calcium ions bind to the **calcium-modulatory** protein, **calmodulin**, which binds to and activates the **calmodulin-dependent kinase (CAM-PK)**, which we will discuss later. Some kinases regulated by calcium and calmodulin include myosin light chain kinase, PI-3 kinase, and CAM-dependent kinases. Ca/CAM also regulates other proteins which include: adenylate cyclase (brain), Ca-dependent Na channel, cAMP phosphodiesterase, calcineurin (phosphoprotein phosphatase 2B), cAMP gated olfactory channels, NO synthase, and plasma membrane Ca/ATPase.

28.3.6: Protein Phosphorylation by activated Receptor Tyrosine Kinases (RTKs)

Figure 28.3.19s shows the dimeric structure of RTKs driven by extracellular signal binding.

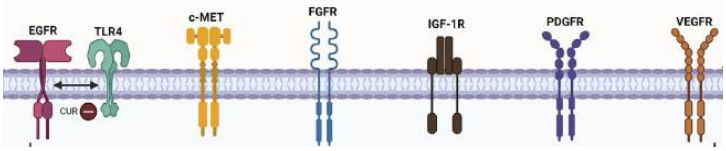

Figure 28.3.19: Dimeric structure of selected RTKs driven by extracellular signal binding. Sareshma Sudhesh Dev et al. Front. Pharmacol., 15 November 2021 | https://doi.org/10.3389/fphar.2021.772510. Creative Commons Attribution License (CC BY).

Table 28.3.2below shows the classification of RTKs into classes and families.

TABLE 1 | Classification of RTKs according to family.

Class	Family	Members
I	EGFR	EGFR, ERBB2, ERBB3, ERBB4
II	Insulin R	INSR IGFR
III	PDGFR	PDGFRα, PDGFRβ, M-CSFR, KIT, FLT3L
IV	VEGFR	VEGFR1, VEGFR2, VEGFR3
V	FGFR	FGFR1, FGFR2, FGFR3, FGFR4
VI	CCK	CCK4
VII	NGFR	TRKA, TRKB, TRKC
VIII	HGFR	MET, RON
IX	EPHR	EPHA1–6, EPHB1–6
X	AXL	AXL, MER, TYRO3
XI	TIE	TIE, TEK
XII	RYK	RYK
XIII	DDR	DDR1, DDR2
XIV	RET	RET
XV	ROS	ROS
XVI	LTK	LTK, ALK
XVII	ROR	ROR1, ROR2
XVIII	MUSK	MUSK
XIX	LMR	AATYK1, AATYK2, AATYK3
XX	Undetermined	RTK106

Table 28.3.2EGFR: epidermal growth factor receptor; InsR: insulin receptor; PDGFR: platelet-derived growth factor receptor; VEGFR: vascular endothelial growth factor receptor; FGFR:fibroblast growth factor receptor; CCK: colon carcinoma kinase; NGFR, nerve growth factor receptor; HGFR: hepatocyte growth factor receptor; EphR: ephrin receptor; Axl: from the Greek word anex-elekto, or uncontrolled, a Tyro3 protein tyrosine kinase; TIE:tyrosine kinase receptor in endothelial cells; RYK: receptor related to tyrosine kinases; DDR: discoidin domain receptor; Ret: rearranged during transfection; ROS: RPTK, expressed in some epithelial cell types; LTK: leukocyte tyrosine kinase; ROR: receptor orphan; MuSK: muscle-specific kinase; LMR: Lemur. Sareshma Sudhesh Dev et al. Front. Pharmacol., 15 November 2021 | https://doi.org/10.3389/fphar.2021.772510. Creative Commons Attribution License (CC BY).

We introduced the activation of RTKs in the previous section and indicated that ligand-induced dimerization led to their activation. Let's expand on that now. As in the case of PKC, the intracellular kinase domains of RTKs are inhibited by specific structures in their chains (cis-autoinhibited). These include the activation loop but in addition C-terminal sequences and the sequence region linking the C-terminal domain with the transmembrane domain. This is called the juxtamembrane region. All of these must be phosphorylated for the activation of kinase activity. The autoinhibition is released on ligand binding and dimerization. The kinase domains can also be allosterically activated by the kinase domain of the dimer. Each domain phosphorylates the cytoplasmic domain of the other, so it's called trans-phosphorylation (i.e. a kinase domain on one monomer does not autophosphorylate itself, which would be called cis-phosphorylation). The now active kinase domains recruit target proteins containing SH2 domains (which bind p-Tyr peptides/proteins) in a fashion that propagates signaling. These include proteins involved in other signaling pathways including MAPK and phosphoinositide-3-kinase (PI3K)/Akt pathways which we will discuss later. A particular phospholipase Cγ (PLC-γ) is also activated by an RTK.

Cancers can arise if the RTK signaling pathways, which control cell growth and division, are overactive. Figure 28.3.20shows four different mechanisms for the expression and/or activation of RTKs that could lead to cancer.

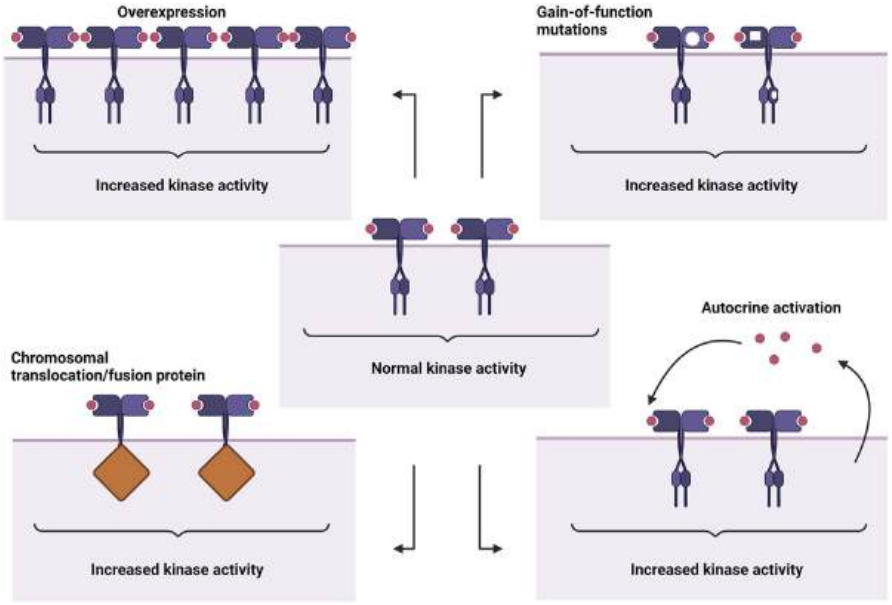

Figure 28.3.20: Possible mechanisms for expression and/or activation of RTKs in cancer cells. Dev et al. Front. Pharmacol., 15 November 2021 | https://doi.org/10.3389/fphar.2021.772510. Creative Commons Attribution License (CC BY).

We will focus on the epidermal growth factor receptor (EGFR) for most of the remaining discussion. One of the most interesting questions is how ligand binding in the extracellular domain of the biotopic integral membrane proteins leads to an intracellular signal in the cytoplasmic domain. It's difficult to imagine such an activation propagating through a single transmembrane helix. We'll discuss how ligand-promoted dimerization of the receptor appears to be the main mechanism of activation of RTKs.

Figure 28.3.21shows the domain structure of three different RTKs, including the insulin receptor (IR) family. The insulin receptor is also synthesized as a single chain but undergoes proteolysis and interchain disulfide bond formation to give the "dimeric" structure shown below.

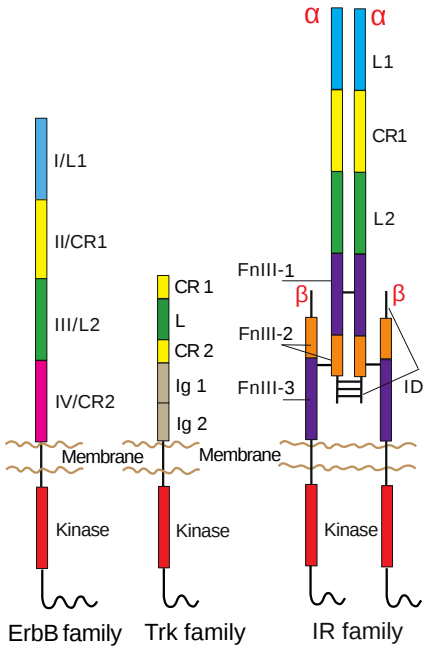

Figure 28.3.21: L,leucine-rich; CR, cysteine-rich; Ig, immunoglobulin-like; FnIII, fibronectin type III; ID, insert domain. The L1, CR1, L2, and CR2 domains of the ErbB family are alternatively termed Domains I–IV. Ichiro N. MaruyamaCells. Cells. 2014 Jun; 3(2): 304-330. doi: 10.3390/cells3020304. (http://creativecommons.org/licenses/by/3.0/). https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4092861/

The EGFR is a member of the **ErbB** family which consists of 4 members: EGFR (also called Erb1 or HER1), ErbB2 (HER2), ErbB3 (HER3), and ErbB4 (HER4). The name ErbB arises from the avian **ER**ythro**B**lastosis oncogene **B**). They are also called HER after the **H**uman **E**pidermal growth factor **R**eceptor). The HER2 gene is often dysregulated in breast cancer. Members of the ErbB family have unique numbers and positions of tyrosine in the C-terminal kinase domains. EGFR has 20, of which 12 are phosphorylated. The EGFR is also a bit unique in that it has only one tyrosine in the activation loop that is phosphorylated but the tyrosine itself is not required for kinase activity. Although we suggested earlier that RTKs are activated on dimerization, studies show that RTKs However, an increasing number of studies demonstrate that RTKs exist as inactive dimers in the absence of the ligand.

