So what does SOS do? The SOS bound to RAS facilitates the exchange of GTP for GDP on Ras, maintaining it in an active state. SOS is a member of another fascinating class of small proteins that catalyze the exchange of GTP for GDP. The family of GTP/GDP exchange proteins is called **Guanine nucleotide Exchange Factors (GEFs)**. We will explore this in the next section.

The EGFR -GRB2-SOS-Ras complex in the figure above looks somewhat similar to the structure of a GPCR-heterotrimeric G protein $G_\alpha G_\beta G_\gamma$ complex, where G_α is also a GTP/GDP exchange protein with intrinsic GTPase activity. When the ligand binds to the GPCR, a conformational change ensues which facilitates the exchange of GTP for GDP on the G_α protein, activating intracellular signaling.

Once RAS is activated (bound to GTP), it binds and activates key kinases in the cell, including the lipid kinase PI3K and **RAF**, a kinase shown in Figure 28.4.8 Control of RAS activity is critical in signaling. It is one of the most commonly mutated proteins in cancer cells. Mutations that inhibit the intrinsic GTPase activity keep the protein active, leading to unregulated cell growth, proliferation, and differentiation, hallmarks of cancer cells.

The domain structures of GRB2 and SOS are shown in Figure 28.4.10 The proline-rich domain (motif) is not shown in the figure.

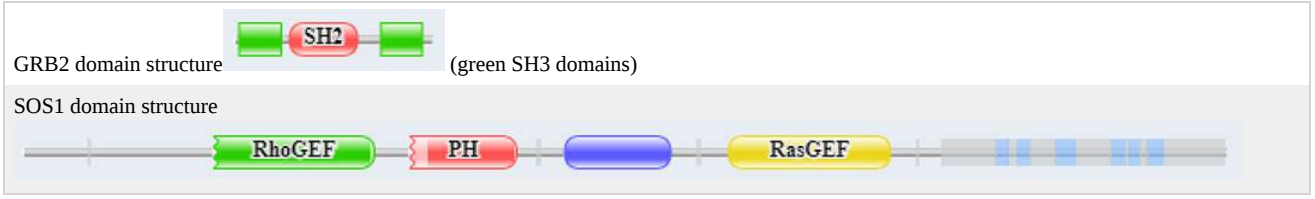

Figure 28.4.10 Domain structure of GRB2 and SOS1 (proline rich domain not shown in SOS)

Note

As we discussed in Chapter xx (domains), new genes encoding proteins with new functionalities can be created by duplicating and adding gene segments for different domains in a preexisting gene. As we have seen with the SH2 and SH3 domains, signaling proteins often share common domains. Table 28.4.1 below, adapted from the excellent book Cell Signaling by Lim, Mayer, and Pawson, shows some common domains found in signaling proteins.

Domains in Signaling Molecules

Domain	Binding Target	Cellular Process	Example protein	Pdb file (examples) Find your own in the PDB

Bromo	Acetyl-Lys	Chromatin reg.	BRD4	2YYN
C1	diacylglycerol	Plasma membrane recruitment	Raf-1	3OMV
C2	Phospholipid (Ca-dependent)	Membrane targeting, vesicle trafficking	PRKCA	3IW4
CARD	Homotypic Interactions	apoptosis	CRADD	3CRD
Chromo	Methyl-Lys	Chromo reg, gene transcription	CBX1	3F2U
Death (DD)	Homotypic inter.	Apoptosis	Fas	3EZQ
DED	Homotypic inter.	Apoptosis	Caspase 8	1F9E
DEP	Memb, GPCRs	Sig trans, protein trafficking	Dsh human disheveled 2	2REY
GRIP	Arf/Art G prot	Golgi traffic	Golgin-97 (Golga5)	1R4A
PDZ	C-term peptide motifs	Diverse, scaffolding	PSD-95 Or discs large homolog 4	1L6O
PH	Phospholipids	Membrane recruirtment	Akt	1O6L 3CQW
PTB	Phospho-Y	Y kinase signaling	Shc 1 SHC-transforming protein 1	1UEF 1irs
RGS	GTP binding pocket of Galpha	Sig trans	RGS4	1EZT
SH2	Phospho-Y	pY-signaling	Src	4U5W
SH3	Pro-rich sequence	Diverse, cytoskeleton	Src	2PTK

TRAF	TNF signaling	Cell survival	TRAF-1	3ZJB
VHL	hydroxyPro	ubiquitinylation	VHL	1VCB

Figure 28.4.11 shows an interactive iCn3D model of the GRB2-SH2 domain in complex with a high affinity phosphopeptide KPFpYVNVEF (1BMB)

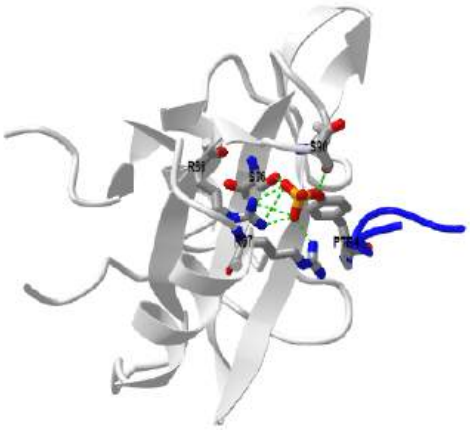

Figure 28.4.11: GRB2-SH2 domain in complex with a high-affinity phosphopeptide KPFpYVNVEF (1BMB) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...gBEpnsN6D8yrR6

Grb2 exists in both a monomeric state which can bind SOS, and a dimeric state which can't. You would expect the equilibrium between the monomer and dimeric form would be highly regulated. When a phospho-tyrosine ligand is bound to Grb2 through its SH2 domain, the dimer dissociated. This also occurs on phosphorylation of tyrosine 160 (Y160) on Grb2, a post-translational modification found in human prostate, colon, and breast cancers.

Figure 28.4.12shows an interactive iCn3D model of the GRB2 N-terminal SH3 domain complexed with a ten-residue proline-rich peptide (1135 Ac-VPPPVPPRRR-NH_2) derived from SOS (1GBQ)

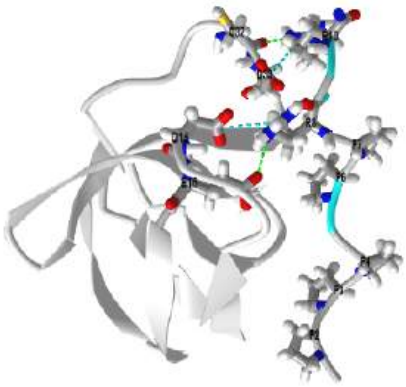

Figure 28.4.12: GRB2 N-terminal SH3 domain complexed with a ten-residue proline-rich peptide (derived from SOS (1GBQ). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...k2jNGaHexaUmT8

We will explore interactive structures of the small G protein Ras with the guanine nucleotide exchange factor SOS in the next chapter section.

After activation of Ras through GTP exchange for GDP, the GTP-Ras protein binds to and activates the kinase Raf. We will continue our exploration of that later in this section.

2. Downstream signaling from the insulin receptor.

When insulin binds to the receptor tyrosine kinase (RTK), it phosphorylates itself, which then leads to the binding of other proteins to the activated receptor and their phosphorylation. These lead to more intracellular signaling and ultimately changes in gene transcription. We'll focus on a specific adaptor protein, the **Insulin Receptor Substrate 1, IRS1,** a "scaffolding protein", which leads to the movement of the glucose transport protein **GLUT4** to the cell surface, allowing glucose uptake. These activities are shown schematically in Figure 28.4.13

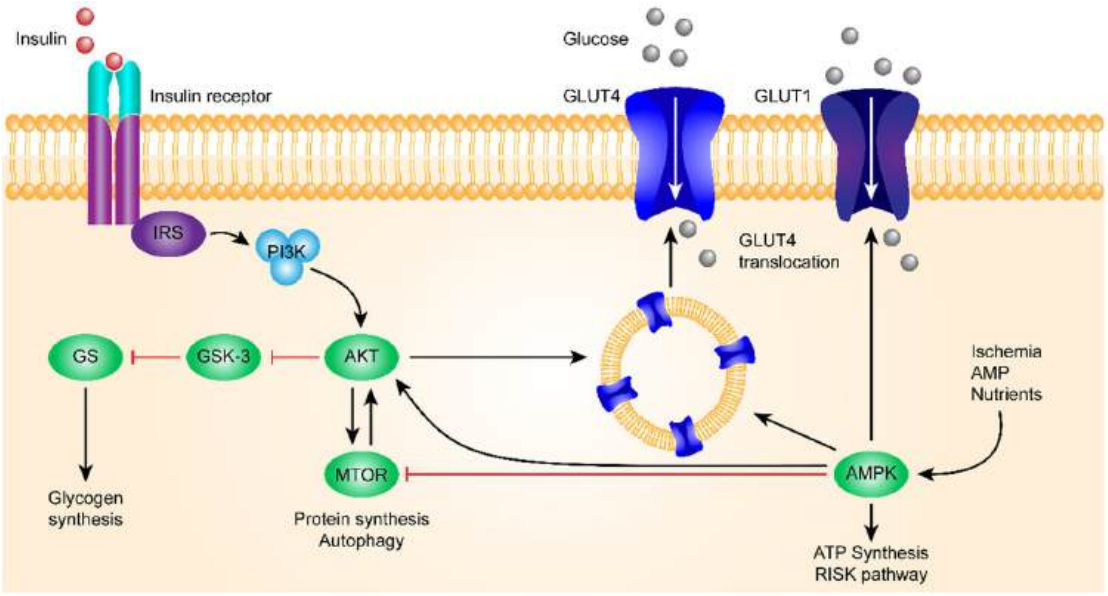

Figure 28.4.13: Binding to insulin stimulates the association of the receptor with downstream mediators, including insulin receptor substrate-1 (IRS-1) and PI3K. The insulin receptor can activate PI3K either directly, by binding to the p85 regulatory subunit, which produces PIP3, or indirectly, which leads to phosphorylation and the activation of AKT. Afterward, AKT phosphorylates the Ser9 site of GSK-3β and inhibits its activity. The PI3K/AKT/GSK-3β signaling pathway is involved in insulin signaling transduction, and GSK- 3β is regulated and controlled by insulin in this signaling pathway. Arneth et al. Int. J. Mol. Sci. 2019, 20, 2467; doi:10.3390/ijms20102467. Creative Commons Attribution (CC BY) license (http://creativecommons.org/licenses/by/4.0/).

Human IRS1 has two domains, a PH domain for binding to membranes through phosphorylated IP2 derivatives and an **IRS/PTB** domain which binds phosphotyrosines on proteins. The PTB and the SH2 domains are the most common domains for binding phosphotyrosines on proteins. PTB binds the NPXY, where X is a pTyr.

We show a more detailed view in Figure 28.4.14 in part, to review many of the signaling proteins we have seen before, including PI3K and PDK1.

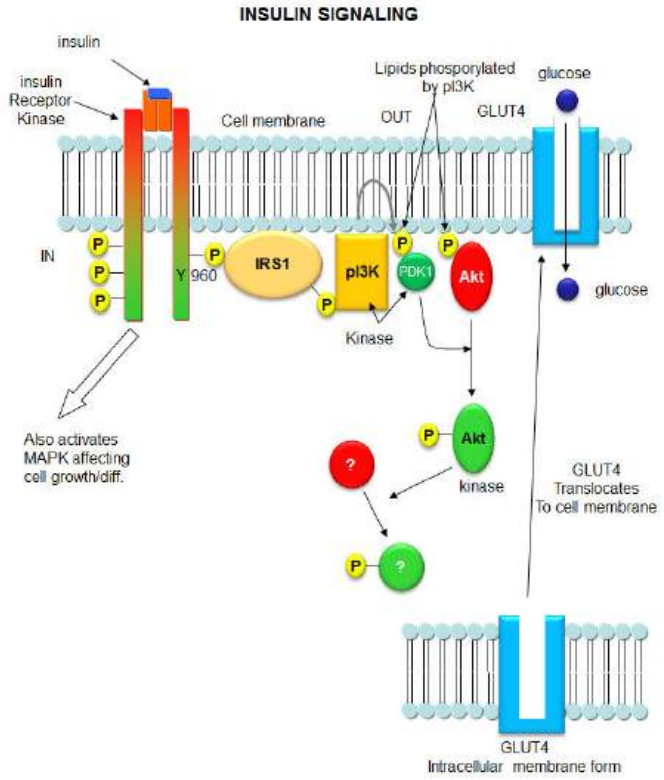

Figure 28.4.14: A more detailed view of the insulin receptor-mediated translocation of GLUT4 to the membrane.

Likewise, another review of PIP2 derivatives is warranted. After phosphorylation by the activated insulin receptor protein tyrosine kinase, IRS-1 binds phosphatidylinositol 3-kinase (PI3K) that causes phosphorylation of the 3'OH on phosphatidyl inositol (PI) in the inner leaflet of the membrane to form PI(3)P. PI3K is a member of a family of kinases that phosphorylates PIP2. The metabolic pathway centered on pI3K is one of the most mutated in human cancers. PI(3)P in turn recruits to the membrane other inactive kinases, phosphoinositide-dependent kinase 1, PDK1, and Akt, also known as PKB. Figure 28.4.15 shows phosphorylated phosphatidylinositol derivatives.

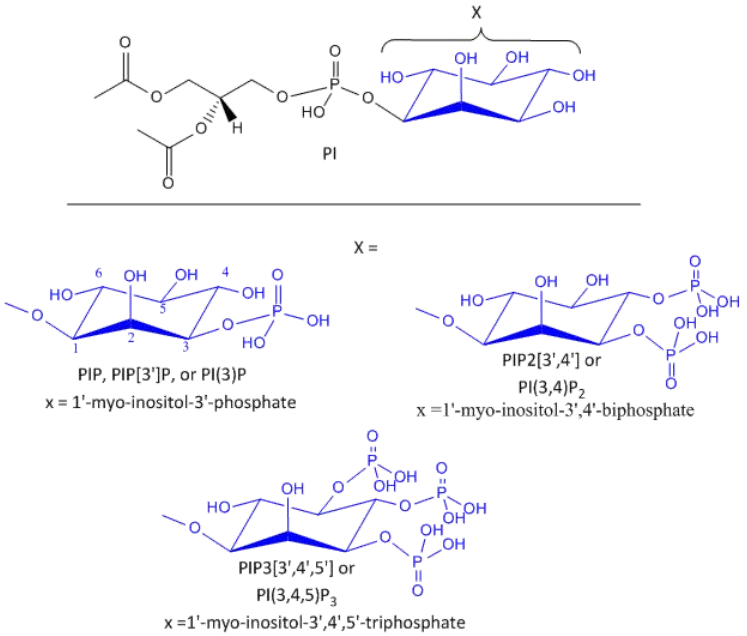

Figure 28.4.15: Phosphorylated phosphatidylinositol derivatives

On binding of PI(3)P, PDK1 becomes an active kinase, which phosphorylates and activates Akt. Akt kinases are major Ser/Thr protein kinase that phosphorylates proteins involved in a host of cell activities, including regulation of glucose transport, cell proliferation, and death. In the insulin signaling pathway, active (phosphorylated) Akt leads to the movement of the GLUT4 protein from intracellular endosomal vesicles to the cell surface, which offers a quicker way to import glucose into the cell than if Akt activated GLUT 4 gene expression. PDK1 phosphorylation of Akt2-T309 is required for insulin-stimulated Glut4 translocation. If T309 is mutated to A309 or if PDK1 is inhibited, GLUT 4 is not translocated to the cell membrane.

Figure 28.4.16 shows an interactive iCn3D model of the activated insulin receptor tyrosine kinase in complex with peptide substrate and ATP analog (1IR3))

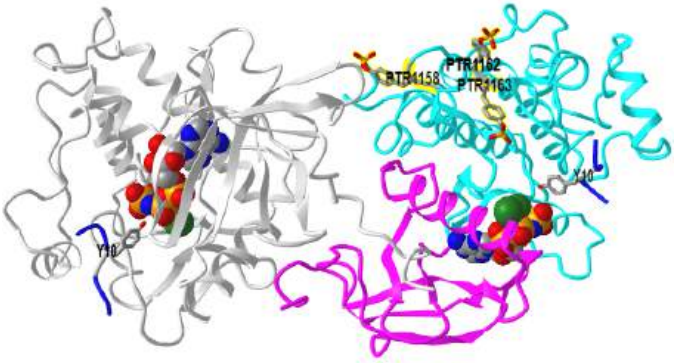

Figure 28.4.16: Activated insulin receptor tyrosine kinase in complex with peptide substrate and ATP analog (1IR3). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...j11LhWKCUnreV9

The dimeric form of the kinase is shown. ANP is shown in spacefill. The peptide substrate containing the interior tyrosine (stick) for phosphorylation is shown in blue. Three key tyrosines in the activation loop that are autophosphorylated (Tyr1158, Tyr1162, and Tyr1163) are shown and labeled in the right-hand monomer.

As with a protein kinase, the activation loop of the insulin receptor kinase domain is phosphorylated and the resulting conformational change allows ATP and target protein access. The activation loop gets phosphorylated on Tyr1158, Tyr1162, and Tyr1163 with Y1163 being key.

28.4.3: Downstream signaling from Cytokine activated Receptors- The JAK/STAT pathway.

Now we explore two signaling pathways mediated by the adaptor protein JAK and STAT. These are abbreviations for the Janus Kinase (JAK) and the Signal Transducer and Activator of Transcription (STAT). These play key roles in embryonic development, stem cell maintenance, hematopoiesis (formation of blood cells), and immune cell signaling. . This pathway is stimulated by cytokines and interleukins, protein modulators released by immune cells, as well as growth factors.

In general, there are five groups of cytokines:

- tumor necrosis factor alpha (TNF-alpha)
- Interleukin-1 family members (IL-1_
- Transforming growth factor-beta (TGF-bet)
- those that signal through RTKs (such as macrophage colony-stimulating factor (M-CSF)
- Chemokines
- cytokines that signal through JAK/STAT

In contrast to RTKs, which have kinase domains activated on receptor dimerization, cytokine receptors that work through JAK/STAT do **NOT** have kinase domains. On cytokine binding to their target cytokine receptor, the now-activated receptors activate the prebound inactive Janus kinase through conformational changes. The kinase domains autophosphorylate themselves in a trans fashion. The active kinase then phosphorylates the cytoplasmic tails of the cytokine receptors. This trigger further signal transduction reactions mediated by the binding of target signaling proteins to the cytoplasmic region of the phosphorylated cytokine receptor. Just to reiterate, the cytokine receptor is NOT a RTK with latent kinase activity. Instead, it becomes phosphorylated by the bound and cytokine-activated JAK. A portion of the pathway is illustrated in Figure 28.4.17.

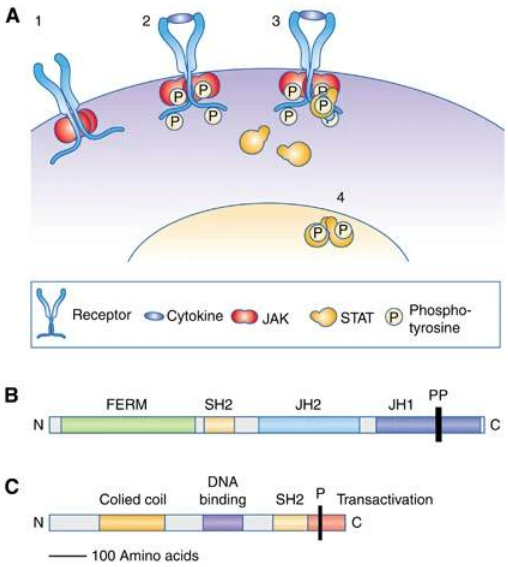

Figure 28.4.17: An overview of the JAK/STAT signaling pathway (A) and the domain structures of JAK (B) and STAT (C). Thomas *et al.* T*Br J Cancer* **113,** 365–371 (2015). https://doi.org/10.1038/bjc.2015.233. Creative Commons Attribution-Non-Commercial-Share Alike 4.0 International License. To view a copy of this license, visit http://creativecommons.org/licenses/by-nc-sa/4.0/

Panel (A1) shows that the kinase JAK is bound constitutively in an inactive state to the cytokine receptor cytoplasmic region, not through its SH2 domain, but through its FERM domain (Panel B). The figure implies the cytokine receptor is dimeric in the absence of a ligand. On cytokine binding, conformational changes and repositioning of the bound JAK activates its kinase domain, which phosphorylated the C-terminal tails of the cytokine receptor. STAT monomers, through their SH2 domains, bind to the phosphorylated cytokine receptor where they get phosphorylated by the active JAK. The phospho-STAT monomers form a dimer, dissociate from the complex, and translocate to the nucleus where they act as transcription factors. the Janus kinase is named after Janus, the two-faced Roman god of beginnings, endings, and duality since JAK has two nearly identical JH kinase domains. One has kinase activity while the other inhibits the first.

Panels (**B**) shows the domain structure of JAK. The FERM domain facilitates JAK:cytokine receptor binding. The JH2 pseudokinase domain regulates the kinase activity of the JH1 kinase domain. Ps show site on JAK necessary for activation

Panel (**C**) shows the domain structure of STAT. The SH2 domain binds phosphorylated tyrosines. The carboxy terminus transactivation domain is required for full transcriptional activation. P marks the conserved tyrosine residue whose phosphorylation is essential for STAT activation.

The pseudokinase domain of JAK interacts with the kinase domain on the same chain and prevents its activity in the inactive monomer and dimer. Cytokine binding to the cytokine receptor induces a conformational change that promotes the interactions of the pseudokinase domain on one JAK monomer with the same domain on another, promoting dimerization and freeing the kinase domains for activity. Figure 28.4.18shows the pseudokinase domain (orange) interactions in the active JAK dimer.

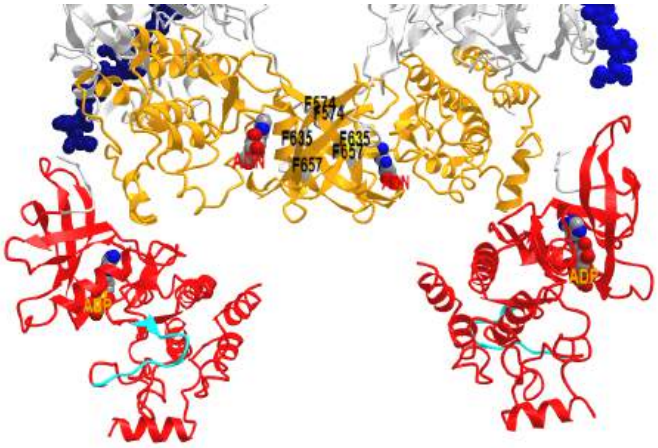

Figure 28.4.18 The pseudokinase domain (orange) interactions in the active JAK dimer.

The kinase domain of each dimer is shown in red and the pseudokinase domain is shown in orange. The activation loop (cyan) and ADP (spacefill, CPK colors) are shown in the red kinase domains. The orange pseudokinase domain has a bound adenosine (not ADP) that is shown spacefill and CPK color. However, it lacks the
DFG motif required for catalysis. The phenylalanine cluster (F635, 657, 574) are labeled. The structure is actually for a mutant that has the V657F mutation that promotes dimerization and JAK activity. Hence the V657F mutation is oncogenic.

JAK activity can be inhibited by the protein suppressor of cytokine signaling **(**SOCS). Transcription of the protein is activated by STAT, and the SOCS protein in a feedback inhibition loop binds to JAKs and also to IFNGR1, which inhibit JAK activity.

Figure 28.4.19 shows an interactive iCn3D model of the structure of the inhibitory protein SOCS1 in complex with JAK1 kinase domain (6C7Y)

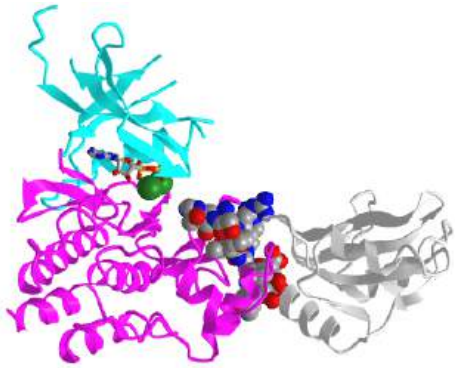

Figure 28.4.19: Structure of the inhibitory protein SOCS1 in complex with JAK1 kinase domain (6C7Y). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...tqtfo2SQ5TxF58

The N-lobe of the JAK1 kinase domain is shown in cyan and the C-lobe in magenta. ADP (sticks) and Mg^{2+} (green) are shown in the interface between the lobes. SOCS1 is shown in gray except for the kinase inhibitor region which is shown as spheres and CPK colors. It binds in the substrate binding grove and prevents substrate access.

Activated JAK activity and signaling do not stop simply with the activation of STAT. In addition to stimulating signaling through phosphorylated dimers of STAT, cytokines also activate other signaling pathways through the same receptors. Examples include the PI3K pathway described in an earlier section and also the MAPK pathways, described in detail later in this section. Both the PI3K and MAPK pathways are activated by binding the cytokine IL6 to its cytokine receptor. The mechanism for PI3K activation is a bit unclear. The MAPK pathway is activated by a phosphatase called SHP2 for Src homology region 2 domain-containing phosphatase 1. This protein binds to pTyr759 on the IL-6 receptor. As binding of the cytokine activates the prebound JAK, it also activates SHP2, ultimately activating signaling through Ras (a small G protein), which activates RAF, a kinase. Figure 28.4.20 shows these three combined signaling pathways for a cytokine receptor: STAT, Ras, and PI3K activations.

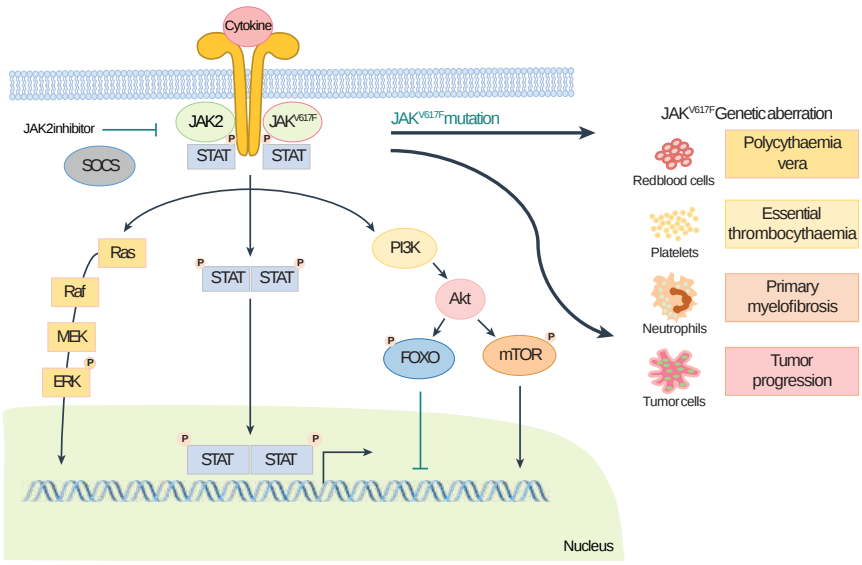

Figure 28.4.20: Schematic representation of the JAK-STAT pathway. Lee et al. Immune Netw. 2017 Aug;17(4):214-227. https://doi.org/10.4110/in.2017.17.4.214. pISSN 1598-2629·eISSN 2092-6685. Creative Commons Attribution Non-Commercial License (https://creativecommons.org/licenses/by-nc/4.0/)

The cytokine receptor induces activation of JAKs after cytokine stimulation following the phosphorylation of STATs. Furthermore, phosphorylated STATs undergo dimerization and translocate to the nucleus to activate target gene transcription. SOCS, suppressors of cytokine signaling; PI3K, phosphatidyl inositol 3 kinase; Akt, protein kinase B; FOXO, Forkhead box protein O; mTOR, mammalian Target Of Rapamycin.

Figure 28.4.21 shows an interactive iCn3D model of the Crystal structure of a tyrosine phosphorylated STAT-1 dimer bound to DNA (1BF5)

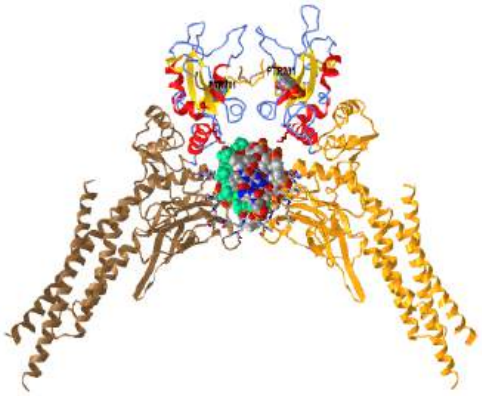

Figure 28.4.21: Crystal structure of a tyrosine phosphorylated STAT-1 dimer bound to DNA (1BF5). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...VEjHZ5t3baKC37

The dimer chains are shown in brown and gold except for those colored-coded by secondary structure (helix red, sheet yellow). The backbone of the nucleotides is shown in spacefill cyan and gray. Zoom in to see noncovalent interactions between the bound DNA and protein monomers. Two phospho-tyrosines labeled pTR701 are shown as well. The DNA binding domain of the STAT dimer has an immunoglobulin fold and forms a "C-shaped clamp" around the DNA. The domains colored by secondary structure are SH2 domains, with each recognizing and binding to the phosphorylated Tyr 701 (labeled pTR701), a very interesting use of the SH2 domain.

Figure 28.4.22 shows an interactive iCn3D model of the active Janus Kinase (JAK) dimer complexed with the intracellular domains (spacefill) of the interferon lambda(a cytokine) receptor (7T6F).

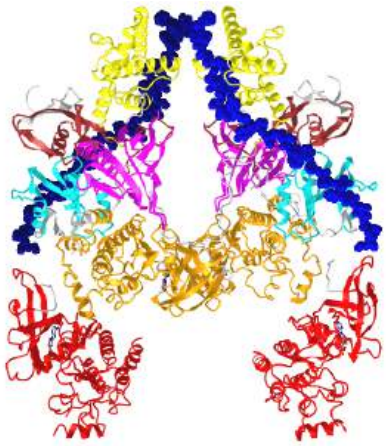

Figure 28.4.22 Active Janus Kinase (JAK) dimer complexed with the intracellular domain of the interferon lambda(a cytokine) receptor (7T6F). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...9s3VBNMxsk7WM7

Domain/protein Coloring

- The gold large sphere represents interferon bound to the extracellular domain of the interferon lambda receptor 1 dimer

Figure 28.4.23shows a model combining the active Janus kinase (JAK) containing the intracellular domain of the interferon alpha receptor 1 dimer (navy and blue spacefill) with AlphaFold models of the extracellular and transmembrane domain of the interferon-alpha receptor ((Q8IU57))

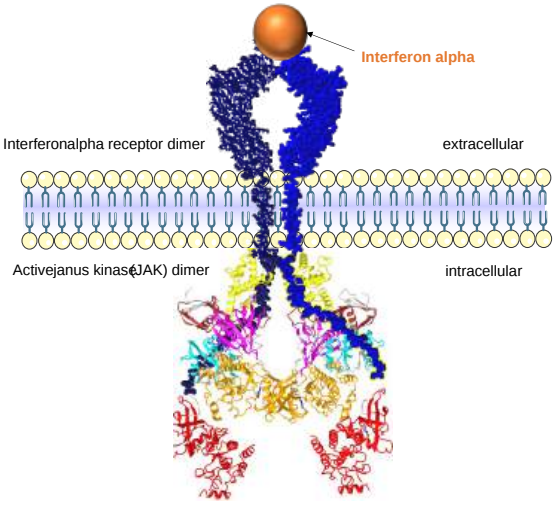

Figure 28.4.23 AlphaFold model of Interferon lambda receptor 1 Extracellular Domain and transmembrane domain (Q8IU57) with Active Janus Kinase (JAK) dimer complexed with cytokine receptor intracellular domain (7T6F)

Again, to reiterate as we did above, the cytokine receptor (in the figure above the interferon lambda receptor) is NOT a RTK with latent kinase activity. Instead, it becomes phosphorylated by the bound and cytokine-activated JAK which is resident in the cytoplasm.

Here is a link to a second iCn3D model which shows the phenylalanine cluster that promotes pseudokinase domain interactions in the active JAK dimer.

28.4.4: Downstream Intracellular signaling through Src Family Kinases - Membrane-associated non-receptor tyrosine protein kinases

Another family of intracellular protein kinases - the Src family - are often activated on upstream activation of many different types of receptors including GPCRs, RTKs, cytokine receptors, as well as integrins and adhesion receptors that we explore in a later chapter section. We have already touched on them when we discussed proteins containing the src homology domains SH2 and SH3. Src, an intracellular Tyr kinase (MW 60,000), is the founding member of this family of protein kinases. Src is activated when it binds through its own SH2 domain to a phosphorylated membrane receptor.

Src has many names including Proto-oncogene tyrosine-protein kinase Sr**c,** proto-oncogene c-Src, pp60c-src, and p60-Sr. These membrane-associated, non-receptor tyrosine kinases regulate cell proliferation, differentiation, apoptosis, migration, metabolism, and cytoskeleton organization. They are one of the major classes of intracellular kinases which are activated after upstream activation of the membrane receptors mentioned above (GPCRs, RTKs, cytokine receptors, as well as integrins and adhesion receptors). They in turn activate further downstream protein kinases by phosphorylation. They even phosphorylate the upstream membranes which led to their activation.

There are 10 members in the Src family: Src, Frk, Lck, Lyn, Blk, Hck, Fyn, Yrk, Fgr, and Yes. They all share the same expanded domain structure shown in Figure 28.4.24

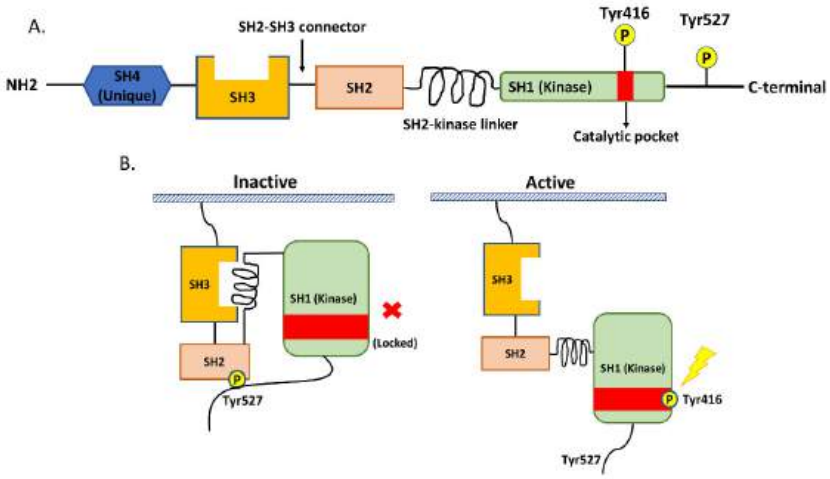

Figure 28.4.24: The domain structure of Src (panel A) and its activation (panel B). Hsu et al, Cancers 12(6):1361. DOI: 10.3390/cancers12061361. CC BY 4.0

They have an SH4 N-terminal region that can be post-translationally modified with fatty acids (myristoylation and palmitoylation), which can anchor it to the membrane. The spacer SH2-SH3 spacer is intrinsically disordered and differs in sequence among members of the Src family. Two key phosphorylation sites (Tyr416 and Tyr527) are important. In inactive Src, Try 527 is phosphorylated, allowing it to bind to the SH2 domain. The SH2-kinase linker also binds to the SH3 domain. This occludes the active site region and prevents the phosphorylation of Try 416 in the "activation loop" of the SH1 kinase domain. When Try 527 is dephosphorylated, a conformation change ensues the opens the binding site allowing autophosphorylation of Tyr 416 and its activation. Hsu et al, Cancers 12(6):1361. DOI: 10.3390/cancers12061361. CC BY 4.0

Figure 28.4.25shows an interactive iCn3D model of the Human tyrosine-protein kinase C-Src in complex with AMP-PNP (2SRC)

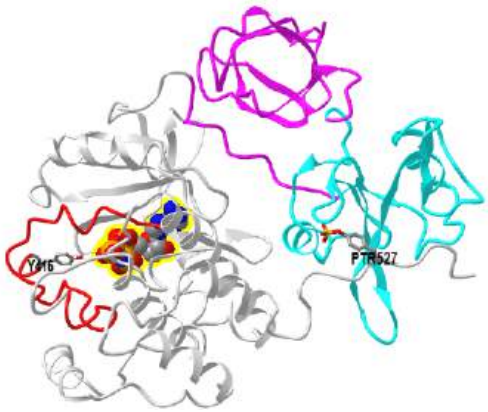

Figure 28.4.25: Human tyrosine-protein kinase C-Src in complex with AMP-PNP (2SRC). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...L45honKx6rrEu7

pY527 is shown in stick and labeled. It binds to the SH2 domain (151-248) shown in cyan. The SH3 domain is in magenta and the kinase domain is shown in gray. The activation loop in the kinase domain is shown in red with the pY416 needed for activation shown in stick and labeled. ANP is shown in spacefill.

We have now seen the structure of many kinase domains. Figure 28.4.26 shows an interactive iCn3D model of the alignment of human c-Src (452 amino acids) (2SRC) and Erk2 (362 amino acids) also called MAPK1 (2Y9Q), a protein kinase will be explored at the end of this section

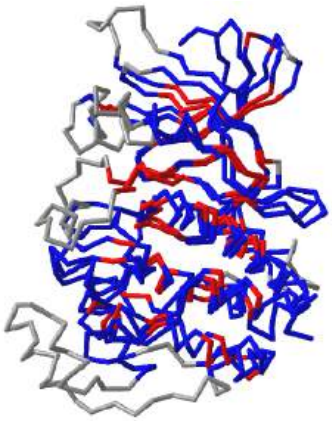

Figure 28.4.26: Aligned structures of human c-Src (2SRC) and Erk2 (2Y9Q). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...ETS1puViPtrQu7

Red shown conserved sequences, blue is aligned (but not conserved), and gray is nonaligned. Use the "a" key to toggle between the states.

After much discussion of the binding of p-Tyrosine side chains to the SH2 domain, we now present Figure 28.4.27, which shows an interactive iCn3D model of a phosphotyrosine peptide bound to the SH2 domain of Fer tyrosine kinase (6KC4)

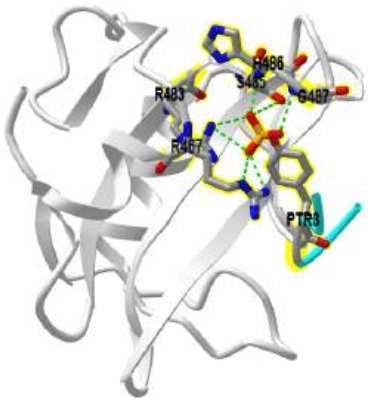

Figure 28.4.27: Phosphotyrosine peptide bound to the SH2 domain of Fer tyrosine kinase (6KC4). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...3eqrcT7NwcHpr8

The SH2 domain is shown in gray. The phosphopeptide (DEpYENVD) is shown in cyan with the labeled pY in sticks. The side chains on the SH2 domains interacting with the pY are shown in stick and labeled.

We are about to explore the last but incredibly important downstream kinases activated in signal transduction cascades, the **mitogen activate protein kinase (MAPK**) cascade. It could also be called the **Erk cascade**. Before we do that, we present parts of three pathways mediated by activated RTKs to refresh your minds and also because the more you see key players in the pathway, the more you start to remember the names, structural features, and function of the signaling molecules.

Figure 28.4.28 offers a quick and abbreviated look at signaling through activated RTKs that proceed through the adaptor protein and the GEF SOS, leading to the activation of Ras, a key small G protein. Ras in turn activates a protein (MAPKKK) in the MAPK cascade.

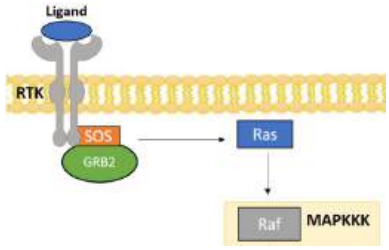

Figure 28.4.28 Simplified cartoon showing the activation of the MAPK cascade protein MAPKKK. Cordover E, Minden A. Signaling pathways downstream to receptor tyrosine kinases: targets for cancer treatment. *J Cancer Metastasis Treat* 2020;6:45. http://dx.doi.org/10.20517/2394-4722.2020.101. Creative Commons Attribution 4.0 International License (https://creativecommons.org/licenses/by/4.0/),

Figure 28.4.29 shows an abbreviated version of the activation of the lipid kinase PI3K and through the activation of PDK1 and AKT, the activation of two major kinase complexes, mTORC1, and mTORC2, which we will explore in its a separate chapter section.

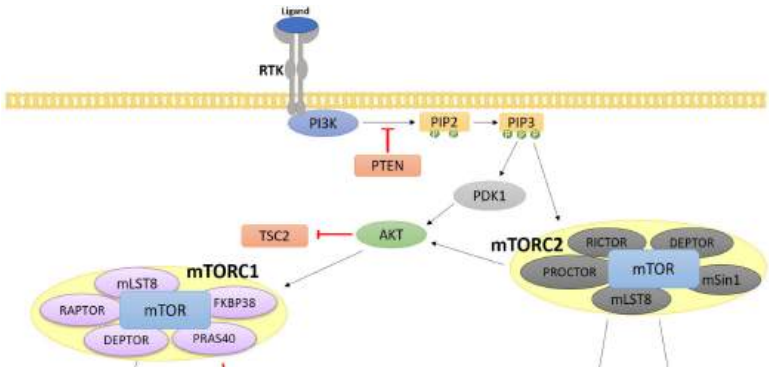

Figure 28.4.29: Activation of mTORC1 and mTORC2, through activation of PI3K, PDK1 and AKT. Cordover E, Minden A. Signaling pathways downstream to receptor tyrosine kinases: targets for cancer treatment. *J Cancer Metastasis Treat* 2020;6:45. http://dx.doi.org/10.20517/2394-4722.2020.101. Creative Commons Attribution 4.0 International License (https://creativecommons.org/licenses/by/4.0/)

Finally, Figure 28.4.30show the combined activation of both the MAPK (ERK) cascade pathway and the mTOR complex through GPCR signaling using the adaptor protein Grb2.

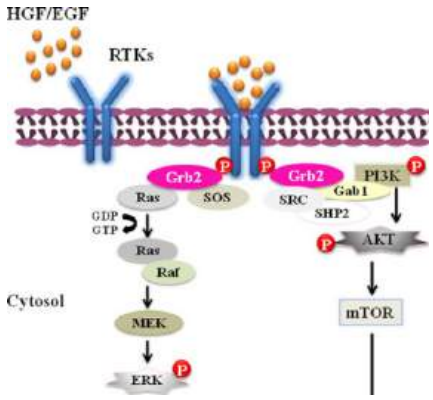

Figure 28.4.30: Combined activation of both the MAPK (ERK) cascade pathway and the mTOR complex through GPCR signaling using the adaptor protein Grb2Yang et al. Journal of Cellular and Molecular Medicine 22(6). DOI: 10.1111/jcmm.13447. License CC BY 4.0

28.4.5: Downstream signaling through the Mitogen-Activated Protein Kinase Cascade

Active upstream kinases like PKA, PKC, and RTKs phosphorylate target proteins and in doing so change their activities. The usual protein targets are kinases, which become active on phosphorylation. They in turn activate other kinases, resulting in a complex cascade and amplification of the original signal. Often the end product of such cascade is a phosphorylated transcription factor that can alter gene expression. Perhaps the most described of these cascades is the **Mitogen-Activated Protein Kinase (MAPK)** pathway. Mitogens are chemical species that lead to mitosis (cell division). The MAPK system has three layers and a confusing nomenclature (until you are used to it). The end (downstream) product of the cascade is the enzyme **mitogen-activated protein kinase**, abbreviated MAPK. It can be phosphorylated several times to produce MAPKP or MAPKPP where the last Ps in the abbreviation signifies the number of added phosphate groups.

The kinase immediately upstream that phosphorylates MAPK is abbreviated **MAPKK** (for mitogen-activated protein kinase kinase) or **MAP2K**. MAPKK (MAP2K) is activated by yet another upstream kinase called **MAPKKK** or **MAP3K**. If these are also targets of another upstream unrelated kinase, they would be abbreviated MAP3KPP for example.

Now, of course, there are families of the MAPK cascade enzyme, each with its own name. Figure 28.4.31shows the names of four different mammalian MAP3Ks leading to the activation of 5 different MAP2Ks which lead to the activation of 4 different MAPKs. Some of these enzymes are so widely discussed in textbooks and journal articles that it is good to remember them specifically with their alternative names. These include the MAP3K enzymes **Raf (**Rapidly Accelerated Fibrosarcoma) and **MEK**, and the MAPK enzymes **ERK** (Extracellular Related Kinase) and **JNK** (c-Jun N-terminal Kinase)

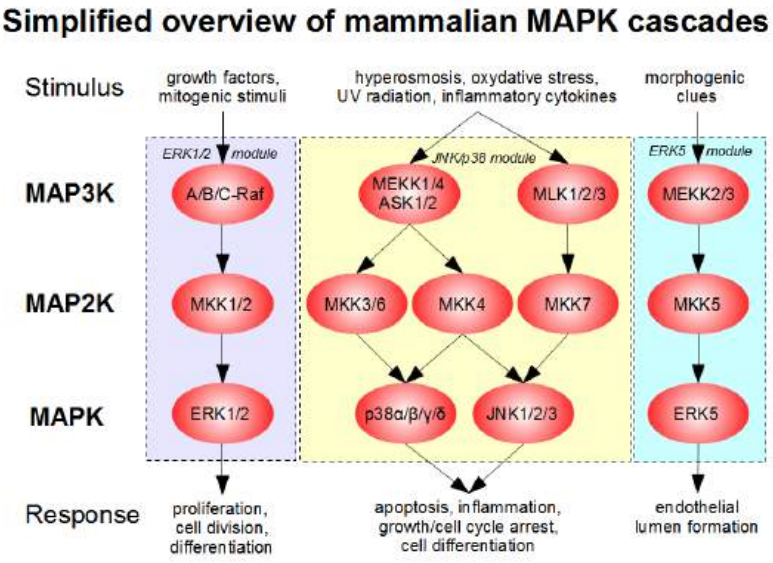

Figure 28.4.31: Simplified overview of the mammalian MAPK cascades https://commons.wikimedia.org/wiki/F...-mammalian.png. Creative Commons Attribution-Share Alike 3.0 Unported

Figure 28.4.32 shows another representation of the MAPK cascade with some different enzyme names and added phosphates shown in circles.

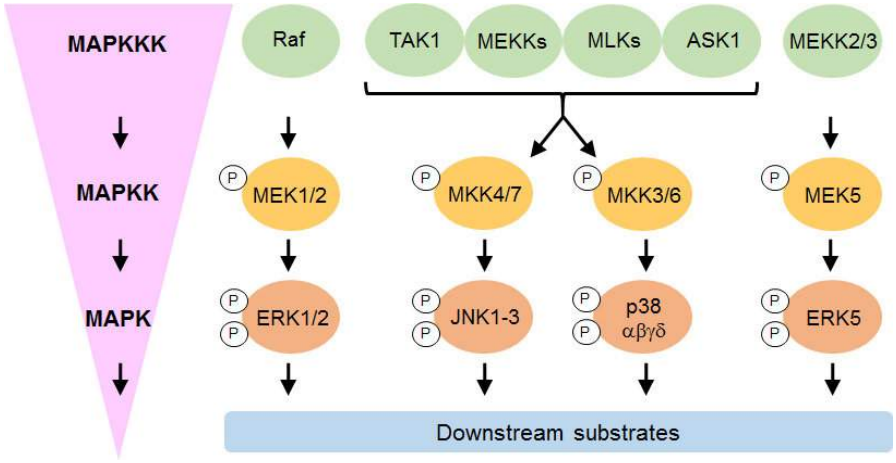

Figure 28.4.32 Another representation of the MAPK cascade. Journal of Cardiovascular Development and Disease 6(3):27. 2019. 10.3390/jcdd6030027. CC BY 4.0

One way to organize a seminar on a complex topic is to use these 3 steps: tell your audience what you will tell them, tell them, and then tell them what you told them. Following that advice, we present in Figure 28.4.33 an integrated view of signaling, starting from the membrane and moving inward to three enzymes in the MAPK kinase cascade, RAF (a MAP3K), MEK (a MAP2K) and ERK (a MAPK). Upstream signaling to the MAPK cascade comes RTKs, GPCRs, and Ca^{2+} signaling, which we will discuss later.

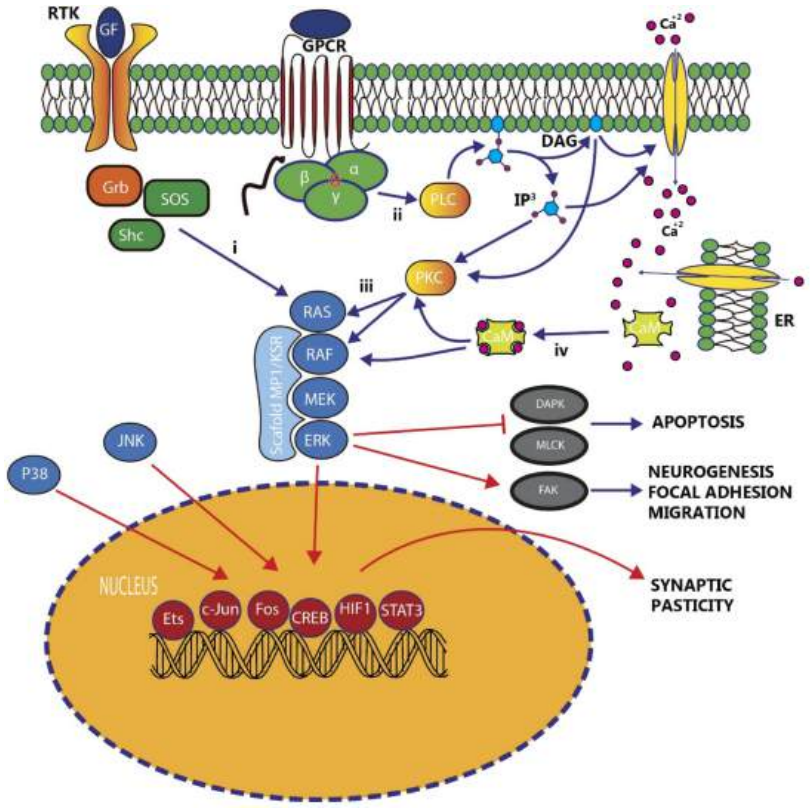

Figure 28.4.33: Upstream signaling to the MAPK cascade from RTKs, GPCRs, and Ca^{2+} signaling Albert-Gasco et al. International Journal of Molecular Sciences 21(12):4471 (2020). DOI: 10.3390/ijms21124471. License CC BY 4.0

The sequence of events is:

- binding of an external signal to membrane receptor and activation of receptor kinase
- phosphorylation of receptor kinase and interaction with an activator GTP binding protein such as Ras
- binding of activated G-protein to and activation of a mitogen-activated protein kinase kinase kinase (MAPKKK)
- MKKK phosphorylates and activates another kinase, MAPKK
- MKK phosphorylates and activates mitogen-activated protein kinase, MAPK
- MAPK phosphorylates inactive transcription factors (or other proteins) and activates them. Unfortunately (from a naming point of view) when the activated proteins are themselves protein kinases, they are called mitogen-activated protein kinase activated protein kinases (MAPKAPK)

There are seven types of MAPKs, four conventional and three atypical. Four typical ones are described in the table below.

Activator GTP binding protein	Ras:GTP			
MAPKKK or MAPK3	Raf-1A/B c-Mos	MEKK1-4 DLK MLK2	MEKK1-4 DLK MLK2	MEKK2/3 Tpl-2
MAPKK or MAPK2	MEK1,2	MEK4,7	MEK3,6	MEK5
MAPK or MAK	ERK1,2	JNK1-3	p38	ERK5
MAPKAPK	RSK 1-4 MNK2 MSK 1,2	MK2,3	MSK1,2 MK2,3	RSK1-4
An eventual Protein Target	c-Jun	c-Jun		

EXTERNAL MAP Kinase System from Cell Signaling

Structural, these proteins are similar in size and domain structure as we have seen for other kinases. Figure 28.4.34 shows an interactive iCn3D model of the alignment of MEK 1 (**4U7Z**) and ERK2 (**5NHJ**)

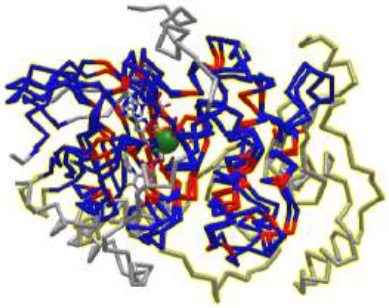

Figure 28.4.34: . (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...Vq6RR7BA6o1Qb7

We now present multiple visual images of the activation of the MAPK cascade. Figure 28.4.35shows two.

Figure 28.4.35 Two visual representations of the activation of the MAPK cascade through to activation of gene transcription.

As with protein kinase A and protein kinase C, signaling efficiency and specificity with minimal phosphorylation of wrong targets occurs when multiple signaling partners are scaffolded. This is also true of the MAPK cascade trio of the kinase. Figure 28.4.36 shows the role of scaffolds KSR and Ste5 in MAPK signaling.

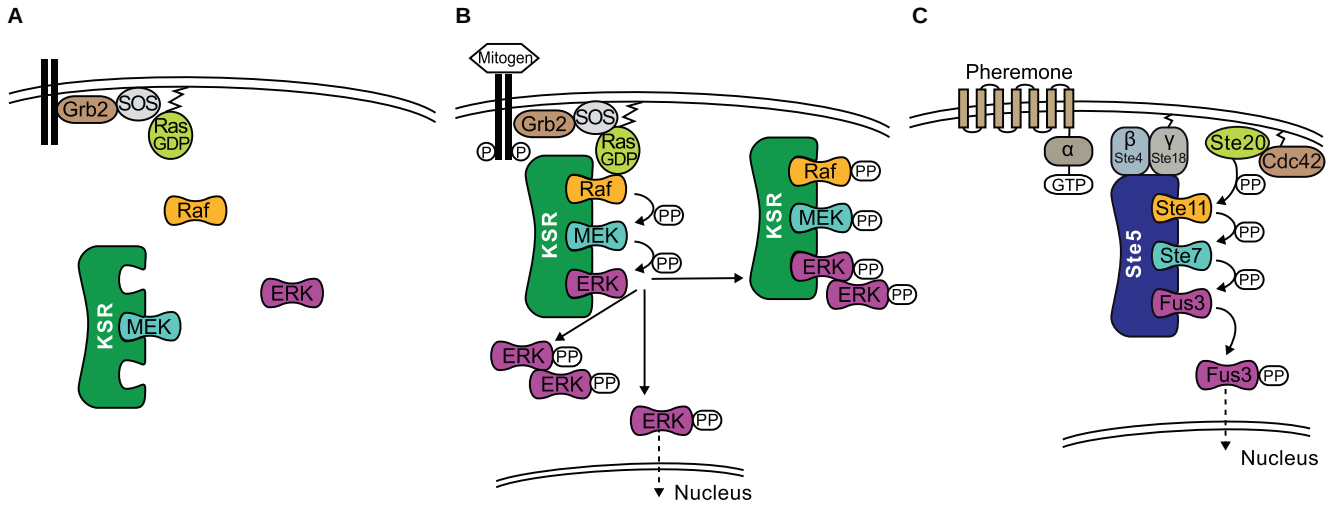

Figure 28.4.36: **The role of scaffolds KSR and Ste5 in MAPK signaling. (A)** In quiescent cells, an inactive KSR/MEK complex exists in the cytosol. **(B)** Upon stimulation of the cell, KSR translocates to the cell membrane and forms an active complex with phosphorylated Raf, MEK, and ERK. Activated ERK detaches from the scaffold with three outcomes; (1) ERK dimerizes in the cytoplasm where the dimer remains or translocates to the nucleus; (2) ERK translocates to the nucleus; (3) KSR acts as a platform where ERK dimers are assembled and the new complex can interact with substrates in the cytoplasm. **(C)** Schematic of the yeast mating pheromone response pathway. 28.4.6: Computational Analyses - MAPK Cascade

You might think that the interconnected reactions of the MAPK cascade are complicated. However, as presented in the figures above, it only consists of 3 enzymes, MAPKKK (MAPK3 or MK3), MAPKK (MAPK2 or MK2), and MAPK. We added complexity by converting the actual enzymes from an inactive state to an active state by phosphorylation. In reality, this pathway is simple compared to the complete signal transduction pathways they are part of, and very simple compared to whole catabolic and anabolic pathways that we will see in Part Two of this book.

We have discussed kinetics in earlier chapters and have shown how it can be used to more fully understand an enzyme and its regulation/control. We need to extend such kinetic analyses to whole pathways as well. We can do that using the VCell. Let's look at two different models of the MAPK cascade using Vcell. One particularly interesting feature is the regulation of the pathway. We will see in the next section on metabolism that pathways are often regulated by the end product of the pathway. This makes sense since if that end product is abundant, it would make biological sense for that product to inhibit the first enzyme in the pathway to avoid making more of the ultimate end product. Of course, that inhibition would be relieved as the concentration of the end product falls. Hence there is a temporal sense to the inhibition.

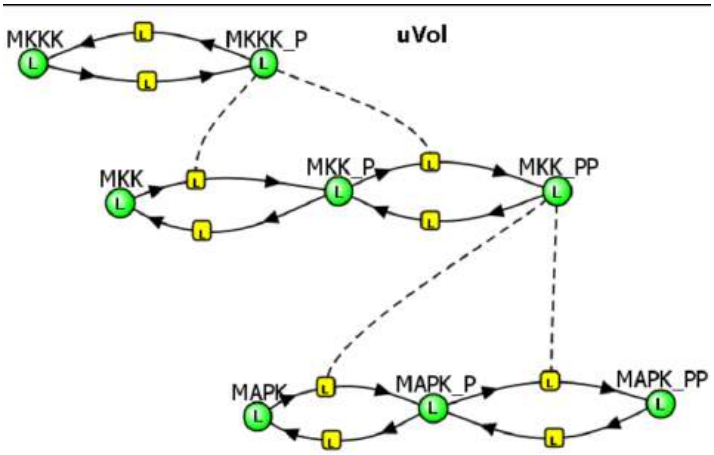
Let's look run two Vcell models for the MAPK Cascade, one with no end product inhibition and one with inhibition of the first step. Since we dealing with linked kinases, the inhibition of the first enzyme (MAP3K=MKKK) and hence the first reaction (MKKK ↔ MKKK_P) is not mediated by a chemical product of the last enzyme (MAPK_PP) but by phosphorylation of the first enzyme (MKKK) by the last (MAPK_PP).

MAPK Cascade - Model 1: **No** feedback inhibition of the MAPK cascade by inhibition of the first step (MKKK ↔MKKK_P) by the "end product" of the cascade (MAPK__PP) try quick

---

VCell MODEL

MAPK Cascade - no feedback inhibition



Initial Condition - See simulation results

Select Load [model name] below

NOFEEDBACK_Load Oscillations_in_MAPK_cascade

Select **Plot** to change Y axis min/max, then **Reset** and **Play** | Select **Slider** to change which constants are displayed. For this model, select Vm, Km, Ki and I | Select **About** for software information.

Move the sliders to change the constants and see changes in the displayed graph in real-time.

Time course model made using Virtual Cell (Vcell), **The Center for Cell Analysis & Modeling**, at **UConn Health**. Funded by NIH/NIGMS (R24 GM137787); Web simulation software (miniSidewinder) from Bartholomew Jardine and Herbert M. Sauro, University of Washington. Funded by NIH/NIGMS (RO1-GM123032-04)

The various concentration vs time curves in the output graph should make "intuitive" sense. There are no surprises!

Now let's add a twist. What if the last active enzyme in the pathway, MAPK that is doubly phosphorylated (MAPK_PP), the "final product" of the cascade, can, in a feedback reaction, inhibit the very first reaction of the cascade, MKKK → MKKK_P through an inhibiting phosphorylation. Run the simulation in Vcell to find out!

MAPK Cascade - Model 2: Feedback inhibition of the MAPK cascade by inhibition of the first step (MKKK ↔MKKK_P) by the "end product" of the cascade (MAPK__PP)

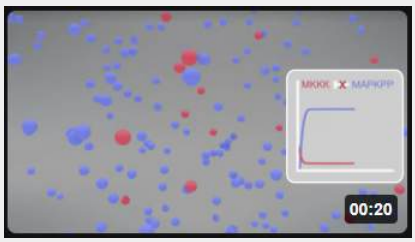
Kholodenko2000 - Ultrasensitivity and negative feedback bring oscillations in the MAPK cascade. https://www.ebi.ac.uk/biomodels/BIOMD0000000010. Based on Kholodenko BN. Negative feedback and ultrasensitivity can bring about oscillations in the mitogen-activated protein kinase cascades. Eur J Biochem. 2000 Mar;267(6):1583-8. doi: 10.1046/j.1432-1327.2000.01197.x. PMID: 10712587.

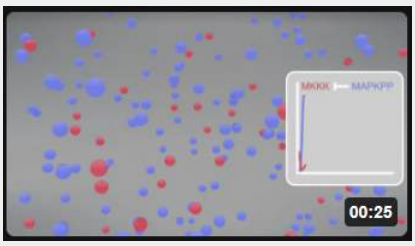
There is utterly no way to have predicted, using intuition or simple mathematical analyses, the oscillatory changes in the concentration of all the enzymes and their phosphorylated variants. Of course, the oscillating concentrations depend on the chosen initial concentrations and on the rate constants.

When enzymes are linked sequentially in signal transduction pathways, their actions are amplified by the preceding enzyme. If the first kinase (MK3) activates a 1000 molecules of the second kinase (MK2), and each of these activates 1000 of the last kinase (MAPK), the net effect of activating the first kinase is a million-fold amplification of the last! This causes this three-kinase pathway to be **ultrasensitive** to small changes to the first enzyme. Add other activating and inhibiting agents and the net activities of the pathway components become even more complicated.

Just the simple feedback inhibition by the last enzyme of the first enzyme in this cascade can bring about the oscillation shown in Vcell model 2. Depending on the concentrations and rate constants used in the model, the oscillations can last from minutes to hours. These oscillations can produce waves of phosphoproteins that propagate through the cytoplasm of the cell.

Here is a simplified animation of the MAPK cascade that shows changes in MKKK (red dots) and MAPK_PP) blue dots with no feedback inhibition (left, Model 1) and feedback inhibition (right, Model 2) in the cascade. (Animations produced by Shraddha Nayak and Hui Lui.)

Model 1: **No** feedback inhibition of the MAPK cascade	Model 2: Feedback inhibition of the MAPK cascade
	




You might expect similar oscillatory behavior in proteins (cyclins and cyclin-dependent protein kinases) controlling the movement of cells through the cell cycle. We will see that in a subsequent section.

28.5: Small G proteins, GAPs and GEFs

28.5.1: G proteins: Cellular Switch for Kinases

In the preceding chapter sections, we discussed two types of small G proteins, Gα, part of the heterotrimeric Gαβγ complex linked to GPCR signaling, and Ras (H, K, and N). Both bind GTP and GDP and have GTPase activity. When bound to GTP they are active while the GDP bound form is inactive. What a perfect molecular switch to turn on signaling and with a built-in off switch (the GTPase activity). It turns out that his simple on/off switch is too simple. For example, a single mutation that inhibits the GTPase activity would leave the protein on continually which could (and does) lead to unregulated growth and tumor formation.

Two new sets of proteins that regulate the on-off activity of small G proteins are found abundantly in cells:

- GTPase activating protein or GAPs: As the name implies they enhance the GTPase activity of the small G proteins, which would decrease G protein signaling;
- Guanine nucleotide exchange proteins or GEFs: These lead to the dissociation of bound GDP and its replacement with GTP, which would increase G protein signaling.

Mammalian cells contain 3 variants of Ras: H, K, and N. They all bind GDP/GTP and have GTPase activity. Ras is targeted to the cell membrane through the post-translational addition of a hydrophobic farnesyl group. When activated by binding to GTP, it can bind to and activate a protein called **Raf**-1, which on binding becomes an active tyrosine kinase. Ras has intrinsic GTPase activity, so eventually, active Ras will deactivate itself.

Ras is just one member of a large superfamily of small G proteins, which all have GTPase activity. However, they are poor GTPases, so they need help to autocatalytically cleave the GTP to GDP. GAPs and GEFs evolved to regulate their activity by modulating the balance of bound GTP (an active form of the protein) and GDP (an inactive form of the small G protein).

Before describing these proteins, we need to have a better understanding of the family of small G proteins.

28.5.2: Small G proteins

Small G proteins in the superfamily have a common 20 K molecular weight catalytic (GTPase) domain with 5 alpha helices, 6 beta strands, and connecting loops. The small G proteins are "active" in the GTP-bound form. Hydrolysis of GTP to GDP causes the protein to become inactive. Figure 28.5.1 shows the domain structures of small G proteins.

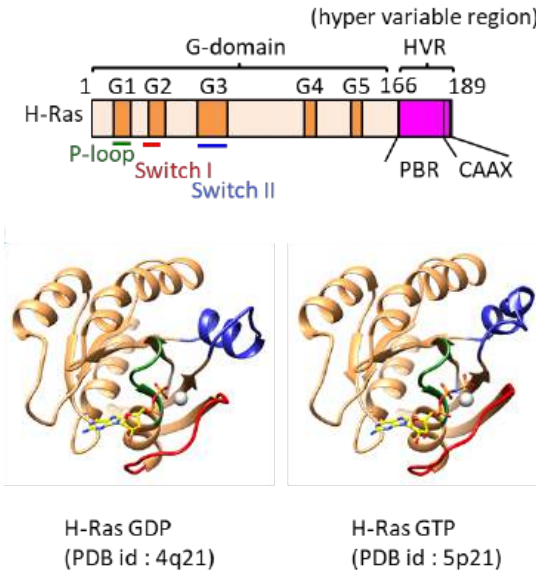


Figure 28.5.1: Domain Structure of small G proteins. Toma-Fukai et al. Molecules 2019, 24, 3308; doi:10.3390/molecules24183308. Creative Commons Attribution (CC BY) license (http://creativecommons.org/licenses/by/4.0/).

G boxes of the G domain are highlighted with orange boxes. The hypervariable region, including a polybasic region and a CAAX motif, is highlighted with pink boxes. The P-loop, switch I, and switch II are shown as bars colored green, red, and blue, respectively. The bottom structures show H-Ras bound to GDP and GTP. The P-loop, switch I, and switch II are colored green, red, and blue, respectively.

Figure 28.5.2 shows an interactive iCn3D model of human KRAS G12C mutant covalently bound to AMG 510, a covalent inhibitor (6OIM). This mutation flips the Ras switch so it is permanently on.

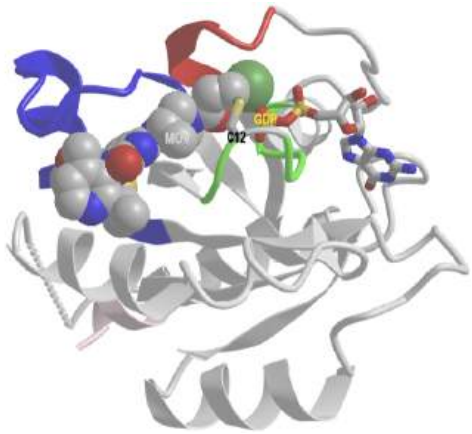

Figure 28.5.2: Human KRAS G12C covalently bound to AMG 510 (6OIM). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...Rx2ksMNmeCB7t6

The coloring coding is the same as in the above Figure 1:

- P-Loop (same as G1) is Green
- Switch 1 is red
- Swithch 2 is blue
- Polybasic region is pink
- The GAAX motif was not observed (low electron density in the crystal structure)

GDP is shown in colored sticks. The covalent inhibitor, AMG 510, is shown in spacefill and labeled MOV. It is covalently attached to the Cys 12 in the mutated version.

The G12C human KRAS mutation is found in about 13% or patients with non-**small cell lung cancer (**NSCLC) with is any type of epithelial lung cancer that is not small cell lung cancer**.** NSCLCs include squamous cell carcinoma, large cell carcinoma, and adenocarcinoma. The G12C mutation causes the protein to be "stuck" in the active conformation, which leads to continued activation of signaling pathways leading to cell proliferation, a trait of cancer cells. Before the discoveryof AMG 510, Ras was considered "undrugable" since it was devote of obvious pockets that could inhibit its activity. The G12C mutation replaces glycine with cysteine, a potent nucleophile that can react with the covalent inhibitor and inhibit the always-switched on G12C mutant in the absence of the inhibitor.

A new generation of inhibitors attempts to affect different aspects of its activity, including its localization to the membrane, the binding of different effectors, and nucletodide exchange.

Figure 28.5.3shows these key structural features of Ras (with different color coding).

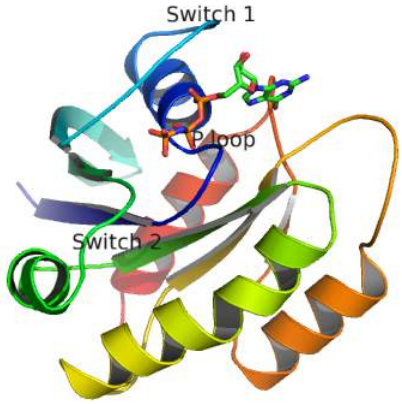

Figure 28.5.3: Key structural features of Ras

Important parts of **Ras** necessary for GTP binding include the phosphate-binding (P loop), residues 10 to 16 (dark blue trace below), switch regions I (30 to 37, light blue trace) and II (60 to 76, green trace), which are flexible loops which sandwich GTP.

Figure 28.5.4is an animation showing structural differences between the GTP bound form (blue, pdb id 5p21) and GDP form (red, pdb id 4q21) of the H-Ras protein. One helix and nearby loops are perturbed.

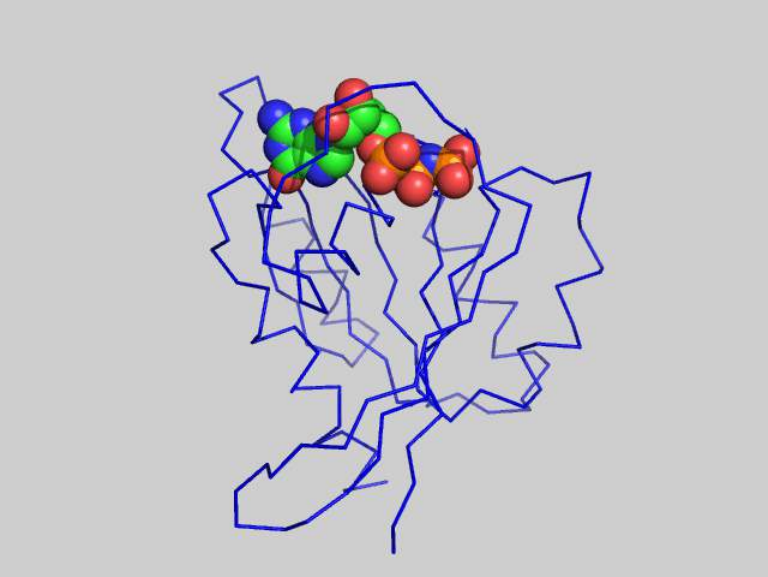

Figure 28.5.4: Structural differences between the GTP bound form (blue, pdb id 5p21) and GDP form (red, pdb id 4q21) of Ras

There are about 150 members of the human Ras superfamily as shown in Figure 28.5.5and Table 1 below.

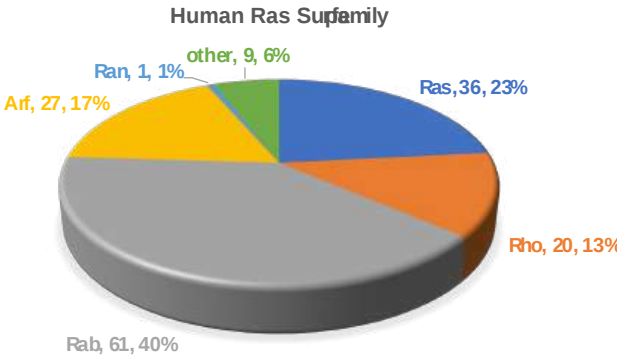

Figure 28.5.5: Members of the human Ras superfamily

Table 28.5.1shows common Ras superfamily functions

Ras	regulation of gene expression, cell proliferation, survival, and differentiation
Rho	regulation of actin cytoskeleton, cell shape, and movement, cell interactions with the extracellular matrix
Rab	vesicle trafficking, endocytosis, secretion
Arf	vesicle trafficking, endocytosis, secretion, microtubule assembly
Ran	nuclear cytoplasm transport, mitotic spindle

We have discussed Ran before as a mediator of protein movement across the nuclear membrane in Chapter 11.5. It's mainly in the GDP-bound form in the cytoplasm and the GTP-bound form in the nucleus. Switches between a cytoplasmic GDP- and a nuclear GTP-bound state by nucleotide exchange and GTP hydrolysis. Nuclear import receptors with bound cargo protein containing a nuclear import signal bind RAN-GTP in the nucleus, leading to the release of the importin and the cargo protein. In contrast, cargo

proteins with a nuclear export signal bind exportins and RAN-GTP in the nucleus and move into the cytoplasm, where the RAN-bound GTP is hydrolyzed on binding a RAN-GAP. This cycle is illustrated in Figure 28.5.6

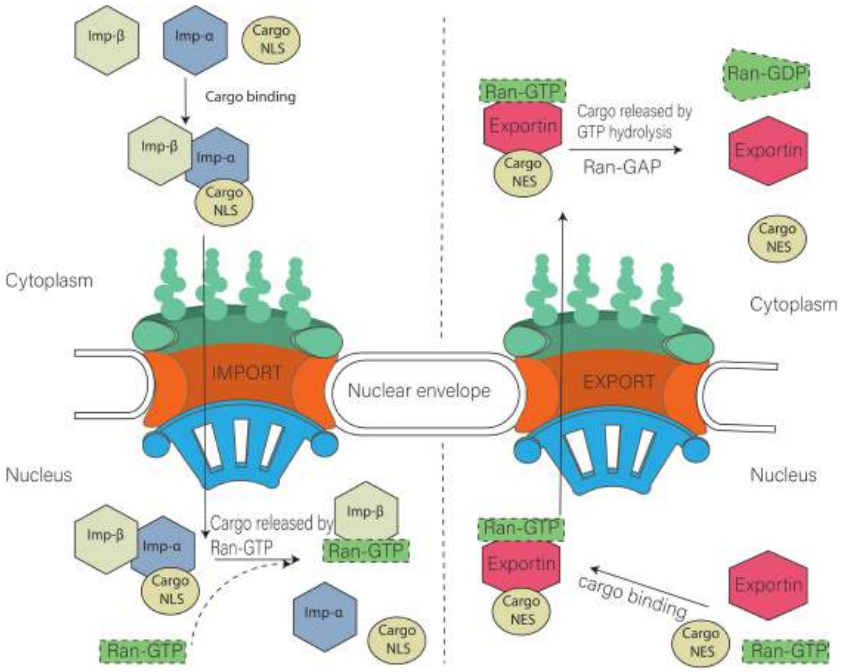

Figure 28.5.6: Model of nuclear import and export. Cargo containing NLS (Nuclear localization signal) is imported with the help of Importin α and importin β heterodimer. Nuclear export of cargo having NES (nuclear export signal) is carried out with the help of exportins. Ran GTP is also required during that process. Khan Asmat Ullah, Qu Rongmei, Ouyang Jun, Dai Jingxing. Front. Physiol., 03 April 2020 | https://doi.org/10.3389/fphys.2020.00239. **Creative Commons Attribution License (CC BY)**.

Small G proteins are a fundamental form of molecular switch. They are simply too important to not be regulated. Probably the most common mutation in human cancer cells involved a single amino acid change in Ras (H, K, and N form). If the GTPase activity is inhibited with mutation, the protein may be constitutively active. Such a Ras mutation is found in almost 90% of pancreatic cancers. Hence researchers have been trying to design drugs that inhibit its GTPase activity. This has proven difficult since it has very few targetable pockets that could bind a drug.

28.5.3: Regulation of small G proteins: GAPs and GEFs

Given the critical importance of small G proteins, it makes biological sense that their on/off activity would be exquisitely regulated. Indeed, they are. Two families of protein have evolved to regulate them by determining whether GTP or GDP is bound to the protein (leading to an active, and inactive small G protein respectively). One family, **GTPase activating proteins (GAPs)** facilitate the hydrolysis of bound GTP, leading to the inhibition of the protein. The other proteins are **GTP exchange proteins (GEFs)**, which facilitate the exchange of GTP for GDP, activating the protein.

The activity of Ras GAPs and GEFs, as well as various proteins interacting with Ras, are depicted in Figure 28.5.7.

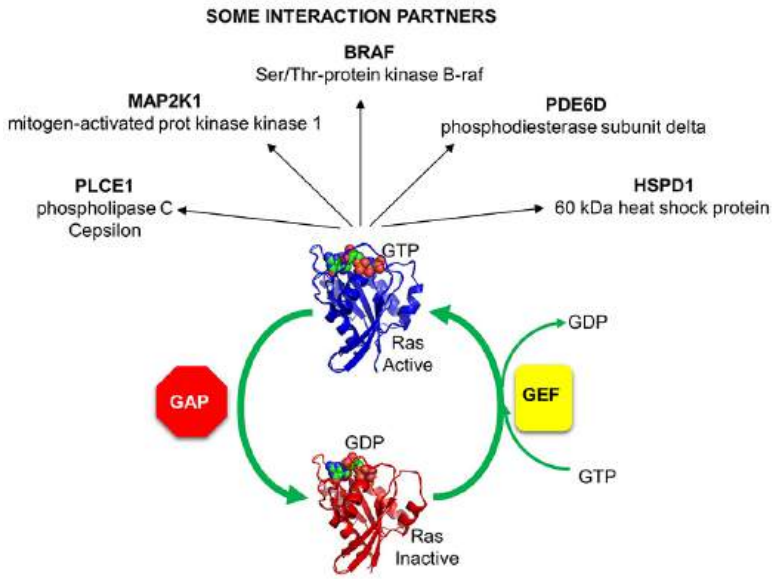

Figure 28.5.7: The activity of Ras GAPs and GEFs, as well as various proteins interacting with Ras

It may seem crazy but the number of GEFs and GAPs is greater than the number of G proteins with which they interact. As shown in Figure 28.5.4, there are 20 Rho G proteins but about 80 GEFs and 70 GAPs for them. This number presumably allows greater control of the specificity of the reactions controlled by the Rho G protein.

GAPs - GTPase Activating Proteins

The hydrolysis of the gamma phosphate of GTP by water in Ras proceeds by a pentavalent transition state with two axial and three equatorial ligands to the P. Developing charge in the transition state would usually be stabilized by catalytic residues in the catalytic domain of Ras. However, Ras is a poor GTPase. That's where GAP comes in. In the Ras/GAP complex, GAP positions its Arg 789 on the GAP in a position to stabilize the transition state for Ras-bound GTP cleavage. This Arg 789 is almost in the same position as Arg 178 in the Galpha inhibitor subunit of a heterotrimeric G protein which inhibits GPCR signaling. Both of these arginines have similar catalytic functions.

Figure 28.5.8shows an interactive iCn3D model of Ras-GAP complex (1WQ1)

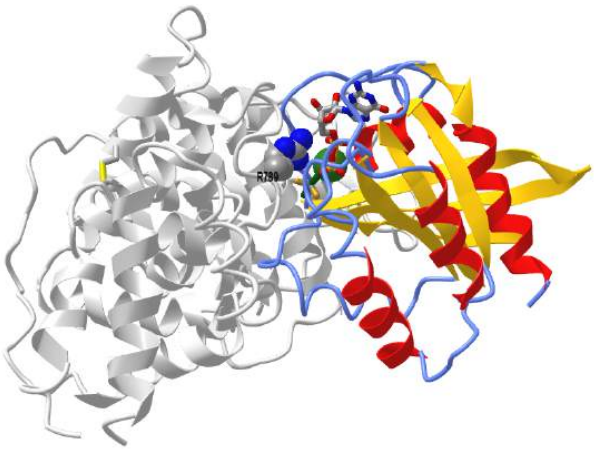

Figure 28.5.8: Ras-GAP complex (1WQ1) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...MJiLGpT4w6kP69

Ras is shown in secondary structure colors, while GAP is shown in gray. GDP-AlF3, a GTP analog, is shown in color spacefill. Arginine 789 in GAP is shown in spacefill with CPK colors and labeled R789. It is a clear position to stabilize the bound GTP in the complex and its cleavage transition state.

GEFs - GTP Exchange Factor

Once bound to Ras, GDP dissociates very slowly. Values of 10^{-5} sec^{-1} have been reported for the first order rate constant of the dissociation of GDP from a small G protein. Assuming that the diffusion is controlled on the rate constant for the complex, the K_D for the G protein:GDP complex would be 0.1 pM and the half-life would be 0.8 days, similar to the lac repressor:DNA operator complex. Hence the protein, when bound to GDP, is essentially locked in the off position. What if it needs to be reactivated quickly? How can the rate at which GDP dissociates be increased so that GTP could replace it? If it were to dissociate, GTP could quickly replace it since from an equilibrium point of view, Ras and other small G proteins would favor GTP binding since its concentration in the cell is higher.

One could envision several ways to change the rate at which GDP dissociates. In organic chemistry, a favorite student response to many questions is to evoke steric effects. In biochemistry, the analog is often conformational changes. How could you change the conformation of Ras such that it might favor GTP binding? That could occur by ligand binding or more likely by a post-translation modification such as phosphorylation as part of a signaling process. It turns out that for the case of small G proteins, another mechanism is evoked: the binding of another protein, a **GTP Exchange Factor** or **GEF**, which promotes GTP exchange for the bound GDP. If the Ras:GEF:GDP complex has a 10,000 increase in k_{off} for GTP, the half-life of the bound GDP is 7 seconds. There are 80 GEFs in the human genome. If you think about it, in GPCR coupled signaling, the ligand-bound GPCR is a GEF for the Gαsubunit of the heterotrimeric Gαβγ protein.

The crystal structure of a Ras GEF, SOS, in complex with Ras allows a detailed understanding of the mechanism. SOS, a cytoplasmic protein, is recruited to the cell membrane where active Ras is found, tethered to the membrane with a hydrophobic farnesyl attachment. Figure 28.5.9 shows an interactive iCn3D model of Ras and SOS (a **GEF**) complex (1bkd).

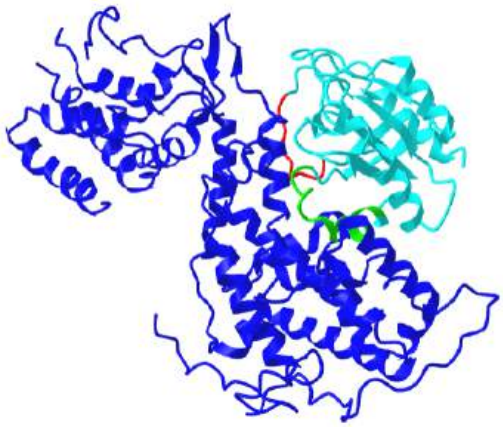

Figure 28.5.9: Ras and SOS (a **GEF**) complex (1bkd) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...XJP4Fajqc9eEL6

The actual biological unit (functional structure) is a hetero 8-mer (A_4B_4) with C_4 symmetry. The iCn3D model shows just a heterodimer for clarity. Ras is shown in cyan and SOS in dark blue. SOS as a GEF affects nucleotide binding to SOS in two essential ways. An alpha helix from SOS displaces Switch 1 (amino acids 30-38, shown in red) in Ras, which opens the binding site for the guanine nucleotides open. Additional conformational changes in Switch II (59–72, green) in Ras and interference from the side chains form the SOS alpha helix interfere with the binding of the phosphates on the bound nucleotide. This promotes the dissociation of the bound nucleotide and Mg^{2+}. Now GTP can preferentially rebind. How?

Before we answer that question, let's explore the conformational differences just in the structure of Ras in the Ras:GDP complex (4q21) and Ras in the Ras:SOS (1bkd) complex. These differences are shown in Figure 28.5.10 The green structure is the Ras:GDP. The cyan structure is Ras without bound GDP but bound to SOS.

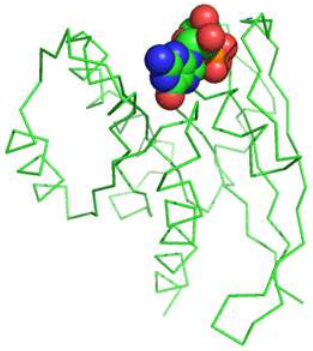

Figure 28.5.10: Structure difference in Ras in the Ras:GDP complex (4q21) and Ras in the Ras:SOS (1bkd) complex

Note the large shift in Switch 1 in the Ras structure from the Ras:SOS complex. This leaves a "gaping" hole from which GDP can "escape". Now how do the opening of the active site and release of bound GDP facilitate GTP binding?

Once bound just to Ras, GDP dissociates very slowly. Values of 10^{-5} sec^{-1} have been reported for the first-order rate constant of the dissociation of GDP from a small G protein. Assuming that the on-rate for complex formation is diffusion-controlled, the K_D for the G protein:GDP complex would be 0.1 pM and the half-life would be 0.8 days, similar to the lac repressor:DNA operator complex. Hence the protein, when bound to GDP, is essentially locked in the off position.

The conformational changes on RAS binding to SOS open up the active site, allowing GDP dissociation. GTP can now replace it since from an equilibrium point of view, Ras and other small G proteins favor GTP binding since the concentration of GTP in the cell is higher than that of GDP. In addition, some additional noncovalent interactions with the extra phosphate on GTP probably help.

Figure 28.5.11shows a cartoon showing the changes in Ras on GEF binding as illustrated in these coupled chemical equilibria:

$$GEF_{loose}:Ras:GDP_{tight} \leftrightarrow GEFtight:Ras:GDP_{loose} \leftrightarrow GEF_{tight}:Ras$$

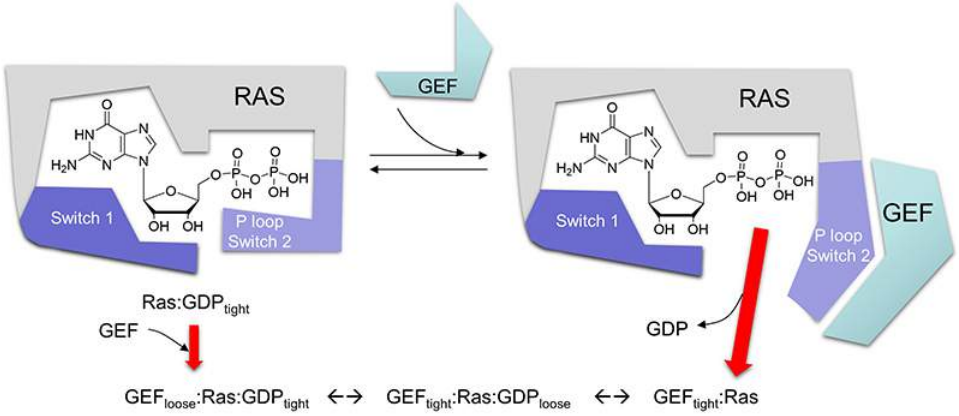

Figure 28.5.11: Chemical equation for Ras:GEF:GDP interactions

28.6: Phosphatases

28.6.1: Introduction

Protein kinases phosphorylate proteins in a process that can either activate or inhibit the target protein's activities. To control signaling processes, the activities altered by protein phosphorylation can be readily reversed by dephosphorylation of the Ser-, Thr- or Tyr-phosphoesters by simple hydrolysis. These reactions are catalyzed by protein phosphatases. Some of these phosphatases also cleave phosphates from lipids as well.

There are three main families of phosphatases, phospho-Tyr phosphatases (PTP), the phospho-Ser/Thr phosphatases, and those that cleave both. Of all phosphorylation sites, most (86%) are on serine, 12% involve threonine and about 2% are on tyrosine. They can also be categorized by molecular sizes, inhibitors, divalent cation requirements, etc. In contrast to kinases which differ in the structure of their catalytic domains, many **p**rotein **p**hosphatases (**PP**s, also abbreviated Ppp for **P**rotein **p**hos**p**hatases) gain specificity by binding protein cofactors which facilitate translocation and binding to specific phosphoproteins. The active phosphatase hence often consists of a complex of the phosphatase catalytic subunit and a regulatory subunit. Regulatory subunits for Tyr phosphatases may contain a SH2 domain allowing binding of the binary complex to autophosphorylated membrane receptor Tyr kinases.

We'll consider examples of all four families. They recognize target proteins through protein:protein interactions and specific binding site motifs. There are over 10,000 pSer and p-Thr sites on target proteins, so targeting specific sites must be quite nuanced.

28.6.2: Serine/Threonine Phosphatases

Important Ser/Thr phosphatases (PPs for Protein Phosphatases) include:

- Protein phosphatase 1 (PP-1 or Ppp1) - This is the most abundant PPP in humans. Different regulatory subunits target this to the liver glycogen particles (GL subunit), striated muscle glycogen, and sarcoplasmic reticulum (GM subunit) or smooth muscle fibers (M subunit). It is also present in the nucleus where it is presumably involved in the regulation of transcription factors. It is also involved in RNA splicing and signaling at neural synapses.
- Protein phosphatase 2A (PP-2A or Ppp2) - is a trimer with catalytic, regulatory, and scaffolding (also regulatory) structural subunits. It is found mainly in the cytoplasm and is involved in a myriad of cellular processes.
- Protein phosphatase 2B (PP-2B or Ppp3) - also called calcineurin or Ca^{2+}/Calmodulin dependent protein phosphatase - It consists of a catalytic subunit (calcineurin A) and a regulatory, calcium-binding subunit (calcineurin B). It is inhibited by the complex of the immunosuppressant cyclosporin and FK506 with immunophilins. PP2B regulates PKA and PKC
- (PP2C) -

The catalytic subunits of PP1, 2A, and 2B share a great deal of amino acid homology, and based on this homology, belong to one family. PP2C belongs to another family. PPs are often categorized into three other families including, phosphoprotein phosphatases (PPPs) and metal-dependent protein phosphatases (PPMs). There are about 30 catalytic PP subunits (many fold fewer than Ser/Thr Kinases). They gain specificity by binding numerous modulatory regulatory subunits.

As with other proteins, the names given to the proteins when discovered often do not reflect an organization scheme that would name different members based on structural similarities. PP-1, 2A, and 2B are better named Ppp1, Ppp2, and Ppp3 which denote members of the Protein PP (PPP) family. PP-2C would be named Ppm1 as the first member of the PPN family. All PPPs have three short sequence motifs that bind divalent cations.

In addition, older names for the given PPs referred to both the catalytic subunit and the dimer with the regulatory subunits. For clarity, the name of the catalytic protein phosphatase 1 is PP1c, and its regulatory subunits as RIPPOs, **r**egulatory **i**nteractors of **p**rotein **p**hosphatase **o**ne.

28.6.2.1: Protein Phosphate-1 (PP-1):

PP-1 is involved in many signaling pathways that control cell division, protein synthesis, etc. It catalyzes most serine–threonine dephosphorylation in cells. It is perhaps best known for its regulation of glycogen mobilization. Insulin signals the well-fed state in healthy people and promotes glucose uptake through the GPCR insulin receptor which we discussed in Chapter 12.4. Under these condition excess glucose is used to elongate glycogen, our main carbohydrate energy storage polymer. In contrast, the starving or low energy state is signaled by the hormone glucagon. You would expect that signaling pathways activated in the presence of insulin would promote glycogen synthesis and inhibit glycogen breakdown. PP-1 is a key factor in the regulation of both processes:

- Insulin activation of glycogen synthesis - PP1 dephosphorylates glycogen synthase (the enzyme that synthesizes glycogen) and in the process ACTIVATES it.
- Insulin inhibition of glycogen breakdown - PPI dephosphorylates two key enzymes involved in glycogen breakdown, phosphorylase kinase and glycogen phosphorylase a (with a pSer14), and in the process INHIBITS them.

PP1c interacts with many different regulatory subunits (RIPPOs) forming unique heterodimers. The regulatory subunits also bind potential substrates for PP1c and help localize the enzyme. at sites. The regulatory subunit involved in the PP1c effect on glycogen is called the glycogen-targeting subunit, G_M. There are 7 such regulatory subunits involved in glycogen metabolism. G_M (R_{GL}) is expressed in muscles and G_L in the liver. All of the regulatory subunits (unfortunately called G-subunits) have a conserved RVxF amino acid sequence which interacts with specific sites on the catalytic subunit typically distal to the active phosphatase site. Binding through the RVxF sequence does not affect the active site of the PP-1c. The binding of the regulatory subunit to the PP-1c can also occur outside of the canonical RVxF sequence. The regulatory subunits also have starch binding domain (SBD), also called the carbohydrate-binding module (CBM21). The subunits are often highly disordered until they are bound.

Figure 28.6.1 shows an interactive iCn3D model of protein phosphatase 1 (PP1) bound to the muscle glycogen-targeting subunit (Gm) and microcystin (6DNO) and the toxin microcystin.

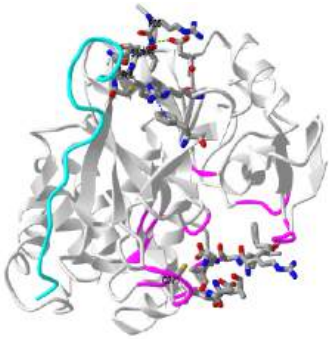

Figure 28.6.1: Protein phosphatase 1 (PP1) bound to the muscle glycogen-targeting subunit (Gm) and microcystin (6DNO). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...6f8f2kBRW4uhv5

PP-1 alpha catalytic chain is shown in gray. Its active site, where it binds Ser/Thr phosphorylated proteins is shown in magenta. Bound in that site is the toxin microcystin. The small chain shown in cyan is protein phosphatase 1 regulatory subunit 3A. PP-1 binds to its regulatory sequence to a 65RVxF68 sequence common on many regulatory PP-1 subunits. This subunit contains a serine 67 which is phosphorylation by protein kinase A. This inhibits the binding of the catalytic and regulatory subunits. (PKA) of the “x” residue in the G_M RVxF motif, Ser^{67}_{GM}, inhibits PP1 binding (*16*). Val79 and Lys80 on GM also form a motif that binds a corresponding pocket in the catalytic subunit.

Note the pi-cation (red) and pi-stack (blue) interactions from Phe 68 of the G_M 65RVSF68 motif of the regulatory subunit to the PPI catalytic subunit. Microcystin is 7-mer peptide ring that has 5 noncanonical amino acids and 2 regular ones. A covalent bond from Cys273 of PP1 (labeled in the above iCn3D model) to the methyl-dehydroalanine (Mdha) of the toxin forms. Microcystins are produced by toxic cyanobacteria and are very toxic and lethal, especially to animals including humans that drink water contaminated with the cyanobacteria. They will pose a greater threat in a warming world from climate change. They also bind to PP-2A.

Another example of a regulatory subunit for PP1 is the PP1 nuclear target subunit (PNUTS). The activity of the complex in the nucleus regulates the phosphorylation state o many proteins involved in the cell cycle including p53, a tumor suppressor in many tumors. It also regulated chromatin structure and RNA processing. As with the muscle glycogen-targeting subunit (Gm), PNUTS is intrinsically disordered when not bound to PP1 and is very extended when bound. The catalytic subunits of PP1c and PP2A have an acidic, hydrophobic, and C-terminal grove. PNUTS binds one of the substrate groves at an arginine subsite, but not the active site.

So far we can say the specificity of the binding of PPP is determined to some degree by the regulatory subunits. We turn to the contributions of the catalytic specificity of PP-1c when we compare it to PP-2Ac below.

Mechanism of PP1-A and PP-2A and B

The catalytical subunits of PP-1 and PP-2 are very homologous with nearly identical key active site side chains. The site contains two Mn^{2+} ions very near each other as shown in Figure 28.6.2

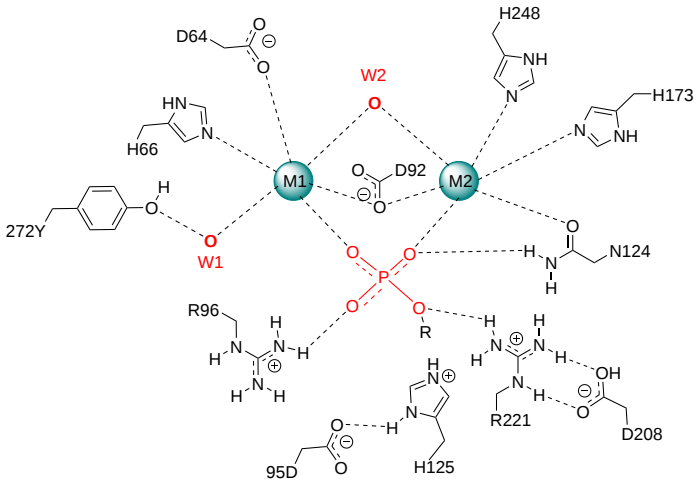

Figure 28.6.2: Interactions with two Mn ions in the active site of protein phosphatase-1 (PP-1). After McWirter et al. *J. Am. Chem. Soc.* 2008, 130, 41, 13673–13682

The figure crudely shows each Mn^{2+} is octahedrally coordinated to side chains and one water oxygen for each metal ion. Water 2 (or more likely OH^-) and an aspartate D92 oxygen bridge the two ions. The phosphate of the target Ser-OPO_3^{2-} or Thr-OPO_3^{2-}, or an inhibitor such as tungstate, also bridges the metal ion.

Figure 28.6.3 shows an interactive iCn3D model of Human Protein Phosphatase 1 Active Site Residue (4mov) which shows the same active site residues

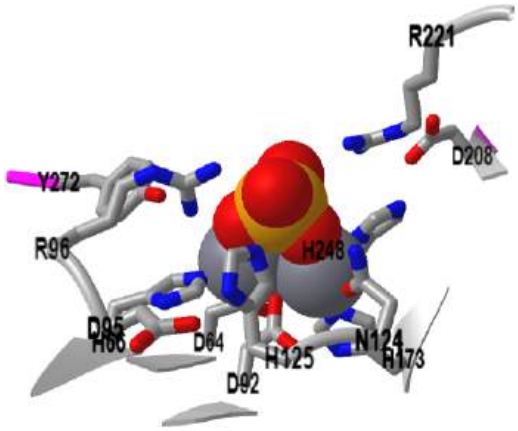

Figure 28.6.3: Human **Protein Phosphatase 1 Active Site Residue** (4mov). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?MYPrWfkX1PBaAggL9

The metals singly or in combination probably reduce the pKa of bound water to produce the deprotonated hydroxide, which engages in an S_N2 attack on the phosphate. Hence the metal ions act as an electrostatic catalyst.

The subtle differences in the active site and the three groups contribute to the specificity of the PPPs.

28.6.2.2: Comparison of the catalytic subunits of PP1A the PP2A

As mentioned above, substrate specificity is altered by subtle changes in the active site and three groves of PPPs. Figure 28.6.4 shows the acidic groves for PP1c and PP2Ac.

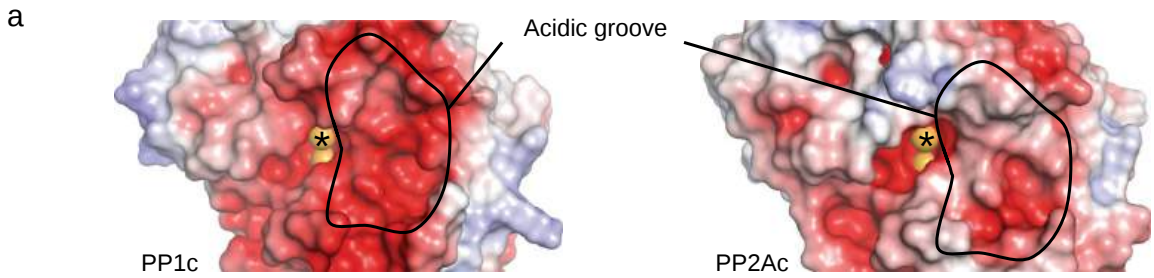

Figure 28.6.4: Acidic groves for PP1c (3EGG, chain A) and PP2Ac (4I5L, chain C)

The color is the electrostatic surface potential with red indicating negative and blue (notably absent) positive. The acidic groove is stronger in PP1c. The asterixis * shows the catalytic cleft containing two Mn^{2+} ions. Hoermann et al. Nature Communication | (2020) 11:3583 | https://doi.org/10.1038/s41467-020-17334-x. Creative Commons Attribution. 4.0 International License, http://creativecommons.org/licenses/by/4.0/.

The negative acidic grove is highly enriched in negatively charged side chains. Figure 28.6.5 shows the actual amino acids contributing to the negative electrostatic potential in aligned PP1c and PP2Ac.

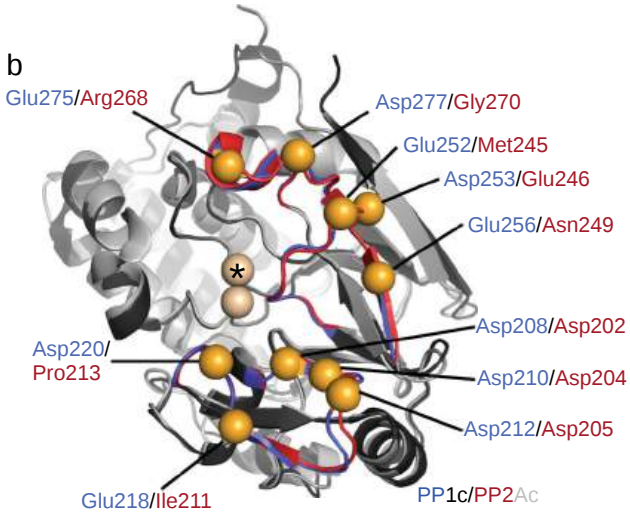

Figure 28.6.5: Amino acids contributing to the negative electrostatic potential in aligned PP1c and PP2Ac. Zhang et al. Hoermann et al. ibid

The orange spheres show the location of acidic side chains. PP1c is shown in blue/black and PP2Ac in red/gray.

The stronger acidic groove in PP1Ac gives it great preferences for pSer/pThr-protein targets with basic motifs than PP2Ac in a fashion that is independent of the bound regulator subunit. In contrast, PP2A needs to interact with regulatory subunits with more acidic composition to target basic motifs in protein targets. These features for PP1c and PP2Ac are compared in Figure 28.6.6

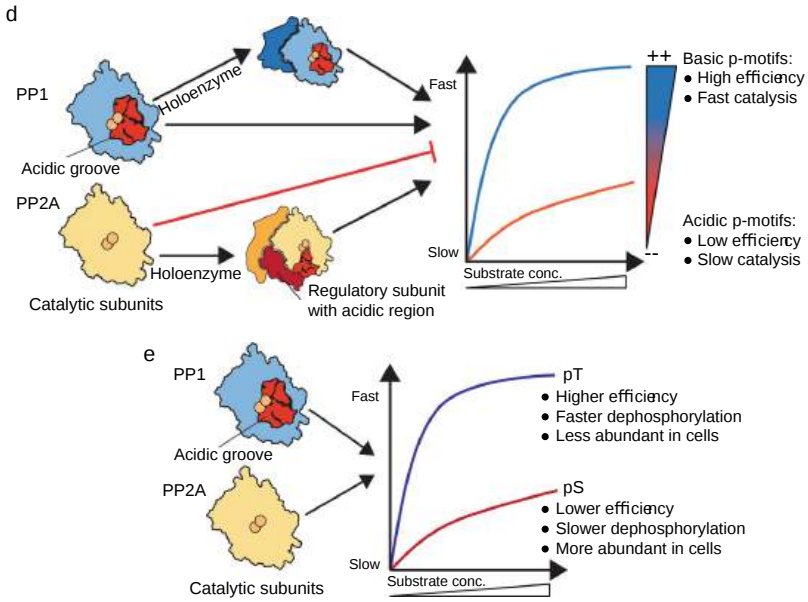

Figure 28.6.6: Comparative activity of PP1 and PP2A to basic target protein substrates.

Panel (d) shows that the holoenzyme for PP1 has a great preference for positive basic motifs than the holoenzyme for PP2A, which needs to associate with a negatively charged regulatory subunit for activity towards target proteins with basic motifs.

Panel (e) also shows that the catalytic subunits of both PP1 and PP2A prefer p-Thr protein targets compared to p-Velocity vs substrate graphs show these effects as well. e Both, PP1 and PP2A holoenzymes have a preference for pT due to higher catalytic efficiency of their respective catalytic subunits towards pT over pS. Hoermann et al. ibid

Figure 28.6.7 shows an interactive iCn3D model of the protein phosphatase 2A catalytic subunit in complex with a larger regulatory subunit and bound to the phosphatase inhibitor and tumor promoter okadaic acid (2IE4). The toxin, found in sponges and shellfish, is produced by dinoflagellates.

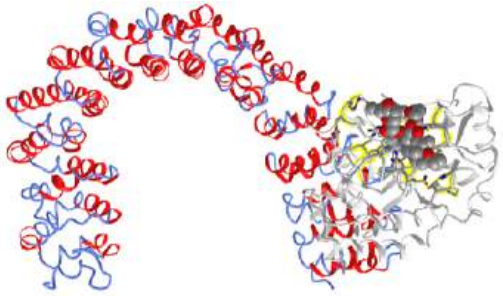

Figure 28.6.7: Protein phosphatase 2A core enzyme (catalytic and regulatory subunit) bound to okadaic acid (2IE4). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...Sb2Vq5iZgbBSz8

The regulatory subunit is shown in secondary structure color. This scaffolding protein is shaped like a horseshoe. The phosphatase inhibitor okadaic acids are shown in spacefill bound to the catalytic subunit shown in gray. The side chains of the catalytic subunit interacting with the 2 Mn^{2+} ions are shown in CPK-colored sticks (zoom in to see them). On binding the catalytic subunit, the scaffolding regulatory subunit is quite flexible and adaptable in interacting with other proteins.

28.6.2.3: Protein Phosphate 2B: Calcineurin (CN)

Calcineurin (CN), or PP2B, is depended on Ca^{2+}. It is involved in the development, immune signaling, and heart function. It consists of a catalytic site (CNA) and a calcium-binding regulatory subunit CNB so it is another example of PPP heterodimers. CNA has a catalytic domain and domains that bind CNB (the regulatory subunit), calmodulin (CAM, a calcium-binding protein that we will explore more in the next chapter section), and an autoinhibitory domain that blocks the active site. On Ca^{2+} release from internal organelles, the ion binds to both CNB and also CAM. These events cause conformational changes that release the bound autoinhibitor.

As with the other phosphatases, much effort has been made to determine how CN interacts with specific pSer- and p-Thr sites on targets. We'll focus on one, the integral membrane Na^+/H exchanger 1 (NHE1). This protein is itself regulated by Ca^{2+} ions and by phosphorylation by kinases we have previously studied, the MAPK ERK1/2 and the JNK kinase. Erk2 phosphorylates NHE1 at 6 Ser/Thr side chains in the recognition sequences name [S/T]P11. Several different phosphatases, including CN, can regulate NHE1 activity through direct dephosphorylation.

CN binds **short linear motifs (SLiMs)** named PxIxIT and the LxVP that are found in interacting partners including regulatory subunits as well as inhibitors and substrates. As we saw above, the regulatory subunits of PP1A and PP2A are highly disordered. Likewise, SLiMs are on intrinsically disordered regions as well as interacting proteins.

- PxIxIT binds to the catalytic domain of CNA22. It also enables interaction between CN and NHE1.
- LxVP binds to a cleft between the CNA and CNB, which is only available in the active form of the protein.

CN doesn't dephosphorylate multiple nearby p-Ser side chains of NHE1 (pS363, pS723, and pS726) since they are close to the NHE1-PxIxIT interaction sit,e which sterically restricts their binding to the active site. However the 3 other phospo S/T sites on NHE1 (pS771, pS785, and the actual target site (pT779) are far enough away from the NHE1's PxIxIT site so they can interact with the CN active site. Making the T779S mutation shows that dephosphorylation of their phosphorylated version shows a faster rate with pT779 and a slower, yet reasonable rate for pS779. Therefore other specificity factors are in play. A newly discovered very short 4-amino acid site motif in NHE1 including pS779 appears to be a source of selectivity. This TxxP motif in NHE1 is 779**T**PAP782. Such short recognition motifs are different than the selection of substrates by PP1 which involved multiple domain binding interactions and steric restrictions imposed by them.

Figure 28.6.8shows a model of the structure of the NHE1 exchanger (left panel a) and the calcineurin CNA/CNB complex.

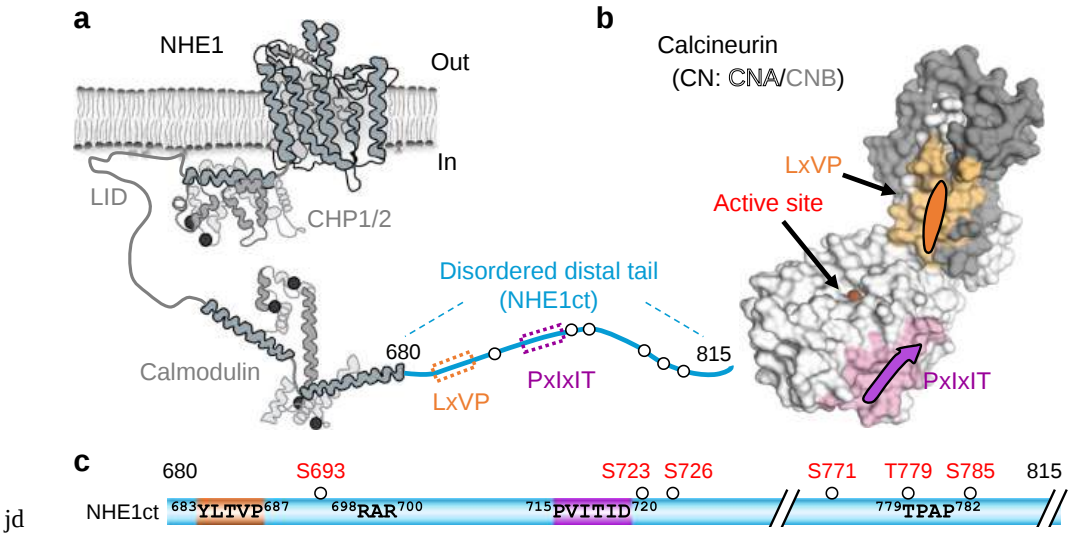

Figure 28.6.8 Docking motifs mediate the interaction of NHE1ct with CN

The motifs present in NHE1 (LxVP and PxIxIT) in the intrinsically disordered tail of NHE are indicated in the left panel and their corresponding binding sites in the CNA dimer are shown in corresponding colors. The calmodulin binding site is also shown. Erk2 phosphorylation sites in NHE1 are shown are listed in panel C along with the consensus motif sequences (PxIxIT in purple, LxVP in orange, and TRAP (uncolored)). Hendus Altenburger et al. Nature Communication (2019) 10:3489 | https://doi.org/10.1038/s41467-019-11391-7Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/.

Figure 28.6.9shows an interactive iCn3D model of calcineurin (PP2B) complex bound to a peptide from the Na^+/H^+-exchanger 1 (6NUC)

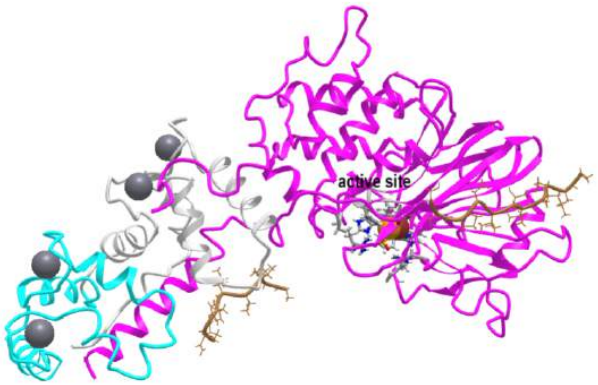

Figure 28.6.9: calcineurin (PP2B) complex bound to a peptide from the Na^+ /H^+ -exchanger 1 (6NUC). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...GgqSWpirpnZGt9

28.6.2.4: Protein Phosphatase 2C

The protein phosphatase 2C (PP2C) is a member of a family of metal-dependent protein phosphatases sometimes abbreviated as PPMs. (Of course, the other phosphatases we discussed above are also metal-dependent.) The required Mg^{2+} or Mn^{2+}. PP2C is a monomeric enzyme with at least four isoforms in humans. In humans, there are at least 17 members. One is unfortunately named protein phosphatase **1D** but also referred to as PPM1D, PP2Cδ, or Wip1). It is involved in heterochromatin silencing and the cycle. Mutations in its gene can accordingly give rise to tumors.

PP2Cs in humans have a binuclear metal cluster which reduces the pKa of water, producing OH^- for S_N2 attack on the phosphorus in the pSer or pThr in target phosphorylated proteins. Figure 28.6.10 describes binding interactions around the binuclear site in PP2Cα.

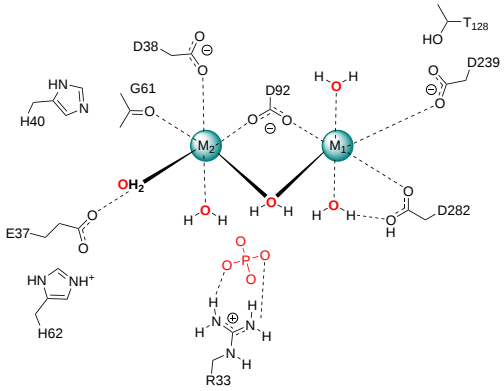

Figure 28.6.10 Binding interactions around the binuclear site in PP2Cα. after Pan et al. *Sci Rep* **5,** 8560 (2015). https://doi.org/10.1038/srep08560htt...cles/srep08560

The metal binding site with many water molecules Interactions with the metals is very different than the PP1 and PP2 active site shown in Figure 28.6.2

If Cd is bound at the M1 site, the activity of the enzyme is blocked so it is required for catalysis. Making the mutations affecting M2 (D38A and D38K) suggests that M2 is involved in binding the phosphate of the substrate, and also stabilizes the transition state and the leaving group in the reaction. H62 probably acts as a general acid catalyst.

Not all PPCs require both metal ions. The plant hormone abscisic acid regulates stress responses in plants. When it binds to a particular receptor called PYL1 (alternative name PYR1-like protein 1), the receptor interacts with a PP-2C called **ABI1** (also

called Absisic acid-insensitive 1). Figure 28.6.11shows an interactive iCn3D model of the ternary complex of Abscisic acid, PYL1 and ABI1 (phospholipase 2C) (3KDJ)

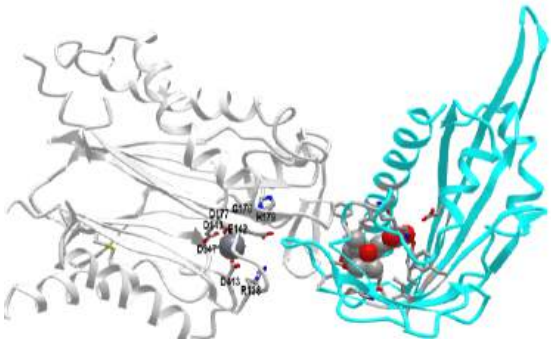

Figure 28.6.11: Ternary complex of Abscisic acid, PYL1, and ABI1 (phospholipase 2C) (3KDJ Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?FbEeZ3n5dWvA6bp56

The catalytic subunit, which in contrast to PP1, PP2A, and PP2B, has only 1 Mn^{2+} ion, is shown in gray with amino acids side chains interacting with the metal ion labeled. The cyan subunit is the receptor of abscisic acid, which is shown in spacefill.

28.6.3: Protein Tyrosine Phosphatases

Protein Tyr phosphatases (PTPs) consist of receptor-like (transmembrane) and intracellular Tyr phosphatases. They more resemble tyrosine kinases in their complexity than the Ser/Thr phosphatases. There are about 100 PTPs in the genome, a number similar to the number of protein tyrosine kinases. PTPs have an active site Cys in a CX5R-(S/T) motif with an active site Cys nucleophile and an Arg in the phosphate binding (P) loop. Some examples we will discuss include:

- Low molecular weight PTPase - These have roles in the metabolism and differentiation of cells. They have a molecular weight of 18,000 and have an active site CX5R-(S/T) motif, where the C (Cys) is an active site nucleophile.
- PTP1B - dephosphorylates many cell surface receptors (insulin, EGF, PDGF) that have been phosphorylated on Tyr residues. Its main activity seems to dephosphorylate nascent receptors in the endoplasmic reticulum before they get to the final cell membrane destination.
- Tyrosine phosphatase nonreceptor type 11, *ptpn11*, commonly called SHP2

Figure 28.6.12shows the protein tyrosine phosphatase (PTP) superfamily.

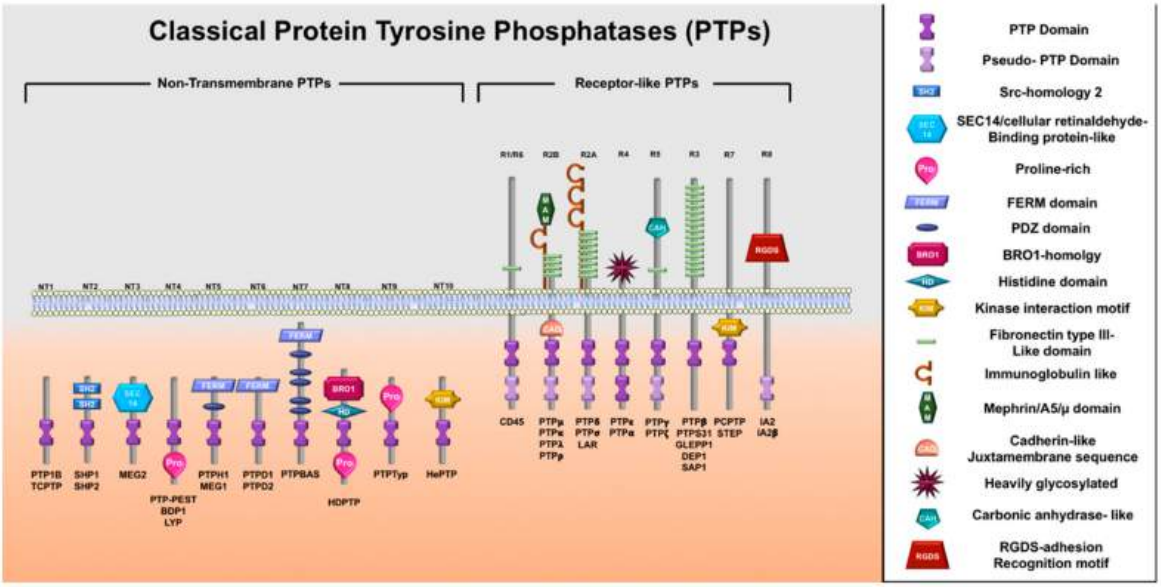

Figure 28.6.12: Protein Tyrosine Phosphatase superfamily Abdelsalam et al. *Biomolecules* **2019**, *9*, 286. https://doi.org/10.3390/biom9070286. Creative Commons Attribution 3.0 Unported License **https://creativecommons.org/licenses/by/3.0/**.

In contrast to the active site of the Ser/Thr phosphatases like PP-1, PP-2A and PP-2B, the active sites of protein tyrosine phosphatases (PTPs) do **not** have a bimetal ion cluster in the active site. Rather they all have an active site cysteine that acts as a nucleophilic catalyst in the hydrolysis of the p-Try phosphoester bond. The active site PTP domain is found in all of the proteins, so all use similar catalytic mechanisms shown in Figure 28.6.13

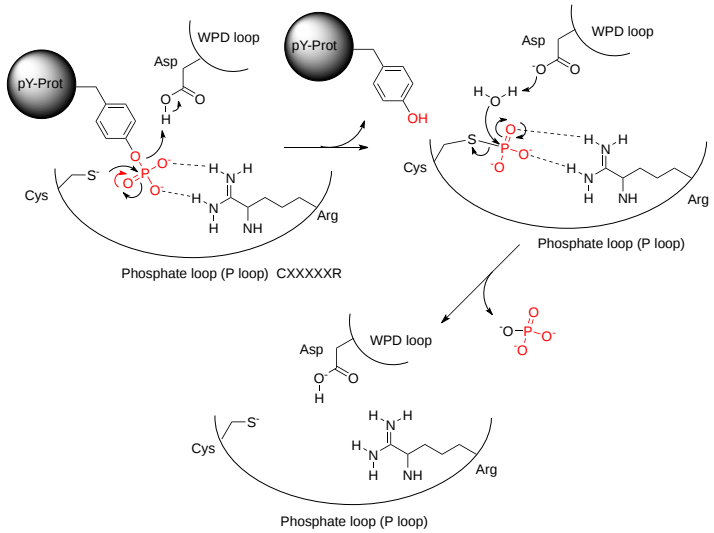

Figure 28.6.13: General catalytic mechanism of protein tyrosine phosphatases

The phosphotyrosine side chain of the target phosphoprotein binds in the phosphate-binding P-loop (H/VCxxxxxRS/T), which contains the nucleophilic Cys 12 and Arg 18 that stabilizes the charge on the phosphate. The Asp in the WPD loop positioned across from the nucleophilic Cys 12 acts as a general acid. Since the active site is nearly identical in the PTPs, it has been hard to design drugs that bind to the active site but that are also selective for specific PTPs.

28.6.3.1: Low molecular weight protein tyrosine phosphatase - LMW-PTP

This protein tyrosine phosphatase is the simplest of all in structure. It has the phosphate-binding P-loop (12CxxxxxR18) with the nucleophilic Cys 12 and Arg 18 that stabilizes the charge on the phosphate. It does not have the conserved WPD loop but deploys Asp 129 across from Cys 12 as a general acid. This enzyme exists as two main isozymes, A and B. Figure 28.6.14 shows an interactive iCn3D model of human low molecular weight protein tyrosine phosphatase bound to sulfate (1xww)

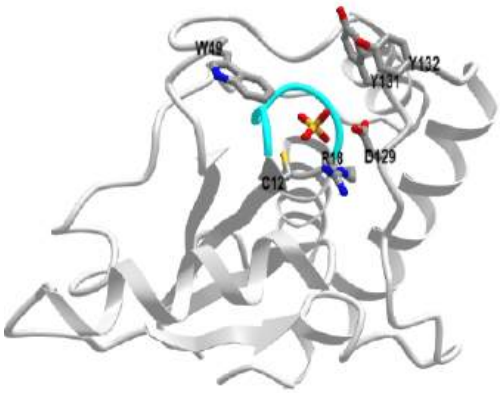

Figure 28.6.14: human low molecular weight protein tyrosine phosphatase bound to sulfate (1xww). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...jaW2syCWWeeLD8

The active site is deep as shown in Figure 28.6.15

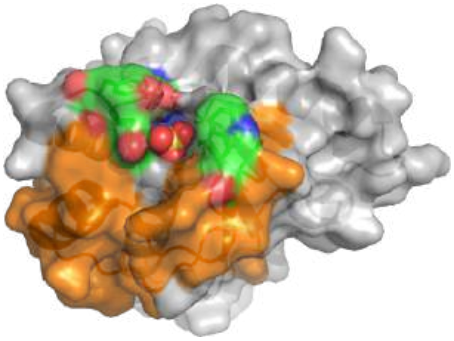

Figure 28.6.15: Active site pocket and surround surface of low molecular weight protein tyrosine phosphatase (1xww)

The sulfate, a mimetic for the phosphate on the p-Try protein target, is deeply buried. The CPK-colored surface (green red, blue) around the sulfate are the side chains of Tyrosine 131 and 132 as well as Trp 49. Y131 and Y132 are part of a loop containing Asp 129, the general acid. This loop is analogous to the WPD loop. The three aromatic amino acids on top of the pocket make it deep enough that pSer and pThr side chains can't reach the active site nucleophile Cys 12. Trp 49 is also in a variable loop (34 amino acids, shown as an orange surface) that differentiates two of the major isozymes, the A and B forms, and contributes to substrate binding specificity.

28.6.3.2: Tyrosine-protein phosphatase non-receptor type 1, also known as PTPN1 or PTP1B PTP1B

PTP-1B regulates the endoplasmic reticulum unfolded protein response and is involved in insulin JAK/STAT and HER2 (ErbB2) signaling. It has a full-length form (MW 50,000) and a C-terminal shortened form (37,000)

Given the difficulty in targeting the active site which is common in all PTPs, efforts have concentrated on the development of allosteric inhibitors that bind to exosites removed from the active site. An example is trodusquemine (MSI-1436) used in the treatment of obesity and type 2 diabetes. It binds much more tightly to the full-length form.

Figure 28.6.16 shows an interactive iCn3D model of the human Protein Tyrosine Phosphatase 1B (1-301) in complex with the inhibitor OTA (5K9W).

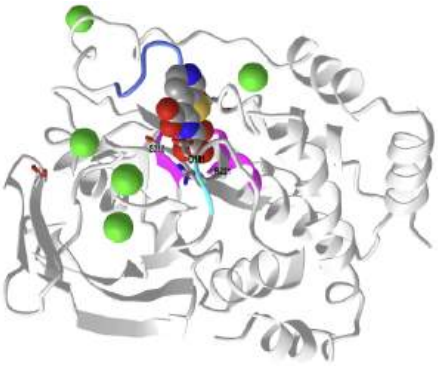

Figure 28.6.16: Human Protein Tyrosine Phosphatase 1B (1-301) in complex with the inhibitor OTA (5K9W). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...fTurfTTFiW2b47

The P-loop is shown in magenta, the WPD loop in cyan, and the substrate binding loop (SBL), which allows entry of pTyr but not pSer and pThr, in blue. The key side chain in the P-loop (Cys 215 and Arg 221) as well as the catalytic general acid (Asp 181) are shown in sticks and labeled. The inhibitor is shown in spacefill, and CPK colors. The movement of the WPD loop is rate-limiting for the hydrolysis of P-Tyr esters. On binding, the WPD starts to close, and in the process Arg 221 moves to form salt bridges with the phosphate. Full closure of the WPD follows, which positions Asp 181 for general acid catalysis. Key interactions of PTP-1B phosphoprotein in insulin and cytokine signaling, are shown in Figure 28.6.17:

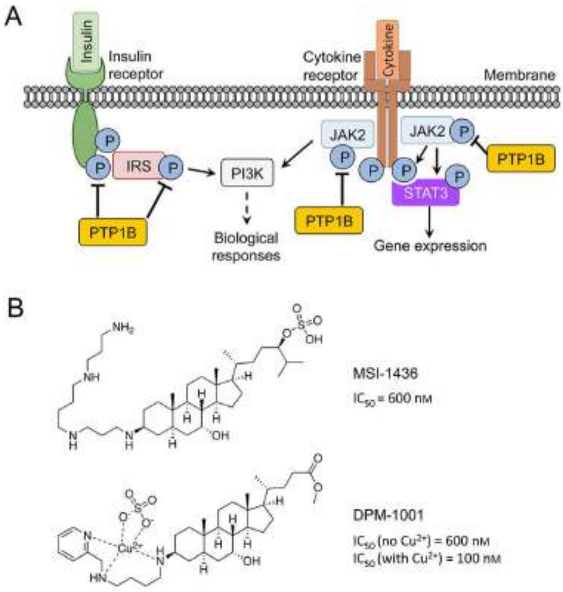

Figure 28.6.17: Protein tyrosine phosphatase 1B (PTP1B) and its effects on signaling. Maja Köhn *ACS Cent. Sci.* 2020, 6, 4, 467–477. Publication Date: March 13, 2020. https://doi.org/10.1021/acscentsci.9b00909. This is an open-access article published under an ACS Author Choice License, which permits copying and redistribution of the article or any adaptations for non-commercial purposes.

Panel (A, left) shows how PTP1B dephosphorylates the insulin receptor and the insulin receptor substrate (IRS), which we have explored in a previous section. Panel (A, right) show its activity in the JAK/STAT pathway, which we have all seen previously. One cytokine receptor that it regulates is the leptin receptor. The hormone leptin, released from fat cells (adipocytes) is a key regulator of lipid metabolism. Pane B shows the structures of key inhibitors of PTP-1B.

28.6.3.3: Protein tyrosine phosphatase nonreceptor type 11 (*ptpn11*) also known as SHP2 (SH2-domain containing phosphatase-2)

This is an example of another phosphatase in which a mutation leads to cancer. It is downstream and activated by most receptor tyrosine kinases (RTKs) involved in the activation of the MAPK pathway with its ultimate links into the nucleus and activation of gene transcription.

Figure 28.6.18shows an interactive iCn3D model of Non-receptor Protein Tyrosine Phosphatase SHP2 in Complex with Allosteric Inhibitor Pyrazolo-pyrimidinone 5 (6MDB)

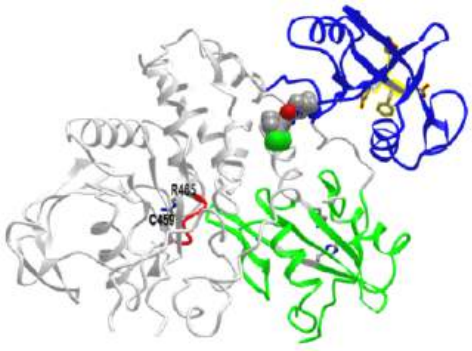

Figure 28.6.18: Non-receptor Protein Tyrosine Phosphatase SHP2 in Complex with Allosteric Inhibitor Pyrazolo-pyrimidinone 5 (6MDB). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?5WCzu8HeY7JrEVyw5

The phosphatase domain is shown in gray. The N- and C-terminal SH2 domains are shown in green and blue, respectively. The allosteric inhibitor is shown in spacefill and CPK colors. The P-loop in the catalytic domain is shown in red with the Cys 459 (active site nucleophile) and R465 (stabilizer of phosphate in the complex) shown in sticks, CPK colors, and labeled. The bound

inhibitor is especially interesting as it binds at an allosteric site. As mentioned above, it is very difficult to design specific inhibitors that target just one PTP given their common active sites and mechanisms. Figure 28.6.19shows multiple features of SHP2.

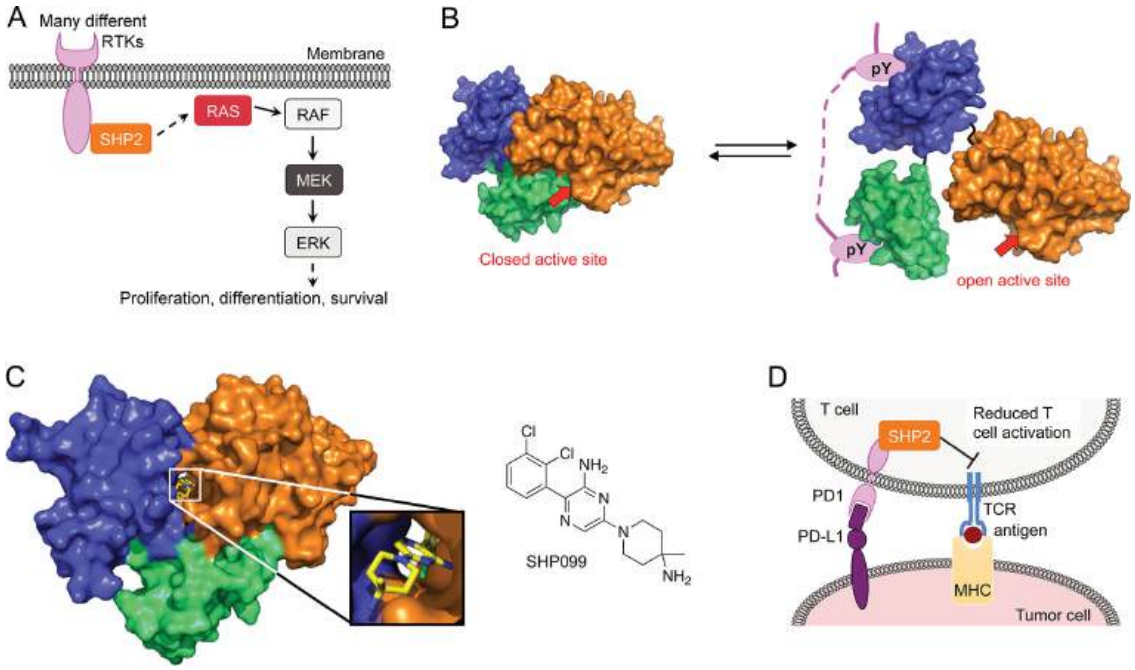

Figure 28.6.19. SH2-domain containing phosphatase-2 SHP2. Köhn ibid.

Panel (A) shows how SHP2 recruited to phosphorylated RTKs activates the MAPK pathway. The dotted line indicates multiple steps. Upon receptor activation, SHP2 is recruited in different ways to activate the MAPK pathway.

Panel (B) shows that in the inactive state, the N-terminal SH2 domain (green) blocks access to the active site. When the N- and C-terminal domains bind pY residues in a single pY-protein, two pY-proteins, or pY residues on its C-terminal tail, a conformational change ensues opening the active site (5EHR).

Panel (C) shows how another allosteric inhibitor keeps the protein in a closed state (5EHR).

Panel (D) shows how SHP2 can decrease T-cell responses through the MHC:Tcell receptor (TCR) complex. Tumor cells express a ligand called PD-L1, which binds to the PD1 receptor on the T cell surface. After binding, SHP2 is recruited to PD1, decreasing T cell activation. This is not a good thing since it inhibits the immune response to the cancer cell.

28.6.4: Dual Specificity Phosphatases (DUSPs)

Another important phosphatase is **phosphatidylinositol 3,4,5-trisphosphate 3-phosphatase and dual-specificity protein phosphatase PTEN (**phosphatase and tensin homolog**).** Dual-specificity protein phosphatase hydrolyzes pTyr- as well as pSer- and pThr- phosphoesters in target proteins. They don't require divalent metal cations and are closer in structure to protein tyrosine phosphatases. They have an active site cysteine in a P-loop also containing arginine. In addition, they are lipid phosphatases, removing phosphate from the inositol ring from phosphatidyl inositol derivatives. These both impact many signaling pathways. Its activity as a lipid phosphatase makes it a tumor suppressor protein as it inhibits the PI3K-AKT/PKB signaling pathway by dephosphorylating phosphoinositides. Hence it modulates both AKT and mTor pathways.

The domain structure of PTEN is shown in Figure 28.6.20

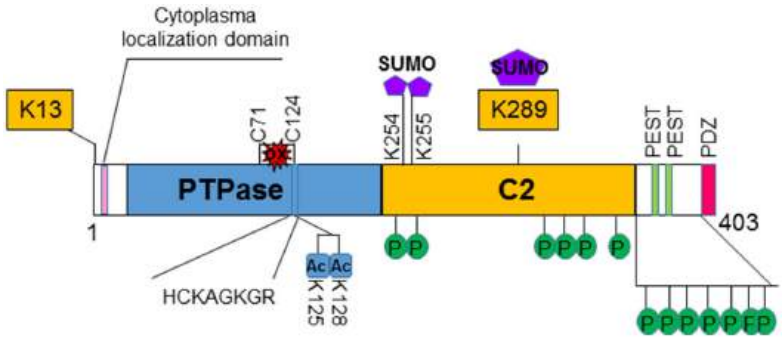

Figure \(\PageIndex{20}\: Structure and regulation of PTEN Chen et al. Endocrinol., 09 July 2018 | https://doi.org/10.3389/fendo.2018.00338. **Creative Commons Attribution License (CC BY)**

The C2 domain enables phospholipid binding. Multiple post-translational modification sites are indicated. The PEST motif is sequence rich in proline (P), glutamic acid (E), serine (S), and threonine (T) and bounded by positively charged amino acids (Lys, Arg, or His) that act as signals for protein degradation. The PDZ domain, often found at the C-terminal of signaling proteins, acts as a scaffolding site for interaction with other signaling proteins. In the next chapter section, we will consider redox signaling, for which PTEN is a great example. Disulfide formation (in a more oxidizing environment) between the nucleophilic Cys 124 and a nearby Cys 71 (figure above) inhibits PTEN phosphatase activity.

Figure 28.6.21 shows an interactive iCn3D model of an AlphaFold computational model of full-length human PTEN (Uniprot P60484).

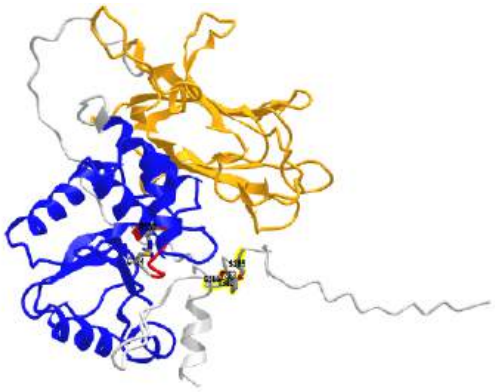

Figure 28.6.21: AlphaFold computational model of full-length human PTEN (Uniprot P60484). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...1nbf3sDfhvMZ19

The phosphatase (PTPase) domain is shown in blue and the C2 domain is in orange. The P-loop is in red with the active site Cys 124 and R130 in colored sticks and labeled. The backbone of the highly extended intrinsically disordered C-terminus region is shown in gray. It contains the clustered residues Ser 380, Thr 382, Thr 383, and Ser 385 (shown in colored sticks and labeled) that are sites for phosphorylation by activated kinases.

iFigure 28.6.22shows key molecules dephosphorylated by PTEN, including the lipid PIP3, and Thr 308 and Ser 473 on AKT.

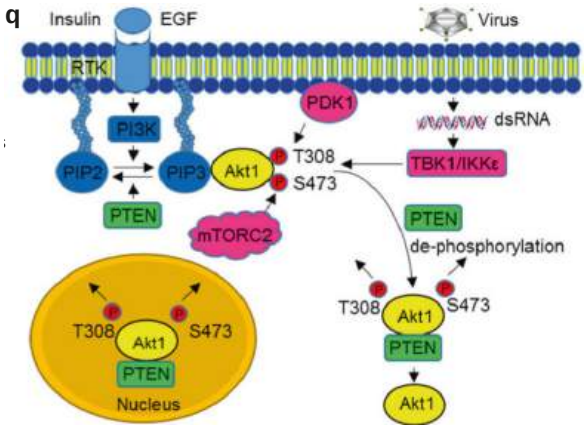

Figure 28.6.22: A model of how PTEN suppresses the activity of Akt. Bu, L., Wang, H., Pan, Ja. *et al*. PTEN suppresses tumorigenesis by directly dephosphorylating Akt. *Sig Transduct Target Ther* **6,** 262 (2021). https://doi.org/10.1038/s41392-021-00571-x. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/.

When PTEN dephosphorylates Akt1, it inhibits AKT activity and effectively antagonizes the main PTEN-PIP3-PDK1-Akt pathway. PTEN is considered a tumor suppressor for this reason. Mutations in PTEN hence are associated with cancer.

28.7: Calcium Signaling

The following is adapted directly and modified from Sharma et al. Biomedicines **2021**, *9*(9), 1077; **https://doi.org/10.3390/biomedicines9091077.** Creative Commons Attribution (CC BY) license (**https://creativecommons.org/licenses/by/4.0/**).

28.7.1: **Introduction**

Ca^{2+} is central to numerous cellular processes and functions. Its chemical features, including a low hydration energy, high polarizability, relative flexibility of coordination sites and bond length, and large concentration gradient across cellular membranes (100 nM intracellular to 2 mM extracellular) due to low intracellular levels make it the ion of choice at the core of cellular signaling in prokaryotes and eukaryotes alike.

In studying calcium ion signaling we will focus on four key areas:

- Buffering of intracellular Ca^{2+} ion concentrations: Basal low levels must be maintained, which allows transient increases to act as signals. Ca^{2+} ions hence are no different from other second messengers like cAMP, for example. What matters is the rise from a basal level to a threshold concentration level that allows binding to signaling proteins and subsequent signal transmission.
- Storage of intracellular Ca^{2+}: Calcium ions are stored in organelles such as ER, mitochondria, and lysosome. The ions must be released in the presence of specific signals, then returned to the storage organelle to maintain basal Ca^{2+} levels.
- Signaling pathways activated by Ca^{2+} ion: We have seen many pathways simulated by a rise in second messengers and by phosphorylation of lipid and protein molecules in interconnected pathways. We will return to several pathways we have previously studied to see how they integrate with Ca^{2+} in signaling processes.
- Ca^{2+} binding proteins and their binding partners in signaling pathways: We will focus on one key Ca^{2+} binding protein, **calmodulin** (**CAM**), and the kinase that it activates, **Ca^{2+}/CAM protein kinases** or **CAMKs**.

The next two sections are adapted and modified from Sharma et al. Biomedicines **2021**, *9*(9), 1077; **https://doi.org/10.3390/biomedicines9091077.** Creative Commons Attribution (CC BY) license (**https://creativecommons.org/licenses/by/4.0/**).

28.7.2: Buffering of intracellular Ca^{2+} on concentrations

Calcium ions, like the hydronium ion, must be buffered in cells otherwise its potential as a signaling agent would be compromised. The mechanisms adopted by cells for intracellular Ca^{2+} buffering involve sequestration by special proteins as shown in Figure 28.7.1.

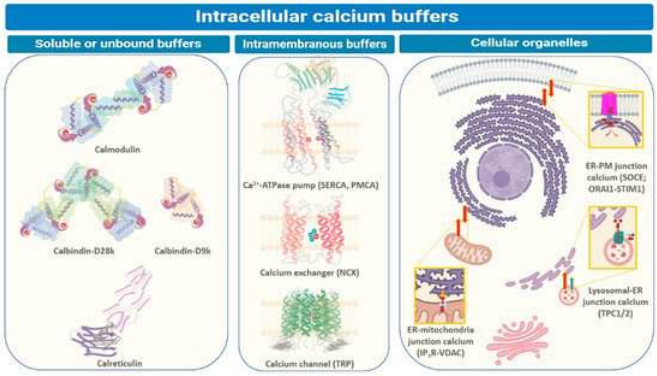

Figure 28.7.1: Types of intracellular Ca^{2+} buffers.

Intracellular Ca^{2+} levels are managed through binding to special proteins or sequestration within different cellular compartments. The three main ways by which intracellular Ca^{2+} is buffered are depicted in Figure 1. These include soluble or unbound proteins that are found in the cytosol or inside organelles, membrane proteins (generally Ca^{2+} channels, ATP-driven pumps (SERCA or PMCA), and ion exchangers (NCX), inside organelles like endoplasmic reticulum (ER), mitochondria, acidic vesicles (mainly lysosomes and Golgi bodies) or organelle junctions (endoplasmic reticulum-plasma membrane (ER-PM), endoplasmic reticulum-mitochondria, or endoplasmic reticulum-lysosomes). The major players regulating inter-organellar Ca^{2+} transfer are IP_3R (inositol-3,4,5-triphosphate receptor), NCX (sodium-Ca^{2+} exchanger), ORAI1/CRACM1 (Ca^{2+} release activated modulator 1), PMCA,

(plasma-membrane Ca^{2+} ATPase), SERCA (sarco-endoplasmic reticulum Ca^{2+} ATPase), STIM1 (stromal interaction molecule 1), SOCE (store-operated Ca^{2+} entry), TPC1/2 (two-pore channel), TRP (transient receptor potential) and VDAC (voltage-dependent anion channel). We will discuss some below.

These proteins are involved in sequestering cytosolic Ca^{2+} upon sensing an increase in its levels and participate in relaying the associated cellular messages. Other proteins that work as intracellular Ca^{2+} buffers exist in the lipid bilayers, plasma membranes, or organelle membranes, like pumps or transporters. Apart from these proteins, intracellular Ca^{2+} is regulated by inter-organellar transport and the influx of Ca^{2+} ions from extracellular space.

28.7.3: Storage of intracellular Ca^{2+} - Proteins

Soluble and Unbound Intracellular Proteins: Calmodulin, Calbindin, and Calretinin

Nonmembrane-associated proteins inside a cell can act as both Ca^{2+} sensors and buffers. Most of these proteins have EF-hand motif(s) that allows Ca^{2+} ions to bind and trigger changes in protein folding, influencing downstream or linked cellular pathways. **Calmodulin (CaM)** is one of the best-studied and ubiquitously expressed Ca^{2+}-sensing proteins known to play a key role in intracellular Ca^{2+} homeostasis. It is a prototype for intracellular Ca^{2+} sensors. It has a 148 amino acid structure with two Ca^{2+}-binding sites in two separate lobes, each with two EF-hand motifs. The lobes are connected in the holo (Ca^{2+}-bound form that binds other proteins. N- and C-termini alpha-helices with a Ca^{2+} coordination loop in between providing affinity for Ca^{2+} ion docking and sequestration. The ability of CaM to transmit a change in free intracellular Ca^{2+} levels into a signal depends on the conformational flexibility of the Ca^{2+}-dependent (apo) form. CaM can exist in a Ca^{2+}-free closed conformational state (Apo-CaM), a semi-open (Ca_2-CaM), or an open state (Holo-CaM or Ca_4-CaM) after Ca^{2+}-binding as shown in Figure 28.7.2

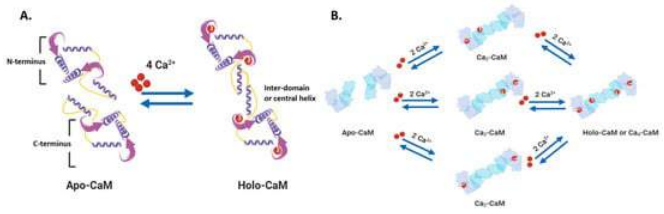

Figure 28.7.2: Overview of calmodulin structure and Ca^{2+} binding conformations.

Figure 28.7.3 shows an interactive iCn3D model of Holo-calmodulin with 4 bound Ca^{2+} ions (1CLL)

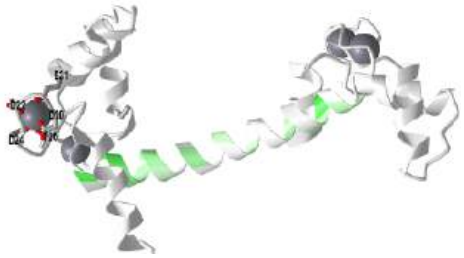

Figure 28.7.3: Holo-calmodulin with 4 bound Ca^{2+} ions (1CLL). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...8nT5HXgNJ4ymc6

Side chains interacting with one Ca^{2+} ion in an EF-hand is shown in the model. The central helix is colored based on hydrophobicity with green indicating more hydrophobic. This amphiphilic helix can bind target proteins in this region through nonpolar interactions.

Figure 28.7.4 shows the change in conformation going from the apo form (without Ca^{2+}) to the holo-form with the fully-formed central helix connecting to the two lobes of the "dumbbell".

Figure 28.7.4: Conversion of apo-CAM to holo-CAM on binding Cal^{2+}.

Differential Ca^{2+} binding to the two lobes of CaM makes fast buffering of a wide range of free intracellular Ca^{2+} possible for this protein. The presence of methionine residues in its lobes and the plasticity of the central linker in its structure also provides CaM with properties to function as an adaptor protein in intracellular Ca^{2+} signaling. CaM can bind to several targets or effector molecules over a variable distance and in multiple orientations to mediate change in intracellular Ca^{2+} signaling. Some major effector proteins that are regulated by CaM binding and are relevant for Ca^{2+} homeostasis include EGFR, PI3K, and connexins.

CaM is required for spatial and temporal regulation of $[Ca^{2+}]$as evident by its role in modulation (activation or inactivation) of Ca^{2+} pumps (such as PMCA and SERCA) and Ca^{2+} channels (such as CaV1.3, TRPV5 and 6, ORAI). CaM also acts via serine/threonine kinases known as Calmodulin-activated Kinases (CaMKs) to influence cellular processes like proliferation (for example, centrosome duplication at G1/S or anaphase to metaphase transition via CaMKII). We will discuss those in detail below.

Integral Membrane protein molecular buffers: SERCA, PMCA, NCX, and TRP

Integral membrane protein Ca^{2+} buffers primarily translocate free Ca^{2+} between domains and organelles. These mainly comprise ion exchangers, channels, and ATP-driven pumps. SERCA, Sarcoendoplasmic Reticulum Ca^{2+} ATPase, is an ATP-dependent ion pump known to significantly maintain free cytosolic Ca^{2+} concentration via actively pumping the ion into the endoplasmic reticulum (or sarcoplasmic reticulum in muscle cell). They share a general structure that includes 10-pass transmembrane helices and three cytoplasmic domain lobes as shown in Figure 28.7.5

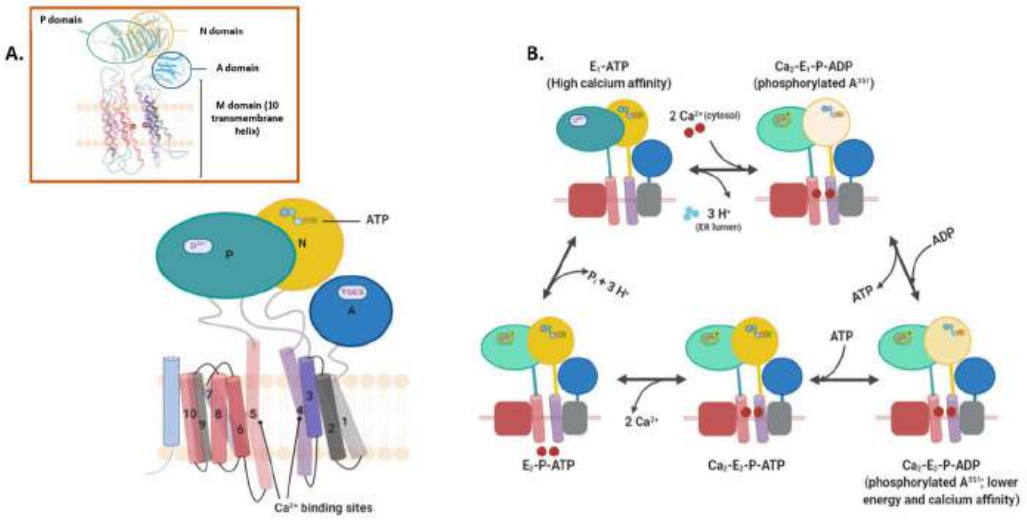

Figure 28.7.5: Sarcoplasmic endoplasmic Ca^{2+}-ATPase structure (Panel A) and mechanism of Ca^{2+} ion transport (Panel B).

P-type Ca^{2+}-ATPases also exist within the plasma membrane and maintain cytosolic Ca^{2+} levels by transferring them into the extracellular space. The Plasma Membrane Ca^{2+} ATPases (PMCAs) can PMCAs transport one Ca^{2+} ion per ATP molecule which differs from the two Ca^{2+} ions per ATP molecule stoichiometry of SERCA. The general structure of such Ca^{2+} transporters comprises 10 transmembrane segments with large cytosolic loops TM 1–2 and TM 3–4, a cytosolic N- and C-termini tails are shown in Figure 28.7.6, panel A below.

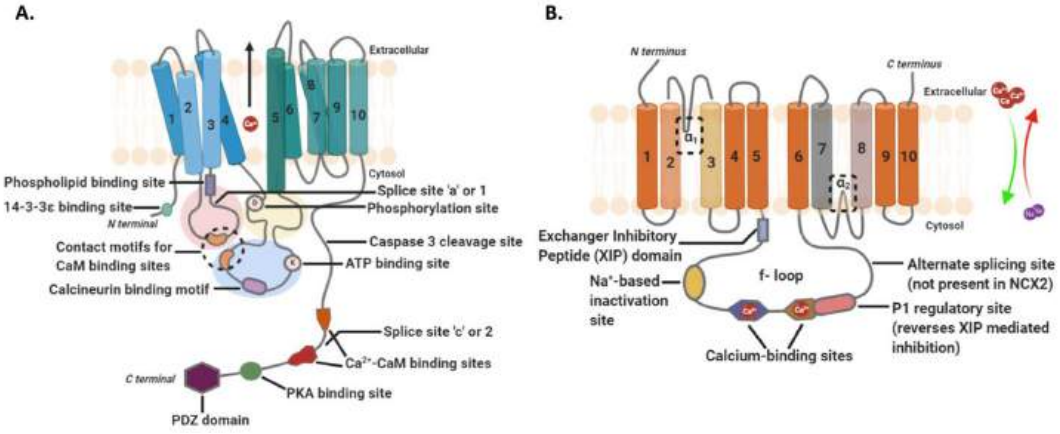

Figure 28.7.6: The general structure of such Ca^{2+} transporters. (A) is the Plasma membrane Ca^{2+}-ATPase (PMCA) and (B) shows the Na^{+}–Ca^{2+} exchanger (NCX)

The cytoplasmic region of PMCA (left) has three loop structures with binding sites for signaling molecules like CAM. They also have phosphorylation sites for additional regulation. The C-terminal tail contains additional CAM sites as well as a PKA site. It has a PDZ domain that can anchor the protein to cytoskeletal components. Differential RNA processing lead to variations in the amino acid sequence in this region and hence binding specificity. The binding of CaM reverses auto-inhibition of the pump due to conformational shifts which displace C-tail from cytosolic loops. Other means of autoinhibition reversal include phosphorylation of C-tail (Ser/Thr residues) by protein kinase A or C, proteolytic cleavage of C-tail, or dimerization via the C-terminus.

Transient Receptor Potential (TRP) channels have a similar function in neurons, epithelial and immune cells. The Mammalian TRP channel superfamily is composed of 28 family members belonging to six subfamilies—TRPC (Canonical), TRPA (Ankyrin), TRPM (Melastatin), TRPV (Vanilloid), TRPP (Polycystin), and TRPML (Mucopilin)—that differ in their sensitivity to various sensory stimulations and affinity for cations (including Ca^{2+} ions) sequestration. Commonly, TRP family members share a structure with six transmembrane domains, intracellular N- and C-termini, and a pore-forming TM 5–6 loop. The cytoplasmic C-terminus of each subunit is a site for protein interaction and post-translational modification. The C-tail of these channels can have PDZ protein binding domains (TRPV and C), sites for interaction with G-proteins (Gq/11)/calmodulin/PLCβ, ADP-ribose binding (NUDIX; TRPM2), or PLC-interacting kinase (PLIK; TRPM6 and 7) domain.

TRP channels act as activators, integrators, as well as downstream effectors of Ca^{2+} signaling at the plasma membrane and in intracellular compartments. Many members of the TRPC subfamily are activated by DAG (diacylglycerol) which is produced by PLC β- or γ-mediated cleavage of phosphatidylinositol 4,5-bisphosphate (PIP_2) after the ligand binding at GPCRs or RTKs. TRPP1/2, TRPA1, TRPM8, and TRPV1-4 are all expressed on the ER membrane. At this site, PLC-independent activation of the TRP channels (such as TRPV1) is suggested to induce ER Ca^{2+} release via inositol triphosphate receptor (IP3R) which further triggers bulk entry of extracellular Ca^{2+} into the cell. On the flip side, cytosolic Ca^{2+} regulates the activity of TRP channels in response to physiological stimuli. This regulatory effect is usually through CaM binding (inhibition of TRPV5, TRPV6, and sensitization of TRPV3) and indirectly through CaM-binding kinase II (CaMKII). These activities are shown in Figure 28.7.7.

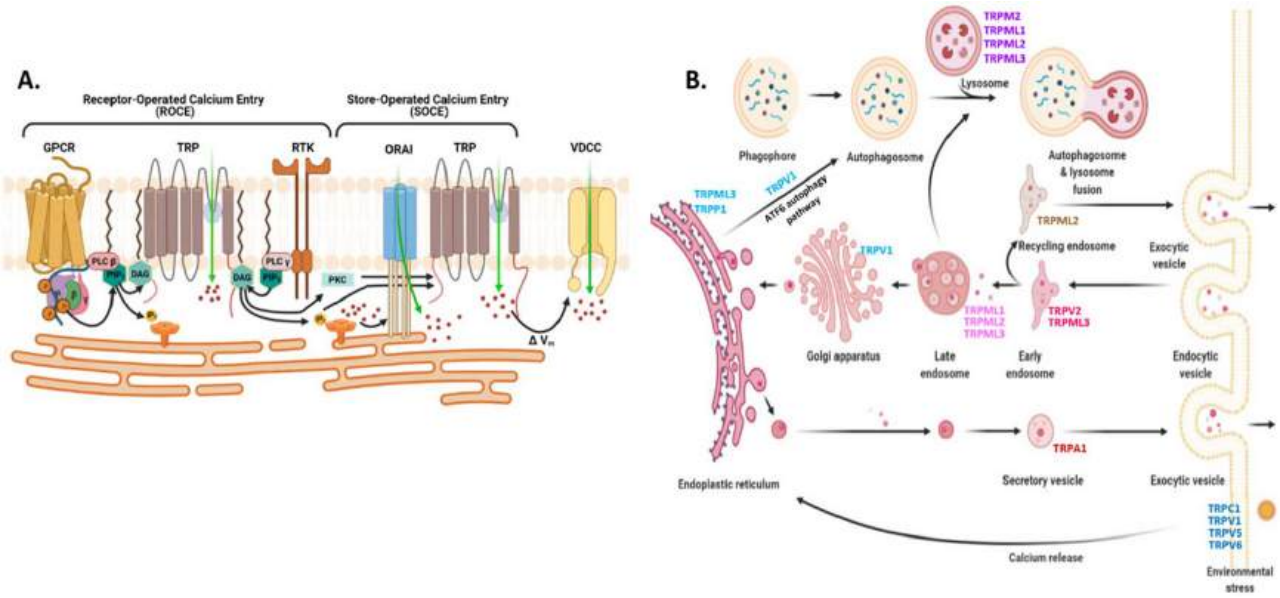

Figure 28.7.7: TRP Channels in Signaling. DAG, Diacylglycerol; GPCRs, G-protein coupled receptors; IP_3, inositol 1,4,5-triphosphate; ORAI (Ca^{2+} release activated Ca^{2+} modulator; RTKs, Receptor-tyrosine kinases; ROCE, Receptor-Operated Ca^{2+} Entry; SOC, store-operated Ca^{2+}; SOCE, Store-Operated Ca^{2+} Entry; STIM, stromal interaction molecule; PIP_2, phosphatidylinositol 4,5-bisphosphate; PKC, protein kinase C; TRP, transient receptor potential; VDCCs, voltage-dependent Ca^{2+} channels.

28.7.4: Storage of intracellular Ca^{2+} ions - organelles

Endoplasmic Reticulum: STIM, ORAI, IP_3Rs, and TRPC1 in SOCE and SOCIC Ca^{2+} Entry Models

The ER serves as the largest and most dynamic organelle reservoir for intracellular Ca^{2+} and is therefore central to many signaling processes for protein synthesis, folding, and post-translational modifications. In contrast to the cytosol, ER Ca^{2+} ion levels can range from 100 uM to 1 mM based on the cell type. ER, and other intracellular organelles buffer excessive cytosolic Ca^{2+} by both housing Ca^{2+}-binding proteins (example: calreticulin in ER) and via active transport (example: SERCA pumps in ER).

- Depletion of Ca^{2+} from the ER lumen actuates an indirect mode of Ca^{2+} entry into the organelle which is termed **Store-Operated Ca^{2+} Entry (SOCE)** or **Ca^{2+} Release Activated Ca^{2+} (CRAC)** entry; it is activated when plasma membrane receptors like PLC-coupled GPCRs (but not voltage-gated channels) trigger Ca^{2+} ion release from the organelle.
- Exhaustion of the intraluminal ER Ca^{2+} ion store following such prolonged release is then sensed by **STIM (Stromal Interaction Molecule**) tethered to the ER membrane and subsequently relayed to the CRAC channels on the plasma membrane.

Figure 28.7.8shows the domain structures of STIM 1/2, ORAI 1-3, and IP3Rs (panel A) and the mechanism of Ca^{2+} influx into the cell (B).

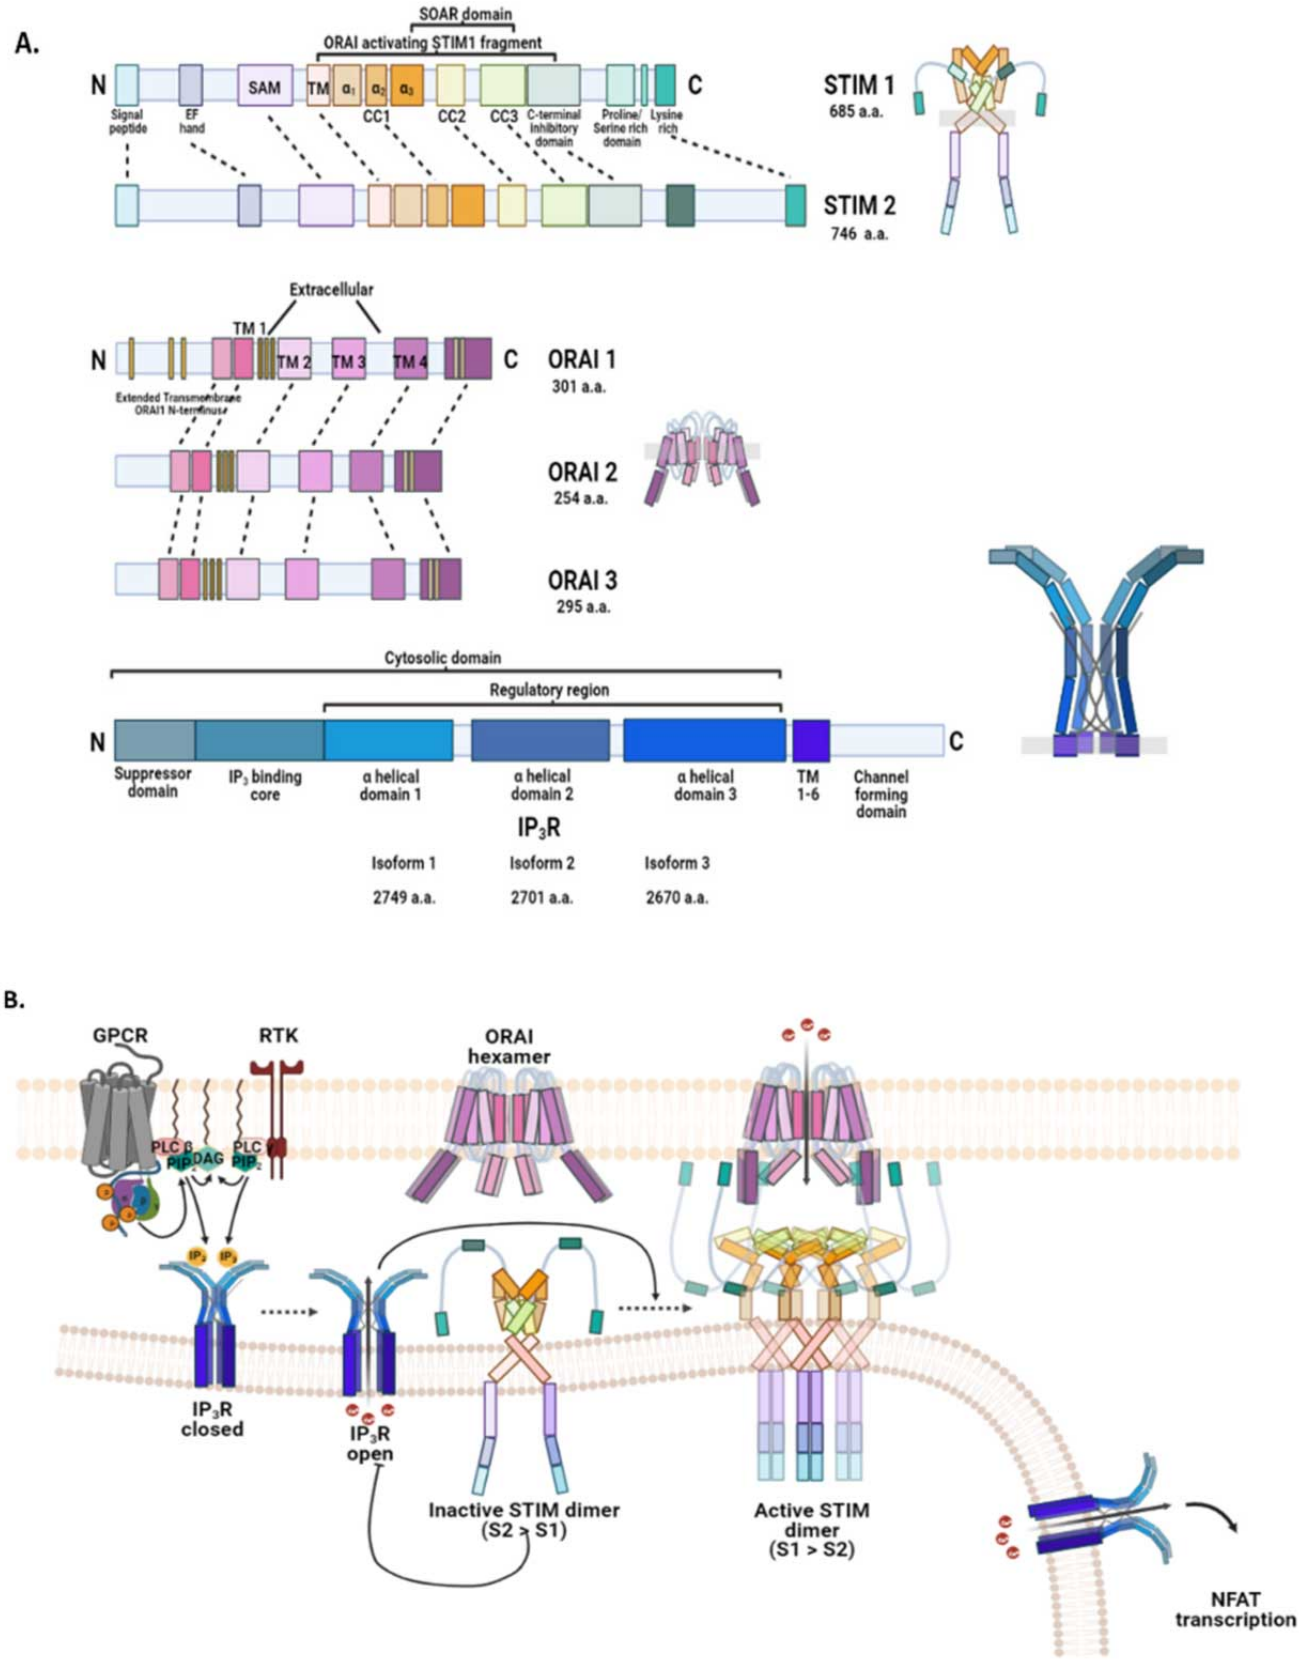

Figure 28.7.8: Role of STIM< ORAI and IP3Rs in Ca^{2+} influx.

IP3 Receptors (IP3Rs), on stimulation by IP3, open and allow Ca^{2+} influx from the organelle lumen into the cytoplasm. After activation of IP3Rs on the ER membrane by ligand IP3 and cytosolic Ca^{2+} from activation of phospholipase C, STIM dimers are activated once the luminal Ca^{2+} concentration drops below basal levels. These receptors provide intracellular Ca^{2+} ions for downstream Ca^{2+} signaling including NFAT-mediated transcription. The red semi-circle in the ER represents high luminal Ca^{2+} levels, the pink semi-circle is for moderately low Ca^{2+} ion concentration, and the pale semi-circle indicates extremely low Ca^{2+} concentration. CC, coiled-coil; NFAT, nuclear factor of activated T-cells; SAM, sterile alpha motif; SOAR, STIM1 Orai1-activating region; TM, transmembrane.

Mitochondria and Acidic Vesicles (Mainly Lysosomes)

Mitochondria also play a critical role in maintaining Ca^{2+} ion levels in the cytosol and endoplasmic reticulum. They are found mostly aggregated around the nucleus and store similar levels of intracellular Ca^{2+} as the cytosol (0.1 μM). Electrochemical proton gradient or membrane potential (Ψmt = −150 to −180 mV) and close association to the ER are the two key factors responsible for Ca^{2+} uptake in mitochondria. The free movement of small molecules (less than 5 kDa) from the outer mitochondrial membrane (OMM) into the inner mitochondrial space and their impermeability across the latter generates a high electrochemical proton gradient for ATP synthesis. This gradient simultaneously draws Ca^{2+} ions from the cytosol.

Transfer of Ca^{2+} ions from ER to mitochondria occurs at specialized microdomains or contact sites known as Mitochondrial Associated Membranes (MAMs). These are characterized by the ER and OMM apposed at 10–25 nm from each other and are strewn with a cluster of channels, transporters, exchangers, and tethering proteins for facilitating Ca^{2+} ion transfer. IP3Rs localized at the ER side of the MAMs release Ca^{2+} ions that gate voltage-dependent anion channels (VDACs) located on the OMM. VDACs (1, 2, and 3) are 30 kDa polypeptides having a 19-strand beta-barrel structure that regulates the flux of metabolites (polyvalent anions like ADP and ATP) across the outer mitochondria membranes. These channels transport cations including Ca^{2+} more readily than anions like chloride. Due to voltage-dependent electrostatic gating, the ion selectivity and flux across VDACs change between open and closed states. Figure 28.7.9 shows couped mitochondrial and lysosomal effects on intracellular Ca^{2+} signaling.

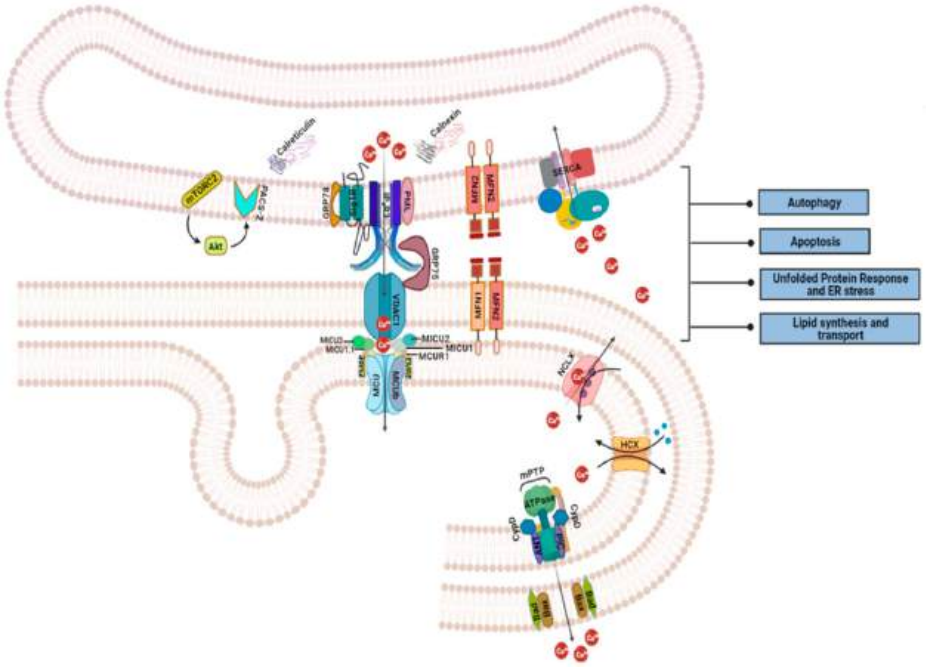

Figure 28.7.9: Mitochondrial and lysosomal impact on intracellular Ca^{2+} signal.

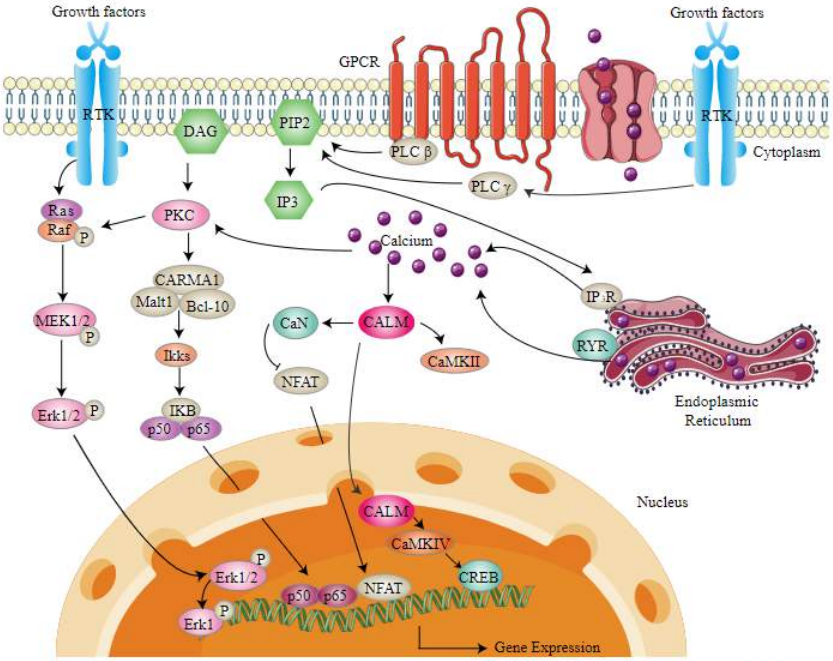
Primary components of Ca^{2+} signaling at the mitochondrial associated membranes (MAMs) include IP_3R3 on the endoplasmic reticulum, VDAC1 on the outer mitochondrial membrane, and MCU complex on the inner mitochondrial membrane [151,154,156,161]. Transport of Ca^{2+} ions from ER to mitochondria plays a crucial role in cellular metabolism (autophagy), cell survival (during unfolded protein response and impinging cell death signals), lipid production, and distribution. F

While IP3 acts as the dominant Ca^{2+}-mobilizing messenger, cADPR (cyclic ADP-ribose) and NAADP (nicotinic acid adenine dinucleotide phosphate) are also known to modulate intracellular Ca^{2+} stores. cADPR evokes Ca^{2+} ion release from ER by acting

on ryanodine receptors (RyR; counterpart of IP3R in myocytes and co-expressed in some other cell types). NAADP releases Ca^{2+} from acidic and/or secretory vesicles such as lysosomes and endosomes. In most mammalian cells, lysosomes comprise ~5 percent of the cell volume and store similar levels of intracellular Ca^{2+} (0.5 mM) as the ER. Due to their relatively smaller size than ER, lysosomes release nearly undetectable amounts of intracellular Ca^{2+} in response to NAADP trigger

28.7.5: Signaling pathways activated by Ca^{2+} ion

It is daunting to both readers and writers to introduce a myriad of new signaling pathways. Instead will show how Ca^{2+} signaling fits into other pathways we have already discussed. A summary showing how Ca^{2+} signaling integrates with other pathways is shown in Figure 28.7.10



Calcium (Ca^{2+}) serves as a ubiquitous second messenger in all eukaryotes. For an ever-increasing number of biological processes, it has been found that temporally and spatially defined changes of Ca^{2+} concentration in the cytoplasm or in defined organelles occur at one point or another. The importance of Ca^{2+} signaling pathway for the implementation of the information provided by Ca^{2+} has been increasingly appreciated, and several distinct families of Ca^{2+} sensing proteins have been identified and characterized.

Figure 28.7.10: https://www.creative-diagnostics.com...ng-pathway.htm

An Overview of Calcium Signaling Pathway

Ca^{2+} signaling, as described above, requires ion buffer, organelle storage, and Ca^{2+} protein pumps and channels. The concentration (amplitude) and frequency of Ca^{2+} release affect signaling. Figure 28.7.10 shows the importance of upstream signaling through GPCRs, phospholipase C, RTKs, and IP3/DAGs. Ca^{2+} also enters the nucleus vs IP3 receptors (IP3Rs) and ryanodine recetors (RYR). An important family of cytoplasmic transcription factors, the **Nuclear factor of activated T-cells** (**NFAT**), which are important in immune responses and development of muscle and nervous systems, are activated in calcium ion signaling.

As we described above, Ca^{2+} release from the ER is sensed by integral ER membrane proteins called STIMs. These bind Ca^{2+} ions as a buffering system, but if most of the ER calcium is depleted, the STIM-bound Ca^{2+} ions are also released. This lead to their self-association and ultimate activation or ORAI1, part of the CRAC complex in the cell membranes which allow extracellular Ca^{2+} ions to flow into the cell in a process called store-operated calcium entry (SOCE). Sufficient calcium now accumulates in the cell to activate the transcription factor NFAT through dephosphoylation by calcineurin (PP2B), also abbreviated CaN in Figure 28.7.10 NFAt then translocates into the nucleus and activates gene transcription. Also, it has been shown that nuclear calcium ions directly can activate the cAMP response element binding protein (CREB), a transcription factor that activates gene transcription. In addition the CAM:CAMKII complex can translocate into the nucleus. Calcium signals also activate ERK1/2-MAPK cascade.

28.7.6: Ca^{2+} binding proteins and their binding partners in signaling pathways

We have already described the key calcium-binding protein, calmodulin. On binding Ca^{2+}, it undergoes a profound conformational change that allows it to interact with a family of key signaling kinases called CAM and Ca^{2+}/CAM-Dependent Protein Kinases (CAMKs).

Ca^{2+}/calmodulin-dependent protein kinase is a key signaling protein activated by Ca^{2+} through the binding of calmodulin to **CAMK**. Activated CAMK is a Ser/Thr kinase. There are many types of CAMKs. We will focus on multifunctional CAMKs that can phosphorylate multiple target proteins. These are important in learning and memory, metabolism, and gene transcription. As with other kinases, they have catalytic and regulatory domains. Some like CAMK II have association domains that allow the formation of CAMKII multimers. In addition, they must have a CAM binding domain. As with all kinases, the CAMKs must be able to switch from an inactive to an active form.

CAMKI has a catalytic, substrate-binding domain and an autoinhibitory domain that blocks the active site. CAMKI is activated by an upstream kinase CAMKK (a naming system similar to the MAPK cascade) on the binding of Ca^{2+} to CAM. It helps regulate transcription, the cell cycle, hormone production, cell differentiation, actin filament organization, and neurite outgrowth. It is found in the cytoplasm and nucleus.

We will focus our attention on **CAMKII**, which has four isoforms (α, β, γ, and δ). It is activated by the binding of Ca^{2+}/CAM which promotes autophosphorylation. After that, it is active in the absence of CAM. It is important in learning and memory and synapse formation in neurons and the regulation of sarcoplasmic reticulum Ca^{2+} transport in skeletal muscles.

They have an N-terminal catalytic domain and a C-terminal association domain that facilitates multimer formation into large holoenzymes with 12 or 14 CAMK monomeric subunits (a homomer or heteromer). These two domains are separated by a linker/regulatory domain that has a CAM binding site, an autoinhibitory region, and key Ser and Thr side chains that are targets for phosphorylation. Figure 28.7.11 shows the domain structure of the CAMKII monomer (a), the overall structure of a homododecamer (b), and the mechanism for activation of kinase activity (c).

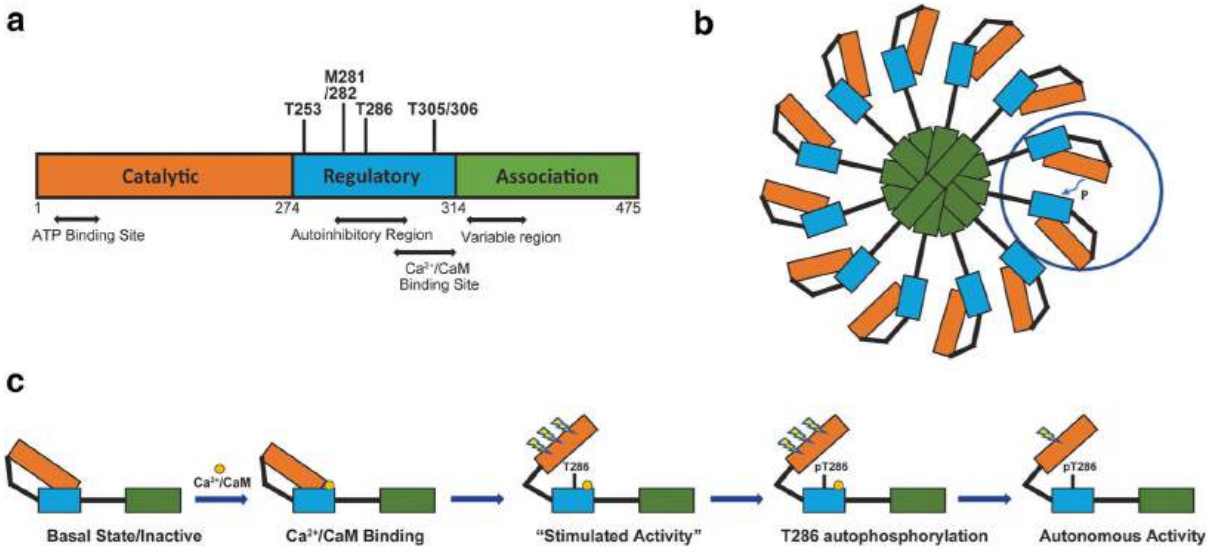


Figure 28.7.11: CamKII - structure and activation. Zhang, X., Connelly, J., Levitan, E.S. *et al.* Calcium/Calmodulin–Dependent Protein Kinase II in Cerebrovascular Diseases. *Transl. Stroke Res.* **12,** 513–529 (2021). https://doi.org/10.1007/s12975-021-00901-9. Creative Commons Attribution 4.0 International License, http://creativecommons.org/licenses/by/4.0/.

T253, T286, and T305/306 are targets of autophosphorylation. M281/282 are also sites for oxidative modification. The C-terminal association domain allows multimer formation. It has a variable region that differentiates CaMKII subtypes. Panel (b) shows the multimer that forms on interactions of multiple association domains on different CAMKIIs. Panel (c) shows binding of CAM promotes the phosphorylation of key residues including T286 (through autophosphorylation).

In the absence of Ca^{2+}/CAM T286 amino acid forms interactions with the catalytic domain to maintain the inactive conformation. The regulatory domain effectively autoinhibits the kinase domain. On the formation of the Ca^{2+}/CAM/CAMKII complex, a conformation change ensues that frees the catalytic domain from autoinhibition and exposes the active site. Each subunit in the dodecamer is activated separately. T286 is now free to be "autophosphorylated" by an adjacent active subunit. Once

phosphorylated, pT286 prevents the rebinding of the autoinhibitory region to the catalytic domain, even when CAM dissociates. At this point, CAMKII is active in the absence of Ca^{2+}/CAM.

Phosphorylation of T286 also regulates its binding to target proteins for their phosphorylation. In addition, CAMKII can autophosphorylate T254 and T306 with further effects on activity. T306 is only autophosphorylated after CAM dissociates and the enzyme is autonomously active. Dephosphorylation by PP1 and PP2A returns the enzyme to an inactive state.