As shown in Figure 28.3.21, ErbB receptors have 4 extracellular domains, a transmembrane domain, the juxtamembrane region (about 40 residues), the cytoplasmic kinase domain and a C-terminal extension that gets autophosphorylated and which binds downstream target protein through their SH2 domains. Extracellular domains I (L1) and III/L2 have β-helix solenoid secondary motifs that bind the ligand. Domains II/CR1 and IV/CR2 are cysteine-rich disulfide bonds. Some fraction (>80% through cross-linking studies) of the ErbB receptors exist as dimers at the cell surface in the absence of ligand, a finding in contrast to the older view that ligand binding is required for dimerization

The structure of the extracellular domains of the free ErbB and ligand-bound EGFR receptors show conformational changes that are required for dimer formation. In the absence of the ligand, a "tether" arm, denoted by an open triangle in domain IV in Figure 28.3.22 is close to a buried "dimerization" arm (asterisk *) in domain II of the extracellular regions of EGFR, ErbB3, and ErbB4, effectively inhibiting dimerization. When the ligand is bound, domains I and III interact, freeing the dimerization domains to interact (** in EGFR). These features are illustrated in Figure 28.3.22

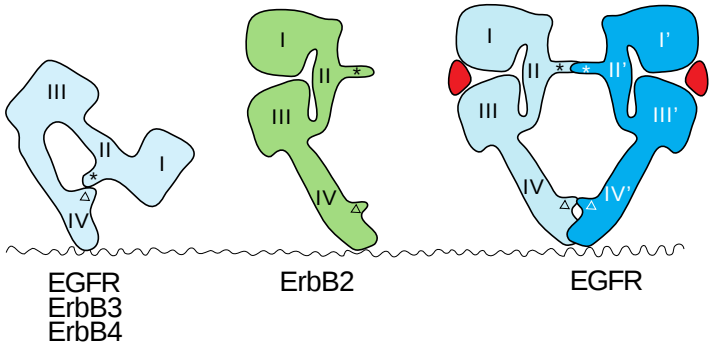

Figure 28.3.12 Schematic representations of the structures of the extracellular regions of the ErbB family. EGFR, ErbB3, and ErbB4 adopt the tethered conformation in the absence of ligand, while ErbB2 adopts an extended, or untethered, conformation that resembles the ligand-activated, dimerization-competent EGFR protomer in the ligand-bound form of the EGFR dimer, shown at the right. The 'dimerization arm' and 'tethering arm' are shown by an asterisk * and an open triangle, respectively. Ligands are shown in red. Domains I–IV correspond to the domains shown in Figure 28.3.21 Not drawn to scale. Ichiro N. MaruyamaCells. Cells. 2014 Jun; 3(2): 304–330. doi: 10.3390/cells3020304' (http://creativecommons.org/licenses/by/3.0/). https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4092861/

In addition, the tether arms on both monomers now interact in the dimer. Note that the ligand binding region is not involved in dimer formation and is not in the dimer interface, as it is with other RTKs where the ligand is involved in direct contact in the dimer interface. Mutations in the II/IV domains that inhibit their interactions do not lead to receptor activation so ligand binding is still required. ErbB2 exists in an extended conformation (no ligand is known for it) so it is free to interact with another ErbB chain in a heterodimer.

Structural studies now suggest that EGFR kinase dimer has a symmetrical inactive conformation in which the activation loop is packed and occluding the active site. In addition, it has an asymmetrical active one in which the activation loop is unpacked and the active site is open. How is this transmitted across the subunits? It appears that the C-lobe of the "activator/donor" kinase interacts with the N-lobe of the adjacent "receiver/acceptor" kinase which activates it through a conformational change. When the ligand binds, the inactive dimer dissociates, and the asymmetric active dimer results.

Two models have been proposed for ligand-gated activation of the Erb dimers: the dimerization and rotation/twist models, as shown in Figure 28.3.23

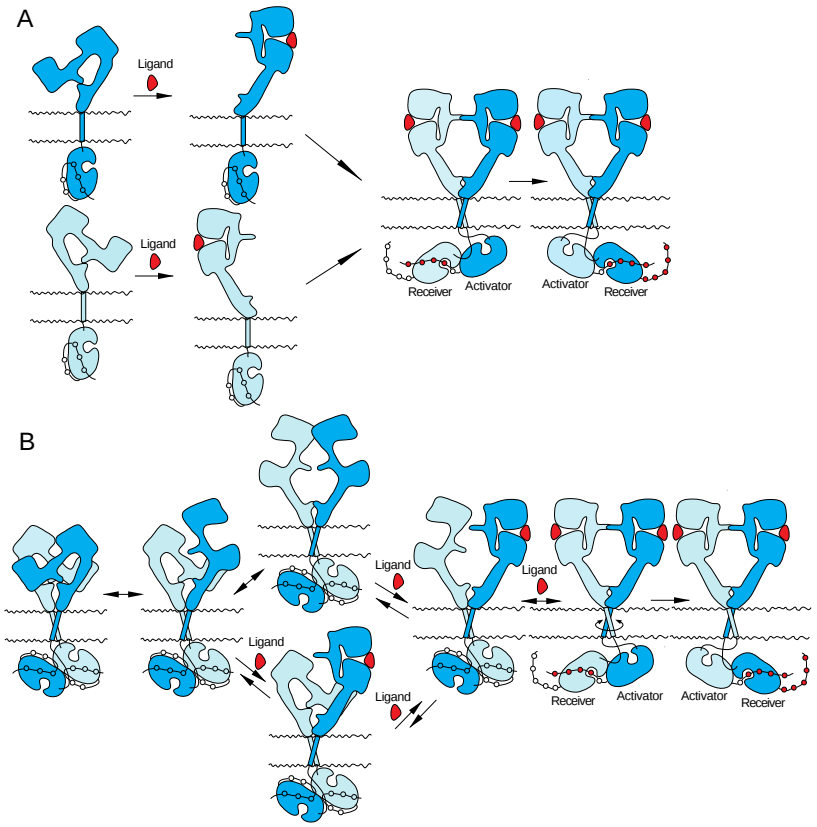

Figure 28.3.23: Models for ligand-induced activation of the ErbB family. (**A**) 'Dimerization' model. (**B**) 'Rotation/twist' model. Not drawn to scale. Ichiro N. MaruyamaCells. Cells. 2014 Jun; 3(2): 304–330. doi: 10.3390/cells3020304' (http://creativecommons.org/licenses/by/3.0/). https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4092861/

- A. Dimerization model: Ligand binding to the I and III extracellular domains of a monomer lead to dimerization by causing the release of the tether arm between I and III, allowing the dimerization arms to become free and interact with each other. This causes the kinases domains to adopt the active state
- B. Rotation/Twist model: The receptor is already a dimer in the unliganded state with the extracellular region untethered and the intracellular kinase domains in an inactive symmetric state. Ligand binding causes the two dimerization arms to extend, causing a twist in the transmembrane segment. This causes the kinase domains to adopt the active asymmetric state with the activator kinase domain of one monomer activating the receiver kinase domain of the second monomer in the dimer, with each forming an extended conformation.

Figure 28.3.24 shows an interactive iCn3D model of the intracellular dimeric EGFR kinase domains in complex with an ATP analog-peptide conjugate (2GS6)

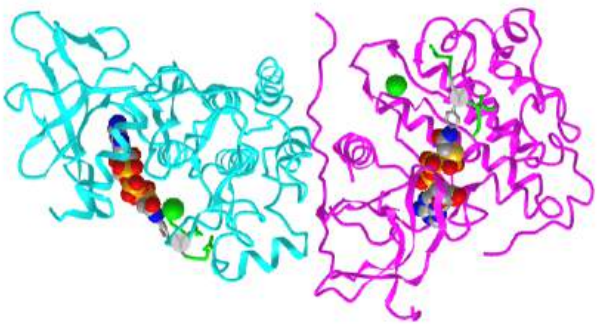

Figure 28.3.24: Dimeric intracellular EGFR kinase domains in complex with an ATP analog-peptide conjugate (2GS6) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...iw1V4T8rsfxDZ7

The two EGFR kinase domains are shown in cyan and magenta. The ATP analogs in each domain (spacefill) are thiophosphoric acid O-((adenosyl-phospho)phospho_-S-acetamidyldiester. The peptide substrates (green stick) are 13-mers with a tyrosine (sticks,

labeled Y, minus the OHs) connected to the ATP analog.

Figure 28.3.25 shows an interactive iCn3D model of a single EGFR kinase domain showing N and C terminal lobes in complex with an ATP analog-peptide conjugate (2GS6)

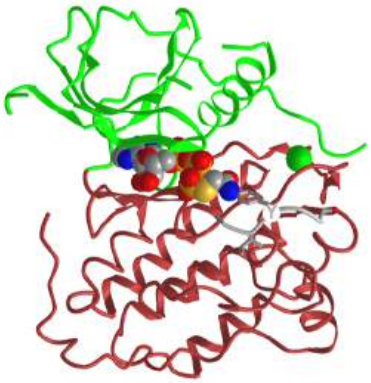

Figure 28.3.25: A single EGFR kinase domain showing N and C terminal lobes in complex with an ATP analog-peptide conjugate (2GS6) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...VLu1jPJYJNoih9

The ATP part of the ATP-peptide conjugate is sandwiched between N-lobe (green) and the C-lobe (brown) just as in PKA. The ATP in the peptide conjugate is shown in spacefill while the peptide is shown in gray. The tyrosine (Y) linked to the peptide is labeled.

Figure 28.3.26 shows an interactive iCn3D model of showing the similarity in structure between the PKA kinase domain (1J3H A chain) and the EGFR kinase domain (2GS6)

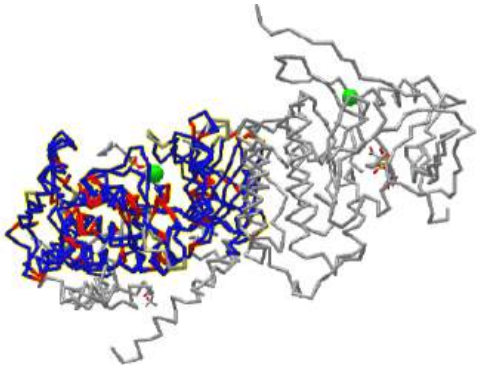

Figure 28.3.26: Alignment of the PKA kinase domain (1J3H A chain) and the EGFR kinase domain (2GS6) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?mVfpwk3Y7EDcM5mq9

The gray structure by itself is the second kinase domain of the EGFR dimer. The superimposed chains are on the other side. Red indicated identical residue and blue nonconserved in the structural alignment. Zoom in on the aligned sequences in blue and red to show how similar the kinase domains are.

In the next chapter section, we will explore the next downstream effects in signaling, mediated by the second messengers cAMP, DAG, and IP_3 and the substrates phosphorylated by the ligand-active receptor tyrosine kinases.

EGFR and HER2 in breast cancer

The HER2 receptor can form homo or heterodimers with single chain ErbB1-ErbB4 (same as HER1-HER4). HER receptors exist as both monomers and dimers, either homo- or heterodimers. Rapid dimerization of HER1, HER3, or HER4 occurs if they form heterodimers with HER2. In addition, any ErbB dimer with HER2 leads to strong intracellular signaling compared to other HER heterodimers. Ligand binding to HERI, HER3, or HER4 induces rapid receptor dimerization, with a marked preference for HER2 as a dimer partner. Since noncancer cells have very little HER2, correspondingly few heterodimers of HER2 around found. If HER2 is overexpressed as in HER2+ breast cancer cells, more heterodimers are found, and anomalously-high levels of signaling occur. This resulted in a poorer prognosis for HER2+ breast cancers in the past.

A revolution in breast cancer therapy has changed that situation. Humanized antibodies (human antibodies made in mice cells) to HER2, called trastuzumab (Herceptin) are now used in therapy. Since the antibodies are derived from human genes, they are not targeted as foreign by the immune system. In early-stage HER2+ breast cancers, the antibody trastuzumab (Herceptin) is administered intravenously periodically for one year. The antibody selectively binds to HER2 on breast cancer cells. Once bound, the Fc portion of the bound antibody signals the immune system, leading to the recruitment of immune cells and modulators to the tumor cell, leading to its destruction.

If the cancers are in a later stage or if tumor cells are found in lymph nodes, a variant of the anti-HER2 antibody can be given in which a chemotherapeutic drug is covalently attached to the antibody. The structure of the drug Ado-trastuzumab emtansine (T-DM1), trade name Kaycyla, is shown in Figure 28.3.27.

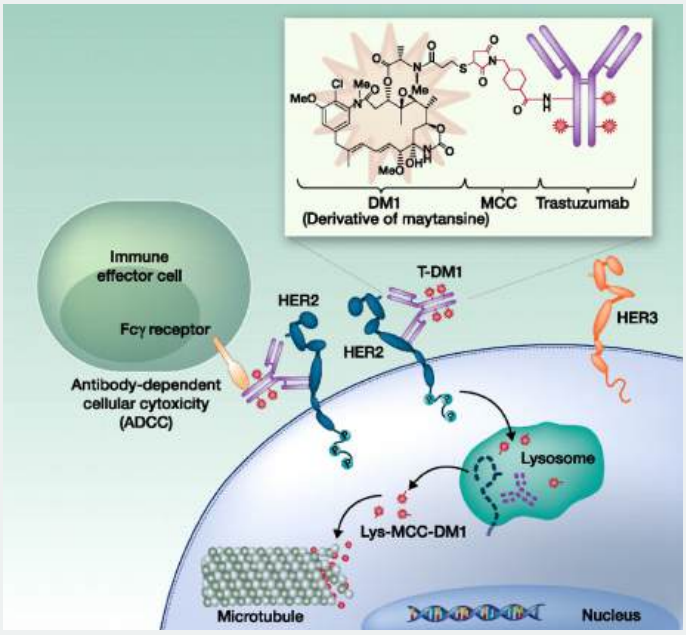

Figure 28.3.27: Ado-trastuzumab emtansine (T-DM1) and its interaction with HER2 positive turmor cells. Sadeghi et al. Pharmacogenomics and Personalized Medicine. 2014 Oct 15;7:329-38. doi: 10.2147/PGPM.S47524. Creative Commons Attribution – Non Commercial (unported, v3.0) License. http://creativecommons.org/licenses/by-nc/3.0/.

When the antibody-drug complex binds to the receptor on cancer cells, it is taken up into the cell. The antibody is degraded and the toxic drug is released into the cell sparing all other types of cells (only ones with the receptor on it are targeted). The released drug binds to microtubules comprising part of the internal cytoskeleton of the cell and prevents changes necessary for cell division. HER2 has a very low level of expression in noncancer cells so side effects can occur. However, these are much less server than traditional chemotherapy, which targets all dividing cells. The antibody acts as a homing device bringing the attached chemotherapy predominantly to tumor cells. It can be likened to a smart bomb or a cruise missile guided to just one target.

A better image of DMI and the linker connecting to the antibody is shown in Figure 28.3.28 The toxic chemotherapy drug is chemically linked to the antibody through a non-reducible thioether linker, N-succinimidyl-4-(N-maleimidomethyl) cyclohexane-1-carboxylate (SMCC).

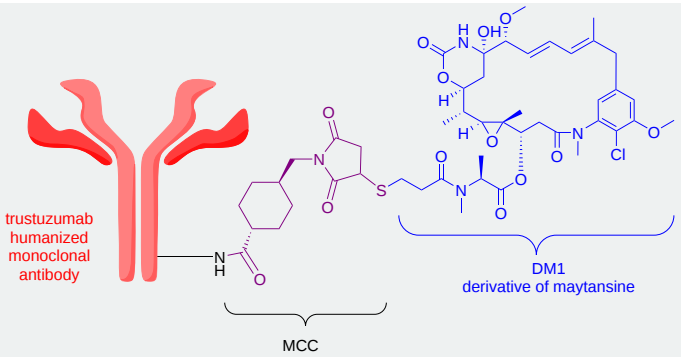

Figure 28.3.28: Ado-trastuzumab emtansine (T-DM1) conjugate used in HER2+ cancers

Figure 28.3.29shows a mechanism for the actual cross-linking reaction. The reaction of the maytansine derivative through its free thiol and the human antibody (trastuzumab) through a free amine should be readily understandable base on the reactions present in Chapter 2.

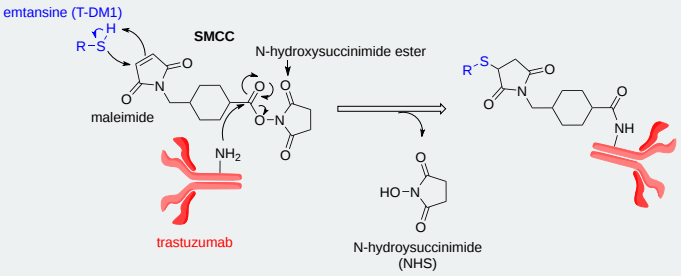

Figure 28.3.29: Cross linking reactions to connect emtansine and trastuzumab

The final linker after the departure of the N-hydroxysuccinimide is designated MCC.