Figure 28.7.12 shows an interactive iCn3D model of a single subunit of human Ca2+ Calmodulin- Dependent Kinase II Holoenzyme (3SOA)

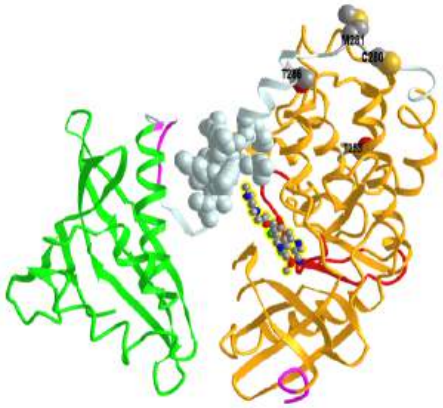

Figure 28.7.12: Single subunit of human Ca2+ Calmodulin- Dependent Kinase II Holoenzyme (3SOA). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...S4XAczeqqPE5Y9

The catalytic domain is shown in orange, the association domain in green, and the linker domain in light cyan. The spacefill light cyan site in the linker domain is the CAM binding site. The side chains of Thr 253 and Thr 286, sites for phosphorylation, are shown in spacefill CPK colors and labeled. The side chains of Cys 280 and Met 281, the site for redox regulation, are shown in spacefill CPK colors and labeled. Bosutinib (shown in ball and stick) is a small molecule BCR-ABL and src tyrosine kinase inhibitor used for the treatment of chronic myelogenous leukemia. It is bound in the ATP binding site of the catalytic subunit. Finally, the activation loop is shown in red.

Figure 28.7.13shows an interactive iCn3D model of Human Ca2+ Calmodulin- Dependent Kinase II Holoenzyme (3SOA)

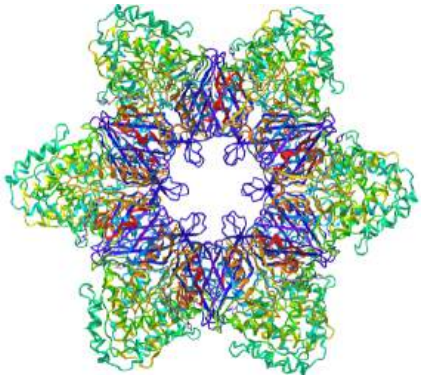

Figure 28.7.13: Human Ca2+ Calmodulin- Dependent Kinase II Holoenzyme (3SOA). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...DPiWLo5VrgiLp9

The response of most protein kinases we have studied depends on the concentration (amplitude) of a binding ligand (like Ca^{2+}). The CAMKII dodecamer also responds to the frequency of Ca^{2+} waves or spikes as it is released from intracellular organelles. This is important in neurons where CAMKII phosphorylates ion channels that control and regulate neuron response. If the frequency of Ca^{2+} spikes reaches a certain threshold level, the enzyme no longer depends on Ca^{2+}.

28.7.7: Modeling of Ca^{2+} signaling

Model for signal-induced Ca^{2+} oscillations and their frequency encoding through protein phosphorylation.

Reference paper: ALBERT GOLDBETER, GENEVIVE DUPONT, AND MICHAEL J. BERRIDGE , Proc. Natl. Acad. Sci. USA, Vol. 87, pp. 1461-1465, February 1990, Biophysics

HVJ: In response to hormones and neurotransmitters, cyclic intracellular oscillations/spikes (as a function of time) and spatial waves of cytoplasmic Ca^{2+} arise. The Ca^{2+} ions derive from the opening of cell membrane channels but also, more importantly, from the release and recapture of the ions from intracellular compartments such as the endoplasmic reticulum (ER). Signaling through membrane GPCRs can lead to the activation of phospholipase C and the formation of inositol 1,4,5-trisphosphate (IP3 or $InsP_3$) as a key second messenger. IP3 can interact with the IP3 receptor on ER membranes, leading to the release of intracellular stores of Ca^{2+} into the cytoplasm in ways that leads to oscillations in its concentration. These processes are shown in Figure 28.7.14below.

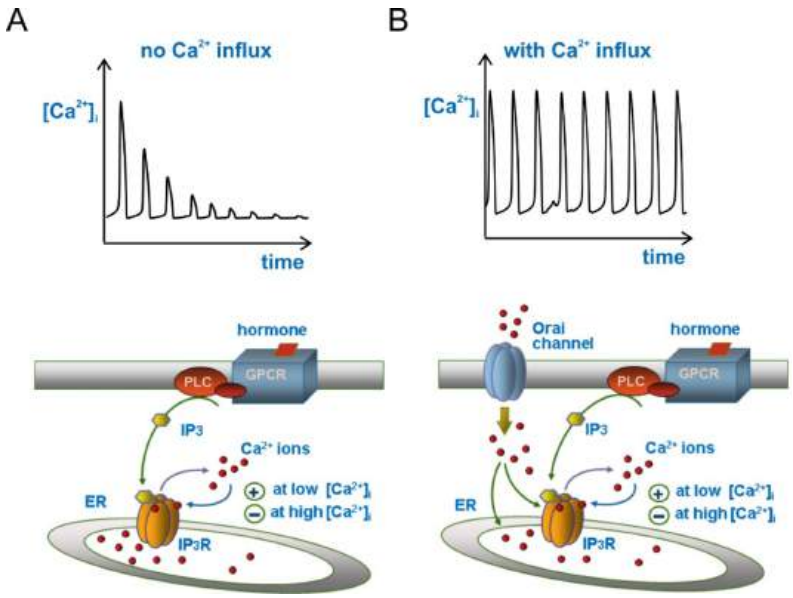

Figure 28.7.14 Ca^{2+} oscillations in response to inositol trisphosphate (IP_3) increase, with and without Ca^{2+} influx from extracellular space. Catacuzzeno L, Franciolini F. Role of KCa3.1 Channels in Modulating Ca^{2+} Oscillations during Glioblastoma Cell Migration and Invasion. Int J Mol Sci. 2018 Sep 29;19(10):2970. doi: 10.3390/ijms19102970. PMID: 30274242; PMCID: PMC6213908. Creative Commons Attribution (CC BY) license (http://creativecommons.org/licenses/by/4.0/).

Panel (**A**) bottom shows a drawing illustrating the hormone-based production of IP_3 that activates the IP_3 receptor to release Ca^{2+} from the endoplasmic reticulum (ER). The biphasic effects of cytosolic Ca^{2+} on IP_3 receptor gating (the basic mechanism for Ca^{2+} oscillations), whereby Ca^{2+} modulates positively the receptor at low [Ca^{2+}] but negatively at high [Ca^{2+}], is also illustrated. Top, Ca^{2+} oscillations as produced from the schematics below. Note the decaying trend of Ca^{2+} spikes due to the absence of Ca^{2+} influx from extracellular space;

Panel (**B**) shows Ca^{2+} influx apparatus from extracellular spaces through ER-depletion by activated Orai channels on the plasma membrane (bottom), which generates sustained Ca^{2+} oscillations (top).

Ca^{2+} levels fall through Ca^{2+} pumps on the sarco/endoplasmic reticulum (SERCA), which moves the ion into the SR/ER or the plasma membrane (PMCA) that then moves it to the outside of the cell. The SERCA and PMCA Ca^{2+} pumps as well as the ER STIM protein are not shown in Figure 14 above. The STIM1 protein is involved in what is known as store-operated Ca^{2+} entry (SOCE). This allows the influx of Ca^{2+} influx after intracellular stores are depleted. The STIM1 protein has an EF-hand so it binds and acts as a sensor for Ca^{2+}. When Ca^{2+} is depleted, the STIM1 protein moves from the ER to the cell membrane and activates ORA1, a subunit of the Ca^{2+} release-activated Ca^{2+} (CRAC) channel to promote Ca^{2+} into the cell.

In a variety of cells, hormonal or neurotransmitter signals elicit a train of intracellular Ca^{2+} spikes. The analysis of a minimal model based on Ca^{2+} -induced Ca^{2+} release from intracellular stores shows how sustained oscillations of cytosolic Ca^{2+} may develop as a result of a rise in inositol 1,4,5-trisphosphate ($InsP_3$) triggered by external stimulation. This rise elicits the release of a certain amount of Ca^{2+} from an $InsP_3$-sensitive intracellular store. The subsequent rise in cytosolic Ca^{2+} in turn triggers the release of Ca^{2+}

from a second store insensitive to $InsP_3$. The model shows how signal-induced Ca^{2+} oscillations might be effectively encoded in terms of their frequency through the phosphorylation of a cellular substrate by a protein kinase activated by cytosolic Ca^{2+}.

The release of intracellular Ca^{2+} release by IP3 can be broken down into 3 steps: β

- agonist binding to GPCRs to activate the Phospholipase C pathway to produce the second messengers IP3 and DAG;
- IP3 induces some Ca^{2+} release from intracellular stores in the SR/ER. This can be called the Primer Step characterized by a rate V1 to produce cytosolic Ca^{2+} of concentration [Z] that prime the next step. This step has a rate of v1β.
- released Ca^{2+}induces more Ca^{2+} release, a self-amplification positive feedback step, which causes the Ca^{2+} spike.

A simplified view of this model is shown in Figure 28.7.15below.

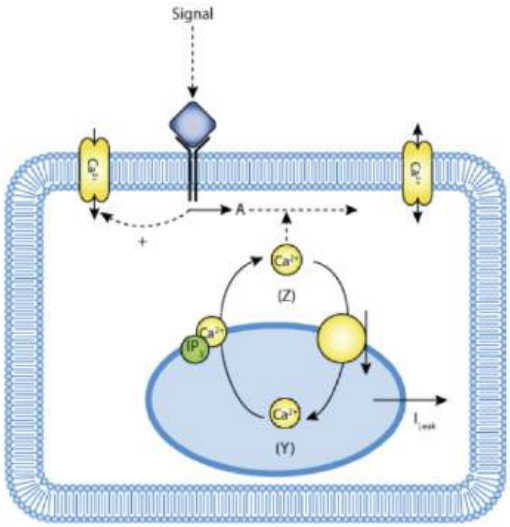

Figure 28.7.15 Schematic representation of the one-pool model based on CICR with Ca2+-stimulated degradation of IP3. Lloyd, C.M., Lawson, J.L., Hunter, P.J. and Nielsen, P.F. The CellML Model Repository. Bioinformatics. 2008 September;24(18):2122-2123 (accessed 4/19/23; 5:40 am EDT). Creative Commons Attribution 3.0 Unported License.

A simple model can be constructed to account for cytosolic Ca^{2+} fluxes. The steps include

- IP3 causes a triggering a constant flux of Ca^{2+} into the cytosol, v1β ,to produce cytosolic [Ca^{2+}] = **Z** (the primer)
- cytosolic Ca^{2+} flows into an IP3-insensitive sequestered pool (concentration **Y**) with rate v2 to keep low levels of cytosolic Ca^{2+}
- Spikes arise when the sequestered pool Y releases Ca^{2+} back into the cytosol at a rate v3 in a process that is activated by cytosolic Ca^{2+}.

Goldbeter at al (Proc. Natl. Acad. Sci. 87, 1461-1465 (1990) constructed a mathematical model to account for the oscillations/spikes In addition to the parameters mentioned above, they included 3 more:

- vo, describing the influx of extracellular Ca^{2+} into the cytosol and k describing the efflux of cytosolic Ca^{2+} from the cell. These are controlled by Ca^{2+} pumps SERCA, PMCA, et al as described above.
- kf, which describes the passive leak of Y into Z.

The Ca^{2+} oscillations then are based on a self-amplified release of Ca^{2+} from intracellular stores.

Here are their equations:

- $dZ/dt = v_0 + v_1 beta - v_2 + v_3 + k_f Y - kZ$
- $dY/dt = v_2 - v_3 + v_3 - k_f Y$
- $v_2 = V_{m2} \frac{Z^n}{K_2^n + Z^n}$
- $v_3 = V_{m3} \frac{Y^m}{K_R^m + Y^m} \cdot \frac{Z^p}{K_A^p + Z^p}$

We'll use Vcell to plot the following species:

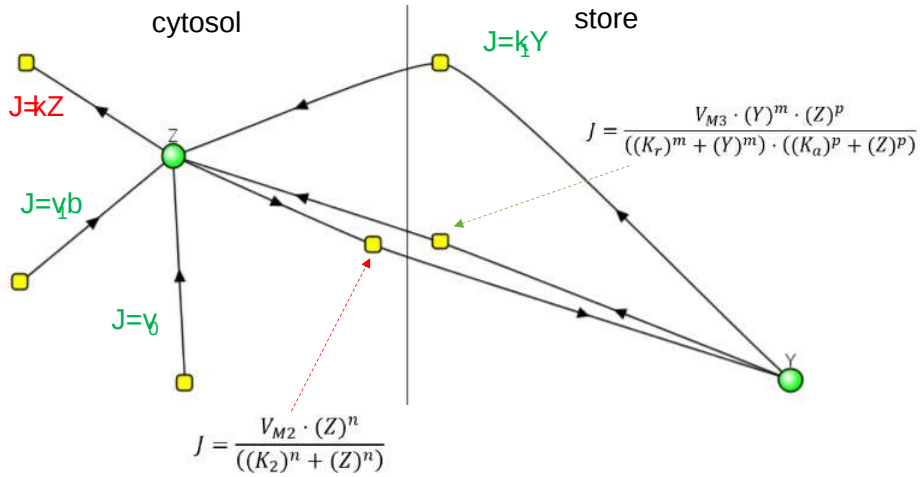
- Species **Z**: Concentration (uM) of cytosolic Ca^{2+}

- Species **Y**: Concentration (uM) of Ca^{2+} stored in the $InsP_3$-insensitive pool.

The model is based on code from EBI-Biomodels: https://www.ebi.ac.uk/biomodels/BIOMD0000000098.

VCell MODEL

Calcium ion oscillation in the cell without oscillations in IP3



Here are the adjustable parameters:

- v0: influx of Ca^{2+} into the cell, uM/s.
- v1: influx of Ca^{2+} into the cell from the $InsP_3$ receptor, uM/s.
- beta: saturation function of the receptor for $InsP_3$, unitless.
- Vm2: maximum rate of Ca^{2+} pumping into the intracellular $InsP_3$-insensitive store, uM/s.
- Vm3: maximum rate of Ca^{2+} released from the intracellular store, uM/s;
- K2: Threshold constant for Ca^{2+} pumping, uM.
- n: Hill function cooperativity coefficient for Ca^{2+} pumping into the store, unitless.
- m: Hill function cooperativity coefficient for Ca^{2+} pumping from the store, unitless.
- Ka: threshold constant for activation, uM.
- kf: efflux of cytosolic Ca^{2+} from the cell, 1/s.
- k: influx of extracellular Ca^{2+} into the cytosol, 1/s.
- p denotes the degree of cooperativity of the activation process, unitless.

Select Load [model name] below

Load Goldbeter_Ca_Oscillations

Select **Start** to begin the simulation.

Select **Plot** to change Y axis min/max, then **Reset** and **Play** | Select **Slider** to change which constants are displayed | Select **About** for software information.

Move the sliders to change the constants and see changes in the displayed graph in real time.

After loading the GoldBeter model, select the '**Start**' button below to simulate the model. Adjust the parameter sliders below the plot to see how they affect Ca^{2+} concentrations (Z, Y). The simulator only displays twelve parameters at a time. To choose others, select the 'Slider' button on the side and chose up to twelve parameters to adjust.

Time course model made using Virtual Cell (Vcell), **The Center for Cell Analysis & Modeling**, at **UConn Health**. Funded by NIH/NIGMS (R24 GM137787); Web simulation software (miniSidewinder) from Bartholomew Jardine and Herbert M. Sauro, University of Washington. Funded by NIH/NIGMS (RO1-GM123032-04)

Adjust the parameter sliders below the plot to see how they affect Ca^{2+} concentrations (Z, Y). The simulator only displays twelve parameters at a time. To choose others, hit the 'Slider' button on the side and chose up to twelve parameters to adjust.

Only two variables, Y and Z, and some intra-connections are required to generate the oscillations, which do NOT required oscillation in the second messenger, IP3. One can imagine that cytosolic Ca^{2+} oscillations might also elicit oscillatory activity of protein kinases activated by it.

Questions:

- Does v0 change the oscillation frequency?
- What other parameters affect the frequency?
- How does Vm2 affect the oscillations?

28.8: Receptor Guanylyl Cyclases, cGMP, and Protein Kinase G

Search Fundamentals of Biochemistry

28.8.1: Introduction

We have considered many signal transduction pathways, starting with an extracellular signal, a primary messenger, that initiates signaling when it binds to a receptor (GPCR, RTK, Cytokine Receptor, etc). It elicits a conformation change in the receptor, which is transmitted to an intracellular domain, from where it can propagate and transmits a signal intracellularly through secondary messengers and phosphorylation of signaling proteins. Some primary messengers, however, actually pass through the cell either passively or through membrane carriers, so there is no need to generate a second messenger. We will consider two signals that translocate through the cell membrane, gases such as nitric oxide (NO), and steroid hormones (which we will discuss in a future section). NO produced within a cell activates the formation of an intracellular second messenger, cyclic GMP (analogous to cAMP). cGMP in turn activates our final member of the AGC Ser/Thr protein kinase family, **protein kinase G (PKG)**. Intracellular NO has an unexpected role on adjacent cells. Given its small size and its nonpolar nature, it can diffuse out of the cell where it is produced and into an adjacent cell, where it can also initiate signaling. Some call this retrograde signaling.

Before we consider cGMP and PKG, let's see how nitric oxide (NO) is produced.

28.8.2: NO formation

NO is synthesized by the enzyme **nitric oxide synthase (NOS)**. There are three isoforms in mammals, neuronal (NOS1 or nNOS), inducible (NOS2 or iNOS), and endothelial (NOS3 or eNO2). Each is a homodimer with a complex domain structure, including a

- N-terminal oxidase (NO_synthase) domain that binds heme
- calmodulin binding site between the N and C terminal domains
- C-terminal reductase domain containing the FMN (Flavodoxin_1) subdomain (which contains an autoinhibitory helix) and FAD/NADPH subdomain.

Ca^{2+} ion activates the enzyme through the binding of Ca^{2+}/CAM. A more detailed description of the domain structures of human NOS is shown in Figure 28.8.1. The dimeric molecular weight of the neuronal NOS1 (321K) is greater than for iNOS (206) and eNOS (266) as it has a N-terminal PDZ domain.

neuronal NOS 1 (MW 321)	 purple NADPH binding
inducible (MW 206K) endothelial (MW 266)	 yellow NADPH binding

Figure 28.8.1: Domain structure of human nitric oxide synthases

NOS catalyzes the conversion of the free amino acid arginine to citrulline and NO, as shown in the chemical equation in Figure 28.8.2

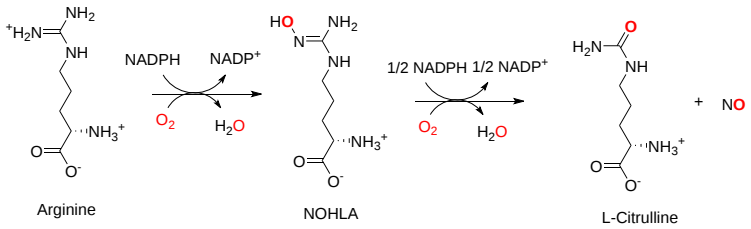


Figure 28.8.2: Synthesis of NO by nitric oxide synthase

The structures of the three enzymes with or without bound CAM are similar. Linkers between the domains and subdomains allow flexibility. Figure 28.8.3 shows the flow of electrons from NADPH into the reductase (NADPH/FAD subdomain to the FMN

subdomain), and on to the NOS synthase domain containing the heme.

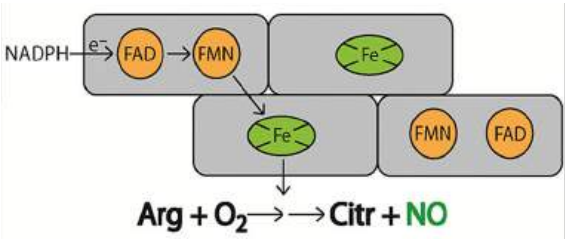

Figure 28.8.3: Electron transfer in nitric oxide synthase. Gephart et al. Nitric Oxide (2019). https://doi.org/10.1016/j.niox.2019.04.007. Creative Commons license

Two monooxygenase reactions occur in NOS synthase (oxidative domain) in which electrons are funneled into the heme and bound dioxygen (O_2) leading to the formation of water and the final product, NO. Electron transfer only occurs within the dimer when calmodulin is bound. However, iNOS is active even at basal Ca^{2+} concentrations.

Figure 28.8.3 shows an interactive iCn3D model of the structure of human neuronal nitric oxide synthase (with its PDZ domain) predicted by AlphaFold (P29475).

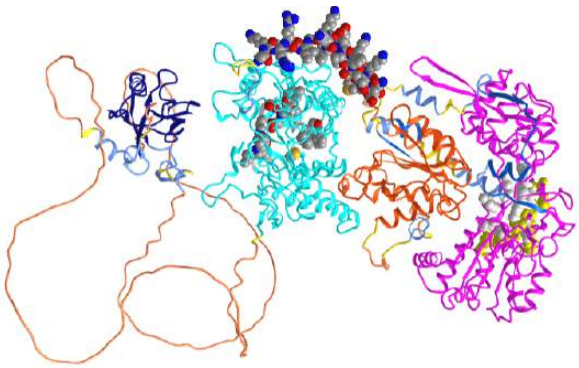

Figure 28.8.10: Human neuronal nitric oxide synthase predicted by AlphaFold (P29475) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...RCgzaSGpc259t6

In the iCn3D model, orient the protein as shown in the figure above. The dark blue (left) is the PDZ domain, and cyan is the oxidase (NOS synthase) domain that contains the heme (which is not shown in AlphaFold models). The spacefill CPK color shown in the cyan domain is active site residues interacting with the heme (not shown). The orange domain is the FMN (Flavodoxin_1) subdomain in the reductase domain. The magenta (far right) shows the FAD/NADPH subdomains of the reductase domain. The yellow spacefill shows the NAD binding pocket and the white spacefill the FAD binding pocket. The structures of amino acids 129-304 between the PDZ domain and the oxidase domain are not predicted with any certainty. Crystal structures are available for the oxidase domain alone. The spacefill CPK-colored helix (amino acid 730-754) represents a helical peptide region that binds to calmodulin.

NO that is synthesized in the cells can signal there or diffuse to another cell and signal there. Figure 28.8.11 shows how NO synthesized in vascular epithelial cells that line blood vessels can move into the nearby muscle cells and initiate signaling through soluble guanylyl cyclase there, leading to vasodilation and a lowering of blood pressure.

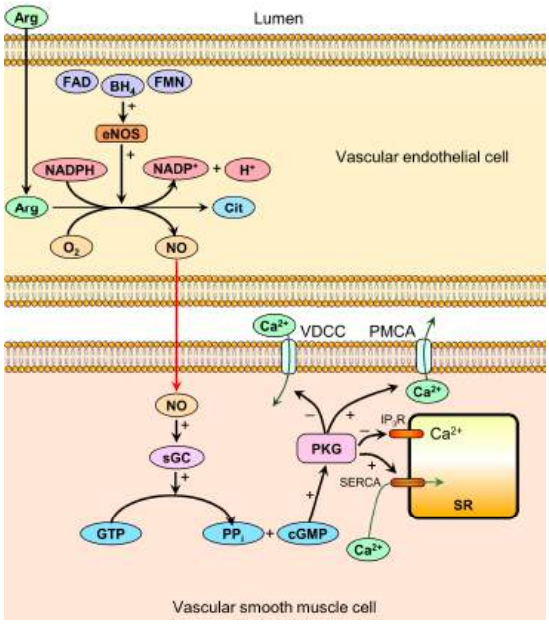

Figure 28.8.11: . Mechanisms of nitric oxide-mediated vasodilation. Khalaf et al. Nutrients 2019, 11, 1679; doi:10.3390/nu11071679 CC BY 4.0

Endothelial nitric oxide synthase (eNOS) located in the vascular endothelium forms NO from plasma arginine. Two substrates, O_2 and NADPH, are required along with the cofactors tetrahydrobiopterin (BH_4), FAD, and flavin mononucleotide (FMN). NO diffuses into smooth muscle cells and activates soluble guanylyl cyclase (sGC), increasing cGMP production. cGMP subsequently activates protein kinase G (PKG), resulting in decreased [Ca^{2+}] by these mechanisms:

- inhibition of voltage-dependent calcium channels (VDCC), reducing calcium influx;
- activation of plasma membrane calcium ATPases (PMCA), increasing ATP-dependent calcium efflux;
- inhibition of inositol triphosphate receptors (IP3R), reducing calcium release from the sarcoplasmic reticulum (SR) to the cytoplasm;
- activation of sarcoplasmic calcium ATPases (SERCA), increasing the ATP-dependent sequestration of calcium from the cytoplasm to the SR.

Decreased [Ca^{2+}] mediates smooth muscle relaxation via the activation of myosin light chain kinase and the inhibition of myosin light chain phosphatase (not shown in the figure), resulting in vasodilation.

Figure 28.8.13 shows retrograde diffusion of NO from an activated post-synaptic neuron back to the presynaptic neuron that excited it on the release of the neurotransmitter glutamate. NO is synthesized by post-synaptic cell nNOS after it's activated by Ca^{2+} inflow and binding to CAM (not shown). NO with the post-synaptic neuron binds to guanylyl cyclase to produce the second messenger cGMP which can directly activate other channels, protein kinase G, or phosphodiesterases (PDEs)

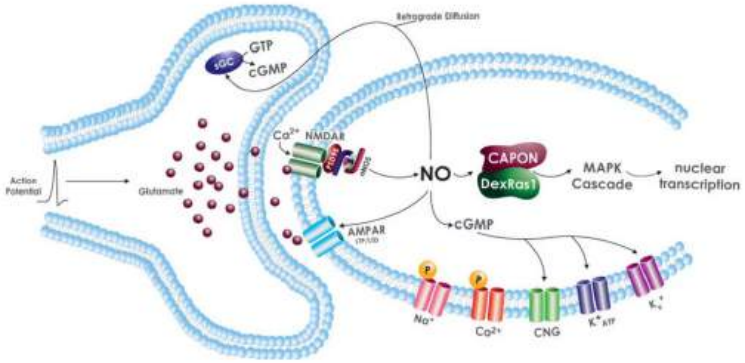

Figure 28.8.13: NO Signaling at a Neuronal Synapse. https://www.caymanchem.com/news/nitr...ion-in-the-cns.

Synaptic glutamate release activates postsynaptic NMDA and AMPA receptors (NMDAR, AMPAR) leading to Ca^{2+}-induced nNOS activation. NO will diffuse back to the presynaptic cell and activate sGC to produce cGMP, which has many signaling roles including affecting presynaptic neurotransmitter release. cGMP directly targets several ion channels in the post-synaptic cell. As we saw in the previous chapter, many ion channels are voltage-gated. However, ion channels can be regulated directly by ions (ex Ca^{2+}, Na^{+}) as well as by cyclic nucleotides such as cAMP and cGMP. The later channels are called cyclic nucleotide-gated (CNG) channels. NO in the post-synaptic cell also associates with CAPON, a nNOS binding protein, leading to downstream MAP kinase cascade.

Carbon Monoxide

Everyone knows that carbon monoxide (CO) in high doses is lethal as it binds to heme Fe^{2+} in hemoglobin and myoglobin with a higher affinity than O_2. Hence it may come as a surprise to you that endogenous CO is a signaling molecule, which now in retrospect might make sense given its similarity in chemical structure to NO.

CO is produced through heme oxygenase (HOs). CO can act as a signaling molecule in neural, cardiovascular, respiratory, gastrointestinal, immune, and reproductive systems. In contrast to the lethal effects of inhaling exogenous CO from incomplete combustion, endogenous CO has anti-inflammatory and antioxidant effects. It can also act to dilate the vasculature system. Other gases like H_2S also are signaling agents.

28.8.3: cGMP formation

The second (or third) messenger cyclic guanosine monophosphate (cGMP) is synthesized after activation of the enzyme **guanylyl cyclase (GC)** by nitric oxide. cGMP has many signaling effects in cells, some of which were outlined above. The cytoplasmic **soluble GC (sGC)** is activated by NO. The membrane-associated "**particulate" GC (pGC)** form is activated on the binding of natriuretic peptides (NPs) to natriuretic peptide receptors, which are NP-activated integral membrane guanylyl cyclase. The peptide hormones (ANP secreted by the atria and BNP secreted by ventricles) decrease blood pressure. The membrane form does not require NO for activation Figure 28.8.14shows the conversion of GTP to cGMP.

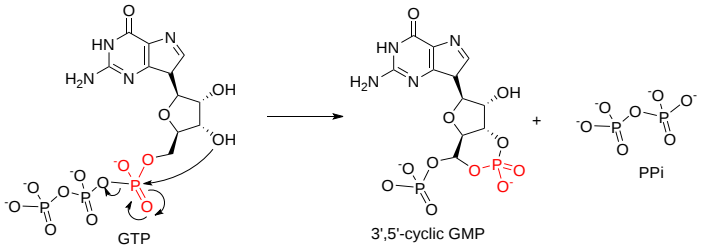

Figure 28.8.14: Conversion of GTP to cGMP

Synthesis of cGMP from soluble GC is activated by NO or molecules like nitrates that can be metabolized to NO. These molecules are called NO donors. Since NO causes vasodilation, they are used to treat angina and hypertension. A class of drugs called **stimulators** (for example riociguat), increases cGMP production from sGC in the absence and synergistically in the presence of NO. They are also used to treat hypertension. Another class of drugs called **activators** can activate sGC even if heme is oxidized or even missing without upstream NO signaling. They are effective even if the heme is oxidized or lost from the NOS catalytic domain.

We saw that cAMP is cleaved to AMP by phosphodiesterase. Likewise, phosphodiesterases (PDEs) cleave cGMP to GMP to attenuate signaling through cGMP. Selective drugs targeting PDE are available. These include sildenafil for the treatment of pulmonary hypertension and erectile dysfunction and tadalafil for benign prostatic hyperplasia (BPH).

Pathways for activation of guanylyl cyclase activity (sGC and pGC) are shown in Figure 28.8.15

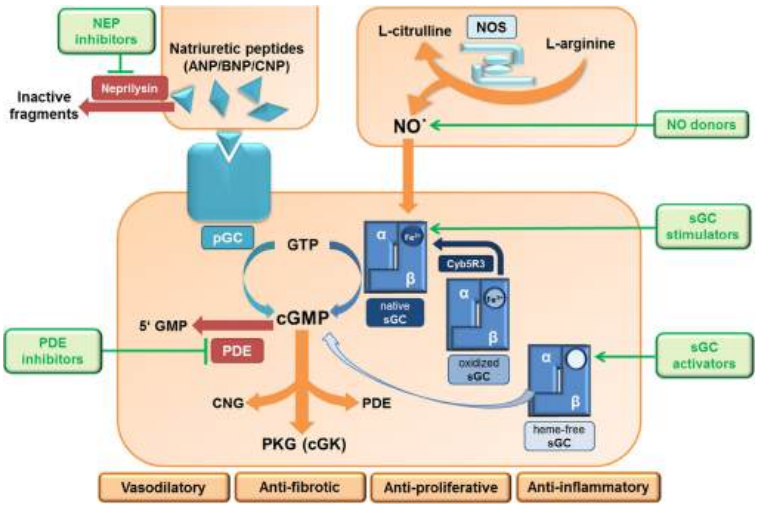

Figure 28.8.15: Pathways for activation of guanylyl cyclase activity (sGC and pGC). NP, atrial natriuretic peptide; BNP, brain natriuretic peptide; cGK, cGMP-dependent protein kinase; cGMP, cyclic guanosine monophosphate; CNG, cyclic nucleotide-gated ion channels; CNP, C-type natriuretic peptide; GTP, guanosine triphosphate; GMP, guanosine monophosphate; NO, nitric oxide; NOS, nitric oxide synthase; NP, natriuretic peptide; PDE, phosphodiesterase; pGC, particulate guanylyl cyclase; PKG, protein kinase G; sGC, soluble guanylyl cyclase. Naunyn Schmiedebergs Arch Pharmacol. 2020; 393(2): 287–302. doi: 10.1007/s00210-019-01779-z. http://creativecommons.org/licenses/by/4.0/.

28.8.4: Soluble guanylyl cyclase (cGC) structure and function

The soluble form of GC is a heterodimer of α and β subunits. The domain structure of guanylyl cyclase is shown in Figure 28.8.16

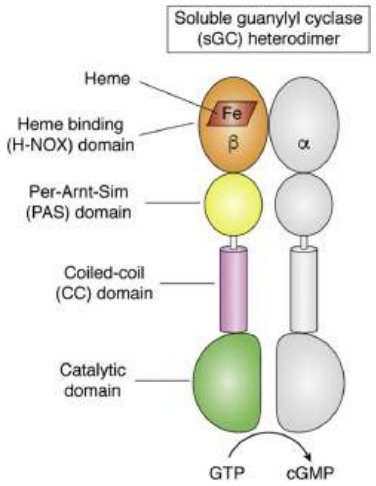

Figure 28.8.16: Domain structure of guanylyl cyclase. Stuehr et al. **JBC REVIEWS**| VOLUME 296, 100336, JANUARY 2021. https://doi.org/10.1016/j.jbc.2021.100336. http://creativecommons.org/licenses/by/4.0/)

It appears that when NO binds to the heme group, a twist in the coiled-coil domain leads to its extension, which leads to the activation of the catalytic domain. Simulators likely cause similar conformational changes initiated by their binding to the top part of the CC domain. Figure 28.8.17 shows an interactive iCn3D model of the human soluble guanylate cyclase in the riociguat (stimulator) and NO-bound state (7D9R)

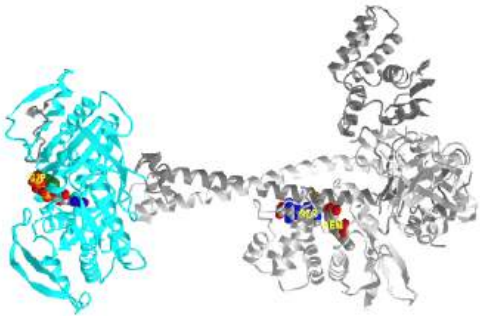

Figure 28.8.17: Human soluble guanylate cyclase in the riociguat and NO-bound state (7D9R) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...vm3dLK1o1odZD6

The A chain is dark gray and the B chain is light gray. The guanylate cyclase domain contributed to by each monomer is shown in cyan. A phosphonate GTP analog (labeled G2P) is shown in spacefill CPK color bound in the guanylyl cylase domain (cyan). The heme (HEM) and the stimulator riociguat (GZO) are shown in the HNOBA (Heme NO Binding Associated) domain and shown in spacefill CPK colors.

The conformation change of A chain of the bent inactive form of guanylyl cyclase (6JT1) to the active extended form (6JT2) is shown in Figure 28.8.18

Figure 28.8.18: The conformation change of A chain of the bent inactive form of guanylyl cyclase (6JT1) to the active extended form (6JT2)

The guanylyl cyclase domain is at the top of the figure. The conformational change is somewhat reminiscent of the change in apo-calmodulin on the binding of Ca^{2+} ions, although the central helix is fully intact in the inactive and active forms of guanylyl cyclase.

Figure 28.8.19 shows how oxidation of the heme iron and S-nitrosation of the protein that occurs in the presence of reactive oxygen species (ROS) and reactive nitrogen species (RNS) leads to heme loss and inactivation of sGC.

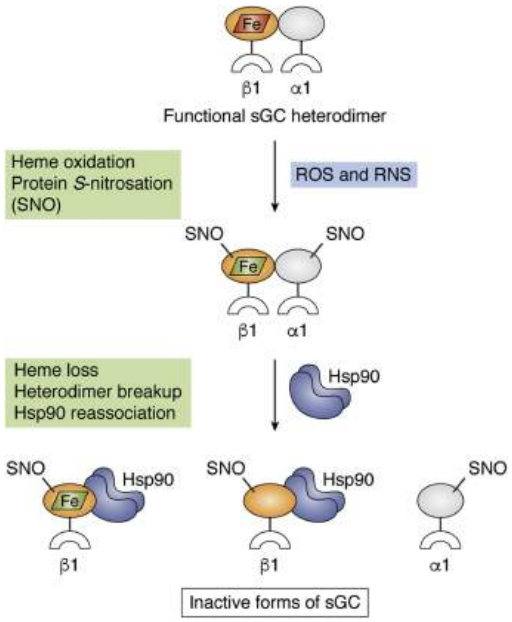

Figure 28.8.19: sGC inactivation pathways and potential structural consequences. sGC inactivation pathways and potential structural consequences. When functional sGC heterodimer (top) is exposed to reactive oxygen and/or reactive nitrogen species (ROS and RNS) it can become unresponsive toward NO by undergoing oxidation of its ferrous heme to ferric (*red* and *green parallelograms*) and protein modifications like Cys S-nitrosation (SNO). These events alone or in combination may lead to the breakup of the sGC heterodimer, heme loss, and/or rebinding of Hsp90 to the freed sGCβ1 subunit. NO, nitric oxide; PAS, Per-Arnt-Sim; sGC, soluble guanylate cyclase. Stuehr et al. ibid.

28.8.5: pGC structure and function

The other source of cytosolic cGMP is **particulate guanylyl cyclase (pGC)**. These are integral membrane protein receptors for natriuretic peptides (NPs), which when bound to the receptor activate the cytoplasmic guanylyl cyclase domain of the receptor. In effect, they are ligand (NPs)-gated receptor enzymes. The peptide hormones (ANP secreted by the atria and BNP secreted by ventricles) decrease blood pressure. There are seven variants of pGC (A-G) found in mammals. GC-A (also called NPR-A or NPR1) and GC-B (NPR-B or NPR2), are both receptors for natriuretic peptides. The domain structure of NPR-A is shown in Figure 28.8.20

Figure 28.8.20: Domain structure of GC-A (also called NPR-A or NPR1)

Figure 28.8.21 shows an interactive iCn3D model of the human atrial natriuretic peptide receptor1 AlphaFold predicted model (P16066)

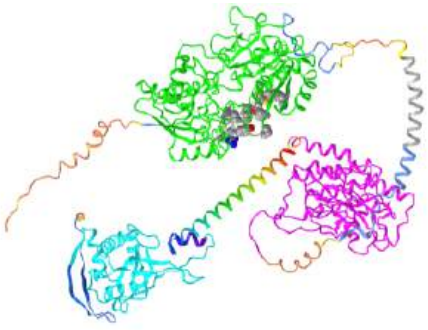

Figure 28.8.21: Human atrial natriuretic peptide receptor1 AlphaFold predicted model (P16066) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...Wd3xvHrY3rEUw6

Orient the model as shown in the figure above. The coloring coding in the model is as follows:

- green: Ligand (ANP)-binding domain of the type A natriuretic peptide receptor (NPR-A);
- magenta: PK-GC pseudokinase domain;
- cyan: cyclase domain;
- rainbow helix: HNOBA domain is found to be associated with the HNOB domain and pfam00211 in soluble cyclases and signaling proteins. The HNOB domain is predicted to function as a heme-dependent sensor for gaseous ligands rainbow;
- gray helix: transmembrane segment amino acids 474-494.

Note the protein is an integral membrane protein that passes through the membrane using a single alpha helix (474-494). The N-terminal domains above it and the C-terminal domains below it would orient like a typical single-pass membrane protein in the presence of a bilayer.

28.8.6: Protein Kinase G (PKG)

To briefly review, NO production leads to the production of cGMP. cGMP can directly bind to and regulate membrane ion channels. In alignment with the basic paradigm of signaling described throughout this chapter, we will now discuss how it activates **Protein Kinase G (PKG)** a member of the Ser/Thr Protein Kinase AGC family.

The are two mammalian genes for PKG1 and PKG2. Both are homodimers. PKG1 acts in the cytoplasm while PKG2 becomes tethered to the membrane by N-terminal myristoylation. Figure 28.8.22 shows the domain structure of PKG-I, which is similar to PKG2.

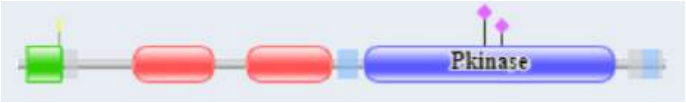

Figure 28.8.22: Domain structure of protein kinase G - I.

Red indicates the two nonidentical cGMP binding domains. Green is the N-terminal coiled-coil dimerization domain, which inhibits kinase activity in the absence of cGMP. On binding of cGMP, autoinhibition of the catalytic domain by the N-terminal domain is relieved. The binding of cGMP to the regulatory domain induces a conformational change which stops the inhibition of the catalytic core by the N-terminus and allows the phosphorylation of self (autophosphorylation) and then substrate proteins. Whereas PKG-I is predominantly localized in the cytoplasm, PKG-II is anchored to the plasma membrane by N-terminal myristoylation.

PKG1 is involved in modulating Ca^{2+} activity, platelet activation, smooth muscle contraction, gene expression as well as neural function. PKG2 helps regulate bone growth, intestinal secretion, and synaptic plasticity. It also regulates gene expression and activates the MAPK cascade in bone cells.

Figure 28.8.23 shows an interactive iCn3D model of the predicted structure of Human cGMP-dependent protein kinase 2 (AlphaFold, Q13237).

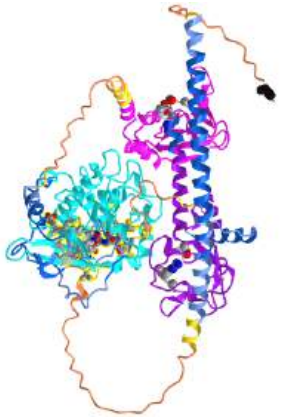

Figure 28.8.23: Predict the structure of Human cGMP-dependent protein kinase 2 (AlphaFold, Q13237). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...A55VorQFGZqpSA

The cyan domain is the STK (Ser/Th Kinase) domain. The magenta and purple domains are the CAP-Ed domains. The spacefill side chain structures within them represent the cGMP (or with lower affinity cAMP) binding sites. The CPK-colored sticks in the cyan kinase domain are the amino acid side chains in the active site where ATP binds. The orange backbone represents the least

confident part of the predicted structure. The black spacefill is the N-terminal Gly (after removal of Met) which is myristoylated, allowing targeting of the modified PKG2 to the cell membrane.

28.9: Gated Ion Channels - Neural Signaling

28.9.1: Introduction to Neural Signaling

Ion channels are membrane proteins that allow the flow of normally impermeant ions across the hydrophobic "sea" of cell or organelle membranes. The channel proteins can be constitutively open or can be "gated" open (or closed) by signals that affect the conformation of the protein. The signals can be ligands (in the form of hormones or neurotransmitters), post-translational modifications (mostly phosphorylation, dephosphorylation), or more difficult-to-understand events (change in transmembrane potential, pressure, or temperature). Gated channels are perhaps best studied through their role in neural signaling.

Neurochemistry is one of the most explosive areas of biological research. Scientists are now starting to unravel the molecular bases for memory, cognition, emotion, and behavior. The next decades will bring a greater understanding of brain chemistry and along with it the potential to alter human mood, and memory, and to treat mental illnesses such as schizophrenia much more effectively. The human brain has about 86 billion neurons. Compare this with some estimates for the number of stars in the Milky Way galaxy (about 100 billion, a number derived from luminosity and mass measurements but some estimates suggest 400 billion). Now imagine that each neuron can form connections - synapses - with 1000 to 10,000 other neurons. Throw in another 86 billion nonneuronal cells like glial cells and you have one of the most complex structures in the universe. This section will explore the biology and chemistry of neurons.

Recent studies suggest that there are around 3300 different types of cells in the brain. We will discuss two kinds of neurons - those that interact with muscles at the neuromuscular junction and those that interact with other neurons in the central nervous system. Neurons consist of a single, nucleated cell body with multiple signal-receiving outgrowths (dendrites) and multiple-signal sending outgrowths (axons) which end in a terminal button. These interact through the synapse with dendrites on other neurons. These characteristics are shown in Figure 28.9.1.

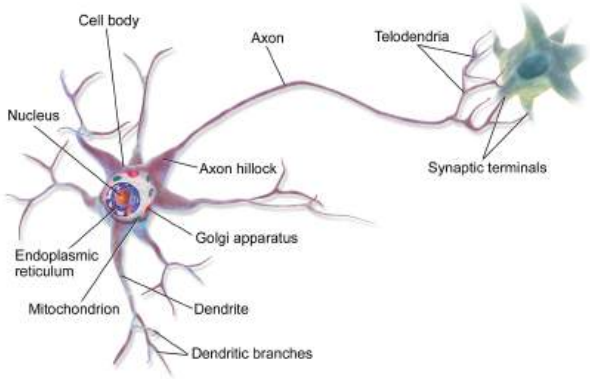

Figure 28.9.1: A neuron. Bruce Blaus - Own work, CC BY 3.0, https://commons.wikimedia.org/w/inde...curid=28761830

A presynaptic neuron can stimulate an adjacent postsynaptic neuron by releasing a neurotransmitter into the synapse between the cells, which binds to a receptor in the membrane of the post-synaptic cell, stimulating the cell, as shown in Figure 28.9.2

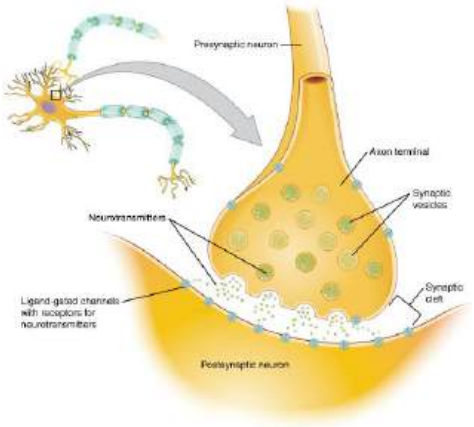

Figure 28.9.2 The synapse. https://cnx.org/contents/FPtK1zmh@8.25:fEI3C8Ot@10/Preface..Creative Commons Attribution 4.0 International license.

We will discuss the events which cause the post-synaptic cell to "fire", but we will not discuss the immediate events which lead to the release of neurotransmitters by the presynaptic neuron.

Neurons (as do all cells) have a transmembrane potential across the membrane. Transient changes in the membrane potential are associated with neuron activation or inhibition. This arises in part due to the imbalance of ions across the membrane which was established by the Na^+-K^+-ATPase in the membrane. This electrogenic antiporter transfers 3 Na ions out of the cytoplasm for every 2 K ions it transports in. Likewise Cl- has a much higher level

outside the cell. Membrane potentials are determined not only by the size of the ion gradients across the membrane but also by the differential permeability of membranes to ions. As we saw previously, synthetic bilayer membranes are not very permeable to ions, as shown in Table 28.9.1 below.

Ion permeability of phosphatidyl serine vesicles

ION	PERMEABILITY (cm/s)
sodium	$<1.6 \times 10^{-13}$ (lowest)
potassium	$<9 \times 10^{-13}$
chloride	$<1.5 \times 10^{-11}$ (highest)

Table 28.9.1: Ion permeability of phosphatidyl serine vesicles

Sodium would be expected to have a lower permeability than potassium since it has a higher charge density. It also is the largest in effective size due to the larger hydration sphere around the ion arising from its higher charge density. Chloride would be expected to have the highest permeability since it has the lowest charge density (due to the repulsion of the electron cloud in the negative ion). Intracellular charged proteins (which are mostly negative) are not permeable and help in creating the negative charge imbalance across the membrane.

Much work has been done on the giant axon of the squid, which has uniquely high intracellular potassium (400 mM compared to 20 mM outside) and high extracellular fluid sodium (440 mM vs, 50 mM inside) and chloride (560 mM vs 52 mM inside). Mammalian cell concentrations are much lower, but the relative size of the gradient is about the same. Typical ion concentrations and permeabilities for mammalian membranes are shown in Table 28.9.2 below.

T

Ion	Cell (mM)	Blood (mM)	Permeability (cm/s)
potassium	140	5	5×10^{-7}
sodium	5-15	145	5×10^{-9}
chloride	4	110	1×10^{-8}
X^- (negative macromolecules)	138	9	0

Table 28.9.2 Typical ion concentrations and permeabilities for mammalian membranes

How can we account for the markedly greater permeabilities of ions (1000x to 1,000,000 x) in mammalian cell membranes compared to synthetic lipid vesicles? Previously, we showed that glucose has a greater permeability through red blood cell membranes than through synthetic liposomes because of a membrane receptor that allows facilitated diffusion across the membrane and down a concentration gradient. The same thing is true of ion permeabilities in intact biological membranes. These membranes have several types of selective ion channels (non-gated - always open, and gated - open only after specific conformational changes). The non-gated channels dramatically increase the permeability of membranes to ions, as the glucose transport protein increases the permeability to glucose. It turns out that this differential permeability contributes to the transmembrane potential. Ion channels in nerves and muscles can move ions across the membrane at a rate of up to 10^9/s, which is comparable to k_{cat} for the best enzymes.

If we envision channels as pores, how can we account for the selectivity of the channel to specific ions? A larger pore should admit any ion less than a maximal size for the pore, so it is hard to imagine the nature of the selectivity filter. Because of this, many people discounted the ideas of channels in favor of a transporter, which would bind the ion selectivity and then, through conformational changes, move the ion across (much like the Na/K ATPase we discussed in the previous guide). This model could not, however, account for the incredible rates of ion flux across the membrane. Selectivity can be accounted for by a channel that contains a narrow opening that acts as an ion sieve. The ion loses most of its hydration sphere and forms specific interactions with amino acid side chains in the pore region. Such an interaction would be transient and not too tight since the ion must pass through the membrane. As we will see later, these ion channels:

- pass ions down a concentration gradient in a thermodynamically favorable process
- are specific for certain ions (although a few are less selective and will pass Na, K, Ca, and Mg ions)
- allow ion flow through either ungated or gated channels.,
- saturate with increasing ion concentration (even though as concentration increases, the ions have a greater thermodynamic drive to pass through the channel). This is consistent with the binding of the ion at a selectivity filter in the narrow part of the pore. The K_D for the interaction is usually in the mM range and indicates weak binding with large dissociation rate constants (k_{off}).

28.9.2: Transmembrane Potentials

Several questions arise about the distribution of ions and the magnitude of the transmembrane potential.

1. How are the ion gradients established?
2. How does the transmembrane ion distribution contribute to the membrane potential?
3. How can the resting electrochemical potential and the ion distribution be maintained?

The answer to these questions will be illustrated using studies on two types of brain cells, glial cells (which function as protectors, scavengers, and feeders for brain neurons) and neurons. Both types of cells have transmembrane potentials.

Glial Cells

The transmembrane ion gradients for ions can be established by different mechanisms. One uses ion-specific ATPases (P-type ion transporters), such as we discussed with the Na/K ATPase. This transporter ejects 3 sodium ions from the inside of the cell for every 2 potassium ions it transports in, all against

a concentration gradient. Since it is an electrogenic antiporter, it helps generate the potential. Additionally, specific ion channels also contribute (as described below) to the transmembrane gradients and potentials.

The harder question is how the ion distribution contributes to the membrane potential. Two things must occur for a membrane potential to exist: First, there must be a concentration gradient of charged ions (for example, sodium, potassium, or chloride) across the membrane. Second, the membrane must be differentially permeable to different ions. If the membrane were completely impermeable to ions, then no movement of ions across the membrane could occur, and no membrane potential would arise. If, however, membranes are differentially permeable to the ions, an electrical potential across the membrane can arise. Remember, synthetic bilayers are quite impermeable to ions, given the hydrophobicity of the internal part of the bilayer. Likewise, it is quite impermeable to glucose. It turns out that glial cells appear to have only a non-gated potassium channel, which allows the outward flow of potassium ions down the concentration gradient. The inside will then have a net negative charge since impermeable anions remain.

The chemical potential gradient causes this outward flow of potassium ions. As more ions leave, the inside gets more negative, and a transmembrane potential develops which resists further efflux of potassium. Eventually, they balance, and the net efflux of potassium stops. The resting transmembrane potential reaches around -75 mV which is exactly the value obtained from the equations we will derive below. Since glial cells appear to only express a non-gated (or leakage) potassium channel, their resting potential is equal to the potassium equilibrium potential. Figure 28.9.3 shows hypothetical transmembrane potentials (Ψ), and the electrical and chemical potentials (ΔG) for K^+ loaded vesicles with and without a non-gated K^+ channel

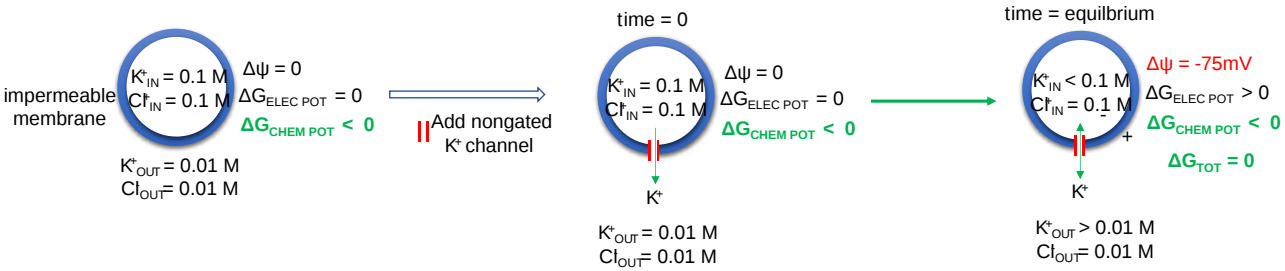

Figure 28.9.3: Visualizing the transmembrane potential in K^+ loaded vesicles with and without a non-gated K^+ channel

As we have shown previously, very little K^+ efflux is required to develop a transmembrane potential. At equilibrium, the K^+_{IN} is simply shown as < 0.1 M while K^+_{OUT} is shown as > 0.1 M

Here is a PhET simulation showing the differences between non-gated (leakage, always open) and gated channels (opened in response to stimuli like ligands, transmembrane potential, mechanical forces, etc).

28.9.3: Neurotransmitter Activation of Neurons

What happens when a neurotransmitter binds to a receptor on the post-synaptic cell? We will study two examples. The first is the simplest: binding of the neurotransmitter acetylcholine, released by a motor neuron, to its receptor on muscle. This region is called the neuromuscular junction. The binding of acetylcholine will lead to a transient depolarization of the muscle cell. Next, we will discuss the interaction of a neurotransmitter with a post-synaptic neuron in the central nervous system. This is a much more complex system. Their differences are described below:

In neurons interacting with muscles:

- Most muscle fibers are innervated by only one neuron - a motor neuron
- Neurotransmitter release at the neuromuscular junction leads only to muscle excitation, not inhibition.
- All fibers are excited by the same neurotransmitter - acetylcholine.

In the central nervous system, life is more complicated:

- Stimuli are received from hundreds to thousands of different neurons.
- Nerves receive both excitatory and inhibitory stimuli from neurotransmitters
- Different kinds of receptors are present to receive stimuli, which control the activity of different kinds of channels.
- The ion channels in neurons are gated by a variety of mechanisms in addition to changes in membrane potential, including gating by heat, cold, stretch, or covalent modification.
- Most nerve cells have a resting potential of about -65 mV compared to -90 mV for a muscle cell.

What happens when a neurotransmitter binds to the receptor on the post-synaptic cell? A depolarization occurs (mediated by conformational changes in the transmitter-receptor complex), raising the membrane potential from the resting equilibrium level. What happens next depends on the identity of the post-synaptic cell. In the muscle cell, the rising potential caused by the binding of acetylcholine ultimately leads to muscle contraction by opening intracellular organelle membrane calcium channels. In a neuron, the rising potential triggers an action potential by opening voltage-gated sodium channels. The potential rises to about + 35 mV but does not reach the Na ion equilibrium potential, because the high positive potential opens a voltage-gated potassium channel. The potential then falls until it reaches the K ion equilibrium potential when the cells are hyperpolarized. It slowly then relaxes

back to the resting potential of -60 mV. This wave of changes in potential sweeps down the post-synaptic cell membrane and is the basis for the "firing" of the neuron. A plot of transmembrane voltage changes vs time for a typical action potential is shown in Figure 28.9.4

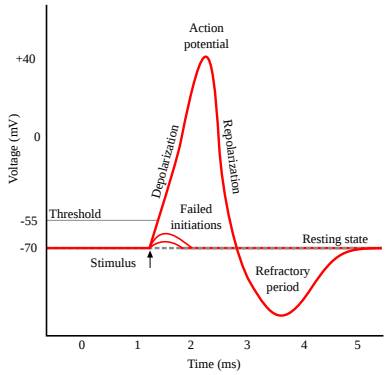

Figure 28.9.4: Action potential of a neuron. Original by en:User:Chris 73, updated by en:User:Diberri, **GNU Free Documentation License**,

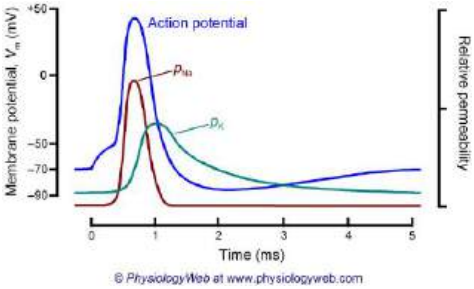
Figure 28.9.5shows the actual changes in ion permeability in various phases of the action potential (replace figure, seek permission)



mine

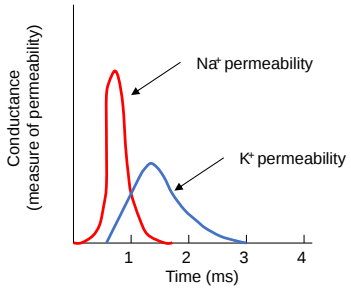


Figure 28.9.5: Na^+ and K^+ permeability during the action potential

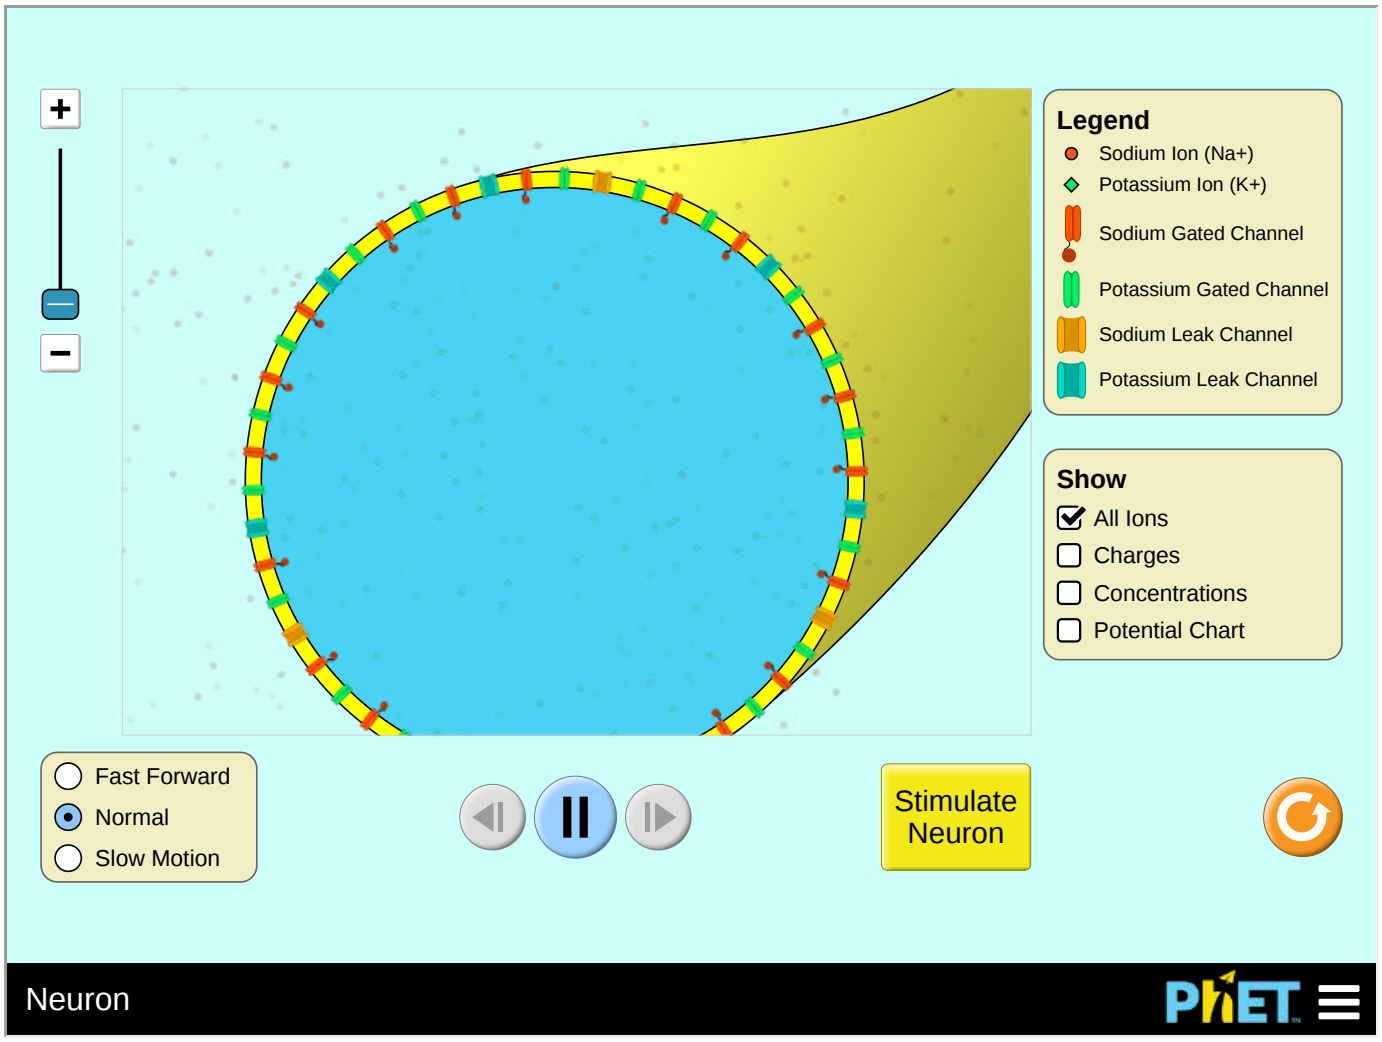
Figure 28.9.6shows an animation of a neuron firing showing all the key players. (produced by PhET, University of Colorado, Boulder).



28.9.4: Proteins of the Neural Synapse

We must now account for the rise and fall of the membrane potential to a variety of neurotransmitters, including the cholinergic transmitters (ex. acetylcholine), catecholamines (dopamine, epinephrine, norepinephrine), amino acid derivatives (ex. Glu, Asp, N-methyl-D-Asp, Gly, gamma-amino-butyric acid -GABA), and peptides (endorphins, enkephalins). We will consider five membrane proteins as shown below in Figure 28.9.7.

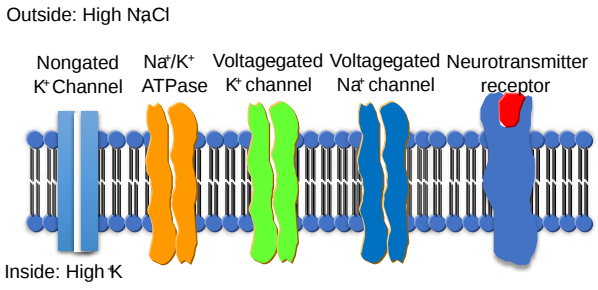


Figure 28.9.7: 5 key membrane proteins involved in the action potential

Many of these we have explored in detail in Chapter 11.3: Diffusion Across a Membrane - Channels, so we will focus on just one new one, the chloride channel, in the following section.

Na^+-K^+-ATPase: It transports both sodium and potassium ions against a concentration gradient using ATP as an energy source. The protein is a sodium-dependent ATPase. Without this protein, the membrane potential could not be maintained since the sodium and potassium gradient would collapse. It also contributes to the potential since it is an electrogenic antiporter. (In addition, we have seen that ungated potassium and sodium channels are also present.)

Neurotransmitter receptor: The receptors we will consider here are typically ligand-gated ion channels. Once the ligand binds, a conformational change occurs in the protein, allowing a flow of ions down a concentration gradient. Depending on the nature of the ion, the channel either initiates depolarization

(when Na^+ enters from the outside and raises ΔΨ) or inhibits depolarization (when Cl^- enters from the outside and lowers ΔΨ). When chloride channels open, they hyperpolarize the transmembrane potential. Stimulatory neurotransmitters (like glutamate) lead to depolarization of the membrane, while inhibitory neurotransmitters (like gamma-aminobutyric acid) lead to hyperpolarization of the membrane (making the potential more negative).

Na^+ channel (voltage-gated): When the ligand-gated channel depolarizes the membrane to some threshold value, sodium channels undergo a conformational change and open allowing Na^+ ions to flood into the cell, raising the potential to a positive approx. 33 mV (a value lower than the equilibrium sodium potential). This membrane protein is a voltage-gated channel, not a ligand-gated one.

Two potent neurotoxins, tetrodotoxin (from Pufferfish) and saxitoxin bind to the channel and act as antagonists (inhibit the activity of the receptor by blocking sodium influx). Their structures are shown in Figure 28.9.8

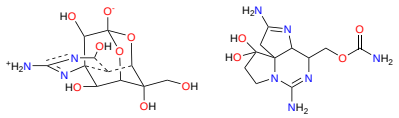

Figure 28.9.8: Structures of tetrodotoxin and saxitoxin

The guanidino group of the tetrodotoxin appears to bind with high affinity to the entrance of the channel that interacts with the hydrated sodium ion. Affinity chromatography using tetrodotoxin beads has been used to purify the protein. Figure 28.9.9 shows the relative sizes of ions used to probe size requirements for the channel. the hydrated K^+ ion can not pass through.

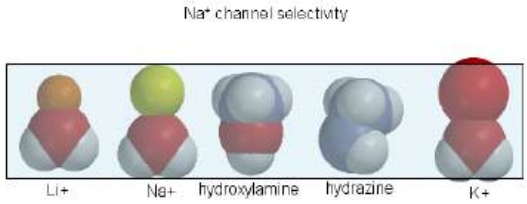

Figure 28.9.9: Na^+ channel ion selectivity

Depolarization of the membrane potential may result in an outward movement and rotation of the positively charged helixes containing Lys and Arg side chains which had presumably formed salt bridges (ion-ion interactions) with negatively charged side chains within the protein. Depolarization of the membrane results in breaking a few salt bridges, and effectively leads to the movement of 1 or 2 charges on the helix through the membrane. Work occurs when charges are moved through an electric field. Work is also related to the ΔG for the system, which is also dependent on the ratio of the open and closed form of the channel. Other voltage-gated ion channels (for potassium and chloride) have a similar membrane topology and an S4 voltage-sensor helix.

K^+ channel *(voltage-gated)*: When the membrane potential reaches around +25 mV or so, the K+ channel, a voltage-gated membrane protein, alters its conformation, allowing K^+ efflux from the cells, lowering the potential until it reaches the potassium equilibrium potential. It slowly relaxes back to the cell resting potential of about -60 mV.

Cl^- channel: If these channels (typically ligand-gated) are open, they will hyperpolarize the cell and make it more difficult to fire.

The selectivity filter is composed of many stacked rings of oxygens that can interact with a dehydrated K ion but not with a dehydrated Na ion which can not approach close enough to form significant interactions. Surrounding the filter are twelve aromatic amino acids which constrain the size of the pore opening. The interactions of the filter O's with the K ion make up for the energetically disfavored dehydration of the ion. The filter contains two K ions which repel each other, assisting in the vectorial discharge of the ions through the membrane. These ions must form weak interactions with the selectivity filter. The actual pore is mostly hydrophobic, which facilitates the flow-through of the ions. The central cavity of the pore can hold some water molecules in addition to the K ions which helps stabilize the ion in the middle of the pore.

28.9.5: Inhibitory Neurotransmitters

The main inhibitory neurotransmitters are GABA (gamma-aminobutyric acid), which is made from glutamic acid through decarboxylation of the α-C group, and glycine. They bind to transmitter-gated chloride channels, which when open hyperpolarize (make more negative) the transmembrane potential. Benzodiazepines (like Valium and Librium - anti-anxiety and muscle-relaxing agents) and barbituates (like phenobarbital-hypnotics) bind at allosteric sites on the GABA receptor and potentiate the binding of each other and GABA. This receptor is also affected by alcohol and anesthetics. Let's focus on the $GABA_A$ channels (also called the GABA(A) receptor or GABA(A)R) since it binds so many interesting pharmaceutical drugs.

Figure 28.9.10 shows an interactive iCn3D model of the human full-length heteromeric α1-β3-γ2L GABA(A)R in complex with picrotoxin, GABA, and megabody Mb38 (6huj) derived from cryo-EM (loads slowly).

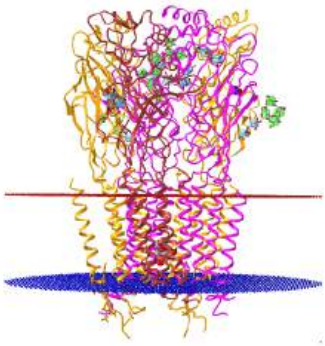

Figure 28.9.10: Human full-length heteromeric alpha1beta3gamma2L GABA(A)R in complex with picrotoxin, GABA and megabody Mb38 (6huj) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...VdExv4QhFPsVX8 (loads slowly)

This structure is a Type-A γ-aminobutyric ($GABA_A$) receptor. It consists of two alpha chains (orange), two beta chains (magenta), and one gamma chain (brown). Two GABAs (spacefill, CPK colors) are bound between the orange and magenta subunits (between the α and β chains). Picrotoxin is shown in spacefill CPK colors in the central pore (bottom), near the cytoplasmic end (blue bilayer dummy atoms). The extracellular domain (above the red) has glycans shown in SNFG cartoon form and shown in Figure 28.9.11.

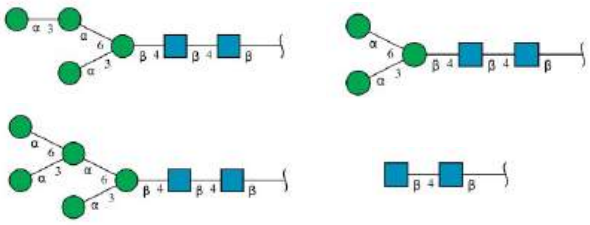

Figure 28.9.11: Glycan structure for the Type-A γ-aminobutyric ($GABA_A$) receptor

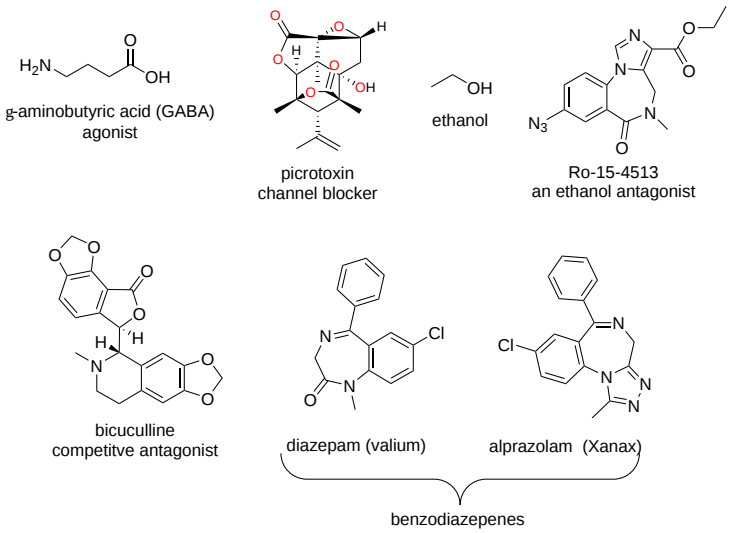
The structure of the receptor bound to many pharmacological agents has been solved. The structure of GABA (the agonist), bicuculline (a competitive antagonist), the benzodiazepines alprazolam (Valium) and diazepam (Xanax), a channel blocker (picrotoxin), ethanol, and Ro-15-4513 (an ethanol antagonist) are shown in Figure 28.9.12



(\PageIndex{12}\): Structures of GABA-R binding molecules -GABA (the agonist), bicuculline (a competitive antagonist), the benzodiazepines alprazolam (Valium) and diazepam (Xanax), a channel blocker (picrotoxin), ethanol, and Ro-15-4513 (an ethanol antagonist)

The benzodiazepine diazepam (Xanax) binds at an allosteric site and promotes GABA binding, so it is considered an "**indirect agonist**". It is also an anxiolytic (a drug used to reduce anxiety) and an anticonvulsant. Ethanol activates the inhibitory GABA channel. Too much ethanol leads to cells hyperpolarized cells so neural responses are greatly inhibited, possibly leading to death. Ethanol acts synergistically with benzodiazepine, which makes this combination so lethal.

Figure 28.9.13 shows an interactive iCn3D model of the human full-length heteromeric α1-β3-γ2L GABA(A)R in complex with diazepam (Valium), GABA (6HUP) (loads slowly). https://structure.ncbi.nlm.nih.gov/i...fTZMqePnpdwTy8

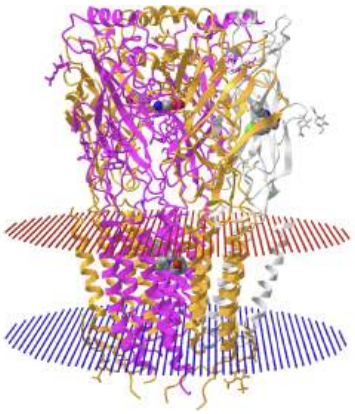


Figure 28.9.13: Human full-length heteromeric α1-β3-γ2L GABA(A)R in complex with diazepam (Valium), GABA (6HUP). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...fTZMqePnpdwTy8

The structure shows two alpha chains (orange), two beta chains (magenta), and one gamma chain (gray). Two GABAs (spacefill, CPK colors) are bound between the orange and magenta subunits (between the α and β chains). Three valiums (spacefill, CPK) are shown in the structure. One is bound to an allosteric site between the orange (alpha) and gray (gamma) chains. Two others are bound within the bilayer, this time between the alpha (orange) and beta chains (magenta) chains. Different benzodiazepines appear to bind in slightly different sites, and binding elicits their specific effects.

A drug, Ro-15-4513, was developed in the 1980s that antagonizes the effect of ethanol. It has a complicated pharmacology. It is considered a benzodiazepine "**partial inverse agonist**". It has no effect by itself. It reverses the anticonvulsant effects of benzodiazepines, and blocks the Cl^- effects of ethanol so it is an inverse agonist of GABA-mediated Cl^- flux. Hence it antagonizes the effect of benzodiazepines and alcohol. If given to intoxicated mice, they act normally! Such drugs have not reached the market as their use poses significant ethical issues.

The effect of pharmacological agents on the GABA receptor

In the "voltmeters" below, draw an arrow indicating if the transmembrane potential becomes more negative or more positive for the conditions given.

28.9.6: Metabotropic Neural Receptors

Some signaling molecules, whose effects are regulated by kinases (β-adrenergic and some olfactory signals by PKA and acetylcholine by PKC for example), are neurotransmitters. In all the examples presented previously, the neurotransmitters gate the inactive ion channels directly. These types of membrane receptors are classified as **ionotropic**. Typical examples of neurotransmitter-gated ion channels are the acetylcholine receptor in neuromuscular

junctions and the Glu, Gly, and GABA receptors in the central nervous system. These receptors are multimeric proteins. Receptors with direct gating of ion flow are fast, with activities that last milliseconds, and are used in eliciting behavioral responses.

However, ion channels can also be gated indirectly when the neurotransmitter binds to its receptor and leads to downstream events which subsequently open an ion channel that is distinct from the receptor. In this case, the occupied receptor communicates to an ion channel indirectly through a G protein for example. Examples of this indirect gating of ion channels include the serotonin, adrenergic, and dopamine receptors in the brain. These receptors are classic single-protein serpentine GPR receptors with 7 transmembrane helices and intracellular domains that can interact with G proteins as described above to increase second messenger levels (cAMP, DAG) in the neuron. The receptors are classified as **metabotropic** since they must activate a series of metabolic steps before ion channels are open. The second messengers can either activate kinases in the cell, which phosphorylate ion channels to either open or close them, or can bind directly to the channel and modulate its activity through an allosteric conformational change. In some cases, the G protein directly acts on the ion channel. These different ways are described in Figure 28.9.14

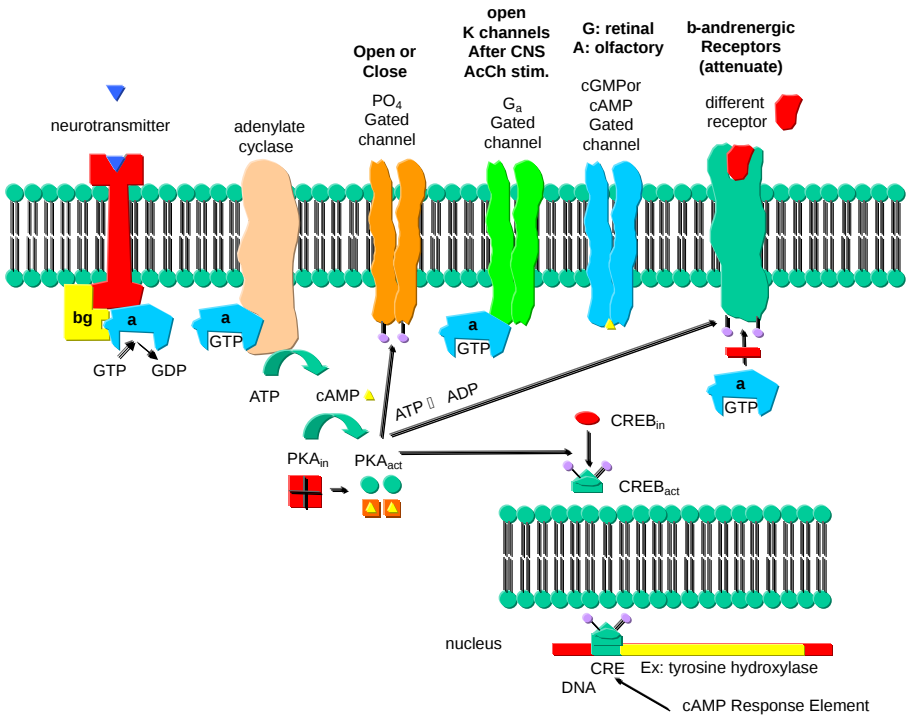

Figure 28.9.14: Neurotransmission: Gating through G Linked Receptors

In contrast to direct gating, receptors that indirectly gate ion channels have activities that are slow and last seconds to minutes. These receptors are usually involved in modulating behavior by changing the excitability of neurons and the strength of neural connections, hence modulating learning and memory. These changes can occur in many ways, summarized below:

Phosphorylating ion channels: Receptors that act through a second messenger system can change ion channel activity by activating kinases that phosphorylate the channels. This may:

- open the channel normally closed at the resting potential and produce an effect like gating.
- close a channel usually opens at the resting potential (such as non-gated K channels which when closed would depolarize the cell and make it more excitable).

Gα interaction with ion channels:

- the Ga subunit of the G protein interacts with K channels after stimulation of the CNS Acetylcholine receptor, opening the channel and hyperpolarizing the cell

Second messenger interaction with ion channels:

- cGMP opens cation channels in retinal cells after activation of the photoreceptor by photons
- cAMP opens cation channels in olfactory cells after activation of the olfactory receptor by odorants.

Second messenger effects on proteins other than ion channels (usually different receptors):

- the β-adrenergic receptors are phosphorylated by PKA and PKC (activated by stimulation of a different neurotransmitter receptor linked through a G protein to produce increased levels of second messengers cAMP and diacylglycerol). When phosphorylated, the β-adrenergic receptor, itself activated through G protein) can't bind Gs. This attenuates the response of the β-adrenergic receptor to its neurotransmitter which leads to desensitization to that signal.

Second messengers regulate gene expression:

- cAMP-activated PKA can phosphorylate an inactive transcription factor in the cell, which then can bind to a section of DNA called the cAMP Response Element (CRE), which is upstream of certain genes, leading to the transcription of the genes. The transcription factor is called CREB for cAMP Response Element Binding protein. Example: tyrosine hydroxylase (a monooxygenase) is involved in the synthesis of epinephrine and norepinephrine. The activity of this protein is increased when it is phosphorylated by PKA. Hence its activity can be increased quickly by this modification of the already present protein. If an animal is subjected to severe or long-term stress (cold or immobilization), presynaptic cells with norepinephrine will be stimulated to release the neurotransmitter. This requires continual synthesis of the neurotransmitter by the presynaptic cell. The increase in the synthesis of this neurotransmitter is caused by the presynaptic cell being stimulated by another neuron, which leads to increased levels of cAMP, and ultimately activation of CREB which increases transcription of the hydroxylase gene.

Caffeine

Caffeine produces a state of arousal in the central nervous system. High levels appear to block the binding of an inhibitory neurotransmitter, adenosine, to the A2A adenosine receptor. In the absence of caffeine, adenosine levels rise during the day, which promotes interaction with its receptor, leading to increased sleepiness and lack of concentration. When adenosine binds normally to its receptors, it activates the adenylate cyclase cascade, which activates PKA, leading to changes in the phosphorylation state of many proteins inside the cell, including protein phosphatase (2A). These changes inhibit neural firing. Caffeine blocks these changes.

Hallucinogenic drugs

Illicit drugs like LSD, psilocybin, and ecstasy can produce hallucinations as they have profound effects on consciousness and perception of self and reality. Recent clinical studies have shown that under tightly controlled conditions and doses, these drugs might have significant therapeutic effects in the treatment of mental health issues such as depression and post-traumatic stress syndrome. Hence their mechanisms of action have been the source of many studies.

All of these drugs bind to the human serotonin 2A receptor (5-HT_{2A}R), a metabotropic GPCR receptor of serotonin (5-hydroxytryptamine)**.** When serotonin binds, it leads to GPCR signaling, partly through beta-arrestins. These are **adapter proteins** that form complexes with ligand-bound and activated GPCRs and GPCR protein kinases.

Structures show that LSD binds to the orthosteric binding site (i.e. the active site, not an allosteric site) for serotonin. The study also found that serotonin and psilocin binding extends into an adjacent site called the extended binding pocket (EBP). These differences suggest that it should be possible to design agonists that have therapeutic, but not hallucinogenic properties. Serotonin binding does not cause hallucinations. A drug, IHCH-7086, in mouse studies seems to not provoke hallucinations but appeared to have antidepressive effects (based on observations of mouse behaviors like twitching and freezing). The structures of serotonin (5HT) and psychotropic drugs that bind the $5HT_{2A}$R are shown in Figure 28.9.15

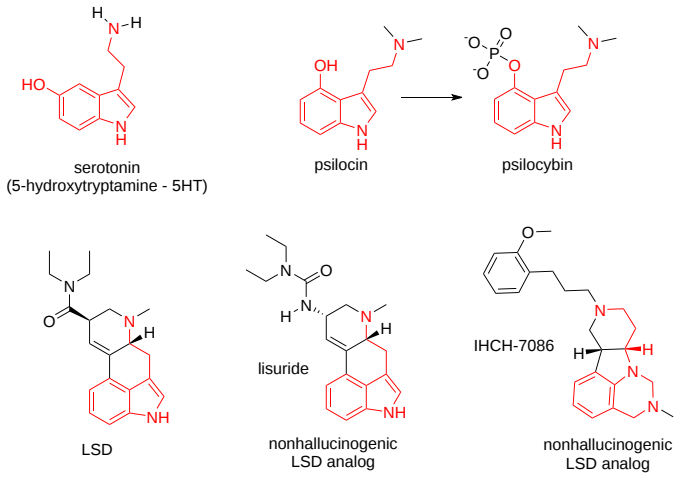

Figure 28.9.15 Structures of serotonin (5HT) and psychotropic drugs that bind the $5HT_{2A}$R

Figure 28.9.16 shows a model of the serotonin receptor (5HT-2A) with each of the bound drugs. Note the different occupancy of the orthosteric and extended binding pockets.

Figure 28.9.16: The serotonin receptor (5HT-2A) with bound serotonin and orthosteric binding analogs.

The GPCRs have been aligned for each of the poses. The ligands are represented in spacefill in a single color, as listed below:

- red: serotonin (5HT), the physiological agonist, 7WC4
- yellow: psilocin, 7WC5 LSD, 7WC6
- magenta: LSD, 7WC6
- cyan: IHCH-7086

An alternative way to explain the fact that serotonin does not cause hallucinations and why the other agonists do is that in addition to binding plasma membrane GPCRs, the agonist might have additional effects that are associated with hallucinations by binding intracellular membrane GPCRs.

The cerebral cortex plays a key role in what it means to be human. It is involved in higher-level processing involving thought, learning, emotion, personality, language, and memory. As such its dysregulation is involved in mental health conditions such as depression et al. in which synaptic plasticity is decreased as evidenced by a reduction in dendritic structure require for synaptic connections. The serotonin (5HT) reuptake inhibitors (SSRIs) used to treat depression appear to increase neural plasticity and connections over time (so they don't give immediate responses). Hallucinogens that target the 5-HT2A receptor (5-HT2AR) also promote neuroplasticity. However, neuron growth in cortical cultures is not affected by serotonin. What is the mechanism that allows various combinations of neuron plasticity and hallucinations all from the same receptor?

One factor that determines these differential effects is that serotonin (5HT) is more polar and cannot readily enter cells, while the HT2AR agonists that are hallucinogenic are less polar (more lipophilic) and could potentially enter cells where they might elicit hallucinogenic effects. Intracellular hallucinogens would bind internal 5-HT2AR receptors, which are found in cortical neurons on the Golgi and other organelles that are more acidic than the cytoplasm or extracellular environment. (In fact, in cortical neurons, the main location of the 5-HT2ARs is intracellular.) This might lead to more prolonged retention of intracellular hallucinogens and longer signaling (LSD has a profound hallucinogenic effect that lasts for 10 hours or more) leading to neuronal growth as well.

If serotonin is given to wild-type mice, no hallucinations occur, as evidenced by the lack of a head twitch response (HTR). However, if given to mutant mice who expressed serotonin transporter (SERT) on cortical neurons, the HTR response was observed. The import of serotonin led to neuroplasticity. It could be that serotonin is not the physiological ligand for intracellular HT2ARs. It might also imply that as with the case with endocannabinoids, we have endogenous psychedelics. The subtle difference in the binding of serotonin and the hallucinogens in Figure 16 might have little to do with their tendency to produce hallucinations.

Recent Updates: LSD binding to the BDNF receptor TrkB 06/09/23

Much is still not known about how antidepressants work and what causes delays in their therapeutic effects. Increased synaptic connections through expanded neuroplasticity appears to be required for their therapeutic effects. The major action of drugs like Prozac, a serotonin reuptake inhibitor, is through blocking the serotonin transporter (SERT), increasing extracellular levels of serotonin in the neural synapse. Tricyclic anti-depressants as well as monoamine oxidase inhibitors (MAOI), also increases monoamine neurotransmitters in the synapse with delayed therapeutic effects (the monomaines act quickly however). Perhaps these agents bind other receptors!

In fact, they do. The binding of both typical and fast antidepressants also occurs in the transmembrane domain of tyrosine kinase receptor 2 (TRKB), the brain-derived neurotrophic factor (BDNF) receptor, which is linked to increases in neuroplasticity. The receptor also binds cholesterol which modulates its activity. The antidepressants binding site is formed on dimerization of their transmembrane domains. Mutations in the transmembrane region block the efficacy of the antidepressants.

LSD and other psychedelics also produce fast and long-lasting antidepressant effects promoted by increases in neuroplasticity. Studies have shown that LSD and psilocin bind to slightly overlapping sites in the transmembrane domain of the BDNF receptor as antidepressants, but with a 1000-fold higher affinity. If the LSD binding site on the serotonin 2A receptor (5-HT_{2A}) is blocked, LSD still has antidepressant and increased neuroplasticity effects.

Figure 28.9.17shows the interaction of LSD and the metabolite of psilocybin, psilocin (PSI), with the TRKB receptor.

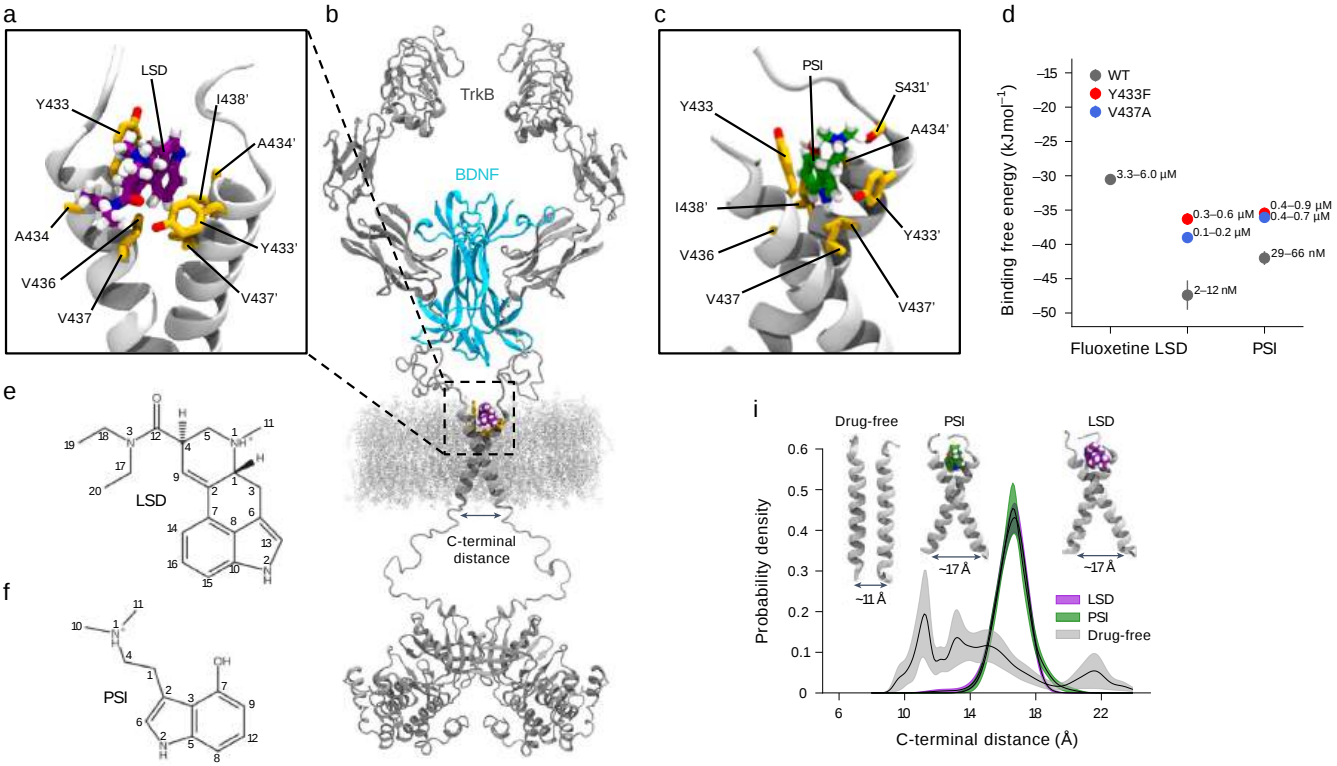

Figure 28.9.17 **Characterization of the psychedelics binding site in the TrkB TMD.** Moliner, R., Girych, M., Brunello, C.A. *et al.* Psychedelics promote plasticity by directly binding to . BDNF receptor TrkB. *Nat Neurosci* **26**, 1032–1041 (2023). https://doi.org/10.1038/s41593-023-01316-5. Panel a–c show representative MD snapshots showing the binding pocket for LSD (purple) (**a**) and PSI (green) (**c**) in the extracellular-facing crevice of the TrkB TMD dimer (gray). Side chains (yellow) of relevant binding site residues are displayed. A structural model of full-length TrkB dimer (gray) embedded in a lipid membrane is shown with bound BDNF (blue) and LSD (purple) (**b**).

Panel d shows in silico binding free energy estimations for fluoxetine, LSD and PSI. Each free energy estimate (ΔG, circles) and its statistical error (SE, bars) were estimated from a separate set of FEP simulations ($n = 1$). Dissociation constants are given as a range with upper and lower bounds converted from ΔG − SE and ΔG + SE, respectively.

Panel e,**f** show chemical structures of LSD (**e**) and PSI (**f**) with atom numbers annotated.

Panel i shows the distributions of TMD dimer C-terminal distance and shows that LSD and PSI stabilize the cross-shaped conformation of TrkB favorable for receptor activation in a 40 mol% CHOL membrane. Lines represent the mean distribution, and bands represent the standard errors ($n = 10$ independent simulations). TMD conformations corresponding to indicated C-terminal distances and drug-bound states are shown in the inset.

Figure 28.9.18shows the different binding modes of LSD and Fluoxetine (Prozac), a selective serotonin reuptake inhibitor (SSRI) for TrkB. Fluoxetine is used to treat depression, obsessive-compulsive disorder (OCD), bulimia nervosa, and panic disorder.

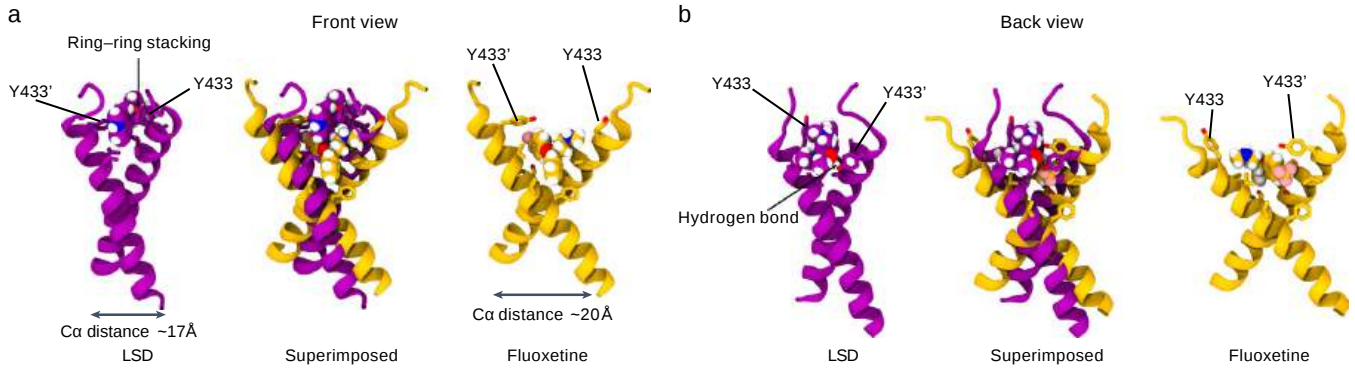

Figure 28.9.18 **Different TrkB binding modes of LSD and fluoxetine.** Moliner et al., ibid.

Panels a,**b**, show representative snapshots of atomistic MD simulations showing the front (**a**) and back (**b**) views of the binding pockets for LSD (purple) and fluoxetine (yellow) in the extracellular-facing crevice of TrkB TMD dimers. Side chains of relevant binding site residues are displayed. Superimposed structures of TrkB optimally bound to LSD or fluoxetine reveal that, while some residues involved in binding are shared (Y433 and V437), the binding modes are different. Fluoxetine binds at a site deeper within the dimer, locking the TMD dimers in a more open cross-shaped conformation (distance between the center of mass L451–L453 Cα atoms of each monomer ~20 Å). In contrast, LSD binds closer to the N-terminus of the TrkB TMD and establishes more stable interactions with the dimer: a hydrogen bond between the oxygen atom of the diethylamide group of LSD and the Y433 residue of one monomer, and pi-stacking of the aromatic backbone of the drug with the Y433 residue of the second monomer, locking the TMD dimer in a tighter cross-shaped conformation (L451–L453 Cα distance ~17 Å) compared with fluoxetine. Drugs are shown in van der Waals representation. Oxygen, nitrogen, and hydrogen atoms are shown in red, blue, and white, respectively.

28.10: Integrins- Bidirectional Cell Adhesion Receptors

This section was derived almost completely, with some modifications and additions, from the following source: Mezu-Ndubuisi, O.J., Maheshwari, A. The role of integrins in inflammation and angiogenesis. *Pediatr Res* **89,** 1619–1626 (2021). https://doi.org/10.1038/s41390-020-01177-9. https://doi.org/10.1038/s41390-020-01177-9. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/. Consult the original article for specific references.

28.10.1: Introduction

Integrins link the extracellular matrix to the intracellular cytoskeleton through a single transmembrane alpha-helical segment. They work with growth factor receptors to regulate cell survival, cell migration, and cell division. They contain a very large extracellular domain comprising most of the protein and a very small intracellular domain.

Integrins are heterodimeric transmembrane cell adhesion molecules made up of alpha (α) and beta (β) subunits arranged in numerous dimeric pairings. These complexes have varying affinities to extracellular ligands. Integrins regulate cellular growth, proliferation, migration, signaling, and cytokine activation and release and thereby play important roles in cell proliferation and migration, apoptosis, and tissue repair, as well as in all processes critical to inflammation, infection, and angiogenesis.

Integrins are a family of ubiquitous αβ heterodimeric receptors that exist in multiple conformations and interact with a diverse group of ligands. These molecules mediate interactions between cells and these cells with the extracellular matrix (ECM) and thereby serve a critical role in signaling and homeostasis. By facilitating dynamic linkages between the intracellular actin cytoskeleton and the ECM, integrins also transduce both external and internal mechanochemical cues and bi-directional signaling across the plasma membrane. Integrins are involved in a diverse range of body processes, including cellular survival, inflammation, immunity, infection, thrombosis, angiogenesis, and malignancy. In this review, we highlight the structure and function of integrins; the mechanisms involved in integrin activation and signaling; their role in inflammation, infection, and angiogenesis; and discuss current advances in integrin-targeted therapies. Understanding the factors that regulate integrin structure, function, and signaling would enable the identification of new therapeutic targets.

28.10.2: Structure of integrins

In mammals, the family of integrins is comprised of 24 αβ pairs of heterodimeric transmembrane adhesion receptors and cell-surface proteins. These pairings are known to involve 18 α and 8 β subunits as shown in Figure 28.10.1

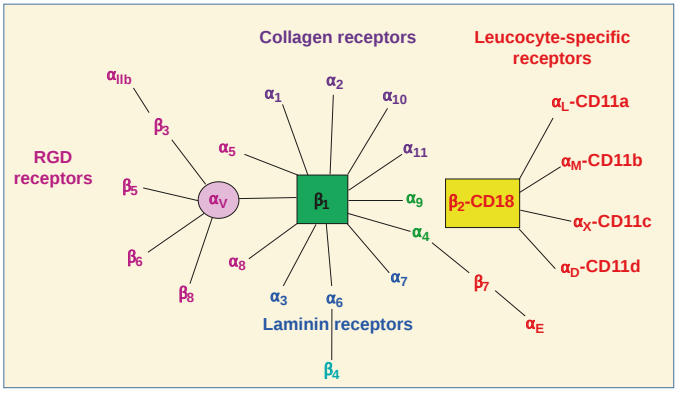

Figure 28.10.1: Integrin heterodimers consist of numerous combinations of α and β subunits.

With respect to ligand specificity, integrins are generally classified as collagen-binding integrins ($\alpha_1\beta_1$, $\alpha_2\beta_1$, $\alpha_{10}\beta_1$, and $\alpha_{11}\beta_1$), Arg-Gly-Asp (RGD)-recognizing integrins ($\alpha_5\beta_1$, $\alpha_V\beta_1$, $\alpha_V\beta_3$, $\alpha_V\beta_5$, $\alpha_V\beta_6$, $\alpha_V\beta_8$, and $\alpha_{IIb}\beta_3$), laminin-binding integrins ($\alpha_3\beta_1$, $\alpha_6\beta_1$, $\alpha_7\beta_1$, and $\alpha_6\beta_4$), and leukocyte integrins ($\alpha_L\beta_2$, $\alpha_M\beta_2$, $\alpha_X\beta_2$, and $\alpha_D\beta_2$).

The right-hand side of Figure 28.10.1 shows that the β_2 integrin subunit (CD18) can pair with one of the four α subunits (α_L-CD11a, α_M-CD11b, α_X-CD11c, and α_D-CD11d), forming leukocyte function-associated antigen-1, Mac1/CR3 (macrophage-1 antigen, complement receptor 3), 150.95/CR4 (complement receptor 4), and CD18/CD11d, respectively.

The structure of the heterodimers and their non-covalent associations are shown in Figure 28.10.2

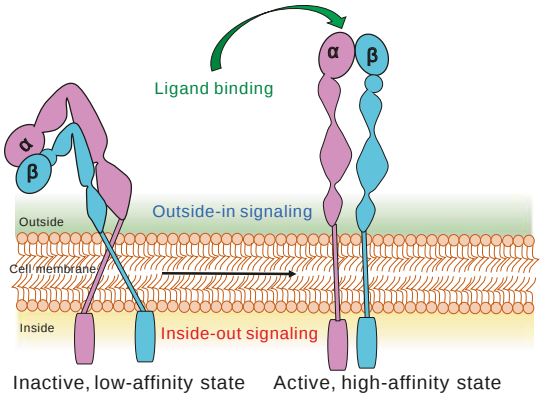

Figure 28.10.2: Structurally, the αβ integrin subunits are type 1 transmembrane proteins.

Each subunit consists of one large multi-domain extracellular segment, one transmembrane helix, and a short cytoplasmic tail. The extracellular region interacts with extracellular matrix (ECM) ligands and is composed of about 1104 residues in the α subunit and 778 residues in the β subunits and shorter cytoplasmic domains with 30–50 residues. The short cytoplasmic tails are composed of 20–70 amino acids and mediate interactions with intracellular cytoskeletal and signaling proteins.

In response to intracellular or extracellular stimuli, integrin activation occurs by ligand binding or by the changes in the cytoplasmic domains, resulting in elongation and separation of the legs. Integrins appear in a closed or “bent” conformation on resting cells and display a low binding affinity for ligands rendering them inactive to ligand binding or signal transduction; while once activated, the integrin shape extends to an open conformation leading to a high affinity. In a closed conformation, integrins show low ligand-binding affinity, partly due to the bend in the center of the α and β subunits, which brings the ligand-binding site within 5 nm of the cell surface. However, when the conformation is open, the two subunits straighten with increased integrin affinity for the ligand. The initial binding of extracellular ligands causes separation of the cytoplasmic domains, allowing interaction with signal transduction and cytoskeletal molecules during outside-in signaling, while separation of the cytoplasmic domains by talin and other activators activates the head to enable ligand binding during inside-out signaling.

The αβ pairings of integrin subunits dictate the specificity of the integrin to a particular ligand, modulate the formation of intracellular adhesion complexes, and regulate downstream signaling. Six α ($\alpha_{1–6}$) and seven β ($\beta_{1–7}$) subunits are known to form several unique αβ subunit associations, as shown in Figure 28.10.1. Interestingly, the earliest discovered integrins, lymphocyte function-associated antigen 1 (integrin $\alpha_L\beta_2$) and macrophage antigen 1 (integrin $\alpha_M\beta_2$), derive their specificity from specific α subunits, but these share the same β subunit.[5]

28.10.3: Integrin α subunit family

The integrin α subunits carry a 200 amino acid “inserted” domain, the I-domain (αI). When present on an integrin, the αI domain is an exclusive ligand-binding site. αI integrins have 13 extracellular domains in 2 subunits, which interact with a variety of ligands. The I-domains are seen in 6 out of the 15 integrin α subunits.

Integrin alpha-1/beta-1 is a receptor for laminin and collagen. It recognizes the proline-hydroxylated sequence G-F-P-G-E-R in collagen. the human α_1 subunit (1179 amino acids) has the domain structure shown in Figure 28.10.3

Figure 28.10.3: Domain structure of human integrin α_1

The green represents the Van Willibrand Factor Type A domain. The middle pinkish domains are FG-GAP extracellular domains. They are repeated up to 7 times in alpha integrins. The reddish domain at the very C-terminus is the transmembrane helix domain (1142-1164). This membrane protein is very different than those we have seen before as it has just a 15 amino acid C-terminal tail exposed in the cytoplasm.

Figure 28.10.4shows an interactive iCn3D model of the predicted structure of human Integrin alpha-1 (AlphaFold, P56199).

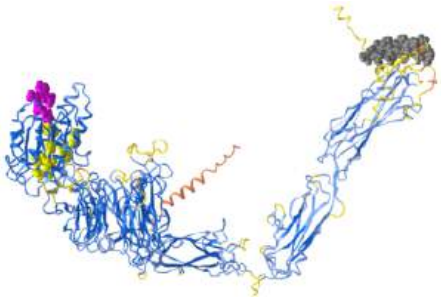

Figure 28.10.4: Predicted structure of human integrin alpha-1 (AlphaFold, P56199) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...9r15PAYYbNbit8

The color coding is gray spacefill for the C-terminal transmembrane helix, yellow spacefill for the inhibitor binding pocket and magenta for the collagen-binding site

28.10.4: Integrin β subunit family

In humans, integrin β subunits have a cytoplasmic tail that has <75 amino acids in length, except the β_4 tail which is about 1000 amino acids long (includes four fibronectin type III repeats). The integrin β tails have one or two NPxY/F motifs (x refers to any amino acid) that recognize protein modules, phosphotyrosine-binding domains, that are involved in several signaling and cytoskeletal proteins at the cytoplasmic face of the plasma membrane through phosphorylation of the tyrosine (Y) in the NPxY/F motif. The integrin β subunit family includes $\beta_{1–7}$, which bind the α subunits in different combinations. The most frequently seen β subunit integrin heterodimers are β_1.

Although β_2 integrins show functional overlap, the corresponding α subunit defines its individual functional properties. The β_2/CD18 chain has also received attention because of its involvement in several inflammatory receptors such as $\alpha_L\beta_2$, lymphocyte function-associated antigen-1 (LFA-1), and the $\alpha_M\beta_2$, Mac-1, complement receptor 3 (CR3). In these β_2 integrins, the α subunits bind specific ligands such as the intercellular adhesion molecules (ICAMs). The non-I-domain α subunits in other integrins, such as the laminin-binding α_3, α_6, and α_7, and others that recognize the arginine (R), glycine (G), aspartic acid (D) (RGD) motif (α_V, α_8, α_5, and α_{IIb}), are also closely related to each other.

- The α subunit of each integrin is the primary determinant of its extracellular ligand specificity.
- The β chain binds acidic residues in ICAMs and cytoplasmic adapters such as paxillin, talins, and kindlins to facilitate cellular adhesions with the ECM. Integrins interact with the actin cytoskeleton through the talin- and kindlin-binding motifs present in the cytoplasmic domains of their β subunits.

28.10.5: Characteristics of specific integrin heterodimers

Integrin αβ heterodimers are divided into four classes (leukocyte, collagen-binding, Arg-Gly-Asp (RGD)-binding, and laminin-binding integrins (as shown in Figure 28.10.1, based on evolutionary associations, ligand specificity, and restricted expression on white blood cells (β_2 and β_7 integrins).

- *Leucocyte integrins* have a common β_2 chain that is linked to CD-18 and binds receptors such as ICAM and plasma proteins such as complement components C3b and C4b.
- *Collagen-binding integrins* have a common β_1 chain that binds various α chains in integrins $\alpha_1\beta_1$, $\alpha_2\beta_1$, $\alpha_{10}\beta_1$, and $\alpha_{11}\beta_1$. The $\alpha_2\beta_1$ integrin binds its primary ligand, collagen, and chondroadherin, a matrix protein.
- The *RGD-binding integrins* have a common α_V chain or β_1 chain. The RGD peptide motif was first discovered in fibronectin but was later found in several other ECM proteins, such as fibronectin, osteopontin, vitronectin, von Willebrand factor (VWF), and laminin.

Among the 24 human integrin subtypes known to date, eight integrin dimers recognize the tripeptide RGD motif within ECM proteins, namely: $\alpha_V\beta_1$, $\alpha_V\beta_3$, $\alpha_V\beta_5$, $\alpha_V\beta_6$, $\alpha_V\beta_8$, $\alpha_5\beta_1$, $\alpha_8\beta_1$, and $\alpha_{IIb}\beta_3$. Laminin-binding integrins ($\alpha_3\beta_1$, $\boldsymbol{\alpha_6\beta_1}$, $\alpha_7\beta_1$, and $\alpha_6\beta_4$) mediate the adhesion of cells to basement membranes in various tissues. The $\alpha_4\beta_1$, $\alpha_9\beta_1$, and $\alpha_4\beta_7$ integrin family binds fibronectin in an RGD-independent manner.

Figure 28.10.5shows an interactive iCn3D model of the structure of **$\alpha_6\beta_1$** integrin in complex with laminin-511 (7CEC)

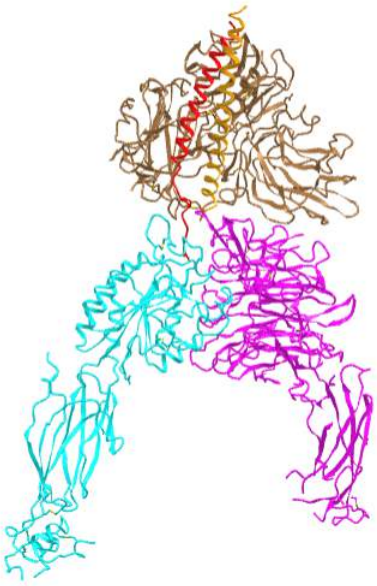

Figure 28.10.5: Structure of $\alpha_6\beta_1$ integrin in complex with laminin-511 (7CEC) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...CxCTt6caaWrPd6

The cyan chain is integrin α_6 and the magenta chain is integrin β_1. The laminin chains are α (brown), β (orange), and γ (red). Note that each of the laminin subunits interacts with the $\alpha_6\beta_1$ integrin. Two carboxylates on the C-terminal region of the laminin γ chain interact with the metal ion-dependent binding sites on the integrin beta subunit and an Asp 189 in the alpha subunit.

28.10.6: Integrin–ligand binding and consequent activation

The structure and function of integrins are complex. Integrins bind numerous extracellular ligands, intracellular signaling molecules, and the cytoskeleton in a bivalent-cation-dependent manner with varying specificities. Integrins also have many states with multiple conformations and affinities.

28.10.6.1: Mechanism of integrin-ligand binding and conformational states

Integrins bind cell-surface ligands to promote cellular interactions with the ECM and with other cells in the transduction of complex signals that modulate many cellular processes, such as adhesion, migration, and differentiation. These soluble, ECM, or cell surface-bound ligands may include growth factors, structural constituents of the ECM, proteases, cytokines, plasma proteins, microbial pathogens, or receptors specific to immune cells. The affinity and avidity of a ligand may change actively by inside-out signaling in specific pathways. Ligand affinity may vary with the strength of interaction and dissociation of a monovalent protein and its ligand, where ligand avidity refers to its ability to form multiple combinations of bonds.

Integrins exist primarily in three conformational states: bent–closed (inactive; the predominant state), extended–closed (active; low affinity or intermediate state), and extended–open (active; high affinity). The affinity of integrins to various inhibitory and stimulatory ligands is modulated by bivalent cations, which induce a range of conformational changes in integrins ranging from a folded, inactive, and low-affinity state to a high-affinity conformation as shown in Figure 28.10.2 These conformational changes in the extracellular domains of integrins modulate both ligand binding and downstream cellular signaling.

28.10.6.2: Integrin activation

The activation of integrins increases the affinity of these molecules to extracellular ligands. Integrin tail domains play a critical role in these steps, and any genetic mutations in these parts of integrins can disrupt downstream intracellular signaling. Integrin-mediated signaling across cell membranes is typically bi-directional and termed “outside-in” and “inside-out” signaling. When integrins interact with ECM ligands, a conformational change allows adherence to downstream adaptor molecules in the cell-membrane plane. Once clustered, integrins can recruit and activate kinases such as Src family kinases, focal adhesion, and scaffold molecules such as the adaptor protein p130CRK-associated substrate/breast cancer anti-estrogen resistance 1 (p130CAS/BCAR1). These integrin-associated complexes include discrete active and inactive integrin organizations, which can activate unique signaling pathways.

The extracellular domains of integrins are known to undergo a diverse range of conformational changes that alter the ligand-binding domains. In the cytoplasmic tails of integrins, α-helices are seen as heterodimers, and the β-strands often bind intracellular proteins, such as talin or filamin. The cytoplasmic tail may undergo several specific conformational changes to bind a range of other signal transducers.

This section is derived from Mechanobiology. https://www.mechanobio.info/what-is-mechanosignaling/what-is-the-extracellular-matrix-and-the-basal-lamina/what-is-integrin/how-is-integrin-activated/. Creative Commons Attribution-NonCommercial 4.0 International License.

Integrin can be activated from two directions, from the inside by the regulated binding of proteins to the cytoplasmic tails, and from the outside by multivalent ligand binding. In either case, **talin** binding to the integrin β tails is an essential and the final common step. Though the two processes are conceptually separate, they are mutually cooperative i.e one can lead to the other. Some structural studies done with force application to mimic ligand/intracellular protein suggested that the combined action of these two events favors the transition from the closed, low affinity to an open, high-affinity conformation of integrin. Activation leads to bidirectional signaling crucial in a variety of anchorage-dependent events such as adhesion, cell spreading, migration, polarity, and organization of the ECM leading to physiological changes. Figure 28.10.6shows the different states of the integrin dimer in inside-out and outside-in signaling.

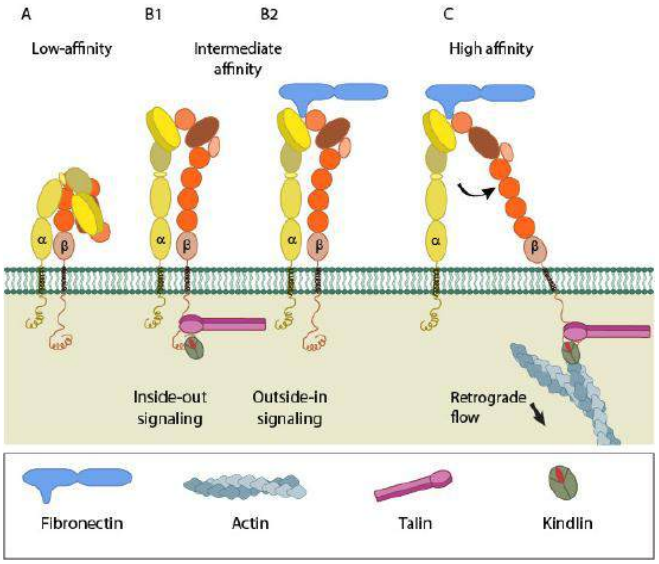

Figure 28.10.6 Integrin dimer in inside-out and outside-in signaling.

(A) shows integrin in a low affinity, inactive, bent, conformation. (B1) and (B2) show inside-out integrin activation by cytoplasmic proteins or outside-in integrin activation via extracellular matrix (ECM) ligands, both of which lead to the complete extension of the extracellular domains. (C) shows high affinity and active integrin characterized by separation of the cytoplasmic leg domains.

28.10.7: Inside-out signaling

Signals received by other receptors foster the binding of **talin** and **kindlin** to the cytoplasmic end of the **integrin β** subunit, at sites of actin polymerization. Substantial information on signaling pathway leading activation is available for integrin αIIbβ3.

Talin binds to integrin β-tail via the F3 phospho-tyrosine binding (PTB) domain, a unique interaction with the membrane-proximal (MP) region of the integrin (NPxY motif). This permits competition between a conserved lysine on talin and an aspartic acid on integrin α essential for α/β salt bridge disruption and sufficient for integrin activation. Addition interactions through the basic patches in the FERM subdomain F2 help to orient the β-subunit to promote spatial separation of the cytoplasmic domains.

Kindlin is also an essential co-activator of integrin and binds to a membrane distal NxxY motif on β-integrin via its FERM F3 subdomain. A preceding threonine patch on integrins β1 and β3 that gets phosphorylated and a tryptophan on kindlin F3 are also required for binding. However, kindlins are not known to activate integrins on their own but may render integrin-specific effects.

28.10.8: Outside-in signaling

Ligand binding to the external domain causes conformational changes that increase ligand affinity, modify protein-interaction sites in the cytoplasmic domains, and thence the resulting signals.

Besides conformational changes that extend integrin dimers, multivalent ligand binding leads to the clustering of integrins, which in turn activates the **Src family of kinases (SFKs)** by autophosphorylation. SFKs phosphorylate tyrosines of the integrin cytoplasmic domain (NPxY motifs) and other proteins leading to

1. control of ligand binding strength
2. alteration of binding with signaling molecules (kinases, GTPases, and adaptors), that constitute dynamic adhesion structures such as focal adhesions and podosomes

Nevertheless, whether clustering triggers outside-in signaling to facilitate integrin activation or occurs after integrin activation is uncertain.

David G. Menter, Raymond N. DuBois, "Prostaglandins in Cancer Cell Adhesion, Migration, and Invasion", *International Journal of Cell Biology*, vol. 2012, Article ID 723419, 21 pages, 2012. https://doi.org/10.1155/2012/723419. Creative Commons Attribution License,

Let's look at another more detailed representation of integrin states. Each αβ dimer recognizes a different intercellular adhesion molecule (ICAM), ligand, or protein substrate in the basement membrane or extracellular matrix. The α subunit dictates the ligand specificity by a seven-bladed β-propeller head domain connected to a leg support structure made of a "thigh", a "calf"-1, a "calf"-2, a transmembrane, and a cytoplasmic domain. The β subunit interacts with the cell cytoskeleton and contains an N-terminal plexin-semaphorin-integrin (PSI) domain, a hybrid domain, a βI domain, four cysteine-rich epidermal growth factor (EGF) repeats, a transmembrane, and a cytoplasmic domain.

In many cases, the N-terminal β-I domain of a β subunit inserts into the 7-bladed β-propeller domain of an α subunit (α1, α2, α10, α11, αL, αM, αX, and αD) to form a bulbous-binding headpiece complex. The formation of integrin receptor complexes depends on divalent cation (i.e., Ca^{2+}, Mn^{2+}, Mg^{2+}) that bind to metal-ion-dependent adhesion site (MIDAS) motifs in the α subunits and adjacent to MIDAS (ADMIDAS) motifs in β subunits found in the N-terminus of these receptors. Together they joined α and β subunit termini form an N-terminal **headpiece**. These detailed features of the integrin dimer structure are shown in Figure 28.10.7.

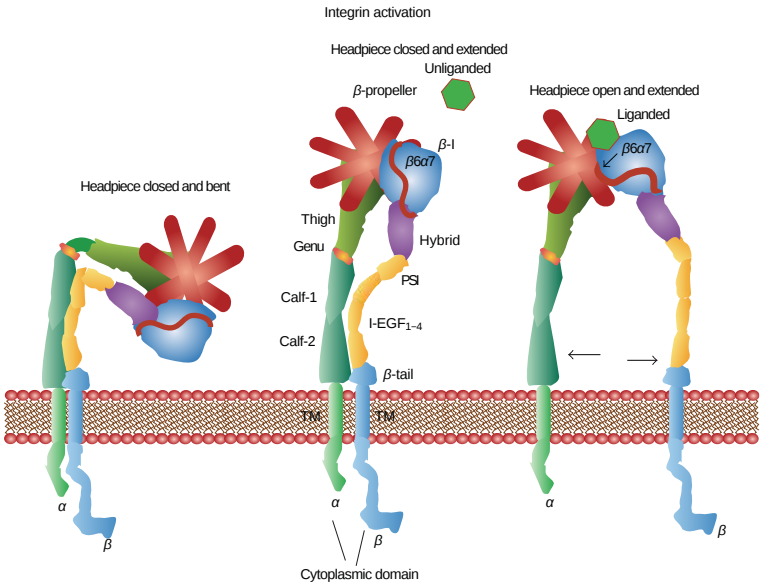

Figure 28.10.7: Detailed domain/motif structures in integrin dimers. Menter and DuBois. https://doi.org/10.1155/2012/723419. Creative Commons Attribution License,

Three conformation states exist for α and β subunit complexes. (1) The unliganded conformation has a closed headpiece and a bent receptor structure with the EGF domains of the β-subunit touching the calf-1-calf-2 domains of the α-subunit. (2) The headpiece remains closed, but structural changes in the β-subunit EGF domains cause a separation from the calf-1-calf-2 domains of the α-subunits causing an extended structure. (3) Conformational changes in the β_6-α_7 loops expose the ligand-binding site along with a

complete separation of the β-subunit from the calf-1-calf-2 domains in the α-subunit. These conformational changes engage the specific integrin headpiece with its ligand"

Figure 28.10.8 shows an interactive iCn3D model of the headpiece of integrin $\alpha_{IIb}\beta_3$ in the headpiece extended and open conformation (3FCU)

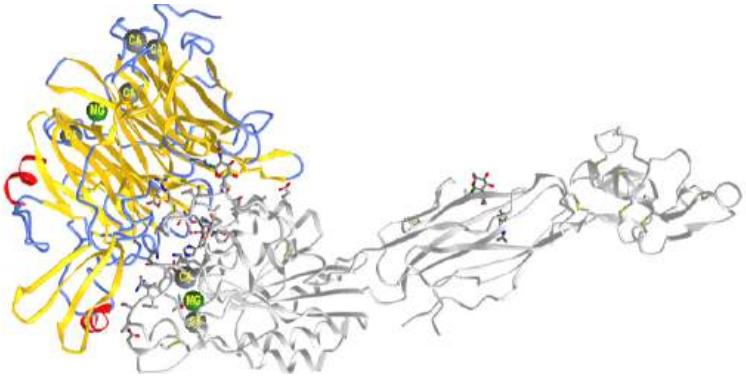

Figure 28.10.8: Headpiece of integrin $\alpha_{IIb}\beta_3$ in the headpiece extended and open conformation (3FCU) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...sG7piAXGhipg4A

The α_{IIb} part of the headpiece is shown colored based on the secondary structure with the yellow sheets comprising the beta propellor secondary structure motif. The gray chain is the β_3 chain. The side chains of the β_3 chain forming the binding interface between the α_{IIb} and β_3 chains are displayed as colored sticks. The three close metal ions (2 Ca^{2+} and 1 Mg^{2+}) are important for ligand binding with the Mg^{2+} involved in coordination to acidic side chains of integrin ligands. These metal ions are present before ligand binding. The RGD binding motif of some integrin ligands binds through their aspartate to the Mg^{2+}. Without bound Mg^{2+}, acidic side chains around the site would interfere with binding.

It appears that lateral forces are most important in activating integrins. This is in contrast to tensile forces which act along the length of the receptor. Tensile forces appear to stabilize the closed, extended low-affinity form, while lateral forces at the beta subunit, a mimic for moving cytoskeletal filaments, stabilized the open, extended, high-affinity form. This links conformational allosteric changes to cytoskeletal changes. The mechanism for activation is hence mechanochemical.

Similar to conventional cell surface signal transducing receptors, integrins bind ligands and transmit information in an “outside-in signaling” as shown in the top panel of Figure 28.10.9 “Outside-in signaling” behavior typically involves the engagement of integrins with the extracellular matrix or ICAM surface receptors. When external factors bind to exposed ligand binding sites on integrins this results in conformational changes described in the previous section. Most ECM proteins exhibit multivalent or recurrent molecular patterns, which trigger integrin clustering. As cells engage the repetitive patterns in the ECM, these events occur simultaneously thereby activating intracellular signals. The myriad of different extracellular signals that cells encounter in their microenvironment mediates cell polarity, cytoskeletal structure, adhesion, migration, invasion, gene expression, cell survival, and proliferation.

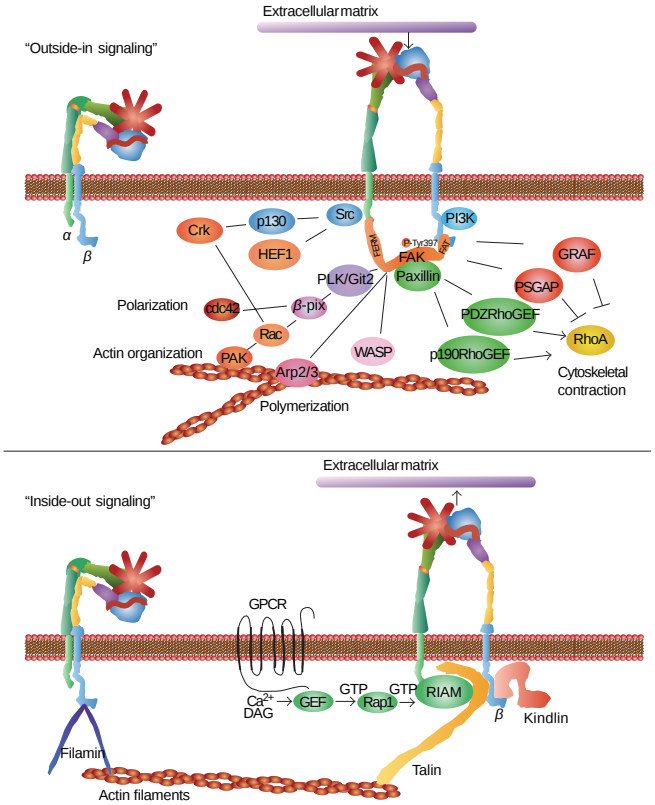

Figure 28.10.9: Detailed view of "outside-in" and "inside-out" integrin signaling. Menter and DuBois, ibid

The "outside-in" binding of ECM ligands to cell surface integrins stimulates conformational changes that activate focal adhesion kinase (FAK). FAK then is autophosphorylated on Tyrosine 397 near the catalytic domain, which binds Src. FAK contains a central kinase domain bordered by FERM (protein 4.1, ezrin, radixin, and moesin homology) domain at the N-terminus and a focal adhesion targeting (FAT) sequence at the C-terminus. Activated Src interacts with human enhancer of filamentation1 (HEF1) and p130 CRK-associated substrate (p130CAS) scaffold proteins that help to positively regulate Src-FAK-Crk interactions with Rac. FAK also activates (PKL/Git2)-β-Pix complexes and β-pix then serves either as an exchange factor for Cdc42 or a scaffold protein to promote signaling via Rac and p21-activated protein kinases (PAK). FAK also interacts with actin-related proteins (ARP2 and ARP3) which are regulated by the Wiskott-Aldrich Syndrome Protein (WASP). ARP2/ARP3 initiates the polymerization of new actin filaments. FAK also influences actin contraction and polarization through another GTPase protein, Rho. The regulation of Rho GTPase hydrolysis of GTP (active) to GDP (inactive) form occurs through the opposing activities of guanine nucleotide exchange factor (GEFs). The GTPase regulator associated with FAK (GRAF) and p190RhoGAP blocks actin cytoskeleton changes. In contrast, PDZRhoGEF and p190RhoGEF both serve to activate Rho. "Outside-in signaling" transfers integrin-mediated external signals to the inside of cells."Inside-out signaling" depends on talin and kindlin. Both talin and kindlin contain FERM (4.1/ezrin/radixin/moesin) domains and a highly conserved C-terminal F3 domains. Talins bind β integrin, actin through the C-terminus, and also vinculin. Kindlins bind integrins, the cell membrane, and various actin adaptor proteins like migfilin, or integrin-linked kinase (ILK). Talin activation occurs through G-protein-coupled receptors that increase cytoplasmic Ca^{2+} and diacylglycerol. This activates GEF function in conjunction with Ras-proximate-1/Ras-related-protein-1-(Rap1-) GTPase. Rap1 then binds to the Rap1-GTP-interacting adaptor molecule (RIAM). RIAM recruits talin to the membrane and the α and β integrin cytoplasmic domains. Kindlin interacts with β integrin cytoplasmic domain stabilizing the activated state of the integrin complex. "Inside-out signaling" strengthens adhesive contacts and the appropriate force necessary for integrin-mediated cell migration, invasion, ECM remodeling, and matrix assembly.

In the case of "outside-in signaling" initiated by ECM proteins, a single ligand-binding event can trigger integrin activation, but repetitive regularly spaced molecular patterns provide a more effective stimulus [122, 123]. This type of mechanoreception has been explored using nanopatterned molecular printing techniques that form regular cRGDfK patch spacings on a polyethylene glycol background matrix [122–125]. These adhesion-dependent sensory mechanisms lead to signal transduction inside the cell by

the activation of multiple pathways. Focal adhesions are often formed as a result of cell interactions with the ECM substrata, which initiate signal transduction via kinase cascades and other mechanisms.

28.10.9: Integrins in inflammation and infection

In the resting state, β_2 integrins are expressed specifically on leucocyte receptors. During inflammation, the inflammatory cytokines activate these integrins and promote cellular adherence to the counter-receptors such as **ICAMs** and promote phagocytosis and cytotoxic killing. Integrin receptors on leukocytes, such as the macrophage-1 antigen (Mac-1, also known as CR3, $\alpha_M\beta_2$, CD11b/CD18) interact with platelet antigens such as the glycoprotein Ibα (GPIbα) during inflammation. Integrins bind to the pro-domain of transforming growth factor (TGF)-β_1 to activate it and promote its secretion. The pro-TGF-βs are biosynthesized and stored in tissues in latent forms, and integrins $\alpha_V\beta_6$ and $\alpha_V\beta_8$ can uniquely bind and activate pro-TGF-β_1 and pro-TGF-β_3. The $\alpha_V\beta_6$ integrin is known to specifically bind the RGDLXXL/I motif in TGF-β_1 and TGF-β_3.

β_2 integrins promote the recruitment of leukocytes to the sites of inflammation by promoting the adhesion of circulating leukocytes to vascular endothelium, transendothelial migration, the formation of immunological synapses in leucocytes, and inflammatory signaling in involved cells. β integrins on the leukocyte surface are also involved in the tethering, rolling, and adhesion of leukocytes to activated endothelial cells. β_2 integrins can also initiate intracellular signaling pathways in macrophages and neutrophils and stimulate cytokine secretion from these cells either directly or in synergy with Toll-like receptors (TLRs). Integrins may also integrate the impact of the epidermal growth factor receptor, platelet-derived growth factor receptor, insulin receptor, met receptor superfamily (hepatocyte growth factor receptor), and the vascular endothelial growth factor receptor (VEGFR) in inflammatory cells.

β_2 integrins are important regulators of adhesion, leukocyte recruitment, and immunological signaling. These integrins mediate adhesive interactions between myeloid cells, endothelial cells, antigen-presenting cells, T cells, and the ECM. **L-selectin**, the CCR7 chemokine receptor, interacts with specific carbohydrate epitopes on the endothelium and promotes leukocyte rolling and transmigration through the vascular endothelium. Leukocyte rolling induces a rapid, although a transient, increase in the affinity of the β1 and β2 integrins to the endothelial ligands. Conformational changes in the structure of the inserted (I) domain of the α_L subunit of LFA-1 enhance firm leukocyte adhesion under shear flow.

28.11: Signaling by Steroid Hormones

28.11.1: Introduction

We will now consider signaling by steroid hormones. These hormones are derivatives of cholesterol, which is found in membrane bilayers and lipoproteins. They are mostly nonpolar. Steroid hormones can affect signaling in two major ways:

- through binding to membrane receptors, which when occupied affect signaling through the myriad of ways we discussed throughout this chapter. These effects would be rapid.
- through binding to cytoplasmic receptors after they diffuse into the cell through passive and active means. This signaling is hence similar to retrograde signaling by nitric oxide, which can passively diffuse out of a cell and enter an adjacent cell to effect signaling in that cell. If the steroid primary messenger is in the cell, it most often can enter the nucleus and regulate gene transcription. Binding to cytoplasmic receptors account for most of the biological effects of steroid hormones. Since transcription is involved, the pathways elicit a slower response.

We will briefly discuss the first type of signaling (binding to membrane receptors) mostly by presenting figures which describe their signaling pathways. Then, we will focus on steroid hormone activation of gene transcription.

There are many classes of steroid hormones. These are illustrated in Figure 28.11.1along with their overall synthetic pathway.

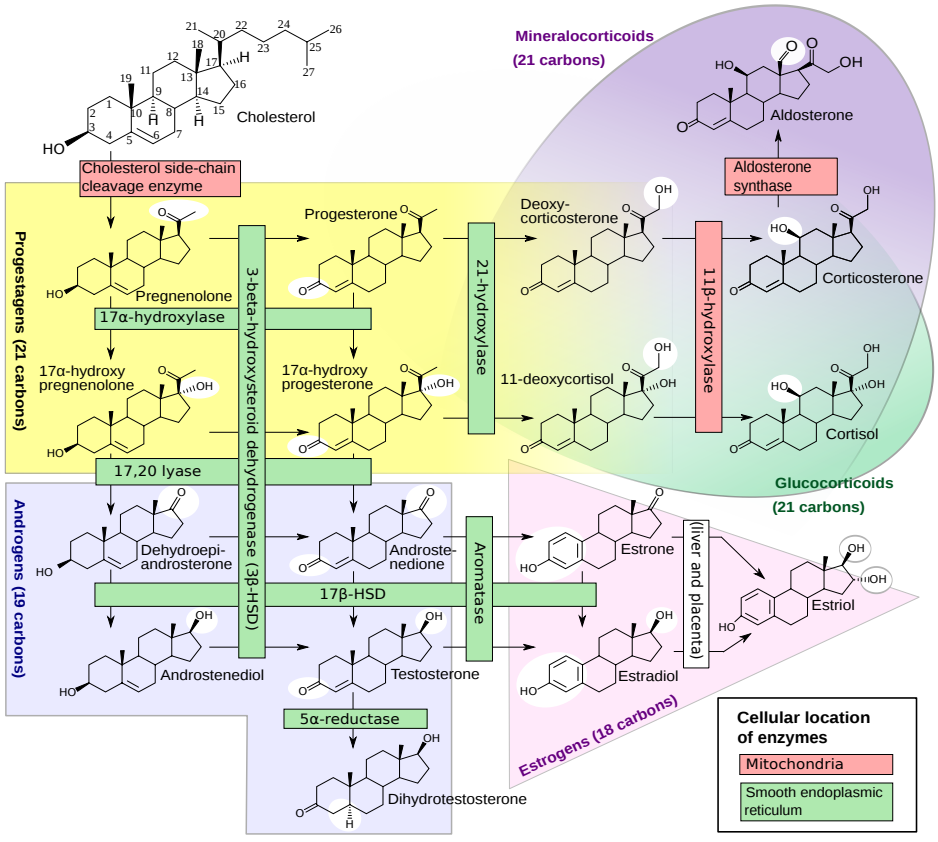

Figure 28.11.1: Diagram of the pathways of human steroidogenesis. *WikiJournal of Medicine* **1** (1). DOI:10.15347/wjm/2014.005. ISSN 20018762.

The overall families include progestogens and estrogens (female sex hormones), androgens (male sex hormones), glucocorticoids (like cortisol which affects immune and metabolic systems), and mineral corticoids (which affect salt/water balance).

We will mostly use the estrogens in the section as a prototypical example because of their involvement in breast cancer and epidermal growth factor receptors.

28.11.2: Steroid hormone signaling through binding to membrane receptors

Most of this subsection is taken from and adapted from the following source: *Masi et al. Cells* **2021**, *10*(11), 2999; **https://doi.org/10.3390/cells10112999.** Creative Commons Attribution (CC BY) license (**https://creativecommons.org/licenses/by/4.0/**).

Most people think of steroid signaling, it is through their nuclear effects on gene transcription (the predominant signaling effect). Signaling at the cell membrane is an emerging area of interest. We will present steroid signaling at the cell nucleus in four figures with their associated captions. We present these lesser-known effects of steroid signaling first since they utilize many of the pathways we have already studied. The figures will also give you a short review of some canonical pathways, which is always good in a field so complicated as signal transduction. The figures focus on the signaling effects in cancer.

Figure 28.11.2shows membrane signaling through androgen receptors.

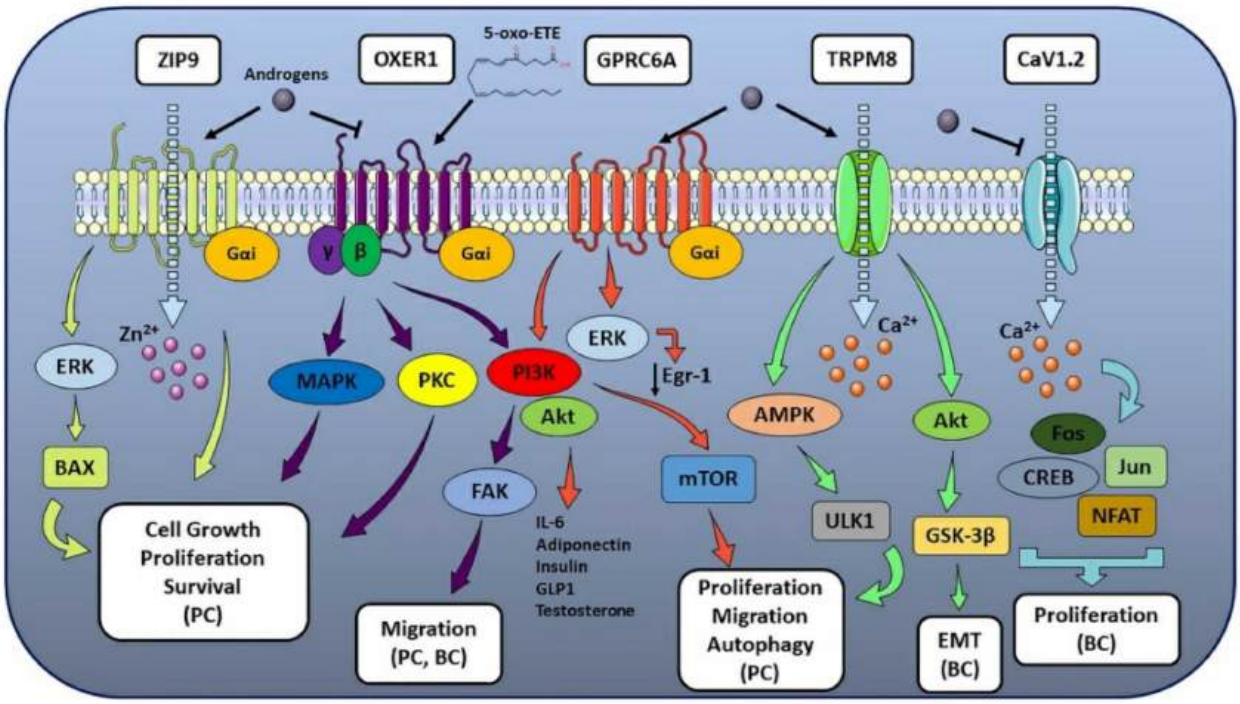

Figure 28.11.2: Membrane androgen receptor-associated pathways and their effect on hormone-sensitive cancer progression (breast cancer as BC, prostate cancer as PC). Receptors are ZIP9 (Zinc transporter), OXER1 (Oxoeicosanoid receptor 1), TRPM8 (Transient receptor potential cation channel subfamily M member 8), CAV1.3 (Voltage-dependent L-type calcium channel subunit alpha-1C). *Masi et al. ibid*

Figure 28.11.3shows membrane signaling through estrogen receptors

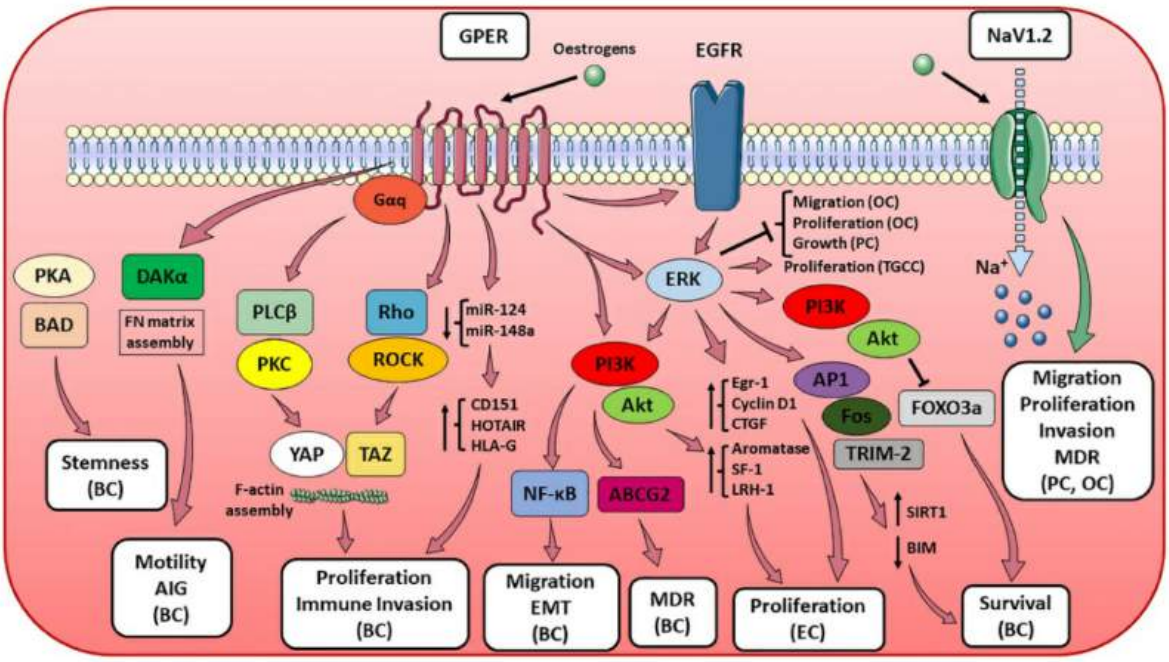

Figure 28.11.3: membrane estrogen receptor-associated pathways and their effect on hormone-sensitive cancer progression (breast cancer as BC, prostate cancer as PC, endometrial cancer as EC, ovarian cancer as OC and testicular germ cell cancer as TGCC). Other abbreviations: multi-drug resistance (MDR), anchorage-independent growth (AIG). Receptors are GPER (G-protein coupled estrogen receptor), NaV1.2 (Sodium channel protein type 2 subunit alpha). Masi et al. Ibid

A tamoxifen (a selective estrogen receptor modulator used in breast cancer therapy) binding site has been found in NavMs voltage-gated sodium channels.

Figure 28.11.4show membrane signaling through membrane progesterone receptors

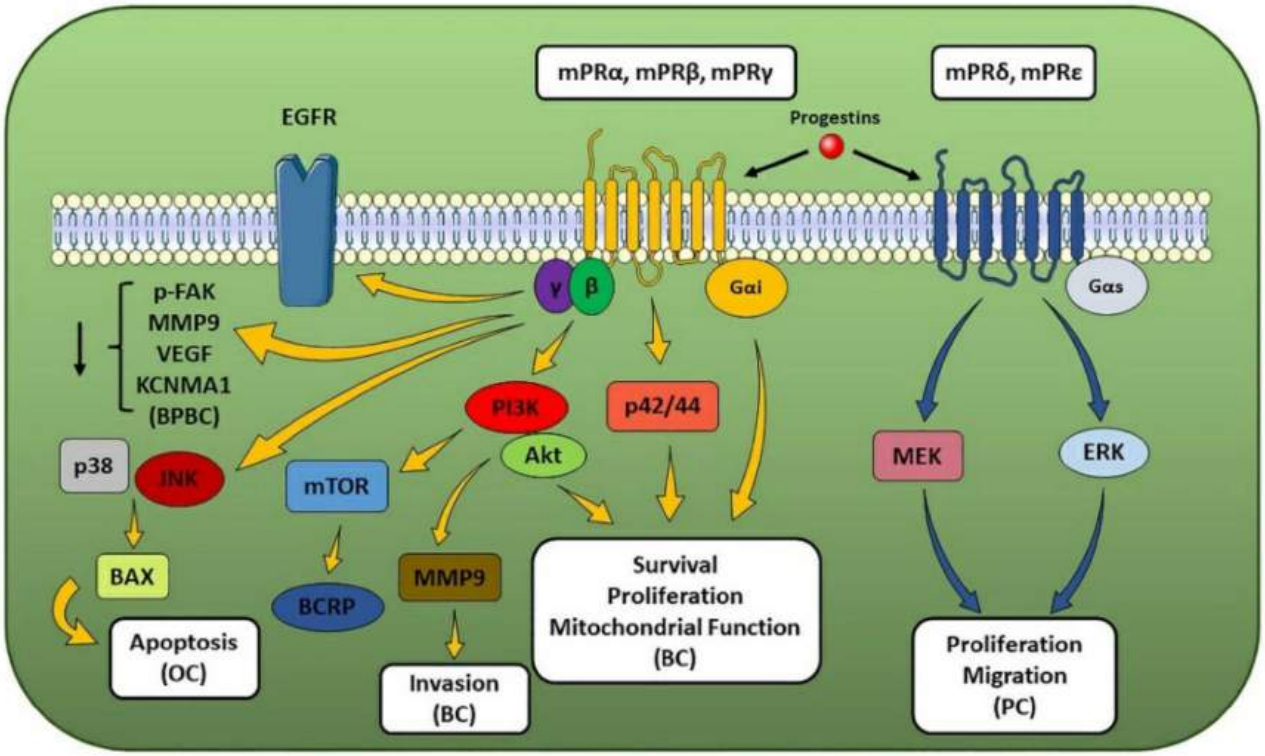

Figure 28.11.4: Membrane progesterone receptor-associated pathways and their effect on hormone-sensitive cancer progression (breast cancer as BC, prostate cancer as PC, ovarian cancer as OC, and basal phenotype breast cancer as BPBC). Receptors are mPR (Membrane progestin receptor). Masi et al. ibid

Figure 28.11.5shows membrane-associated progesterone receptor effects from progesterone signaling.

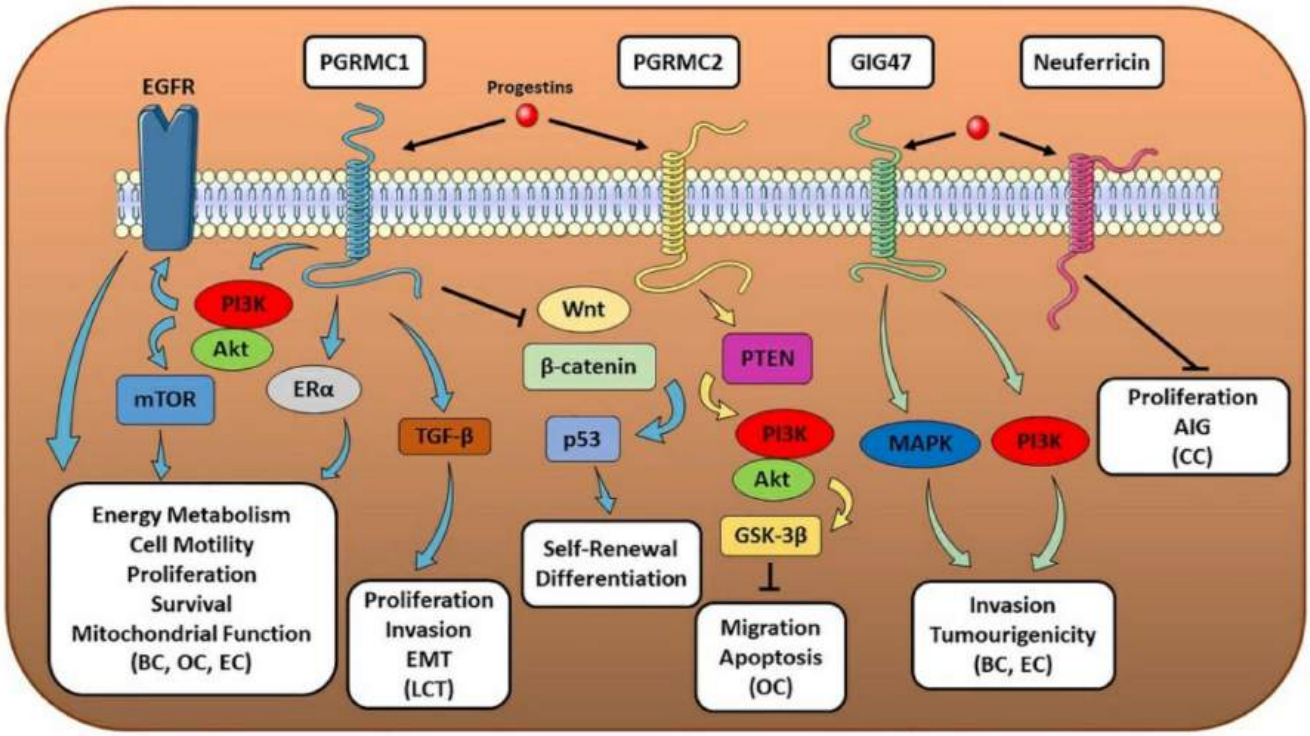

Figure 28.11.5: MAPK-associated pathways breast cancer as BC, endometrial cancer as EC, ovarian cancer as OC, Leydig cell tumor as LCT, and cervical cancer as CC). Other abbreviations: anchorage-independent growth (AIG). Receptors are PGRMV (Membrane-associated progesterone receptor component 1), GIG47 (Neudesin). Masi et al. ibid.

28.11.3: Steroid hormone signaling through binding to cytoplasmic receptors and activation of gene transcription

Now we will explore the major effects of steroid hormones on signaling, in which steroids enter the cell, bind to cytoplasmic receptors, and then translocate into the nucleus where they regulate gene expression. The naming of steroid receptors can be confusing since it is important to differentiate steroid receptors that are resident in the cell membrane and those that move to the nucleus. An added complexity arises from the factor that some nuclear receptors can be covalently modified with a fatty acid (palmitoylated) and targeted to the cell membrane. Estrogen receptors targeted to the membrane can then act independently of their nuclear transcriptional activity.

We will primarily focus on estrogen effects in breast cancer (most diagnosed cancer) that are mediated through the nuclear steroid receptors, which belong to the nuclear receptor superfamily. Tamoxifen, a commonly used drug in the treatment of breast cancer is an estrogen receptor antagonist (also called an estrogen receptor modulator—SERM).

28.11.4: Molecular Function of Steroid Receptors—Common Features

Steroid receptors (SR) consist of four main domains, the C-terminal ligand-binding domain (LBD), the DNA-binding domain (DBD), the hinge region, and amino-terminal domain (NTD). Each SR contains also two motifs called activation function 1 and 2 (AF1 and AF2) within NTD and LBD, respectively, and are crucial for the regulation of gene transcription. Two zinc fingers are located in the DBD. Figure 28.11.6

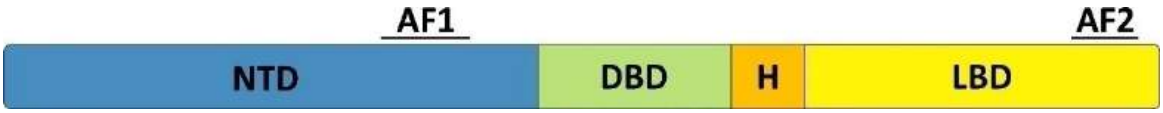

Figure 28.11.6: Schematic illustration of steroid receptor structure. NTD—amino-terminal domain, DBD—DNA-binding domain, H—hinge region, LBD—ligand-binding domain, AF1—activation function 1, AF2—activation function 2. The diagram does not show the exact length proportion of the domains because it differs between distinct SRs. Kowalczyk, W.; Waliszczak, G.; Jach, R.; Dulińska-Litewka, J. Steroid Receptors in Breast Cancer: Understanding of Molecular Function as a Basis for Effective Therapy Development. *Cancers* **2021**, *13*, 4779. https://doi.org/10.3390/cancers13194779. Creative Commons Attribution (CC BY) license (**https://creativecommons.org/licenses/by/4.0/**).

The domains are often labeled A-F. The N-terminal domain (NTD) is also called the A/B domain. It can also bind DNA and can weakly activate transcription in the absence of hormones. The C domain is the DNA binding domain (DBD) containing Zn fingers, which bind to the steroid response element in promoters of key genes. The D domain is the hinge domain, and The E domain binds hormones (like estrogen) and protein regulators and when bound can activate gene transcription. The last domain (F) varies in length and its function is not completely clear.

The specific DNA structure for the estrogen receptor from Pfam is shown in Figure 28.11.7

Figure 28.11.7: Estrogen receptor domain structure.

The green is the N-terminal Oest_recep domain (NTD, A/B). The red zf-C4 is the DNA binding domain which has two Zn fingers that bind DNA (DBD, C). The blue Hormone_Receptor is the ligand (estrogen) binding domain (LBD, domain E). The yellow is the C-terminal domain (F).

These two genes for the estrogen receptor encoding ERα and ERβ. The transcriptionally active form is a dimer that forms on the binding of estrogens. The dimer then translocates to the nucleus and activates transcription at ERE sites. The ERα dimer promotes estrogen-dependent growth while the ERβ dimer inhibits it. Heterodimers can form which seem to reduce the proliferative effects of ERα. Both ERα and ERβ can be expressed in

Figure 28.11.8shows an interactive iCn3D model of the human estrogen receptor computational model (P03372, AlphaFold)

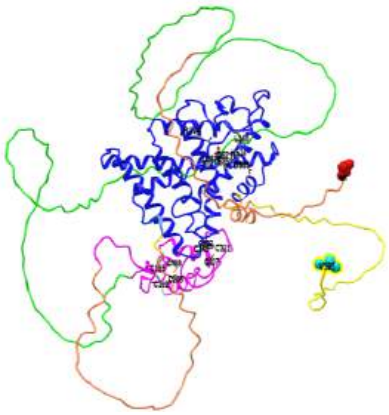

Figure 28.11.8: Full human estrogen receptor computational model (P03372, AlphaFold) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...XAk1jUHred87c9

- red spacefill: N-terminal Met
- green backbone trace: N-terminal domain disordered, which can bind DNA
- magenta backbone trace: DNA binding domain with Zn fingers. The Cys side chains of the Zn fingers are shown in sticks, CPK colors, and labeled.
- blue: Hormone_Receptor is the ligand (estrogen) binding domain (LBD, domain E)
- yellow: C-terminal tail (domain)
- Cyan spacefill: C terminal Val

There are no full-length crystal structures of ER dimer. Most available structures are for the estrogen-binding domain. It's really useful to see the full predicted structure to see how all the domains are connected, but perhaps more interestingly, the extended regions of disordered structures, which you should imagine adopting specific structures on interaction with key signaling partners.

Figure 28.11.9 shows an interactive iCn3D model of the ligand binding domain of human estrogen receptor ERα bound to the antagonist tamoxifen (3ERT).

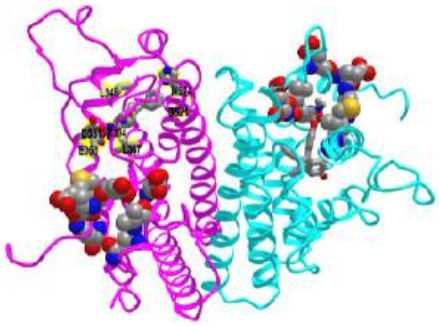

Figure 28.11.9: Ligand binding domain of human estrogen receptor ERα bound to the antagonist tamoxifen (3ERT) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?hhKXF19sVHS5RPys9

The ligand binding domains (one for each of the ERα monomers) are shown in magenta and cyan. The antagonist Tamoxifen, one bound in each of the ligand binding domains, is shown in sticks, CPK color. The amino acids comprising the binding site for tamoxifen, are shown in stick, and CPK colors and labeled in the magenta subunit. The CPK-colored spheres show the binding site on the ligand binding domain for other binding proteins called **corepressors** or **coactivators** (not shown, discussed below).

Figure 28.11.10 shows the structures of estrogens and selective estrogen receptor modulators (SERMs).

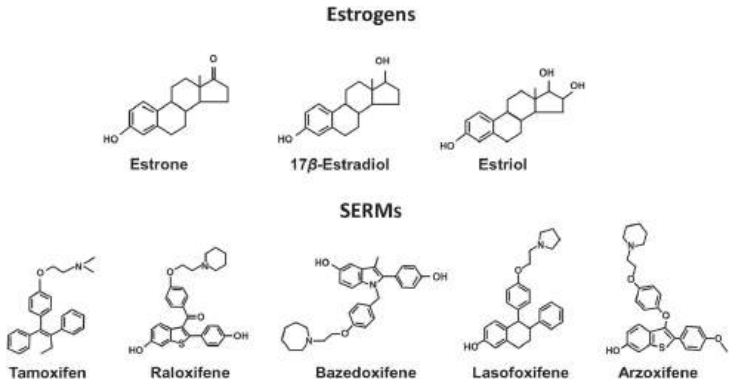

Figure 28.11.10: Structures of estrogens and selective estrogen receptor modulators (SERMs). Smith et al. Breast Cancer Research. 2014, 16:212. http://breast-cancer-research.com/content/16/3/212. CC BY 2.0

The iCn3D model for the human estrogen receptor ERα bound to the antagonist tamoxifen (3ERT) showed binding sites for other proteins called coactivators or corepressors. The ER-estrogen complex, after binding to DNA, can also bind a protein **coactivator**, which activates transcription. Likewise binding of a **corepressor** to the DNA-bound complex inhibits transcriptional activity. Tamoxifen binding to the ERα monomer leads to dimerization and DNA binding. The DNA-bound dimer can then bind either a corepressor (the usual case for tamoxifen binding to ER in the breast), leading to inhibition of DNA transcription (i.e. tamoxifen antagonizes ER transcriptional function), or a coactivator which stimulates gene transcription.

A cartoon diagram illustrating the role of ER coactivators and corepressors is shown in Figure 28.11.11.

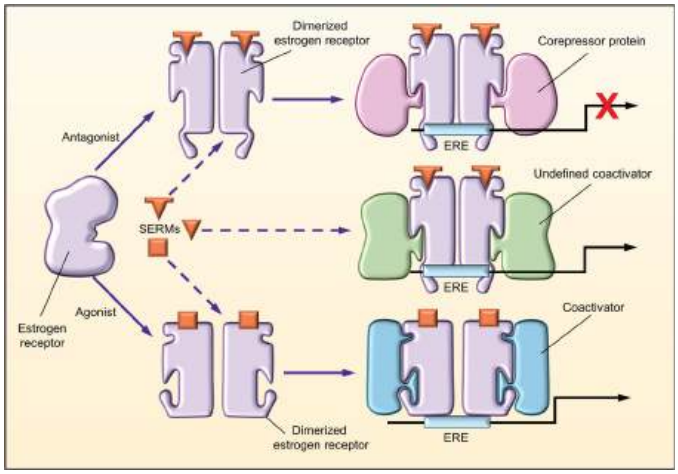

Figure 28.11.11: Molecular activity of selective estrogen receptor modulators (SERMs) at estrogen receptors. Smith et al. ibid

When a SERM binds to the estrogen receptor, the receptor adopts a unique conformation that allows dimerization and interaction with estrogen response elements (EREs) of the target genes. The unique conformational change induced by the binding of the SERM may result in a distinct pattern of cofactor recruitment.

Before steroid binding, most steroid receptors are found in the cytoplasm bound to heat shock proteins like Hsp90. Phosphorylation of the Hsp:SR complex leads to dissociation of the Hsp, followed by dimerization and translocation into the nucleus. In some cases, hormone binding occurs in the nucleus.

Figure 28.11.12shows an interactive iCn3D model of the estrogen receptor DNA-binding domain bound to DNA (1HCQ).

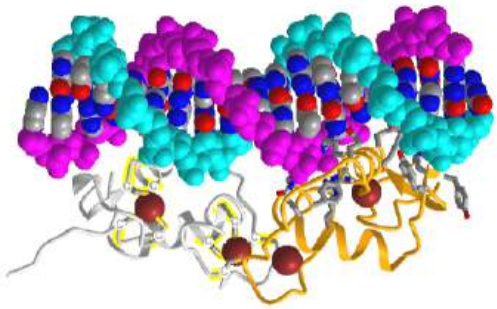

Figure 28.11.12: Estrogen receptor DNA-binding domain bound to DNA (1HCQ) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...rUUhnx8J8ezh8A

The backbones of the dsDNA are shown in spacefill cyan and magenta. The DNA bases are shown in CPK colors. The two chains of the DNA binding domain of the estrogen receptor are shown in gray and gold. Zn^{2+} ions are shown as brown spheres. The coordinating Cys side chains in the gray DNA binding domain are shown in sticks, CPK colors, and labeled "C". The amino acid side chains from the gold DNA binding domain that interact with DNA are shown in sticks CPK colors.

There are two types of ways that steroid hormones activate gene transcription, a direct and an indirect method

Direct (classical): The DNA binding domain (containing the Zn fingers binds) of the dimer bind to the target hormone response element (HRE) or for steroids the steroid response element (SRE) sequences in the promoter site of specific genes under steroid hormone control. As seen in the iCn3D above, one of the two Zn fingers on each of the hormone receptors binds to the target site in the major groove of DNA. The other Zn fingers are involved in the dimerization of the hormone receptor. The SRE contains two 6-base pair repeats separated by 3 base pairs. The DNA sequence shown in the iCn3D above is CCAPGGTCA. The general consensus sequence for steroid hormones is 5′-GGTACAnnnTGTTCT-3′. The ER binds to 5′-GGTCAnnnTGACC-3′. Note that the complementary strand sequence is 5'-GGTCAnnTGACC so the sequence is a palindrome (the complementary strand has the same sequence going in the opposite direction. After binding the hormone:receptor dimer to DNA, coregulators bind. These modify histones and remodel the DNA to facilitate or inhibit transcription.

Indirect: In this method, the steroid receptors bridge other DNA-bound transcription factors without the steroid hormone binding to its response element.

The direct and indirect methods for steroid hormone effects on transcription are shown in Figure 28.11.13

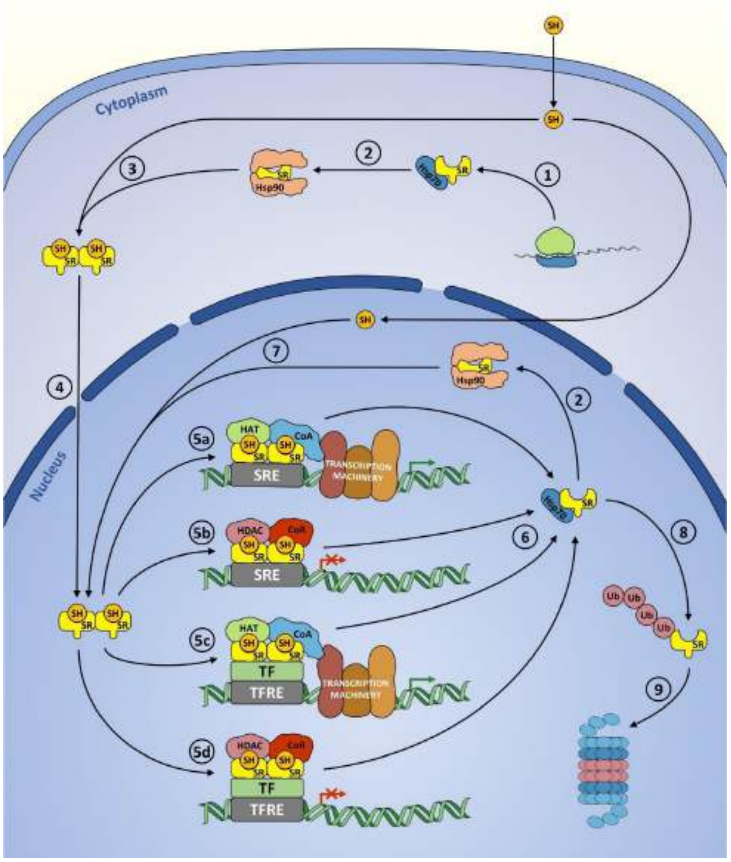

Figure 28.11.13: SR synthesis, genomic signaling, and degradation.

(1) Translation of a SR and binding of Hsp70. (2) Hsp70 to Hsp90 transition. (3) Ligand binding, Hsp90 dissociation, and dimerization. (4) Nuclear translocation. (5) Transcriptional action: induction (5a, 5c) or inhibition (5b, 5d) of target gene expression, performed either in the classical mechanism involving SRE-binding (5a, 5b) or by tethering other TFs (5c, 5d). (6) Ligand dissociation followed by disassembly of the transcriptional complex and SR binding to a molecular chaperone. (7) Rebinding of the ligand. (8) Ubiquitination. (9) Proteasomal degradation. SR—steroid receptor, SH—steroid hormone, Hsp 70—heat shock protein 70, Hsp90—heat shock protein 90, SRE—steroid response element, CoA—coactivators, CoR—corepressors, HAT—histone acetyltransferase, HDAC—histone deacetylase, TF—transcription factor, TFRE—transcription factor response element, Ub—ubiquitin. Although histone acetyltransferases (HATs) and histone deacetylases (HDACs) are classified as coregulators, here they are shown separately to emphasize their role. Illustration created using elements from Servier Medical Art **https://smart.servier.com/**, reproduced under Creative Commons Attribution 3.0 Unported License **https://creativecommons.org/licenses/by/3.0/**.

Hormone dissociation leads to steroid hormone dissociation from DNA by chaperone proteins. The Hsp90-SR complex can reenter the cycle. The steroid hormone receptor can be targeted by proteolysis by the proteasome by ubiquitination in either the nucleus or the cytoplasm.

28.11.5: Modulation of ER function by phosphorylation

No pathways stand in isolation, so it should be no surprise the estrogen receptor (again used as an example) is regulated by post-translational modification, especially by phosphorylation. Phosphorylation can be ligand dependent or independent. Multiple kinases are involved in the phosphorylation of the N-terminal region. An especially important one occurs at Ser 118 at a cyclin-dependent kinase (involved in cell cycling) when the receptor is bound to estradiol. Ser 118 also gets phosphorylation through epidermal growth factor signaling by MAPK. This may increase cell proliferation in breast cancers even in the absence of estrogen. Figure 28.11.14shows the activation of ER by phosphorylation through growth factor and cytokine signaling pathways.

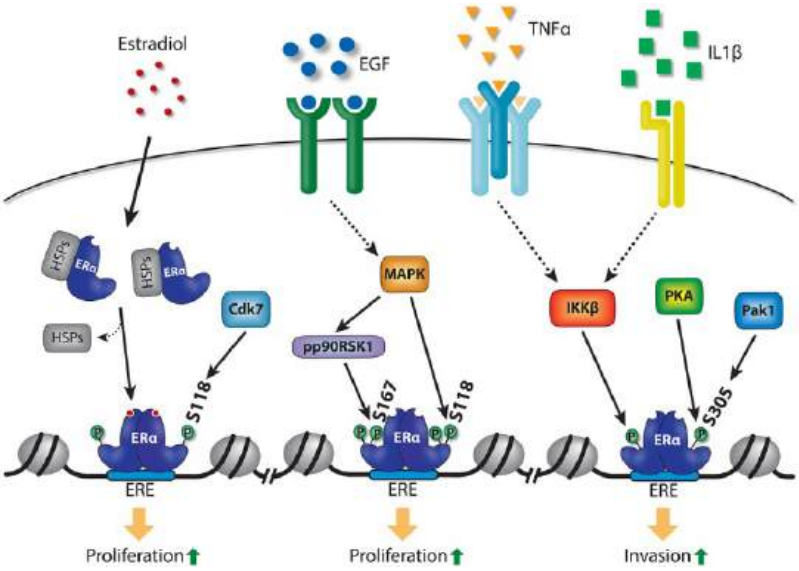

Figure 28.11.14: Activation of ER by phosphorylation induced by growth factor and cytokine signaling pathways. Siersbæk et al ,Genes Dev. 2018 Sep 1; 32(17-18): 1141–1154. doi:10.1101/gad.316646.118. 28.12: mTOR and Nutrient Signaling

28.12.1: Introduction: mTOR and AMPK

Imagine when you were in high school, you weighed 135 pounds (61 kg). Let's say it's 50 years later and you still weighed 135 pounds. In the intervening years, think of how much food and liquid you consumed. In 2011, the USA Food and Drug Administration indicated that the average American consumed about 2000 pounds (907 kg) each year, including liquids other than drinking water. (Compare this to 365 kg for someone in Somalia!) So over 50 years you would have consumed 100,000 lbs (45,400 kg) of food or 740 times your body weight. These numbers are essentially unchanged even if you gained one pound a year for a total of 50 pounds.

These figures suggest that we have an elaborate system that regulates how much we eat and how much weight we gain or lose. There are obvious times in our lives when we are growing and actively gaining body mass. Incoming food is not only processed into energy but also into net protein, lipid, carbohydrate, and nucleic acid synthesis. This system has become dysregulated in an ever-increasing number of people with type II diabetes and obesity throughout the world. Obvious candidates for regulators in general of net body weight and in specific of protein and lipid synthesis are the nutrients we consume and store. Many systemic hormones and neurotransmitters are involved in hunger, satiety, and eating behavior. This chapter will not focus on those but rather on mechanisms of nutrient signaling pathways in growth which requires new protein, lipid, and nucleic acid synthesis for cell growth and division. Likewise, it will not focus on nutrient signaling through hexosamines and UDP-GlcNAc.

A key player in these signaling pathways is mTORC (mammalian or mechanistic Target Of Rapamycin Complex). A key protein in this multiprotein complex is mTOR, a Ser/Thr kinase that regulates cell growth, division, protein synthesis, RNA synthesis (transcription), and even autophagy (the major process whereby cells die and their contents are recycled for use). There are two physiologically relevant complexes of mTOR, mTORC1, and mTORC2. These two complexes have been called the master regulators of metabolic and growth processes.

- mTORC1 activates protein, lipid, and nucleotide synthesis, all required for cell growth and division; it is inhibited by rapamycin. For activation, it needs two obvious conditions: energy and growth factors. In addition, it needs amino acids.
- mTORC2 activates many processes through phosphorylation; it is not inhibited by rapamycin.

What is Rapamycin? It sounds like an antibiotic but it is an antifungal agent produced by certain bacteria as a defense against fungal (eukaryotic) pathogens. It blocks cell division in fungi by stopping cell growth. The cell cycle consists of the following general sequential steps: (Go-G1)→S →G2→M→ G1. Gap 0 (Go) is a quiescent phase outside of the cycle. In G1, cells are growing and preparing for DNA synthesis which occurs in the S phase. After DNA replication/synthesis (S phase), cells grow again and prepare for mitotic cell division (M phase). Rapamycin traps fungal cells in the G1 phase. It also traps mammalian cells, and in particular immune lymphocytes in G1 as well, preventing lymphocytes from dividing. Hence rapamycin has been used to prevent rejection of transplanted tissue as it suppresses the immune system. Rapamycin inhibits mTORC1. That it inhibits mTOR is consistent with its immunosuppressive (antigrowth and antiproliferative) effects

Another key player regulated by mTOR is the energy sensor AMP Protein Kinase (AMPK). We will discuss both below.

28.12.2: mTOR Inhibition by Rapamycin

The structure of the mTORC1 complex is complex itself, in part, since some of its components were studied and named before their roles in the mTORC1 complex were elucidated. Investigators were interested in the molecular target(s) of rapamycin. Yeast (a fungus) was an easy organism to study using genetic techniques. Three genes were found that when mutated inhibited the effect of the inhibitor rapamycin (i.e. so that rapamycin did not inhibit mTOR). Two of these were the Ser/Thr kinases mTOR1 and mTOR2. The other was an analog of a protein found in humans (FK Binding Protein 12 - FKBP12). The family of FK binding proteins act as protein chaperones and have Pro-X peptidyl-prolyl isomerase activity (PPI). FKBP12 specifically binds a drug (FK506 also called Tacrolimus) that is an immunosuppressant (do you see the general link with immune cell division and growth?). The binary complex of FK506 and FKBP12 binds a third protein, a phosphatase called calcineurin, and blocks its phosphatase activity and signal transduction required for T cell activation and proliferation. This activity of FKBP12 strangely does not require its PPI activity.

Now back to mTORC1. Here are the known components of the core complex:

- mTOR, a Ser/Thr kinase;
- Raptor, a Regulatory-associated protein of mTOR; modulates the specificity of the kinase;

- mLST8, the mammalian lethal with SEC13 protein 8 (also called Mammalian Lethal With SEC13 Protein 8 e

In addition, other proteins associate with the core complex

- PRAS40, a proline-rich Akt substrate of Akt
- DEPTOR, DEP Domain Containing MTOR-Interacting Protein (where DEP is Disheveled, Egl-10 and Pleckstrin domain found in these 3 proteins and others involved in G-protein signaling)
- FKBP, which binds rapamycin.

mTORC2 is not sensitive to rapamycin. Instead of RAPTOR, it has a protein called RICTOR (rapamycin-insensitive companion of TOR).

Figure 28.12.1 shows an interactive iCn3D model of the human mTORC1 containing mTOR, Raptor and mLST8 bound to FK506 binding protein (FKBP)-rapamycin complex (5FLC)

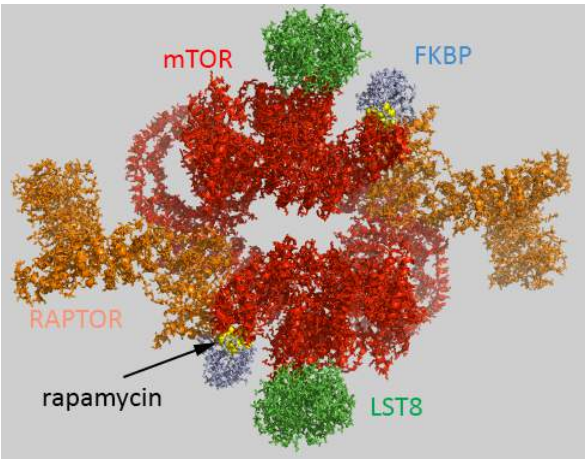

Figure 28.12.1: Human mTORC1 containing mTOR, Raptor and mLST8 bound to FK506 binding protein (FKBP)-rapamycin complex (5FLC). Click the image for a popup or use this external link https://structure.ncbi.nlm.nih.gov/i...iSuYwaymutw867

The complex acts physiologically as a dimer with rotational C2 symmetry. The static image in Figure 28.12.1 is color coded as below. The iCn3D image is similarly.

- chains B ,F ,1-4: pieces of mTOR (mol ID 1-3) as a homodimer - Red;
- chains A and E: Raptor (mol id 4) orange;
- chains D and H: LST8 (mol id 5) green;
- chains C and G: FKBP (mol id 6) light blue;
- rapamycin in C and G, yellow spacefill.

Raptor has been likened to tape as it interacts with the two mTOR subunits, holding them together into a larger, donut-like structure, and stabilizing the dimer.

How does rapamycin inhibit mTOR? You have studied many kinds of inhibitors (competitive, uncompetitive, mixed, or noncompetitive inhibition) in which the inhibitor binds to either free E or the ES complex. The figure above suggests that rapamycin binds at the interface of the mTOR kinase (red) and FKBP. Presumably the RAP:FKBP complex binds to mTOR.

Figure 28.12.2 shows how rapamycin (shown in sticks) is sandwiched between mTOR (red) and FKBP (light blue). This offers clues as to how it inhibits mTOR. The rapamycin:FKBP complex is an allosteric inhibitor with its effect dependent on both substrate and post-translational phosphorylation.

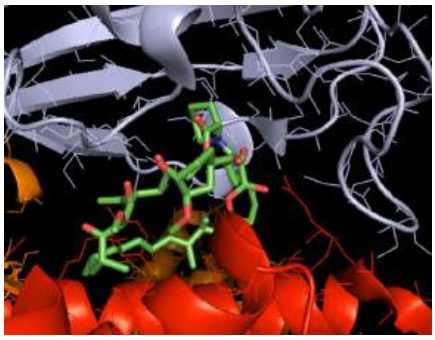

Figure 28.12.2: Rapamycin (shown in sticks) interactions with mTOR (red) and FKBP (light blue)

Right across from the light blue FKBP protein is the green LST8 protein (see above). In between these is a cleft which is the active site. One could imagine that RAP:FKBP binding to mTOR might interfere with substrate binding in mTORC1 but not in mTORC2. RAPTOR in mTORC1 probably helps recruit substrates and hence is involved in the determination of substrate specificity. RAPTOR interacts with a short section called the TOR signaling (TOS) motif in mTORC1 substrates. The part of RAPTOR that binds TOS in substrates is at the base of the mTORC1 active site, probably narrowing it further as it provides exquisite substrate selectivity.

28.12.3: mTOR Protein Kinase Structure and Activity

How does the structure of such an important kinase (mTOR) differ from other kinases? Remember that there are 388 S/T Kinases, 90 Y Kinases, and 40 atypical protein kinases in the human genome. The generic structure is shown below with ATP and substrate binding between N- and C-terminal lobes. The C lobe has a catalytic lobe which contains an Asp side chain acting as a general base in nucleophilic attack on the gamma P of ATP. A disordered activation loop in the C lobe often prevents substrate binding to the enzyme and keeps the kinase in an inactive state. On phosphorylation of the activation loop or elsewhere, or substrate binding, conformational changes lead to movement of the activation loop away from the active site, activating the kinase activity. The structure of generic kinases is shown in Figure 28.12.3

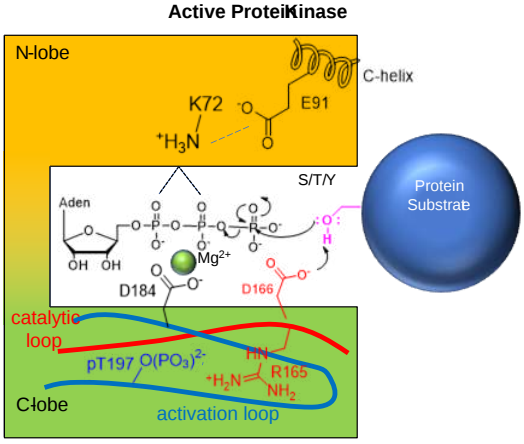

Figure 28.12.3: (Adapted from the superlative text, Cell Signaling by Lim, Mayer, and Pawson)

Compared to generic protein kinases, mTOR has several insertions (about 200 amino acids) into the protein sequence and these must be involved in the determination of its specificity toward protein substrates. The C-terminal domain structure of the mTOR kinase is shown in Figure 28.12.4

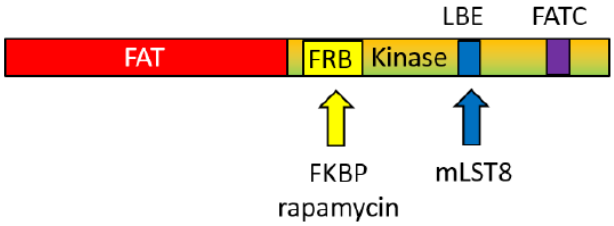

Figure 28.12.4: Domain structure of mTor

The FAT domain precedes the mTOR kinase domain. The FRB is inserted into the N lobe of the kinase domain whereas the LBE and FATC are inserted into the C lobe of the kinase domain.

Figure 28.12.5shows an interactive iCn3D model of the mTOR with the LST8 protein bound through the kinase LBE domain and with bound AGS, a nonhydrolyzable ATP analog (4JSP).

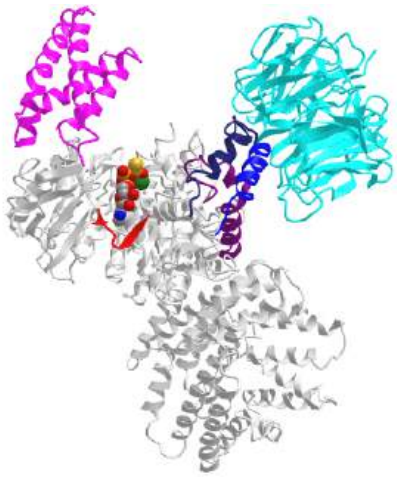

Figure 28.12.5: mTOR - LST8 complex with bound AGS, a nonhydrolyzable ATP analog (4JSP) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...TfzH75NecRodj7

Key regions are:

- FAT domain: 1385-2000
- N Lobe: 2003-2240
- C Lobe: 2241-2549
- FRB domain (magenta) inserted into N lobe: 2021-2118
- LBE domain (medium blue) inserted into C lobe: 2259 (ILL) to 2296 (TAG)
- Catalytic Loop (red): 2337 (GDR) to 2344 (SNL)
- Activation loop (dark blue): 2357 (DFG) to 2379 (FRL)
- FATC domain (purple) inserted in C lobe: 2519 (LDV) to 2549 (PFW)

Now imagine the FKBP:RAMP complex binding to the FRB domain in the figure above and you can easily imagine how RAMP could inhibit a large protein substrate from binding.

A close-up of the active site of the kinase showing bound AGS, the catalytic loop (red) containing the general base Asp 2388, and the activation loop is shown in Figure 28.12.6

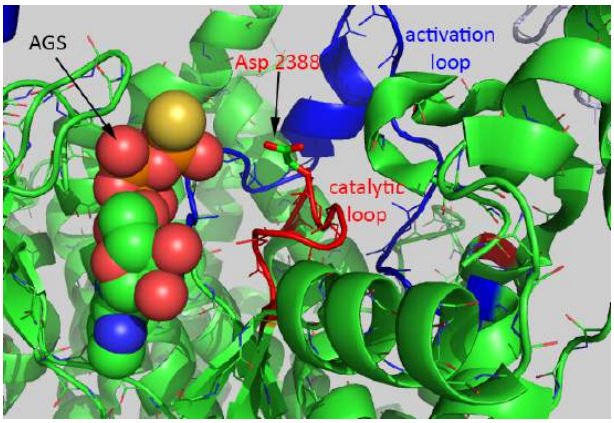

Figure 28.12.6: mTOR with bound AGS, the catalytic loop (red) containing the general base Asp 2388, and the activation loop

The mTOR kinase seems to be always primed for catalysis since the Asp 2388 is in a position to act as a general base. The FRB domain seems to be involved in directing substrate access (such as S6K1) and hence in controlling substrate specificity. Binding of FKBP:RAMP to the FRB domain would prevent substrate binding. Important substrates for each complex are shown below.

mTORC1:

Eukaryotic Translation Initiation Factor 4E Binding Protein 1 (EIF4EBP1): This protein inhibits translation by binding eukaryotic translation initiation factor 4EIF (eIF4E). In the absence of active IF4EBP1, eIF4E is part of a complex that recruits 40S ribosomal subunits to the 5' end of mRNAs, which allows the initiation of translation. The binding protein inhibits complex assembly and represses translation. Active mTORC1 phosphorylates the binding protein in a variety of conditions (UV irradiation and insulin) which leads to dissociation of the binding protein which allows eIF4E to initiate translation.

Ribosomal S6 kinase 1 (RPS6KB1 aka S6K1): This is a Ser/Thr kinase involved in proliferation, protein synthesis, cell growth, and cell proliferation. It phosphorylates eIF4B. In nutrient depletion (non-growth conditions), it forms a complex with the EIF3 translation initiation complex which inhibits translation. Under growth conditions, it is phosphorylated by mTORC1, causing its dissociation from the EIF3 complex and activation of translation. The active form then phosphorylates and activates several substrates in the pre-initiation complex, including the EIF2B complex and the cap-binding complex component EIF4B. In the presence of amino acids, both *EIF4EBP1 and S6K1* are phosphorylated. If amino acids are depleted, they are dephosphorylated.