The C-MET receptor, illustrated as an example in Figure 19, is an RTK involved in cell proliferation and survival, and as such, alterations in its expression can lead to cancer. Its mature form results from selective proteolysis by furin. Its physiological ligand is hepatocyte growth factor (HGF), a multisubunit protein in its mature form. It also binds a naturally occurring smaller splicing variant of HGF called NK1. The structure of C-MET bound to both HGF and NK1 has been solved. Binding of either lead to dimerization of the C-MET receptor, as illustrated in the cartoon representation of Figure 28.3.30

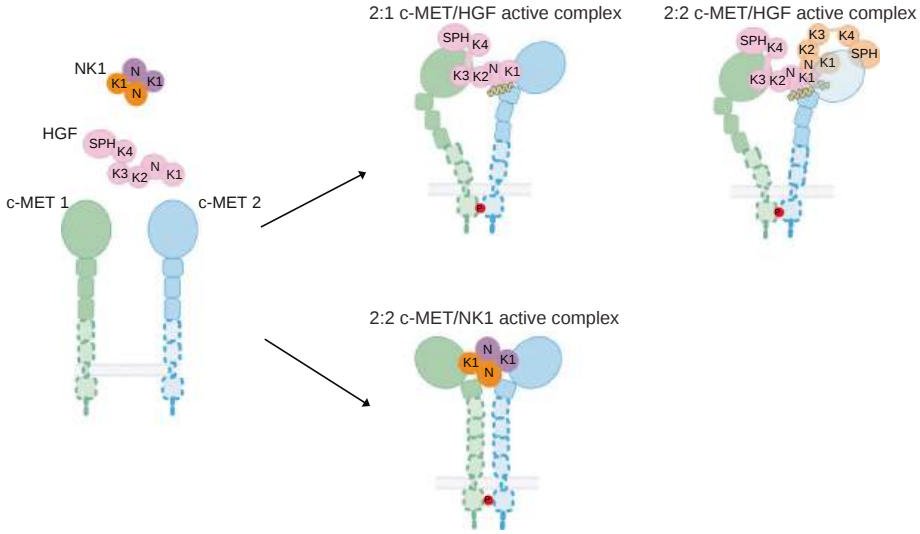

Figure 28.3.30: Cartoon representation of a working model for HGF and NK1-induced c-MET activation. HGF induces an asymmetric c-MET signaling complex, whereas NK1 induces a symmetric c-MET signaling complex. The bindings of a second HGF and heparin strengthen the 2:1 c-MET/HGF active complex. Uchikawa et al. Nature Communications (2021) 12:4074 | https://doi.org/10.1038/s41467-021-24367-3 . Creative Commons Attribution 4.0 International License, http://creativecommons.org/ licenses/by/4.0/.

The glycosaminoglycan heparin enhances c-MET activation by HGF. This is illustrated in Figure 30 above. Heparin binds between the N domain of HGF I and the IPT1 domain of c-MET II, facilitating the interactions between the two domains. In addition, a long enough heparin chain could bridge both HGF I and II, further strengthening the full complex. Structural representations of the c-MET:HGF asymmetric dimer are shown in cartoon form in Figure 28.3.31

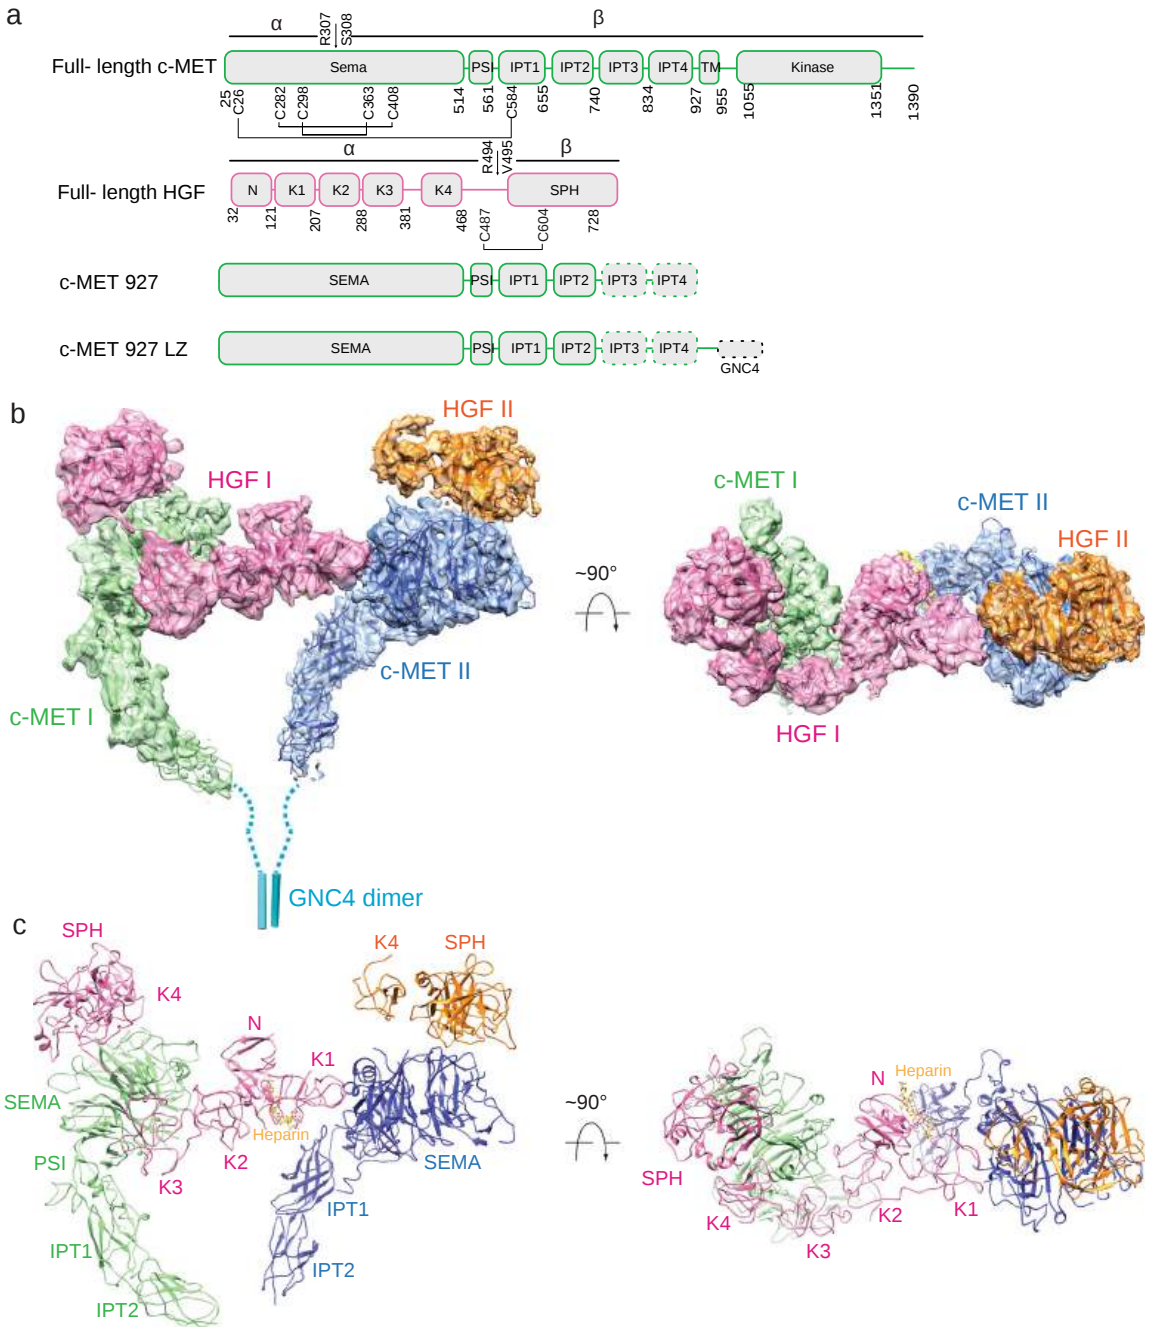

Figure 28.3.31: Overall structure of the c-MET/HGF holo-complex.

Panel (a) shows the domain structures of human c-MET and HGF. The proteolytic cleavage site of c-MET is located between Arg307 and Ser308. The proteolytic cleavage site of HGF is located between Arg494 and Val495. C-MET927-LZ and full-length HGF were used for structural determination in this study. The dash boxes indicate the domains that were unsolved in cryo-EM maps. Panel (b) shows the 3D reconstruction of the 2:2 c-MET/HGF holo-complex and the corresponding ribbon representation of this complex fitted into the cryo-EM map at 4.8 Å resolution, shown in two orthogonal views. Panel (c) shows the ribbon representation of the c-MET/HGF holo-complex shown in two orthogonal views

Figure 28.3.32 Shows the structure of the c-MET/NK1 symmetrical dimer.

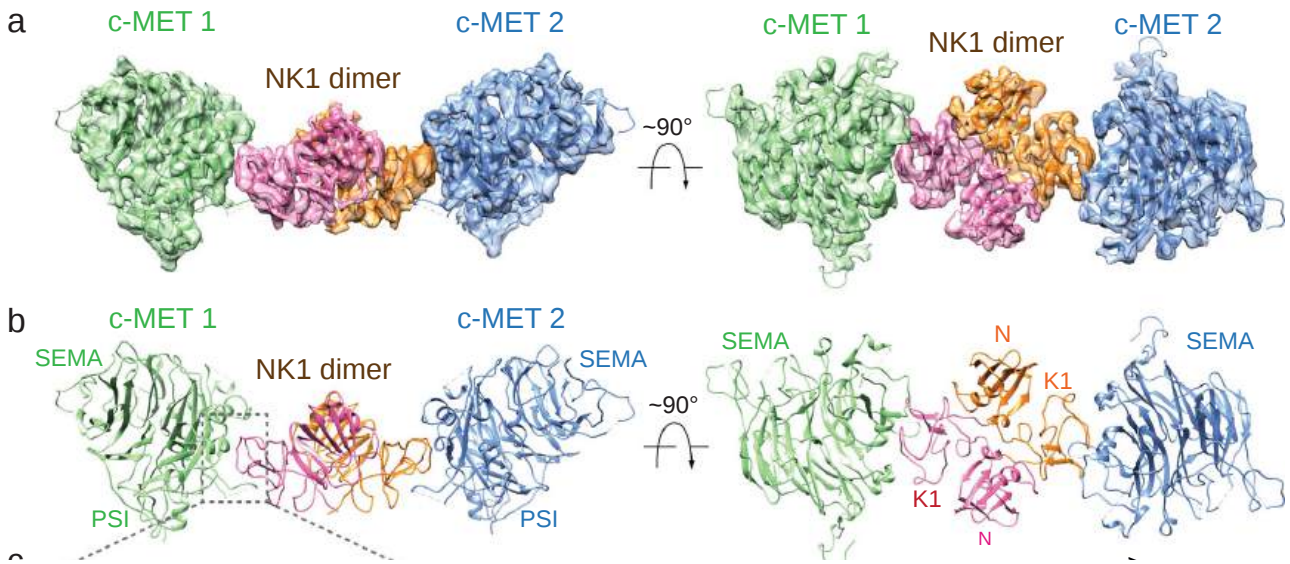

Figure 28.3.32: Overall structure of the c-MET/NK1 complex. a 3D reconstruction of the 2:2 c-MET/NK1 complex, and the corresponding ribbon representation of this complex fitted into the cryo-EM map at 5 Å resolution, shown in two orthogonal views. b The ribbon representation of the 2:2 c-MET/NK1 complex is shown in two orthogonal views.

Nuclear RTKs

What makes signal transduction so complicated yet interesting is the unexpected. It turns out that some RTKs (EGFR, VEGFR, FGFR, IR, and NGFR have been found in the nucleus. It's experimentally easy to localize proteins in cells using immunofluorescence microscopy. It's hard to determine their functions. ErbB-2 is one that is also found in the nucleus. Kinase inhibitors blocked the expression of ErbB-2 in the nucleus suggesting that its kinase activity is required for it to translocate to the nucleus. The structure of the membrane forms of ErbB-2, EGFR, and ErbB-3 appear to be the same as the structure of the nuclear forms.

The carboxy-terminal ends of EGFR and ErbB-4 can activate gene transcription as measured by the expression of luciferase (a fluorescent protein) reporter proteins. Hence they appear to act as transcription factors that bind DNA to promote gene expression. For example, nuclear EGFR increases the expression of cyclin D1 which drives progression through the cell cycle. ErbB-2 appears to activate transcription from the promoter of the gene for cyclooxygenase 2 (COX-2). The protein COX-2 leads to the synthesis of inflammatory prostaglandins. It also increases blood vessel growth and is dysregulated in tumors.

Since proteomic analysis of these growth factor receptors shows no DNA binding motifs or domains, they must promote gene transcription through binding to other protein transcription factors in the nucleus.

28.3.7: Back to AGC Kinase - AKT (Protein Kinase B)

We've just explored the:

- activation of Protein Kinase A (an AGC Kinase) through GPCR signaling, activation of the integral membrane protein adenylyl cyclase, production of the second messenger cAMP, which binds to inactive PKA and leads to its activation
- activation of Protein Kinase C, (an AGC Kinase) again through GPCR signaling, which leads to activation of the peripheral membrane protein phospholipase C, production of the second messengers DAG and IP3 from PIP_2, and activation of PKC at the membrane.
- activation of receptor tyrosine kinases (RTKs) leading to autophosphorylation of the cytoplasmic kinase domain, followed by recruitment of downstream signaling proteins through binding the phosphorylated RTKs through the downstream protein's SH2 domain

Now let's explore another AGC kinase called **AKT** or **protein kinase B (PKB)** that links signaling through RTKs to phosphoinositol-related signaling in a fashion similar to the link between phospholipase C and Protein Kinase C activities. In the process, we will introduce in this section our first nonprotein kinase involved in signaling. It's a **lipid** kinase called **phosphoinositide 3-kinase (P13K)** and it's very important.

Since Protein Kinase B is usually referred to as AKT, we will stick with that abbreviation. As with other AGC kinases, AKT is a Ser/Thr protein kinase. There are three variants, AKT1, AKT2, and AKT3. These are involved in metabolism, growth, and proliferation so they are key players in signaling. It is a key player in the uptake of glucose into cells as it regulates the translocation of the glucose transporter SLC2A4/GLUT4 to the cell surface in response to insulin.

You would expect aberrant expression of these would lead to cancer. The abbreviation AKT appears to derive from "a serine/threonine protein kinase encoded by the oncogene in the transforming retrovirus isolated from the thymoma cell line AKT-8, which is derived from the Stock A Strain k AKR".

As with Protein Kinase C as phospholipase C, AKT is recruited to the inner leaflet of membranes. Recruitment is mediated by its binding through its pleckstrin homology (PH) domain to phosphatidylinositol (3,4,5)-trisphosphate, a modified form of PIP_2, abbreviated either as PtdIns(3,4,5)P_3 or more simply as **PIP_3**. Note that PIP_2 has 3 phosphate groups while PIP_3 has 4.) The mechanism of membrane recruitment is similar to that of phospholipase C, which also binds membrane PIP_2 through its pleckstrin homology (PH). (This is in contrast to PKC which is recruited through its C1 and C2 domains.)

PIP_3 is generated in the membrane from PIP_2 by the enzyme **phosphoinositide 3-kinase (P13K)**, a **lipid** kinase, whose own activation occurs through stimulation of insulin and growth factors receptor tyrosine kinases (RTKs). Class 1 PI3K has a regulatory/adapter subunit (p85) and a 110 kDa catalytic subunit (p110). The regulatory subunit has SH2 domains which recruit it to autophosphorylated RTKs.

Figure 28.3.33 shows how membrane PIP_2 can be converted to the second messengers DAG and IP_3 by phospholipase C, or to PIP_3 by the enzyme phosphoinositide 3-kinase (P13K), which is a **lipid** kinase.

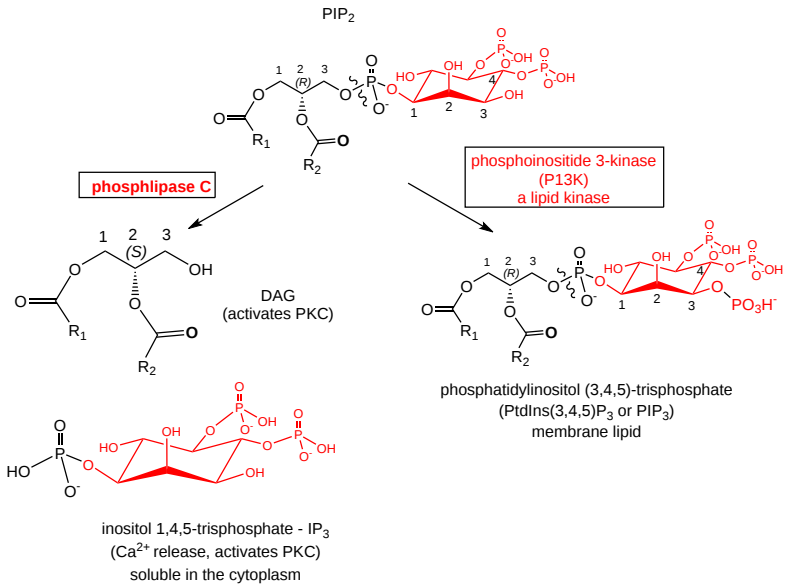

Figure 28.3.33: Conversion of membrane PIP_2 to the second messengers DAG and IP_3 by phospholipase C, or to PIP_3 by phosphoinositide 3-kinase (P13K)