Lipin 1 (LPIN1): This is a phosphatase that converts phosphatidic acid to diacylglycerol in triglyceride synthesis. Interestingly, it is also a transcriptional coactivator with PPARs (peroxisome proliferator-activated receptors) to modulate genes involved in lipid synthesis.

A summary figure of mTORC1 signaling is shown in Figure 28.12.7.

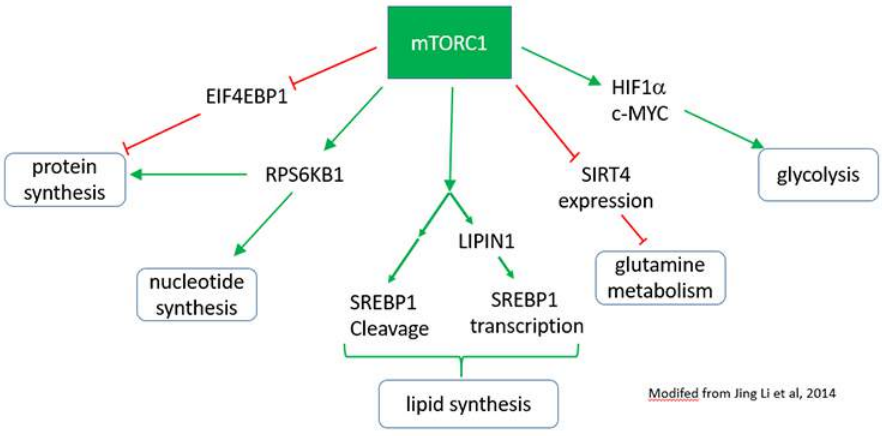

Figure 28.12.7: Summary figuring showing mTORC1 signaling

mTORC2:

Akt (also known as Protein Kinase B): This is a Ser/Thr kinase that is involved in the regulation of metabolism, proliferation, cell survival, growth, and angiogenesis. It has a notable role in the movement of the glucose GLUT4 transporter to the cell membrane in response to insulin signaling. Akt also interacts with mTORC1.

Serum/Glucocorticoid Regulated Kinase 1 (SGK1): This serine/threonine protein kinase is involved in cellular stress response. It activates certain potassium, sodium, and chloride channels. It also activates membrane transporters, enzymes, and transcription factors. Its effects regulate neuronal activity, cell growth, proliferation, survival, migration, and apoptosis.

Protein Kinase C alpha (PRKCA): This is a Ser/Thr kinase involved in cell adhesion, proliferation, differentiation, and migration.

Rho and Rac: These are small G-protein involved in cytoskeletal structure and cell cycle.

Figure 28.12.8 shows a more complete pathway of activation, regulation, and activity of both mTORC1 and mTORC2. Figure 28.12.x below is used with courtesy of Cell Signaling Technologies (www.cellsignal.com). This chapter section will mostly focus on mTORC1.

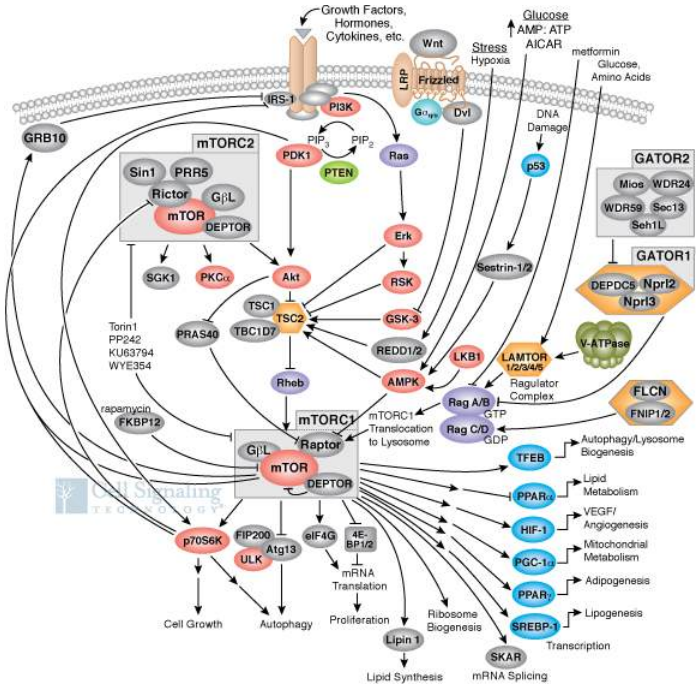

Figure 28.12.8: mTOR1 and mTOR2 signaling.

28.12.4: Regulation of mTORC1 by Leucine

mTORC1 is a key regulator of protein synthesis but that begs the question as to how it determines that protein synthesis is required. How does it sense that? Rregulators of mTORC1 might be amino acids in cells, but who would have thought that the master regulator would be **leucine**, a simple branched chain hydrophobic amino acid.

It would be nice if free leucine bound directly to mTORC1, but it's not that simple. Rather, it binds to a "leucine" receptor, sestrin 2 (SESN2). Figure 28.12.9shows the binding interactions between Leu (spacefill) and key side chains in sestrin 2 (5dj4).

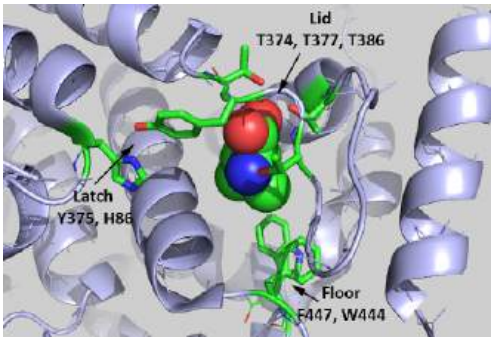

Figure 28.12.9: Binding interactions between Leu (spacefill) and key side chains in sestrin 2 (5dj4)

The Leu is rather buried, which suggests a conformational change ensues on binding to the protein. Saxton et al (2016) describe three types of sestrin2 side chains involved in the interaction:

Lid: Thr374, Thr377, and Thr386 form H bonds with the Leu amine and carboxyl group. Leucine is represented as a stick model (orange).

Latch: Tyr375 and His86 form hydrogen bonds to the Leu. Note that these residues are distal in the chain and are probably pulled together during the conformational changes which occur after binding to form a latch to sequester the bound Leu.

Floor: F447 and W444 which interact with the nonpolar side chain of Leu.

Figure 28.12.10shows an interactive iCn3D model of Leucine-bound Sestrin2 (5DJ4).

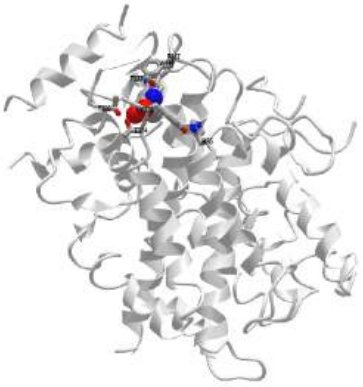

Figure 28.12.10: Leucine-bound Sestrin2 complex (5DJ4) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...nPyYVRUr9oQfv8

What happens after leucine binds? It's a complicated but understandable process described below in words and images. But first a quick review. Kinases must be regulated to be turned on and off at the right time. They are often regulated by phosphorylation, as mTOR is. In addition, they can be regulated by binding proteins as mTOR is (by Raptor, FKBP, etc). They can also be regulated by small G proteins (like Ras) which are active when bound to GTP and inactive when bound to GDP. Of course, whether small G proteins have GTP bound depends in part if they interact with **GAPs** (GTPase activating protein which inactivates small G proteins) or **GEFs** (which facilitate the exchange of GDP for GTP and activate them). Such a master regulator of growth as mTORC1 is regulated by all of these, in addition to the presence of abundant leucine.

In the absence of leucine, sestrin 2 is bound to a protein called GATOR2 (GTPase-activating protein - GAP - activity toward Rags 2). The binding of leucine to sestrin 2 causes the dissociation of GATOR2. This is shown in Figure 28.12.11

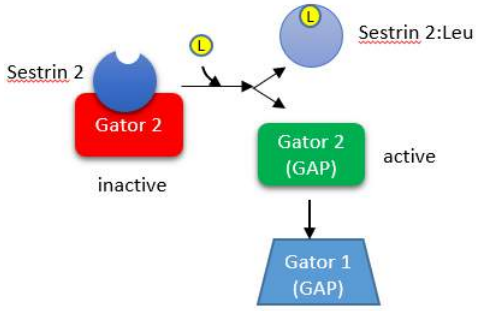

Figure 28.12.11: Sestrin 2 - GATOR interactions

Free GATOR2 is a GAP that regulated mTORC1. Specifically, it regulates the activity of a heterodimer of small GTP binding proteins, RagA/B:RagC/D (see pathway above) which are associated with the outer leaflet of the lysosome. There they interact with a membrane protein, SLC38A9, and a protein that regulates the Rag proteins, which of course is named Ragulator. Active RagA/B:RagC/D recruits mTORC1, presumably through the Raptor subunit) from the cytoplasm to the lysosome membrane. Small G proteins like Ras, when activated by exchanging bound GDP for GTP, can interact with and activate kinases (like the Raf kinase for Ras). When mTORC1 binds to active RagA/B:RagC/D, it becomes activated.

We often think of activating a protein by ligand binding, which promotes a conformational change, or by post-translational modification, which can provide a binding interaction or conformational change to activate the protein. Another way is to inhibit an inhibitor of a protein, as shown in Figure 28.12.12: Y inhibits Z as denoted by the blunt blunt-ended. If X inhibits Y, then Y can't inhibit Z, which is now active. This is analogous to the quote that "the enemy of my enemy is my friend", which has been attributed to Kautilya (from India) in the 4th century BCE.

Figure 28.12.12: An inhibitor of an inhibitor is an activator

Leucine binding to sestrin 2 leads to free GATOR, which activates mTORC1 by blocking downstream inhibitors. Figure 28.12.13 (after Buel and Blenis, 2016) shows the interactions from an activation (arrow) or inhibition (blunt arrow) perspective.

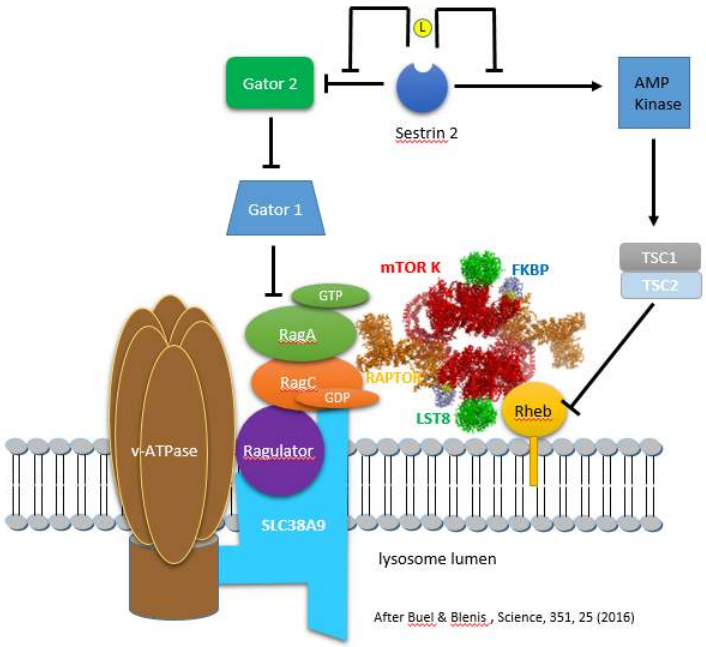

Figure 28.12.13: Leucine binding to sestrin 2 leads to free GATOR, which activates mTORC1 by blocking downstream inhibitors

The figure above shows the involvement of multiple proteins in the lysosome membrane that are involved in mTORC1 activation. There is yet another way that the RagA/B and RagC/D proteins are regulated (other than by the GATOR GAP activity. The main one appears to be **Ragulator**, which is a **GEF** for the Rag proteins. Here is a summary of the components of this lysosomal membrane recruitment center for mTORC1.

- Ragulator (what a great name) binds and recruits the small G proteins Rag to the lysosome membrane where Ragulator acts as a GEF for RagA/B
- SLC38A9 is a weak amino acid transporter in the lysosome membrane, with a preference towards polar amino acids. More likely it is yet another sensor of amino acids, particularly of arginine, which has a high concentration in the lysosome. The protein has a high Km for the transport of Arg. It has a Ragulator binding domain and is hence part of the complex that recruits mTORC1 to the lysosome
- vacuolar adenosine triphosphatase (v-ATPase): function unclear

These interactions, which involve multiple activations and inhibitions, are difficult to follow even with a diagram. The actions of small G proteins can be especially difficult to understand since the G protein is biologically **INACTIVE** in its GDP-bound form towards its target binding protein. This occurs when the GTPase activity of the G protein is **ACTIVE**. The arrows and blunt end arrows in the figure above represent the activity of the protein toward its target protein.

Here are two alternative ways to make sense of the interactions:

- Stepping backward from Rag A/B, Gator 1 (a GAP) inhibits the ACTIVITY of the protein Rag A/B as it acts as a GAP to leave Rag A/B in the inactive GDP-bound state. Paradoxically this occurs as the inherent GTPase activity of the protein is activated as

described above). Free Gator 2 (also a GAP) appears to inhibit the GAP activity of Gator 1 (through an unknown mechanism), thereby increasing the amount of GTP-bound Rag A/B, which then can activate mTORC1. Free Gator 2 does this only if Sestrin 2 is bound to Leu which allows the Gator 2 to dissociate from the inactive sestrin 2:Gator 2 complex.

- The diagram above shows that in the absence of leucine, three blunt end (inhibition) arrows occur between Sestrin 2 and Rag A/B. One blunt arrow denotes inhibition, two activation (inhibition of inhibition), and hence three net inhibition Hence in the absence of Leu (when Sestrin is bound to Gator 2, Rag A/B is **inhibited in its ability to activate mTORC1** as Rag A/B is in the GDP-bound state. However, free leucine unblocks the inhibitor action of sestrin 2 as Gator 2 is now free and active on its own.

Amino acids (especially arginine, which is abundant) in the lumen of the lysosome activate, through the v-ATPase and SLC38A9, the GEF activity of Ragulator. When Rag A/B has sufficient GTP, some conformational changes must ensue to allow mTORC1 recruitment to the lysosomal membrane.

28.12.5: Regulation of mTORC1 by Energy Availability - AMP Kinase

Believe it or not, another small G protein with GTPase activity, Rheb (Ras homolog enriched in the brain), is involved in both mTORC1 recruitment to the lysosomal membrane and activation of mTOR. This interaction is also shown in the figure above. Mostly, Rheb is involved in the activation of the kinase activity of the mTORC1 complex and specifically the phosphorylation by mTOR of the substrates S6K1 and EIF4EBP1. In the presence of growth factors, Rheb is localized to the membrane by a lipid anchor (a farnesyl group). The mTORC1 kinase-activating activity of Rheb stands in contrast to the role of the Rag G proteins which appears to be chiefly recruitment.

How is the small G protein Rheb regulated? Of course, by its interaction with yet another GAP, named the tuberous sclerosis complex (TSC). In the absence of growth factors, TSC binds to Rheb and, acting as a GAP, promotes GTP hydrolysis. This inactivates Rheb, inhibiting mTOR kinase activity.

How then is Rheb regulated? One way is through phosphorylation by **AMP Kinase (AMPK)**, an enzyme that is itself regulated by the energy level of the cells. AMPK phosphorylates and activates the TSC, which, acting as a GAP, inactivates the small G protein Rheb complex (TSC complex). Sestrins 1 and 2 may also regulate AMPK. Let's look at the energy sensor of the cell in more detail.

AMP Kinase is one of the cell's major fuel sensors and also in mammals responds systemically to hormone and nutrient levels. The enzyme is a heterotrimeric protein consisting of an alpha (catalytic), beta (regulatory), and gamma (regulatory) subunit that binds AMP, ADP, and ATP. Cellular ATP levels are determined in part by the enzyme **adenylate kinase** which helps interconvert adenine nucleotide (AXPs) as shown in the following equilibrium:

Adenylate Kinase: ADP + ADP ↔ ATP + AMP, Keq = 0.44

In red blood cells, the concentrations of ATP, ADP, and AMP are approximately 1850 uM, 145 uM, and 5 uM. Even in cells that use lots of ATP (muscle for example), ATP never falls by much. Using the values above and simple general chemistry, an 8% drop in ATP would lead, through the action of adenylate kinase, to an ATP concentration of about 1710 uM and an AMP concentration of 20 uM. This value for AMP is still much lower than ADP and ATP. However, this change represents a 4 fold increase in AMP which, even with the low actual concentration of AMP, leads to the activation of AMPK.

Another "normalized" indicator of cell energy status (or "charge") is the Energy Charge, EC. It is defined by an equation that gives a value from 0-1 where 0 indicates that all AXPs are in the AMP form and 1 where only ATP is present. The numerator of the equation of EC below represents the number of moles of phosphoanhydride linkages in the AXP pool (two for each ATP and one for ADP) and the denominator is the number of moles of AXPs (mass balance). The 1/2 term allows the bracketed term to equal 1 when only ATP exists and 0 when only AMP exists. The EC values of cells are regulated to remain around 0.85.

$$\mathrm{EC} = \frac{1}{2}\left[\frac{2\mathrm{ATP} + \mathrm{ADP}}{\mathrm{ATP} + \mathrm{ADP} + \mathrm{AMP}}\right] \tag{28.12.1}$$

Before we explore the mechanism of energy sensing by AMPK, let's look at the domain structure of the three subunits of AMPK. They are shown in Figure 28.12.14

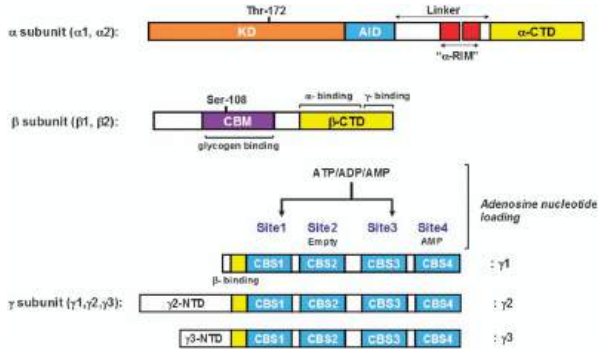

Figure 28.12.14 Domain structure of the alpha, beta, and gamma subunits of AMPK. Kim et al. Experimental & Molecular Medicine (2016) 48, e224. https://www.nature.com/articles/emm201616.pdf. a Creative Commons Attribution-NonCommercial-ShareAlike 4.0 International License. http:// creativecommons.org/licenses/by-nc-sa/4.0/

The mammalian α1/α2 and β1/β2 isoforms are very similar, and their characteristic features are shown. AMPKα subunits: KD, kinase domain containing Thr-172 for the activation by upstream kinases; AID, autoinhibitory domain; two α-RIM, regulatory subunit interacting motifs triggering the conformational changes in response to AMP binding to the AMPKγ subunit; α-CTD, C-terminal domain binding to the β-subunit. AMPKβ subunit: CBM, carbohydrate-binding module, in which Ser108 is important for the action of some direct AMPK activators, such as thienopyridone (A-769662) and salicylate; β-CTD, C-terminal domain containing α-subunit-binding site and immediately followed by the domain for γ-subunit interaction. AMPKγ subunit: three γ-subunit isoforms have variable N-terminal domains (NTDs); four CBS, cystathione-β-synthase domain, which forms two Bateman domains that create four adenosine nucleotide-binding sites (Sites 1–4). Site 2 appears to be always empty and Site 4 has a tightly bound AMP, whereas Sites 1 and 3 represent the regulatory sites that bind AMP, ADP, or ATP in competition.

How AMPK detects this exponential but still small molar increase in AMP is interesting, especially given the much higher concentrations of ADP and ATP. AMPK contains four binding sites that can bind AMP, ADP, and ATP (AXPs) in the regulatory subunit (gamma). This is in addition to the binding of ATP and ADP at the active site in the catalytic subunit (alpha). What binds depends on the Kd for binding of different AXPs as well as their concentrations. Bound AMP seems to have three effects on AMPK. When bound to the gamma subunit, AMP

- increases phosphorylation of Thr 172 in an "activation" loop in the catalytic alpha subunit by an upstream kinase which increases the kinase activity of AMPK by 100-200 fold. Phosphorylation is essential for the activity of the enzyme;
- inhibits dephosphorylation of Thr 172 which is perhaps the major way that AMP enhances the kinase activity of the catalytic subunit. ADP binding also inhibits dephosphorylation as shown by studies that show that the binding of ADP and the dephosphorylation of the phospho-AMPK have the same ADP concentration dependency;
- allosterically activates ten-fold the kinase activity of the catalytic alpha subunit (a secondary effect). ADP has no such effect.

These effects are altered by the markedly higher concentrations of ATP which counteracts all these effects, enhancing the Energy Charge sensor activity of this enzyme.

The gamma regulatory subunit has 4 binding sites for AXP. Crystal structures show site 2 is empty, site 4 is always bound to AMP, and sites 1 and 3 can bind AMP, ADP, or ATP. Site 1, which mediates the allosteric effects on AMPK binds all AXPs with similar affinity. This appears paradoxical since given the high energy charge, one would expect ATP and ADP to out-compete AMP for binding. However, it was found that the Mg^{2+} -ATP complex has marked lower affinity for the site, allowing both AMP and ADP, which under cellular conditions are mostly not bound to Mg^{2+} while ATP is, to out-compete Mg^{2+} -ATP for binding. Site 3 binds AMP and ADP with a 30-fold lower affinity but on binding protects p-AMPK from dephosphorylation of Thr 172.

Figure 28.12.15 shows an interactive iCn3D model of human AMPK (a2b2g1) in complex with a small molecule activator SC4 (6B2E)

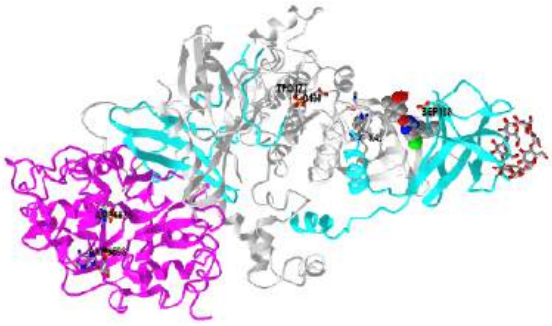

Figure 28.12.15: Human AMPK (a2b2g1) in complex with a small molecule activator SC4 (6B2E). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...HpqpDGibsRqQt7

SC4 or similar molecules may be important drugs to target AMPK and be useful in the treatment of insulin resistance and Type II diabetes. SC4 activates α2 complexes and glucose uptake into muscle cells. Some would call this type of drug an importagog, as it increases the uptake of important metabolites into cells.

The alpha catalytic kinase subunit is shown in gray with key catalytic residues and phosphorylated Thr and Ser shown in sticks, CPK coloring, and labeled. The beta subunit is shown in cyan. It appears to be two chains since the connecting section is not ordered in the crystal structure. The gamma subunit with bound AMP (spacefill, CPK colors, labeled) is shown in magenta.

What effect does activated AMPK have on the cell? Active AMPK has an amazing number of effects (see figure below). It activates liver glycolysis (by phosphorylating phosphofructokinase 2 which forms F2,6-BP, an activator of PFK) and inhibits by phosphorylation enzymes involved in fatty acid synthesis (acetyl-CoA carboxylase), glycogen synthesis (glycogen synthase) and cholesterol synthesis (HMG-CoA reductase). Yeast AMPK has recently been shown to be also controlled by acetylation of the equivalent beta subunit (Sip2). Acetylation increases its interaction with the alpha catalytic subunit (Snf1) which decreases its kinase activity. This decreases the phosphorylation of downstream kinases (including an analog of Akt1 called Sch9) which slows the growth and increases longevity. Normal aging is associated with decreased acetylation of Sip2.

Figure 28.12.16shows how the many signaling pathways we have studied interact with AMPK

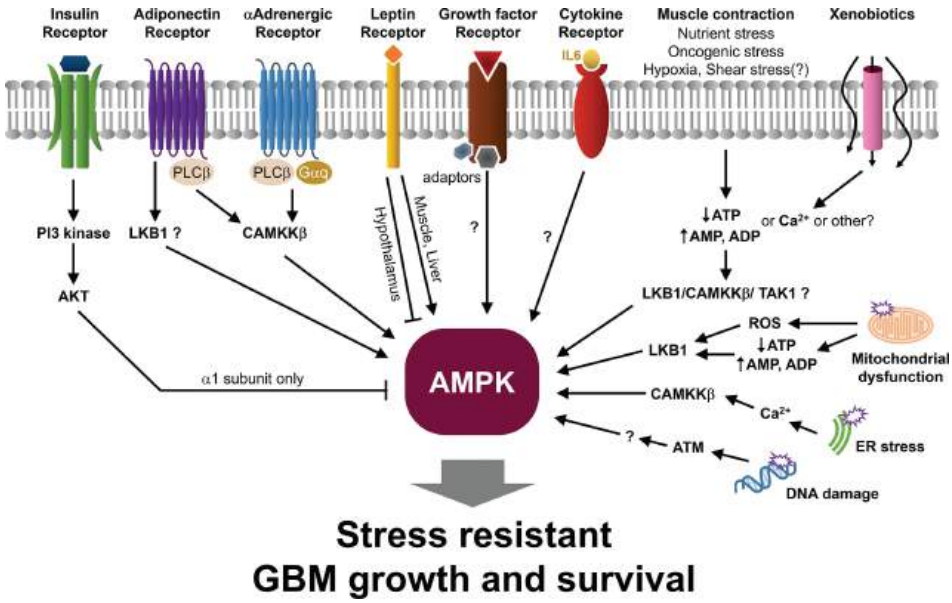

Figure 28.12.16: Signaling from membrane proteins to AMPK. Chapter 7, Targeting Energy Metabolism to Overcome Therapeutic Resistance of Glioblastoma and Tumor-associated Edema. Figure 28.12.17 shows a more complete pathway of activation, regulation, and activity of AMPK. The illustration is used with courtesy of Cell Signaling Technologies (www.cellsignal.com).

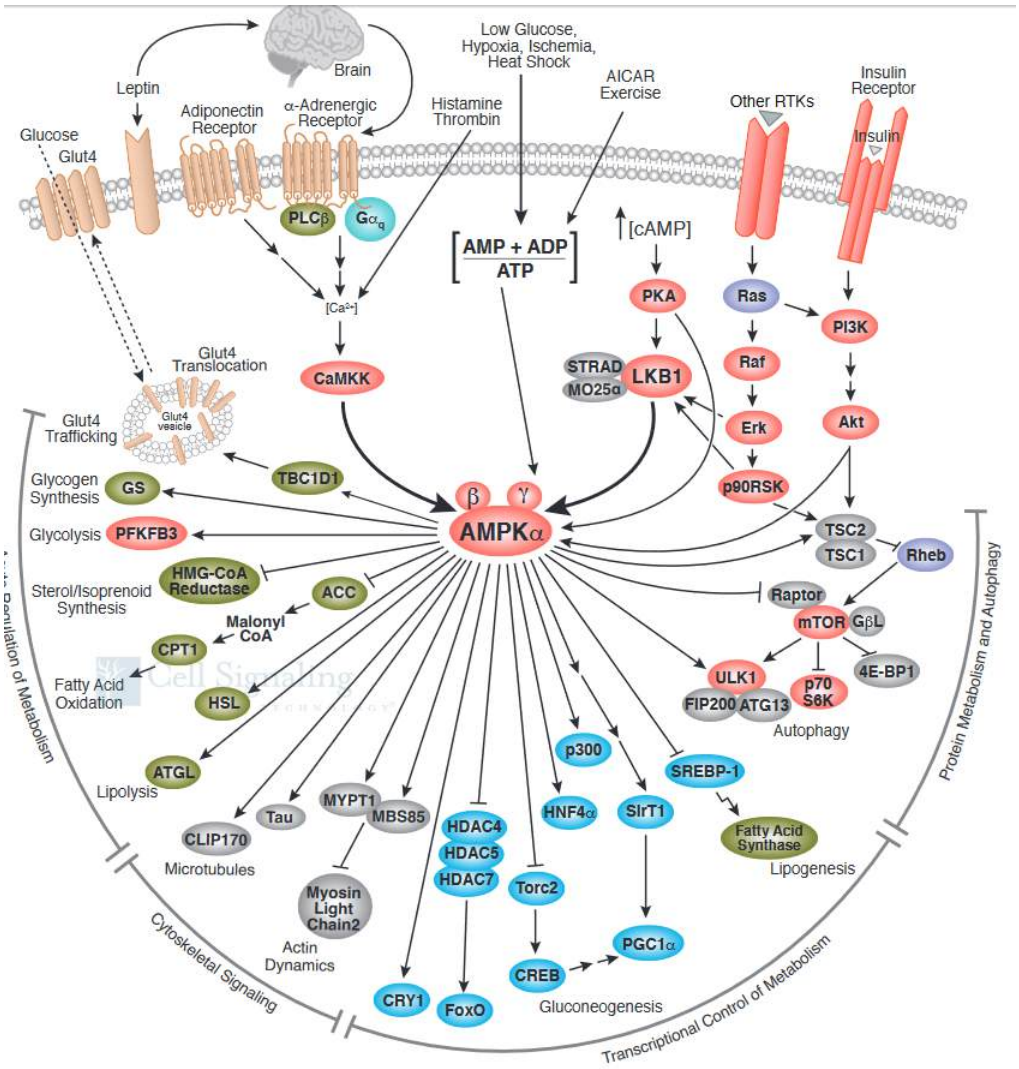

Figure 28.12.17: Signaling through AMPK

It also shows the effect of AMPK on the master regulator of protein, lipid, and nucleic acids synthesis, mTOR. Synthesis of these molecules is necessary for cell growth and proliferation, two activities that cells do not engage in when AMP levels are high, which signifies an energy-depleted state.

28.12.6: Regulation of mTORC1 by Insulin and Growth Factors

mTORC1 is regulated by local factors (amino acids, energy state) and systems factors (growth factors). This list is growing daily. The following have been shown to lead to mTORC1 activation including small molecules such as amino acids, ATP (through AMP kinase), oxygen, and glucose, and larger ones such as insulin, other growth factors, cytokines (immune growth factors and regulators), oncogenes (which promote cell proliferation) and some infectious agents. Other molecules or processes inhibit mTORC1, including tumor suppressors and stress.

mTORC1 promotes mRNA and protein synthesis as described above but also nucleotide and lipid synthesis, which is not described in detail above. In addition, it promotes aerobic glycolysis (Warburg effect), to supply not energy but intermediates for biosynthesis, as well as the pentose pathway, which forms NADPH for reductive biosynthesis and ribose for nucleic acid synthesis.

Let's look at 2 specific external hormones, insulin and epidermal growth factor (EGF), and how they affect mTORC1 activity;

Insulin:

Insulin binding to its receptor leads to the activation through phosphorylation of the kinase Akt (aka Protein Kinase B) after upstream phosphorylation of membrane phosphoinositides in the membrane and activation of phosphoinositide-dependent kinase 1, PDK1. Atk, as shown in the signaling figure for AMPK, phosphorylates TSC2, the GAP for Rheb. The arrows on the AMPK

kinase figure above **are not** consistent with our previous use of arrows. In the figure from CST, arrows show that both AMPK and Akt phosphorylate TSC2. The phosphorylated TSC is shown to inhibit Rheb, the small G protein. This would not make physiological sense. Phosphorylation of TSC2 by AMPK (signaling energy depletion) activates the TSC2 GAP protein which would inhibit RheB (the G protein) and hence inhibit mTORC1. In contrast, phosphorylation of TSC2 by Akt (signaling the abundance of glucose) leads to the **inhibition** of the GAP activity of TSC2. That would keep Rheb in the active, GTP-bound form, which leads to the activation of the bound mTORC1. A more complete description of the pathway where insulin binds to its receptor (an insulin-gated receptor tyrosine kinase) and leads to activation of mTORC1 through Akt is shown in Figure 28.12.18

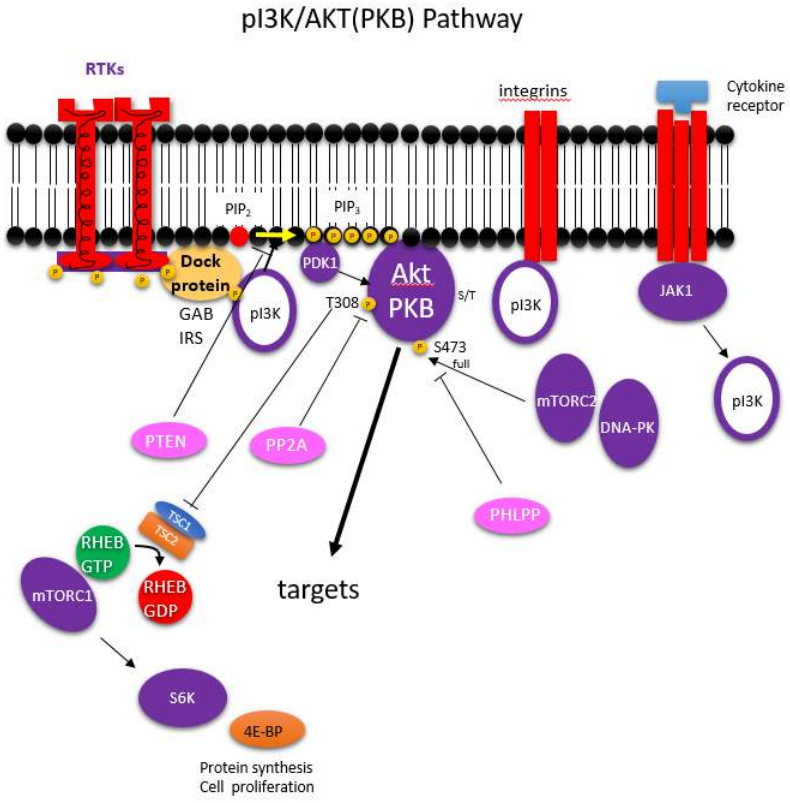

Figure 28.12.18: Insulin Receptor and mTOR signaling

MAPK Cascade:

EGF binds its receptor, activating it as a receptor tyrosine kinase. Typical of other receptor kinases, it activates the mitogen activate protein kinase system. This process is mediated by Ras (a small G protein) activator of Raf (a mitogen-activated protein kinase kinase kinase or MAP3K). Active Raf phosphorylates and activates MEK (a MAPK2) which activates ERK (a MAPK). Erk phosphorylates mTORC1 directly, which activates it. It also phosphorylates TSC2/TSC1, which inhibits this GAP protein, leading indirectly to the activation of the small G protein Rheb, which also activates mTORC1. These steps are shown in Figure 28.12.19

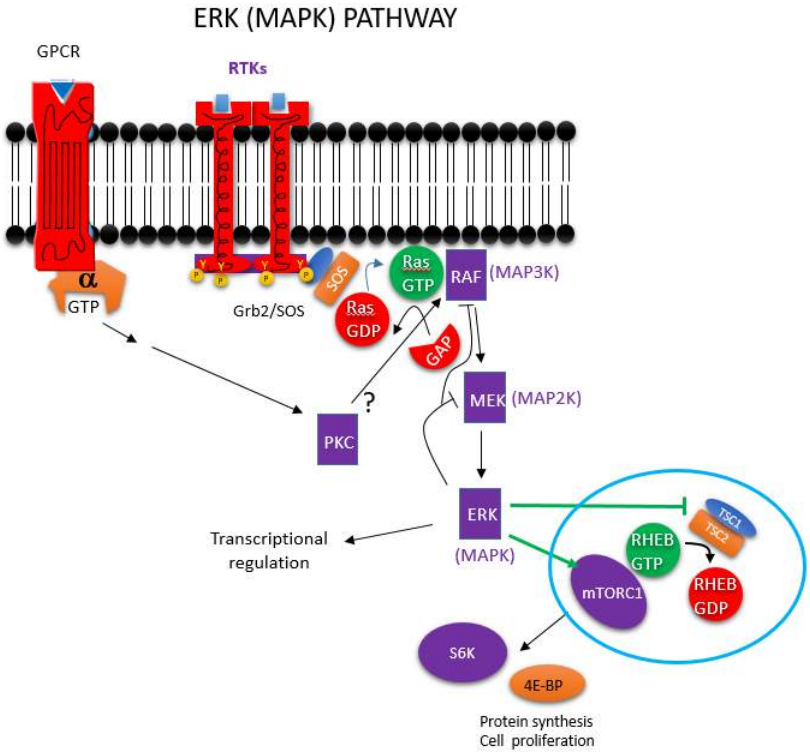

Figure 28.12.19: MAPK and mTOR signaling

A summary showing the kinases that activate or inhibit TSC2/1 is shown in Figure 28.12.20 We tend to concentrate on our favorite protein and confer it with special status as critically important in a pathway. One could pick the GAP protein TSC2 as especially important in regulating the activity of mTORC1.

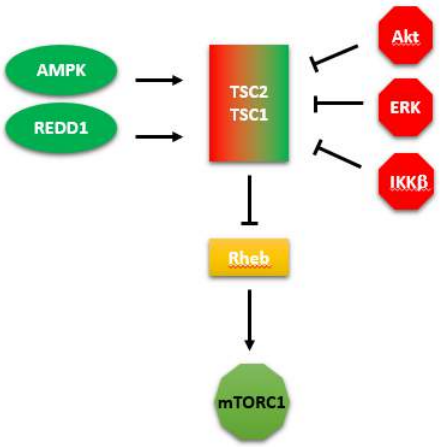

Figure 28.12.20 kinases that activate or inhibit TSC2/1

The figure above shows two additional proteins. One is REDD1 (not a kinase), which activates the GAP protein TSC2, leading to the inhibition of the small G protein Rheb, and hence the inhibition of mTORC1.

REDD1 (regulated in development and DNA damage responses 1) is also called DDIT4 (DNA-Damage-Inducible Transcript 4). It is a gene whose expression is activated during hypoxia by hypoxia-inducible factor-1 and also during DNA damage. Hypoxia alters metabolism very quickly. The protein is degraded by the proteasome after it is targeted for degradation by the post-translational addition of ubiquitin. This suggests yet another way to regulate the activity of mTORC1.

The other is IKK beta, also known as IKBKB (Inhibitor Of Kappa Light Polypeptide Gene Enhancer In B-Cells, Kinase Beta). It is a kinase that phosphorylates and inhibits TSC2 which inhibits Rheb, leading to the activation of mTORC1.

This kinase is activated by many stimuli including inflammation (mediated by cytokines), bacterial or viral infections, and DNA damage. It phosphorylates a bound inhibitor of NF-kappa beta. This allows ubiquitinylation of the inhibitor, targeting it for proteasomal degradation. The free NFKB can then enter the nuclease and alter the transcription of genes involved in the immune response and hence promote proliferation. Under these conditions, one would expect the activation of mTORC1.

A final note: Less is known about how lipids regulate mTORC1. Two possible lipid signaling molecules, phosphatidic acid, and phosphatidyl inositol -3-phosphate are probably involved. The enzyme that makes them, phospholipase D and phosphoinositide 3-kinase (from the PIK3C3 gene), also known as VPS34 (for vacuolar protein sorting from yeast), are found in phagosomal and lysosomal vesicles and are involved in their processing, seem to be involved in mTOR signaling. Obesity and people with high-fat diets have elevated mTOR activity.

28.13: Regulation of the Cell Cycle by Protein Kinases

This section is an integration of materials as referenced, with significant modifications and additions.

Aleem and Arceci. Targeting cell cycle regulators in hematologic malignancies. Article in Frontiers in Cell and Developmental Biology 2015. DOI: 10.3389/fcell.2015.00016.

28.13.1: Introduction

For a cell to undergo successful division, it has to perform four key tasks in a highly ordered fashion. First, there is a preparatory synthetic phase (G1) that results in increased cell size in anticipation of DNA replication (S phase). Cells then proceed through (G2-phase) to prepare to equally segregate duplicated DNA (M phase) and finally divide into two equal daughter cells. From G1 a cell can also exit the cell cycle and enter a state of quiescence (G0), undergo differentiation, or re-enter the cell cycle to proliferate in response to mitogenic signals.

The core molecular machinery controlling the mammalian cell cycle consists of a family of serine/threonine protein kinases called **cyclin-dependent kinases (CDKs**). These are catalytic subunits, which are activated in most cases by association with **cyclin regulatory subunits**. The activity of CDK/cyclin complexes is further regulated by CDK inhibitors **(CKIs)**, phosphorylation and dephosphorylation, ubiquitin-mediated degradation, transcriptional regulation, substrate recognition, and subcellular localization. The family of CDKs/cyclins/CKIs contains more than 30 members. They are implicated in essential cellular functions such as transcription, DNA damage repair, epigenetic regulation, metabolism, proteolytic degradation, stem cell self-renewal, neuronal functions, and spermatogenesis. Figure 28.13.1shows the cell cycle and the involvement of CDKs/cyclins at key points.

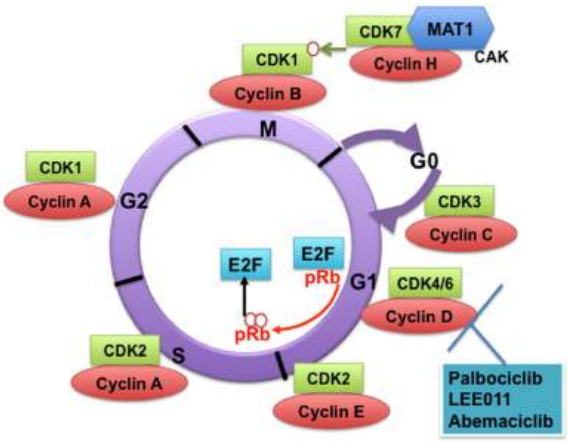

Figure 28.13.1: Cyclin-dependent kinases (CDKs) and their cyclin regulatory subunits. CDK-cyclin complexes with direct functions in regulating the cell cycle. Aleem and Arceci. Frontiers in Cell and Developmental Biology 2015. DOI: 10.3389/fcell.2015.00016.

CDK3/cyclin C drives cell cycle entry from G0. CDK4/6/cyclin D complexes initiate phosphorylation of the retinoblastoma protein (pRb) and they sequester $p21^{Cip1}$ and $p27^{kip1}$ (not shown), which are both inhibitors of CDK2, thus promoting the activation of CDK2/cyclin E complex. In late G1, the CDK2/cyclin E complex completes phosphorylation and inactivation of pRb, which releases the E2F transcription factors and the G1/S transition takes place. DNA replication takes place in the S phase. CDK2/cyclin A complex regulates progression through the S phase and CDK1/cyclin A complex through the G2 phase in preparation for mitosis (M). Mitosis is initiated by **CDK1/cyclin B** complex (which will model at the end of this section). The activity of CDK1/cyclin B is tightly regulated by activating phosphorylation by the CDK-activating kinase CAK (a heterodimer of cyclin H-CDK7-MAT1) and inhibitory phosphorylations by Wee1 and Myt1 on Tyr15 and Thr14 (not shown). Some specific CDK4/CDK6 pharmacological inhibitors are also shown

28.13.2: CDKs with Direct Functions in Cell Cycle Regulation

The classical CDKs that directly regulate the mammalian cell cycle in complexes with cyclin subunits include CDK3, CDK4, CDK6, CDK2, and CDK1. CDK3 promotes cell cycle entry from quiescence in association with cyclin C. CDK8 has also been suggested to play a role in cell cycle entry from G0 and in the G1/S transition. In its simplest model, the mammalian cell cycle proceeds as follows:

- In early G1, CDK4/CDK6 in complex with cyclin D receive mitogenic signals that result in activation of cell cycle entry, as shown in Figure 28.13.1 Key signaling events include the initiation of retinoblastoma protein (pRb) phosphorylation and the sequestration of $p21^{Cip1}$ and $p27^{kip1}$, which are both inhibitors of CDK2, thus promoting the activation of CDK2/ cyclin E complex. In late G1, CDK2 in complex with cyclin E completes the phosphorylation and hence inactivation of pRb, which in turn releases the E2F transcription factors. E2F promotes transcription of cyclin E which is necessary for the G1/S transition.
- Progression through the S phase is mediated by CDK2/cyclin A complex.
- Mitosis is then initiated by **CDK1/cyclin B complexes**. We will model the regulation of CDK1 later in this section. CDK1/cyclin A complexes contribute to the preparation for mitosis in the G2 phase. The activity of CDK1/cyclin B is tightly regulated by activating phosphorylation by the CDK-activating kinase (CAK) (a heterodimer of cyclin H and CDK7) and inhibitory phosphorylations by WEE-1 and Myt1 on Tyr15 and Thr14. Mitosis starts after WEE-1 is degraded and CDC25C phosphatase releases the inhibitory phosphorylation on CDK1/cyclin B.

The cyclins are also expressed in a coordinated fashion throughout the cell cycle. The cyclin expression cycle is shown in Figure 28.13.2 The timing of expression is consistent with the explanations above.

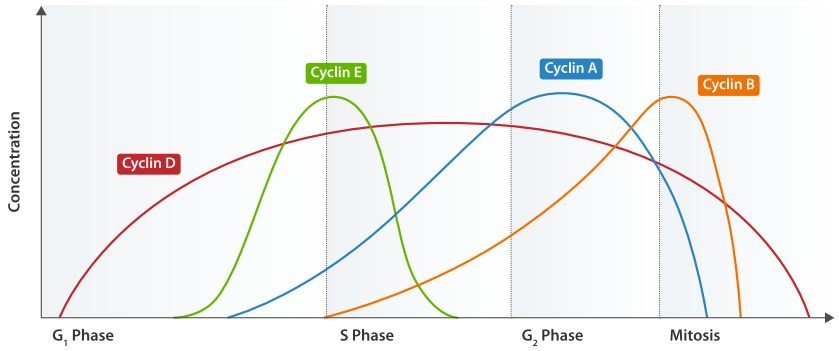

Figure 28.13.2: Cyclin expression cycle. https://commons.wikimedia.org/wiki/F...Expression.svg

A graph showing multiple progressions through the cell cycle is shown in Figure 28.13.3

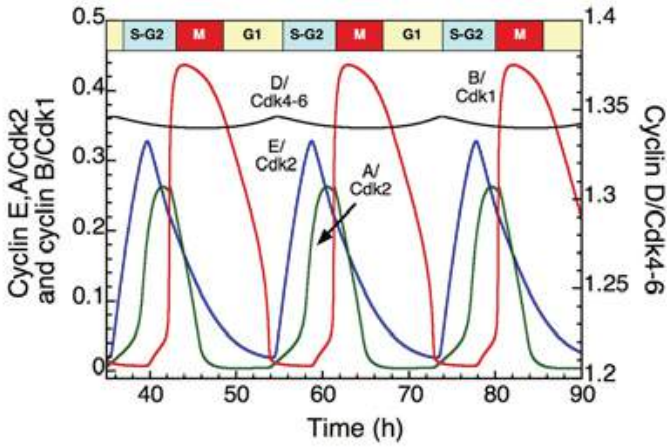

Figure 28.13.3 Sustained oscillations of the CDK network in mammalian cells. Gérard and Goldbeter, Front. Physiol., 02 November 2012
Sec. Systems Biology Archive. https://doi.org/10.3389/fphys.2012.00413. Creative Commons Attribution License

The time evolution of cyclin D/Cdk4–6 (in black), cyclin E/Cdk2 (in blue), cyclin A/Cdk2 (in green), and cyclin B/Cdk1 (in red) is shown in the presence of a suprathreshold level of growth factor. Cyclin D/Cdk4–6 is the total active form of the kinases, which is composed of cyclin D/Cdk4–6 and also the complex formed by cyclin D/Cdk4–6 and p21/p27.

Note again the oscillatory nature of the cyclin B/Cdk1 complex, which will explore at the end of this section.

28.13.3: CDKs with Transcriptional and Other Functions

In addition to their direct role in the mitotic cell cycle regulation, some classical CDK/cyclin complexes have essential functions in meiosis, such as CDK2, in transcription and/or DNA repair. Other CDKs act by activating the classical CDKs, such as CDK7/cyclin H (CAK) and the related CDK20, also known as cell cycle-related kinase (CCRK). Some CDKs function mainly in influencing transcription by phosphorylating the carboxy-terminal domain (CTD) of ribonucleic acid (RNA) polymerase II (RNA pol II). This phosphorylation also serves as a platform for RNA processing and chromatin regulation.

CDKs that have important transcriptional roles include CDK7/cyclin H/MAT1 complex, a component of the basal transcription factor, TFIIH, and facilitate transcriptional initiation. CDK8/cyclin C, in addition to its role in transcription, is also involved in the Wnt/β-catenin pathway and inhibition of lipogenesis. Cyclin C can recruit CDK8 or CDK19 to the CDK8 module of the Mediator complex, which can function as a positive or negative regulator of transcription by RNA pol II. CDK3/cyclin C also plays a role in NHEJ-mediated DNA damage repair. While CDK9 in complex with cyclin T forms the phospho-transcription elongation factor b (p-TEFb) and promotes transcriptional elongation, CDK9 also functions in the DNA damage response when complexed with cyclin K. CDK10/cyclin M phosphorylates the Ets2 transcription factor and positively controls its degradation by the proteasome. Ets2 plays a key role in cancer and development. CDK11/cyclin L controls the assembly of the RNA pol II mediator complex. CDK12 and CDK13 in complex with cyclin K control RNA pol II transcription, and CDK12/cyclin K controls DNA damage response.

28.13.4: Structure of CDKs–cyclins

The structures of inactive cyclin-free kinases are very similar but vary at the N-terminal and C-terminal ends. Figure 28.13.4shows an interactive iCn3D model of the prototypical active human cyclin-dependent kinase 2 with a bound ATP (1HCK).

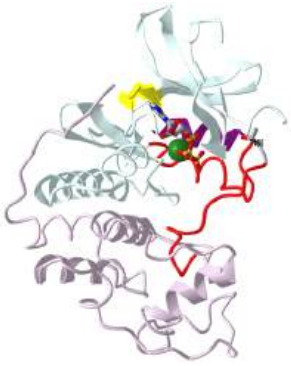

Figure 28.13.4: Human cyclin-dependent kinase 2 with a bound ATP analog (1HCK) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...3Sf81pwLKQZx9A

The model shows that CDK2 has structural features shown in all the kinases we have studied previously:

- a smaller N-terminal lobe (light cyan) and larger C-terminal lobe (light magenta) in between which ATP binds (along with Mg^{2+}).
- the C-helix (residues 45 – 55, purple), which contains a conserved Glu. It forms an interaction with and helps position a key Lys in the active, which facilitates ATP binding and transition state stabilization;
- hinge (residues 80 – 84, yellow),
- activation loop (residues 145– 172, red), which contains T160 (sticks, CPK colors, labeled) that becomes phosphorylated on activation by yet another kinase called **CDK-activation kinase (CAK).** When T160 is phosphorylated, the kinase binds to cyclin A. The loop starts and ends with the conserved residue DFG and APE, respectively.
- Not highlighted in the model is a conserved conformationally flexible glycine-rich region (residue 12-16) with the motif GXGXXG

In the inactive form, the N-terminal end of the activation loop has a short alpha helix that prevents the C-helix from adopting the correct position for catalysis. Activation requires movement of the C-helix allowing the Glu in the C-helix to position the active site Lys.

28.13.5: CDK2–cyclin A activation

The binding of cyclin A to CDK2 activates it through the repositioning of the C-helix and the activation loop. When CDK2 is phosphorylated and bound to cyclin A, there is a large shift in the C-helix allowing the interaction of the C-helix Glu with the active site Lys.

First, let's look at the structure of cyclins. Each cyclin has a unique sequence and structural features that allow them to interact with specific CDKs and associated proteins. However they all have a conserved "cyclin box" structure containing about 100 amino acids.

Figure 28.13.5shows an interactive iCn3D model of bovine cyclin A (1VIN).

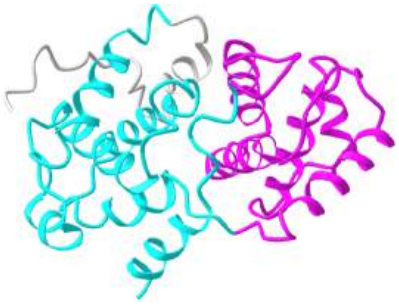

Figure 28.13.5: Bovine cyclin A (1VIN) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...6j7kLcPzpRTAA9

Cyclin A has two linked cyclin box folds, each containing around 100 amino acids and comprised of five helices. They interact with the more disordered parts of unphosphorylated CDK2, which result in some low levels of activity. Cyclin binding causes a large movement of the C-helix enabling the Glu -- Lys interaction. Phosphorylation of T160 leads to the repositioning of the activation loop.

Figure 28.13.6shows an interactive iCn3D model of Phosphorylated cyclin-dependent kinase 2 bound to cyclin A (1JST)

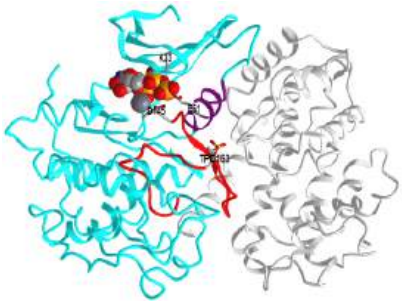

Figure 28.13.6: Phosphorylated cyclin-dependent kinase 2 bound to cyclin A (1JST) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...cP6YsNcgUtGHW8

CDK2 is shown in cyan and cyclin A in gray. Here are some structural features represented in the model.

- the C-helix (residues 45 – 55, purple),
- activation loop (residues 145– 172, red), which contains pT160 (sticks, CPK colors, labeled)
- the catalytic "triad" Lys^{33}, Glu^{51}, and Asp^{145}

Figure 28.13.7shows an animation of structural changes in just CDK2 when "apo"-CDK2 (without bound cyclin A, pdbID 1HCK) binds cyclin A (1JST).

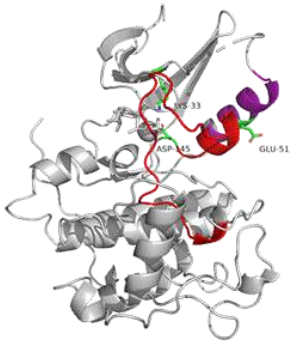

Figure 28.13.7: Structural changes CDK2 when it binds cyclin A

Gray represents the structure of CDK2 in the absence of cyclin A. The structure of just CDK2 in the presence of cyclin A is shown in magenta. Note that large shifts in the C-helix (purple) and activation loop (red) on binding cyclin A.

28.13.6: Cyclin partners of CDK1 and CDK2

CDK1 is the closest member of the CDK family to CDK2 and for which structures of the cyclin-free and authentic cyclin-bound forms can also be compared.

Depending on cyclin availability and concentration, CDK2 can bind cyclin A, B (if CDK1 expression is knocked down), and E (see Figure 28.13.1. The binding interface between CDK2 and the cyclins is quite large compared to the interface between CDK1 and cyclins. Three large aromatic side cyclin side chains (Y170, Y177, and Y258) are conserved in the binding interface. In cyclin E, the corresponding amino acids are smaller (N112, I119, and L202).

The binding interface between CDK1 and the cyclins is smaller so it appears that it might preferentially interact with cyclins A and B to gain binding affinity through the more robust interactions with the aromatic groups in the interface in the CDK2: Cyclin A and CDK2:cyclin B complexes.

A comparison of the CDK1–cyclin B and CDK2–cyclin A/B/E structures also highlights the potential for these closely related CDKs to be differentially regulated by reversible phosphorylation. The antagonistic activities of Wee1/Myt1 kinases and Cdc25 phosphatases regulate the phosphorylation status of the CDK glycine-rich loop (defined by the GXGXXG motif, residues 11–16 in CDK2). The structure of CDK2–cyclin A phosphorylated on Y15 illustrates how phosphorylation promotes a glycine loop structure that antagonizes both peptide substrate binding and the ATP conformation required for catalysis. The flexibility of the glycine-rich loop is compatible with a model in which the phosphorylated Y15 side chain is solvent exposed and accessible to both kinases and phosphatases. CDK1 is also regulated by active-site phosphorylation, and the conserved nature of the structure in this region suggests that the mechanism of inhibition is also conserved.

28.13.7: CDK substrate recognition

Local and distal sequence motifs must be used to confer specificity to the binding of specific cyclins and other proteins to specific CDKs. One interesting example is provided by examining the structure of a phospho-CDK2 Cyclin A in complex with a peptide substrate derived from the protein CDC6. Figure 28.13.8shows an interactive iCn3D model of Phospho-CDK2:Cyclin A complex with a peptide containing both the substrate and recruitment sites of CDC6 (2CCI)

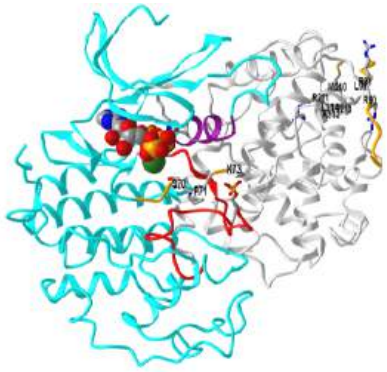

Figure 28.13.8: Phospho-CDK2 Cyclin A in complex with a peptide containing both the substrate and recruitment sites of CDC6 (2CCI) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...Ge8kdSBjxkaNd8

The color coding is the same as the models above:

- CDK2 is shown in cyan and cyclin A in gray.
- the C-helix (residues 45 – 55, purple),
- activation loop (residues 145– 172, red), which contains pT160 (sticks, CPK colors, labeled)
- the catalytic "triad" Lys^{33}, Glu^{51}, and Asp^{145}

The 30 amino acids peptide (numbers 67-96) shown in gold is a substrate for phosphorylation by the CDK2:cyclin A complex. It derives from an actual biological substrate in the protein cell division control protein 6 homolog, also called CDC6-related protein. It is involved in a checkpoint control of the cell cycle that "checks" that DNA replication is completed before mitosis. It is discontinuous in the model since part of the bound peptide is intrinsically disordered and not observed in the crystal structure.

- The 1st fragment of the CDC6 peptide (67-73) contains the binding motif sequence S/T)P*X*(K/R) (the CDC6 substrate has the sequence 70Ser-Pro-Arg-Lys). Ser 70 is the target amino for phosphorylation by CDK2:cyclin A.
- The second fragment seen in the model (amino acid 85-96) contains another binding motif, RXL (in this peptide RRL), which acts to recruit cyclin A. This binds to the sequence MRAIL (210-214) in cyclin A.

What is so interesting is that this second binding site on cyclin A for its target protein is so far away from the active site of the CDK2:cyclin A. These kinds of interactions work to determine the specificity for CDKs and the binding cyclin partners.

CDKs 7, 9, 12, and 13 phosphorylate the RNA polymerase carboxy-terminal domain (CTD). The sequence of the CTD is unusual, composed of 52 heptad repeats in humans, with the consensus sequence YSPTSPS. Extracted from cells, CTD residues S2 and S5 are the most abundantly phosphorylated serine residues, while S7 is phosphorylated to a lesser extent. CDK7 has been shown to predominantly phosphorylate S5 and S7, CDK9 to have activity towards all three serines, and CDK12 and CDK13 to predominantly phosphorylate S2.

CDKs form complexes not only with target protein substrates but other proteins which can serve as scaffolding anchors that bind both the CDK and the cyclin. Figure 28.13.9 shows an interactive iCn3D model of human CDK-activating kinase (CAK), a complex composed of cyclin-dependent kinase (CDK) 7, cyclin H, and the scaffolding protein MAT1 (6xbz).

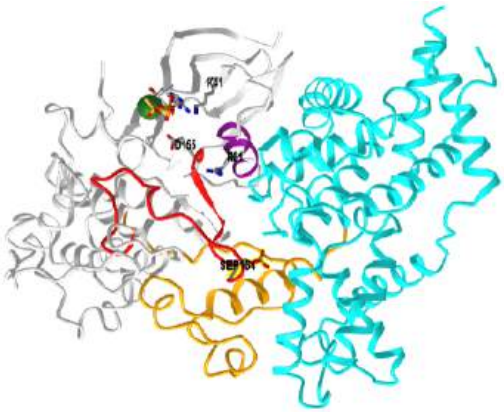

Figure 28.13.9: Human CDK-activating kinase (CAK), a complex composed of cyclin-dependent kinase (CDK) 7, cyclin H, and MAT1 (6xbz)(Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...3bdn39ARgLijB7

The gray protein is CDK7, the cyan is cyclin H and the orange MAT1. The purple again represents the C-helix of the CDK, and the red is the activation loop. The catalytic triad side chains in the active site of the CDK are shown in CPK-colored sticks. Also shown is phospho-Ser in the activation loop.

The CDK activating kinase (CAK) shown above phosphorylates the target S/T in the activation loop (which is also called the T-loop) in CDKs, activating the kinase. In addition, it regulates the initiation of transcription by phosphorylating the YSPTSPS repeats in the C-terminus of RNA polymerase II subunit RPB1. There are 15 consecutive repeats in the sequence as well as others dispersed in the C-terminal domain.

We already mentioned the motif RXL found in cyclin binding proteins that recruit them to cyclins (through, for example, their interaction with MRAIL (210-214) in cyclin A. Likewise short motifs in cyclins are used to bind to proteins that increase CDK activity or decrease it.

A number of cyclin-encoded protein-binding sites or short peptide motifs have been structurally characterized. A well-characterized example is the recycling of the cyclin RXL recruitment site that is exploited to either enhance or inhibit CDK activity. Alternatively, short motifs encoded within the cyclin sequence can be used both to dock cyclins to substrates to enhance CDK activity and alternatively to localize them to CDK regulators frequently resulting in a loss of CDK activity. Members of the p27KIP1/p21CIP1 cyclin-dependent kinase inhibitor (CKI) family share an RXL motif with RXL-containing substrates and compete with them for CDK–cyclin association. The INK (inhibitors of CDK) family of CKIs selectively inhibits CDK4 or CDK6 and, through an allosteric mechanism, disfavors CDK–cyclin binding [15]. Their tandem ankyrin repeat structures exemplified bCy CDK6–p19INK4d bind in the vicinity of the CDK hinge on the interface opposite to the surface remodeled upon cyclin association.

28.13.8: Modeling the Cell Cycle - Oscillations

Lastly, we will focus on mathematical models that show how the oscillatory behavior of CDK1/Cyclin B arises (remember than CDKs become active on binding to a cyclin). When CDK1 is activated, the cell is driven into mitosis. It is driven out of mitosis by the activation of the anaphase-promoting (APC) complex, which contains APC-Cdc20, an E3 ubiquityl ligase. Yeast Cdc20 is an activator protein that regulates the ubiquitin ligase activity of APC by binding at the right time in the cell cycle to B cyclins that contain a D box motif. This recruits the B cyclin:CDK1 to APC which ubiquitinates the cyclin B, leading to its degradation by the proteasome.

Figure 28.13.10shows the levels of both cyclin B/CDK1 (red) and cyclin A/CDK2 (green) with time. Now in your mind, imagine another curve on the graph showing similar oscillations of activated APC, only frameshifted a bit in time so that the active APC trails that of active cyclin B/CDK1. When cyclin B/CDK1 is at iitsactive peak, active APC is already beginning its rise.

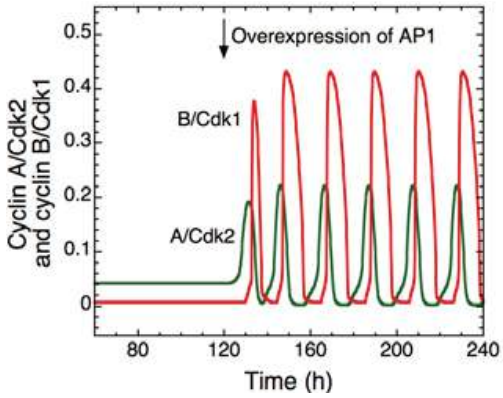

Figure 28.13.10 The switch to sustained oscillations of cyclin A/Cdk2 (in green) and cyclin B/Cdk1 (in red) is shown following the overexpression of AP1. Gérard and Goldbeter, ibid.

The dissociation constant, K_D, for CDK1 and cyclin B is about 28 nM, which represents high affinity binding. Ubiquitinylation of cyclin B and its degradation allows for the freeing of CDK1 and inhibition of its activity. The oscillatory behavior in activity occurs only on the overexpression of yet another protein, AP1.

Let's explore in detail a model proposed by Ferrell et al that accounts for the 25 min oscillatory behavior of CDK1 in Xenopus (frog) eggs. The eggs are very large and perhaps because of their size have different constraints on their cell cle cycle. For example, cells can enter mitosis before the completion of DNA synthesis. The players which regulate its activity are shown below in Figure 28.13.11

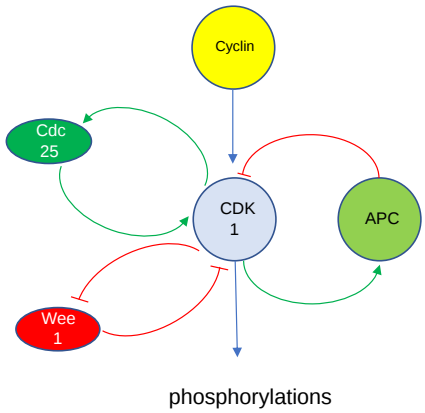

Figure 28.13.11: Proteins that help regulate the activity of CDK1 in Xenopus eggs.

- Cyclin: binds to and activates CDKs; active CDK1 drives cells into mitosis.
- APC: anaphase-promoting complex; active APC drives cell out of mitosis with its E3 ubiquitin ligase activity, modifying cyclin and targeting it for proteolysis;
- Wee1: nuclear Ser/Thr kinase
- Cdc25: cell cycle division phosphatase that activates cyclin-CDK1.

Our goal in this discussion is not only to model the actual oscillatory behavior of CDK1 but also to show you how models are built and tested. When modeling enzyme inhibition data, it is important to fit the data to many models (reversible competitive, uncompetitive, mixed, noncompetitive) to find out which best fits the data. Typically one starts with the simplest possible model and then advances to more complicated models until the data with the best statistical fit to the data is found. Other examples, which are more relevant here, involve fitting binding and kinetic data using equations that give hyperbolic (for saturation binding and simple Michaelis-Menten kinetics) and sigmoidal fits (for cooperative binding and allosteric enzymes).

So let's start with the simplest model that might lead to oscillatory activity of CDK1. In this section, active CDK1 will be designed as CDK1*.

Model 1: One-step process with negative feedback - CDK1* inhibits its own activation (for example by activating APC and hence ubiquitinylation of cyclin)

We saw in the Vcell models for the MAP kinase cascade that feedback phosphorylation of the first enzyme in the cascade (MAPKKK) by the last enzyme in the cascade, MAPKPP, leads to oscillations in enzyme activity. Could it explain the oscillations in the activity of CPK1 in Xenopus eggs? Let's make the following set of assumptions, which all be understandable from the material presented in previous chapters:

1. CDK1* is inhibited by APC* (active APC), and to make it simpler, APC* can be expressed as a simple function of CDK1* so there is just one species that vary in the flux equation;
2. CDK1 activation occurs on rapid high-affinity binding of cyclin, which is synthesized at a constant rate a1;
3. The rate of CDK1 activation to produce CDK1* is given by mass action = rate activation - rate inactivation;
4. APC is activated to APC "instantaneously" by CDK1* so APC* is a very sensitive “cooperative” function of CDK1* which can replace the APC*. For this type of "instantaneous (or highly cooperative effect), we will use the Hill equation which gives a sharp, sensitive, cooperative rise in complex instead of a simple formation of a complex between CDK1* and APC. We explored this property of the Hill equation in Chapter section 5.3.5 on Mathematical Analysis of Cooperative Binding.

Here is the Hill expression commonly use to **empirically fit** the fractional saturation of a species

$$Y = \frac{L^n}{K_D^n + L^n} \tag{28.13.1}$$

It's a bit different than the Hill equation we saw for modeling the cooperative binding of O_2 to hemoglobin (Chapter 5.3.5) since the K_D term is also raised to the power n (which is not in the actual Hill equation). However, we did see that for oxygen binding to hemoglobin,

$$\mathrm{K_D = P_{50}^n} \tag{28.13.2}$$

Hence the empirical expression used in fitting Model 1 is completely in accord with the Hill treatment of cooperativity. Again we use the Hill equation when modeling binding and kinetic data that show significant sensitivity to conditions. It gives yet another parameter to help fit the data and to test models.

Two different representations of a reaction diagram showing Model 1 are shown in Figure 28.13.12

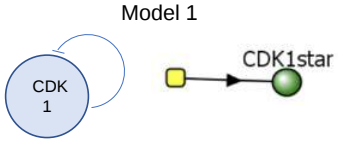

Figure 28.13.12 Two different representations of a reaction diagram for Model 1 - Activity of CDK1.

The representation on the right is from Vcell. The one on the left shows that CDK1 can inhibit itself.

Model 1 and its associated assumptions lead to the following differential equation that can easily be solved numerically in Vcell. All of the VCell outputs shown below were obtained from Vcell models kindly provided by Leslie Loew.

$$v = \frac{dCDK1^*}{dt} = a_1 - b_1\,(CDK1^*)\,(APC^*) = a_1 - b_1\,(CDK1^*)\left(\frac{CDK1^{*n1}}{K_1^{n1} + CDK1^{*n1}}\right) \tag{28.13.3}$$

This rate equation has two terms (assumption 3). The first is the rate that CDK1* forms (a constant a1 defined by the rate of cyclin synthesis) and the rate at which it is degraded by APC*. The constant b1 in the second term can be thought of as a second-order rate constant for the interaction of CDK1* and APC*, a process that inactivates CDK1*.

The [APC*] in the middle equation is replaced with the Hill equation for the effective fractional saturation concentration of APC (see assumption 4 of Model 1 described above) in the right-hand side.

$$(APC^*) = \left(\frac{CDK1^{*n1}}{K_1^{n1} + CDK1^{*n1}}\right) \tag{28.13.4}$$

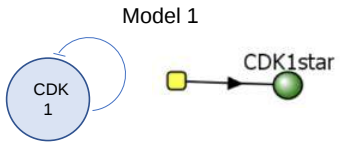
We will define the activity of the system as the rate at which CDK1* forms.

$$\text{Activity} = \frac{dCDK1^*}{dt} \tag{28.13.5}$$

Now let's see if changing the Hill coefficient n1 can cause oscillations in CDK1*.

VCell MODEL

CDK - Model 1



Initial Conditions

J	reaction rate	$\left(a1 - \frac{b1 \cdot CDK1star \cdot (CDK1star)^{n1}}{(K1)^{n1} + (CDK1star)^{n1}}\right)$
a1	user defined	0.1
n1	user defined	8.0
K1	user defined	0.5
b1	user defined	1.0

Select Load [model name] below

Load Model1CDK

Select **Start** to begin the simulation.

Select **Plot** to change Y axis min/max, then **Reset** and **Play** | Select **Slider** to change which constants are displayed | Select **About** for software information.

Move the sliders to change the constants and see changes in the displayed graph in real-time.

Time course model made using Virtual Cell (Vcell), **The Center for Cell Analysis & Modeling**, at **UConn Health**. Note that all the graphs plateau quickly at which point the CDK1* activity is constant. The graph (gray) of the curve with the highest value of the Hill coefficient (n1=24) is linear and then abruptly plateaus. The slope of the velocity curve over the entire linear part of the n1=24 graph curve is 0.1, which is the value set for the rate of activation of CDK1. Then suddenly at around 4 seconds, an "almost infinitely cooperative" shift to a constant rate of formation occurs arising from an abruptly reached rate of inactivation of CDK1* by the APC complex. These graphs do not show oscillations.

Now let's see the graph with no feedback inhibition, much as we did with the MAPK cascade in Chapter 12.4. The easiest way to do that is to set b1, the "second" order rate constant for the interaction of CDK1* and APC* in the model to 0. The graph is shown in Figure 28.13.13

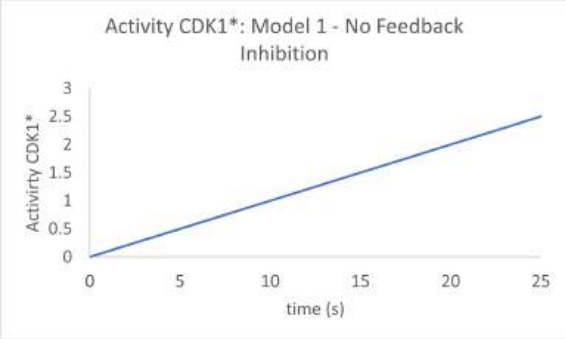

Figure 28.13.13 Activity of CDK1* in Model 1 in the absence of feedback inhibition.

The activity of CPK1* continually increases. When feedback inhibition is added, the curve "bends" to a plateau, but it does **not** start to decrease and shows no signs of oscillations. Time to move on to a more complex model!

Model 2: Two-species model with activation and inhibition-

This model is more complicated and shows 2 species (CDK1 and APC) both of which are activated and inhibited. We need 2 mass action differential equations, one for each. Figure 28.13.14

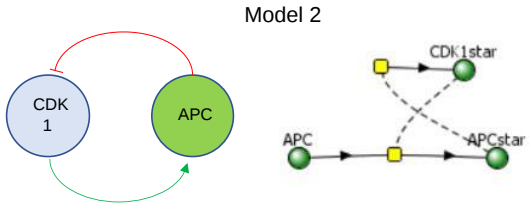

Figure 28.13.14 Two different representations of a reaction diagram of Model 2

The equation for dCDK1*/dt is the same as in Model 1, as is repeated below.

$$v = \frac{dCDK1^*}{dt} = a_1 - b_1 \left(CDK1^*\right)\left(APC^*\right) = a_1 - b_1 \left(CDK1^*\right)\left(\frac{CDK1^{*n1}}{K_1^{n1} + CDK1^{*n1}}\right) \tag{28.13.6}$$

Likewise, the equation for dAPC*/dt consists of two terms, one for its activation and one for its inhibition.

$$v = \frac{dAPC^*}{dt} = k_f APC - k_r APC^* \tag{28.13.7}$$

Assume that k_f, the rate constant of the activation of APC, is equal to a constant a_2 times a Hill function of CDK1*, and k_r, the rate constant for the inactivation of APC*, is simply b_2. Then the equation becomes

$$v = \frac{dAPC^*}{dt} = a_2 \left(\frac{CDK1^{*n2}}{K_2^{n2} + CDK1^{*n2}}\right) APC - b_2 APC^* \tag{28.13.8}$$

Let's look at the output graphs for the following initial condition:

- CDK1* = 0 uM
- APC = 1 uM
- APC* = 0 uM

VCell MODEL

Select **Start** to begin the simulation.

Select **Plot** to change Y axis min/max, then **Reset** and **Play** | Select **Slider** to change which constants are displayed | Select **About** for software information.

Move the sliders to change the constants and see changes in the displayed graph in real-time.

Time course model made using Virtual Cell (Vcell), **The Center for Cell Analysis & Modeling**, at **UConn Health**. Funded by NIH/NIGMS (R24 GM137787); Web simulation software (miniSidewinder) from Bartholomew Jardine and Herbert M. Sauro, University of Washington. Funded by NIH/NIGMS (RO1-GM123032-04)

Figure 28.13.15shows statics graphs of just CDK1* activity vs time for n1 values of 1, 4, 8, and 24 for Model 2.

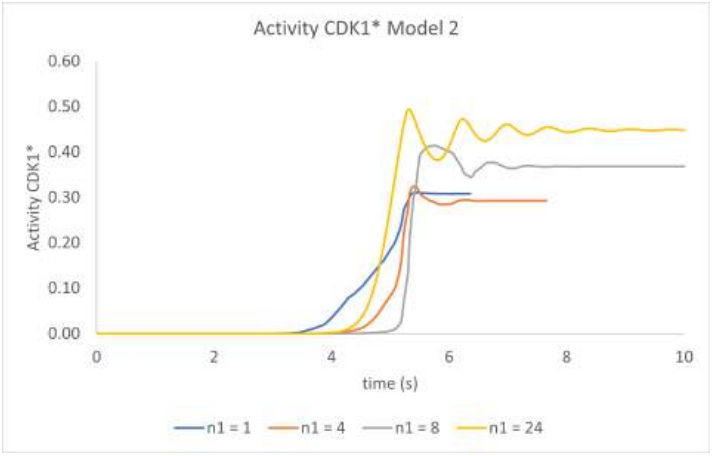

Figure 28.13.15 Graphs of just CDK1* activity vs time in Model 2 for n1 values of 1, 4, 8, and 24.

Wow! By simply adding an additional species to the model and a second differential equation for it, we see the first signs of oscillatory behavior in the activity of CDK1*. The output at higher n1 values is best described as damped oscillations. Now let's try a final third model.

Model 3: Three species model with activation and inhibition-

This model contains the enzyme Plk1 (Polo-like kinase 1, also called serine/threonine-protein kinase 10-A), along with APC and CDK1. These three species are all activated and inhibited. Assume that Plk1 is activated by CDK1 and that it also helps activate APC. Following the arrows in the left part of the figure below shows that it acts as an "intermediary" between CDK1 and APC. Two different representations of a reaction diagram of Model 3 are shown in Figure 28.13.16

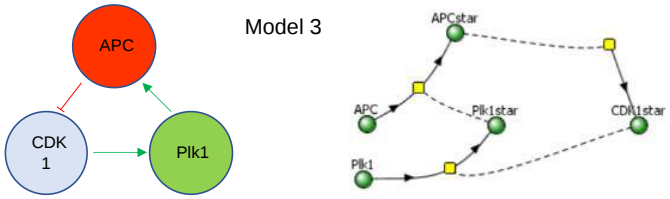

Figure 28.13.16 Two different representations of a reaction diagram of Model 3

We have 3 species, so we need three differential equations, as shown below.

$$v = \frac{dCDK1^*}{dt} = a_1 - b_1 \left(CDK1^*\right)\left(\frac{APC^{*n1}}{K_1^{n1} + APC^{*n1}}\right) \tag{28.13.9}$$

$$v = \frac{dPlk1^*}{dt} = a_2 \left(1 - Plk1^*\right)\left(\frac{CDK1^{*n2}}{K_2^{n2} + CDK1^{*n2}} - b_2 CDK1^*\right. \tag{28.13.10}$$

and

$$v = \frac{dAPC^*}{dt} = a_3 \left(1 - APC^*\right)\left(\frac{Plk1^{*n3}}{K_3^{n3} + Plk1^{*n3}} - b_3 APC^*\right. \tag{28.13.11}$$

The equation for activation of CDK1 is the same as in Models 1 and 2.

The equation for the activation of APC is similar to Model 2 with k_f modeled as a Hill function of Plk1star, which activates APC

The equation for the activation of Plk1 is similar to Models 2 and 3 with k_f modeled as a Hill function of CDK1star which activates Plk1

Although you probably can't write these differential equations by yourself, hopefully, you can see that they make sense.

Figure 28.13.17shows graphs of just CDK1* activity vs time for n1 values of 1, 4 and 8 for Model 3

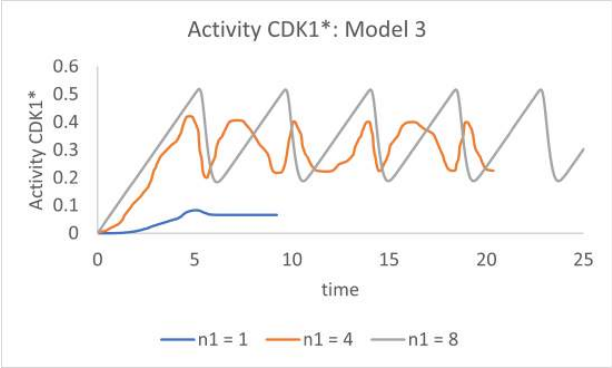

Figure 28.13.17: Graphs of CDK1* activity vs time for n1 values of 1, 4 and 8

Finally, we observe oscillatory behavior in the activity of CDK1*, but only for higher values of the Hill coefficient (n1 = 4 and 8).

Other models can produce oscillation, but this one seems perhaps most comprehensible to students who have studied mass action equations along with Hill binding and kinetic equations. The three-component system described in Model 3 is of course embedded

in a large pathway of inputs and outputs so other factors most likely affect the oscillatory behavior.

28.14: Programmed Cell Death

28.14.1: Introduction

We have discussed often how cell signaling might go awry and lead to cancer. However, there are signaling systems that lead to cell death. There are many ways in which cells can die. We'll discuss not "accidental" cell death but one, **apoptosis**, that is programmed into the genome and highly regulated. Figure 28.14.1 shows how normal cell proliferation and growth can be modulated by two classes of genes, oncogenes that cause proliferation, and tumor suppressor genes that inhibit it.

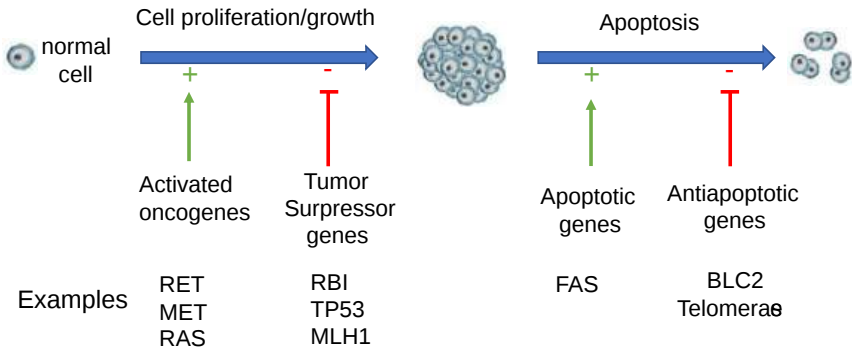

Figure 28.14.1: Overview of oncogenes, tumor suppressor genes, apoptotic genes, and antiapoptotic genes. Adapted from https://www.researchgate.net/figure/...fig1_332774933. Creative Commons Attribution 3.0 Unported

Apoptosis involves chromatin aggregation and cleavage, the concentration of cell material, and apoptosis body formation. Mutations to aberrantly activate oncogenes or inhibit the expression of tumor suppressor genes lead to cancer. These cells would ideally undergo programmed cell death or **apoptosis**. As with control of proliferation, some genes promote apoptosis as well as anti-apoptotic genes which inhibit programmed cell death. Dysregulation of these can also cause cancer. Apoptosis is an important mechanism to kill viral-infected cells. However, this can go too far. For example, T helper cells (T_H) infected with the HIV virus die. However, the collapse of the population of these cells is in part attributed to apoptosis.

As we learn more about programmed cell death, it is clear that apoptosis is not the only way the genome is programmed to cause cell death. These other ways include:

autophagy - This is a catabolic pathway in which intracellular proteins, protein complexes, and organelles are collected into large autophagosomes in which incorporated lysosomes and their degradative enzymes reprocess damaged or unneeded cell material. It is a highly programmed process, which if dysregulated, could lead to cell death.

necroptosis: Infections and toxins are known to cause necrosis, which is a "passive" form of cell death. In contrast, programmed necrosis is called necroptosis.

28.14.2: Overview of apoptosis.

Apoptosis consists of 4 steps:

- the decision to activate the pathway;
- the actual "suicide" of the cell;
- engulfment of the cell remains by specialized immune cells called phagocytes;
- degradation of the engulfed cell.

The actual steps in cell death require:

- condensing the cell nucleus and breaking it into pieces
- condensing and fragmenting of cytoplasm into membrane-bound apoptotic bodies; and
- breaking chromosomes into fragments containing multiple numbers of nucleosomes (a nucleosome ladder)

To commit suicide must be an extremely important cellular decision. Hence you would expect this process to be regulated and highly complicated. When would it be advantageous to the organism to want a cell to kill itself (or be told

to kill itself)? Cell death would be used to:

- "sculpt" an organism during development such as during embryo development, metamorphosis, and tissue atrophy
- regulate the total number of cells.
- defend and remove unwanted or dangerous cells like tumor cells, virally infected cells, or immune cells that recognize self (which could lead to autoimmune disease).

Unregulated apoptosis could exacerbate or cause diseases such as:

- AIDS, in which T helper cell numbers plummet. Part of the dramatic decline in these cells might be caused by health T helper cells being tricked into committing suicide;
- neurodegenerative diseases like Alzheimer's;
- ischemic stroke, when restricted blood flow to certain regions of the brain can lead to neural death through increased apoptosis'
- cancer, in which tumor cells lose their ability to undergo apoptosis;
- autoimmune disease, in which self-reactive immune cells trick normal body cells to kill themselves;
- viral disease;

Apoptosis does not require new transcription or translation, suggesting that the molecular machinery required for cell death lay dormant in the cell, and just requires appropriate activation. What "signals" induce apoptosis?

Signals can be extracellular:

- a hormone (such as thyroxine that causes apoptosis in tadpole tails
- a lack of a "survival" signal (which inhibits apoptosis) such as a growth factor
- a cell:cell contact from an adjacent cell

Signals can be intracellular:

- ionizing radiation
- virus infection
- oxidative damage from free radicals

28.14.3: Apoptosis

Much of this section was derived directly from the following reference, with modifications and additions.

There are two apoptotic pathways in cells:

- The **extr**insic pathway: **extr**acellular apoptotic ligands bind to membrane death receptors, leading to the assembly of the **death-inducing signaling complex (DISC)**. Similar to the inflammatory response we have already discussed in Chapter 5, two specific cysteine-aspartic proteases (caspases) are activated, caspases 8 and 10. These activate other caspases in an amplification of the process.
- The **intr**insic pathway: intracellular signals such as damaged DNA or proteins are sensed by Bcl-2 proteins on the outer membrane of mitochondria. The BcL-2 (B-cell lymphoma-***2***) family of proteins all have Bcl homology domains. Their functions are carried out at the outer mitochondrial membrane. Some members of this family are antiapoptotic (Bcl-2, Bcl-xL, Mcl-1, Bcl-w, A1/Bfl-1, and Bcl-B/Bcl2L10), while others are proapoptotic (Bid, Bim, Puma, Noxa, Bad, Bmf, Hrk, Bik Bax, Bak, and Bok/Mtd). Apoptosis leads to activation of Bax/Bak, which initiate mitochondria degradation, starting with damage to the outer membrane and release of pro-apoptotic proteins like the inner membrane space protein cytochrome C into the cytoplasm. This leads to the assembly of the apoptosome and activation of caspases 9 and 13. Again this is very similar to the formation and activity of the inflammasome which we saw in Chapter 5.

An overview of the extrinsic and intrinsic apoptotic pathways is shown in Figure 28.14.2 We will explore some of the proteins involved in the section below.

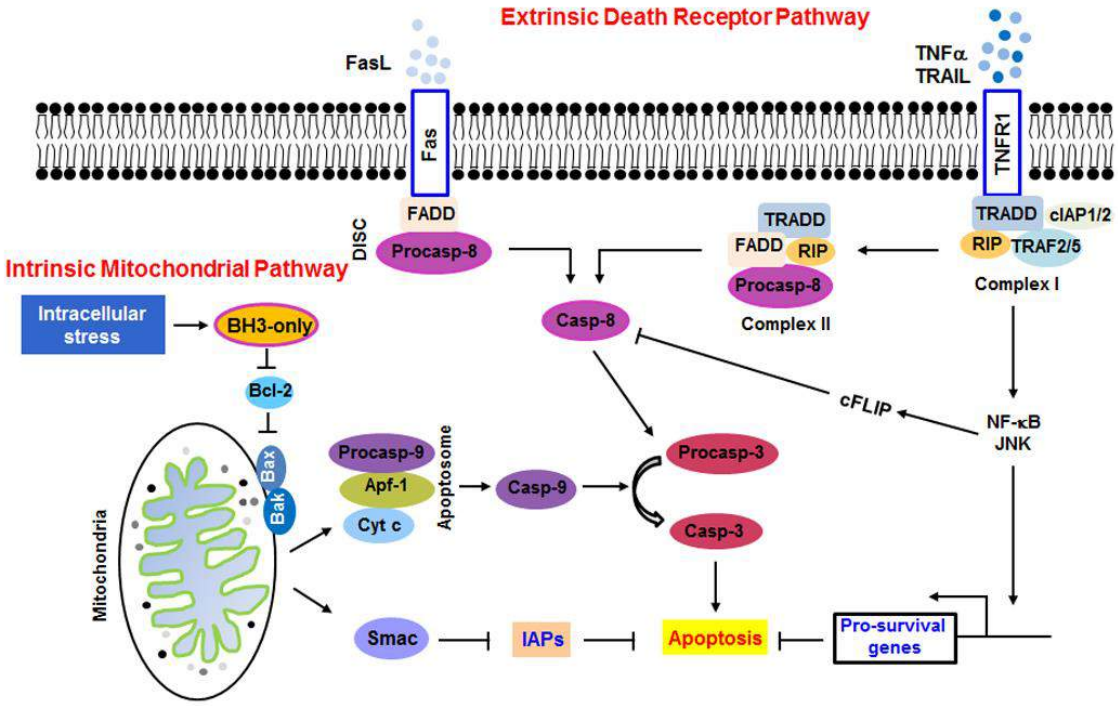

Figure 28.14.2: Overview of the extrinsic and intrinsic apoptotic pathways

The extrinsic death receptor pathway is activated by death receptor ligands, including FasL, TNF-α, DR3, DR4, and DR5 or TRAIL, etc. FasL is an integral membrane protein found in cells. In addition, there are soluble versions of it. The binding of FasL to Fas, an integral membrane protein, initiates the recruitment of FADD, TRADD, and caspase-8 to form the DISC complex, which in turn activates caspase-8 and downstream caspases. The binding of tissue necrosis factor alpha (TNF-α) to its receptor, TNFR1 (a Fas protein), initiates the recruitment of TRADD, RIP, TRAF2/5, and cIAP1/2 to form complex I, which activates NF-κB and JNK pathways and increases the transcription of pro-survival genes. However, the modification of RIP or degradation of cIAP1/2 can lead to the disassociation of complex I. TRADD and RIP then associate with FADD and caspase-8 to form complex II, the so-called death complex.

The intrinsic death receptor pathway is initiated by the BH3-only protein, BCL-2 homology 3 (BH3-only), under intracellular stress such as DNA damage. The BH3-only proteins activate **apoptosis by binding and neutralizing the pro-survival proteins**, allowing Bax/Bak to homo-oligomerize and permeabilize the mitochondria. For example, BH3-only protein can inactivate Bcl-2 and prevent Bcl-2 from effectively neutralizing Bax and Bak, leading to the activation of Bax and Bak. The activated Bax and Bak on the mitochondrial membrane alter its permeability, depolarizes the membrane, and leads to the release of cytochrome c and Smac, normally found in the inner membrane space, from mitochondria. Figure 28.14.3shows how monomeric BAK can form an altered dimeric form in the presence of detergent.

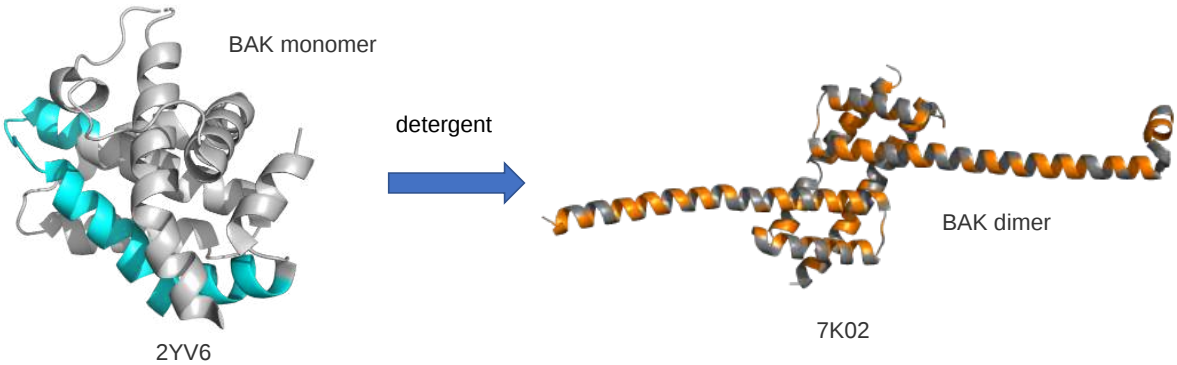

Figure 28.14.3: Monomeric and membrane associated dimeric BAK

The extended left-hand helix on the right-hand side is color-coded to show nonpolar residue (orange) and the polar/charged amino acids in gray. That same section of the protein is shown in cyan in the monomeric protein to the right. One can easily imagine how the apparent amphiphilic helices of the BAK dimer could bind to the outer mitochondrial membrane and alter its structure.

Cytoplasmic cytochrome c associates with Apaf-1 and caspase-9 to form the apoptosome, which activates caspase-9 and downstream executing caspases. Smac can regulate apoptosis by inhibiting the inhibitor of apoptosis proteins (IAPs)." Zhou and Li. Chapter 9, Apoptosis in Polycystic Kidney Disease: From Pathogenesis to Treatment.

Another diagram of the extrinsic and intrinsic apoptotic pathways that show more detail on the domain structures of some key protein and the "executioner" caspases is shown in Figure 28.14.4

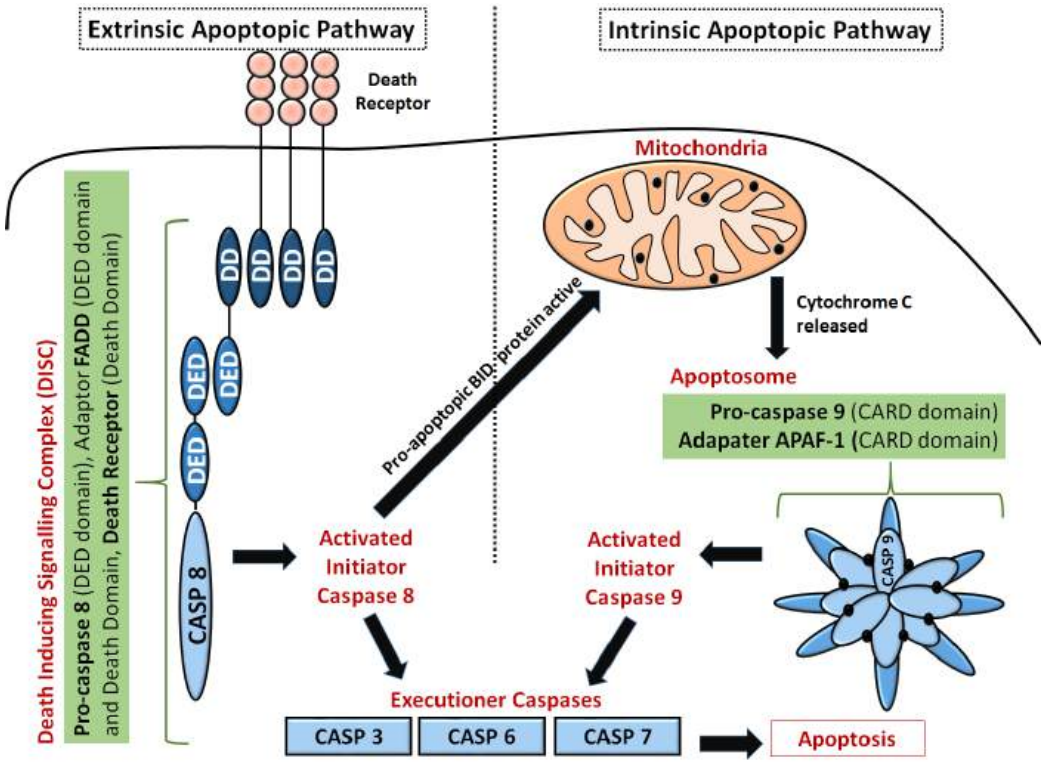

Figure 28.14.4: Extrinsic and intrinsic apoptotic pathways https://commons.wikimedia.org/wiki/File:Apop1.png

Extrinsic pathway: The first step is an association of death receptors with their cognate ligands, which leads to the recruitment of adaptor molecules, including FAS-associated death domain protein (FADD), and then caspase 8. Caspase 8 cleaves and activate caspase 3 and caspase 7 and can proteolytically activate BH3-only protein BH3-interacting domain death agonist (BID). Proteolytically activated BID (tBID) promotes mitochondrial membrane permeabilization through the activation of the assembly of BAX-BAK channels and represents the main link between the extrinsic and intrinsic pathways.

Now let's look more closely at the ligands that activate the extrinsic pathway, as shown in Figure 28.14.5

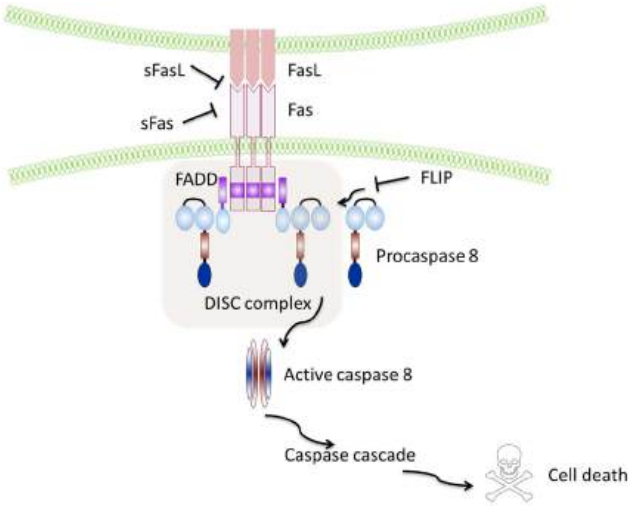

Figure 28.14.5: Fas/FasL activation pathway

Soluble Fas and soluble FasL bind to the respective ligands inhibiting activation of the pathway. FLIP inhibits the activation of caspase-8 and is thus a major anti-apoptotic protein. Volpe E et al. (2016) Fas–Fas Ligand: Checkpoint of T Cell Functions in Multiple Sclerosis. Front. Immunol. 7:382. doi: 10.3389/fimmu.2016.00382. Creative Commons Attribution License (CCBY).

Now we are in a position to examine the actual structure of some key components of the extrinsic pathway.

28.14.4: Active human apoptosome with procaspase-9 (5JUY)

Figure 28.14.6shows an interactive iCn3D model of the active human apoptosome with procaspase-9 (5JUY)

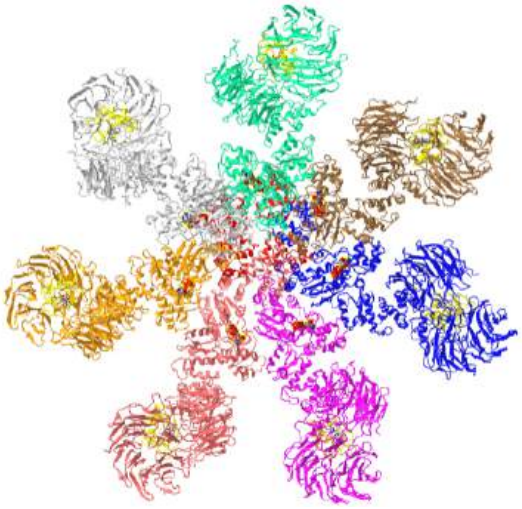

Figure 28.14.6: Active human apoptosome with procaspase-9 (5JUY) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...ek6wzp36TGUpp6 (long load time)

Each of the 7 different subunits of the apoptotic protease-activating factors (Apaf-1) is shown in a different color. The seven yellow subunits are cytochrome Cs. The 4 red subunits underneath the disk plane of the other subunits are the zymogen procaspase 9s. The small spacefill CPK color ligands are 2'-deoxyadenosine 5'-triphosphate. The Apaf-1:pc9 pairs, interacting through their CARD domains, form a spiral underneath the disk.

Apaf-1 can be considered an adaptor protein with an N-terminal **c**aspase **a**ctivation and **r**ecruitment **d**omain (**CARD**), followed by a **nucleotide-binding and oligomerization domain (NOD**, also known as **NB-ARC**).

Figure 28.14.7shows the domain structure of caspase 9 and Apaf-1.

Figure 28.14.7: domain structure of caspase 9 and Apaf-1.

The presence of CARD domains in both allows their mutual binding and the assembly of the full apoptosome.

28.14.5: An AlphaFold model of the Cas 9 zymogen

Figure 28.14.8shows an interactive iCn3D model of human Cas 9 AlphaFold model (P55211)

Figure 28.14.8: Human Cas 9 AlphaFold model (P55211) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...74TiVhNfiX4376

The green is the CARD domain and the salmon is the caspase (peptidase_C14) domain. Procaspase 9 is cleaved at Asp 315 (sticks, CPK colors, labeled) into two chains for activation. The activated Cas 9 has two key active site residues, His 237 and the catalytic nucleophile C287 (sticks, CPK colors, labeled). Phosphorylation at Thr-125 by MAPK1/ERK2 blocks procaspase activation by proteolysis. to block caspase-9 processing

28.14.6: Apaf-1

Oligomeric Apaf-1 mediates the cytochrome c-dependent autocatalytic activation of pro-caspase-9 (Apaf-3), leading to the activation of caspase-3 and apoptosis

Figure 28.14.9shows an interactive iCn3D model of Human Apaf-1 AlphaFold model (O14727)

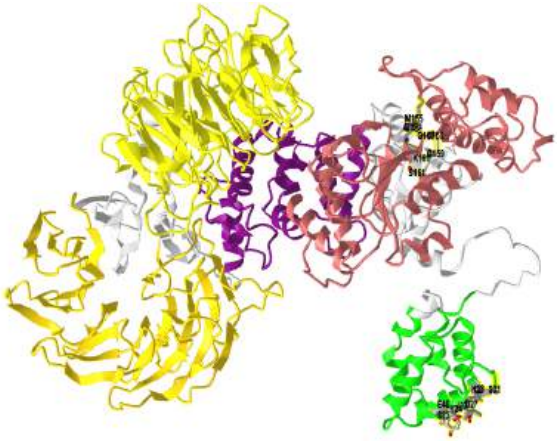

Figure 28.14.9: Human Apaf-1 AlphaFold model (O14727) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...9ZrDFxEpdHR9K6

Domain colors:

- The green is the N-terminal CARD domain
- light red NB-ARC (nucleotide-binding and oligomerization domain - NOD)
- purple is Apaf
- yellow is WD40, gold the C-terminal WD40.

Again the model above does not show the actual structure since the intrinsically disordered regions are not more structured.

The CARD domain of Cas 9 inhibits the catalytic domain of Cas 9. When the CARD domain of Cas 9 interacts with the CARD domain of Apaf-1, the autoinhibition is removed. In addition, the Apaf-1 stimulates the catalytic activity of the protease.

Before assembly into the apoptosome, Apaf-1 is monomeric and in an inactive dATP or ATP conformation. When cytochrome C is released into the cytoplasm, it binds to the WD domains, facilitating a dATP/ATP-cleavage associated conformation change in the Apaf-1, which in the presence of heat shock protein 70 (Hsp) folds to form which leads to the assembly of the active apoptosome.

28.14.7: Fas - **Tumor necrosis factor receptor superfamily member 6 -** P25445

Figure 28.14.10shows an interactive iCn3D model of Fas-Tumor necrosis factor receptor superfamily member 6 AlphaFold model (P25445)

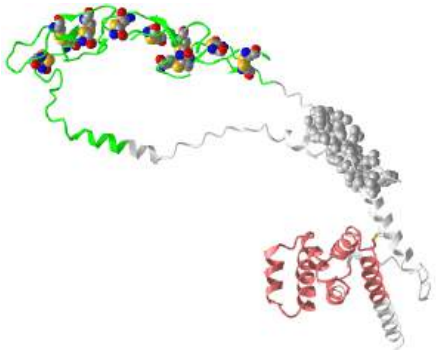

Figure 28.14.10: Fas-Tumor necrosis factor receptor superfamily member 6 AlphaFold model (P25445) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...Dpm3neKspeCrP8

The green is the N-terminal TNFR/NGFR domain that is highly enriched in Cys (spacefill, color CPK) in disulfide bonds. The gray spheres are the transmembrane helix. The Red shows the Death Domain.

The death domains are common protein:protein binding domains that serve as adaptors or scaffolds. They can form homo- or heterodimers with other proteins containing the domain which is a part of the CARD domain, DED (Death Effector Domain), and PYRIN.

28.14.8: Human FasL and a soluble Fas Receptor DcR

Figure 28.14.11shows an interactive iCn3D model of the complex of Human FasL and Its Decoy Fas Receptor DcR (4MSV)

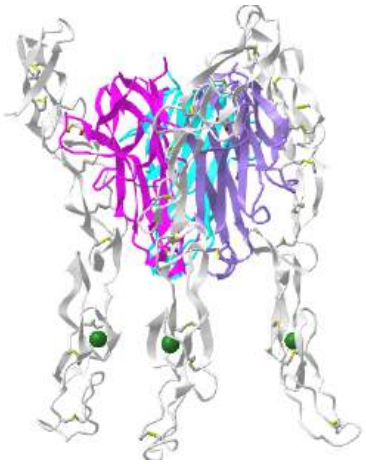

Figure 28.14.11: Complex of Human FasL and Its Decoy Fas Receptor DcR (4MSV). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...bHLh8fBNZ7E5Q9

The three gray subunits are soluble decoy receptor (DcR) versions of the Fas TNFR/NGFR domain, which again is highly enriched in Cys. It is structurally very similar to its typical membrane receptor ligand Fas (**tumor necrosis factor receptor superfamily member 6** - P25445)

DcR is a secreted member of the TNF family and disrupts apoptosis, which can allow tumors to survive.

28.14.9: Fas and FADD death domain interactions

Figure 28.14.12shows an interactive iCn3D model of two Fas death domains bound to two FADD death domains (3EZQ)

tetrameric arrangement of four FADD death domains bound to four Fas death domain

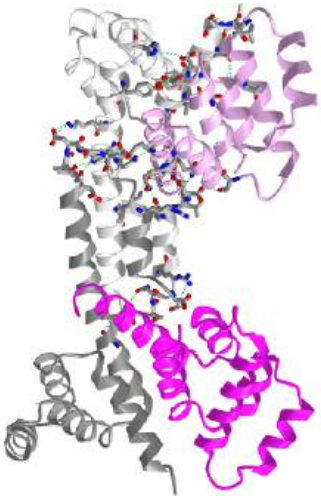

Figure 28.14.12: two Fas death domains bound to two FADD death domains (3EZQ). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...S9Uj45N4mqT5G8

Two Fas death domains are shown in a different shade of gray. The two FADD death domains are shown in a different shade of magenta. Each domain consists of six alpha-helical bundles. Interaction between the dark and light grays Fas death domains and between the light gray Fas and light magenta FADD death domains are shown with side chains in stick with CPK colors.

The Fas-FADD-procaspase 8 complex is collectively called the **Death Inducing Signaling Complex (DISC)**. The Fas-FADD interactions lead to the binding of capase 8 and the completion of the DISC. The actual disc appears to contain 4 FADD death domains bound to 4 Fas death domains. Conformational changes allow both FADD:Fas and Fas:Fas interactions, some of which are weak but when formed switch on the activity of the building complex. The need for 4 monomers probably prevents accidental assembly which would be deadly to the cell.

28.14.10: **Mechanism and regulation of apoptosis**

Caspases

Characterization of apoptotic mechanisms and cellular players started with the study of *C. elegans*, a roundworm. The mature worm has about 1000 cells. During development, 131 cells die. Two mutations were found in which the 131 cells did not die. These mutations were called ced3 and ced4 (**ced** stands for **ce**ll **d**eath). The sequence of ced 3 was very homologous to a protein called **i**nterleukin **c**onverting **e**nzyme (**ICE**) which is required for proteolytic activation of the precursor to interleukin 1, a protein hormone released by certain immune cells during activation and which can promote inflammation. This suggested that proteolysis was required for apoptosis. Subsequent studies show that a whole family of proteases (about 10 in humans) called caspases (ICE has been renamed caspase 1) are required for programmed cell death. These proteases are found in the cell in an inactive form which must undergo limited proteolysis for activation. These caspases form a cascade of proteases which are activated in this process. They are endoproteases that have an active site Cys (**C**) and cleave at the C-terminal side of Asp residues (**asp**) and hence are known as **casp**ases - **c**ys containing-**asp** specific prote**ases**).

ICE is not normally involved in apoptosis, but its artificial activation in cultured mammalian cells can lead to it. Each caspase had the same sequence as they are designed to cleave, so it became evident that they probably cleave each other in an activation cascade mechanism, similar to the coagulation protease cascade of activation of precursors (zymogens) of serine proteases which activate the next in the series. Two series of caspases seem to be involved. One set initiates the process of caspase activation. Just as in the clotting system, the question of what activates the first caspase appeared problematic until investigators found that the initiator caspase can be activated if they aggregate to a critical concentration. This could occur by binding a suicide signal molecule at the cell surface. Conformational

changes in the receptor can lead to aggregation of surface receptor molecules with concomitant aggregation of intracellular caspases which interact with the aggregated receptors.

Intracellular signals

How might intracellular activators of apoptosis (like radiation or reactive oxygen species) work? Research indicated the involvement of mitochondria in the apoptotic pathway. Believe it or not, **cytochrome C**, the heme protein which acts as a water-soluble mobile carrier of electrons in mitochondrial oxidative phosphorylation, shuttling electrons through cytochrome C oxidase or complex IV, leaks out of the intermembrane space and binds to a cytoplasmic protein called **Apaf-1** for **a**poptotic **p**rotease **a**ctivating **f**actor-**1**. This then activates an initiator caspase-9 in the cytoplasm.

These proteins seem to leak out of mitochondria after a collapse of the electrochemical potential across the inner membrane. The potential collapses as a consequence of the opening of a channel called a nonspecific inner membrane **permeability transition pore**, composed of both an inner membrane protein (**a**denine **n**ucleotide translocator - **ant**) and an outer membrane protein (porin, the **v**oltage-gate**d** **a**nion **c**hannel - **VDAC**). These proteins act together, probably at sites where the inner and outer membranes are in contact. This channel passes anything smaller than molecular weight 1500. Collapsing the proton gradient uncouples oxidation and phosphorylation in the mitochondria. Changes in ionic strength cause a swelling of the matrix. Since the inner membrane is highly convoluted and has a much greater surface area than the outer membrane, swelling of the matrix leads to a rupture of the outer membrane, spilling the inner membrane space proteins (cytochrome C and Apaf-1) into the cytoplasm.

What causes all these changes in the mitochondria? Several interrelated events appear to be involved:

1. disruption of ox-phos. and electron transport, caused by irradiation and certain second messengers such as ceramide.
2. changes in cell redox potential and generation of **r**eactive **o**xygen **s**pecies (**ROS**).
3. DNA damage (caused by radiation, ROS, etc). A protein called p53 is often expressed in cells with DNA damage. Expression of this protein results in inhibition of cell division, or apoptosis, both of which would keep the damaged cell from becoming a tumor cell. Hence the p53 gene is a tumor suppressor gene. It is inactivated by mutation in approximately 50% of all human tumor cells studied. p53 can induce gene expression. Of the 14 different genes whose expression is significantly altered by p53, many seem to be used by cells to generate or respond to oxidative stress. Cells undergo p53 apoptosis through oxidative damage.
4. increases in intracellular calcium ions through signal transduction.

Caspase targets:

Apoptosis involves:

1. condensing of the cell nucleus and breaking into pieces
2. condensing and fragmenting of cytoplasm into membrane-bound apoptotic bodies
3. breaking chromosomes into fragments containing multiple numbers of nucleosomes (a nucleosome ladder)

How does caspase activation lead to these events? A protein has been uncovered that when cleaved by a caspase leads to a nuclear breakup. The target protein is usually bound to another protein, a DNA endonuclease. When the target protein is cleaved, the DNase is free to migrate to the nucleus and begin the execution. Membrane changes in apoptosis occur when caspase 3 cleaves gelsolin, a protein involved in maintaining cell morphology. The cleaved gelsolin cleaves actin filaments inside the cell. Another protein is necessary to form apoptotic bodies: a kinase named **p21-activated kinase 2 (PAK-2)**. This kinase is activated by caspase-3 by limited proteolysis. Caspases also cleave beta-amyloid precursor protein which might generate more beta-amyloid protein, causing neural cell death in Alzheimer patients.

Controlling Apoptosis

It should be clear that cells keep tight control of the caspases. Two players which appear to inhibit apoptosis are the mitochondrial proteins **Bcl-2** and **Bcl-X**, which can block the release of cytochrome C from the mitochondria. The Bcl family of proteins has a hydrophobic tail and binds to the outside surface of mitochondria and other organelles like the

nucleus and endoplasmic reticulum. These proteins seem to be able to form ion channels in liposomes. So far 15 members of this family (related to ced-9 of C. elegans) have been discovered in humans. Bcl-2 can also bind to Apaf-1 (mentioned above) and inhibit its activation of initiator caspase-9. Bcl-2 is regulated by changes in the expression of the Bcl-2 gene, by post-translational phosphorylation by kinases, or by cleavage by caspases. Overexpression of Bcl-2 can cause a cell to become a tumor cell. Other members of the family, **BAX** and **BAD** bind to mitochondria and facilitate apoptosis by stimulating cytochrome C release.

In addition, other proteins called **IAP**s (**i**nhibitors of **ap**optosis) can inhibit caspase or other apoptotic proteins. Some viruses make the protease to keep their host cells viable.

Cell Membrane Events

Cells can be instructed to undergo apoptosis through cell surface interactions with other cells which are often immune cells. One of the jobs of the immune cell is to destroy an altered cell (for example a virally-infected cell or a tumor cell). Immune cells themselves must also die after they are activated in an immune response. Activated lymphocytes (like cytotoxic T cells or natural killer cells) can target and kill cells using several ways which can involve apoptosis. In one, an activated lymphocyte binds to a target cell (like a virally infected cell) and secretes perforin, a protein that assembles in the target cell membrane to form a transmembrane channel. Other proteins released by the activated lymphocyte can enter the target cell through the pore and initiate apoptosis. One such protein that enters, granzyme B is a protease that activates caspases in the target cell.

Target cells that express a specific membrane protein called **CD95 (**also called **Fas**) are also targeted for apoptosis. This protein receptor, a member of the tumor necrosis factor receptor (TNFR) binds to a membrane protein-ligand on the surface of an activated lymphocyte called CD95 Ligand - CD95L- (also called the **Fas ligand**). On binding, the CD95 (Fas) receptors on the target membrane aggregate after conformation changes. An adapter protein in the cell, FADD (Fas-associated death domain) binds to the aggregated cytoplasmic domain (the death domain) of CD95 (Fas) and recruits inactive caspase-8 to the site, where their concentration increases. This leads to the activation of the caspases.

This mechanism is used to get rid of activated lymphocytes after they have finished their work. Activated immune cells start expressing Fas a few days after activation, targeting them for elimination. Some cells which have been stressed express both Fas and Fas ligands and kill themselves. Various cells express CD95 (Fas), but CD95L (Fas-Ligand) is expressed predominately by activated T cells.

Cell surface events also can inhibit apoptosis. The binding of "survival" factors (like growth factors) to cell surface receptors can shut off apoptotic pathways in the cells. Some survival factor receptors are coupled to **PI-3-kinase (phosphoinositol-3-kinase**) through the G protein **ras (p21)** which is targeted to the cell membrane by post-translational addition of a hydrophobic anchor. The activated kinase produces PI-3,4-P2 and PI-3,4,5-P3, which activates **Akt**, a Ser/Thr protein kinase. This activated kinase phosphorylates the proapoptotic-protein BAD, which then becomes inactive. In addition, active Akt phosphorylates procaspase, which in its phosphorylated form will not interact with cytochrome C, hence inhibiting apoptosis.

The endpoint of apoptosis is the engulfment of the fragmented cell by a phagocytic cell (such as a macrophage). In a recent article (Nature, 405, pg 85, 2000), it was shown that the activity of phagocytes could be inhibited stereospecifically by the addition of phosphatidyl serine (PS) to the mixture, but not by other negative phospholipids. If you remember from our description of lipids, PS is found exclusively in the inner leaflet of red blood cells). The investigators cloned a gene from the phagocytic cell for a receptor that recognizes PS. When added to ordinary T and B lymphocytes (immune cells), these cells could also take up apoptotic cells. The gene is homologous to genes in Drosophila (fruit fly) and *C. elegans* (roundworm) suggesting that it is conserved in nature. The message: when cells undergo apoptosis, PS, normally found only in the inner leaflet, is exposed to the outside. It can then bind to receptors on phagocytic cells to complete the process of apoptosis.

28.14.11: Therapeutics

Figure 28.14.13shows points of therapeutic intervention in the intrinsic and extrinsic apoptotic signaling pathways.

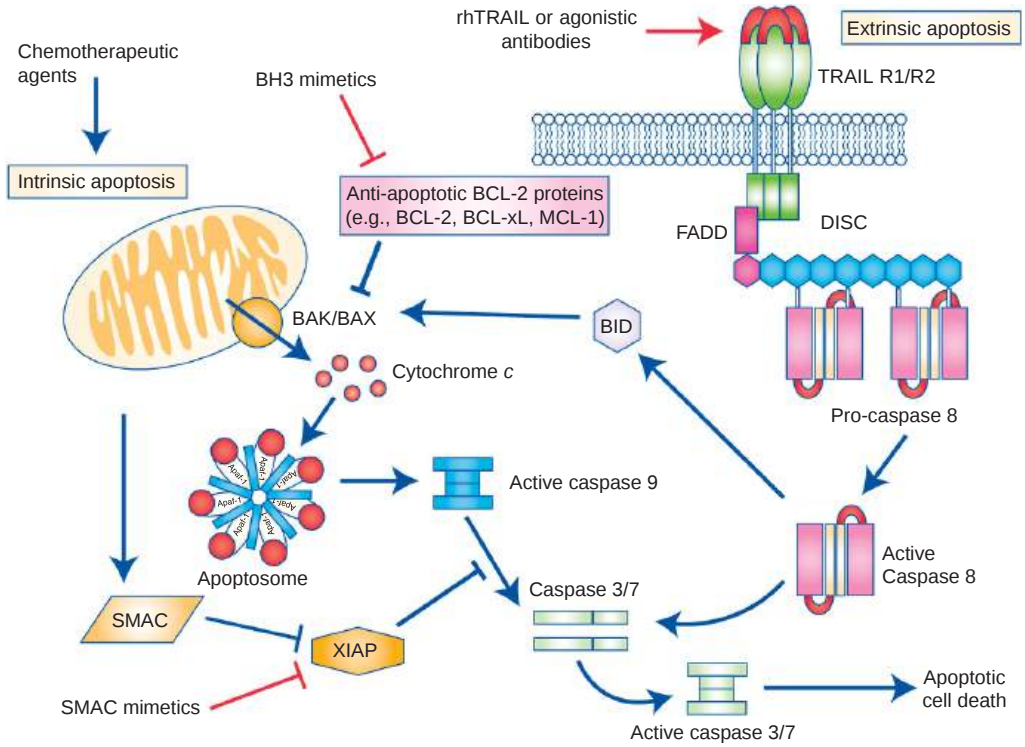

Figure 28.14.13: **Intrinsic and extrinsic apoptotic signaling pathways and points of therapeutic intervention.** Fox, J., MacFarlane, M. Targeting cell death signaling in cancer: minimizing 'Collateral damage'. *Br J Cancer* **115,** 5–11 (2016). https://doi.org/10.1038/bjc.2016.111. Intrinsic and extrinsic apoptotic signaling pathways and points of therapeutic intervention. Apoptosis can be initiated by signals originating from either the plasma membrane via death receptor ligation (extrinsic pathway) or at the mitochondria (intrinsic pathway). Stimulation of the extrinsic pathway by TRAIL results in TRAIL receptor (TRAIL-R) aggregation and formation of the DISC, in which pro-caspase 8 becomes activated and initiates apoptosis by direct cleavage of downstream effector caspases. The addition of either agonistic TRAIL-R1/R2 antibodies or recombinant human TRAIL (rhTRAIL) has been used to trigger the extrinsic pathway for therapy. The intrinsic pathway is regulated by the BCL-2 family of proteins, which regulate pore formation in the outer mitochondrial membrane and the release of apoptogenic factors such as cytochrome *c* or SMAC from the mitochondria. The release of cytochrome *c* into the cytosol triggers caspase 9 activations through the formation of the cytochrome *c*/Apaf-1/caspase 9-containing apoptosome complex. SMAC promotes caspase activation through the neutralizing the inhibitory effect of IAPs. The intrinsic pathway has been targeted for therapy either by blocking the inhibitory action of the pro-survival BCL-2 family proteins with BH3 mimetics or by inhibiting the anti-apoptotic action of IAPs with SMAC mimetics. The extrinsic and intrinsic pathways are interconnected, for example, by BID, a BH3 domain-containing protein of the BCL-2 family, which upon cleavage by caspase 8 triggers intrinsic apoptosis, thereby further amplifying the signal from the extrinsic pathway.

28.14.12: The entire pathway

Now we can present detailed pathways showing apoptosis in its complexity. Trace the interconnections in the different views.

28.15: Signaling in Microorganisms

The main organization of this section derives from **Bacterial transmembrane signaling systems and their engineering for biosensing. Jung et al :25 April 2018https://doi.org/10.1098/rsob.180023.** Creative Commons Attribution License http://creativecommons.org/licenses/by/4.0/. Significant content from the source has been integrated into the section.

28.15.1: Introduction

Bacteria constantly interact with their surroundings. They identify and actively acquire nutrient resources, sense and respond to environmental stresses, and exchange information with other cells, while commensals and pathogens adapt their lifestyles for survival in their hosts. The cytoplasmic (inner) membrane of bacterial cells separates the cytoplasm from the outer world. Therefore, all information from the outside must be transferred across this interface, which contains various sensors that carry out this function.

Bacteria use three major types of signaling systems: membrane-integrated one-component systems (for example -ToxR-like receptors), two-component systems consisting of a **receptor histidine kinase** and a **response regulator**, and extracytoplasmic function (ECF) sigma factors. These are shown in Figure 28.15.1.

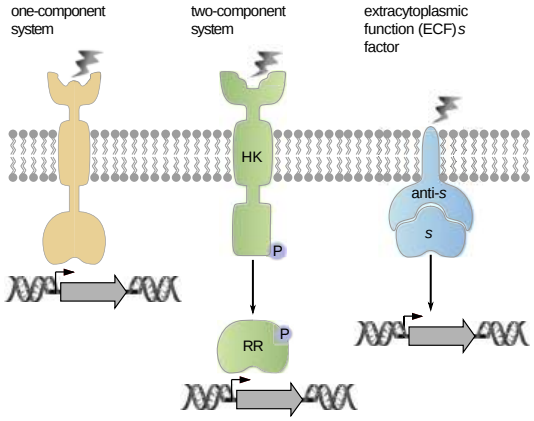

Figure 28.15.1: Schematic presentation of the major types of transmembrane signaling systems in bacteria. One-component signaling systems, consisting of sensor and DNA-binding domain (yellow), two-component systems with a membrane-integrated histidine kinase (HK) and a response regulator (RR) (green), and extracytoplasmic function (ECF) sigma factors (σ) that will be released from the anti-sigma factor (anti-σ) upon stimulus perception (blue).

The one-component signaling family ToxR (named after the main regulator of virulence in *Vibrio cholerae*) is the simplest. They have a periplasmic sensor domain, a single transmembrane helix, and an intracellular winged helix-turn-helix DNA-binding domain. The family is named after the main regulator of virulence in *Vibrio cholerae*, ToxR.

In two-component systems, the membrane-integrated histidine kinase generally acts as a sensor for various stimuli and is also responsible for information transfer across the membrane. This process usually results in the autophosphorylation of the protein and the phosphoryl group is subsequently transferred to a specific soluble response regulator which usually acts as a transcription factor (see Figure 28.15.1). The number of histidine kinase/response regulator systems varies widely between bacterial species, ranging from 30 in *Escherichia coli* and 36 in *Bacillus subtilis* to 132 in *Myxococcus xanthus*. In chemotactic systems, a soluble histidine kinase perceives the signal(s) conveyed by membrane-integrated chemoreceptors and transduces this information via phosphorylation/protein–proteins interaction to the flagellar motor.

The ECF sigma factors are small regulatory proteins that bind to RNA polymerase and stimulate the transcription of specific genes. Many bacteria, particularly those with more complex genomes, contain multiple ECF sigma factors, and these regulators often outnumber all other types of sigma factors. Little is known about the roles or the regulatory mechanisms employed by the majority of ECF sigma factors. Most of them are co-expressed with one or more negative regulators. Often, these regulators include a transmembrane protein that functions as an anti-sigma factor, which binds and inhibits the cognate sigma factor.

Let's look at three examples.

28.15.2: One-component system: pH sensor CadC

pH in E. Coli is regulated by a series of Cad proteins. CadA is a cytoplasmic decarboxylase, which converts lysine to cadaverine, while CadB is a membrane-integrated lysine/cadaverine antiporter. CadC acts as a homodimeric one-component regulator. Together, their activities lead to an increase in both internal and external pH, which favors the survival of *E. coli* under moderate acid stress and helps to maintain pH homeostasis. Their activities are shown in Figure 28.15.2

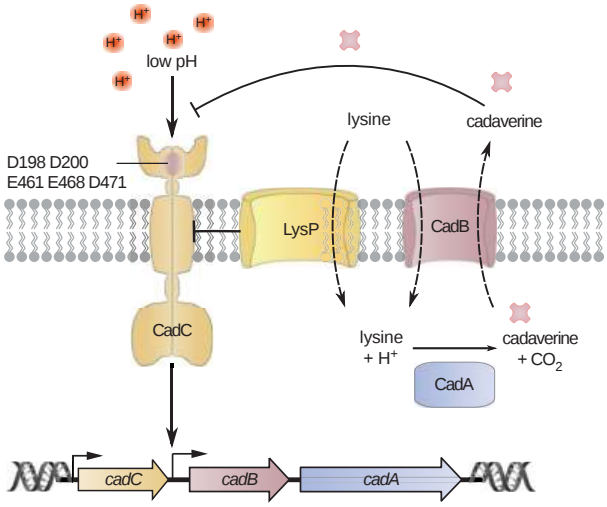

Figure 28.15.2: The regulation of CadC, a one-component system representative.

CadC is the regulator of the *cadBA* operon encoding the lysine decarboxylase CadA and the lysine/cadaverine antiporter CadB. Under non-inducing conditions, the lysine-specific transporter LysP inhibits CadC. When cells are exposed to low pH in the presence of lysine, the interaction between LysP and CadC is weakened, rendering CadC susceptible to protonation and transcriptional activation. The end-product of decarboxylation, cadaverine, binds to CadC and thereby inactivates this receptor.

CadC is activated by two stimuli, low pH (less than 6.8) and the presence of external lysine (greater than 0.5 mM), which are perceived by different mechanisms. The periplasmic domain of CadC directly senses a decrease in pH. It has two distinct subdomains: the N-terminal subdomain comprises a mixture of β-sheets and α-helices, and the C-terminal subdomain consists of a bundle of 11 α-helices. A patch of acidic amino acids (D198, D200, E461, E468, D471) detect changes in the external pH through protonation changes, altering their charges and noncovalent interactions between the subdomains/monomers. This in turn leads to dimer formation of the periplasmic domain, triggering receptor activation.

Figure 28.15.3shows an interactive iCn3D model of a Transcriptional activator CadC One Component Model - AlphaFold Model (P23890)

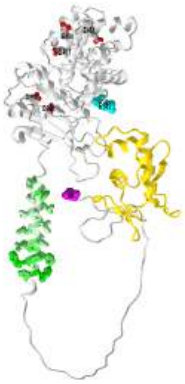

Figure 28.15.3: Transcriptional activator CadC One Component Model - AlphaFold Model (P23890) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...UfZh5LVeoaToj6

The gold represents the N-terminal CadC DNA binding domain. The green (hydrophobic) is the transmembrane helix and the gray is the outside periplasmic domain containing the acidic side chains (D198, D200, E461, E468, D471). The N term Met is magenta spacefill and the C-terminal Ser is cyan spacefill. Again, the long intrinsically disordered region between the DNA binding domain and the transmembrane domain would have a more defined structure in the actual membrane-bound form and probably form

additional interactions with other molecules. It also presumably leads to a conformation change in the DNA binding domain which leads to its interaction with the target DNA.

CadC senses external lysine only in interaction with the lysine-specific permease LysP. In addition, the products of lysine decarboxylation, CO_2, and cadaverine, act as feedback inhibitors on CadC. Cadaverine binds to the periplasmic domain of CadC, thereby switching off *cadBA* transcription.

28.15.3: Two Component System

Two-component Histine kinase systems have (in general) two main components

- A HK **sensor protein** binds a ligand in a receptor binding domain leading to the transfer of a gamma-phosphate from ATP to a His by the kinase domain. This component is often called a **transmitter**. The conserved His located in the **H box**.
- a separate **response regulator** (or effector) protein containing a reactive Asp which receives the phosphate from p-Histidine. The conserved Asp (D) is located in the **D box**. This activates the response regulator protein. This component is often called the **receiver**. It may also transfer it to another His in a phospho-relay system.

Histidine kinase/response regulator systems are the most commons in bacterial signaling across the membrane. In contrast to the myriad of serine/threonine (S/T) and less abundant tyrosine (Y) kinases that dominate signaling in mammals, the histidine kinase predominates in bacterial signaling.

Before we present more detail on the two-component system, let's looks at protein kinases in general and see what is different about histidine kinases. ATP is a donor of a gamma-phosphate in both S/T/Y and H kinases. However, their products are very different energetically. pS, pT, and pY of the O-phosphoproteome are all phosphoesters, which are not high energy compared to their hydrolysis products. (**Remember, there is no such thing as a "high energy" bond.**) In contrast, pHis, a member of the N-phosphoproteome (along with pLys and pArg), is not a phosphoester but more analogous to the mixed anhydride of a carboxylic acid as in the case of phosphorylated aspartic acid. In pHis and pAsp, there is an electronegative N (in pHis) and O (in pAsp) bridging two atoms which are each connected to another atom by double bonds. This type of structure, which allows for bridging resonance between the center N (in pHis) and O (in pAsp) is also high energy compared to its hydrolysis products. Hence the phosphorylation of His by ATP is not as energetically favored as the phosphorylation of Ser, Thr, or Tyr since it produces another high-energy molecule (with respect to its hydrolysis products.

Since the pHis is also considered high energy compared to its hydrolysis products, it can act as a phosphate donor to another receiving group. That could be water in a simple hydrolysis reaction or, if sheltered from water in an active site of an enzyme or receptor, to a carboxylate receiver like Asp to form another high energy mixed anhydride which is isoenergetic with the pHis. This is the process that occurs in the two-component His kinase signaling pathways in bacteria. Figure 28.15.4compares Ser, Thr, Tyr, and His kinase reaction and their products.

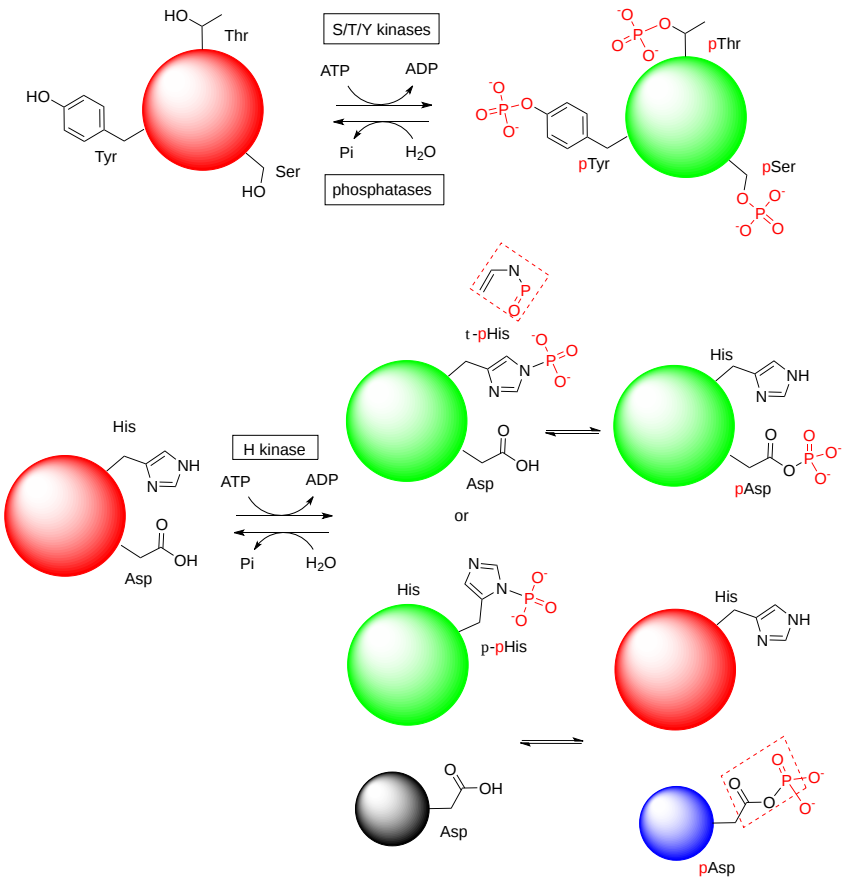

Figure 28.15.4: A comparison of Ser, Thr, Tyr, and His kinases

The more common mammalian S/T/Y kinases are shown at the top and the histidine kinase at the bottom. Note that phosphorylation of His can occur at either nitrogen to produce either τ- or π-pHis. In the two-component system, instead of water being the receiver of the phosphate from the pHis (hydrolysis), the receiver is an Asp or another His in the same His Kinase receptor or in another receiver protein (shown in gray and its phosphorylated blue form in Figure 28.15.9 You can imagine the phosphate on the original pHis jumping to a receiver, which then donates it to another receiver in the signaling process in a relay process.

Proteins like the receptor His-kinase proteins in two-component systems have multiple domains with different functions. It's really helpful to present domain structure diagrams to help in understanding the protein's structure and activities. At the same time, the domain structures determine by various bioinformatic programs vary. Nevertheless is it useful to see multiple representations of domain structure, especially if they are shown in conjunction with actual structures.

The first component of the two-component signaling system is the **receptor His-kinase** which can be viewed as a stimulus-activated kinase (much like receptor tyrosine kinases - RTKs). The second component is the **response regulator protein,** which is typically a second protein. Each of these in turn has its own domain structure. For example, the periplasmic sensing domain regulates the kinase domain of the receptor His-kinase (component one). The phosphate from the p-His in the first component is transferred to an Asp in the second component. The domain structures and phospho-transfer are illustrated in Figure \ (\PageIndex{5\) below.

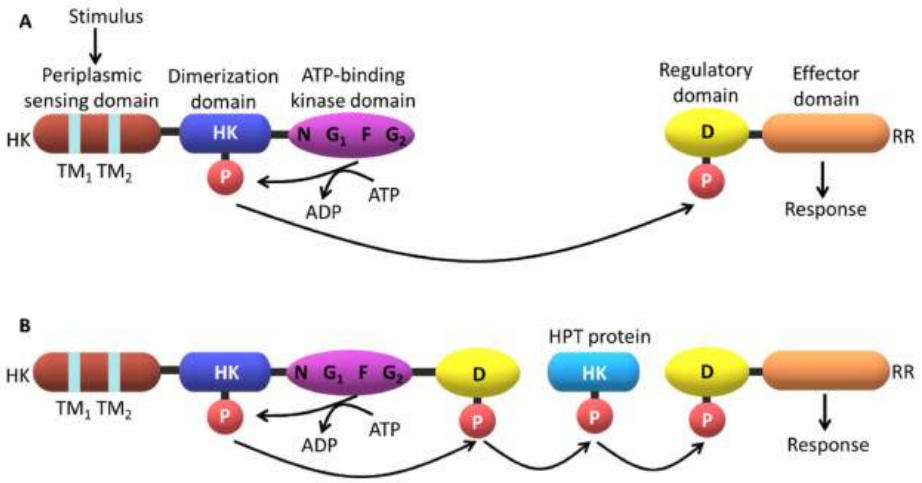

Figure 28.15.5: Domain structures and phosphotransfer mechanisms in two-component systems. Silva et al. *Int. J. Mol. Sci.* **2021**, *22*(16), 9034; **https://doi.org/10.3390/ijms22169034.** Creative Commons Attribution (CC BY) license (**https://creativecommons.org/licenses/by/4.0/**).

Panel (**A**) shows a prototypical two-component pathway. The transmembrane sensor HK (component one) and a cytoplasmic response regulator (RR) protein (component two) are shown. (Note: the actual protein is a **dimer** in the membrane.) The transmembrane segments are labeled TM_1 and TM_2. N, G_1, F, and G_2 are conserved sequence motifs in the ATP-binding domain. HK catalyzes ATP-dependent autophosphorylation of a specific conserved His residue within the HK dimerization domain. The phosphoryl group (P) is then transferred to a specific aspartate residue (D) at the conserved RR domain (component two). Phosphorylation of this domain usually triggers an associated (or downstream) effector domain, which ultimately produces a specific cellular response.

Panel(**B**) shows a multi-component phospho-relay system that often involves a variant of HK with an additional internal C-terminal RR domain. In these complex systems, at least two His–Asp phosphoryl transfer events occur, typically involving a His-containing phosphotransfer protein (HPT) operating as a His-phosphorylated intermediate.

In most prokaryotic systems, the response is directly carried by the RRD which functions as a transcription factor. Two-component systems also exist in some eukaryotes. They often interact with other downstream signaling pathways such as the MAPK system. However, in eukaryotic systems, the TCS are placed at the start of the pathways and establish an interface with more conventional signaling strategies such as mitogen-activated protein (MAP) kinase and cyclic nucleotide cascades

The domain structure shown in Figure 28.15.10 doesn't show the actual orientation of the proteins in a membrane sytem. Orientation is important since the sensing domain of the HK receptor must be in the environment of the stimuli. Stimuli can be encountered in the periplasmic (equivalent to extracellular) region, in the transmembrane region and in the cytoplasm. Variants of the HisK receptors exist that recognize stimuli in each of these locations as shown in Figure 28.15.6

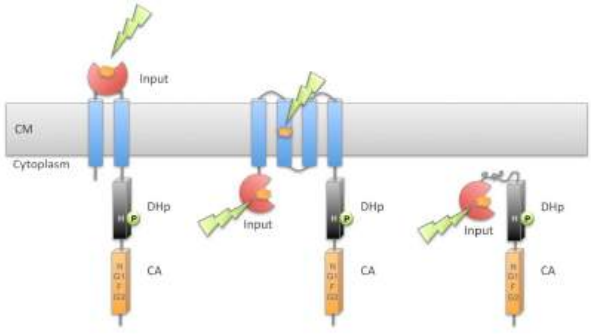

Figure 28.15.6: Hannah Schramke. https://edoc.ub.uni-muenchen.de/2103...mke_Hannah.pdf

Most histidine kinases sense extracellular signals (left-hand structure). All have their cytoplasmic transmitter domains which contain the pHis. As mentioned previously, the histidine kinases are dimeric, so when activate they phosphorylate a His on the other monomer (transphosphorylation). In addition to the H box with the reactive histidine, they also have N, G1, F, and G2 boxes. The H box is also involved in dimerization The transmitter domain can be further divided into two parts: the H-box is involved in

dimerization and obviously in phosphotransfer. The figure also shows the CA domain (HK-type ATPase catalytic or HATPase_c), also known as the catalytic and ATP-binding (CA) domain (Figure 1.3-3)

The histidine kinase senses a variety of stimuli in its sensory domain. The stimuli can be generally grouped into organic (e.g. dicarboxylates, citrate, etc), ions (e.g. Mg^{2+}, H^+, K^+), gaseous ligands (e.g. O_2, N_2), and physical changes (osmolarity/turgor, light, and temperature). Stimuli are "sensed" by a variety of different characterized folds. Some common sensing domains are PAS (Per-ARNT-Sim), CHASE (cyclase/histidine kinase-associated sensing extracellular), four-helix bundle (4HB), and NIT (nitrate and nitrite-sensing) classes. We will focus on one particular His kinase system, histidine kinase KdpD.

28.15.3.1: Histidine kinase KdpD and the regulation of K^+ ion concentration

It is often difficult to identify the primary stimulus for a receptor, as exemplified by the histidine kinase KdpD which, together with the response regulator KdpE, controls the expression of a high-affinity K^+-uptake system in many bacteria. K^+ is the most abundant cation in all living cells, especially in bacteria it is crucial for the regulation of cell turgor and intracellular pH and the activation of several enzymes. To ensure a sufficient supply of K^+, most bacteria have more than one K^+-uptake system. For example, *E. coli* has at least three such systems, the constitutively expressed systems Trk and Kup, and the inducible high-affinity K^+-uptake system KdpFABC. The genes *kdpF*, *kdpA*, *kdpB*, and *kdpC* form an operon that codes for four inner membrane proteins. The *kdp* operon is induced when *E. coli* is grown under K^+ limitation, lacks the major K^+ transporter Trk or has an increased need for K^+ when under hyperosmotic stress. Under all these conditions, the membrane-integrated histidine kinase KdpD autophosphorylates and transfers the phosphoryl group to the cytoplasmic transcriptional (response) regulator KdpE, resulting in the induction of the *kdp* operon, as shown in Figure 28.15.7.

What is amazing is that KdpD has not only kinase activity but also phosphatase activity towards phosphorylated KdpE, which switches the signaling cascade off. It is a bifunctional enzyme/receptor. A single substitution (T677A) in the C-terminal domain results in no phosphatase activity.

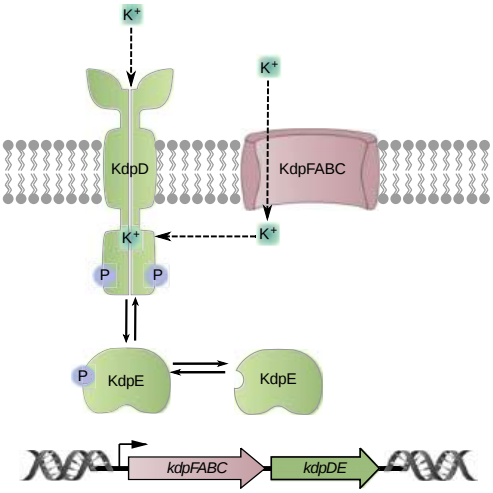

Figure 28.15.7: Schematic of the KdpD regulation system.

Hence KdpD can be thought of as a bifunctional receptor acting as both kinase and phosphatase to regulate gene expression. The bifunctional receptor histidine kinase KdpD acts as both an autokinase (including phosphotransferase) and phosphatase for the response regulator KdpE. Phosphorylated KdpE activates the expression of the genes encoding the high-affinity K^+ transporter KdpFABC. KdpD autokinase activity depends on the external K^+ concentration, and the phosphatase activity is influenced by the internal K^+ concentration. K^+ ions don't move through a channel in KdpD but through the KdpFABC.

The cartoon in Figure 28.15.7, as with all cartoons, can be misleading with respect to scale. Figure 28.15.8 shows an interactive iCn3D model of the actual membrane domain of E. coli histidine kinase receptor KdpD (2KSF)

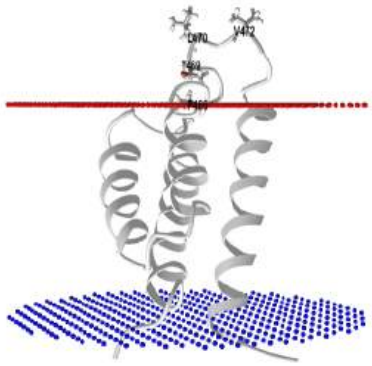

Figure 28.15.8: Membrane domain of E. coli histidine kinase receptor KdpD (2KSF)Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...yMgkv2fxn9RKo8

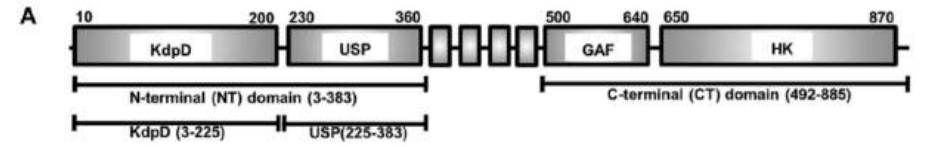
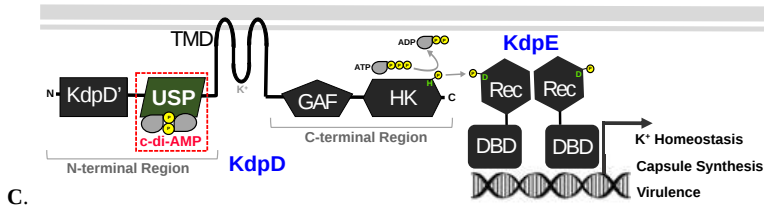
4 helices space the membrane. Hence both the N-terminal and C-terminal domains are actually in the cytoplasm, not one in the periplasmic space and one in the cytoplasm as you would infer from Figure 28.15.7. The actual periplasmic (outsithe de of cell" domain) consists of only about 6 amino acids. Hence it most clearly is represented by the middle model in Figure 28.15.6 Mutations of key residues in the periplasmic loop region (P466A, T469A,, L470A and V472A) drastically affect K^+ recognition. Actually how it "senses" periplasmic K^+ ions is not clear.

Domain representation

We present three different domain diagrams for KdpD in Figure 28.15.9 not to confuse readers, but to show the utility of mulrepresentationstation they are likely to encounter in reading the literature.



Moscoso et al. Journal of Bacteriology. 198 (2016) http://dx.doi.org/10.1128 /JB.00480-15. Creative Commons Attribution 3.0 Unported license



Dutta et al. JBC. 296, 100771 (2021). DOI:https://doi.org/10.1016/j.jbc.2021.100771. Creative Commons Attribution (CC BY 4.0)

Figure 28.15.9 Multiple representations of the domain structure of the histidine kinase KdpD

In panel A, the 4 boxes btw 360 and 500 are 4 transmembrane helices, which would not be evident in a simple cartoon as in Figure 28.15.7. In panel B, the domains are shown as follows:

- Green: K+ channel His kinase sensor domain 21-230;
- Red: 4 transmembrane helices 402-508; the helices are lumped together in the red domain representation;
- Blue: GAF domain 527-644;
- Yellow and Purple combo: HK domain;
  - Yellow: HisKinase A phosphoacceptor domain 663-730 which contains the His acceptor, in effect the substrate of the kinase domain;
  - Purple: His Kinase/HSP 90 is like ATPase 773-883.

The domain structure in panel C is the most detailed and also has the domain structure of the receiver (response regulator). Again the periplasmic domain which senses K^+ consists of only a few amino acids, 424-427 and 467-474. Neither representations A nor B show that the major N-terminal and C-terminal halves of the protein are in the cytoplasm. Panel C shows more information about the domains, their function, and their orientation in the intracellular environment. It turns out there is also a sensor for intracellular K^+ions, which is depicted in Figure 28.15.7.

A central question is how histidine kinase KdpD responds to changes in K^+ concentrations. Both the kinase and phosphatase activities are regulated by K^+.

- When periplasmic (extracellular) K^+ is > 5 mM (high), the ion appears to bind to the small extracellular loops (see Figure 28.15.8), which inhibits the autokinase activity. Under the same conditions the intracellular C-terminal tail senses K^+ and activates the phosphatase activity, which cleaves its pHis. These combined effects inhibit high-affinity K^+ transport.
- When periplasmic K^+ becomes low, kinase activity is activated and the protein is autophosphorylated, ultimately leading to the activation of the gene for the high-affinity K^+ transporter KdpFABC. As long as intracellular K^+ levels are high, the phosphatase is active. When intracellular K^+ levels drop sufficiently, the phosphatase becomes inhibited, which further simulations the transcription of both high-affinity K^+ transporter KdpFABC.

Hence the histidine kinase KdpD system is regulated by **both** periplasmic and cytoplasmic K^+ ions.

Yet another signal regulates the KdpD His Kinase receptor two-component signal. What has been conspicuously absent from this discussion about signaling in bacteria is the involvement of second messengers like cAMP (which activates Protein Kinase A and some membrane proteins). There does appear to be one major second messenger in bacteria - cytoplasmic di-AMP (c-di-AMP), whose structure is shown in Figure 28.15.10

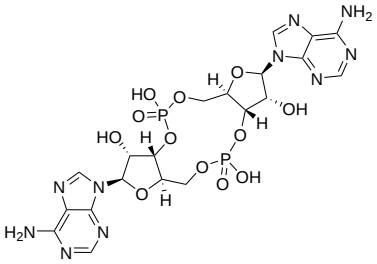


Figure 28.15.10: The bacterial second messenger cytoplasmic di-AMP (c-di-AMP)

It binds in the N-terminal region of KdpD His Kinase receptor protein "sensor" domain region to a specific domain called the Universal stress protein (USP) domain as shown in panels A and C of Figure 28.15.9 Figure 28.15.11shows an interactive iCn3D model of the Staphylococcus aureus universal stress protein (USP) domain of KdpD histidine kinase in complex with second messenger cyclic diadenosine phosphate (c-di-AMP) (**7JI4)**

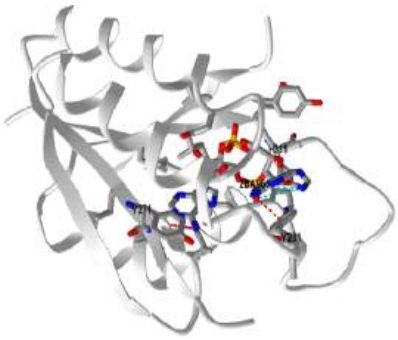

Figure 28.15.11: Staphylococcus aureus universal stress protein (USP) domain of KdpD histidine kinase in complex with second messenger c-di-AMP (**7JI4).** (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...ij5DqgazLFvV5A

"Dual sensing thus emerges as a highly optimized regulation strategy. The key advantage of this strategy is that it confers on cells the ability to directly sense changes in both the supply of and demand for the limiting resource. It is, in fact, analogous to strategies that are widely used in control engineering, e.g. modern heating systems work with both exterior and interior thermometers to ensure constant room temperature."

28.15.3.2: *Escherichia coli* nitrate/nitrite sensor kinase NarQ

Let's examine another TCS protein, the *Escherichia coli* nitrate/nitrite sensor kinase NarQ, to see how the binding of a ligand to the periplasmic domain might transmit a signal so far into the cell through the plasma membrane. We won't discuss the His Kinases that lack transmembrane regions (about 1/4). The sensor domain hence is mostly in the periplasm, followed by the transmembrane domain (see Figure 28.15.8), followed often by a cytoplasmic HAMP domain, with a four-helical parallel coiled-coil. The HAMP domain transmits the signal to downstream signaling domains like Dhp in the protein.

Nitrate/nitrite is sensed by two different two-component systems, sensing systems NarX-NarL and NarQ-NarP, which regulate anaerobic respiration. NarQ phosphorylates two different proteins, NarL and NarP in the presence of nitrate or nitrite and dephosphorylates both proteins in the absence of ligands. Both NarQ (and NarX) have seven domains: a four-helical periplasmic sensor domain, TM bundle, HAMP domain, so-called signaling helix, (S-helix), GAF-like domain, dimerization and histidine phosphotransfer domain, and, finally, catalytic kinase domain, as shown in Figure 28.15.12

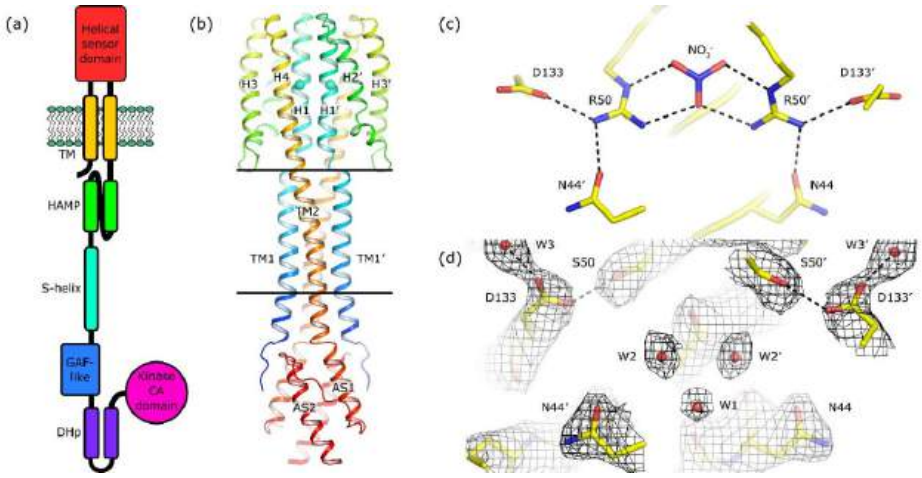

Figure 28.15.12: Architecture of NarQ and structure of the R50S mutant. Elements belonging to the second protomer in the dimer are marked with primes. Gushchin et al. Int. J. Mol. Sci. 2020, 21, 3110; doi:10.3390/ijms21093110. Creative Commons Attribution. (CC BY) license. (http://creativecommons.org/licenses/by/4.0/).

Pane (**a**) shows the architecture of NarQ. Note that the functional protein is homodimeric. Approximate domain boundaries, according to InterPro [17], are TM1, residues 14–34; sensor, 39–146; TM2, 147–167; HAMP, 172–227; S-helix, 228–246; GAF-like, 247–360; DHp, 361–425; CA, 424–560.

Panel (**b**) shows the overall structure of the sensor-TM-HAMP fragment of the R50S mutant (which allowed crystallization). The position of Ser50 is highlighted with spheres. The backbone structure is identical to that of the WT protein.

Panel (**c**) shows the structure of the ligand (nitrate) -binding site in the WT protein.

Panel (**d**) shows the structure of the ligand-binding pocket in the R50S mutant. Asp133 is reoriented towards Ser50. $2F_o–F_c$ electron density maps are contoured at the level of 1.2 × r.m.s. Putative water molecules are shown as red spheres. Gushchin et al. Int. J. Mol. Sci. 2020, 21, 3110; doi:10.3390/ijms21093110. Creative Commons Attribution. (CC BY) license. (http://creativecommons.org/licenses/by/4.0/).

Although the sequence identity between NarQ and NarX is ~28%, their ligand binding sites—membrane-proximal parts of the sensor domain's helices H1 called P boxes—are very well conserved: 14 out of 15 amino acids (residues 42–56 in NarQ) are identical, and the differing ones, Ile 45 in NarQ and Lys49 in NarX, are responsible for the differentiation between nitrate and nitrite.

It appears that the ligand-induced conformational change in the ligand-binding site is helical rotation, which results in diagonal scissoring of the sensor domain helices, leading to the change in the secondary structure of the sensor-TM linker and, eventually, piston-like shifts of the transmembrane α-helices.

Nitrate causes changes in the transmembrane region when the apo (nitrate free) and holo (nitrate bound) state structures of NarQ are compared. On binding of nitrate, the induced conformation changes in NarQ have been described as a "combination of changes in the lateral arrangement of the TM helices and piston-like shifts of the helices in the direction perpendicular to the membrane plane." This results in either symmetric or asymmetric changes and scissoring of the transmembrane helices (based on two different crystal structures of the holo-form. A "piston-like" movement of the helices is observed on both holo-forms.

Results show that the binding of ligand to NarQ causes a piston-like displacement of the TM helices, which is accompanied by extensive symmetric or asymmetric rearrangements and scissoring of the TM helices. The rearrangements are different in the two presented holo-state structures, but the piston-like displacement is perfectly conserved. Thus, the latter appears to be a more robust mechanism of TM signal transduction.

Figure 28.15.13 shows an interactive iCn3D model of a fragment of nitrate/nitrite sensor histidine kinase NarQ (mutant R50K) in the symmetric holo state (5IJI)

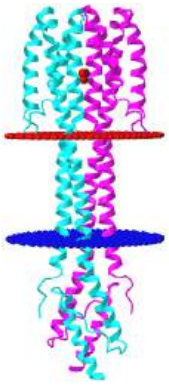

Figure 28.15.13: Fragment of the nitrate/nitrite sensor histidine kinase NarQ (mutant R50K) in the symmetric holo state (5IJI) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...gsRXjmKBbqbis8

A homodimer (cyan and magenta) is shown with the N-terminus and C-terminus on the cytoplasmic side. Each monomer passes through the membrane with an alpha-helical domain twice. Nitrate is shown in spacefill in the extracellular domain outside of the outer leaflet (red spheres) of the membrane.

Figure 28.15.14 shows the conformational transition going from the symmetric apo state (5JEQ) magenta to the symmetric holo state (IJI) (cyan) with bound nitrate (not shown).

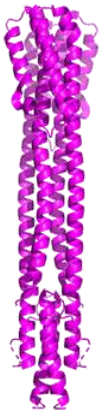

Figure 28.15.14: Conformational transition in the nitrate/nitrite sensor histidine kinase fragment going from the symmetric apo state (5JEQ) magenta to the symmetric holo state (IJI) (cyan)

Conformational changes in the HAMP domain seem to amplify and convert the piston-like conformational changes in the transmembrane domain. Note the splaying out to the helices at the bottom (cytoplasmic end) in the apo form.

28.15.3.3: Phototaxic Photoreceptors

We have discussed two-component systems that have a His-Kinase receptor transmitter protein. There are two other major types of bacterial receptors, chemoreceptors (involved in chemotaxis) and photoreceptors, involved in phototaxis. These often have similar modular domain structures. Chemotaxis receptors are, like the His Kinase receptor, dimers with extracellular domains that bind the chemotactic signal. The photoreceptors appear to be active as a trimer of dimers.

The basic dimeric structure contains the microbial light sensor rhodopsin which contains the chromophore opsin, and its transducer Htr. In the halobacteria *N. pharaonis*, *(*archaeal, not a bacterial cell) the proteins are sensory rhodopsin II (NpSRII) with its transducer (NpHtrII), mediates negative phototaxis in halobacteria *N. pharaonis*.

Microbial **rhodopsins** are phototransducing proteins with a conjugated chromophore retinal, covalently attached to the protein opsin through a Schiff base (imine) linkage. The holoprotein (opsin with the attached retinal) is called rhodopsin. Retinal is derived from beta-carotene. The structures of animal and microbial retinals are shown in Figure 28.15.15

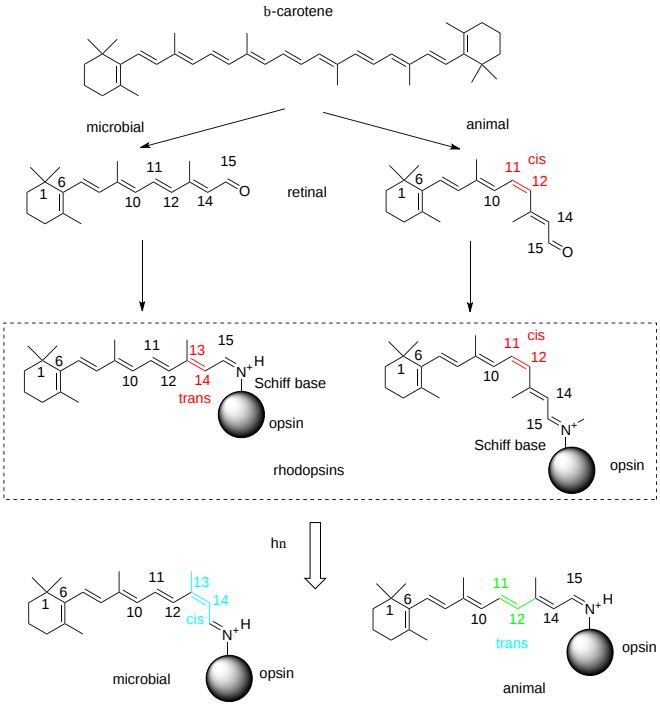

Figure 28.15.15: Structures of animal and microbial retinals

When light of the correct wavelength is absorbed, an electron in a pi molecular orbital in retinal is promoted to a pi antibonding molecular orbital, breaking a 2 electron pi bond in the structure at a certain site in the isoprenoid chain, allowing rotation around the now single bond. The final result after the electrons return to the ground state is photoisomerization of the trans 13-14 and cis 11-12 bonds in microbial and animal retinal, respectively, to their respective cis 13-14 and trans 11-12 configuration. This conformational change in the bound retinal induces a conformational change in the protein opsin, leading to signaling.

Figure 28.15.16 shows an interactive iCn3D model of one monomeric of bacteria rhodopsin (1C3W) containing retinal attached through a Schiff base to Lys 216.

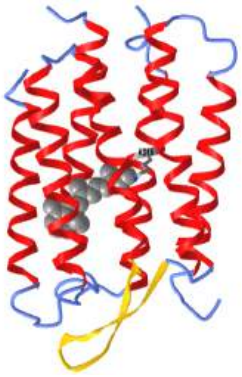

Figure 28.15.16: Bacterial rhodopsin (1C3W). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...9HzvfdFvb9kcc6

The covalently attached retinal is shown in gray spacefill. The protein opsin is a membrane protein that spans it with seven helices. Hence it is very similar to a GPCR.

In the phototaxic receptor, when light is absorbed by rhodopsin (NpSRII), the resulting conformational change in the protein causes conformational changes in the transducer protein NpHtrII associated with it, leading to signaling through a two-component signal system. (The chemotaxis response to chemical signals occurs through a similar but ligand-induced process.) Figure 28.15.17 shows the structure of the Archaeal photoreceptor complex.

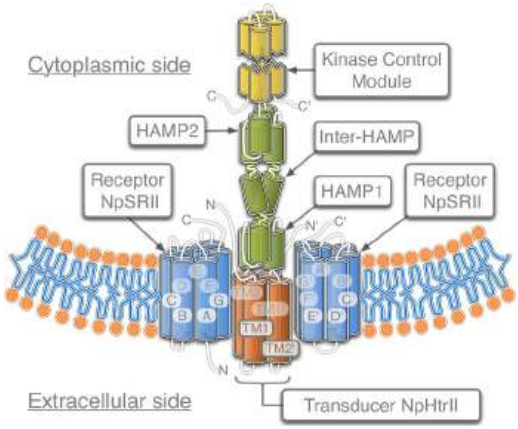

Figure 28.15.16: The dimer of two NpHtrII proteins is flanked by two NpSRII proteins.

A-G, TM1, and TM2 are the transmembrane helices. The cytoplasmic part of NpHtrII consists of two HAMP domains (HAMP1 and HAMP2) connected by an α-helical linker (Inter-HAMP) and the kinase control module. Primes denote symmetry mates of the complex. Ishchenko, A., Round, E., Borshchevskiy, V. *et al.* New Insights on Signal Propagation by Sensory Rhodopsin II/Transducer Complex. *Sci Rep* **7,** 41811 (2017). https://doi.org/10.1038/srep41811. Pane (**A**) shows Light activated sensory rhodopsin II (*Np*SRII) induces conformational and/or dynamical changes in the transducer (*Np*HtrII), which are converted by two HAMP domains and conveyed along the 200 Å long transducer to the tip region. Activated by the transducer histidine kinase CheA (bound to the adapter protein CheW) undergoes auto-phosphorylation and further transfers the phosphate group to the response regulators CheY or CheB. CheY affects the rotational bias of the flagellar motor, while the methylesterase CheB along with the methyltransferase CheR controls the adaptation mechanism.

Panel (**B**) shows cartoon representations of the chemoreceptor dimer (Tar and Tsr in complex with kinases) from *E. coli* and of the photosensor dimer of the complex of the sensory rhodopsin II with its cognate transducer *Np*HtrII and kinases from *N. pharaonis*.

28.16: Signaling in Plants

28.16.1: Introduction

Plants are obviously comprised of cells. Hence they must engage in cell signaling within and between cells. It is beyond the scope of this book to give a detailed description of cell signaling in plants. Instead, we focus on 5 key classic plant hormones, **auxins, cytokinins, ethylene, gibberellins, and abscisic acid**, which are produced by leaves, flowers, shoots, roots, or fruit, and see how they initiate signaling in plants. Finally, we would be remiss if we didn't include the profound signaling in plants initiated by light. Most of this section comes directly from a series of sources, with modifications and additions (mostly molecule models).

Auxins (3-indolebutyric acids derivatives) are regulators of growth and development and are found in actively growing parts of the plant (root, shoot, leaves) but mostly in the cell stem. Auxins facilitate the bending of plants toward the light, for example. They work in conjunction with other hormones like **cytokinins**. When auxins are higher than cytokinins, roots will form, while the opposite produces shoots. Auxins facilitate the elongation of cells, while cytokinins promote cell division and growth as well as wound repair. **Gibberellins** also are plant growth regulators and facilitate cell elongation. They also help in germination, elongation of the stem, fruit ripening, and flowering. **Abscisic acid** affects **seed development and maturation** and helps plants tolerate environmental or biotic stresses. It also inhibits growth and metabolism. **Ethylene** affects fruit ripening, organ abscission, and growth by restricting cell elongation.

We will focus on the hormones, their protein receptors, and how the hormone:receptor complex initiates some key events in the cell.

28.16.2: Auxin

Auxins, the first plant hormones discovered, regulate plant growth and development. The most common auxin is 3-indole acetic acid. Figure 28.16.1shows the structures of naturally occurring auxins.

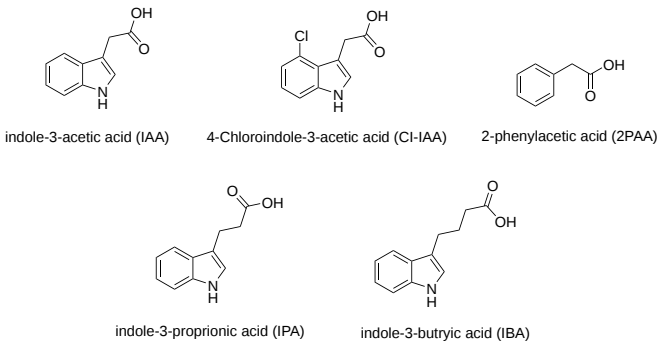

Figure 28.16.1: Structures of naturally occurring auxins.

Figure 28.16.2shows an interactive iCn3D model of auxin bound to its receptor, TIR1 ubiquitin ligase (2P1Q)

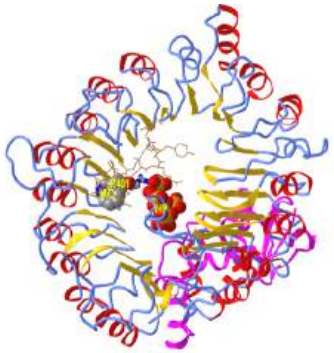

Figure 28.16.2 Auxin bound to its receptor TIR1 ubiquitin ligase (2P1Q) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...6xSkEZ3aJA4gT6

Auxin (IAA) is shown in spacefill CPK colors along with an unexpected binding cofactor, inositol hexakisphosphate (IHP), shown in spacefill CPK colors. The peptide shown in light brown sticks is part of the protein Auxin-responsive protein IAA7, a member of a class of proteins called **AUX/IAAs**. These are short-lived transcriptional factors that function as repressors of early auxin response genes at low auxin concentrations.

The magenta subunit, TIR1 (transport inhibitor response 1), is part of the larger TIR1 complex, the SCF(TIR1) E3 ubiquitin ligase, of which only TIR1 is shown. Its mere name suggests that it is involved in the ubiquitinylation of a key protein involved in auxin activity, which will be targeted for proteolysis. That protein is the repressor protein IAA7 (an AUX/IAA protein).

Auxin binds in a hydrophobic pocket, which accounts for the binding of the other largely hydrophobic auxins shown in Figure 28.16.1 Note however that Arg 401 that forms a salt bridge (ion-ion interaction) with the carboxylate of 3-indole acetic acid

Figure 28.16.3shows an interactive iCn3D model of auxin bound in the hydrophobic pocket of its receptor, TIR1 ubiquitin ligase (2P1Q).

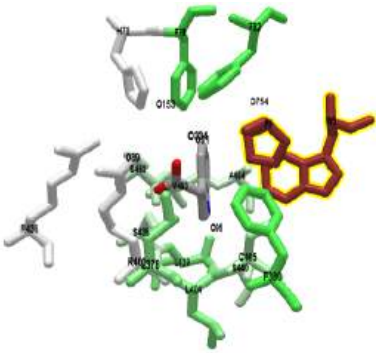

Figure 28.16.3: Auxin bound in the hydrophobic pocket of its receptor TIR1 ubiquitin ligase (2P1Q) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...TFkf6HdMYMiZT9

The green color represents nonpolar side chains. The brown side chains, Trp and Pro, are from the auxin-responsive protein IAA7 peptide. To reiterate, the protein IAA7 is a member of a class of proteins called AUX/IAAs which repress auxin activity. The IAA7 peptide packs over the auxin in the binding pocket.

Now we can see how auxin function to regulate gene transcription. First, we must introduce another protein family, the **auxin response factors (ARFs)**. These are transcription factors that bind to a key DNA sequence, the auxin response element (AuxRE) in promoter sequences of auxin-activated genes. Once bound they can either activate or repress transcription from target genes. Auxin binds its receptor TIR1 enabling the binding of an AUX/IAAs (like IAA7) repressor and the binding of the complex to ARF. The TIR1 ubiquitin ligase activity of the complex ubiquitinylates the bound AUX/IAAs (like IAA7) repressor, targeting it for degradation, freeing the ARF to become active in the regulation of gene transcription in the nucleus.

ARFs are structurally similar, with most members containing three regions: DBD (DNA-binding domain), MR (middle region), and PB1 (Phox and Bem 1). Figure 28.16.4shows a model of how auxin affects ARF transcriptional activity.

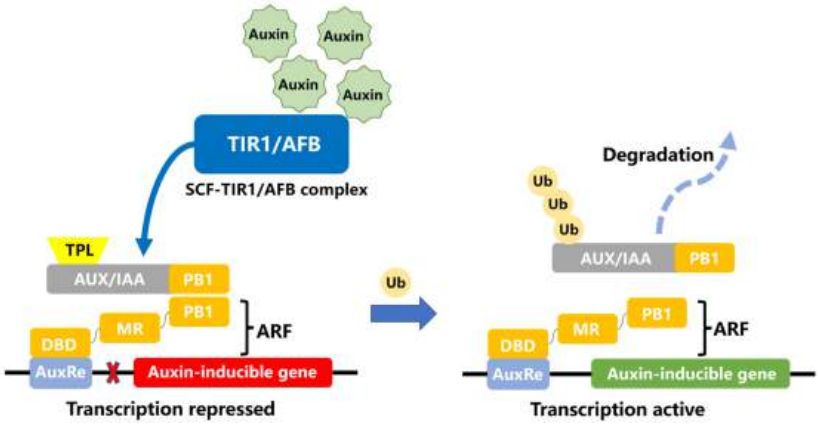

Figure 28.16.4: Model of ARF involvement in auxin response. DBD, DNA-binding domain; MR, middle region; PB1, Phox, and Bem 1. *Kou et al. Appl. Sci.* **2022**, *12*(3), 1360; **https://doi.org/10.3390/app12031360.** Creative Commons Attribution (CC BY) license (**https://creativecommons.org/licenses/by/4.0/**).

At low concentrations of auxin, the AUX/IAA repressor binds to the ARF transcription factor through their PB1 domains. The PB1 (Phox and Bem1) domain is about 80 amino acids in length. It acts as a protein binding module allowing heterodimerization or homo-oligomerization with proteins have also contained the PB1 domain.

The dimer of AUX/IAA and ARF recruits the co-repressor TPL (TOPLESS) to inhibit the ARF activity and the expression of auxin-responsive genes. When the concentration of auxin is increased, Aux/IAA binds to the SCF TIR1/AFB complex and is ubiquitinated and then degraded by 26S protease. The ARF transcription factors are released to activate the transcription of downstream genes. DBD, DNA-binding domain; MR, middle region; PB1, Phox, and Bem 1.

- At low concentrations of auxin, the AUX/IAA repressor binds to the ARF transcription factor and forms a dimer that recruits the co-repressor TPL (TOPLESS) to inhibit the ARF activity and the expression of auxin-responsive genes;
- When the concentration of auxin is increased, Aux/IAA binds to the auxin:SCF TIR1/AFB complex (remember that the auxin receptor is the TIR1 component of the complex) and is ubiquitinated by the TIR1, which is also a ubiquitin ligase;
- The ubiquitinated AUX/IAA protein is degraded by proteolysis by the 26S protease, allowing the ARF to become an active transcription factors

It appears that the MR domain of ARF determines whether it activates or inhibits transcription. If it is rich in proline, serine, and threonine, it acts as an inhibitor. If it is enriched in glutamine and leucine it acts as an activator. Some reports show that Aux/IAA and ARFs can form not only dimers but also larger complexes (oligomers), noting that oligomerization of Aux/IAA proteins may be essential for the inhibition of ARF proteins and only sufficient amounts of Aux/IAA proteins can exert the inhibitory effect of ARF proteins.

Figure 28.16.5 shows an interactive iCn3D model of the DNA binding domain of arabidopsis thaliana auxin response factor 1 (ARF1) in complex with auxin response element-like sequence ER7 (4LDX)

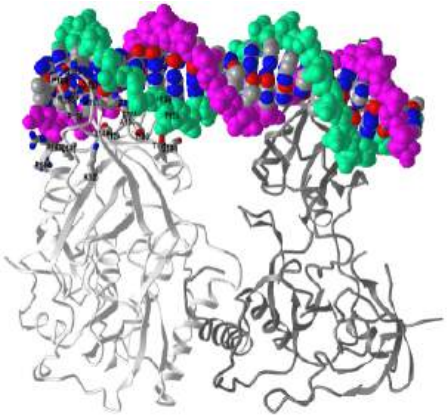

Figure 28.16.5: DNA binding domain of arabidopsis thaliana auxin response factor 1 (ARF1) in complex with promoter-like sequence ER7 (4LDX) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...9fNHEiFaVANAk6

The ARF protein must translocate to the nucleus to regulate gene transcription. ARF7 and ARF19 have been shown to form micron-sized aggregates in the cytoplasm. These have low responses to auxin. Aggregation occurs through PB1 domain interactions between ARFs as well as through intrinsically disordered regions. Mutation of a single lysine in the PB1 prevents aggregation and leads to morphological changes in the plant. This shows the importance of regulating not only transcription but also the translocation of proteins to the nucleus.

Figure 28.16.6reviews the activation of ARFs and some of the genes affected by ARF.

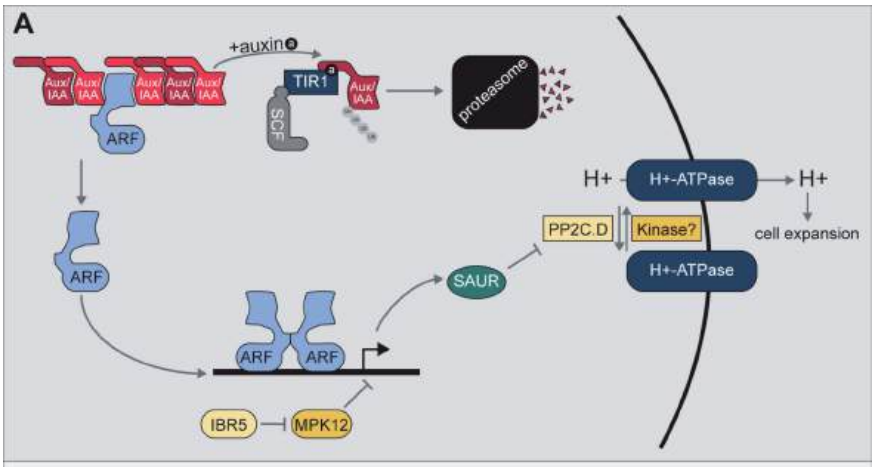

Figure 28.16.6: Auxin signal transduction pathways. Powers and Strader. Up in the air: Untethered Factors of Auxin Response (doi:10.12688/f1000research.7492.1). License CC BY 4.0

Auxin promotes the formation of the TIR1/AFB Auxin/Indole-3-acetic acid inducible (Aux/IAA) co-receptor to promote the ubiquitylation and subsequent degradation of the Aux/IAA repressor. Aux/IAA degradation relieves repression of auxin response factor (ARF) transcription factors, allowing for auxin-responsive gene expression. One of the transcript families upregulated by auxin is the SAUR family. The **s**mall **a**uxin **u**p **R**NA (SAUR) proteins encoded by these transcripts have been suggested to play roles in multiple processes, one of which is interaction with and inhibition of members of the PP2C.D family of phosphatases, which act to regulate H^+-ATPase activity. Further, indole-3-butyric acid response 5 (IBR5) and mitogen-activated protein kinase 12 (MPK12) have been implicated in regulating auxin-responsive gene transcription; this regulation is not through destabilization of the Aux/IAA repressors, suggesting a yet-to-be-discovered mechanism of regulating auxin-responsive gene expression. F

28.16.3: Cytokinins (CKs) and Ethylene (ET)

Much of this material derives from Bidon et al. Cells 2020, 9, 2526; doi:10.3390/cells9112526 . Creative Commons Attribution (CC BY) license. (http://creativecommons.org/licenses/by/4.0/).

Cytokinins (CKs) and ethylene (ET) are among the most ancient organic chemicals on Earth. The structure of a representative cytokinin (kinetin) and ethylene are shown in Figure 28.16.7.

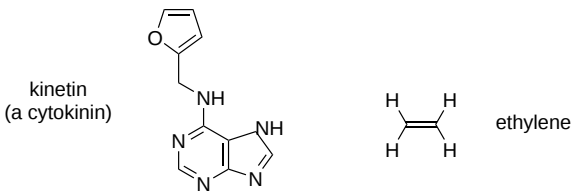

Figure 28.16.7: Structure of kinetin (a cytokinin) and ethylene

A wide range of organisms including plants, algae, fungi, amoebae, and bacteria use these substances as signaling molecules to regulate cellular processes. Because of their ancestral origin and ubiquitous occurrence, CKs and ET are also considered to be ideal molecules for inter-kingdom communication. Their signal transduction pathways were first determined in plants and are related to the two-component systems of bacteria (which we explored in a previous section), using histidine kinases as primary sensors.

CKs share a common structure of N^6-substituted adenine (see Figure 28.16.7), with biological activities defined by the N^6-substituents (isoprenoids or aromatic groups). They were originally described as the major hormones regulating cell division but are also implicated in the control of morphogenesis and embryogenesis and inhibition of senescence. Conversely, ET is a simple gas, often referred to as the senescence hormone in plants, acting to stimulate the senescence of leaves and petals as well as the ripening of fruits. Both CK and ET are also well known to orchestrate plant responses to many types of biotic and abiotic stresses.

Signaling pathways in plants are related to the two-component systems typically described in prokaryotes. CKs and ET are perceived by two types of membrane-bound **histidine kinase receptors, CRE1** and **ETR1** as shown in Figure 28.16.8

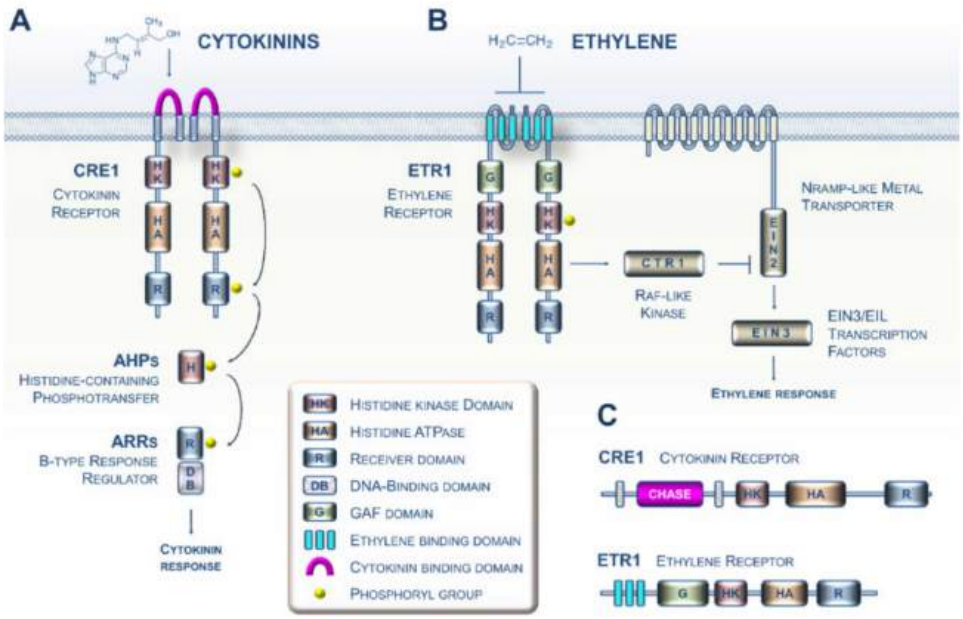

Figure 28.16.8: Perception and transduction of cytokinin (CK) and ethylene (ET) signals in the model plant *Arabidopsis*.

Panel **A** shows the cytokinin signaling pathway. CKs in *Arabidopsis* primarily are recognized by dimerized receptors such as the CRE1 receptor via the **cyclase/histidine kinase-associated sensing extracellular (CHASE) domain**. CRE1 then auto-phosphorylates (histidine kinase (HK) activity) and immediately transfers its phosphate group to the conserved histidine of a protein belonging to the histidine-containing phosphotransfer (HPt) family. This small protein then acts as a cytoplasm-to-nucleus shuttle and in turn phosphorylates a type B response regulator, which, when activated, positively regulates the transcription of response genes to the CK signal.

Panel (**B**) shows the ET signaling pathway. Ethylene molecules are detected by ethylene receptors (labeled ETR1) with ethylene binding to the three transmembrane helices (shown in sky blue). The binding of ET to the dimerized ETR1 receptor downregulates its activity. In the absence of ET, ETR1 activates the serine/threonine kinase CTR1. The CTR1 protein then phosphorylates the EIN2 protein located in the ER membrane, leading to the proteolysis of EIN2. In the presence of ET, ETR1 activity is reduced, leading to less CTR1 activity; this leads to lower phosphorylation and accumulation of EIN2 protein and subsequent activation of the EIN3 and related transcription factors. EIN3 then positively regulates the transcription of ET signal response genes.

Panel (**C**) shows the domain structure of the *Arabidopsis* ET (ETR1) and CK (CRE1) receptors.

Mechanistically, the two pathways use fundamentally different families of downstream modules.