The binding of AKT (PKB) to inner leaflet PIP_3 through its PH domain causes a conformational change that activates AKT for phosphorylation by **phosphoinositide-dependent kinase 1 (PDK1)** a membrane protein kinase. Once activated. AKT dissociates from the membrane and acts enzymatically in the cytosol and nucleus. The overall activation of AKT is shown in Figure 28.3.34

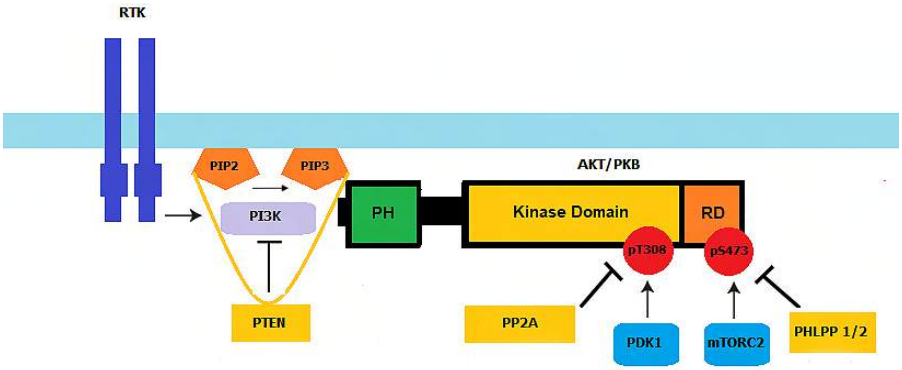

Figure 28.3.34: Activation of AKT through RTK signaling and PI3K activation https://commons.wikimedia.org/wiki/F...activation.png

.

The blunt arrows in the figure above show inhibition by the enzymes indicated. These (PTEN, PP2A, and PHLPP 1/2) are phosphatases.

- PTEN is lipid phosphatase (phosphatidylinositol 3,4,5-trisphosphate 3-phosphatase), which removes a phosphate from the lipid PIP_3.
- PP2A and PHLPP 1/2 are protein phosphatase that removes phosphates added by the kinase PDK1 in the kinase domain and mTORC2 in the C-terminal domain.

Figure 28.3.35shows an interactive iCn3D model of AKT bound to a novel allosteric inhibitor is shown below (3o96).

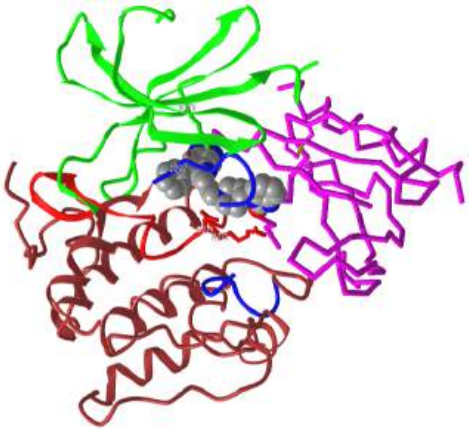

Figure 28.3.35: AKT bound to a novel allosteric inhibitor is shown below (3o96) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...wTWYdpU1Y5JnP9

The PH domain (at N-terminus, bind to PIP3) is shown in magenta, the N-lobe in green, and the C-lobe in brown. The activation loop is in dark blue and the catalytic loop is in red. The blue activation loop is shown in two parts as the interior part, which contains T305 (equivalent to T197 in AGC kinases without a PH domain) is too disordered to resolve. Table 28.3.1 shows the numbering of key amino acids and features of generic AGC kinase and the corresponding numbers in AKT. They are different since AKT has an N-terminal PH domain.

Table 28.3.1

SITE	Generic	Akt (+108)
N lobe	K72	K180
N lobe	E91	E199
C lobe, cat loop	R165	R273
C lobe, cat loop	D166	D274
C lobe, act loop	D184	D292

SITE	Generic	Akt (+108)
C lobe, act loop	T197	T308* missing in this structure)
Approx Cat Loop	163-179	271V—287H
Approx Act loop Start DFG (292-294) to APE	184-200	292-308 308Tmiss toAPE end 319

The allosteric inhibitor shown in the structure above is especially interesting in that it requires both the PH domain as well as the kinase domains for its effect.

Figure 28.3.36 shows an interactive iCn3D model of the structural overlap between the inactive form (shown above, 3o96 containing a bound allosteric inhibitor) with an active form of AKT(3cqw), which has a bound substrate (from glycogen synthase kinase-3 beta, yellow spacefill).

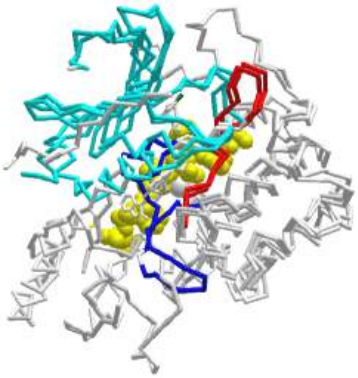

Figure 28.3.36: Alignment of inactive AKT (3o96 with bound allosteric inhibitor) and active AKT(3cqw with bound substrate) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...V2LbSdXLdTA9NA

The bound decapeptide substrate (GRPRTT**S**FAE) in the active form becomes phosphorylated on the **Ser** chain by active AKT. The N-lobe is shown in cyan, while the catalytic loop is in red and the activation loop is in blue. By pressing the "a" key you can toggle between the inactive 3o96 form and the active 3cqw forms. Note the large change in the blue activation loop.

Figure 28.3.37 below shows a series of coupled equilibria reactions that regulate the activity of AKT1.

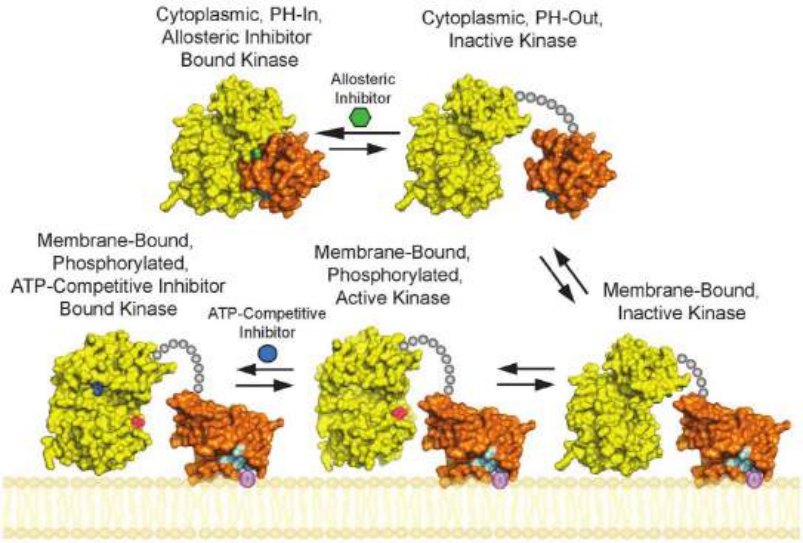

Figure 28.3.37: **Citation:** Wu W-I, Voegtli WC, Sturgis HL, Dizon FP, Vigers GPA, Brandhuber BJ (2010) Crystal Structure of Human AKT1 with an Allosteric Inhibitor Reveals a New Mode of Kinase Inhibition. PLoS ONE 5(9): e12913. https://doi.org/10.1371/journal.pone.0012913. This is an open-access article distributed under the terms of the Creative Commons Attribution License, which permits unrestricted use, distribution, and reproduction in any medium, provided the original author and source are credited.

The top part of the figure shows the cytoplasmic, nonmembrane-bound form of the enzyme. The PH domain is shown in orange. The top-right figure shows the inactive N- and C-lobes of the kinase loosely interacting with an "out" (or away) conformation of the PH domain with respect to the kinase domains. In the presence of the allosteric inhibitor (green hexagon, green bound ligand), the kinase domains tightly interact with the PH domain in the "in" conformation.

The bottom three structures show AKT bound to the membrane through the interaction of the PH domain with PIP3 (purple). The bottom right kinase domains are identical in representation to the two in the top part of the figure, showing that they are inactive. Only when bound to the membrane is AKT phosphorylated on Thr 308 (red in the bottom middle figure), which activates the enzyme. The bottom left and middle structures show the yellow kinase domains in a different conformation (3cqw), both of which are phosphorylated (red). The active form can bind ATP and protein substrates for phosphorylation. It can also bind ATP analogs which would competitively inhibit the active form of the enzyme by occupying the ATP binding site.

The activation loop in the inhibited form is missing part of its sequence which reflects its disorder. In this state, the loops partially occludes substrate interactions. On phosphorylation of Ser 308 in the activation loop, the loop adopts a different conformation which allows less restricted access to the active. The loop itself on phosphorylation has more local ordering as it shifts away from the active site as seen in the iCn3D model above. Another change decreases inhibitory noncovalent interactions of activation loop amino acids with catalytic residues, which increases catalytic efficiency. In summary, these two types of changes in the activation loop lead to more access by substrates and enhanced catalysis of bound substrates.