It is now known that bacteria also use CK and ET signaling, as described in Figure 28.16.9

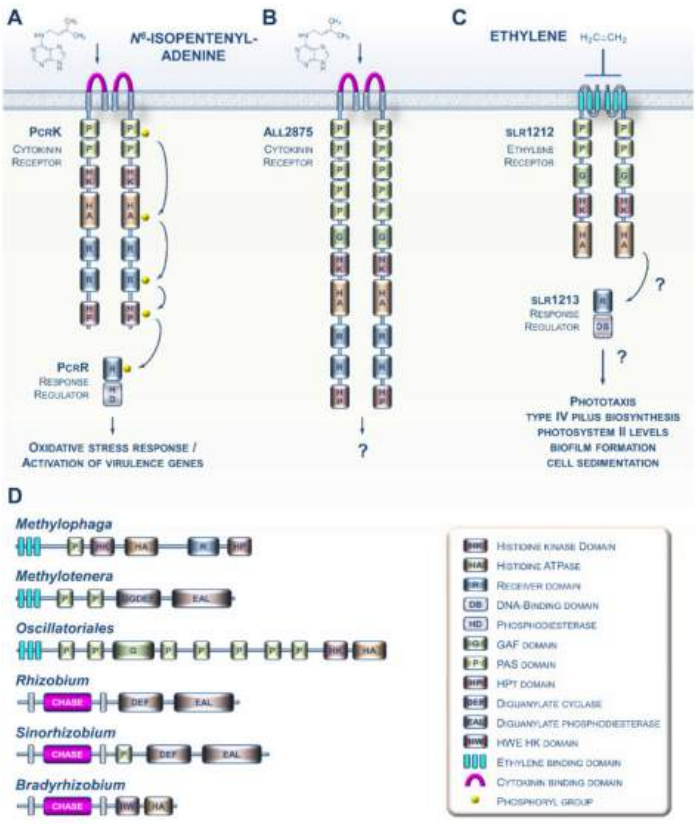

Figure 2.

Let's look in more detail at CRE1, cytokinin response 1, the main cytokinin receptor in plants. Different computational programs often show different domain structures. Figure 28.16.10shows the domain structure determined by Pfam.

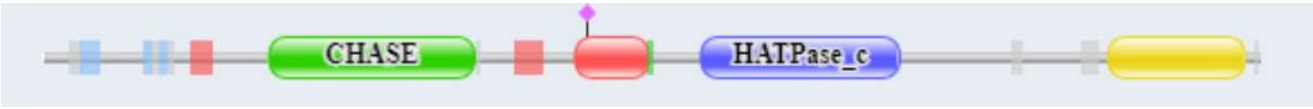

Figure 28.16.10: Domain structure of cytokinin response 1, the main cytokinin receptor in plants.

Uniprot describes this domain structure, color-coded as in Figure 28.16.11

- 131-149: transmembrane
- 200-382: Green Chase (**C**yclases/**H**istidine kinases **A**ssociated **S**ensory **E**xtracellular)
- 420-443 transmembrane
- 472-537: Red His Kinase A Phosphoaccepter domain
- 584-760 Blue HK kinase, DNAgyrase, HSP-like ATPase
- 786-920: Yellow Reg REsp 1
- 946-1071: Yellow Reg Regulator receiver domain

Figure 28.16.11shows an interactive iCn3D model of Histidine kinase 4 - Cytokinin receptor 1 (CRE) from Arabidopsis thaliana (AlphaFold model - Q9C5U0). The coloring matches the Pfam domains shown in Figure 28.16.10

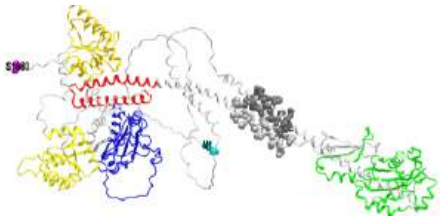

Figure 28.16.11: Histidine kinase 4 - Cytokinin receptor 1 (CRE) from Arabidopsis thaliana (AlphaFold model) - Pfam Domain organization (Q9C5U0) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...jq7BTpshpS3d46

Figure 28.16.12 shows an interactive iCn3D model of Histidine kinase 4 - Cytokinin receptor 1 (CRE) from Arabidopsis thaliana (AlphaFold model) - Domain organization (Q9C5U0) that clearly shows the extracellular and intracellular domains.

Figure 28.16.12: Histidine kinase 4 - Cytokinin receptor 1 (CRE) from Arabidopsis thaliana (AlphaFold model) - Domain organization (Q9C5U0) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...2Q9WsRkZk75ZZ8

The N-terminal methionine is in cyan spacefill and the C-terminal Ser is in spacefill. Two transmembrane helices are shown in dark gray spacefill (125-145) and light gray spacefill (430-450). These connect the extracellular domain (cyan, 146-429) and the two cytoplasmic domains (magenta 1-124, which is mostly disordered in the model, and 451-1080). This model does not reflect the relative disposition of the protein in the actual structure, but clearly shows the extracellular and cytoplasmic domains. The extracellular domain (cyan, 146-429) is the CHASE domain.

Here are the step involved in cytokinin signaling through its receptor (shown in Figure 28.16.8:

- the cytokinin binds to the CHASE domain
- the receptor autophosphorylates a His in the HK domain
- a phosphotransfer from the pHis to an Asp in the Yellow Reg (Regulator) Receiver domain
- a phosphotransfer from pAsp to the His in the histidine-containing phosphotransfer protein (HPt)
- a final transfer from pHIs to an Asp in a response regulator (RR)

The MAPK cascade is activated in the cytokinin signaling pathway. Phosphorylated pRR can also regulate target gene transcription. Type-A RRs are negative regulators of cytokinin signaling. It also acts with phytochromes (discussed at the end of this section) to regulate red light signaling. Cytokinin receptors can bind synthetical chemicals that act as defoliants and herbicides.

Intermolecular interactions in the cytokinin signaling pathway leading to transcriptional effects are illustrated in Figure 28.16.13

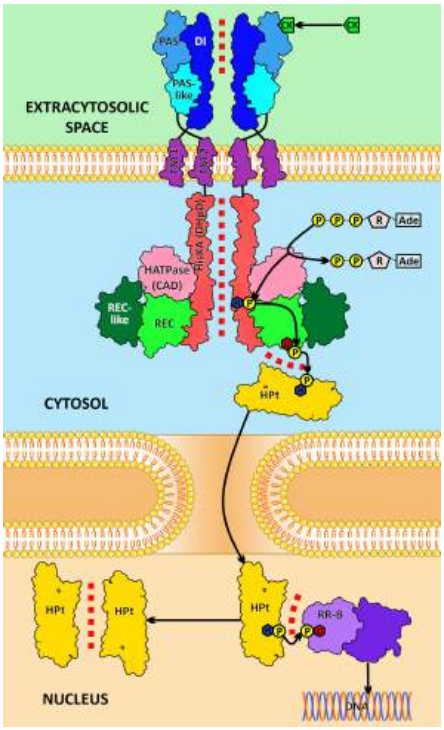

Figure 28.16.13: Intermolecular interactions in the cytokinin signaling pathway. CK, cytokinin; Ade, adenine; R, ribose; P, phosphate; D, conserved aspartate; H, conserved histidine; DI, dimerization interface domain of the sensor module; PAS and PAS-like are subdomains of the CHASE domain of the sensor module; TM1 and TM2, transmembrane domains; HisKA (DHpD), histidine kinase A domain (dimerization and histidine phosphotransfer domain); HATPase (CAD), adenosine triphosphatase domain (catalytic and ATP-binding domain); REC-like, receiver-like domain; REC, receiver domain; HPt, histidine-containing phosphotransfer protein (phosphotransmitter); RR-B, type B response regulator (transcription factor). Protein–protein interactions (PPI) are indicated by a red dotted line. *Arkhipov et al. Int. J. Mol. Sci.* **2019**, *20*(9), 2096; **https://doi.org/10.3390/ijms20092096**Creative Commons Attribution (CC BY) license (**http://creativecommons.org/licenses/by/4.0/**).

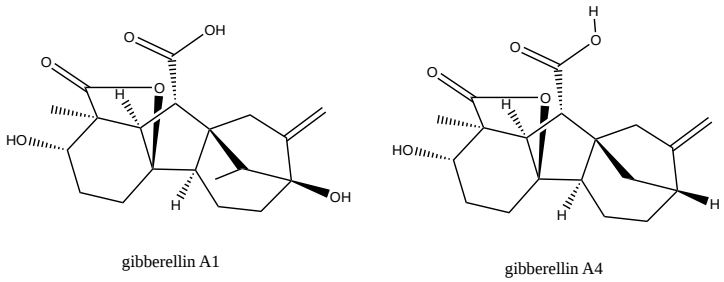
28.16.4: Gibberellin

Much of this material derives from Hedden, P., Sponsel, V. A Century of Gibberellin Research. *J Plant Growth Regul* **34,** 740–760 (2015). https://doi.org/10.1007/s00344-015-9546-1. https://doi.org/10.1007/s00344-015-9546-1. Creative Commons Attribution 4.0 International License (http://creativecommons.org/licenses/by/4.0/)

Gibberellin controls growth and development pathways in plants and fungi. They act in plants by removing growth limitation by promoting the degradation of the growth-inhibiting DELLA proteins which contain the Asp-Glu-Leu-Leu-Ala (DELLA) motif. The name gibberellin derives from the fungus *Gibberella fujikuroi*. There are many types of gibberellins, which are all diterpenoids. The structures of the main bioactive GAs in plants, GA_1 and GA_4, are shown below in Figure 28.16.14



gibberellin A1 gibberellin A4

Figure 28.16.14: Structures of gibberellin A1 and A4

Gibberellin initiates signaling by binding to the nuclear gibberellin receptor. One such receptor is the Gibberellin Insensitive Dwarf1 (GID1). When bound, it leads to the proteolysis of another protein bound to it called a DELLA protein (an example is GAI), a transcriptional regulator that inhibits growth. The control of transcriptional activity by gibberellins is hence reminiscent of that of auxins.

Figure 28.16.15 shows an interactive iCn3D model of the gibberellin(GA3)- active gibberellin receptor GID1L1 bound to the DELLA domain of GAI (2ZSH).

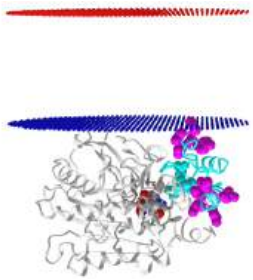


Figure 28.16.15: gibberellin(GA3)- Active gibberellin receptor GID1L1 bound to the DELLA domain of GAI (2ZSH). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...jVpzjnbUoQMhz5

The gibberellin receptor is gray and associated with the inner leaflet (blue) of the membrane. The plant hormone gibberellin A3 is bound to the receptor. Amino acid side chains in the receptor involved in the interactions with gibberellin A3 are shown in sticks, colored CPK. The DELLA protein GAI RAG protein is shown in cyan. The 3 amino acid motifs within it (DELLA, cyan spacefill; and VHYNP and LExLE, both magenta spacefill) are also shown. As with the auxin receptor, GID11A binds gibberellin in a deep pocket, which is covered by an N-terminal helix of the receptor. That helix recognizes and binds to the DELLA sequence in the DELLA transcription regulator protein.

Figure 28.16.16shows the effects of a mutation that leads to deficiencies in gibberellin 1-3 (right-hand side).

Figure 28.16.16: Physiological action of GA as illustrated by a comparison of the Landsberg *erecta Arabidopsis* plant with a GA-deficient mutant (ga1-3). In the absence of a GA, response stem elongation, leaf enlargement, floral development, seed set, and fruit development do not occur

The mechanism by which GAs promote growth is shown in Figure 28.16.17.

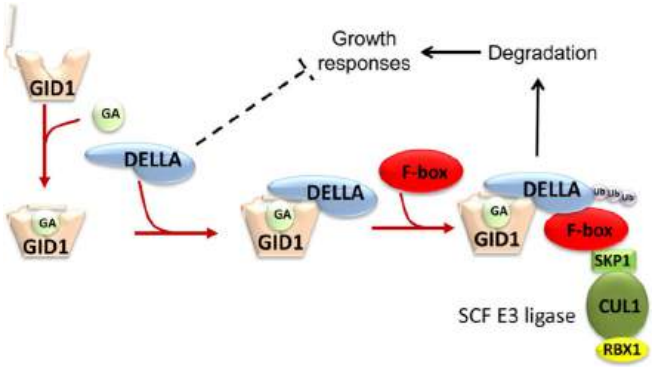

Figure 28.16.17: Representation of GA perception and signal transduction.

Binding of bioactive GA results in a conformational change in the GID1 receptor that promotes interaction with DELLA proteins. Recruitment of an F-box protein initiates ubiquitination of DELLA by an SCF E3 ubiquitin ligase targeting the DELLA for proteasomal degradation. Loss of DELLA relieves growth repression and suppresses other DELLA-mediated responses

28.16.5: Abscisic acid

Much of this material derives from Hewage et al. (2020). Advanced Science. https://doi.org/10.1002/advs.202001265. This is an open-access article under the terms of the Creative Commons Attribution License.

The phytohormone abscisic acid (ABA) is the best-known stress signaling molecule in plants As such it will be key as plants struggle to adapt to climate change. Its structure is shown in Figure 28.16.18

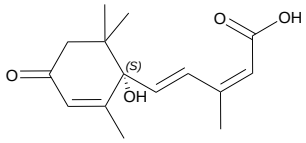

Figure 28.16.18: Structure of abscisic (ABA)

ABA protects land plants from biotic and abiotic stresses. ABA receptors proteins (**PYLs**) contain a conserved pyrabactin resistance/pyrabactin resistance-like/regulatory domain (**PYR/PYL/RCAR**) that binds ABA and triggers a cascade of signaling events.

ABA has significant roles throughout a plant's life cycle. From the single-celled zygotic stage to the mature multicellular plant, plant developmental stages involve ABA. ABA allows germination only under optimum conditions and inhibits growth under stress conditions. The adult plant as well as the seedling experience biotic and abiotic stressors that vary in severity and persistence. ABA allows that plant to survive by inducing both short-term and long-term stress responses, including rapid and reversible stomatal closure, long-term growth inhibition, dormancy, senescence, and abscission. ABA is therefore both a developmental and a stress-signaling molecule with diverse roles, as shown in Figure 28.16.19

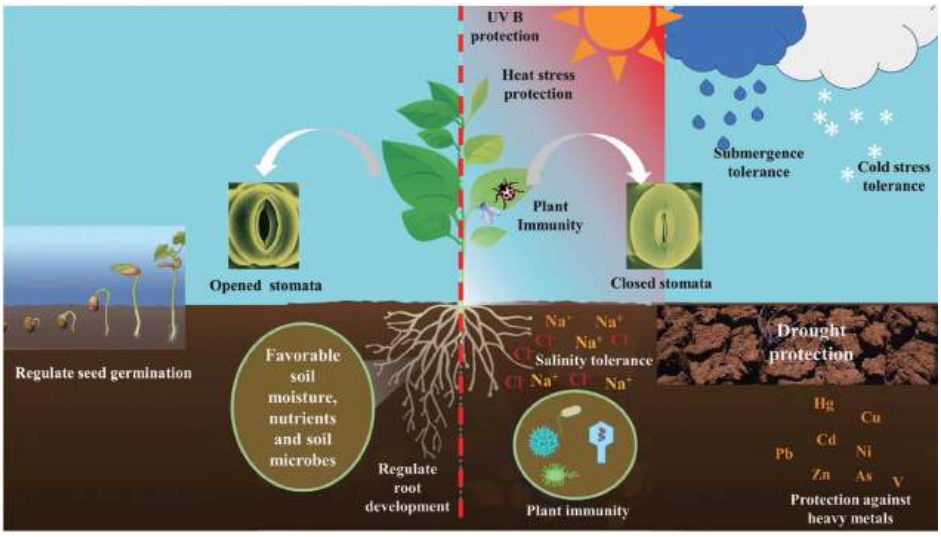

Figure 28.16.19: Summary of ABA involvement in the development and stress tolerance.

ABA signaling in drought

Let's look at a specific example of ABA signaling in the presence of drought, stress that will expand as the world's climate changes due to the combustion of fossil fuels.

Insufficient levels of soil water can result in an imbalance of water between the cells and the outer environment. A resulting change in the cellular electrolyte content affects metabolism, resulting in an osmotic imbalance or stress. The osmotic stress thus leads to the accumulation of ABA in cells and triggers ABA signaling. The cellular pool of ABA is dramatically increased during drought. Biosynthesis, catabolism, conjugation, and transportation of ABA are coordinated to increase ABA levels. ABA rapidly regulates plant water levels by controlling stomata. Stomata, which are microscopic pores controlled by two highly differentiated epidermal cells (guard cells), have the primary role in regulating gas exchange between the air and plant. Open stomata allow CO_2 to diffuse into the leaf mesophyll and reach the sites of photosynthesis. They also allow water vapor to exit from the plant interior to the atmosphere.

By allowing transpirational water loss, stomata allow the cooling of the plant and the managing of the interior water levels. Thus, stomata are essential regulators that connected the plant interior to the outside environment. Increases in osmotic pressure in guard cells lead to water uptake and then to cell expansion; as the cells expand, the pore opens because of differential thickenings of guard cell walls. Stomatal movements are regulated by numerous environmental signals such as light, plant growth regulators, pathogens, drought, cold, and nutrient status. Stomatal movement is the quickest response to ABA signaling. Therefore, the core

ABA signaling is essential for guard cell function. The involvement of ABA signaling events in guard cell function is summarized in Figure 28.16.20

Figure 28.16.20: Simplified representation of ABA-mediated core signaling events in guard cells.

In the absence of ABA, (left) ABA receptors (PYLs) are in ligand-free form. H^+ATPase action pumps H^+ ions outside of the plasma membrane. The SnRK2 protein kinases and the S-type anion channel SLAC1 are kept dephosphorylated by PP2Cs. The dephosphorylation state of SLAC1 prevents the nonspecific activation of S-type anion channels.

In the presence of ABA (right) PYLs bind to and inhibit PP2Cs. ABA inhibits H^+ATPase activity, blocking the H^+ pumping outside. The Ca^{2+}-independent protein kinases (SnRK2s) are released from PP2C inhibition and activated by auto-phosphorylation. Ca^{2+}-permeable cation (I_{Ca}) channels are released from PP2C-mediated inhibition, causing increases of ABA-responsive Ca^{2+} in cytosol leading to activate CPKs. The activated SnRK2s and CPKs phosphorylate SLAC1 The SnRK2.6/OST1 protein kinase phosphorylates and activates the R-type anion channel ALMT12/QUAC1. The K^+ ions are effluxed via voltage-dependent outward K^+ (K^+_{out}) channel GORK, causing a guard cell turgor decrease leading to stomatal closure. PYLs: ABA receptors; ABA: abscisic acid; PP2C: protein phosphatase 2C proteins; OST1: open stomata 1/SnRK 2.6 protein kinase; Ca/CPK: $Ca^{2+/}$calcium dependent protein kinases; I_{Ca2+}: plasma membrane nonselective cation channel permeable to Ca^{2+} SLAC1: slow anion channel-associated 1 (SLAC1); QUAC: aluminum-activated malate transporter 12/quickly activating anion channel 1 (ALMT12/QUAC1); GORK: guard cell outward rectifying K^+ channel (GORK); KAT1: K^+ activated 1 potassium ion channel; A−: anions; K^+: potassium ions.

The ABA receptor core complex

There are three main phases of ABA signaling: ABA synthesis/metabolism, long-distance transport, and ABA binding to its receptor. Downstream signaling ensues. through transcriptional activators/repressors and plasma membrane-located channel proteins. The main components of the core ABA signaling pathway are shown in Figure 28.16.21

Figure 28.16.21: Components of the Core ABA signaling pathway.

In the absence of ABA (A above), SnRK2 kinases are dephosphorylated by protein phosphatase 2C (PP2Cs). In the presence of ABA (B above) PP2Cs are inhibited by the complexes PYLs-ABA. Thus, the SnRK2 kinases are released and make a cascade of downstream transcription factors, NADPH transporters, and ion channels phosphorylate the transcription factors that induce ABA-responsive gene transcription, and ion channels act on the guard cells to bring about transpirational control.

ABA receptors (PYLs) bind ABA, PP2C, and protein kinases. The ABA:PYL complex binds PP2Cs, leading to conformational changes in the active sites of PP2Cs that inhibits the phosphatase. This in turn leads to the release of downstream protein kinases (SnRK2s) from PP2C-mediated inhibition. The SnRK2s undergo autophosphorylation to activate a series of ion channels, NADPH oxidases, and transcription factors via phosphorylation. This activates both short-term and long-term ABA responses such as stomatal closure and upregulation of ABA-dependent gene expression. MAPKKKs (MAPK3s) also activate SnRK2.6 by phosphorylating a specific site during salinity stress.

ABA binding regulates a double-negative regulatory system, in which the ABA receptor (PYLs) act as ABA receptors, PP2Cs as negative-regulatory coreceptors, and SnRK2s as negative regulators. In addition to the regulation by SnRK2 and PP2Cs, several post-translational modifications also regulate ABA signaling. Phosphorylation, dephosphorylation, ubiquitination, farnesylation, and sumoylation have been found to modulate ABA signaling by targeting core components (PYLs or PP2Cs) or other interacting proteins downstream.

ABA Receptors (PYLs)

PYLs are soluble proteins, and among the 14 PYLs in *Arabidopsis*, 13 functions as ABA receptors. All PYLs are known to share a dominant helix-grip structure. This characteristic motif consists of a seven-stranded antiparallel β-pleated sheet, which is flanked by two α helices. The β-pleated sheets enfold a long carboxy-terminal α-helix of PYLs. The apo-PYLs contain a sufficiently large hydrophobic pocket of 543˚A between the C-terminal helix and β sheet. The size of this pocket is estimated to be 480˚A in the ABA-bound state. The 23 pocket residues are highly conserved and are more hydrophobic than the other parts of PYLs. The interactions of ABA and PYL2 are shown in Figure 28.16.22

Figure 28.16.22 The binding mode of ABA and PYL2 (PDBID: 3KDI) in A) 3D and B) 2D (redrawn).[211] In the 3D structure, the cartoon of PYL2 is colored in white (A). The important residues and ABA are shown in sticks with blue and yellow colors

respectively. The H-bonds are marked with red dotted lines.

Figure 28.16.23shows an interactive iCn3D model of Abscisic acid bound to the Abscisic Acid Receptor (PYL2) (pdbid: 3KDI)

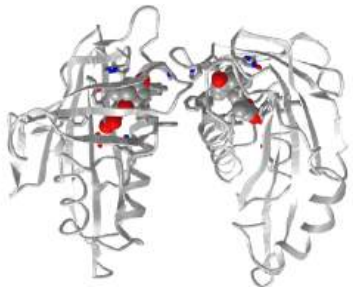

Figure 28.16.23: Abscisic acid bound to the Abscisic Acid Receptor (PYL2) (pdbid: 3KDI) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...uToGsSPpnZfPeA

In the absence of ABA, the apo-PYL2 has a pocket surrounded by four surface loops. When ABA binds, one loop (CL2) closes onto the pocket, forming a PP2C binding site for the phosphatase ABI1 and ABI2. This blocks the active site of the phosphatase.

Figure 28.16.24shows an interactive iCn3D model of ABA-bound PYL1 and the Protein Phosphatase 2C ABI1 (pdbid 3kdj)

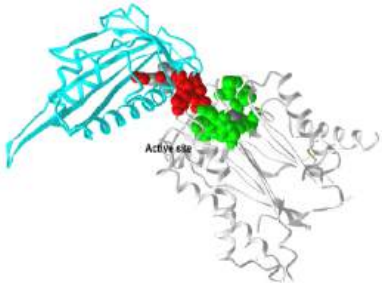

Figure 28.16.24: ABA-bound PYL1 and the Protein Phosphatase 2C ABI1 (pdbid 3kdj) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...tQgyC7NVXk1UVA

The PP2C phosphatase (ABI1) is shown in gray with its active site highlighted in green spacefill. The ABA receptor PYL1 is shown in cyan with ABA shown in sticks, colored CPK. The CL2 loop of the ABA-bound PYL1 receptor is shown in red spacefill. It projects into the PP2C active site, inhibiting its activity.

28.16.6: Light Signaling through Phytochromes

Much of this material derives from Liu, Y., Jafari, F. & Wang, H. Integration of light and hormone signaling pathways in the regulation of plant shade avoidance syndrome. *aBIOTECH* **2,** 131–145 (2021). https://doi.org/10.1007/s42994-021-00038-1. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/. get rid of this

Plants deal with competing plants in regions of high plant density by sensing changes in the intensity and wavelengths of light. Signaling leaves to responses (stem elongation, reduced branching, early flowering, etc) called shade avoidance syndrome (SAS). A photosensory system initiates signaling that alters gene transcription. In the SAS in plants in a large canopy, the upper leaves used red and blue light for photosynthesis. Multiple photoreceptors are used. Some transcription factors are also sensitive to light. For example, PIF3, a transcription factor, binds to light-responsive genes only when it binds to another transcription factor called Pr. Pr is resident in the cytoplasm but moves to the nucleus after altering conformation on absorbing red light.

Legris, M., Ince, Y.Ç. & Fankhauser, C. Molecular mechanisms underlying phytochrome-controlled morphogenesis in plants. *Nat Commun* **10,** 5219 (2019). https://doi.org/10.1038/s41467-019-13045-0. Phytochromes are present in bacteria, cyanobacteria, fungi, algae, and land plants. We will focus mostly on phytochromes in Arabidopsis. In land plants, phytochromes are red and far-red light receptors that exist in two forms. They are synthesized in the inactive Pr state, which upon light absorption converts to the active Pfr conformation. Pfr is inactivated upon far-red (FR) light absorption or through thermal relaxation, which depends on temperature. Phytochromes act as dimers, resulting in three possible phytochrome species: Pr–Pr, Pfr–Pr, and Pfr–Pfr. Pr and Pfr have different absorption maxima, but due to overlapping spectra both conformers are always present in the light while only prolonged darkness returns all phytochrome to Pr. Given that phytochrome

responses depend on the proportion of Pfr conformers, signaling is influenced by a combination of light quantity, color, and temperature. These features of phytochromes are summarized in Figure 28.16.25

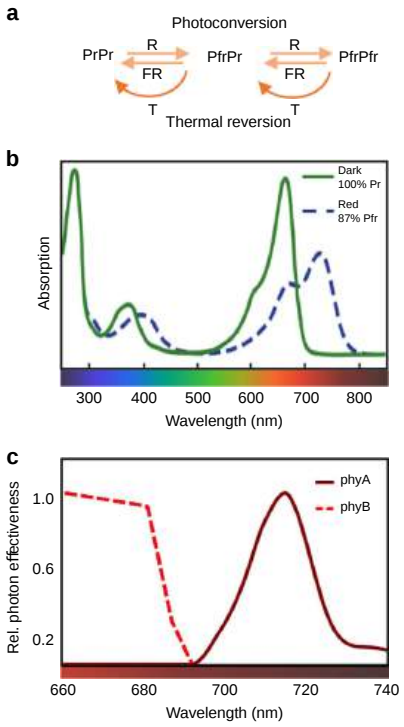

Figure 28.16.25: Control of phytochrome activity.

Panel a shows factors that control phytochrome activity. Phytochromes exist in two conformations, Pr and Pfr, the latter being the active form. They exist as dimers so three species can be found. Each monomer can be activated by red light (R) and inactivated by far-red light (FR) or by thermal reversion, a process that depends on temperature (*T*). At least in the case of phyB, Pfr in heterodimers reverts much faster than that in homodimers, allowing phyB to perceive temperature both during the day and during the night.

Panel b shows plant phytochrome absorption spectra of the Pr and Pfr conformations. In dark-adapted seedlings, phytochromes are in the Pr form. Upon a saturating R pulse, due to overlapping absorption spectra of Pr and Pfr, only 87% of Pfr is achieved.

Panel c shows action spectra for phyA and phyB in the control of hypocotyl elongation. Fluence rate (number of particles passing per unit time) response curves are measured at different wavelengths and fluence rate that leads to 40% inhibition compared with dark control is determined. To specifically determine action spectra for phyA and phyB, for phyB the curve was performed with phyB-GFP/*phyAphyB* seedlings, and for phyA using *phyB-5* seedlings. Values are relative to the response obtained at the most efficient wavelength in each case

Plant phytochrome structure

Plant phytochromes are dimeric, each monomer consisting of ~1150 amino acids. The chromophore, a linear tetrapyrrole named phytochromobilin (PΦB), whose structure is shown in Figure 28.16.26, is attached to the protein.

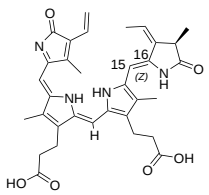

Figure 28.16.26: Structure of phytochromobilin (PΦB)

The domain structure of phytochromes is shown in Figure 28.16.27.

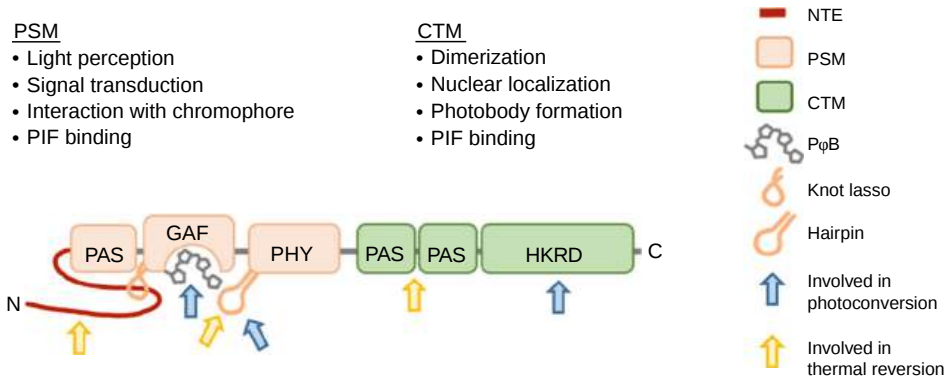

Figure 28.16.27: Structural domains of phytochromes and their role in the perception of environmental signals and downstream signaling. NTE N-terminal extension, PSM photosensory module, CTM C-terminal module.

The apoprotein can be divided into the N-terminal PSM, which consists of the N-terminal extension (NTE), for which structural information remains scarce, and three structurally related domains Period/Arnt/SIM (PAS), cGMP phosphodiesterase/adenylyl cyclase/FhlA (GAF), and a phytochrome-specific domain (PHY) and a C-terminal module (CTM) comprising two PAS domains and a histidine kinase-related domain (HKRD). The chromophore is bound covalently to a conserved cysteine in the GAF domain, which has intrinsic chromophore lyase activity. Light perception triggers a Z to E isomerization around the C15–C16 double bond of PΦB, which leads to a cascade of structural modifications in the protein. Figure 28.16.28shows an interactive iCn3D model of phytochrome (Deinococcus) Pfr form in the Photoactivated State (5C5K)

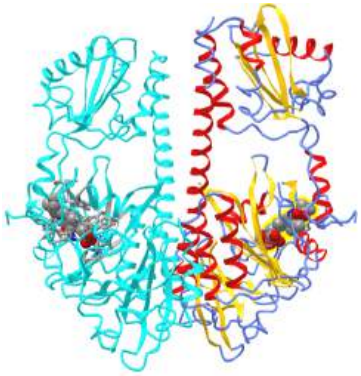

Figure 28.16.28: Phytochrome (Deinococcus) Pfr form in the Photoactivated State (5C5K) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...VzE7AqtgejbfeA

The protein is shown in its active dimeric state. One chain is shown in secondary structure colors and the other in cyan. The chromophore (heme derivatives) are shown in spacefill in both subunits. Side chains surrounding the chromophore are shown in colored sticks in the cyan chain.

At first glance, the presence of the histidine kinase-related domain (HKRD) would seem to suggest that phytochromes transduce their signal through the C-terminal module (CTM). Although many bacterial and cyanobacterial phytochromes have a C-terminal histidine kinase domain and act as light-regulated histidine kinases, plant phytochromes are not histidine kinases, and their role as Ser/Thr kinases remains contentious. The photosensory module (PSM) fused to a nuclear localization signal and a dimerization sequence is sufficient to restore most phyB functions, pointing to key signaling functions of the PSM.

Major The major of the plant phytochrome CTM are dimerization, nuclear import, and localization to sub-nuclear structures known as photobodies. However, it was recently shown that the C-terminal part of phyB also engages in light-regulated interactions and regulation of PIF activity. Moreover, the activity of the CTM is controlled by post-translational modification with SUMOylation limiting the ability of active phyB to interact with downstream signaling targets thereby limiting light responses. In addition, the CTM modulates active (Pfr) phytochrome levels with the HKRD inhibiting the Pr–Pfr photoconversion while the PAS–PAS promotes thermal reversion. Hence, while the division of plant phytochromes into PSM and a CTM helps describe the molecule, both parts of the photoreceptor contribute to the regulation of active Pfr levels and downstream signaling activities.

Figure 28.16.29shows a simplified mechanism for phytochrome control of transcription factors in different light environments.

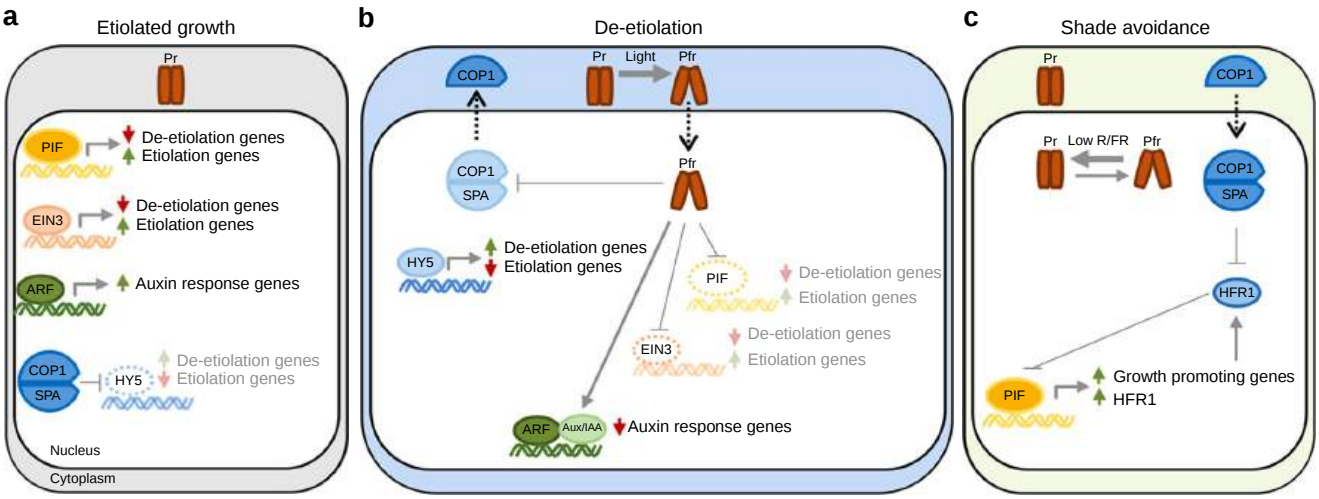

Figure 28.16.29: Simplified mechanism for phytochrome control of transcription factors in different light environments.

Panel a shows the response below the soil surface during growth in partial or a complete absence of light (called etiolated growth). For simplicity, we consider that phytochromes remain inactive (Pr) below the soil surface, which results in the accumulation of transcription factors PIFs, EIN3, and ARFs and subsequent induction of etiolation and auxin response genes. The COP1/SPA ubiquitin E3 ligase accumulates in dark and leads to proteasome-mediated degradation of HY5, a transcription factor that suppresses the expression of genes required for etiolation and induces expression of genes required for de-etiolation.

Pane b shows changes that occur when light intensity increases (de-etiolation). Light perception activates phytochromes (Pfr) which promote de-etiolation by directly inhibiting PIFs and EIN3, and indirectly inhibiting ARFs by stabilizing Aux/IAA proteins. The Pfr form of either phyA or phyB interacts with SPA proteins, resulting in the inhibition of COP1/SPA. This results in the stabilization of HY5 leading to the induction of de-etiolation-related gene expression and repression of etiolation genes.

Pane c shows de-etiolated plant in response to shade (reduced R/FR). Low R/FR in shade reduces the fraction of active phytochrome (Pfr/Ptot). PIFs accumulate and induce growth-promoting gene expression. In addition, PIFs induce a negative feedback loop exemplified by *HFR1* expression. HFR1 (and other HLH proteins) binds to PIFs forming non-DNA-binding heterodimers. COP1/SPA is also involved in this loop by leading HFR1 to proteasome-mediated degradation. Arrows indicate positive regulation, blunt-ended arrows indicate negative regulation and dotted-lined arrows indicate nucleo-cytoplasmatic relocalization

Figure 28.16.30summarizes how phytochromes affect transcription.

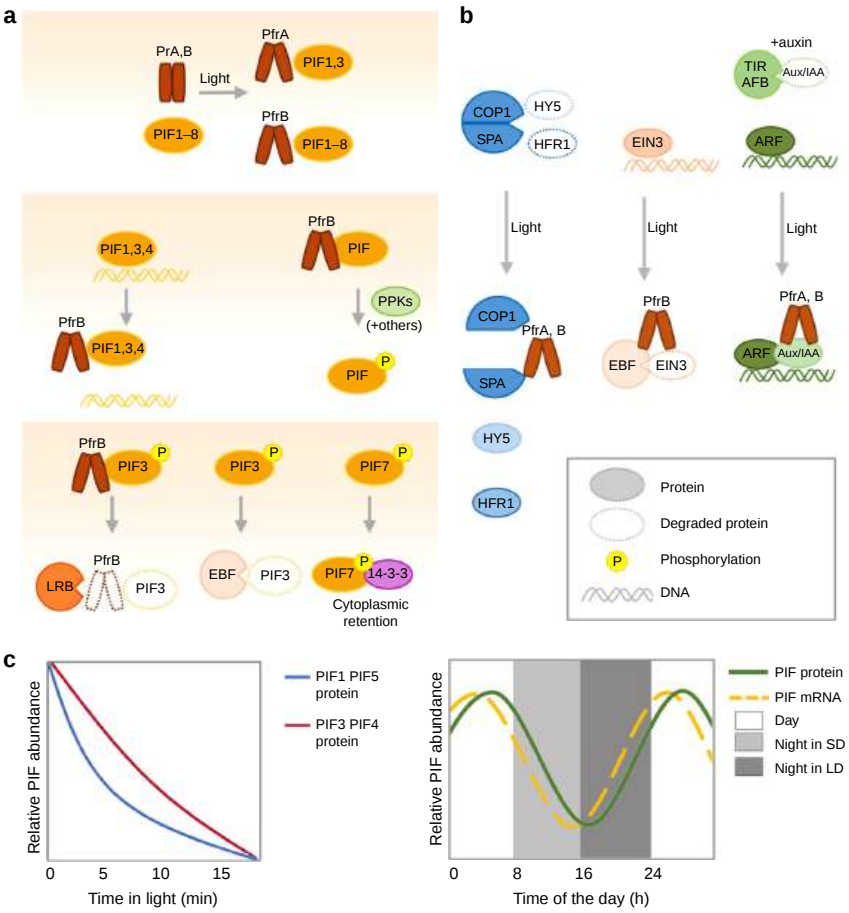

Figure 28.16.30: Mechanisms of phytochrome-mediated regulation of transcription factors.

Panel a (top to bottom) shows sequential steps by which Pfr inhibits PIFs. Top: PfrA interacts with PIF1 and PIF3 while PfrB interacts with PIF1–PIF8. Middle left: for PIF1, 3, and 4 phytochrome inhibits DNA binding. Middle right: Interaction with Pfr leads to the phosphorylation of PIFs. Many kinases have been found to phosphorylate PIFs (see text) with PPKs phosphorylating PIFs in response to light. Bottom: after light-induced phosphorylation, PIF3 is degraded by LRBs and EBFs with phyB co-degradation occurring in the LRB-mediated process (left, center), phosphorylated PIF7 interacts with 14-3-3 proteins and remains in the cytoplasm (right).

Panel b shows other mechanisms of transcriptional control by phytochromes. Left: PfrA and PfrB interact with SPA and inhibit the COP1/SPA complex. Center: PfrB interacts with EIN3 to promote ERF-mediated EIN3 degradation. Right: PfrA and PfrB interact with Aux/IAA to prevent their degradation by $SCF^{TIR1/AFB}$.

Panel c shows Patterns of PIF abundance depending on the developmental state and growth conditions. In etiolated seedlings PIFs accumulate to high levels, promoting etiolated growth. Upon light exposure, PIFs are rapidly degraded in a phytochrome-dependent manner, with half-lives of ~5 min for PIF1 and PIF5, and ~10 min for PIF3 and PIF4 (left). In contrast, in light-grown seedlings PIFs are under strong transcriptional control, allowing accumulation of the protein even in conditions when phytochrome activity is predicted to be high (right), SD (short days), LD (long days)

28.17: Signal Transduction - Vision and Olfaction

28.17.1: Sensory Transduction in Photoreceptors and Olfactory Sensory Neurons

Photoreceptors and olfactory sensory neurons (OSNs) have highly specialized structures that enable them to capture their respective stimuli of light and odorant ligands. Both photoreceptors and OSNs have evolved highly specific abilities to detect and discriminate light wavelengths or odors. They use intricate transduction mechanisms to convert sensory stimuli into electrical signals. Their transduction cascades not only can greatly amplify the signal but also to enhance the signal to noise, enabling these cells to detect and distinguish minute stimuli within very noisy background conditions. Such transduction mechanisms provide for modulation at multiple steps to adapt the sensory neurons to different background stimulation and optimize the capture of useful information about the surrounding world.

In this review, we summarize some of the key structural and functional features of vertebrate rod and cone photoreceptors and of OSNs, and the molecular mechanisms that underlie their function. While describing the features of both cell types, we emphasize the similarities and differences between photoreceptors and OSNs and the unique features of each cell type that make them perfectly suited to perform their function.

28.17.2: Signal Detection in Photoreceptors and Olfactory Sensory Neurons' Specialized Cilia

Vertebrate rod and cone photoreceptors as well as OSNs are ciliary neurons (Figure 1) with specialized cilia where the initial detection of the sensory stimulus takes place to activate a sensory transduction cascade. Rods and cones have a single cilium that has evolved to accommodate a stack of ~1,000 membrane disks where the visual pigment is expressed at a very high 3–5 mM concentration (Figure 1A; Palczewski, 2006). In the case of rods, the disks are enveloped by the plasma membrane, whereas in cones the disks are formed by invaginations of the plasma membrane. As light enters the eye and reaches the retina, it travels along the length of the rod and cone outer segments. The orientation of the elongated outer segments along the light path, together with the high density of visual pigment in their disks results in ~50% probability that an incident photon is absorbed by a visual pigment molecule (Bowmaker and Dartnall, 1980). In the case of OSNs (Figure 1B), odorant ligands are detected in the ~20 cilia protruding from each dendritic knob which are immersed in the mucus layer covering the olfactory epithelium. The olfactory cilia, which are motile in amphibians but not in rodents, are only about 0.1–0.2 μm thin but can reach up to 100 μm in length depending on the species (Kleene and Gesteland, 1981; Ukhanov et al., 2021). While this greatly increases the surface membrane area available to incorporate olfactory receptor (OR) proteins to detect odorants, it also greatly reduces the ciliary volume with potentially detrimental effects (see below).

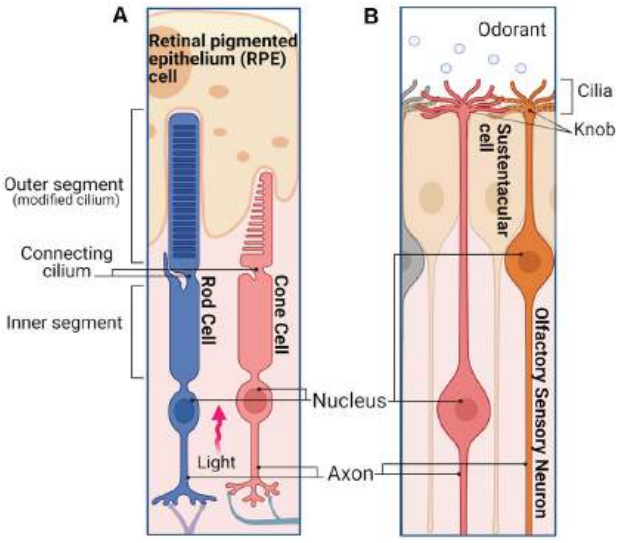

Figure 1. Photoreceptors and olfactory sensory neurons (OSNs). **(A)** Simplified schematic representation of a rod and a cone in the retina. Photoreceptors are polarized neurons with a specialized morphology optimized to detect light stimuli. The outer segments of

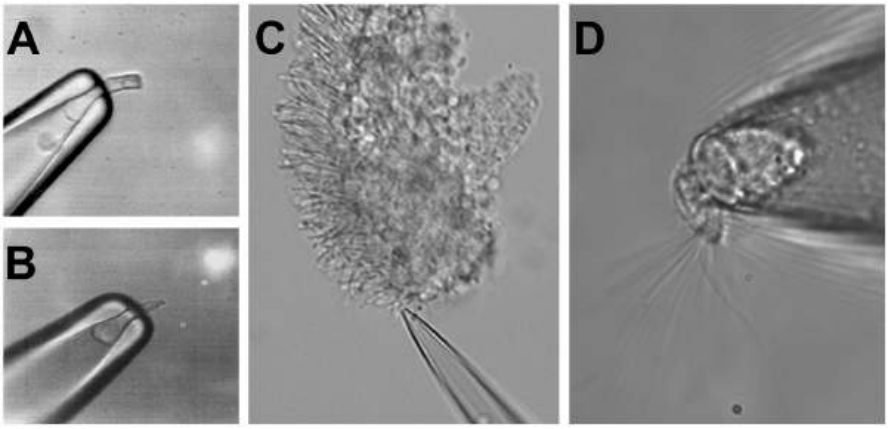
both rods and cones are modified sensory cilia, containing membrane disks organized in a stack. In the case of rods, the outer segment has a slim rod-like structure in which the disks are enclosed by the plasma membrane. The outer segment of the cones has a stocky conical-shaped structure, in which the disks are constituted by invaginations of the plasma membrane. The outer segment does not contain any proteins of the cell translation machinery, which are mostly localized in the inner segment, including the endoplasmic reticulum, Golgi, and mitochondria. Outer and inner segments are connected by the connecting cilium, while distal to the inner segment is the cell body containing the nucleus, followed by the axon and synaptic termini that extend into the outer plexiform layer where they synapse with the second-order neurons. When the light enters the eye, after reaching the retina, it travels along the length of the rod and cone inner segment until finally reaching the outer segments. **(B)** Simplified schematic of an OSN in the olfactory epithelium. OSNs are ciliated bipolar neurons, their apical dendrites extend to the surface of the epithelium terminating with a spherical structure called a dendritic knob, from which the sensory cilia enter the mucus layer. The ciliary membrane contains the olfactory receptors (ORs) necessary to detect different odorants. Distal from the knob is the cell body of the OSN with its nucleus, followed by a long axon that projects to the olfactory bulb, where it synapses with the second-order neurons. Images created with BioRender.com.

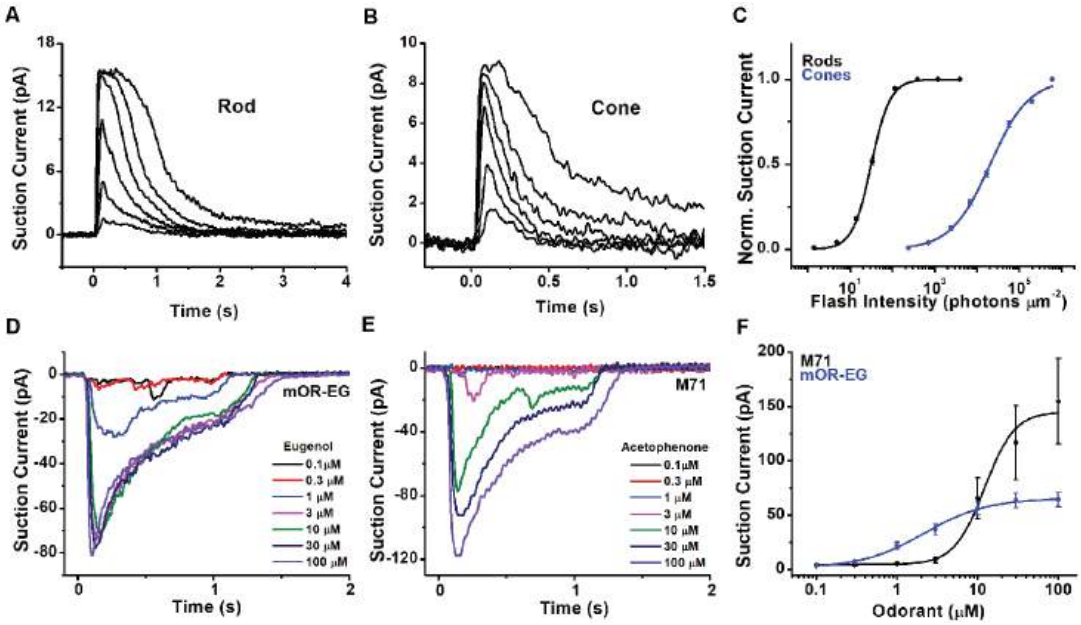
28.17.3: Electrophysiological Approaches to Record Light- and Odorant-Induced Responses

The similar morphological structure of rods, cones, and OSNs, with a ciliary part able to detect the respective stimuli and an adjacent cell body, allows similar electrophysiological approaches to recording stimulus-induced responses in these cell types. The cell body of a photoreceptor or an OSN can be sucked into the tip of a recording pipette by using a loose-patch (or suction pipette) recording configuration (Baylor et al., 1979; Lowe and Gold, 1991). This leaves the outer segment of photoreceptors or the olfactory cilia exposed and accessible to bath solution changes, e.g., the application of pharmacological agents or odorants, in the case of OSNs. Suction pipette recordings can be performed from isolated sensory neurons, as shown in Figures 2A,B,D (respectively, a salamander rod, salamander cone, and salamander OSN) but also from dissected retina tissue, as in the case of the outer segment of a mouse rod drawn in the recording electrode from a piece of the retina (Figure 2C). This recording configuration measures the transduction current entering the photoreceptor outer segment or olfactory cilia, and leaving *via* the cell body.



Figures modified from Reisert and Matthews (2001), Kefalov et al. (2010), and Kefalov (2012) with permission.

A fundamental difference between photoreceptors' and OSNs' responses to stimuli lies in their polarity. In the absence of light, rods, and cones are kept depolarized by a standing inward current of approximately 20–40 pA for amphibian cones and rods, and 7–15 pA for mouse photoreceptors. This depolarizing current is gradually suppressed upon light stimulation until, for sufficiently high light intensities, it is reduced to zero (Figures 3A, B, mouse rod, and cone responses, respectively), leading to photoreceptor hyperpolarization. Similar to rods, but differently from cones, the OSNs show comparatively little spontaneous activity in absence of stimuli (Reisert, 2010; Connelly et al., 2013). Different OSNs show varying levels of spontaneous basal activity determined by the constitutive activity of their ORs (Reisert, 2010; Connelly et al., 2013).



Figures modified from Kefalov et al. (2010), Sakurai et al. (2011), Deng et al. (2013), and Dibattista and Reisert (2016) with permission.

In the presence of odorants, OSNs generate an inward receptor current which leads to depolarization, and the generation of action potentials (Firestein and Werblin, 1989; Kurahashi, 1989; Reisert and Matthews, 1999). This receptor current is odorant concentration-depend and increases progressively with increasing stimulation until it eventually saturates at high odorant concentrations. Responses recorded from OSNs expressing different olfactory receptors can generate fairly different response amplitudes when stimulated with their respective agonists (Figures 3D, E: responses recorded from mouse OSNs that express the mOR-EG or the M71 olfactory receptor, which are activated by the ligands eugenol and acetophenone, respectively).

The hyperpolarization and signals carried by graded potentials in photoreceptors vs. depolarization and signals carried by action potentials in OSNs represent another fundamental difference between these two types of sensory neurons. These topics and the differences in synaptic structure and transmission between photoreceptors and OSNs go beyond the focus of this review and are discussed in an excellent recent review on this topic (Lankford et al., 2020).

28.17.4: Sensitivity of Photoreceptors and Olfactory Sensory Neurons

In part due to their unique structure, photoreceptors, and, to a lesser extent, OSNs have achieved exquisite sensitivity that optimizes the detection of stimuli within the respective sensory organs. In addition, both sensory receptors use a transduction cascade to amplify the signal (see below). As a result, rod photoreceptors can reliably detect single photons (Baylor et al., 1979), enabling humans to perceive light with as few as six photons detected by adjacent rods (Hecht et al., 1942). This renders rods perfectly suited for dim light vision, with a dynamic range spanning lights from a dark cloudy night to sunrise (Fain et al., 2010). Cones are ~100-fold less sensitive than rods, making them suited for daytime light conditions. Figure 3C compares the intensity-response function of mouse rods and cones, demonstrating the much lower sensitivity of cones compared to rods.

Most OSNs respond to odor concentrations in the low micromolar range (Bozza et al., 2002; Grosmaitre et al., 2009; Saito et al., 2009; Lee et al., 2011; Dibattista and Reisert, 2016), but they can also reach exquisite sensitivity and are capable of detecting odors at the nanomolar concentration range. Picomolar sensitivity is reached by a subset of OSNs that express receptors specialized in detecting amines, the trace-amine-associated receptors (Zhang et al., 2013). In comparison to rods, OSNs do not reach such high sensitivity, and cannot be activated by a single odorant molecule but instead require around 30 odorant binding events to begin firing action potentials reliably (Bhandawat et al., 2010). The detection of odorants in the olfactory epithelium can be further enhanced by the expression of a wider number of different OR genes, more than 350 in humans and 1,000 in mice (Malnic, 2007), with overlapping response profiles to odorants. A larger number of OSNs, particularly in species relying heavily on their sense of smell, may enhance further the detection of odorants. For instance, the human olfactory epithelium covers ~3–4 cm^2 and contains approximately 5–6 million OSNs while in the case of dogs, the area of the olfactory epithelium is 18–150 cm^2 and contains 150–300 million OSNs (Lippi and Heaney, 2020).

28.17.5: Detection of Stimuli

In both photoreceptors and OSNs, the detection of stimuli is mediated by G protein-coupled receptors. In photoreceptors, this function is achieved by rod and cone visual pigments, which consist of a protein, opsin, covalently attached to the visual chromophore, typically 11-cis-retinal (Ebrey and Koutalos, 2001). The chromophore serves as a reverse agonist, keeping the receptor molecule in the inactive ground state (Crouch et al., 1996). Absorption of a photon by 11-cis-retinal triggers its conformational change to all-trans-retinal, which, in turn, results in the rearrangement of the opsin transmembrane helices and switch of the visual pigment molecule into its active state.

We discussed bacterial rhodopsin in an earlier section. We present it here again to show and note its similarity to animal light-sensing proteins.

Review: Retinal, Opsin and Light Transduction in Bacteria

Microbial **rhodopsins** are phototransducing proteins with a conjugated chromophore retinal, covalently attached to the protein opsin through a Schiff base (imine) linkage. The holoprotein (opsin with the attached retinal) is called rhodopsin. Retinal is derived from beta-carotene. The structures of animal and microbial retinals are shown below.

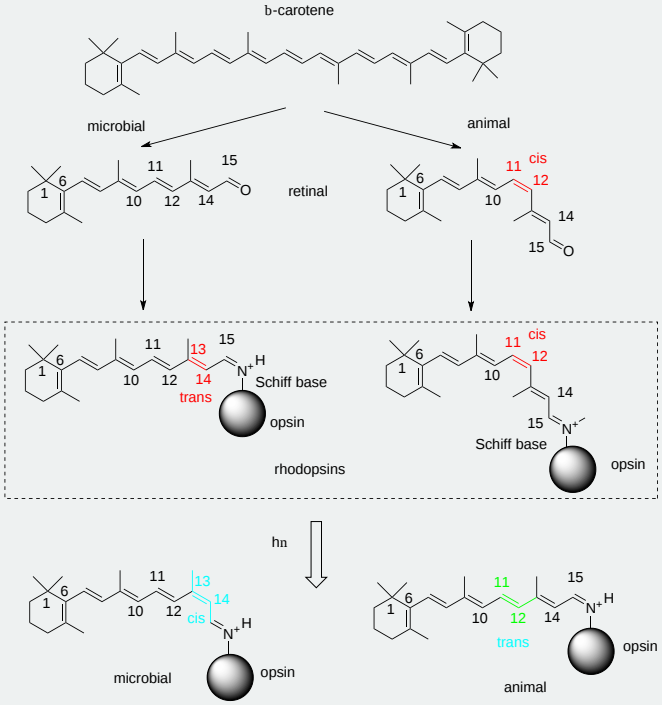


Figure 28.17.15: Structures of animal and microbial retinals

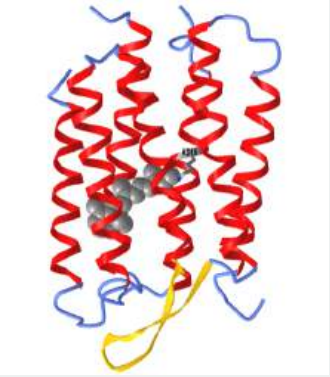
When light of the correct wavelength is absorbed, an electron in a pi molecular orbital in retinal is promoted to a pi antibonding molecular orbital, breaking a 2 electron pi bond in the structure at a certain site in the isoprenoid chain, allowing rotation around the now single bond. The final result after the electrons return to the ground state is photoisomerization of the trans 13-14 and cis 11-12 bonds in microbial and animal retinal, respectively, to their respective cis 13-14 and trans 11-12 configuration. This conformational change in the bound retinal induces a conformational change in the protein opsin, leading to signaling.

The figure below shows an interactive iCn3D model of one monomeric of bacteria rhodopsin (1C3W) containing retinal attached through a Schiff base to Lys 216.



Bacterial rhodopsin (1C3W). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...9HzvfdFvb9kcc6

The covalently attached retinal is shown in gray spacefill. The protein opsin is a membrane protein that spans it with seven helices. Hence it has very similar to a GPCR.

The activated visual pigment then binds to a G protein, transducin, activating it. The activation of transducin triggers the transduction cascade that ultimately generates the cellular response (Pugh and Lamb, 1993). Eventually, the all-trans-retinal chromophore is released from opsin after the covalent Schiff base between them is hydrolyzed, leaving behind chromophore-free opsin (Saari, 2016). Notably, without chromophore, opsin has residual activity, and in sufficient quantities can produce steady activation of the photoreceptors, similar to steady background light, thus modulating the sensitivity of photoreceptors (Fain et al., 1996). This process is known as bleaching adaptation, indicating the production of free opsin after the photoactivation of the visual pigment and dissociation of the visual chromophore.

Unlike in photoreceptors, where the ligand, a light-sensitive reverse agonist, is covalently attached to opsin, in olfaction, the ligands are dissolved in the mucus covering the surface of the olfactory epithelium and come into direct contact with the OR proteins expressed in the OSN ciliary membrane. This results in the activation of the receptor protein that, in turn, is transduced downstream to a G protein to trigger a transduction cascade resulting in the cellular response. The binding of the ligand to the receptor protein is noncovalent and rapidly reversible. ORs, like other G protein-coupled receptors, do display antagonism, inverse, and partial agonism, leading to suppressed responses to their agonists, a reduction in basal activity in the absence of stimulation or suppression of the maximal response (Firestein et al., 1993; Oka et al., 2004; Reisert, 2010).

28.17.6: Discrimination Between Stimuli

The spectral sensitivity of individual rod and cone photoreceptors is dictated by the absorption properties of their visual pigments. Typically, each photoreceptor type expresses only one type of opsin; in the case of the human retina, rods express rod opsin, whereas cones express long wavelength (LW, red), middle wavelength (MW, green), or short wavelength (SW, blue) opsin (Nathans, 1987). When bound to the chromophore, the amino acid structure of each opsin determines the optical properties of the resulting visual pigment and the spectral sensitivity of the photoreceptors expressing it. As a result, species existing in environments with characteristic light distribution, such as deep-sea fish, have visual pigments that have evolved to optimize their spectral sensitivity (Hope et al., 1997). A second factor controlling the optical properties of the visual pigment is the structure of the visual chromophore. Most species, including mice and humans, use 11-cis-retinal, a derivative of Vitamin A, also known as A1. However, some amphibians and fish also use 3,4-dehydro 11-cis retinal, also known as A2. This chromophore has an extra conjugated double bond in its structure, which shifts the absorption spectrum of A2 visual pigments to longer wavelengths compared to the A1 visual pigment embedded in the same opsin molecule (Corbo, 2021). Some aquatic and amphibian species use the A1/A2 chromophores to shift their spectral sensitivity from murky waters dominated by longer wavelengths of light to seawater and air, dominated by shorter wavelength lights (Bridges, 1964). One notable example includes the toad, where the retina is populated by A1 visual pigment in its ventral section, receiving light from above the surface of the water, and by A2 visual pigment in its dorsal section, receiving light from below the surface of the water (Reuter et al., 1971). A shift in the chromophore can also occur during the lifetime of the animal as its environment changes, such as the A2 to A1 shift in salamanders as they metamorphose from the larval (aquatic) to the adult (terrestrial) stage (Ala-Laurila et al., 2007), or the A2 to A1 shift in Atlantic salmon during migration from sea to freshwater (Beatty, 1966).

Similar to photoreceptors, the ligand specificity of the OSNs is also dictated by the expression of OR genes in their cilia. As photoreceptors, each OSN expresses generally only one receptor gene so that its ligand specificity is determined by the structure of the OR expressed in that particular cell. However, photoreceptors typically use no more than five opsin genes to cover the visible spectrum, while OSNs can use hundreds, in the case of humans, to thousand and more, for rodents and dogs, OR genes to cover the odor space (Malnic, 2007). The same OR can be activated by multiple odorants with different sensitivities, and a given odorant can activate different ORs with different half-maximal concentrations (Buck, 1996; Ache, 2020). This generates a complex mosaic of ORs and odorants response pairs. Figure 3F compares the dose responses of OSNs expressing either the mOR-EG or the M71 OR to eugenol and acetophenone, respectively. In this case, mOR-EG OSNs display higher sensitivity to their agonist compared to M71 OSNs. However, this does not preclude the possibility that the M71 OR is more sensitive to another ligand resulting in a more left-shifted dose-response relation than the one seen with acetophenone. Conversely, the dose-response relation of M71 OSNs to benzaldehyde is approximately 10-fold right-shifted compared to acetophenone (Bozza et al., 2002).

Determining the ligand specificity of ORs is an ongoing endeavor (Abaffy et al., 2006; Saito et al., 2009; Kurian et al., 2021). Due to the large number and diversity of OR genes, as well as the nearly endless number of odorant molecules, understanding the overall mechanisms that control their ligand binding affinity and specificity remains a challenge. Receptor modeling approaches to understand and predict OR–odorant molecule interactions can provide valuable insights but are somewhat hampered by the lack of a crystal structure of any vertebrate OR. The rhodopsin structure is often used as a guide and homology model to predict the structure of ORs (Katada et al., 2005; Bavan et al., 2014).

28.17.7: Sensory Transduction Activation

In both photoreceptors and OSNs, the detection of stimuli by their respective G protein-coupled receptors is converted into electrical signals *via* the activation of a G protein-coupled to a second messenger transduction cascade. The two pathways, though distinct, share an amazing level of similarity (Figure 4). Thus, in both cases, the second messenger is a cyclic nucleotide, cGMP in photoreceptors (Pugh and Lamb, 1990) and cAMP in OSNs (Sklar et al., 1987; Bakalyar and Reed, 1990). As a result, the activation of both transduction cascades results in a rapid shift in the equilibrium between synthesis and hydrolysis of the respective cyclic nucleotide, which is then sensed by the cyclic nucleotide-gated (CNG) transduction channels in the plasma membrane of the photoreceptor outer segment or olfactory cilium.

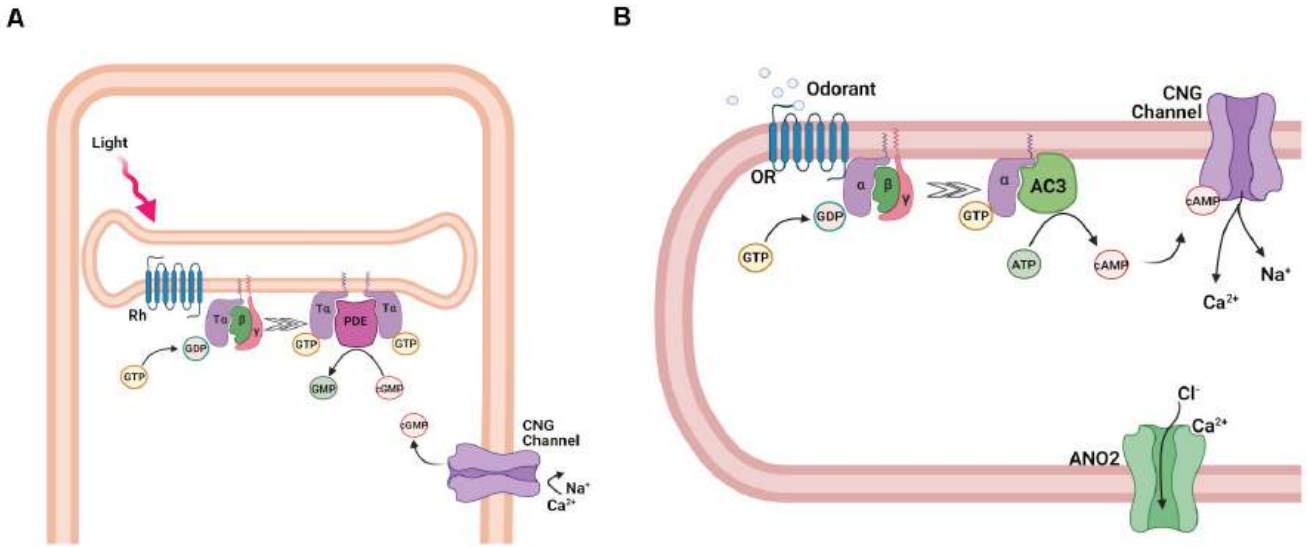


Figure 4. Activation of the transduction cascade in rod photoreceptors and OSNs. **(A)** Schematic representation of phototransduction cascade in rods. Abbreviations: rhodopsin (Rh), Tα, β, and γ subunits of the retinal G protein, transducin (T), guanosine-5′-triphosphate (GTP), guanosine-5′-diphosphate (GDP), phosphodiesterase (PDE), guanosine monophosphate (GMP), and cyclic guanosine monophosphate (cGMP), and cyclic nucleotide-gated (CNG) channel. **(B)** Schematic representation of the olfactory transduction cascade in OSNs. Abbreviations: Olfactory receptor (OR), guanosine-5′-triphosphate (GTP), guanosine-5′-diphosphate (GDP), $G\alpha_{olf}$, *β*, and *γ*, subunits of the olfactory G protein; adenylyl cyclase 3 (AC3), adenosine-5′-triphosphate (ATP), cyclic adenosine monophosphate (cAMP), cyclic nucleotide-gated (CNG) channel; Ca^{2+}-activated Cl^- channel anoctamin 2 (ANO2). Images created with BioRender.com.

In the case of photoreceptors, the photoactivated visual pigment binds to and activates the trimeric G protein transducin (T) (Figure 4A), causing the exchange of GDP for GTP on its α-subunit, which is part of the $G\alpha_t$ protein family. Following the subsequent dissociation of the α-subunit (Tα) from its β/γ complex (Tβγ), Tα then binds to the cGMP phosphodiesterase (PDE) complex, relieving the inhibition of its catalytic α- and β-subunits by its inhibitory γ-subunits (Ebrey and Koutalos, 2001; Burns and Arshavsky, 2005). All these transduction proteins are embedded in or tethered to the disc membranes inside rods or are contained in the cell membrane of cones. As a result of their activation, the hydrolysis of free cGMP in the outer segment is upregulated, causing its rapid decline, and partial or complete closure of the cGMP-gated channels expressed in the rod and cone cell membrane (Luo et al., 2008). The closure of the CNG channels leads to the reduction of the inward transduction current, followed by the hyperpolarization of the cells, and a reduction of neurotransmitter release to second-order neurons within the retina. Inversely, in the absence of light, the opening of CNG channels and the resulting inward transduction current is sustained by the continuous cGMP production by guanylyl cyclase (GC).

Similarly, in OSNs (Figure 4B), the ligand-activated OR proteins bind to the G protein G_{olf}, causing its dissociation into active $G\alpha_{olf}$ and olfactory β- and γ-subunit, $G\beta\gamma_{olf}$. In contrast to transducin, however, $G\alpha_{olf}$ is part of the $G\alpha_s$ protein family and binds to adenylyl cyclase 3 (AC3), activating it. As a result, the synthesis of cAMP in the olfactory cilia is upregulated, causing its rapid increase and the opening of cAMP-gated channels (Kleene, 2008; Su et al., 2009; Boccaccio et al., 2021).

While both photoreceptors and OSNs use CNG transduction channels, their respective channels have different subunit compositions (Bradley et al., 2005). Rods and cones express heterotetramers consisting of the main A1 and A3 and the modulatory B1a and B3 subunits in 3:1 and 2:2 stoichiometries respectively. The olfactory CNG channel is a heterotetramer consisting of two units of the main A2 subunits and one each of the modulatory A4 and B1b subunits. Interestingly, the rod and the olfactory CNG channels express different splice variants of the same B1 subunit. In OSNs, the initial inward Na^+ and Ca^{2+} current generated by the opening of the CNG channel raises ciliary Ca^{2+} and opens a secondary ion channel, the Ca^{2+}-activated Cl^- channel Anoctamin 2. A high intraciliary Cl^- maintained by the $Na^+/K^+/2Cl^-$ cotransporter 1 ensures a Cl^- efflux which further depolarizes the OSNs (Dibattista et al., 2017; Boccaccio et al., 2021). This depolarization triggers the generation of action potentials which further propagate along the axons, inducing glutamate release at synapses with the second-order neurons in the olfactory bulb (Murphy et al., 2004). In photoreceptors, the transduction cascade upon stimulation does not ultimately generate action potentials in the receptor cell, but only a graded receptor potential that directly causes a change in neurotransmitter release.

28.17.8: Amplification

As for any other sensory modality, proper amplification of the signal is required to detect small stimuli and the resulting high sensory sensitivity is critical for the survival and propagation of the species. Nature has reached the highest physically possible sensitivity in the case of rod photoreceptors that can produce a detectable electrical response to the absorption of a single photon. This impressive feat is achieved by employing a transduction cascade that allows tremendous amplification of the signal. During the ~50 ms active lifetime, a single photoactivated rhodopsin molecule activates ~20 transducins, producing an immediate 20-fold amplification (Burns and Pugh, 2010). The following activation of PDE by transducin does not directly produce amplification as each transducin has to bind to a PDE molecule to activate it. However, once activated, each PDE enzyme can hydrolyze thousands of cGMP molecules. Lastly, as the binding of cGMP to the CNG transduction channels is cooperative, a slight change in cGMP levels can reduce the number of cGMP molecules bound to the channel from 3 to 2. This results in channel closure and a sharp reduction in the transduction current, further enhancing the detection of photostimulation. Despite the similarities in the transduction cascades of rods and cones, the amplification in cone photoreceptors is substantially lower as a result of fine-tuning at several of the phototransduction steps (Yau, 1994; Kawamura and Tachibanaki, 2008). Interestingly, even though rod and cone visual pigments activate transducin with similar efficiencies, the lower thermal stability of the cone visual pigment results in higher intrinsic activity in cones compared to rods in darkness (Kefalov et al., 2003), effectively desensitizing the cones and shifting their function towards brighter daytime light conditions (see Figure 3C).

Curiously, the activation of G_{olf} by the OR molecule does not result in amplification. Indeed, the dwell time of the odorant ligand on the OR appears to be very short and on a millisecond timescale (Bhandawat et al., 2005). As a consequence, on average, this results in the activation of less than one G protein per activated receptor. As such, in contrast to phototransduction, where the lifetime of the activated rhodopsin greatly influences the response size and kinetics, in OSNs the response depends more prominently on the coupling efficacy of downstream transduction components while the odorant presence keeps the OR activated. To compensate for the lack of initial amplification at the G protein level, OSNs employ a secondary amplification step on top of the cAMP transduction cascade. The activation of AC3 by G_{olf} results in the synthesis of most likely hundreds of cAMP molecules, the opening of the CNG channels which is followed by a unique secondary amplification based on excitatory Ca^{2+}-activated Cl^-

channels in the cilia (Figure 4B). The Cl^- current carries up to 80% of the overall transduction current (Dibattista et al., 2017). Physiological experiments with pharmacological and genetic modulation of the Cl^- conductance indicates that the Cl^- channels serve to set the length of the action potential train generated in response to odorant stimulation (Pietra et al., 2016) and to promote recognition of novel odorants (Pietra et al., 2016; Neureither et al., 2017).

A puzzling aspect of the secondary amplification step is why Cl^- is the charge-carrying ion and not Na^+, which could be achieved easily by increasing the expression level and/or the ion permeation and conductance of the olfactory CNG channel. Recent theoretical work hinted at two main advantages of Cl^-, instead of Na^+, as the charge carrier. As the external environment of cilia is the nasal mucus, currents will depend on the ion concentration in the mucus, which can be unstable. A current that depends on the intracellular ion concentration, as is the case for Cl^- but not for Na^+, is much less dependent on the mucosal ion concentration. For instance, this could become an issue in the case of a cold with a runny nose or during swimming, when the mucus becomes diluted. The second advantage results from the "compromise" to increase the ciliary surface area, at the expense of having a very small ciliary volume, in the femtoliter range. In such small volumes, even small ionic currents can lead to large changes in ion concentration and osmotic pressures. If the main charge carrier was Na^+ this would lead to a large increase (tens of mM). This would cause a large increase in osmotic pressure and also would prevent Ca^{2+} clearance *via* the olfactory Na^+/Ca^{2+}, K^+ exchanger (see below) with greatly deleterious effects. In contrast, high intracellular Cl^- is maintained throughout the OSN so that its local depletion in the cilia upon ligand activation is rapidly reversed by diffusion from the cell soma. Both these issues do not exist for photoreceptors as they are embedded in the interstitial fluid of the eye and photoreceptors are sufficiently large and their transduction currents are sufficiently small that ion concentration changes due to changes in transduction currents are relatively small (Reisert and Reingruber, 2019). Nevertheless, rod photoreceptors undergo osmotically-driven length changes upon light activation, an effect that is mitigated by the translocation of G protein subunits into the cytosol (Zhang et al., 2017).

28.17.9: Receptor and G Protein Inactivation

Timely and effective transduction inactivation is critical for allowing sensory neurons to continue to detect stimuli with high temporal resolution. Equally important is to extract behaviorally relevant information from the presented stimuli. In both photoreceptors and OSNs, all active transduction components need to be turned off and the level of cyclic nucleotides within the cells needs to be restored to the resting level before the sensory cell can be reset to the inactive state and become ready for subsequent activation (Figure 5). In the case of photoreceptors, the identity of the step determining the overall kinetics of the photoresponse inactivation was the subject of intense research and debate over several decades. As the visual chromophore ligand is covalently attached to opsin, inactivation of the visual pigment could potentially be extremely slow. Indeed, if left on its own, the active state of rhodopsin decays with a time constant of ~50 s (Imai et al., 2007). Its inactivation in photoreceptors is a two-step process, involving phosphorylation of the rhodopsin C-terminus by rhodopsin kinase (GRK1) which partially quenches its activity, followed by the binding of arrestin1, which completely inactivates the visual pigment (Figure 5A). Though the decay of the active state of cone pigment is significantly faster at ~2 s (Fu et al., 2008), this is still clearly too slow to enable the timely termination and reset of phototransduction. Thus, in both rods and cones, the visual pigments are inactivated by phosphorylation by rhodopsin kinase and the subsequent binding of arrestin long before they would decay spontaneously (Makino et al., 2003). The effective time constant of rod visual pigment inactivation is ~50 ms (Krispel et al., 2006). The slowest step in the inactivation of rod phototransduction turned out to be the hydrolysis of GTP which shuts off Tα, a reaction driven by the transducin GTPase activity and enhanced by a GTPase (GTPase activating protein, GAP) complex consisting of Gβ5 and the membrane anchoring protein R9AP (Arshavsky and Wensel, 2013). Inactivation of transducin results in its release from PDE, allowing the two PDE γ inhibitory subunits to resume their inhibition on the two catalytic subunits (α and β) of this enzyme. The kinetics of this reaction determines the overall kinetics of response inactivation in rod photoreceptors. In contrast, work from amphibian cones suggests that in cones the photoresponse duration is Ca^{2+}-dependent and involves the quenching of the cone visual pigment (Matthews and Sampath, 2010).

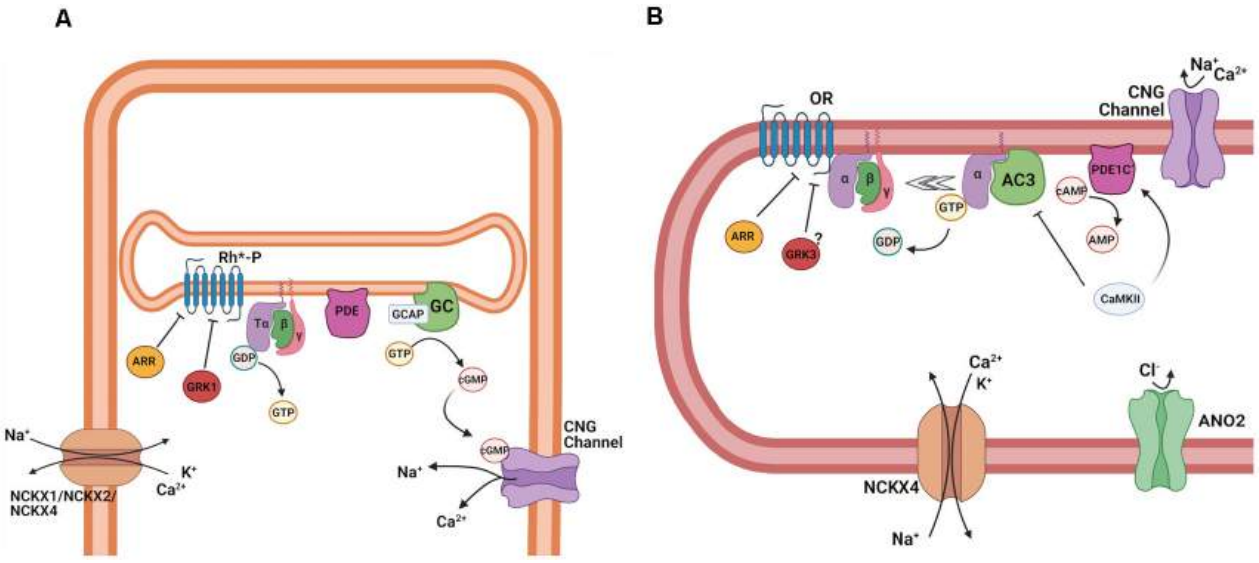

Figure 5. Termination of transduction cascade in rod photoreceptors and OSNs. **(A)** Schematic representation of the termination of phototransduction in rods. Abbreviations: Phosphorylated light-activated rhodopsin (Rh*-P), arrestin (ARR), G protein-coupled receptor kinase 1 (GRK1), Tα, β, and γ subunits of the retinal G protein, transducin (T), guanosine-5′-triphosphate (GTP), guanosine-5′-diphosphate (GDP), phosphodiesterase (PDE), guanosine monophosphate (GMP) and cyclic guanosine monophosphate (cGMP), and cyclic nucleotide-gated (CNG) channel, guanylate cyclase (GC), guanylate cyclase-activating protein (GCAP), cyclic nucleotide-gated (CNG) channels, K^+ dependent Na^+/Ca^{2+} exchanger 1, 2 and 4 (NCKX1, NCKX2, NCKX4). **(B)** Schematic representation of the termination of the olfactory transduction cascade. Abbreviations: Olfactory receptor (OR), arrestin (ARR), G protein-coupled receptor kinase 3 (GRK3) $G\alpha_{olf}$, *β*, and *γ*, subunits of the olfactory G protein, guanosine-5′-triphosphate (GTP), guanosine-5′-diphosphate (GDP), adenylyl cyclase 3 (AC3), activated phosphodiesterase 1C (PDE1C), cyclic adenosine monophosphate (cAMP), adenosine monophosphate (AMP), Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII), cyclic nucleotide-gated channel (CNG); Ca^{2+}-activated Cl^-channel anoctamin 2 (ANO2), K^+-dependent Na^+/Ca^{2+} exchanger 4 (NCKX4). Images created with BioRender.com.

In OSNs, the inactivation by phosphorylation and arrestin are potentially not needed for the timely shutoff of the olfactory transduction cascade, due to the extremely short lifetime of the active ligand-bound receptor molecule. Early biochemical experiments suggested that OR phosphorylation does control cAMP kinetics (Dawson et al., 1993; Schleicher et al., 1993; Peppel et al., 1997), but it seems to play little, if any, role in the control of odorant-response kinetics for one particular OR, mOR-EG (Kato et al., 2014). It remains to be established whether this applies to all ORs, or whether a subset of ORs is subject to phosphorylation and inactivation. β-arrestin interacts with ORs, mediating internalization during prolonged stimulation and altering adaptation to repetitive odor stimuli (Mashukova et al., 2006). Experiments on isolated human and rat OSNs suggested a role for protein kinases A (PKA) and C (PKC) in the termination of the olfactory response. Ca^{2+} imaging showed that the inhibition of PKA and PKC increases intracellular Ca^{2+} responses in the presence of odorant mixtures, and blocks their termination after odorant stimulation ceases. While the inhibition of both PKA and PKC modulated the odor-induced intracellular Ca^{2+} increase in the human OSNs, only PKC and not PKA affected the Ca^{2+} response to odorants in rat OSNs, suggesting differences among species in the termination of the olfactory response (Gomez et al., 2000).

The control of the lifetime of the olfactory G protein seems to be more complex and less well-understood compared to phototransduction. Ric-8B (resistant to inhibitors of cholinesterase-8B) has been identified as a GTP exchange factor (GEF) expressed in OSNs, which facilitates the exchange of GDP for GTP on $G\alpha_{olf}$ and its activation. Unusually, Ric-8B not only interacts with the G protein α-subunit but also with γ13, the olfactory γ-subunit. In a heterologous system, Ric-8B co-expression with olfactory transduction components can greatly increase cAMP production, suggesting that it could indeed modulate olfactory transduction (Von Dannecker et al., 2005; Kerr et al., 2008). A knockout mouse for Ric-8B displays impaired olfactory behavior, and, surprisingly, greatly reduced odorant responses. Ric-8B is localized primarily in the cell body and the dendritic knob of OSNs. Ric-8B knockout OSNs are devoid of $G\alpha_{olf}$ (Machado et al., 2017), suggesting that this gene is needed for the stable expression of $G\alpha_{olf}$, and excludes addressing its potential role as a GEF in the odorant response. The Ric-8B knockout mice also display higher OSN cell death. Regulators of G protein signaling (RGS) are GAPs that modulate the lifetime of an activated G protein as described above. RGS2, instead of functioning as a GAP, directly inhibits AC3 to control the size of the odorant response (Sinnarajah et al., 2001). However, inconsistent and contradictory data on RGS2 and RGS3 expression and their roles in OSNs suggest that more research is needed (Norlin and Berghard, 2001; Kanageswaran et al., 2015; Saraiva et al., 2015).

28.17.10: Adaptation

Adaptation plays a critical role in the capacity of our sensory neurons to remain able to detect stimuli above the background in a complex and rapidly changing environment. For instance, in constant light conditions, the dynamic range for both rods and cones is only 100-fold, spanning a range from threshold stimulation to saturation (Figure 3C). However, as a result of light adaptation, photoreceptors can shift their functional range over a very wide span of light conditions, ranging from cloudy night to sunrise for rods, and starry night to bright sunny day for cones (Weale, 1961). Thus, using the adaptation of individual photoreceptors, the visual system can remain responsive to stimuli over a wide range of light conditions. In contrast, the ability of OSNs to adapt is rather limited even at modest levels of background odorant (Reisert and Matthews, 1999). Nevertheless, increasing concentrations of the same odorant can recruit less sensitive ORs, and therefore less sensitive OSNs, preserving its perception at higher concentrations and ensuring to report the presence of that odorant to the brain.

In both types of sensory neurons, adaptation is mediated by a change in Ca^{2+} upon stimulation. This change is sensed by several Ca^{2+}-binding proteins that trigger a negative feedback on the vision and olfaction transduction cascades by modulating several of their steps. In the outer segments of rods and cones and olfactory cilia, Ca^{2+} levels are controlled by the balance of influx *via* the CNG channels, whose current is carried in part by Ca^{2+}, and efflux *via* Na^+/Ca^{2+}, K^+ exchangers (NCKXs) that use the electrochemical gradient for Na^+ and K^+ to extrude Ca^{2+} (Figure 5; Yau and Nakatani, 1984). In rods (Figure 5A), this task is accomplished by rod-specific NCKX1, whereas cones employ two separate exchangers, NCKX2 and NCKX4 (Vinberg et al., 2017). At rest, both in darkness and in steady-state light, the influx of Ca^{2+} is matched with its extrusion and, as a result, the level of free Ca^{2+} in the outer segments is maintained constant. Upon photostimulation, the transduction cascade is activated, resulting in the depletion of cGMP, closure of CNG channels, and reduction in the influx of Ca^{2+} into the outer segments. However, Ca^{2+} extrusion by the Na^+/Ca^{2+}, and K^+ exchangers carry on for at least a while and, as a result, the level of Ca^{2+} in the outer segments declines. Direct Ca^{2+} measurements in amphibian photoreceptors indicate a dynamic range from 670 to 30 nM in rods (Sampath et al., 1998) and 400–5 nM in cones (Sampath et al., 1999), in darkness and bright light, respectively.

The light-driven decline in Ca^{2+} causes its release from several Ca^{2+}-binding proteins. The dominant Ca^{2+}-dependent feedback mechanism in both rods and cones controls the synthesis of cGMP by membrane-bound GC *via* a pair of GC-activating proteins (GCAPs)—GCAP1 and GCAP2. When Ca^{2+} in the outer segments is high, Ca^{2+}-bound GCAPs bind to and partially inhibit the activity of GC. Upon photoactivation and the decline in Ca^{2+}, GCAPs become Ca^{2+}-free and release from GC, resulting in the upregulation of cGMP synthesis which restores the dark current after photostimulation and modulates the activation of the transduction cascade in the presence of background light (Dizhoor, 2000; Sakurai et al., 2011). Another mechanism by which Ca^{2+} modulates phototransduction involves the Ca^{2+}-binding protein recoverin. As GCAPs, recoverin is a member of the EF-hands protein family, and when bound to Ca^{2+} in darkness, it inhibits rhodopsin kinase, thus slowing down the inactivation of the visual pigment (Makino et al., 2004; Sakurai et al., 2015). When the photoreceptors are activated and Ca^{2+} declines, it is released from recoverin, which in turn dissociates from rhodopsin kinase and relieves its inhibition. This enhances the phosphorylation of visual pigments and accelerates their inactivation, effectively reducing the activation of the transduction cascade by the background light. Finally, direct modulation of the CNG channels has also been suggested. However, in the case of rods, such modulation appears to play a marginal, at best, role (Koutalos and Yau, 1996) and is not mediated by the Ca^{2+}-binding protein calmodulin (Chen et al., 2010). In zebrafish cones, the modulation of the CNG channels appears to play a more substantial role and is mediated by the Ca^{2+}-binding protein CNG-modulin (Korenbrot et al., 2013). It is still unclear whether the mammalian homolog of CNG modulin, EML1 plays a similar role in mammalian cones.

Adaptation in OSNs is less well understood compared to phototransduction. Early data, mostly of biochemical nature or obtained from heterologously-expressed proteins of interest, suggested three main molecular targets for adaptation. All three of them are mediated by the Ca^{2+} influx during the odorant response: Ca^{2+}/calmodulin-mediated desensitization of the olfactory CNG channel to close the channel even in the presence of high cAMP (Chen and Yau, 1994); phosphorylation *via* CaM-kinase 2 of AC3 to reduce the rate of cAMP production (Wei et al., 1996, 1998); and Ca^{2+}-mediated upregulation of phosphodiesterase 1C, which is expressed in olfactory cilia, and is assumed to degrade cAMP to AMP to terminate the response (Borisy et al., 1992). Follow-up experiments using recordings from OSNs all seem to indicate that none of these mechanisms plays as prominently or as originally thought role in transduction (Reisert and Zhao, 2011). A mouse with a mutation in the CNGB1b channel subunit that entirely prevents desensitization by Ca^{2+} surprisingly displays normal olfactory adaptation but instead shows a delayed response termination, suggesting that Ca^{2+}/calmodulin-mediated desensitization of the CNG channel speeds up response termination (Song et al., 2008). A mouse model that carries a mutation in AC3 that prevents phosphorylation does not show a discernable phenotype of the olfactory response (Cygnar et al., 2012), although it might be possible that other, unknown phosphorylation sites in AC3 might be important. Finally, a knockout mouse for PCE1C has no deficits in response termination but instead shows much-reduced

response amplitudes for unclear reasons (Cygnar and Zhao, 2009). This begs the obvious question as to what the role of PDE1C might be and what might actual to cAMP that is generated during the odorant response. For the latter, an interesting option is that cAMP diffuses out of the cilia into the cell body as a means to reduce ciliary cAMP, allowing OSNs to recover from stimulation (Cygnar and Zhao, 2009). One aspect that is reasonably understood is NCKX4, the Ca^{2+} exchanger in OSNs that is required to lower intraciliary Ca^{2+} during and after odorant stimulation, allowing the transduction cascade to recover from adaptation (Reisert and Matthews, 1998; Stephan et al., 2012).

28.17.11: Diseases

Disorders affecting photoreceptors are among the leading causes of blindness in the human population. One of the prevalent visual disorders, called retinitis pigmentosa, is a complex disease caused by a wide range of mutations in photoreceptors. Many of these mutations affect the expression, structure, and function of the rod's visual pigment (Athanasiou et al., 2018). Because of the very high expression of opsin in the outer segments of rods, this protein plays not only a functional role but is also critical for the proper formation of the outer segment itself. As a result, mutations affecting the expression, folding, or targeting of opsin to the rod outer segments, cause gradual degeneration of the rods. Other genes implicated in rod dysfunction and degeneration include those for phosphodiesterase (e.g., rd1, rd10; Chang et al., 2002), the CNG channels A and B subunits (channelopathies; Michalakis et al., 2018), GC, and GCAPs (Olshevskaya et al., 2002). Another diverse set of visual disorders is caused by abnormal chromophore production or supply to photoreceptors, which limits the ability to detect light and can also lead to degeneration (Ku and Pennesi, 2020). Notably, the efficiency of the visual system to produce chromophore seems to decline with age, which may result in poor rod function in dim light even in normally aging adults. It is also an early indicator of age-related macular degeneration, a devastating blinding disorder that affects the function of cones in the central retina responsible for acute vision and color discrimination (Jackson et al., 2002). Interestingly, rods and cones seem to coexist synergistically in the retina, and diseases caused by rod-specific mutations that result in rod degeneration, eventually lead to the loss of cones and central vision as well. Thus, considerable efforts are currently focused on developing methods for preserving rods even when they are not functional, as a way of protecting daytime cone-driven vision. Because the eye is a relatively accessible organ, novel therapeutic approaches for vision protection and restoration have led the field, with successful examples of gene therapy and stem cell therapy in experimental and clinical trial phases (Ovando-Roche et al., 2017).

Compared to vision, in olfactory transduction, very few mutations in transduction components are known that lead to deleterious effects. Several aspects might account for this. Mutations causing a partial reduction of olfaction might go unnoticed in the human population as very little systematic olfactory testing is done. OSNs regenerate throughout life and only have a lifespan of a few weeks. Hence any slow degeneration as those seen in photoreceptors might not manifest in that time window. In a screen of families with congenital anosmia, no potentially causative mutations were found in three main transduction proteins ($G_{\alpha olf}$, CNGA2, AC3), with these genes also being under purifying selection (Feldmesser et al., 2007). An interesting exception is patients suffering from retinitis pigmentosa, which is caused by mutations in the gene encoding the CNGB1 subunit expressed in both rods and OSNs. Those patients, identified because of their visual function decline, were found to be hyposmic or anosmic when tested for their olfactory ability (Charbel Issa et al., 2018). If congenital anosmia is considered to be a relatively rare and little-understood condition, more known and frequently detected are specific anosmias, which manifest in the inability to detect certain odorants (Keller et al., 2007; Trimmer et al., 2019). Broadly speaking, this is the olfactory equivalent of color blindness and is caused by known OR mutations.

Arguably, the most common causes of smell loss are events that lead to the destruction of the olfactory epithelium and/or the olfactory nerves connecting it to the central nervous system (CNS). These events include head or face trauma, inhalation of toxic chemicals, or viral infection (such as SARS-CoV2), and, neurodegenerative diseases such as Alzheimer's and Parkinson's disease (Attems et al., 2015; Cooper et al., 2020). In the former, the origin of the smell disorder can be tracked down to the periphery, the olfactory epithelium. In the case of neurodegenerative diseases, it has been thought that olfactory dysfunction originates centrally in the CNS, but it is becoming clearer now that peripheral olfaction can be affected in these cases as well, although the respective mechanisms have not been fully elucidated.

28.18: Signal Transduction - Taste (Gustation)

28.18.1: G Protein-Coupled Receptors in Taste Physiology and Pharmacology

Heterotrimeric G protein-coupled receptors (GPCRs) comprise the largest receptor family in mammals and are responsible for the regulation of most physiological functions. Besides mediating the sensory modalities of olfaction and vision, GPCRs also transduce signals for three basic taste qualities of sweet, umami (savory taste), and bitter, as well as the flavor sensation kokumi. Taste GPCRs reside in specialized taste receptor cells (TRCs) within taste buds. Type I taste GPCRs (TAS1R) form heterodimeric complexes that function as sweet (TAS1R2/TAS1R3) or umami (TAS1R1/TAS1R3) taste receptors, whereas Type II are monomeric bitter taste receptors or kokumi/calcium-sensing receptors. Sweet, umami, and kokumi receptors share structural similarities in containing multiple agonist binding sites with pronounced selectivity while most bitter receptors contain a single binding site that is broadly tuned to a diverse array of bitter ligands in a non-selective manner. Tastant binding to the receptor activates downstream secondary messenger pathways leading to depolarization and increased intracellular calcium in TRCs, that in turn innervates the gustatory cortex in the brain. Despite recent advances in our understanding of the relationship between agonist binding and the conformational changes required for receptor activation, several major challenges and questions remain in taste GPCR biology that is discussed in the present review. In recent years, intensive integrative approaches combining heterologous expression, mutagenesis, and homology modeling have together provided insight regarding agonist binding site locations and molecular mechanisms of orthosteric and allosteric modulation. In addition, studies based on transgenic mice, utilizing either global or conditional knock-out strategies have provided insights to taste receptor signal transduction mechanisms and their roles in physiology. However, the need for more functional studies in a physiological context is apparent and would be enhanced by a crystallized structure of taste receptors for a more complete picture of their pharmacological mechanisms.

28.18.2: Introduction

G protein-coupled receptors (GPCRs) are the largest and the most diverse group of membrane receptors in eukaryotes. They are activated by a wide variety of ligands in the form of light energy, lipids, sugars, peptides, and proteins (Billington and Penn, 2003; Schoneberg et al., 2004; Lundstrom, 2009) which convey information from the outside environment into the cell to mediate their corresponding functional responses. The conformational changes of GPCRs upon ligand binding initiate a series of biochemical reactions within the cell. These intracellular reactions regulate sensory functions of smell, taste, and vision, and a wide variety of physiological processes such as secretion, neurotransmission, metabolism, cellular differentiation, inflammation, and immune responses (Lagerström and Schiöth, 2008; Rosenbaum et al., 2009; Venkatakrishnan et al., 2013; Ahmad et al., 2015). Taste is one of the most important sensations in human life, enabling us to perceive different tastes from the diverse range of food available in nature, and is a major determinant of our ingestion decisions.

The anatomical units of taste detection are taste receptor cells (TRCs) that are assembled into taste buds distributed across different papillae of the tongue and palate epithelium. Taste processing is first achieved at the level of TRCs that are activated by specific tastants. They transmit information *via* sensory afferent fibers to the gustatory cortex in the brain for taste perception (Figure 1). Three different morphologic subtypes of TRCs in taste buds sense the different tastes we perceive. Type I glial-like cells detect salty taste while type II cells expressing GPCRs detect sweet, umami, and bitter tastes. Type III cells sense sour stimuli (Janssen and Depoortere, 2013).

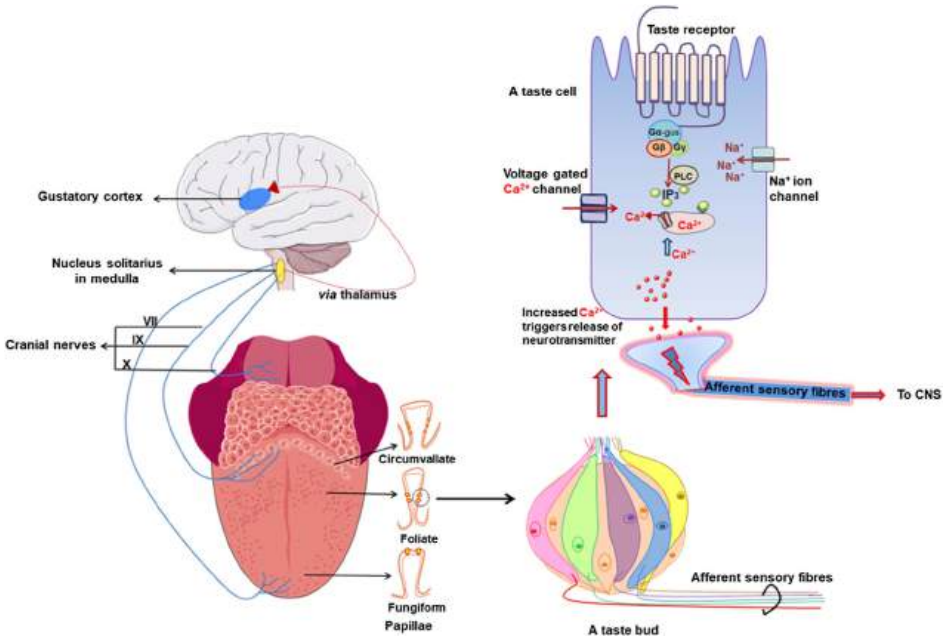

FIGURE 1. A schematic diagram shows taste signal transmission between the tongue and brain. Taste buds present in different papillae in the tongue and palate contain taste receptor cells (TRC) which contain taste G protein-coupled receptors (GPCRs). The left side shows how afferent nerves transmit a signal to the gustatory cortex in the brain via cranial/glossopharyngeal nerves. The right side shows taste buds with taste TRCs and a simplified signal transduction pathway of taste receptors where taste GPCRs are activated by a tastant that in turn recruits a specific G protein that further induces intracellular calcium release (created with BioRender.com).

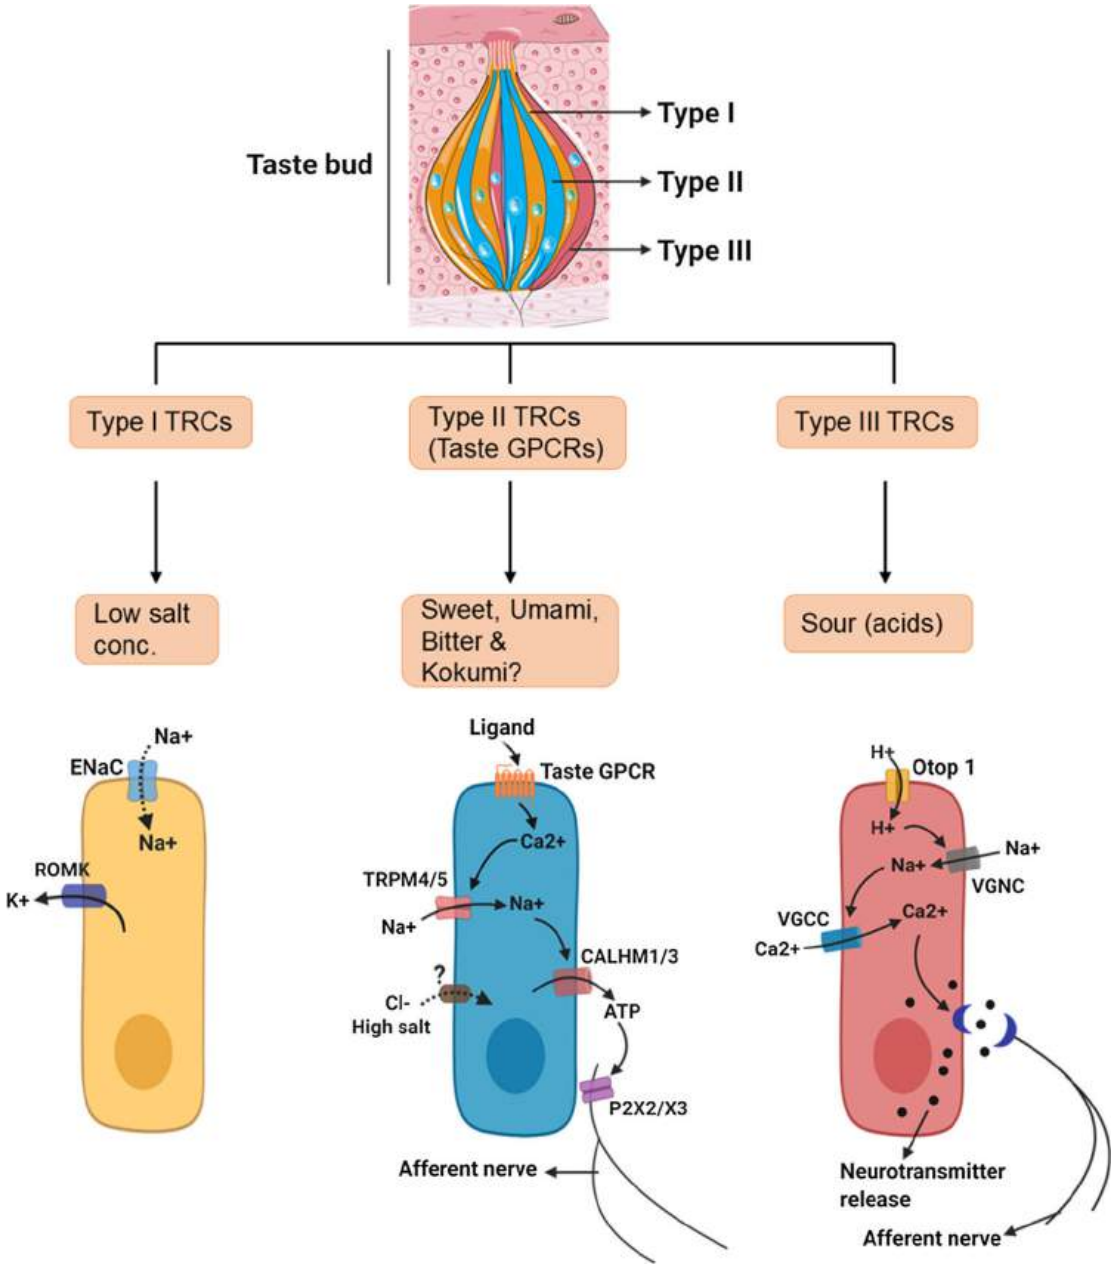
Sweet and umami stimuli are transduced by Type 1 taste GPCRs while the bitter taste is sensed by Type 2 taste GPCRs (Figure 2; Table 1). The more recently described kokumi sensation is mediated by another GPCR, the calcium-sensing receptor (CaSR) (Figure 2; Table 1). Taste GPCRs are activated by specific taste ligands present in foods and recruit G proteins to activate downstream signaling effectors (Figure 3).



Figures 1, 3) (created with BioRender.com).

TABLE 1 | Taste GPCRs classification and their downstream signaling regulators.

Taste/flavor sensation	Sweet	Umami	Bitter	Kokumi
GPCRs	TAS1R2 + TAS1R3	TAS1R1 + TAS1R3	TAS2Rs	Calcium sensing receptor
Class of GPCR	Class C	Class C	Class A	Class C
Type	Type 1 taste GPCRs	Type 1 taste GPCRs	Type 2 taste GPCRs	ND
Oligomerization	Heterodimer	Heterodimer	Monomer	Homodimer
GαSubunit	Gα-gustducin	Gα-gustducin	Gα-gustducin	Gq/11, Gi/o, G12/13, Gs
Signaling pathway	Gβγ-PLCβ2-TRPM5 pathway-semaphorin 7A	Gβγ-PLCβ2-TRPM5 pathway	Gβγ-PLCβ2-TRPM5 pathway-semaphorin 3A	Gβγ-PLCβ2-TRPM5 pathway
Ligand binding sites	VFT; TMD	VFT, TMD	ND	VFT, TMD
Potent ligands	Sucrose, aspartame, sucralose, cyclamate	L-amino acids, Gultamate	Peptides, alkaloids, flavonoids	Ca^{2+}, divalent and trivalent cations, Glutathione, *γ*-glutamyl peptides, polyamines, amino acids
Antagonists/NAMs	Lactisole, gymnemic acid	Lactisole, clofibric acid	GIV3727, probenecid	NPS2143
Food source	Sugar/sweets, dairy products	Savoury food, fermented dairy/meat/fish/chicken broth, mushroom, tomato	Wine, tea, coffee, cheese, broccoli	Garlic/onion meat/fish/broth/mushroom, soy sauce

TAS2R, bitter taste receptors; GPCR, G protein-coupled receptors; VFT, extracellular Venus flytrap domain; TMD, seven transmembrane domain; ND, not defined.

TABLE 1. Taste GPCRs classification and their downstream signaling regulators.

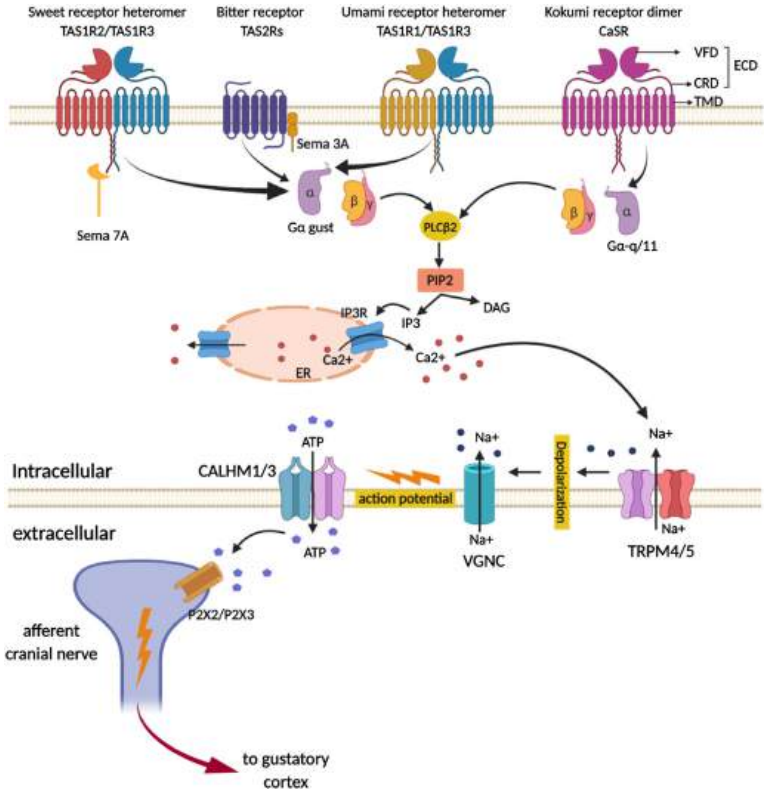


FIGURE 3. Schematic representation of signal transduction pathway of sweet, umami, bitter, and kokumi-calcium sensing receptors (CaSR) in taste receptor cells on the tongue. Ligand-induced stimulation of the sweet (TAS1R2/TAS1R3), umami (TAS1R1/TAS1R3), bitter receptors (TAS2Rs) and kokumi sensation expressed in type II taste cells within taste bud activate a trimeric G protein composed of α-gustducin (Gα-gust) in sweet, umami, bitter and Gα-q/11 in kokumi-receptor and a complex consisting of Gβγ proteins. The released Gβγ-complex activates phospholipase C isoform β2 (PLCβ2) which then induces the production of inositol 1,4,5-trisphosphate (IP3) and diacylglycerol (DAG); the second messenger IP3, in turn, activates the IP3 receptor (IP3R), an intracellular ion channel that allows Ca^{2+} release from the intracellular endoplasmic reticulum (ER store). An increase in intracellular Ca^{2+} then activates the complex of transient receptor potential cation channel subfamily M member 4 and 5 (TRPM4/5) that are plasma membrane-localized sodium-selective channels which leads to depolarization and subsequent activation of voltage-gated sodium channels (VGSC). The combined action of increased Ca^{2+} and membrane depolarization activates the complex of calcium homeostasis modulator 1 and 3(CALHM1/3) channel and pannexin1 channels, thus resulting in the release of

the neurotransmitter ATP. Increased ATP, in turn, activates P2X ionotropic purinergic receptors 2 and 3 (P2X2/P2X3) on the afferent cranial nerve generating an action potential that subsequently signals to the gustatory cortex for sensory perception. Besides well-known taste GPCR pathways, connecting proteins semaphorin 7A (Sem 7A) and 3A (Sem 3A) are depicted in close contact with sweet and bitter receptors as they provide instructive signals that fine-tune to sweet or bitter ganglion neurons, respectively. VFT, venus flytrap domain; CRD, cystine-rich domain; ECD, extracellular domain. (created with BioRender.com).

In this review, we will first explore the basic architecture of the gustatory sensory system and its peripheral signal transmission. Then we will discuss taste GPCR signal transduction mechanisms for the different taste modalities, their molecular structure, and the conformational changes that occur following orthosteric/allosteric binding of endogenous and food-derived ligands.

28.18.3: Taste Buds and Neural Transmission

In mammals, taste buds on the tongue comprise 50–100 elongated epithelial cells and a small number of proliferative basal cells (Sullivan et al., 2010). Ultrastructural studies and patterns of gene expression with cell function reveal three distinct anatomical types of TRCs within each taste bud: Type I, Type II and Type III (Murray, 1986) (refer to Figure 2; Table 2).

TABLE 2 | Summary of taste receptor cell characteristics.

Taste receptor cells	Type I	Type II	Type III
Cell type	50% of the total population	20–30%	5–10%
Taste responses	Low salt taste amiloride sensitive response	Sweet, biiter, umami and probably kokumi flavor response (?) via GPCRs	Sour response via otopterin 1
Morphology	Spindle shaped with long brush like microvilli (1–2 mm), no synapse	Long and slender short microvilli, no synapse	Single large microvillus, have synaptic contact with afferent nerve
Other functions	Support function, ion redistribution, neurotransmitter clearance	High salt taste amiloride insensitive response?	Probable salt response?
Marker proteins	GLAST, K^+ channel (ROMK)	CALHM1, CALHM3, pannexin, connexins	Kir2.1, PDK2L1, SNAP25, synapsinII, NCAM

GLAST, glutamate aspartate transporter; ROMK, renal outer medullary potassium channel; PDK2L1, polycystin 2 like 1, transient receptor potential cation channel; CALHM, calcium homeostasis modulator; Kir2.1, inward rectifier K(+) channel; NCAM, neural cell adhesion molecule; SNAP25, synaptosome associated protein 25 kDa.

TABLE 2. Summary of taste receptor cell characteristics.

Type II TRCs express either sweet, umami, or bitter taste receptors at their cell surface. These receptors share some commonality with their signal transduction mechanisms that are intrinsic to TRCs. Taste GPCRs (sweet, umami, and bitter) couple to heterotrimeric G proteins that include Gα-gustducin, Gβ3, and Gγ13 (Huang et al., 1999) and initiate a series of signal transduction cascades involving activation of phospholipase C-β2 (PLCB2), production of inositol-1,4,5-triophosphate (IP3), and IP3-dependent Ca^{2+} release from the endoplasmic reticulum (ER) via the IP3 receptor (IP3R). The increased intracellular $[Ca^{2+}]_i$ then activates the transient receptor potential cation channel subfamily M member 4 and 5 (TRPM4/5) in the basolateral plasma membrane, leading to membrane depolarization that triggers Na^+ action potential firing, and depolarization-induced release of ATP. In turn, ATP acts as the primary neurotransmitter stimulating purinergic receptors 2 and 3 (P2X2 and P2X3) on afferent cranial nerves whose activation triggers an action potential that subsequently activates the gustatory cortex in the brain (McLaughlin et al., 1992; Wong et al., 1996; Margolskee, 2002). α-gustducin is a distinct G protein selectively expressed in ∼30% of type II TRCs and shares 80% identity with retinal protein α-transducin (McLaughlin et al., 1992) and is a key contributor to signal transduction for sweet and bitter taste receptors (McLaughlin et al., 1992; Wong et al., 1996; Margolskee, 2002).

An important aspect of taste transduction is how ATP signaling is conducted. Recent studies have discovered that calcium homeostasis modulators 1 and 3 (CALHM1/3) are enriched in type II TRCs where they interact and form a functional complex. Their genetic deletion abolishes responses to sweet, bitter, and umami tastes, supporting the requirement of the CALHM1/3 complex as an ATP release channel for the GPCRs mediated tastes (Taruno et al., 2013; Ma et al., 2018).

New information has provided insight into how specific taste qualities are fine-tuned to recognize their partner ganglionic neurons in the brain. Lee et al. (2017) discovered semaphorin proteins, 7A and 3A as the physical links between sweet and bitter TRCs, respectively, and their partner ganglion neurons in the brain. It remains to be determined what physical links exist between umami TRCs and their corresponding neurons in the brain. Delineating the underlying molecular basis for this interaction would provide a further understanding of purinergic transmission in the taste system. In addition, whether these mechanisms are relevant for kokumi sensation has not yet been investigated, despite CaSR having distinct expression in TRCs and significant functional synergy with other prominent taste qualities (sweet, umami, and salty). Moreover, there is still debate regarding the recognition of kokumi as a

sixth taste entity, consequently, the calcium-sensing receptor (CaSR) is not yet included in the nomenclature for any subtypes of taste GPCRs, although it would best fit with Type 1 taste receptors.

28.18.4: Type 1 Taste G Protein-Coupled Receptors (Sweet and Umami)

The type 1 taste receptors (TAS1Rs) belong to the class C GPCRs, which possess a large N-terminal extracellular domain (ECD) fused to the heptahelical seven transmembrane domain (TMD). The ECD is further divided into two ligand-binding domains (LBD1 and LBD2), having a bi-lobed structure called a Venus flytrap domain (VFT) due to its resemblance to this shape (Hoon et al., 1999). Except for $GABA_B$ receptors, a cysteine-rich domain (CRD) connects the VFT to the TMD (Leach and Gregory, 2017).

In contrast to other receptors from this class C of GPCRs, such as the metabotropic glutamate receptor (mGluR) or γ-aminobutyric acid type B receptors (GABABRs) which function as homo- or heterodimers, respectively (Jones et al., 1998; Kaupmann et al., 1998; White et al., 1998; Kunishima et al., 2000), the TAS1Rs function as obligatory heterodimers. The distinct expression pattern of TAS1R1 and TAS1R2 in different subsets of murine cells led to the idea that they could detect two different taste profiles. However, following the discovery of the TAS1R3 subtype, it was clear that when TAS1R1 heterodimerizes with TAS1R2, the receptor detects sweet taste substances (Nelson et al., 2001; Ohkuri et al., 2009; Kim et al., 2017). On the other hand, if heterodimerized with TAS1R3 (TAS1R1/TAS1R3), it is responsible for umami or amino acid taste detection (Li et al., 2002; Nelson et al., 2002). Please refer to figure 4A for the basic structure of sweet and umami receptors.

The gray is the predicted transmembrane helices. The cyan is the intracellular domain. The blue is the extracellular domain. The predicted model of the structure has high confidence except for the yellow/orange at the distal end of the extracellular domain. Key residues in the ligand binding domain are shown as sticks, CPK colors, and labeled.

28.18.5: Sweet Taste Signal Transduction Mechanisms

The TAS1R2/TAS1R3 receptor recognizes a wide variety of sweet substances including natural sugars, artificial sweeteners, amino acids, and proteins (Li et al., 2002; Xu et al., 2004; Jiang et al., 2005a; Jiang et al., 2005c) (Table 3). This was demonstrated in studies using heterologous expression systems as well as knockout mice for TAS1R2 and/or TAS1R3 subtypes that showed a blunted response to sugars, sweeteners, and D-amino acids, confirming the TAS1R2/TAS1R3 heterodimer as the main sweet taste receptor *in vivo* (Li et al., 2002; Zhao et al., 2003; Xu et al., 2004).

TABLE 3 | Agonists of sweet taste receptors along with their EC50 values.

Agonists	Nature	Binding pocket	EC50 (mM)	References
Sucrose	Natural carbohydrate	VFT (TAS1R2 and TAS1R3)	62	(Li et al., 2002; Servant et al., 2010; Zhang et al., 2010; Zhang

TABLE 3. Agonists of sweet taste receptors along with their EC50 values.

The sweet receptor couples to heterotrimeric Gα-gustducin which include Gβ3 and Gγ13, as mice lacking Gα-gustducin, showed a reduced response to sweet substances either natural or artificial (McLaughlin et al., 1992; Wong et al., 1996; Margolskee, 2002). Moreover, a point mutation in the C-terminal region of gustducin (G352P) (critical for its receptor interaction) results in the loss of its ability to activate taste GPCRs while keeping other functions intact. Further, G352P acts as a dominant negative to block heterotrimeric G protein interaction with taste receptors and disrupts the responses to sweet and bitter compounds in both wild-type (WT) and null mice (Ruiz-Avila et al., 2001). In addition, the G352 mutant further reduces any residual sweet/bitter taste responses of the null mice by acting as a "βγ sink" to bind all unbound βγ-subunits and remove them from the viable pool of G protein heterotrimers available to the receptor (Ruiz-Avila et al., 2001). These observations confirm the essential requirement of Gα-gustducin in sweet and bitter taste transduction.

In addition to the Gα-gustducin pathway, sweet taste transduction occurs *via* two additional signaling pathways involving different secondary messengers. The first one involves cAMP and the second one involves IP3. Normally, sugars elevate the level of cAMP, while sweeteners stimulate IP3 production (Tonosaki and Funakoshi, 1988; Uchida and Sato, 1997). Sucrose or other sugars bind to either TAS1R2 or TAS1R3 and recruit Gαs protein that leads to increased cAMP levels which initiate the influx of cations through ion channels. Alternatively, cAMP activates protein kinase A that leads to TRC cell depolarization resulting in an influx of calcium ions and neurotransmitter release (Avenet et al., 1988; Tonosaki and Funakoshi, 1988; Margolskee, 2002). Sweetener binding to the TAS1R2/TAS1R3 heterodimer recruits Gα-gustducin proteins that stimulate PLCβ2 which in turn hydrolyzes phosphatidylinositol 4,5-bisphosphate (PIP2) to diacylglycerol (DAG) and IP3 (Margolskee, 2002; Chandrashekar et al., 2006). IP3R3 (Hisatsune et al., 2007) induced Ca^{2+} release from ER stores (Figure 3) activates TRPM5 (Zhao et al., 2003; Hisatsune et al., 2007; Dutta Banik et al., 2018) that leads to an action potential (Yoshida et al., 2005; Yoshida et al., 2006) and subsequent release of neurotransmitters.

Interestingly, Dutta Banik et al. (2018) confirmed that TRPM4 also mediates taste signaling independent of TRPM5, and knocking out both channel proteins (TRPM4/5) abolishes the sweet, umami, and bitter taste response completely. This revealed another layer of complexity to sweet signal transmission. This in-depth mechanistic research has increased our understanding of sweet and bitter receptors and presents a challenge to dissect the taste signal transmission pathways for umami and kokumi as well.

28.18.5.1: Structural, Molecular, and Conformational Changes of Sweet Receptor

Since the sweet taste receptor has not yet been crystallized, determining the structure of the sweetener binding site and mechanism of activation has been a challenge. Based on homology with other class C GPCRs (mGluRs and $GABA_BRs$), multiple studies propose similar activation mechanisms for the sweet receptor (Kunishima et al., 2000; Tsuchiya et al., 2002; Jingami et al., 2003; Muto et al., 2007; Perez-Aguilar et al., 2019). The many different sweet agonists and their diverse binding sites across receptor domains (VFT, TMD, and CRD) (Table 3) may explain its complex yet broadly tuned nature. For example, a single residue in VFT (I60) of TAS1R3 of the TAS1R2/TAS1R3 heteromer is required for a saccharin preference in inbred mouse strains (Max et al., 2001; Reed et al., 2004).

Several studies utilizing homology and computational modeling based on the crystal structure of mGluR and $GABA_BRs$ have predicted structural and functional aspects of orthosteric and allosteric binding sites for the sweet receptor (Kim et al., 2017; Cheron et al., 2019; Park et al., 2019). They reported that both VFT regions undergo ligand-dependent conformational changes and intersubunit interactions between ECDs that further stabilize heterodimer formation for subsequent downstream signaling (Perez-Aguilar et al., 2019). The binding of orthosteric agonists to VFT of TAS1R2 leads to major conformational changes that form a TMD6/TMD6 interface between TMDs of TAS1R2 and TAS1R3, which is consistent with the activation process observed biophysically on the mGluR2 homodimer. The initial role of the bound agonist is to pull the bottom part of VFT3 (VFT of TAS1R3) toward the bottom part of VFT2 (VFT of TAS1R2) to transmit this movement from VFT2 (where agonists bind) through the VFT3 and the CRD3 (VFT and CRD of TAS1R3) to the TMD3 (TMD of TAS1R3). This facilitates G protein coupling and downstream signaling. The CRDs are crucial in this streamlined relay of structural changes where disulfide bonds provide rigidity to the CRD and amplify the mechanical constraints that help in attaining an active conformation (Cheron et al., 2019). This is empirically supported by a study in which a single mutation (A537P) in the CRD of TAS1R3 abolished the response to all sweeteners, indicating that the CRD3 must couple ligand binding in VFT2 to the conformational changes required in TMD3 for receptor activation.

Trafficking and cell surface expression are also crucial factors for sweet taste transduction. Molecular modeling with mutagenesis scanning revealed specific regions consisting of hydrophobic residues in ECD (site II; at the tip of CRD) and TMD regions (site IV; includes TMD6 and the cytoplasmic base of TMD5) of the TAS1R2 subunit to be important for dimerization with TAS1R3. Moreover, the CRD region and ECL2 domain of the transmembrane region seems to be important for surface co-expression of the TAS1R2/TAS1R3 dimer. In particular, the cytosolic C-terminus portion of the CRD region of TAS1R2 needs to be properly folded for coexpression and trafficking (Park et al., 2019). This reflects the difficulty in expressing these receptors at consistent levels in mammalian cell lines (Li et al., 2002; Shimizu et al., 2014).

28.18.5.2: Positive Allosteric Modulation of Sweet Receptor

Class C GPCRs pose an ideal target for allosteric modulation either positive (PAM) or negative (NAM). PAMs show little or no agonist activity on their own but significantly enhance agonist activity. Sweet taste is a major target of the food industry globally and non-caloric sweeteners are highly sought to exploit a huge commercial market. In a first comprehensive high throughput screen by Servant et al. (2010), novel PAMs (SE1, SE2, SE3; Table 4) for the sweet heteromer were reported that were not sweet on their own but significantly enhanced the sweetness of sucralose or sucrose. Agonist binding to the VFT region of TAS1R2 facilitates a closed conformation which constitutes an active state of the sweet receptor, while its open conformation represents an inactive state. Molecular modeling and mutagenesis studies revealed that these PAMs follow a similar mode of binding as that reported for umami PAMs (IMP and GMP). They bind near the opening of the binding pocket of the VFT region adjacent to their agonists, through Van der Waals and hydrogen bonding interactions, and utilize several critical residues for their activity. Although these residues are not in direct contact with any receptor-bound sweetener, mutation of some of them (K65, Y103, L279, D307, and R383) diminishes the response to sweeteners suggesting that these residues normally stabilize the closed conformation. The initial closing of the VFT region by agonist binding and further stabilization of the closed conformation by subsequent binding of SE modulators occurs in two steps. First, by interacting with the ECD region of TAS1R2, and second, by strengthening the hydrophobic interactions between the two lobes of ECD and lowering the free energy needed for their closure (Zhang et al., 2010).

TABLE 4. Sweet taste receptor's positive allosteric regulators with concentration (used in cell-based assays in studies) and negative allosteric modulators with their IC50 values.

Using a high throughput chemical screening approach and heterologous expression of the TAS1R2/TAS1R3 heteromer, several unnatural tripeptides with a novel core biaryl structure were found as potential sweet enhancers (Yamada et al., 2019). This study divided the potential molecule into three parts namely, "head and linker" which together are essential for its sweet enhancer activity, while the "tail" determines the level of activity. This approach provided some useful inputs toward the synthesis of potent PAMs. Firstly, an amine incorporated at the α-position of carbonyl moiety in the tail structure interacts with the TAS1R2 subunit thereby increasing allosteric activity. Secondly, additional hydrophobic substitutions in the tail structure provided an increased allosteric activity to the molecule. Lastly, the distance between the head and linker and the insertion of an amide bond is crucial for its synthesis. Although their binding characteristics and allosteric mechanisms are not yet known, these observations provide a starting point to identify and synthesize new sweet PAMs in the future.

Small molecule PAMs can also bind to the transmembrane domain in class C GPCRs, in contrast to agonist which binds to the extracellular domain (Urwyler, 2011). For example, the flavonoid sweetener, neohesperidin dihydrochalcone (NHDC) binds to TMD regions to enhance the agonist-induced sweet response. It interacts with a receptor binding pocket in the TMD of TAS1R3 and requires seventeen critical residues in TMDs and extracellular loop 2 for its allosteric activity (Winnig et al., 2007). These residues also contribute to cyclamate and lactisole binding sites. Among seventeen residues, eight alter receptor activation by NHDC ($Q637^{3.29}$, $S640^{3.32}$, $H641^{3.33}$, $Y699^{4.60}$, $W775^{6.48}$, $F778^{6.51}$, $L782^{6.55}$, and $C801^{7.39}$) and influence lactisole mediated inhibition. Similarly, nine of the seventeen residues ($Q637^{3.29}$, $H641^{3.33}$, $H721^{ex2}$, $S726^{5.39}$, $F730^{5.43}$, $W775^{6.48}$, $F778^{6.51}$, $L782^{6.55}$, and $C801^{7.39}$) mediate activation by cyclamate, while six ($Q637^{3.29}$, $H641^{3.33}$, $W775^{6.48}$, $F778^{6.51}$, $L782^{6.55}$, and $C801^{7.39}$) influence receptor inhibition by lactisole as well as receptor activation by cyclamate [superscript refers to the nomenclature suggested for class C GPCRs by Pin et al. (2003) where first number denotes TMD region and the second number denotes residue position from the most conserved residue].

Notably, three critical residues in TMD6 ($W775^{6.48}$, $F778^{6.51}$, $L782^{6.55}$) and one in TMD7 ($C801^{7.39}$) of TAS1R3 were found crucial for allosteric binding, as their mutation to alanine altered the receptor's sensitivity to NHDC and cyclamate, as well as to the inhibitor lactisole (Winnig et al., 2005). Therefore, TMD6 and TMD7α helices of TAS1R3 are integral to allosteric modulation of the sweet receptor, implicating them in TAS1R2 and TAS1R3 subunit interactions and indicating an important role for this

structural region in the conformational changes involved in receptor activation. Furthermore, these residues are conserved across mammalian species (Cheron et al., 2019).

28.18.5.3: Negative Allosteric Modulation of Sweet Receptor

Like PAMs, negative allosteric modulators (NAM) such as lactisole and gymnemic acid bind to the TMD region of TAS1R3 and inhibit sweet substance-induced responses. Lactisole, an aralkyl carboxylic acid not only inhibits sweet but also the umami receptor response in humans and presents a rare opportunity to study the structural cross-talk between these two taste qualities. Using heterologous expression and mutagenesis, Jiang et al. (2005b) reported that lactisole's sweet inhibition might be mediated by its binding to TMD3, TMD5, and TMD6 of TAS1R3 and induce a conformation change which restricts the movement required to stabilize the active state. Residues A733$^{5.46}$ in TMD5, L798$^{7.36}$ in TMD7, and R790^{ex3} in extracellular loop 3 were found to be crucially important for sensitivity to lactisole in humans (Jiang et al., 2005b). These observations were confirmed in a recent study where 2-(2,4-dichlorophenoxy)propionic acid (2,4-DP) was found to be a more potent antagonist and utilize the same residues as well as four additional ones (H641$^{3.37}$, H734$^{5.43}$, F778$^{6.53}$, and Q794$^{7.32}$) in binding to TAS1R3. Moreover, the (S)- isomer of both compounds was found to be more strongly bound to the TMD of TAS1R3 and be a more effective inhibitor [lactisole; (S)-lactisole IC50, 20 μM while (R)- lactisole exerted no inhibition at this concentration.; 2,4-DP: (S)-isomer was 10-fold more effective than (R)-2,4DP]. The (S)- lactisole isomer interacts with the TMD via its carboxyl group and stabilizes in only one orientation in the binding pocket that does not allow for very strong binding. In contrast, (S)-2,4- DP binds through two moieties simultaneously, a carboxyl group and an aromatic ring with two Cl^- groups and stabilizes in several different orientations through hydrophobic interactions that allow stronger binding, resulting in stronger negative allosteric modulation (Nakagita et al., 2019).

These observations provide information about the relevance of structural modification in NAM compounds that could affect their interaction with the receptor. Although TMDs of TAS1R3 are the most likely regions responsible for allosteric modulation, TMDs and VFT regions of TAS1R2 cannot be ruled out completely. For example, the diuretic amiloride binds to TAS1R2 (TMD3, TMD5, TMD7) and inhibits the sweet response in a species-dependent manner (Zhao et al., 2018). Further, the umami compound [monosodium glutamate (MSG)] and peptides (Glu-Asp, Glu-Glu) bind to the VFT region of TAS1R2 and inhibit the sweet-induced response (Shim et al., 2015). These observations suggest that both subunits are important for the allosteric activity of TAS1R2/TAS1R3 and further structural studies are required to design novel sweet allosteric modulators.

28.18.6: Umami Taste Signal Transduction Mechanisms

In contrast to four well-known basic human tastes (sweet, bitter, salty, and sour), umami or ‘savory taste’ is relatively recent and was introduced in early 2000 by Kikuna Ikeda (Ikeda, 2002) as a new seasoning element in food. The main stimulus for the umami taste is the amino acid, L-glutamate present in the diet mainly in the form of MSG (Roper, 2007). Glutamate was first extracted from konbu/kombu (dried kelp of *Fucus vesiculosus*) and described as having a “unique taste” and “very different from other tastes”. The terminology “umami” comes from the Japanese word “umai” meaning “delicious.” Moreover, the taste of umami is also produced by food such as mushrooms and soy sauce that contain amino acids (L-aspartate), peptides, and synthetic ingredients similar to glutamate and some organic acids (Roper, 2007; Kinnamon, 2009) (Table 5).

TABLE 5. Umami receptor agonists with their EC50 values and other pharmacological properties.

The umami receptor (TAS1R1/TAS1R3) is a heteromeric member of the class C GPCRs, whereas most other receptors of this class exist as homodimers (Nelson et al., 2002; Temussi, 2009; Leach and Gregory, 2017). TAS1R1/TAS1R3 is the predominant umami taste receptor (Zhao et al., 2003; Behrens and Meyerhof, 2011) and the TAS1R1 subtype is critical for sensing umami taste as its

deletion abolished the response to umami taste stimuli (Mouritsen and Khandelia, 2012). However, TAS1R1/TAS1R3 is not the only receptor capable of detecting umami ligands (Chaudhari et al., 2000; Kunishima et al., 2000; Li et al., 2002; Nelson et al., 2002). Studies using heterologous expression, afferent nerve recordings, and behavioral experiments have confirmed that metabotropic glutamate receptors 1, and 4 (taste-mGluR1 and taste-mGluR4) also sense umami stimuli (Chaudhari et al., 2000; Kunishima et al., 2000; Li et al., 2002; Nelson et al., 2002). Notably, TAS1R3 knock-out mice show a strongly diminished response to glutamate and sweet stimuli (Damak et al., 2003) and taste cells isolated from these mice respond to IMP and glutamate which is abolished in presence of mGluR antagonists (Pal Chaudhry et al., 2016). TAS1R1/TAS1R3 is not only activated by glutamate but this activation is strongly enhanced in the presence of 5′-ribonucleotides, (inosine 5′ monophosphate; IMP) a response that is a hallmark of umami taste (Rifkin and Bartoshuk, 1980).

The main transduction components following the activation of TAS1R1/TAS1R3 are similar to those for sweet taste (Zhang et al., 2003), i.e., α-gustducin (and γ13/β1 or β3), PLCβ2, IP3R, and TRPM4/5. Cyclic nucleotides may also contribute to the transduction of umami taste in TRCs. When taste tissue is stimulated with umami, its cyclic AMP level is decreased (Abaffy et al., 2003). However, the consequence of decreased cAMP in TRCs has not yet been fully elucidated. Both α-transducin and α-gustducin are involved in umami taste signal transduction, as mice lacking the gene for one of these proteins showed a reduced response to this taste (He et al., 2004; Leach and Gregory, 2017). In the taste palate fungiform papillae, α-gustducin and α-transducin activate PDE that reduces cAMP levels. Ligand binding to the TAS1R1/TAS1R3 heterodimer releases Gβγ subunits to stimulate PLCβ2, which hydrolyzes PIP2 to DAG and IP3 (Kinnamon, 2009). IP3 then activates IP3R3 which results in the release of calcium ions from intracellular compartments (Clapp et al., 2001; Leach and Gregory, 2017) (Figure 3). Calcium ions activate TRPM5 and TRPM4 channels, leading to an influx of sodium ions, subsequent cell membrane depolarization, and finally release of ATP, which activates ionotropic purinergic receptors located in sensory fibers (Perez et al., 2002; Sugita, 2006). This pathway was confirmed when mice devoid of TRPM5, TRPM4, PLCβ2, and IP3R3 showed a reduced response to umami taste perception following glutamate stimuli (Damak et al., 2006; Kinnamon, 2009; Eddy et al., 2012).

28.18.6.1: Structural, Molecular, and Conformational Changes of Umami Receptor

In the last decade, several in-depth modeling and mutagenesis approaches have improved structural and molecular understanding of the umami receptor. The VFT regions of both subunits of TAS1R1/TAS1R3 comprise orthosteric and allosteric ligand binding sites for umami stimuli.

Mutagenesis and molecular modeling studies reveal that the cognate agonist glutamate binds in the VFT region of the TAS1R1 subunit of TAS1R1/TAS1R3 and stabilizes the closed active receptor conformation. Moreover, four residues in the TAS1R1 VFT region (S172, D192, Y220, and E301) showed no detectable response to glutamate when they were mutated to alanine suggesting that they are critical for glutamate binding. The glutamate binding and stabilization of the closed conformation of TAS1R1, activates the downstream signaling pathway, while TAS1R3 remains in an open (inactive) conformation. Therefore, closure of the VFT is the key event that sensitizes umami taste receptor signal transduction (Lopez Cascales et al., 2010). Apart from glutamate, other L amino acids were also found to elicit functional responses by binding to the corresponding VFT region of TAS1R1. Six residues that contributed to the acidic amino acid agonist (L-glutamate and L-alanine) responses have been identified (S148, R151, A170, E174, A302, and D435).

28.18.6.2: Allosteric Modulation of Umami Receptor

Because of significant advancements in understanding and food industry application of umami taste, its allosteric modulators are sought after. Several allosteric umami ligands have been discovered with varying potency, only a few of which have been characterized at the molecular level. The best-characterized umami PAMs, the 5′-ribonucleotides: inosine 5′-monophosphate (IMP) and guanosine 5′-monophosphate (GMP), interact with the VFT region of the TAS1R1 subunit to enhance the glutamate-induced response that is the hallmark of umami taste (Table 6). IMP and GMP binding sites in the VFT are adjacent to that for glutamate binding. The mutation of four residues (H71, R277, S306, and H308) abolished the IMP/GMP-induced glutamate response suggesting their involvement in the allosteric binding of these nucleotides. Structurally, IMP and GMP stabilize the closed form of the TAS1R1 VFT region through electrostatic interactions and coordinate the positively charged residues that act as pincers. The ability of IMP and GMP to interact with the VFT region (as opposed to the TMD region) represents a unique mechanism of positive allosteric regulation within class C GPCRs (Urwyler, 2011).

TABLE 6. Umami receptor allosteric modulators with concentrations used in cell-based assays and other pharmacological properties.

In contrast to IMP and GMP which bind to the TAS1R1 extracellular domain, the well-known flavor compound methional and its analogs bind to the TMD region and allosterically regulate the umami receptor in a species-dependent manner (Toda et al., 2018). Importantly, methional utilizes several distinct residues in different TAS1R1 transmembrane domains (TMD2-7) to act as a PAM in the human umami receptor, yet it behaves as a NAM in the mouse counterpart. This unusual phenomenon provided an opportunity to study the mechanisms of both positive and negative modulation in TAS1R1 simultaneously (Toda et al., 2018).

Construction of chimeric receptors between human (h) and mouse (m) and their functional analysis demonstrated that the TMD of TAS1R1 is the key domain for switching the PAM/NAM activities of methional. Point mutation substitutions between these species identified four residues (h/m; F768/L769, N769/H770, S799/T800, and S802/G803) that are collectively required to switch PAM/NAM activities. A similar mode of allosteric regulation and PAM/NAM mode switching has been reported for mGluR5 (Gregory et al., 2013) suggesting this is an unusual and distinct phenomenon of the class C GPCRs. Further, alanine scanning mutagenesis in TAS1R1 of the corresponding residues vital for the activity of other taste inhibitors (sweetener inhibitors; NHDC and cyclamate; sweet and umami taste inhibitor; lactisole) revealed three residues required for PAM (W697$^{4.50}$ F728$^{5.40}$ and F732$^{5.44}$) and a single residue (F642$^{3.40}$) for NAM. These results suggest that both the PAM and NAM activities of methional are conferred by residues that are distinct from those required for the PAM/NAM switch. Knowing that methional is an important part of food seasoning globally, these observations could help in maximizing its use in enhancing flavors along with amino acids and nucleotides.

Despite PAMs being a central focus for umami allosteric modulation, there has also been considerable research on negative allosteric modulation where lactisole emerged as a prominent NAM of the umami receptor, TAS1R2/TAS1R3. Because umami and sweet receptors share the TAS1R3 subunit, findings from studies on sweet receptor lactisole binding are relevant. A comprehensive study on the sweet receptor identified critical residues within the TMD regions (S640$^{3.32}$, H641$^{3.33}$ in TMD3 and F778$^{6.51}$, L782$^{6.55}$ in TMD6) of TAS1R3 required for lactisole binding pocket and showed a large effect on sensitivity to lactisole (Xu et al., 2004; Jiang et al., 2005b). Because lactisole shares structural similarities with two other classes of compounds: fibrates and phenoxy-herbicides, researchers studied them to search for novel sweet/umami inhibitors (Maillet et al., 2009). The lipid-lowering drug, clofibric acid inhibits the TAS1R3 umami receptor-mediated response both *in vitro* and *in vivo* (Table 6). Like lactisole, clofibrate inhibits the umami taste from glutamate by binding with a similar affinity to TAS1R1/TAS1R3. However, its specificity against the umami receptor still needs to be validated alongside other umami taste receptors (mGluR1, mGluR4, or NMDA).

28.18.7: TYPE 2 TASTE G PROTEIN-COUPLED RECEPTORS (BITTER RECEPTORS)

Type 2 taste GPCRs are represented by bitter taste receptors that have a distinct subset of bitter sensing cells in type II TRCs and notably, 25 bitter taste receptors (TAS2Rs) are reported to be expressed in humans (Chandrashekar et al., 2000; Devillier et al.,

2015; Behrens and Meyerhof, 2018). A significant amount of work has been done to explore the diversity among TAS2Rs and their agonists in taste biology (Adler et al., 2000; Behrens and Meyerhof, 2009; Behrens and Meyerhof, 2018). Some TAS2Rs (TAS2R3, TAS2R5, TAS2R13, TAS2R50) are narrowly tuned to structurally similar bitter compounds, whereas others are broadly tuned (TAS2R10, TAS214, TAS2R46), responding to several bitter compounds. Initially, it was believed that each bitter-sensitive type II TRC expressed every TAS2R isoform (Adler et al., 2000) but other studies suggest that TAS2Rs can be expressed differentially, allowing for possible discrimination among bitter compounds (Caicedo and Roper, 2001; Behrens and Meyerhof, 2009; Behrens et al., 2009). Please refer to figure 4B for the basic structure of the bitter receptor.

28.18.7.1: Bitter Taste Signal Transduction Mechanisms

The bitter taste is the most complex of all the five basic tastes and protects against the ingestion of toxic substances by eliciting an innate aversive response across species (Chandrashekar et al., 2006; Behrens and Meyerhof, 2018). The TAS2Rs that mediate bitter taste perception are among ∼50 TAS2Rs identified in mammals, and 25 are known to be expressed in humans (Adler et al., 2000; Devillier et al., 2015; Yoshida et al., 2018). The TAS2R family is the most diverse and binds to a wide range of agonists compared with the other taste GPCRs (Jaggupilli et al., 2016) (Supplementary Table 1).

TAS2Rs are distinctive among class A GPCRs in that many of them bind agonists with low apparent affinity in the micromolar range, rather than the nanomolar range (Di Pizio et al., 2016). The activation of TAS2Rs by harmless, minute amounts of bitter compounds such as those contained in most vegetables would limit the availability of food resources appearing safe for consumption and therefore could negatively affect survival. Hence, the concentration ranges at which bitter taste receptors are activated are well-balanced to allow species to maintain a healthy diet yet avoid ingestion of spoiled food containing strongly bitter ligands.

Hundreds of bitter compounds have been reported to evoke bitterness and activate human bitter receptors in different cell-based assays. These bitter agonists include plant-derived and synthetic compounds such as peptides, alkaloids, and many other substances (Supplementary Table 1). (Pronin et al., 2004; Meyerhof et al., 2010; Iwata et al., 2014). Some TAS2Rs are activated by a wide range of compounds, whereas others show strict specificity for a single bitter compound (Behrens et al., 2009; Sakurai et al., 2010a; Born et al., 2013). Interestingly, TAS2R31, TAS2R43, and TAS2R46 have around 85% sequence homology, but they bind to different agonists (Brockhoff et al., 2010; Jaggupilli et al., 2016), reinforcing the idea that each TAS2R might have a unique ligand-binding pocket.

The canonical TAS2R signal transduction cascade signaling molecules shared among bittersweet and umami receptors (Wong et al., 1996; Huang et al., 1999; Mueller et al., 2005), includes the heterotrimeric G protein subunits (Gα-gustducin, Gβ3, and Gγ13), (Ishimaru, 2009; Shi and Zhang, 2009), a phospholipase C (PLCβ2), an inositol trisphosphate receptor (InsP3R), and the TRPM5 ion channel. Upon receptor activation by bitter ligands, the G protein α-gustducin dissociates from its βγ subunits. The latter activates PLCβ2, leading to a release of Ca^{2+} from IP3-sensitive Ca^{2+} stores, resulting in Na^{+} influx through TRPM5 channels. This Na^{+} influx depolarizes the cells and causes the release of neurotransmitter ATP through gap junction hemichannels or CALHM1 ion channels (Finger et al., 2005; Chaudhari and Roper, 2010; Taruno et al., 2013) (Figure 3).

28.18.7.2: Structural, Molecular, and Conformational Changes of Bitter Receptors

Classification of TAS2Rs has always been ambiguous because they were originally considered to be a distinct family (Horn et al., 2003) or grouped with the frizzled receptors (Fredriksson et al., 2003; Jaggupilli et al., 2016), but most recent analyses (Di Pizio et al., 2016) support their classification with Class A GPCRs. The ability of bitter taste receptors to interact with numerous structurally diverse substances compared to other GPCRs is remarkable and includes a wide range of drugs/antibiotics, polyphenols, bacterial metabolites, salts, and metal ions (Supplementary Table 1). Therefore, exploring the criteria for the identification of highly heterogeneous bitter compounds with pronounced selectivity has become a major research area. Some of these studies rely solely on in silico homology/computational modeling (Dai et al., 2011; Tan et al., 2012; Di Pizio et al., 2020; Dunkel et al., 2020) and others on *in vitro* genetic modification and functional assay systems (Pronin et al., 2004; Nowak et al., 2018; Jaggupilli et al., 2019).

As a group of over ∼50 receptor subtypes, TAS2Rs recognize structurally diverse agonists where some are broadly tuned (TAS2R46, TAS2R14, TAS2R10, and TAS2R43) recognize diverse agonists, while others (TAS2R1, TAS2R4, TAS2R7) show strong selectivity and narrow tuning (Liu et al., 2018; Wang et al., 2019). The agonist binding cavity in most bitter GPCRs is located deep within their transmembrane domain (TMD), except TAS2R7 in which it resides on the extracellular surface (Liu et al., 2018). TAS2Rs are also distinct in containing highly conserved TMD regions, with thirteen key residues and two motifs (LXXXR in TMD2 and LXXSL in TMD5) that are absent in class A GPCRs, and may reflect their different activation mechanisms (Singh et

al., 2011). LXXSL plays a structural role by stabilizing the helical conformation of TMD5 at the cytoplasmic end and a functional role by interacting with residues in intracellular loop 3 (ICL3) which is important for proper receptor folding and function (Singh et al., 2011). Moreover, mutation of the conserved residues in LXXSL and LXXXR motifs results in protein misfolding and poor surface expression (Singh et al., 2011; Pydi et al., 2014a).

The initial study highlighting the structure–activity relationship of bitter taste receptors was performed with receptors belonging to a subfamily of closely related TAS2Rs (Pronin et al., 2004). By physically swapping the extracellular loop 1 (ECL1) between TAS2R43 and TAS2R31, chimeric TAS2R31/TAS2R43 (ECL) gained responsiveness to the compound n-isopropyl-2methyl-5-nitrobenzenesulfonamide (IMNB), whereas the reverse chimera TAS2R31 (ECL)/TAS2R43 lost responsiveness for IMNB. Although this report supports an important contribution of residues located within the transmembrane region of the investigated receptors, the extracellular loops appear to be of importance for agonist selectivity. This empirical finding contrasts with earlier computational studies which predicted the agonist binding site to lie within the helical bundle of TAS2Rs without particular contacts between extracellular loops and docked agonists (Floriano et al., 2006; Miguet et al., 2006).

28.18.7.3: Bitter Receptor Ligand Binding Pocket

The emergence of TAS2Rs as the most broadly tuned taste receptors might give the impression that their specific interaction with numerous agonists is because of several binding pockets that accommodate subgroups of bitter compounds. However, structure–function analysis of TAS2Rs (except for TAS2R7) has demonstrated the presence of only a single agonist binding pocket comprising the upper parts of TMD2, TMD3, TMD5, TMD6, and TMD7. The reason for their broad tuning and recognition of such a broad spectrum of agonists might most likely be attributed to the presence of an additional extracellular binding site called a “vestibular site,” in addition to the orthosteric selecting as reported for TAS2R46 (Sandal et al., 2015). This two-site architecture offers more ligand recognition points than a single one and thus might help in selecting the appropriate agonists. Moreover, the presence of the vestibular site may also help to discriminate among the wide spectrum of bitter ligands.

Although broadly tuned receptors (TAS2R46, TAS2R31, and TAS2R43) have high homology in amino acid sequence, their agonist profiles only slightly overlap (Kuhn et al., 2004; Brockhoff et al., 2007; Di Pizio and Niv, 2015) which suggests the involvement of key residues at different positions in agonist specificity. Consequently, when strychnine interacting positions in TAS2R46 (residues differ at this position in TAS2R31, TAS2R43) were exchanged between these two receptors not only was the strychnine responsiveness transferred to the recipient receptor (TAS2R31, TAS2R43), but also sensitivity to additional TAS2R46 agonists (absinthin and denatonium). Sensitivity to activation by aristolochic acid was lost in the mutant receptors (Brockhoff et al., 2010). This experimental evidence supports the presence of a common agonist binding pocket and agrees with other studies on TAS2R16, TAS2R14, and TAS2R7 receptors (Sakurai et al., 2010a; Sakurai et al., 2010b; Thomas et al., 2017; Liu et al., 2018; Nowak et al., 2018).

Recent studies used homology modeling and mutagenesis to elucidate the nature of the ligand-binding pocket in TAS2R7, TAS2R14, and TAS2R16 receptors (Thomas et al., 2017; Liu et al., 2018; Nowak et al., 2018). They reported that the binding pocket is flexible and wide open to accommodate molecules of diverse sizes and shapes, and thus permits chemical modifications among agonists as well (Thomas et al., 2017; Liu et al., 2018; Nowak et al., 2018). Although the molecular basis for the promiscuity of bitter receptors is attributed to their apparent flexible spacious binding site, future work elucidating the contact points between TAS2Rs binding site residues and its agonists in terms of additional binding locations is required.

28.18.7.4: Bitter Receptors Ligand Binding Domain and Amino Acid Residues

A majority of the TAS2R studies are based on molecular modeling, mutagenesis, and heterologous expression systems (Biarnes et al., 2010; Brockhoff et al., 2010; Tan et al., 2012; Nowak et al., 2018; Shaik et al., 2019) suggest that the ligand binding pocket is formed by several key residues in most TMDs (TMD1, TMD2, TMD3, TMD5, TMD6, and TMD7), except for TMD4.

Studies show similarities as well as differences regarding residues and positions involved in agonist-receptor interactions. However, most of them agree that besides position $N^{3.36}$ in TMD3 (superscript as per Ballestros-Weinstein nomenclature for class A GPCRs) (Ballesteros and Weinstein, 1995) and other residues ($L^{3.32}$, $L^{3.33}$, and $E^{3.37}$) in its close proximity, play a role in agonist activation of several broadly tuned TAS2Rs (TAS2R1, TAS2R16, TAS2R30, TAS2R38, TAS2R46) (Pronin et al., 2004; Biarnes et al., 2010; Brockhoff et al., 2010; Sakurai et al., 2010b; Dai et al., 2011). In contrast, for the narrowly tuned TAS2R7, one position in TMD3 ($H94^{3.37}$) and another in TMD7 ($E264^{7.32}$) were found crucial for metal ion binding (Wang et al., 2019). Mutagenesis and molecular modeling revealed that these two residues contribute to the metal ion binding pocket in TAS2R7. Moreover, metal ions bind distinctively to residues lining the binding pocket and interestingly, the presence of calcium in the assay solution appears to affect the TAS2R7 response to metal ions. It is not clear how calcium affects metal ion binding to TAS2R7, but it might work

cooperatively with certain ions and not others. Future studies focusing on structural interactions between the receptor and metal ions will provide further insights into how they activate the receptor.

In TMD2, two studies suggest that position $N^{2.61}$ is critical for binding in TAS2R1 (Singh et al., 2011) and TAS2R46 (Brockhoff et al., 2010). Likewise, in TMD7, position $265^{7.39}$ is implicated in binding to TAS2R46 (E265) and TAS2R1 (I263) (Dai et al., 2011). In TMD5, position $H^{5.43}$ is implicated in binding in TAS2R16 and $E^{5.46}$ in TAS2R1 (Dai et al., 2011) while, in TMD7, position $E^{7.32}$ was crucial for metal ion binding (Wang et al., 2019). These residues represent putative contact points for agonist interaction and form a pattern of being spaced one helical turn from each other.

Recent mutagenesis studies (Nowak et al., 2018; Di Pizio et al., 2020) performed in broadly tuned TAS2R14 with agonists (aristolochic acid, picrotoxinin, thujone) found several residues in TMDs to be involved in agonist binding. However, in contrast to TAS2R10 (Born et al., 2013) and TAS2R46 (Brockhoff et al., 2007), mutation of TAS2R14 did not result in a complete loss of function for all agonists but a varied reduction in responsiveness or selectivity toward agonists. Among several mutants, only mutation of W89A resulted in a complete loss of responsiveness against picrotoxinin while others showed more subtle agonist selective changes. This indicates that TAS2R14 is not streamlined for the most sensitive detection of selected agonists, but rather tailored to detect numerous diverse agonists, with comparatively lower apparent affinity.

The binding characteristics of bacterial acyl homoserine lactones (AHLs) on TAS2Rs (TAS2R4, TAS2R14, and TAS2R20) suggest the presence of a single orthosteric site situated close to the extracellular surface and reinforce the significant role of the extracellular loop structure (ECL2) in TAS2R ligand binding and activation (Jaggupilli et al., 2018). The crucial AHL binding residues in TAS2R4 and TAS2R14 are predominantly located in the ECL2, while in TAS2R20 they are present in TMD3 and TMD7 helices. The ECL2 residues, N165 in TAS2R4, and R160 and K163 in TAS2R14 were found crucial for lactone binding. In contrast, TAS2R20 residues W88 (TMD3) and Q265 (TMD7) are essential for agonist binding (Pydi et al., 2014c; Zhang et al., 2017; Jaggupilli et al., 2018). In addition, the hydrophobic amino acids in the three TAS2Rs are considered important in directing the orientation of the hydrophobic acyl chains of lactones that facilitate receptor activation.

The transmembrane domain in GPCRs is composed mainly of hydrophobic amino acids accommodated in the plasma membrane. Therefore, hydrophobic properties of the receptor binding pocket are important for any membrane-accessible agonist. Hydrophobic residues in TMD3 and TMD7 of TAS2R16 are important in forming a wide ligand-binding pocket (Thomas et al., 2017) that accommodates larger ligands like the β-glycosides. By using salicin analogs as TAS2R16 novel agonists (differ structurally from salicin in β-glucoside core constituents), several critical residues were identified that are required for signaling. Interestingly, these were identical to the residues critical for salicin signaling, except for W261, which was not required for activation by the analog 4-NP-β-mannoside. Importantly, all these residues are in the TMD helices or intracellular face of the receptor, consistent with classical GPCR signal transduction. These results suggest that larger ligands bind to the wide binding pocket of TAS2R16 on the extracellular side, and then their signal is transduced via conserved residues on the intracellular side. This can account for the broad spectrum of ligand recognition conferred by TAS2R16.

Unlike broadly tuned receptors, narrowly tuned ones like TAS2R7 show two different types of critical residue in ligand binding. The first type includes D86, W170, and S181 which are agonist independent and their mutation significantly reduces the ability of TAS2R7 to bind agonist, while a second group consisting of D65 and W89 are selective for quinine and enhance binding to a specific category of ligand (Liu et al., 2018).

Despite the variation in the amino acid type and location important for agonist binding among receptors of the bitter family, for the most part, ligand binding pockets are present on the extracellular surface of TMDs or ECL2. The function of the residues at these binding pockets is dictated by multiple factors that include the type of ligand, the movements in TMDs, and the associated movement of ECL2 to accommodate the ligand. Structure–function studies have identified a conserved KLK/R motif in the intracellular carboxyl-terminal domain of 19 TAS2Rs that is critical for cell surface expression, trafficking, and receptor activation (Upadhyaya et al., 2015; Jaggupilli et al., 2016).

28.18.7.5: Agonist, Antagonist Binding and Modulation of Bitter Receptors

In simple pharmacological terms, an antagonist is a ligand that inhibits the biological response induced by an agonist and does not induce any response of its own, while a ligand that reduces the constitutive/basal activity of a GPCR is considered an inverse agonist. An antagonist acts as a competitive inhibitor to block receptor activity. Large numbers of agonists have been identified for bitter receptors, but few antagonists have been found so far (Table 7). Finding an antagonist/inhibitor for bitter taste would not only help in understanding the TAS2R mechanism of signal transduction but have potential use in foods to overcome unwanted bitterness in consumer products. Such bitter blockers have been proposed to increase the palatability of bitter-tasting food and

beverages, increase compliance in taking bitter-tasting drugs, especially children's formulations and reduce or prevent off-target drug effects in extra-oral tissues (Clark et al., 2012)

ND, not determined.					

TABLE 7. Bitter taste receptor inhibitors with their IC50 values and other pharmacological properties.

To date, ~12 bitter inhibitors have been reported to interact with only 10 TAS2Rs subtypes (Table 5) by binding to transmembrane domains in a similar manner to agonists. GIV3727 (4-(2,2,3-trimethylcyclopentyl) butanoic acid) was the first TAS2R antagonist discovered and to be well characterized structurally (Slack et al., 2010) that acts as an orthosteric competitive antagonist for TAS2R31. It competes with the acesulfame K agonist both *in vitro* and *in vivo*. GIV3727 is moderately selective because it inhibits multiple bitter receptors including, TAS2R4, TAS2R40, and TAS2R43. Homology modeling revealed that the -COOH group in GIV3727 is important for ligand-receptor interactions as its replacement with an ester or the corresponding alcohol abolished its antagonist activity. Moreover, a mutagenesis study in TAS2R31 and TAS2R43 revealed residues $K265^{7.39}$ and $R268^{7.39}$ in TMD7 to be crucial for its antagonistic activity (Slack et al., 2010). Similarly, another non-selective inhibitor, probenecid (p-(dipropylsulfamoyl) benzoic acid) was found to act as NAM of TAS2R16 activity and inhibits TAS2R38 and TAS2R43 as well (Greene et al., 2011). Two point mutations, P44T and N96T in TMD3 of hTAS2R16 were found to significantly suppress the ability of probenecid to inhibit salicin activity. Hydrophobicity seems important for their pharmacological activity as observed for both probenecid and GIV3727. The sesquiterpene lactone, 3β-hydroxydihydrocostunolide (3HDC) is an interesting bitter blocker as it acts as a competitive antagonist of TAS2R46, TAS2R30, TAS2R40, yet activates TAS2R4, TAS2R10, TAS2R14, and TAS2R31 as an agonist (Brockhoff et al., 2011).

Similarly, various flavanones were also noted as antagonists for TAS2R31, and TAS2R39 with varying efficacy. Taken together most of the currently known antagonists are non-selective and there is an urgent need for studies that focus on selective antagonists of major broadly tuned TAS2Rs (such as TAS2R10, TAS2R14, TAS2R16, and TAS2R46). To target bitterness in terms of food industry needs, potential peptide inhibitors from different protein sources such as hen protein hydrolysates (inhibits TAS2R4, TAS2R7, TAS2R14) and beef proteins (inhibits TAS2R4) (Zhang et al., 2018; Xu et al., 2019) are reported to be effective. Several umami glutamyl peptides isolated from soybeans have been found to act as non-competitive allosteric inhibitors of TAS2R16 against the salicin-induced response (Kim et al., 2015).

28.18.7.6: Constitutive Activity of Bitter Receptors

A phenomenon in GPCR activity is that of constitutive activity, essentially an active state occurring in the absence of an agonist which has been demonstrated in more than 60 GPCRs (Seifert and Wenzel-Seifert, 2002). It is the production of a second messenger or downstream signaling by a receptor in a ligand-independent manner. The constitutive activity provides another possibility for taste inhibitor discovery using inverse agonists. Inverse agonists can inhibit both agonist-dependent and agonist-independent activity, while antagonists can inhibit only agonist-dependent activity (Chalmers and Behan, 2002). Interestingly, some mutations in GPCRs can lead to constitutive activity and receptors with this characteristic (including constitutively active mutants or CAM) are important tools to investigate new bitter inhibitors. Although constitutive activity has not been observed naturally in TAS2Rs, when induced by mutation these receptors provide a useful means to investigate the relationship between an active receptor conformation and inverse agonist pharmacology.

Molecular modeling and functional assays report five CAMs critical residues for TAS2Rs, one in TMD7 ($S285^{7.47}$) and four others in intracellular loop 3 (H214A, Q216A, V234A, and M237A) (Pydi et al., 2014a; Pydi et al., 2014b). Of the five CAMs, only the TAS2R4 with H214A mutation shows a 10-fold increase in constitutive activity. This histidine residue is highly conserved in most TAS2Rs. Mutation of H214 (H214A) helped in finding two new inverse agonists (GABA and ABA; Table 7) (Pydi et al., 2015). Similar pharmacological approaches can be used to generate mutants of all TAS2Rs to screen for their inverse agonist/bitter taste blockers. However, for better characterization and interpretation of TAS2Rs, future *in vivo* studies should be performed to understand the functional relevance of these CAMs. At the same time, it is worth noting that the potential presence of endogenous agonists makes it difficult to determine the true constitutive activity of GPCRs including TAS2Rs (Devillier et al., 2015).

28.18.8: Kokumi Sensation Signal Transduction

In addition to the five basic tastes, sensations beyond these add another dimension to taste perception. One such example is “kokumi” which is distinct from the other five tastes in that it does not have a taste as such but rather induces a sensation of “mouthfulness,” depth, thickness, and aftertaste in the flavors. Although this flavor has been used historically and is well recognized in Japanese cuisine, it was first characterized by Ueda et al. (1990) who isolated a kokumi taste substance from water extracts of garlic and onion and identified, γ-glutamylcysteinylglycine or glutathione (GSH) as the main active ingredient of kokumi flavor (Ueda et al., 1990; Ueda et al., 1997; Dunkel et al., 2007). GSH is abundantly present in food-grade yeast extract and has been used to make foods more flavorsome.

Kokumi signal transduction was unknown until CaSR expression was reported in a subpopulation of taste cells in mice and rats that suggested it could function as a taste receptor for calcium and amino acids (San Gabriel et al., 2009; Bystrova et al., 2010).

However, its apparent role in kokumi stimuli detection was not confirmed. Ohsu et al. (2010) for the first time reported that kokumi peptides (GSH, γ-Glu-Val-Gly, and various γ-glutamyl peptides; Table 8) signal through CaSR and can synergize with sweet, salty, and umami taste qualities to impart an augmented kokumi sensation, i.e., increased depth of flavor which was further complemented by later studies (Maruyama et al., 2012; Kuroda and Miyamura, 2015). By using heterologous expression systems and human sensory analysis these studies demonstrated that kokumi peptides impart kokumi sensation to sweet, salty, and umami taste via CaSR as the kokumi component was specifically suppressed in the presence of the CaSR-specific NAM NPS-2143. To further validate this idea, Maruyama et al. (2012) identified a distinct population of taste cells expressing CaSR in mouse lingual tissue which did not express either sweet or umami receptors. Notably, these cells are specifically responsive to kokumi substances and elicit a Ca^{2+} response to focally applied kokumi stimuli in mouse lingual slices. Moreover, this response was inhibited in the presence of NPS-2143. These findings support the idea that CaSR mediates kokumi sensation effects in TRCs

TABLE 8. Kokumi sensation receptor agonists, allosteric modulators with concentrations used in cell-based assays.

More recently, kokumi peptides have been found to have an extraoral physiological role in the gastrointestinal tract where they stimulate the secretion of hormones (cholecystokinin and glucagon-like peptide1 by activating CaSR (Depoortere, 2014; Yang et al., 2019). However, future studies with tissue-specific deletion of CaSR in taste buds would help delineate its role in taste physiology.

CaSR involvement in taste is a relatively recent discovery, but its central role in extracellular calcium homeostasis in mammals is well recognized (Brown et al., 1993; Brown, 2013). Diverse ligands activate CaSR, including cations (Ca^{2+} and Gd^{3+}), peptides, polyamines (Brown and MacLeod, 2001), and amino acids (Conigrave et al., 2000; Conigrave and Hampson, 2006) (Table 8). Unlike other taste modalities (sweet, bitter, and umami), CaSR–ligand binding and recruitment of G protein results in the activation of an intricate, amplifying signaling network that initiates numerous intracellular functions. The functional diversity of CaSR results from its ability to activate multiple Gα proteins (Gq/11, Gi/o, G12/13, and Gs) (Magno et al., 2011; Conigrave and Ward, 2013) which subsequently affect multiple signaling pathways related to the pathophysiology of parathyroid hormone secretion, cancer, and metastasis (Kelly et al., 2007; Wettschureck et al., 2007; Mamillapalli et al., 2008).

Kokumi substrates activate CaSR and transmit their signal through Gαq/11 proteins which further activate PLCβ that results in the release of intracellular Ca^{2+} stored through activation of IP3 receptor channels in the ER. Whether the kokumi pathway strictly relies on Gαq/11 protein or can also use Gα-gustducin, like other taste modalities for downstream signaling, is still unknown (Figure 3). The growing number of reports on kokumi flavor signal transduction are shedding light on its potential use as a flavor enhancer.

28.18.8.1: Structural, Molecular, and Conformational Changes of Kokumi Receptor

CaSR belongs to the class C GPCR. Within this class, CaSR and metabotropic glutamate receptors (mGluRs) are known to function as disulfide-linked homodimers (Bai et al., 1998; Ward et al., 1998; Pidasheva et al., 2006) (Figure 4A). Structurally, the human CaSR is similar to sweet and umami taste receptors but differs in being a homodimer instead of a heterodimer (Hendy et al., 2013). The ECD of CaSR not only senses nutrients (Ca^{2+}, L-Phe, and polypeptides; Table 8) and allows ligands to modulate CaSR cooperatively, but is also required for its dimerization (Ray et al., 1999; Zhang et al., 2014). The binding of Ca^{2+} and other ligands

to the ECD changes the conformation of the seven transmembrane domains, causing alterations in the intracellular loops and the intracellular domain (ICD), which further trigger downstream signaling pathways (Brown et al., 1975). The ICD is relatively diverse among species and participates in controlling CaSR signaling in multiple ways by modulating receptor expression, trafficking, and desensitization (Gama and Breitwieser, 1998; Ward, 2004; Huang et al., 2006).

Homology modeling, mutagenesis, and heterologous expression revealed distinct and closely located binding sites for Ca^{2+} and aromatic L-amino acids, in VFT and the cleft of the VFT, respectively (Silve et al., Conigrave et al.,2000; Huang et al., 2009). Notably, four putative Ca^{2+} binding sites of varying affinity have been predicted in the VFT of the CaSR and in which the interaction between site 1 and the other three sites plays a central role in positive cooperativity in sensing Ca^{2+} (Zhang et al., 2014). Besides Ca^{2+}, aromatic L amino acids (L-Trp, L-Phe) also activate the CaSR by binding adjacent to the VFT region through three serine and one threonine residue (S169/S170/S171/T145). Interestingly, the double mutation T145/S170 was found to selectively impair L amino acid (Phe, Trp, His) sensing of CaSR, while Ca^{2+} sensing remained intact (Mun et al., 2004; Mun et al., 2005).

The recent crystal structure of the entire extracellular domain of CaSR (Geng et al., 2016) identified four novel Ca^{2+} binding sites in each protomer of the homodimer including one at the homodimer interface which does not correspond to any of the sites reported previously by Huang et al., (2007). It is unclear why these additional calcium-binding sites were not found in earlier studies. This might be due to the different expression systems used, crystallization conditions, and methods of analysis. The conditions of the more recent studies may have stabilized an active conformational state in which these calcium sites become available (Geng et al., 2016). Among these four Ca^{2+}-binding sites, site 4 seems most relevant to receptor activation as it directly participates in the active CaSR conformation. Moreover, a previously reported natural mutation G557E (Hendy et al., 2009) reduced the potency of Ca^{2+} possibly by affecting backbone conformation, thereby weakening the affinity of Ca^{2+} for this site. This confirms that a Ca^{2+} ion at site 4 stabilizes the active conformation of the receptor by facilitating homodimer interactions between the membrane-proximal LBD2 region and CRD of CaSR.

The most interesting aspect of Ca^{2+} and L-amino acid interplay was reported by Zhang et al. (2014) who studied L-Phe binding characteristics by monitoring intracellular $[Ca^{2+}]_i$ oscillations in living cells and performing molecular dynamic simulations. Their findings supported a previous observation that the L-Phe binding pocket is adjacent to the Ca^{2+} binding site 1. Importantly, by binding to this site, L-Phe influences all Ca^{2+} binding sites in the VFT region and enhances CaSR functional cooperativity through positive heterotropic cooperativity to Ca^{2+}. Moreover, the dynamic communication of L-Phe at its predicted binding site in the hinge region with the Ca^{2+} binding sites not only influences the adjacent Ca^{2+} binding site 1 but also globally enhances cooperative activation of the receptor in response to alterations in extracellular Ca^{2+}.

The crystal structures (Geng et al., 2016) of the entire ECD region of CaSR in the resting and active conformations have provided additional information about the dynamics between calcium and L-amino acid binding (Geng et al., 2016). Most importantly, by using L-Trp, the study provided direct evidence that L-amino acids are CaSR co-agonists, and they act concertedly with Ca^{2+} to achieve full receptor activation. Several lines of evidence support this contention: 1) L-Trp binds at the interdomain cleft of the VFT, which is a canonical agonist-binding site for class C GPCRs (Kunishima et al., 2000; Muto et al., 2007; Geng et al., 2016) and shares a common receptor-binding mode with the endogenous agonists (amino acids or their analogs) of mGluR and $GABA_B$ receptors, (Kunishima et al., 2000; Tsuchiya et al., 2002; Muto et al., 2007; Geng et al., 2016). 2) L-Trp interacts with both LBD1 and LBD2 in ECD to facilitate its closure, a crucial first step during CaSR activation. In contrast, no Ca^{2+} ion is found at the putative orthosteric agonist-binding site to induce domain closure. 3) Mutations of L-Trp-binding residues (S147A, S170A, Y218A, and E297K) severely reduced Ca^{2+} induced IP accumulation and intracellular Ca^{2+} mobilization (Zhang et al., 2002; Silve et al., 2005), indicating that L-Trp is required for a Ca^{2+} induced receptor response. Notably, the presence of extracellular Ca^{2+} above a threshold level is required for amino-acid-mediated CaSR activation, amino acids increase the sensitivity of the receptor toward Ca^{2+}. Taken together, amino acids and Ca^{2+} ions act jointly to trigger CaSR activation.

Knowing that aromatic L-amino acids (Trp, Phe, His) are important tastants in kokumi flavor, CaSR becomes more relevant for taste biology. Moreover, the kokumi tripeptide, glutathione (GSH), and glutamyl peptide are suggested to bind allosterically to CaSR at the same site as L-amino acids (Wang et al., 2006; Broadhead et al., 2011) and enhance its activity in the presence of 0.5–1 mM free calcium, thereby acting as a positive allosteric modulator. In addition, an ECD crystal structure might help to explain the structural and molecular details of the GSH binding pocket such as the nature of critical residues and their binding characteristics. Given recent reports of calcium emerging as a taste modifier, it would be worth investigating how GSH and Ca^{2+} operate in kokumi human perception.

28.18.8.1.1: Allosteric Modulation of Calcium-Sensing Receptor

Classically CaSR is known to be involved in the pathophysiology of parathyroid and renal-related diseases by sensing calcium ions in the extracellular fluid (Brown, 2007). Research on related therapeutic applications has identified several classes of PAMs and NAMs that modulate CaSR agonist sensitivity. More recently this has been applied to kokumi taste signal transduction.

28.18.8.2: Endogenous Modulators (L-amino Acids, Anions, and Glutathione Analogs)

Several studies based on molecular modeling and mutagenesis report L-amino acids (L-Phe, L-Tyr, L-His, and L -Trp) as PAMs because they enhance the Ca^{2+}-induced response of CaSR. Aromatic L-amino acids bind in the VFT domain (Mun et al., 2004) and require a highly conserved five residue binding motif (S147, S170, D190, Y218, and E297) (Conigrave and Hampson, 2006; Geng et al., 2016). Among these residues, E297 was identified through the natural mutation E297K as essential for structural and functional activity (Table 8) (Pollak et al., 1993; Bai et al., 1998; Conigrave et al., 2000; Zhang et al., 2002; Mun et al., 2004).

As recently identified NAMs, anions SO_4^{2-} and PO_4^{3-} are important modulators of the Ca^{2+}-induced response. They bind in the VFT region and act as moderate NAMs for CaSR activity (Geng et al., 2016; Centeno et al., 2019). Based on anomalous difference maps, four anion-binding sites were identified in the inactive and active CaSR ECD structures. Sites 1 and 3 are located above the interdomain cleft in LBD1, while site 4 lies in the LBD2 region. Sites 1 and 3 appear to stabilize the inactive conformation while site 2, which is present in both active and inactive conformations appears important for receptor function as mutations in its residues (R66H, R69E, and S417L) abolished the Ca^{2+}-induced response. In addition, each protomer structure contains one Ca^{2+} ion and three SO_4^{2-} ions which together contribute to the structural integrity of the receptor (Geng et al., 2016). Taken together, anions along with Ca^{2+} and amino acids are involved in an intricate interplay for CaSR activation to maintain conformational equilibrium between inactive and active states.

As positive allosteric modulators, γ glutamyl peptides including glutathione (γGlu-Cys-Gly) and its analogs (Table 8) are predicted to have overlapping binding sites with L-amino acids in the VFT region (Wang et al., 2006; Ohsu et al., 2010; Broadhead et al., 2011). Kokumi peptides that activate CaSR resemble amino acids in having free α-amino and free α-carboxylate groups because they contain both amide bond formation between the γ-carboxylate group of L-glutamate and the α-amino group of its neighboring Cys residue. However, compared to amino acids, glutathione analogs have much larger side chains and are more potent activators of CaSR (Wang et al., 2006). Nonetheless, free sulfhydryl is not required for CaSR activation (Ohsu et al., 2010; Maruyama et al., 2012).

The crystal structure of ECD enables mapping of the GSH binding site and investigation into how GSH binding works in synergy with Ca^{2+} to modulate the kokumi sensation. NPS2143, the sole kokumi NAM identified to date has been reported to inhibit kokumi taste sensation to GSH and its analogs which provides an opportunity to screen for novel kokumi-enhancing molecules in a cell-based assay.

28.18.8.3: Synthetic Drugs as Allosteric Ligands of Calcium-Sensing Receptor

Because of its pathophysiological importance, various synthetic PAMs and NAMs of CaSR have been identified and are in clinical use. The allosteric modulation of CaSR by synthetic drugs has been recently reviewed (Hannan et al., 2016; Chavez-Abiega et al., 2020; Leach et al., 2020). Since the 1990's the terms calcimimetics and calcilytics, have been used for drugs that mimic or antagonize the effect of extracellular Ca^{2+} on CaSR activity, respectively. Pharmacologically, a calcimimetic activates the CaSR and includes agonists (type I) and allosteric ligands (type II). Most type I calcimimetics are either inorganic or organic polycations (e.g., Mg^{2+}, Gd^{3+}, neomycin), whereas type II calcimimetics are small naturally occurring molecules (aromatic amino acids or GSH) or synthetic drugs and peptides (NPS R-568, cinacalcet). Type II calcimimetics (like aromatic amino acids) bind in the ECD while others (e.g., NPS R-568, NPS R-467) bind in the TMD of the CaSR. Calcilytics are thus small organic molecules that appear to act as NAMs and bind in the TMD of the receptor (Widler, 2011; Nemeth, 2013).

Homology modeling and mutational studies show that both PAMs and NAMs have overlapping but non-identical binding sites in TMD and can partially allosterically modulate CaSR activity in the complete absence of the ECD, but their potencies vary among structurally different compounds (Collins et al., 1998; Ma et al., 2011) (Table 8). Several residues reportedly critical for allosteric modulation, $W818^{6.48}$, $F821^{6.51}$ (TMD6) and $E837^{7.39}$, $I841^{7.43}$ (TMD7), $R680^{3.28}$, $F684^{3.32}$, $F688^{3.36}$ (TMD3) impair calcimimetic and calcilytic induced CaSR signaling (Miedlich et al., 2004; Petrel et al., 2004; Leach et al., 2016). Nevertheless, subtle differences in ligand–receptor interactions drive negative vs. positive modulation of CaSR signaling, by NPS2143 or cinacalcet and NPSR-568, respectively (Miedlich et al., 2004; Leach et al., 2016; Keller et al., 2018). The details of CaSR allosteric modulation by synthetic drugs is out of the scope of the current review, for a comprehensive explanation refers to these studies (Chaves-López et al., 2014; Hannan et al., 2016; Leach et al., 2020).

28.18.8.4: Conclusion

Taste GPCR research has advanced rapidly over the past two decades providing a more thorough understanding of receptor molecular pharmacology and signal transduction pathways. Except for the kokumi receptor ECD, high-resolution crystal structures for any taste receptor would be a major step toward designing novel and potent surrogate taste receptor ligands and selective antagonists. This has been a challenge due to low taste GPCR functional heterologous expression, appropriate post-translational modifications, high conformational flexibility, and low detergent stability. However, significant advancements in structural biology technologies of serial femtosecond crystallography using X-ray free-electron lasers and high-resolution cryo-electron microscopy provide promising tools for understanding conformational dynamics and visualizing the process of receptor activation with high spatial and temporal resolution. The physiological relevance of taste GPCRs will be further advanced through *in vivo* studies to help provide information on potential synergies in taste signal transduction mechanisms, particularly among bitter, umami, sweet, and kokumi receptors.

28.19: Signal Transduction - Temperature

This chapter section is taken in entirety from: **Ion Channels and Thermosensitivity: TRP, TREK, or Both?** Lamas et al. *Int. J. Mol. Sci.* **2019**, *20*(10), 2371; **https://doi.org/10.3390/ijms20102371.** Creative Commons Attribution (CC BY) license (**http://creativecommons.org/licenses/by/4.0/**).

28.19.1: Introduction

Mammals and other animals spend large amounts of energy in maintaining a nearly constant body temperature, irrespective of the temperature of the environment. The mechanisms controlling thermal regulation are complex and often rely on negative feedback, where it is first necessary to determine the body and ambient temperature. The temperature of the environment can be sensed by external receptor cells, mainly located in the skin, whereas body temperature is sensed by internal receptors expressed by cells located in several internal organs. Traditionally, only the skin and core thermoreceptors (spinal cord, hypothalamus) have attracted the attention of researchers, but more recently, some very interesting information has emerged regarding visceral thermal receptors, even in humans. Although a hypothesis conceived many years ago, the terminals of receptor neurons are thought to contain branches of nerve fibers without any apparent structural specialization. Indeed, only recently have we begun to understand the molecular basis of thermoreception by cells.

Many biochemical processes like chemical reactions, and physical processes like conformational changes, are extraordinarily dependent on temperature, and although these processes generally occur faster at higher temperatures, the relationships can be very complex [3]. If we consider the nervous system (NS), the effects of temperature on the resting membrane potential (RMP) were the first to be studied, as were its effects on the kinetics and speed of compound and single action potentials, long before the existence of ion channels was demonstrated.

All neurons and ion channels are affected by changes in temperature, not least because channel gating is generally a temperature-dependent process. However, only some neurons can be called thermoreceptors and very few ion channel types can be designated as thermosensors. In general, only channels with a temperature coefficient (Q10) ≥2–5 are considered temperature dependent. (Q10 is the ratio of a reaction at two different temperatures that differ by 10^{o} C. See Chapter 32.11 for more details.) Thermoreceptors are sensitive to changes in temperature rather than to the value of the temperature itself, probably due to their characteristic strong adaptation. These receptors are classified into two groups depending on whether their discharge frequency increases when they are heated or cooled (**Figure 1**). Based on this classification, it is common to speak of four thermal sensations (cold −10 to 15 °C, cool 16–30 °C, warm 31–42 °C and hot 43–60 °C), whereby cold and hot are potentially noxious and/or painful [11,12].

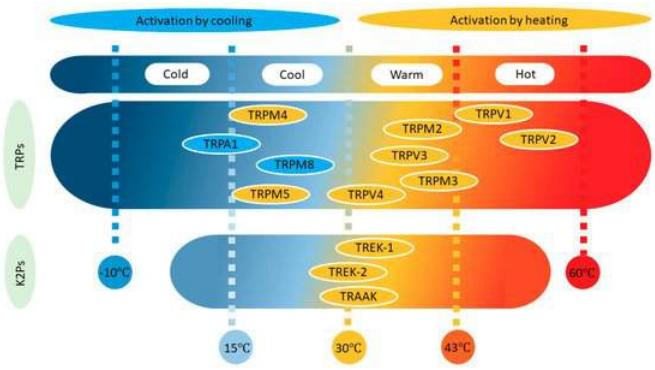

Figure 1. Distribution of transient receptor potential (TRP) and TWIK-related potassium (TREK) channels as a function of their temperature threshold. Note that while TREK channels are activated by increases in temperature (orange), TRP channels may also be activated by lowering the temperature (blue).

The modulation of TWIK-related potassium (TREK) channels by temperature has been touched on in several reviews, yet very few have dealt exclusively with this exciting topic. Conversely, after transient receptor potential (TRP) channels sensitive to temperature were discovered, they were studied extensively to understand how thermal stimuli were transduced. Such interest led to the appearance of good reviews covering this issue. In this review, we will focus on the less well-known role of TREK channels in thermosensation, and we will compare the behavior of these channels to that of TRP channels. Other thermosensitive proteins have also been described, like the Na/K ATPase and ENaC channels, or P2X receptors, and while these should also receive attention, we consider this to fall beyond the scope of this review. Indeed, cell thermosensitivity seems to be governed by the interplay of a number of channel types, as reported in hypothalamic neurons.

28.19.2: TREK Channels

The TWIK-related potassium channel (TREK) subfamily belongs to the two-pore domain potassium channels family (K2P) and is comprised of three members: TREK1, TREK2, and TRAAK (TWIK-related arachidonic acid-activated potassium channel). These are background potassium channels characteristically modulated by several physical and chemical stimuli, such as membrane stretch, pH, unsaturated fatty acids, general anesthetics, and temperature. In general, TREK channels display very weak activity at room temperature and normal pressure, even when overexpressed in heterologous systems. However, their activity increases strongly when a number of different stimuli are applied, including an increase in temperature. From a physiological point of view, it is important to note that at 37 °C, all three members of the TREK subfamily respond to stimuli (pH, membrane stretch, or arachidonic acid), much like they do at room temperature. TREK channels may fulfill a dual role in the transmission of thermal pain. Thus, their strong activation by noxious heat results in an outward current that provokes membrane hyperpolarization and a reduction of thermoreceptor firing, provoking heat-pain relief. Conversely, inhibition of TREK channels by noxious cold should depolarize thermoreceptors and increase their excitability, cooperating in the transduction of noxious cold sensations (see **Figure 2**).

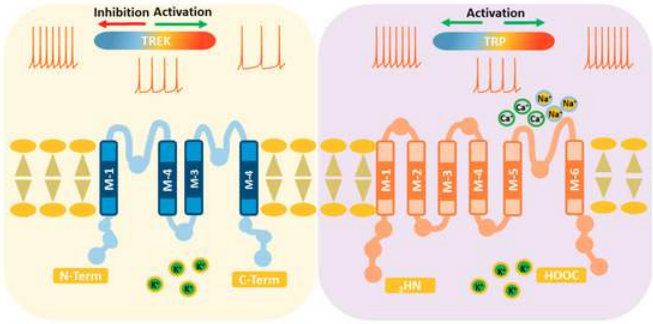

Figure 2. Proteins forming TREK channels have four transmembrane segments and two pore domains so that they assemble as dimers. Activation of TREK channels by increasing the temperature reduces the excitability of thermoreceptors (left). In contrast, TRP channels possess six transmembrane segments and only one pore domain, so they are tetramers. Activation of TRPs increases the excitability of thermoreceptors, but some are activated by an increase and others by a decrease in temperature (right).

28.19.2.1: TREK1

Soon after their discovery, it was shown that TREK1 channels are strongly and reversibly activated by an increase in temperature when expressed in heterologous systems (cell lines derived from kidney (COS) cells, oocytes). If we consider that these are mostly voltage-independent channels open at resting potentials, TREK1 channels should function as cold sensors because low temperatures would dampen their activity and depolarize these thermoreceptors (see **Figure 2**). Many authors have demonstrated that macroscopic TREK1 currents are strongly outwardly rectifying at room temperature. While the outward current is not evident at 12 °C, it is strongly enhanced at 37 °C, and the current progressively increases as the temperature gradually augments. Indeed, the current increases around 7-fold with an increase of 10 °C in the range of 14 to 42 degrees, and importantly, maximal sensitivity (0.9-fold per degree) was reached at nearly physiological temperatures, between 32 and 37 °C. The current induced by heating is also outwardly rectifying, and it reverses at potentials close to the equilibrium potential for potassium (E_K). In heterologous systems, the activation of TREK1 by temperature may be reversibly inhibited by cAMP, and this inhibition is suppressed by mutation of the C-terminal region that harbors a phosphorylation site for protein kinase A (PKA). Moreover, chicken embryonic atrial myocytes express TREK-like currents, and they have a resting membrane potential of around −20 mV in culture, which increases to −70 mV when the temperature rises to 35 °C, a change that was ascribed to the activation of TREK1/2 channels. In voltage-clamp, the outward current recorded at +60 mV increased 9-fold. Both TREK1 and TWIK-related arachidonic acid-activated potassium (TRAAK) channels have been proposed to shut down the firing of hippocampal neurons when the temperature rises too high.

Figure 28.19.*a* shows an interactive iCn3D model of the mouse temperature sensitive K2P2.1 (TREK-1) potassium channels (6W84)

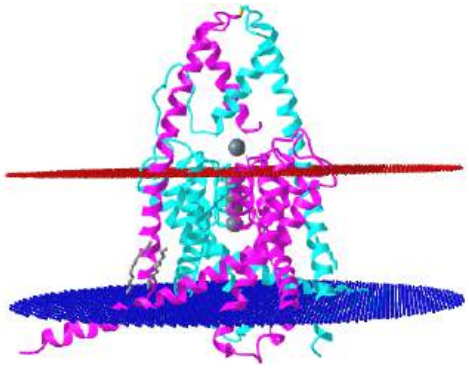

Figure 28.19.*a*: Mouse temperature sensitive K2P2.1 (TREK-1) potassium channels (6W84). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...U28PvTKakHpHW9

The red dots represent the outer leaflet, The gray spheres are potassium ions.

The threshold for the activation of slowly conducting C-fibers by noxious heat (30–50 °C) recorded in a skin-nerve preparation decreases in TREK1 KO mice, and the range of activation of these fibers by heat corresponds closely to the range in which TREK1 is activated (30–45 °C). The number of action potentials in response to a heating ramp (30–50 °C) was higher in the KO mice, although the response of C-fibers to a cooling ramp (32–10 °C) was similar in native and KO mice. Indeed, TREK1 KO mice were hypersensitive to thermal pain up to 50 °C but not at higher temperatures (52–56 °C), indicating that TREK1 channels may be important for the perception of low-threshold but not high-threshold thermal stimuli, for which TRP channels may be more important. Accordingly, the proportion of small diameter, cultured, dorsal root ganglia (DRG) neurons that respond to noxious heat (34%) increases in TREK1 KO (64%) and TREK1/TRAAK KO (74%) mice, as does the proportion of heat-responsive C-fibers in nerve-skin preparations from the single and double KO. TREK1 and TRAAK channels may counteract the stimulatory effect of heat-activated TRP channels in pain-transducing fibers when temperatures increase, such that the overall response may reflect a balance of the activity of these two functionally contrasting channel types. The threshold of thermoreceptors should certainly increase in the presence of TREK channels as temperatures increase.

Cooling of DRG neurons in culture from 32 to 20 °C induces a depolarization of about 10 mV and often the firing of action potentials, an effect shown to be due to the inhibition of a background potassium current. Accordingly, the inhibition of a native TREK1-like current may underlie the excitation (depolarization and firing) produced by cold in small, cultured, trigeminal ganglion (TG) neurons (see **Figure 2**). Interestingly, cold induces subthreshold oscillations in cold-sensitive DRG neurons. Transduction seems to be rather complex, involving the dampening of a hyperpolarization-activated cationic current and a permissive role for a slowly inactivating potassium current. Interestingly, the TREK1/TRAAK double KO mutant shows a consistent cool allodynia (pain due to a stimulus that does not normally provoke pain), and oxaliplatin, a cancer therapy that causes peripheral nerve neuropathy, exacerbates cold sensitivity in many patients and animals, inducing allodynia to cool temperatures.

Neither the deletion of TREK1 nor TRAAK increases the fraction of small DRG neurons sensitive to noxious cold stimuli (below 20 °C and down to about 10 °C), although the TREK1/TRAAK KO and the triple TREK1/TREK2/TRAAK KO showed a significant increase in such neurons. Similar results were obtained when recording C-fibers in a skin-nerve preparation, in which case the double KO C-fibers fired more strongly than the single TRAAK KO and wild-type fibers. Oxaliplatin also induced hypersensitivity to noxious cold temperatures, while double and triple KO mice but not the TREK1 KO mice are hypersensitive to cold, which is not further affected by oxaliplatin. Hence, the deletion of two of the three TREK channels appears to be sufficient to reach maximal hypersensitization. The neuroprotective agent riluzole induces an analgesic effect against painful cold in normal animals, but also in oxaliplatin-pretreated TREK2 KO and TRAAK KO animals. However, riluzole did not affect pain sensitivity in TREK1 KO animals treated with oxaliplatin, in animals treated with the TREK1 inhibitor spadin, or in untreated TREK1 KO mice or triple KO animals. Similarly, a presumed TREK leak outward current recorded in DRG neurons was inhibited by riluzole and fluoxetine at 22 and 30 °C but not at 14 °C, probably because the current was already inhibited at low temperatures. Together, these

experiments suggest that TREK1 channels fulfill an essential role in the perception of noxious cold and that TREK1 and TRAAK channels work together in sensing cold.

Cell-attached patches demonstrated that the basal activity of expressed TREK1 channels is insignificant at room temperature, gradually increasing as the temperature rises (17-fold for an increase of 20 °C) and with a threshold around 25 °C. The current activated by temperature also displays outward rectification and reverses around the equilibrium potential for K^+ [31], although the single-channel conductance remains unaffected TREK1-like channels naturally expressed in cardiac ventricular myocytes and DRGs and recorded in cell-attached patches, do not open at 24 °C, yet they are very active at 37 °C Surprisingly, temperature increases fail to modulate TREK1 activity in outside-out and inside-out patches, but under the same conditions, TREK1 is still strongly activated by arachidonic acid

TREK1 channels are ideally positioned to act as thermosensors because they are expressed in structures related to thermosensitivity and thermoregulation such as DRGs, the TG, nodose ganglia (NG), or the anterior and preoptic hypothalamus .

28.19.2.2: TREK2

Heterologously expressed TREK2 channels also produce strong outward rectification when recorded in whole-cell configuration at room temperature, which increases greatly at temperatures around 37 °C in several heterologous systems In COS cells, a small TREK2 current was observed at 0 mV that augmented progressively with a gradual rise in temperature to about 40 °C. Notwithstanding, the response of TREK2 to abrupt changes in temperature was rapid. Importantly, the IVs of the TREK2 current at different temperatures (24 and 37 °C) showed that the effect of temperature was not voltage-dependent: both inward and outward currents increased to the same degree. In this range of temperatures, the current increased 14-fold per 10 °C, indicating a very strong temperature dependence that was even bigger than that of TREK1. Much like TREK1, TREK2 responds to temperature changes around the physiological range, with current activated reasonably well at 37 °C and at resting membrane potential (RMP). Most experiments on TREK channels have been carried out at room temperature and at 0 mV. However, in the future these currents should be investigated using more physiological parameters, around a resting potential and 37 °C, providing a more precise idea of their role in the behavior of central neurons

Figure 28.19.*b* shows an interactive iCn3D model of the human two-pore domain temperature-sensitive potassium ion channel TREK2 (K2P10.1)(4BW5)

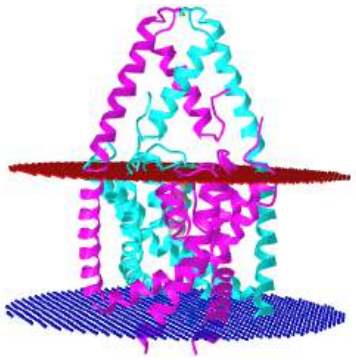

Figure 28.19.*b*: Human two-pore domain temperature-sensitive potassium ion channel TREK2 (K2P10.1)(4BW5). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...wSt9GE2pbDwfq5

Cerebellar granule and DRG neurons expressed native TREK2-like channels with weak activity at 24 °C in cell-attached patches, yet when the temperature increased to 37 or 41 °C they became very active at all voltages (−80 to +80 mV). Moreover, cultured cortical astrocytes have TREK2-like whole-cell outward currents that are strongly enhanced in the temperature range of 23–40 °C. Interestingly, ischemia significantly augmented the outward current provoked by an increase in temperature in these astrocytes In addition, it was recently reported that TREK2 channels contribute about 10 mV to the RMP of DRG neurons at about 30 °C Furthermore, single TREK2 and triple TREK1/TREK2/TRAAK KO mice were more sensitive to warm temperatures (40–42 °C) when tested with the tail-flick reflex.

Using a skin-nerve preparation, it was demonstrated that the proportion of heat-sensitive C-fibers and their activity (the number of action potentials) increased in the TREK2 and triple KO mice when temperatures rose to noxious heat levels (ramped from 30 to 50 °C), whereas the temperature threshold for firing decreased At high temperatures (between 40 and 50 °C), the triple but not the single KO fibers were more active than their wild-type counterparts, indicating that TREK2 regulates C-fiber responses at

temperatures below 40 °C, while at higher temperatures other TREK channels participate in these responses. Both KOs suffered hyperalgesia at temperatures around 45 °C, but only the triple KO showed the same behavior above this temperature.

The withdrawal latency in the tail immersion test was reduced in both the TREK2 KO and the triple KO mice when innocuous cooling temperatures were tested (20–25 °C). As such, the KOs show enhanced sensitivity to temperatures in the normal range, and similar results were obtained in a temperature preference test. The percentage of C-fibers responding to moderate cold (30–21 °C) was higher in single and triple KOs when compared to those recorded from the nerve-skin preparation of wild-type mice. Interestingly, the cold threshold for C-fiber firing (21 °C) was lower in the triple KO (24 °C) but not in the TREK2 KO (23 °C) mice [63]. Moreover, oxaliplatin induces mice to spend more time on a hot plate (30 °C) than on a cold plate (20–25 °C) when compared to untreated animals, indicating that neuropathic mice have enhanced sensitivity to moderate cold [63]. It has been suggested that TREK2 is implicated in the neuropathic hypersensitivity induced by this drug and indeed, oxaliplatin almost halved the TREK2 mRNA detected in DRG neurons. Generally, the data suggest that TREK2 channels may be essential for the control of the C-fiber response to cold at moderate temperatures. The tail immersion test showed that triple KO mice were hypersensitive to noxious cold temperatures (15–5 °C), while the single TREK2 KO mice behaved much like the wild-type mice. Moreover, very similar results were obtained in the nocifensive dynamic cold plate test. Accordingly, it was suggested that TREK2 may not be important in noxious cold sensitivity but that it might be essential for thermoreception at moderately cool temperatures (25–20 °C).

A clear, fast, and reversible increase in activity was also reported for single TREK2 channels in cell-attached patches held at −40 mV when the temperature increased (24 to 37 °C), with a threshold for this increase at 25 °C (from 24 °C) and not affecting the conductance. It should be noted that in these circumstances, the activity of TREK2 single channels was very low at 24 °C. Significantly, neither TASK3 nor TRESK2 showed such dependence on temperature. However, like TREK1, the activity of TREK2 in inside-out patches was not modified by changes in temperature (24 to 42 °C). Finally, it is important to consider that TREK2 channels are expressed strongly in the DRG, TG, and hypothalamus, yet less than TREK1 in the NG.

28.19.2.3: TRAAK

Much like the other members of the family, TRAAK currents showed a strong open-channel outward rectification when recorded in whole-cell configuration, and these currents increase strongly when the temperature rises (24 to 42 °C). Moreover, the percentage of small-diameter DRG neurons responding to noxious heat, in culture, is increased in TRAAK and TRAAK/TREK1 KO mice. Consistently in skin-nerve preparations, the percentage of fibers responding to heating (30–50 °C) and the number of action potentials in response to a heating ramp also clearly increases, while the firing threshold is reduced. Notably, TRAAK and TRAAK/TREK1 KO mice suffer heat hyperalgesia when evaluated in the tail immersion test in the 46–50 °C range. Moreover, the double but not the single KO also shows hypersensitivity at higher temperatures (52–56 °C) in the hot plate test.

Knock-out of TRAAK did not modify the percentage of DRG neurons in culture that respond to noxious (12 °C) cold. Moreover, in the cold plate assay, TRAAK KO mice behave like wild-type mice, whereas TREK1/TRAAK KO mice are more sensitive to cooling in the 10 to 20 °C range. The activity of single TRAAK channels heterologously expressed in COS cells and recorded in cell-attached patches at −40 mV was very low at 24 °C, yet it increased progressively as the temperature rose from 24 to 37 °C. The threshold for activity was around 30 °C, slightly higher than that reported for TREK1 and TREK2. However, the behavior of TRAAK channels in inside-out patches mimics that of TREK1 and TREK2 such that their activity was not affected by changes in temperature (from 24 to 42 °C). Native TRAAK-like channels in DRG neurons displayed little activity at room temperature, but there was clear activity in all cell-attached patches at 37 °C [36, 48]. Finally, TRAAK channels are clearly expressed in the hypothalamus, TG, and DRG , yet they are only weakly expressed in the NG.

28.19.2.4: Molecular Origin of Thermosensitivity

When first discovered, mouse TREK1 was reported to have four transmembrane segments, two pore domains, and a sequence of 370 aa [37]. The activation of heterologously expressed TREK1 currents by increasing temperature is unaffected by the deletion of the cytoplasmic N-terminal region. By contrast, partial deletion of the C-terminal region (Δ103) or replacement of this region with that of TASK1 strongly dampens the activation of TREK1 by heat. The sensitivity of the TREK1 channels to temperature can be eliminated by mutating helix 1 of the pore (G137I), suggesting that temperature affects the TREK1 and TREK2 channels by manipulating the C-type gate. It was suggested that functional coupling between the C-terminal domain and the C-type gate through the M4 segment is crucial for the heat sensitivity of the TREK1 channel. Thus, it is tempting to speculate that increasing the affinity of the C-terminal domain for phospholipids of the inner leaflet would increase the activity of TREK1 by heat, as proposed for other stimuli like stretch, PUFAs, phospholipids, or pH. Conversely, dissociation of this domain from the membrane would result in TREK1 inhibition. Surprisingly, the replacement of the C-terminus of TREK2 with that of TASK3 did not reduce

the sensitivity of the channel to changes in temperature in the range of 24 to 37 °C under similar conditions, although it became insensitive to pH and arachidonic acid. Heat enhances the activity of TREK1, TREK2, and TRAAK in whole-cell and cell-attached recordings, yet not in outside- and inside-out patches, indicating that the integrity of the cell, and probably also a second messenger, are necessary for this modulation. The contribution of TREK channels to maintaining the RMP has often been questioned; however, this assertion is mostly based on experiments carried out at room temperature. Thus, new experiments should be performed at physiological temperatures to ascertain the role of these channels on both the RMP and neuronal excitability.

28.19.3: TRP Channels

Six transient receptor potential (TRP) channels are considered thermosensors, four of them responding to heat and two to cool. Temperature-sensitive TRP channels (Thermo-TRP) are extremely dependent on temperature, showing very high Q10 values (>20).

28.19.3.1: Heat-Sensitive TRP Channels

Four TRP subtypes are activated by an increase in temperature (**Figure 1**). Two of them respond to warm stimuli (TRPV4 Warm >27 °C and TRPV3 Warm >34 °C), and the other two to hot-painful stimuli (TRPV1 Hot >43 °C and TRPV2 Hot >52 °C).

TRPV1s are voltage- and temperature-dependent channels that display outward rectification when expressed in human embryonic kidney (HEK) cells and that is strongly enhanced by heating (to 48 °C) and by capsaicin.

Figure 28.19.*c*shows an interactive iCn3D model of human TRPV1 with capsaicin at 48 degrees Celsius in an open state (7LPE)

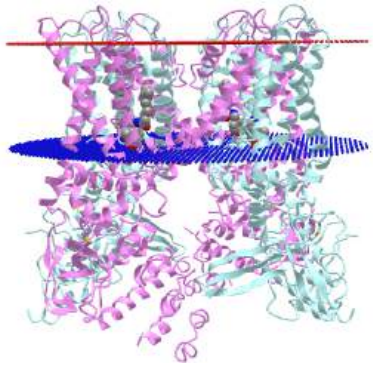

Figure 28.19.1: Human TRPV1 with capsaicin at 48 degrees Celsius in an open state (7LPE). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...7Hsf5zpDQoQu99

At room temperature, the current passing through these channels is negligible below 0 mV, but at 42 °C the channel activates more or less between −100 and +50 mV. These cationic channels are ten times more permeable to Ca^{2+} than to Na^{+} (P_{Ca}/P_{Na} ~10) and are thought to be sensors for noxious heat but not activated by innocuous heat. Indeed, the response to noxious heat in mice lacking TRPV1 (KO) or DRG neurons was clearly weaker, although other channels may also contribute to the perception of noxious thermal stimuli because heat still evokes receptor activation in several preparations. The NG sensory neurons that innervate the lungs produce an inward current in response to an elevation in temperature (from 23 to 41 °C, with a threshold around 35 °C and a Q10 of about 30 in the range of 35–41 °C) as well as membrane depolarization and action potential firing. This response was ascribed to the presence of TRPV1 channels, even though the participation of TRPV2-4 could not be ruled out. We obtained similar results with NG neurons in culture, although these were slightly more complex because a hyperpolarization was observed before the depolarization and firing (unpublished data). It is interesting to note that inflammatory mediators like ATP and bradykinin strongly reduce the threshold of TRPV1 activation (30 °C) such that warm temperatures become painful. TRPV1 is strongly expressed in small-diameter sensory neurons of the DRG, TG, and NG, but also in the hypothalamus, sites where they may exert an important role in thermoreception.

TRPV2 is activated at extremely high temperatures (52 °C), although it is not affected by capsaicin and shows an outwardly rectifying IV curve and a P_{Ca}/P_{Na} ~3 . This channel has a Q10 of around 100, and it is thought that the temperatures that activate TRPV2 are more harmful than those that activate TRPV1. These channels are strongly expressed by myelinated medium-large diameter DRG neurons (Aδ and Aβ), as well as in the hypothalamus and the NG.

TRPV3 channels are activated at warm, close to hot, temperatures (around 34–39 °C, with a Q10 around 6), generating currents with pronounced outward rectification and a P_{Ca}/P_{Na} ~12. They are capsaicin-insensitive channels but stimulated by camphor, and they are thought to be involved in thermosensation and thermal nociception. Indeed, it has been suggested that TRPV3 channels

contribute more to the speed with which mice select a more comfortable temperature than to the choice of the value of the temperature itself. By contrast, TRPV4 channels are more likely to be involved in choosing the preferred temperature from a non-painful range. Interestingly, it was proposed that TRPV3 channels transmit thermal stimuli through skin keratinocytes, which in turn will transmit this information to sensory endings. TRPV3 channels are expressed in sensory DRG and NG neurons but also in the hypothalamus. Interestingly, they co-localize with TRPV1 in DRG neurons.

TRPV4 are cationic (P_{Ca}/P_{Na} ~6) channels activated at even lower warm temperatures (around 27 °C, with a Q10 of about 10), generating outwardly rectifying currents and responding dynamically to temperature changes in the physiological range. These channels were proposed to play a role in thermosensation and thermoregulation although some authors were unable to activate these channels by increasing the temperature. Similarly, some behavioral studies reported a reduced response to temperature changes in TRPV4 KO mice, a behavior that was less clear in other studies. Much like TRPV3, the expression of these channels in keratinocytes was proposed to play an important role in the transmission of thermal information, which probably contributed to the controversy generated. The sensitivity of this channel to temperature is lost in excised patches, suggesting that it requires a soluble intracellular factor TRPV4 channels are expressed in DRG, TG, NG, and preoptic/anterior hypothalamic neurons, although in the hypothalamus they seem to be expressed in terminals rather than in the soma, such that their role in body thermoregulation is unclear.

TRPM2 (>35 °C), TRPM3 (>40 °C), TRPM4 (>15 °C), and TRPM5 (>15 °C) are channels that can also be activated by warming (**Figure 1**), yet they have received less attention, probably because it was initially thought that they were not expressed by somatosensory neurons or keratinocytes. TRPM2 is voltage-insensitive, shows a P_{Ca}/P_{Na} ~1, activates at 35 °C, and has a Q10 of around 15. TRPM3 is expressed broadly, generating an outwardly rectifying current, having a P_{Ca}/P_{Na} between 0.1 and 10, and activating at >40 °C with a Q10 of 7. It is important to say that TRPM3 has been described as part of a triad of TRPs, together with TRPV1 and TRPA1, involved in the transduction of acute noxious heat in mice. The combined ablation of these channels (triple KO) was necessary for the complete reduction of acute noxious sensing; single or double KO combinations resulted in deficits in heat responsiveness, but mice still conserved vigorous withdrawal responses to noxious heat. Heat activation of TRPM2 and TRPM5 was obtained in inside-out patches, suggesting a membrane-delimited mechanism. Interestingly, TRPM2 activation seems to result from the increase in the IV slope while that of TRPM4 and TRPM5 results from a shift of the activation curve to negative potentials. These last two channels are essentially not permeable to calcium.

28.19.3.2: Cold-Sensitive TRP Channels

Two TRP channels are activated by decreases in temperature (**Figure 1**), TRPM8 (<25 °C) activates in the cool range while TRPA1 (<18 °C) senses cold-painful temperatures. Similarly, cool fibers (Aδ and C) have activation thresholds at about 30 °C, and cold fibers (C) have activation thresholds <20 °C. Accordingly, two populations of TG neurons were described in terms of their activation threshold when temperatures decrease: 30 and 20 °C for a low and high threshold, respectively. In general, cold fibers fire continuously at normal skin temperatures and they increase their firing frequency when the skin is cooled down, or they shut down when the skin is warmed. In addition, cold fibers can adapt to small decreases in temperature.

TRPM8 channels are voltage-dependent cationic channels that are permeable to Na^+, K^+, Cs^-, and Ca^{2+} (P_{Ca}/P_{Na} ~3). When expressed in HEK cells and recorded in the whole-cell configuration, they show a voltage-dependent outwardly rectifying current that strongly increases upon cooling from 30 to 15 °C or through the application of menthol.

Figure 28.19.*d* shows an interactive iCn3D model of TRPM8 ion channel in complex with the menthol analog WS-12 and PI(4,5)P2 (6NR2)

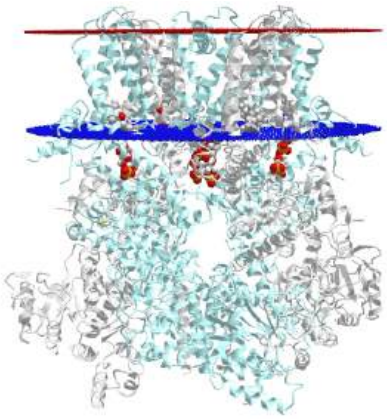

Figure 28.19.*d*: TRPM8 ion channel in complex with the menthol analog WS-12 and PI(4,5)P2 (6NR2). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...94muQHwYr7eij6

The methanol analog is shown in spacefill and CPK colors in the membrane bilayers. PI(4,5)P2 is shown in spacefill just below the lower cytoplasmic leaflet.

The TRPM8 receptor is a Ca^{2+} cation channel. Cooling compounds like menthol and WS-12 depend on allosteric interactions and membrane phosphatidylinositol 4,5-bisphosphate (PIP_2).

Importantly, both basal and cold-stimulated currents reverse around 0 mV and were almost negligible below this potential. Cooling CHO cells expressing TRPM8 (in the range of 25 to 15 °C) also induces an increase in intracellular calcium, and the Q10 in the range of 25 to 18 °C is around 24. The effect of temperature is due to an increase in the open probability and a shift in the conductance–voltage relationships along the voltage axis [9]. Similar results were obtained in inside-out macropatch recordings, although the stimulation occurred at lower temperatures, suggesting that the integrity of the cell is important but not indispensable. The role of this channel as a detector of painful cold has been questioned in experiments on KO mice, but it is accepted that it is an important cold sensor in vagal, TG, and especially DRG afferents. It was predicted that cold transduction may require the activation and inhibition of several different ion channels (see **Figure 3**), such as TRP, TREK, and ENaC channels. If this were the case, TRP channels would probably be more important in the noxious-cold range, whereas TREK channels might participate more strongly in the cool range of temperatures (**Figure 1**). TRPM8 is expressed in small-diameter DRG and TG neurons, presumably thermoreceptors, yet it seems not to co-localize with TRPV1.

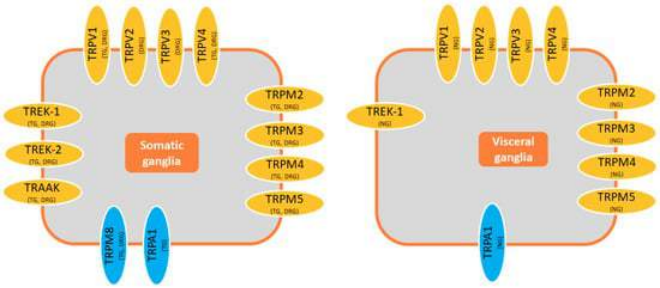

Figure 3. Most temperature-modulated channels are expressed in both somatic and visceral afferents. The expression of TREK2, TRAAK, and TRPM8 in visceral ganglia seems to be low when compared with other channels; however, colocalization of all these channels in the same neuron should be investigated to have a real picture of their relative importance in temperature sensing.

TRPA1 is activated by lower temperatures than TRPM8 (<18 °C), and while it would be expected to be involved in cold nociception, this is not that clear. TRPA1 generates an outward rectifying cationic current, both in control conditions and when cold activated (about 10 °C), with similar permeability for Ca^{2+} and Na^{+} (P_{Ca}/P_{Na} ~1). Cinnamaldehyde can selectively activate currents through this channel in native DRG neurons, as can bradykinin (when co-expressed with BK receptors), strongly suggesting a role in sensing nociceptive stimuli. However, TRPA1 KO mice do not seem to have difficulties in sensing cold stimuli through the skin, while the response of TRPM KO mice to cold is significantly dampened. By contrast, about 50% of NG neurons in culture were activated by cooling (<24 °C), mainly through TRPA1 channel activation (increase in $[Ca]_i$, depolarization, and AP firing). Interestingly, about 10% of the NG neurons responded to cold through a TRPA1- and Ca-independent pathway. TRPA1 often co-localizes with TRPV1, and in fact, this could explain the paradoxical hot sensation experienced with an extremely cold stimulus. Interestingly, most NG neurons sensitive to cold are also sensitive to heat. TRPA1 is expressed in DRG and TGs, while TRPA1 and

TRPM8 are not co-expressed in DRG neurons, but they are in TG neurons. In summary, the data available suggest that TRPA1 is the principal ion channel involved in cold sensation in visceral (NG) neurons, while TRPM8 would fulfill the same role in somatic neurons.

28.19.3.3: Molecular Origin of Thermosensitivity

The mechanism by which temperature modulates TRP channels is still unclear, yet several hypotheses have been proposed: (1) changes in temperature could produce a ligand that binds to a receptor and affects the channel; (2) changes in temperature could produce a structural change in the channel that provokes its opening; (3) temperature changes could affect the structure of the membrane, causing changes in tension that would, in turn, affect ion channels. Because capsaicin induces burning pain, it has been hypothesized that both capsaicin and heat may use a common mechanism to activate TRPV1 and produce pain. Both stimuli affect excised patches, and in general, it is accepted that TRPV1 is directly activated by noxious heat, so that it can be considered a true heat sensor.

The fact that TRPM8 can be activated by cooling in inside-out patches suggests that the mechanism is membrane delimited, also arguing against the participation of a second messenger pathway. Notwithstanding, inhibition of phospholipase C strongly dampened the increase in calcium provoked by cold stimuli in TRPM8-expressing CHO cells. Cooling activates TRPM8-expressed channels by causing a shift in the voltage dependence of activation to negative values, and the same mechanism is responsible for the activation of TRPV1 by heatbut not the activation of TRPM2. It has been proposed that temperature induces large rearrangements of the protein and thus, the existence of a temperature-sensing domain or “temperature sensor” in the structure of TRPM8 channels. Much like for TRPM8, inhibition of phospholipase C strongly reduces the increase in calcium provoked by cold stimuli in TRPA1-expressing CHO cells.

28.19.4: Conclusions

There are several important differences between the two main types of thermosensor channels that have been reviewed in this article (see **Figure 2**). First, TREKs are potassium channels with negative reversal potentials, such that their activation would result in a reduction in thermoreceptor activity. By contrast, as the reversal potential of TRPs (cationic channels) is close to 0 mV, their activation will result in increased thermoreceptor excitability. Second, the three TREK channels appear to increase their open probability as temperatures increase, while there are two possible situations in the case of TRPs: one in which its activity increases by increasing the temperature; and another in which activity increases when the temperature decreases (**Figure 2**). Although the activation of these channels generates opposing effects on thermoreceptors (depolarization versus hyperpolarization), the information available to date regarding the participation of TRP and TREK channels in thermosensitivity strongly suggests that both types of channels collaborate and complement each other to generate the sensations of heat, cold, and thermal pain. In support of this hypothesis, TREK, and TRP channels are very often co-expressed in thermoreceptors and other sensory neurons TRP channels are generally accepted as the primary thermosensors; however, several lines of evidence indicate that other channels are necessary to explain the full plethora of mechanisms involved in thermosensation. TREK2 channels appear to be important in thermoreception at moderate temperatures and sensing innocuous cold but not aversive cold, while TREK1 and TRAAK acting together may be important in sensing painful cold.

28.20: Signal Transduction - Pressure

This chapter section is taken in entirety from Fang, XZ., Zhou, T., Xu, JQ. *et al.* Structure, kinetic properties, and biological function of mechanosensitive Piezo channels. *Cell Biosci* **11,** 13 (2021). https://doi.org/10.1186/s13578-020-00522-z Creative Commons Attribution 4.0 International License, http://creativecommons.org/licenses/by/4.0/. We added iCn3D molecular models.

28.20.1: Introduction

Mechanotransduction, the process by which mechanical stimuli are converted into electrochemical signals, is essential for various biological processes, including neuronal cell development, pain sensation, and red blood cell volume regulation. As pivotal mechanosensors of in the mechanotransduction process, mechanosensitive (MS) ion channels have been found in organisms from bacteria to mammals. Extensive studies have revealed a variety of ion channels in eukaryotic cells that can sense various forms of mechanical forces (Table 1). These ion channels include transient receptor potential (TRP) channels and voltage-gated Na^+, $K^{+,}$ and Ca^{2+} channels, whose dysfunction may be associated with human genetic diseases. Notably, the MS candidates identified in invertebrates either have no homologs (e.g., TRPN) or no functional conservation (e.g., DEG/ENaC/ASIC) in mammals. Furthermore, most MS candidates (the TRP channel in particular) are activated not only by mechanical stimuli but also by chemicals, temperature, osmolarity, and heat (> 27–34 °C). Defining the molecular details of MS cation channels in mammals is therefore of paramount importance to understand the mechanotransduction process and find potentially novel therapeutic strategies for mechanosensitivity disorders.

In 2010, Coste et al. revealed a novel family of mechanically activated (MA) cation channels in eukaryotes consisting of Piezo1 and Piezo2 channels, which have been proposed as the long-sought-after MS ion channels in mammals. The Piezo1 channel is present in nonsensory tissues, with particularly high expression in the lung, bladder, and skin; by contrast, the Piezo2 channel is predominantly present in sensory tissues, such as dorsal root ganglia (DRG) sensory neurons and Merkel cells. Since their discovery, tremendous effort has been made to reveal the structures and biological functions of Piezo 1 and 2. The partial molecular structure of a Piezo channel was determined by cryo-electron microscopy (cryo-EM). Furthermore, Piezo channels have been linked to various pathological and physiological processes, including erythrocyte volume regulation, cell division, and innate immunity. Moreover, Piezo channel mutations are associated with multiple hereditary human diseases, such as autosomal recessive congenital lymphatic dysplasia, hereditary xerocytosis (a rare, autosomal dominant congenital hemolytic anemia characterized by macrocytic stomatocytosis, and decreased red cell osmotic fragility due to a defect in cation permeability), and an autosomal recessive syndrome of muscular atrophy with perinatal respiratory distress. Considerable progress has been made toward characterizing the structural features, physiological significance, and biophysical properties of Piezo proteins. Given the importance of Piezo channels in understanding mechanotransduction processes, this review focuses on their structural details, kinetic properties, and potential functions as mechanosensors. We also briefly review the hereditary diseases caused by mutations in the Piezo genes, which is key to understanding their functions.

28.20.2: Structure of Piezo channels

Piezo proteins have an uncommonly large predicted size of approximately 2500 amino acids and encompass numerous transmembrane (TM) regions. Subsequent research has revealed that the mouse Piezo1 (mPiezo1) channel is an evolutionarily conserved pore-forming ion channel directly gated by membrane stretch. Several published cryo-EM studies have revealed that mPiezo1 exhibits a three-bladed, propeller-shaped homotrimeric structure that includes a central cap, three peripheral blade-like structures on the extracellular side, three long beams on the intracellular side that bridge the blades to the cap, and a TM region between these features (Fig. 1).

28.20.3: **Structure of the Piezo1 channel**

28.20.3.1: Unprecedented 38-TM topology

Piezo channels are predicted to possess an unusually large number of TM regions, ranging from 10 to 40. Zhao et al. recently produced high-resolution structures of mouse Piezo1 (mPiezo1), revealing a unique 38-TM topology in each subunit (Fig. 2a, b). The two TM regions (TM37 and TM38) closest to the center of the protein are designated as the inner helix (IH) and outer helix (OH), respectively, and enclose the transmembrane pore of the central pore module. The other 36 TM regions (TM1-36) form a curved blade-like structure with nine repetitive folds containing 4 TM regions each, named transmembrane helical units (THUs)

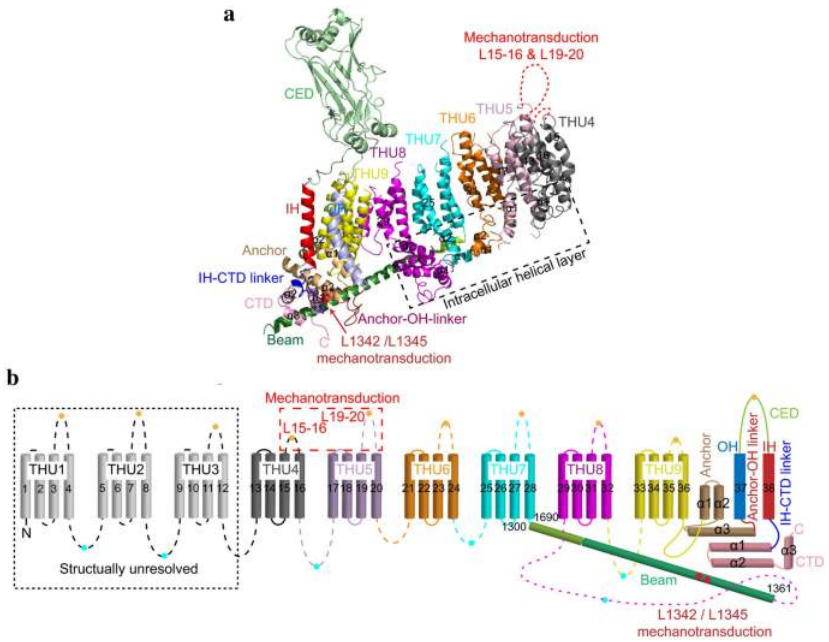

Figure 2: A 38-TM topology model and key functional sites in mPiezo1(adapted from Zhao et al.). **a** A model showing one subunit with individual THUs and featured structural components. Residues L1342 and L1345 in the beam are indicated by red spheres. **b** A 38-TM topology model color-coded to match the cartoon model in A

Figure 28.20.a shows an interactive iCn3D model of the mouse mechanosensitive Piezo1 channel (5Z10) (long load time)

28.20.3.1: Central cap

Kamajaya and colleagues [48] employed topological prediction modeling and found that residues 2210 to 2457 in Piezo1 form an extracellular loop following the last TM region from the C-terminus, defined as the C-terminal extracellular domain (CED) **(**Fig. 1**)**. The deletion of residues 2218 to 2453 from the Piezo1 protein abolished expression of the central cap, suggesting that this region trimerizes to form the central cap (Figs. 1 and 3). Further analysis revealed that the central cap consists of the CED in the form of a trimeric complex that encloses an extracellular vestibule (EV) with openings (Fig. 3).

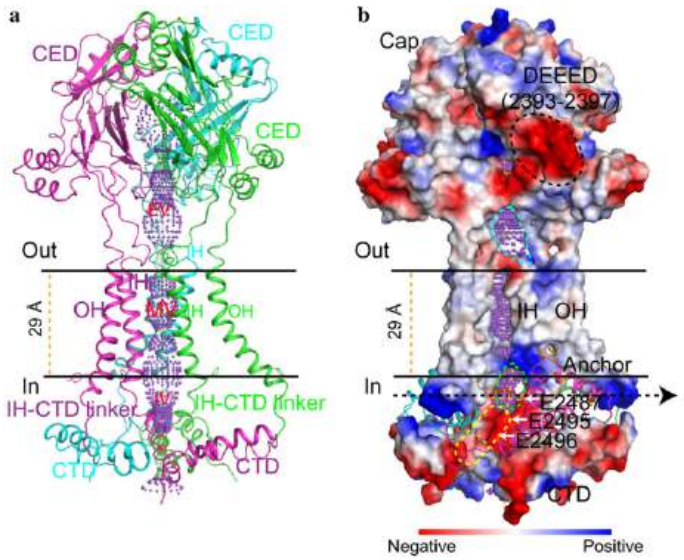

Figure 3. Structure of the central pore module (adapted from Zhao et al. [35]). **a** Ribbon diagram of the ion-conduction pore comprising the OH, CED, IH, and CTD from three color-coded subunits. The central solvent-accessible pathway is marked with a dotted mesh generated by the program HOLE. **b** Pore module presenting the surface electrostatic potentials showing negative (red) and positive (blue) potential. Extracellular and intracellular fenestrations are marked by cyan and green dashed lines, respectively. The lateral portal is marked by yellow dashed lines

28.20.3.1: Anchor

A hairpin structure, referred to as the anchor, connects the OH-IH pair to the C-terminal domain (CTD) plane, which moves the OH-CED-IH-containing region of one subunit into the neighboring subunit in a clockwise direction (Figs. 1 and 2). The anchor is made up of three helices (α1, α2, and α3). Helices α1 and α2 were found to organize into an inverted V-shaped structure, which maintains the integrity of the ion-conducting pore (Fig. 2b). In parallel with the membrane plane, the long α3 helix links to the OH via a lysine-rich anchor-OH linker that interacts with the polar residue-rich α2–3 turn in the anchor and the glutamate-rich region of the CTD. A few mutations in Piezo1 at locations including KKKK (2182-K2185), T2143, T2142 (T2127 in human Piezo1), R2514, E2523, and E2522, which are located in α3 in the anchor, have been reported to cause severe disease. Additionally, SERCA2, a Piezo-interacting protein, suppresses Piezo1 by acting on the anchor-OH linker. These findings support the structural and functional importance of the anchor region.

28.20.3.1: The long intracellular beam

On the intracellular surface, Piezo1 contains three beam-like structures 90 nm in length that are organized at a 30° angle relative to the membrane plane (Figs. 1 and 2). Residues H1300-S1362 form the beam structure. The large intracellular THU7-8 loop, which contains approximately 390 residues, might provide the beam with the structural basis for mechanical transmission. Functionally, the three long intracellular beams not only support the whole TM skeleton but also physically bridge the distal THUs to the central ion-conducting pore. When residues 1280 to 1360 (which form this beam structure) were deleted, the resulting mutant protein was absent, suggesting the structural importance of the beam.

28.20.3.1: Highly curved blades

The nine peripheral THUs in each subunit form blade-like structures, with each blade twisted clockwise (Fig. 1b). The proximal TM25–TM36 and peripheral TM13-24 interact at a 100° angle, as viewed from 90º relative to the plasma membrane plane, and a 140° angle, as viewed from a line parallel to the plasma membrane plane. Another important feature of the blades is the L-shaped helical structures formed by TM13, TM17, TM21, TM25, and TM29. Both identifiable structural features appear to be ideal not only for mechanosensation but also for the induction of local membrane curvature. Intriguingly, the peripheral TM13-24 appears to be within a highly curved membrane plane, indicating that the Piezo1 channel can curve the membrane in which it resides. This is consistent with past studies implying that Piezo1 ion channels can be regulated by cellular membrane curvature and tension.

28.20.3.1: The ion-conducting pathway

As pore-forming ion channels, Piezo proteins contain a trimeric ion-conducting channel made up of residues 2,189 to 2,547, which contain the last two TMs (Fig. 3). The continuous central channel consists of three parts, an EV within the cap region, a transmembrane vestibule (MV) within the membrane, and an intracellular vestibule (IV) underneath the membrane. Both the EV

and IV possess an opening that connects to the MVs, which are positioned above and below the membrane. Importantly, DEEED (2393–2397), a patch of negatively charged residues residing in the opening of the extracellular “cap” structure consisting of the CED, is required to ensure efficient ion conduction and determine the selection of cations over anions. Additionally, two critical acidic residues, E2495 and E2496, located at the CTD-constituted IV, may be responsible for divalent calcium ion selectivity, unitary conductance, and pore blockage.

28.20.4: **Structure of the Piezo2 channel**

Similar to Piezo1 channels, Piezo2 channels are large membrane proteins consisting of over 2,800 residues. However, the Piezo2 channel and Piezo1 channel share approximately only 42% sequence homology. Recent studies have shown that the overall structure of the Piezo2 channel is very similar to that of Piezo1 in that it forms a three-bladed, propeller-like homotrimeric structure comprising a central ion-conducting pore module and three peripheral blades with 38 TMs.

Figure 28.20.*b*shows an interactive iCn3D model of the mammalian tactile channel PIEZO2 (6KG7) (long load time)

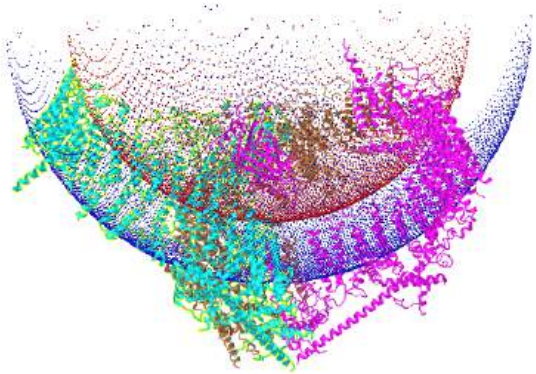

Figure 28.20.*b*: Mammalian tactile channel PIEZO2 (6KG7). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...4FaL71AL23KiA9 (long load time)

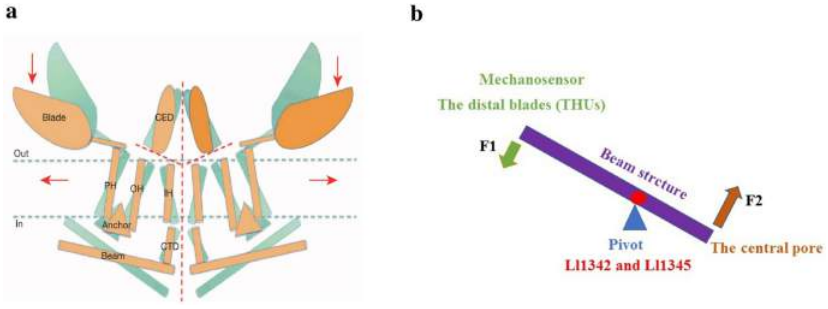
In the Piezo2 channel, the charged residues at the interface between the beam and the CTD are required to ensure the normal mechanosensitivity of the channel. Moreover, single-channel recordings indicated that a previously unrecognized intrinsically disordered domain adjacent to the beam acts as a cytosolic plug that limits ion permeation, possibly by clogging the inner vestibule in both Piezo1 and Piezo2. Furthermore, by structurally comparing the Piezo1 and Piezo2 channels, Wang et al. found that the Piezo2 channel has additional constriction sites at L2743, F2754, and E2757 that might serve as a transmembrane gate controlled by the cap domain.

28.20.5: Lever-like mechanotransduction mechanism

Based on the unique topological features of the mPiezo1 channel, a lever-like mechanotransduction mechanism to explain its extraordinary mechanosensitivity was proposed (Fig. 4). In the mPiezo1 channel, the curved blades composed of THUs can act as a mechanosensor, while the beam structure, with the residues Ll1342 and Ll1345 acting as a pivot, can act as a lever-like apparatus. Coupling the distal blades and the central pore through the lever-like apparatus converts mechanical force into a force used for cation conduction.



Adapted from Ge et al. **b** A lever-like mechano-gating model in Piezo1. The blue and red dashed arrows indicate input and output forces, respectively

Figure 4: Model of the lever-like mechanotransduction model. The curved blades can act as a mechanosensor, while the beam structure, with residues Ll1342 and Ll1345 acting as a pivot, can act as a lever-like apparatus. Coupling of the distal blades and the central pore through the lever-like apparatus converts mechanical force into cation conduction. **a** Proposed model of the force-induced gating of Piezo channels. The blue and orange models represent the channel in its closed and open states, respectively. Red dashed lines indicate possible ion-conduction pathways.

Because the pivot of the lever is positioned closer to the central pore than to the distal blades, the input force is effectively amplified through the lever-like apparatus. Additionally, a large conformational change in the distal blades is converted into a relatively slight opening of the central pore, allowing cation-selective permeation.

28.20.6: Kinetics properties of Piezo channels

28.20.6.1: Activation mechanisms of Piezo channels

Normal Piezo channel kinetics can be modeled with three states: open, closed, and inactivated; these states have emerged, collectively, as an important mechanism in the Piezo channel function. Studies have proposed that the Piezo1 channel is gated directly by bilayer tension that can be modified by cytoskeletal proteins and linkages to the extracellular matrix (ECM). For example, in overhydrated red blood cells (RBCs), Piezo1-mediated Ca^{2+} influx activates K^{+} efflux through the Gardos channel (KCa3.1), which in turn leads to water loss and RBC dehydration.

Piezo1 and Piezo2 channels not only exhibit a three-bladed, propeller-shaped trimeric architecture but also can locally deform lipid membranes into a dome-like shape. In addition, changes in the projection area of Piezo channels from closed to open are essential for their mechanosensitivity; this was investigated by calculating the available free energy. Based on these findings, the membrane dome mechanism was proposed and experimentally proved to explain the activation mechanisms of Piezo channels (Fig. 5). Essentially, the dome shape created by Piezo channels in their closed conformation acts as a potential energy source for MS gating. Under tension, lateral membrane tension flattens the Piezo dome, which increases the energy of the membrane-channel system in proportion to the expansion of the projected area of the dome. Piezo channels then open due to the relative energy difference. This mechanism can account for the highly sensitive mechanical gating of Piezo channels with a cation-selective pore. Although the membrane dome mechanism explains the exquisite mechanosensitivity of Piezo channels, it does not consider the shape of the surrounding membrane. Haselwandter et al. [57] proposed the membrane footprint hypothesis, which states that the Piezo1 channel deforms the shape of the membrane outside the perimeter of the channel such that it exhibits a curved membrane footprint, which amplifies the sensitivity of Piezo1 to changes in the membrane tension. Nevertheless, further experiments are needed to test and refine these hypotheses.

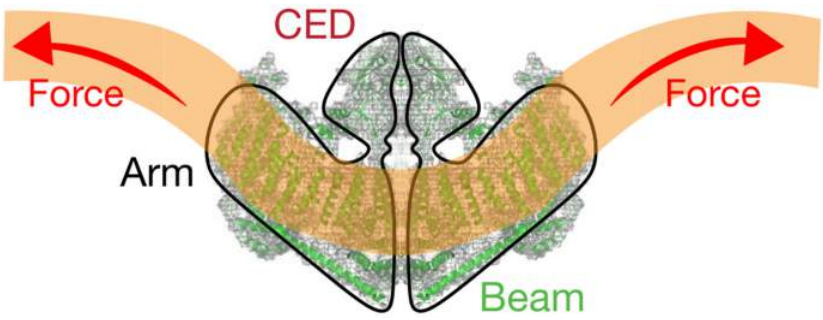


Figure 5: Model of the membrane doming mechanisms. Changes in membrane curvature lead to a gating force applied to the Piezo1 channel

28.20.6.1: Inactivation kinetics of Piezo channels

Various types of mechanical stimulation trigger Piezo channel activation and sequentially elicit an MA current with rapid decay, even in the presence of continued stimulation, due to rapid inactivation. Coste et al. first described detailed information about the voltage-dependent inactivation kinetics of Piezo channels, characterized as fast at rather negative membrane potentials and slow at rather positive membrane potentials. Additionally, Piezo1 channel inactivation is relatively slow compared with Piezo2 channel inactivation. Several point mutations in Piezo channels have been reported to slow down the inactivation process, which produces larger cation fluxes and results in various human diseases. Given its demonstrated key role in normal channel function, we next review what is known about the inactivation kinetics of Piezo channels with a focus on the inactivation mechanism.

The available information regarding the structures (residues/domains) and human disease-related point mutations have helped to clarify the mechanisms of ion channel inactivation. Currently, six gain-of-function mutations associated with dehydrated hereditary xerocytosis (DHS) have been found to slow the inactivation rate of Piezo channels (Table 2), most of which are clustered at the central core region of the Piezo channel structure. This implies that the pore region, which contains an OH, an IH, an extracellular cap domain, and an intracellular CTD, determines the kinetics of inactivation. Further detailed links between structural domains and inactivation kinetics have been investigated. Wu et al. identified that the distinct inactivation kinetics of Piezo1 and Piezo2 channels and characteristic voltage-dependent inactivation appears to be determined by the C-terminal extracellular domains (cap domain). Two potential inactivation gates within the IH and CTD have been thought to be sufficient for the normal inactivation of the Piezo1 and Piezo2 channels. Recently, three small subdomains within the extracellular cap were shown to individually confer Piezo channel inactivation. These results support the idea that the ion-conducting pore region of Piezo channels is essential for their inactivation properties.

Table 2 Mutations in Piezo1 and Piezo2 Associated with Human Diseases: Full-size table

Interestingly, a slowly inactivating MS current in mouse embryonic stem cells (mESs) has been described that is dependent on the Piezo1 channel. However, heterologous expression of Piezo1 cDNA from mES cells displays fast inactivation kinetics, indicating that additional regulatory mechanisms other than the amino acid sequence determine the slow kinetics of the Piezo1 channel in mES cells [70]. Recently, sphingomyelinase activity has been revealed to be a crucial determinant of Piezo1 inactivation. Various modulators, such as pH, temperature, divalent ion concentrations, alternative splicing, osmotic swelling, membrane lipid composition, co-expression of other membrane proteins, and G-protein-coupled pathways have also been reported to regulate the Piezo channel kinetics; however, we still know very little about the relationships among these factors and pivotal structural domains.

28.20.6.1: Pharmacological modulators of Piezo channels

Despite the relatively recent discovery of Piezos, there has been progress regarding small-molecule modulators of Piezo1. Piezo1 chemical activators, including Yoda1 and Jedi1/2, were able to open Piezo1 ion channels in the absence of mechanical stimulation. Jedi1/2, a novel hydrophilic Piezo1 chemical activator, acts through the peripheral blades and utilizes a peripheral lever-like apparatus consisting of the blades and a beam to gate the central ion-conducting pore whereas Yoda1 acts as a molecular wedge, facilitating force-induced conformational changes, effectively lowering the channel's mechanical threshold for activation However, the reason why Yoda1 does not efficiently activate the Piezo2 channel is unclear. Specific inhibitors of Piezo1 are in their infancy. As nonspecific inhibitors of the ion pore in stretch-activated ion channels, gadolinium, and ruthenium red have also been shown to block mouse Piezo1 channels with IC50 values of approximately 5 mM. The commonly used toxin inhibitor of mechanosensitive channels, GsMTx4, was also found to inhibit the Piezo1channel, but it might not bind Piezo1 directly, rather acting via modulating local membrane tension near the channel. Dooku1, an analog of Yoda1 without a stimulatory effect, antagonizes Yoda1-evoked activation of Piezo1 and aortic relaxation.

28.20.7: The function of Piezo channels

Piezo channels are expressed in a wide range of mechanically sensitive cells and allow Ca^{2+} influx in response to different types of external forces, such as fluid flow, pulling, and ultrasonic forces. The biological function of Piezo channels was recently investigated in a number of studies (Fig. 6). The results of these studies verified the pivotal roles of Piezo channels in mechanotransduction under physiological and pathophysiological conditions. Here, we focus on reviewing the biological function of Piezo channels in several different types of MS tissues and cells.

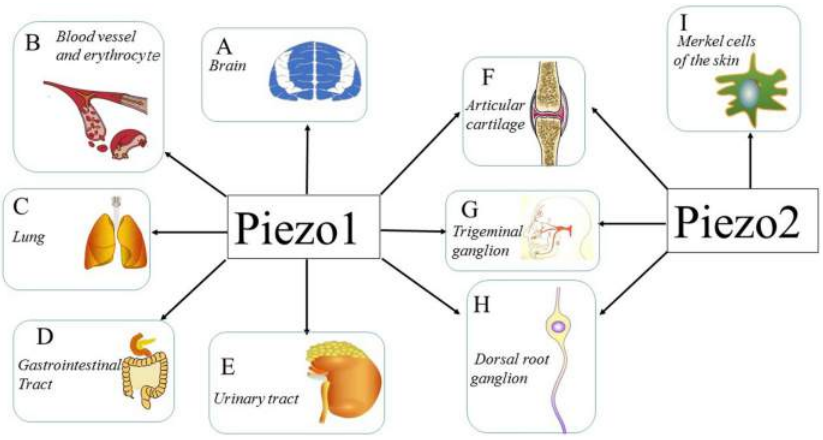

Figure 6: Expression and function of Piezo channels Multiple tissues and cells express Piezo channels, and each of those shown is discussed in this review. **a–e** demonstrate the vital role of the Piezo1 channel in the CNS, blood vessels, erythrocytes, lungs, gastrointestinal tract, and urinary tract. **f–h** illustrate the expression of both the Piezo1 channel and Piezo2 channel in articular cartilage, trigeminal ganglia, and dorsal root ganglia. **i** shows that the Piezo2 channel is expressed in Merkel cells, which are involved in sensing light touch

Consult the original article for details on the roles of Piezo channels on the systems above.

29.1: OVERVIEW OF METABOLISM

29.1.1: AN OVERVIEW OF METABOLIC PATHWAYS - CATABOLISM

Biological cells have a daunting task. They must carry out 1000s of different chemical reactions required to carry out cell function. These reactions can include opposing goals such as energy production and energy storage, macromolecule degradation and synthesis, and breakdown and synthesis of small molecules. All of these reactions are catalyzed by proteins and RNAs enzymes whose activities must be regulated, again through chemical reactions, to avoid a futile and energy wasting scenario of having opposing pathways functioning simultaneously in a cell.

Metabolism can be divided into two main parts, catabolism, the degradation of molecules, usually to produce energy or small molecules useful for cell function, and anabolism, the synthesis of larger biomolecules from small precursors.

CATBOLISM: Catabolic reactions involve the breakdown of carbohydrates, lipids, proteins, and nucleic acids to produce smaller molecules and biological energy in the form of heat or small thermodynamically reactive molecules like ATP whose further degradation can drive endergonic process such as biosynthesis. Our whole world is reliant on the oxidation of organic hydrocarbons to water and carbon dioxide to produce energy (at the expense of releasing a potent greenhouse gas, CO2). In the biological world, reduced molecules like fatty acids and partially oxidized molecules such as glucose polymers (glycogen, starch), as well as simple sugars, can be partially or fully oxidized to ultimately produce CO2 as well. Energy released from oxidative reactions is used to produce molecules like ATP as well as heat. Oxidative pathways include glycolysis, the tricarboxylic acid cycle (aka Kreb's cycle) and mitochondrial oxidative phosphorylation/electron transport. To fully oxidize carbon in glucose and fatty acids to carbon dioxide requires splitting C-C bonds and the availability of series of oxidizing agents that can perform controlled, step-wise oxidation reactions, analogous to the sequential oxidation of methane, CH4 to methanol (CH3OH), formaldehyde (CH2O) and carbon dixoxide.

- Glycolysis: This most primitive of metabolic pathways is found in perhaps all organisms. In glycolysis, glucose (C6H12O6), a 6C molecule, is split (or lysed) into two, 3C carbon molecules, glyceraldehyde-3-phosphate, which are then partially oxidized under anaerobic conditions (without O2) to form two molecules of pyruvate (CH3COCO2-). Instead of the very strong oxidizing agent, O2, a weaker one, NAD+ is used, which is reduced in the process to form NADH. Since none of the carbon atoms is oxidized to the state of CO2, little energy is released compared to the complete oxidation to CO2. This pathway comes to a screeching halt if all cellular NAD+ is converted to NADH as NAD+ is not replenished by the simple act of breathing as is the case with O2 in aerobic oxidation. To prevent the depletion of NAD+ from inhibiting the cycle and to allow the cycle to continue under anaerobic conditions, excess NADH is reconverted to NAD+ when the other product of glycolysis, pyruvate is converted to lactate by the enzyme lactate dehydrogenase. Glycolysis occurs in the cytoplasm of the cell.

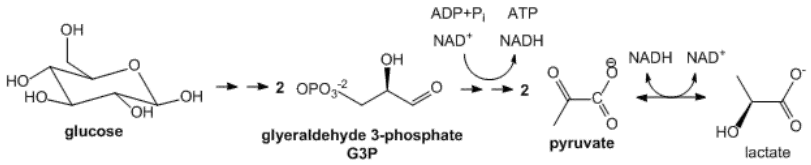

Figure 29.1.1: Summary of Glycolysis (Copyright; author via source)

- Tricarboxylic Acid (Kreb's) Cycle: The TCA cycle is an aerobic pathway which takes place in an intracellular organelle called the mitochondria. It takes pyruvate, the incompletely oxidized product from glycolysis, and finishes the job of oxidizing the 3C atoms all the way to CO2. First the pyruvate moves into the mitochondria where is is oxidized to the 2C molecule acetylCoA with the release of one CO2 by the enzyme pyruvate dehydrogenase. The acetyl-CoA then enters the TCA cycle where two more CO2 are released. As in glycolysis, C-C bonds are cleaved and C is oxidized by NAD+ and another related oxidizing agent, FAD. What is very different about this pathway is that instead of being a series of linear, sequential reactions with one reactant (glucose) and one product (two pryuvates), it is a cyclic pathway. This has significant consequences since if any of the reactants within the pathways becomes depleted, the whole cyclic pathway can slow down and stop. To see how this happens consider the molecule oxaloacetate (OAA) which condenses with acetyl-CoA to form citrate (see diagram below). In this reaction, one OAA is consumed. However, when the cycle returns, one malate is converted to OAA so there is no net loss of OAA, unless OAA is pulled out of the TCA cycle for other reactions, which happens.

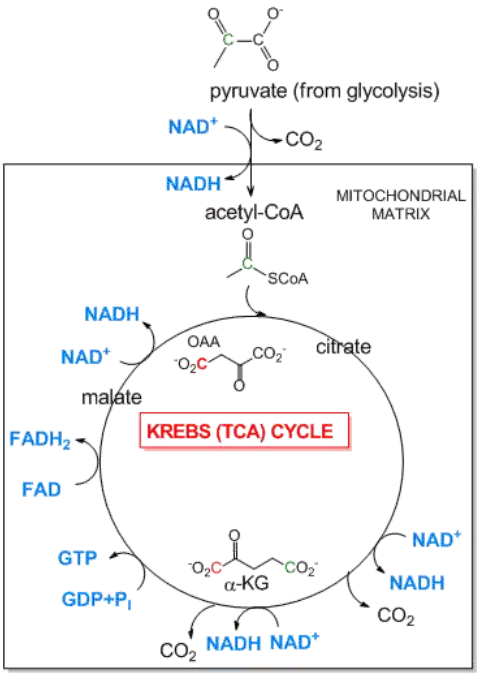

Figure 29.1.2: Pyruvate Dehydrogenase (mitochondrial) and the TCA Cycle. (Copyright; author via source)

- Mitochondrial Oxidative Phosphorylation/Electron Transport: The TCA cycle accomplishes what glycolysis didn't, that is the cleavage of all C-C bonds in glucose (in the form of pyruvate and acetyl-CoA, and the complete oxidation of all C atoms to CO2. Yet two problem remains. The pool of oxidizing molecules, NAD+ and FAD get converted to their reduced forms, NADH and FADH2. Unless NAD+ and FAD are regenerated, as was the case in anaerobic conditions when pyruvate gets converted to lacate, the pathway would again come to a grinding halt. In addition, not much ATP is made in the cycle (in the form of a related molecule GTP). Both these problems are resolved as the resulting NADH and FADH2 formed are reoxidized by mitochondrial membrane enzyme complexes which pass electrons from the oxidized NADH and FADH2 to increasingly potent oxidizing agents until they are accepted by the powerful oxidant O2,which is converted reduced to water. The net oxidation of NADH and FADH2 by dioxygen is greatly exergonic, and the energy released by the process drives the synthesis of ATP from ADP and Pi by an mitochondrial enzyme complex, the F0F1ATPase.

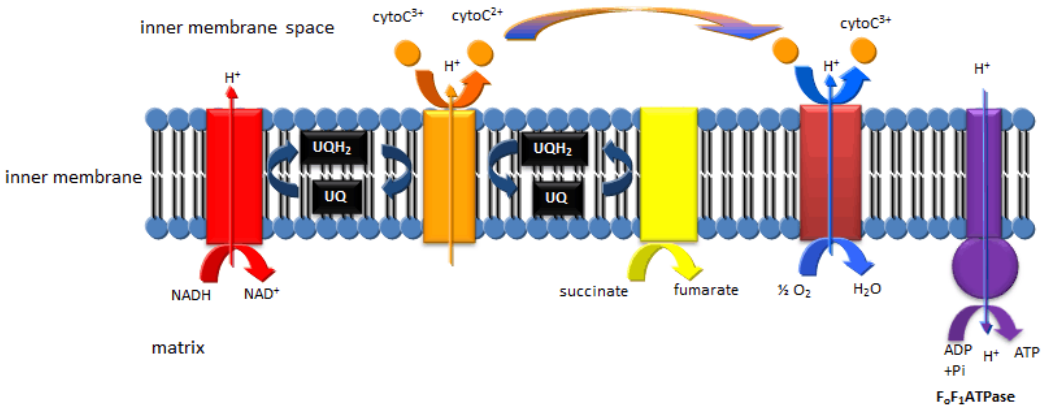

Figure 29.1.3: Mitochondrial Electron Transport/Oxidative Phosphorylation. (Copyright; author via source)

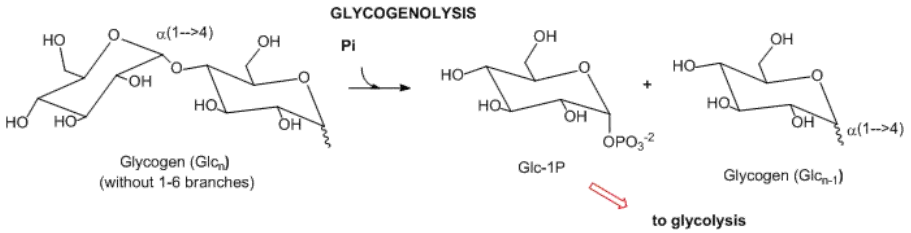
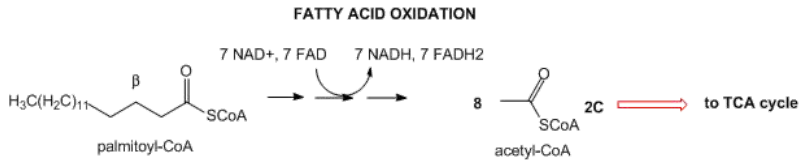
Feeder Pathways: Other catabolic pathways produce products that can enter glycolysis or the TCA cycle. Two examples are given below.

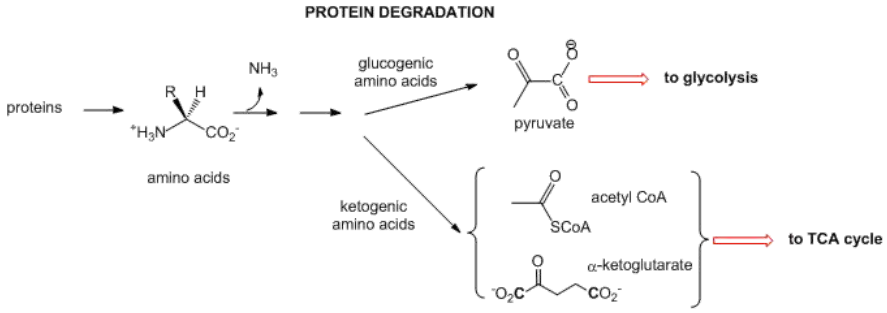
- Complex carbohydrates: In mammals, the major carbohydrate storage molecule is glycogen, a polymer of glucose linked a1-4 with a1-6 branches. The terminal acetal linkages in this highly branched polymer is cleaved sequentially at the ends not through hydrolysis but through phosphorolysis to produce lots of glucose-1-phosphate which can enter glycolysis.



- Lipids: Lipids are stored mostly as triacylglycerides in fat cells (adipocytes). When needed for energy, fatty acids are hydrolyzed from the glycerol backbone of the triacylglyceride, and send into cells where they broken down in an oxidative process to form acetyl-CoA with the concomitant production of lots of NADH and FADH2. These can then enter the mitochondrial oxidative phosphorylation/electrons transport system, which produces, under aerobic conditions, lots of ATP.



- Proteins: When intracellular proteins get degraded, they from individual amino acids. The amine N is lost as it enters the urea cycle. The rest of some amino acid structures can be ultimately converted to acetyl-CoA or keto acids (like alpha-ketoglutarate- a-KG) that are TCA intermediate. These amino acids are called ketogenic. Alternatively, some amino acids, after deamination, are coveted to pyruvate which can either enter the TCA cycle or in the liver be used to synthesize glucose in an anabolic process. These amino acids are called glucogenic. Chemical reactions such as these can be used to replenish intermediates in the TCA cycle which can become depleted as they are withdraw for other reactions.



29.1.1.1: ANABOLIC REACTIONS

Anabolic reactions are those that lead to the synthesis of biomolecules. In contrast to the catabolic reactions just discussed (glycolysis, TCA cycle and electron transport/oxidative phosphorylation) which lead to the oxidative degradation of carbohydrates and fatty acids and energy release, anabolic reactions lead to the synthesis of more complex biomolecules including biopolymers (glycogen, proteins, nucleic acids) and complex lipids. Many biosynthetic reactions, including those for fatty acid synthesis, are reductive and hence require reducing agents. Reductive biosynthesis and complex polymer formation require energy input, usually in the form of ATP whose exergonic cleavage is coupled to endergonic biosynthesis.

Cells have evolved interesting mechanism so as not to have oxidative degradation reactions (which release energy) proceed at the same time and in the same cell as reductive biosynthesis (which requires energy input). Consider this scenario. You dive into a liver cell and find palmitic acid, a 16C fatty acid. From where did it come? Was it just synthesized by the liver cell or did it just enter the cell from a distant location such as adipocytes (fat cells). Should it be oxidized, which should happen if there is a demand for energy production by the cell, or should the liver cell export it, perhaps to adipocytes, which might happen if there is an excess of energy storage molecules? Cells have devised many ways to distinguish these opposing needs. One is by using a slightly different pool of redox reagents for anabolic and catabolic reactions. Oxidative degradation reactions typically use the redox pair NAD^+/NADH (or FAD/FADH2) while reductive biosynthesis often uses phosphorylated variants of NAD^+, $NADP^+$/NADPH. In addition, cells often carry out competing reactions in different cellular compartments. Fatty acid oxidation of our example molecule (palmitic acid) occurs in the mitochondrial matrix, while reductive fatty acid synthesis occurs in the cytoplasm of the cell. Fatty acids entering the cell destined for oxidative degradation are transported into the mitochondria by the carnitine transport system. This transport system is inhibited under conditions when fatty acid synthesis is favored. We will discuss the regulation of metabolic pathways in a subsequent section. One of the main methods, as we will see,

is to activate or inhibit key enzymes in the pathways under a given set of cellular conditions. The key enzyme in fatty acid synthesis, acetyl-CoA carboxylase, is inhibited when cellular conditions require fatty acid oxidation.

The following examples give short descriptions of anabolic pathways. Compare them to the catabolic pathways from the previous section.

- Glucose synthesis, better known as Gluconeogenesis: In glycolysis, glucose ($C_6H_{12}O_6$), a 6C molecule, is converted to two, 3C molecules (pyruvate) in an oxidative process that requires NAD^+ and makes two net ATP molecules. In a few organs, most predominately in the liver, the reverse pathway can take place. The liver does this to provide glucose to the brain when the body is deficient in circulating glucose, for example, under fasting and starving conditions. (The liver under these conditions can get its energy from oxidation of fatty acids). The reactions in gluconeogenesis are the same reactions in glycolysis but run in reverse, with the exception of three glycolytic steps which are essentially irreversible. These three steps have bypass enzymes in the gluconeogenesis pathway. Although the synthesis of glucose is a reductive pathway, it uses NADH instead of NADPH as the redundant as the same enzyme used in glycolysis is simply run in reverse. Gluconeogenesis, which also occurs in the cortex of the kidney, is more than just a simple reversal of glycolysis, however. It can be thought of as the net synthesis of glucose from non-carbohydrate precursors. Pyruvate, as seen in the section on catabolism, can be formed from protein degradation to glucogenic amino acids which can be converted to pyruvate. It can also be formed from triacylglycerides from the 3C molecule glycerol formed and released from adipocytes after hydrolysis of three fatty acids from triacylglycerides. However, in humans, glucose can not be made in net fashion from fatty acids. Fatty acids can be converted to acetyl-CoA by fatty acid oxidation. The resulting acetyl-CoA can not form pyruvate since the enzyme that catalyzes the formation for acetyl-CoA from pyruvate, pyruvate dehydrogenase, is irreversible and there is no bypass reaction known. The acetyl-CoA can enter the TCA cycle but since the pathway is cyclic and proceeds in one direction, it can not form in net fashion oxaloacetate. Although oxaloacetate can be remove from the TCA cycle and be use to form phosphoenolpyuvate, a glycolytic intermediate, one acetyl-CoA condenses with one oxaloacetate to form citrate which leads back to one oxaloacetate. Hence fatty acids can not be converted to glucose and other sugars in a net fashion.

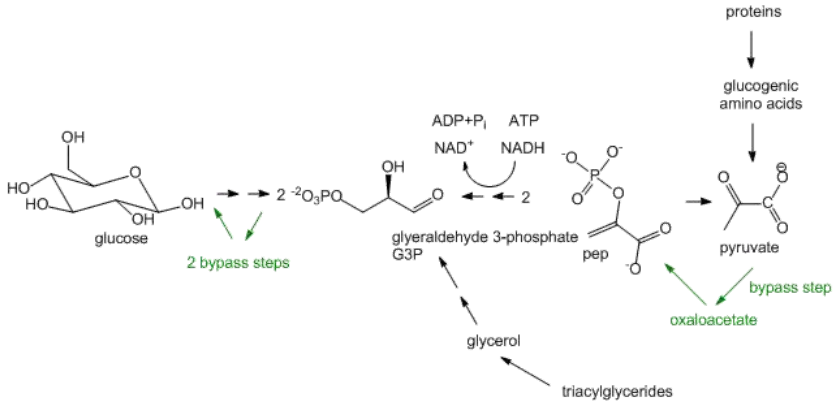


Figure 29.1.4: Gluconeogenesis. (Copyright; author via source)

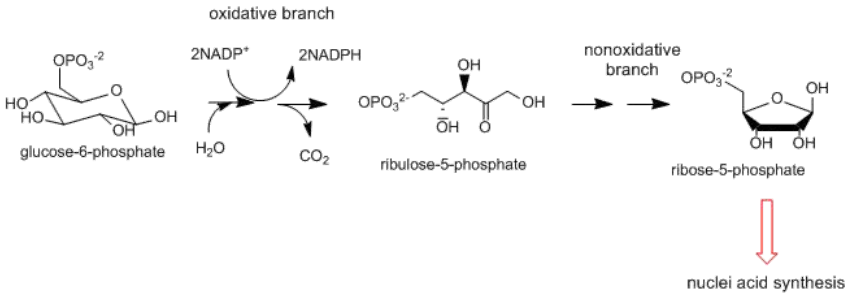
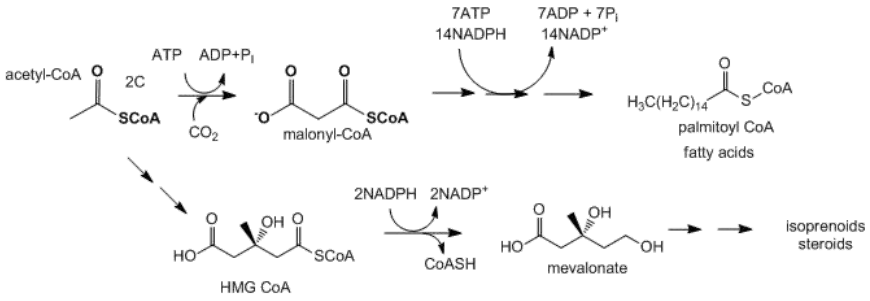
- Pentose Phosphate Shunt: This two-part pathway doesn't appear to start as a reductive biosynthetic pathway as the first part is the oxidative conversion of a glycolytic intermediate, glucose-6-phosphate, to ribulose-5-phosphate. The next, nonoxidative branch leads to the formation of ribose-5-phosphate, a key biosynthetic intermediate in nucleic acid synthesis as well as erythrose-4-phosphate used for biosynthesis of aromatic amino acids . The oxidative branch is important in reductive biosynthesis as it is a major source of the reductant NADPH used in biosynthetic reactions.



- Fatty acid and isoprenoid/sterol biosynthesis: Acetyl-CoA is the source of carbon atoms for the synthesis of more complex lipids such as fatty acids, isoprenoids, and sterols. When energy needs in a cell are not high, citrate, the condensation product of oxaloacetate and acetyl-CoA in the TCA cycle, builds up in the mitochondrial matrix. It is then transported by the citrate transporter (an inner mitochondrial membrane protein) to the cytoplasm, where it is cleaved back to oxaloacetate and acetyl-CoA by the cytoplasmic enzyme citrate lyase. The oxaloacetate is returned to the mitochondria by conversion first to malate (reduction reaction using NADH), which can

move back into the mitochondria through the malate transporter, or further conversion to pyruate, using the cytosolic malic enzyme, which uses NADP+ to oxidize malate to pyruvate which then enters the mitochondria. The acetyl-CoA formed in the cytoplasm can then be used in reductive biosynthesis using NADPH as the reductant to form fatty acids, isoprenoids, and sterols. The NADPH for the reduction comes from the oxidative branch of the pentose phosphate pathway and from the reaction catalyzed by malic enzyme. The liver cells can still run the glycolytic pathway as the NADH/NAD+ ratio is low in the cytoplasm while NADPH/NADP+ ratio is high.



29.1.1.2: REGULATION AND INTEGRATION

None of these pathways exist in isolation. They are connected in a complicated web of interactions. Instead of cursory summaries of how these pathways are all interconnected, we have chosen to present a series of published articles that are freely available for reuse through Creative Common's licenses. They describe organ- and systems-specific metabolisms and emerging understanding of metabolism in disease states. These include:

29.2.2: ABSTRACT

Glucose homeostasis is tightly regulated to meet the energy requirements of the vital organs and maintain an individual's health. The liver has a major role in the control of glucose homeostasis by controlling various pathways of glucose metabolism, including glycogenesis, glycogenolysis, glycolysis and gluconeogenesis. Both the acute and chronic regulation of the enzymes involved in the pathways are required for the proper functioning of these complex interwoven systems. Allosteric control by various metabolic intermediates, as well as post-translational modifications of these metabolic enzymes constitute the acute control of these pathways, and the controlled expression of the genes encoding these enzymes is critical in mediating the longer-term regulation of these metabolic pathways. Notably, several key transcription factors are shown to be involved in the control of glucose metabolism including glycolysis and gluconeogenesis in the liver. In this review, we would like to illustrate the current understanding of glucose metabolism, with an emphasis on the transcription factors and their regulators that are involved in the chronic control of glucose homeostasis.

29.2.3: OVERVIEW OF GLUCOSE METABOLISM IN THE LIVER

Under feeding conditions, dietary carbohydrates are digested and processed by various glucosidases in the digestive tract, and the resultant monosaccharides, mainly hexose glucose, are transported into various tissues as a primary fuel for ATP generation.[1] In most mammalian tissues, the catabolism of glucose into pyruvate, termed glycolysis, is preserved as a major pathway in eliciting ATP. In tissues with abundant mitochondria, cytosolic pyruvate is transported into the mitochondrial matrix, converted to acetyl-CoA by pyruvate dehydrogenase complex, and incorporated into the tricarboxylic acid cycle in conjunction with oxaloacetate. The cycle generates energy equivalent to ATP (that is, GTP) as well as both NADH and $FADH_2$, which serve as important electron carriers for electron transport chain-oxidative phosphorylation, resulting in the generation of ATP.

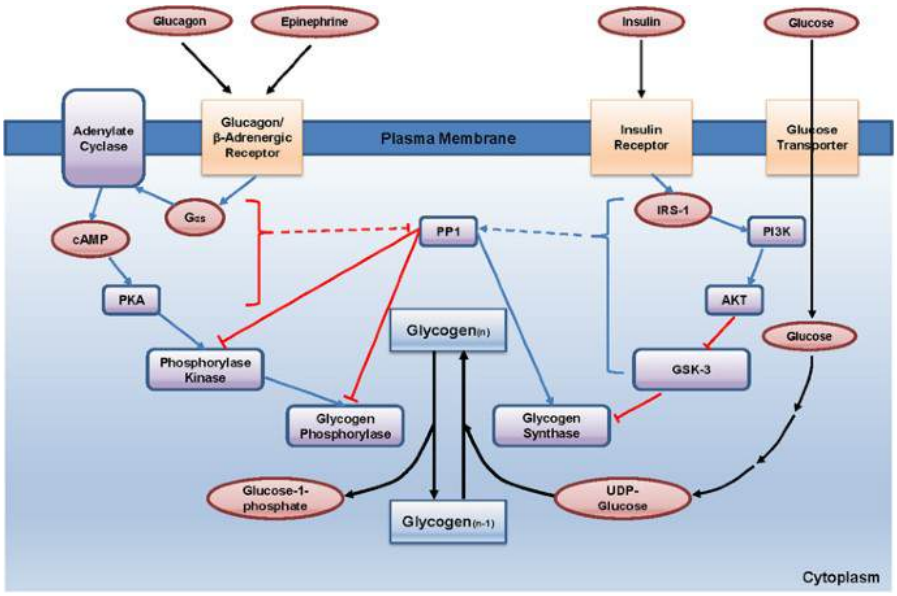
In some cases, such as red blood cells lacking mitochondria or cells under ischemic conditions, pyruvate is converted into lactate in the cytosol to regenerate the NAD^+ that is necessary for the continued generation of ATP by substrate-level phosphorylation via anaerobic glycolysis. Excessive carbohydrates in the liver are first converted into glycogen, a storage form of glucose in animals, by glycogenesis. In addition, in a carbohydrate-rich diet, the excessive carbohydrates are also converted into fatty acids via lipogenesis using the acetyl-CoA generated from glycolysis-driven pyruvate, which is incorporated into very low density lipoproteins for transport to white adipose tissue for the storage.[2] The regulation of glycogen metabolism is examined in detail in this section, and the transcriptional control of glycolysis and lipogenesis is delineated in the following section.

Under fasting conditions, the liver has a major role in generating glucose as a fuel for other tissues, such as the brain, red blood cells and muscles. Initially, an increase in the pancreatic hormone glucagon initiates the cascade of kinase action (stated below in detail) that releases glucose from the stored glycogen via glycogenolysis.[1] Normally, stored glycogen is critical for maintaining glucose homeostasis in mammals during an overnight fasting period. During a longer term fast or starvation, essentially all of the stored glycogen in the liver is depleted (after ~30 h of fasting), and *de novo* glucose synthesis or gluconeogenesis is responsible for the generation of glucose as a fuel for other tissues. Major non-carbohydrate precursors for gluconeogenesis are lactate, which is transported from peripheral tissues such as skeletal muscles or red blood cells, and glycerol, which is released from the adipose tissues via enhanced lipolysis during fasting. Most of the initial precursors for gluconeogenesis are generated in the mitochondria (except glycerol 3-phosphate via glycerol kinase activity), but the majority of the reaction occurs in the cytosolic part of the cell. The complex regulatory mechanism is delineated in detail in the following section, with an emphasis on the transcriptional control of key regulatory enzyme genes.

29.2.4: REGULATION OF GLYCOGEN METABOLISM IN THE LIVER

The accumulation of glycogen in the liver during feeding conditions provides a storage form of glucose that can be used in times of reduced food intake (Figure 1). Multiple layers of regulation are required for this process for both the activation of glycogen synthase, which is a key enzyme of glycogenesis (glycogen synthesis), and the inhibition of glycogen phosphorylase, which is a key enzyme of glycogenolysis (glycogen breakdown) in the liver. Glycogen synthase is a major enzyme that facilitates the elongation of glycogen chains by catalyzing the transfer of the glucose residue of UDP-glucose to the non-reducing end of a pre-existing glycogen branch to produce a new $\alpha 1 \rightarrow 4$ glycosidic linkage. The regulation of glycogen synthase has been mostly studied using a muscle-specific isoform. In the muscle, glycogen synthase is inactivated via phosphorylation on multiple serine residues by various serine/threonine kinases such as casein kinase-1, protein kinase A (PKA), and glycogen synthase kinase-3 (GSK-3). Most notably, the phosphorylation of glycogen synthase by GSK-3 at serine residues 640, 644 and 648 has been linked to the most important inhibitory post-translational modification for its catalytic activity.

Figure 1



Regulation of hepatic glycogen metabolism. Under fasting conditions, glucagon and epinephrine induce cAMP-dependent signaling cascades, leading to the activation of glycogen phosphorylase and glycogenolysis while inhibiting glycogenesis. Conversely, feeding enhances insulin-mediated signaling in the liver, leading to the activation of both PP1 and Akt, thus promoting glycogen synthesis in response to increased glucose uptake in the liver. See the main text for more specific regulatory pathways. cAMP, cyclic AMP.

Under fasting conditions, dephosphorylated and active GSK-3 phosphorylate and inactivate glycogen synthase, leading to the inhibition of hepatic glycogen synthesis. On feeding, increased insulin signaling activates Akt in the cell, which in turn phosphorylates and inactivates GSK-3, thus resulting in the activation of glycogen synthase. In addition, increased concentrations of glucose 6-phosphate allosterically activate this enzyme, thus potentiating its catalytic activity under feeding conditions.[3, 4] One recent publication argues against the role of GSK-3 in the regulation of the liver-specific isoform of glycogen synthase. In that study, Guinovart *et al.*[5] mutated the corresponding serine residues that are shown to be regulated by GSK-3 in the liver-isoform of glycogen synthase. They found that the mutation of those residues did not affect the overall enzyme activity but that the mutation of serine 7 to alanine, a site that is recognized and regulated by PKA, led to the increased activity of this enzyme. Further study is necessary to determine whether these results can be verified *in vivo* using animal models such as liver-specific knock-in mice for S7A liver glycogen synthase. The protein phosphatase 1 (PP1) may be responsible for the dephosphorylation and activation of glycogen synthase. Accordingly, both glucose and insulin have been shown to activate PP1 activity, whereas glucagon and epinephrine have been linked to the inhibition of its activity.

Glycogen phosphorylase is a major enzyme involved in glycogenolysis (Figure 1). This enzyme catalyzes the reaction of the removal of a glucose residue from the non-reducing end of a glycogen chain, leading to the generation of glucose 1-phosphate.[6] Glucose 1-phosphate can be converted into glucose 6-phosphate by phosphoglucomutase, and glucose 6-phosphate can be incorporated into glycolysis or further converted into glucose by glucose 6-phosphatase, depending on the energy status of the organism. Glycogen phosphorylase is active when it is phosphorylated at its serine 14 residue. The phosphorylation of glycogen phosphorylase requires a cascade mechanism of epinephrine and glucagon in the liver. On the activation of Gαs by the binding of hormones to cell surface G protein-coupled receptors (beta adrenergic receptor or glucagon receptor), the intracellular cyclic AMP (cAMP) levels increase via adenylate cyclase, leading to the activation of PKA. PKA is then responsible for the phosphorylation and activation of glycogen phosphorylase kinase, which in turn phosphorylates and activates glycogen phosphorylase to enhance glycogen breakdown. Under feeding conditions, this kinase cascade is inactive due to the lack of secretion of catabolic hormones. In addition, insulin promotes the activation of PP1, which dephosphorylates and inactivates glycogen

phosphorylase. In essence, the anabolic hormone insulin promotes glycogenesis and inhibits glycogenolysis via the activation of PP1, leading to the dephosphorylation of glycogen phosphorylase (inactivation) and glycogen synthase (activation), and via the activation of Akt, leading to the phosphorylation of GSK-3 (inactivation) that is unable to phosphorylate and inactivate glycogen synthase.

29.2.5: CONTROL OF HEPATIC GLYCOLYSIS

As stated above, glycolysis is critical to the catabolism of glucose in most cells to generate energy. The key rate-limiting enzymes for this pathway include glucokinase (GK, also termed hexokinase IV), which converts glucose into glucose 6-phosphate; phosphofructokinase-1 (PFK-1), which converts fructose 6-bisphosphate into fructose 1,6-bisphosphate; and liver-type pyruvate kinase (L-PK), which converts phosphoenolpyruvate (PEP) into pyruvate in the liver. These enzymes are tightly regulated by allosteric mediators that generally promote the catabolism of glucose in the cell.[2, 7, 8, 9]

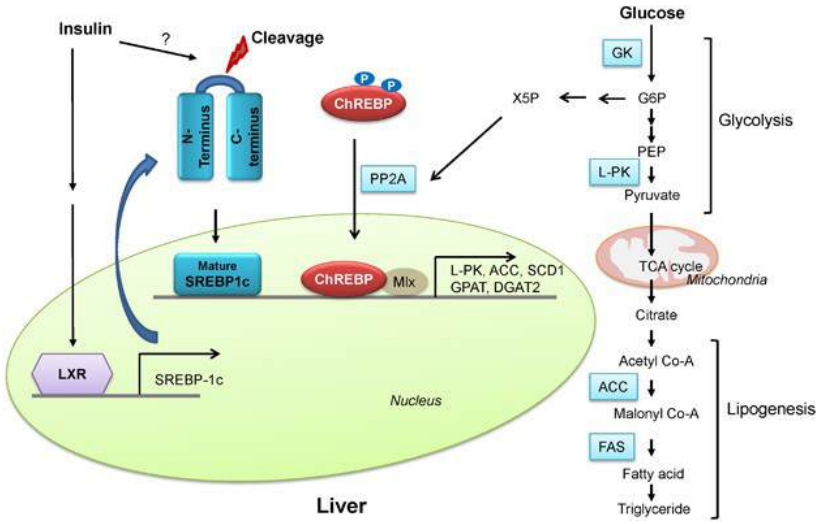
GK is a high Km hexokinase that is present in the liver and the pancreatic beta cells, thus functioning as a glucose sensor for each cell type. Unlike the other hexokinase isotypes, GK activity is not allosterically inhibited by its catalytic product, glucose 6-phosphate in the cell, thus enabling the liver to continuously utilize glucose for glycolysis during conditions of increased glucose availability, such as during feeding conditions. GK is regulated via its interaction with glucokinase regulatory protein (GKRP). In the low intracellular glucose concentration during fasting, the binding of GK and GKRP is enhanced by fructose 6-phosphate, leading to the nuclear localization of this protein complex. Higher concentrations of glucose during feeding compete with fructose 6-phosphate to bind this complex, which promotes the cytosolic localization of GK that is released from GKRP, thus causing the increased production of glucose 6-phosphate in this setting.[10]

PFK-1 catalyzes the metabolically irreversible step that essentially commits glucose to glycolysis. This enzyme activity is allosterically inhibited by ATP and citrate, which generally indicate a sign of energy abundance. Reciprocally, it is allosterically activated by ADP or AMP, making it more efficient to bring about glycolysis to produce more ATP in the cell. In addition, PFK-1 activity is allosterically activated by fructose 2,6-bisphosphate (F26BP), a non-glycolytic metabolite that is critical for the regulation of glucose metabolism in the liver. F26BP is generated from fructose 6-phosphate by the kinase portion of a bifunctional enzyme that contains both a kinase domain (phosphofructokinase-2, PFK-2) and a phosphatase domain (fructose 2,6-bisphosphatase, F-2,6-Pase). PFK-2 is activated by the insulin-dependent dephosphorylation of a bifunctional enzyme that activates PFK-2 activity and simultaneously inhibits F-2,6-Pase activity to promote the increased F26BP concentration. Glucagon-mediated activation of PKA is shown to be responsible for the phosphorylation and inactivation of the kinase portion of this enzyme.[7]

Unlike its muscle counterpart, L-PK is also a critical regulatory step in the control of glycolysis in the liver. As in the case of other glycolytic enzymes, L-PK activity is regulated by both allosteric mediators and post-translational modifications. L-PK activity is allosterically activated by fructose 1,6-bisphosphate, an indicator for the active glycolysis. By contrast, its activity is allosterically inhibited by ATP, acetyl-CoA, and long-chain fatty acids, all of which signal an abundant energy supply. Additionally, the amino acid alanine inhibits its activity, as it can be readily converted to pyruvate by a transamination reaction. L-PK is inhibited by PKA following a glucagon-mediated increase in intracellular cAMP during fasting and is activated by insulin-mediated dephosphorylation under feeding conditions.[7]

In addition to the acute regulation of key regulatory enzymes, glycolysis is regulated by a transcriptional mechanism that is activated during feeding conditions. Two major transcription factors, sterol regulatory element binding protein 1c (SREBP-1c) and carbohydrate response element binding protein (ChREBP), are responsible for the transcriptional activation of not only glycolytic enzyme genes but also the genes involved in fatty acid biosynthesis (such as fatty acid synthase (FAS), acetyl-CoA carboxylase (ACC), and stearoyl-CoA desaturase 1 (SCD1)) and triacylglycerol formation (such as glycerol 3-phosphate acyltransferase (GPAT) and diacylglycerol acyltransferase 2 (DGAT2)), a process that is normally activated by a carbohydrate-rich diet (Figure 2).[11] Because these processes are often coordinately regulated, that is activated during feeding and inhibited by fasting, they are sometimes collectively called lipogenesis.

Figure 2



Regulation of hepatic glycolysis. Under feeding conditions, increased glucose uptake in hepatocytes promotes glycolysis and lipogenesis to generate triglycerides as storage forms of fuel. This process is transcriptionally regulated by two major transcription factors in the liver, SREBP-1c and ChREBP-Mlx heterodimer, which mediate the insulin and glucose response, respectively. See the main text for more specific regulatory pathways.

Full size image

SREBPs are the major regulators of lipid metabolism in mammals. They are members of the basic helix-loop-helix leucine zipper (b/HLH/LZ) type transcription factor families comprising SREBP-1a, SREBP-1c, and SREBP-2. SREBP is translated as an endoplasmic reticulum (ER)-bound precursor form that contains the N-terminal transcription factor domain and the C-terminal regulatory domain linked with the central transmembrane domain.[12] Within this family of transcription factors, SREBP-2 is linked to the control of cholesterol uptake or biosynthesis in the liver by the transcriptional activation of the genes involved in the pathway including low density lipoprotein receptor (LDLR), 3-hydroxy-3-methylglutaryl-coenzyme A reductase (HMGCR), hydroxy-3-methylglutaryl-coenzyme A synthase 1 (HMGCS1), and farnesyl diphosphate synthase (FDPS). SREBP-1c, however, activates the genes encoding the enzymes for lipogenesis (FAS, ACC, SCD1, and DGAT2) as well as GK, which is a first enzyme in the commitment step of glucose utilization in the liver. Indeed, liver-specific SREBP-1c knockout mice showed an impaired activation of lipogenic genes in a high carbohydrate diet, thus confirming the importance of this transcription factor in the regulation of hepatic glycolysis and fatty acid biosynthesis.[13] SREBP-1a is not highly expressed in the liver but was shown to be involved in the formation of inflammasomes in response to lipopolysaccharide (LPS) treatment in macrophages by transcriptional activation of Nlrp1.[14] The regulation of SREBP-2 and SREBP-1c are quite distinct in the liver. The expression of SREBP-2 is not controlled by sterols, but its proteolytic processing is tightly regulated by intracellular concentrations of cholesterol. It is normally bound in the ER via the interaction of SREBP-cleavage-activating protein (SCAP) and insulin-induced gene protein (INSIG) in the presence of high intracellular cholesterol levels, and the reduction in the cholesterol concentration releases the interaction of SCAP and SREBP-2/INSIG complex, resulting in the translocation of the latter complex into the Golgi apparatus and the liberation of the active SREBP-2 factor by sequential proteolytic cleavages.[15] Unlike SREBP-2, SREBP-1c is mainly regulated at the transcription level by insulin. The exact transcription factor that mediates this insulin-dependent signal is not yet clear, although SREBP-1c itself might be involved in the process as part of an auto-regulatory loop. Interestingly, the oxysterol-sensing transcription factor liver X receptor (LXR) is shown to control the transcription of SREBP-1c, suggesting that SREBP-1c and SREBP-2 could be regulated differently in response to cellular cholesterol levels.[16] Recent studies have revealed the involvement of various kinases in the control of SREBP-1c activity. In HepG2 cells, PKA was shown to reduce the DNA binding ability of SREBP-1a by the phosphorylation of serine 338 (equivalent of serine 265 for SREBP-1c).[17] A report by Bengoechea and Ericsson suggested that GSK-3, a kinase known to reduce glycogen synthesis by targeting glycogen synthase, downregulates SREBP-1 activity via the phosphorylation of the C-terminal residue that promotes the ubiquitin ligase Fbw7-dependent degradation of SREBP-1 proteins.[18] In addition, both AMP activated protein kinase (AMPK) and its related kinase salt-inducible kinase (SIK) 1 are involved in the down-regulation of its activity through inhibitory phosphorylation (serine 372 for AMPK, which blocks proteolysis and nuclear localization of SREBP-1c, and serine 329 for SIK1, which directly reduces its transcriptional activity).[19, 20] These data suggest that the fine-tuning of SREBP-1c activity is critical to the maintenance of glucose and lipid homeostasis in the liver.

The other prominent transcription factor for controlling glycolysis and fatty acid biosynthesis in the liver is ChREBP. ChREBP was initially known as Williams-Beuren syndrome critical region 14 (WBSCR14) and was considered one of the potential genes that instigate Williams-Beuren syndrome. Later, by using a carbohydrate response element (ChoRE) from L-PK, ChREBP was isolated as a bona fide transcription factor for binding ChoRE of glycolytic promoters.[21] Indeed, ChREBP is highly expressed in tissues that are active in lipogenesis such as the liver, brown adipocytes, white adipocytes, small intestine, and kidney. As in the case for SREBP, ChREBP belongs to the b/HLH/LZ

transcription factor family and forms a heterodimer with another b/HLH/LZ transcription factor Max-like protein X (Mlx) on the glycolytic promoter.[22] As in the case for the SREBP-1c, the expression of ChREBP is increased in the liver as a result of a high carbohydrate diet, and the effect was recapitulated in primary hepatocytes with high glucose treatment.

A recent report indeed suggested a role for LXR in the transcriptional activation of ChREBP in response to glucose, although the study needs to be further verified because the transcriptional response is shown not only by the treatment of D-glucose, a natural form of glucose present in animals, but also by the treatment of unnatural L-glucose, a form of glucose that is not known to activate lipogenesis in the liver.[23] Moreover, studies performed in LXR knockout mice revealed no changes in ChREBP expression in the liver, arguing against the role of LXR in the control of ChREBP.[24] Glucose is also shown to regulate ChREBP activity by controlling its nuclear localization. There are three prominent serine/threonine residues that are targeted by serine/threonine kinases. PKA is shown to phosphorylate serine 196, which is critical for cellular localization, and threonine 666, which is critical for its DNA binding ability, whereas AMPK phosphorylate serine 568 dictates its DNA binding ability. All three sites are phosphorylated under fasting conditions by these kinases and are dephosphorylated under feeding by xylulose 5-phosphate (X5P)-mediated activity of protein phosphatase 2A (PP2A).[25, 26] However, the current model needs to be further verified due to the contrasting data that have been published regarding the role of these phosphorylations on ChREBP activity.

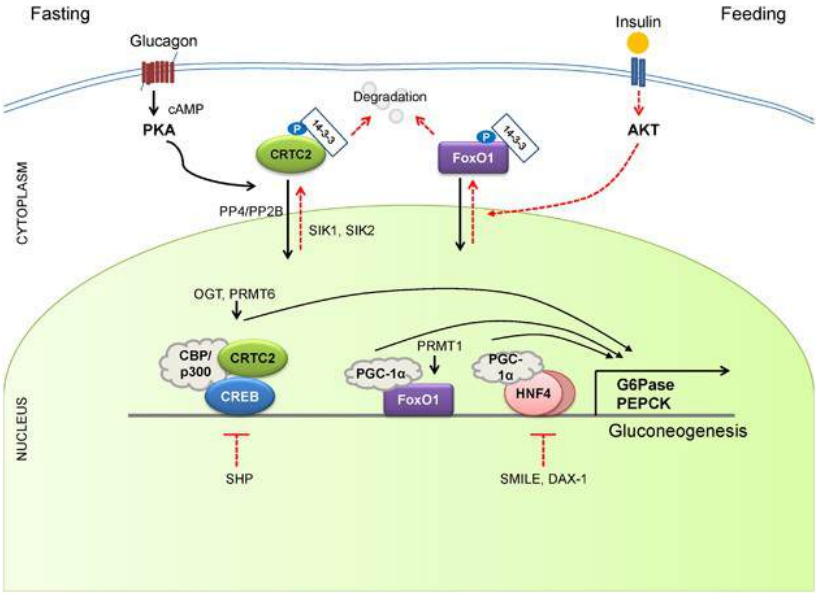
First, high glucose concentrations in primary hepatocytes do not result in decreased cAMP levels or PKA activity, suggesting that other signals might be necessary to mediate the high glucose-dependent nuclear translocation of ChREBP. In addition, a serine to alanine mutant of ChREBP still requires high glucose for its full activity, suggesting that additional actions are necessary to recapitulate the high glucose-mediated activation/nuclear localization of ChREBP in the liver.[27, 28] The physiological role of ChREBP in liver glucose metabolism was verified by *in vivo* studies. ChREBP knockout mice were born in a Mendelian ratio and showed no developmental problems. The knockout animals showed reduced liver triacylglycerol levels together with a reduction in lipogenic gene expression, thus confirming the role of ChREBP in the control of hepatic glycolysis and fatty acid synthesis.[29] Interestingly, the compensatory increase in glycogen was observed in the livers of these mice, suggesting that these mice adapted to store more glycogen as a storage form of fuel as opposed to triacylglycerol. In ob/ob mouse liver, increased accumulation of nuclear ChREBP was shown, suggesting that this phenomenon might be causal to the fatty liver phenotype in these mice. Indeed, knockdown of ChREBP in ob/ob mice reduced the rate of lipogenesis with decreased expression of most lipogenic genes.[30] Furthermore, the depletion of hepatic ChREBP in ob/ob mice improved hyperglycemia, hyperlipidemia, and hyperinsulinemia, suggesting that regulation of ChREBP might be critical in the control of metabolic disorders in the presence of obesity and insulin resistance.

29.2.6: CONTROL OF HEPATIC GLUCONEOGENESIS

Prolonged fasting or starvation induces de novo glucose synthesis from non-carbohydrate precursors, termed hepatic gluconeogenesis. This process initiates from the conversion of pyruvate to oxaloacetate by pyruvate carboxylase (PC) in the mitochondria and eventually concludes in the conversion into glucose via several enzymatic processes in the cytosol.[7, 8, 9] Among the substrates for gluconeogenesis are amino acids, which can be converted into either pyruvate or intermediates of the tricarboxylic acid cycle; lactate, which can be converted into pyruvate by lactate dehydrogenase; and glycerol (from increased lipolysis in the white adipocytes under fasting), which can be converted into dihydroxyacetone phosphate, a gluconeogenic intermediate (a two-step process that is catalyzed by glycerol kinase and glycerol 3-phosphate dehydrogenase). Key regulatory enzymes in that pathway, including glucose 6-phosphatase (G6Pase), fructose 1,6-bisphosphatase (Fbpase1), PC, and phosphoenolpyruvate carboxykinase (PEPCK), are activated under fasting conditions to enhance gluconeogenic flux in that setting.

Mitochondrial acetyl-CoA (derived from the increased fatty acid oxidation under fasting) functions as a key allosteric activator of PC, leading to the increased production of oxaloacetate for the gluconeogenesis. In addition, F26BP, which is a key allosteric regulator for glycolysis by activating PFK-1, was shown to inhibit gluconeogenesis via the allosteric inhibition of Fbpase1, which helps reciprocally control gluconeogenesis and glycolysis under different dietary statuses. Because Fbpase2 is activated but PFK-2 is inhibited under fasting, the lack of F26BP enables the activation of Fbpase1 and the increased production of fructose 6-phosphate in gluconeogenesis. The chronic activation of gluconeogenesis is ultimately achieved via transcriptional mechanisms. Major transcriptional factors that are shown to induce gluconeogenic genes include CREB, FoxO1, and several nuclear receptors (Figure 3).[31]

Figure 3



Regulation of hepatic gluconeogenesis. Under fasting conditions, hepatic gluconeogenesis is enhanced via a decreased concentration of insulin and an increased concentration of insulin counterregulatory hormones such as glucagon. CREB/CRTC2, FoxO1, and a family of nuclear receptors are critical in coordinating the fasting-mediated activation of gluconeogenesis in the liver. See the main text for more specific regulatory pathways. FoxO1, forkhead box O 1

Full size image

Under fasting conditions, glucagon and epinephrine can increase the cAMP concentration in the liver via the activation of adenylate cyclase, leading to the activation of PKA and the subsequent induction of CREB via its serine 133 phosphorylation. The phosphorylation event is crucial in the recruitment of histone acetyltransferases (HAT) CBP/p300, leading to the histone H3 and H4 acetylation and the transcriptional activation of target genes.[32, 33] CREB-dependent transcription is further enhanced by association with additional transcriptional coactivators CREB regulated transcription coactivators (CRTCs), which are a target for CBP/p300-mediated acetylation, which in turn promotes a tighter association of CREB, CBP/p300, and CRTC on the promoter.[34, 35, 36] The role of CREB in the control of hepatic gluconeogenesis has been confirmed by *in vivo* studies by utilizing albumin promoter-driven ACREB (CREB inhibitor) transgenic mice and siRNA-mediated CREB knockdown mouse models.[37, 38] In both mouse models, the inactivation of CREB reduced blood glucose levels and reduced the expression of gluconeogenic genes in mice, showing that CREB is a bona fide physiological transcriptional regulator of hepatic gluconeogenesis *in vivo*. In contrast, the role for CBP in gluconeogenesis is still controversial. Disruption of CREB-CBP interaction does not appear to affect glucose homeostasis because mice exhibiting a stable expression of mutant CBP that was unable to bind CREB showed normal glycemia.[36] Furthermore, mutant mice producing CH1 null products (ΔCH1-a domain that is critical for insulin-mediated depression of CBP activity) displayed normal fasting gluconeogenesis.[39] Thus, further studies are required to describe the potential role of HATs in the transcriptional control of CREB activity in this setting.

The CRTC family of transcriptional coactivators consists of CRTC1, CRTC2 and CRTC3, which were isolated by the expression library screening as activaters of CREB-dependent transcription.[34] CRTC activity is regulated by cellular localization, and the AMPK family of serine/threonine kinases, such as AMPK, SIK1 or SIK2, was shown to be involved in the inhibitory phosphorylation of this factor (serine 171 for CRTC2).[40] In addition, the phosphorylation status of CRTC is regulated by a pair of serine/threonine phosphatases (PP2B or PP4) in response to cAMP signaling or calcium concentration in the cell.[41, 42] CRTC activity is also further enhanced by *O*-GlcNAcylation on serine 171 and arginine methylation by protein arginine methyltransferase (PRMT) 6.[43, 44] Among the family members, CRTC2 is the prominent isoform in the liver. Recent studies have delineated the role of CRTC2 in the regulation of hepatic gluconeogenesis in vivo. Knockdown of CRTC2 in mice by RNAi reduced blood glucose levels and led to a concomitant repression of gluconeogenic gene expression.[36] In addition, CRTC2 knockout mice displayed lower plasma glucose levels and improved glucose tolerance, indeed showing that CRTC2 is crucial in controlling hepatic glucose metabolism *in vivo*.[45] A recent study indicated that CRTC2 could also coactivate other bZIP transcription factors that are implicated in the regulation of glucose homeostasis.[46, 47] Further study is required to delineate the potential contributions from other bZIP factors in the control of hepatic gluconeogenesis by using tissue-specific knockout mouse models.

The forkhead box O (FoxOs) belongs to a class of forkhead families of transcription, which recognize the AT-rich insulin response element on the promoter.[48, 49] Of the four major isoforms in mammals (FoxO1, FoxO3, FoxO4, and FoxO6), FoxO1 is the predominant isoform in the liver. The activity of this protein is also regulated by phosphorylation-dependent subcellular localization, and three major serine and threonine residues (threonine 24, serine 253 and serine 316 for murine FoxO1) are targeted by the insulin/Akt pathway. Following phosphorylation, FoxO1 moves to the cytosol via an association with 14-3-3, where it is degraded by the ubiquitin/proteasome-dependent

pathway.[50, 51, 52] In addition to phosphorylation, FoxO1 was shown to be regulated by the HAT-dependent acetylation of specific lysine residues (lysine 242, 245 and 262 for murine FoxO1), which also inhibit its transcriptional activity.[53] In the liver, FoxO1 regulates hepatic gluconeogenesis via the transcriptional regulation of key genes in the pathway such as PEPCK and G6Pase and is considered a major regulatory point for the insulin-mediated repression of hepatic gluconeogenesis.[54] Indeed, mice with liver-specific knockout of FoxO1 showed lower plasma glucose levels that those associated with reduced hepatic glucose output, thus underscoring the physiological significance of this factor in the control of glucose homeostasis *in vivo*.[54, 55] As in the case for CREB, FoxO1 requires transcriptional coactivators for optimal transcriptional activity.

Peroxisome proliferator-activated receptor gamma coactivator 1 alpha (PGC-1α), a known coactivator for nuclear receptors, functions as a key transcriptional coactivator for FoxO1 in hepatic gluconeogenesis.[56] PGC-1α was originally isolated in brown adipocytes and was shown to control adaptive thermogenesis in response to cold shock in that setting.[57] In the liver, the expression of PGC-1α is upregulated under fasting conditions via a CRTC2-CREB-dependent mechanism and is critical in maintaining prolonged gluconeogenesis under starvation by enhancing the transcriptional activity of FoxO1 as a coactivator.[38, 57, 58] Indeed, the depletion of hepatic PGC-1α in mice results in lower fasting glucose levels with a concomitant reduction in hepatic gluconeogenesis, thus showing the physiological relevance of this coactivator in the control of glucose homeostasis.[59, 60] As is the case for CRTC2, FoxO1 activity is enhanced by arginine methylation by PRMT. In this case, PRMT1 promotes the asymmetric dimethylation of arginine 248 and 250 in FoxO1, which blocks the binding of Akt and the subsequent Akt-mediated phosphorylation of the adjacent serine residue (serine 253), thus enhancing the nuclear localization of FoxO1.[61] Consequently, the chromatin occupancy of FoxO1 onto the gluconeogenic promoter and gluconeogenesis itself are increased due to the PRMT1-dependent arginine methylation.[62] Acute knockdown of hepatic PRMT1 in mice reduces FoxO1-mediated glucose production, confirming that PRMT1 is crucial in modulating FoxO1 activity and subsequent gluconeogenesis in the physiological context.

Nuclear receptors belong to the superfamily of transcription factors that possess two Cys2-His2 type zinc finger motifs as a DNA binding domain as well as both ligand-independent and ligand-dependent transactivation domains.[63] The latter activation domain also contains a ligand-binding domain. Nuclear receptors can be classified into one of three subgroups based on their dimer-forming potential. Homodimeric nuclear receptors are also called cytosolic receptors because they reside in the cytosol and associate with molecular chaperones such as heat-shock proteins. On binding to the ligand, they form homodimers and translocate to the nucleus to bind a specific response element termed the hormone response element to elicit the ligand-dependent transcriptional response. Most of the steroid hormone receptors, such as the glucocorticoid receptor (GR), estrogen receptor (ER), and progesterone receptor (PR), belong to this subfamily. By contrast, heterodimeric nuclear receptors reside in the nucleus and are bound to their cognate binding sites together with the universal binding partner retinoid X receptor (RXR). In the absence of the ligands, these factors repress the transcription of target genes in association with transcriptional corepressors such as histone deacetylase or nuclear receptor corepressor (NCoR)/silencing mediator of retinoid and thyroid hormone receptors (SMRT). Ligand binding initiates the conformational changes of these heterodimeric nuclear receptors, which promotes the dissociation of corepressors and the association of coactivators such as CBP/p300, p160 steroid receptor coactivator family, and PGC-1α.

Examples of this class of nuclear receptors include members of peroxisome proliferator-activated receptors, LXRs, vitamin D receptors and thyroid hormone receptors. The final subclasses of nuclear receptors are types that function as monomers. They usually lack specific endogenous ligands and are often called orphan nuclear receptors. Some of them also lack DNA binding domain and thus function as transcriptional repressors of various transcription factors, including members of nuclear receptors. They are called atypical orphan nuclear receptors. Among the homodimeric nuclear receptors, the role of GR has been linked to the control of hepatic gluconeogenesis. GR is activated by cortisol, which is released from the adrenal cortex in response to chronic stresses such as prolonged fasting.[64, 65] GR was shown to directly bind to the cognate binding sites found in the promoters of gluconeogenic genes such as PEPCK and G6Pase and to enhance transcription of these genes under fasting conditions. The same response elements were also shown to be recognized and regulated by hepatocyte nuclear factor 4 (HNF4), a member of heterodimeric nuclear receptors, which suggests that these nuclear receptors could coordinately function to control hepatic gluconeogenesis in response to fasting.[58]

In accordance with this idea, the activity of these nuclear receptors can be effectively integrated by the function of transcriptional co-activator PGC-1α. Recently, estrogen-related receptor gamma (ERRγ), a member of monomeric nuclear receptors, was shown to be involved in the regulation of hepatic gluconeogenesis.[66, 67] In the liver, ERRγ expression is increased under fasting or by insulin resistance in a CRTC2-CREB-dependent manner. This factor regulates hepatic gluconeogenesis by binding to unique response elements that are distinct from the known nuclear receptor-binding sites in the promoters of PEPCK and G6Pase. Inhibition of ERRγ activity by injecting either RNAi or the inverse agonist GSK5182 effectively reduced hyperglycemia in diabetic mice, suggesting that the control of this factor might potentially be beneficial in the treatment of patients with metabolic diseases. As is the case for other nuclear receptors that control hepatic gluconeogenesis, ERRγ activity is further enhanced by interaction with the transcriptional coactivator PGC-1α, showing that this coactivator functions as a master regulator for the hepatic glucose metabolism.

Three members of atypical orphan nuclear receptors, the small heterodimer partner (SHP, also known as NR0B2); the dosage-sensitive sex reversal, adrenal hypoplasia critical region, on chromosome X (DAX-1, also known as NR0B1); and the SHP-interacting leucine zipper protein (SMILE) are implicated in the transcriptional repression of hepatic gluconeogenesis.[68, 69, 70] SHP is ubiquitously expressed in mammalian tissues, with the highest expression occurring in the liver. Interestingly, metformin directly activates the transcription of SHP

via an AMPK-mediated pathway. SHP directly inhibits cAMP-dependent transcription by binding to CREB, resulting in the reduced association of CREB with CRTC2.[71, 72] The adenovirus-mediated overexpression of SHP could effectively reduce blood glucose levels in diabetic mice, thus showing the importance of this pathway in the control of hepatic glucose metabolism.

These results provide a dual mechanism for a metformin-AMPK dependent pathway to inhibit hepatic gluconeogenesis at the transcriptional level; an acute regulation of CRTC2 phosphorylation to inhibit the CRTC2-CREB-dependent transcriptional circuit; and a longer-term regulation of gluconeogenic transcription by enhanced SHP expression. Both DAX-1 and SMILE were shown to repress hepatic gluconeogenesis by inhibiting HNF4-dependent transcriptional events.[73, 74] SIK1, a member of the AMPK-related kinases, was shown to enhance DAX-1 expression in the liver, whereas Akt was shown to activate the transcription of SMILE to target the HNF4 pathway under feeding conditions. Interestingly, SMILE was shown to directly replace PGC-1α from HNF4 and the gluconeogenic promoters, suggesting that this factor could potentially function as a major transcriptional repressor of hepatic gluconeogenesis in response to insulin signaling. Further study is necessary to fully understand the relative contribution of these nuclear receptors in the control of glucose homeostasis in both physiological conditions and pathological settings.

29.2.7: CONCLUDING REMARKS

In this review, we attempted to describe the current understanding of the regulation of glucose metabolism in the mammalian liver. Under feeding conditions, glucose, a major hexose monomer of dietary carbohydrate, is taken up in the liver and oxidized via glycolysis. The excess glucose that is not utilized as an immediate fuel for energy is stored initially as glycogen and is later converted into triacylglycerols via lipogenesis. Glycogenesis is activated via the insulin-Akt-mediated inactivation of GSK-3, leading to the activation of glycogen synthase and the increased glycogen stores in the liver. Insulin is also critical in the activation of PP1, which functions to dephosphorylate and activate glycogen synthase. In addition, PP1 inhibits glycogenolysis via the dephosphorylation/inactivation of glycogen phosphorylase. Glycolysis is controlled by the regulation of three rate-limiting enzymes: GK, PFK-1 and L-PK. The activities of these enzymes are acutely regulated by allosteric regulators such as ATP, AMP, and F26BP but are also controlled at the transcription level. Two prominent transcription factors are SREBP-1c and ChREBP, which regulate not only the aforementioned glycolytic enzyme genes but also the genes encoding enzymes for fatty acid biosynthesis and triacylglycerol synthesis (collectively termed as lipogenesis).

The importance of these transcription factors in the control of glycolysis and fatty acid biosynthesis has been verified by knockout mouse studies, as described in the main text. The liver also has a critical role in controlling glucose homeostasis under fasting conditions. Initially, insulin counterregulatory hormones such as glucagon and epinephrine are critical in activating the PKA-driven kinase cascades that promote glycogen phosphorylase and glycogenolysis in the liver, thus enabling this tissue to provide enough fuel for peripheral tissues such as the brain, red blood cells and muscles. Subsequently, these hormones together with adrenal cortisol are crucial in initiating the transcriptional activation of gluconeogenesis such as PC, PEPCK and G6Pase. The major transcription factors involved in the pathway include CREB, FoxO1 and members of nuclear receptors, with aid from transcriptional coactivators such as CRTC, PGC-1α and PRMTs. These adaptive responses are critical for maintaining glucose homeostasis in times of starvation in mammals. Further study is necessary by using liver-specific knockout mice for each regulator of hepatic glucose metabolism to provide better insights into the intricate control mechanisms of glucose homeostasis in mammals.

29.3: EMERGING ROLE OF THE BRAIN IN THE HOMEOSTATIC REGULATION OF ENERGY AND GLUCOSE METABOLISM

Roh, E., Song, D. & Kim, MS. Emerging role of the brain in the homeostatic regulation of energy and glucose metabolism. *Exp Mol Med* **48,** e216 (2016). https://doi.org/10.1038/emm.2016.4

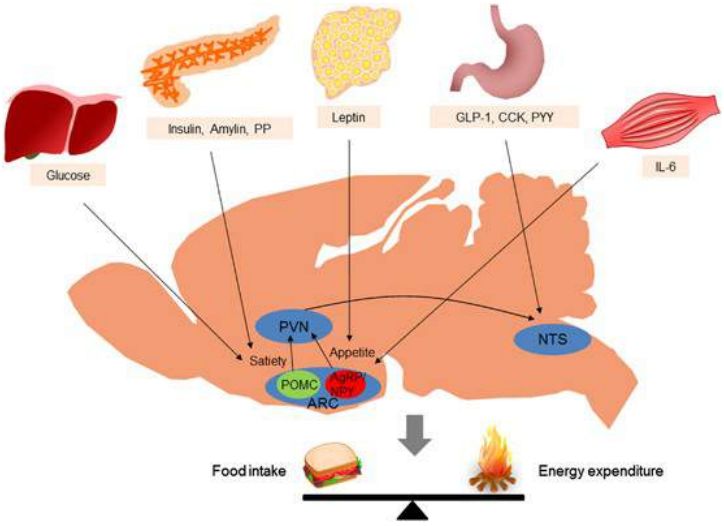
29.3.1: ABSTRACT

Accumulated evidence from genetic animal models suggests that the brain, particularly the hypothalamus, has a key role in the homeostatic regulation of energy and glucose metabolism. The brain integrates multiple metabolic inputs from the periphery through nutrients, gut-derived satiety signals and adiposity-related hormones. The brain modulates various aspects of metabolism, such as food intake, energy expenditure, insulin secretion, hepatic glucose production and glucose/fatty acid metabolism in adipose tissue and skeletal muscle. Highly coordinated interactions between the brain and peripheral metabolic organs are critical for the maintenance of energy and glucose homeostasis. Defective crosstalk between the brain and peripheral organs contributes to the development of obesity and type 2 diabetes. Here we comprehensively review the above topics, discussing the main findings related to the role of the brain in the homeostatic regulation of energy and glucose metabolism.

29.3.2: CENTRAL REGULATION OF ENERGY METABOLISM

In normal individuals, food intake and energy expenditure are tightly regulated by homeostatic mechanisms to maintain energy balance. Substantial evidence indicates that the brain, particularly the hypothalamus, is primarily responsible for the regulation of energy homeostasis.[1] The brain monitors changes in the body energy state by sensing alterations in the plasma levels of key metabolic hormones and nutrients. Specialized neuronal networks in the brain coordinate adaptive changes in food intake and energy expenditure in response to altered metabolic conditions (Figure 1).[2, 3]

Figure 1



Integration of peripheral metabolic signals andthe central nervous system maintains energy homeostasis. The brain integrates metabolic signals from peripheral tissues such as the liver, pancreas, adipose tissue, gut and muscle. Specialized neuronal networks in the brain coordinate adaptive changes in food intake and energy expenditure in response to altered metabolic conditions. Neuropeptide Y/agouti-related protein- and proopiomelanocortin-producing neurons in the hypothalamic arcuate nucleus primarily sense the body energy state. These neurons project to other hypothalamic nuclei and to the nucleus of the solitary tract in the brain stem to control multiple aspects of the homeostatic regulation of energy balance. ARC, arcuate nucleus; CCK, cholecystokinin; GLP-1, glucagon-like peptide-1; IL-6, interleukin-6; PP, pancreatic polypeptide; PVN, paraventricular nucleus; PYY, peptide YY.

Full size image

29.3.2.1: BRAIN REGULATION OF FOOD INTAKE

The hypothalamus is considered a key organ in the regulation of food intake. The hypothalamic arcuate nucleus (ARC) is adjacent to the median eminence, one of the circumventricular organs, and surrounds the third cerebroventricle. Thus, hormones and nutrients in the systemic circulation and the cerebrospinal fluid can easily access the ARC. Anatomically, the ARC is considered a hypothalamic area that primarily senses metabolic signals from the periphery via the systemic circulation.[4] In the ARC, there are two distinct neuronal populations: one group of neurons produces the orexigenic neuropeptides neuropeptide Y (NPY) and agouti-related peptide (AgRP), whereas the other subset of neurons expresses the anorexigenic neuropeptides proopiomelanocortin (POMC), and cocaine- and amphetamine-regulated transcript. These neurons are the first-order neurons on which peripheral metabolic hormones, including leptin, insulin, ghrelin and nutrients, primarily act.[5] The anorexigenic effect of monoamine serotonin is also mediated by the 5HT-2C receptor in POMC neurons.[6] POMC neurons project axonal processes to second-order neurons in hypothalamic areas such as the paraventricular nucleus (PVN), ventromedial hypothalamus (VMH) and lateral hypothalamus (LH), and to autonomic preganglionic neurons in the brain stem and spinal cord.[7]

The anorexigenic neuropeptide α-melanocyte-stimulating hormone (α-MSH) is produced by posttranscriptional processing of POMC and is released from the presynaptic terminals of POMC neurons. Upon binding to the melanocortin-3 and -4 receptors (MC3R and MC4R) on second-order neurons, α-MSH activates catabolic pathways, leading to reduced food intake and increased energy expenditure. Targeted deletion of the MC4R in mice induces hyperphagia, reduces energy expenditure and leads to obesity.[8] In humans, MC4R mutations account for ~6% of severe early-onset obesity cases,[9] suggesting an important role for the central melanocortin system in the maintenance of normal body weight.

The endogenous MC-3/4R antagonist AgRP is released from the terminals of NPY/AgRP-producing neurons to the synaptic space of second-order neurons where it competes with α-MSH for MC3Rs and MC4Rs and antagonizes its effects.[10] Selective ablation of NPY/AgRP neurons in young mice results in a significant decrease in food intake and body weight,[11] suggesting that these neurons are critical for promoting food intake and preventing weight loss. Administration of NPY stimulates food intake via Y1 or Y5 receptors.[12] NPY is required for the rapid stimulation of feeding, whereas AgRP stimulates feeding over a prolonged period.[13]

PVN neurons synthesize and secrete neuropeptides that have a net catabolic action, including corticotrophin-releasing hormone, thyrotropin-releasing hormone, somatostatin, vasopressin and oxytocin. On the other hand, PVN neurons control sympathetic outflow to peripheral metabolic organs, resulting in increased fatty acid oxidation and lipolysis.[14] Destruction of PVN and haploinsufficiency of Sim1, a critical transcriptional factor in the development of PVN, cause hyperphagia and obesity,[15] implying a inhibitory role of the PVN in food intake and weight gain.

The VMH mainly receives neuronal projections from the ARC and projects their axons to the ARC, dorsomedial nucleus (DMN), LH and brain stem regions. The VMH contains neurons that sense glucose and leptin.[16, 17] Moreover, the anorexigenic neuropeptide brain-derived neurotrophic factor is produced in the VMH.[18] Destruction of the VMH causes hyperphagia, obesity and hyperglycemia.[19] Thus, the VMH is regarded a pivotal area in generating satiety and maintaining glucose homeostasis. The DMN contains a high level of NPY terminals and α-MSH terminals originating from the ARC.[20] Destruction of the DMN also results in hyperphagia and obesity.[21]

In contrast to the PVN, VMH and DMN, destruction of the LH leads to hypophagia and weight loss. Therefore, LH is considered a feeding center. LH contains two neuronal populations producing the orexigenic neuropeptides melanin-concentrating hormone (MCH) and orexin, also called hypocretin. NPY/AgRP- and α-MSH-immunoreactive terminals from ARC neurons are in contact with MCH- and orexin-expressing neurons.[22] Orexin-producing neurons are also involved in glucose sensing and the regulation of sleep–awake cycles.[23] Alterations in the orexin receptor-2 and orexin genes produce narcolepsy in animal models and humans.[24] On the other hand, depletion of MCH or the MCH-1 receptor in mice attenuates weight gain, suggesting that MCH is an endogenous orexigenic molecule.[25]

The brain stem is another key brain area involved in the regulation of food intake. Satiety signals from the gastrointestinal tract are relayed to the nucleus tractus solitaries (NTS) through the sensory vagus nerve, a major neuronal connection between the gut and brain. Transection of sensory vagal fibers decreases meal size and meal duration, confirming that vagal afferents transfer meal-related signals to the brain.[26] Like the ARC, the NTS is anatomically close to the area postrema, another circumventricular organ.[27] Therefore, the NTS is perfectly located for receiving both humoral and neural signals. Meanwhile, the NTS receives extensive neuronal projections from the PVN and vice versa,[28] indicating that there are intimate communications between the hypothalamus and the brain stem. Like hypothalamic neurons, NTS neurons produce appetite-regulating glucagon-like peptide-1 (GLP-1), NPY and POMC, and sense peripheral metabolic signals.[29] For instance, NTS POMC neurons show the signal transducer and activator of transcription 3 (STAT3) activation in response to exogenous leptin.[30] Thus, circulating hormones and nutrients may relay metabolic signals to the brain by acting on both the hypothalamus and brain stem.

On the other hand, the brain reward system is involved in the control of hedonic feeding, that is, intake of palatable foods. Like other addiction behaviors, the mesolimbic and mesocortical dopaminergic pathways are involved in hedonic feeding. Intake of palatable foods elicits dopamine release in the ventral tegmental area (VTA), which in turn activates the neural pathways from the VTA to the nucleus accumbens via the medial forebrain bundles. Interestingly, hedonic feeding is modulated by metabolic signals. Leptin acts on the

dopaminergic neurons in the VTA to suppress feeding.[31] Conversely, hedonic feeding can override satiety signals. Mice lacking the D_2 receptor are more sensitive to leptin.[32]

29.3.2.1: BRAIN REGULATION OF ENERGY EXPENDITURE

The brain modulates various processes that consume energy, such as locomotor activity, fatty acid oxidation in the skeletal muscle and thermogenesis.[33] Tumor growth factor-α, produced in the suprachiasmatic nucleus in a circadian manner, strongly inhibits locomotor activity by acting on the epidermal growth factor receptors expressed in the hypothalamic subparaventricular zone.[34] Orexin-A produced by LH neurons promotes locomotor activity and wakefulness through orexin-1 and orexin-2 receptors.[35] A role for orexin in food-seeking behavior in food-deprived conditions has been suggested.[36] Leptin stimulates locomotor activity via a mechanism that depends on hypothalamic POMC neurons[37]. Leptin also enhances fatty acid oxidation in skeletal muscle via both central and peripheral mechanisms.[38]

Thermogenesis is theprocess that dissipates energy as heat to maintain body temperature. Thermogenesis mainly occurs in brown adipose tissue (BAT).[39] Brown fat-like adipocytes, so-called browning of white adipose tissue (WAT), are found in the subcutaneous inguinal WAT under certain circumstances. Cold exposure or intracerebroventricular (ICV) coinjection of insulin and leptin induces WAT browning.[40] Induction of WAT browning results in increased energy expenditure and attenuation of diet-induced obesity in mice. Conversely, inhibition of WAT browning by depletion of Prdm16 leads to obesity.[39]

The brain regulates BAT thermogenesis through modulation of the sympathetic nervous system. Norepinephrine released from sympathetic nervous terminals acts on the β3-adrenergic receptors in adipocytes in the BAT and inguinal fat pads. Activation of adrenergic receptors triggers cyclic-adenosine monophosphate signaling, which in turn increases the expression of uncoupling protein-1 in the mitochondria. BAT thermogenesis is important for maintaining body temperature in response to cold exposure and dissipating excess energy after high-calorie intake. Because metabolic fuel substrates such as glucose and fatty acid are consumed during BAT thermogenesis, BAT thermogenesis can affect body weight and body fat mass.[41] In the past, BAT was thought to be present only in human infants. However, ^{18}F-fluorodeoxyglucose positron emission tomography revealed the presence of BAT in the adult humans. Human BAT depots are distributed in the supraclavicular area and in perivascular and periviscus areas (for example, around the heart, airway, gut, liver and adrenal gland) of the chest and abdomen.[42] BAT activity, determined by ^{18}F-fluorodeoxyglucose positron emission tomography, is affected by outdoor temperature, age, sex, body mass index and the coexistence of diabetes. Because the amount of BAT is inversely correlated with body mass index, especially in older subjects, a potential role of BAT in adult human metabolism has been suggested.[43]

In thermogenic regulation, the hypothalamus integrates the sensation of body temperature with efferent sympathetic outflow. Hypothalamic areas such as the prooptic area, VMH, DMN and ARC modulate thermogenic activity by influencing the sympathetic nervous system.[44] The prooptic area is an important area in the control of body temperature.[45] VMH was the first hypothalamic nucleus to be studied regarding the regulation of BAT activity. The DMN also contains sympathoexcitatory neurons,[46] which regulate thermogenic activity.[47, 48] BAT thermogenesis is also related to the ARC melanocortin system because α-MSH stimulates BAT activity.[49]

Hormonal- and nutrient-mediated metabolic signals can influence sympathetic outflow to the BAT. Central administration of leptin, MC3/4R agonist, glucagon and GLP-1 stimulates BAT activity.[50, 51] Central administration of insulin either stimulates or inhibits BAT thermogenesis, depending on the insulin dose. Central administration of high doses of insulin increases sympathetic nerve activity in the BAT, whereas low doses of insulin decrease it.[52, 53] Food consumption or dietary composition also affects BAT thermogenesis. Although the mechanism of postprandial thermogenesis is unclear, norepinephrine turnover in the BAT is increased after a meal.[54] Glucose administration increases thermogenesis, whereas fasting or food restriction inhibits thermogenesis. Low-protein diet and high-fat diet increase BAT activity.[55]

29.3.2.1: PERIPHERAL SIGNALS MODULATING ENERGY METABOLISM

29.3.2.0.1: ADIPOSITY SIGNALS

Adiposity signals refer to the peripheral signals that circulate in proportion to the total amount of stored fat and inform the brain about the stored energy state. They modulate energy balance through the regulation of food intake and energy expenditure.[2, 56] Insulin is a hormone that was first identified as an adiposity signal.[5, 57] Insulin is secreted by β-cells in response to energy flux. Plasma insulin concentrations increase in proportion to the amount of stored fat.[58] When insulin is administered directly into the central nervous system, it induces a dose-dependent reduction in food intake and body weight.[59, 60] Thus, insulin is thought to signal adiposity to the brain. In hypothalamic neurons, insulin activates the insulin receptor substrate-2 (IRS2)–phosphatidylinositol 3-kinase (PI3K) signaling pathway. Neuronal deletion of insulin receptor and IRS2 results in increased food intake and susceptibility to diet-induced obesity.[61, 62]

The adipose tissue-derived hormone leptin was discovered by positional cloning of the obesity locus (*ob*) in 1994.[63] Leptin is now considered a representative adiposity signal.[64] The receptors activated by leptin are highly expressed in several regions of brain, including the hypothalamus.[65] Genetic deficiency in leptin or the long-form leptin receptor (LepRb) is associated with hyperphagia, hypoactivity and obesity.[66] Of several brain regions, the ARC is an important area that mediates leptin actions. Injection of leptin directly into the ARC reduces food intake and body weight.[67] Leptin also stimulates locomotion through signaling in POMC neurons.[37] Consistently, ICV administration of leptin in leptin-deficient (*ob*/*ob*) mice attenuates obesity.[66] In hypothalamic neurons, leptin provokes several signaling cascades such as the Janus kinase–STAT pathway, IRS–PI3K signaling, the mammalian target of rapamycin–S6 kinase signaling, AMP-

activated protein kinase (AMPK) signaling and ERK signaling.[68] Of those, STAT3 signaling represents hypothalamic leptin signaling and is frequently used as a marker of leptin signaling activity.

29.3.2.0.2: NUTRIENT SIGNALS

Nutrients such as glucose, fatty acids and amino acids provide information on nutrient availability to the brain. Glucose signals the presence of anenergy supply to the brain, whereas hypoglycemia signals an energy deficit.[69] Thus, central administration of glucose and long-chain fatty acids decreases food intake.[70] In contrast, ICV administration of the glucose anti-metabolite 2-deoxy-D-glucose increases food intake.[71] The malonyl-CoA content in hypothalamic neurons has been suggested to be a fuel gauge.[56, 72] Administration of the fatty acid synthase inhibitor C75 induces accumulation of malonyl-CoA in hypothalamic neurons, leading to decreased food intake and body weight.[73] Long-chain fatty acyl-CoA (LCFA-CoA) content in hypothalamic neurons also acts as a cellular nutrient sensor. An increased hypothalamic LCFA-CoA level due to ICV long-chain fatty acid (LCFA) administration leads to decreased food intake.[70] Hypothalamic inhibition of carnitine palmitoyltransferase-1 inhibits food intake by elevating LCFA-CoA content in hypothalamic neurons.[74]

29.3.2.0.3: GASTROINTESTINAL SIGNALS

Hormones secreted by the gut in response to a meal provide information on energy intake. Cholecystokinin, peptide YY and GLP-1 released from the gut induce satiety by acting on the vagus nerve or in the brain.[75] For example, GLP-1 is secreted from intestinal L-cells after a meal. GLP-1 receptors are prevalent in vagus nerve terminals,[76] as well as in the central nucleus of the amygdala, the PVN and ARC of the hypothalamus, and the caudal brain stem.[77] Both central and peripheral administration of GLP-1 promotes satiety.[78, 79] In contrast, ghrelin is secreted by the stomach during a fast and promotes food intake.[80]

29.3.2.0.4: SIGNALS FROM OTHER ORGANS

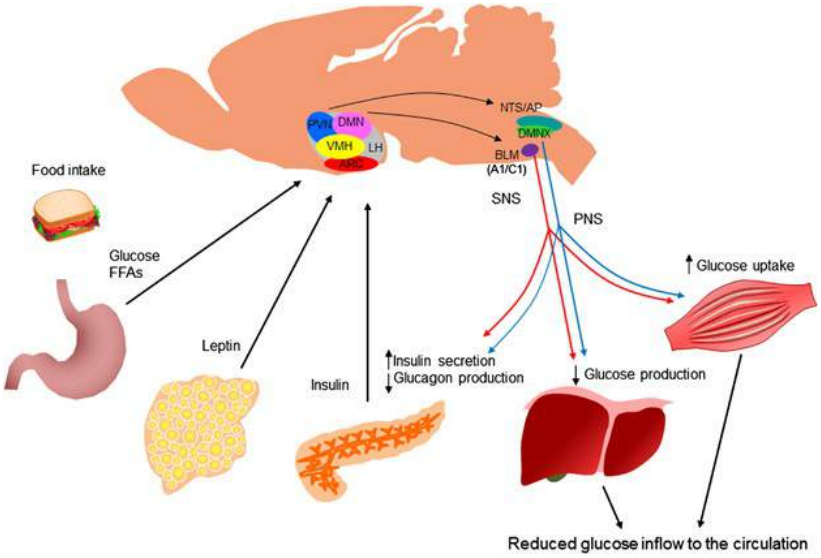
Interleukin-6 (IL-6) is synthesized and released from contracting skeletal muscle during exercise. The elevation in the plasma IL-6 concentration during exercise correlates with exercise intensity and duration and the muscle mass recruited.[81] IL-6 enters the brain across the blood–brain barrier. IL-6 may mobilize fat from storage sites to provide energy to the muscle. ICV administration of IL-6 stimulates energy expenditure, and mice lacking IL-6 develop mature-onset obesity.[82]

Hormones secreted from the endocrine pancreas are also involved in energy homeostasis. Insulin and amylin are co-secreted by β-cells. Like insulin, amylin acts as a satiety signal and reduces food intake via amylin receptors in the area postrema. Other brain sites mediating amylin action include the NTS and the lateral parabrachial nucleus.[83] Amylin also acts as an adiposity signal because amylin levels are well correlated with body fat content. Glucagon, a counter-regulatory hormone to insulin, is secreted from α-cells. Glucagon reduces meal size by acting on the vagus nerves and stimulates energy expenditure through central and peripheral mechanisms.[84] Pancreatic polypeptide is also secreted from the endocrine pancreas. Pancreatic polypeptide regulates gastric motility, pancreatic exocrine secretion and food intake. Systemic administration of pancreatic polypeptide reduces food intake and weight gain.[85] The anorectic effect of pancreatic polypeptide is mediated by Y4 receptors in the dorsal vagal complex.[86]

29.3.3: BRAIN REGULATION OF GLUCOSE METABOLISM

The earliest demonstration of the role of the brain in glucose homeostasis was provided by the physiologist Claude Bernard in 1854. Dr Bernard demonstrated that a puncture in the floor of the fourth ventricle of the rabbit brain resulted in glycosuria.[87] In the past few decades, the concept of central regulation of glucose metabolism has been further established by the subsequent discovery of glucose-sensing neurons in the hypothalamus[88, 89] and the demonstration of their roles in maintaining normal glucose levels.[90] A specialized neuronal population in the brain senses hormones (insulin and leptin) and nutrients (glucose and fatty acids) to regulate glucose homeostasis. The major sites of convergence of these metabolic signals are the hypothalamus and brain stem (Figure 2).

Figure 2



Brain regulation of glucose homeostasis. The brain senses peripheral metabolic signals through hormones (insulin, leptin and so on) and nutrients (glucose, free fatty acids and so on) to regulate glucose metabolism. The sites of the convergence of these metabolic signals are the hypothalamus and brain stem. The autonomic nervous system intervenes in the brain and peripheral metabolic organs to modulate pancreatic insulin/glucagon secretion, hepatic glucose production and skeletal muscle glucose uptake. AP, area postrema; ARC, arcuate nucleus; BLM, basolateral medulla; DMN, dorsomedial nucleus; DMNX, dorsal motor nucleus of the vagus; FFA, free fatty acids; LH, lateral hypothalamus; NTS, nucleus of the solitary tract; PNS, parasympathetic nervous system; PVN, paraventricular nucleus; SNS, sympathetic nervous system; VMH, ventromedial hypothalamus.

29.3.3.1: NEURONAL POPULATIONS CONTROLLING GLUCOSE METABOLISM

Brain regions related to the control of glucose metabolism contain neurons whose excitability changes with alterations in glucose concentrations in the extracellular fluid. These glucose-sensing neurons are found in the hypothalamic nuclei and brain stem, which are also important areas in the control of energy balance. Glucose-sensing neurons are subgrouped into two types. Glucose-excited neurons are excited when extracellular glucose levels increase. In contrast, glucose-inhibited neurons are activated by a fall in extracellular glucose concentrations.[91] Glucose-excited neurons are mostly located in the VMH, the ARC and the PVN,[92] whereas glucose-inhibited neurons are distributed in the LH, ARC and PVN.[89, 91] Both types of neurons are also located in the dorsal vagal complex in the brain stem, which encompasses the NTS, area postrema and the dorsal motor nucleus of the vagus.[93, 94, 95]

29.3.3.1: PERIPHERAL SIGNALS AFFECTING BRAIN REGULATION OF GLUCOSE METABOLISM

29.3.3.0.1: INSULIN

During the past decade, the brain has been recognized to be a site of insulin action with regard to glucose homeostasis. Obici *et al.*[96] showed that insulin acts on the brain to modulate hepatic glucose metabolism. They showed, by injecting insulin receptor antisense oligonucleotides into the cerebroventricle, that inhibition of central insulin action impaired insulin-mediated suppression of hepatic glucose production (HGP) during hyperinsulinemic clamp studies in rats. They also demonstrated that infusion of insulin into the cerebroventricle suppressed HGP, irrespective of circulating insulin levels. Moreover, central administration of insulin antibodies or inhibitors of the downstream signaling of insulin diminished the ability of insulin to inhibit glucose production.[97] The hypothalamic insulin signaling pathway was investigated in subsequent studies. Overexpression of the insulin signaling molecules IRS2 and Akt in the hypothalamus enhances the glucose-lowering effect of insulin in streptozotocin-induced diabetic rats.[98] These data support a role for hypothalamic insulin actions in controlling glucose metabolism in peripheral organs.

The ATP-sensitive potassium (K_{ATP}) channel mediates insulin actions in hypothalamic neurons.[99] Activation of neuronal K_{ATP} channels by ICV injection of a K_{ATP} channel activator (diazoxide) lowers glucose production,[100] whereas infusion of a K_{ATP} blocker (sulfonylurea) negates the glucose production-lowering effect of centrally and peripherally administered insulin.[96, 100] Moreover, mice lacking the sulfonylurea receptor subunit SUR1 of the K_{ATP} channel show a diminished response to central insulin action.[100] Vagal efferent fibers constitute the brain–liver axis of insulin actions because hepatic vagotomy blocks central insulin actions.[100] Interestingly, ICV infusion of insulin increases hepatic IL-6 expression, which leads to the activation of hepatic STAT3 signaling.[101] Activated STAT3 inhibits FoxO1 activity and gluconeogenic gene expression in the liver. Collectively, central insulin actions are mediated via neuronal K_{ATP} channel–vagus nerve–hepatic IL6/STAT3 signaling, although the detailed mechanisms involved remain to be determined.

29.3.3.0.2: LEPTIN

Leptin has an important role in the control of glucose metabolism. A lack of leptin (*ob/ob* mice) or its functional receptor (*db/db* mice) leads not only to obesity, but also metabolic derangement, including insulin resistance and diabetes.[102] Leptin treatment of *ob/ob* mice improves glucose homeostasis.[103, 104] Notably, acute leptin treatment via both systemic and central routes in *ob/ob* mice restores glucose metabolism independently of changes in food intake and adiposity.[105, 106] Consistently, leptin-treated *ob/ob* mice display a marked reduction in serum glucose and insulin concentrations.[107] Leptin treatment in lipodystrophy mice improves insulin resistance and hyperglycemia independently of food intake.[108, 109] Thus, leptin regulates glucose homeostasis independently of its anorectic effects.

The hypothalamus is a key site of action of leptin-mediated control of glucose metabolism. ICV administration of leptin in the lipodystrophy mice model corrects insulin resistance and improves impaired insulin signaling in the liver. In contrast, peripheral injection of the same dose of leptin did not have a similar effect.[110] Acute ICV injection of leptin suppresses glycogenolysis and reduces hepatic insulin resistance induced by high-fat feeding.[111] Restoration of leptin signaling in the unilateral ARC by viral gene therapy in leptin receptor-null mice markedly improves hyperinsulinemia and normalizes blood glucose levels, with a mild decrease in body weight and food intake. These data demonstrate that leptin signaling in the ARC is critical for the maintenance of glucose homeostasis.[112]

Leptin-mediated regulation of glucose metabolism is mediated by hypothalamic STAT3 and PI3K signaling pathways. As in *db/db* mice, *s/s* mice with a mutated leptin receptor, which are unable to activate STAT3, exhibit severe hepatic insulin resistance.[113] Blockade of leptin-induced STAT3 activation in the hypothalamus abolishes the suppressive effect of leptin on HGP, confirming the importance of leptin-induced STAT3 signaling.[113] Conversely, hypothalamic deletion of suppressor of cytokine signaling 3, a negative regulator of STAT3 signaling, enhances leptin sensitivity and improves glucose metabolism.[114] On the other hand, reconstitution of leptin receptors in the ARC of leptin-receptor-deficient fa^k/fa^k rats improves insulin sensitivity, which is attenuated by ICV infusion of PI3K inhibitor. Consistently, ARC expression of constitutively active Aktin fa^k/fa^k rats mimics the effect of restored hypothalamic leptin signaling.[115] These findings indicate that PI3K–Akt signaling mediates leptin actions on glucose homeostasis.

29.3.3.0.3: GLUCOSE

Glucose sensing in the hypothalamus is important in glucose homeostasis. Injection of 2-deoxy-D-glucose into the VMH increases plasma glucose levels by elevating plasma glucagon and catecholamine levels.[116] Conversely, intra-VMH glucose infusion suppresses counter-regulatory hormonal responses to hypoglycemia.[90] The brain stem is also involved in glucoprivic feeding and counter-regulatory hormone secretion during hypoglycemia. Injection of another glucose anti-metabolite, 5-thio-D-glucose, into the NTS and the basolateral medulla, which contain A1/C1 catecholaminergic neurons projecting to the hypothalamic PVN and ARC, induces feeding and glucose responses, as seen in hypoglycemia.[117] Similarly, destruction of hindbrain catecholaminergic neurons by immunotoxins blocks 2-deoxy-D-glucose-induced feeding and blood glucose responses.[118]

The glucose-sensing mechanisms in hypothalamic neurons are similar to those in pancreatic β-cells.[119] Glucose signaling in glucose-excited neurons requires glucose uptake via the type 2 glucose transporter, which is followed by glucose phosphorylation by glucokinase, intramitochondrial glucose oxidation, and an increased cellular ATP/ADP ratio. This leads to the closure of ATP-sensitive K_{ATP} channels, depolarization of the membrane potential, and influx of Ca^{2+} through voltage-dependent calcium channels, which stimulate neuronal activity and neurotransmitter release.[120] The role of hypothalamic type 2 glucose transporter, glucokinase and K_{ATP} channels in sensing hypoglycemia and counter-regulatory hormone responses has been demonstrated.[121, 122, 123, 124, 125, 126] How glucose inhibits neuronal activity in glucose-inhibited neurons is unclear. One possibility is that glucose increases the ATP/ADP ratio, which stimulates the Na^+/K^+-ATPase pump and triggers hyperpolarizing currents.[127] Alternatively, glucose-induced activation of ATP-dependent Cl^- channels may induce hyperpolarization of the plasma membrane.[91, 128]

AMPK functions as a ‘fuel gauge’ that monitors cellular energy status and provokes adaptive responses to maintain cellular energy levels[129, 130]. ICV administration of glucose suppresses feeding via inhibition of hypothalamic AMPK activity.[131, 132] Hypothalamic AMPK activation is critical for feeding and counter-regulatory responses to hypoglycemia.[131] Intra-VMH administration of AICAR (5-aminoimidazole-4-carboxamide ribonucleotide), a chemical AMPK activator, increases HGP without changing the plasma levels of counter-regulatory hormones.[133] AMPK activation in the VMH restores reduced counter-regulatory responses induced by repeated hypoglycemia.[134] Consistent with these findings, inhibition of hypothalamic AMPK activity attenuates the counter-regulatory response during hypoglycemia.[135]

29.3.3.0.4: FATTY ACIDS

LCFA signals nutrient availability to the brain and modulates peripheral glucose metabolism.[70] ICV administration of oleic acid suppresses HGP during basal insulin clamping. ICV administration of K_{ATP} channel blocker attenuates the inhibitory effect of oleic acid on glucose production, indicating an involvement of brain K_{ATP} channels in this process.[70] Increased LCFA-CoA levels in hypothalamic neurons suppresses endogenous glucose production.[74] Pharmacological inhibition of hypothalamic esterification of fatty acids or surgical resection of the hepatic branch of the vagus nerve increases HGP.[136] Therefore, hypothalamic lipid sensing regulates glucose homeostasis via a mechanism involving the esterification of LCFAs to LCFA-CoAs, intact K_{ATP} channels and vagal outflow to the liver.

29.3.3.1: EFFECTOR PATHWAYS IN THE BRAIN CONTROL OF GLUCOSE METABOLISM

29.3.3.0.1: TO THE LIVER

In rodents, direct action of insulin on the liver is necessary, but is insufficient to inhibit HGP, unless the indirect brain pathway is not fully functional. Restoration of insulin receptor expression in either the liver or brain of insulin receptor-null mice does not completely restore the ability of insulin to inhibit HGP.[137] In contrast, restoration of insulin receptor expression in both the brain and liver normalizes insulin actions on HGP.[138] Whether neuronal control of HGP is unique to rodents remains uncertain. ICV insulin infusion in the dog augments hepatic glucose uptake and glycogen synthesis without altering HGP,[139] indicating that the regulation of gluconeogenesis by brain insulin signaling may differ among species. The basal HGP rate per weight is almost 5–10 times higher in rodents than in dogs and humans.[140] Dogs and humans maintain hepatic glycogen storage even after a 42-h fasting.[141, 142] In contrast, hepatic glycogen content is significantly depleted in rodents after a relatively short fast, which may be due to higher metabolic rates.[143] Therefore, the contribution of the gluconeogenic pathway to HGP may be greater in rodents than in animals with a larger body size.[139] Thus, changes in gluconeogenesis may be more easily detected in rodents.

29.3.3.0.2: TO THE SKELETAL MUSCLE

Electrical stimulation of VMH neurons and local injection of leptin into the VMH increases glucose uptake in the skeletal muscle of rats independently of circulating insulin levels.[144, 145] These effects appears to be mediated by the sympathetic nervous system as they are abolished by blockade of the sympathetic nervous system.[146, 147] Consistently, central infusion of leptin improves glucose tolerance and enhances insulin-stimulated Akt phosphorylation in skeletal muscle.[148, 149] Activated Akt leads to translocation of the glucose transporter GLUT4 from its sequestered cytoplasmic location to the cell membrane, facilitating glucose uptake[150].

In the skeletal muscle, AMPK activation is induced by muscle contraction and adrenergic agonist and mediates insulin-independent glucose uptake.[151] Leptin activates skeletal muscle AMPK through the hypothalamus and sympathetic nervous system.[152] Therefore, leptin may promote glucose uptake to the skeletal muscle through the sympathetic nervous system–muscle AMPK signaling pathway. On the other hand, orexin-producing neurons in the LH are activated by sweet foods. Orexin regulates skeletal muscle glucose uptake through VMH neurons expressing orexin receptors and the sympathetic nervous system.[153]

29.3.3.0.3: TO THE PANCREAS

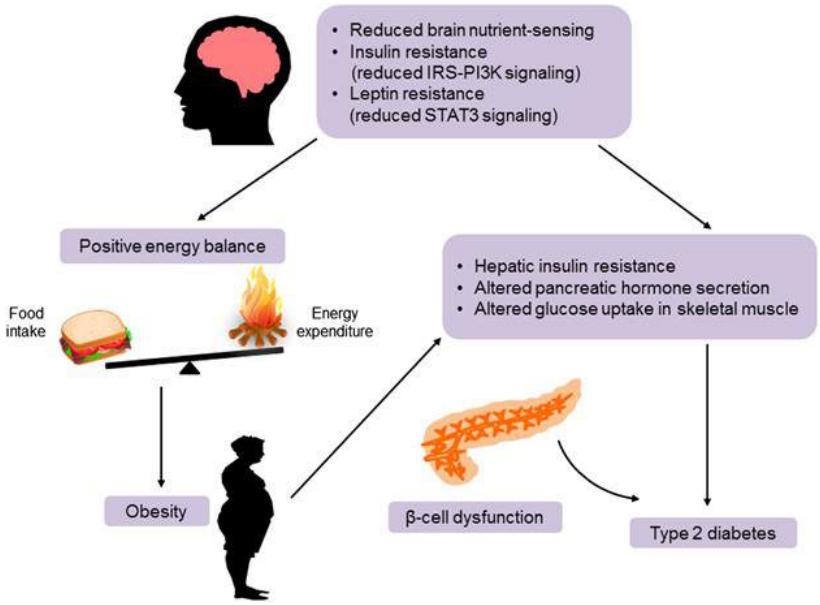
The autonomic nervous system controls the secretion of insulin and glucagon in the pancreas. Sympathetic and parasympathetic nerve endings are foundin pancreatic islets.[154] Moreover, α- and β-cells express neurotransmitter receptors.[155] Both sympathetic and parasympathetic nerve branches can stimulate glucagon secretion. In contrast, parasympathetic branches stimulate insulin secretion, whereas sympathetic branches inhibit it.[156] Neurons in the dorsal motor nucleus of the vagus project nerve terminals to the pancreatic ganglions via the vagus nerve, and thus vagus nerves connect the dorsal motor nucleus of the vagus and endocrine pancreas.[157]

Insulin regulates whole-body glucose metabolism by acting on the brain, and modulating insulin and glucagon secretion. ICV administration of insulin increases pancreatic insulin output, demonstrating that pancreatic β-cells are influenced by insulin-sensitive cells of the brain.[158] Moreover, insulin injection into the VMH inhibits glucagon secretion by pancreatic α-cells, indicating that insulin controls glucagon secretion via brain-mediated mechanisms.[159] Taken together, the brain, especially the hypothalamus and brain stem, modulates pancreatic insulin and glucagon secretion via the parasympathetic and sympathetic efferent nerves that innervate pancreatic α- and β-cells.[160]

29.3.4: DYSREGULATION OF ENERGY/GLUCOSE METABOLISM IN OBESITY AND DIABETES

In healthy conditions, energy intake matches energy expenditure to maintain normal body weight. Impaired ability of the brain to maintain energy homeostasis may underlie pathological weight gain and obesity (Figure 3). Several defects in the negative-feedback pathway in energy homeostatic mechanisms have been suggested.[3] Defects in the secretion of key metabolic hormones such as insulin and leptin may predispose weight gain. Because leptin primarily acts on hypothalamic neurons to regulate the energy balance, leptin transfer to the brain may be critical for its action.[5] Leptin concentrations in the plasma increase in proportion to body mass index, an indicator of fat mass. However, the increase in leptin concentrations in the cerebrospinal fluid of obese individuals is less than that of plasma leptin concentrations.[161] Therefore, reduced leptin transport to the brain may be due to reduced action of leptin in obesity.

Figure 3



Pathogenesis of obesity and type 2 diabetes due to defective central regulation of energy and glucose homeostasis. Reduced nutrient sensing and impaired insulin and leptin signaling in the hypothalamus may result in a positive energy balance and predispose weight gain, causing insulin resistance in peripheral metabolic organs. Obesity-associated insulin resistance may lead to type 2 diabetes when it is combined with β-cell dysfunction. IRS, insulin receptor substrate; PI3K, phosphatidylinositol 3 kinase; STAT3, signal transducer and activator of transcription 3.

Full size image

Defective hypothalamic sensing of these hormones favors a positive energy balance because loss of leptin receptors in the hypothalamus leads to obesity in mice.[13] Rats with diet-induced obesity have reduced expressions of leptin receptors in the hypothalamus.[162] Impaired postreceptor signaling in hypothalamic neurons may also result in pathological weight gain. Disruption of the hypothalamic IRS–PI3K signaling pathway causes resistance to peripheral metabolic signals and leads to obesity.[163] Likewise, mice with disrupted neuronal STAT3 signaling develop hyperphagia and obesity.[164]

In rodents, long-term high-fat feeding reduces the anorectic response and hypothalamic STAT3 activation induced by leptin, which is called leptin resistance.[165] Increased hypothalamic expression of suppressor of cytokine signaling 3 has been suggested to be a mechanism of hypothalamic leptin resistance. Ablation of suppressor of cytokine signaling 3 expression in neurons mitigates high-fat diet-induced weight gain and hyperleptinemia and improves glucose tolerance and insulin sensitivity.[166] Protein-tyrosine phosphatase 1B, a well-known negative regulator of insulin and leptin signaling,[167, 168] has also been suggested to cause leptin and insulin resistance in hypothalamic neurons. Neuronal Protein-tyrosine phosphatase 1B knockout mice are hypersensitive to exogenous leptin and insulin, and display improved glucose tolerance during chronic high-fat feeding.[169] Increased IKKβ-NFκB and endoplasmic stress have been found in the hypothalamus of obese rodents and shown to disrupt hypothalamic leptin and insulin signaling.[170, 171] However, a recent paper has shown, using a leptin receptor antagonist, that endogenous leptin signaling and actions in high-fat diet-fed obese mice treated are comparable to those of chow diet-fed mice, arguing against the concept of leptin resistance.[172] Thus, further studies are needed to clarify the issue of leptin resistance in obese humans and animals.

Diabetes mellitus is a metabolic disorder characterized by hyperglycemia that affects ~9% of adults worldwide.[173] It results from deficits in pancreatic insulin secretion and insulin signaling/actions in insulin target organs. Experimental evidence suggests that defective metabolic sensing in hypothalamic neurons may lead to dysregulation of glucose homeostasis and diabetes (Figure 3). Hypothalamic insulin–PI3K signaling is markedly impaired in rats with streptozotocin-induced diabetes.[98] Pharmacological inhibition of hypothalamic PI3K signaling attenuates the glucose-lowering effect of insulin. Conversely, enhanced hypothalamic PI3K signaling via adenoviral gene therapy potentiates insulin-induced glucose lowering.[98] Notably, central insulin actions are blunted by short-term high-fat diet feeding.[174] Thus, a fat-rich diet may contribute to the development of diabetes by disrupting insulin signaling in the hypothalamus.[174]

29.3.5: CONCLUDING REMARKS

This review highlights the role of the brain in the homeostatic regulation of energy and glucose metabolism. The brain detects energy intake by sensing gut hormones released in response to food intake and detecting nutrients in circulating blood. The brain also monitors body energy stores by sensing adiposity-related signals. Information on nutrient availability and stored fat is transferred to specialized neurons in the hypothalamus and brain stem. In the control of the energy balance, outflow pathways from the brain regulate food intake and energy expenditure (thermogenesis or locomotor activity).

The brain also has an important role in the maintenance of glucose homeostasis, which is achieved by the modulation of insulin/glucagon secretion in the endocrine pancreas, HGP, and skeletal muscle glucose uptake. The autonomic nervous system constitutes the outflow pathways from the brain to peripheral metabolic organs. Defective crosstalk between the brain and peripheral metabolic organs observed in the obese condition may lead to type 2 diabetes development and obesity progression. Therefore, better understanding of neural mechanisms involved in the regulation of glucose/energy homeostasis will provide us with the opportunity to develop new therapeutics combating obesity and diabetes.

29.4.0.1: ABSTRACT

Skeletal muscle is recognized as vital to physical movement, posture, and breathing. In a less known but critically important role, muscle influences energy and protein metabolism throughout the body. Muscle is a primary site for glucose uptake and storage, and it is also a reservoir of amino acids stored as protein. Amino acids are released when supplies are needed elsewhere in the body. These conditions occur with acute and chronic diseases, which decrease dietary intake while increasing metabolic needs. Such metabolic shifts lead to the muscle loss associated with sarcopenia and cachexia, resulting in a variety of adverse health and economic consequences. With loss of skeletal muscle, protein and energy availability is lowered throughout the body. Muscle loss is associated with delayed recovery from illness, slowed wound healing, reduced resting metabolic rate, physical disability, poorer quality of life, and higher health care costs. These adverse effects can be combatted with exercise and nutrition. Studies suggest dietary protein and leucine or its metabolite β-hydroxy β-methylbutyrate (HMB) can improve muscle function, in turn improving functional performance. Considerable evidence shows that use of high-protein oral nutritional supplements (ONS) can help maintain and rebuild muscle mass and strength. We review muscle structure, function, and role in energy and protein balance. We discuss how disease- and age-related malnutrition hamper muscle accretion, ultimately causing whole-body deterioration. Finally, we describe how specialized nutrition and exercise can restore muscle mass, strength, and function, and ultimately reverse the negative health and economic outcomes associated with muscle loss.

ONS

Skeletal muscle is integral to physical movement, posture, and vital actions, such as chewing, swallowing, and breathing.[1, 2] Skeletal muscle also serves as a regulator of interorgan crosstalk for energy and protein metabolism throughout the body, a less recognized but critically important role. As such, skeletal muscle is a key site for glucose uptake and storage.[3] Skeletal muscle is likewise a reservoir of amino acids that can support protein synthesis or energy production elsewhere in the body when other sources are depleted.[4]

This review of muscle metabolism describes how amino acids stored as protein in muscle can be broken down through proteolysis for ultimate use in energy production. Such breakdown occurs when energy demands are high (as with stress-induced hypermetabolism), or when supplies are low (as in severe starvation or longer-term protein energy malnutrition). Both of these states can be hallmarks of many diseases, either directly as a result of disease-related dysregulation of metabolism (such as in the extreme case of cancer-cachexia) or, more subtly, as a result of the general illness-associated loss of appetite. Muscle is therefore crucially important during illness, both for its role in balancing the metabolic needs of other organs and for its reserves of protein for use in energy production. Yet, during illness, the maintenance of muscle mass through exercise and nutrition are often overlooked or difficult to address, and muscle atrophy develops. Even more subtle is aging-related muscle loss, which can dramatically increase morbidity and mortality of otherwise survivable illnesses in the aged. This review also illustrates the consequences of muscle atrophy in aging and illness and proposes steps to combat these challenges.

29.4.0.1: MUSCLE BASICS

29.4.0.0.1: MUSCLE STRUCTURE AND CLASSIFICATION

Skeletal muscle comprises the fibrillar proteins myosin (a thick filament) and actin (a thin filament) that interact to cause muscle contraction, a process requiring energy in the form of adenosine triphosphate (ATP). Different muscle types have been classified according to histochemical features, structural protein composition, and major metabolic properties.[5, 6] Most commonly, skeletal muscles are referred to as either “slow” or “fast” to reflect speeds of contraction, or the shortening of myosin heavy chain (MHC) protein.[6] The velocity of this shortening is dependent on the MHC isoform present; “fast” fiber isoforms MHCIIa and IIb demonstrate a higher shortening velocity than their “slow” fiber MHCI counterparts.[6, 7] Classic histochemical staining methods also classify muscle as type I (slow) and type II (fast) based on the myosin ATPase enzyme forms revealed. Recently, these types have been further distinguished based on histology (types I, IC, IIC, IIAC, IIA, IIAB, and IIB).[6]

29.4.0.0.2: MUSCLE METABOLISM AND INTERORGAN CROSSTALK

Glucose regulation is central to energy balance both within muscle fibers and throughout the body. In the cytoplasm of most cells, glucose undergoes glycolysis to produce the substrate for ATP generation. Muscle fibers are also characterized on the basis of the speed and manner in which they metabolize glucose. The terms “fast” and “slow” can indicate the type of glucose metabolism occurring within the fiber. Slow muscles, which use aerobic metabolism, contain a high density of capillaries and oxidative enzymes that allow a greater resistance to fatigue.[7] Fast muscles, which depend on anaerobic metabolism, or glycolysis, can quickly generate ATP and therefore contract more readily. Fast muscles also fatigue sooner than slow fibers, as the conversion of glucose to pyruvate generates less ATP than can be generated by using the rest of central metabolism, ultimately generating CO_2.

Muscle has the ability to store glucose in the form of glycogen, which facilitates the rapid initiation of energy production for contraction even when glucose is not readily available from the diet. This unique capacity, shared also by the liver and kidneys, makes skeletal muscle an important metabolic organ that helps all organs have access to essential energy substrates during fasting. Furthermore, the amino acids stored in muscle as protein can be broken down as a last resort during times of starvation or extreme energy shortfalls.[4] Patterns of glucose utilization throughout the body as a whole reflect feeding status (Figure 1; Table 1). Based on a classic study of the fed state (measurement within 3 hours of eating), researchers estimated that 25% to 35% of an ingested carbohydrate load was quickly extracted from circulation and stored by the liver.[3] Of the remaining glucose, approximately 40% was disposed in the muscle and 10% in the kidney.[3] The brain used 15% to 20% of post-meal glucose.[3]

Fig. 1. Glucose metabolism in fed, fasted and malnourished states. A, Glucose, lipids, and amino acids from the diet circulate during the fed state for use or storage in body organs. In the fasted state, glucose is released from the muscles, kidneys, and liver for whole-body metabolism, along with lipids from adipose tissue and amino acids from the muscle. B, When glucose stores have been depleted, amino acids are provided by the muscles to support crucial bodily functions.

Table 1. Glucose Metabolism in Fasted and Fed States

Fed State	Fasted State
Diet-sourced glucose (exogenous glucose) is absorbed from the intestine to circulate in blood; glucose serves as an energy source in cells throughout the body. Cytoplasmic glucose undergoes glycolysis, in turn producing ATP.	Little or no blood glucose from dietary sources; alternative energy sources are needed for function of tissues body-wide.
Glucose is primarily taken up by muscle and liver, where it can be used for energy or stored as glycogen (Glycogen synthesis).	Glycogen stored in liver, kidney, and muscle is broken down to provide glucose as energy source (Glycogenolysis). Muscle uses glycogen-sourced glucose internally; liver and kidney can supply glucose to circulation.
Gluconeogenic substrates are stored in various organs (eg, pyruvate in liver, glycerol in fat, and amino acids in muscle).	Endogenous generation of glucose from noncarbohydrate carbon substrates, such as pyruvate, lactate, glycerol, and glucogenic amino acids (Gluconeogenesis); occurs primarily in the liver and muscle, and to a lesser extent in the kidney.

In the fasted state (after 14 to 16 h without eating), the liver provides approximately 80% of glucose that is released into circulation. About half of this glucose comes from the breakdown of stored glycogen, and the rest from the metabolism of sources other than carbohydrate or glycogen, including certain amino acids, through a process known as gluconeogenesis.[8] Interactions between muscle and liver are largely responsible for regulating carbohydrate metabolism and for achieving energy balance in normal fed and fasted states; the kidneys play a role similar to that of the liver, but to a lesser extent.3, 8 In addition, muscle tissue stores amino acids as protein, and adipose tissue serves as a depot of glycerol and fatty acids. As needed, amino acids and fatty acids can be metabolized to form acetyl coenzyme A for the tricarboxylic acid (TCA) cycle.

As glycogen stores become depleted, increasingly more glucose is produced by gluconeogenesis. Gluconeogenesis provides 70% of glucose released into the body 24 hours after eating, and 90% by 48 hours.[8] As fasting is prolonged, the kidneys contribute increasingly higher amounts of glucose from gluconeogenesis.

Ultimately, amino acids stored in skeletal muscle are metabolized when the need for gluconeogenesis substrate is greatest. Skeletal muscle houses nearly 75% of all protein in the body and constitutes an important contributor to gluconeogenesis in states of drastic depletion. Maintenance of muscle protein content depends on the balance between protein synthesis and degradation.[5] Under normal conditions, muscle protein mass gains during the fed state balance losses during the fasted state.[4] However, under severe metabolic stress generated by serious illness or injury, muscle protein can become depleted by catabolism, and this can lead to harmful functional limitations.

Skeletal muscle proteolysis can provide amino acid substrates for glucose and glycogen formation, notably glutamine and alanine. Alanine is released into circulation and reaches the liver, where it serves as an excellent substrate for gluconeogenesis. Glutamine also has a beneficial role in this process: the carbon skeleton of glutamine is a gluconeogenic precursor that can regulate gluconeogenesis independently of the insulin/glucagon ratio. Therefore, glutamine supplementation may also enhance glycogen synthesis and increase muscle glycogen stores even when insulin levels are low or when insulin resistance is present.[9]

In summary, dietary glucose is supplied by meals, and glucose is stored as glycogen in liver, kidney, and muscle for metabolic energy functions, as needed (Table 1). At times when glucose supplies are not sufficient to meet energy needs, breakdown of glycogen (glycogenolysis) occurs. When stored glucose products are no longer available, energy is released by breakdown of substrates other than glucose. In this review of muscle metabolism, we emphasize that amino acids stored as protein in muscle can be broken down by way of gluconeogenesis, ultimately entering the TCA cycle for energy production. Such breakdown occurs when energy demands are high, as with stress-induced hypermetabolism of disease, or when supplies are low, as in severe starvation or disease-associated loss of appetite. Such use can become problematic in that it reduces skeletal muscle mass and produces waste nitrogen, which requires further energy to sequester and secrete. Prolonged reliance on these processes can accelerate existing health problems and must be addressed by the health care provider.

29.4.0.1: MUSCLE PLASTICITY: CHANGES IN MUSCLE MASS, STRENGTH, AND FUNCTION

Skeletal muscle is remarkably plastic. It changes continuously in response to calorie and nutrient intake, illness, and physical stress. Changes in adult skeletal muscle also may occur as fiber-type switching, which is influenced by changes in physical activity, loading, nerve stimulation, or hormone and cytokine levels.7, 10, 11, 12

29.4.0.0.1: MECHANISMS OF MUSCLE GROWTH AND STRENGTH INCREASE

Muscle adapts positively to demands placed on it, such as the increased contractile activity associated with endurance training or the increased loading attributable to strength training. This tremendous plasticity is evident as muscle tissue accretion, specific changes within muscle, and muscle tissue breakdown.[1] Muscle growth, or hypertrophy, occurs when protein synthesis within the muscles outpaces protein degradation. This process can be positively regulated by mammalian target of rapamycin (mTOR) signaling induced by insulin after calorie ingestion, by hormones such as testosterone, and by exercise.[10]

29.4.0.0.2: MECHANISMS OF MUSCLE LOSS IN AGING, INACTIVITY, SICKNESS, AND FRAILTY

This ability of skeletal muscle to change dynamically in response to body conditions is also manifest as changes resulting from injury, illness, or aging. When the metabolic demands placed on muscle outweigh the protein synthesis that occurs from dietary intake and after exercise, muscle mass is lost, metabolic storage products are depleted, and muscle fiber balance changes.

Aging may lead to a loss of muscle mass resulting from both the shrinking of muscle fibers (atrophy) and the elimination of fibers altogether (Figure 2).[6] This condition is known as primary sarcopenia, the age-related loss of muscle mass and function. Although both fiber types I and II lose mass, aging causes preferential atrophy of type II fibers; the net change is thus from type II to type I fibers, or from fast to slow muscle fibers.[6, 13] Because fast muscle fibers mobilize ATP and create tension more readily than slow fibers, this shift can leave older adults without the energy to perform daily tasks.[14] This shift to type I slow fibers leads to a corresponding increase in their characteristic oxidative metabolism relative to the glycolytic metabolism that occurs in type II fast fibers. Exacerbating the problems caused by muscle degradation in aging, it is possible that type I oxidative fibers normally experience higher protein turnover (i. protein synthesis and degradation), are less able to grow in size, and have different responses to insufficient nutrient intake, although these fiber-type differences remain poorly understood.[7, 15, 16]

Fig. 2. Effects of aging and illness on muscle mass.

Beyond aging, muscle wasting is associated with many pathological states and chronic diseases, such as malnutrition, cancer, chronic kidney disease, chronic obstructive pulmonary disease, burns, muscular dystrophies, acquired immunodeficiency syndrome, sepsis, and immune disorders, and forced immobilization and bed rest are devastating to patients who are already challenged by these factors (Figure 2).[14, 17] Most of these pathological conditions are associated with variable degrees of local and/or systemic chronic inflammation, which plays a crucial role in the onset of muscle atrophy. Loss of muscle mass is frequently associated with increased production of proinflammatory cytokines. Systemic inflammation is associated with reduced rates of protein synthesis paralleled by enhanced protein breakdown, both accounting for the loss of muscle mass. The effects exerted by proinflammatory cytokines on muscle mass are partially mediated by activating the transcription factor nuclear factor κB (NF-κB).[18] The transcriptional activity is regulated by the phosphorylation and consequent degradation of the inhibitor Iκ-Bα, allowing the positive regulation of muscle RING-finger protein-1 (MuRF1) and other atrophy-related genes. Proinflammatory cytokines act on muscle protein metabolism not only by activating catabolic pathways, but also by downregulating the anabolic pathways.[19] Elevated tumor necrosis factor-alpha (TNF-α) and interleukin-1 (IL-1) lead to inhibition of the Akt/mTOR signal transduction pathway and a subsequent reduction in protein synthesis. The inflammatory process that takes place during trauma or fractures is controlled and finely regulated. In the short term, it can facilitate complete and efficient reconstruction of muscle fibers through the stimulation of myogenesis. However, chronic inflammation can be deleterious, driving uncontrolled muscle atrophy and affecting contraction ability. Balance between pro- and anti-inflammatory cytokines is well known to be important in regulating physiological muscle protein turnover and myogenesis, and evidence suggesting that inflammation can impair force generation in muscles is also growing.[20, 21]

As inflammation accelerates muscle catabolism, resting energy expenditure increases and amino acids are released from muscles to serve as substrates for gluconeogenesis in liver and elsewhere in the body (Table 2).[22] The efficiency of energy production is low when amino acids are used to generate energy, so muscle is at further risk for breakdown to meet needs.[23] In addition, the liver changes metabolic priorities, using amino acids to produce acute phase reactant proteins instead of normal proteins, such as serum albumin, and to support

gluconeogenesis. This process continues until the cause of stress has subsided. Thus, when the dietary proteins supplied are inadequate to meet needs, muscle protein is broken down to supply amino acids throughout the body. This reaction releases waste nitrogen, which requires further energy to convert to urea, thereby exacerbating the problem of the energy shortfall.[24]

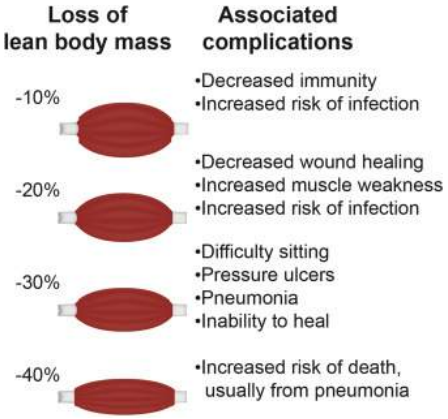
Table 2. Major Molecular Pathways Influencing Muscle Accretion

Effector	Mediator	Major Pathway(s)	Consequence
Mammalian target of rapamycin (mTOR)	+Induced by BCAAs, HMB	Interacts with protein translation machinery to facilitate initiation and elongation	mTOR stimulation by a number of pathways increases protein synthesis
Insulinlike growth factor (IGF1)	+Stimulated by meal-induced insulin	IGF1R → PI3K → AKT → mTOR	Reduced IGF1 from decreased eating and/or exercise leads to reduced protein synthesis and to muscle wasting
	+Stimulated by exercise		
Myostatin/Activin	+Produced by skeletal muscle	Activin receptors (ACTRIIA/B) → Smad2/3 –I mTOR	Myostatins negatively regulate protein synthesis
	–Inhibited by Follistatin	ACTRIIA/B → FoxO → UPS	
Inflammatory cytokines (TNFα, IL-1)	+Upregulated by illness, injury	Cytokine receptors → NFKB, p38, JAK, Caspases, E3 ligases	Inflammation leads to apoptosis or autophagy-mediated muscle cell loss
	–Inhibited by exercise	FoxO transcription factors → MAFBX; MURF1 → UPS (ubiquitin-proteasome system)	
Vitamin D	+Levels are increased by diet and sunlight	Vitamin D receptor → gene expression or repression in myogenic cells	Vitamin D positively influences muscle growth

AKT, protein kinase B; BCAA, branched-chain amino acid; FoxO, forkhead box protein O; HMB, β-Hydroxy β-Methylbutyrate; IGF1R, insulinlike growth factor 1 receptor; JAK, janus kinase; MURF1, muscle RING-finger protein-1 p38, mitogen-activated protein kinase; PI3K, phosphatidylinositide 3-kinase; UPS, ubiquitin-proteasome system.

29.4.0.0.3: COMPLICATIONS ASSOCIATED WITH LOSS OF MUSCLE

As aging and illness lead to muscle breakdown and atrophy, reduced muscle mass leaves patients without a crucial reservoir of amino acids and effector molecules, such as myokines, cytokines released by muscle, to help the body combat illness, infection, and wasting (Figure 3).[23, 25, 26, 27] Therefore, muscle atrophy is associated with a wide range of harmful health effects that can be life changing, especially for older people.[28, 29, 30, 31, 32, 33, 34, 35, 36] The most relevant condition associated with the presence of sarcopenia in this population is a clinical syndrome called frailty. The most accepted physiological framework explaining frailty and its consequences was proposed by Walston and Fried,[37] who described a relationship between sarcopenia and energy imbalance called the "frailty cycle." This cycle affects multiple systems, especially those susceptible to changes in hormones (mainly sexual hormones, IGF-1, and insulin) and the progressive development of a proinflammatory state.[38, 39, 40] Additional biomarkers have recently been identified for roles in frailty, such as those related to endothelial dysfunction or micro RNAs central to the aging process.[41, 42] Frailty can be defined as an age-associated biological syndrome characterized by a decreased biological reserve resulting from a decline in multiple physiological systems that leaves the individual at risk for developing poor outcomes (disability, death, and hospitalization) in the presence of stressors.[43, 44] The prevalence of frailty in people older than 65 is approximately 10%, increases with age, and is greater in women.[45]



1. Download : Download high-res image (273KB)
2. Download : Download full-size image

Fig. 3. Complications of lean body mass (muscle) loss.

Frailty is now a recognized clinical medical syndrome that provides a biological framework for understanding vulnerabilities resulting from aging or chronic conditions.[44, 46] It is clinically important to detect frailty in those at risk of developing disability. As aging progresses, frailty increases as the prognostic factor for death and incident disability.[47, 48] Frailty and its underlying sarcopenia have been shown to

predict risk of death, disability, and other adverse outcomes, including muscle mass atrophy, metabolic deterioration, slowed wound or postsurgical healing, and delayed recovery from illness.[32, 34, 35] Frailty and the weakness that follows muscle loss lead to higher risk of falls, fractures,[30] physical disability,[29] need for institutional care,[29] reduced quality of life,[36] and heightened mortality.[29, 33] Early identification of frailty risk provides the opportunity to provide interventions and avoid or delay disability as well as enhance recovery.

Loss of muscle associated with disease, injury, disuse, or aging significantly increases the cost of health care.[34, 49, 50] Results of a recent study showed that older adults (mean age=70 years) who were very frail spent (Euro) 1917 more on total health costs in an interval of 3 months than did those who were not frail.[51] In the United States, the direct cost of cachexia/sarcopenia to health care was reported to be 1.5% of annual total health care expenses.[50] Such costs arise from the increased rate of hospitalization, incidence of complications, lengths of stay, and likelihood of readmission.[52, 53] In the face of an aging population, the importance of identifying, preventing, and treating muscle loss cannot be overstated.

29.4.0.1: DETECTION AND TREATMENT OF MUSCLE LOSS

29.4.0.0.1: WHO IS AT RISK OF MUSCLE ATROPHY, AND HOW DO WE IDENTIFY IT?

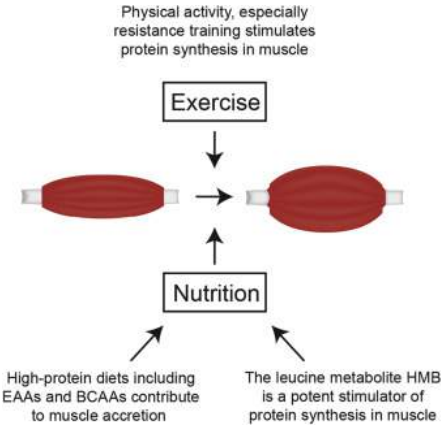
Screening is crucial for predicting risk, and proper, timely intervention can reduce or eliminate the ensuing muscle mass and metabolic atrophy, substantially affecting morbidity, mortality, and cost. Special attention should be paid to the main risk categories: people who are malnourished or at risk of malnutrition for any reason[33, 54]; frail adults, especially the very old; people who become deconditioned and lose muscle due to age- and disability-related physical inactivity[35]; those with diseases or conditions with inflammatory components, such as chronic heart failure,[55] chronic or acute kidney disease,[56] cancer,[57, 58, 59] severe infection and sepsis,[60] insulin resistance/diabetes,[61] intensive care unit–acquired weakness,[25] and wound/surgical recovery.[34]

Reaching an accurate diagnosis of age- or disease-related muscle atrophy is difficult, and a number of criteria have been proposed but have not yet assessed in the clinical setting.[14] Nonetheless, specific criteria and measures can be used to diagnose sarcopenia or cachexia.[13, 27, 62, 63] Sarcopenia can be diagnosed when a patient has muscle mass that is at least 2 SDs below the relevant population mean and also presents with a low gait (walking) speed. In addition, low muscle strength and general physical performance may be taken into consideration.[14] Cachexia can be diagnosed when at least 5% of body weight is lost within 12 months in the presence of underlying illness, and 3 of the following criteria are also met: decreased muscle strength, increased fatigue, anorexia, low fat-free mass index, abnormal biochemistry, increased inflammatory markers C-reactive protein (>5.0 mg/L) or IL-6 (>4.0 pg/mL), anemia (<12 g/dL), or low serum albumin (<3.2 g/dL).

Recent research into the molecular adaptations associated with the development of or that result from muscle atrophy and metabolic depletion may lead to the identification of biomarkers and, therefore, improvements in early detection (Table 2). A variety of signaling pathways known to positively influence muscle growth (bone morphogenetic proteins, brain-derived neurotrophic factors, follistatin, and irisin), as well as those known to negatively regulate muscle growth (transforming growth factor β, myostatin, activins, and growth and differentiation factor-15) and factors associated with muscle function and dysfunction (C-terminal agrin fragment and skeletal muscle specific troponin T) may emerge as biomarkers for muscle atrophy in aging and disease.[64] To date, there is no universally recognized biomarker for muscle atrophy, but recent research in the field suggests that the combination of several biomarkers may facilitate the adequate diagnosis of muscle atrophy. Identification of such biomarkers and their incorporation into validated testing instruments should allow early identification of muscle atrophy (improving prognosis, and likely reducing cost to health care systems), but may also provide exciting targets for the development of new medications.

29.4.0.0.2: NUTRITIONAL STRATEGIES FOR MAINTAINING AND REBUILDING MUSCLE

Treatment of patients at risk can prevent or delay onset of muscle atrophy, or even target rebuilding of muscle when muscle atrophy is already evident (Figure 4).[65] As a first step, treatment must provide adequate energy so that muscle proteins and their constituent amino acids are spared as an energy source. In addition, high protein intake is vital to treatment of muscle atrophy or for delaying its onset.[7, 66, 67, 68, 69] It should be noted that the range of protein needs can vary widely from patient to patient. Because muscle mass may decrease or remain the same (based largely on how much protein synthesis outpaces protein degradation), the most direct way to prevent muscle loss is to ensure that sufficient protein is ingested. Use of high-protein oral nutritional supplements (ONS; ≥20% of total calories as protein) may be beneficial to such patients.[70]



1. Download : Download high-res image (190KB)
2. Download : Download full-size image

Fig. 4. Treatments for sarcopenia. It is currently recommended that patients at risk of or suffering from sarcopenia consume a diet high in protein, engage in resistance exercise, and take supplements of the leucine metabolite HMB.