Additional regulation of the kinase occurs through the PH domain which adds additional conditions on Akt conformational changes and subsequent activity. The PH domain "appears to lock the kinase in an inactive conformation and the kinase domain disrupts the phospholipid binding site of the PH domain".

Figure 28.3.38 shows an interactive iCn3D model of the separate AKT Pleckstrin Homology (PH) domain bound to the inner member through just the head group of PIP3 (inositol (1,3,4,5)-tetrakisphosphate) (1unq). Waters H bonded to the ligands is not shown.

28.4: The next step - Downsteam intracellular signaling

28.4.1: Intracellular signaling from activated PKA and PKC

We discussed the basics of the activation of the protein kinase A holoenzyme (R_4C_4) by cAMP binding to the regulatory subunit, which frees the catalytic subunit C for activity. Likewise, we discussed the activation of PKC at the cell membrane by DAG, Ca^{2+} ions, and phosphorylation of key Ser/Thr in the protein. Where in the cell are the downstream protein targets of activated PKA and PKC? This is a much simpler question for RTKs since downstream signaling proteins come to them through the interaction of their SH2 domains with the autophosphorylated RTKs. For activated PKA and PKC, it turns out that their location is controlled by **scaffolding proteins**, which bind them either before their activation or after.

Let's discuss a particularly important scaffolding protein, the **A-kinase-anchoring protein (AKAP)**. There are 13 classes of these containing 50 different members. These proteins bind PKA through its regulatory subunit, where cAMP can mediate the activation of the holoenzyme (R_4C_4). In addition, AKAPs can bind other signaling proteins including PKC and phosphatases, the latter of which in turn counter-regulate signaling by phosphoproteins. For example, the bound phosphatases can dephosphorylate PKC to deactivate it as well as other downstream phosphoproteins. AKAPs can also bind phosphodiesterase, the enzyme that converts cAMP to AMP, returning signaling to baseline levels. AKAPs localize key signaling enzymes to sites where biologically appropriate protein targets are localized. In addition, they decrease indiscriminate phosphorylation of other off-target proteins elsewhere in the cell. They may also allosterically regulate the activity of bound signaling proteins.

There are at least 50 **A-kinase anchoring proteins** or **A-kinase anchor proteins** (**AKAPs**) that bind the regulatory subunit of protein kinase A (PKA) and localize PKA to specific sites in the cell. By binding multiple signaling enzymes at specific sites, they integrate signaling pathways mediated by cAMP (for example) with others mediated by PKC (again for example).

Here are some examples of AKAPs in humans (from UniProt). Note that one (12) also binds PKC

- **1, mitochondrial:** Binds to type I and II regulatory subunits of protein kinase A and anchors them to the cytoplasmic face of the mitochondrial outer membrane;
- **6:** Binds to type II regulatory subunits of protein kinase A and anchors/targets them to the nuclear membrane or sarcoplasmic reticulum;
- **7 isoforms alpha and beta:** Targets the cAMP-dependent protein kinase (PKA) to the plasma membrane, and permits functional coupling to the L-type calcium channel;
- **7 isoform gamma:** targets cAMP-dependent protein kinase (PKA) to the cellular membrane or cytoskeletal structures;
- **8:** Acts as an anchor for a PKA-signaling complex onto mitotic chromosomes, which is required for the maintenance of chromosomes in a condensed form throughout mitosis;
- **8-like:** Required for cell cycle G2/M transition and histone deacetylation during mitosis and recruitment of signaling enzymes into the nucleus;
- **9:** assembles several protein kinases and phosphatases on the centrosome and Golgi apparatus;
- **12:** Anchoring protein that mediates the subcellular compartmentation of protein kinase A (PKA) and protein kinase C (PKC)
- **17A:** Splice factor regulating alternative splice site selection for certain mRNA precursors. Mediates the regulation of pre-mRNA splicing in a PKA-dependent manner.

Figure 28.4.1 illustrates the localization/binding of signaling enzyme (PKA, PKA substrates, PDE, other kinases) to AKAPs.

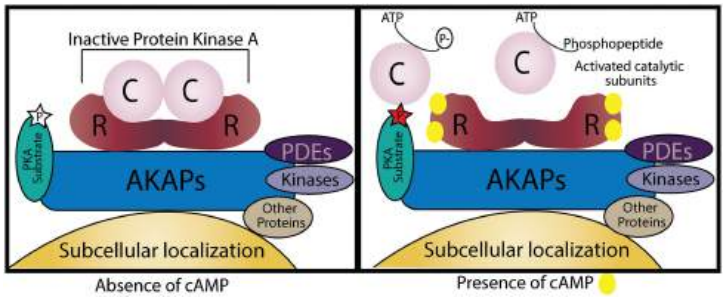

Figure 28.4.1: Localization/binding of signaling enzyme (PKA, PKA substrates, PDE, other kinases). Calejo et al. Frontiers in Pharmacology 6:192 (2015) DOI: 10.3389/fphar.2015.00192. License CC BY 4.0

Note that some AKAPs can also bind PKA substrates, facilitating their phosphorylation and minimizing the phosphorylation of the wrong targets.

AKAPs use an amphiphilic helix to interact with the R_2 regulatory dimer of the PKA. Some AKAPs bind to just one of the regulatory subunits. Note that some AKAPs can also bind PKA substrates, facilitating their phosphorylation and minimizing the phosphorylation of the wrong targets.

Figure 28.4.2 shows specific AKAP complexes in the heart that could be targeted for drug therapies.

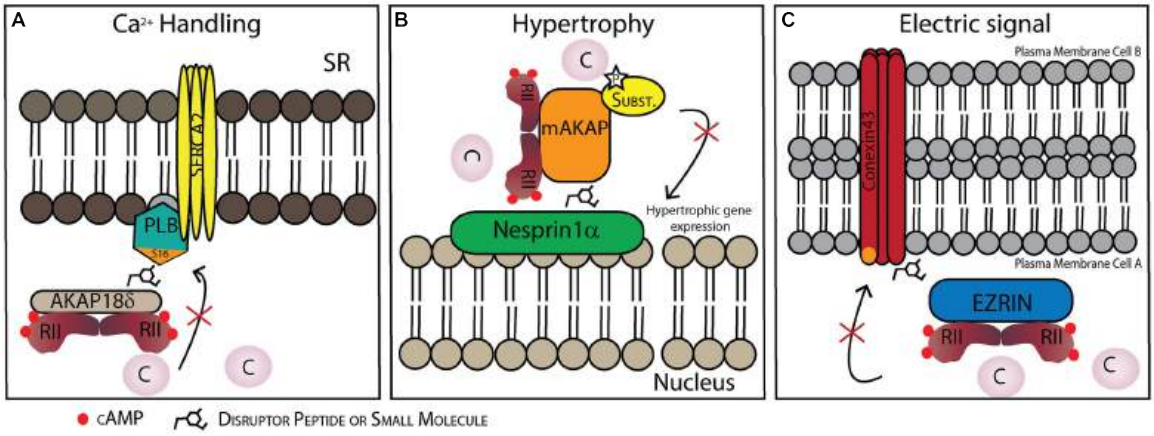

Figure 28.4.2: AKAP complexes in the heart.

Panel (A): Disruption of the AKAP18γ/δ-PLB (another phospholipase involved in signaling) interaction prevents PLB phosphorylation on Ser16 and dislocation from SERCA2 **(Sarcoplasmic/endoplasmic reticulum calcium ATPase 2)**. This inhibits SERCA2 activation and consequently Ca^{2+} uptake into the sarcoplasmic reticulum

Panel (B): Disruption of the nesprin-1α /mAKAP interaction promotes AKAP/PKA complex dissociation from the perinuclear membrane and might be a strategy to reduce hypertrophy. Nesprin 1 is a protein that forms a linking network between organelles and the actin cytoskeleton to maintain the subcellular spatial organization.

Panel (C): Disruption of the connexin 43-ezrin interaction could prevent PKA-mediated phosphorylation increasing inter-cardiomyocyte conductivity which could be cardioprotective following myocardial infarction damage. Connexin is a gap junction protein. Ezrin is involved in the connections of major cytoskeletal structures to the plasma membrane.

To add to the complexity of PKA activation and signaling, there are different forms of the regulatory subunits of the holoenzyme PKA. These include RIalpha (RIA), RIbeta (RIB), RIIalpha (RIIA), and RIIbeta (RIIB). They have different affinities for cAMP, the catalytic subunits Cs, and different AKAPs.