By definition, the essential amino acids (EAAs) play a central role in protein nutritional status. Some amino acids play roles that are distinct from the traditional one of protein building blocks; many of these have little or nothing to do with protein synthesis, and are thus not included here. However, of central importance to the current discussion are the branched-chain amino acids (BCAAs), especially leucine.65, 71, 72 BCAAs promote protein synthesis in the muscles through a number of pathways.[66] In particular, they are now known to have a key role in altering tissue response to a meal, the post-prandial response, especially in muscle, where they signal a reduction in protein breakdown and an increase in protein synthesis, resulting in net accretion of protein in muscle and helping to regulate blood amino acid levels. However, aspects of this postprandial regulation are not as robust in aged muscle, and muscle in hypercatabolic conditions, such as cancer, is challenged and its normal system is overwhelmed. In these cases, a substantial body of research suggests that significantly more of these amino acids are required in the diet to overcome resistance to protein anabolism; very high doses, such as 10 to 15 g of BCAAs, or 3 g or more of leucine per meal, have been studied to combat muscle loss in the elderly,[44] although this may be a result of improved protein synthesis that does not lead to muscle mass accretion.73, 74, 75

This resistance to the normal of BCAAs in muscle protein homeostasis has prompted studies into leucine's mechanism of action. These have identified the leucine metabolite β-hydroxy β-methylbutyrate (HMB) as a potent stimulator of protein synthesis as well as an inhibitor of protein breakdown in the extreme case of cachexia.65, 72, 76, 77, 78, 79, 80, 81, 82, 83, 84 A growing body of evidence suggests HMB may help slow, or even reverse, the muscle loss experienced in sarcopenia and improve measures of muscle strength.44, 65, 72, 76, 77, 78, 79, 80, 81, 82, 83, 84 However, dietary leucine does not provide a large amount of HMB: only a small portion, as little as 5%, of catabolized leucine is metabolized into HMB.[85] Thus, although dietary leucine itself can lead to a modest stimulation of protein synthesis by producing a small amount of HMB, direct ingestion of HMB more potently affects such signaling, resulting in demonstrable muscle mass accretion.71, 80 Indeed, a vast number of studies have found that supplementation of HMB to the diet may reverse some of the muscle loss seen in sarcopenia and in hypercatabolic disease.65, 72, 83, 86, 87 The overall treatment of muscle atrophy should include dietary supplementation with HMB, although the optimal dosage for each condition is still under investigation.[68]

In addition to dietary protein, EAAs/BCAAs including leucine, the leucine metabolite HMB, a number of other dietary or supplemental components have been explored for their ability to positively influence muscle mass during sarcopenia. These include creatine monohydrate, a variety of antioxidants, ornithine α-ketoglutarate, omega-3 fatty acids, ursolic acid, and nitrates.68, 88, 89, 90 Given the length of this list, its growing nature, and the difficulty many aged individuals experience ingesting proper calories and nutrients, additional studies will be needed to determine which components are most beneficial to maintaining muscle mass, as well as their optimal doses and administration routes both in isolation and in combination.

29.4.0.0.3: PHYSICAL ACTIVITY IS ALSO KEY

Nutrition is important and can counteract metabolic alterations induced during periods of significant stress and inflammation; however, sufficient exogenous provisions of protein and energy substrates alone cannot completely eliminate or reverse the deteriorations associated with aging or the deleterious impact inadequate control and regulation of inflammation have on muscle.23, 66, 69 Protein synthesis occurs in muscle fibers following their contraction,[91] and physical activity has been shown to induce a number of anabolic signaling pathways.[92] Physical activity can likewise reduce degradation of muscle protein.93, 94 Even more, a lack of physical activity increases the resistance of muscle to anabolism, particularly the synthesis of proteins from amino acids.[95] An exercise component to muscle atrophy treatment is therefore highly recommended, and exercise also may prevent the onset of sarcopenia later in life, possibly by increasing the presence of type I fibers that are less susceptible to degradation during sarcopenia.7, 25, 66, 89 Although aerobic and other types of exercise are all

preferable to a lack of physical activity, resistance exercise in particular has been shown repeatedly to improve rates of protein synthesis and reverse muscle loss.[88, 89, 94] This may be attributable to differential effects on muscle fiber types.[7] It is therefore recommended that patients with muscle atrophy or at risk of developing muscle atrophy engage a regular exercise program containing both aerobic and anaerobic components, and the importance of appropriate resistance training cannot be overstated. Although this must be tailored to the individual's current physical status, it should also periodically be reviewed and increased to maximize its impact.

Although resistance exercise and general physical activity are important to the stimulation of protein synthesis from amino acids in the diet, some aged and ill individuals experiencing extensive muscle atrophy are likely to have difficulty engaging in physical activities because of low energy and other medical complications. Nutrition and some supplements can be used to bolster results of exercise, both preventively and during sarcopenia. For example, bioactive substances known as nutraceuticals that mimic the molecular effects of exercise can induce signaling pathways that are thought to support or even underlie exercise's effects on health and muscle mass accretion. Found in a variety of foods, including some common fruits, green tea, and even red wine, these compounds can be isolated and added to nutritional supplements used in the treatment of muscle atrophy.[44]

29.4.0.1: SUMMARY AND CONCLUSIONS

The classic physical functions of skeletal muscle are well known, but skeletal muscle is increasingly recognized as a one of the key regulators of energy and protein metabolism by way of metabolic crosstalk between body organs. Skeletal muscle is the primary site for glucose uptake and storage, and it is likewise a reservoir of amino acids that sustain protein synthesis in all other body sites. When dietary glucose intake decreases or metabolic needs increase, stored glucose is mobilized from liver, while energy is released from fat depots. When these energy supplies are depleted, the muscle reservoir of amino acids stores is tapped, and muscle proteins are broken down to provide amino acids for gluconeogenesis, thereby supplying energy to other parts of the body.

Undernutrition and resultant muscle loss (muscle atrophy), as associated with aging and disease, can lead to adverse health and economic consequences. Conditions and diseases that lower dietary intake and increase nutrient needs are associated with catabolism of skeletal muscle, which in turn limits availability of protein and energy throughout the body. Loss of muscle mass, strength, and function has adverse consequences: slowed wound healing and recovery from illness, physical disability (due both to overall reduction of muscle status), as well as selective losses in type I fibers, which are essential for balance recovery (and thus fall prevention), poorer quality of life, and higher health care costs.

Nutrition and exercise are key to growth and maintenance of muscle promoting overall health, well-being, and recovery from disease. A wealth of research underscores the importance of a few key dietary components: protein (EAAs/BCAAs in particular), and the leucine metabolite HMB. Others will very likely be added to this list as our knowledge base grows. In addition, physical activity, especially resistance strength training, is essential to the treatment of muscle atrophy. Others will very likely be added to this list as our knowledge base grows. Considerable evidence shows that ONS and enteral feeding formulations can help maintain and rebuild muscle mass and strength. Further studies are needed to show support for functional outcomes, such as ability to perform activities of daily living and maintain or restore independence.

29.4.0.1: ACKNOWLEDGMENTS

The authors thank Jeffrey H. Baxter and Abby Sauer from ANR&D for their critical review of this article, as well as Cecilia Hofmann, PhD, and Hilary North Scheler, PhD (C Hofmann & Associates, Western Springs, IL), for valuable assistance with efficient compilation of the medical literature and with editing this English-language review article.

29.5: INTESTINAL FRUCTOSE AND GLUCOSE METABOLISM IN HEALTH AND DISEASE

Merino, B.; Fernández-Díaz, C.M.; Cózar-Castellano, I.; Perdomo, G. Intestinal Fructose and Glucose Metabolism in Health and Disease. *Nutrients* **2020**, *12*, 94. https://doi.org/10.3390/nu12010094

29.5.1: ABSTRACT

The worldwide epidemics of obesity and diabetes have been linked to increased sugar consumption in humans. Here, we review fructose and glucose metabolism, as well as potential molecular mechanisms by which excessive sugar consumption is associated to metabolic diseases and insulin resistance in humans. To this end, we focus on understanding molecular and cellular mechanisms of fructose and glucose transport and sensing in the intestine, the intracellular signaling effects of dietary sugar metabolism, and its impact on glucose homeostasis in health and disease. Finally, the peripheral and central effects of dietary sugars on the gut–brain axis will be reviewed.

Keywords: **fructose**; **glucose**; **small intestine**; **liver**; **brain**; **gut-brain axis**; **non-alcoholic fatty liver**; **insulin resistance**; **metabolic syndrome**; **type 2 diabetes mellitus**

29.5.2: 1. INTRODUCTION

According to the World Health Organization, obesity is the epidemic of the 21th century. About 13% of the world's adult population is obese [1]. Worldwide, between 1975–2016, the global obesity rate was nearly triplicated, increasing from 1% up to 6%–8% among children and adolescents [1]. As a major public health issue, clinical interventions based on low-fat diets attracted significant interest. However, over decades, the consumption of sugars has risen significatively worldwide, and has been partially associated to the rapid increase in the prevalence of obesity [2].

From the Industrial Revolution, the consumption of sweeteners has increased dramatically, causing a dietary switch in the world population [3]. Most of this increase in sugar consumption is derived from refined or processed fructose, which is obtained from the conversion of glucose from sugar cane and corn through a chemical process developed in 1957 [4,5]. Fructose constitutes a significant portion of the caloric intake in many countries [3]. The average daily consumption of added sugars (13%–17% of daily energy intake), of which about half is fructose, is above the recommended limit of 10% in many countries [6]. Of note, 16% of total energy in children's diets comes from added sugars [7]. The increase in total fructose intake parallels a decrease in the proportion of dietary fructose coming from fruits, but augmented proportion from fructose-based sweeteners [3]. In the past, fructose was considered sweeter, more soluble, and less gluconeogenic than glucose and sucrose, and was proposed as a substitute for these sugars [8]. Over time, this idea has been reconsidered in view of the impact of high-fructose consumption on whole-body metabolism, and because it is a risk factor for developing obesity and diabetes [9,10,11].

Although fructose and glucose share the same molecular formula ($C_6H_{12}O_6$) and caloric value (4 kcal/g), fructose tastes sweeter than glucose (relative to sucrose, which by consensus agreement is equal to one; the sweetness of glucose is 0.75, and fructose is 1.7), and has a lower glycemic index than glucose (23 versus 100, respectively) [12]. In addition, fructose is less satiating than glucose, increasing food intake [13]. As reviewed in detail below, intestinal fructose and glucose absorption are also quite different, because glucose transport is an energy-requiring process mediated by the sodium-glucose co-transporter 1 (SLGT1), whereas fructose moves through a facilitated passive transport mediated by GLUT5 [14]. Furthermore, fructose metabolism has a negligible impact on circulating insulin levels compared to glucose metabolism, which is related to insufficient leptin (the satiety hormone) secretion, and suppression of ghrelin (the hunger-promoting hormone) [15].

29.5.3: 2. INTESTINAL FRUCTOSE TRANSPORT AND METABOLISM: IMPLICATIONS FOR HEALTH AND DISEASE

Whole body fructose homeostasis results from two main processes: Intestinal absorption and clearance, the latter is commonly assumed to be mainly mediated by the liver (~55%–71%) and, to a lesser extent, by kidneys (<20%) [16]. Dietary fructose moves from the intestinal lumen to the circulation through a facilitated passive transport [3] across enterocyte membranes by members of the facilitative glucose transport (GLUT; Slc2a) family [14]. Upon its intestinal absorption, fructose reaches the liver through the hepatic portal vein and undergoes metabolization in hepatocytes [16]. Fructose transport and metabolism has been extensively reviewed (see refs. [3,14,17]). Exhaustive description of fructose hepatic metabolism is out of the scope of this review. Here, we briefly describe the regulation of intestinal fructose transport and transporters and its intracellular metabolism. We focus on revisiting the role of the liver and small intestine in fructose clearance, the relevance of endogenous fructose production in human diseases, and plant extract inhibitors of fructose transporters.

29.5.3.0.1: 2.1. INTESTINAL FRUCTOSE TRANSPORT

Fructose uptake into enterocytes is an insulin-independent process [18]. Among the members of the GLUT family able to transport fructose (GLUT5, GLUT8 and GLUT11), GLUT5 (*Slc2a5*) is primarily responsible for fructose uptake into the enterocyte at the apical side of the membrane, whereas GLUT2 (*Slc2a2*) moves most of fructose from the cytosol into blood vessels at the basolateral side of the enterocyte [14,19,20,21] (Figure 1). Although GLUT5 belongs to the GLUT family, it only transports fructose without the ability to transport glucose or galactose. Conversely, GLUT2 can transport glucose and galactose in addition to fructose, with an affinity (K_m) for fructose more than five-fold higher than that of GLUT5 [22,23].

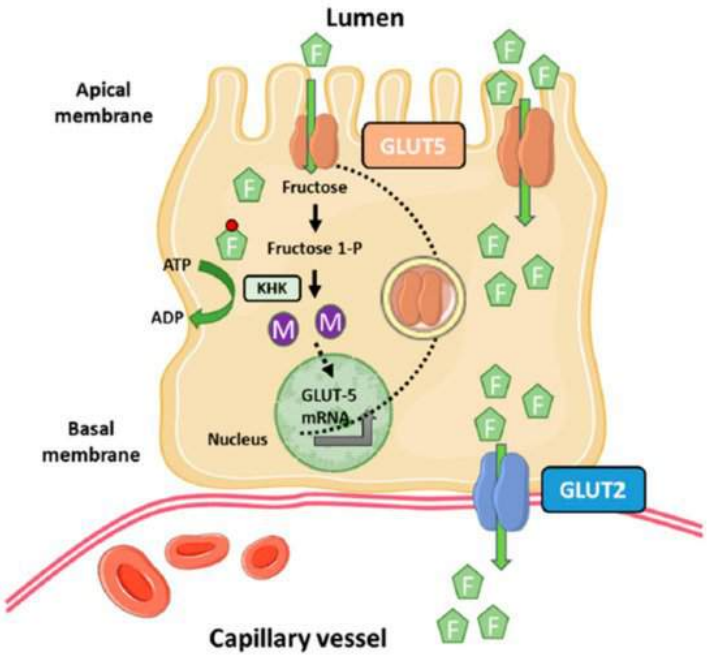

Figure 1. Fructose transport in the small intestine. Fructose (**F**) is transported by GLUT5 through the brush border membrane and enters cytosol of enterocytes, where it is rapidly phosphorylated by ketohexokinase (KHK), leading to a rapid depletion of intracellular ATP levels. A pool of phosphorylated fructose is partially or totally metabolized yielding metabolites (**M**) that induce *Slc2a5* gene expression. The remaining fructose is released across the basolateral membrane into portal circulation down the concentration gradient by GLUT2. In this conceptual model, the small intestine passively transport fructose to portal circulation and the liver is a major organ for fructose metabolism. This figure was created using Servier Medical Art (available at https://smart.servier.com/).

The main site of GLUT5 expression is the apical membrane of intestinal epithelial cells, although to a much lower extent is also expressed in kidneys, brain, fat, testes, and muscle [24]. However, the physiological relevance of GLUT5 expression in these extraintestinal human tissues is uncertain. On the other hand, GLUT2, in addition to the basolateral membranes of intestinal epithelial cells, is highly expressed in hepatocytes, pancreatic β-cells, and the basolateral membranes of kidney epithelial cells [22].

The K_m of GLUT5 for fructose varies depending on the study model and the species used for its assessment. Thus, Burant et al. reported a K_m of ~6 mM in *Xenopus* oocytes expressing the mammalian GLUT5 [19]. In contrast, Kane et al. reported a K_m of 11–15 mM using the same expression system for human GLUT5 [25]. Similar values (K_m of 11–13 mM) were found for mouse and rabbit GLUT5 transporter expressed in oocytes [26,27]. Finally, Mate et al. reported a K_m of ~8–11 mM in ileal brush border membrane vesicles of normotensive Wistar-Kyoto rats and their spontaneously hypertensive rats [28]. Assuming a K_m value ranging from 11–15 mM for GLUT5, this K_m is similar to that reported for intestinal luminal fructose concentrations (26 mM) in rats fed dietary fructose [29]. On the other hand, the K_m of GLUT2 for fructose is ~11–17 mM [22,23].

29.5.3.0.1: 2.2. DIETARY FRUCTOSE METABOLISM

High concentrations of dietary fructose in foods and drinks lead to elevated intestinal luminal fructose concentrations that are needed for driving the facilitated fructose transport across the enterocyte membrane, and fluctuate around the K_m of GLUT5 for fructose [3]. Unlike the high fructose concentration in luminal small intestine, fructose concentrations in systemic circulation are relatively low as a result of intestinal absorption and liver clearance rates. In humans, estimates of fasting systemic blood fructose concentrations are low (<0.05 mM), even in those healthy humans consuming high-fructose or sucrose diets (~0.2–0.5 mM) [30,31,32,33], which is still very low compared to fasting blood glucose levels (5.5 mM). Finally, type 1 and type 2 diabetic patients exhibited 0.016 mM and 0.009–0.013 mM fasting fructose concentrations, respectively [34,35]. The low fructose concentrations in peripheral blood support the notion that the liver and kidneys are much more sensitive to small changes in circulating fructose levels than the small intestine. Nonetheless, it is unclear how hepatocytes or nephrons reabsorb fructose from the sinusoidal capillaries or glomerular filtrates, respectively, containing very low fructose levels.

Metabolization of dietary fructose in the small intestine is a process regulated at various steps. In the first step of the classical Hers pathway for fructose metabolism, fructose is mobilized from intestinal lumen into the cytosol of enterocytes by GLUT5, where it is rapidly phosphorylated by the ketohexokinase (KHK, *Khk*), also known as fructokinase, to fructose-1-phosphate using ATP as a phosphate donor [36]. The *Khk* gene encodes two isoforms of the enzyme as a result of alternative splicing of the adjacent exons 3A and 3C of the gene leading to the KHK-A and KHK-C isoforms, respectively [37,38]. Studies of expression analysis in several human and rat tissues indicated that only one mRNA variant is expressed in each tissue [38], but the pancreas is an exception to this pattern because, although KHK-C expression predominates, some KHK-A is also expressed. The KHK-C mRNA variant is expressed at high levels in the liver, kidneys, and duodenum, and is considered more physiological than the KHK-A variant because its K_m for fructose is <1 mM [39,40]. On the other hand, KHK-A is expressed at a low level in a wide range of tissues including skeletal muscle and adipose tissue [39,40]. KHK-A K_m for fructose is 8 mM, suggesting that it poorly phosphorylates fructose at physiological concentrations and that it may have a more important role when fructose intake is excessive [41].

In the second step of the fructose pathway, fructose-1-phosphate is split into glyceraldehyde and dihydroxyacetone phosphate by aldolase B (ALDOB; *Aldob*) [16]. In the third and final step of the pathway, the triokinase (TKFC; ATP:D-glyceraldehyde 3-phosphotransferase) catalyzes the phosphorylation of glyceraldehyde by ATP to form glyceraldehyde-3-phosphate [16,36]. Both ALDOB and TKFC are highly expressed in the liver, kidneys, and small intestine, relative to other organs [42].

Unlike glycolysis, the catabolism of fructose (fructolysis) bypasses major regulatory steps of glycolysis and gluconeogenesis (i.e., phosphofructokinase and fructose-1,6-bisphosphatase), and it is not regulated by feedback inhibition [16,43]. In addition, fructolysis bypasses the glucose-6-phosphate and fructose-6-phosphate production from the pentose phosphate pathway for de novo synthesis of nucleotides and nucleic acids [44]. Thus, it is plausible that in conditions of excessive fructose consumption, KHK-mediated fructolysis leads to increased glyceraldehyde, dihydroxy-acetone-phosphate, and glyceraldehyde-3-phosphate production, which are the source of gluconeogenic and lipogenic substrates (e.g., pyruvate, lactate, acetyl-CoA, and glycerol-3-phosphate), leading to elevated rates of gluconeogenesis, glycogenesis, and/or lipogenesis. Another consequence of the fructolysis is a rapid ATP and Pi intracellular depletion [45,46].

29.5.3.0.1: 2.3. REGULATION OF GLUT5

In addition to dietary fructose catabolism, metabolism of fructose comprises its biosynthesis from glucose through the polyol pathway [16]. This two-step pathway becomes active when intracellular glucose concentrations are elevated. In the first step, glucose undergoes reduction by NADPH to sorbitol (polyol) by the rate-limiting enzyme in the pathway, the aldose reductase (AR), followed by metabolization of sorbitol into fructose by sorbitol dehydrogenase (SDH) in the presence of NAD+ as a cofactor [16].

Intestinal fructose metabolism is not only important for the metabolic fate of fructose but for the up-regulation of GLUT5, KHK, ALDOB, TKFC, fructose-1,6-bisphosphatease, and glucose-6-phosphate (**Figure 1**) [47,48]. Thus, it has been extensively shown that chronic or acute fructose exposure increases GLUT5 levels and activity in rodents and human proximal intestine regions [3,17]. The response of GLUT5 to its substrate requires partial or total metabolization of fructose because the nonmetabolizable fructose analog 3-*O*-methylfructose has a modest effect on GLUT5 expression [49], and blocking intracellular fructose metabolism in the $HKH^{-/-}$ mouse model prevents fructose up-regulation of GLUT5 [47]. Furthermore, these effects of fructose on GLUT5 expression are very specific because fructose, glucose, and nonmetabolizable glucose analogs have similar changes on GLUT2 expression in intestinal cells [49]. The molecular mechanisms underlying fructose-mediated regulation of GLUT5 in enterocytes remain incompletely understood. In rats, fructose-induced cAMP stimulates fructose uptake without affecting transcriptional regulation of *Slc2a5* [50], whereas in human Caco-2 cells, fructose increases *Slc2a5* mRNA stability mediated by the cAMP pathway [51]. On the other hand, the use of inhibitors or activators of the phosphatidylinositol 3-kinase (PI3K) and/or protein kinase B (PKB) have demonstrated that this signaling pathway mediates the fructose-induced increase in fructose transport without affecting transcriptional regulation of GLUT5 [52]. How does the PI3K/AKT signaling pathway mediate the effects of fructose on GLUT5 upregulation? It is known that Class II PI3Ks control the endocytic trafficking of transporters through the production of phosphatidylinositol 3-phosphate (PtdIns3*P*). This second messenger is required for Rab11 activation, a small GTPase of the Rab family that coordinates endosome recycling to the plasma membrane [53]. Enterocyte-specific $Rab11a^{\Delta IEC}$ ablation (Rab11a-KO mouse model) blunted fructose-induced upregulation of GLUT5 in the small intestine, most likely by impairing endosomal trafficking of the fructose transporter towards the apical membrane of the enterocyte [47].

The expression of GLUT5 in the intestine can also be regulated by the carbohydrate response element-binding protein (ChREBP), a liver glucose-responsive basic helix-loop-helix-leucine zipper transcriptional factor [54]. High fructose diet feeding increases intestinal ChREBP protein levels, accompanied by increased fructose transport (GLUT5), fructolytic (fructokinase, ALDOB, TKFC, and lactate dehydrogenase) and gluconeogenic (glucose-6-phosphatae and fructose-1,6-bisphosphatase) gene expression in mice [55]. Conversely, genetic ablation of ChREBP (ChREBP-KO mice) leads to fructose intolerance due to insufficient induction of these genes involved in fructose transport and metabolism [55,56,57,58,59]. The molecular mechanism by which fructose mediates ChREBP-induction of *Slc2a5* gene expression involves direct interaction of ChREBP with the promoter of *Slc2a5* [55] in mice, whereas ectopic co-expression of ChREBP and its heterodimer partner Max-like protein X (MLX) binds to carbohydrate response elements (ChoREs) and activates *Slc2a5* promoter in Caco-2BBE human cells [55]. Further work is required to confirm whether, similarly to glucose, fructose might regulate

ChREBP activity by posttranslational modifications such as *O*-glycosylation, phosphorylation and conformational changes in intestinal cells [57].

Another identified regulatory protein of intestinal fructose transport is the thioredoxin-interacting protein (TXNIP, *Txnip*), an arrestin-like protein that can bind to thioredoxin protein that regulates cellular metabolism and redox state [60,61]. In response to glucose, the transcriptional complex ChREBP/MLX and MondoA/MLX binds to the ChoRE on the *Txnip* promoter to induce mRNA expression [62,63]. Glucose-induced TXNIP inhibits glucose transport through interaction with GLUT1 and inducing its internalization through clathrin-coated pits, as well as reducing the expression of GLUT1, whereas energy stress leads to TXNIP degradation through phosphorylation by AMP-dependent protein kinase (AMPK), resulting in increased GLUT1 function and mRNA expression [61,64]. Dotimas et al. demonstrated that TXNIP regulates fructose absorption in the small intestine [65]. Although the precise mechanisms remains elusive, TXNIP is upregulated in response to fructose consumption and co-immunoprecipitates with GLUT2 and GLUT5. It may be possible that the link between fructose transport and TXNIP may be mediated by phosphorylation of the protein mediated by AMPK, similar to what we described above for GLUT1 [65].

The expression of GLUT5 and its activity is also regulated by early development in the intestine of mammalians (i.e., rat, rabbit, and humans). In rats, under normal conditions (suckling and weaning), intestinal fructose transport and GLUT5 mRNA levels are very low due to the fact that maternal milk is fructose-free, unless there is a precocious exposure to luminal intestine fructose signal, which in turn stimulates GLUT5 expression and activity [17]. The mechanism by which fructose increases GLUT5 expression and activity during weaning is complex and involves systemic levels of glucocorticoids, but not thyroxine [17,66,67,68]. In addition, the diurnal rhythm regulates GLUT5 mRNA and protein expression in adult rats, but this regulation is not present in neonates [69]. Independently of fructose uptake, 3–4 h before the onset of peak feeding, GLUT5 levels increase by four-fold. This diurnal rhythm is also accompanied by upregulation of GLUT2 [8].

29.5.3.0.1: 2.4. FRUCTOSE METABOLISM IN HUMAN DISEASES

Major pathways of fructose metabolism are conversion to glucose and lipids [16]. Therefore, excessive fructose intake would result in increased portal fructose concentrations that stimulates endogenous glucose production and lipid synthesis in the liver, which is associated with metabolic syndrome (MetS) [70,71,72], non-alcoholic fatty liver disease (NAFLD) [73,74,75,76,77,78,79,80,81], obesity, and type 2 diabetes mellitus (T2DM) [9,10,11,82,83,84,85,86,87,88]. Although there is mounting epidemiological and experimental evidence linking fructose consumption to metabolic diseases, the relative contribution of fructose to these human diseases remains controversial [87,89,90,91].

29.5.3.0.1: 2.5. REVISITING THE ROLE OF LIVER AND SMALL INTESTINE IN FRUCTOSE CLEARANCE

Traditionally, the liver has been considered as the main organ that metabolizes fructose before entering systemic circulation [16]. This assumption is based on the following evidences: (1) Intestinal absorption of fructose is primarily driven to the liver through portal circulation; (2) peripheral tissues, such as skeletal muscle, have low capacity for fructose metabolism; and (3) the ketohexokinase isoform KHK-C is expressed at the highest level in the liver relative to extrahepatic tissues, leading to a high capacity for fructose phosphorylation and extraction from the blood. In this way, the liver would prevent high fructose doses to spill over peripheral tissues [16].

The current notion that the liver is the main site of dietary fructose metabolism and clearance has been recently challenged by Jang et al. [92]. They used sophisticated and elegant isotopic tracing techniques and arterio-venous blood sampling to demonstrate that most ingested fructose is metabolized by the small intestine in mice. At low-doses of fructose (<0.5 g kg^{-1}), ~90% of fructose phosphorylation occurs in the jejunum, duodenum, or ileum. Most of this fructose is metabolized in the small intestine, appearing in the portal circulation as glucose and lactate (~60%), and the remaining as fructose (<20%). In contrast, high-doses of fructose (≥1 g kg^{-1}) saturate the absorption and catabolism of fructose in the small intestine, leading to fructose spill-over into the liver (>30%) and the colonic microbiota in mice [92] (**Figure 2**). This work challenges our current knowledge about the role of the small intestine in dietary fructose metabolism and spurs the notion that the small intestine shields the liver from toxic fructose exposure. However, several questions arise from this work and remain to be fully addressed: (1) A limitation of the study is regarding the dose-response to fructose, which may vary between mice and humans. Humans may saturate the capacity for fructose metabolism in the small intestine at relatively lower doses than mice. It is necessary to understand the associated dose-response pattern in humans. (2) The role of the small intestine in fructose metabolism in mice and humans may have diverged across evolution. In fact, humans have a relative shorter gut and smaller intestinal area than rodents [93]. (3) The long standing view is that the liver and kidneys are the only gluconeogenic organs in humans, but not the small intestine because it does not express glucose-6-phosphatase (G-6-Pase) [16]. This critical issue is important to translate experimental evidences from mice to humans. In this line, one study have shown the expression of G-6-Pase in the small intestine of humans [94], and another one showed some evidence of the existence of a conversion of fructose to glucose in human jejunum [95].

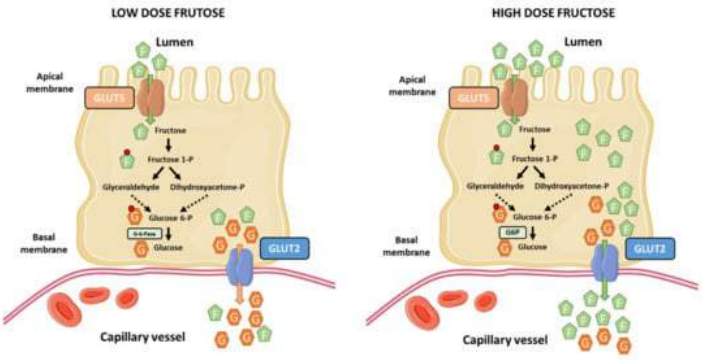

Figure 2. Current view of intestinal fructose metabolism in mice. Under conditions of low-dose dietary fructose (**F**) consumption, most of the fructose is metabolized by the Hers pathway appearing into portal circulation mainly as glucose (**G**), and the remaining as unmetabolized fructose. Conversely, under high-dose dietary fructose consumption, intestinal capacity is overwhelmed, leading to most of the fructose to spill over to the liver. Further work is needed to validate or refute this model in humans. G-6-Pase; glucose-6-phosphatase. This figure was created using Servier Medical Art.

29.5.3.0.1: 2.6. RELEVANCE OF ENDOGENOUS FRUCTOSE PRODUCTION IN HUMAN DISEASES

In addition to exogenous fructose, fructose can be synthesized from glucose through the polyol pathway [16,96], which has drawn attention on the potential role of endogenous fructose production in metabolic diseases.

The biosynthetic fructose pathway is constituted by two enzymes; the aldose reductase that converts glucose into sorbitol, and the sorbitol dehydrogenase that converts sorbitol into fructose [16]. Under physiological conditions, this pathway is mostly inactive in the majority of body tissues and organs, which has been associated to lower fasting and postprandial circulating fructose levels [97]. However, this pathway can be activated after ingestion of a drink containing glucose (~30 g) and fructose (~30 g) in healthy individuals. Tracer dilution analysis estimated endogenous fructose production ~ 55 mug kg^{-1}·min^{-1}. This work evidenced, for the first time, the capacity for endogenous fructose production in humans [97]. Further research demonstrated the presence of an active polyol pathway in tissues other than those involved in metabolizing dietary fructose, such as the human brain [98,99,100]. Numerous studies using animal models have linked the polyol pathway to metabolic alterations such as obesity, insulin resistance, diabetes, diabetic nephropathy, chronic kidney disease, acute kidney injury, blood pressure, and MetS [101,102,103,104]. Nonetheless, although the presence of an active polyol pathway has been described in humans, and mounting evidences obtained in animal models of the importance of this pathway in diseases, its significance in human metabolic diseases awaits further confirmation.

29.5.3.0.1: 2.7. PLANT EXTRACTS INHIBITORS OF FRUCTOSE TRANSPORTERS

As described above, multiple studies in humans and animal models have linked fructose consumption with diseases, which has spurred the notion of the potential use of GLUT5 inhibitors for preventing fructose-induced diseases. So far, no potent and specific inhibitors of GLUT5 have been discovered, although phloretin and cytochalasin B are used to inhibit GLUT2 for assessing fructose transport in vitro, whereas GLUT5 is insensitive to both inhibitors [22,25].

In the last decade, plant extracts have been used to screen compounds with inhibitory effects on intestinal GLUT5 transporters. Thus, green tea catechins inhibited D-fructose transport in *Xenopus laevis* oocytes expressing the mammalian GLUT5. Inhibition of D-fructose transport via GLUT5 was more efficient by catechins containing a gallate group [apparent *Ki* values between ~113 and ~117 μM for (−)-epigallocatechin-gallate and (−)-epicatechin-gallate, respectively] than by catechins lacking this group [apparent *Ki* values >500 μM for (−)-epicatechin and (−)-epigallocatechin] [105]. In this line of evidence, it has been shown that chamomile tea and green tea [containing (−)-epigallocatechin gallate (240 mg/g extract), (−)-epigallocatechin (70 mg/g extract), (−)-epicatechin (40 mg/g extract), and (+)-catechin (17 mg/g extract)] effectively inhibited fructose transport through GLUT2 in differentiated Caco-2 cells [106]. In addition, chamomile also inhibits D-fructose transport via GLUT5 in Caco-2 cells and in *Xenopus* oocytes expressing the mammalian GLUT5 [106]. Likewise, Satsu et al. demonstrated that epicatechin gallate inhibited fructose uptake in Caco-2 cells. Interestingly, this reduction in fructose uptake was not related to changes in the affinity (K_m) of GLUT5 for fructose, but with a decrease in the maximal velocity (V_{max}) [107]. Furthermore, authors demonstrated that epicatechin gallate suppressed fructose permeation in Caco-2 cells, suggesting that this compound suppressed the transepithelial transport of fructose across epithelial cell monolayers, in addition to its effect on fructose uptake. Lastly, authors reported that similar effects on fructose uptake and permeation were observed with nobiletin, another phytochemical tested in this study [107].

An additional compound extracted from the Chinese blackberry tea (rubusoside) inhibited GLUT5-mediated fructose transport in liposomes reconstituted with human GLUT5 purified from insect cells transduced with baculoviruses [18]. Likewise, astragalin-6-glucoside (a glycosylated derivative of astragalin) inhibited GLUT5-mediated fructose transport in these proteoliposomes [18]. The same group performed a virtual screening (in silico) for potential GLUT5 inhibitors using a 3D inward-facing GLUT5 model against a library of >600,000 chemicals [108]. The ability of the top ranked compounds for inhibiting GLUT5-mediated fructose transport were tested in GLUT5 proteoliposomes, identifying the N-[4-(methylsulfonyl)-2-nitrophenyl]-1,3-benzodioxol-5-amine (MSNBA) as an specific inhibitor, which did not affect the fructose transport of human GLUT2 or the glucose transport of human GLUT1-4 [108]. Additionally, whole-cell

systems for high-throughput screening of potential GLUT5 inhibitors and activators have been developed using a yeast strain deficient in fructose uptake [109].

The ability of culinary plant extracts containing phytochemicals to inhibit fructose transport has also been assessed in Caco-2 cells. Lee et al. found that demethoxycurcumin and curcumin from turmeric extracts inhibited fructose transport by GLUT2- and GLUT5-mediated fructose uptake, respectively [110]. Similarly, catechin from guava leaf (*Psidium guajava*) inhibited GLUT5-mediated fructose uptake, whereas quercetin inhibited both GLUT5- and GLUT2-mediated fructose transport [110]. In addition, the ability of guava leaf and guava fruit extracts to inhibit glucose transport have also been demonstrated by Müller et al. in Caco-2 cells and mice (C57BL/6N) [111]. The effect of these extracts on glucose uptake in Caco-2 cells were related to inhibition of GLUT2, although the effects on fructose uptake were not assessed [111]. More recently, König et al. demonstrated that fruit extracts prepared from guava inhibited intestinal glucose resorption in a clinical trial [112].

The effects of hesperidin, a flavonoid present in orange juice, on fructose uptake in Caco-2 cell monolayers was studied by Kerimi et al. [113]. They showed that hesperidin inhibited fructose uptake in these cells using fructose (130 mM) as the only source of sugars. Of note, the inhibitory effect of hesperidin on fructose uptake was abolished in the presence of other sugars, such as glucose and sucrose, at high concentrations (120 mM and 130 mM, respectively). Using *Xenopus laevis* oocytes expressing human GLUT2 or GLUT5, they gained insights into the molecular mechanisms by which hesperidin inhibited fructose transport. Thus, hesperidin inhibited the uptake of fructose by GLUT5 expressed in *Xenopus* oocytes. In addition to its effects on fructose uptake, hesperidin lowered glucose uptake in Caco-2 cells and inhibited GLUT2 and GLUT5 transporters when expressed in *Xenopus* oocytes. Lastly, in an attempt to reproduce in vivo these previously observed effects of hesperidin, authors conducted three separated human intervention studies on healthy volunteers using orange juice with different amounts of added hesperidin and a control drink containing equivalent amounts of glucose, fructose, and sucrose, and measured the postprandial glycemic response as biomarker for the effect of hesperidin. They observed that the biggest difference in postprandial blood glucose between orange juice and the control drink was when the juice was diluted [113]. The inhibitory effects of other flavonoids, such as apigenin, on fructose uptake have also been investigated by Gauer et al. in *Xenopus* oocytes. Apigenin, as well as (−)-epigallocatechin gallate, inhibited fructose uptake in oocytes expressing GLUT5 [114].

Finally, acarbose, an α-glucosidase inhibitor that improves insulin sensitivity and decreases postprandial hyperglycemia [115], does not inhibit fructose transport in human Caco-2 cells or in *Xenopus* oocytes expressing the mammalian GLUT2 and GLUT5 [106]. These results suggest that the effects of acarbose on fructose absorption would be mediated by its well-known effects on attenuating sucrose digestion [116], rather than direct effects on fructose transport across the intestinal epithelium.

29.5.4: 3. INTESTINAL GLUCOSE TRANSPORT AND METABOLISM: IMPLICATIONS FOR HEALTH AND DISEASE

Glucose is the main catabolic and anabolic substrate for the great majority of complex organs that controls energy homeostasis in the body. Glucose homeostasis is the result of three physiological events: Intestinal glucose absorption in the post-prandial state, hepatic glucose production (which accounts for ~90% of endogenous glucose production and is the net balance between gluconeogenesis, glycogenolysis, glycogen synthesis, glycolysis, and other pathways), and extrahepatic glucose usage, mainly by the brain, the skeletal muscle, and the adipose tissue. Glucose controls hormonal secretion in endocrine pancreas (i.e., insulin, glucagon, and somatostatin) [117,118,119] and neuronal signaling involved in glucose homeostasis, feeding regulation, and energy expenditure [120].

29.5.4.0.1: 3.1. INTESTINAL GLUCOSE TRANSPORT.

Gastric emptying and intestinal glucose absorption determine the glucose appearance rate in the bloodstream after a meal. Intestinal enterocytes are polarized cells responsible for glucose uptake from the intestinal lumen to capillary blood vessels, which is the main mechanism of glucose entrance into the body. Enterocytes express two glucose transporters named sodium-glucose co-transporter 1 (SGLT1; expressed in the brush border membrane) and GLUT2 (localized in the basolateral membrane). SGLT1 couples the transport of one glucose molecule and two sodium ions, which provides the energy to drive glucose accumulation in the enterocyte against its concentration gradient due to the energy stored in the sodium electrochemical potential gradient across the brush border membrane generated by the sodium transport. Sodium is then transported out into the blood vessels by the Na^+/K^+-ATPase in the basolateral membrane, maintaining the driving force to transport glucose. As a result, glucose accumulates within the enterocyte and diffuse out of the cell through GLUT2 into the blood stream. This process is ATP-dependent [121,122] (**Figure 3**).

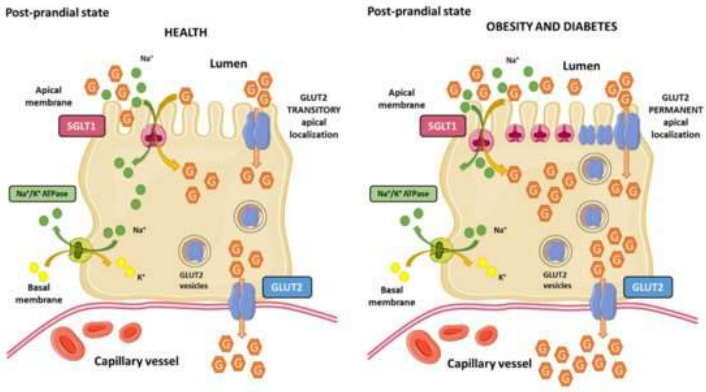

Figure 3. Glucose transport in enterocytes in health and disease. (**Left panel**): After a meal, luminal glucose (**G**) is transported across the apical membrane by SGLT1, and the Na^+ is then transported out the enterocyte through the basolateral membrane by the Na^+/K^+-ATPase. Glucose is phosphorylated and accumulates within the cell. Dephosphorylated glucose passively is transported out of the cell through the basolateral membrane by GLUT2. Alternatively, in response to high glucose luminal concentrations, a pool of endosomal GLUT2 is rapidly and transiently translocated to the apical membrane leading to increased glucose uptake. (**Right panel**): In the setting of obesity and/or diabetes, insulin resistance provokes the loss of GLUT2 trafficking control leading to a permanent localization of GLUT2 in the apical and/or endosomal enterocyte membranes and to increased transepithelial glucose transport from lumen to blood circulation. This figure was created using Servier Medical Art.

Intestinal SGLT1 is a high-affinity (K_m ~0.4 mM), low-capacity transporter able to transport glucose or galactose. It is a monomeric integral membrane protein embedded in the lipid bilayer composed by 664 amino acids with 14 transmembrane-spanning regions and it has one glucose binding-site and two sodium binding-sites in the center of the protein. In humans, SGLT1 is encoded by the *Slc5a1* gene, and it is highly expressed in the duodenum and skeletal muscle [123,124]. SGLT1 activity varies diurnally to meet fluctuating availability of glucose. The maximal transport capacity occurs when food is anticipated, and it could be regulated by clock genes [125,126].

After energy-dependent glucose uptake via SGLT1, glucose exits the enterocyte passively through GLUT2 located in basolateral membrane. Intestinal GLUT2 is a facilitative glucose uniporter with low glucose affinity (K_m ~17 mM), but high transport capacity, located in basolateral membrane of the enterocytes. GLUT2 can also transport galactose, mannose, and fructose (with low affinity), and glucosamine with high affinity (K_m ~ 0.8 mM) [127].

29.5.4.0.1: 3.2. REGULATION OF SGLT1 AND GLUT2

SGLT1 expression in the intestinal lumen is regulated by dietary carbohydrate content. Thus, luminal glucose, but not intravenous administration of glucose, increases intestinal SGLT1 expression. High-diet glucose feeding increases SGLT1 expression and activity (rat, mouse, and sheep), which is accompanied by increased glucose transport. Similarly, obese mice exhibit increased intestinal glucose transport mediated by augmented SGLT1 transporters, without increased activity [128,129,130,131,132].

In addition to glucose-mediated regulation of SGLT1, phosphorylation by protein kinase A (PKA) and protein kinase C (PKC) regulates its activity. In humans, SGLT1 contains one consensus site for regulation by PKA and five consensus sites for PKC. The number of consensus sites and conserved sequences varies between species (rat, rabbit, and humans) [133,134]. In Chinese hamster ovary (CHO) cells overexpressing human SGLT1, activation of PKA increased the amount of SGLT1 in the membrane [135]. In contrast, stimulation of human embryonic kidney cells expressing human SGLT1 with 8-Br-cAMP (a brominated derivative of cyclic adenosine monophosphate that activates cAMP-dependent protein kinase) significantly reduced glucose transport [136]. On the other hand, PKC activation in the absence of RS1 increases transport capacity of human SGLT1, while in the presence of RS1, glucose transport is decreased [137].

The adipocyte-derived hormone leptin also regulates SGLT1. Although leptin is not required for intestinal SGLT1 expression, hyperleptinemia or leptin administration drastically reduce intestinal SGLT1 expression. The intracellular signaling pathways by which leptin regulates intestinal SGLT1 remain incompletely understood, but may include PKA, PKC, and the leptin receptor isoform b [138,139]. Finally, as in the case of GLUT5, green tea catechins markedly inhibit SGLT1-mediated glucose transport in the small intestine, being more pronounced by catechins containing a gallate group [(−)-epigallocatechin-gallate and (−)-epicatechin-gallate] than by catechins lacking this group [140].

The classical view of intestinal glucose absorption is underlined by the evidence that SGLT1 is in the apical membrane of enterocytes, while GLUT2 is located exclusively in the basolateral membrane, leading to the transepithelial glucose transport from the lumen into the portal circulation. This classical theory explains glucose absorption at low luminal glucose concentrations (≤10 mM) but it fails to explain the marked increase at glucose concentrations that surpass SGLT1 (≥25 mM) transport capacity. GLUT2 levels are also regulated by glucose concentrations in enterocytes. As part of an adaptive physiological mechanism in response to increased luminal glucose concentrations, caloric demand, and glucagon-like peptide 2 (GLP-2); GLUT2 is rapidly and transiently recruited to the brush border membrane of the enterocyte, leading to a three-fold enhancement of glucose transport [141,142] (Figure 3). This adaptive mechanism that is known as the

"GLUT2 translocation" theory, which in addition to other theories, such as the "solvent drag" theory, have been proposed to explain the marked increase in glucose absorption in response to high luminal glucose concentrations [143].

Conversely, it has also been demonstrated that in addition to high luminal glucose concentrations, insulin decreases GLUT2 membrane levels as a result of the internalization of GLUT2 from plasma membranes back into intracellular pools, leading to the inhibition of glucose transport [144]. The regulation of intestinal glucose absorption by insulin is probably another physiological mechanism at the enterocyte level by which the hormone limits sugar excursions in the blood circulation during a sugar-rich meal. This evidence raised the idea that insulin resistance may provoke a loss of insulin-mediated control of GLUT2 membrane trafficking, leading to unleash intestinal glucose absorption upon high-sugar diets consumption. Tobin et al. demonstrated that insulin resistance in mice provoked a loss of GLUT2 trafficking control, where GLUT2 levels remain permanently elevated in the brush border membrane and low in the basolateral membrane of the enterocyte [144]. Ait-Omar et al. investigated the relevance of these previously described mechanisms in the small intestine of morbidly obese insulin resistant humans and lean control subjects. They found that GLUT2 was accumulated in apical and/or endosomal membranes of enterocytes in obese subjects. Interpretation of these findings is complex, but authors proposed that permanent apical GLUT2 localization in obese subjects would mediate blood-to-lumen glucose flux during fasting hyperglycemia, leading to glucose secretion into the intestinal lumen. In contrast, after consumption of a sugar-rich meal, permanent apical GLUT2 localization would provide a large glucose uptake from the intestinal lumen to the portal circulation [145].

29.5.4.0.1: 3.3. INTESTINAL GLUCOSE METABOLISM IN HUMAN DISEASES

29.5.4.0.1: 3.3.1. RELEVANCE OF GLYCEMIC INDEX AND GLYCEMIC LOAD FOR T2DM

The glycemic response (GR) is the appearance of glucose in blood after a meal. It depends on the amount of glucose absorbed, the rate of glucose entry into circulation, the rate of disappearance due to tissue uptake from circulation, and the regulation of hepatic glucose production [146]. Blood glucose concentrations will rise and fall rapidly or slowly depending on the carbohydrate content of food. The glycemic index (GI) is a tool developed to compare the postprandial responses to constants amounts of different carbohydrate-containing food. It is a useful tool for people with diabetes, providing information on the GR that might be expected when a person consumes the quantity of a food containing a fixed amount of carbohydrates [147]. The glycemic load (GL) concept was introduced as a mean of predicting the GR, considering the GI and the amount of available carbohydrate in a portion of the food eaten [148]. Thus, foods have been classified by GI into low (GI ≤ 55), medium (GI 56–69), and high (GI ≥ 70) categories, and classified by GL as being low (GL ≤ 10), medium (GL 11–19), and high (GL ≥ 20). Since these concepts were introduced, numerous studies have been performed to ascertain how GI and GL relate to health and disease. Of note, the American Diabetes Association (ADA) indicated that current knowledge is insufficient to relate low–GL diet with a reduction on diabetes risk, and that it has not been demonstrated that one method of assessing the relationship between carbohydrate intake and blood glucose response is better than other methods [149].

To shed light into this issue, Livesey et al. performed a review meta-analysis of prospective cohort studies for a comprehensive examination of evidence on the dose-response that links GL to T2DM. The analysis concluded that a GL over a dose range of 100 g/2000 kcal, increases the risk of T2DM by 45%, supporting the notion that GL is an important and underestimated dietary characteristic that contributes to the incidence of T2DM [150]. Greenwood et al., in a systematic review and dose-response meta-analysis of prospective studies, showed that there is a protective effect of low dietary GI and GL and risk of T2DM [151]. In addition, two previous systematic reviews concluded that there is evidence of a positive association between both dietary GI and GL and risk of T2DM [152,153]. In summary, despite the fact that epidemiological studies of GI and GL in relation to diabetes risk have yielded inconsistent results, there is important research in support of significantly positive associations between dietary GI and GL and the risk of T2DM, thus reducing the intake of high-GI foods may bring benefits in diabetes prevention.

29.5.4.0.1: 3.3.2. REGULATION OF SGLT1 IN DIABETES MELLITUS

Several studies in rodent models of T2DM and type 1 diabetes mellitus (T1DM) have shown a link between intestinal SGLT1 expression and diabetes. Streptozotozin (STZ)-induced diabetes in mice and rats (STZ; a toxic drug that produces a destruction of pancreatic β-cells causing insulin deficiency and hyperglycemia [154]) produces increased SGLT1 intestinal expression [155]. Likewise, a rat model of T2DM (Otsuka Log-Evans Tokushima Fatty rats) exhibited increased intestinal mRNA expression of SGLT1 associated with impaired glucose tolerance and occurred before the onset of insulin resistance and hyperinsulinemia [156]. Similar results were confirmed in patients with noninsulin-dependent diabetes mellitus where mRNA and protein levels were increased three- to four-fold in brush border membranes of enterocytes in the small intestine [157]. Finally, in morbid obese non-diabetic patients, increased SGLT1 expression in the intestine was found and it correlated with accelerated intestinal absorption [158].

Taken together, these findings are consistent with the concept that SGLT1-mediated glucose absorption in the intestine underlies the rapid post-prandial rise in blood glucose levels observed in obesity and T2DM. This knowledge has prompted the concept that pharmacological inhibition of SGLT1 in the small intestine can lower hyperglycemia by inhibiting glucose absorption and increasing GLP-1. The pharmacological tools that have been used to determine the potential of SGLT1 inhibition include phlorizin (or phloridzin), canagliflozin, LX4211 (or sotagliflozin), LP-925219, KGA-2727, and GSK-1614235 [159]. The use of these inhibitors in rodent models of T2DM and in humans has lent support to this pharmacological approach in the treatment of T2DM, but more studies are needed on long-term safety of SGLT1 inhibition.

29.5.5: 4. PERIPHERAL AND CENTRAL EFFECTS OF DIETARY SUGARS IN THE GUT–BRAIN AXIS IN HEALTH AND DISEASE

29.5.5.0.1: 4.1. THE GUT–BRAIN AXIS

In the early 20th century, Ivan Pavlov discovered the existence of a close interaction between the gut and the brain. Pavlov observed in dogs how a stimulus associated with feeding induced vagal-dependent gastric acid secretion [160]. Since then, this interaction has been widely described and is enclosed in the term of “gut–brain axis”, a complex bidirectional communication system that maintains constant crosstalk between the gastrointestinal system and the enteric and central nervous system. This intimate connection involves numerous endocrine, immune, and neuronal pathways [161]. Through this complex system, the gut can send modulating signals to the brain via visceral messages that influence emotional and cognitive brain centers producing different psychobehavioural responses [161]. In the other direction, the brain is able to send orders for proper maintenance of gastrointestinal homeostasis (such as by modulating intestinal motility and mucin production) and can also modulate the immune system (such as by modulating cytokine production by mucosal cells) [161].

The gut–brain axis uses mostly four major information carriers to communicate with each other: Neural messages via vagal and spinal afferent neurons, immune mediators carried by cytokines, endocrine signals carried by gut hormones, and microbiota-related factors that reach the brain directly from the blood stream [162,163]. The integration of all these signals allows the maintenance of a large number of vital functions such as the control of food intake and satiety, the repulsion of harmful foods, and the adaptation of our gastrointestinal system to the environment, giving rise in pathological conditions to the sensation of nausea, pain, or even may result in gastrointestinal dysfunction [164,165].

29.5.5.0.1: 4.2. REGULATION OF THE GUT–BRAIN AXIS BY ENTEROENDOCRINE CELLS AND SENSING OF INTESTINAL SUGARS

Enteroendocrine cells (EECs) form the largest endocrine organ in the body and play a key role in regulating nutrients intake and postprandial metabolism. Following a meal, EECs in the small intestine sense luminal and circulating levels of nutrients, and simultaneously are stimulated by prevailing nutrients through multiple nutrient transporters and G protein-coupled receptors (GPCRs), leading to activation of intracellular signaling pathways that produce secretion of peptides and hormones. These hormones enter circulation and act on multiple distant tissues such as the brain, gallbladder, and pancreas, as well as, on neighboring enteric neurons, endothelial cells, and the gastrointestinal epithelium. Thus, the physiological role of the enteroendocrine system in response to ingested glucose and fructose is to detect nutrients in the intestinal lumen, to monitor energy status of the body, and to elaborate an appropriate response, through the production of more than 30 different hormones and neurotransmitters to control postprandial whole-body metabolic homeostasis [166].

EECs are endoderm-derived epithelial cells widely distributed in the villi and crypts, where they are interspersed between non endocrine cells [166]. The intestinal epithelium is in a constant turnover that is replenished from pluripotent stem cells at the base of intestinal crypts and their progenies migrating up the crypt–villus axis [167]. The spatial distribution and differentiation of EECs is regulated by an interplay of the surface protein Notch and three basic helix-loop-helix transcriptional factors (Math1, Neurogenin 3, and NeuroD), among other factors [167,168]. EECs are classified depending on their morphology and position in the gastrointestinal mucosa into “open-type” with a bottle neck shape and an apical prolongation with microvilli facing towards the intestinal lumen or “closed type” that are located close to the basal membrane, do not reach the lumen of the gut, and lack microvilli [169,170,171]. The open-type cells are activated by luminal content through the microvilli, whereas the close type cells are activated by luminal content indirectly through neuronal or humoral pathways. In both cases, hormones and peptides accumulate into cytoplasmatic secretory granules that are released by exocytosis at the basolateral membrane upon chemical, mechanical, or neural stimulation [170,172].

29.5.5.0.1: 4.2.1. FRUCTOSE-INDUCED HORMONAL SECRETION IN INTESTINAL CELLS

Using specialized organoid cultures enriched in a single intestinal cell type, primarily enterocytes, Paneth or goblet, but not intestinal stem cells, Kishida et al. demonstrated that fructose can be sensed by absorptive enterocytes and secretory goblet and Paneth cells, but not stem cells [173]. In response to fructose there was an increased expression of fructolytic genes without affecting non-fructolytic gene expression. Sensing was independent of Notch, Wnt, and glucose concentrations in the culture medium, but required fructose uptake and metabolism. Stronger responses were found in more mature enterocyte- and goblet-enriched organoids. Of note, the response to fructose in enterocyte organoids was retained upon forced dedifferentiation to reacquire stem cells characteristics [173].

Fructose increases secretion of human peptide tyrosine tyrosine (PYY), cholecystokinin (CCK), neurotensin, and serotonin (5-HT) in EECs subtypes L, I, N, and enterochromaffin cells (EC), respectively [174,175]. Likewise, fructose stimulates secretion of glucagon-like peptide 1 (GLP-1) from L-subtype EECs in humans, rats and mice, but not glucose-dependent insulinotropic polypeptide (GIP; glucose-dependent insulinotropic polypeptide or gastric inhibitory peptide) [174,176]. On the other hand, fructose induced the secretion of GIP from K-subtype EECs in mice [176] but is unaffected or reduced in rats and humans [174,177].

29.5.5.0.1: 4.2.2. GLUCOSE-INDUCED HORMONAL SECRETION IN INTESTINAL CELLS

Oral glucose, but not intravenous glucose, leads to a greater stimulation of insulin secretion and modulation of glucagon secretion in the pancreas. This physiological response to glucose is called the incretin effect, which is due to the release of incretin hormones (GIP and GLP-1) from specialized EECs [178,179]. Of the three signals originating in the gut (glucose, incretins, and neutral signals transmitted by

the autonomic nervous system) that regulate pancreatic insulin secretion, the incretin effect makes a substantial contribution to maintenance of glucose homeostasis [178,179].

GIP is secreted in response to glucose by K-cells located in the duodenum and upper jejunum. GIP is synthesized as a precursor pro-peptide (pro-GIP), which is cleaved to GIP by posttranslational processing. GLP-1 and GLP-2 are secreted in response to glucose by L-cells in the small and large intestine, with a gradient from low density in the duodenum to high density in the ileum, but also in the colon and rectum [180,181]. The proglucagon gene is cleaved to GLP-1 and GLP-2 by posttranslational processing. The biological active forms of GLP-1 are GLP-1 [7-36 amide] (amidated GLP-1), and GLP-1 [7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22,23,24,25,26,27,28,29,30,31,32,33,34,35,36,37] (glycine-extended GLP-1), which are "truncated" forms in comparison to the originally proposed sequences GLP-1 [1-36 amide] by the N-terminal six amino acids [182,183,184]. In pancreatic α-cells, the same proglucagon gene is processed in a different manner, yielding glucagon and a "major proglucagon fragment that is not further processed to GLP-1 and GLP-2 [185]. Finally, in addition to its role in the regulation of pancreatic insulin secretion, GLP-1 and GLP-2 promotes nutrient absorption [180].

5-HT is secreted in response to glucose by EC cells located throughout the gastrointestinal tract, and regulates intestinal motility and brain control of appetite [186,187]. 5-HT and GLP-1 activate 5-HT_3 and GLP-1 receptors in the intestinal vagus nerve, respectively, leading to vagal reflexes, which in turn slow the subsequent emptying of carbohydrates from the stomach and induce satiation [188,189].

29.5.5.0.1: 4.2.3. INTESTINAL SWEET SENSING AND GLYCEMIC CONTROL

The gastrointestinal tract is a major determinant of metabolic homeostasis. Sensing of nutrients, and particularly glucose, in the EECs provides feedback signals from the intestine to slow the rate of gastric emptying, limit postprandial glycemic excursions, and induce satiation.

Intestinal sweet sensing is regulated by the sweet taste receptor (STR), which has been described on K-cells, L-cells, and EECs in humans. Additionally, STRs have been described in metabolic tissues that sense and respond to carbohydrates, such as hypothalamic neurons, hepatocytes, adipocytes, and β-cells (for review see refs. [190,191,192,193]). STR senses hexose sugars, D-amino acids, sweet proteins, and low-calorie sweeteners. The receptor is comprised of a heterodimer of class C, G-protein coupled receptors T1R2 and T1R3. The mechanisms of sweet taste transduction have been mostly studied in lingual sweet taste cells (this topic is out of the scope of this manuscript, for review see refs. [194,195,196,197]). Briefly, the interaction of sweet tastings with STR initiates the dissociation of the gustducin (the G-protein) into Gα and Gβγ subunits and activation of phospholipase C. Then, intracellular Ca^{2+} is released from inositol 1,4,5-triphosphate (IP3)-sensitive stores, leading to opening of the melastatine type-5 transient receptor potential cation (TRPM5) channel allowing sodium influx. Increases in intracellular Na^{+} and Ca^{2+} levels lead to depolarization of the basolateral membrane, which via 5-HT and ATP-dependent pathways activate intermediary taste cells and nerves involved in lingual sweet taste that convey information centrally to the cortex.

Numerous studies in rodents and human cells support the notion that intestinal STR is a glucose sensor on the gut luminal membrane responsible for the regulation of SGLT1 expression and GLP-1 secretion. First, it was demonstrated that T1R2, T1R3, and the α-subunit of gustducin were co-expressed in K- and L-endocrine cells in rodents and humans [198], and to a lesser extend in EC cells containing serotonin in pig intestine [199]. Second, Parker et al. proposed that secretion of GLP-1 by L-cells and GIP by K-cells was through uptake of glucose by SGLT1, suggesting that SGLT1 was likely the mediator of the direct responsiveness of K- and L-cells to luminal glucose [200]. Third, genetic deletion of T1R3 or gustducin in mice abolished the ability of mouse intestine to upregulate SGLT1 expression in response to increased dietary carbohydrate, providing convincing evidence for the involvement of the STR in intestinal sweet transduction [198]. Fourth, genetic deletion of T1R3 and gustducin exhibited deficiencies in secretion of GLP-1 [201]. Fifth, luminal glucose above a threshold results in secretion of GPL-1, GLP-2, and GIP through a signaling pathway involving STR in enteroendocrine cells [198]. These evidences beg an important question: How does glucose activation of STR in EECs cause increased expression of SGLT1 in enterocytes? The communication between EECs and neighboring enterocytes likely resides in the involvement of intermediaries such as GLP-1 and/or GLP-2 and enteric neurons. Thus, GLP-2 receptors are present on enteric neurons [202,203], while enterocytes respond to GLP-2 in an enteric neuron-dependent manner [203]. In addition, GLP-2 upregulates SGLT1 expression [204,205,206], and STR-dependent release of GLP-1 and GLP-2 is detected at higher concentrations in the portal and lymphatic circulation in rodents [204,207].

All these evidences have led to a model of intestinal dietary glucose sensing. Luminal glucose is sensed by STR expressed on the luminal membrane of enteroendocrine cells. Above a threshold level of luminal glucose, the hexose binds to and activates STR, initiated by dissociation of gustducin into Gα and Gβγ subunits, which leads to activation of phospholipase C β_2. Then, IP3-sensitive stores release intracellular Ca^{2+} that opens the TRPM5 channel increasing sodium influx. Intracellular elevation of Ca^{2+} and Na^{+} depolarizes the basolateral membrane resulting in the release of GLP-2. GLP-2 binds to its receptor on enteric neurons evoking an action potential that triggers the release of an unknown neuropeptide to the vicinity of neighboring enterocytes. The neuropeptide binds to its receptor located on basolateral membranes of enterocytes leading to a rise in intracellular levels of cAMP, which increases stabilization of the 3′end of *Slc5a1* mRNA and ultimately augmented SGLT1 translation and insertion into the apical brush border membrane of the enterocyte (**Figure 4**).

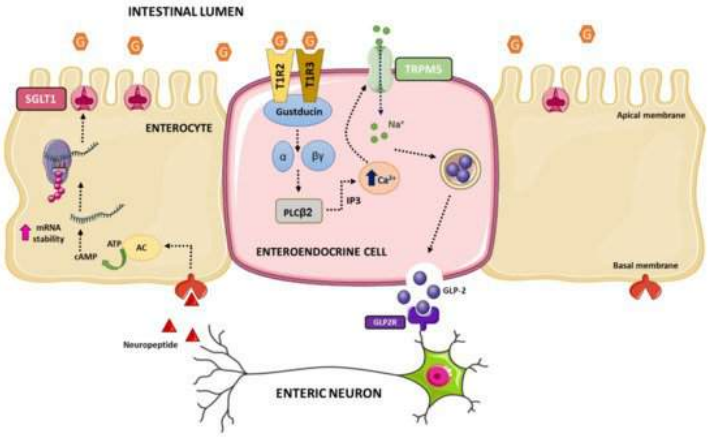

Figure 4. Model of intestinal glucose sensing and signaling pathways. Glucose (G) binds and activates the taste receptor type 1 member (STR) comprised of a heterodimer T1R2+T1R3 and G-protein gustducin, leading to its dissociation into Gα and Gβγ subunits and activation of phospholipase C β_2 (PLCβ_2) in enteroendocrine cells. Inositol 1,4,5-triphosphate (IP3) triggers intracellular calcium release resulting in increased sodium flux through type-5 transient receptor potential cation channel (TRPM5). Depolarization of the basal membrane results in GLP-2 release, which triggers release of an unidentified peptide from enteric neurons at neighbor enterocytes. Signal transduction in enterocyte leads to cAMP-mediated adenylate cyclase (AC) production that increases stabilization of *Slc5a1* mRNA and ultimately augmented translation and insertion of SGLT1 into apical membrane. This figure was created using Servier Medical Art.

29.5.5.0.1: 4.3. CENTRAL EFFECTS OF GLUCOSE AND FRUCTOSE CONSUMPTION

Sugar overconsumption has been associated with detrimental metabolic effects, such as obesity, dyslipidemia, MetS, and impaired insulin sensitivity [71,208,209]. Therefore, it is necessary to understand the specific molecular mechanisms by which dietary sugars cause an addictive eating behavior and how sugar intake affects the gut–brain axis. Herein, we will review the effects of the two main dietary monosaccharides: Glucose and fructose, the latter of which is usually consumed in the form of sucrose disaccharide (50% glucose, 50% fructose) or in the form of high-fructose corn syrup (HFCS) (range 47%–65% fructose, and 53%–35% glucose) [210], the major component of sweetened soft drinks.

Appetite control is a complex crosstalk between the periphery and the central nervous system that involves a large number of peptides and hormones [211]. Disturbances in food intake control will ultimately be responsible for large changes in energy balance and different metabolic effects. The appetite regulatory hormones are secreted from peripheral tissues such as the pancreas (e.g., insulin), adipose tissue (e.g., leptin), or the gastrointestinal tract [e.g., ghrelin, CCK, PYY, GLP-1 and GIP], and bind to receptors located in the arcuate nucleus of the hypothalamus, where they inhibit or stimulate appetite or satiety [212].

Many studies have demonstrated that circulating levels of satiety hormones are regulated by the type of sugar consumed. In response to glucose stimuli, a cascade of hormonal secretion is triggered. Thus, glucose produces a repression of the hunger hormone ghrelin (secreted by the stomach), whereas there is a stimulation of the secretion of satiety hormones such as leptin, insulin, GIP, GLP-1, and PYY. However, fructose produces lower repression of ghrelin and a decreased stimulation of satiety hormones (leptin, insulin, GIP, GLP-1, and PYY) than glucose [13,83,212,213,214,215,216,217]. These effects may be related to different explanations such as the lower ratio of intestinal fructose uptake, the lower intestinal levels of GLUT5 compared to the high levels of GLUT2, and also due to the low expression of GLUT5 in pancreatic β-cells leading to decreased insulin release [218,219,220].

Some of these hormones regulated differentially by fructose or glucose convey signals to brain structures. Specifically, there are two neuronal types in the arcuate nucleus that integrate signals from the periphery, acting as metabolic sensors: Neurons co-expressing agouti-related peptide (AgRP) and neuropeptide Y (NPY), whose activation triggers orexigenic effects; and neurons expressing pro-opiomelanocortin (POMC), whose activation triggers anorexigenic effects [221,222,223]. These different types of neurons are sensitive to changes in hormone levels promoting or suppressing food intake. Therefore, the differential effect of dietary sugars on hormonal levels affects neuronal stimulation causing both short-term and long-term central effects in the regulation of food intake and energy homeostasis [224,225]. The low stimulatory capacity of fructose on satiety hormones such as leptin and insulin will lead to low stimulation of POMC neurons and the maintenance of the signal on NPY/AgRP neurons, thus promoting less satiety than glucose, and therefore increased food intake. In the same way, the hypothalamic AMPK functions as a ‘fuel gauge’ to monitor cellular energy status, and its inhibition promotes anorexigenic effect [226]. AMPK activity is inhibited by leptin and insulin. Intracerebroventricular glucose administration in rodents inhibits hypothalamic AMPK activity and suppresses food intake, whereas fructose activates it, thus promoting an orexigenic effect [227,228,229,230] (Figure 5).

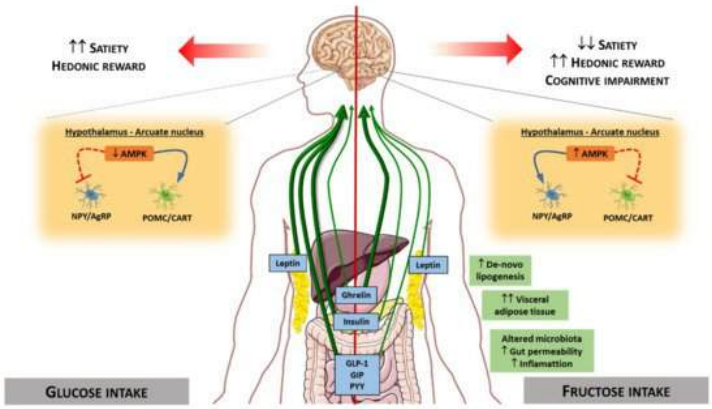

Figure 5. Peripheral and central effects of glucose and fructose on food intake. Upon nutrient ingestion, glucose triggers the secretion of anorexigenic peptides such as leptin, insulin, GLP-1, GIP, PYY, and blocks the secretion of the orexigenic hormone ghrelin. These peptides will induce AMPK inhibition, which will lead to the stimulation of POMC/CART neurons, contributing to satiety response. However, upon fructose consumption, the secretion of anorexigenic peptides is decreased, as well as the repression of ghrelin secretion. These facts will cause the increase in AMPK activity, which will lead to the repression of POMC/CART neurons and the activation of NPY/AgRP, leading to reduced satiety suppression, as well as higher hedonic reward to food and increasing food intake, in addition to playing a possible role in cognitive functions. This figure was created using Servier Medical Art.

With the use of new technological advances, it is possible to evaluate the brain activity produced by the intake of different nutrients. In humans, differences in cerebral blood flow have been reported between subjects undergoing glucose and fructose infusions [231], and compared to glucose, fructose causes poor satiety stimulation in specific appetite-regulating regions (e.g., hypothalamus) [13]. It has also been observed that fructose ingestion compared to glucose resulted in a significantly greater incentive value of food cues [232]. These findings suggest that fructose promotes effects on brain activity that affect appetite, probably promoting less satiety than other sugars in humans.

In addition to the above-mentioned findings, it has been described that high-fructose intake may affect central appetite regulation by altering specific components of the endocannabinoid system in rats. Fructose consumption has been reported to significantly increase the mRNA expression of the cannabinoid 1 receptor (CB1) [233], and induces an increase in fatty acid amide hydrolase (FAAH) and diacylglycerol lipase (DAG) 1β, but a decrease in DAG1α mRNA [234]. These changes in the endocannabinoid system suggest that fructose consumption may lead to increased hedonic reward for food, thus leading to disturbances in the eating behavior pattern.

The consumption of dietary sugars has not only been related to central effects that control appetite and satiety, but also to disturbances in cognitive functions. In rodents, studies have shown that fructose consumption reduced phosphorylation levels of the insulin receptor, leading to impaired brain insulin signaling [235,236], a harmful feature associated with cognitive impairment [237]. Moreover, diminished phosphorylation of cAMP-response element binding and synapsin I, and reduced synaptophysin levels have been observed after fructose intake [236]. Together, these findings indicate that excessive fructose consumption could lead not only to detrimental effects in eating behavior, but also can trigger impaired cognitive function. Further work is required to investigate these evidences.

29.5.5.0.1: THE FRUCTOSE HYPOTHESIS

In view of the association between fructose consumption in Western diets and MetS, fructose has been suggested as one of etiological factor of MetS. The “fructose hypothesis” proposed that a high amount of fructose consumption is a leading risk factor for the development and progression of MetS, covering obesity, insulin resistance, dyslipidemia, fatty liver, and cardiovascular disease [238,239,240].

Fructose may cause insulin resistance by accumulation of triglycerides in the liver. There are two metabolic pathways to increased hepatic lipid content, i.e., lipogenesis and/or reduced mitochondrial fatty acid oxidation. Hepatic fructolysis leads to increased gluconeogenic sources resulting in elevated rates of lipogenesis [16,45,46]. Hepatic accumulation of toxic intermediary lipid metabolites, such as diacylglycerol (DAG) results in PKCε activation that impairs hepatic insulin signaling through phosphorylation of serine residues on the insulin receptor substrate 1 and 2 (IRS1/2). When hepatic insulin signaling is impaired, gluconeogenesis and glycogenolysis are unleashed, contributing to hyperglycemia and hyperinsulinemia. Under these circumstances, hepatic lipid synthesis is enhanced due to hyperinsulinemia [241,242]. Likewise, reduced fatty acid oxidation leads to hepatic triglycerides accumulation. Of note, Ohashi et al. demonstrated that excessive amounts of fructose consumption lead to epigenetic modifications, such as DNA hypermethylation of promoter regions of peroxisome proliferator-activated receptor alpha (PPARα) and carnitine palmitoyl transferase 1A (CPT1A) that results in lower amounts of mRNA levels [243]. Hepatic triglyceride accumulation results in augmented secretion of very low-density lipoprotein (VLDL) leading to increased lipid uptake in skeletal muscle and peripheral tissues. Similarly to what happens in the liver, intramyocellular lipid accumulation (particularly DAG) activates the PKCθ isoform that phosphorylates and inactivates IRS1 resulting in impaired insulin-stimulated glucose uptake, contributing to hyperglycemia, increased delivery of glucose to the liver, and hyperinsulinemia [241,242].

Fructose-induced hyperuricemia has also been proposed as a causal agent in the etiology of insulin resistance [244,245,246]. This notion arises from the observation that lowering uric acid levels prevents the development of MetS induced by fructose [244,245,246], defective endothelial NO production in mice leads to development of MetS [247], and that uric acid inhibits endothelial NO in in vitro and in vivo [248]. Two mechanisms have been proposed: The first mechanism proposed is that uric acid inhibits endothelial nitric oxide (NO) release, and NO increases blood flow ensuing enhanced insulin delivery and glucose disposal in skeletal muscle and peripheral tissues [249]. The second mechanism states that uric acid promotes inflammation and oxidative stress within the adipocyte [250,251,252]. In addition, uric acid-mediated insulin resistance in the adipose tissue, via the classical mechanisms (i.e., low-grade chronic inflammation mediated by proinflammatory cytokines secreted by the adipocytes, increased lipolysis, and reduced lipogenesis), may result in MetS [241,242].

Additionally, persistent high fructose consumption leads to higher levels of leptin and leptin resistance, which in turn increases food and energy intake [253]. Potential molecular mechanisms underlying leptin resistance may be related to impaired leptin transport across the blood-brain barrier and/or reduced basal levels of phosphorylated signal transducer and activator of transcription 3 (STAT3; a downstream component of the leptin receptor signaling cascade), despite equivalent expression of leptin receptors, in the hypothalamus [253].

However, the fructose hypothesis is not universally accepted. It has been argued that fructose is rarely consumed in its pure form and many published studies have used fructose levels that far exceed dietary composition [254]. Likewise, many animal studies have used extremely high-fructose doses or unusual glucose to fructose ratio that are not representative of actual human diets, which makes it difficult to extrapolate this phenomenon to humans. Therefore, caution in interpreting studies of the effects of fructose on health should be taken into consideration [254]. Another proposed argument to refute the fructose hypothesis is that the causative role of fructose in increasing the risk for the development and progression of MetS is not fully demonstrated. Carefully designed studies should be performed to tease apart the contribution of each risk factor associated to MetS (e.g., obesity, diabetes, or insulin resistance) from fructose, per se [254].

29.5.5.0.1: 4.4. PERIPHERAL EFFECTS OF GLUCOSE AND FRUCTOSE CONSUMPTION

29.5.5.0.1: GUT MICROBIOTA, LIPID METABOLISM, AND LIVER DISEASE

The gut microbiota is a complex and dynamic population of microorganisms that, in addition to acting as an immune barrier and protecting against pathogens, plays a crucial role as a metabolic organ itself modulating intestinal permeability, and therefore the nutrient availability [255]. It is generally known that diet exerts a large effect on the gut microbiota, which may affect intestinal permeability and ultimately cause a great metabolic impact [255,256,257,258].

High-fructose or high-glucose diets have been described as an intestinal microbiota modulator that increases inflammation, gut permeability, and metabolic endotoxemia, causing metabolic disturbances such as hepatic lipid accumulation, liver damage, and insulin resistance [258,259]. Likewise, sugar overconsumption also affects lipid metabolism. In obese and overweight subjects, the consumption of glucose-sweetened beverages leads to a lower increase in plasma triglycerides, de novo lipogenesis, and visceral adipose tissue compared to those that consumed fructose-sweetened beverage [71]. However, in rodents, both high-glucose and -fructose diets stimulated similar hepatic lipogenic gene expression [260].

Liver is the principal metabolic organ within the human body and has a major role in regulating carbohydrate metabolism [261]. Many studies point out to the direct implication of high-sugar diets in the development of serious liver diseases, such as NAFLD, hepatic steatosis, liver fibrosis, and dysfunction [262,263,264]. Multiple studies showed that fructose more potently stimulates hepatic de novo lipogenesis than glucose [78,265,266], and the effect is much higher when both monosaccharides were consumed simultaneously [265]. These differences in de novo lipogenesis between both sugars can be explained by differences in their hepatic metabolism. Fructose is directly phosphorylated by fructokinase, bypassing the enzyme phosphofructokinase, a major rate-limiting step in glucose metabolism, providing a larger available substrate for de novo lipogenesis than glucose [261,267].

Regarding the effect of isocaloric diets with different sugar composition, various studies have observed no differences in liver fat content between high-fructose or high-glucose diets [268,269], nor between isocaloric diets with high-fructose corn syrup or sucrose [270]. However, when comparing different doses of fructose in the diet, liver fat content was increased in high-fructose diet, probably associated with increased de novo lipogenesis and reduced whole-body fatty acid oxidation [266,270]. In the same direction as the previous findings, when comparing hypercaloric diets enriched in either fructose or glucose, no significant changes are observed between both diets, suggesting that high-glucose and high-fructose diets provide the same risk for the development of NAFLD [269,271,272].

Taken together, these data would point to the detrimental effect of fructose compared to glucose in terms of hepatic and lipid metabolism. However, there is controversy between different studies, probably due to differences in the doses of sugars administered and their form of administration (oral, intraperitoneal injection, etc.). Many of the above-mentioned studies were performed using supra-doses of fructose in rodents. Since humans typically do not consume fructose as a single sugar, and it is frequently consumed in the form of HFCS, the direct relationship with the real effect of fructose human consumption is not entirely clear. Therefore, more detailed studies on the pattern of sugar consumption in humans should be carried out.

29.5.5.0.1: 4.5. IMPACT OF EXCESSIVE DIETARY SUGARS CONSUMPTION ON INCRETIN SECRETION

There are many associations reported between high-sugar consumption and the development of pathologies such as diabetes, obesity, and MetS [10,273,274,275]. These associations are mainly due to the current consumption of sugar-sweetened beverages, whose main sweetener

is the HFCS. HFCS represents >40% of caloric sweeteners and its consumption has been increased by >1000% between 1970 and 1990. This sugar overconsumption can lead to important changes in the secretion of gut hormones, and therefore, lead to central effects that affect appetite and satiety control.

Many authors have focused their studies on the effect that different GIs and GLs have on incretin secretion. Runchey et al. observed that 28-days consumption of a high-GL diet in weight-maintained healthy individuals led to statistically significant increased post-prandial GIP and lower GLP-1 concentrations compared with low-GL diets [276]. However, other authors did not corroborate these findings clearly. One study performed in healthy sedentary women reported that GLP-1 concentrations did not differ significantly following high- or low-GI meals [277]. In the same way, another study in overweight subjects observed no differences in GLP-1 concentrations when comparing consumption of low- and high-GI beverages [278]. Other authors suggest that the rate of small intestinal glucose exposure (i.e., GL) is a major determinant of the magnitude of the incretin effect, since they observed that the incretin effect was stronger when they administered larger intraduodenal glucose load [279].

However, it is necessary to be cautious with this upregulation of incretins in response to high-sugar diets, because it has been described that in diabetic patients, who have increased levels of incretins, a reduced incretin effect is observed, which suggest the development of an "incretin resistance" process [280,281,282,283].

29.5.6: 5. FUTURE DIRECTIONS

During human evolution, ancestral human diets contained low carbohydrate levels and most of the sugars were derived from fruits and honey. In the last century, changes in lifestyle, nutritional habits in the world population, and the abusive use of sweeteners by the food industry have dramatically increased dietary sugar consumption, particularly constituent monomers, such as glucose and fructose, and fructose-based sweeteners. International and national health organizations have called attention into this issue and recommend reductions in sugars consumption due to concerns in their potential role as risk factors for developing human diseases such as obesity and T2DM.

In the last decades, the scientific community has made great efforts to understand intestinal sugar absorption, identifying molecular and physiological mechanisms of fructose and glucose sensing and transport. In the case of fructose metabolism, the current notion that fructose is mainly metabolized by the liver has been challenged, and the new paradigm proposes that the small intestine shields the liver from toxic fructose exposure. This provocative view of intestinal fructose metabolism is awaiting confirmation in humans. Similarly, the finding that humans can synthesize fructose by the polyol pathway leaves open the question about the significance of this pathway in human metabolic diseases. In addition, more meta-analysis studies should be performed to clearly demonstrate the causal role of dietary fructose and glucose in developing human metabolic diseases.

On the other hand, the role of intestinal glucose metabolism on the etiology of hyperglycemia remains incompletely clarified. Despite studies relating chronic hyperglycemia with impaired glucose transport and metabolism in the small intestine, more studies in humans are required to reveal if chronic hyperglycemia is a cause or consequence of impaired glucose homeostasis in the small intestine. The identification of molecular mechanisms by which glucose and insulin regulate SGLT1 have set this transporter, and its potential role in the physiopathology of hyperglycemia and intestinal insulin resistance, in the spotlight. In this line of thinking, further research is required to demonstrate the efficacy of SGLT1 inhibitors in the treatment of T2DM and obesity. Likewise, it remains to be clarified whether the apical localization of GLUT2 in response to high glucose levels in obese and/or diabetic patients is an adaptive mechanism to protect the body from excessive glucose concentrations, or if it is a consequence of hyperglycemia and insulin resistance.

Finally, the differentiated effects of glucose and fructose on eating behavior and impaired cognitive function observed in rodent models are difficult to extrapolate to humans due to the use of extremely high-fructose diets or unusual glucose to fructose ratio. To clarify the causality of fructose in human eating disorders leading to metabolic diseases, it is necessary to develop new research tools and experimental approaches in humans.

29.5.7: AUTHOR CONTRIBUTIONS

I.C.-C. and G.P. conceptualized the manuscript. B.M., C.M.F.-D., I.C.-C., and G.P. drafted the manuscript. B.M. and C.M.F.-D. prepared the figures. I.C.-C. and G.P. revised and edited the manuscript. All authors have read and agreed to the published version of the manuscript.

29.5.8: FUNDING

This research was funded by the Spanish MINISTERIO DE ECONOMÍA, INDUSTRIA Y COMPETITIVIDAD, grant numbers SAF2016-77871-C2-1-R and SAF2016-77871-C2-2-R to I.C-C. and G.P. respectively; the EFSD European Research Programme on New Targets for Type 2 Diabetes supported by an educational research grant from MSD to I.C-C. and G.P.; the FUNDACIÓN LA-CAIXA Y FUNDACIÓN CAJA DE BURGOS, grant number CAIXA-UBU001 to G.P.

29.5.9: CONFLICTS OF INTEREST

The authors declare no conflict of interest.

29.6: METABOLIC CONSEQUENCES OF OBESITY AND TYPE 2 DIABETES-BALANCING GENES AND ENVIRONMENT FOR PERSONALIZED CARE

29.6.1: METABOLIC CONSEQUENCES OF OBESITY AND TYPE 2 DIABETES: BALANCING GENES AND ENVIRONMENT FOR PERSONALIZED CARE

Nicolas J. Pillon, Ruth J.F. Loos, Sally M. Marshall, Juleen R. Zierath,. Metabolic consequences of obesity and type 2 diabetes: Balancing genes and environment for personalized care. Cell, Volume 184, Issue 6, 2021, Pages 1530-1544, ISSN 0092-8674, https://doi.org/10.1016/j.cell.2021.02.012.

SUMMARY

The prevalence of type 2 diabetes and obesity has risen dramatically for decades and is expected to rise further, secondary to the growing aging, sedentary population. The strain on global health care is projected to be colossal. This review explores the latest work and emerging ideas related to genetic and environmental factors influencing metabolism. Translational research and clinical applications, including the impact of the COVID-19 pandemic, are highlighted. Looking forward, strategies to personalize all aspects of prevention, management and care are necessary to improve health outcomes and reduce the impact of these metabolic diseases.

29.6.1.1: INTRODUCTION

The COVID-19 pandemic has brought the deleterious health consequences of obesity and type 2 diabetes into sharp focus. Individuals with type 2 diabetes and/or obesity are more likely to have severe disease and to die than are individuals without diabetes (Barron et al., 2020). Fasting glucose level at the time of hospital admission predicts 28-day mortality even in those without a previous diagnosis of diabetes (Wang et al., 2020a). Glycemic control and body mass index along with older age, male sex, socio-economic deprivation, non-white ethnicity, and pre-existing renal and cardiovascular disease all independently increase mortality (Holman et al., 2020). COVID-19 is also a timely reminder that diabetes is not merely a state of glucose dysregulation but a multi-faceted syndrome driven by many medical and social risk factors and associated with pathophysiological changes throughout the body.

The World Health Organization estimates that worldwide, 422 million people have diabetes, the majority living in low- and middle-income countries, and most having type 2 diabetes (who.int/health-topics/diabetes). The prevalence has risen dramatically for decades, as the population ages and becomes less active and more overweight (GBD 2019 Risk Factors Collaborators, 2020). Early detection is vital, particularly as long-term complications, such as referable diabetic retinopathy, may be present at diagnosis of type 2 diabetes (Kohner et al., 1998). Many developed countries have systematic screening programs of individuals deemed to be at high risk (American Diabetes Association, 2020). However, there is disagreement as to how to define “high risk” and how to screen (oral glucose tolerance test, fasting glucose or glycated hemoglobin, HbA1c). Glucose-based tests and HbA1c each identify slightly different populations. We do not know if these differences in diagnoses lead to important clinically different outcomes or if they signal slightly different pathological metabolic forms of glucose dysregulation (American Diabetes Association, 2020).

The WHO defines overweight and obesity as body mass indexes (BMI) ^{3} 25 and 30 kg/m^2, respectively and estimated that 1.9 billion adults were overweight and 650 million obese in 2016 (https://www.who.int/news-room/fact-sheets/detail/obesity-and-overweight). Obesity is now regarded as a chronic, progressive disease with remissions and relapses (Bray et al., 2017) and an important driver of the development of diabetes and many of its associated features (GBD 2019 Risk Factors Collaborators, 2020). The deleterious effects of obesity and type 2 diabetes are seen in most, if not all, tissues in the body, with consequences resulting in significantly increased premature morbidity and mortality (GBD 2019 Risk Factors Collaborators, 2020). Social and cultural factors are also extremely important in the development, management, and clinical outcomes of obesity and type 2 diabetes.

Despite advances in diabetes care over the recent decades, there remain vast challenges: developing an improved understanding of the heterogeneity of obesity and diabetes, how best to assess risk, to screen, to select individualized treatments and vitally how to engage the relevant populations in these programs. This review explores the genetic and metabolic aspects of diabetes and obesity (Figure 1) and discusses some of the latest work and emerging ideas related to basic biological mechanisms, translational research, and clinical applications.

Figure 1. Gene-environment interactions regulating disease risk of obesity and type 2 diabetes

Individual genetic predispositions and environmental factors interact to promote or impair molecular processes, such as circadian regulation, thermal tolerance, and/or chronic inflammation. Accumulation of genetic and environment risk factors eventually leads to the development of complications, reducing both healthspan and lifespan.

29.6.1.1.1: GENETICS AND METABOLISM

The current obesogenic environment, favoring high-calorie foods and physical inactivity, is a major driver of the growing obesity and diabetes epidemic. However, not everyone exposed to this environment gains weight or develops type 2 diabetes. The way people respond to environmental factors is, at least in part, determined by their genetic predisposition to obesity and type 2 diabetes. Traditionally, the genetic contribution has been quantified by the heritability, which is a population-level estimate of how much of the variation in disease susceptibility is attributable to genetic variation. For obesity and type 2 diabetes, the heritability has been estimated to be moderate-to-high, ranging between 30% and 70% (Elks et al., 2012; Willemsen et al., 2015). The search for contributing genes started in the 1990's with early success largely confined to monogenic forms of obesity and diabetes. Mutations that segregate in families or occur *de novo* were found to cause major disruptions in the function of genes in which they are located, providing the first insights in the pathophysiology of body-weight regulation and glucose metabolism (Hattersley and Patel, 2017; van der Klaauw and Farooqi, 2015). The search for genetic variants that contribute to common forms of obesity and diabetes began slowly with candidate gene and genome-wide linkage studies. However, the advent of genome-wide association studies (GWASs) in the mid-2000's accelerated the pace of gene discovery.

GWASs have identified thousands of genetic loci that are robustly associated with complex diseases and traits, including 700 for obesity (Yengo et al., 2018) and at least 400 for type 2 diabetes (Mahajan et al., 2018). From the earliest GWAS, tissue enrichment and pathway analyses for BMI-associated loci have suggested that the central nervous system plays a key role in body weight regulation (Locke et al., 2015). Loci associated with type 2 diabetes act predominantly through the perturbation of insulin secretion, pointing to the importance of beta cell function or mass, whereas few loci affect insulin resistance through an effect on body weight or fat distribution (Barroso and McCarthy, 2019).

Despite the success of GWASs, pinpointing the causal gene(s) and variant(s) within each locus remains an ongoing challenge. So far, about 20% of loci associated with type 2 diabetes and a handful of loci associated with obesity have been mapped to the most likely causal variant, whereas the underlying biology of hundreds of additional loci remain to be elucidated (Larder et al., 2017; Mahajan et al., 2018; Rathjen et al., 2017). However, with increasing availability of high-throughput genome-scale technologies for mapping regulatory elements, comprehensive multi-omics databases, advanced computational tools, and the latest genetic engineering and molecular phenotyping approaches, we are poised to accelerate the translation of GWAS loci into meaningful biology in the years ahead.

With GWASs, genetic susceptibility to disease can be assessed using polygenic scores. A polygenic score represents an individual's overall genetic susceptibility to disease and is calculated by summing the number of disease-increasing alleles that were inherited from either parent, weighted by each variant's effect size observed in a GWAS. Even though each locus has a small effect on disease risk and explains only a fraction of the variation in disease susceptibility, when aggregated in a polygenic score, their contribution can be substantial. Polygenic scores are normally distributed, with most individuals having an average score, and thus an average genetic susceptibility, whereas individuals at the extremes of the distribution have a (very) high or low genetic risk of disease. For example, in the UK Biobank, the average BMI of individuals with a high polygenic score (top decile) is 2.9 kg/m^2 (equivalent to 8 kg in body weight) higher and their odds of severe obesity (BMI ^{3} 40 kg/m^2) is 4.2-fold higher, compared to those with a lower polygenic score (bottom 9 deciles) (Khera et al.,

2019). Similarly, individuals with a very high polygenic score (top 5%) for type 2 diabetes have a 2.75-fold increased risk of disease compared to the remainder of the population (Udler et al., 2019).

These observations have fueled expectations that genotype information, including polygenic scores, can soon be used in clinical care for early diagnosis of high-risk individuals, to tailor prevention and treatments strategies, and to improve disease prognostics. In fact, many online direct-to-consumer genomic companies are already informing customers about their risks and predispositions for a range of common diseases and traits based solely on genetic profiling, including for obesity and type 2 diabetes (Figure 2). However, even though the genetic associations observed in GWASs are robust, their ability to predict who will be at a high risk of obesity or type 2 diabetes is still low-to-moderate, and not ready for use in clinical settings (Udler et al., 2019). For example, a recent polygenic score applied to individuals of European ancestry of the UK Biobank explains only 8%–9% of the variation in BMI and is a weak predictor of obesity, with an area under the receiver operating characteristic curve (AUC_{ROC}) of 0.64 (Khera et al., 2019). Findings are similar for polygenic scores for type 2 diabetes, with AUC_{ROC} of 0.64–0.66 (Udler et al., 2019). The predictive ability of polygenic scores are expected to improve as GWASs increase in sample size and the per-variant effect estimates become more precise, and as algorithms to aggregate millions of genetic variants across the genome improve. Nevertheless, given the importance of socio-demographic, lifestyle and clinical risk factors in the etiology of obesity and type 2 diabetes, it is unlikely that a polygenic score on its own will ever be able to accurately predict obesity or type 2 diabetes. More comprehensive approaches that include a broad spectrum of genetic, demographic, environmental, clinical, and possibly also molecular markers are needed to accurately predict who is at risk of gaining weight and/or developing type 2 diabetes.

Figure 2. Genetic prediction of body weight—context matters

A 49-year old woman, who eats a balanced diet, runs 6 miles/day, and commutes by bike to work, does a direct-to-consumer genetic test with one of the many online personalized genomics companies. The company claims to provide genetic insight into her health to make it easier for her to take action. She provides a saliva sample and completes numerous questionnaires on her physical and mental health, family medical history, and more. Her reported results show that, based on the genetic variants tested, she carries 376 weight-lowering variants and 332 weight-increasing variants, predisposing her to weigh about “average” or 157 lbs (71.2 kg, based on the company’s customers’ weight of the same age, height, and sex). However, the woman’s real weight was 120 lbs (54.4 kg). A likely reason for why this genetic test overpredicted the woman’s weight by 30% is because her lifestyle—even though information was shared in detail—was not appropriately incorporated in the prediction models.

The vast amount of new genetic information generated by GWASs is being used in sub-typing disease at a population level. Obesity and type 2 diabetes are highly heterogeneous diseases, and the diagnosis of these metabolic diseases is unrefined, based on a single marker (BMI ^{3} 30 kg/m^2 and hyperglycemia, respectively). Consequently, individuals with the same diagnosis may differ considerably in disease pathogenesis, clinical presentation, disease course and response to treatments. Subtypes of obesity and type 2 diabetes have been typically based on phenotypic differences and similarities. As the number of GWAS-identified loci continues to increase, subtyping of obesity and type 2 diabetes based on genetic information has become possible. In a recent study, 141 variants previously identified for diabetes and diabetes-related traits were clustered in five groups, based on their association with more than 75 traits (Udler et al., 2018). Variants with a

similar association profile cluster in the same group, and the group-specific association profile can inform about the mechanisms underlying a given subtype of type 2 diabetes. For example, two of the five groups identified for diabetes-related traits represent reduced beta-cell function, of which one cluster is characterized by high and the other by low proinsulin levels. The three other groups of variants show features of insulin resistance, of which one group represents obesity-mediated insulin resistance, a second group represents abnormal body fat distribution ("lipodystrophy-like"), and a third group represents disrupted liver lipid metabolism. Genetic risk scores based on variants in each cluster are associated with distinct clinical outcomes (Udler et al., 2018). Further for obesity, genotype information has been used to identify individuals who are predisposed to increased adiposity and, concomitantly, are protected from cardiometabolic outcomes (representing the so-called metabolically healthy obesity phenotype) (Ji et al., 2019). Subtyping of heterogenous diseases, like obesity and type 2 diabetes, is key to precision medicine. Indeed, these more homogeneous subgroups are characterized by distinct underlying biological mechanisms, such that diagnosis and prognosis will be more precise and optimization of treatment more efficient (Chung et al., 2020). As GWASs continue to identify more loci, additional and possibly better-defined clusters may be identified to more accurately represent the heterogenous group of individuals with obesity and type 2 diabetes.

As more GWAS loci are being discovered, Mendelian Randomization (MR) becomes an increasingly powerful approach to determine causality between an exposure (e.g., health-related behaviors, biomarkers [e.g., lipid levels, metabolites]) and an outcome (e.g., obesity, type 2 diabetes). Genetic variants that are robustly associated with the exposure are used to randomize a population in individuals with high exposure (i.e., carriers of the risk alleles) and those with low exposure (i.e., carriers of non-risk alleles). If the same genetic variants also associate with the disease outcome, through their association with the exposure, then causality between exposure and disease is inferred. For example, a large-scale MR study examined the causal role of a wide range of possible risk factors for type 2 diabetes, mostly confirming established risk factors, but also revealing new ones (e.g., insomnia) (Yuan and Larsson, 2020). As more GWAS data becomes available for a range of multi-omics biomarkers, MR analyses may reveal novel disease-causing biomarkers, broadening insights in the pathogenesis of obesity and type 2 diabetes.

29.6.1.1.2: EPIGENETIC IMPACT ON METABOLISM

Beyond genetic risk, the genes we inherit and the environmental factors we are exposed to can interact synergistically to modify our physiology and risk for obesity and type 2 diabetes through epigenetic modifications (Figure 3). Epigenetic modifications are biochemical processes that influence gene activity and expression, and ultimately modify cellular and whole-body physiology, without altering the DNA sequence of an organism's genome (Barrès and Zierath, 2016). Mechanistically, epigenetic modifications can arise from chemical alterations of nucleosides in the DNA molecule itself by methylation or hydroxymethylation, alterations in chromatin structure or post-translational modifications of histones (i.e., methylation, phosphorylation, acetylation, ubiquitylation, and sumoylation) or RNA-associated gene silencing (Bošković and Rando, 2018). Although epigenetic modifications are generally thought to be fixed during development and maintained over an organism's lifetime, there is some degree of plasticity in the epigenome, which engenders organismal adaptation to rapid environmental changes.

Figure 3. Epigenetic modifications in response to environmental factors lead to transgenerational effects on the phenotypes of offspring

Diet and exercise influence the cellular availability of nutrients impacting methylation, acetylation and phosphorylation of chromatin. Paternal or maternal environmental exposure can therefore influence metabolism and manifest obesity- or type 2 diabetes-related traits in the offspring through transgenerational epigenetic inheritance.

Alterations in nutritional status, food supply, physical activity/exercise, thermal stress, toxins, or other environmental insults can trigger epigenetic modifications and lead to genomic changes in somatic cells within an individual that directly disrupt metabolic homeostasis (Barrès and Zierath, 2016; Bošković and Rando, 2018). These same factors may also modify the physiology of an organism by transgenerational epigenetic inheritance, whereby paternal or maternal environmental exposure can influence metabolism and manifest obesity- or type 2 diabetes-related traits in the offspring. Prenatal undernutrition affects glucose tolerance and risk of diabetes in the offspring, as demonstrated by epidemiological studies of several famines over the past century (Li et al., 2010; Ravelli et al., 1998). In rodents, paternal and maternal diet and exercise influence metabolic and cardiovascular outcomes in offspring over several generations (de Castro Barbosa et al., 2015; Murashov et al., 2016; Stanford et al., 2015). Thus, nutritional status *in utero* during fetal development may affect the epigenome for several generations, but the molecular transducers remain to be clarified. Additionally, food restriction during childhood, at different growth phases around puberty, also leads to epigenetic changes that influence the risk of cardiovascular and metabolic disease of offspring over several generations (Kaati et al., 2002). Accordingly, epigenetic factors passed on by the gametes may contribute to the global increase in obesity and type 2 diabetes. Thus, an area of emerging interest is the influence of the environment on epigenetic mechanisms, and how this modifies metabolic disease risk.

A variety of dietary agents, as well as micronutrients and metabolites synthesized *de novo*, can serve as substrates or co-factors to influence the epigenome and potentially affect metabolic disease risk in humans, in part by affecting genomic plasticity (Tiffon, 2018). One-carbon metabolism encompasses folate and methionine cycles, which transfer one-carbon moieties and methyl groups for nucleotide synthesis, methylation reactions and reductive metabolism (Newman and Maddocks, 2017). Metabolites including acetyl-coA, AMP, NAD+, and *S*-adenosylmethionine are required for histone modifications (acetylation, phosphorylation) and methylation of DNA and histones. The extent to which nutritional factors, metabolites, and other co-factors directly modify the epigenome within a generation remains to be fully substantiated in humans.

While it is important to stress that type 2 diabetes and obesity are complex multi-factorial, progressive metabolic diseases with diverse etiology, and not simply “lifestyle disorders,” diet and exercise regimes can prevent or delay disease progression. Changes in the concentration of cellular metabolites, nucleotides, or calcium levels in skeletal muscle in response to acute exercise alter DNA methylation or histone modifications and influence gene expression through epigenetic mechanisms (Barrès and Zierath, 2016). In humans, acute exercise alters DNA methylation of the promoters of genes involved in metabolic regulation in skeletal muscle (Barrès et al., 2012; Nitert et

al., 2012). Epigenetic modifications have also been observed in skeletal muscle and adipose tissue in humans with obesity and weight loss (Barres et al., 2013; Multhaup et al., 2015). Thus, the impact of environmental exposures and epigenetic influences on the risk for metabolic diseases throughout the lifespan is an important aspect of biology to unravel.

29.6.1.1.3: CIRCADIAN CONTROL OF METABOLISM

An evolutionarily conserved mechanism by which environmental factors can impact whole-body physiology is through internal biological clocks and the control of circadian rhythms (Young, 2018). Circadian rhythms are driven by cell-autonomous intrinsic clocks that anticipate day/night cycles in order to optimize the physiology and behavior of organisms. Circadian programs are regulated at both the central and peripheral level with the master clock, located in the suprachiasmatic nucleus region of the hypothalamus, acting as conductor to synchronize and direct peripheral oscillators (Young, 2018). Synchronization of these intrinsic circadian clocks can be achieved in response to photic and non-photic *zeitgebers* (time-givers). The most powerful *zeitgeber* is light, which synchronizes the central clock. In addition to receiving cues from the central clock, peripheral clocks are synchronized by external *zeitgebers*, including food intake, temperature, energetic stressors, and drive the expression of a broad network of genes, many of which are involved in metabolic homeostasis (Gabriel and Zierath, 2019). The precise mechanism by which circadian clocks coordinate whole-body homeostatic processes is an area of emerging interest given the importance of external *zeitgebers* and the regulation of gene programs controlling metabolism and development.

One mechanism by which the circadian machinery influences metabolism is through the diurnal patterns of hormone secretion (Gamble et al., 2014). Endocrine organs release a variety of hormones in response to diverse environmental factors including diurnal cycles of light/dark, fasting/feeding, and temperature changes. For example, there are diurnal or circadian patterns of secretion of cortisol, growth hormone, prolactin, thyroid hormone, gonadal steroids, and melatonin related to sleep/wake cycles, whereas metabolic hormones including insulin, leptin, ghrelin, and glucagon vary in response to nutritional cues related to fasting/feeding cycles (Gamble et al., 2014). Many of these hormones including insulin, insulin-like growth factor 1, and glucocorticoids can act as *zeitgebers* to reset or fine tune the clock (Balsalobre et al., 2000; Crosby et al., 2019). Thus, an intimate relationship between circadian clocks and endocrine systems exists. This relationship is clinically relevant since disruption of the circadian clock is linked to metabolic disease.

In humans, long duration of shift work is associated with an increased risk of type 2 diabetes, which is only partly explained by lifestyle factors and BMI (Vimalananda et al., 2015). Epidemiological studies show that disruption of the sleep/wake cycle through extended periods of rotating night shift work is associated with obesity and increased risk of type 2 diabetes (Lin et al., 2009; Pan et al., 2011). Chronic jet lag in mouse models disrupts exergy homeostasis and leptin signaling and leads to circadian dysfunction-induced obesity (Kettner et al., 2015). Similarly, a population-based cohort study indicates that social jet lag, defined as the discrepancy between circadian and social clocks, is associated with increased risk of metabolic syndrome and diabetes/prediabetes (Koopman et al., 2017). Thus, chronobiology has implications for obesity and type 2 diabetes pathogenesis.

A basic paradigm of circadian regulation of metabolism is that oscillations of gene expression generate daily rhythms in cellular metabolism (Kim and Lazar, 2020). At the molecular level, circadian rhythms are generated by a cell autonomous and self-sustained transcriptional auto-regulatory feedback loop that is composed of transcriptional activators and their target genes, which rhythmically accumulate and form a repressor complex to inhibit transcriptional activity (Figure 4). Energy, nutrient, and oxygen sensors interact with the circadian clock machinery to control metabolic outputs including mitochondrial function, substrate utilization, insulin sensitivity, and glycemic control (Lamia et al., 2009; Peek et al., 2017; Sato et al., 2019). These sensors monitor oxygen availability and energy stress via hypoxia-inducible factor-1 alpha (HIF1α) and AMP-activated protein kinase (AMPK), respectively. Cells also integrate signals from nutrients and growth factors via mammalian target of rapamycin (mTOR). These energetic sensors not only exhibit circadian rhythmicity, but also regulate components of the core clock machinery through epigenetic modifications, mainly involving histone modifications (Kim and Lazar, 2020). Thus, cross-talk exists between the circadian clock and epigenetic factors that influence the genomic plasticity of organs controlling metabolic homeostasis. In rodents, dysregulation of the intrinsic molecular clock in a variety of tissues leads to obesity, insulin resistance, and altered glucose homeostasis (Rudic et al., 2004; Turek et al., 2005). Nevertheless, the mechanisms underlying disrupted circadian rhythmicity in people with type 2 diabetes are unknown. There is potential to coordinate behavioral changes with the body's daily rhythm to improve metabolic homeostasis. Timing of exercise training bouts or meals and distribution of calories throughout the day may lead to improved outcomes for people with obesity or type 2 diabetes (Lundell et al., 2020; Savikj et al., 2019).

Figure 4. Circadian control and influence of energy sensing pathways

Mitochondrial function, substrate utilization, insulin sensitivity, and glycemic control exhibit diurnal rhythms that are influenced by a variety of factors including energetic stressors such as diet, exercise, and metabolic disease, as well as intrinsic clocks. The molecular circadian clock is composed of transcriptional activators, circadian locomotor output cycles kaput (CLOCK), and brain and muscle ARNTL-like protein 1 (BMAL1), and their target genes period (*PER*), cryptochrome (*CRY*), *NR1D1* (which encodes REV-ERBα) and *DBP*, which rhythmically accumulate and form a repressor complex that interacts with CLOCK and BMAL1 to inhibit transcriptional activity. Energetic stressors influence the circadian program and metabolism. AMPK-mediated phosphorylation of CRY and PER promotes their destabilization and degradation, while mTOR activation induces CRY1 expression. PER2 inhibits mTOR complex activity via the tuberous sclerosis complex 1. HIF1α regulates PER2 transcription and interacts with BMAL1 at the chromatin level. CRY1 reduces HIF1α half-life by interacting with its basic-helix-loop-helix domain.

29.6.1.1.4: IMPACT OF ENERGETIC STRESSORS ON THE CONTROL OF METABOLISM

Obesity, diabetes, exercise, and food restriction are energetic stressors that represent major challenges to organismal homeostasis, triggering wide-ranging responses in numerous cells and tissues controlling glucose and energy metabolism. An essential component of an organism's survival is the ability to sense energy availability and to adapt accordingly. Metabolic flexibility, the ability to shift between fat and glucose oxidation with fasting and feeding, is reduced in individuals with metabolic diseases and contributes to the overall insulin resistance phenotype (Kelley et al., 1992). Skeletal muscle exhibits metabolic flexibility in fuel preference, likely due to its crucial role in hunting and surviving predation, situations requiring movement even if nutrient availability is not optimal (Freese et al., 2017). A body of literature supports the idea that metabolic flexibility can be directly influenced by physical activity, independent of changes in energy balance (Rynders et al., 2018). Physical exercise enhances skeletal muscle insulin sensitivity and improves whole-body glucose metabolism in people with type 2 diabetes (Savikj and Zierath, 2020). However, recent findings, based on stable-isotope tracer and liquid chromatography tandem mass spectrometry, demonstrate that skeletal muscle mitochondrial substrate preference is not altered in insulin resistant rodents and humans, calling into question the central role of metabolic flexibility in the pathogenesis of metabolic diseases (Song et al., 2020). Nevertheless, there is growing appreciation that insulin resistance, obesity, and type 2 diabetes can be avoided or at least delayed by lifestyle intervention strategies, including diet and exercise, which initiate diverse homeostatic responses across multiple organs (Savikj and Zierath, 2020).

The concept of "time-restricted feeding" has gained traction as a dietary means to restore metabolic homeostasis, enhance insulin sensitivity, and curb obesity. Time-restricted feeding refers to restricting daily food intake to a few hours, without caloric restriction (Chaix et al., 2014). In rodents, time-restricted feeding synchronizes the feeding/fasting cycle with the central clock, thereby promoting robust circadian and metabolic cycles, which mitigates obesity and metabolic dysfunction (Hatori et al., 2012). Thus, timing of food intake with the molecular circadian clock may fine-tune metabolism. In humans, time-restricted feeding paradigms improve cardiometabolic health in people with obesity or metabolic disease (Cienfuegos et al., 2020; Wilkinson et al., 2020). Short-term time-restricted feeding schedules in men with obesity modulate the diurnal rhythm of lipid and amino acid metabolism, without affecting core clock gene expression in skeletal muscle (Lundell et al., 2020). Furthermore, the timing and type of nutritional intake throughout a day influences carbohydrate metabolism and protein synthesis (Areta et al., 2013). Whether this is dependent upon the release of hormones, metabolites, or thermogenesis warrants further investigation. Moreover, the weight and cardiometabolic benefits achieved with time-restricted feeding schedules may be related to reductions in calorie intake, rather than meal timing. Concordantly, a prospective randomized clinical trial including 116 men and women with overweight or obesity found that modest reductions in weight loss and energy intake from time-restricted eating did not differ from the control group (Lowe et al., 2020), hinting at the possibility that benefits of time-restricted feeding programs are mainly due to reductions in calorie intake.

Diet and exercise have a synergistic effect on insulin sensitivity, which may be influenced by altering the timing of the meal or an exercise bout throughout the day. In rodents, there is a time-of-day-dependent effect of acute exercise on the diurnal oscillations of skeletal muscle metabolites and transcripts, with a greater reliance on glycolytic metabolism when exercise is performed during the early active phase of the day (Sato et al., 2019). Moreover, in a preliminary clinical investigation comparing the time-of-day impact of high intensity exercise in men with type 2 diabetes, greater blood glucose control was achieved with afternoon versus morning exercise (Savikj et al., 2019).

The oxygen-sensitive transcription factor HIF1α links time-of-day-specific effects of exercise on gene expression and carbohydrate metabolism in mice models (Peek et al., 2017; Sato et al., 2019). This finding has clinical relevance, since intense exercise acutely increases skeletal muscle protein abundance and DNA binding activity of HIF1α in humans (Ameln et al., 2005). Moreover, energetic stressors, such as exercise and hypoxia, increase skeletal muscle glucose uptake in healthy and insulin resistant humans and rodents (Ranheim et al., 1997; Ryder et al., 2000). Thus, perturbing energy, nutrient, and/or oxygen sensors may have a varied response on cellular metabolism depending on the time of day. Collectively, these studies provide evidence that the timing of exercise bouts throughout the day is clinically relevant for the diurnal control of glycemia or systemic metabolism. Adjusting the timing of external cues (i.e., meal/exercise timing) may sustain or amplify circadian clock signals to prevent or mitigate metabolic disease.

29.6.1.1.5: THERMAL TOLERANCE

Excess energy can be dissipated in the form of heat, a process that occurs in brown adipose tissue and is stimulated by food intake and cold exposure (Chouchani et al., 2019). Feedback loops involving temperature sensors, thermogenesis, sweating, and the control of blood circulation are tightly regulated to maintain body temperature in humans at ∼37°C. Alterations in ambient temperature trigger acute and chronic changes in whole-body physiology, making climate a major environmental stressor that affects all individuals on the planet. Acute exposure to cold triggers shivering in skeletal muscle, where ATP is used to generate movement and its associated production of heat. Chronic adaptation to cold involves different mechanisms, the main one being activation of brown adipose tissue thermogenesis (Chouchani et al., 2019). Uncoupling protein 1 dissipates the proton gradient in the mitochondria to generate heat instead of ATP. Consequently, oxidative phosphorylation increases to maintain mitochondrial membrane potential. Therefore, exposure to cold temperatures increases the metabolic rate during sleep cycles, as well as diet-induced thermogenesis, thereby increasing total energy expenditure (Chouchani et al., 2019). A rise in ambient temperature above thermoneutrality also increases metabolism by promoting heat dissipation (Chouchani et al., 2019).

The processes involved in heat acclimation have been extensively studied in humans and involve an increase in total body water, increased sweat volume and decreased sweat concentration, as well as adaptations of heart rate and skin blood flow (Périard et al., 2015). Mechanisms involved in heat acclimation and associated cardiovascular events are related to increased central heat production and dehydration and the ensuing deleterious consequences on blood pressure and cardiovascular function (Meade et al., 2020).

Acute exposure to extreme ambient temperatures, often referred to as “cold stress” or “heat stress,” is associated with an increased risk of cardio-pulmonary mortality (Achebak et al., 2019). In this context, age, weight, obesity, and type 2 diabetes are major risk factors (Hajat et al., 2017; Huang et al., 2012). The mechanisms for increased risk of cardiovascular events secondary to extreme temperatures in people with metabolic diseases are poorly understood. Reduced heat tolerance in obesity might be due to impairments in blood flow and sweat production (Vroman et al., 1983). The reduced sweating ability is possibly linked to a decreased body surface area-to-body mass ratio in a person with obesity as compared to a leaner person. Individuals with type 2 diabetes also exhibit reduced skin blood flow in response to local and whole-body heating, likely due to impaired endothelial function (Meade et al., 2020). However, chronic exposure to mild electrical stimulation with heat shock improves visceral adiposity, glucose homeostasis, and insulin sensitivity in people with type 2 diabetes (Kondo et al., 2014). This paradox suggests that increasing heat tolerance by repeated acute exposures to heat might mitigate heat-induced cardiovascular events in individuals with metabolic diseases.

Heat stress from both exercise and environmental factors can increase thermal strain in unacclimated individuals (Figure 5). Acute exercise increases core body temperature and high-intensity exercise can lead to heat illness consisting of symptoms ranging from minor cramps and syncope to major heat stroke, even in highly trained athletes (Charlot et al., 2017). The capacity to dissipate an exercise-induced elevation in body temperature is reduced in people with type 2 diabetes, but this can be overcome by regular exercise training, which is associated with improved heat tolerance (Kenny et al., 2016). Regular exercise training also reduces cardiovascular mortality and improves glucose control in people with type 2 diabetes (Savikj and Zierath, 2020). At a molecular level, exercise training increases heat shock protein abundance, a process that could contribute to the beneficial effects of exercise to enhance insulin sensitivity (Archer et al., 2018). Individuals with obesity or type 2 diabetes exhibit decreased levels of heat shock proteins in skeletal muscle (Chung et al., 2008). This decrease is reversible, and induction of heat shock proteins by mild electrical stimulation with heat shock improves visceral adiposity as well as plasma glucose and insulin levels (Kondo et al., 2014). Regular exposure to thermal stressors, such as exercise or environmental temperature, may improve heat tolerance through overlapping adaptive mechanistic responses (sweat volume and composition, body water, heart rate), thereby improving metabolism and decreasing risk of cardio-pulmonary events in individuals exposed to extreme ambient temperatures.

2. Download : Download full-size image

Figure 5. Beneficial effects of exercise training on metabolic risk

Decreased thermal tolerance, increased chronic inflammation, deregulated circadian rhythms, and poor glucose control worsen with age and disease development, increasing the susceptibility to life-threatening infections and extreme temperatures and eventually the risk of cardiovascular events (CVD). Exercise triggers acute and transient changes in inflammation and body temperature. These acute events are required for the beneficial effects of exercise training. Exercise training slows the progression of chronic inflammation, limits the decrease in heat-tolerance, and helps synchronize circadian clocks, thereby improving metabolism.

Presently, most of the human population lives under conditions of thermoneutrality, which is made possible due to appropriate clothing and heating systems in homes and workplaces. Reduced energy expenditure, due to the comforts of our modern society and the decline in our prolonged exposure to cold environments, may contribute to the worldwide rise in obesity, although this is difficult to firmly establish. However, there is a clear link between thermal regulation, metabolic diseases, and associated complications. Most of the temperature-related cardio-pulmonary events occur on moderately hot and moderately cold days (Gasparrini et al., 2015), suggesting that steady increases in the average global temperature has the potential to impact the numbers of these events worldwide. The combination of an epidemic of obesity and type 2 diabetes, juxtaposed with an aging population and climate change, may potentially lead to a dramatic increase in cardio-vascular morbimortality. Understanding the molecular basis of heat intolerance in people with obesity or type 2 diabetes could open novel preventative and therapeutic perspectives.

29.6.1.1.6: INFLAMMATORY RESPONSES

The stress that temperature, obesity, diabetes, exercise, and food exert on organismal homeostasis triggers activation of the immune system and different states of metabolic inflammation. The immune system is composed of specialized cells present in every organ that protect against a wide variety of insults, including infections, mechanical injuries, and a variety of diseases. The immune response comes in waves, starting with a pro-inflammatory activation and finishing with a resolving anti-inflammatory phase (Feehan and Gilroy, 2019). When the immune system fails to recover after an insult, a chronic inflammatory state occurs, leading to long-term deleterious consequences. This typically happens in obesity, where immune cells infiltrate tissues and lead to chronic low-grade inflammation, associated with increased risk of cardiovascular complications. The association of inflammation with type 2 diabetes and obesity has been extensively studied, as evidenced by the rapid development of the field of "*immunometabolism*," which includes the analysis of the complex interactions between metabolic and inflammatory pathways in immune and metabolic tissues (Lee et al., 2018).

Obesity and type 2 diabetes are associated with an accumulation of immune cells in key tissues involved in metabolic homeostasis. A link between metabolic diseases and immunology emerged with the detection of macrophage infiltration in adipose tissue, followed by the discovery that lymphocytes, neutrophils, and other specific subtypes of immune cells accumulate not only in adipose tissue but also in skeletal muscle and liver (Hotamisligil, 2017). Even neuroinflammation is part of the systemic inflammatory syndrome in metabolic

diseases (Cai, 2013). The accumulation of triglycerides in adipocytes increases adipocyte size (hypertrophy) and number (hyperplasia), resulting in the rapid expansion of adipose tissue, which triggers hypoxia and the production of soluble mediators likely responsible for the attraction of immune cells. The first immune cells reaching adipose tissue are likely attracted to support tissue remodeling in a beneficial manner, but the chronic increase in adipose tissue volume and the establishment of a new obese steady-state leads to increasing lipolysis and circulating free fatty acids, which activate immune cells toward a pro-inflammatory phenotype and promote the establishment of chronic inflammation (Lee et al., 2018). Immune cells also respond to metabolic changes and are susceptible to the deleterious effects of an excessive lipid or glucose accumulation (i.e., "*lipotoxicity*" or "*glucotoxicity*"), as well as other metabolism-related danger signals that are released by tissues during metabolic stress (Wang et al., 2020b). The composition and phenotype of circulating immune cells is altered in blood of individuals with obesity, with an increase in CD16+ monocytes, and immune cell activation in response to high concentrations of glucose or fatty acids (Pillon et al., 2016). These findings suggest that the immune system is profoundly affected by whole-body glucose and lipid homeostasis.

The mechanisms by which non-adipose tissues establish a state of inflammation is unclear. However, lipotoxicity, including the excessive accumulation of toxic lipid mediators such as ceramides, diacylglycerol, or acylcarnitine, and increased levels of circulating free fatty acids likely play a role. In addition, activated immune cells primed to respond to metabolism-related danger signals can impair whole-body metabolism. There is ample evidence to suggest that inflammation is associated with the development of metabolic diseases and the ensuing complications, but pharmacological targeting of pathways controlling immunometabolism has shown limited benefits for the treatment of metabolic diseases (Pålsson-McDermott and O'Neill, 2020). Perhaps the key to successful clinical intervention will be to identify relevant patient groups early, before the manifestation of a chronic low-grade inflammatory state.

Acute exercise, especially intense and/or eccentric exercise, triggers an acute inflammatory response, which is necessary for skeletal muscle repair and adaptations to exercise training. Exercise training has beneficial anti-inflammatory effects (Gleeson et al., 2011). Thus, repeated peaks of inflammation triggered by acute bouts of moderate intensity exercise may be beneficial to reduce long-term basal concentrations of pro-inflammatory mediators. In severely obese individuals, combining exercise and dietary interventions can reduce macrophage infiltration and pro-inflammatory polarization in adipose tissue (Bruun et al., 2006). The anti-inflammatory effects of exercise could be secondary to an increased capacity for fatty acid utilization, as exercise training in people with obesity or type 2 diabetes reduces the level of deleterious lipid species such as DAG, acetylcarnitines, and ceramides in skeletal muscle (Lancaster and Febbraio, 2014). However, exercise training in healthy individuals also improves insulin sensitivity without changes in these lipid species, making the role of intramyocellular lipids on insulin sensitivity ambiguous and perhaps more relevant in an obesity context (Reidy et al., 2020).

29.6.1.1.7: UNSUSPECTED CAUSES

Currently known genetic, lifestyle, and environmental risk factors only partly explain the development of obesity and diabetes. Other yet unknown factors must be at play. A recent example of potential novel causes of diabetes is the high prevalence of extreme hyperglycemia/ketoacidosis in patients not known to have diabetes admitted to hospital with COVID-19 (Rubino et al., 2020). This seems both more common and more severe than has been seen with other infections/serious illnesses, so it may not represent "stress hyperglycemia" or unmasking of pre-existing, undiagnosed diabetes. Instead, these observations may suggest a specific pathological entity. The SARS-CoV-2 spike protein penetrates cell membranes by binding to the angiotensin converting enzyme (ACE) 2 receptor. This receptor is present on pancreatic beta cells (Hamming et al., 2004). Infection may result in acute loss of insulin secretory capacity and/or beta cell destruction (Apicella et al., 2020). ACE2 receptor is also present on adipocytes so that SARS-CoV-2 may also exacerbate chronic inflammation in adipose tissue (Kassir, 2020).

The mechanisms whereby widely accepted risk factors such as obesity result in disease may have novel aspects. It is generally assumed that individuals with type 2 diabetes who are not obese have a different pathophysiological cause unrelated to weight. However, this belief has been challenged recently. The concept of a "personal fat threshold" arose from observations that the median BMI in the UK Prospective Diabetes Study was only 28 kg/m^2 (Taylor and Holman, 2015) and that reversal of type 2 diabetes by weight loss could be achieved equally successfully in individuals with higher and lower BMI (Lim et al., 2011). The underlying mechanism appears to be lipotoxicity, an individual's propensity to accumulate liver and pancreas fat, and their susceptibility to the adverse effects of fat accumulation. At any given body weight or BMI, at-risk individuals will accumulate more liver fat and be more susceptible to developing hepatic insulin resistance at any given liver fat content. The subsequent increase in VLDL-TG export from the liver drives fat accumulation in the pancreas and declining insulin secretion, both also dependent on the individual's susceptibility. Remission of type 2 diabetes by weight loss is accompanied by reduction in liver and pancreatic fat, decreased hepatic VLDL export, and increased insulin secretion (Al-Mrabeh et al., 2020). Conversely, weight re-gain leading to re-emergence of diabetes is associated with increased liver fat export and pancreatic fat, with recurrent pancreatic dysfunction. The importance of these observations underscores the usefulness of weight loss in the management of diabetic individuals even of normal weight. However, diabetes does not remit in everyone following substantial weight loss, so weight loss is not a universal panacea. Further work is needed to establish if this relates to longer duration diabetes, perhaps with irreversible beta cell damage, or to different pathological mechanisms of disease.

29.6.1.1.8: BENDING THE CURVE

Weight loss is clearly the key to reducing rates of obesity and type 2 diabetes, with considerable individual and societal benefits. There is a continuum of action required in prevention of obesity and diabetes, and management and care if they develop (Chan et al., 2020). Many intervention programs have demonstrated successful short-term weight loss and reversal of diabetes, but perhaps the bigger challenge is in preventing weight re-gain (Forouhi et al., 2018). There may be a weight "set-point," at which compensatory hormonal, metabolic and neurochemical mechanisms prevent further weight loss and drive weight regain (Blüher, 2019). However, a significant proportion of individuals who lose a substantial amount of weight, whether by diet or bariatric surgery, do not regain weight over years and maintain the metabolic benefits of the initial weight loss. Thus, weight loss programs must have two parts: an initial phase of weight loss, followed by a weight maintenance program. Obviously, reduction in energy intake by some means is essential for weight loss. Exactly how this is achieved is probably less important than an individual's ability to adhere to the program long term (Johnston et al., 2014). The benefits of one regimen over another have been debated (Forouhi et al., 2018), but no one size fits all, and many different approaches are needed.

Understanding the influence of social and cultural aspects in the development and management of obesity and diabetes is also crucial (Blüher, 2019). Individuals from socially deprived backgrounds are more likely to be at high risk to develop obesity and type 2 diabetes, to have poorer glycemic control, to develop more complications, and to have a greater reduction in life expectancy (Chan et al., 2020). Identifying and overcoming barriers to participation in screening and prevention programs and in diabetes and obesity care are vital. Most programs do not reach individuals from ethnic minorities or low socioeconomic class, who are most at need (Timpel et al., 2019). Involving overweight and obese individuals from a wide diversity of backgrounds in the identification of barriers to adherence and then in the design of weight loss and diabetes prevention/reversal programs is essential to improve engagement.

29.6.1.1.9: PERSONALIZED MEDICINE

Although we talk about type 2 diabetes as one disease, this "blanket" diagnosis covers important heterogeneity (Ahlqvist et al., 2018). Only rarely is the heterogeneity obvious and explainable: slim rather than obese, or young age at presentation with a striking family history in monogenic diabetes. On many occasions, individuals with apparently similar phenotypes have very different clinical courses and respond quite differently to glucose lowering agents. Dissecting out particular forms of "type 2 diabetes," whether by genetic analyses and risk scores or by improving our understanding of the underlying pathophysiological bases to dysglycemia, is currently possible at the population level but remains extremely difficult at an individual level. As a result, the selection of glucose-lowering agents for individuals is a "best guess" approach, far removed from personalized medicine.

Personalized medicine is defined simply as the right treatment for the right person at the right time. The recent American Diabetes Association/European Association for the Study of Diabetes consensus report describes the ambition to personalize all aspects of an individual's diabetes, including precision diagnosis, lifestyle and pharmacological management, and prognosis (Chung et al., 2020). Currently, for a very small number of individuals (for example, those with congenital leptin deficiency [Montague et al., 1997] and GCK-MODY [MODY 2] [Froguel et al., 1992; Hattersley et al., 1992]), precision diagnosis is possible. However, there are major challenges in precision diagnosis for individuals with the polygenic common forms of obesity and type 2 diabetes. Likewise, there are only a small number of examples of precision therapeutics (for example, leptin for management of severe obesity in congenital leptin deficiency [Farooqi et al., 2002] and sulphonylureas rather than insulin for individuals with neonatal diabetes due to mutations in the genes encoding the potassium channel [KCNJ11 and ABCC8] [Pearson et al., 2006]). For many individuals with obesity and type 2 diabetes, we have extremely blunt "precision" tools. For example, analysis of data from participants in the RECORD and ADOPT trials demonstrated that individuals with insulin resistance have a greater sustained fall in HbA1c on thiazolidenediones compared to sulphonylureas (Dennis et al., 2018). Additionally, there are benefits of SGLT2 inhibitors in individuals with high cardiovascular risk and/or renal disease (Lo et al., 2020). Work is beginning to examine possibilities for personalization of lifestyle measures.

29.6.1.1.10: GRAND CHALLENGES

Prevention of obesity is probably the most important factor in reducing the prevalence of obesity and related metabolic diseases. This will require action at an individual and societal level (Chan et al., 2020). Societal action is necessary in many areas, including changes to road, rail, and cycling transport plans to encourage increased physical activity, as well as negotiations with the food industry (Chan et al., 2020). Governments also need effective communication plans that reach all sections of society (Timpel et al., 2019). Moreover, different strategies are required for different life stages. The lifestyles of almost everyone must change radically, and this must be facilitated by appropriate action by governments and many branches of industry. The challenges to overcome the status quo and vested interests are considerable.

There is abundant evidence that many individuals with obesity at high risk of metabolic disease can lose substantial amounts of weight, reversing pre-diabetes and diabetes. A significant proportion then maintain the weight loss and improved metabolic status for years. Weight loss programs are projected to be more effective per quality-adjusted life year and cost-saving over a lifetime compared to standard care in individuals with type 2 diabetes (Xin et al., 2020). The challenge then is to expand and adapt these successful programs so that all individuals can access them and be supported through them. We must work with individuals who find current programs inappropriate for them, identifying barriers to participation and working together to develop practical solutions. Most current weight loss programs center on improving basic diet, with or without advice on exercise (Forouhi et al., 2018). Further incremental benefit may well be obtained by incorporating additional "personalized" measures, perhaps based on genes, occupation, and inflammatory status, such as advice on specific

micronutrients, timing of food intake and exercise, and light exposure. However, the challenge will be to ensure that the message does not become so complex that adherence falls.

There is a particular challenge for young people (Chan et al., 2020). The WHO estimated in 2016 that world-wide, 340 million children and adolescents aged 5–19 years were overweight or obese and, in 2019, that 38 million children aged <5 years were overweight/obese (https://www.who.int/news-room/fact-sheets/detail/obesity-and-overweight). Associated with this, type 2 diabetes is increasingly diagnosed in children, adolescents, and young adults (IDF Diabetes Atlas 9th edition 2019, www.diabetesatlas.org). A recent meta-analysis has demonstrated the greater impact of type 2 diabetes presenting at younger age: each one-year increase in age at diabetes diagnosis was associated with a 4%, 3%, and 5% decreased risk of all-cause mortality, macrovascular, and microvascular disease respectively (Nanayakkara et al., 2020). These changes underscore the need to prevent obesity and/or manage it appropriately in young people.

Paralleling the rise in obesity in younger people is the rise in the number of women with hyperglycemia during pregnancy. The IDF estimated that, in 2017, 16% of women with live births had some form of hyperglycemia during pregnancy, and that 86% of them had gestational diabetes (IDF Diabetes Atlas 9th edition 2019, www.diabetesatlas.org). In addition to the immediate maternal and fetal adverse effects of hyperglycemia during pregnancy, many of these women will develop type 2 diabetes in the subsequent 5-10 years. There are also longer-term consequences to the offspring of increased risk of obesity, type 2 diabetes, hypertension, and cardiovascular disease (Catalano and Shankar, 2017). Some of these adverse consequences are now being reported over several generations of offspring, implicating an epigenetic influence (Catalano and Shankar, 2017). Thus, in addition to the immediate management of the index pregnancy, it is extremely important that further studies of the index in women, their children, and potentially subsequent generations are conducted urgently.

Low levels of fitness are a risk factor for hospitalizations and all-cause mortality, and predict morbidity after surgical interventions (West et al., 2016). During the COVID-19 pandemic, public health recommendations regarding confinement and closure of recreation areas decreased daily activity in the general population (Sánchez-Sánchez et al., 2020), aggravating already high levels of inactivity in most countries (https://www.who.int/news-room/fact-sheets/detail/physical-activity). In young adults who only developed mild symptoms, COVID-19 decreased the predicted maximal aerobic capacity (Crameri et al., 2020), while persons more severely infected with SARS-CoV-2 exhibited anorexia and skeletal muscle loss, aggravated by long hospital stays, raising the question of whether COVID-19 could be a major cause of cachexia and sarcopenia (Morley et al., 2020). As obesity and type 2 diabetes are risk factors for COVID-19 complications, the underlying inflammatory conditions in combination with impaired skeletal muscle function may contribute to worse outcomes after infection (Guisado-Vasco et al., 2020). Whether exercise can protect against viral infection or influence disease severity is unclear, but the benefits of physical activity to prevent skeletal muscle wasting are important factors for prevention and rehabilitation of people in risks groups. Understanding the molecular mechanisms underlying the beneficial effects of physical exercise as an inflammatory modulator could thus potentially prevent or mitigate complications due to unexpected infections (da Silveira et al., 2021; Krause et al., 2020).

29.6.1.1.11: ON THE HORIZON

How do we move forward? Progress will only come if we tackle the problems at both a population and an individual level. Putting into practice what we already know will benefit many individuals (Chan et al., 2020). Incorporating the newer evidence described above—for example, around the timing of eating and exercise—and light exposure, in ways that do not overwhelm people, will bring added benefits. Better personalization of all aspects of prevention, management, and care should help adherence. In-depth large-scale analysis of genetic and environmental factors may help clarify why people respond differently to the whole gamut of care, allow stratification into refined sub-groups with specific risk factors and genetic predispositions, and potentially thus optimize the efficacy of both lifestyle and pharmacological interventions. Ongoing initiatives like the Innovative Medicines Initiative (www.imi.europa.eu) have demonstrated that combining large databases from multiple public and private organizations is possible, generating power to tackle relevant genetic and biomarker questions. Such initiatives, bringing together diverse stakeholders with people with obesity or diabetes, are essential in our efforts to provide personalized, timely, affordable, and equitable access to high-quality health interventions, with the aim of improving health outcomes for all.

29.7.2: ABSTRACT

Metabolic syndrome (MetS) has a worldwide tendency to increase and depends on many components, which explains the complexity of diagnosis, approaches to the prevention, and treatment of this pathology. Insulin resistance (IR) is the crucial cause of the MetS pathogenesis, which develops against the background of abdominal obesity. In light of recent evidence, it has been shown that lipids, especially fatty acids (FAs), are important signaling molecules that regulate the signaling pathways of insulin and inflammatory mediators. On the one hand, the lack of n-3 polyunsaturated fatty acids (PUFAs) in the body leads to impaired molecular mechanisms of glucose transport, the formation of unresolved inflammation. On the other hand, excessive formation of free fatty acids (FFAs) underlies the development of oxidative stress and mitochondrial dysfunction in MetS. Understanding the molecular mechanisms of the participation of FAs and their metabolites in the pathogenesis of MetS will contribute to the development of new diagnostic methods and targeted therapy for this disease. The purpose of this review is to highlight recent advances in the study of the effect of fatty acids as modulators of insulin response and inflammatory process in the pathogenesis and treatment for MetS.

29.7.3: 1. INTRODUCTION

Metabolic syndrome (MetS) is a complex of several disorders (abdominal obesity, hyperglycemia, hypertriglyceridemia, and hypertension), which together dramatically raise the risk of developing atherosclerotic cardiovascular disease, insulin resistance, and diabetes mellitus [1, 2]. Because the prevalence of obesity has doubly increased worldwide over the past 30 years, the prevalence of MetS has markedly boosted in tandem [2–5]. Currently, clinicians and researchers have not identified an optimal treatment for MetS, and consequently, it is critical to identify new ways of approaching this syndrome in order to identify efficacious methods of diagnosing, screening, and treating MetS. Most researchers believe that hyperinsulinemia and/or insulin resistance (IR) is the first link in the chain of clinical-metabolic disturbances of MetS [5–7]. The development of IR is the result of a long chain of pathological events. Lipids play the crucial role in the pathogenesis of IR and the subsequent development of MetS [8–18]. All lipids are no longer considered the same. It is well known that excessive consumption of saturated fats contributes to the development of obesity and related diseases [19]. It has now been shown that high plasma levels of free fatty acids (FFAs), particularly saturated fatty acids (SFAs), may be associated with insulin resistance in obese patients with type 2 diabetes mellitus [17]. The lack of polyunsaturated fatty acids (PUFAs), especially n-3 PUFAs, some phospholipids, and plasmalogens in the cell membrane, is the cause of changes in glucose-insulin homeostasis and the development of inflammation [10, 13, 20–23]. Conversely, multiple investigations have established a connection between inflammation and changes in lipids and their derivatives in the setting of MetS [24–29]. Alteration in the metabolism of fatty acids affects the synthesis of eicosanoids and pro-resolving lipid mediators responsible for immune-metabolic homeostasis [30–33]. Recent studies have further elucidated the role of these metabolites in the contribution to the chronic, low-grade inflammatory state in MetS [34–36]. A comprehensive understanding of the importance of lipids in the pathogenesis of MetS contributes to the development of preventive and targeted lipid-correcting therapy. The aim of the review is to analyse the modern views on the role of lipids, particularly PUFAs and FFAs, in the pathogenesis of MetS. In this review, we summarized the molecular mechanisms of the relationship between fatty acids and glucose transport, inflammatory response, mitochondrial dysfunction, and endoplasmic reticulum stress in the development of MetS.

29.7.4: 2. METABOLIC SYNDROME: DEFINITIONS AND CRITERIA

Metabolic syndrome (MetS) has become a widely debated scientific, medical, and social problem worldwide. Indeed, the definition of metabolic syndrome is important for clinical practice and deserves serious scientific and medical research. MetS is characterized by the following clinical criteria: abdominal obesity, decreased peripheral tissue sensitivity to insulin, and hyperinsulinemia, which cause metabolic disorders of carbohydrates, lipids, and purines [1, 2]. This combination of metabolic disorders is often found in one person and, thus, significantly increases the risk of cardiovascular disease (CVD), type 2 diabetes mellitus (T2DM), arthritis, chronic kidney disease, schizophrenia, nonalcoholic fatty liver disease (NAFLD), and several types of cancer [37–42].

MetS is characterized by a steadily increasing prevalence [3, 4]. However, its prevalence rates vary depending on the criteria used to determine MetS, genetic component, gender, age, population and area of residence, education, level of physical activity, nutrition, and lifestyle [39]. Approximately one-fourth of world's adult population have MetS [43, 44]. Urbanization and its associated sedentary lifestyle and surplus nutrition are the root cause of this global epidemic.

The determination of MetS uses the criteria of the following medical communities: WHO (World Health Organization), NCEPATP III (National Cholesterol Education Program-Adult Treatment Panel III), AACE (American Association of Clinical Endocrinologists), IDF (International Diabetes Federation), EGIR (European Group for the Study of Insulin Resistance), The International Diabetes Federation (IDF), American Heart Association/National Heart, Lung and Blood Institute (AHA/NLHBI), World Heart Federation (WHF), International Atherosclerosis Society (IAS), and The International Association for the Study of Obesity (IASO) [3]. A guideline was made in 2009 to unify the criteria for the diagnosis of MetS. According to this guide, three of the five criteria are necessary for diagnosing MetS: (1) waist circumference ≥102 cm for males and ≥88 cm for females (for Asians ≥90 cm for males and ≥80 cm for females); (2) systolic blood pressure ≥130 mmHg or diastolic blood pressure ≥85 mmHg or antihypertensive medication; (3) fasting plasma glucose ≥5.6 mmol/L or on medication for high blood glucose; (4) HDL cholesterol <1.03 mmol/L for males and <1.30 mmol/L for females or on medications for reduced HDL cholesterol; and (5) triglycerides ≥1.7 mmol/L or on medications for elevated triglycerides [3].

Although the exact etiology of the MetS is not clearly understood, insulin resistance (IR) is considered as the principal factor for the pathogenesis of this syndrome [6, 11, 18, 45]. As found by the insulin-modified, frequently sampled intravenous glucose tolerance assay, insulin sensitivity is significantly lower in patients with two or more components of the MetS compared to those with none of these components [2]. Dysregulation of lipid metabolism is considered as an important link in the overall development chain of IR. It is well known that lipids play a critical role in the regulation of energy metabolism, glucose transport, and immune process in many organs and tissues such as the liver, adipose tissue, muscle, heart, and gastrointestinal tract [46]. However, the molecular mechanisms of this regulation remain largely unexplored. The study of lipid metabolism disorders is a promising direction for the development of methods for the effective treatment of this pathology.

29.7.5: 3. POLYUNSATURATED FATTY ACIDS AND METABOLIC SYNDROME RISK

Fatty acids (FAs) play multiple roles in humans and other organisms. Most importantly, FAs are a substantial part of lipids. Fatty acids are either saturated or unsaturated carboxylic acids with carbon chains varying between 2 and 36 carbon atoms. Polyunsaturated fatty acids with an acid end containing the functional carboxylic acid group and a methyl end are also known as omega end. In omega-3 (ω-3 or n-3) and omega-6 (ω-6 or n-6) fatty acids, the first site of desaturation is located after the third and the sixth carbon from the omega end, respectively. Our body cannot synthesize some PUFAs, such as alpha-linolenic acid (18:3n3) and linoleic acid (18:2n6). These essential PUFAs enter our bodies only through diet. The dietary sources of n-3 PUFAs include fish oils rich in eicosapentaenoic acid (20:5n3) and docosahexaenoic acid (22:6n3), whereas the n-6 PUFA linoleic acid is mostly found in plants and vegetable oils [47].

Nowadays, there is growing evidence showing that dietary n-3 PUFAs have a variety of healthy properties such as the reduction of plasma atherogenic lipids and inflammation [16, 21, 25, 41, 47–49]. The associations between n-3 PUFAs and metabolic syndrome risk demonstrate inconsistent results [50]. Several cross-sectional and case-control studies have indicated that plasma/serum n-3 PUFAs were significantly higher in healthy subjects compared with those in patients with MetS, while some studies have suggested opposite and null associations [51]. Meanwhile, Guo et al. showed that higher circulating n-3 PUFAs were significantly associated with decreased MetS risk [52]. A study by Kim et al. demonstrated that in healthy individuals the level of long-chain n-3 PUFAs is positively correlated with insulin sensitivity [53]. A decrease in the level of PUFAs has been established in patients with T2DM and diabetic retinopathy. It was found that the development of insulin resistance is preceded by a reduction of essential n-3 PUFAs in the cell membranes [6]. There are several reasons why n-3 PUFAs are important in the pathogenesis and prevention of MetS. PUFAs perform a structural function, being important components of the cell membrane and determining its physical and chemical properties [10, 16]. The efficiency of glucose transport and expression of many receptors depend on the composition and ratio of PUFAs in the cell membrane [17]. Also, PUFAs are the precursors for inflammatory and pro-resolving lipids mediators' synthesis [29, 32]. The imbalance between the synthesis of inflammatory and pro-resolving lipids mediators determines the development of chronic inflammation in MetS. Furthermore, we will summarize the main molecular mechanisms underlying the ability of n-3 PUFAs to prevent and/or ameliorate insulin resistance and inflammation in MetS.

29.7.5.1: 3.1. POLYUNSATURATED FATTY ACIDS AND GLUCOSE TRANSPORT

The identification of a causal relationship between the composition of fatty acids of cell membranes and MetS pathogenesis significantly contributes to an understanding of the main pathophysiological mechanisms of the disease.

Polyunsaturated fatty acids affect the fundamental properties of the cell membrane, including its fluidity, elasticity, receptor expression activity, the functionality of embedded proteins, and signal transmission through lipid rafts, which leads to changes in cell signaling and modification of gene expression [54, 55]. The length and degree of the FA chain unsaturation have a profound effect on the physical and chemical properties of cell membranes [48]. The ratio of polyunsaturated to saturated fatty acids determines the membrane flexibility, which affects the efficiency of glucose transport using insulin-independent glucose transporters (GLUTs) and insulin-dependent GLUT4 [54].

GLUT1 is a monomeric protein with 12 transmembrane helical segments [56]. One molecule GLUT1 covers an area of about 17 molecules of a phosphatidylcholine bilayer with saturated fatty acids (SFAs), which requires a high membrane flexibility for pore formation. GLUT4 is inserted into the membrane of intracellular vesicles, which demands the flexibility of the vesicular membrane. The GLUT4 containing vesicles take part in a fusion process with the cell membrane. The increased flexibility of the membrane provides a smooth bending of the cell membrane bilayer and the fused pores formation [54]. Thus, decreased membrane flexibility causes a reduction in all Class 1 glucose

transporters which, in turn, reduces the glucose flux and increases the plasma glucose concentration. Therefore, high membrane flexibility is a crucial factor in glucose transport. Changes in the fatty acid composition of membranes will result in disturbance in the physicochemical properties of the bilayer, such as flexibility and fluidity. Tighter membrane packaging due to increased saturated fatty acids in it leads to a reduction in the capacity for GLUT4 glucose transport [54].

A number of other studies have also revealed that an increase in the level of saturated fatty acids in the cell membrane is associated with a growth in blood glucose level and the development of insulin resistance [13, 14]. The important role of PUFAs in maintaining glucose-insulin homeostasis is confirmed by many studies [13–15, 21, 25, 47, 49, 51, 53]. Comprehensive evidence shows that diet n-3 PUFAs can improve insulin signal transduction in adipocytes, affecting in turn the insulin-stimulated glucose uptake through the regulation of the expression or the translocation of the GLUT4 [11]. In vitro studies have found that adipocytes from n-3 PUFAs-depleted rats had lower basal and insulin-stimulated glucose incorporation, while cultured adipocytes supplemented with fish oil increased levels of GLUT4 and GLUT1 [41]. González-Périz et al. [11] reported that feeding with a marine n-3 PUFAs-enriched diet improved insulin resistance in association with an increased expression of Irs-1 and Glut4mRNA in the adipose tissue of genetically obese ob/ob mice. The above indicates the huge importance of n-3 PUFAs in the development and regulation of components in the MetS, such as insulin resistance and glucose tolerance.

29.7.5.2: 3.2. POLYUNSATURATED FATTY ACIDS AND INFLAMMATION

Numerous studies have suggested that MetS, like its downstream sequelae of atherosclerotic cardiovascular disease and T2DM, is largely an inflammatory disease [24]. A chronic, low-grade inflammatory state caused by obesity leads to metabolic alterations responsible for multiple organ damage [57, 58]. This metabolic dysfunction could determine clinical conditions such as hypertension, hypercholesterinemia, and insulin resistance [40]. The contribution of inflammation to insulin resistance has been widely studied, and immunological changes occurring in various tissues are thought to be etiological factors affecting the development of insulin resistance [58]. A characteristic of obese people is a chronic, low-grade inflammation state promoted by the release of many inflammatory mediators by the adipose tissue and, more importantly, by infiltrating macrophages. PUFAs and their oxidized metabolites are important participants of the inflammatory processes of MetS [13, 15, 27, 28]. Understanding the molecular mechanisms of the participation of PUFAs and their metabolites in the pathogenesis of MetS will contribute to the development of new diagnostic methods and targeted therapy for this disease.

29.7.5.2.1: 3.2.1. SPECIALIZED PRO-RESOLVING MEDIATORS

Inflammation is a complex, multifactorial adaptive process with different periods of development. Inflammation is a natural reaction to harmful irritants, such as bacterial infections, virus infections, and tissue damage. This is a host's defensive reaction in which immune and endothelial cells and proinflammatory mediators are attracted to eliminate inflammatory agents, clear damaged cells and tissues, and initiate tissue repair. This response, when properly functioning, is self-limiting and leads to the cessation of the inflammatory response and a return to homeostasis, a process called the resolution of inflammation [16, 48]. Resolution of inflammation is now known to be an active process involving the activation of negative feedback mechanisms, such as anti-inflammatory cytokine secretion, reduction in receptor expression, activation of regulatory cells, and production of pro-resolving lipid mediators [57]. However, when acute inflammation is intense or prolonged, the resolution process is not successful, which leads to excessive tissue damage and ultimately resulting in chronic inflammation [16]. Many studies have confirmed that unresolved inflammation is the main mechanism for the pathogenesis of MetS [15, 16, 24, 48, 57, 58].

PUFAs are a source of synthesis of inflammatory and pro-resolving lipid mediators. The major substrate for the synthesis of inflammatory lipid mediators is arachidonic acid (20:4n6) (see Figure 1). The high content of 20:4n6 provides a direct link with inflammation since 20:4n6 released from cell membrane phospholipids acts as a substrate for cyclooxygenase (COX), lipoxygenase (LOX), and cytochrome P450 enzymes [29]. Eicosanoids are important regulators and mediators of acute inflammatory processes and include prostaglandins (PGs), thromboxanes (TBs), and leukotrienes (LTs). Many anti-inflammatory therapies, such as nonsteroidal anti-inflammatory drugs and COX inhibitors, target arachidonic acid metabolism [29, 35, 59, 60].

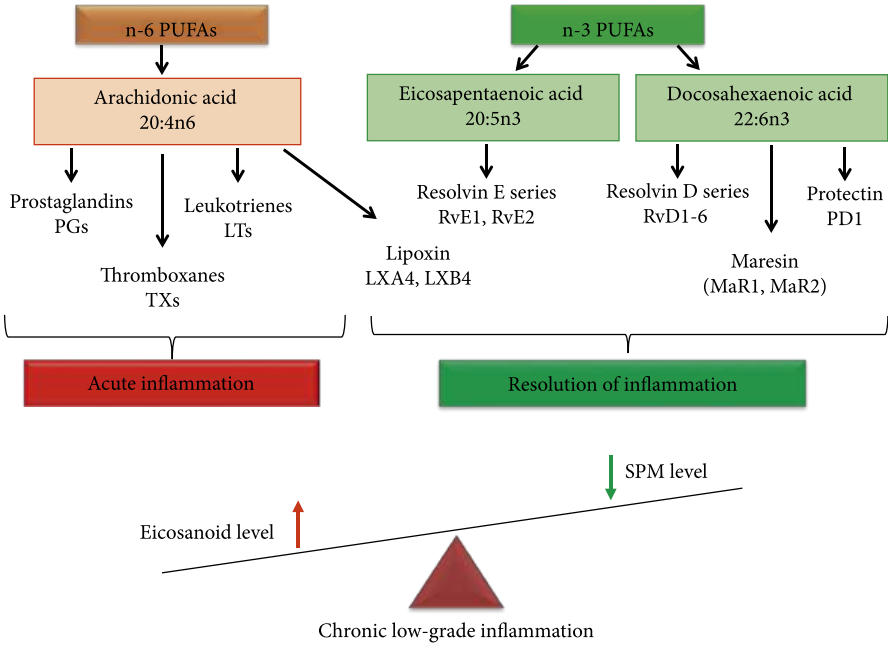

Figure 1

PUFA pathway and role of lipid mediators in the development and resolution of inflammation.

Eicosapentaenoic acid (20:5n3) and docosahexaenoic acid (22:6n3) from the n-3 PUFAs family are a source of synthesizing specialized pro-resolving mediators (SPMs): maresins, resolvins, and protectins (see Figure 1) [32–35]. SPMs are a class of cell compounds generated at a later stage of the inflammation and initiate the resolution of the inflammatory process [33, 34, 61]. SPMs actively facilitate the resolution stage of acute inflammation unlike eicosanoids, which mainly act during the first stage of inflammation. A balanced n-6 : n-3 PUFAs ratio (where 1 : 1 to 2 : 1 is optimal) is important for homeostasis and normal development throughout the lifespan. High n-6 PUFA intake in the Western diet increases the n-6 : n-3 ratio to a range from 10 : 1 to 20 : 1 and may play a role in the pathogenesis of MetS and related diseases [36]. The balance between n-3 PUFAs and n-6 PUFAs determines the path of inflammatory response. The prevalence of n-6 PUFAs and the shortage of n-3 PUFAs may contribute to impaired inflammation resolution [31].

Docosahexaenoic acid- and eicosapentaenoic acid-derived SPMs are identified in the adipose tissue. At the same time, the levels of certain SPMs are markedly reduced with obesity, suggesting adipose SPM deficiency, potentially resulting in unresolved inflammation [36].

Resolvins are synthesized spontaneously from eicosapentaenoic and docosahexaenoic acids during inflammation and thus are designated as E-series (RvE) and D-series (RvD), respectively [32]. The anti-inflammatory effect of RvE1 is due to interaction with peroxisome proliferator-activated receptors (PPARs), which are classified as nuclear transcription factors with anti-inflammatory activity. Leukotriene B4 receptor 1 (BLT1) and G protein-coupled receptor, Chemerin Receptor 23 (ChemR23), are receptors for RvE1. RvE2 has a similar biologic effect; it regulates neutrophil chemotaxis and activates phagocytosis and proinflammatory cytokines synthesis [31, 62].

Protectins (PD) are another class of pro-resolving molecules produced from 22:6n3 during the resolution of inflammation. Protectins are synthesized by a number of cells including brain cells, monocytes, and CD4+ lymphocytes [33]. PD1, the key representative of the protectin family, demonstrates a strong anti-inflammatory and neuroprotective effect. This mediator functioning is based on PPARs interacting and NF-κB blocking [62].

An alternative process for docosahexaenoic acid oxygenation is found in human macrophages and platelets, leading to the synthesis of maresin 1 (MaR1). In addition, 13S, 14S-epoxy-maresin, which has important biological activities of its own, is the precursor for maresin 2 (MaR2) [36].

Lipoxins (LXs) are powerful anti-inflammatory bioregulators suppressing inflammation and activating resolution and recovery processes, in particular in MetS [34]. The substrate for LXs synthesis is arachidonic acids. Two members of the LXs family, LXA4 and LXB4, have been well studied [31]. In general, LXs are a branch of the leukotriene family. For example, their production by platelets is catalyzed by 12-LOX through converting LTA4 [32]. Unlike proinflammatory LTs, LXs act as powerful anti-inflammatory bioregulators, suppressing the inflammation and activating the processes of resolution and recovery. The result of their action is the inhibition of chemotaxis and migration of macrophages and neutrophils to the inflammatory focus, blocking of the lipid peroxidation, the activation of NF-κB, and the suppression of the synthesis of proinflammatory cytokines. In addition, LXs are actively involved in functioning of macrophages that are associated with homeostasis restoration processes [32].

There is a considerable amount of evidence regarding the contribution of n-3 PUFAs to diseases with inflammatory conditions, such as metabolic syndrome [25, 34–36, 47, 49, 51, 53]. It was reported that SPM levels reduced in metabolic syndrome as well as sensitivity to

SPM of the adipose tissue [36]. Obesity reduces the levels of PD1, intermediates in the synthesis of D-series resolvins and protectins (17-HDHA), and intermediates in the maresin biosynthesis (14-HDHA) for the adipose tissues from diet- and genetically-induced obese mice [36]. One of the mechanisms resulting in a decrease in the SPM level in obesity is a change in the enzyme activities involved in biosynthesis or conversion of certain SPMs. N-3 PUFAs supplementation increased the level of SPM in the blood of individuals with obesity and MetS. The effects of n-3 PUFAs are mediated by their ability to interfere with arachidonic acid metabolism and promote the synthesis of SPMs. The supply of n-3 PUFAs increases the levels of resolvins, enhances resolution, and improves insulin sensitivity in an experiment with fat-1 mice. In addition, n-3 PUFAs prevent macrophage increase, adipokine secretion, and insulin resistance induced by a high-fat diet. Synthetic pro-resolving lipid mediators (17-hydroxy-DHA) or n-3 PUFAs added to the treatment contributed to higher levels of pro-resolving lipid mediators in the adipose tissue, reduced inflammation, and increased insulin sensitivity [31]. N-3 PUFAs increased RvE-series levels in patients with MetS but did not affect RvD-series, which requires further studies into the mechanism of n-3 PUFAs influence in MetS. For instance, intraperitoneal administration of 17-HDHA or RvD1 significantly reduced adipose inflammation and improved the glucose tolerance in diet-induced obese mice and in db/db mice [63]. Treatment with either RvD1 or RvD2 also reduced the secretion of proinflammatory cytokines including TNF-α, IL-1β, and IL-12 in the adipose tissue [64]. The MaR1 treatment improved insulin sensitivity, determined with an insulin tolerance test. MaR1 also increased adiponectin gene expression and Akt phosphorylation in the adipose tissues and attenuated adipose tissue inflammation in both ob/ob and diet-induced obese mice [36]. PD1 treatment acutely increased the adiponectin transcripts in adipose tissue explants isolated from ob/ob mice. A potent ability to induce adiponectin expression/secretion has been demonstrated with synthetical RvD1, RvD2, and PD1 and their biosynthetic intermediate, 17-HDHA [63].

Therefore, one of the pathogenetic mechanisms of the development of MetS is a reduction of the processes of resolving inflammation and the development of chronic, low-grade inflammatory. A decrease in the synthesis of specialized pro-resolving lipid mediators is the basis of the above disorders [65]. Thus, the anti-inflammatory effect of n-3 PUFAs in MetS can be mediated through the regulation of the SPM synthesis.

29.7.5.2.2: 3.2.2. TOLL-LIKE RECEPTOR 4

The inflammatory process observed in individuals with metabolic syndrome differs from the classical inflammatory response and this type of inflammation characterized by a chronic, low-intensity reaction [58]. The toll-like receptor 4 (TLR4) signaling pathway is acknowledged as one of the main triggers of the obesity-induced inflammatory response [57]. TLR4 plays a significant role in the pathogenesis of inflammation mediated by insulin resistance in MetS [57]. Toll-like receptors, including TLR4, are type 1 transmembrane proteins with three domains: (1) extracellular domain with leucine-rich repeats (LRRs) responsible for ligand recognition; (2) transmembrane domain; and (3) intracellular toll/interleukin-1 receptor (TIR) domain. These provide signal transmission from the cell surface to adapter proteins. TLR4 was the first TLR reported in humans; it is expressed in innate immune cells, including monocytes, macrophages, and dendritic cells, as well as in other cell types, such as adipocytes, enterocytes, and muscle cells. TLR4 is a membrane-associated receptor involved in lipid recognition [66]. TLRs are activated both by the influence of endogenous ligands and by the participation of lipids—cholesterol, SFAs, and oxidized forms of phospholipids [67].

Humans with type I diabetes exhibit greater expression of TLR4 in the cellular membrane in monocytes. Individuals with T2DM show increased cellular membrane levels of TLR4 in blood monocytes, as well as a higher concentration of IL-1, IL-6, IL-8, and TNF in serum. Similarly, TLR4 is more highly expressed in blood mononuclear cells and in the abdominal subcutaneous white adipose tissue of obese and diabetic individuals [57, 68].

Lipids from foods change the expression of TLRs by cells [69]. On the one hand, SFAs activate the TLR4 signaling pathway (see Figure 2). Among the SFAs, lauric acid (12 : 0) and palmitic acid (16 : 0) had the strongest activation capacity through TLR4 [69]. On the other hand, TLRs can be inhibited by PUFAs [70]. Consumption of n-3 PUFAs, particularly 22:6n3, is associated with anti-inflammatory and cardioprotective effects. It is believed that the use of n-3 PUFAs is associated with anti-inflammatory activity due to inhibition of arachidonic acid metabolism [71]. The molecular effect of n-3 PUFAs, especially 20:5n3 and 22:6n3, on inflammatory-response modulation are based on the ability of these PUFAs to inhibit the expression of inflammatory genes, such as COX-2, iNOS, and IL-1 in macrophages [72]. PUFAs of the n-3 family reduce the activation of the NF-κB transcription factor pathway that is induced by various agonists [70].

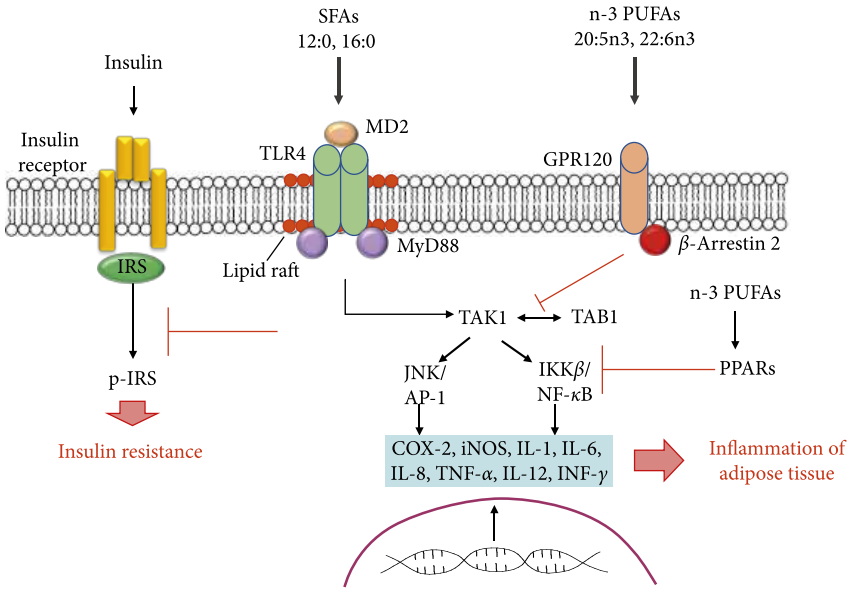

Figure 2

The role of TLRs and FAs in the signaling mechanisms of inflammation in the adipose tissue and insulin resistance. The saturated fatty acids (SFAs) act as nonmicrobial TLR4 agonists or indirectly promote the TLR4 activation, triggering its inflammatory response and inflammation of the adipose tissue. Inflammatory signaling caused by saturated fatty acids via TLR4/MD-2 inhibits the phosphorylation of the insulin receptor, leading to the development of insulin resistance. GPR120 activation induced by n-3 PUFA leads to a decrease in the activity of IKK-β/NF-κB and JNK/AP-1 signaling pathways, which reduces the expression of proinflammatory genes. The anti-inflammatory properties of PPARs are achieved by inhibiting nuclear factor-kappa B (NF-κB). N-3 PUFAs directly interact with PPARs and modulate the expression of proinflammatory genes.

Other mechanisms modulate the inflammatory response by fatty acids based on binding G protein-coupled receptor 120 (GPR120) [66]. GPR120 is a free fatty acid 4 receptor (FFAR4), and GPR120 activation induced by n-3 PUFA leads to β-arrestin 2 recruitment to the plasma membrane where this protein binds to GPR120 (see Figure 2) The GPR120/β-arrestin 2 complex is internalized into the cytoplasmic compartment where this complex binds to the TAK1-binding protein (TAB1). This process impairs the association between TAB1 and the kinase activated by the growth factor beta (TAK1) and, consequently, results in reduced TAK1 activation and decreases the activity of the IKK-β/NF-κB and JNK/AP-1 signaling pathways. The mitigation of TAK-1 activation by n-3 PUFAs leads to the reduced expression of TNF-α and IL-6 genes with proinflammatory actions [17, 57].

One more important molecular mechanism that is associated with the n-3 PUFA effects concerns their capacities to bind to PPARs [62]. Three isoforms of PPARs are known: PPARα (NR1C1), PPARβ/δ (NR1C2), and PPARγ (NR1C3). PPARs are involved in the regulation of inflammatory reactions and lipid metabolism. The anti-inflammatory properties of PPARs are mainly achieved by inhibiting nuclear factor-kappa B (NF-κB) which, in turn, is the proinflammatory nuclear transcription factor [73]. The interactions between PPARs, NF-κB, and toll-like receptors (TLRs) are of great interest. Along with the anti-inflammatory mechanism of action of PPARs, the proinflammatory activity of some isoforms of PPARs is also being studied. For example, PPARγ is considered a mediator of interactions between dendritic and T cells in the development of type 2 (or T2) inflammation [73]. N-3 PUFAs directly interact with PPARs and, therefore, modulate the expression of genes that are involved in lipid metabolism and the inflammatory response [57]. Anti-inflammatory effects of 20:5n3 and 22:6n3 on this signaling pathway can occur due to diminished nicotinamide adenine dinucleotide phosphate (NADPH) oxidase activity, which leads to lower TLR4 recruitment for lipid rafts and TLR4 dimerization [16]. Also, another possible mechanism of action of the n-3 PUFA concerns the capacity of incorporating 22:6n3 into the plasma membrane, which can lead to reduced TLR4 translocation for lipid rafts formation [74, 75]. The variety of molecular mechanisms in lipids and TLR4 signaling pathway interaction indicates the complexity of the pathogenesis of MetS and associated diseases.

29.7.5.3: 3.3. POLYUNSATURATED FATTY ACIDS AND PLASMALOGENS

Permanent exogenous use of PUFA is a necessary condition for maintaining immune-metabolic homeostasis. The profile of fatty acids that are present in the Western diet consists of a high level of saturated fatty acids and trans fatty acids. While the total consumption of marine and plant n-3 polyunsaturated fatty acids in contemporary society is significantly reduced [7, 76].

Another reason for PUFAs reduction is deterioration in the plasmalogen synthesis [77]. Plasmalogens are a subclass of phospholipids characterized by having a vinyl ether bond linking the fatty aldehyde to the glycerol molecule in the 1-position and a fatty acyl bond in the 2-position. The sn-1 position consists of palmitic acid (16 : 0), stearic acid (18 : 0), or oleic acid (18 : 1) carbon chains, and the head group is

usually either ethanolamine or choline. Thus, there are two main types of plasmalogens: ethanolamine plasmalogens and choline plasmalogens. The sn-2 position is generally occupied by PUFAs, specifically arachidonic acid or docosahexaenoic acid [78, 79].

The highest concentrations of plasmalogens are found in the brain, red blood cells, skeletal muscle, and spermatozoa and can represent as much as 18–20% of the total phospholipids in cell membranes [78, 79]. Plasmalogens are either derived from dietary sources and/or are synthesized mainly in the liver and gastrointestinal epithelium. Plasmalogens are not only important structural phospholipids in the cell membranes but they are also reservoirs of secondary messages and mediators of membrane dynamics and involved in membrane fusion, ion transport, cholesterol efflux, membrane-bound enzyme activity, and diffusion of signal-transduction molecules [80].

Secondary deficiency of plasmalogens triggered by their synthesis reduction or their degradation growth is associated with metabolic and inflammatory disorders such as cardiac diseases and diabetes mellitus [77]. The specificity of choline plasmalogens as a sensitive biomarker of an atherogenic state was confirmed. On the one hand, positive correlations of the choline plasmalogen content with serum adiponectin concentration and high-density lipoproteins (HDL), and on the other hand, inverse relationships with waist circumference, including triacylglycerides and low-density lipoproteins (LDL) content, have been identified. Reduced levels of ethanolamine plasmalogens in plasma have been shown to be also closely associated with cardiovascular, metabolic, and cancer diseases [81]. The content of plasmalogens is relatively stable in all lipoprotein fractions. However, the correlation between the levels of choline plasmalogens and HDL is stronger than that between the levels of ethanolamine plasmalogens and HDL. In the study by Pietiläinen et al., a decrease in the level of plasmalogens in adipocyte membranes in obese twins was established compared with metabolically healthy twins. Conversely, plasmalogen levels increase in trained people and dietary patients [82]. At the same time, it was found that the level of plasmalogens increases in the liver of rats receiving a high-fat diet [83].

The adaptation of the phospholipid composition of cells to exogenous lipid changes has been verified [83]. The compensatory response to a decrease in the plasmalogen level is the regulation of the level of phosphatidylethanolamine [84]. However, with plasmalogen deficiency, the total amount of PUFAs in phosphatidylethanolamine remains constant in human fibroblasts and in the brains of mice. Plasmalogens have been noted to play an important role as neuroprotectors and modulators of the signaling mechanisms of cell membranes [85]. Plasmalogens also act as endogenous antioxidants, protecting lipids and lipoproteins from oxidative stress [86]. This can be attributed to the fact that the hydrogen atoms adjacent to the vinyl ether bond are more susceptible to oxidation, protecting PUFAs from it that are found in the sn-2 position of the glycerol residue. Plasmalogen oxidation products are not capable of further initiation of lipid peroxidation processes. Another important function of plasmalogens is their participation in cell metabolism and transmembrane transport of FAs. The presence of PUFAs in the side chains of plasmalogens preconfigures their significant depositing function [77]. Cholesterol esterification depends on the level of plasmalogens. So, for example, the cells characterized by plasmalogen deficiency demonstrated a lower level of esterified cholesterol and a higher level of free and total cholesterol [84].

Therefore, the important role of plasmalogens as modulators of signaling mechanisms in protecting cells from lipid peroxidation and participation in PUFA metabolism has been made clear. However, the exact biological functions of plasmalogens and the underlying molecular mechanisms still remain to be discovered [52, 55].

29.7.6: 4. FREE FATTY ACIDS AND METABOLIC SYNDROME RISK

Free fatty acids (FFAs), or nonesterified fatty acids (NEFAs), in circulating plasma are derived from the ingestion of dietary fat or from the triglycerides stored in adipose tissue that are distributed to cells to serve as fuel for muscle contraction and systemic metabolism [87]. As FAs are insoluble in water, they are transported by binding to plasma albumin. FFAs can be taken up from circulating plasma by all mitochondria-containing cells, and they are metabolized by β-oxidation [17]. FFAs carry out many important biological functions in the body, and they are a source of energy, signal molecules, and structural components of cell membranes [17]. FFAs are involved in the pathogenesis of insulin resistance and subsequent development of metabolic syndrome [12, 17, 87]. Chronic energy imbalance can trigger adipocyte hypertrophy, endoplasmic reticulum stress, and mitochondrial dysfunction, which lead to the systemic release of FFAs [17, 88–90]. When plasma FFA levels rise, as occurs in obesity, a lipotoxicity state is induced, which induce activation of different cell responses: oxidative stress, apoptosis, and inflammation [17]. Consequently, FFAs play a highly important role in the association between obesity and insulin resistance.

29.7.6.1: 4.1. FFAS AND MITOCHONDRIA

There is an interesting hypothesis that IR is associated with the development of mitochondrial dysfunction [87, 90]. Lipid degradation occurs in mitochondria. On top of that, the normal functioning of mitochondria provides glucose-stimulated insulin secretion from β-cells of the pancreas. Initially, the theories have suggested that impaired mitochondrial function leads to impaired β-oxidation of lipids, which is accompanied by the accumulation of FFAs in peripheral tissues (lipotoxicity theory) [91]. The accumulation of lipid metabolites brings about the activation of kinases involved in the disruption of insulin signaling at the level of insulin receptor substrate 1 (IRS-1). In skeletal muscles, insulin signaling pathway disorder is accompanied by a decrease in the production of GLUT4 and glucose uptake by cells. In this case, an improvement in insulin sensitivity can be achieved by enhancing the β-oxidation of lipids. This theory was supported by studies that proved an increase in the rate of β-oxidation of lipids to be followed by protection against the development of IR [17].

Nevertheless, the early stages of obesity and IR development are characterized by an increase in β-oxidation of lipids. Besides, an impairment of fat oxidation results in higher insulin production. Therefore, mitochondrial dysfunction in skeletal muscles cannot be the only reason for the development of IR [92].

An alternative explanation of the relationship between mitochondria and insulin resistance is focused on the production of a reactive oxygen species (ROS) by mitochondria as a result of excess accumulation of FFAs in them [92]. Oxidative stress is known to be a pathogenetic component of chronic inflammation development and IR [88]. An oxidized redox environment can induce insulin resistance by directly affecting the protein involved in glucose uptake [89].

On the other hand, changes in redox cell homeostasis have been argued to step up the activity of the serine-/threonine-sensitive stress kinases that inhibit the transmission of insulin signals, inducing the development of IR [93, 94].

Oxidative stress also can stimulate the activation of transcriptional factors, such as nuclear factor-kappa B (NF-κB), activator protein 1 (AP-1), and hypoxia-inducible factor 1 (HIF-1), which promote the synthesis of inflammatory cytokines (IL-1β, IL-6, and TNF-α) (see Figure 3). These inflammatory cytokines contribute to obesity-associated local inflammation and directly induce insulin resistance. Also, chronic prolonged FFAs excess is the cause of pancreatic β-cells dysfunction. In addition, FFAs inhibit insulin gene expression and induce apoptosis in these cells [17].

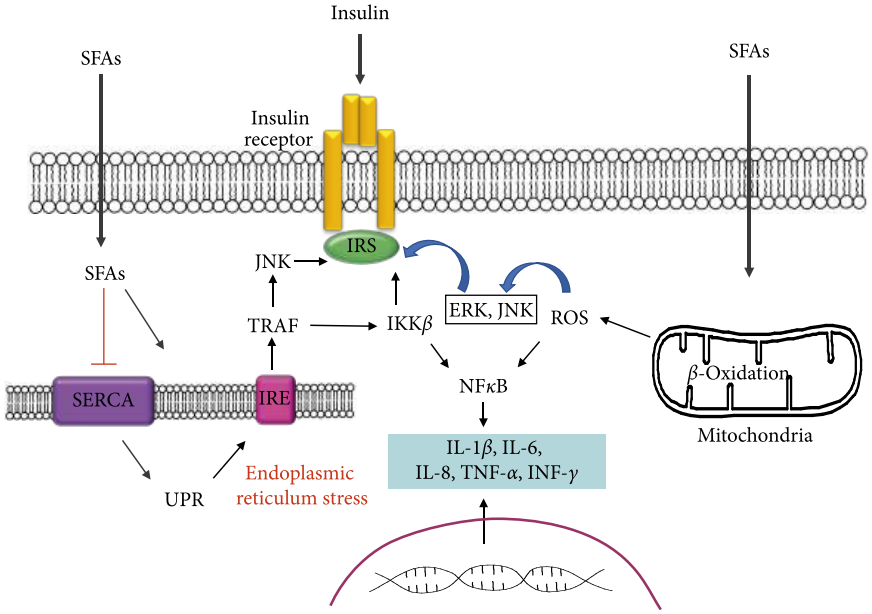

Figure 3

FFA-induced insulin resistance through endoplasmic reticulum stress and oxidative stress. A high level of FFA induces an increase in the production of ROS by mitochondria and the formation of oxidative stress. ROS stimulates NF-κB, which promotes the synthesis of L-1β, IL-6, and TNF-α. These inflammatory cytokines contribute to obesity-associated local inflammation and directly induce insulin resistance. In response to the enhanced level of FFAs and other nutrients in fats, adipose cells can develop signs of ER stress. A decrease in SERCA expression promotes the development of ER stress. UPR triggers the activation of IRE. Activation of IRE induces interaction with TRAF protein, which stimulations activation of IKKβ and JNK kinases. Its reaction can phosphorylate the IRS, thus blocking insulin signaling. JNK and IKKβ also lead to NF-κB activation and the development of inflammation.

Although discussing the role of mitochondrial skeletal muscle dysfunction in the pathogenesis of IR and type 2 diabetes is still underway [93], it is generally accepted that a mitochondrial defect does occur in these diseases. The connection between IR and mitochondrial dysfunction of liver cells, visceral, and subcutaneous adipose tissue has been proved [95]. Moreover, in the mitochondria of individuals suffering from obesity and type 2 diabetes, ATP synthesis is reduced, which correlates with the accumulation of FFAs and inhibition of insulin-stimulated glucose utilization.

29.7.6.2: 4.2. FFAS AND ENDOPLASMIC RETICULUM STRESS

Results of numerous studies establish that dysregulation of the endoplasmic reticulum (ER) function contributes to the development of MetS [96, 97]. Mitochondria are known to be both functionally and structurally associated with ER [97]. Obviously, the changes of the structure and function of these organelles can serve as a trigger for the development of metabolic homeostasis disorders [96]. ER is involved in maintaining Ca2+ homeostasis and participates in maturation and expression of membrane and secretion proteins. Cell stress conditions that increase ER demand and entail an overload of its functional capacity cause a series of alterations known as “endoplasmic reticulum stress.” Under these conditions, the ER activates a compensatory mechanism called the “unfolding protein response” (UPR), which attempts to restore the homeostasis of ER functions. With the stressful effects lasting for a long time, ER stress results in cell death (apoptosis) [17, 98].

UPR triggers activation of inositol-requiring endoribonuclease enzyme (IRE) (see Figure 3). The activation of IRE induces interaction with TRAF protein, which stimulations activation of IKKβ and JNK kinases. Its reaction can phosphorylate IRS, thus blocking insulin signaling. In response to the enhanced level of FFAs and other nutrients in fats, adipose cells can develop signs of ER stress [17]. ER stress produces insulin resistance mainly through JNK activation. JNK activity has been detected to be elevated in animal models of obesity, and JNK isoforms 1 and 2 deletion protects mice from insulin resistance induced by a fat-rich diet. Experimental evidence indicates that, on the one hand, JNK phosphorylates serine IRS-1, and on the other, it phosphorylates IKKβ, which leads to NF-κB activation and to inflammation development [96]. Remarkably, that change in expression of sarco/endoplasmic reticulum Ca2+ ATPase (SERCA), which has calcium elimination from the cytosol and returns it to the ER as their function, is associated with ER stress and subsequently with insulin resistance. The treatment of people with diabetes mellitus by rosiglitazone, an antidiabetic drug, increased SERCA expression, thus restoring the pump expression reduction observed in diabetic patients with altered hyperglycemia [17]. This way, the decrease in SERCA expression promotes the development of ER stress, with JNK ensuing activation, which desensitizes the insulin signal, thus generating a state of insulin resistance and contributing to chronic metabolic deterioration.

29.7.6.3: 4.3. FFAS AS LIGANDS FOR FFAR

FFAs serve not only as energy sources but also as natural ligands for a group of orphan G protein-coupled receptors (GPCRs) termed free fatty acid receptors (FFARs) [99]. The GPCR superfamily is the largest one in the human genome and encompasses some subfamilies (Gq, Gi, Gs, and G12/13) [100]. These receptors respond to various ligands and, therefore, are involved in the pathogenesis of many diseases, e.g., MetS, and are the target for more than half of pharmaceutical products [101–106]. There are four main members of FFAR family: FFAR1 (GPR40), FFAR2 (GPR43), FFAR3 (GPR41), and FFAR4 (GPR120 and GPR84) (see Table 1) [75].

Table 1

Family of FFARs and their ligands.

FFAR1 expression was revealed in neurons and in pancreas β-cells [99]. FFAR2 and FFAR3 are common in leukocytes and adipose tissues. Besides, FFAR3 is also expressed by pancreas cells, in the sympathetic nervous system and vessel plain muscles [100]. FFAR4 is expressed in adipocytes, the intestinal tract, macrophages, and in the central nervous system [105]. There are other specific receptors for FFA: GPR119 and GRP84. GPR119 is expressed in intestinal endocrine cells and pancreatic β-cells and activates the synthesis of GLP-1 and insulin. GPR84 is expressed in the spleen, thymus, leukocytes, and macrophages [99]. Long- and medium-chain length fatty acids are endogenous ligands for FFAR1, FFAR4, and GPR84. FFAR2 and FFAR3 are activated by short-chain FAs. FFAR2 is capable of binding with Gq and Gi proteins, whereas FFAR3 binds only with Gi. FFAR4 is activated by n-3 or n-6 PUFAs [99]. Thus, each FFAR can act as an FFA sensor with selectivity for a particular FFA carbon chain length derived from food or food-derived metabolites. FFARs have been reported to have physiological functions such as facilitation of insulin and incretin hormone secretion, adipocyte differentiation, anti-inflammatory effects, neuronal responses, and taste preferences [106]. Dysfunction of FFARs underlies the pathogenesis of many metabolic diseases, such as MetS and diabetes mellitus.

It has been found that FFAR4 acts as an anti-inflammatory receptor in proinflammatory macrophages and mature adipocytes. Signaling of FFAR4 activated by n-3 PUFAs inhibits TLR signaling and TNF-α-induced inflammatory responses. FFAR4 dysfunction leads to obesity and glucose intolerance in humans and mice [107]. Many results strongly support that FFAR4-mediated anti-inflammatory effects reduce the infiltration of proinflammatory macrophages into the adipose tissue and improve insulin sensitivity [102].

The activation of FFAR1 signaling enhances glucose-stimulated insulin secretion (GSIS) directly via stimulation of insulin secretion from pancreatic β cells and indirectly via the production of incretin hormones. Also, the activation of FFAR1 signaling reduces the expression of inflammatory cytokines such as TNF-α and IL-8. It has been shown that α-linolenic (18:3n3) and oleic (18:1n9) acids improve insulin resistance in obesity and type 2 diabetes [108].

There is some scientific evidence that short-chain fatty acids (SCFAs) are a substantial modulator of MetS inflammation [109]. SCFAs are the end products of metabolic fermentation of dietary fibers by gut microbiota. FFAR2 is a receptor for SCFAs and is expressed in enteroendocrine cells, adipose tissues, and pancreatic β-cells [99]. Dietary fiber intake reduces the risk of obesity, diabetes, inflammatory bowel disease, colon cancer, and cardiovascular disease. SCFAs supplementation with a high-fat diet improved insulin sensitivity and increased energy expenditure in a mouse model of diet-induced obesity [110, 111]. SCFAs are involved in intestinal immune homeostasis due to their role in regulating T cell polarization and differentiation. In human monocytes, SCFAs decrease the production of TNF-α and increase the production of PGE2 [109]. Activation of FFAR2 by SCFAs regulates metabolic disorders, increases energy expenditure, and preferentially enables fat consumption by inhibition of insulin signaling in adipose tissues. The expression of FFAR2 in neutrophils and mononuclear cells regulates intestinal homeostasis and inflammation. In light of this evidence, regulation FFAR2 expression and/or high fiber consumption may be a potential target for therapeutic intervention of MetS.

FFAR3 is also a receptor for SCFAs. FFAR3 is widely expressed in enteroendocrine cells, adipose tissues, the peripheral nervous system, peripheral blood mononuclear cells, monocytes, and macrophages [99]. FFAR3 expression in intestinal epithelial cells enhances the synthesis of proinflammatory mediators through extracellular signal-regulated kinase 1/2 and p38 MAPK [100]. Since these pathways help

to protect against bacterial infection, FFAR3 can stimulate acute inflammatory reactions in the intestine that have beneficial effects on host homeostasis [112]. Thus, FFAR 3 can exhibit proinflammatory properties.

29.7.7: 5. CONCLUSION

The wide phenotypic heterogeneity of MetS and its complex pathogenesis make it difficult to identify a therapeutic target. This syndrome is considered as a cluster of pathogenetically related conditions caused by metabolic disorders and the development of chronic, low-grade inflammation. In this review, we examined the molecular mechanisms of the development of MetS driven by impaired lipid metabolism. PUFAs and FFAs have been shown to play an important role in both the pathogenesis and treatment of MetS. Fatty acids perform structural, energy, signaling, and immunoregulatory functions. These FAs properties underlie the pathogenetic mechanisms of glucose transport disturbance, the development of IR and chronic inflammation, the formation of oxidative stress, and mitochondrial dysfunction in MetS. Correction in lifestyle and nutrition is considered as the main way to minimize complications caused by an imbalance in the body between saturated and polyunsaturated fatty acids. At the same time, there are controversial data about the therapeutic efficacy of dietary n-3 PUFAs in MetS [50]. SPMs have shown potent pro-resolving actions in different disease models, including MetS [61]. SPM-based therapeutics could be one of the most optimistic treatments for MetS. Further studies are needed to detail the mechanisms of FA participation and their oxidized metabolites in the development of inflammation and pathogenesis of MetS.

29.7.8: CONFLICTS OF INTEREST

The authors declare that there are no conflicts of interest regarding the publication of this paper.

29.8.1.1: ABSTRACT

Tumors reprogram pathways of nutrient acquisition and metabolism to meet the bioenergetic, biosynthetic, and redox demands of malignant cells. These reprogrammed activities are now recognized as hallmarks of cancer, and recent work has uncovered remarkable flexibility in the specific pathways activated by tumor cells to support these key functions. In this perspective, we provide a conceptual framework to understand how and why metabolic reprogramming occurs in tumor cells, and the mechanisms linking altered metabolism to tumorigenesis and metastasis. Understanding these concepts will progressively support the development of new strategies to treat human cancer.

29.8.1.1: INTRODUCTION AND OVERARCHING PRINCIPLES

Cancer metabolism is one of the oldest areas of research in cancer biology, predating the discovery of oncogenes and tumor suppressors by some 50 years. The field is based on the principle that metabolic activities are altered in cancer cells relative to normal cells, and that these alterations support the acquisition and maintenance of malignant properties. Because some altered metabolic features are observed quite generally across many types of cancer cells, reprogrammed metabolism is considered a hallmark of cancer (*1*, *2*). Precisely how metabolism becomes reprogrammed in cancer cells, whose functions or malignant properties are enabled by these activities, and how to exploit metabolic changes for therapeutic benefit are among the key questions driving research in the field.

This review covers several fundamental principles in cancer metabolism, with the goal of introducing non-experts to the concepts motivating ongoing research. With the explosion of research in cancer metabolism over the past decade, no single review can possibly cover it all. The sections below highlight some of the essential, recent papers supporting these core principles. An overarching theme in cancer metabolism is that reprogrammed activities improve cellular fitness to provide a selective advantage during tumorigenesis. Most of the classical examples of reprogrammed activities either support cell survival under stressful conditions or allow cells to grow and proliferate at pathologically elevated levels. Three of these—altered bioenergetics, enhanced biosynthesis, and redox balance—are discussed at length below. It logically flows that if these activities provide benefit to the malignant cell, then some of them might be suitable therapeutic targets. This rendering of cancer metabolism is supported by many examples in which inhibition of an enhanced metabolic activity results in impaired growth of experimental tumors (*3*, *4*). In some cases, the particular metabolic liabilities of cancer cells have been translated into effective therapies in human cancer. Asparaginase, an enzyme that converts the amino acid asparagine to aspartic acid and ammonia, is an essential component of treatment for acute lymphoblastic leukemia (ALL) (*5*). Because of their high rates of protein synthesis and poor ability to synthesize asparagine de novo, ALL cells require a constant supply of asparagine from the plasma. This supply is essentially eliminated by systemic administration of asparaginase. Ultimately, effective metabolic therapy will require defining the stage of tumor progression in which each pathway provides its benefit to the cancer cell. Some activities first become essential very early in tumorigenesis as the nascent tumor begins to experience nutrient limitations (*6*). In other cases, altered pathways may be dispensable in primary tumors but essential for metastasis (*7*, *8*). Because new therapeutic targets are nominated from simple experimental models like cultured cells, it will be essential to define their context-specific roles in biologically accurate models of tumor initiation and progression.

29.8.1.1: METABOLIC REPROGRAMMING AND ONCOMETABOLITES IN CANCER

Altered metabolic activity supports anabolic growth during nutrient-replete conditions, catabolism to support cell survival during nutrient limitation, and fortification of redox homeostatic systems to counteract the metabolic effects of oncogene activation, tumor suppressor loss, and other stresses (*9*). Discovery and characterization of reprogrammed activities may provide opportunities to image tumor tissue noninvasively, predict tumor behavior, and prevent tumor progression by blocking essential pathways. It is important to differentiate "metabolic reprogramming" from "oncometabolites," two terms widely used in the recent cancer metabolism literature (*10*). We propose that the term metabolic reprogramming be used to describe conventional metabolic pathways whose activities are enhanced or suppressed in tumor cells relative to benign tissues as a consequence of tumorigenic mutations and/or other factors. Oncometabolite is a relatively new term that refers to metabolites whose abundance increases markedly in tumors. We suggest that this term be reserved for metabolites for which (i) there is a clear mechanism connecting a specific mutation in the tumor to accumulation of the metabolite, and (ii) there is compelling evidence for involvement of the metabolite in the development of malignancy.

The classical example of a reprogrammed metabolic pathway in cancer is the Warburg effect or aerobic glycolysis (*11*). Glycolysis is a physiological response to hypoxia in normal tissues, but Otto Warburg in the 1920s observed that tumor slices and ascites cancer cells constitutively take up glucose and produce lactate regardless of oxygen availability, an observation that has been seen in many types of cancer cells and tumors (*12*). The increase in glycolytic flux allows glycolytic intermediates to supply subsidiary pathways to fulfill the metabolic demands of proliferating cells (*11*). Like glycolytic intermediates, tricarboxylic acid (TCA) cycle intermediates are also used as precursors for macromolecule synthesis (*13*). Their utilization in biosynthetic pathways requires that carbon be resupplied to the cycle so that intermediate pools are maintained; pathways that “refill” the cycle are termed anaplerotic pathways, and they generate TCA cycle intermediates that can enter the cycle at sites other than acetyl-CoA (coenzyme A) (*14*). Two activities that provide anaplerotic fluxes in cancer cells are glutaminolysis, which produces α-ketoglutarate from glutamine, and pyruvate carboxylation, which produces oxaloacetate from glucose/pyruvate. Oxidation of the branched-chain amino acids (BCAAs) isoleucine and valine also provides an anaplerotic flux in some tissues.

Despite the incredible genetic and histological heterogeneity of tumors, malignancy seems to involve the common induction of a finite set of pathways to support core functions like anabolism, catabolism, and redox balance (*15*). The general induction of these pathways may reflect their regulation by signaling pathways that are commonly perturbed in cancer cells (Fig. 1). Normal cells, upon stimulation by growth factors, activate phosphatidylinositol 3-kinase (PI3K) and its downstream pathways AKT and mammalian target of rapamycin (mTOR), thereby promoting a robust anabolic program involving increased glycolytic flux and fatty acid synthesis through activation of hypoxia-inducible factor–1 (HIF-1) and sterol regulatory element–binding protein (SREBP), respectively (*16*). Tumor cells very frequently contain mutations that allow the PI3K-AKT-mTOR network to achieve high levels of signaling with minimal dependence on extrinsic stimulation by growth factors (*17*). Many of the best-characterized oncogenes and tumor suppressors reside in the PI3K-AKT-mTOR network, and aberrant activation of this pathway is among the most frequent alterations seen in a diverse set of cancers.

Fig. 1 Signaling pathways that regulate cancer metabolism.

Tumor cells have aberrant activation of mTORC1 that induces an anabolic growth program resulting in nucleotide, protein, and lipid synthesis. Loss of tumor suppressors like p53 or activation of oncogenes like MYC further promotes anabolism through transcriptional regulation of metabolic genes. Metabolism controls signaling through regulating reactive oxygen species (ROS), acetylation, and methylation. PPP, pentose phosphate pathway; G6P, glucose-6-phosphate; 3-PG, 3-phosphoglycerate; ATP, adenosine 5′-triphosphate; mTORC1, mTOR complex 1; α-KG, α-ketoglutarate; RTK, receptor tyrosine kinase.

Another commonly deregulated pathway in cancer is gain of function of MYC by chromosomal translocations, gene amplification, and single-nucleotide polymorphisms. MYC increases the expression of many genes that support anabolic growth, including transporters and enzymes involved in glycolysis, fatty acid synthesis, glutaminolysis, serine metabolism, and mitochondrial metabolism (*18*). Oncogenes like Kras, which is frequently mutated in lung, colon, and pancreatic cancers, co-opt the physiological functions of PI3K and MYC pathways to promote tumorigenicity. Aside from oncogenes, tumor suppressors such as the p53 transcription factor can also regulate metabolism (*19*). The p53 protein–encoding gene *TP53* (tumor protein p53) is mutated or deleted in 50% of all human cancers. The tumor-suppressive functions of p53 have been ascribed to execution of DNA repair, cell cycle arrest, senescence, and apoptosis. However, recent studies indicate that p53 tumor-suppressive actions might be independent of these canonical p53 activities but rather dependent on the regulation of metabolism and oxidative stress (*20*, *21*). Loss of p53 increases glycolytic flux to promote anabolism and redox balance, two key processes that promote tumorigenesis (*19*).

A salient feature of many tumors is that they reside in a low-oxygen environment (hypoxia) ranging from 0 to 2% O_2 because the tumor cell proliferation rate often exceeds the rate of new blood vessel formation (angiogenesis) (*22*). The metabolic adaptation to hypoxia is coordinated by HIF-1, which induces metabolic genes involved in increasing glycolytic flux (*23*). Some tumors display constitutive activation of HIF-1 under normoxic conditions through a variety of mechanisms, including (i) hyperactivation of mTORC1, (ii) loss of von Hippel–Lindau, (iii) accumulation of ROS, and (iv) accumulation of the TCA cycle metabolites succinate or fumarate due to cancer-specific mutations in succinate dehydrogenase (SDH) or fumarate hydratase (FH), respectively (*24*).

The robust coordinated induction of metabolic pathways that support tumorigenesis by combination of deregulation of PI3K-AKT-mTOR signaling pathways, loss of tumor suppressors, and activation of oncogenes alleviates the necessity of having mutations or amplifications in metabolic enzymes per se. Thus, examples of metabolic enzyme deregulation through genetic mutation are rare. One example is the elevated expression of phosphoglycerate dehydrogenase (PHGDH) due to amplification in a fraction of breast cancer and melanoma (*25*, *26*). PHGDH catalyzes the conversion of the glycolytic intermediate 3-phosphoglycerate to 3-phosphohydroxypyruvate in the first step of the serine biosynthesis pathway. Serine metabolism supplies methyl groups to the one-carbon and folate pools contributing to nucleotide synthesis, methylation reactions, and NADPH (reduced nicotinamide adenine dinucleotide phosphate) production (*27*). Inhibiting serine biosynthesis by silencing PHGDH in cells with high levels of this enzyme results in growth suppression, and the enzyme displays oncogenic properties in gain of function assays (*25*, *26*).

The other examples of mutational deregulation of metabolic enzymes are those that generate oncometabolites. The current list of true oncometabolites is short (*28*). The term is most commonly and appropriately applied to D-2-hydroxyglutarate (D2HG), a reduced form of the TCA cycle intermediate α-ketoglutarate. D2HG is scarce in normal tissues but rises to millimolar concentrations in tumors with mutations in isocitrate dehydrogenase 1 or 2 (IDH1 or IDH2). These mutations occur commonly in gliomas, acute myelogenous leukemias (AMLs), and other types of cancer (*29*–*31*). D2HG and its relationship to mutant IDH1 and IDH2 have been reviewed extensively elsewhere (*32*). The most relevant point here is that D2HG production requires a neomorphic enzyme activity imparted to IDH1/IDH2 by specific active-site mutations (*33*, *34*). High levels of D2HG interfere with the function of dioxygenases requiring α-ketoglutarate as a cosubstrate. These include prolyl hydroxylases, cytosine hydroxylases, and histone demethylases, whose inhibition influences gene expression in part via an altered epigenetic state characterized by a failure to express differentiation programs (*35*–*41*). Thus, although D2HG arises from an alteration of the metabolic network, its role in cancer seems to depend on nonmetabolic effects. Currently, D2HG is being used as a biomarker for disease monitoring, and inhibitors specific to mutants IDH1/IDH2 are in clinical trials for AML and solid tumors.

The metabolite 2HG also exists as the enantiomer L-2HG (L2HG), which is not produced by mutant forms of IDH1/IDH2. This metabolite arises from the noncanonical activity of various dehydrogenases, including malate dehydrogenase and lactate dehydrogenase, whose promiscuous behavior reduces α-ketoglutarate to L2HG (*42*–*44*). L2HG may be oxidized back to α-ketoglutarate by a FAD-linked enzyme, L2HG dehydrogenase (L2HGDH). L2HGDH deficiency, also called L2HG aciduria, is a rare neurometabolic disease of childhood caused by the inheritance of biallelic mutations in the gene encoding L2HGDH (*45*). Affected children have seizures, mental retardation, white matter abnormalities of the brain, and systemically elevated levels of L2HG. Remarkably, a number of these children have developed malignant brain tumors (*46*), providing an early clue to the significance of D2HG in IDH1/IDH2-mutant gliomas and raising the question of whether L2HG is also an oncometabolite. L2HG and D2HG exhibit different effects on dioxygenase function (*38*), suggesting that the sensitivity of a particular tissue to the presence of either metabolite may depend on which dioxygenases are expressed. Recent work has demonstrated modest accumulation of L2HG in cells experiencing hypoxia or electron transport chain (ETC) dysfunction (*42*, *47*) and in human renal cell carcinomas, which frequently display epigenetic silencing of L2HGDH (*48*). It is unknown whether reducing L2HG levels in these settings will promote cellular differentiation or suppress tumor progression.

The principle that oncometabolites exert their effects outside of the conventional metabolic network also applies to the other two molecules that can reasonably be called oncometabolites: fumarate and succinate (*28*). Both are TCA cycle intermediates found throughout the body, but some tumors accumulate massive levels of fumarate and/or succinate as a consequence of loss-of-function mutations in FH or the SDH complex, respectively (*49*–*51*). Although these mutations markedly reprogram metabolism by impairing TCA cycle flux, the extent to which fumarate and succinate participate in cancer development likely involves their nonmetabolic functions (*28*). Like D2HG, evidence indicates that succinate and fumarate interfere with dioxygenase activity, supporting the notion that a general property of oncometabolites is the ability to regulate epigenetics (*52*, *53*). PHGDH overexpression and mutations in IDH1/IDH2, SDH, and FH all alter metabolite levels that control epigenetics (*54*). Several other metabolites, including acetyl-CoA, α-ketoglutarate, and *S*-adenosylmethionine also participate in epigenetic reprogramming, and time will tell whether genetically specific alterations of these metabolites in tumors promote tumorigenesis (*54*). Some metabolites, notably fumarate, covalently bind to sulfhydryl groups in glutathione, proteins, and peptides, altering their function and perhaps accounting for another mechanism by which oncometabolites promote or perpetuate malignant phenotypes (*55*–*58*).

29.8.1.1: BIOENERGETICS

Otto Warburg's hypothesis that cancer cells take up glucose and generate a substantial amount of lactate in the presence of ambient oxygen due to impaired mitochondrial function led to the widely held misconception that cancer cells rely on glycolysis as their major source of ATP (*59*, *60*). Today, it is clear that cancer cells exhibit aerobic glycolysis due to activation of oncogenes, loss of tumor suppressors, and up-

regulation of the PI3K pathway, and that one advantage of high glycolytic rates is the availability of precursors for anabolic pathways (2, 61). Warburg's observation that tumors display a high rate of glucose consumption has been validated in many human cancers with fluorodeoxyglucose positron emission tomography, which uses a radioactive glucose analog to image glucose uptake in tumors and adjacent normal tissue. Nevertheless, many studies have demonstrated that the great majority of tumor cells have the capacity to produce energy through glucose oxidation (that is, the process by which glucose-derived carbons enter the TCA cycle and are oxidized to CO_2, producing ATP through oxidative phosphorylation). Furthermore, limiting glycolytic ATP production by inhibiting the activity of pyruvate kinase fails to prevent tumorigenesis, suggesting that the major role of glycolysis is not to supply ATP (62). Moreover, mitochondrial metabolism is necessary for cancer cell proliferation and tumorigenesis (63–65). Thus, despite their high glycolytic rates, most cancer cells generate the majority of ATP through mitochondrial function, with the likely exception of tumors bearing mutations in enzymes involved in mitochondrial respiration (for example, SDH and FH) (66). Nevertheless, cells harboring mutations in FH or SDH still rely on mitochondrial metabolism by metabolically rewiring themselves to provide the necessary TCA cycle intermediates and ROS for cell proliferation (55, 67–70).

In addition to pyruvate derived from glycolysis, fatty acids and amino acids can supply substrates to the TCA cycle to sustain mitochondrial ATP production in cancer cells (Fig. 2). The breakdown of fatty acids (β-oxidation) in the mitochondria generates acetyl-CoA and the reducing equivalents NADH and $FADH_2$, which are used by the ETC to produce mitochondrial ATP. The amino acid glutamine can generate glutamate and subsequently α-ketoglutarate to fuel the TCA cycle through a series of biochemical reactions termed glutaminolysis (71). Furthermore, the BCAAs isoleucine, valine, and leucine, which are elevated in plasma of patients with pancreatic cancers, can be converted into acetyl-CoA and other organic molecules that also enter the TCA cycle (72). The metabolic flexibility afforded by multiple inputs into the TCA cycle allows cancer cells to adequately respond to the fuels available in the changing microenvironment during the evolution of the tumor (9). A combination of the local tumor microenvironment and oncogenic lesions is likely to dictate the fuel used by mitochondria to sustain tumor growth.

Fig. 2 Metabolic pathways under nutrient-replete and nutrient-deprived conditions.

Accessibility to nutrients within solid tumors is regulated by proximity to the vasculature. Cells located adjacent to the vasculature use nutrients and oxygen to fuel anabolic pathways that support proliferation. However, cells distant from the vasculature have diminished accessibility to nutrients and oxygen and may engage in alternative forms of metabolism including oxidation of fatty acids and BCAAs as well as macromolecular degradation through autophagy and macropinocytosis to support cell viability.

Solid tumors contain significant heterogeneity of perfusion, such that many tumor cells reside in nutrient- and oxygen-poor environments. Cancer cells have therefore adapted multiple mechanisms to sustain mitochondrial function for survival. For example, the mitochondrial ETC can function optimally at oxygen levels as low as 0.5% (73). Moreover, hypoxic tumor cells (<2% O_2) can continue to cycle and use glutamine as a fuel for oxidative ATP production (74–76). Kras-driven pancreatic cancer cells in nutrient-depleted conditions use proteins scavenged from the extracellular space to produce glutamine and other amino acids to fuel the TCA cycle for cell survival and growth (Fig. 2) (77). Furthermore, if pyruvate oxidation to acetyl-CoA is compromised by hypoxia or ETC impairment, glutamine can provide acetyl-CoA as a biosynthetic precursor to sustain tumor growth (69, 78, 79).

When tumor cells become nutrient-deprived, they adapt to the microenvironment by decreasing their demand for ATP. The resultant increase in ATP availability maintains an adequate ATP/ADP (adenosine 5´-diphosphate) ratio to drive unfavorable biological reactions. The anabolic kinase mTOR, discussed in greater detail below, drives the energetically demanding growth of tumor cells. This kinase is inhibited when amino acids and oxygen levels are diminished (*80*). Furthermore, decreased mTOR activity increases autophagic flux. In oncogenic Kras- or Braf-driven non–small-cell lung cancer (NSCLC) cells, autophagy provides an intracellular glutamine supply to sustain mitochondrial function (*81*, *82*). To survive the hypoxic tumor microenvironment, cancer cells also diminish their demand for ATP by decreasing highly demanding ATP-dependent processes, such as running the Na/K-dependent adenosine triphosphatase. If diminishing ATP demand is not sufficient to maintain ATP/ADP ratio, the rise in ADP activates adenylate kinase, a phosphotransferase enzyme that buffers the fall in ATP levels by converting two ADP molecules into adenosine 5´-monophosphate (AMP) and ATP (*83*). The rise in AMP during nutrient deprivation triggers the activation of AMP kinase (AMPK), which activates catabolic pathways like fatty acid oxidation to stimulate ATP production (*84*). In conditions of metabolic stress, certain Ras-driven cancer cells scavenge lipids to support ATP production (*85*). Ovarian cancer cells use fatty acids from neighboring adipocytes to fuel mitochondrial ATP production (*86*). Thus, there are multiple mechanisms by which cancer cells maintain their ATP/ADP ratio to sustain viability in nutrient- and oxygen-poor environments.

29.8.1.1: BIOSYNTHESIS OF MACROMOLECULES

Biosynthetic or anabolic pathways are an essential aspect of cancer metabolism because they enable cells to produce the macromolecules required for replicative cell division and tumor growth. As a general theme, these pathways involve the acquisition of simple nutrients (sugars, essential amino acids, etc.) from the extracellular space, followed by their conversion into biosynthetic intermediates through core metabolic pathways like glycolysis, the PPP, the TCA cycle, and nonessential amino acid synthesis, and finally the assembly of larger and more complex molecules through ATP-dependent processes (Fig. 3). The three macromolecular classes most commonly studied in cancer metabolism are proteins, lipids, and nucleic acids, which comprise approximately 60, 15, and 5% of the dry mass of mammalian cells, respectively. Evidence indicates that biosynthesis of all three classes is under the control of the same signaling pathways that govern cell growth and are activated in cancer via tumorigenic mutations, particularly PI3K-mTOR signaling.

Fig. 3 Anabolic pathways that promote growth.

Glucose metabolism generates glycolytic intermediates that can supply subsidiary pathways including the hexosamine pathway, PPP, and one-carbon metabolism, all of which support cell growth. Mitochondrial TCA cycle intermediates such as oxaloacetate (OAA) and citrate are used to generate cytosolic aspartate and acetyl-CoA for nucleotide and lipid synthesis, respectively. Mitochondria also generate H_2O_2 and acetyl-CoA for redox signaling and acetylation, respectively. NADPH is used to drive anabolic reactions and to maintain antioxidant capacity. Cytosolic sources of NADPH include the oxidative PPP, IDH1, and enzymes from one-carbon metabolism including MTHFD1. Mitochondrial sources of NADPH include MTHFD2, MTHF2L, and IDH2. HK2, hexokinase 2; G6PDH, glucose-6-phosphate dehydrogenase; GAPDH, glyceraldehyde-3-phosphate dehydrogenase; LDH, lactate dehydrogenase; ACLY, ATP citrate lyase; GLS, glutaminase; SHMT, serine hydroxymethyltransferase; MTHFD2, methylenetetrahydrofolate dehydrogenase 2; MTHFD2L, MTHFD2-like; ACSS2, acyl-CoA synthetase short-chain family member 2; THF, tetrahydrofolate.

Protein biosynthesis is highly regulated and requires access to a full complement of essential and nonessential amino acids. Cancer cells and other cells under the influence of growth factor signaling express surface transporters that allow them to acquire amino acids from the extracellular space (*87*). This not only provides cells with the raw materials needed for protein synthesis but also allows them to maintain activity of the mTOR signaling system, specifically mTORC1. mTORC1 is stimulated by the presence of amino acids and activates protein synthesis via its effects on translation and ribosome biogenesis (*80*). Most nonessential amino acids are produced through transamination reactions, which transfer the amino group from glutamate to a ketoacid. Proliferating cancer cells take up glutamine and convert it to glutamate through a variety of deamidation and transamidation reactions, most notably the mitochondrial amidohydrolase glutaminase (*71*). Together, these enzymes generate a large intracellular glutamate pool available for nonessential amino acid synthesis. Both glutamine uptake and glutaminase activity are stimulated by mTORC1, providing glutamate for transamination reactions and/or maintenance of the TCA cycle, which also contributes to amino acid synthesis. Furthermore, when the intracellular glutamine supply exceeds the cell's demands, glutamine can be exported in exchange for essential amino acids to stimulate mTORC1 and protein synthesis (*88*). Thus, growth conditions in which glutamine and essential amino acids are abundant enable mTORC1-mediated activation of protein synthesis.

When nutrients are scarce, cells have access to a number of catabolic pathways to degrade macromolecules and resupply key pools of intracellular metabolic intermediates. Protein degradation pathways have been characterized extensively as mechanisms to supply amino acids in cancer cells. Intracellular proteins and other macromolecules can be recycled through autophagy, a highly regulated process through which proteins and organelles are delivered to the lysosome and degraded (*89*). Autophagy is an essential survival pathway during nutrient or growth factor deprivation, and genetic studies demonstrate that it contributes to some forms of cancer in mice (*90*, *91*). However, because autophagy supplies amino acids through protein degradation, it does not serve as a source of net protein synthesis. It is also potently suppressed by mTORC1. Macropinocytosis allows cells to internalize proteins and other components of the extracellular milieu and deliver them for degradation via the endocytic pathway. Under conditions of nutrient depletion, macropinocytosis supplies both nitrogen and carbon to central metabolic pathways (*92*). Evidence indicates that extracellular protein degradation, like autophagy, is suppressed by mTORC1 (*93*). Suppressing pathways of protein degradation may help maximize rates of net protein synthesis when extracellular amino acids are available and mTORC1 is active.

Tumor cells rapidly produce fatty acids for membrane biosynthesis, lipidation reactions, and cellular signaling. Fatty acid synthesis requires sources of acetyl-CoA and reducing power in the form of cytosolic NADPH; effective fatty acid synthesis therefore requires integration with other pathways of carbon and redox metabolism. In most cultured cells, glucose is the most prominent acetyl-CoA source for fatty acid synthesis (*94*, *95*). Glutamine and acetate have been demonstrated to provide alternative carbon sources when access to glucose-derived acetyl-CoA is impaired by hypoxia or mitochondrial dysfunction (*69*, *78*, *79*, *96*). Leucine degradation can also supply acetyl-CoA in some cell lines (*97*). The relative importance of these nutrients for fatty acid synthesis in vivo is unknown, although early studies suggested that most fatty acyl carbon in experimental tumors is derived from glucose (*98*, *99*). Isotopic tracing experiments designed to assess the cytosolic NADPH pool have recently suggested that most NADPH used for fatty acid synthesis arises from the PPP (*100*, *101*).

Transcription of genes involved in fatty acid synthesis is regulated by the SREBP-1 transcription factor (*102*). SREBP-1 regulates not only the enzymes needed to convert acetyl-CoA into fatty acids but also the enzymes of the PPP and pathways required to convert acetate and glutamine into acetyl-CoA (*103*). This transcription factor therefore regulates genes encoding proteins that catalyze or facilitate fatty acid synthesis. In lipid-replete conditions, SREBP-1's transcriptional activity is suppressed by its sequestration in the endoplasmic reticulum. Under conditions of sterol depletion, proteolytic cleavage releases the transcriptionally active domain, which travels to the nucleus and binds to sterol response elements in the promoters of lipogenic genes (*104*).

In cancer cells with constitutively high rates of fatty acid synthesis, additional mechanisms help keep SREBP-1 in a transcriptionally active state. mTORC1 signaling, via its effector S6 kinase (S6K), activates a transcriptional program that includes both SREBP-1 and the related protein SREBP-2, which regulates transcription of genes in sterol biosynthesis (*103*). Both SREBP-1 and SREBP-2 are required for mTORC1-mediated cell proliferation. The mechanism of SREBP activation by mTORC1 is incompletely understood but involves nuclear entry of the phosphatidic acid phosphatase Lipin-1, which enhances nuclear SREBP abundance and activity on the promoters of lipogenic genes (*105*).

Both fatty acids and lipids can also be acquired from the extracellular space to supply membrane biosynthesis. PI3K signaling activates fatty acid uptake and suppresses fatty acid oxidation, thereby maximizing lipogenesis in proliferating cells under the control of growth factors (*106*). Lipid uptake may acquire further importance during conditions of metabolic stress, when the ability to meet oncogene-driven demands for biosynthesis is compromised. The ability to scavenge lysophospholipids (lipid intermediates containing a glycerophosphate backbone with one acyl chain) is required for maximal cancer cell growth during hypoxia, which suppresses de novo fatty acid synthesis from glucose (*85*). Furthermore, in cancer cells with constitutive mTORC1 signaling, hypoxia induces a state of dependence on access to extracellular desaturated fatty acids to maintain endoplasmic reticulum integrity in support of protein biosynthesis (*107*). Notably, SREBP-1 was first identified as the transcription factor responsible for expression of the low-density lipoprotein receptor (LDLR) (*108*), implying that enhanced de novo lipogenesis occurs concomitantly with enhanced import of lipids from the extracellular space. These parallel pathways appear to be essential in glioma, where oncogenic activation of epidermal growth factor receptor (EGFR) signaling stimulates SREBP-1 and expression of LDLR (*109*). These cancer cells are highly sensitive to inhibitors of fatty acid and cholesterol biosynthesis. Inhibition of the EGFR-PI3K signaling axis but not of mTORC1 suppresses nuclear translocation of SREBP-1 in glioma cells with oncogenic EGFR,

suggesting an alternate, mTORC1-independent mode of SREBP-1 activation in glioma cells (*109*). This transcriptional program includes LDLR expression and induces reliance on cholesterol uptake to maintain the intracellular pool (*110*). Impairing intracellular cholesterol availability by activating liver X receptor induced cell death both in culture and in vivo, suggesting a pharmacological approach to silence lipogenic programs in glioma (*110*).

Purine and pyrimidine nucleotides are required for synthesis of RNA and DNA. De novo biosynthesis of nucleotides is complex, requiring input from several pathways in a coordinated fashion. The phosphoribosylamine backbone of these molecules is produced from ribose-5-phosphate, an intermediate of the PPP, and an amide donation reaction using glutamine as a substrate (*111*). The purine and pyrimidine bases are constructed from various nonessential amino acids and methyl groups donated from the one-carbon/folate pool. The TCA cycle contributes oxaloacetate, which is transaminated to aspartate, an intermediate required to synthesize both purine and pyrimidine bases. Conversion of ribonucleotides to deoxynucleotides by ribonucleotide reductase requires a source of NADPH. Well-characterized mechanisms of feedback inhibition exist to prevent excessive accumulation of nucleotides, and mutations interrupting these mechanisms can produce pathological accumulation of nucleotide intermediates (for example, precipitation of uric acid crystals in gout).

Clearly, nucleotide biosynthesis is a targetable vulnerability in cancer cells because nucleoside analogs and antifolates have been a mainstay of chemotherapeutic regimens for decades (*112*). However, relatively little is known about how oncogenic signaling interfaces with nucleotide biosynthesis. It is likely that the effects of numerous signaling pathways on glucose and amino acid metabolism influence the availability of precursors for purines and pyrimidines. In the case of mTORC1, evidence points to a distinct mechanism by which activation of the signaling pathway enables nucleotide biosynthesis. The mTORC1 effector ribosomal S6K1 phosphorylates the trifunctional enzyme CAD (carbamoyl-phosphate synthetase 2, aspartate transcarbamoylase, dihydroorotase), which catalyzes the first three steps of pyrimidine synthesis (*113*). Phosphorylation on CAD S1859 is required for mTORC1-dependent stimulation of pyrimidine biosynthesis (*113*). Additional work is needed to determine how other aspects of de novo nucleotide synthesis, purine and pyrimidine salvage pathways, and accessory activities like folate metabolism are regulated in cancer cells in support of cell proliferation.

29.8.1.1: REDOX BALANCE

ROS are intracellular chemical species that contain oxygen and include the superoxide anion (O_2^-), hydrogen peroxide (H_2O_2), and the hydroxyl radical (OH·) (*114*). The mitochondria and cytosolic NADPH oxidases (NOXs) produce O_2^- from the one-electron reduction of oxygen (*115*). O_2^- is converted into H_2O_2 by the enzymatic activity of superoxide dismutase 1 or 2, which are localized to the cytosol or mitochondrial matrix, respectively. H_2O_2 is subsequently detoxified to water by the enzymatic activity of mitochondrial and cytosolic peroxiredoxins (PRXs), which, as a consequence, undergo H_2O_2-mediated oxidation of their active-site cysteines (*116*). Thioredoxin (TXN), thioredoxin reductase (TrxR), and the reducing equivalent NADPH reduce oxidized PRXs to complete the catalytic cycle (*117*). Glutathione peroxidases (GPXs) can also convert H_2O_2 to water in the mitochondrial matrix and cytosol through H_2O_2-mediated oxidation of reduced glutathione (GSH) (*118*). Glutathione reductase (GR) and NADPH reduce oxidized glutathione (GSSG) back to GSH. Additionally, catalase, an abundant antioxidant in peroxisomes, can detoxify H_2O_2 to water without any cofactors. However, in the presence of ferrous or cuprous ions, H_2O_2 can become OH· and quickly cause the oxidation of lipids, proteins, and DNA, resulting in cellular damage. NADPH is required to maintain multiple antioxidant defense systems. The cytosol has multiple sources of NADPH generation, including the oxidative PPP, malic enzyme 1, IDH1, and one-carbon metabolism. NADPH generation in the mitochondria, in part, is controlled by one-carbon metabolism and IDH2.

Historically, ROS have been thought of as lethal metabolic by-products of cellular respiration and protein folding. However, studies over the past two decades have unveiled a previously underappreciated role of ROS in cellular signaling. Low levels of ROS, particularly H_2O_2, can reversibly oxidize the cysteine residues of proteins to positively regulate cell proliferation and cellular adaptation to metabolic stress (*119*). As H_2O_2 levels increase, however, cell death signaling pathways are initiated, and H_2O_2 is converted to OH·, which can directly damage DNA, proteins, and lipids. Cancer cells have an increased rate of spatially localized mitochondria- and NOX-dependent ROS production compared to normal cells. This allows for the proximal activation of signaling pathways [PI3K and mitogen-activated protein kinase/extracellular signal–regulated kinase (MAPK/ERK)] and transcription factors [HIF and nuclear factor κB (NF-κB)] necessary for tumorigenesis. The cancer cell–specific increased rate of spatially localized ROS production is due to a combination of oncogenic lesions and the tumor microenvironment. For example, the activation of oncogenes, PI3K signaling pathway induction, and hypoxia (low-oxygen levels) stimulate the increased rate of ROS production from the mitochondria and NOXs in cancer cells (*120*–*122*). Thus, mitochondria-targeted antioxidants and NOX inhibitors can prevent cancer cell proliferation, hypoxic activation of HIF, tumorigenesis, and metastasis (*64*, *123*–*125*).

The increased localized ROS in cancer cells, which activates signaling pathways and transcription factors to promote tumorigenesis, needs to be buffered from reaching levels of ROS that incur cellular damage by the increased expression of antioxidant proteins (*126*). Thus, cancer cells have higher levels of ROS scavenging enzymes than normal cells, preventing ROS-mediated activation of death-inducing pathways like c-Jun N-terminal kinase (JNK) and p38 MAPK and oxidation of lipids, proteins, and DNA, resulting in irreversible damage and cell death. One mechanism by which cancer cells increase their antioxidant capacity is by activating the transcription factor nuclear factor (erythroid-derived 2)–related factor-2 (NRF2) (*127*). Specifically, NRF2 is activated following disruption of the interaction of NRF2 with its binding partner Kelch-like ECH-associated protein 1 (KEAP1). Critical cysteine residues within KEAP1 can undergo oxidation,

succination, and glutathionylation, thereby inhibiting the KEAP1-NRF2 interaction, leading to the proteasomal degradation of NRF2. Additionally, NRF2 activation can occur independently of KEAP1 (*128*). Once activated, NRF2 induces the transcription of many antioxidant proteins including GPXs and TXNs as well as enzymes involved in GSH synthesis and cysteine import through the cystine/glutamate antiporter. Furthermore, to maintain the antioxidant capacity of GPXs and TXNs, NADPH is required. NRF2 plays an important role in activating enzymes that increase cytosolic NADPH levels. NRF2 also regulates the serine biosynthesis pathway, generating NADPH in the mitochondria, which is critical for redox balance under hypoxic conditions (*129*, *130*). Therefore, inactivating NRF2 or disabling antioxidant proteins in cancer cells would allow for the accumulation of excessive amounts of ROS to levels that initiate toxicity and reduce tumorigenesis (*128*, *131*, *132*).

During tumorigenesis and metastasis, redox homeostasis is required (Fig. 4). An emerging model of redox balance is that as a tumor initiates, the metabolic activity of cancer cells is increased, resulting in an increase in ROS production and subsequent activation of signaling pathways that support cancer cell proliferation, survival, and metabolic adaptation (*126*). Accordingly, to prevent toxic levels of ROS, tumor cells increase their antioxidant capacity to allow for cancer progression (*133*). The harsh tumor microenvironment increases ROS levels due to hypoxia, and the low glucose levels limit flux through the cytosolic oxidative PPP, thus decreasing cytosolic NADPH levels. Cells in these nutrient-deprived conditions activate AMPK to increase NADPH levels by stimulating PPP-dependent NADPH and diminishing anabolic pathways, such as lipid synthesis, that require high levels of NADPH (*134*, *135*). ROS-dependent signaling and increased mitochondrial respiration are also necessary for tumor metastasis (*124*, *136*). However, when tumor cells detach from a matrix, they encounter high levels of ROS that incur cellular damage and require activation of adaptive ROS-mitigating pathways to survive and grow (*137*, *138*). The ability to up-regulate antioxidant proteins and increase flux through NADPH-producing metabolic pathways enables distant metastasis to occur (*8*). These findings suggest that perhaps disabling antioxidant capacity in cancer cells to raise ROS levels might be beneficial in preventing metastasis.

Fig. 4 Cancer cells maintain redox balance.

Cancer cells have increased rates of ROS production due to activation of oncogenes and loss of tumor suppressors that promote signaling pathways supporting proliferation and survival. However, cancer cells prevent the buildup of ROS to levels that incur damage by increasing antioxidant capacity through induction of NRF2-dependent genes and, in glucose replete conditions, the use of PPP to generate NADPH. As cells encounter hypoxia and low glucose due to limited vasculature accessibility, the levels of ROS further increase, requiring AMPK and one-carbon metabolism to enhance NADPH production to raise antioxidant capacity. Loss of matrix attachment and escape of cancer cells into the blood for dissemination to distant sites incur further increases in ROS levels, which require additional enhancements of antioxidant defenses to avoid cell death. It is important to note that too little ROS or too high steady-state ROS levels within cancer cells result in failure for solid tumor progression and metastasis.

29.8.1.1: TARGETING METABOLISM FOR CANCER THERAPY

There are a few things to consider when determining what makes a good metabolic target for cancer therapy. First, inhibition of some metabolic enzymes is likely to be systemically toxic because of their physiological functions in normal tissues (*139*). The feasibility of targeting these pathways therapeutically depends on whether systemic blockade of the pathway can be tolerated. Normal proliferating cells, such as immune cells and stem cells, also reprogram their metabolism in a manner similar to cancer cells (*140*, *141*). Metabolic inhibitors should likely not interfere with the adaptive immune system. Nevertheless, there are excellent examples of pathways whose reprogramming does provide an adequate therapeutic window in cancer. Enhanced nucleotide and DNA synthesis in tumor cells is targeted by antifolates

(methotrexate, pemetrexed, and others) (112). Although these drugs do produce toxicity in normal proliferative tissues like the intestinal epithelium and bone marrow, they are essential components of highly successful chemotherapeutic regimens. Thus, it is critical to elucidate in normal cells any toxic effects of metabolic enzyme inhibition. To circumvent this challenge, one approach is to target a metabolic enzyme in a deregulated pathway specific to cancer cells. To date, many of the genetic and pharmacologic interventions on metabolic enzymes have been conducted using human cancer cells subcutaneously injected into athymic mice. Therefore, it will be important for future experiments to not only use patient-derived xenograft (PDX) models but also make use of genetically engineered mouse cancer models and syngeneic mouse models that have intact immune systems, especially given the promising results from immunotherapy. An emerging theme is that cancer cells display metabolic plasticity and can alter their metabolic profile during the course of tumorigenesis and metastasis. Thus, it is conceivable that cancer cells could develop resistance to inhibition of a particular metabolic pathway by expressing alternate protein isoforms or up-regulating compensatory pathways. Therefore, a rational cancer therapeutic strategy should involve targeting multiple metabolic pathways simultaneously or targeting a particular metabolic pathway in combination with therapies against oncogenic or signaling pathways. Here, we highlight a few promising metabolic targets in glycolytic, one-carbon, mitochondrial, and redox metabolism.

Glycolysis was an early attractive target for cancer therapy given the clinical observation that many tumors exhibit a significant increase in glucose uptake compared with adjacent normal tissue (112). LDH-A, a metabolic enzyme that converts pyruvate (the final product of glycolysis) to lactate, was identified as the first metabolic target of the oncogene MYC (142). Genetic or pharmacologic inhibition of LDH-A has been shown to diminish MYC-driven tumors in xenograft models (143, 144). Furthermore, recent studies indicate that inhibition of LDH-A leads to the regression of established tumors in genetically engineered mouse models of NSCLC without systemic toxicity (145). Genetic ablation of LDH-A also delays the progression of myeloid leukemia (146). Thus, the increased expression of LDH-A, specifically in MYC-mutant cancer cells, may prove to be an attractive target. Another potential therapeutic target is the glycolytic protein HK2. Many tumor cells overexpress HK2, and preclinical mouse models of genetically engineered NSCLC and breast cancer demonstrate that HK2 inhibition delays tumor progression (3). Furthermore, systemic HK2 deletion in mice does not cause adverse physiological consequences. However, the effect of LDH-A and HK2 on the adaptive immune system is currently unknown. Lactate has been shown to inhibit cytotoxic T cells; thus, LDH-A inhibition may cooperate with immune checkpoint inhibitors to unleash host inflammatory T cells that will specifically attack tumor cells (147). Lactate can also reprogram macrophages to promote tumorigenesis (148). Thus, it may be efficacious to target LDH-A or HK2 in highly glycolytic tumors that overexpress these proteins.

Another potential glucose-dependent target is PHGDH, an enzyme in the de novo serine synthesis pathway. High levels of PHGDH have been found in a subset of human melanoma and breast cancers, and these cancer cells require PHGDH for their growth in vitro (25, 26). Serine starvation in mice diminishes tumorigenicity of p53-null cancers (149). De novo synthesis or exogenous uptake of serine can enter the mitochondria where SHMT2 converts it into glycine to generate folate intermediates (101, 150). In many cancer types, SHMT2 expression is elevated and correlates with a poor prognosis. Furthermore, the transcription factors MYC and HIF induce SHMT2 under hypoxia to promote survival (130, 151). Currently, it is not known whether targeting PHGDH, SHMT2, or other enzymes in the one-carbon metabolism pathway would be effective in delaying or regressing tumor progression in genetically engineered, PDX, or syngeneic mouse models of cancer without incurring systemic toxicity. However, given the importance of one-carbon metabolism in supporting the anabolic needs of cancer cells and its up-regulation in cancer cells, it is likely that this pathway is needed for in vivo tumor progression (152).

Mitochondrial metabolism has also emerged as a key target for cancer therapy, in part, due to the revelation that the antidiabetic drug metformin is an anticancer agent (153). Numerous epidemiological studies first suggested that diabetic patients taking metformin, to control their blood glucose levels, were less likely to develop cancer and had an improved survival rate if cancer was already present (154). Laboratory-based studies have also provided evidence that metformin may serve as an anticancer agent (155–157). Biochemists recognized that metformin reversibly inhibits mitochondrial complex I (158–160). Recent studies indicate that metformin acts as an anticancer agent by inhibiting mitochondrial ETC complex I (161). Specifically, metformin inhibits mitochondrial ATP production, inducing cancer cell death when glycolytic ATP levels diminish as a result of limited glucose availability. Metformin also inhibits the biosynthetic capacity of the mitochondria to generate macromolecules (lipids, amino acids, and nucleotides) within cancer cells (162). The remarkable safety profile of metformin is due to its uptake by organic cation transporters (OCTs), which are only present in a few tissues, such as the liver and kidney (163). Certain tumor cells also express OCTs to allow the uptake of metformin (164). However, in the absence of OCTs, tumors would not accumulate metformin to inhibit mitochondrial complex I. Ongoing clinical trials using metformin as an anticancer agent should assess the expression levels of OCTs to identify the tumors with highest expression, which are likely to be susceptible to metformin. Moreover, it is not clear whether the current antidiabetic dosing of metformin used in clinical trials allows for metformin accumulation to levels necessary to inhibit mitochondrial complex I in tumors. Thus, it is possible that metformin at doses higher than those currently used for diabetes might be more efficacious without causing toxicity. Like metformin, the biguanide phenformin exhibits anticancer properties by inhibiting mitochondrial complex I (165). In contrast to metformin, phenformin is readily transported into tumor cells and has been withdrawn from human use in most parts of the world due to its clinical increase in the incidence of lactic acidosis. However, it is worth considering phenformin as a possible cancer therapy because lactic acidosis can be monitored. Biguanide sensitivity can be improved in mice starved for serine or in tumors that have lost p53 or LKB1 (155, 166, 167). Thus, biguanides, and possibly other mitochondrial complex I inhibitors, may be effective anticancer agents.

Another potential therapeutic strategy to inhibit mitochondrial metabolism in certain tumors would be to use autophagy or glutaminase inhibitors. Autophagy provides amino acids, such as glutamine, that fuel the TCA cycle in NSCLC and pancreatic cancers, and short-term autophagy inhibition has been shown to decrease tumor progression without incurring systemic toxicity in mouse models of NSCLC (*168*, *169*). Some tumors are addicted to using glutamine to support TCA cycle metabolism even in the absence of autophagy; thus, glutaminase inhibitors can reduce tumor burden in these models (*4*, *75*, *170*). An alternative approach is to target acetate metabolism. Although a major function of the mitochondria is to provide acetyl-CoA to the cell, cancer cells can also use acetate to support cell growth and survival during metabolic stress (hypoxia or nutrient deprivation) (*96*, *171*). The cytosolic enzyme acetyl-CoA synthase 2 (ACCS2), which converts acetate to acetyl-CoA, is dispensable for normal development; thus, ACCS2 is a promising target of acetate metabolism. ACCS2 knockout mice do not display overt pathologies, but genetic loss of ACCS2 reduces tumor burden in models of hepatocellular carcinoma (*171*). Human glioblastomas can oxidize acetate and may be sensitive to inhibitors of this process (*172*). Thus, targeting metabolism with inhibitors of autophagy, acetate metabolism, and other pathways that supply key metabolic intermediates may be efficacious in some contexts.

Because mitochondrial inhibitors are unlikely to be effective cancer therapies as single agents, combination therapy is likely the best approach. For example, the use of metformin with the current clinical PI3K inhibitors, which reduce glucose uptake and glycolysis (*173*), is one approach that would impair both sources of ATP within cells. Targeted therapies against oncogenes such as KRAS, BRAF, and NOTCH1 kill a large majority of cancer cells but ultimately yield resistant cells that exhibit an increased sensitivity to inhibitors that impair mitochondrial metabolism (*174*–*176*). Cancer-initiating cells also have increased sensitivity to mitochondrial inhibitors, adding further evidence that inhibiting mitochondrial metabolism may suppress tumor recurrence (*177*, *178*).

Furthermore, to counterbalance the increased production of ROS encountered during tumorigenesis and metastasis, cancer cells increase their antioxidant capacity (*126*). Thus, an additional therapeutic approach is to target redox metabolism, that is, selectively disable the antioxidant capacity of cancer cells causing ROS levels to rise and induce cancer cell death (*133*). The reducing equivalent NADPH is required to maintain multiple antioxidant defense systems. The cytosol has multiple sources of NADPH generation, including the oxidative PPP, malic enzyme 1, IDH1, and one-carbon metabolism. By contrast, NADPH generation in the mitochondria is controlled in part by one-carbon metabolism and IDH2. Many of these NADPH-generating systems are critical for normal cell survival and function. Nevertheless, there are two NADPH-generating systems that may serve as potential therapeutic targets. It is estimated that 400 million people worldwide are deficient in G6PDH, an enzyme in the oxidative PPP that converts $NADP^+$ to NADPH. However, certain tumors rely on this pathway as a major source of cytosolic NADPH; therefore, it may be therapeutic to disable this pathway and induce oxidative stress and diminish tumor growth. Moreover, RNA profiling of metabolic enzymes identified the mitochondrial one-carbon metabolism protein MTHFD2, which can generate NADPH, as being highly expressed in 19 different cancer types but not in normal adult proliferating cells (*152*). Loss of MTHFD2 in cancer cells increases ROS levels and sensitizes the cells to oxidant-induced cell death in vitro. An interesting approach to depleting NADPH levels and increasing ROS is to administer high doses of vitamin C (ascorbate). Vitamin C is imported into cells through sodium-dependent vitamin C transporters, whereas the oxidized form of vitamin C, dehydroascorbate (DHA), is imported into cells through glucose transporters such as GLUT1 (*179*). When the cell takes up DHA, it is reduced back to vitamin C by glutathione (GSH), which consequently becomes GSSG. Subsequently, GSSG is converted back to GSH by NADPH-dependent GR. Because the blood is an oxidizing environment, vitamin C becomes oxidized to DHA before being taken up by the cell. Thus, high doses of vitamin C diminish the tumorigenesis of colorectal tumors that harbor oncogenic KRAS mutations and express high levels of GLUT1 by depleting the NADPH and GSH pools and consequently increasing ROS levels to induce cancer cell death (*179*, *180*). Vitamin C administered at high doses intravenously is safe in humans and, in conjunction with conventional paclitaxel-carboplatin therapy, demonstrated a benefit in a small number of patients (*181*). Additional strategies to diminish GSH include the administration of buthionine sulfoximine, an irreversible inhibitor of γ-glutamylcysteine synthetase, which can be safely administered to humans and is efficacious in preclinical tumor models (*182*). Moreover, glutathione is a tripeptide consisting of cysteine, glutamate, and glycine. Thus, decreasing glutamate levels using glutaminase inhibitors or diminishing cysteine levels by preventing extracellular cystine (two linked cysteine molecules) uptake can also raise ROS levels in cancer cells to induce cell death.

An important consideration is that normal stem cells are sensitive to ROS levels; thus, it is important to stratify patients on the basis of their expression levels of a particular antioxidant protein or antioxidant pathway. It is critical to determine which antioxidant pathways are likely up-regulated as a result of the high rate of ROS production within cancer cells. Many cancer types use the NRF2 pathway to maintain redox balance; therefore, targeting this pathway may provide a viable therapeutic opportunity (*128*). Additionally, superoxide dismutase 1 (SOD1) is overexpressed in NSCLC, and its inhibition kills human NSCLC cells and decreases the tumor burden in mouse models of NSCLC (*183*). Because NRF2 and SOD1 knockout mice develop normally, short-term inhibition of these pathways might be an effective way to kill cancer cells.

29.8.1.1: TECHNOLOGIES ENABLING DISCOVERY IN CANCER METABOLISM

Many recent advances in our understanding of cancer metabolism have been propelled by advanced technologies to detect metabolites and metabolic activities (*184*). A key concept is that quantifying metabolites (that is, metabolomics) is a more distinct form of metabolic analysis than measuring the activities of metabolic pathways [that is, metabolic flux analysis (*185*)]. Although these two approaches can provide complementary types of information, they are not interchangeable. One cannot infer metabolic activity from changes in metabolite

levels, and altered metabolic fluxes may or may not cause changes in metabolite levels (186). Both of these approaches have provided important recent insights into cancer metabolism, and using the two techniques together provides the most complete assessment of metabolic phenotypes.

Metabolomics experiments seek to characterize and quantify the metabolites in a biological sample, usually by nuclear magnetic resonance (NMR) or, more commonly, mass spectrometry. Depending on the methods of extraction, separation, and detection, metabolomics experiments may focus on particular classes of metabolites or provide a comprehensive analysis of as many metabolites as possible. Targeted approaches typically detect a few dozen to a few hundred molecules, whereas untargeted analyses may detect more than 1000. Detecting alterations of metabolite levels in cancer can be extremely valuable. The massive accumulation of D2HG in IDH1-mutant gliomas was initially discovered through a metabolomics approach (33). Because altered metabolite levels can be detected noninvasively using ^{1}H magnetic resonance spectroscopy (MRS), perturbed metabolite levels discovered through metabolomics can sometimes be translated into clinical diagnostic techniques. Elevated levels of lactate, choline, glycine, and other metabolites are detected by MRS in glioma. More recently, MRS techniques have been developed to monitor specific metabolic states programmed by tumor-specific mutations in metabolic enzymes. Applications include elevated 2HG in IDH1/IDH2-mutated gliomas (187) and elevated succinate in SDH-deficient paragangliomas (188).

Metabolic flux studies use isotope tracers like ^{13}C, ^{15}N, and ^{2}H to track flow through metabolic pathways. Typically, a nutrient of interest is labeled by an isotope (for example, ^{13}C-glucose) and supplied to cancer cells in the culture medium. Metabolites extracted from the culture are analyzed for isotope enrichment using mass spectrometry or NMR. The extent and distribution of labeling within informative metabolites encode information about which pathways are active in the cells. Incorporating additional data (for example, definitive rates of nutrient consumption, waste secretion, and biomass production) allows quantitative fluxes to be determined across a metabolic network.

Isotope tracing studies provide information about metabolic alterations in cancer cells that cannot be detected by metabolite levels alone. For example, hypoxia and mutations in the ETC induce a restructuring of the TCA cycle in which many of the intermediates are produced in the reverse order from the conventional form of the cycle. The key reaction in this pathway involves the reductive carboxylation of α-ketoglutarate to isocitrate in a NADPH-dependent carboxylation reaction catalyzed by IDH1 and/or IDH2. Although metabolomics experiments can detect altered levels of TCA cycle metabolites in cells using the reductive carboxylation pathway or in cells with deficiencies in pyruvate import into mitochondria, the marked restructuring of the cycle is apparent only through isotope tracing experiments, particularly experiments using ^{13}C-glutamine as the tracer (69, 78, 79, 189–191). An example of the use of isotope tracers to identify metabolic liabilities involves the surprising discovery that a significant fraction of cellular NADPH, particularly in the mitochondria, is produced through folate metabolism (100, 101). These studies involved a sophisticated combination of ^{13}C and ^{2}H tracers, coupled with quantitative measurements of metabolic flux.

Several recent studies have begun to use stable isotopes to investigate metabolism in intact tumors. Because these isotopes do not undergo radioactive decay, they are safe for administration to animals and human subjects. Systemic administration of ^{13}C-labeled nutrients through either boluses or continuous infusions has been shown to generate substantial labeling of glycolytic and TCA cycle intermediates in tumors. In mice bearing orthotopic transplants of high-grade human gliomas, continuous infusion of ^{13}C-glucose was demonstrated to produce steady-state labeling of metabolites from the TCA cycle within the tumor, enabling the assessment of several metabolic pathways (192). Here, tumors with diverse oncogenotypes oxidized glucose-derived pyruvate in the mitochondria and synthesized glutamine from glucose carbon. In contrast to most cultured glioma cell lines, these tumors did not demonstrate significant levels of ^{13}C-glutamine oxidation in vivo, and primary cell lines derived from the tumors did not require glutamine for survival or proliferation. In another study, metabolism of ^{13}C-glucose and ^{13}C-glutamine in autochthonous models of *MYC*- or *MET*-driven tumorigenesis revealed that metabolic phenotypes depend not only on the tumor's genetic driver but also on the tissue or origin. *MYC* but not *MET* stimulated glutamine catabolism in liver tumors, whereas *MYC*-driven lung tumors expressed glutamine synthetase and accumulated glutamine (193). Thus, in vivo isotope tracing can detect metabolic activities of intact tumors and characterize some of the factors that specify the metabolic phenotype.

Administration of ^{13}C-labeled nutrients has also proven to be valuable in human cancer (172, 194–197). Fan *et al.* (196) used ^{13}C-glucose to demonstrate that human non–small cell lung tumors metabolize glucose through glycolysis and the TCA cycle concurrently, with metabolites from both pathways demonstrating higher levels of labeling in tumors relative to adjacent lung tissue. In a subsequent study, these investigators demonstrated that the anaplerotic enzyme pyruvate carboxylase (PC) was highly expressed in lung tumors and contributed to ^{13}C labeling in TCA cycle intermediates (195). Enhanced glucose oxidation involving both PC and pyruvate dehydrogenase (PDH) was demonstrated in a separate cohort of non–small cell lung tumors, in which formal analysis of metabolic fluxes was used to complement measurements of ^{13}C labeling (197). An important conclusion from these studies, and from a similar study in mice bearing *KRAS*-driven tumors (198), is that non–small cell lung tumors demonstrate higher levels of both glycolysis and glucose oxidation relative to adjacent, benign lung. This finding sharply contrasts with the frequently invoked "switch" from oxidative metabolism to glycolysis in malignant tissue, commonly used to explain the Warburg effect (Fig. 5A). Rather, the data support a model in which the amplitude of both pathways is increased simultaneously, perhaps through increased substrate delivery and enzyme expression in tumor cells (Fig. 5B). It is also significant that human tumors exhibit substantial heterogeneity of metabolic phenotypes, both between tumors and even within distinct regions of the same tumor (197). The extent of glucose-dependent labeling of TCA cycle intermediates is predicted by noninvasive

assessment of tumor perfusion by magnetic resonance imaging, providing an approach to identify areas of regional metabolic heterogeneity in human cancer (*197*).

Fig. 5 Relationship between glycolysis and oxidative phosphorylation in cancer cells.
(**A**) A common view of cancer cell metabolism invokes a switch from glucose oxidation in normal tissues toward glycolysis and suppressed oxidative phosphorylation (OxPhos) in cancer. (**B**) Analysis of metabolic activity in intact tumors from humans and mice argues against a switch. Rather, tumors appear to enhance both glycolysis and glucose oxidation simultaneously relative to surrounding tissue.

Metabolomics and metabolic flux analysis can be integrated with functional genomics to identify and understand metabolic vulnerabilities in cancer cells. This approach has produced several good examples of screens that identified potential therapeutic targets while stimulating entirely new lines of investigation in cancer cell biology. For example, the serine biosynthetic enzyme PHGDH was first identified as a metabolic vulnerability in breast cancer cells through a large-scale in vivo short hairpin RNA screen targeting thousands of metabolic enzymes (*25*). *PHGDH* is frequently amplified at the genomic level in breast tumors and melanomas and exhibits oncogene-like features in cell culture (*25*, *26*). Subsequent work on serine biosynthesis, much of it involving metabolomics and metabolic flux analysis, has uncovered novel functions and liabilities of this pathway in cancer cell growth and stress resistance (*129*, *150*, *151*). Combining functional screens with metabolic analysis can also identify context-specific vulnerabilities that may be therapeutically actionable. A CRISPR (clustered regularly interspaced short palindromic repeats)–based loss-of-function screen identified GOT1, the cytosolic aspartate aminotransferase, as conditionally essential for survival during treatment with the ETC inhibitor phenformin (*199*). Isotope labeling then demonstrated that ETC blockade caused the direction of this enzyme to reverse from aspartate consumption in untreated cells to aspartate synthesis during ETC blockade (*200*). In addition to the discovery of synthetic lethality between ETC and GOT1 inhibition, these studies led to the novel biological concept that a major function of the ETC in proliferating cells is to support the synthesis of aspartate for nucleotide and protein synthesis (*199*, *200*).

29.8.1.1: CONCLUSIONS AND CURRENT CHALLENGES

Substantial progress has been made in the past decade toward understanding the mechanisms, biological consequences, and liabilities associated with metabolic reprogramming in cancer. Several common themes have emerged from this research (Box 1). First, metabolic reprogramming is essential for the biology of malignant cells, particularly their ability to survive and grow by using conventional metabolic pathways to produce energy, synthesize biosynthetic precursors, and maintain redox balance. Second, metabolic reprogramming is the result of mutations in oncogenes and tumor suppressors, leading to activation of PI3K and mTORC1 signaling pathways and transcriptional networks involving HIFs, MYC, and SREBP-1. Third, alterations in metabolite levels can affect cellular signaling, epigenetics, and gene expression through posttranslational modifications such as acetylation, methylation, and thiol oxidation. Fourth, taken together, studies on cultured cells have demonstrated a remarkable diversity of anabolic and catabolic pathways in cancer, with induction of autophagy and

utilization of extracellular lipids and proteins complementing the classical pathways like glycolysis and glutaminolysis. We have exited the period when cancer metabolism could be considered synonymous with the Warburg effect.

Box 1

Key Principles and Lessons Learned

Reprogrammed metabolic pathways are essential for cancer cell survival and growth.

Frequently reprogrammed activities include those that allow tumor cells to take up abundant nutrients and use them to produce ATP, generate biosynthetic precursors and macromolecules, and tolerate stresses associated with malignancy (for example, redox stress and hypoxia).

An emerging class of reprogrammed pathways includes those allowing cancer cells to tolerate nutrient depletion by catabolizing macromolecules from inside or outside the cell (for example, autophagy, macropinocytosis, and lipid scavenging).

Reprogramming may be regulated intrinsically by tumorigenic mutations in cancer cells or extrinsically by influences of the microenvironment.

Oncometabolites (for example, 2HG) accumulate as a consequence of genetic changes within a tumor and contribute to the molecular process of malignant transformation.

Many metabolites exert their biological effects outside of the classical metabolic network, affecting signal transduction, epigenetics, and other functions.

New approaches to assess metabolism in living tumors in humans and mice may improve our ability to understand how metabolic reprogramming is regulated and which altered pathways hold opportunities to improve care of cancer patients.

Several challenges will likely shape research over the next decade. First, the studies cited above were performed primarily in cancer cell lines rather than intact tumors. These straightforward experimental models have been highly informative about the molecular mechanisms of metabolic reprogramming, particularly those linking aberrant signaling to altered metabolic fluxes. But it is challenging (perhaps impossible) to model an accurate tumor microenvironment in culture. Direct analysis of metabolic fluxes in intact tumors should begin to play a more prominent role in the field and may prove essential in determining precisely how to deploy metabolic inhibitors in clinical trials. Along these lines, it is remarkable that some tumor cell metabolic vulnerabilities observed in vivo are absent from cultured cell models (*198*) and that metabolic phenotypes are inconsistent even across single solid tumors in patients (*197*). Developing rational therapeutic strategies will be aided by learning how to derive metabolic information efficiently and comprehensively from both preclinical and clinical models of intact tumor growth. A further challenge for these in vivo studies will be to develop analytical or computational approaches to deconvolute the distinct metabolic phenotypes of discrete cell types (cancer cells, cancer-associated fibroblasts, lymphocytes, and endothelial cells) within solid tumors. This may allow us to understand the metabolic cooperativity among populations of cells within a tumor and whether metabolic reprogramming of stromal cells provides therapeutic opportunities. Second, by far the best recent candidate for a targetable, tumor-specific metabolic activity is the neomorphic function of mutant IDH1/IDH2. This has stimulated intense interest in finding other metabolic alterations for which the therapeutic window may be wide enough for real clinical opportunities. Third, although we have learned a great deal about the metabolic pathways that support cancer cell proliferation, we know much less about the metabolism that supports survival of nonproliferating tumor cells, which constitute the bulk of the malignant cells in most solid tumors. Along these lines, the metabolism of tumor-initiating cells/cancer stem cells is just now beginning to be investigated, and it will be of major interest to devise strategies to target metabolism in these cells. Finally, we still know relatively little about metabolic interactions between tumor and host. This area has the potential for enormous impact on public health. It is clear that obesity and diabetes, both of which are reaching epidemic proportions in the developed world, increase cancer risk, but we lack insight into how to break these links.

Acknowledgments: We are grateful to J. Schaffer for illustrating the figures. **Funding:** This work was supported by NIH grants RO1 CA12306708 (to N.S.C.) and RO1 CA157996 to (R.J.D.). **Author contributions:** N.S.C. wrote the abstract, bioenergetics, redox, and targeting metabolism for cancer therapy sections. R.J.D. wrote the introduction, biosynthesis, technology, **Box 1**, and conclusion sections. N.S.C. and R.J.D. both wrote the metabolic reprogramming and oncometabolites sections. **Competing interests:** R.J.D. is on the Advisory Boards of Agios Pharmaceuticals and Peloton Therapeutics. N.S.C. declares no competing interests. **Data and materials availability:** All data needed to evaluate the conclusions in the paper are present in the paper and/or the Supplementary Materials. Additional data related to this paper may be requested from the authors.

29.9: IMMUNOMETABOLISM- CELLULAR METABOLISM TURNS IMMUNE REGULATOR

Róisín M. Loftus and David K. Finlay. Immunometabolism: Cellular Metabolism Turns Immune Regulator. Journal of Biological Chemistry. **MINIREVIEWS**| VOLUME 291, ISSUE 1, P1-10, JANUARY 01, 2016. https://www.jbc.org/article/S0021-92...233-5/fulltext

ABSTRACT

Immune cells are highly dynamic in terms of their growth, proliferation, and effector functions as they respond to immunological challenges. Different immune cells can adopt distinct metabolic configurations that allow the cell to balance its requirements for energy, molecular biosynthesis, and longevity. However, in addition to facilitating immune cell responses, it is now becoming clear that cellular metabolism has direct roles in regulating immune cell function. This review article describes the distinct metabolic signatures of key immune cells, explains how these metabolic setups facilitate immune function, and discusses the emerging evidence that intracellular metabolism has an integral role in controlling immune responses.

METABOLIC CHALLENGES FACING IMMUNE CELLS

During the course of an immune response, immune cells can traverse multiple tissues containing diverse conditions of nutrient and oxygen availability. Additionally, in response to activation, immune cells often dramatically change their functional activities; a lymphocyte transforms from a relatively inert cell to a cell engaging in robust growth and proliferation, often producing large amounts of effector molecules such as cytokines. These microenvironmental and functional alterations represent significant metabolic stresses that are efficiently managed by immune cells due their ability to dynamically reprogram their cellular metabolism.

INFLAMMATORY MICROENVIRONMENTS

Most normal tissue is well vascularized and replete with nutrients and oxygen. However, during an immune response, conditions in the local immune microenvironment can often be significantly less accommodating due to competition for nutrients. For example, tumor cells have a prodigious appetite for glucose and other nutrients. As a result, the microenvironment within solid tumors can become depleted of glucose, resulting in decreased rates of glycolysis in tumor infiltrating lymphocytes (1, 2, 3). Bacterial infections can also compete for nutrients with immune cells. Infection with *Staphylococcus aureus*, a common human pathogen, can result in localized tissue hypoxia due to elevated levels of oxygen consumption by the invading bacteria. As glucose is a key fuel for this bacteria, the levels of glucose available to immune cells will also be reduced (4). Viral infection can also result in a decrease in the amount of glucose that is available to infiltrating immune cells; viruses can reprogram infected cells to up-regulate glucose uptake and metabolism to facilitate viral replication (5, 6, 7). Additionally, various cells at sites of inflammation can release enzymes that consume nutrients in the local microenvironment, including arginase and indoleamine-2,3-dioxygenase, which deplete arginine and tryptophan, respectively (1). Inflammatory sites can also become hypoxic due to the pronounced influx of inflammatory cells such as neutrophils and monocytes (8).

DYNAMIC CHANGES IN CELLULAR FUNCTION

Immune activation is accompanied by substantial changes in cellular activities, such as those accompanying T cell activation. Naïve T cells are long-lived, relatively inert, exhibit low levels of cellular biosynthesis, and primarily require ATP to meet cellular demands (Fig. 1*A*). Following activation, T cells undergo substantial changes in function and engage in robust cellular growth and rapid cellular proliferation (9). Essential in supporting these cellular activities is the provision of sufficient biomolecules (amino acids, nucleotides, lipids) for the biosynthesis of new cellular components. Therefore, in activated T cells, the objectives of cellular metabolism have shifted from primarily generating ATP to the generation of sufficient ATP plus large amounts of biomolecules for the generation of biomass (10). Therefore, immune cells adapt their cellular metabolism to accommodate altered functional outputs.

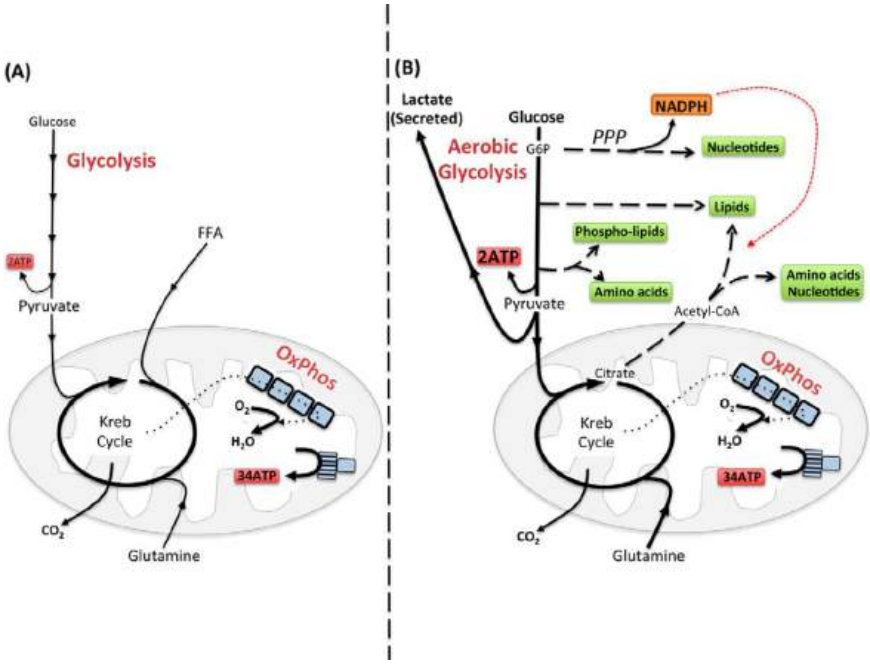

FIGURE 1.Configuring metabolism to match immune cell function. *A*, ATP is the key molecule that provides energy for cellular processes. Maintaining cellular ATP levels is essential for bioenergetic homeostasis and cell survival. Glucose, a key fuel source for mammalian cells, can be metabolized via two integrated metabolic pathways, glycolysis and OxPhos, that efficiently convert this simple sugar glucose into ATP. Glycolysis converts glucose to pyruvate through a series of enzymatic steps that occur in the cytosol, generating two molecules of ATP. Following its transportation into the mitochondria, pyruvate is further metabolized to CO_2 by the Krebs cycle, which drives OxPhos and the translocation of protons across the mitochondrial inner membrane. The resulting proton gradient drives the enzyme ATP synthase, converting ADP to ATP, generating up to 34 ATP per molecule of glucose. In addition to the breakdown of glucose via glycolysis, cells have the ability to metabolize alternative substrates, such as lipids and glutamine, which feed into the Krebs cycle and drive OxPhos. Fatty acid β-oxidation and glutaminolysis replenish the Krebs cycle intermediates acetyl-CoA and α-ketoglutarate, respectively, thereby fueling OxPhos and the efficient generation of cellular ATP. *B*, aerobic glycolysis supports biosynthetic processes of the cell as it allows the uptake of larger amounts of glucose and the maintenance of elevated glycolytic flux. Glycolytic intermediates are then diverted into various pathways for the synthesis of biomolecules that support biosynthetic processes. For instance, glucose 6-phosphate (*G6P*), generated by the first step in glycolysis, can feed into the pentose phosphate pathway (*PPP*) to support nucleotide synthesis. This pathway also generates NADPH, a cofactor that is essential for various biosynthetic processes including lipid synthesis. Glucose can also be converted into cytoplasmic acetyl-CoA via citrate in the Krebs cycle for the production of cholesterol and fatty acids for lipid synthesis. Other glycolytic intermediates can also be converted into biomolecules used for protein and lipid synthesis. During aerobic glycolysis, a significant proportion of pyruvate is also converted to lactate and secreted from the cell. Although aerobic glycolysis is an inefficient way to generate ATP (generating only two ATP molecules per glucose) due to the high rates of flux through the pathway, the rate of ATP production can be sufficient to maintain energy homeostasis even when mitochondrial ATP synthesis is impaired. Alternative fuels including glutamine feed into the Krebs cycle and can also supply biomolecules for biosynthetic processes under certain conditions.

CONFIGURING METABOLISM FOR BIOSYNTHESIS, INFLAMMATION, AND LONGEVITY

AEROBIC GLYCOLYSIS FOR CELLULAR BIOSYNTHESIS

A common feature of pro-inflammatory immune cells is that they adopt a distinct metabolic signature termed “aerobic glycolysis” to support cellular biosynthetic processes: that is, glucose metabolized to lactate in the presence of abundant oxygen (Fig. 1*B*). Aerobic glycolysis is adopted by cells engaging in robust growth and proliferation because it provides the biosynthetic precursors that are essential for the synthesis of nucleotides, amino acids, and lipids (10). Many intermediates of the glycolytic pathway act as a source of carbon that feeds into a range of biosynthetic pathways (Fig. 1*B*). Therefore, for cells engaged in aerobic glycolysis, the function of glucose is not just as a fuel to generate energy but also as a source of carbon that can be used for biosynthetic purposes (11). Hence, aerobic glycolysis provides immune cells with the components needed to facilitate proliferation and the synthesis of inflammatory molecules.

Metabolic reprogramming to aerobic glycolysis has advantages beyond enhanced biosynthetic capacity. This metabolic signature allows cells to adapt and survive as they encounter metabolically restrictive conditions, such as hypoxia. Although hypoxia prevents efficient ATP synthesis through OxPhos (Fig 2), high rates of glycolysis can generate enough ATP to maintain energy homeostasis. Glycolytic reprogramming involves increased expression of glucose transporters, especially Glut1, that facilitates elevated glucose uptake and enables immune cells to compete for glucose in nutrient restrictive environments (12). Immune cells also have a degree of metabolic plasticity in

response to limiting glucose availability. For instance, when glucose levels are low, effector T cells have the ability to adapt and increase glutamine uptake and glutaminolysis to support cellular metabolism (13).

AEROBIC GLYCOLYSIS IN ACTIVATED LYMPHOCYTES

Upon stimulation through antigen or cytokine receptors, lymphocytes increase the rates of both glycolysis and OxPhos (Fig. 2) (10). Although glucose is an essential fuel during T cell activation, glutamine is also important, and effector T cell differentiation is impaired when the supply of glutamine is disrupted (9, 14, 15). T cells that differentiate into effector subsets maintain aerobic glycolysis in response to various cytokines (16). In contrast, FoxP3$^+$ regulatory T cells (Tregs) switch to low levels of glycolysis and preferentially use oxidative metabolism (17). However, another type of regulatory T cell, FoxP3$^-$ regulatory T cells (Tr1), maintains elevated glycolysis similar to effector T cells (18). Although many of the functions of Tr1 cells overlap with those of Tregs, others are unique to Tr1 cells including granzyme/perforin-mediated cytolysis of target cells. Therefore, perhaps the distinct metabolic characteristics of these regulatory cells reflect the different mechanisms through which they regulate T cell responses. Similarly, B lymphocytes and NK cells also increase rates of glycolysis and OxPhos in response to various stimuli (19,20, 21,22). However, as metabolic analyses of B lymphocytes have all been performed using *in vitro* stimulated splenic B cells, the metabolic profile of distinct B cell subsets is currently unknown. Similarly, the metabolic signatures of distinct NK subsets, or indeed other innate lymphoid cells, also remain to be characterized.

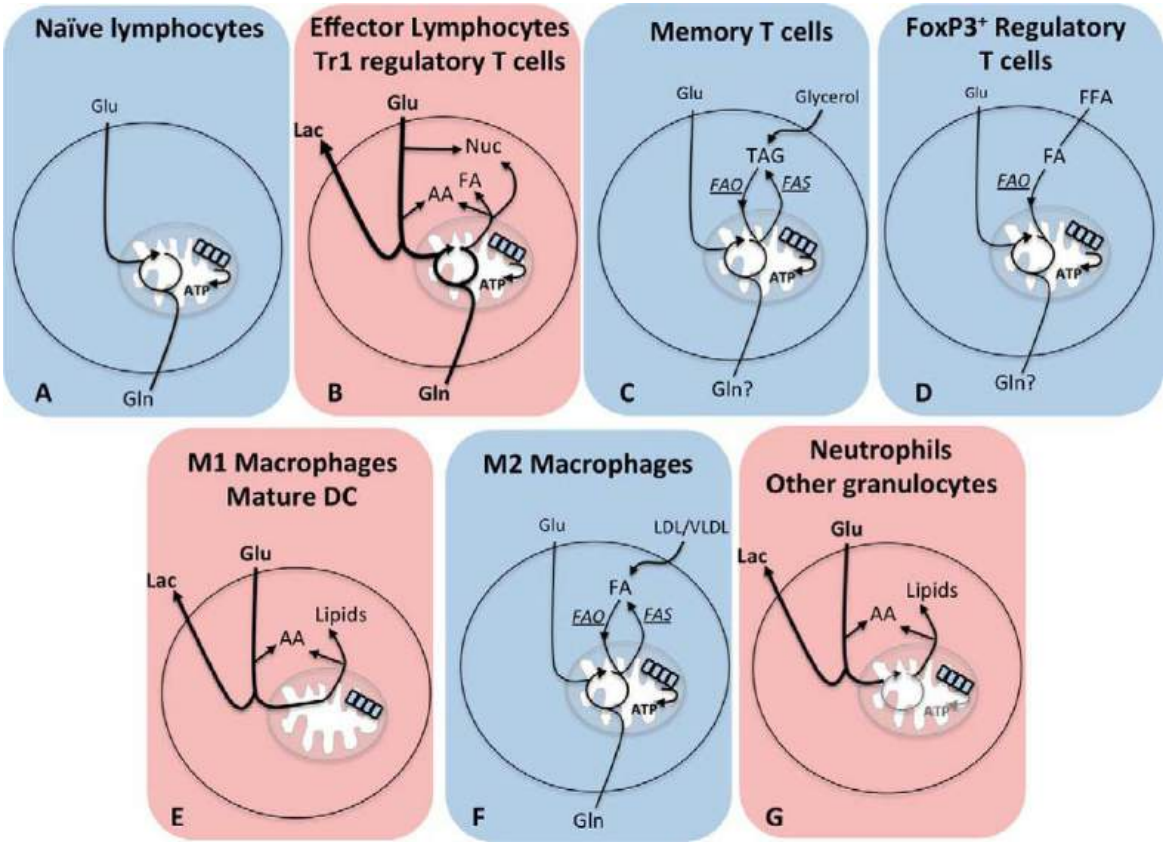

FIGURE 2.Distinct metabolic configurations of different immune cell subsets. *Blue panels* represent cells with oxidative metabolism, and *red panels* represent cells with glycolytic metabolism. *A*, naïve T cells use glucose and glutamine and OxPhos. *B*, effector lymphocytes and Tr1 regulatory T cells have high rates of both glycolysis and OxPhos, metabolize glucose to lactate, and use metabolic intermediates to support biosynthetic processes. *Nuc*, nucleotides; *FA*, fatty acids; *AA*, amino acids; *Lac*, Lactate. *C*, memory T cells use glucose to generate mitochondrial citrate, which is exported into the cytosol to support lipid synthesis. These *de novo* synthesized fatty acids are used with imported glycerol to generate and store TAGs. OxPhos is fueled by acetyl-CoA generated following β-oxidation of these TAGs. *FAO*, fatty acid oxidation; FAS, fatty acid synthesis. *D*, FoxP3$^+$ regulatory T cells use exogenously derived fatty acids metabolized by β-oxidation to support OxPhos. *E*, M1 macrophages and mature DC engage aerobic glycolysis for ATP synthesis and to support biosynthesis while also inactivating OxPhos. *F*, M2 macrophage metabolism is characterized by fatty acid β-oxidation and OxPhos. β-Oxidation is fueled by lipids that are scavenged from the external microenvironment and also by lipids generated by *de novo* fatty acid synthesis. *G*, neutrophils are highly glycolytic with few functional mitochondrial and very low rates of OxPhos.

Although the exact molecular mechanisms controlling glycolytic metabolism are not universal for all lymphocyte subsets, it is clear that mammalian target of rapamycin (mTOR) has a fundamental role (10, 23). mTOR complex 1 (mTORC1) activity is essential for the initial induction of glycolysis in T cells and is also required to maintain aerobic glycolysis in effector T cells subsets (9, 23, 24). The data also

suggest that mTORC1 has an important role for cytokine-induced glycolysis in NK cells (22). A number of transcription factors are involved in glycolytic reprogramming of T cells including both hypoxia-inducible factor 1α (HIF1α) and c-Myc (9, 25, 26). In B cells, c-Myc but not HIF1α is important for the glycolytic response (21). HIF1α and c-Myc directly bind the promoters of an array of genes, notably those of glycolytic enzymes and glucose transporters.

AEROBIC GLYCOLYSIS IN MYELOID CELLS

Unlike lymphocytes, mature myeloid cells tend to be non-proliferative and so have substantially different metabolic requirements. Activated M1 macrophages, dendritic cells (DC), and granulocytes are all highly glycolytic with little or no flux through OxPhos (27,28, 29, 30, 31,32). In activated M1 macrophages and DC, OxPhos is inactivated following inducible NOS-dependent nitric oxide production, which directly inhibits oxidative phosphorylation (33, 34). In these cells, the Krebs cycle is no longer cycling, which allows the repurposing of Krebs cycle enzymes to generate molecules that are important for proinflammatory functions (27, 33). M1 macrophages generate high levels of the Krebs cycle metabolite succinate, which can lead to increased HIF1α activity and sustained IL1β production (27). Levels of citrate are also elevated and are used to generate the antimicrobial metabolite itaconic acid that inhibits the growth of bacteria such as *Salmonella enterica* and *Mycobacterium tuberculosis* (34, 35). The metabolic changes following DC activation occur in two phases and result in a metabolic switch from fatty acid β-oxidation and OxPhos to glycolysis (33). An initial increase in glycolysis occurs within minutes of DC activation to support *de novo* lipid biosynthesis, facilitating the expansion of endoplasmic reticulum and Golgi apparatus and increasing the biosynthetic capacity that is essential for mature DC function (36). Over the course of 18 h, activated DC sustain elevated glycolysis and inactivate OxPhos (33). This metabolic shift is important in regulating DC-induced T cell responses, in part due to the fact that it impacts upon DC lifespan and thus the duration over which DC can activate T cells (37, 38). The metabolism of granulocytes is best characterized for neutrophils, which rely almost entirely on glycolysis and exhibit very low levels of OxPhos (28, 29,30, 39). Neutrophil effector functions, including the formation of neutrophil extracellular traps, require mTORC1/HIF1α signaling and glucose metabolism (29, 30, 39, 40,41). Although the metabolism of other granulocytes such as basophils and eosinophils remains poorly characterized, there is some evidence that these cells are also glycolytic and rely upon metabolic regulators such as HIF1α to maintain glycolysis and normal function (42). For instance, HIF1α accumulation upon basophil activation was shown to be required for VEGF and IL4 production (42).

OXIDATIVE CELLULAR METABOLISM IN NAÏVE LYMPHOCYTES AND MEMORY T CELLS

As previously mentioned, naïve lymphocytes are relatively inert cells with limited biosynthetic demands, and so ATP alone is relatively sufficient to sustain these cells. Given that these cells reside in well oxygenated tissues, oxidative metabolism is a consistent and efficient way to meet cellular metabolic demands. Memory cells generated during the course of an immune response share many of the same characteristics of naïve lymphocytes; they are long-lived, relatively inert cells with limited biosynthetic demands. As nothing is known regarding the metabolism of memory B cells, only memory T cells will be considered here. The key distinction between naïve and memory T cells is the rapid recall responses characteristic of memory T cells when compared with primary T cell responses. Although both naïve and memory T cells adopt oxidative metabolism, there are key differences in the metabolic configurations of these cells that contribute to rapid memory T cell recall responses. Memory T cells predominantly use fatty acid β-oxidation to generate acetyl-CoA to fuel OxPhos (43) (Fig. 2). β-Oxidation is an efficient method for generating ATP with each fatty acid molecule generating significantly more ATP (about 106 ATP/molecule of palmitate) when compared with one molecule of glucose (about 36 ATP/molecule of glucose). Indeed, fatty acid oxidation is essential for rapid memory T cell responses (43). Interestingly, these fatty acids are not taken up from the surrounding microenvironment, but rather memory T cells use glucose and glycolysis to generate citrate for *de novo* fatty acid synthesis and the generation and storage of triacylglycerides (TAGs) (44, 45). These endogenously derived TAGs are then broken down by β-oxidation in the mitochondria to generate acetyl-CoA to fuel OxPhos (45). From a bioenergetics standpoint, this would seem like an inefficient mechanism to fuel OxPhos as fatty acid synthesis utilizes both ATP and NADPH. Nonetheless, this seemingly futile cycle of fatty acid synthesis and fatty acid oxidation is important for memory T cell survival (44, 45). This approach may be taken by memory T cells, for which long term survival is of utmost importance, as glucose levels are stringently controlled in the blood, making glucose a more dependable fuel source than fatty acids, whose levels can vary in different tissues. Another advantage of this cycle of fatty acid synthesis and oxidation may be that it allows the cell to concurrently engage both glycolysis and OxPhos, thus maintaining the machinery required for rapid induction of metabolic flux through these pathways upon antigen recognition and so facilitating rapid functional responses. Indeed, memory T cells can induce rates of glycolysis much more rapidly and robustly than naïve T cells (43, 46).

OXIDATIVE CELLULAR METABOLISM IN CELLS WITH SIGNIFICANT BIOSYNTHETIC OUTPUT

$FoxP3^+$ Tregs also primarily engage in oxidative metabolism, but in contrast to naïve lymphocytes and memory T cells, $FoxP3^+$ Tregs are not inert cells and are in fact producing relatively large quantities of biomolecules (17, 47). Tregs make immunosuppressive cytokines IL10 and TGFβ and can also engage in cellular proliferation in response to IL2. In this respect, M2 macrophages are similar to $FoxP3^+$ Tregs; M2 macrophages engage in oxidative metabolism and yet have significant biosynthetic outputs. M2 macrophages have roles in tissue repair and secrete anti-inflammatory cytokines, growth factors, and factors involved in tissue remodeling (48). Tregs and M2 macrophages oxidize both glucose and fatty acids in the mitochondria to sustain OxPhos (17, 49,50, 51,52). In contrast to memory T cells, Tregs fuel β-oxidation and the Krebs cycle using exogenously derived fatty acids. Meanwhile, in M2 macrophages, there is evidence that both exogenously derived lipids scavenged from the microenvironment and *de novo* synthesized lipids fuel β-oxidation and OxPhos (52). It is likely that Tregs and M2

macrophages use glutamine metabolites to sustain cellular biosynthetic processes (Fig. 1) (53). Indeed, M2 macrophages have increased glutamine metabolism when compared with M1 macrophages (34). Additionally, given that M2 macrophages are professional scavengers of apoptotic debris, it is tempting to speculate that M2 macrophages sustain cellular biosynthesis using biomolecules scavenged from the surrounding microenvironment (48, 52).

OXIDATIVE METABOLISM SUPPORTS IMMUNE CELL LONGEVITY

Controlling the longevity of immune cells is an important aspect of a healthy immune system. For example, a long lifespan (years) is essential for naïve and memory T cells to maintain functional primary and recall T cell responses. In contrast, it is crucial that upon resolution of a viral infection, the large population of CTL undergoes apoptosis as these effector T cells have the potential to cause significant immunopathology (54). Therefore, CTL have a short lifespan of days to weeks. Similarly, differences in lifespan are apparent in different subsets of macrophages. M1 macrophages are short-lived and are a key component of the innate immune system that forms the first line of defense occurring within hours to days of an immunological challenge. In contrast, M2 macrophages are longer-lived as they have important roles within the resolution phase and in tissue repair and remodeling. Strikingly, the cellular metabolic signature of an immune cell corresponds to the longevity of the cell; aerobic glycolysis is characteristic of short-lived immune cells, whereas oxidative metabolism is characteristic of long-lived cells (Fig. 2).

It is perhaps unsurprising that OxPhos is important for longevity in immune cells given the importance of mitochondrial membrane potential in controlling the induction of apoptosis. Certainly, in activated DC, preserving OxPhos results in an increased cellular lifespan (38). Moreover, in macrophages, switching cellular metabolism from glycolysis to oxidative metabolism promotes a shift from short-lived M1 macrophages to longer-lived M2 macrophages (50). In addition, manipulating glycolytic *versus* oxidative metabolism impacts upon the formation of long-lived memory T cells; inhibiting glycolysis promotes memory T cell formation, whereas inhibiting fatty acid oxidation-dependent OxPhos represses memory T cell formation (55, 56). These reports are consistent with a number of other studies that also support the notion that promoting oxidative phosphorylation enhances cell survival and lifespan (57, 58,59). On the other hand, there are also numerous reports on a variety of cell types showing that manipulating glycolytic metabolism has profound impacts upon cellular viability (60,61, 62, 63,64). Growth factors that promote elevated levels of cellular glycolysis also have the consequence of making that cell highly dependent on continued growth factor signaling and glycolysis for survival (64). This provides an elegant mechanism for terminating effector T cell responses. For instance, glycolytic metabolism in $CD8^+$ CTL is sustained by IL2, and upon IL2 withdrawal, as will occur upon resolution of a viral infection, glycolytic metabolism is rapidly lost and the CTL will die (24, 65).

METABOLIC CONTROL OF IMMUNE CELL FUNCTION

METABOLIC ENZYMES OR REGULATORS CONTROLLING IMMUNE CELL FUNCTION

Cellular metabolism is crucial for facilitating immune cell functions, but in addition, there is emerging evidence that metabolic enzymes and regulators can also have a direct role in controlling immune cell functions. For instance, in CD4 T cells, GAPDH has been described to bind to the 3′-UTR of IFNγ and IL2 mRNA and inhibit translation (66). This function of GAPDH is perhaps unsurprising due to the numerous reports describing RNA binding activities for GAPDH over the past two decades (67, 68, 69,70). Indeed, in myeloid cells, GAPDH is a component of the IFNγ-activated inhibitor of translation (GAIT) complex that binds defined 3′-UTR elements within a family of inflammatory mRNAs and suppresses their translation (71). Importantly, GAPDH functions in glycolysis and mRNA binding are likely to be mutually exclusive so that in glycolytic cells, GAPDH is preferentially engaged in glycolysis, and thus the translation of IFNγ and IL2 mRNA is unconstrained. This mechanism provides a direct link between rates of glycolysis and the expression of important immunological effector molecules. Intriguingly, it appears that many other metabolic enzymes can bind to mRNA molecules including numerous glycolytic enzymes, Krebs cycle enzymes, and enzymes involved in other metabolic pathways (72). Although the specific mRNA transcripts that these metabolic enzymes bind to still have to be identified, this study highlights the abundant potential for cellular metabolism to directly impact upon cellular functions.

Various metabolic regulators that evolved to control cellular metabolic pathways have since acquired roles in directly controlling immune cell function. The glycolytic regulator HIF1α also promotes the expression of IL1β in M1 macrophages and programmed death ligand-1 (PD-L1), a ligand for the immune checkpoint receptor PD-1, on various myeloid cells (27, 73). The aryl-hydrocarbon receptor (AhR), which together with HIF1α controls glycolytic metabolism in Tr1 regulatory T cells, also directly regulates T cell responses. AhR promotes Th17 differentiation, while inhibiting Treg differentiation, and is required for the production of the Th17 cytokines IL17 and IL22 (74, 75, 76). Additionally, AhR is important for Tr1 regulatory T cell differentiation, directly promoting the expression of IL10 and IL21 (18, 77). The transcription factor sterol regulatory element-binding protein (Srebp), a central regulator fatty acid and cholesterol synthesis, has dual roles in controlling T cell metabolism and directly controlling genes required for immune function. $CD8^+$ T cells lacking Srebp activity fail to undergo metabolic reprogramming and blastogenesis and do not mount a functional T cell response (78). In $CD4^+$ T cells, the Srebp1c isoform is involved in Th17 differentiation and directly binds to the IL17 promotor to inhibit AhR-induced IL17 expression (79). Moreover, the Srebp1a isoform is required for pro-inflammatory functions in myeloid cells, including IL1β production, as it promotes the expression of a key component of the inflammasome, Nlrp1 (80). Therefore, there is growing evidence that multiple important regulators of cellular metabolism have additional functions in directly controlling immune responses.

METABOLITES CONTROLLING IMMUNE CELL FUNCTION

Distinct metabolic configurations will result in different levels of metabolites that can directly impact upon cellular function. It has recently been shown that the glycolytic intermediate phosphoenolpyruvate is important in sustaining T cell receptor (TCR) signaling and T cell effector functions. Phosphoenolpyruvate inhibits Ca^{2+} re-uptake into the endoplasmic reticulum, thus sustaining nuclear factor of activated T-cells (NFAT) signaling (2). Mitochondrial reactive oxygen species generated as a side product of OxPhos are also important for optimal TCR signal transduction. T cells that cannot produce mitochondrial reactive oxygen species fail to activate nuclear NFAT, produce IL2, or engage in proliferative expansion (81). In M1 macrophages, the levels of Krebs cycle metabolites are substantially altered, leading to dramatically elevated levels of succinate, the stabilization of HIF1α, and prolonged production of IL1β (27, 34). Succinate can stabilize HIF1α by inhibiting the α-ketoglutarate-dependent prolyl-hydroxylases responsible for tagging HIF1α for proteasomal degradation (27, 82, 83). Indeed, succinate can inhibit other α-ketoglutarate-dependent enzymes that can impact upon immune cells due their roles in controlling cellular epigenetics, namely TET2 DNA hydroxylates and Jumonji C (JmjC) domain-containing histone demethylases (discussed further below) (84, 85). Succinate can act as a signaling molecule that acts through the receptor SUCNR1 and can also be used as a substrate for the post-translational modification of proteins (that is, succinylation) (86). Succinate acting through SUCNR1 impacts upon DC functions and also induces DC chemotaxis to enhance DC-induced T cell responses (87). Numerous metabolic enzymes are succinylated on lysine residues, but at present, it is not clear whether this modification impacts upon the regulation of immune responses (86). Citrate levels are also elevated in M1 macrophages, and this metabolite is important for the production of various proinflammatory molecules: nitric oxide, reactive oxygen species, and prostaglandins (27, 88).

Cellular metabolites are also important substrates for various enzymes involved in the epigenetic control of gene expression via covalent modification of DNA and histones. Given that the distinct metabolic configurations that characterize immune cells result in different levels of these cellular metabolites, it follows that the epigenetic control of gene expression will differ in parallel with differences in metabolism. For example, TET family enzymes, which oxidize methylcytosine, leading to DNA demethylation, and JmjC domain-containing histone demethylases both require α-ketoglutarate as a substrate and are both inhibited by succinate (Fig. 3). Indeed, TET2 has recently been shown to regulate the expression of IFNγ, IL17a, and IL10 in Th1 and Th17 cells (89). Jmjd3 has been shown to be of particular importance in controlling gene expression in LPS-stimulated macrophages (90). Acetylation of histones is another post-translational modification that impacts on DNA structure and gene expression. Acetylation of histones by histone acetyl transferases (HATs) requires acetyl-CoA, which is supplied via the export of mitochondrial citrate (Fig. 3). Indeed, there is evidence in yeast that the concentration of acetyl-CoA is important for histone acetylation (91). Histone acetylation levels are also controlled by the rate of deacetylation. The activity of sirtuin histone deacetylases is linked to cellular metabolism as these deacetylases are sensitive to the ratio of oxidized NAD^+ to reduced NADH, which is affected by the balance of glycolysis and OxPhos (92). Oxidized NAD^+ is an essential substrate for sirtuins, whereas reduced NADH acts to inhibit sirtuin activity (Fig. 3) (93). In fact, sirtuins can also deacetylate targets other than histones, which are important in immune regulation. For example, Sirt1 deacetylates FoxP3 to inhibit Treg responses and RORγt to promote Th17 responses (94,95, 96,97). Additionally, sirtuins can also have a negative impact upon inflammatory responses, in part through inhibition of NFκB activity (98, 99). Although there are numerous studies suggesting that cellular metabolism impacts upon epigenetic programming of immune cells to affect immune cell fate and function, the best evidence of this comes from a study of trained immunity in macrophages. Cheng *et al.* (92) elegantly demonstrated that mTORC1/HIF1α-stimulated glycolysis is required for changes in the epigenome of human or murine myeloid cells that provides enhanced nonspecific protection from secondary infections. Therefore, it is clear that metabolites can impact directly on immune cell function, and it is likely that further examples of this will be revealed as the field of immunometabolism progresses.

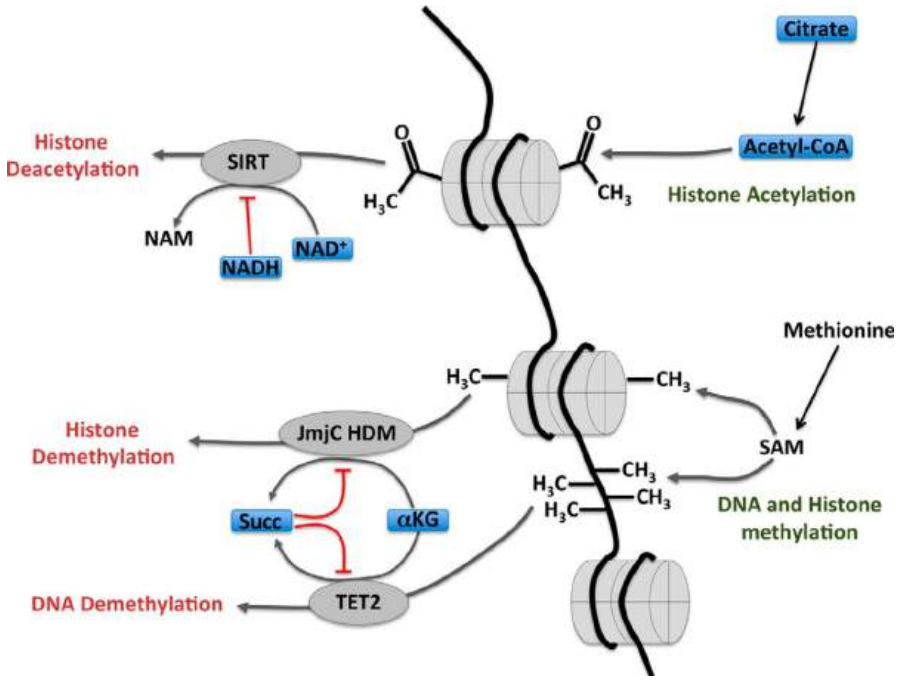

FIGURE 3.Links between cellular metabolism and epigenetic modifications. Histone deacetylation by sirtuin (SIRT) family members requires NAD^+ as a substrate, and the activity of these enzymes is inhibited by NADH. The balance of oxidized NAD^+ and reduced NADH is affected by levels of glycolysis and OxPhos. Methylation of DNA and histones is controlled by the rates of methylation and demethylation. The activities of JmjC domain-containing histone demethylases and the TET2 hydroxylase lead to histone and DNA demethylation, respectively, and can be regulated by Krebs cycle intermediates α-ketoglutarate (α-KG) and succinate (*Succ*). α-Ketoglutarate is a substrate for these enzymes, and succinate acts as an inhibitor. *NAM*, nicotinamide; *HDM*, histone demethylase; *SAM*, *S*-adenosylmethionine.

IMMUNE METABOLISM RELAYS EXTERNAL SIGNALS TO REGULATE IMMUNE CELL FUNCTION

The data now support an important role for cellular metabolism in controlling the function of immune cells. Given that metabolic regulators and pathways are acutely sensitive to external levels of nutrients, oxygen, and growth factors, cellular metabolism represents a means to relay information from the local microenvironment to modulate immune cell function accordingly. Nutrients such as glucose, glutamine, and fatty acids that directly supply metabolic pathways also regulate the activity of important regulators of immune metabolism and function including mTORC1, HIF1α, and Srebp. Other nutrients are important for providing the substrates for enzymes that impact upon immune cell function. For example, methionine, which is an essential amino acid and so must be imported into the cell, is used to generate *S*-adenosylmethionine for epigenetic methylation of DNA and histones. Although most studies have focused on how activating immune receptors affect cellular metabolism, it is now becoming apparent that ligation of inhibitory receptors also alters metabolic pathways. Recent research has demonstrated that ligation of the inhibitory receptors PD-1 and CTLA-4 expressed on human CD4 T cells has pronounced effects on cellular metabolism, inhibiting aerobic glycolysis, and in the case of PD-1, promoting fatty acid oxidation (100). These data suggest that the inhibitory actions of these receptors may be mediated, at least in part, due to changes in cellular metabolism.

FINAL COMMENTS

The emerging data now argue that metabolism has duel roles in immune cells to facilitate requirements for energy and biosynthesis and to directly regulate immune cell functions. There are likely to be numerous opportunities for novel therapeutic strategies that modulate this metabolic regulatory axis.

29.10: ETHANOL METABOLISM- THE GOOD, THE BAD, AND THE UGLY

David F.WilsonFranz M.Matschinsky. Medical Hypotheses, Volume 140, July 2020, 109638
https://doi.org/10.1016/j.mehy.2020.109638. Under a Creative Commons license

ABSTRACT

Throughout the world, ethanol is both an important commercial commodity and a source of major medical and social problems. Ethanol readily passes through biological membranes and distributes throughout the body. It is oxidized, first to acetaldehyde and then to acetate, and finally by the citric acid cycle in virtually all tissues. The oxidation of ethanol is irreversible and unregulated, making the rate dependent only on local concentration and enzyme activity. This unregulated input of reducing equivalents increases reduction of both cytoplasmic and intramitochondrial NAD and, through the latter, cellular energy state {[ATP]/([ADP][Pi])}. In brain, this increase in energy state stimulates dopaminergic neural activity signalling reward and a sense of well being, while suppressing glutamatergic neural activity signalling anxiety and unease. These positive responses to ethanol ingestion are important to social alcohol consumption. Importantly, decreased free [AMP] decreases AMP-dependent protein kinase (AMPK) activity, an important regulator of cellular energy metabolism. Oxidation of substrates used for energy metabolism in the absence of ethanol is down regulated to accommodate the input from ethanol. In liver, chronic ethanol metabolism results in fatty liver and general metabolic dysfunction. In brain, transport of other oxidizable metabolites through the blood-brain barrier and the enzymes for their oxidation are both down regulated. For exposures of short duration, ethanol induced regulatory changes are rapid and reversible, recovering completely when the concentrations of ethanol and acetate fall again. Longer periods of ethanol exposure and associated chronic suppression of AMPK activity activates regulatory mechanisms, including gene expression, that operate over longer time scales, both in onset and reversal. If chronic alcohol consumption is abruptly ended, metabolism is no longer able to respond rapidly enough to compensate. Glutamatergic neural activity adapts to chronic dysregulation of glutamate metabolism and suppression of glutamatergic neural activity by increasing excitatory and decreasing inhibitory amino acid receptors. A point is reached (ethanol dependence) where withdrawal of ethanol results in significant metabolic energy depletion in neurons and other brain cells as well as hyperexcitation of the glutamatergic system. The extent and regional specificity of energy depletion in the brain, combined with hyperactivity of the glutamatergic neuronal system, largely determines the severity of withdrawal symptoms.

OVERVIEW: ETHANOL AND HUMAN METABOLISM

In nature, ethanol is rarely found in foodstuffs at levels where consumption can raise blood concentrations to the levels reached by humans during social drinking. When it does occur, such as when fruit ferments either on the tree or after falling to the ground, exposure to that food source is brief. As a result, the amount of ethanol consumed is a tiny fraction of that consumed by even modest social drinkers. Ethanol is a “rogue” nutrient for which there was no evolutionary pressure for its regulation. Ethanol dependence became a problem only after humans developed methods for preservation of food, one of which was fermentation. In order to provide a framework for understanding the importance of ethanol metabolism and its effect on metabolic homeostasis in humans, Table 1 summarizes some aspects of ethanol consumption important to understanding its impact. Dettling et al. [25] measured the rate of elimination of ethanol by humans following ingestion of 0.9 g/kg body weight over a period of 2 h, an amount that resulted in maximal blood alcohol levels near 0.08 g/dl (legal limit for driving in US). After consumption stopped, ethanol disappearance, measured by decrease in blood levels, occurred at a constant rate (zero order) of about 0.016 g/dl/h for men and 0.018 g/dl/h for women. Translated into kilocalories (cal), for an 80 kg man this is 73 cal/h while for 60 kg women it is 55 cal/h. A 70 kg (155 lb) person expends about 102 cal/h working on a computer, 120 cal/h sitting in meetings, 130 cal/h during desk work or sitting in class, 186 cal/h doing police work, bartending or waitressing (Table 2). Maintenance diets for average adults are 2000 cal/day for females (83 cal/h) and 2600 cal/day (108 cal/h) for males. As such, ethanol becomes responsible for more than 50% of each individual’s energy metabolism until it is eliminated. Elimination requires about 5hr after consumption stops (7h total) and throughout that time, ethanol oxidation is the largest carbon source for energy metabolism. Further increase in alcohol consumption, either acutely or chronically, extends the time before blood alcohol levels return to near zero but not the rate at which it is removed. For ethanol dependent individuals, blood alcohol levels remain significant throughout each day. This means ethanol contributes about 1700 cal/day (80 kg male) and 1300 cal/day (60 kg female), and many metabolic and nutrient deficiencies may develop [66], [69], [62], [63], [64].

Table 1. Ethanol metabolism and the human diet (social drinking).

0.9 g/kg (male)	Blood max 0.084 g/dl	Elimination 0.016 g/dl/h	time 7 h#; 5 h*
0.84 g/kg (female)	Blood max 0.082 g/dl	Elimination 0.018 g/dl/h	Time 6.6 h#; 4.6hr*
80 kg/male (176 lb)	Total, 72 g (5drinks)	511 calories	73 calories/h
60 kg/female (132 lb)	Total, 50 g (3.6 drinks)	355 calories	54 calories/h

Measurements of the rate of elimination of ethanol from the body in human volunteers [25]. Ethanol ingestion followed a typical breakfast and consisted of consuming drinks of the subject’s choice. The number of drinks was calculated for 14 g of pure ethanol per drink. The amount consumed raised blood alcohol to near 0.08 mg/dl (17 mM, legal limit for driving in US) by the end of the 2 h period for

consumption. After consumption stopped, ethanol disappeared from the blood at a nearly linear (zero order) rate of about 0.016 g/dl/h for men and 0.018 g/dl/h for women. The times required for blood alcohol to fall to near zero, h# and h*, were measured from beginning and end of consumption, respectively.

Table 2. Metabolic energy utilization by a 70 kg (155 lb) person.

Sitting (computer work)	102 calories/h
Sitting in meetings	120 calories/h
Desk work or sitting in class	130 calories/h
Police work, bartending, waitressing	186 calories/h

As noted in Table 1, for a 70 kg person ethanol contributes about 63 calories/h while the total hourly caloric expenditure is shown in the table. Assuming a drinker is awake and at activities similar to sitting in class both while and after drinking, they would be expected to expend about 130 calories/h. In that case, ethanol would provide about 50% of whole body energy metabolism until the blood alcohol fell below about 0.006 g/dl (below the K_M for ADH1 of 1.4 mM).

Oxidation of ethanol occurs through three enzymes, alcohol dehydrogenase (ADH), catalase, and P450 (CYP2E1), and they all produce acetaldehyde. In the present paper, focus is on the first two because they are responsible for oxidation of most of the consumed ethanol. Ethanol readily passes through most biological membranes, and the concentration in all water spaces, including the brain, approximates that in blood plasma. Thus, tissues and cells throughout the body are nearly equally exposed to ethanol and its rate of metabolism is determined by local enzyme content. The reactions of the three ethanol oxidizing systems and the K_M of each for ethanol are:

1. Alcohol dehydrogenase; ADH1, K_M = 1.4 mM [12]:

(1)Ethanol + NAD^+ → Acetaldehyde + NADH + H^+

2. Catalase; K_M = 12 mM [103]:

(2)Ethanol + H_2O_2 → Acetaldehyde + 2 H_2O

3. Cytochrome P450 2E1 (CYP2E1); K_M = 8–10 mM (12):

(3)Ethanol + O_2 + NADPH → $NADP^+$ + acetaldehyde + acetate

The equilibrium constant for the ADH reaction at pH 7.0 is approximately 10^{-4} [1], [6], [83]. In the cytoplasm, where the reaction occurs, the [NAD^+]/[NADH] is greater than 100 and acetaldehyde concentrations remain less than 20 μM [83]. The [NAD^+)/(NADH) is high enough that the ratio of the forward to reverse reactions of ADH is about 10 and the net reaction is strongly toward acetaldehyde (and NADH) formation. The reactions of catalase and CYP2E1 are irreversible under all physiological conditions. Acetaldehyde is chemically reactive and can react nonenzymatically with other cellular components to form products that are metabolically active and/or cytotoxic. The concentration of acetaldehyde is kept low through rapid removal by aldehyde dehydrogenase (ALDH) which is widely distributed in tissues [12], [127], [128]. ALDH oxidizes acetaldehyde to acetate, passing the reducing equivalents to NAD^+:(4)Acetaldehyde + NAD^+ → Acetate + NADH + H^+

ALDH2 is localized in the mitochondrial matrix, has a high affinity for acetaldehyde (K_M = 1.3 μM in brain cortex [40], and high specific activity. The equilibrium constant for this reaction at pH 7.0 is approximately 4×10^9, and it is irreversible under physiological conditions [1]. As a result of ALDH activity, systemic levels of acetaldehyde are kept low [40]. Acetaldehyde is a chemically reactive compound with significant toxicity and, for individuals who express an inactive form of ALDH2, ethanol consumption can have side effects ranging from unpleasant sensations to serious illness [12], [60]. Neither ethanol oxidation (ADH, catalase, CYP2E1) nor acetaldehyde oxidation (ALDH) is subject to significant regulation and increasing alcohol concentration reduces both cytoplasmic (by ADH) and mitochondrial (by ALDH2) NAD pools. Because ethanol oxidation is not regulated, local (individual cell) rates of oxidation are cell specific, determined by the activity and degree of saturation of the responsible enzyme(s) in each cell.

Acetate, the major product of ethanol oxidation, has roles both in energy metabolism and in regulation of metabolism. Acetate is converted to acetylCoA by acetylCoA synthetase:(5)acetate + CoASH + ATP → acetylCoA + AMP + pyrophosphate

In mitochondria, acetylCoA primarily enters the citric acid cycle and is oxidized, but at the cellular level is also used to acetylate proteins, altering the activity of individual enzymes and, through histone acetylation, gene expression [74]. The regulatory role of protein acetylation, although important, is outside the scope of this paper and will not be further discussed.

In summary: Ethanol readily distributes throughout the body and can be a major fraction of caloric utilization. Oxidation of ethanol and its products, acetaldehyde and acetate, is irreversible and unregulated. This “pushes” energy metabolism and can increase reduction of both cytoplasmic and mitochondrial NAD, thereby increasing cellular energy state. The rate of ethanol oxidation, and its associated metabolic disturbance, is dependent on ethanol concentration and local (cellular) enzyme content.

ETHANOL OXIDATION IN LIVER AND ITS METABOLIC CONSEQUENCES

Most of consumed alcohol is oxidized in liver by ADH1 to acetate [52], [67]. In the process, there are profound alterations in hepatic metabolism (Fig. 1, including: excessive reduction of cytoplasmic and mitochondrial NAD pools, inhibition of gluconeogenesis and fatty acid oxidation, increased [ATP]/([ADP]$_f$[Pi]), and decrease in [AMP]$_f$. The subscript f is used to emphasis that the concentrations of ADP and AMP relevant to metabolic regulation are free concentrations, not total amounts in the cell. Lundquist and coworkers [67] reported that, in healthy humans infused iv with ethanol at rates sufficient to result in blood concentrations near 26 mM (0.12 g/dL) oxidation of ethanol to acetate accounted for most of hepatic oxygen consumption. Although some of the acetate produced in liver was further oxidized through the citric acid cycle, most (>75%) was released into the blood. The rate of NADH production from ethanol oxidation to acetate is high enough that flux through the citric acid cycle (CAC), and therefore CO_2 production by the liver, is substantially decreased [52]. The lactate/pyruvate ratio is increased, indicating reduction of cytosolic NAD, as is the β-hydroxybutyrate/acetoacetate ratio, indicating increased reduction of intramitochondrial NAD [29], [52], [67]. Increase in intramitochondrial NAD reduction with little or no change in oxygen concentration or the rate of oxygen consumption [97] is consistent with increase in cellular energy state {[ATP]/([ADP]$_f$[Pi])} [115], [118]. In liver, increase in energy state suppresses the activity of pyruvate dehydrogenase (increased acetylCoA, [NADH]/[NAD$^+$], and [ATP]/[ADP]$_f$), activates pyruvate carboxylase (high acetylCoA), decreases [AMP]$_f$, lowering AMP-dependent protein kinase (AMPK) activity [61], [98], [105], [124]. Decreased AMPK activity increases acetylCoA carboxylase activity [19], [30], [38], [39], [42], [124] and the concentration of malonylCoA [19]. MalonylCoA inhibits carnitine palmitoyl transferase 1 [30], [73] suppressing uptake and oxidation of long chain fatty acids by mitochondria. Fatty acid synthesis is activated and this, combined with excess fatty acids taken up by the liver, results in excess fatty acids being made into triglycerides. Interestingly, Galli and coworkers [32] reported that expression of ADH1 in HeLa cells was sufficient to result in ethanol induced fat accumulation, consistent with ethanol oxidation induced inhibition of AMPK being responsible for cellular lipid accumulation.

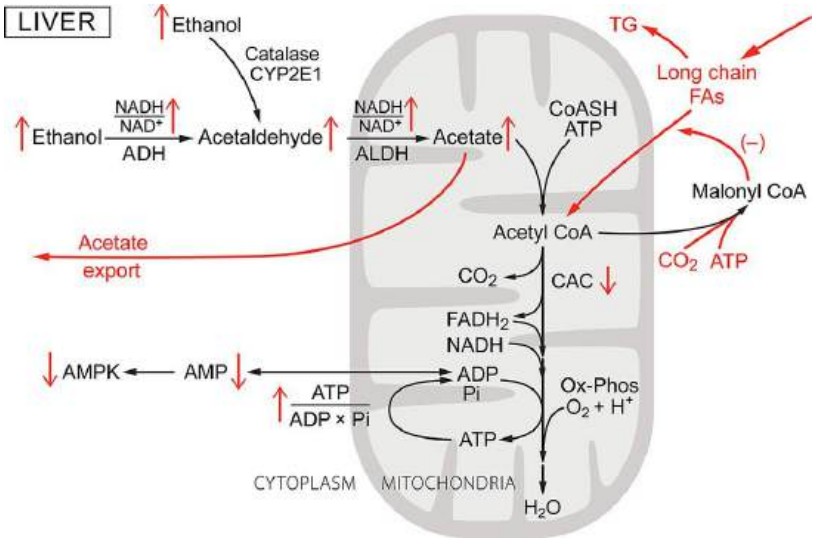

Fig. 1. **Ethanol metabolism in the liver: a general schematic of its metabolism and effect on liver metabolism**. As the ethanol concentration in blood increases it enters all tissues and is oxidized, mostly through alcohol dehydrogenase 1 (ADH1) in the liver. Whether a particular metabolic parameter is increased or decreased is indicated by an up or down arrow. The metabolic steps characteristic to liver are shown in red. ADH is cytoplasmic and as ethanol concentration increases ethanol oxidation increases cytoplasmic NADH/NAD$^+$ (lactate/pyruvate) ratio. Acetaldehyde, the product of ethanol oxidation, enters the mitochondria and is oxidized to acetate by mitochondrial acetaldehyde dehydrogenase (ALDH2), increasing intramitochondrial NADH/NAD$^+$ (β-hydroxybutyrate/acetoacetate) ratio. The acetate formed is mostly exported into the blood. Both the ADH and ALDH reactions are irreversible and the rate of ethanol oxidation by ADH1 is determined by enzyme content and degree of saturation (K_M = 1.4 mM). At blood alcohol greater than about 0.01 g/dl (2.2 mM), the rates are high enough that hepatic citric acid (CAC) activity, as measured by CO_2 production, is markedly suppressed. Oxygen consumption (Ox-Phos) is slightly decreased due to the higher ATP/O ratio when oxidizing NADH than for long chain fatty acids. The energy state is increased, decreasing the concentration of free AMP ([AMP]$_f$) and thereby the activity of AMP-dependent protein kinase (AMPK). MalonyCoA is increased and this inhibits acylcarnitine transferase 1, inhibiting long chain fatty acid transport into the mitochondria and subsequent oxidation. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Acetate, the primary product of ethanol oxidation by the liver, is a short (shortest) chain fatty acid and oxidation of short chain fatty acids is not subject to the regulation imposed on oxidation of long chain fatty acids. Acetate produced by the liver results in a large increase in acetate concentration in the blood, to about 1 mM [44], [78]. The rate at which acetate is taken up, and oxidized, by other tissues is

dependent on concentration in the blood. In both humans and rats, if blood acetate concentrations are maintained near 1 mM or higher, this results in under consumption of long chain fatty acids and activation of fatty acid synthesis [19], [30], [62], [64], [95], [122]. Since ethanol and acetate are only two carbons long, their products cannot be used for net synthesis of glucose or for anaplerotic support of the citric acid cycle or net glucose synthesis. The lactate/pyruvate ratio is increased, in large part due to decrease in pyruvate [52], and this limits the activity of pyruvate carboxylase, suppressing gluconeogenesis [29], [52], [53]. Blood glucose concentrations decrease [53], but only slightly because the set point for glucose homeostasis in only slightly decreased [72] and glucose consumption by peripheral tissue and brain is decreased.

AMP-DEPENDENT PROTEIN KINASE AND THE METABOLIC RESPONSES TO ETHANOL OXIDATION.

Essentially all cells have adenylate kinase and the activity is sufficient to maintain the reaction:(1)ATP + AMP = 2 ADPnear equilibrium. The equilibrium constant is approximately 1.0, and [ATP] is maintained nearly constant, so $[AMP]_f$ decreases as the square of the decrease in free $[ADP]_f$. This makes $[AMP]_f$ a very sensitive measure of the energy state [51], [115], [118]. As a result, energy metabolism has evolved with $[AMP]_f$ as a core regulatory parameter in setting metabolic homeostasis. It is notable that metabolic homeostasis in eukaryotes has an $[AMP]_f$ “set point” and cellular metabolism operates over a narrow range of $[AMP]_f$ [115], [118]. Central to maintaining metabolic homeostasis is AMP-dependent protein kinase (AMPK) [30], [38], [39], [42], [49], [118]. Although $[AMP]_f$ also contributes to the regulation of many other enzymes and regulatory pathways, the importance of AMPK is shown schematically in Fig. 2A. This includes modulation not only of complex cellular functions, such as protein synthesis, autophagy, mitophagy, and gene expression, but also of individual enzymes and regulatory proteins (Fig. 2B). Most discussions of metabolic regulation involving AMPK focus on the conditions where $[AMP]_f$ increases, as occurs in exercise, hypoxia, or inhibition of oxidative phosphorylation, and AMPK activity increases. Activation of AMPK is designed to increase ATP production by increasing catabolic ATP production and inhibiting anabolic ATP consumption. Ethanol ingestion, however, decreases $[AMP]_f$ and thereby AMPK activity, suppressing catabolic metabolism and enhancing anabolic metabolism. Indeed, treatment with 5-aminoimidazole-4-carboxamide-1-β-D-ribofuranoside (AICAR), which activates AMPK, has been reported to provide significant protection from alcohol induced fatty liver in rats [105]. Because oxidation of ethanol and acetate is cell specific and largely unregulated, the metabolic consequences differ among cell types and overall metabolic integration disrupted.

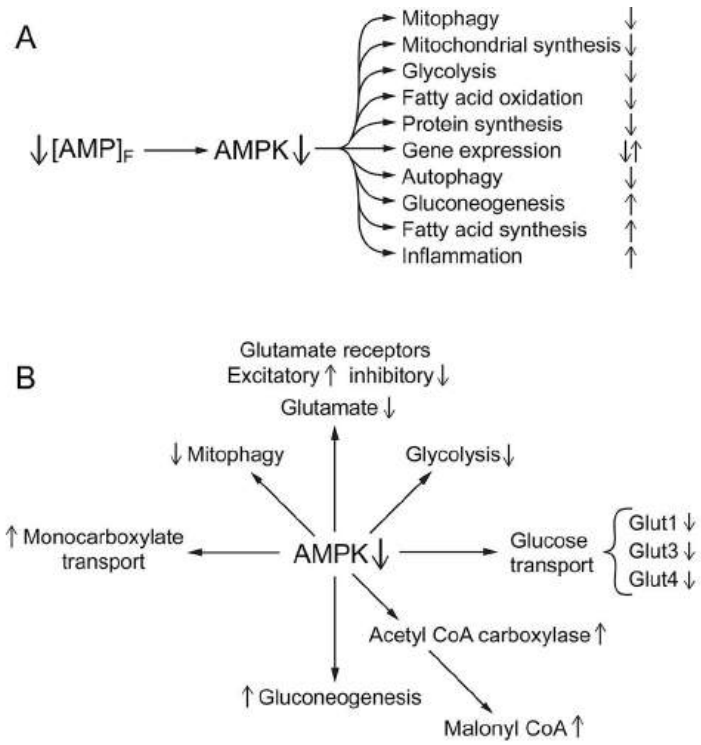

Fig. 2. **A, B. The central role of AMPK in the metabolic responses to ethanol consumption**. Ethanol oxidation, by increasing intramitochondrial [NADH]/[NAD^+] and cellular energy state, decreases the concentration of free AMP ($[AMP]_f$). This suppresses phosphorylation of AMPK and thereby its activity. AMPK has a central role in maintaining metabolic homeostasis (for reviews see [38], [39], [49]). Fig. 2A indicates some of the wide range of metabolism related processes that respond to alterations in AMPK activity. Some of these are expected to increase and others decrease in response to the ethanol induced decrease in AMPK activity with the direction indicated by up or down arrows on the right. Fig. 2B indicates a few effects of decreased [AMPK] on specific enzymes/processes that are noted in the text. When ethanol is consumed, its high caloric content and lack of regulation results in wide spread disruption of metabolism. Central to this disruption is suppression of "normal" $[AMP]_f$ and AMPK activity.

ETHANOL/ACETATE METABOLISM AND ITS EFFECTS ON MUSCLE

Although liver and brain are the primary tissues of concern in when considering the consequences of ethanol consumption, other tissues are also affected. This includes cardiac and skeletal muscle. Although neither has significant ADH activity, they have high acetylCoA synthetase and acetylCoA carboxylase and rely heavily on fatty acid oxidation for energy metabolism. This is particularly true when only moderately active (heart) or during rest and after endurance exercise (skeletal muscle) (Fig. 3). Chen et al. [16] reported that chronic ethanol feeding in rats suppresses expression of AMPK, myocyte enhancer factor 2, and glucose transporter 4 (Glut4) in myocardium. The effects of ethanol on muscle metabolism would be expected to be indirect, arising from elevated blood acetate. This is consistent with the report by Kiviluoma [48] that addition of acetate to the perfusate of isolated rat hearts increases incorporation of fatty acids into myocardial lipids. In addition, adding acetate at mM concentrations to the perfusate of isolated rat hearts increases reduction of intramitochondrial NAD and energy state relative to glucose perfusion [48], [99]. Similar observations have been reported for rat skeletal muscle *in vivo* by Bertocci et al. [11]. When lactate and acetate consumption were measured in resting skeletal muscle, acetate provided most of the acetylCoA (65%) oxidized by the citric acid cycle (CAC). In contracting muscle, the fraction provided by acetate decreased, but only to 43%. Thus, in heart under moderate work load and in resting skeletal muscle, acetate taken up from the blood can be oxidized at rates sufficient to maintain energy metabolism. Acetate displaces (down regulates) oxidation of the physiologically preferred substrate, long chain fatty acids. Putman et al. [82] measured metabolites and pyruvate dehydrogenase activity in muscle during acetate infusion in humans. The reported changes included increase in acetylCoA/CoASH and acetyl-carnitine, as well as decrease in active pyruvate dehydrogenase (PDHa). Uncontrolled production of acetylCoA from acetate in mitochondria and the resultant increase in acetylCoA/CoA, if sustained, would deplete intramitochondrial CoASH. CoASH is required for citric acid cycle. Synthesis of acetyl-carnitine by carnitine acetyl transferase allows export of excess active acetyl groups to the cytoplasm but at the expense of intramitochondrial carnitine. This process appears to be self limiting due to depletion of intramitochondrial CoASH for acetylCoA synthase combined with decreased oxalacetate for citrate synthase limits input of acetylCoA to the rate of oxidation through the citric acid cycle. Evidence supports the view that, following ethanol ingestion, elevated blood acetate becomes a major energy source for resting and moderately active muscle, consistent with associated suppression of

AMPK activity [16], [48], [99]. Interestingly, tissues from alcohol dependent humans show dysfunctions in protein synthesis, mitochondrial content, and morphology, consistent with chronic suppression of AMPK activity (Fig. 2A).

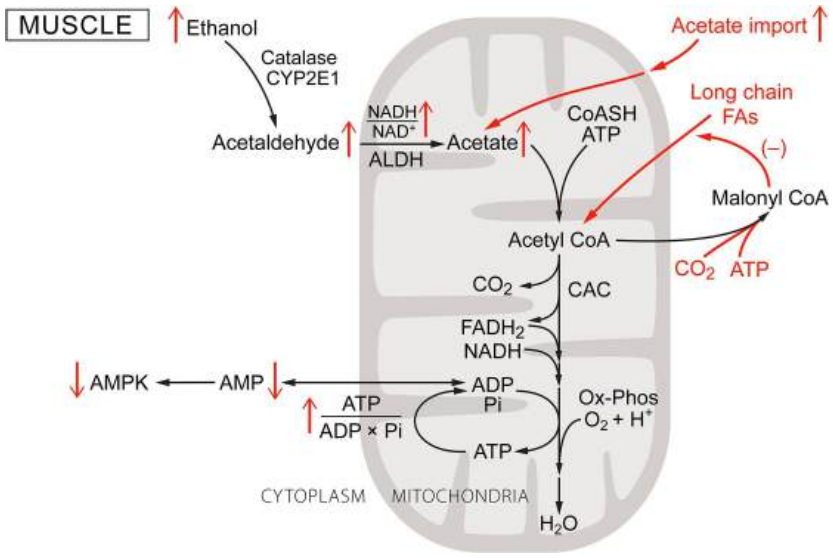

Fig. 3. **Ethanol metabolism in muscle: A schematic of metabolism in muscle, which does not have alcohol dehydrogenase**. Muscle, due to the lack of ethanol dehydrogenase, may oxidize some ethanol through catalase and/or CYP2E1, but these rates are low. Acetate is, however, taken up from the blood, activated by acetylCoA synthetase, and oxidized through the CAC and oxidative phosphorylation. This uncontrolled input of acetylCoA increases the acetylCoA/CoASH ratio and energy state, decreasing $[AMP]_f$ and thereby AMPK activity. Decreased AMPK activity suppresses long chain fatty acid oxidation.

ETHANOL METABOLISM IN BRAIN AND ITS METABOLIC CONSEQUENCES: A. GENERAL CONSIDERATIONS

Brain is a complex organ with several types of specialized cells, each with its own metabolic requirements and supporting complement of enzymes and metabolite transporters. Ethanol produces major metabolic disturbances in brain metabolism (shown schematically in Fig. 4) including: decreased glucose uptake and metabolism, increased monocarboxylate uptake and metabolism, stimulation of dopaminergic neural activity, suppression of glutamatergic neural activity, and disruption of glutamate metabolism. Catalase, ADH, and P450 systems for oxidizing ethanol are all present in brain, and brain actively takes up acetate from the blood. Determining the role of ADH, however, is complicated by the presence of multiple different forms of alcohol dehydrogenase as well as heterogeneous distributions among cells and tissues [5], [12], [13], [47]. Initial reports by Raskin and Sokoloff [84] of low, but significant, rates of oxidation of ethanol by ADH in subfractions of brain tissue were largely discounted because of the low activity and concerns about the method of analysis [126], [127]. The enzyme properties reported, however, were consistent with the presence of small amounts of ADH1. Initial immunohistochemical data focused on ADH3, an alcohol dehydrogenase that is widely distributed in brain but has negligible activity for ethanol [27], [126], leading some to conclude that metabolism of ethanol by ADH in brain was not significant. Later measurements using antibodies grown to purified liver ADH indicated that while the total amount of enzyme are low, it is concentrated in individual neurons of cerebral cortex, hypothalamus, infundibular stalk of pituitary, and Purkinje cells of cerebellum. This distribution correlates with known sites of ethanol toxicity (13. 47). More recently, selective antibodies for ADH1 (K_M = 1.4 mM) and ADH4 (K_M = 37 mM) have been used [27]. Again the total amounts were low but concentrated in a small fraction of the brain cells. Martinez et al [70] examined tissue sections from several regions of adult rat brain by *in situ* hybridization to detect expression of genes encoding ADH1. ADH1 mRNA was found in granular and Purkinje cell layers of cerebellum, in pyramidal and granule cells of hippocampal formation, and in some types of cells in cerebral cortex. ADH4 expression was detected in Purkinje cells, pyramidal and granule cells of the hippocampal formation, and pyramidal cells of cerebral cortex. Substantial levels of both ADH1 and ADH4 mRNAs were detected cells of the CNS epithelial and vascular tissues: leptomeninges, choroidplexus, ependymocytes of ventricle walls, and endothelium. Thus, current evidence is consistent with oxidation of ethanol by ADH capable of significantly affecting brain function in subpopulations of cells in which ADH1 and/or ADH4 are expressed.

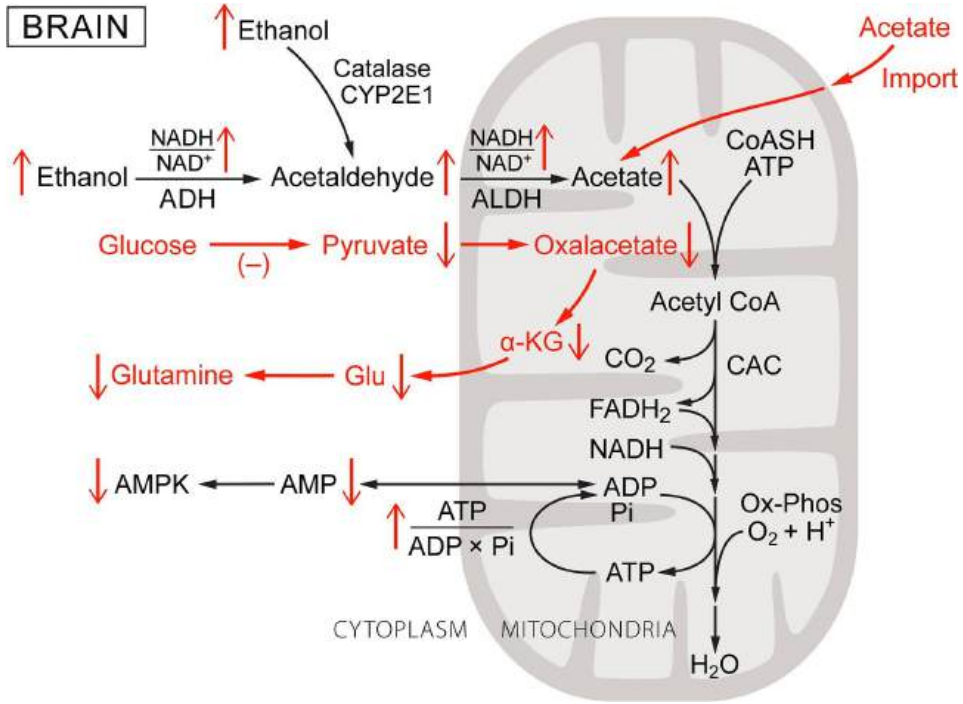

Fig. 4. **Ethanol metabolism in the brain: a schematic of its metabolism and the changes induced with respect to normal brain metabolism.** As was the case for Fig. 1, Fig. 2, Fig. 3, increase or decrease in each metabolic parameter is indicated by an up or down arrow. Metabolic steps characteristic brain cells and important to the effects of ethanol are shown in red. Heterogeneity in cell types and cell metabolism in brain precludes a general characterization but cells can be roughly separated into those with ADH1, ADH4 and those without this activity. Those without ADH1 and/or ADH4 oxidize ethanol by catalase or cytochrome P450 (CYP2E1) to acetaldehyde without reducing NAD. The amounts of ADH1 and ADH4 in brain are small but concentrated in a small fraction of the total number of cells. In cells with ADH1 and/or ADH4, ethanol oxidation increases the cytoplasmic NADH/NAD^+. All brain cells have mitochondrial aldehyde dehydrogenase and produce acetaldehyde, if not by ADH, by catalase and CYP2E1. Oxidation of acetaldehyde and/or acetate taken up from blood augments that produced within the cell, increasing intramitochondrial NADH/NAD^+. Brain cells, notably astrocytes, normally consume glucose and produce pyruvate for anaplerosis through pyruvate carboxylase. Ethanol and acetate catabolism, however, down regulates glucose consumption by decreasing both glucose transport and glycolysis. Decreased pyruvate production from glucose, combined with increased lactate/pyruvate, limits the rate of pyruvate carboxylation and thereby *de novo* synthesis of glutamate. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

ETHANOL AND ACETATE METABOLISM IN BRAIN: B. RATES AND CONTRIBUTIONS TO TOTAL ENERGY PRODUCTION

Ethanol, acetaldehyde, and acetate have been shown to be oxidized in brain and the combined rates are high enough to disrupt glucose and amino acid metabolism. Wang and coworkers [111] studied the rate of ethanol oxidation in rat brain cortex *in vivo by* ^{13}C MRI. Using a combination of 2-^{13}C labeled ethanol and 1,2-^{13}C labeled acetate, they reported significant rates of incorporation of carbon from ethanol into glutamate and glutamine. The authors calculated ethanol oxidation accounted for 12% and 20% cortical oxidative metabolism in ethanol naïve and ethanol pre-treated rats. The measurements were specifically of ethanol oxidation and did not include oxidation of acetate taken up from the blood. Measurements of acetate metabolism in rat brain *in vivo* using ^{13}C MRI [21], [81], [107] show it is readily transported through the blood-brain barrier and metabolized. As acetate concentration in blood was raised to 2–3 mM, the rate of metabolism by the brain saturated. At saturation, enrichment of glutamine and glutamate at the C4 position were consistent with most of the

acetylCoA entering the citric acid cycle in astrocytes arising from acetate with the remaining coming from unlabeled glucose. The models used in the interpretation assumed, however, that acetate metabolism occurred almost entirely in astrocytes with negligible contribution by neurons. This may not be appropriate [87] particularly as the neurons contain substantial levels of acetylCoA synthase. As noted earlier, when ethanol is ingested, acetate is produced in the liver and released into the blood. Blood acetate levels rise rapidly to about 1 mM or more [44], [78], and ethanol oxidation in brain is augmented by oxidation of acetate taken up from the blood. When these are combined, ethanol becomes a major source of acetylCoA for production of ATP used for ATP production in many brain cells. Recent reports include evidence that in mice ethanol consumption leads to rapid increase in histone acetylation in the brain with the acetyl moiety arising from ethanol [74]. This acetylation is reported to alter gene expression in hippocampus and to affect cellular mechanisms related to learning. The level of acetylCoA and the acetylCoA/CoASH ratio are important regulators of protein acetylation and are coupled to cellular energy state and AMPK activity.

ETHANOL EXPOSURE PHASE 1: ACUTE EFFECTS OF ETHANOL INGESTION ON METABOLISM

As noted above, alcohol ingestion results in rapid changes in the metabolism of brain and other tissues. Following ingestion, oxidation of ethanol takes precedence over other metabolites used for energy metabolism and the latter are down regulated to accommodate the input from ethanol. The effects are cell and tissue specific and depend on how rapidly ethanol is oxidized and/or acetate is taken up through the monocarboxylate transporter. Liver, due to its large size, immediate exposure to the ingested alcohol from the portal circulation, and high content of ADH1 dominates systemic ethanol disposal. Effects of acute ethanol ingestion on liver include rapid increase in metabolic energy state, production and export of acetate, suppression of long chain fatty acid oxidation and synthesis, increased β-hydroxybutyrate/acetoacetate ratios, and under production of glucose by gluconeogenesis. The response of other tissues to ethanol exposure is heterogeneous. In pancreas, increased energy state due to ethanol/acetate metabolism slightly lowers the glucose homeostasis set point [116], [117], [119]. In most other tissues, input of acetylCoA from ethanol and acetate largely replaces acetylCoA from long chain fatty acids and amino acids for energy metabolism [31], [107], [110]. The oxidation of ethanol and/or acetate induces an increase in energy state and associated decrease in $[AMP]_f$ and AMPK activity [19], [30], [31], [38], [39]. Increase in blood acetate in rats to 300 μM, for example, decreased AMPK phosphorylation in hypothalmus by about 50% [31]. Decreased AMPK activity suppresses GLUT1, GLUT3, and GLUT4, the dominant glucose transporters in brain [31], [37], [75], [119]. Handa et al. [37] isolated plasma membranes and low density microsomal fractions from rat brain 4 h after their treatment with ethanol (3 g/kg body weight) and reported immunoblot measured protein decreased by 17% and 71% for GLUT1 and 54% and 21% for GLUT3, respectively. In addition, immunofluorescence imaging showed decreased GLUT1 in choroid plexus and cortical microvessels. This is consistent with reports by Muneer and coworkers [75] that chronic ethanol treatment suppresses glucose transport and GLUT1 protein expression in microvessels of the blood-brain barrier of rats and by Frost et al. [31] that it decreased GLUT1 in the plasma membrane of brain cells in primary culture. Accompanying ethanol induced decrease in glucose transporters is increase in monocarboxylate transporter [65]. Pyruvate is needed not only for anaplerotic maintenance of citric acid cycle activity but also for *de novo* synthesis of glutamate in astrocytes through the activity of pyruvate carboxylase [125]. Increased uptake of lactate from the blood [65] would normally provide increased pyruvate through oxidation by cytoplasmic NAD^+. For cells with ADH1 and/or ADH4, however, oxidation of ethanol in the cytoplasm results in increased reduction of the cytoplasmic NAD pool and an increase in the lactate/pyruvate ratio [52]. In these and other cells, acetaldehyde and acetate oxidation in the mitochondria also increases reduction of intramitochondrial NAD, suppressing aspartate-glutamate shuttle activity. Although intracellular lactate concentrations in brain increase during ethanol oxidation, this is due to elevated systemic lactate/pyruvate and pyruvate concentrations actually decrease. Intracellular pyruvate concentrations are normally less than the K_M of pyruvate carboxylase, which is near 400 μM [92], making the rate of pyruvate carboxylation strongly dependent on intracellular pyruvate concentration [52]. Ethanol induced decrease in intracellular pyruvate suppresses *de novo* synthesis of oxalacetate, and thereby of glutamate, in astrocytes and this disrupts glutamate homeostasis in astrocytes and glutamatergic neurons.

ETHANOL EXPOSURE PHASE 2: METABOLIC CONSEQUENCES OF ALCOHOL INGESTION IN GREATER AMOUNTS AND OVER INTERMEDIATE PERIODS OF TIME (DAYS, WEEKS)

Ethanol dependence arises after significant periods of nearly continuous alcohol consumption, typically months to years. This is not an all or nothing phenomenon, however, and there is a transition period during which withdrawal of alcohol results in a progressively greater sense of unease, anxiety, and irritability that can be overcome by consuming alcohol. The shortest time of exposure that generates significant ethanol dependence may be binge drinking, in which substantial amounts of ethanol are consumed over periods of one or more days. A few hours after drinking stops, ethanol levels approach zero and there is a period that often includes severe headaches and other unpleasant after effects, referred to as a hangover. The colloquial antidote for a hangover is “hair of the dog that bit you”, i.e. drinking some of the same alcoholic beverage consumed during the binge in order to alleviate the hangover. This antidote acutely relieves many of the symptoms, consistent with hangovers arising in part through deficiency in oxidizable substrates for energy metabolism in brain. The extended time and extent of alcohol exposure during a binge allows participation of slower regulatory processes, including altered rates of protein turnover and gene expression. When the levels of alcohol and acetate fall too quickly for regulation to fully compensate by switching back to the usual (non-ethanol) energy sources, the deficiency can be overcome by providing some alcohol. This temporarily relieves the deficiency in energy

metabolism, and thereby the hangover, as well as providing additional time for metabolic regulation to compensate for lack of ethanol/acetate.

ETHANOL EXPOSURE PHASE 3: ETHANOL DEPENDENCE RESULTING FROM HEAVY ALCOHOL CONSUMPTION OVER PERIODS OF MONTHS AND YEARS

Individuals with alcohol dependence consume a substantial fraction of their daily caloric intake as ethanol, typically near 50% of the total calories [5], [25]. This large intake, spread throughout the day and sustained for weeks to months, results significant (mM) levels of ethanol being in the blood most of the time. Diets of individuals with ethanol dependence are often deficient in essential nutrients, including vitamins, minerals, unsaturated fatty acids, and amino acids. In addition, ethanol is only 2 carbons long and can not be used for *de novo* synthesis of glucose, glutamate and other metabolites critical to long term metabolic homeostasis. In brain, chronic suppression of the oxidation of glucose and other (non-ethanol related) metabolites results in depletion of their associated transporters and enzymes. Conversely, the capacity for metabolism of ethanol and acetate increases [43], [65], [107]. If ethanol consumption ends abruptly, ethanol and acetate levels in the body fall to near zero within a few hours. The oxidizable metabolites used to support energy metabolism in non-ethanol dependent animals have been chronically down regulated and can no longer increase sufficiently to maintain the cellular energy state.

As noted above, for individuals who are ethanol dependent, ethanol normally provides 50% or more of the daily caloric intake. Glucose consumption in brain is substantially decreased by ethanol consumption [107], [108], [110], [112]. Oxidation of one mole of glucose provides slightly more ATP (38 ATP/mole) than does oxidation of two moles of ethanol. Oxidation of alcohol to acetaldehyde by ADH and of acetaldehyde to acetate by ALDH each contributes one NADH for oxidative phosphorylation (6 ATP/ethanol) and oxidation of acetate through the citric acid cycle provides an additional 3 NADH and 1 $FADH_2$ (total of 17 ATP/ethanol, 11 ATP/acetate). Even after correction for the ATP required for acetate activation (acetylCoA synthetase), oxidation of 2 mol of ethanol provides 30 mol of ATP, about 80% of that supplied by oxidation of 1 mol of glucose. Volkow et al. [108] measured brain glucose metabolism in twenty healthy control subjects using positron emission tomography (PET) and fluorodeoxyglucose after administration of placebo or either 0.25 g/kg, or 0.5 g/kg of ethanol over a 40 min period. Both doses of ethanol significantly decreased whole-brain glucose metabolism (10% and 23% respectively). Similar decreases have been reported by other authors, i.e. 26% for 0.75 g/kg [112], 25% for approximately 0.6 g/kg iv [91]. Volkow et al. [107] reported that the response to ethanol is regionally specific; whereas 0.25 g/kg predominantly reduced glucose metabolism in cortical regions, 0.5 g/kg reduced metabolism in cortical as well as subcortical regions (i.e. cerebellum, mesencephalon, basal ganglia and thalamus). As noted earlier, suppression of brain glucose consumption is in response to combination of oxidation of ethanol within the brain and of acetate taken up from the blood [107], [108], [110], [111]. Indeed, in heavy drinkers studied during sobriety, acetate metabolism in the occipital cortex is reported to be increased [43].

Persistent reliance on acetate for energy metabolism of alcoholics during early alcohol detoxification may explain why the decreased brain glucose consumption observed in alcoholics mostly disappears within the first 2 weeks of detoxification [109]. It can be inferred that for cells in brain for which ethanol (and/or acetate) oxidation is responsible for substantial fraction of their ATP production, sudden withdrawal of this important support of energy metabolism results in cellular malfunction and thereby abnormal brain activity. In ethanol dependent mice, withdrawal symptoms correlate with decrease in blood alcohol and acetate, symptoms maximizing as the concentrations approach zero [85]. Derr and coworkers [22], [23], [24] reported that, for ethanol dependent rats, providing acetate during withdrawal significantly alleviated, and providing a mixture of butyrate, lactate, and β-hydroxybutyrate fully suppressed [22],the tremulous portion of their withdrawal symptoms. It did not affect the handling induced convulsions. This is consistent with the tremulous, but not the convulsive, part of the withdrawal symptoms arising from a deficiency in energy metabolism needed to support neuronal activity in the brain.

NEUROLOGICAL RESPONSES TO ETHANOL CONSUMPTION: A PROLOG

Our paper focuses on metabolism of ethanol and the impact of ethanol consumption on metabolism as a whole. This is an integral and important part of understanding how alcohol influences human biochemistry, physiology, and social behavior. In brain, we focus on effects of ethanol on metabolism of neurons and astrocytes, where changes in energy state directly influences not only all aspects of neurotransmitter function (release, receptor sensitivity, transport, and metabolism) but also induces long term alterations in the underlying cellular machinery (through gene expression, etc). It is recognized, however, that connections between cellular metabolism and neuronal function, and from neural function to behavior, are very complex. Others have made great effort to understand how ethanol alters neuronal function; receptor affinities, ion channel conductance, synaptic connections etc, but many of the particulars remain poorly understood. There is general agreement that ethanol induces substantial changes in neural function but the relative contribution of metabolism and concentration remains under discussion. Due to the complexity of the neurological consequences of ethanol consumption we will address only those we consider to be primarily responses to ethanol and acetate metabolism. There is, for example, an extensive literature on the role of ethanol metabolism and of AMPK activity in modulation of neuronal function (see as examples, [3], [93], [94], [123]). We emphasize the role of energy metabolism and $[AMP]_f$ in order to illustrate not just their importance in the response to ethanol but also their central role in coordinating metabolic processes essential to biological existence as we know it.

NEUROLOGICAL RESPONSES TO ETHANOL CONSUMPTION A: EARLY ALTERATIONS IN THE DOPAMINERGIC SYSTEM AND POTENTIATION OF CONSUMPTION

Ethanol induces dopamine release and increased activity in the striatum as indicated by functional imaging [91]. Dopaminergic neurons that respond to nutrients, such as glucose, involve metabolism of that nutrient. Increase in nutrient concentration causes an increase in energy state and modulates ion channel (such as the K_{ATP} channel) conductance to initiate the dopaminergic signaling cascade. Ethanol, in contrast to other nutrients, has access to neurons behind the blood-brain barrier and this augments the usual nutrient reward circuitry. Dopaminergic projections go to the nucleus accumbens, which has a crucial role in the reward system of human brain. These dopaminergic effects have been attributed to inhibition of GABAergic interneurons of the ventral tegmental area (VTA) by alcohol. Ethanol-induced dopamine release in nucleus accumbens has been reported to be antagonized by administration of an opiate receptor antagonist [34], suggesting inhibition of GABAergic VTA interneurons are at least partly mediated by opioidergic afferents to these neurons. It is reasonable to suggest ethanol induced dopamine release is in response to increased energy state (nutrient sensing) in GABAergic and dopaminergic neurons.

Considerable attention has been paid to acetaldehyde in relation to the dopaminergic response. Inhibition of catalase activity has been reported to prevent ethanol induced dopaminergic signaling in nucleus accumbens [46]. The authors attributed this effect to decrease in acetaldehyde concentration, but inhibiting catalase alters metabolism in many ways, of which acetaldehyde concentration is only one. Follow-up studies have reported that, in rats bred for ethanol preference, administration of a lentiviral vector coding for aldehyde dehydrogenase-2 (ALDH2) into the ventral tegmental area decreased long term ethanol consumption. This decrease was observed, however, only for ethanol naïve rats and not rats that had consumed ethanol on a 24-hour basis for 81 days [46]. Rivera-Meza et al. [86] reported that treating naïve UChB alcohol preferring rats with N-(1,3-benzodioxol-5-ylmethyl)-2,6-dichlorobenzamide, a drug that increased ALDH2 activity in brain by 3 fold, markedly lowered the amount of alcohol they consumed. The authors suggested that activation of ALDH2 in brain decreased acetaldehyde concentrations and this was responsible for inhibiting both acquisition and maintenance of chronic ethanol intake by alcohol-preferring rats. It has also been suggested that acetaldehyde produced from ethanol reacts with dopamine to form salsolinol and that salsolinol is an agonist for μ-opioid receptors, contributing to the reward response to alcohol [10]. There is, however, little evidence for a role for salsolinol in ethanol consumption and metabolism in humans [56], [57] and the contribution of acetaldehyde concentration remains to be established. In humans, expression of inactive aldehyde dehydrogenase 2 (ALDH2) is protective against alcohol use disorders [12], [60]. This decrease in ethanol consumption, however, has been attributed to the unpleasant side effects of systemic increased acetaldehyde. Lack of ALDH2 also suppresses oxidation of acetaldehyde in mitochondria, disrupting ethanol induced increase energy state, particularly in cells with ADH1 and the reward response to ethanol consumption.

Studies in mice by Tabakoff et al. [101] indicated that ethanol tolerance and physical dependence involve different mechanisms. The authors used intraventricular injection of 6-OH dopamine to deplete dopamine and norepinephrine in the brain. Injected prior to chronic ethanol exposure, this prevented development of tolerance to the hypnotic and hypothermic effects of ethanol without significantly affecting development of physical dependence as measured by withdrawal symptoms (convulsions etc). Once tolerance was established, however, 6-OH dopamine injection did not alleviate that tolerance. It is reasonable to conclude that dopaminergic and noradrenergic systems contribute substantially to the positive physiological response to ethanol and to development of alcohol tolerance, but not to alcohol dependence or withdrawal symptoms.

NEUROLOGICAL RESPONSES TO ETHANOL CONSUMPTION B: EARLY EFFECTS ON GLUTAMATE AND GABA METABOLISM

Chronic ethanol intake in rodents, primates, and humans results in physical dependence and it is widely considered that dependence involves excitatory glutamate and inhibitory GABA neurons. Ethanol oxidation is particularly disruptive of glutamate and GABA metabolism and handling in brain. It is hypothesized that metabolism of astrocytes and neurons is coordinated through glutamate/glutamine cycling [90] and/or lactate transfer [9]. Our version of that metabolic coordination in the absence of ethanol is shown schematically in Fig. 5. Astrocytes have high glycolytic activity and glycogen storage as well as high pyruvate carboxylase activity whereas neurons are oxidative and have high pyruvate dehydrogenase activity. Pyruvate carboxylase in astrocytes is responsible for *de novo* synthesis of oxaloacetate (and thereby glutamate and glutamine) from pyruvate provided by glycolysis (anaplerosis). Pyruvate carboxylase provides α-ketoglutarate (α-KG) for synthesis of glutamate by aspartate/α-KG aminotransferase. Glutamate is then condensed with ammonia (glutamine synthetase) to form glutamine which is exported and taken up by neurons. In neurons, the glutamine is deaminated (glutaminase) and used as both a neurotransmitter and energy source. In order to be used for ATP production, glutamate is first deaminated by either glutamate/oxalacetate aminotransferase [41] or glutamate dehydrogenase to α-KG which enters the CAC. The CAC, however, does not carry out net oxidation of substrates with chain lengths of 4 or more carbons [50]. α-KG is oxidized to malate in the CAC and malate is exported to the cytoplasm where malic enzyme oxidatively decarboxylates malate to pyruvate. In neurons, pyruvate dehydrogenase is active and pyruvate from either malate or lactate is oxidized to acetylCoA and then to CO_2 and water by CAC plus Ox-Phos. Glutamate released at the synapse during neural activity is taken up partly by synaptic glutamate transporters [26], [120] while glutamate that diffuses out of the synapse into the perisynaptic space is taken up by astrocytes. Glutamate consumed for energy metabolism in neurons is replaced by *de novo* synthesis from pyruvate in astrocytes. Metabolism of ethanol and/or its metabolites inhibits both glucose uptake and glycolytic production of pyruvate through increased energy state (decreased $[AMP]_f$) and increased NADH. Ethanol induced increase in systemic lactate/pyruvate also

suppresses intracellular pyruvate concentrations, despite an increase in intracellular lactate through increased monocarboxylate transport. Intracellular pyruvate concentrations are typically below the K_M for pyruvate carboxylase (about 400 μM), and decrease would be expected to suppress astrocytic *de novo* glutamate synthesis. Extracellular glutamate levels in the synapse also decrease due to increase in energy state through its effect on the energy dependence of synaptosomal glutamate transport [26]. The net early effects of ethanol on glutamatergic neural activity include decreased glutamate release in response to the increased energy state in neurons and increased levels of inhibitory neurotransmitter GABA [33]. These contribute to the calming effects of ethanol through suppression of glutamatergic anxiety producing neural activity.

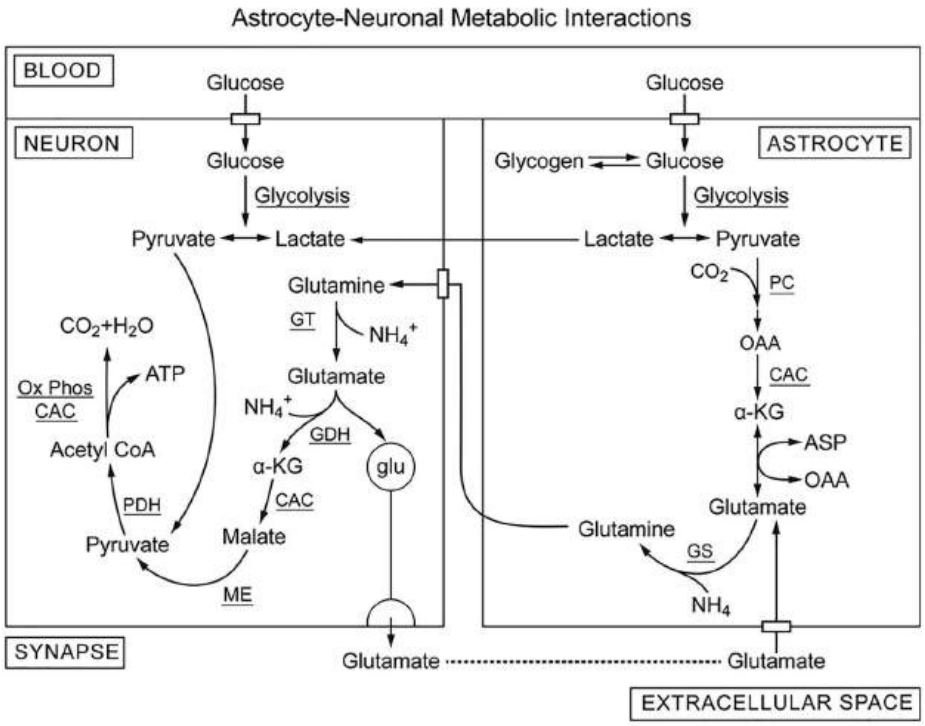

Fig. 5. **Our version of the glutamate/glutamine cycle that helps to support glutamatergic neural activity (no ethanol)**. The astrocytes are primarily glycolytic, using puruvate from glycolysis for *de novo* synthesis of oxalacetate by pyruvate carboxylase whereas glutamatergic neurons are more oxidative and consume lactate and glutamate for energy metabolism. Pyruvate carboxylase is activated when acetylCoA and the acetylCoA/CoASH ratio are high, conditions for which pyruvate dehydrogenase activity is suppressed. In addition, the CAC does not catalyze net oxidation of intermediates with 4 or more carbon atoms. As a result, astroctes take up glucose and produce pyruvate by glycolysis for net synthesis of oxalacetate. Oxalacetate is converted to citrate and then oxidized to α-ketoglutarate (α-KG) in the CAC. The α-KG is transaminated to form glutamate and then condensed with ammonia glutamine synthetase (GS). Glutamine released from astrocytes is taken up by neurons which reverse this process. Glutamine is deaminated by glutaminase and then oxidatively dehydrogenated to α-KG by glutamate dehydrogenase (GDH). α-KG is oxidized to malate in the CAC and exported to the cytoplasm where it is converted to pyruvate by malic enzyme (ME). In neurons, pyruvate from lactate and glutamate is oxidized by pyruvate dehydrogenase and provides acetylCo-A for energy metabolism. Most of the glutamate released during neural activity is taken up by glutamate transporters in the synapse but some diffuses out to the surrounding perisynaptic space, is taken up by astrocytes and recycled. *De novo* synthesis of glutamate in astrocytes replaces that used by neurons for energy metabolism, maintaining stable glutamate/glutamine levels in support of glutamatergic neuronal function.

NEUROLOGICAL RESPONSES TO ETHANOL CONSUMPTION: C. LONG TERM ALTERATIONS IN GLUTAMATERGIC NEURAL SYSTEM AND ALCOHOL WITHDRAWAL SYNDROME

It has been proposed that neurophysiological and pathological effects of ethanol are mediated, to an important extent, by glutamatergic neurons [35], [36], [79], [96], [106]. Biochemical and electrophysiological studies have reported that chronic ethanol treatment increases the number of excitatory N-methyl-D-aspartate (NMDA) receptor-ionophore complexes in hippocampus, a brain area associated with ethanol withdrawal seizure activity [35], [36], [96]. Withdrawal symptoms vary, but in mice removal of ethanol from the diet induces withdrawal-associated tremors and handling-induced seizures [35], [36], [85]. The withdrawal symptoms are reported to correlate with decrease in blood alcohol and acetate levels, with the most severe seizure activity occurring when these concentrations fall to near zero. In mice, the NMDA receptor levels return to control in 24 h and the mice no longer have handling induced seizures. Treatment with NMDA during

withdrawal exacerbated handling induced withdrawal seizures, while administration of MK-801, a noncompetitive NMDA receptor antagonist, decreased the occurrence and severity of seizures [35]. Treatment with MK-801 did not, in alcohol dependent mice, suppress the tremors which occur during withdrawal [35], [36]. Thus, following chronic ethanol treatment the glutamate receptors, particularly NMDA receptors, appear to mediate handling induced seizures, but not tremors, associated with ethanol withdrawal. Blocking NMDA receptors by memantine, a moderate affinity but clinically approved NMDA receptor antagonist, has been shown to reduce withdrawal induced-seizures and neurotoxicity in mice [100]. In clinical studies, memantine has been reported to attenuate cue-induced craving for alcohol and withdrawal symptoms associated with alcohol consumption [54], [55].

In rodents, exposure to alcohol has been reported to induce a significant increase in the expression and synaptic localization of α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptors (AMPA receptors) in brain regions with reward circuitry [15], [17]. AMPA receptors are ionotropic transmembrane receptors for glutamate that mediate fast synaptic transmission in the CNS. Infusion of an AMPA receptor inhibitor into the dorsomedial striatum exhibited promising results in reducing alcohol consumption in rats [113] and an AMPA/kainate receptor antagonist, topiramate, is reported to suppress withdrawal symptoms in humans [55]. Another drug, acamprosate, known to affect two neurotransmitter systems, GABA (as an agonist) and glutamate (as an NMDA receptor agonist and mGluR5 antagonist), has been reported to be effective in increasing complete abstinence rate as well as cumulative abstinence duration in several long-term placebo-controlled trials in alcohol-dependent patients [59], [80], [88]. In a large clinical trial involving 1383 patients in nine possible treatment groups, however, acamprosate neither alone nor with naltrexone or combined behavioral intervention showed statistically significant reduction in alcohol consumption over placebo [4]. Despite the inconsistencies in findings, overall advantageous pharmacological effects of acamprosate on alcohol consumption are such that it is approved for treatment of alcohol use disorders in Europe and USA.

Understanding how glutamate signaling may contribute to addiction needs to account for multiple pools of intra- and extra-cellular glutamate. Glutamate concentrations within glutamatergic synapses are determined by balance of vesicular release and energy dependent glutamate reuptake whereas that in the perisynaptic space is determined by diffusion from the synapse and extrasynaptic release/uptake [28], [104]. Perisynaptic glutamate regulates neurotransmission by stimulating group II glutamate receptors (mGluRs) in the presynaptic area [7], [121]. These are presynaptic receptors capable of inhibiting vesicular release [8], [18], [89]. Thus, presynaptic receptors permit cross talk between the two pools and altered nonvesicular glutamate release may contribute to pathological glutamate signaling linked to addiction [110]. As indicated above, under normal physiological conditions, plasma acetate concentration is low but with ethanol ingestion it rapidly increases to about 1 mM. Acetate is readily taken up and metabolized by brain [20], [81], [114], largely by astrocytes. Calculated rates of utilization of acetate from the blood were reported to be 15–25% of total glucose consumption in non-stimulated tissue and to range from 28 to 115% of estimated rates of glucose oxidation in astrocytes [20], [114]. During intoxication, blood acetate concentrations are higher for alcoholics than for controls [78]. This would facilitate metabolism of acetate by glial cells, as shown for laboratory animals chronically exposed to alcohol [107], [111].

Madayag and coworkers [68] reported that repeated N-acetylcysteine administration alters plasticity-dependent effects of cocaine. The authors provided evidence that the ability of N-acetylcysteine to regulate drug-seeking behavior results from actions on cystine-glutamate exchanger (system x_c^-) and is associated with suppression of the large release of glutamate that occurs in accumbens during drug seeking. *In vitro* measurements have been reported to show that cystine induced activation of cystine/glutamate exchange system x_c^- results in release of glial glutamate and stimulation of mGlu2 receptors [45]. This inhibits neuronal glutamate release. In cocaine addiction, decrease in reinstated cocaine seeking elicited by activating x_c^- with N-acetylcysteine is prevented by pretreatment with an mGlu2/3 antagonist [58]. Pharmacological treatment with N-acetylcysteine is reported to modulate responses to stress and depressive-like behaviors by increasing x_c^- expression and to indirectly activate mGlu2 receptors [76]. The fact that pharmacological blockade of the x_c^- system also blocked N-acetylcysteine effects on mGlu2 receptors further supports linkage of mGlu2 regulation in promoting resilience to stress. A consistent biomarker of mood-related behaviors associated with electrophysiological changes in the dentate gyrus is reduction in the mGlu2 receptors that regulate vesicular release of glutamate at synapses [77].

ETHANOL METABOLISM AND ASSOCIATED ALCOHOL WITHDRAWAL SYNDROME: A SYNOPSIS

Ethanol, through its role as a major but essentially unregulated metabolite for energy metabolism, causes a truly metabolic disease. An initial positive sense of well being is induced by “pushing” energy metabolism and increasing energy state to above its homeostatic set point. The positive sense of well being is part of the neurological signaling system that has evolved to guide adaptation to the environment. Positive reward feelings associated with adequate food, warmth etc. are enhanced and negative feelings associated with hunger, anxiety, etc are suppressed. This leads to a euphoric state with an enhanced sense of being well fed and unstressed. Short exposures are reversible and cause little long term injury, but as ethanol exposure continues there is progressive disruption of critical regulatory mechanisms that maintain metabolic homeostasis. The extent of disruption is dependent on individual tissues and their metabolic requirements with many other contributing parameters (including genetic differences, diet, etc). A key aspect of ethanol metabolism appears to be the decrease in $[AMP]_f$ and attendant decrease in AMPK activity. Both chronic decrease in AMPK activity and alcohol dependence are reported to cause decreased activity of oxidative phosphorylation, abnormally shaped mitochondria and other cellular morphological and enzymatic changes [14], [102]. In addition to the debilitating effects of prolonged ethanol consumption, it is necessary to deal with alcohol withdrawal syndrome. As described earlier, this is a complex response to stopping ethanol consumption and correlates with disappearance of ethanol

and its metabolic products from the body. The symptoms can be severe and life threatening but do not arise from a single cause. Due to the multiplicity in causes, a single drug is unlikely to fully alleviate the withdrawal symptoms. Effective treatment is likely to require simultaneous treatment of multiple causes. Identifiable primary metabolic contributions to alcohol withdrawal symptoms and treatments that should substantially suppress the symptoms include:

1). Correct the energy deficiency in specific brain cells (neurons and astrocytes). Derr and coworkers [22] reported this can be addressed by providing a metabolite "cocktail" (butyrate, lactate, and β-hydroxybutyrate) for energy metabolism and anaplerotic support of the citric acid cycle. Derr and Derr [23] quantified the tremulous and rigidity symptoms of alcohol withdrawal in rats and concluded that feeding β-hydroxybutyrate suppressed the tremulous, but not the rigidity, symptoms. Other suitable nutrients include branched chain amino acids and branched short chain fatty acids, as these also rapidly cross the blood-brain barrier. Importantly, each can provide both acetylCoA for oxidative metabolism and pyruvate for anaplerotic synthesis of glutamate. Given the importance of carnitine in acetate metabolism, supplementing with carnitine and/or acetyl-L-carnitine may also be helpful [71].

2A). Stabilize glutamate distribution and metabolism in the brain. Treatment with N-acetylcysteine has been reported to modulate responses to stress and depressive-like behaviors in several ways. These include increasing expression of glutamate-cystine antiporter (system x_c^-), increasing the concentrations of cysteine and cystine, and indirectly by activating mGlu2 receptors [2], [76]. This helps to rebalance glutamate homeostasis and glutamatergic neuronal/astrocyte interactions.

2B). Pharmacological compensation for increased sensitivity of the glutamatergic neural system. As noted above, chronic ethanol consumption induced suppression of glutamatergic activity results in increase in excitatory (NMDA, AMPA) and decrease in inhibitory (mGluR) glutamate receptors. The contribution of enhanced glutamatergic sensitivity and neurotoxicity of excessive NMDA receptor activity to ethanol withdrawal symptoms can be suppressed by antagonists for excitatory glutamate receptors. Among the glutamate receptor antagonists currently clinically approved or in trials are acamprosate, memantine, and MK-801. Suppression of glutamatergic sensitivity through the critical withdrawal period has been reported to decrease the severity of symptoms [55]. Once energy and glutamate metabolism have normalized, receptor numbers should return to near normal.

Alcohol dependence is not just a metabolic disease, and there are substantial genetic, psychological, and social contributions. Identifying and characterizing the metabolic consequences of ethanol ingestion and of alcohol dependence is important to understanding the disease and how to more effectively treat alcohol dependence. This is, however, just one piece of a complex medical and social problem.

CONFLICT OF INTEREST STATEMENT

Neither DFW nor FMM have any financial and personal relationships that could influence the work presented in this manuscript.

ACKNOWLEDGEMENT

The authors are indebted to Dr. Joseph J. Higgins for insightful and memorable discussions concerning ethanol metabolism and its regulation.

29.11: GUT MICROBIOTA-DERIVED METABOLITES AS CENTRAL REGULATORS IN METABOLIC DISORDERS

ABSTRACT

Metabolic disorders represent a growing worldwide health challenge due to their dramatically increasing prevalence. The gut microbiota is a crucial actor that can interact with the host by the production of a diverse reservoir of metabolites, from exogenous dietary substrates or endogenous host compounds. Metabolic disorders are associated with alterations in the composition and function of the gut microbiota. Specific classes of microbiota-derived metabolites, notably bile acids, short-chain fatty acids, branched-chain amino acids, trimethylamine N-oxide, tryptophan and indole derivatives, have been implicated in the pathogenesis of metabolic disorders. This review aims to define the key classes of microbiota-derived metabolites that are altered in metabolic diseases and their role in pathogenesis. They represent potential biomarkers for early diagnosis and prognosis as well as promising targets for the development of novel therapeutic tools for metabolic disorders.

KEY MESSAGES

- Metabolic disorders, a growing worldwide health challenge, are associated with alterations in the composition and function of the gut microbiota.
- Microbial metabolites are key factors in host-microbiota cross-talk.
- Specific classes of microbiota-derived metabolites, notably bile acids, short-chain fatty acids, branched-chain amino acids, trimethylamine N-oxide, tryptophan and indole derivatives, have been strongly implicated in the pathogenesis of metabolic disorders.
- Gut microbiota-derived metabolites represent potential biomarkers for the early diagnosis and show promise for identifying targets for the development of novel therapeutic tools for metabolic disorders.

INTRODUCTION

The human intestine harbours a complex and diverse system of mutualistic microorganisms, consisting of bacteria, fungi, viruses, archaea and protozoa. This rich ecosystem contributes to a large number of physiological functions: fermentation of indigestible dietary components and vitamin synthesis, defenses against pathogens, host immune system maturation and maintenance of gut barrier function. Thus, this central regulator, sometimes qualified as the ‘second brain’, plays a significant role in maintaining host physiology and homeostasis. All the species interconnected in the gut produce an extremely diverse reservoir of metabolites from exogenous dietary components and/or endogenous compounds generated by microorganisms and the host. Notably, while food is generally examined for calories and macronutrients and micronutrients, microbial metabolism (and even human enzymes) recognises food molecules and transforms them into metabolites. These microbial metabolites are key actors in host-microbiota cross-talk. The beneficial or detrimental effect of specific microbiota-derived metabolites depends on the context and the host state, suggesting the primordial nature of the symbiotic microbiota in ensuring optimal health in humans.

With the widespread westernisation of lifestyles, alteration of the gut microbiota composition and functions has become a worldwide phenomenon. Despite the difficulty to distinct a direct causal relationship and an association between dysbiosis and diseases, several lines of evidence demonstrate that the alteration of the gut microbiota is involved in the pathogenesis of multiple diseases affecting the GI tract, such as IBD or colorectal cancer, as well as many non-digestive systems. Metabolic disorders have been recognised to be massively impacted by gut microbiota. In the last two decades, increasing calorie intake and decreasing levels of physical activity have contributed to a progression in the prevalence of metabolic disorders. Metabolic disorders represent a group of disorders with the clustering of various inter-related pathological conditions combining obesity, non-alcoholic steatohepatitis (NASH), dyslipidaemia, glucose intolerance, insulin resistance, hypertension and diabetes that, when occurring together, strongly increase the incidence of cardiovascular diseases and mortality. Deciphering the mechanisms of host-intestinal microbiota interactions represents a major public health challenge in the development of new preventive or curative therapeutic strategies. In the present review, we will focus on the results from the most significant studies dealing with the role of microbiota-derived metabolites in metabolic disorders.

DISRUPTED EQUILIBRIUM OF THE GUT MICROBIOME-HOST INTERACTIONS IN METABOLIC DISORDERS

The gut microbiota plays a crucial role in maintaining the physiological functions of the host. A disruption of the fragile host-microbiota interaction equilibrium can play a role in the onset of several metabolic diseases. The gut microbiota can interact with the host by producing metabolites, which are small molecules (<1500 Da) representing intermediates or end-products of microbial metabolism. These metabolites can derive directly from bacteria or the transformation of dietary or host-derived substrates.

GUT MICROBIOTA INCRIMINATION

The implication of the gut microbiota in the regulation of host metabolic balance has been demonstrated in the last decade. Studies conducted both in animal models and humans revealed a significant role of the gut microbiota in the pathogenesis of metabolic disorders, strongly influenced by diet and lifestyle modifications.

EVIDENCE FROM ANIMAL EXPERIMENTS

The gut microbiota modulates energy expenditure and homeostasis in several animal models, including germ-free mice (GF mice) and genetically induced mice with obesity (ob/ob mice). GF mice are protected against obesity in a Western diet setting. Independent of daily food intake, Bäckhed *et al* reported a 60% increase in body fat, hepatic triglycerides and insulin resistance in conventionalised adult GF mice compared with GF mice, notably due to better absorption of monosaccharides. Interestingly, the transfer of gut microbiota from ob/ob mice to GF mice results in a significant increase in body weight and fat mass compared with colonisation with a lean microbiota, showing a causal relationship. The gut microbiota composition is unique to each individual. Caecal microbiota transplantation, from two mice with different responses to high-fat diet (HFD), into GF mice leads to the transmission of the donor's responder (RR) or non-responder (NR) phenotype. The gut microbiota of severely hyperglycaemic RR mice is enriched in Firmicutes, whereas NR is dominated by Bacteroidetes and Actinobacteria. Moreover, the transplantation of faecal microbiota from human twin pairs, discordant for obesity, into GF mice led to the acquisition of lean and obese phenotypes according to the donor. This phenotype transmission is strongly diet-dependent and notably favoured by a low-fat diet enriched in vegetables and fruits and thus enriched in fibre. The effect of the gut microbiota seems to occur even before birth, as the maternal gut microbiota, through short-chain fatty acid (SCFAs), triggers embryonic GPR41 and GPR43 and influences prenatal development of neural, enteroendocrine and pancreatic systems of the offspring to maintain postnatal energy homeostasis and eventually prevent metabolic disorder development.

Overall, these animal studies demonstrate the tight interconnection between diet and the gut microbiome in the pathogenesis of metabolic disorders as well as in its vertical transmissibility.

EVIDENCE FROM HUMAN STUDIES

Alterations in the gut microbiome composition and functions are associated with various traits observed in metabolic disorders. Although there are some conflicting results, the obesity-associated gut microbiota has been characterised by a decline in Bacteroidetes and a compensatory expansion of the Firmicutes phylum and by a reduction in microbial diversity and richness. There is notably a negative correlation between the severity of metabolic markers and the richness of the gut microbiota. Individuals with low microbiota gene content present more adiposity, insulin resistance and dyslipidaemia than high bacterial richness populations. Even in severe obesity conditions, those with diminished gut microbiota richness have a more severe metabolic condition.

In patients with diabetes, the higher proximity of the altered microbiota to epithelial cells could promote pro-inflammatory signals, contributing to the development of aggravated metabolic alterations. In humans, faecal microbiota transplantation (FMT) demonstrated some positive but moderate effects in patients with metabolic syndrome traits, proving the involvement of the gut microbiota in the pathogenesis and its potential therapeutic role.However, the efficiency of FMT in improving metabolic amelioration was dependent on the recipient gut microbiota profile, with low baseline richness promoting gut microbiota engraftment.

GUT MICROBIOTA-DERIVED METABOLITE IMPLICATIONS IN METABOLIC DISEASES

THE GUT METABOLOME

Metabolomics, which consists of the study of the small molecules present in any type of biological sample, has proven to be helpful in enriching the knowledge on microbiota-host interactions. Several hundred faecal or serum metabolites have been associated with clinical features associated with metabolic disorders. Moreover, a combination of metagenomics and metabolomics was used to elucidate the associations between gut microbiota imbalances and metabolic disturbances. This field is still in its infancy and, for some metabolites, it remains difficult to determine whether they are fully microbiota-derived or if other sources are involved, including diet or the host itself.

Metagenome and metabolome studies led to the discovery of new associations between microbial-derived metabolites and metabolic syndrome, but additional arguments are needed to establish a potential causality link. Notably, the decreased abundance of *Bacteroides thetaiotaomicron*, a glutamate fermenting commensal, in subjects with obesity is inversely correlated with serum glutamate. Furthermore, positive correlations between insulin resistance and microbial functions are driven mainly by a few species, such as *Prevotella copri* and *Bacteroides vulgatus*, suggesting that they may directly impact host metabolism. Metabolomics studies in plasma, saliva or urine identified different biochemical classes of metabolites that may be altered in metabolic disorders in association with gut microbiota perturbations. Dysregulation of lipolysis, fatty acid oxidation and aminogenesis and ketogenesis, as well as changes in the levels of triglycerides, phospholipids and trimethylamine N-oxide (TMAO) are described in samples from humans with metabolic disorders, and more recently, imidazole propionate (IMP) was discovered as being involved in insulin resistance. Shotgun metagenomics data suggest that hepatic steatosis and metabolic alterations are associated with dysregulated aromatic and branched-chain amino acid (BCAA) metabolism. The dysregulation of SCFA and bile acid (BA) metabolism are also associated with metabolic diseases, including obesity, type 2 diabetes mellitus and non-alcoholic fatty liver diseases.

BILE ACIDS

BAs are small molecules synthesised in hepatocytes from cholesterol. The primary BAs chenodeoxycholic acid (CDCA) and cholic acid (CA), conjugated to glycine or taurine, are essential for lipid/vitamin digestion and absorption. Ninety-five per cent of them are reabsorbed actively from the terminal ileum and are recycled in the liver (enterohepatic circulation). Primary BAs are also transformed into secondary BAs and deconjugated by gut microbiota. They can be either passively reabsorbed to reenter the circulating BA pool or excreted in the faeces as shown in Figure 1 below.

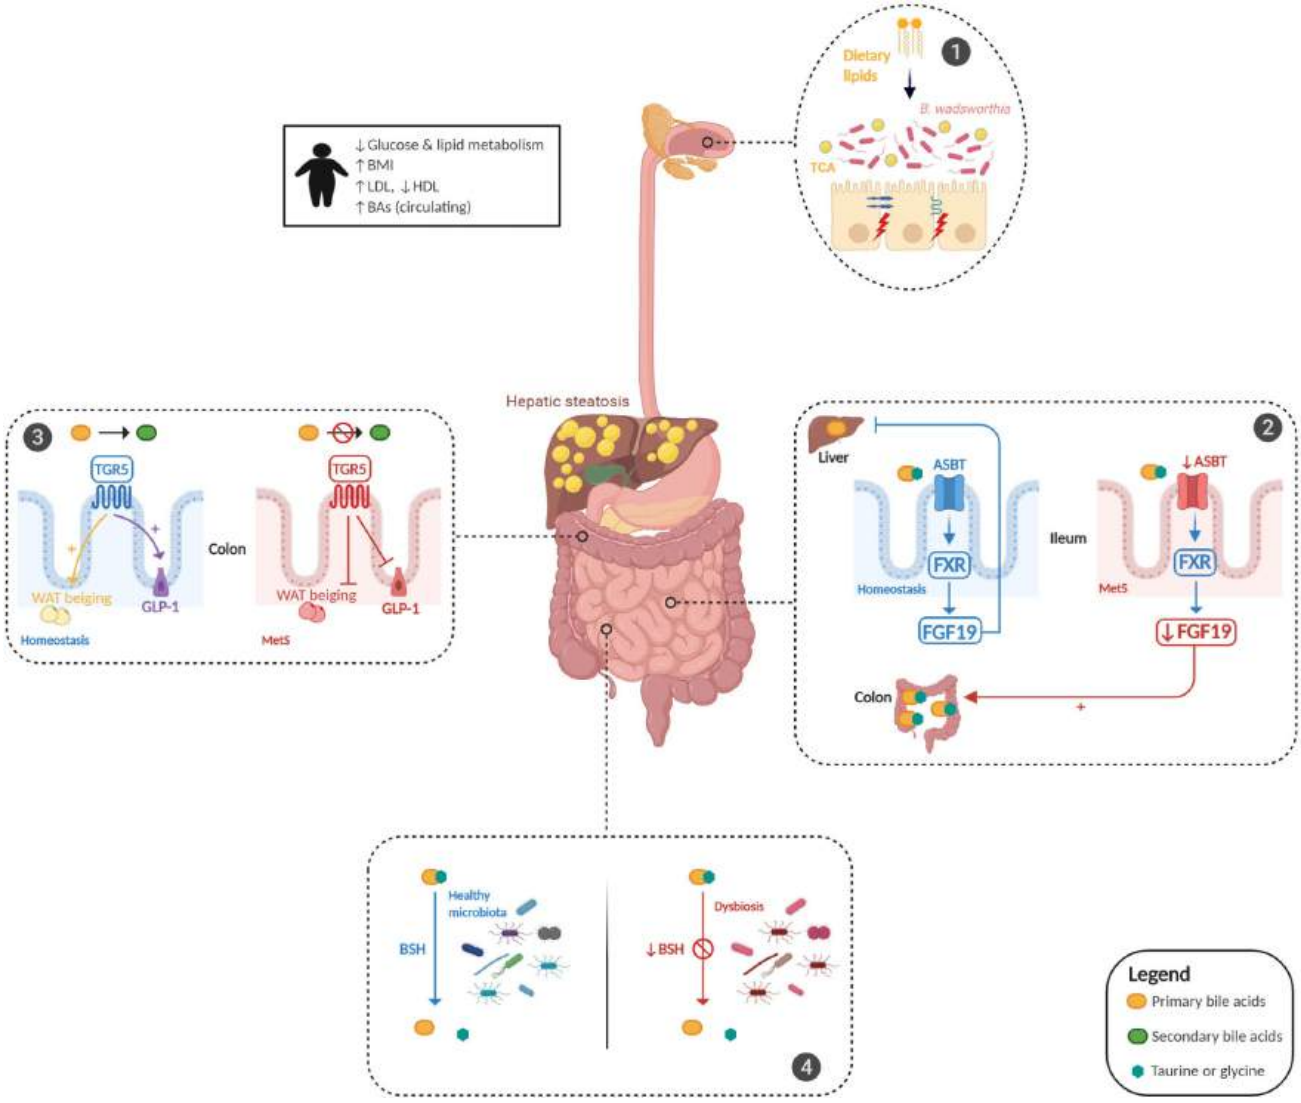

Figure 1

Bile acid (BA) dysmetabolism in metabolic syndrome. BA metabolism is altered in patients with metabolic syndrome (MetS) and is associated with hepatic steatosis and glucose and lipid dysmetabolism. Dietary animal fat consumption promotes taurocholic acid (TCA) production, which favours the proliferation of sulfite-reducing bacteria, *Bilophila wadsworthia*, leading to an increase in intestinal permeability and inflammation (panel 1). Gut microbiota alterations induce an impairment in the ileal absorption of BAs, which occurs normally via the apical-sodium BA transporter (ASBT). This induces a decrease in the expression of nuclear Farnesoid-X receptor (FXR) and fibroblast growth factor 19 (FGF19) in intestinal epithelial cells and the abundance of colonic primary conjugated BAs (panel 2). Gut microbiota dysfunction leads to a decreased transformation of primary conjugated BAs to secondary BAs in the colon, leading to defective activation of Takeda-G-protein-receptor-5 (TGR5). The effect of TGR5 activation on the increase in glucagon-like peptide 1 (GLP-1) and white adipose tissue (WAT) browning was thus inhibited (panel 3). Gut microbiota alterations impair bile salt hydrolase (BSH) activity, leading to primary conjugated BA accumulation in the colon (panel 4). BMI, body mass index; HDL, high-density lipoprotein; LDL, low-density lipoprotein.