Figure 28.4.3 shows an interactive iCn3D model of the amphiphilic anchoring peptide AKAP-IS for AKAP binding to the docking and dimerization (D/D) domain of the RIIalpha regulatory subunit of PKA (2IZX)

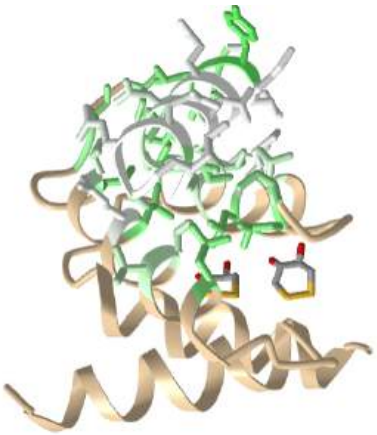

Figure 28.4.3: Amphiphilic anchoring peptide AKAP-IS for AKAP binding to the docking and dimerization (D/D) domain of the RIIalpha regulatory subunit of PKA (2IZX) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...pWKiYgQeGA32e6

The brown represents the RII dimer D/D domains of the regulatory subunit. The anchoring peptide AKAP-IS is shown in gray. In both, the side chains involved in binding of the peptide to the regulatory subunit domains are shown as sticks and colored coded based on the hydrophobicity of the side chains. Green indicates the most hydrophobic. Rotate the model carefully to differentiate the side chains and note that the hydrophobic face of the peptide is interacting with hydrophobic side chains projecting into a groove made by the two RII dimer D/D domains. Polar side chains in AKAP help target the correct isoform of the R subunit.

In addition to binding to some AKAP scaffolds, PKC also binds to **Receptors for Activated C-Kinases (RACKs)**, heat shock proteins (HSP), importing, and annexins (AnxA1, A2, A5, and A6). The interactions of activated PKC with RACK1 and downstream events are shown in Figure 28.4.4

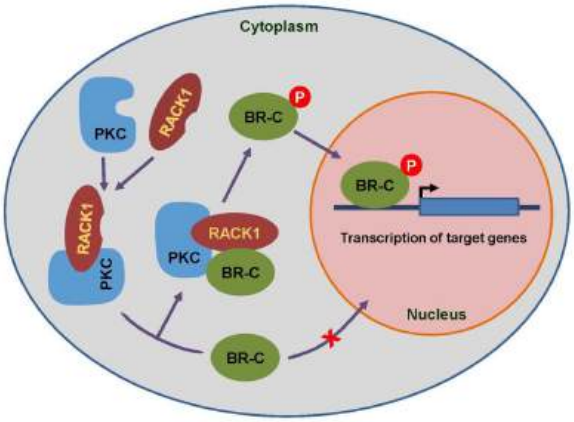

Figure 28.4.4: Interactions of PKC with RACK1 and downstream signaling. Meng et al. PLoS ONE · (2014) DOI: 10.1371/journal.pone.0109111. Creative Commons Attribution License - https://creativecommons.org/licenses/by/4.0/

The insect protein BR-C (Broad Complex) has a DNA binding domain (two zinc fingers) domain for the activation of gene transcription and a BTB) domain that allows binding to RACK1. On binding the PKC:RACK1 complex, BR-C is phosphorylated at Ser373 and Thr406, after which it is translocated into the nucleus where it binds DNA and activates gene transcription

The binding of PKC to RACK1 stabilizes PKC for the phosphorylation of targets. PKC binds to RACK through its C2 regulatory domains. Binding may be to specific forms of PKC including unphosphorylated, inactive, and activated phosphorylated forms, as well as to specific isozymes of PKC. RACK1 may also recruit PKC to the ribosome and it inhibits the activity of SRC kinases which we will discuss later. PKC activity occurs in many cellular locations, including the cell membrane, nucleus, Golgi apparatus, mitochondria, and cytosol. RACKS also bind and recruit other signaling proteins including PLCγ, Src, and integrins. In addition to interactions of PKC with RACK through the C2 domain, PKC can localize through its C1 domain.

Structure of RACK1

RACK1 (317 amino acids) has a very interesting structure. It is a member of a family of over 100 proteins that have tryptophan-aspartate (WD) repeats that are 44-60 amino acids and ending in WD or a variant. It is homologous to the beta subunit of the

heterodimeric Gαβγ signaling protein. RACK 1 interacts with proteins through a 7-bladed propeller structure that allow the binding of proteins with SH2 domains, plextrin homology (PH) domains, and C2 domains (PKCs). Figure 28.4.5 shows the WD repeats in human RACK1. Note that the N-terminal end of the WD repeat often is glycine-histidine (GH).

28.4.2: Downstream signaling from activated receptor tyrosine kinases

To review once again, when receptor tyrosine kinases get activated by binding a primary messenger such as a growth factor, the receptors dimerize, activating their cytoplasmic kinase domains. The activated RTK then autophosphorylates itself. The phosphorylated intracellular domain provides a docking site for other cellular "adaptor" proteins that contain an SH2 domain. The bound adaptor protein binds other signaling molecules within the cell leading to downstream propagation of the signal. Figure 28.4.8 shows some RTKs and downstream signaling events. We have already discussed the activation of the lipid kinase phosphoinositide 3-kinase (P13K) which leads to the activation of Akt (PKB). In the rest of this section, we will focus on the next step after the activation of RTKs. We focus on the epidermal growth factor receptor (EGFR, ErbB1) again.

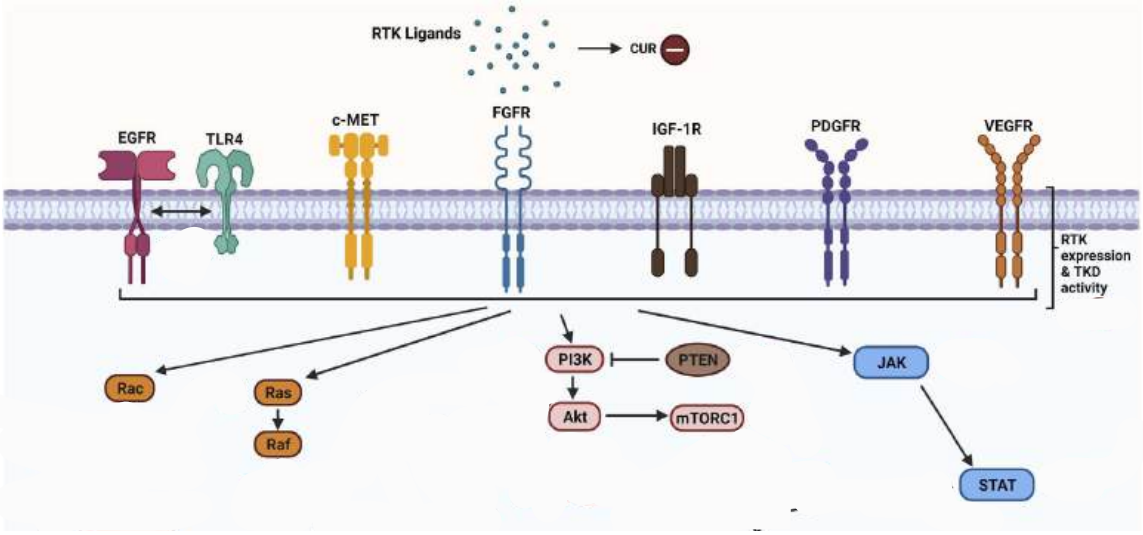

Figure 28.4.8: Some RTKs and downstream signaling events Dev et al. Frontiers in Pharmacology, 12 (2021). https://www.frontiersin.org/article/...ar.2021.772510. DOI=10.3389/fphar.2021.772510. **Creative Commons Attribution License (CC BY).**

1. Downstream signaling from the epidermal growth factor receptor.

Figure 28.4.9 shows events associated with the activation of EGFR.

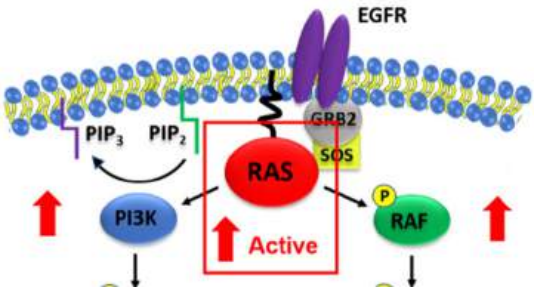

Figure 28.4.9: Near downstream signaling molecules after activation of EGFR

Once bound and activated by binding of growth factors protein signals, the intracellular domains of the now dimeric EGFR autophosphorylates themselves on selected tyrosine side chains. This then recruits a protein called **Growth factor receptor-bound protein 2 (GRB2)**, which has an **SH2 (Sarc Homology 2)** domain that binds phosphotyrosine motifs in proteins. GRB2 acts as an adaptor protein in that in addition to the SH2 domain, it has two **SH3 (Sarc Homology 3)** domains that bind **proline-rich domains** on other signaling proteins, including the protein **Son of sevenless homolog (SOS)**. GRB2 does not have enzymatic activity.

The adaptor protein GRB2 binds through its SH3 domain to the protein SOS, which then interacts with the protein Ras. This last member in the recruited complex is named because it causes **Ra**t **S**arcomas. There are many variants of these proteins but three are key in humans, HRas, KRas, and NRas. Ras is perhaps the key member of the family of intracellular small G proteins that bind GDP/GTP and are activated on the exchange of GTP for GDP. The proteins also have intrinsic GTPase activity as is found in the G_α protein of the heterotrimeric Gαβγ protein.