Increased total circulating BA levels in individuals with obesity positively correlate with body mass index and serum triglycerides in patients with hyperlipidaemia. BAs regulate their synthesis through FGF19/FGF15, but they also have metabolic effects through their

receptors Farnesoid-X receptor (FXR) and Takeda-G-protein-receptor-5 (TGR5). Activation of FXR and TGR5 (1) promotes glycogen synthesis and insulin sensitivity in the liver; (2) increases insulin secretion by the pancreas; (3) facilitates energy expenditure, especially in the liver, brown adipose tissue and muscles (browning); (4) favours thermogenesis, resulting in a decrease in body weight and (5) mediates satiety in the brain. BAs also impact lipid metabolism, especially by exerting profound effects on triacylglycerol. The perturbations of the intestinal microbiota composition in metabolic disorders strongly impact BA metabolism, especially characterised by a failure to metabolise primary BAs, thus leading to their accumulation. Indeed, an increase in primary CDCA levels induces a decrease in very low-density lipoprotein production and plasma triglyceride concentrations. Short-term antibiotic supplementation in mice induces a decrease in secondary BA-producing bacteria and a reduction in hepatic deoxycholic acid (DCA) and lithocholic acid concentrations as well as serum triglyceride levels, suggesting that secondary BAs can act as regulators to maintain metabolic host homeostasis. Moreover, this alteration in the primary to secondary BA pool in metabolic disorders might play a role in the observed low-grade intestinal inflammation, as conjugated primary BAs exhibit pro-inflammatory effects on intestinal epithelial cells. Conversely, secondary BAs have anti-inflammatory properties. In addition, Parséus *et al* showed that the promoting effect of the gut microbiome on obesity and hepatic steatosis is dependent on the FXR pathway.However, the FXR-dependent role of secondary BAs in the regulation of glucose and lipid metabolism is debated and might be context-dependent. The accumulation of hepatic lipids, triglycerides and cholesterol has been observed in FXR-deficient mice on a normal chow diet, while in HFD-fed mice or an obese background, FXR deficiency improves glucose homeostasis and decreases body weight, possibly a consequence of different basal gut microbiota. The effects of FXR in the pathogenesis of metabolic disorders are also likely to be different from one tissue to the other, as demonstrated by studies in conditional knockout mice. FXR induces the transcription of fibroblast growth factor 19 (FGF19) in intestinal epithelial cells, which reach the liver and inhibit BA synthesis in a feedback loop. Mice overexpressing FGF19 exhibit increased metabolic activity and energy expenditure by increasing brown adipose tissue and decreasing liver expression of acetyl coenzyme A carboxylase 2, thus leading to protection against HFD-induced metabolic injury. Gut microbiota perturbations induce impairment in the ileal absorption of BAs, which normally occurs via the apical-sodium bile acid transporter, resulting in decreased expression of FXR and FGF19 and an imbalance of BAs, notably characterised by an increase in colonic primary conjugated BAs. Transgenic mice overexpressing TGR5 exhibit improved glucose tolerance with increased secretion of glucagon-like peptide 1 (GLP-1) and insulin. This BA-TGR5 axis elicits beige remodelling in subcutaneous white adipose tissue and may contribute to improvement in whole-body energy homeostasis. The alteration of gut microbiota-dependent BA metabolism, through qualitative (primary vs secondary and conjugated vs deconjugated BAs) or quantitative modification of the BA pool, is likely to participate in the pathogenesis of metabolic disorders. Moreover, BAs have an important impact on intestinal epithelium function. Primary BAs, such as CA and CDCA, and some secondary deconjugated BAs, such as DCA, increase epithelial permeability through the phosphorylation of occludin in intestinal Caco-2 cells. Some correlations have been observed between BA levels and intestinal permeability in mouse models. The effect of the BA-microbiota dialogue is massively impacted by diet. High consumption of animal fat promotes taurocholic acid production, leading to a shift in microbiota composition with a bloom of sulfite-reducing microorganisms such as *Bilophila wadsworthia* and to increased susceptibility to colitis in IL-$10^{-/-}$ mice and more severe liver steatosis, barrier dysfunction and glucose metabolism alteration in HFD-fed mice. Moreover, bile salt hydrolase (BSH) activity, which is responsible for BA deconjugation in the normal gut microbiota, is impaired in metabolic disorders and likely plays a role in the accumulation of primary conjugated BAs in the colon of these patients. In mouse models, correcting BSH defects by the administration of BSH-overexpressing *Escherichia coli* improved lipid metabolism, homeostasis and circadian rhythm in the liver and GI tract, resulting in protection against metabolic disorders.

SHORT-CHAIN FATTY ACIDS

SCFAs, such as butyrate, propionate and acetate, are end-products of microbial fermentation implicated in a multitude of physiological functions. SCFAs participate in the maintenance of intestinal mucosa integrity, improve glucose and lipid metabolism, control energy expenditure and regulate the immune system and inflammatory responses as shown in Figure 2 below. They act through different mechanisms, including specific G protein-coupled receptor family (GPCR) and epigenetic effects.

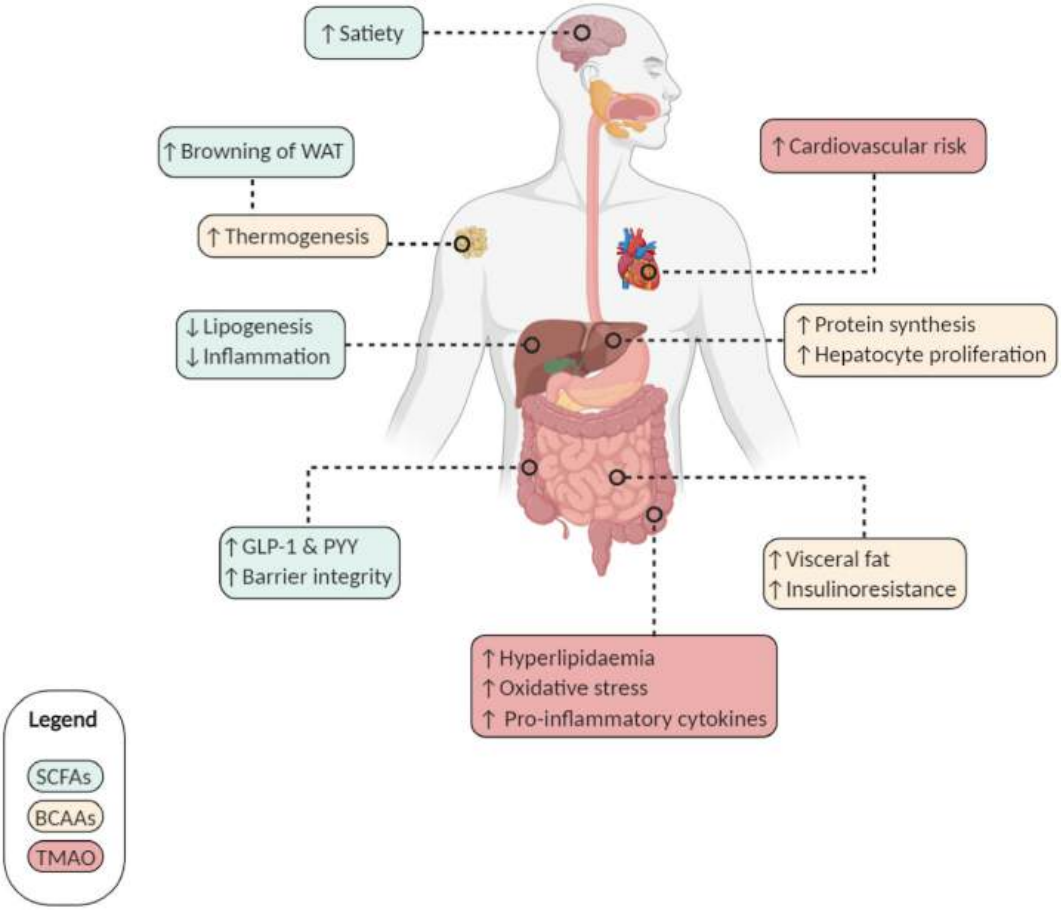

Figure 2

Short-chain fatty acids (SCFAs), branched-chain amino acids (BCAAs) and Trimethylamine N-oxide (TMAO): relevant effects for metabolic syndrome on the host. Microbiota-derived metabolites mediate diverse effects on host metabolism. SCFAs (green frame): (i) increase satiety and browning of white adipose tissue (WAT); (ii) induce a decrease in lipogenesis and associated inflammation; (iii) increase the secretion of glucagon-like peptide 1 (GLP-1) and peptide YY (PYY) and (iv) participate in the maintenance of intestinal barrier integrity. BCAAs (yellow frame): (i) increase thermogenesis, protein synthesis and hepatocyte proliferation but (ii) are also associated with insulin resistance and visceral fat accumulation. TMAO (red frame): increases cardiovascular risks by inducing hyperlipidaemia, oxidative stress and pro-inflammatory cytokines.

The amount of SCFA-producing bacteria and SCFAs is reduced in faecal samples of dysmetabolic mice and in humans with obesity and diabetes. In rodents with diabetes and obesity, supplementation with SCFAs improves the metabolic phenotype by increasing energy expenditure, glucose tolerance and homeostasis. Adding back fermentable fibres (inulin) to an HFD seems to be enough to protect against metabolic alterations. In humans, SCFA administration (inulin-propionate ester, acetate or propionate) stimulates the production of GLP-1 and PYY, leading to a reduction in weight gain. The protective effects of SCFAs on metabolic alterations might occur as early as in utero. In mice, high-fibre diet-induced propionate from the maternal microbiota crosses the placenta and confers resistance to obesity in offspring through the SCFA-GPCR axis.

BRANCHED-CHAIN AMINO ACIDS

The most abundant BCAAs, valine, isoleucine and leucine, are essential amino acids synthesised by plants, fungi and bacteria, particularly by members of the gut microbiota. They play a critical role in maintaining homeostasis in mammals by regulating protein synthesis, glucose and lipid metabolism, insulin resistance, hepatocyte proliferation and immunity. BCAA catabolism is essential in brown adipose tissue (BAT) to control thermogenesis. It occurs in mitochondria via SLC25A44 transporters and contributes to an improvement in metabolic status. Moreover, supplementation of mice with a mixture of BCAAs promotes a healthy microbiota with an increase in *Akkermansia* and *Bifidobacterium* and a decrease in Enterobacteriaceae. However, the potential positive effects of BCAAs are controversial. Elevated systemic BCAA levels are associated with obesity and diabetes, probably a consequence of the 20% increased consumption of calories over the last 50 years. In genetically obese mice (ob/ob mice), BCAA accumulation induces insulin resistance. The gut microbiota is a modulator of BCAA levels, as it can both produce and use BCAAs. *Prevotella copri* and *B. vulgatus* are potent producers of BCAAs, and their

amounts correlate positively with BCAA levels and insulin resistance. In parallel, a reduced abundance of bacteria able to take up BCAAs, such as *Butyrivibrio crossotus* and *Eubacterium siraeum*, occurs in patients with insulin resistance. Further studies are needed to more precisely elucidate the effects of BCAAs in the pathogenesis of metabolic disorders.

TRIMETHYLAMINE N-OXIDE

The gut microbiota can metabolise choline and L-carnitine from dietary sources (eg, red meat, eggs and fish) to produce trimethylamine (TMA). This gut microbiota-derived TMA is then absorbed and reaches the liver where it is converted into TMAO through the enzymatic activity of hepatic flavin monooxygenases 3.

In humans, the level of TMAO increases in patients with diabetes or at risk of diabetes and in obesity. Increasing evidence demonstrates that the gut microbiota-dependent metabolite TMAO is also associated with a higher risk of developing cardiovascular disease and kidney failure. In mice, dietary supplementation with TMAO, carnitine or choline alters the caecal microbial composition, leading to TMA/TMAO production that increases the atherosclerosis risk. This effect is dependent on the gut microbiota, as it is lost in antibiotic-treated mice. Moreover, transferring the gut microbiota of high-TMAO mice recapitulates atherosclerosis susceptibility in recipient low-TMAO mice. Importantly, the role of the gut microbiota in the production of TMAO from TMA has also been demonstrated in humans. Overall, in metabolic disorders, the altered microbiota associated with an increased intake of choline and L-carnitine from dietary sources leads to an increase in plasma levels of TMAO, which is directly involved in the pathogenesis of metabolic disease comorbidities and particularly cardiovascular disorders. However, detailed investigations are needed in populations from different countries to understand the interaction between food consumption patterns, TMAO production and cardiovascular risks.

TRYPTOPHAN AND INDOLE-DERIVATIVE METABOLITES

Tryptophan is an essential aromatic amino acid acquired through common diet sources, including oats, poultry, fish, milk and cheese. In addition to its role in protein synthesis, tryptophan is a precursor for crucial metabolites. Dietary tryptophan can follow two main pathways in host cells, namely, the kynurenine and serotonin routes. The third pathway implicates gut microorganisms in the direct metabolism of tryptophan into several molecules, such as indole and its derivatives, with some of them acting as aryl hydrocarbon receptor (AhR) ligands, as shown in Figure 3 below.

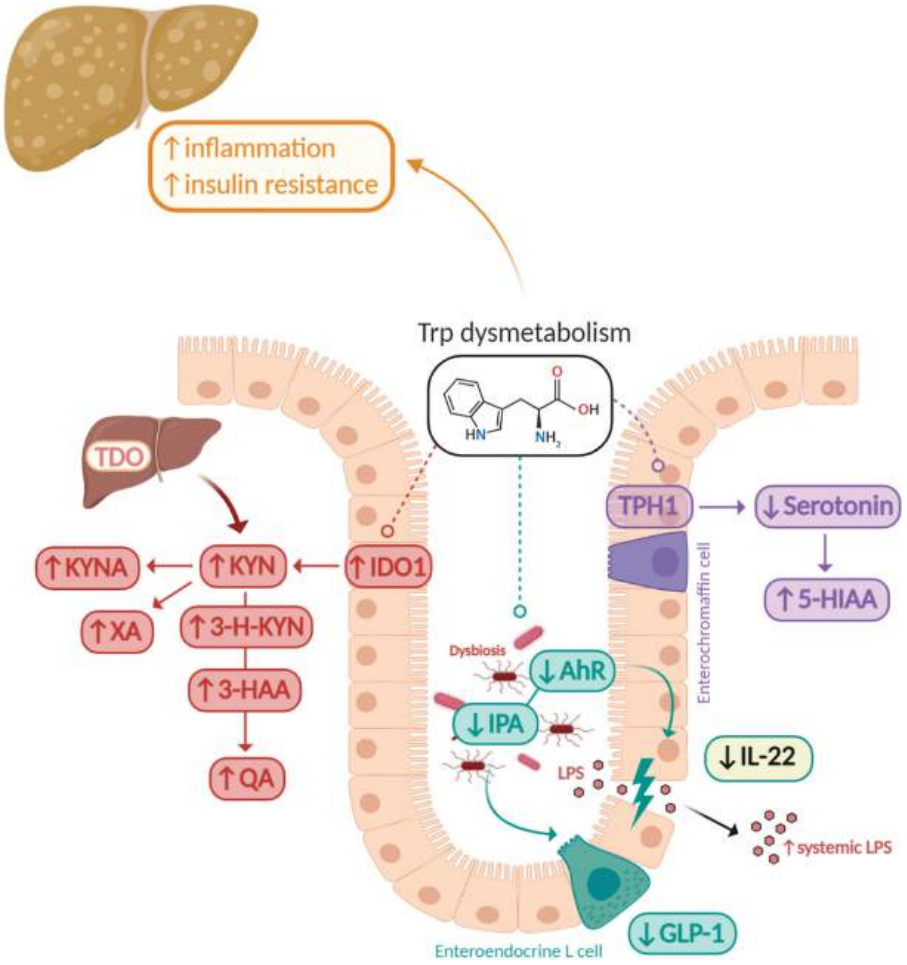

Figure 3

Tryptophan metabolism alterations in metabolic syndrome. Tryptophan dysmetabolism is associated with liver inflammation, steatosis and insulin resistance. In metabolic syndrome (MetS), the inflammatory state is associated with kynurenine (KYN) production through the activation of indoleamine 2,3-dioxygenase 1 (IDO1). This leads to an increase in kynurenine-derived metabolites, such as kynurenic acid (KYNA), xanthurenic acid (XA), 3-hydroxykynurenine (3-H-KYN), 3-hydroxyanthranilic acid (3-HAA) and quinolinic acid (QA). In parallel, the gut microbiota presents a defect in the production of aryl hydrocarbon receptor (AhR) ligands such as indole-3-propionic acid (IPA). The incretin hormone glucagon-like peptide 1 (GLP-1) secretion from intestinal enteroendocrine L cells and interleukin (IL)-22 production are decreased, altering gut permeability and promoting lipopolysaccharide (LPS) translocation. Serotonin (5-HT) biosynthesis from intestinal enterochromaffin cells is also reduced in the context of MetS due to a decrease in the production of microbiota-derived metabolites inducing the production of host 5-HT.

We have identified in a previous study, in both preclinical and clinical settings, that metabolic disorders are characterised by a reduced capacity of the microbiota to metabolise tryptophan into AhR agonists. Defective activation of the AhR pathway leads to decreased production of GLP-1 and IL-22, which contribute to intestinal permeability and lipopolysaccharide (LPS) translocation, resulting in inflammation, insulin resistance and liver steatosis. In this context, treatment with AhR agonists or administration of *Lactobacillus reuteri*, which naturally produces AhR ligands, can reverse metabolic dysfunction. Similarly, indole prevents LPS-induced alterations of cholesterol metabolism and alleviates liver inflammation in mice. Moreover, exploring human jejunum samples from patients with severe obesity led to the observation that a low AhR tone correlated with a high inflammatory score. Interestingly, the use of the AhR ligand is able to prevent damage to barrier integrity and inflammation in Caco-2/TC7 cells.

We and others also showed strong activation of the kynurenine pathway in metabolic diseases. Genetic or pharmacological approaches inhibiting the activity of indoleamine 2,3-dioxygenase (IDO), the rate-limiting enzyme of the kynurenine pathway, are protective against HFD-induced obesity and metabolic alterations. The mechanism is likely to be mediated by the microbiota and AhR. The increased amount of available tryptophan, due to the inactivation of IDO, can be converted by the microbiota in AhR agonists. Conversely, in obesity, the overactivation of IDO, associated with an increase in plasma levels of downstream metabolites such as kynurenic acid, xanthurenic acid, 3-hydroxykynurenine, 3-hydroxyanthranilic acid and quinolinic acid, decreases the tryptophan pool, which is less available for the production of AhR agonists by the microbiota. The third pathway of tryptophan metabolism, serotonin (5-HT), is also involved, as it affects feeding behaviour and satiety and is thus important for obesity development. The gut microbiota, and primarily indigenous spore-forming bacteria, represent an essential modulator of the intestinal production of 5-HT in enterochromaffin cells that represents >80% of the whole body 5-HT synthesis. These effects are notably mediated by SCFAs and BAs. Mice deficient for the production of peripheral serotonin are protected from HFD-induced obesity. Mechanistically, 5-HT inhibits brown adipose tissue thermogenesis, thus leading to fat accumulation. Human data support these results, as elevated plasma levels of 5-hydroxyindole-3-acetic acid, an end-product of serotonin metabolism, are increased in patients with metabolic disorders.

IMIDAZOLE PROPIONATE

Exploring the interaction between food intake, gut microbiota and derived metabolites might be of interest to discover metabolites impacting metabolic health. As such, it was recently shown that IMP, a metabolite produced by histidine utilisation of gut microbiota, was enhanced in type 2 diabetes and associated with insulin resistance. In the liver, IMP appeared to affect the insulin signalling pathway via mammalian target of rapamycin complex 1 (mTORC1). The examination of IMP in large human cohorts also links it with metabolic health and lifestyle. IMP was elevated in subjects with prediabetes and diabetes in the MetaCardis cohort and in subjects with low bacterial gene richness and Bacteroides 2 enterotype in this cohort. Associations between IMP levels and markers of low-grade inflammation were also identified. Importantly, relationships were observed between serum IMP levels and unhealthy diet measured by dietary quality scores emphasising the importance of nutrition in this context. Thus, this study confirms that in type 2 diabetes, the intestinal microbiota may is switched towards IMP production, which can impact host inflammation and metabolism.

THERAPEUTIC RELEVANCE

The mechanistic links between gut microbiota-derived metabolites and metabolic disorders make these interactions a promising therapeutic target in these complex diseases.

LESSONS FROM FAECAL MICROBIOTA TRANSPLANTATION

FMT is a drastic strategy to modify the gut microbiome. It is highly effective in the treatment of recurring *Clostridioides difficile* infections and has been evaluated in small trials in metabolic syndrome and obesity. The clinical efficacy of this strategy is so far mild, with mostly some positive effects on insulin sensitivity in subgroups of patients. However, these studies had several limitations, including small size and limited duration of intervention. Nevertheless, they provide relevant information to identify the critical molecules involved in biological effects. Following successful FMT, both the microbiota composition and metabolomics, such as BA and SCFA profiles, can be restored. In patients with obesity, FMT can induce engraftment of the butyrate-producing and bile-hydrolysing genus *Faecalibacterium*, leading to a restoration of the BA profile and microbiota BSH activity. FMT increases the relative abundance of SCFA-producing bacteria such as *Roseburia intestinalis* and the protective strain *Akkermansia muciniphila*, with a possible role in the improvement in insulin sensitivity through regulation of GLP-1. *A. muciniphila* supplementation alone improves metabolic parameters in overweight/obese insulin-resistant

volunteers characterised by better insulin sensitivity and a reduction in plasma total cholesterol levels and fat mass. In mice, *A. muciniphila* promotes the production of SCFAs and the restoration of HFD-induced alterations in tryptophan metabolism. These data highlight the key family of microbiota-derived metabolites with potential therapeutic effects.

SYNTHETIC AGONISTS OF BILE ACID RECEPTORS

Given their potential benefits in metabolic diseases, BAs and synthetic FXR and TGR5 agonists are currently under development in the metabolic field. Preclinical trials based on in vitro and in vivo studies identified potent synthetic FXR and TGR5 agonists, which are currently being investigated in phase II or III clinical trials. Due to the regulatory roles of FXR and TGR5 receptors on glucose and lipid metabolism, multiple specific agonists have been designed. Obeticholic acid (OCA), one of the best-characterised FXR agonists, protects the liver from damage in mice with a reduction in hepatic steatosis and inflammation and is currently being evaluated in a phase III trial in patients with NASH. The synthetic FXR agonist GW4064 improves hyperglycaemic and hyperlipidaemia in mice with diabetes and is able to correct BA dysmetabolism and alleviate liver toxicity in rodents with short bowel. The intestine-restricted FXR agonist fexaramine can also promote adipose tissue browning and GLP-1 secretion in wild type (WT) and leptin receptor-deficient diabetic mice. Finally, a TGR5 agonist ameliorated insulin resistance and glucose homeostasis in mice with diabetes by the cyclic AMP/protein kinase A pathway in skeletal muscles.

SHORT-CHAIN FATTY ACID AND BRANCHED-CHAIN AMINO ACID TREATMENT

Dietary supplementation with fermentable fibres, such as inulin in HFD-fed mice or inulin-propionate ester in overweight humans, protects against metabolic disturbances by restoring the gut microbial composition and the action of the IL-22-mediated axis.Oral SCFA treatment in obese mice can modulate lipid synthesis and insulin receptors by upregulating peroxisome proliferator-activated receptor-γ. It also improves intestinal barrier functions with a lower serum LPS concentration. SCFAs exert their beneficial effects partly through specific G-protein-coupled receptors, and their activation by specific agonists is an attractive strategy in the treatment of MetS. GPR40/FFA1, GPR41/FFA3, GPR43/FFA2 and GPR120/FFA4 agonists induce protection against diet-induced obesity in mice through the improvement in insulin, GLP-1 and incretin secretion and anti-inflammatory effects. In addition, a link between dietary BCAAs and energy balance was noted in animals with obesity, and reducing the proportion of dietary BCAAs was associated with a restoration of metabolic health.

CONCLUDING REMARKS

Gut microbiota-derived metabolites have a central role in the physiology and physiopathology of metabolic disorders. The microbial metabolites described above, specifically BAs, SCFAs, BCAAs, TMAO, tryptophan and indole derivatives, are implicated in the pathogenesis of these complex disorders and represent potential biomarkers for the early diagnosis and prognosis of these diseases. Moreover, microbiota-derived metabolites and their host receptors, possibly in combination with dietary intervention, represent promising targets for the development of novel therapeutic tools for metabolic disorders.

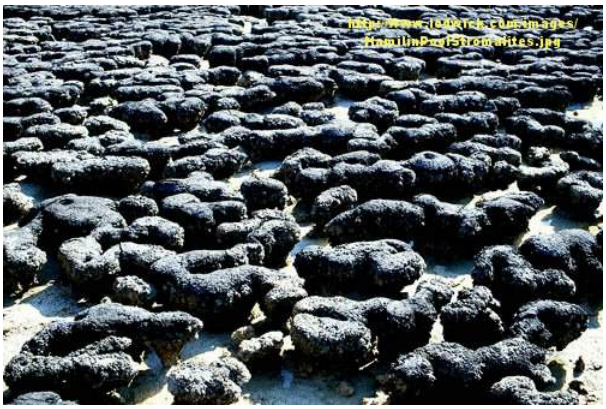
30: Abiotic Origins of Life

30.0.1: The Start of Life

This book began with the notion that understandings derived from the study of simple molecules can be applied to complex biological macromolecules and systems. We developed an understanding of the structural, thermodynamic, and kinetic properties of the "simplest" biomolecules, including single chain amphiphiles like fatty acids, and double chain ones like phospholipids, and how these properties could explain the propensity of these molecules to form complex lipid aggregates (micelles and bilayers). We extended these ideas to the process of protein folding and the assembly of biological complexity. Is there something intrinsic to the property of molecules such that their localization together in the right microenvironment could lead to a "living cell"? How did life originate? That is the topic of this last capstone chapter.

Defining life is actually quite difficult. Here is a list of requirements that seem reasonable, but other have noted that this list would exclude the mule. Life can self-replicate, self-sustain, evolve, respond to environmental changes, and die. The earliest known fossils (stromatolites from cyanobacteria) are approximately 3.5 billion years old.



We have just finished studying the complex interactions involved in cell signaling. How could they have evolved? Consider the central dogma of biology. In the present biological world, proteins (DNA polymerase, RNA polymerase, transcription factors) are necessary for DNA synthesis, replication and gene transcription. But you need DNA to encode the proteins. This "chicken vs egg" dilemma has been addressed when it was realized that RNA can both carry genetic information as well as enzymatic activity (even at the level of the ribosome used for protein synthesis).

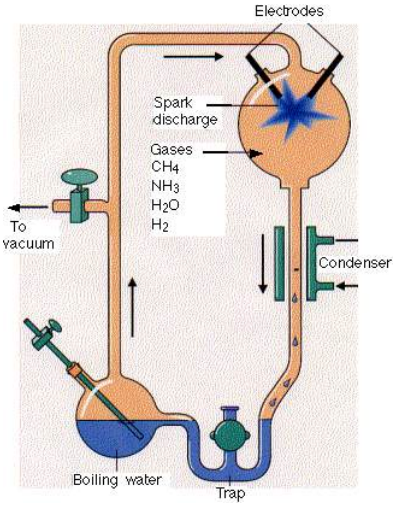
30.0.1: Abiotic Synthesis of Amino Acids and Peptides

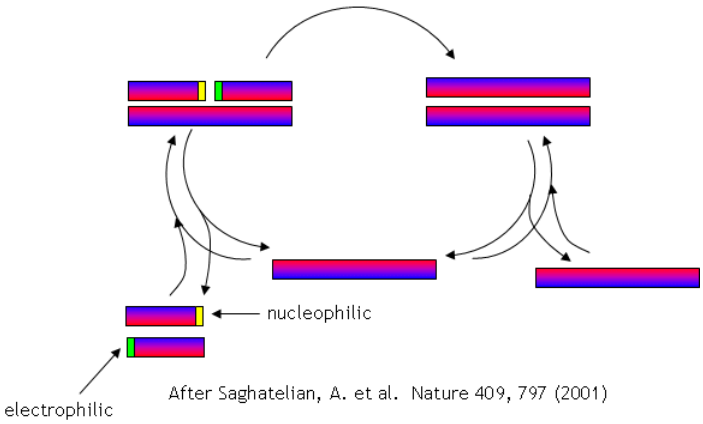
Much work has been done to determine if the building blocks for present biological molecules could have been synthesized early in Earth's history. Amino acids and fatty acids have been found in meteors suggesting the possibility. Earth's early atmosphere would have had little oxygen, so most components should have been reduced. It probably consisted of methane, ammonia, hydrogen and water similar to the atmospheres of other planets in our solar system. The composition of the early atmosphere is still contentious. In 1953 (the same year that Watson and Crick published the structure of double-stranded

DNA), Stanley Miller showed that electric discharges (to simulate lightening) in a reducing atmosphere over a "simulated sea" produced many amino acids. Up to 11 different amino acids have been produced in this fashion along with purines and pyrimidines (these required concentrated reaction mixtures) necessary for nucleic acids. Adenine can be produced just through the reaction of hydrogen cyanide and ammonia in an aqueous solution. Other nucleic acid bases can be made with hydrogen cyanide, cyanogen (C2N2) and cyanoacetylene (HC3N).



http://www.hencoup.com/Photo%20Stanley%20Miller.jpg

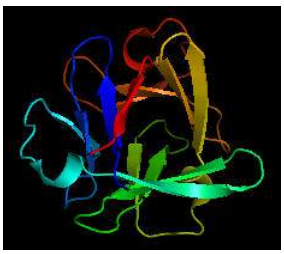
No complex polymers arise through these reactions. However, in 2004, Lehman, Orgel and Ghadiri were able to show that in the presence of carbon disulfide, a gas discharged from volcanoes, homo- and hetero-peptides were produced. Amphiphilic peptides can even catalyze their own formation from peptide fragments, if the fragments are activated. The fragments would bind to the larger "template" peptide through nonpolar actions of the side chains which are oriented along one face of the helical axes. If the fragments bind in a fashion in which the electrophilic end is adjacent to the nucleophilic end of the other peptide fragment, condensation of the two peptide fragments results. The larger template peptide acts as a template (effectively as an "enzyme") in orienting the two fragments for chemical reaction and effectively increasing their local concentration. The reaction of the bound fragments is essentially intramolecular. The reaction even proceeds with amplification of homochirality.



Could the prebiotic amino acids have polymerized into a protein that could fold in a fashion similar to modern proteins? That question has recently been addressed by Longo et al (2013). They asked the question whether the amino acids found in Miller-type prebiotic synthesis mixture and in comets/meteors (Ala, Asp, Glu, Gly, Ile, Leu, Pro, Ser, Thr and Val), a restricted set (10) compared to the present 20 naturally-occurring amino acid, could form a polymer that could fold. Notice that this reduced ensemble of amino acids lacks aromatic and basic amino acids. These proteins would be acidic with a low pI and may have trouble, given the lack of nonpolar aromatic amino acids, in forming a buried hydrophobic core which stabilize proteins. Nevertheless

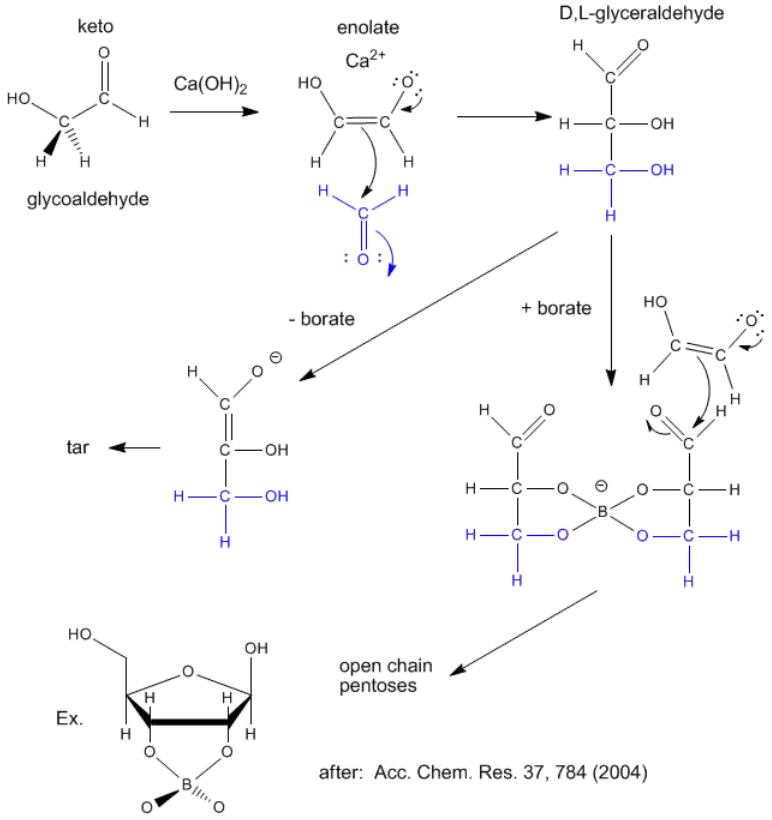
Longo et al were able to synthesize a protein with a slightly expanded set of amino acids (12, including Asn and Gln, with 70% prebiotic amino acids). The structure of one of the proteins, PV2, is shown below. The protein was more stable in 2 M NaCl (compared to 0.1 M) in which it showed a cooperative thermal denaturation with a melting point near 650C using differential scanning calorimetry. The protein had properties similar to those from halophilic organisms that thrive in high salt. These properties include low pIs and high negative charge density, which allows cation-protein interactions in the high salt environment, and lower stability in low salt environments. Earlier oceans were saltier. Halophiles are an example of extremeophiles which are highly represented in archea. Although most halophiles are aerobic, some are anerobic. Perhaps life arose in high salt environments.

Figure: Structure of PV2 protein comprised of a reduced alphabet of mainly prebiotic amino acids.



30.0.1: **Abiotic Synthesis of Sugars**

Sugars are required for present energy production but also as a part of the backbone (ribose, deoxyribose) of present genetic material. Many sugars can be synthesized in prebiotic conditions, using carbon based molecules with oxygen, such as glycoaldehyde and formaldehyde (both found in interstellar gases), as shown in the figure below. Glycoaldehyde was recently found in star forming regions of the Milky Way where planets are likely to form. The presence of borate, which stabilizes vicinal OHs on sugars, is required for the production of sugars instead of tars.



RNA molecules containing sugars such as threose, aldopentopyraonses and hexopyranose can also form stable secondary structures like helices. (Remember, RNA probably preceded DNA as the genetic carrier of information given that is also has enzymatic activity). Is there something special about ribose that made it selected over other sugars for nucleic acids, especially since it is

found in low abundancy in the products in synthesis reactions conducted under prebiotic conditions? One probable reason is it unusually high (compared to other sugars) permeability coefficient through vesicles made of phospholipids or single chain fatty acids, as shown below.

Table 1. Solute permeability coefficients (P_s) across fatty acid and phospholipid membranes

		Membrane composition					
	Solute	Myristoleate*	Palmitoleate*	Oleate*	Oleate†	POPC*	DPPC/C/PA‡

*Experiments performed at 23°C in 1 buffer, 0.5 M solute.
†Conditions as above but with 0.1 M solute.
‡Conditions as above, values are relative initial slopes only (D-xylose set to 1.0).
§Literature P_s values across lecithin membranes: glycerol, 540×10^{-8} cm/s (33); erythritol, 75×10^{-8} cm/s (34); glucose, 0.003×10^{-8} cm/s (35); and fructose, 0.04×10^{-8} cm/s (35).

In general, the greater the number of carbon atoms, the smaller the permeability. However, the table above clearly shows large differences in permeability for sugar isomers with the same number of C atoms, and the difference is not affected by the lipid composition. Ribose has markedly elevated permeability compared to other 5C sugars (as do erythritol and threitol among 4 C sugar alcohols). What is so unique about ribose? 20% of the sugar is in the furanose form. Rate constants for ring opening of furanoses are elevated, suggesting greater flexibility. The α-furanose anomer is amphiphilic in that one face is hydrophobic and the other hydrophilic. All of these may promote ribose permeability.

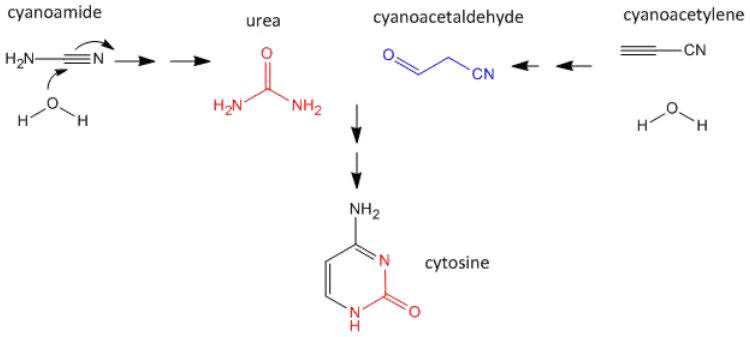
30.0.1: **Abiotic Synthesis of Nucleobases**

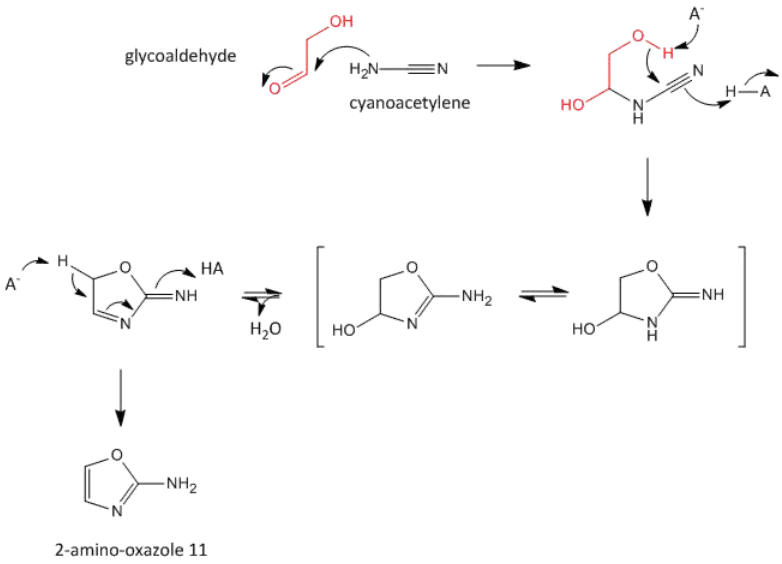
As mentioned above, nucleobases can be made under abiotic conditions with appropriate sources of carbon molecules with nitrogen. These include hydrogen cyanide, cyanoamide (NH2CN) (along with ammonia), hydrogen cyanide, cyanogen (C2N2) and cyanoacetylene (HC3N). Cyanoamide and cyanoacetylene can both react with water to form urea and cyanoacetaldehyde, respectively. The latter two can condense to form cytosine as shown below.

Figure: Abiotic Synthesis of Cytosine



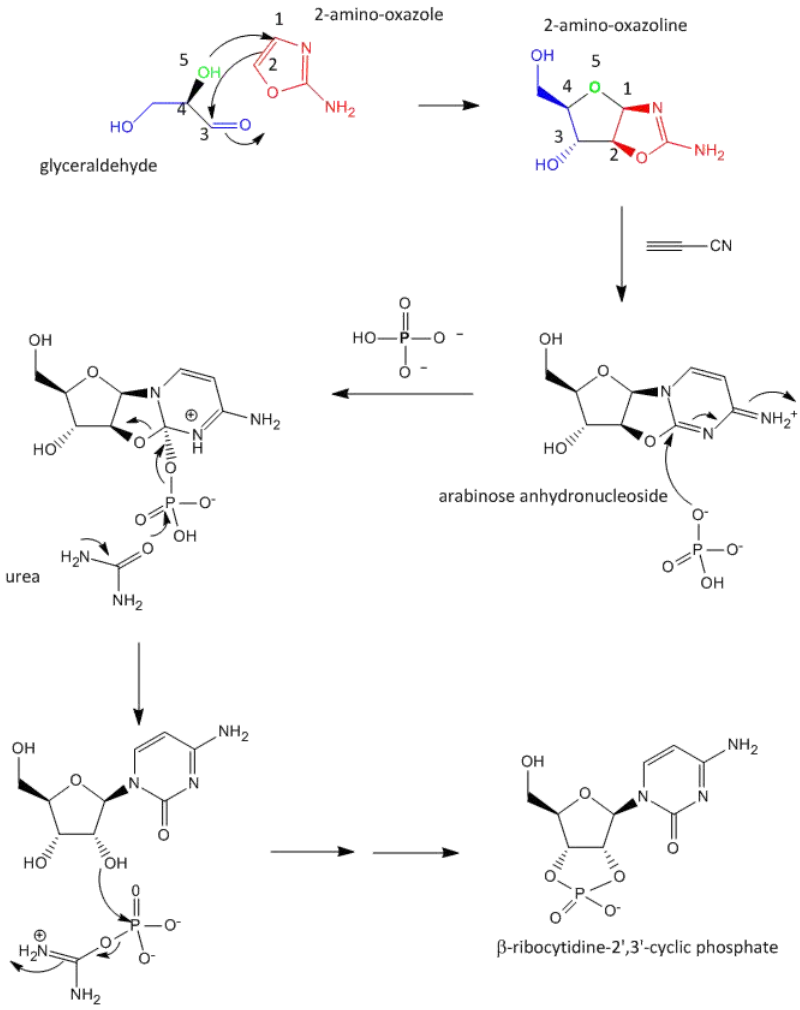
A major problem that has plagued prebiotic researchers is how the product of the carbon-oxygen compound (sugar) links to the product of the carbon-nitrogen compound (nucleobase) to form the nucleoside. Recent research by Powner et al has offered an innovative solution. Instead of forming the sugar and base in separate reaction, and then linking them covalently, the combined molecule could be synthesized in a single set of linked reactions. Inorganic phosphate serves as both a general acid/base catalyst (HA/A- in the figure below) in these new reactions in the formation of an important intermediate, 2-amino-oxazole, and as a nucleophilic catalyst.

Figure: Abiotic Synthesis of 2-amino-oxazole



Glyceraldehyde, 2-amino-oxazole, and inorganic phosphate can react to form a ribocytidine phosphate. Possible reaction mechanisms are shown below.

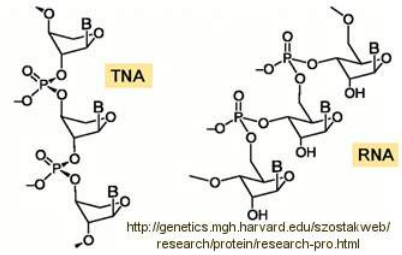
Figure: Abiotic synthesis of a ribocytidine phosphate without condensation of a preformed ribose and cytosine



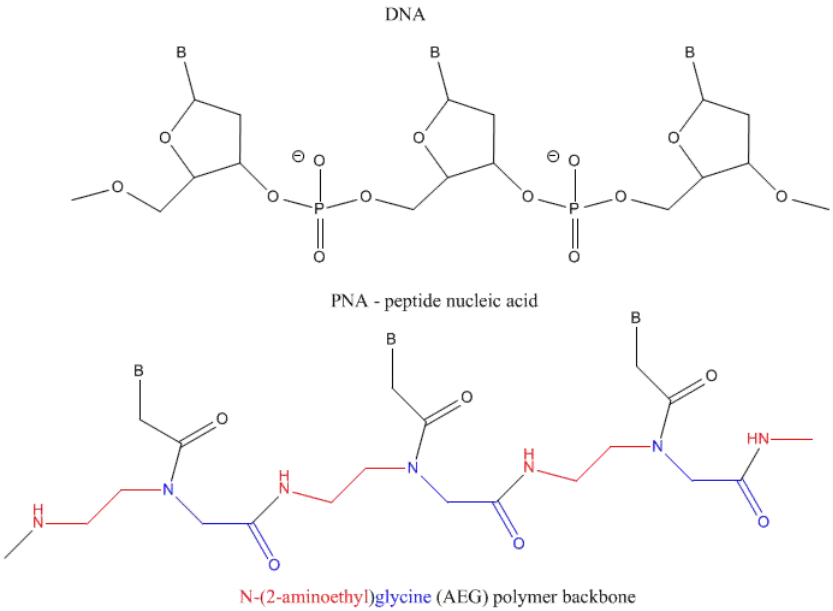
30.0.1: **Abiotic Synthesis of Genetic Polymers**

Abiological synthesis of polymer precursors is a long way from creating genetic polymers like RNA and DNA. These genetic polymers have one property that at first glance seems not conducive to a genetic molecule. Both are polyanions, which must be packed into a cell and folded onto itself to form the classic dsDNA helix and many different RNA structures. This problem is solved to some degree by the presence of counterions that help mask the charge on the negative backbone of the nucleic acids. The presence of phosphate in the phospodiester backbone linkage does confer an important advantage over other possible links (carboxylic acid esters, amides and anhydrides). The electrophilic phosphorous atom is hindered from nucleophilic attack by the negative O attached to the phosphorous. Also, the phosphorous is sp3 hybridized compared to the sp2 hybridization of the electrophilic carbon atom in anhydrides, esters, and amides, and hence is less accessible to nucleophilic attack. Most people now believe that RNA, which can act both as an enzyme and genetic template, preceded DNA as the genetic carrier. The evolution of DNA as the primary genetic carrier required an enzyme to convert ribose to deoxyribose. This would make the nucleic acid less likely to cleave at the phosphodiester bond with the replacement of a nucleophilic 2' OH with an H, and make the genetic molecule more stable. Other types of genetic carriers might have preceded the RNA world, especially if the monomer required could be more readily synthesized from abiological sources. One such alternative are threose nucleic acids (TNA). Synthetics ssTNA can base pair with either RNA, DNA, or itself to form duplexes.

EXTERNAL http://genetics.mgh.harvard.edu/szostakweb/research/protein/research-pro.html



Other possible candidate include peptide nucleic acids (PNA). These can also form double stranded structures with DNA, RNA, or PNA single strands. They were initially designed to bind to dsDNA in the major grove forming a triple-stranded structure. Binding could alter DNA activity, possibly by inhibiting transcription, for example. The structure of a single-stranded PNA is shown. Note that the backbone, a polymer of N-(2-aminoethyl)glycine (AEG) which can be made in prebiotic soups, is not charged, making it easier to bind to dsDNA. AEG polymerizes at 100oC to form the backbone.

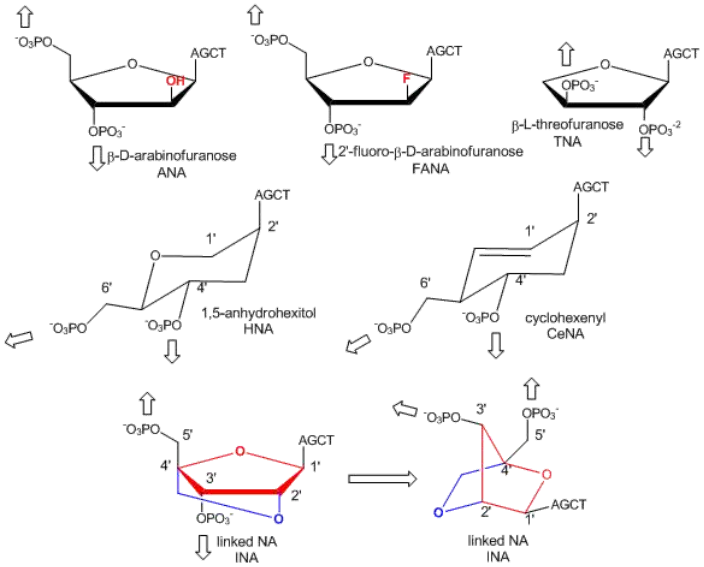


after Gamesh, K. & Nielsen, P. Peptide Nucleic Acids: Analogs and Derivatives. Current Organic Chemistry. 4, 931 (2000)

In addition to changing the backbone, additional bases other than A, C, T, G, and U can be accommodated into dsDNA and ssRNA molecules (Brenner, 2004)

In a recent extension, Pinheiro et al have shown that 6 different foreign backbone architectures can produce xeno-nucleic acids (XNAs) that can be replicated by engineered polymerases which make XNAs from a complementary DNA strand, and a polymerase that can make a complementary copy of DNA from an XNA. XNAs can also be evolved as aptamers to bind specific target molecules. The investigators replaced the deoxyribose and ribose backbone sugar with xenoanalogs (congeners) including 1,5-anhydrohexitol (HNAs), cyclohexene (CeNA), 2'-O,4'-C-methylene-b-D ribose (locked nucleic acids - LNA), L-arabinose (LNA), 2'-fluoro-L-arabinose (FANAs) and threose (TNAs) as shown in the figure below.

Figure: Xeno-nucleic acid sugar congeners

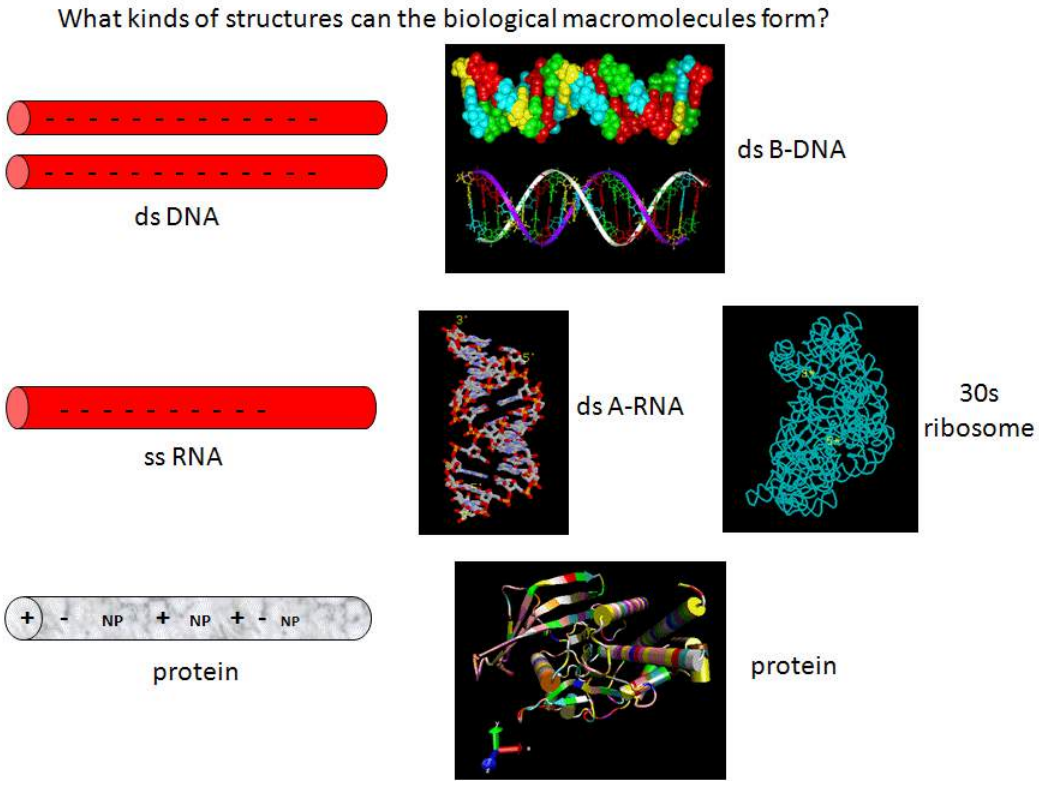


Polymers of these XNA can bind to complementary RNA and DNA and as such act as nuclease-resistant inhibitors of translation and transcription.

Von Kiedrowski, in an experiment similar to the self-replication of peptides described above, has shown that a single stranded 14 mer DNA strand, when immobilized on a surface, can serve as a template for the binding of complementary 7 mers and their conversion to 14 mers. When released by base, this process can occur with exponential growth of the complementary 14 mers. (von Kiedrowski Nature, 396, Nov 1998). Ferris has shown that if the clay montmorillonite is added to an aqueous solution of diadensosine pyrophosphate, polymerization occurs to produce 10 mers which are 85% linked in a 5' to 3' direction.

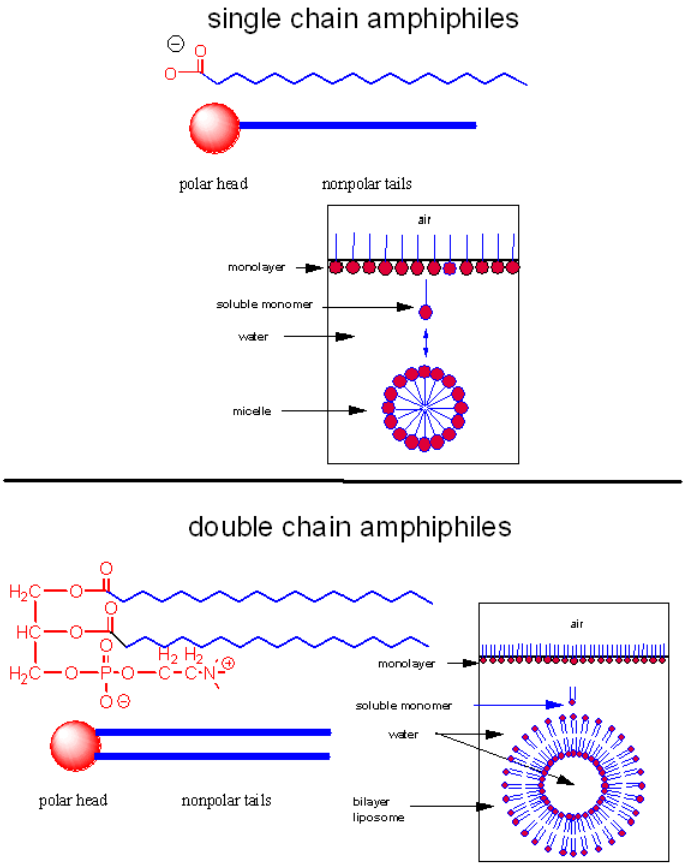
Polyanions as Carriers of Genetic Information

There are other reasons why polyanions are useful genetic molecules, other than their resistance to nucleophilic attack. The biological form of DNA is a large double stranded polyanionic polymer, in contrast to RNA which is a single-stranded polyanion polymer and protein which are polymers with varying combination of anionic, cationic, and hydrophobic properties. Even with counterions, it would be difficult to fold DNA into complicated and compact 3D structures as occurs for proteins, given the large electrostatic repulsions among the charged phosphates. Rather it forms a elongated double stranded rod, not unlike the rod-like structure of proteins denatured with sodium dodecyl sulfate (used in SDS PAGE gels). The elonged rod-shaped structure of ds-DNA is critical for the molecule which is the main carrier of our genetic information since mutations in the bases (leading to a switch in base pairs) causes no change in the overall structure of dsDNA. This enables evolutionary changes in the genetic material to produce new functionalities. A single change an amino acid of a protein, however, can cause a large change in the structure of a whole protein, a feature unacceptable for a carrier of genetic information. RNA structure effectively lies between that of DNA and proteins. Since it has less charge density than dsDNA, it can actually form dsRNA helices, so it can carry genetic information, as well as form complex 3D shapes necessary for its activity as an ribozyme. Perhaps more importantly, steric interference prevents ribose in RNA from adopting the 2'endo conformation, and allows only the 3'endo form, precluding the occurrences of extended ds-B-RNA helices.

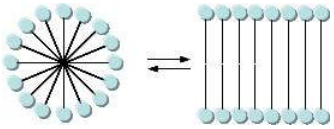


30.0.1: **The Lipid World**

Let's assume that abiological precursors would react to form polymer-like molecules that might be complex enough to fold to structures that would allow binding, catalysis, and rudimentary replication. All this would be worthless unless they could be sequestered in a small volume which would limit diffusion and increase their local concentration. What is required is a membrane structure. Amphiphilic molecules, like lipids, with which we started this book, would be prime candidates since they spontaneously assembly to form micelles and bilayers, as shown in the review diagram below.



As mentioned in Chapter 1, alternative lipid phases are possible. Bilayers can also be formed from single chain amphiphiles, such as certain fatty acids, as illustrated in the equilibrium shown below. This occurs more readily at pH values close to the the pKa of the fatty acid, at which the fatty acids are not all deprotonated with full maximal negative charges. Single chain amphiphiles like fatty acids, which were more likely to formed in abiotic conditions, have been found in meteorites.



Clay surfaces, which have been shown to facilitate the formation of nucleic acids polymers, can also promote the conversion of fatty acid micelles to bilayers (Szostak). One such clay surface, montmorillonite, whose structure is shown below, promotes bilayer formation. It has an empirical formula of $Na_{0.2}Ca_{0.1}Al_2Si_4O_{10}(OH)_2(H_2O)_{10}$.

EXTERNAL Chime Molecule Modeling: montmorillonite EXTERNAL: montmorillonite

The effect of montmorillonite on vesicle formation can be shown by simple measurements of turbidity with time. Microscopy of fluorophore-encapsulated vesicles also shows encapsulated montmorillonite. The fatty acids presumably absorb to the cation layer of the clay particles. Time studies using light scattering also indicate that the vesicles grow in the presence of fatty acid micelles. To differentiate between the formation of new vesicles and the increase in size of pre-existing vesicles (which couldn't be done by simple light scattering without separation of the vesicles), investigators used two different fluorescent molecules to label fatty acid vesicles. The two probes were selected such that if the two probes came in close contact, energy transfer from the excited state of one fluorophore to the other fluorophore could occur, an example of fluorescence resonance energy transfer (FRET). FRET is observed when emission of the second dye occurs after excitation of the first dye, at a wavelength outside of the excitation

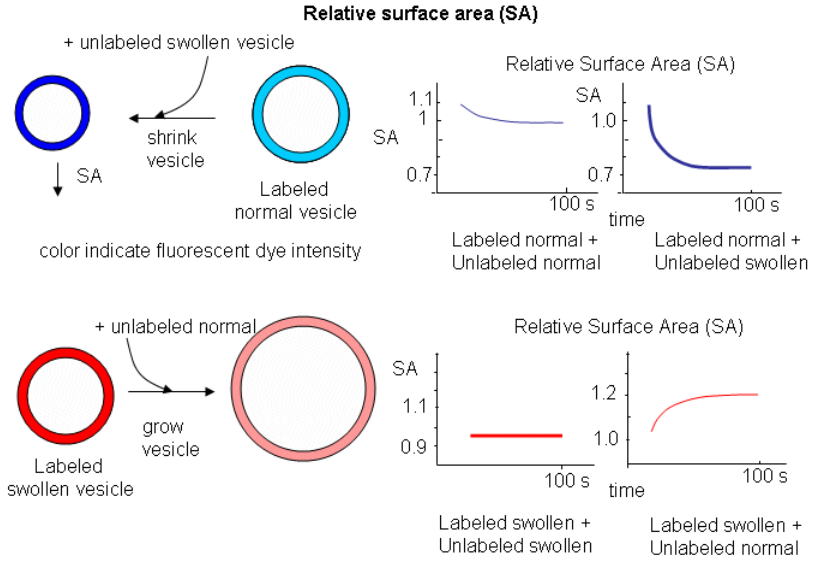
wavelength of the second dye. If unlabeled vesicles were added to either labeled vesicles, no changes in FRET were observed, suggesting that the dyes did not move between vesicles. If fatty acid micelles were added, a decrease in FRET was observed, suggesting that new fatty acids were transferred to the doubly-labeled vesicles, effectively diluting the dye concentrations in the bilayer and their relative proximity, both which would decrease FRET. Most of the new fatty acid was incorporated into pre-existing vesicles which grew. The vesicles could also divide if extruded through a small pore. Later we will see that the energy to grow the vesicles can derive in part from a transmembrane proton concentration collapse. Division of vesicles might be promoted by bilayer assymetries associated with addition of substances to the outer leaflet, causing membrane distortion.

30.0.1: **Protocells**

At some point, early genetic material must have been encapsulated in a membranous vesicles. Would new properties emerge from this mixture that might have a competitive (evolutionary) advantage over either component alone, and thus be a step on the way to the formation of a "living" cell? The answer appears to be yes. Chen et al. have incorporated RNA into fatty acid vesicles with interest effects. They asked the question as whether those vesicles could grow at the expense of vesicles without encapsulated RNA. RNA, with a high charge density and its associated counter ions would create osmotic stress on the vesicles membranes. To relieve that stress they could acquire fatty acids from other fatty acid vesicles (or fatty acid micelles), increasing their surface area, and concomitantly reducing tension in the membrane.

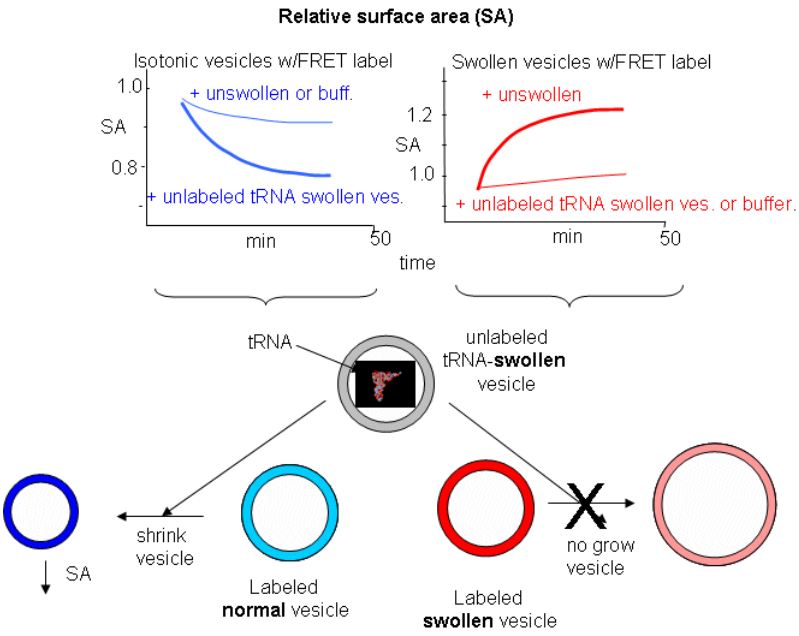
Oleic acids vesicles were first placed under stress by encapsulating 1 M sucrose in the vesicle and then diluting it in hypotonic media. Water would enter and swell the vesicle (but without bursting and resealing, as evident from control experiments). Then they prepared stressed and unstressed oleic acid vesicles in the presence of two nonpolar flurophores, NBD-PE (excitation at 430 nm, emission at 530 nm) and Rh-DHPE (emission at 586 nm). These fluorophores were chosen for fluorescence resonance energy transfer measurements. If the membrane vesicles changed size, the FRET signal would change, based on the relative concentration and proximity of the dual fluorophores. If the separation between probe molecules increased, the FRET signal would decrease. Conversely, if the vesicle shrunk, the FRET signal would increase.

The results showing the effect of adding unlabeled swollen vesicles to labeled normal vesicles, and labeled swollen vesicles to unlabeled normal are shown below. The surface area of normal labeled vesicles decreased by about 25% when unlabeled swollen vesicles were added, but not when unlabeled normal vesicles were added. Labeled swollen vesicles increased 25% in size only if mixed with unlabeled normal vesicles, not with unlabeled swollen vesicles. Hence swollen vesicles win the competition and "steal" lipid from normal vesicles.



After Chen et al. Science 305, 1474 (2004)

Now what about vesicles swollen with encapsulated RNA? RNA, with its associated charge and charged counter ions also placed an osmotic stress on the vesicles. FRET labels (the two fluorophores) were place in vesicles without RNA. Fatty acids were removed from isotonic labeled vesicles in the presence of unlabeled tRNA swollen vesicles (left panel below). Labeled vesicles swollen with glycerol took fatty acids from unswollen vesicles (without tRNA), but not from tRNA swollen vesicles, as both were swollen so no net drive to reduce swelling by lipid exchange was present.

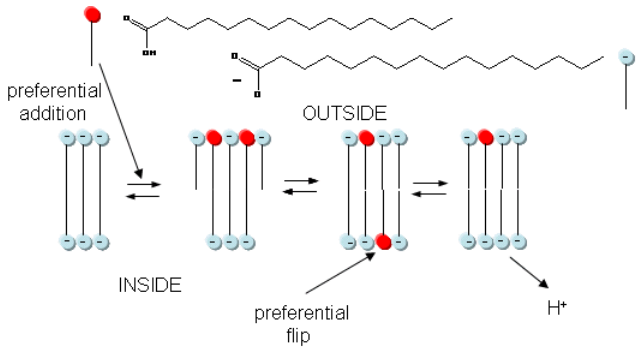


After Chen et al. Science 305, 1474 (2004)

These results show the vesicles with encapsulated RNA have a competitive (evolutionary) advantage over normal vesicles. This data suggests that having a polyanion as the source of genetic material is actually advantageous to the protocell. In addition the move in modern membranes to phospholipids with esterified fatty acids (instead of free ones) may actually have stabilized membranes, given the movement of free fatty acids to different membranes.

30.0.1: Energy Transduction in Protocells

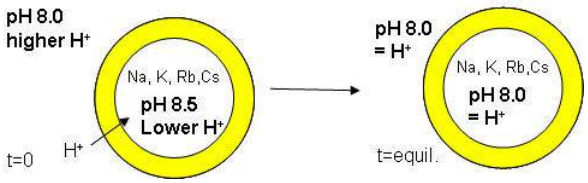
In addition to a genetic macromolecule and a semipermeable membrane, a source of energy to drive intracellular processes must be present. A common source of free energy used in many cells to drive unfavorable processes is a proton gradient, whose formation in modern cells can be coupled to energy input from oxidation, ATP cleavage, light, or the collapse of another gradient. Could a proton gradient be formed in protocells? It can, quite easily, when coupled to the growth of fatty acid vesicles. If a fatty acid vesicle is to grow, more fatty acid must be added to the outer leaflet. The protonated, uncharged form of the fatty acid would preferentially be added, since it would lead to less electrostatic repulsion between adjacent head groups. The protonated, uncharged form of the fatty acid would also be most likely to flip to the inner leaflet to minimize stress asymmetries in the leaflets. Once in the inner leaflet, it could deprotonate to form H+(aq) in the inside of the membrane, creating a transmembrane proton gradient and transmembrane potential. The energy released on growth of the membrane is partly captured in the formation of a proton gradient, as shown in the figure below.



Generation of proton gradient on growth of fatty acid vesicle

The proton gradient would soon inhibit its own formation since further movement of protons into the cell would be attenuated by the positive transmembrane potential unless metal ions inside moved outside. In addition, the gradient would collapse after growth stopped. The investigators made fatty acids vesicles in the presence of pH 8.5 buffers whose pH was adjusted with an alkali metal

hydroxide. The external pH was reduced to 8.0, resulting in a 0.5 pH unit proton concentration gradient. (Changes in intravesicular pH were measured with pH-sensitive fluorophore, HPTS.) Inward movement of protons down a concentration gradient, as shown in the figure below, would occur with time, collapsing the imposed concentration gradient.



With fatty acid vesicles, this artificial pH gradient collapsed quickly, suggesting the vesicle permeability to protons was high. The rate was too high for simple flip-flop diffusion. Inward movement of protons appeared to be facilitated by outward movement of the M+ ions. The rate of decay of the proton gradient was exponential, and the resulting first order rate constant was easily determined. A graph of the rate constant for pH gradient collapse vs unsolvated ionic radius of M+ decreased with increasing radius (i.e. kNa > kK > KRb > KCs, suggesting that the pH gradient would be more stable if large, impermeable or otherwise trapped cations were encapsulated. When vesicles were made with encapsulated Arg+, the imposed pH gradient did not collapse for hours. If oleic acid micelles were added to oleic acid vesicles with encapsulated Arg+, with no artificial pH gradient induced across the membrane, the vesicle grew with concomitant movement of protons into the vesicle, producing a pH gradient of 0.3 within seconds.

These experiments show that membrane growth and energy storage could be coupled, and the right composition of encapsulated material could lead to a stable transmembrane pH gradient, a source of energy to drive biological processes. It even suggests that a charge polyanion would be beneficial as a genetic carrier.

30.0.1: Hydrothermal Vents or Primordial Soup

The case for the origin of life in deep sea hydrothermal vents and not in a primordial "Campbell's" soup has been argued convincingly by Lane et al (2010). What's needed for life are reasonably complex molecules and an energy source to drive unfavorable reactions. It's the latter on which that Lane et al focus. In an early primordial world that was low in oxygen, exergonic oxidation reaction of organic molecules would provide little energy. This can be surmised from the low energy yield (compared to aerobic respiration) achieved in present day glycolytic (fermentative) pathways from all major domains of life, archaea, bacteria, and eukaryotes.

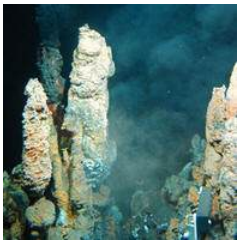
> Background: Based on rRNA sequences, a primordial cell evolved into two different types of cells, one that became bacteria, and another that split further into archaea (single cells, similar to bacteria) and eukaryotic cells (complex cells with internal organelles that eventually formed multicellular organisms). Bacterial and archaea are collected called prokaryotic cells.

In addition, these pathways required the evolution of up to dozen different enzymes to produce their relatively meager energy yield which ultimately depends on the oxidation of an organic molecule by another organic molecule instead of by a powerful oxidant like dioxygen. An anisotropic arrangement of molecules in a concentrated soup could lead to transient chemical potential fluctuations but these would be inefficient and impermanent sources of energy. Effectively the primordial soup would be at equilibrium and hardly expected to provide the energy for synthesis of RNA enzymes and replicators. UV light leads to photo-damage and photolysis not replication of complex molecules. What is needed is a way to drive the synthesis of molecule with high chemical potential energy (like sulfur esters and phosphoanhydrides) compared to their lytic products. These could then provide an energy sources to drive ATP synthesis, for example.

A detailed look a the bioworld shows that the earliest organisms used energy from the collapse of the proton gradient (chemisomotic principle elucidated by Peter Mitchell). All present autotrophs (organisms that can fix CO2 and form complex organic molecules) and many heterotrophs (use complex organic molecules of other organisms for fuel) use redox complexes in membranes coupled to membrane gradients. These complexes would take reduced molecules and pass electrons from them to oxidizing agents (electron acceptors), including O2, CO2, and Fe3+ to form H2O, CH4, and Fe2+. Fermentors also use ATPase membrane enzymes to transport nutrients. Yet genomic analysis of bacteria and archaea show that enzymes involved in fermentation differ significantly, suggesting that they evolved separately towards a convergent function. Structure in common include DNA, RNA, ribosomes and membrane ATPases, which Lane et al suggest were in a the Last Universal Common Cell (LUCA).

All autotrophs produce their energy source by fixing CO2 using either H2 directly or indirectly using H2O and H2S. All of the are available in nonhydrothermal deep sea vents. Volcanic vents, however, are extremely hot (not optimal for organic molecule synthesis), very acidic, and lack hydrogen gas. A different type of nonvolcanic vent, an alkaline hydrothermal one, might produce more conducive as a site of the origin of life. In these vents, water chemically reacts with minerals in the crust (such as olivine) leading to their hydroxylation and subsequent fracture, with promotes more water entry into the crust. It has been reported that there is more water found as hydroxylated minerals in the crust, that there is liquid water in the oceans. These processes result in temperatures up to 200 degrees Celsius and release of hydrogen gas into a moderately alkaline vents into the sea water at temperatures more conducive (70 degrees C) to the origin of life.

Figure: Alkaline Vent



30.0.1: Fixing CO_2

Of the five different pathways known to fix CO2, all require ATP except one. That one is present in both methanogen, which produce methane from CO2 and H2 and in the acetogens, which produce acetate (CH3CO2-) in the form of acetylCoA. The simpler reactions of forming acetic acid and methane are shown below:

2CO2 + 4H2 --> CH3CO2H + 2H2O.

CO2 + 4H2 --> CH4 + 2H2O.

The DG0 values for these reaction (calculated using DG0f for gas phase H2, CO2 and CH4 and liquid acetic acid and water are -75 and -131 kJ, respectively, at 250C, showing that they are thermodynamically favored. Making AcetylCoA, a "high" energy molecule compared to its hydrolysis products (as is ATP) from acetic acid and CoASH, a would require energy input. A proton gradient is the likely source.

Some bacteria and Achaea cells (primordial or present) use the reductive acetylCoA pathway, also known as the Wood-Ljungdahl pathway, to form, in a noncyclic process, acetyl CoA from CO2 and at the same time makes ATP. This process is paid for by a proton gradient. This has been described by Shock as "a free lunch you get paid to eat". The energetics of the present acetyl CoA pathway based on the overall reaction below show an approximate DG0 value of -59 kJ/mol which can drive ATP synthesis.

2CO2 + 4H2 + CoASH --> CH3COSCoA + 3H2O.

The concentration of carbon dioxide in the primordial ocean was 1000 times higher than now. Vents produced large amounts of methane and hydrogen gas. There was little oxygen and hence lots of Fe2+. The enzymes involved in this acetyl-CoA pathway of carbon fixation have FeS clusters. It has also been shown that bubbles (which are really membrane bound spaces) of FeS and NiS can be made in deep sea vents. These could not only encapsulate precursor molecules but also serve as catalysts. Vents also can catalyze the fixation of nitrogen (to ammonia) and laboratory studied show that FeS can catalyze the conversion of formate (found in vents) into pyrimidines and purines. The studies of present methanogens and vent chemistry suggest that the critical ingredients and conditions for development of the first biological cells probably occurred in the vents.

To produce polymers, an energy source and monomers must exists. Concentration gradients found in simulations of vents produce million fold concentrated molecules. The transient heating and cooling of any double-stranded nucleic acids could lead to concentration amplification by a PCR like strand separation followed by reannealing. In addition, these vent regions possess a powerful, reoccurring energy source, a pH gradient, as the alkaline vented material entered the acidic oceans that exists with high CO2 concentrations, creating a gradient across an inorganic membrane. This is startlingly analogous to the pH gradient across membranes (acidic outside, alkaline inside) driven by the membrane complexes in the mitochondria and bacteria. Lane et al argue that the existence of membrane proton gradients as an energy source in all cells (eukaryotes, bacteria, and archaea) and in chloroplasts, mitochondria, corroborate their hypothesis. Bacteria and archaea share homologous ATPases and electron carriers (ferredoxins, quinones, and cytochromes). These similarities contrast to the differences in enzyme structures in fermentative pathways. Arguments that proton pumps evolved to pump proteins (and reduce pH gradients) can't explain their ubiquitous

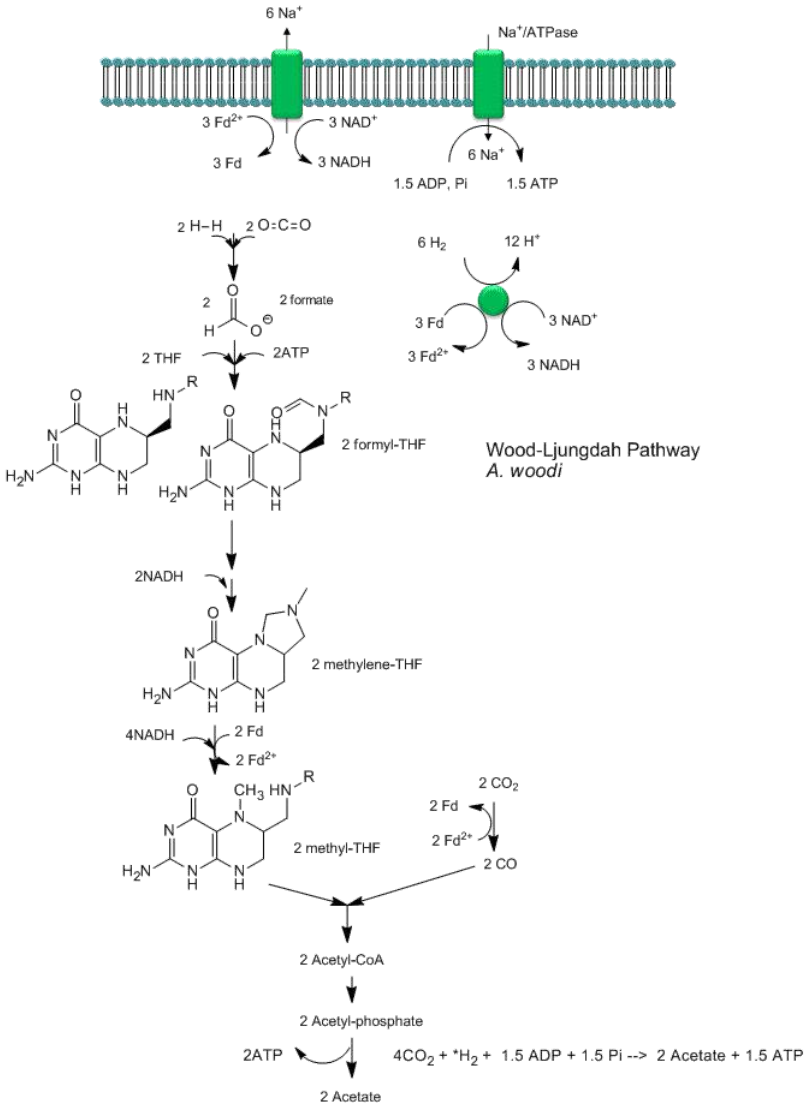
presence even in organisms not subjected to low pH. Hence the ubiquity of proton pumps supports the conjecture that they arose from the first protocells, possible comprised of inorganic walls and ultimately with amphiphilic molecules synthesized from precursors.

Creationists would argue that it would be impossible to evolve a structure with the complexity of membrane ATPase (which serve to collapse a pH gradient as the power the synthesis of molecules with large negative DG0 of hydrolysis). Lane et al propose that the earliest cells evolved ATPase like molecules in alkaline vents where pH gradients analogous to those in cells today arose. They envision cell-like columns lined by FeS membrane like structure with alkaline conditions inside and acid conditions outside. Nonpolar or amphiphilic molecule would line the inside of the cells/columns. A ATPase-like system could then take advantage of the pH gradient which constantly replenishes itself. If structures as complicated as ribosomes evolved from a subsequent RNA world, surely ATPase-like molecules could also. Other chemistry might have evolved earlier to utilize the energy source provided by the pH gradient.

If life originated in the vents, it would need an energy source to leave the vents. Presumably it would have evolved one to utilized pH gradient to replace the one it left in the alkaline vents. The substrate level phosphorylation of glycolysis that requires ATP input to make ATP would not provide the energy source needed. Cells that left would have had to produce their own proton gradient. Perhaps all the was needed initially was concerted conformational changes in proteins that upon exposure of a different pH changed their shape inducing pKa shifts in adjacent proton donors/acceptors leading to vectorial discharge of protons across a membrane. Perhaps the method described above in protocells was sufficient.

Recent analyses by Poehlein et a show that CO2 reduction (fixation) can be coupled to the production of a sodium ion gradient, which could collapse to drive ATP synthesis. Analysis of the genome of a gram positive bacteria, Acetobacterium woodii, an acetogen, shows the it has an ancient pathway for production of acetyl-CoA that can, in an anabolic fashion form biomass or in a catabolic fashion be cleaved to acetate with the production of ATP. It does not require classic electron carriers like ubiquinone or cytochrome C linked to protein gradient formation to drive ATP synthesis. Rather it has only a ferredoxin:NAD+ oxioreductase which couples oxidation to the formation of a sodium ion gradient, which collapses through an sodium ion transporter/ATP synthase to drive ATP synthase. A plausible reaction scheme based on genomic analysis is shown below:

Figure: Acetyl-CoA Synthase and Acetogenesis



30.0.1: **The Role of Fe/S Center**

Let's return to the chicken and egg dilemma one more time. What is needed for biological polymer formation are monomeric precursors, an energy source, and a way to compartmentalized them all. We discuss how monomeric precursors could form, but wouldn't it be far better if even the synthesis of precursors could be catalyzed? One source of catalysis mostly absent from the "bioorganic" abiotic chemistry in the above discussion is the transition metals. Transition metals can form complexes. Ligands containing lone pairs on O, N, and S atoms can donate them to transition metals ions, which can hold up to 18 electrons in s, p, and d orbitals. Hence as many as 9 lone pairs on ligand molecules (which are often multidentate) could be accommodated around the transition metal ion. Many present small molecule metabolites and their abiotic precursors (H2O, CO, CO2, NH3 and thiols) bind cations as mono- or polydentate donors of electrons. Hence transition metal ions would have a thermodynamic tendencies to be bound in complexes.

Bound ligands that contain potentially ionizable hydrogens could become deprotonated and made better nucleophiles for reactions. Hence the transition state metal ion, acting with the complex, becomes a catalyst as it decreases the pKa of a bound ligand (such as water). In addition, since transition metals ions can have multiple charge and oxidation states, they can easily act as redox centers in the oxidation/reduction of bound ligands that were redox active. Given the relative anoxic conditions of the early oceans, Fe2+ would predominant. It could easily be oxidized to Fe3+ as it reduced a bound ligand. Highly charged transition states would withdraw electron density from bound ligands leading to their possible oxidation.

Metals obviously still play a strong role in catalysis, both indirectly in promoting correct protein folding and directly in stabilizing charge in both the transition state and intermediates in chemical reaction pathways. FeS clusters are of significant importance.

Their biosynthesis involves removal by an active site Cys in a desulfurase enzyme of a sulfur from a free amino acid Cys followed by its transfer to an Fe in a growing FeS cluster in a FeS scaffold protein, which then transfers the cluster to an acceptor protein where it acts as a cofactor. FeS clusters can adopt a variety of stoichiometries and shapes, as well as redox states for the participating Fe ions. The continuing importance of FeS clusters in all cells, their involvement in not only redox enzymes in which electron transfer is facilitated by delocalization of electrons over both Fe and S centers, but also in coupled electron/proton transport in mitochondrial electron transport, Fe storage (ferrodoxins), and in regulation of enzyme activity and gene expression, suggests that they were of primordial importance in the evolution of life. T

hey are often found at substrate binding sites of FeS enzymes involved in both redox and nonredox catalysis. A ligand can bind to a particular Fe in the cluster, activating it for hydration or dehydrogenation reactions. Fe 4 of the FeS cluster in the TCA enzyme aconitase can have a coordination numbers of 4, 5, or 6 as it binds water, hydroxide or substrate. It acts to both decrease electron density in the transition state and to change the pKa of bound water as the enzyme catalyzes an isomerization of tricarboxylic acids (citric and isocitric acid) through an elimination/addition reaction with water. In another example it can bind S-adenosylmethionine through its amine and carboxylate groups, which activates the molecule for cleavage and radical formation. In some cases metals other than Fe (Ni for example) are incorporated into the cluster. FeS effects on transcription factors involves facilitation of optimal structure for DNA binding. FeS and FeNi centers in proteins are similar in structure tp FeS units in minerals like greigite and presumably to FeS structure formed when H2S and S2- react with Fe2+ (present in abundance in the early ocean) and other metals in vents Metal sulfides participate in reduction of both CO and CO2. For example the synthesis of CH3SH from CO2 and H2S is catalyzed by "inorganic" FeS.

30.0.1: **The Minimal Genome**

This question is being addressed by eliminating "unnecessary" gene from simple bacteria. Cells placed in a rich nutrient broth with essential lipids, vitamins, and amino acids would need fewer genes than those placed in a more nutrient-poor medium. Bacteria cells like Mycoplasma genetalium, that live within "nutrient rich" eukaryotic cell, have been genetically manipulated to delete unnecessary genes. Based on knockout studies, it may be possible for the cell to survive with only 300-350 genes. Bacillus subtilis has approximately 4100 genes. Estimates have been made that it could survive with as few as 271 genes.

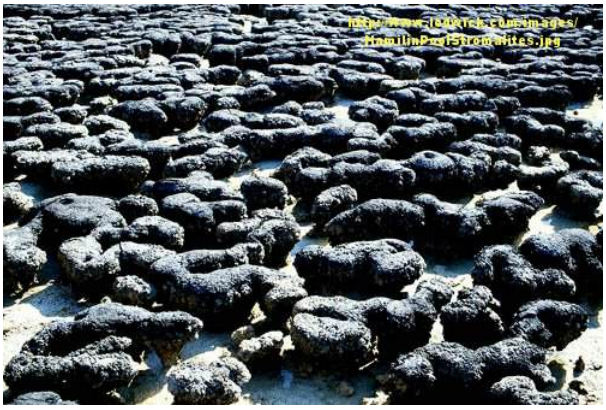
30.1: Abiotic Origins of Life

"Ugly giant bags of mostly water" -
The crystal life form describing humans on Star Trek Next Generation, Home Soil Episode.

30.1.0.1: **The Start of Life**

This book began with the notion that understandings derived from the study of simple molecules can be applied to complex biological macromolecules and systems. We developed an understanding of the structural, thermodynamic, and kinetic properties of the "simplest" biomolecules, including single chain amphiphiles like fatty acids, and double chain ones like phospholipids, and how these properties could explain the propensity of these molecules to form complex lipid aggregates (micelles and bilayers). We extended these ideas to the process of protein folding and the assembly of biological complexity. Is there something intrinsic to the property of molecules such that their localization together in the right microenvironment could lead to a "living cell"? How did life originate? That is the topic of this last capstone chapter.

Defining life is actually quite difficult. Here is a list of requirements that seem reasonable, but other have noted that this list would exclude the mule. Life can self-replicate, self-sustain, evolve, respond to environmental changes, and die. The earliest known fossils (stromatolites from cyanobacteria) are approximately 3.5 billion years old.



We have just finished studying the complex interactions involved in cell signaling. How could they have evolved? Consider the central dogma of biology. In the present biological world, proteins (DNA polymerase, RNA polymerase, transcription factors) are necessary for DNA synthesis, replication and gene transcription. But you need DNA to encode the proteins. This "chicken vs egg" dilemma has been addressed when it was realized that RNA can both carry genetic information as well as enzymatic activity (even at the level of the ribosome used for protein synthesis).

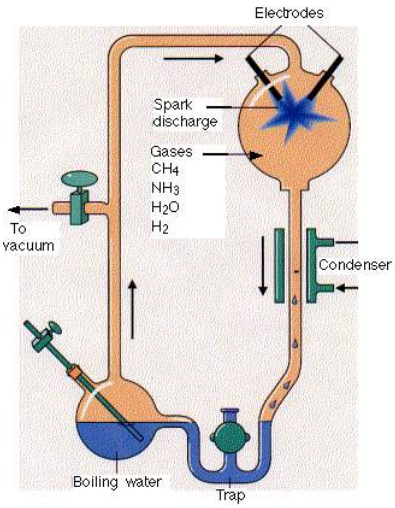
30.1.0.1: Abiotic Synthesis of Amino Acids and Peptides

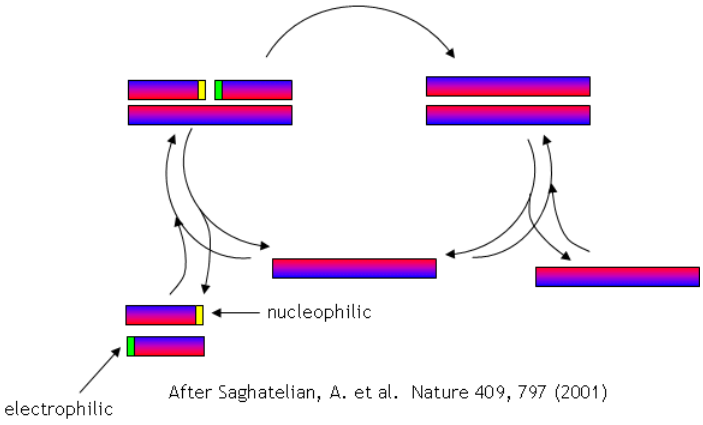
Much work has been done to determine if the building blocks for present biological molecules could have been synthesized early in Earth's history. Amino acids and fatty acids have been found in meteors suggesting the possibility. Earth's early atmosphere would have had little oxygen, so most components should have been reduced. It probably consisted of methane, ammonia, hydrogen and water similar to the

atmospheres of other planets in our solar system. The composition of the early atmosphere is still contentious. In 1953 (the same year that Watson and Crick published the structure of double-stranded DNA), Stanley Miller showed that electric discharges (to simulate lightening) in a reducing atmosphere over a "simulated sea" produced many amino acids. Up to 11 different amino acids have been produced in this fashion along with purines and pyrimidines (these required concentrated reaction mixtures) necessary for nucleic acids. Adenine can be produced just through the reaction of hydrogen cyanide and ammonia in an aqueous solution. Other nucleic acid bases can be made with hydrogen cyanide, cyanogen (C2N2) and cyanoacetylene (HC3N).



http://www.hencoup.com/Photo%20Stanley%20Miller.jpg

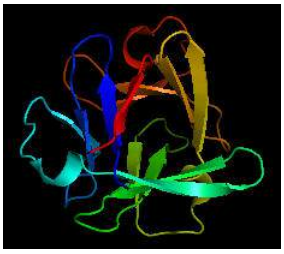
No complex polymers arise through these reactions. However, in 2004, Lehman, Orgel and Ghadiri were able to show that in the presence of carbon disulfide, a gas discharged from volcanoes, homo- and hetero-peptides were produced. Amphiphilic peptides can even catalyze their own formation from peptide fragments, if the fragments are activated. The fragments would bind to the larger "template" peptide through nonpolar actions of the side chains which are oriented along one face of the helical axes. If the fragments bind in a fashion in which the electrophilic end is adjacent to the nucleophilic end of the other peptide fragment, condensation of the two peptide fragments results. The larger template peptide acts as a template (effectively as an "enzyme") in orienting the two fragments for chemical reaction and effectively increasing their local concentration. The reaction of the bound fragments is essentially intramolecular. The reaction even proceeds with amplification of homochirality.



Could the prebiotic amino acids have polymerized into a protein that could fold in a fashion similar to modern proteins? That question has recently been addressed by Longo et al (2013). They asked the question whether the amino acids found in Miller-type prebiotic synthesis mixture and in comets/meteors (Ala, Asp, Glu, Gly, Ile, Leu, Pro, Ser, Thr and Val), a restricted set (10)

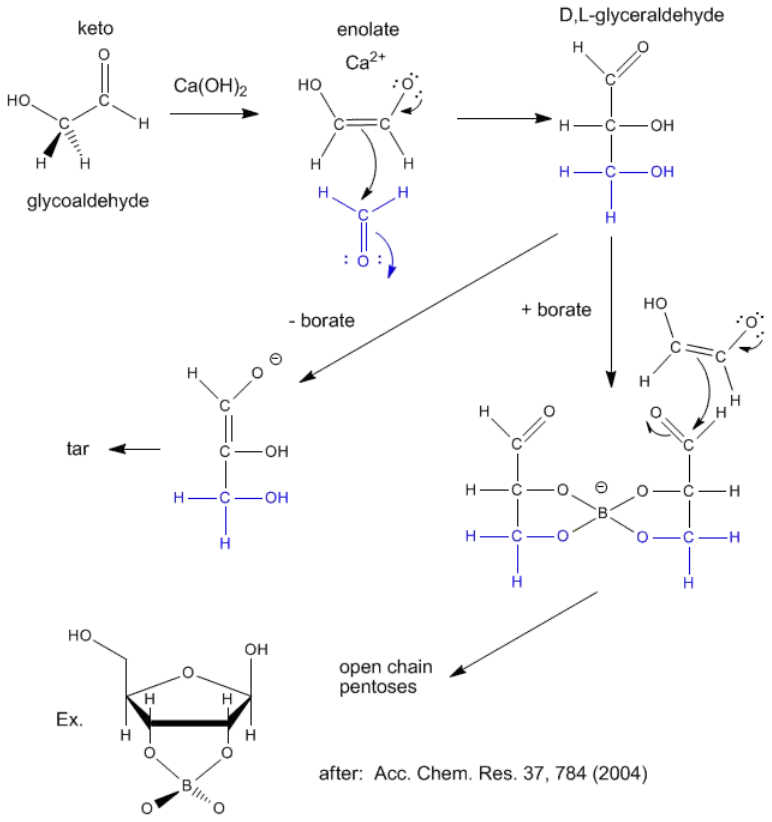
compared to the present 20 naturally-occurring amino acid, could form a polymer that could fold. Notice that this reduced ensemble of amino acids lacks aromatic and basic amino acids. These proteins would be acidic with a low pI and may have trouble, given the lack of nonpolar aromatic amino acids, in forming a buried hydrophobic core which stabilize proteins. Nevertheless Longo et al were able to synthesize a protein with a slightly expanded set of amino acids (12, including Asn and Gln, with 70% prebiotic amino acids). The structure of one of the proteins, PV2, is shown below. The protein was more stable in 2 M NaCl (compared to 0.1 M) in which it showed a cooperative thermal denaturation with a melting point near 650C using differential scanning calorimetry. The protein had properties similar to those from halophilic organisms that thrive in high salt. These properties include low pIs and high negative charge density, which allows cation-protein interactions in the high salt environment, and lower stability in low salt environments. Earlier oceans were saltier. Halophiles are an example of extremeophiles which are highly represented in archea. Although most halophiles are aerobic, some are anerobic. Perhaps life arose in high salt environments.

Figure: Structure of PV2 protein comprised of a reduced alphabet of mainly prebiotic amino acids.



30.1.0.1: Abiotic Synthesis of Sugars

Sugars are required for present energy production but also as a part of the backbone (ribose, deoxyribose) of present genetic material. Many sugars can be synthesized in prebiotic conditions, using carbon based molecules with oxygen, such as glycoaldehyde and formaldehyde (both found in interstellar gases), as shown in the figure below. Glycoaldehyde was recently found in star forming regions of the Milky Way where planets are likely to form. The presence of borate, which stabilizes vicinal OHs on sugars, is required for the production of sugars instead of tars.



RNA molecules containing sugars such as threose, aldopentopyraonses and hexopyranose can also form stable secondary structures like helices. (Remember, RNA probably preceded DNA as the genetic carrier of information given that is also has enzymatic activity). Is there something special about ribose that made it selected over other sugars for nucleic acids, especially since it is found in low abundancy in the products in synthesis reactions conducted under prebiotic conditions? One probable reason is it unusually high (compared to other sugars) permeability coefficient through vesicles made of phospholipids or single chain fatty acids, as shown below.

Table 1. Solute permeability coefficients (P_s) across fatty acid and phospholipid membranes

In general, the greater the number of carbon atoms, the smaller the permeability. However, the table above clearly shows large differences in permeability for sugar isomers with the same number of C atoms, and the difference is not affected by the lipid composition. Ribose has markedly elevated permeability compared to other 5C sugars (as do erythritol and threitol among 4 C sugar alcohols). What is so unique about ribose? 20% of the sugar is in the furanose form. Rate constants for ring opening of furanoses are elevated, suggesting greater flexibility. The α-furanose anomer is amphiphilic in that one face is hydrophobic and the other hydrophilic. All of these may promote ribose permeability.

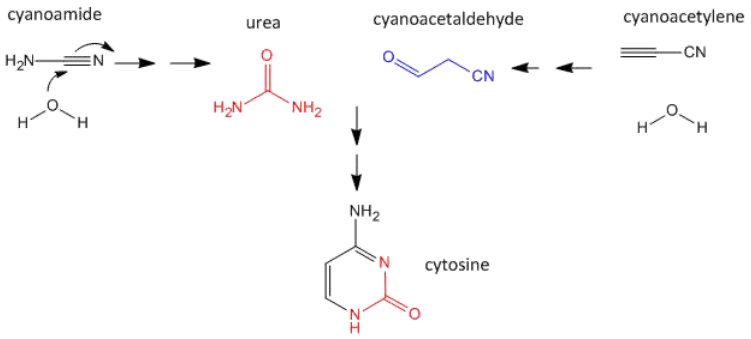
30.1.0.1: Abiotic Synthesis of Nucleobases

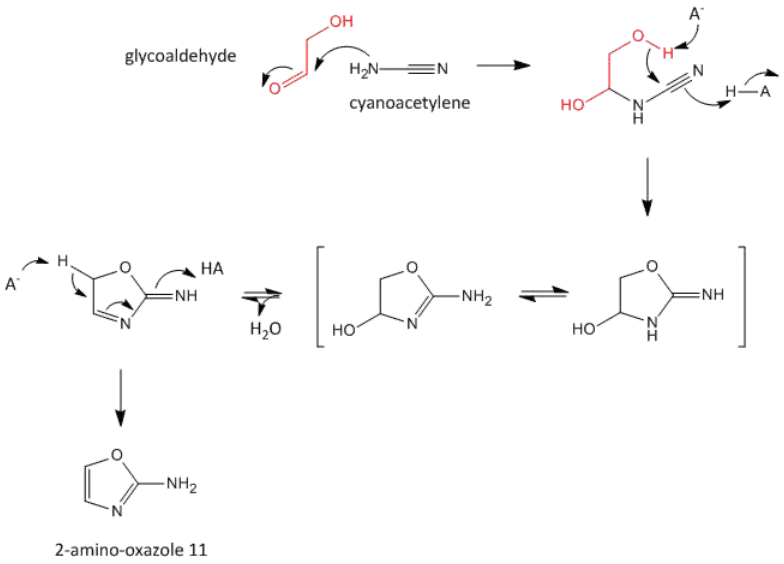
As mentioned above, nucleobases can be made under abiotic conditions with appropriate sources of carbon molecules with nitrogen. These include hydrogen cyanide, cyanoamide (NH2CN) (along with ammonia), hydrogen cyanide, cyanogen (C2N2) and cyanoacetylene (HC3N). Cyanoamide and cyanoacetylene can both react with water to form urea and cyanoacetaldehyde, respectively. The latter two can condense to form cytosine as shown below.

Figure: Abiotic Synthesis of Cytosine



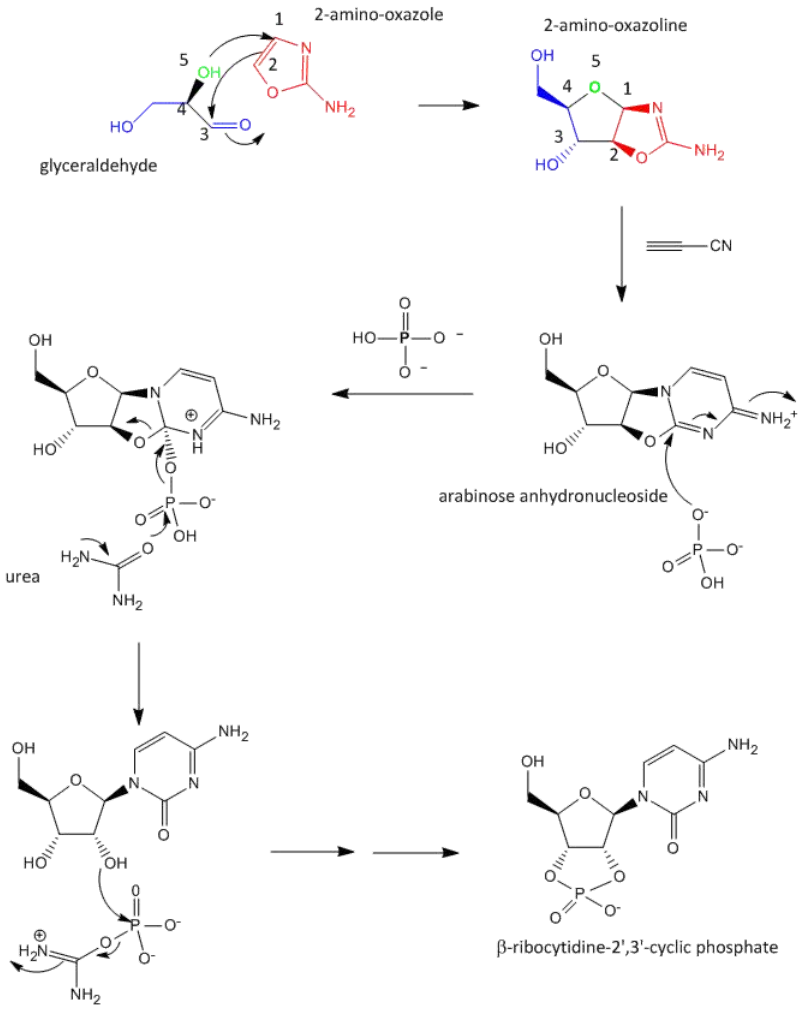
A major problem that has plagued prebiotic researchers is how the product of the carbon-oxygen compound (sugar) links to the product of the carbon-nitrogen compound (nucleobase) to form the nucleoside. Recent research by Powner et al has offered an innovative solution. Instead of forming the sugar and base in separate reaction, and then linking them covalently, the combined molecule could be synthesized in a single set of linked reactions. Inorganic phosphate serves as both a general acid/base catalyst (HA/A- in the figure below) in these new reactions in the formation of an important intermediate, 2-amino-oxazole, and as a nucleophilic catalyst.

Figure: Abiotic Synthesis of 2-amino-oxazole



Glyceraldehyde, 2-amino-oxazole, and inorganic phosphate can react to form a ribocytidine phosphate. Possible reaction mechanisms are shown below.

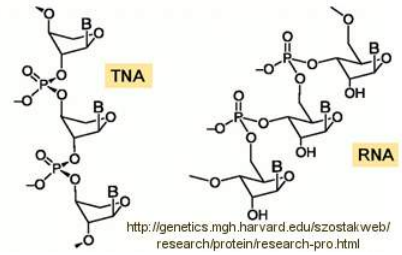
Figure: Abiotic synthesis of a ribocytidine phosphate without condensation of a preformed ribose and cytosine



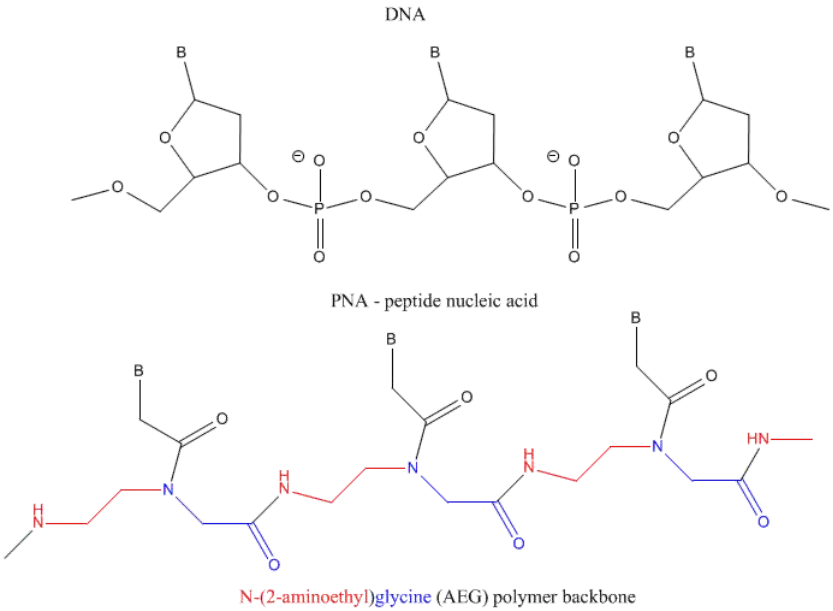
30.1.0.1: Abiotic Synthesis of Genetic Polymers

Abiological synthesis of polymer precursors is a long way from creating genetic polymers like RNA and DNA. These genetic polymers have one property that at first glance seems not conducive to a genetic molecule. Both are polyanions, which must be packed into a cell and folded onto itself to form the classic dsDNA helix and many different RNA structures. This problem is solved to some degree by the presence of counterions that help mask the charge on the negative backbone of the nucleic acids. The presence of phosphate in the phospodiester backbone linkage does confer an important advantage over other possible links (carboxylic acid esters, amides and anhydrides). The electrophilic phosphorous atom is hindered from nucleophilic attack by the negative O attached to the phosphorous. Also, the phosphorous is sp3 hybridized compared to the sp2 hybridization of the electrophilic carbon atom in anhydrides, esters, and amides, and hence is less accessible to nucleophilic attack. Most people now believe that RNA, which can act both as an enzyme and genetic template, preceded DNA as the genetic carrier. The evolution of DNA as the primary genetic carrier required an enzyme to convert ribose to deoxyribose. This would make the nucleic acid less likely to cleave at the phosphodiester bond with the replacement of a nucleophilic 2' OH with an H, and make the genetic molecule more stable. Other types of genetic carriers might have preceded the RNA world, especially if the monomer required could be more readily synthesized from abiological sources. One such alternative are threose nucleic acids (TNA). Synthetics ssTNA can base pair with either RNA, DNA, or itself to form duplexes.

EXTERNAL http://genetics.mgh.harvard.edu/szostakweb/research/protein/research-pro.html



Other possible candidate include peptide nucleic acids (PNA). These can also form double stranded structures with DNA, RNA, or PNA single strands. They were initially designed to bind to dsDNA in the major grove forming a triple-stranded structure. Binding could alter DNA activity, possibly by inhibiting transcription, for example. The structure of a single-stranded PNA is shown. Note that the backbone, a polymer of N-(2-aminoethyl)glycine (AEG) which can be made in prebiotic soups, is not charged, making it easier to bind to dsDNA. AEG polymerizes at 100oC to form the backbone.

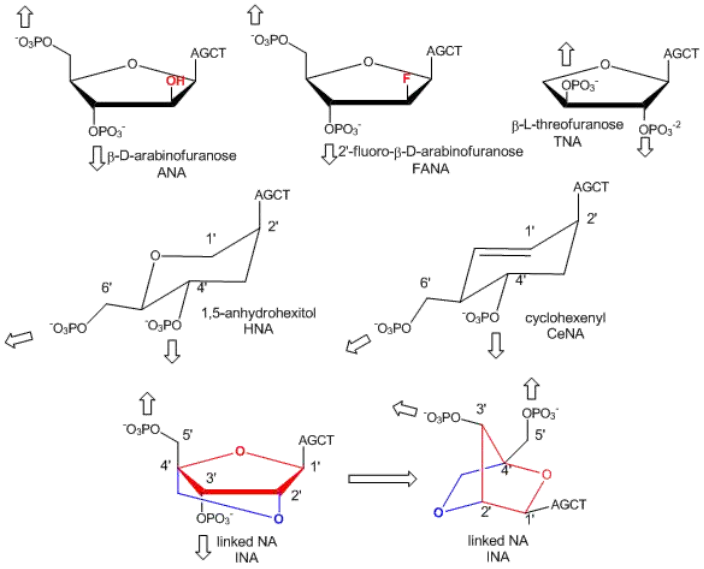


after Gamesh, K. & Nielsen, P. Peptide Nucleic Acids: Analogs and Derivatives. Current Organic Chemistry. 4, 931 (2000)

In addition to changing the backbone, additional bases other than A, C, T, G, and U can be accommodated into dsDNA and ssRNA molecules (Brenner, 2004)

In a recent extension, Pinheiro et al have shown that 6 different foreign backbone architectures can produce xeno-nucleic acids (XNAs) that can be replicated by engineered polymerases which make XNAs from a complementary DNA strand, and a polymerase that can make a complementary copy of DNA from an XNA. XNAs can also be evolved as aptamers to bind specific target molecules. The investigators replaced the deoxyribose and ribose backbone sugar with xenoanalogs (congeners) including 1,5-anhydrohexitol (HNAs), cyclohexene (CeNA), 2'-O,4'-C-methylene-b-D ribose (locked nucleic acids - LNA), L-arabinose (LNA), 2'-fluoro-L-arabinose (FANAs) and threose (TNAs) as shown in the figure below.

Figure: Xeno-nucleic acid sugar congeners



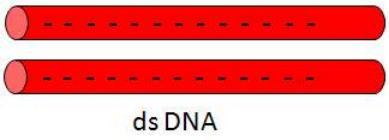
Polymers of these XNA can bind to complementary RNA and DNA and as such act as nuclease-resistant inhibitors of translation and transcription.

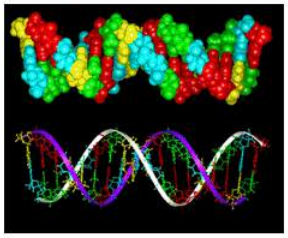
Von Kiedrowski, in an experiment similar to the self-replication of peptides described above, has shown that a single stranded 14 mer DNA strand, when immobilized on a surface, can serve as a template for the binding of complementary 7 mers and their conversion to 14 mers. When released by base, this process can occur with exponential growth of the complementary 14 mers. (von Kiedrowski Nature, 396, Nov 1998). Ferris has shown that if the clay montmorillonite is added to an aqueous solution of diadensosine pyrophosphate, polymerization occurs to produce 10 mers which are 85% linked in a 5' to 3' direction.

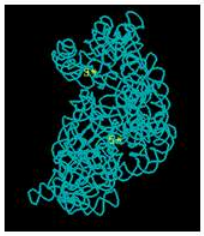
30.1.0.1: Polyanions as Carriers of Genetic Information

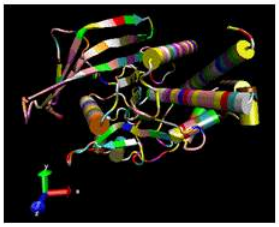
There are other reasons why polyanions are useful genetic molecules, other than their resistance to nucleophilic attack. The biological form of DNA is a large double stranded polyanionic polymer, in contrast to RNA which is a single-stranded polyanion polymer and protein which are polymers with varying combination of anionic, cationic, and hydrophobic properties. Even with counterions, it would be difficult to fold DNA into complicated and compact 3D structures as occurs for proteins, given the large electrostatic repulsions among the charged phosphates. Rather it forms a elongated double stranded rod, not unlike the rod-like structure of proteins denatured with sodium dodecyl sulfate (used in SDS PAGE gels). The elonged rod-shaped structure of ds-DNA is critical for the molecule which is the main carrier of our genetic information since mutations in the bases (leading to a switch in base pairs) causes no change in the overall structure of dsDNA. This enables evolutionary changes in the genetic material to produce new functionalities. A single change an amino acid of a protein, however, can cause a large change in the structure of a whole protein, a feature unacceptable for a carrier of genetic information. RNA structure effectively lies between that of DNA and proteins. Since it has less charge density than dsDNA, it can actually form dsRNA helices, so it can carry genetic information, as well as form complex 3D shapes necessary for its activity as an ribozyme. Perhaps more importantly, steric interference prevents ribose in RNA from adopting the 2'endo conformation, and allows only the 3'endo form, precluding the occurrences of extended ds-B-RNA helices.

What kinds of structures can the biological macromolecules form?



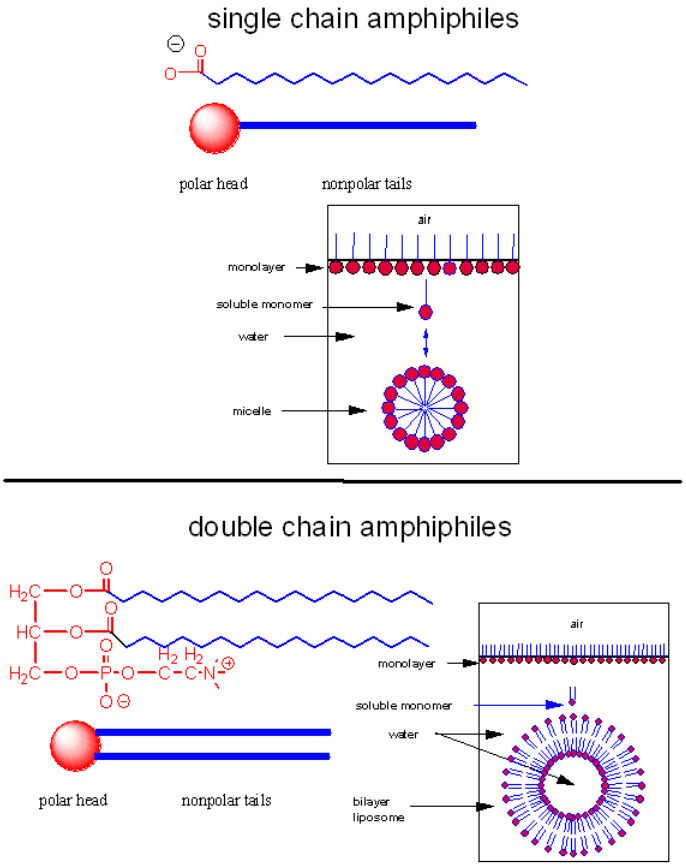




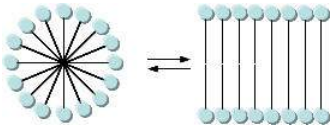


30.1.0.1: The Lipid World

Let's assume that abiological precursors would react to form polymer-like molecules that might be complex enough to fold to structures that would allow binding, catalysis, and rudimentary replication. All this would be worthless unless they could be sequestered in a small volume which would limit diffusion and increase their local concentration. What is required is a membrane structure. Amphiphilic molecules, like lipids, with which we started this book, would be prime candidates since they spontaneously assembly to form micelles and bilayers, as shown in the review diagram below.



As mentioned in Chapter 1, alternative lipid phases are possible. Bilayers can also be formed from single chain amphiphiles, such as certain fatty acids, as illustrated in the equilibrium shown below. This occurs more readily at pH values close to the the pKa of the fatty acid, at which the fatty acids are not all deprotonated with full maximal negative charges. Single chain amphiphiles like fatty acids, which were more likely to formed in abiotic conditions, have been found in meteorites.



Clay surfaces, which have been shown to facilitate the formation of nucleic acids polymers, can also promote the conversion of fatty acid micelles to bilayers (Szostak). One such clay surface, montmorillonite, whose structure is shown below, promotes bilayer formation. It has an empirical formula of $Na_{0.2}Ca_{0.1}Al_2Si_4O_{10}(OH)_2(H_2O)_{10}$.

EXTERNAL Chime Molecule Modeling: montmorillonite EXTERNAL: montmorillonite

The effect of montmorillonite on vesicle formation can be shown by simple measurements of turbidity with time. Microscopy of fluorophore-encapsulated vesicles also shows encapsulated montmorillonite. The fatty acids presumably absorb to the cation layer of the clay particles. Time studies using light scattering also indicate that the vesicles grow in the presence of fatty acid micelles. To differentiate between the formation of new vesicles and the increase in size of pre-existing vesicles (which couldn't be done by simple light scattering without separation of the vesicles), investigators used two different fluorescent molecules to label fatty acid vesicles. The two probes were selected such that if the two probes came in close contact, energy transfer from the excited state of one fluorophore to the other fluorophore could occur, an example of fluorescence resonance energy transfer (FRET). FRET is observed when emission of the second dye occurs after excitation of the first dye, at a wavelength outside of the excitation

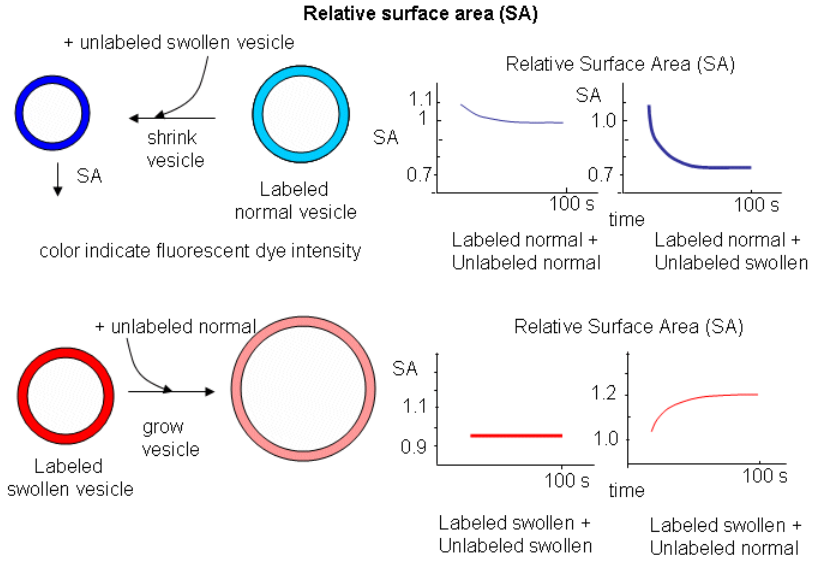
wavelength of the second dye. If unlabeled vesicles were added to either labeled vesicles, no changes in FRET were observed, suggesting that the dyes did not move between vesicles. If fatty acid micelles were added, a decrease in FRET was observed, suggesting that new fatty acids were transferred to the doubly-labeled vesicles, effectively diluting the dye concentrations in the bilayer and their relative proximity, both which would decrease FRET. Most of the new fatty acid was incorporated into pre-existing vesicles which grew. The vesicles could also divide if extruded through a small pore. Later we will see that the energy to grow the vesicles can derive in part from a transmembrane proton concentration collapse. Division of vesicles might be promoted by bilayer assymetries associated with addition of substances to the outer leaflet, causing membrane distortion.

30.1.0.1: Protocells

At some point, early genetic material must have been encapsulated in a membranous vesicles. Would new properties emerge from this mixture that might have a competitive (evolutionary) advantage over either component alone, and thus be a step on the way to the formation of a "living" cell? The answer appears to be yes. Chen et al. have incorporated RNA into fatty acid vesicles with interest effects. They asked the question as whether those vesicles could grow at the expense of vesicles without encapsulated RNA. RNA, with a high charge density and its associated counter ions would create osmotic stress on the vesicles membranes. To relieve that stress they could acquire fatty acids from other fatty acid vesicles (or fatty acid micelles), increasing their surface area, and concomitantly reducing tension in the membrane.

Oleic acids vesicles were first placed under stress by encapsulating 1 M sucrose in the vesicle and then diluting it in hypotonic media. Water would enter and swell the vesicle (but without bursting and resealing, as evident from control experiments). Then they prepared stressed and unstressed oleic acid vesicles in the presence of two nonpolar flurophores, NBD-PE (excitation at 430 nm, emission at 530 nm) and Rh-DHPE (emission at 586 nm). These fluorophores were chosen for fluorescence resonance energy transfer measurements. If the membrane vesicles changed size, the FRET signal would change, based on the relative concentration and proximity of the dual fluorophores. If the separation between probe molecules increased, the FRET signal would decrease. Conversely, if the vesicle shrunk, the FRET signal would increase.

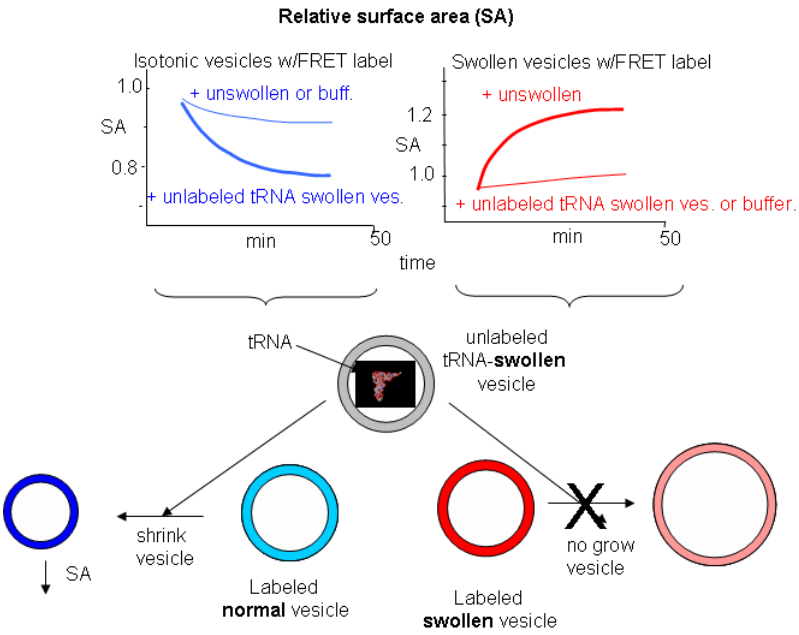
The results showing the effect of adding unlabeled swollen vesicles to labeled normal vesicles, and labeled swollen vesicles to unlabeled normal are shown below. The surface area of normal labeled vesicles decreased by about 25% when unlabeled swollen vesicles were added, but not when unlabeled normal vesicles were added. Labeled swollen vesicles increased 25% in size only if mixed with unlabeled normal vesicles, not with unlabeled swollen vesicles. Hence swollen vesicles win the competition and "steal" lipid from normal vesicles.



After Chen et al. Science 305, 1474 (2004)

Now what about vesicles swollen with encapsulated RNA? RNA, with its associated charge and charged counter ions also placed an osmotic stress on the vesicles. FRET labels (the two fluorophores) were place in vesicles without RNA. Fatty acids were removed from isotonic labeled vesicles in the presence of unlabeled tRNA swollen vesicles (left panel below). Labeled vesicles

swollen with glycerol took fatty acids from unswollen vesicles (without tRNA), but not from tRNA swollen vesicles, as both were swollen so no net drive to reduce swelling by lipid exchange was present.

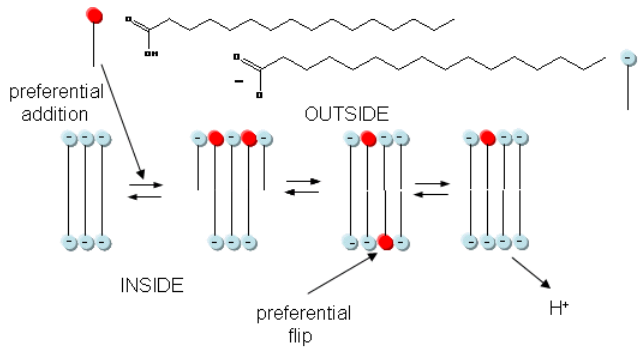


After Chen et al. Science 305, 1474 (2004)

These results show the vesicles with encapsulated RNA have a competitive (evolutionary) advantage over normal vesicles. This data suggests that having a polyanion as the source of genetic material is actually advantageous to the protocell. In addition the move in modern membranes to phospholipids with esterified fatty acids (instead of free ones) may actually have stabilized membranes, given the movement of free fatty acids to different membranes.

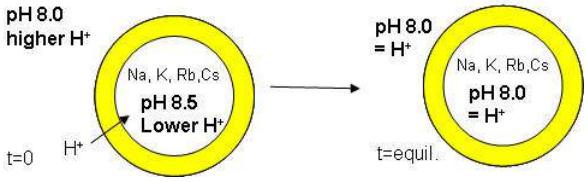
30.1.0.1: Energy Transduction in Protocells

In addition to a genetic macromolecule and a semipermeable membrane, a source of energy to drive intracellular processes must be present. A common source of free energy used in many cells to drive unfavorable processes is a proton gradient, whose formation in modern cells can be coupled to energy input from oxidation, ATP cleavage, light, or the collapse of another gradient. Could a proton gradient be formed in protocells? It can, quite easily, when coupled to the growth of fatty acid vesicles. If a fatty acid vesicle is to grow, more fatty acid must be added to the outer leaflet. The protonated, uncharged form of the fatty acid would preferentially be added, since it would lead to less electrostatic repulsion between adjacent head groups. The protonated, uncharged form of the fatty acid would also be most likely to flip to the inner leaflet to minimize stress asymmetries in the leaflets. Once in the inner leaflet, it could deprotonate to form H+(aq) in the inside of the membrane, creating a transmembrane proton gradient and transmembrane potential. The energy released on growth of the membrane is partly captured in the formation of a proton gradient, as shown in the figure below.



Generation of proton gradient on growth of fatty acid vesicle

The proton gradient would soon inhibit its own formation since further movement of protons into the cell would be attenuated by the positive transmembrane potential unless metal ions inside moved outside. In addition, the gradient would collapse after growth stopped. The investigators made fatty acids vesicles in the presence of pH 8.5 buffers whose pH was adjusted with an alkali metal hydroxide. The external pH was reduced to 8.0, resulting in a 0.5 pH unit proton concentration gradient. (Changes in intravesicular pH were measured with pH-sensitive fluorophore, HPTS.) Inward movement of protons down a concentration gradient, as shown in the figure below, would occur with time, collapsing the imposed concentration gradient.



With fatty acid vesicles, this artificial pH gradient collapsed quickly, suggesting the vesicle permeability to protons was high. The rate was too high for simple flip-flop diffusion. Inward movement of protons appeared to be facilitated by outward movement of the M+ ions. The rate of decay of the proton gradient was exponential, and the resulting first order rate constant was easily determined. A graph of the rate constant for pH gradient collapse vs unsolvated ionic radius of M+ decreased with increasing radius (i.e. kNa > kK > KRb > KCs, suggesting that the pH gradient would be more stable if large, impermeable or otherwise trapped cations were encapsulated. When vesicles were made with encapsulated Arg+, the imposed pH gradient did not collapse for hours. If oleic acid micelles were added to oleic acid vesicles with encapsulated Arg+, with no artificial pH gradient induced across the membrane, the vesicle grew with concomitant movement of protons into the vesicle, producing a pH gradient of 0.3 within seconds.

These experiments show that membrane growth and energy storage could be coupled, and the right composition of encapsulated material could lead to a stable transmembrane pH gradient, a source of energy to drive biological processes. It even suggests that a charge polyanion would be beneficial as a genetic carrier.

30.1.0.1: Hydrothermal Vents or Primoridal Soup?

The case for the origin of life in deep sea hydrothermal vents and not in a primordial "Campbell's" soup has been argued convincingly by Lane et al (2010). What's needed for life are reasonably complex molecules and an energy source to drive unfavorable reactions. It's the latter on which that Lane et al focus. In an early primordial world that was low in oxygen, exergonic oxidation reaction of organic molecules would provide little energy. This can be surmised from the low energy yield (compared to aerobic respiration) achieved in present day glycolytic (fermentative) pathways from all major domains of life, archaea, bacteria, and eukaryotes.

> Background: Based on rRNA sequences, a primordial cell evolved into two different types of cells, one that became bacteria, and another that split further into archaea (single cells, similar to bacteria) and eukaryotic cells (complex cells with internal organelles that eventually formed multicellular organisms). Bacterial and archaea are collected called prokaryotic cells.

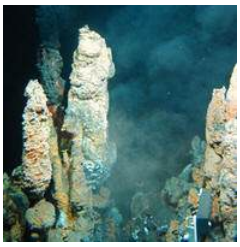
In addition, these pathways required the evolution of up to dozen different enzymes to produce their relatively meager energy yield which ultimately depends on the oxidation of an organic molecule by another organic molecule instead of by a powerful oxidant like dioxygen. An anisotropic arrangement of molecules in a concentrated soup could lead to transient chemical potential fluctuations but these would be inefficient and impermanent sources of energy. Effectively the primordial soup would be at equilibrium and hardly expected to provide the energy for synthesis of RNA enzymes and replicators. UV light leads to photo-damage and photolysis not replication of complex molecules. What is needed is a way to drive the synthesis of molecule with high chemical potential energy (like sulfur esters and phosphoanhydrides) compared to their lytic products. These could then provide an energy sources to drive ATP synthesis, for example.

A detailed look a the bioworld shows that the earliest organisms used energy from the collapse of the proton gradient (chemisomotic principle elucidated by Peter Mitchell). All present autotrophs (organisms that can fix CO2 and form complex organic molecules) and many heterotrophs (use complex organic molecules of other organisms for fuel) use redox complexes in membranes coupled to membrane gradients. These complexes would take reduced molecules and pass electrons from them to oxidizing agents (electron acceptors), including O2, CO2, and Fe3+ to form H2O, CH4, and Fe2+. Fermentors also use ATPase membrane enzymes to transport nutrients. Yet genomic analysis of bacteria and archaea show that enzymes involved in

fermentation differ significantly, suggesting that they evolved separately towards a convergent function. Structure in common include DNA, RNA, ribosomes and membrane ATPases, which Lane et al suggest were in a the Last Universal Common Cell (LUCA).

All autotrophs produce their energy source by fixing CO2 using either H2 directly or indirectly using H2O and H2S. All of the are available in nonhydrothermal deep sea vents. Volcanic vents, however, are extremely hot (not optimal for organic molecule synthesis), very acidic, and lack hydrogen gas. A different type of nonvolcanic vent, an alkaline hydrothermal one, might produce more conducive as a site of the origin of life. In these vents, water chemically reacts with minerals in the crust (such as olivine) leading to their hydroxylation and subsequent fracture, with promotes more water entry into the crust. It has been reported that there is more water found as hydroxylated minerals in the crust, that there is liquid water in the oceans. These processes result in temperatures up to 200 degrees Celsius and release of hydrogen gas into a moderately alkaline vents into the sea water at temperatures more conducive (70 degrees C) to the origin of life.

Figure: Alkaline Vent



30.1.0.1: Fixing CO_2

Of the five different pathways known to fix CO_2, all require ATP except one. That one is present in both methanogens, which produce methane from CO_2 and H_2, and in the acetogens, which produce acetate ($CH_3CO_2^-$) in the form of acetyl-CoA. The simpler reactions of forming acetic acid and methane are shown below:

$2CO_2 + 4H_2 \rightarrow CH_3CO_2H + 2H_2O$.

$CO_2 + 4H_2 \rightarrow CH_4 + 2H_2O$.

The ΔG^0 values for these reaction (calculated using ΔG^0_f for gas phase H_2, CO_2 and CH_4 and liquid acetic acid and water are -75 and -131 kJ, respectively, at 250C, showing that they are thermodynamically favored. Making AcetylCoA, a "high" energy molecule compared to its hydrolysis products (as is ATP) from acetic acid and CoASH, requires an additional source of energy to drive the reaction. A proton gradient is the likely source.

Some bacteria and Achaea cells (primordial or present) use the reductive acetyl-CoA pathway, also known as the Wood-Ljungdahl pathway, to form, in a noncyclic process, acetyl CoA from CO_2 and at the same time makes ATP. This process is paid for by a proton gradient. This has been described by Shock as "a free lunch you get paid to eat". The energetics of the present acetyl CoA pathway based on the overall reaction below show an approximate ΔG^0 value of -59 kJ/mol which can drive ATP synthesis.

$2CO_2 + 4H_2 + CoASH \rightarrow CH_3COSCoA + 3H_2O$.

The concentration of carbon dioxide in the primordial ocean was 1000 times higher than now. Vents produced large amounts of methane and hydrogen gas. There was little oxygen and hence lots of Fe^{2+}. The enzymes involved in this acetyl-CoA pathway of carbon fixation have FeS clusters. It has also been shown that bubbles (which are really membrane-bound spaces) of FeS and NiS can be made in deep-sea vents. These could not only encapsulate precursor molecules but also serve as catalysts. Vents also can catalyze the fixation of nitrogen (to ammonia) and laboratory studies show that FeS can catalyze the conversion of formate (found in vents) into pyrimidines and purines. The studies of present methanogens and vent chemistry suggest that the critical ingredients and conditions for the development of the first biological cells probably occurred in the vents.

To produce polymers, an energy source and monomers must exist. Concentration gradients found in simulations of vents produce million-fold concentrated molecules. The transient heating and cooling of any double-stranded nucleic acids could lead to concentration amplification by a PCR-like strand separation followed by reannealing. In addition, these vent regions possess a powerful, reoccurring energy source, a pH gradient, as the alkaline vented material entered the acidic oceans that exist with high CO2 concentrations, creating a gradient across an inorganic membrane. This is startlingly analogous to the pH gradient across membranes (acidic outside, alkaline inside) driven by the membrane complexes in the mitochondria and bacteria. Lane et al argue

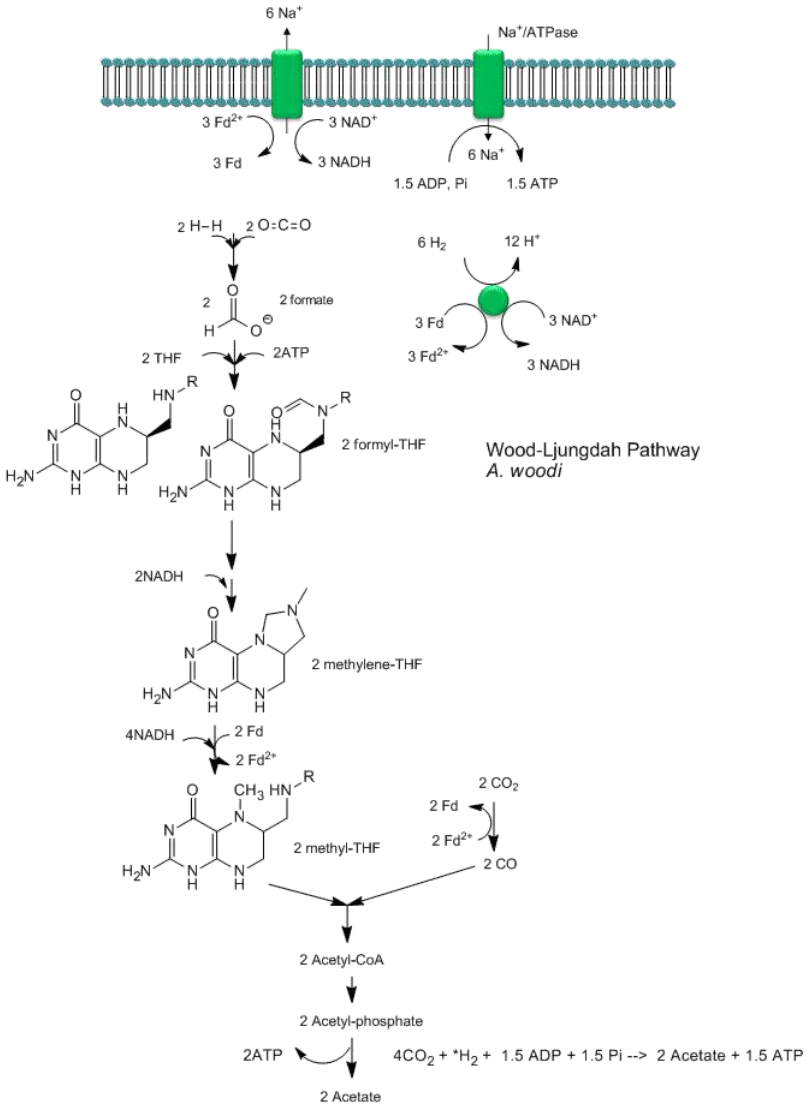
that the existence of membrane proton gradients as an energy source in all cells (eukaryotes, bacteria, and archaea) and in chloroplasts and mitochondria, corroborate their hypothesis. Bacteria and Archaea share homologous ATPases and electron carriers (ferredoxins, quinones, and cytochromes). These similarities contrast to the differences in enzyme structures in fermentative pathways. Arguments that proton pumps evolved to pump proteins (and reduce pH gradients) can't explain their ubiquitous presence even in organisms not subjected to low pH. Hence the ubiquity of proton pumps supports the conjecture that they arose from the first protocells, possibly comprised of inorganic walls and ultimately with amphiphilic molecules synthesized from precursors.

Creationists would argue that it would be impossible to evolve a structure with the complexity of membrane ATPase (which collapse a pH gradient as the power the synthesis of molecules with large negative ΔG^0 of hydrolysis). Lane et al propose that the earliest cells evolved ATPase-like molecules in alkaline vents where pH gradients analogous to those in cells today arose. They envision cell-like columns lined by FeS membrane-like structures with alkaline conditions inside and acid conditions outside. Nonpolar or amphiphilic molecules would line the inside of the cells/columns. An ATPase-like system could then take advantage of the pH gradient which constantly replenishes itself. If structures as complicated as ribosomes evolved from a subsequent RNA world, surely ATPase-like molecules could also. Other chemistry might have evolved earlier to utilize the energy source provided by the pH gradient.

If life originated in the vents, it would need an energy source to leave the vents. Presumably it would have evolved one to utilized pH gradient to replace the one it left in the alkaline vents. The substrate level phosphorylation of glycolysis that requires ATP input to make ATP would not provide the energy source needed. Cells that left would have had to produce their own proton gradient. Perhaps all the was needed initially was concerted conformational changes in proteins that upon exposure of a different pH changed their shape inducing pKa shifts in adjacent proton donors/acceptors leading to vectorial discharge of protons across a membrane. Perhaps the method described above in protocells was sufficient.

Recent analyses by Poehlein et a show that CO2 reduction (fixation) can be coupled to the production of a sodium ion gradient, which could collapse to drive ATP synthesis. Analysis of the genome of a gram positive bacteria, Acetobacterium woodii, an acetogen, shows the it has an ancient pathway for production of acetyl-CoA that can, in an anabolic fashion form biomass or in a catabolic fashion be cleaved to acetate with the production of ATP. It does not require classic electron carriers like ubiquinone or cytochrome C linked to protein gradient formation to drive ATP synthesis. Rather it has only a ferredoxin:NAD+ oxioreductase which couples oxidation to the formation of a sodium ion gradient, which collapses through an sodium ion transporter/ATP synthase to drive ATP synthase. A plausible reaction scheme based on genomic analysis is shown below:

Figure: Acetyl-CoA Synthase and Acetogenesis



30.1.0.1: The Role of Fe/S Centers

Let's return to the chicken and egg dilemma one more time. What is needed for biological polymer formation are monomeric precursors, an energy source, and a way to compartmentalized them all. We discuss how monomeric precursors could form, but wouldn't it be far better if even the synthesis of precursors could be catalyzed? One source of catalysis mostly absent from the "bioorganic" abiotic chemistry in the above discussion is the transition metals. Transition metals can form complexes. Ligands containing lone pairs on O, N, and S atoms can donate them to transition metals ions, which can hold up to 18 electrons in s, p, and d orbitals. Hence as many as 9 lone pairs on ligand molecules (which are often multidentate) could be accommodated around the transition metal ion. Many present small molecule metabolites and their abiotic precursors (H2O, CO, CO2, NH3 and thiols) bind cations as mono- or polydentate donors of electrons. Hence transition metal ions would have a thermodynamic tendencies to be bound in complexes.

Bound ligands that contain potentially ionizable hydrogens could become deprotonated and made better nucleophiles for reactions. Hence the transition state metal ion, acting with the complex, becomes a catalyst as it decreases the pKa of a bound ligand (such as water). In addition, since transition metals ions can have multiple charge and oxidation states, they can easily act as redox centers in the oxidation/reduction of bound ligands that were redox active. Given the relative anoxic conditions of the early oceans, Fe2+ would predominant. It could easily be oxidized to Fe3+ as it reduced a bound ligand. Highly charged transition states would withdraw electron density from bound ligands leading to their possible oxidation.

Metals obviously still play a strong role in catalysis, both indirectly in promoting correct protein folding and directly in stabilizing charge in both the transition state and intermediates in chemical reaction pathways. FeS clusters are of significant importance.

Their biosynthesis involves removal by an active site Cys in a desulfurase enzyme of a sulfur from a free amino acid Cys followed by its transfer to an Fe in a growing FeS cluster in a FeS scaffold protein, which then transfers the cluster to an acceptor protein where it acts as a cofactor. FeS clusters can adopt a variety of stoichiometries and shapes, as well as redox states for the participating Fe ions. The continuing importance of FeS clusters in all cells, their involvement in not only redox enzymes in which electron transfer is facilitated by delocalization of electrons over both Fe and S centers, but also in coupled electron/proton transport in mitochondrial electron transport, Fe storage (ferrodoxins), and in regulation of enzyme activity and gene expression, suggests that they were of primordial importance in the evolution of life. T

hey are often found at substrate binding sites of FeS enzymes involved in both redox and nonredox catalysis. A ligand can bind to a particular Fe in the cluster, activating it for hydration or dehydrogenation reactions. Fe 4 of the FeS cluster in the TCA enzyme aconitase can have a coordination numbers of 4, 5, or 6 as it binds water, hydroxide or substrate. It acts to both decrease electron density in the transition state and to change the pKa of bound water as the enzyme catalyzes an isomerization of tricarboxylic acids (citric and isocitric acid) through an elimination/addition reaction with water. In another example it can bind S-adenosylmethionine through its amine and carboxylate groups, which activates the molecule for cleavage and radical formation. In some cases metals other than Fe (Ni for example) are incorporated into the cluster. FeS effects on transcription factors involves facilitation of optimal structure for DNA binding. FeS and FeNi centers in proteins are similar in structure tp FeS units in minerals like greigite and presumably to FeS structure formed when H2S and S2- react with Fe2+ (present in abundance in the early ocean) and other metals in vents Metal sulfides participate in reduction of both CO and CO2. For example the synthesis of CH3SH from CO2 and H2S is catalyzed by "inorganic" FeS.

30.1.0.1: The Minimal Genome

This question is being addressed by eliminating "unnecessary" gene from simple bacteria. Cells placed in a rich nutrient broth with essential lipids, vitamins, and amino acids would need fewer genes than those placed in a more nutrient-poor medium. Bacteria cells like Mycoplasma genetalium, that live within "nutrient rich" eukaryotic cell, have been genetically manipulated to delete unnecessary genes. Based on knockout studies, it may be possible for the cell to survive with only 300-350 genes. Bacillus subtilis has approximately 4100 genes. Estimates have been made that it could survive with as few as 271 genes.

LEARNING OBJECTIVES

- to demonstrate how climate has changed over geological time through the present
- to explain mechanisms, using knowledge from biology, chemistry, and physics, for climate change
- to show the central role of atmospheric CO_2 as a causative agent of past and present climate change
- to contrast the effects of anthropogenic burning of fossil fuels on climate change with causes of past climate changes
- to address arguments made by climate change skeptics

INTRODUCTION

We've known for a very long time that burning fossil fuels and releasing CO_2 into the atmosphere would warm our climate. Perhaps the first paper addressing this, Circumstances affecting the Heat of the Sun's Rays, was published in 1856, before the US Civil War, by a woman scientist, Eunice Foote. John Tyndall (of the Tyndall effect) published more comprehensively on greenhouse gases in 1859. Given the complexity of the biosphere's climate, it was not until the 1980s that climate models became sophisticated enough for scientists like James Hansen to become convinced and alarmed enough to discuss in Congressional hearings the role of anthropogenic (made by humans) CO_2 released into the atmosphere as a cause of ever-worsening global warming. The knowledge of human-induced climate change has been politicized and subjected to an orchestrated campaign of misinformation and disinformation by fossil fuel companies and their political contributors. We have delayed global actions for so long that we must act immediately and aggressively to address climate change before we reach climatic conditions that are so austere for humans that parts of the world become uninhabitable. Homo sapiens evolved in a world dominated by repetitive glaciation and deglaciation. Hans Joachim Schellnhuber, an atmospheric physicist, climatologist, and founding director of the Potsdam Institute for Climate Impact Research, has stated that humans have so affected the world that we have eliminated the possibility of the next glaciation cycle.

Many readers might not be familiar with the data and models supporting human-caused climate change and that climate scientists are almost unanimous in their support of the data and models. As in any field, however, you will find outliers who don't and whose ideas carry disproportionate weight among climate change skeptics. Hence, we provide the basic data to show the relationship between increasing atmospheric CO_2 to global warming, both drought and flooding, ocean acidification, and loss of biodiversity. We also provide supportive information that would allow users to address questions from those who question the reality of present human-induced climate change. We don't shy away from using basic physics as well since most students studying biochemistry at the level found in this book have also studied physics as well as biology. In subsequent sections, we will then address the biochemistry of climate change and its mitigation.

GREEN HOUSE EFFECT

Before the advent of the Industrial Revolution, the Earth's climate was fairly constant since the last ice age, which peaked about 22,000 years ago (YA) and ended about 12,000 YA. There have been short (on a geological time scale) periods of cooling since the end of the last ice age. Humans evolved around 200,000 years ago with modern civilizations arising about 4000 BCE so it could be said that humans are ice-age peoples (a distinctly Northern Hemisphere perspective). Humans have had the benefits of a fairly stable climate since then.

The sun's energy warms the Earth. If the Earth did not radiate back into space an equivalent amount of energy, it would slowly and continually warm. The Earth reflects energy back in the form of light. In addition, as the Earth is heated by the sun, the Earth releases heat in the form of infrared light (as do all warm objects). Earth's temperatures are stable when the sum of the energy emitted by the Earth equals the energy it receives from the sun. This is illustrated in Figure 32.1.1.

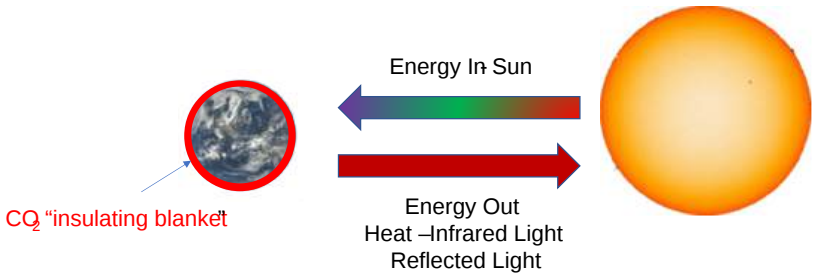

Figure 32.1.1: Energy balance for Earth as it adsorbs and emits solar radiation

Our stable climate has been enabled by fairly constant levels of atmospheric CO_2, a trace atmospheric gas, which has hovered around 280 parts per million (ppm) until the start of the Industrial Revolution in 1770. CO_2 is a greenhouse gas, which as anyone who has run an IR spectra knows, absorbs in the infrared. CO_2 in the atmosphere absorbs some of the infrared radiation released by the Earth, allowing the Earth to be warmer than in its absence. The CO_2 effectively acts as an insulating blanket. In fact, without CO_2 or other "greenhouse" gases, the Earth would be completely covered by snow.

Other greenhouse gases in the atmosphere include methane and nitrous oxide. The IR spectra of these gases are shown in Figure 32.1.2. Students who have taken organic chemistry labs and obtained IR spectra of samples always blank the instrument to remove spectral signals from both CO_2 and H_2O.

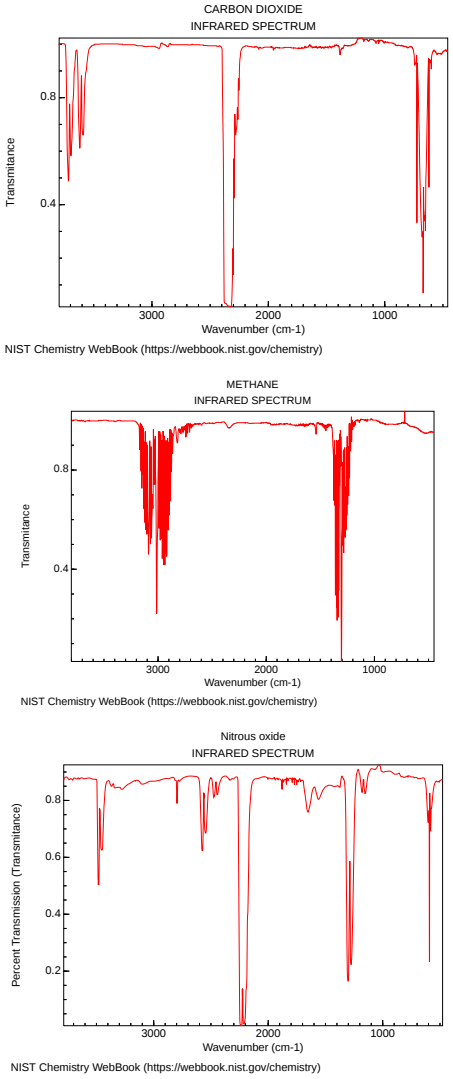

Figure 32.1.2: IR spectra of some greenhouse gases. NIST (ex: https://webbook.nist.gov/cgi/cbook.c...ndex=1#IR-SPEC)

Since the start of the Industrial Revolution, humans have been releasing into the atmosphere ever-increasing amounts of CO_2 from the burning of fossil fuels and methane from agricultural practices and natural gas production. CO_2 levels, as of November 2022 have reached 415 ppm, while methane has increased to 1900 part per billion (ppb) or 1.9 ppm. Increasing methane in the atmosphere contributes about 20% of the global warming effect of the more concentrated CO_2, given methane's intense IR absorbance spectra. It has a short half-life in the atmosphere (about 20 years) compared to that of CO_2 (hundreds of years). Nitrous oxide (N_2O) is also a powerful greenhouse gas, which also depletes ozone in the stratosphere. Our increased use of synthetic fertilizers and manure is the primary anthropogenic source of N_2O. Its emission is accelerated from poorly drained farmlands.

The net effect is that the Earth is no longer in energy balance. The net contributions of energy input and output are expressed as energy/sec/m^2 of the Earth's surface area. Hence the units are Joule/s·m^2 = Watts/m^2, where 1 Watt is 1 J/s. From around 2005 to 2019, the average **Earth Energy Imbalance (EEI)** (or budget) was about +460 x 10^{12} W or 460 terrawatts (TW) = 4.6 x 10^{14} W. Dividing this by the surface area of the planet (5.1 x 10^{14} m^2), gives an average global value of +0.90 ± 0.15 W/m^2 (or J/(m^2s)). Newer and more refined estimates show it to be +1 W/m^2 with most of the excess energy stored in the Earth's Oceans, which have a high specific heat capacity and

cover 71% of the surface area of the planet. Most of the rest of the excess energy is used to warm land masses and melt ice shields and glaciers. 1 W/m^2 might not seem like a lot but it is (pardon the pun), astronomically big.

The atomic bomb dropped on Hiroshima released about 1.8 x 10^{13} Joules (some estimates are as high as 9 x 10^{13} Joules) of energy. Assume for the sake of calculation that this energy was released in 1 second over the entire surface of the planet (5.1 x 10^{14} m^2). The earth energy imbalance for that 1 explosion was 0.035 J/m^2·s (0.176 J/m^2·s for the higher estimate). The ratios of the present imbalance (+1 W/m^2) to the distributed bomb's imbalances are 1/0.035 = 28x for the lower energy estimate bomb or 1/0.176 = 5.7 for the higher energy estimate. Hence the present imbalance, 1 J/m^{2}s from human-caused climate change, is equivalent to detonating from 6-28 Hiroshima-type atomic bombs every second. Other estimates are lower and closer to 600 bombs per **day** but the bases for the calculation are not readily available. Regardless, these values should give you a dramatic sense of the imbalance and how unsustainable it is.

Figure 32.1.3 below shows a graphical representation of the Earth's energy budget.

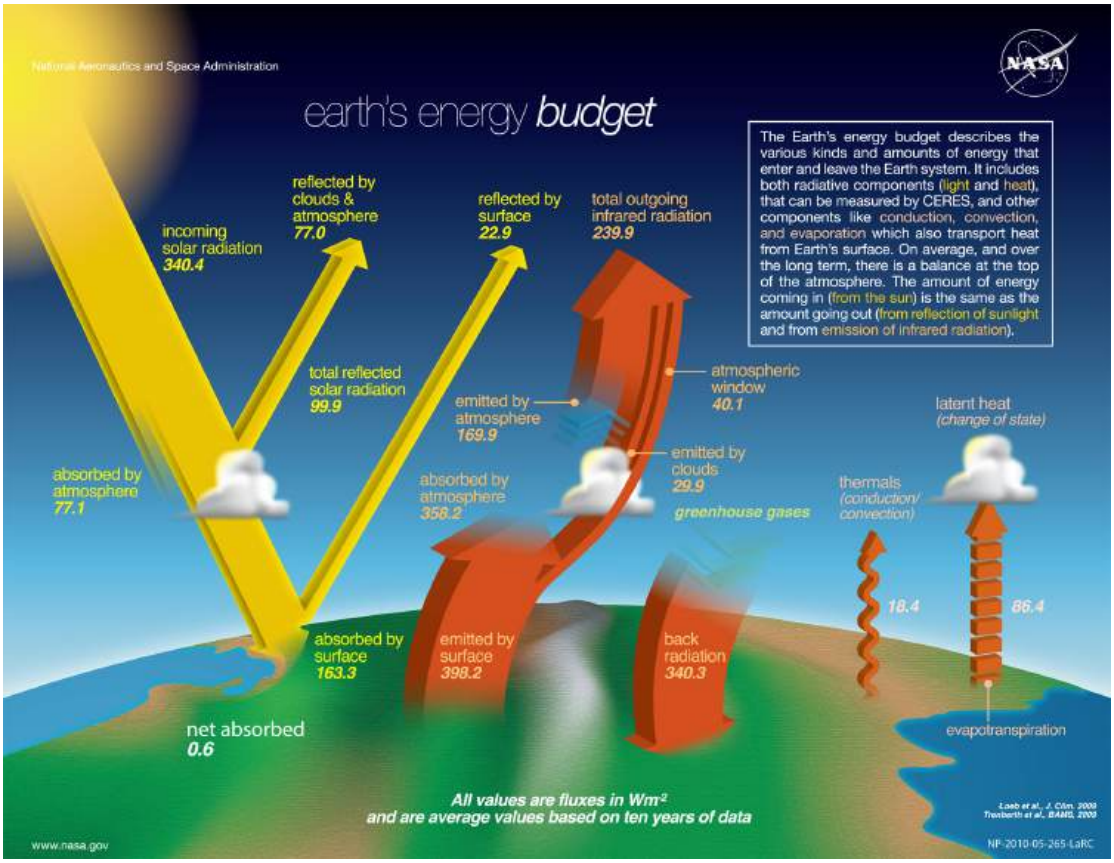

Figure 32.1.3: Earth's energy budget, with incoming and outgoing radiation (Values are shown in W/m^2). Satellite instruments (CERES) measure the reflected solar and emitted infrared radiation fluxes. **Year 2021 update**: Net absorbed energy (shown as 0.6) rose to above 1.0 W/m^2 based on independent CERES and ocean heat content measurements.(see fig.1 in Loeb et al.(2021), Geoph. Res. Let 48 (13), doi:10.1029/2021GL093047). Public Domain

GLOBAL WARMING POTENTIAL

The **global warming potential (GWP)** is used to calculate the total contribution of all emitted greenhouse gases. It is expressed in units of CO_2 equivalents. It adds the contribution of other greenhouse gases like CH_4 and nitrous oxide (N_2O), each of which has unique IR absorption spectra (as shown in Figure 2 above) and atmospheric half-lives. The IPCC uses a 100-year time frame for the calculation of the GWP, which is often abbreviated as GWP100, and uses this formula:

$$\text{CO}_2 \text{ equivalent kg} = \text{CO}_2 \text{ kg} + (\text{CH}_4 \text{ kg} \times 28) + (\text{N}_2\text{O}kg \times 265) \quad (32.1.1)$$

- CO_2 has GWP of 1 by definition since it is the reference. Its time frame in the atmosphere (100s to 1000 years) doesn't matter since it is the reference.
- CH_4 has a GWP of around 27-30 over 100 years. It reflects its higher IR absorbance but lower life-time (around 12 years).
- N_2O has a GWP of around 265-273 over a 100-year timescale. N_2O has a life-time of around 109 years.

Water is also a greenhouse gas as you can attest to on humid days and how its lack in the atmosphere in deserts leads to a large temperature drop at night. It's very different than other greenhouse gases. Its concentration varies enormously (from 40 ppm to 40000 or more) based on humidity and precipitation events, which remove it from the atmosphere. The amount of water in the atmosphere increases with increasing global temperatures, which gives rise to more intense precipitation events and also to warmer temperatures in a positive feedback loop. Its concentration in the atmosphere hence changes enormously on the time scale of hours and days, so its half-life in the atmosphere is short. In contrast, the half-life of CO_2 in the atmosphere is measured in decades to centuries.

CLIMATE CHANGES OVER THE LAST MILLION YEARS

THE SKEPTIC'S CORNER: CLIMATE CHANGE MISINFORMATION

Climate has always changed. Our present period is no different, so there is no need for action.

Indeed, the Earth has been subject to cycles of glaciation and deglaciation for hundreds of thousands of years. Luckily, we are able to determine atmospheric levels of CO_2 dating back to hundreds of thousands of years ago by measuring entrapped CO_2 in ice cores from Antarctica and Greenland. In addition, we've been able to infer the temperature over this time frame using proxies for temperature (tree rings, fossils, and more as described in section 31.2). Figure 32.1.4 shows how atmospheric CO_2 and temperature have varied over the last 800,000 years using ice core data.

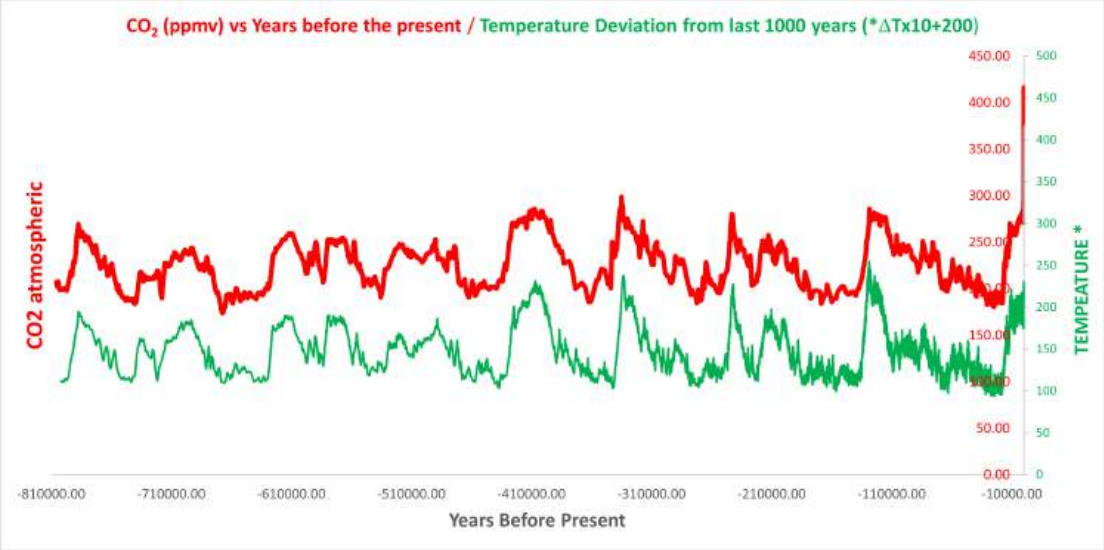

Figure 32.1.4: Atmospheric CO2 concentrations (ppm, red) and temperature deviations from the past 1000 years (green) using ice core date and temperature proxies.

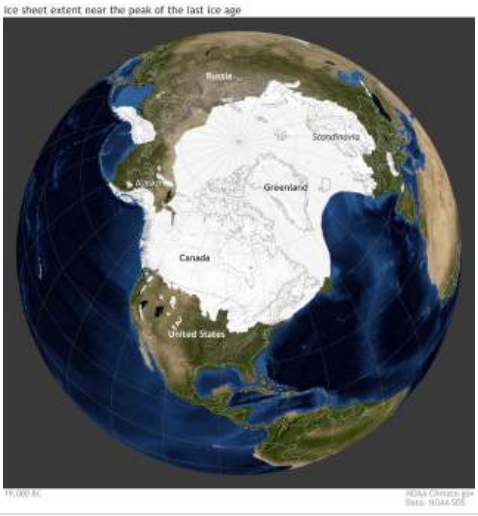
Several key features of the graph should be apparent:

- Both atmospheric CO_2 and temperature change (ΔT) are periodic. So yes, it is obviously true that "climate changes" as climate change skeptics argue
- Both CO_2 and ΔT change in synchrony. An obvious question might be what changes first. Does ΔT drive CO_2 changes or vice versa? More on that in a bit.
- **The CO_2 levels in more modern times (right hand side of the graph) have soared in ways not seen in the last 800,000 years**! This change is caused by CO_2 emissions from the burning of fossil fuels.

In those 800K years, the Earth has experience cycles of glaciation/deglaciation with recurring ice ages. Figure (\PageIndex{5}\) below shows a depiction of the last ice age which peaked 21,000 years ago (left). At that time, the ice cap over New York City was about 1 mile high (right) as CO_2 was at 185 ppm!



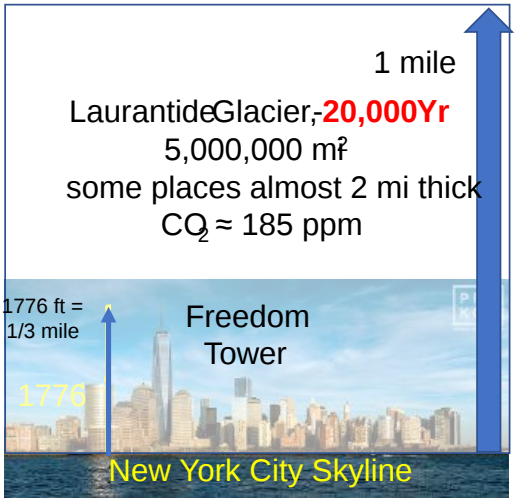


Figure 32.1.5: The Laurentide glacier during the last ice age (left) and its peak height over present-day Manhattan. https://www.climate.gov/news-feature...oming-sunlight

By 5000 BCE, the glacier had retreated to more modern levels, leaving ice over the Arctic Ocean, and over Greenland. CO_2 levels were then around 260 ppm. A change of just 100 ppm in CO_2 was sufficient to lead to the melting of the Northern Hemisphere glaciers. The image above is not "Northern Hemisphere-Centric" since the great glaciers were localized in the Northern Hemisphere in the ice ages. That's because glaciers grow over land and most of the land on the planet is in the Northern Hemisphere. (Our climate studies won't include the time when one continent - Pangea- existed.) The video below shows an animation of the Northern Hemisphere ice shield as it changed with time from 19,000 BCE to now to a projected future that assumes little action to change CO_2 emissions. Pay special attention to the graphs which show sea level changes as well.

Best estimates by Tierney et al now show that during the last ice age, the average global temperature was 6 degrees Celsius (11 F) cooler than today, which in the 20th century is 14 C (57 F). The Arctic however was much colder (about 14 C or 25 F). The group also came up with an estimate of **climate sensitivity**, the increase in temperature with increasing CO_2. That value is a **rise of 3.4 °C (6.1 °F) for a doubling in CO_2**. In 1896, Arrhenius, recognizing that CO_2 was a greenhouse gas, actually calculated that doubling atmospheric CO_2 would cause a rise of 4-5 °C. No one can say we haven't known!

A new value for climate sensitivity giving a **rise of 4.8 °C (8.6 °F) for a doubling of CO_2** was determined by Hansen et al (2023) using more precise data about temperatures and CO_2 concentrations derived from isotopic analyses of ice core samples. If this value holds, the environment needed for human life and our present society is in serious jeopardy unless we take immediate measures to stop emissions and actually cool the planet. In addition, the rate of increase in global and ocean temperatures has accelerated after 2010 and the likely culprit is an actual decrease in toxic SO_2 aerosols released by ocean vessels in the North Pacific and Atlantic Oceans and in China from the reduction of dirty coal-burning facilities. Aerosols reflect incident solar light and also increase cloud formation, both of which help cool the planet. Paradoxically, the reduction of anthropogenic aerosols, while great for cardiovascular and pulmonary health, will accelerate global warming. India would be much warmer now if not for the high aerosol concentrations from smog that covers many of its large cities and countryside.

WHAT THE SCIENCE SHOWS

Climate, CO_2 and temperature have always changed over geological time, but our present rise in anthropogenic CO_2 in such a brief time is unprecedented and has led to CO_2 levels that far exceed those during the warmer interglacial periods when Northern Hemisphere glaciers had retreated.

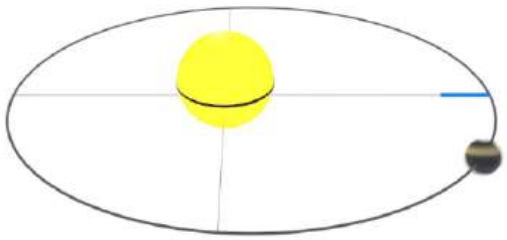
THE ICE AGES, CO_2 AND TEMPERATURE

THE SKEPTIC'S CORNER: CLIMATE CHANGE MISINFORMATION

It's not increasing CO_2 that is causing any observed increases in temperature. CO_2 is going up after temperature increases so we don't have to worry about CO_2 levels. It's just a natural process and requires no action to reduce fossil fuel use. Why reduce it if it doesn't cause global warming?

Data and models show that the global increase in temperature is driven mostly by increases in CO_2 (and not increasing temperatures driving increasing CO_2) as the predominant cause. That begs the question as to what starts the process of deglaciation. It turns out that cyclic increases in solar irradiance that increase temperatures, especially in the Northern Hemisphere, start deglaciation. A prime factor is the changes in the orbital dynamics of the Earth with respect to the sun. As you know, the orientation of the Earth's rotation axis remains generally fixed and pointed in the same orientation as the Earth rotates around the sun. This fixed orientation leads to our annual spring, summer, fall, and winter cycles on Earth. In the winter, the northern hemisphere is pointed away from the sun, leading to decreased solar irradiance per square meter in the Northern Hemisphere, causing winter there. When the Earth is on the opposite side of the sun, the axis points in the same direction but tilts towards the sun, leading to summer in the northern hemisphere. However, the orbital dynamics of the Earth do change in cyclic fashions over long periods of time. These long-term changes in the Earth's orbital shape (eccentricity), tilt (obliquity), and wobble (precession) are called the Milankovitch Cycle, and are illustrated in Figure 32.1.6. These cycles cause small temperature increases that start deglaciation. **Click on each image below** to download and view very short videos illustrating these orbital changes.

Change in eccentricity (orbital shape) - (100,000 yr cycle)



Change in obliquity (tilt) (41,000 yr cycle)

Axle precession (wobble) (26,000 yr cycle)

Figure 32.1.6: The Milankovitch cycle showing changes in the Earth's orbital dynamics with respect to the sun. https://climate.nasa.gov/news/2948/m...arths-climate/

Based on these cycles, Milankovitch calculated that recurring ice ages should occur approximately every 41000 years. Ice ages did occur at this interval from about 3 million years ago (MYA) to 1 million years ago (MYA). About 800,000 YA they lengthened to about 100,000 years, which corresponds to the Earth's eccentricity cycle. The increased duration of the cycle led to longer-lasting glaciers which moved further south in the Northern Hemisphere. One likely explanation for the increase in time between ice ages is that repeated glaciation/deglaciation eroded the bedrock in the Northern Hemisphere, converting it to **regolith** (rocks, soil, and dust). This allowed an increased velocity of movement of the glaciers to the south due to decreased frictional resistance, and thicker ice cap formation (more time to accrue ice), which required a longer time to melt. This also provided a positive feedback loop as the increased northern ice area would reflect more of the sun's energy back into space, cooling the planet. Punctuating these rhythmic orbital and ice age cycles are other events such as large volcanic eruptions, asteroid impacts, etc, that could produce minor to major changes in climate, and resulting mass extinctions.

Figure 32.1.7 shows how a combination of tilt angle, precession axis, and orbital shape at around 200 KYA (narrow rectangle across all the graphs) combined to lead to low glacial ice volume (bottom graph).

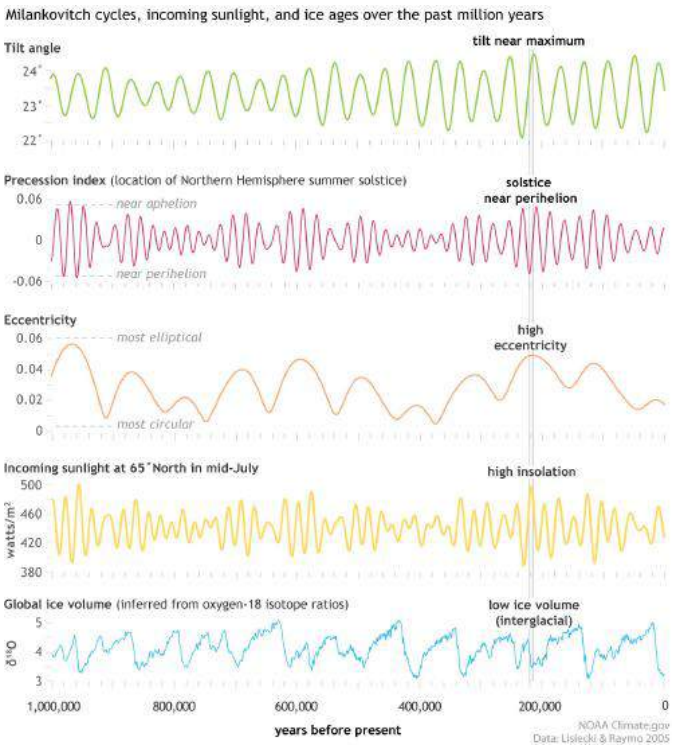


Figure 32.1.7: Milankovitch cycle contribution to ice volume over the past 1M years

If orbital changes (or **forcing**) trigger deglaciation, what is the role of increasing levels of the greenhouse gas CO_2, which clearly covary with temperature (see Fig 3)? Temperature increases derived from orbital and hence solar "forcing" seem to precede CO_2 increases for just short periods of time (perhaps 100 - 200 years). After that, CO_2 causes almost all of the global increase in temperatures during deglaciation, with CO_2 and temperature going up together. A global increase of about 0.3 C due to the Milankovitch cycle leads to greater Northern Hemisphere irradiance. This causes localized and limited melting of the Northern ice shield, leading to increases in ocean temperatures in the northern oceans. These increases slow a major ocean current (the Atlantic Meridional Overturning Circulation - AMOC) which inhibited the burial and return of cold water in tropical and southern oceans. This in turn led to a warming in the south accompanied by the release of large amounts of CO_2 stored in the oceans (see Carbon Cycle in 31.3). The release of this greenhouse gas was then responsible for most of the warming that lead to massive deglaciation. This "interhemispheric see-saw" transfer of heat from the north waters to the southern waters is key. For the far majority of the warming during glacial melting, CO_2 and temperature change synchronously.

Interpreting climate data is difficult. For example, it was found through measuring $^{15}N/^{14}N$ ratios that gases like N_2 and by extension CO_2 could rapidly diffuse through the compacting snow (firn, comprising the top 50-100 meters of the ice cap) until it became trapped in the solid ice beneath it. This would lead to the presence of "newer" CO_2 in older ice samples, and the conclusion the temperature changes preceded changes in CO_2. Corrections are made to the data to address the "apparent" time shift.

The CO_2 trapped in bubbles in the ice core samples from Antarctica reflects **global** CO_2 levels given atmospheric circulation but the temperatures measured from the same core samples (see Chapter 31.2) represent **local** (Antarctic) temperatures. Ice core samples from Greenland and ocean sediment samples from around the world are used to measure temperature at different locations over time. All of these data are required to model climate. Combined they lead us to our present interpretation of the linkage of CO_2 and temperature rise over time.

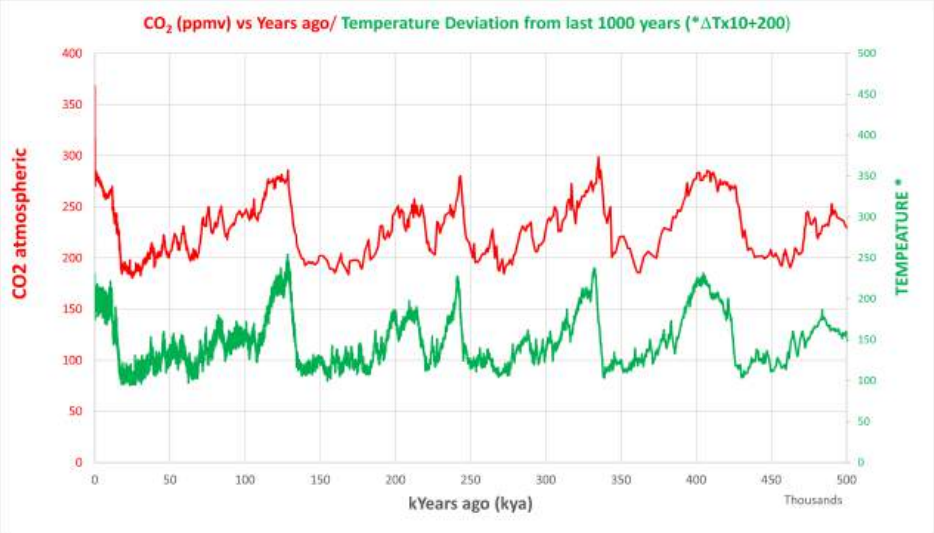
WHAT THE SCIENCE SHOWS

Increased solar irradiance on Earth arising from cyclic changes in the Earth's orbit leads to short, small temperature increases in the North Hemisphere. These lead to the **release of the greenhouse gas CO_2 from the oceans, which causes synchronous warming of the planet and subsequent deglaciation.**

So when skeptics say that temperature increases preceded CO_2 increases, you can acknowledge they did but that the bulk of the warming is attributed to increasing CO_2 released from ocean stores which leads to synchronous temperature increases and deglaciation. Using the words of chemistry, small temperature increases from orbital forcing catalyzed the release of huge amounts of CO_2 dissolved in the ocean. In Chapter 31.3 we will explore the carbon cycle in more detail and look at how it affects CO_2 levels.

TERMINATION OF THE ICE AGES

How did the ice ages terminate? Contributions from the orbital forcing derived from the Milankovitch cycle play a part. Another factor seems to be dust derived from regolith, itself made by glacier movement as we mentioned above. How can that hypothesis be tested? By using proxies for dust, namely iron and long-chain n-alkanes (derived from plant waxes) that have been deposited in sediments. First let's look at a graph of CO_2 and temperature changes and superimpose those on iron and long-chain fatty acid levels, as shown in Figure 32.1.8.



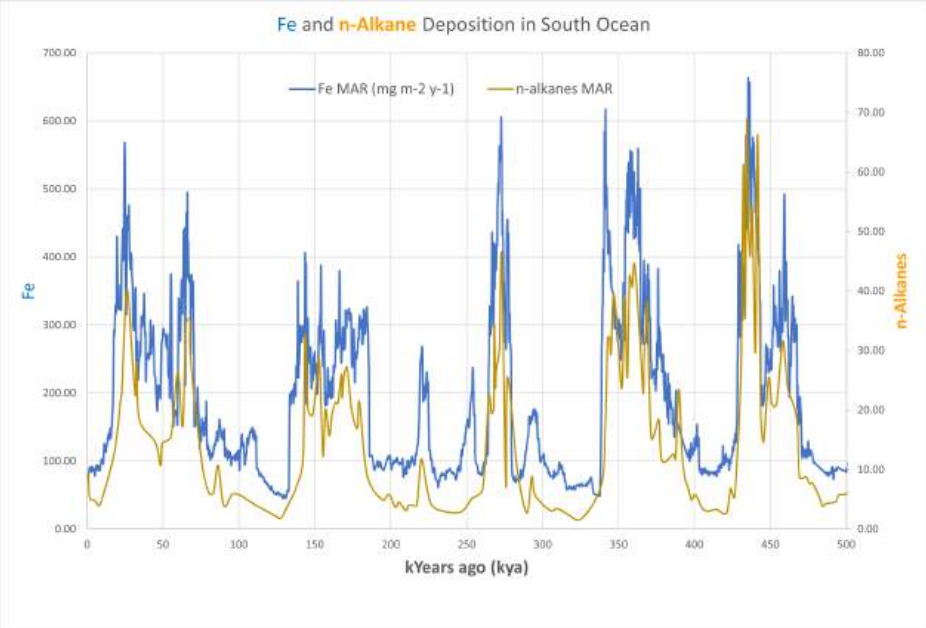


Figure 32.1.8: Fe and n-alkane deposition compared to CO_2 and temperatures in the Southern Ocean over the last 500,000 years. Note that the x axis shows time in kYA going to the right. (so the past is towards the right).

A close examination of the two vertically aligned graphs from around 120 K to 130 KYA shows that the iron and n-alkane depositions are at a minimum at the same that CO_2 and temperature are peaking! What explains this negative correlation? It depends on the intimate connection of the biosphere with the nonbiological world (an arbitrary distinction).

Iron and n-alkanes are circulated and delivered in dust. The long-chain alkanes, highly abundant in waxes and enriched in odd carbon number chains, were presumably derived from leaf waxes which prevent water loss from plants, especially during higher temperatures. Dust deposits were first observed in geological time in the switch from the warmer Pliocene (5.3 to 2.6 MYA) to the Pleistocene (2.6 MYA to 11.7KYA, see Fig 8 below). During the warmer Pliocene, the difference in global and atmospheric temperatures was lower, and with this

smaller temperature gradient, winds that could globally transfer dust would be diminished. Also, the warmer Plicoene (5.3 to 2.6 MYA) would have more rain, which would have removed dust from the global circulation.

As temperatures cooled in the Pleistocene (2.6 MYA to 11.7KYA), cycles of glaciation would produce more dust-containing regolith (rocks, soil, and dust), which would be dispersed through stronger global winds from higher temperature gradients and less rain. Dust contains carbon (for example long chain fatty acids) and perhaps more importantly iron, which is needed for oceanic phytoplankton growth. Without Fe, the uptake of CO_2 by phytoplankton (primary production) would not occur, leading to increased CO_2 in the atmosphere. Stronger regional atmospheric winds would lead to increased upwelling of nutrients as well as deep ocean CO_2. The CO_2 would enter the atmosphere more readily in the absence of dust deposition of iron.

In summary:

- High CO_2 and high temperature (lower global temperature gradients, more rain) are associated with low dust, as measured with the proxies Fe and n-alkanes). Low dust leads to low deposition of Fe and n-alkanes in the ocean, which decreases phytoplankton **primary production**, the fixing of CO_2 into biomass), leading to increased CO_2 movement from the ocean to the atmosphere, increasing temperature. This is an example of a positive feedback loop (higher temperatures leading to higher temperatures.
- Low CO_2 and low temperature (higher global temperature gradients, stronger winds, less rain) are associated with high dust with Fe and n-alkanes deposition. This increases phytoplankton primary production and decreases CO_2 movement from the ocean to the atmosphere, in a negative feedback loop.

By the end of a glacial deposition cycle, dust, blown by stronger winds from higher temperature gradients, was increasingly deposited on the ice sheets. Along with leading to more heat absorption by the sheets, it would also decrease their reflectivity (albedo). Both effects would promote ice sheet melting. Also, a cooler planet during glacial maximum had less precipitation, which along with lower CO_2, would lead to more plant and tree death, increasing soil erosion and desertification, both effects which would have increased dust production and its deposition on ice sheets. Then when CO_2 rose to 280 ppm, plant life renewed itself, and dust levels dropped.

CLIMATE CHANGE FROM 66 MILLION YEARS AGO TO NOW

Antarctic ice core data are now available for the past 2 M years. Ocean sediment data can be used to go back even further in time to 66 million years ago (MYA) just before the dinosaurs died after the massive asteroid impact forming the Chicxulub ***crater*** buried underneath the Yucatán Peninsula in Mexico. A brief review of geological eras, periods and epochs is shown below in Figure 32.1.9

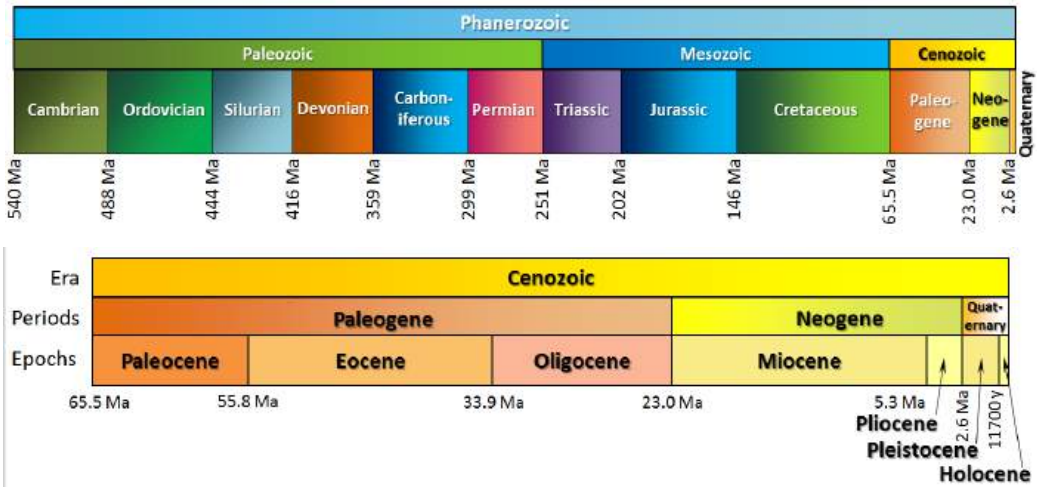

Figure 32.1.9: Geological Era, Periods and Epochs

CO_2 levels and associated temperatures derived from ocean sediment cores going back to 66 MYA are shown in Figure 32.1.10.

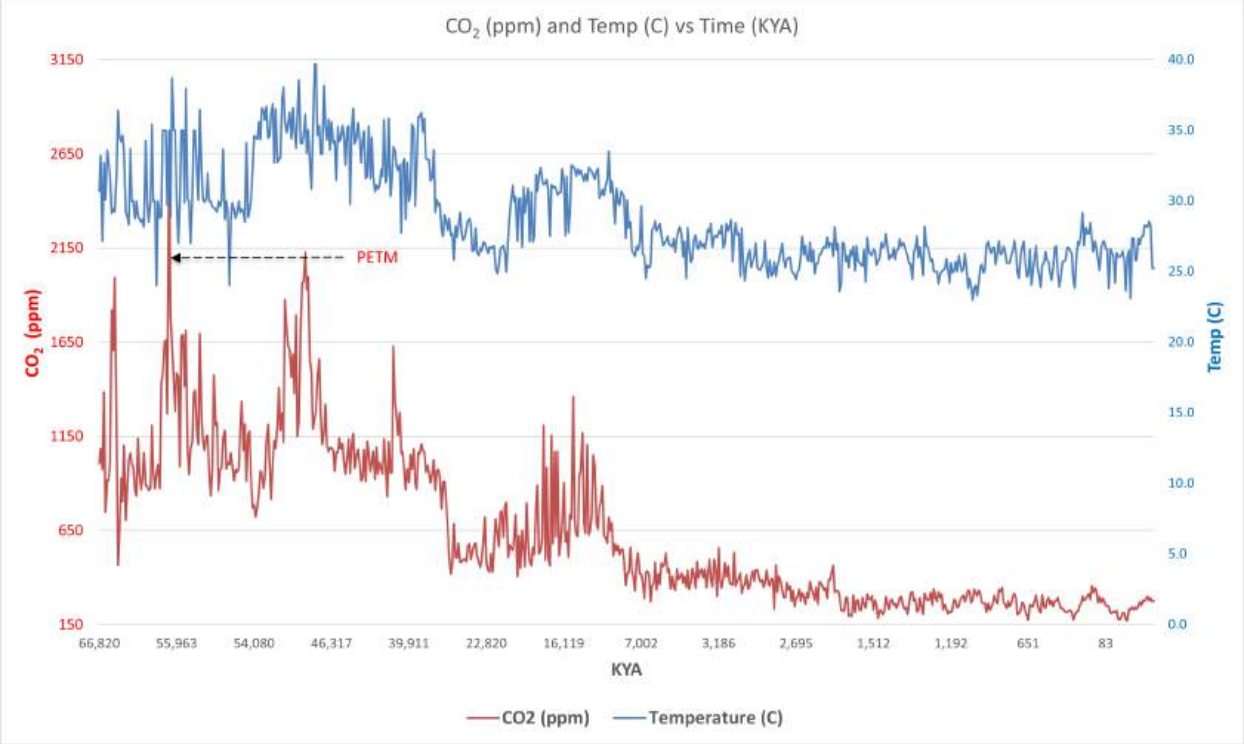

Figure 32.1.10 CO_2 levels (red) and temperatures (blue) derived from ocean sediment cores going back to 66 MYA = 66,000 KYA . Data from Rae et al. Annual review of Earth and planetary sciences, 49, 2021

Note again the parallel rise and fall of CO_2 and temperature. Eventually, they fall further in the Pliocene (5.3 to 2.6 MYA) and Pleistocene (2.6 MYA to 11.7KYA) epochs with cyclic glacier/interglacial periods we've discussed above. It wasn't until the late Miocene (10 to 6 MYA) that Northern hemisphere glaciation started and both poles of the planet had glacial sheets.

The time frame shown in Figure 9 encompasses the Cenozoic era (65 MYA when the dinosaurs died to about now). CO_2 levels were much higher than today in the greenhouse Paleocene and Eocene eras but decreased to about 500 ppm in the Oligocene (34 MYA). An almost stepwise drop in CO_2 and temperature occurred in the **Eocene to Oligocene transition (EOT)**, about 33 MYA. Data shows the development of large ice sheets appearing on Antarctica at this time. Before the EOT (33 MYA), Antarctica was ice-free, as shown in the recreation in Figure 32.1.11.

Figure 32.1.11: Reconstruction of the West Antarctic mid-Cretaceous temperate rainforest. Image credit: J. McKay / Alfred-Wegener-Institut / CC-BY 4.0. https://www.sci.news/othersciences/p...ing-09921.html

Proxy data for temperatures show that the transition was most likely caused by a decrease in CO_2 and some orbital forcing was probably involved. Present models still struggle to explain the EOT (33 MYA) transition, but it is clear that both CO_2 and temperature decreased. Where did the CO_2 go? Most assuredly into the oceans.

To understand that, we have to understand a bit about the carbon cycle, which we will discuss more fully in the next chapter section. Let's briefly discuss the role of atmospheric CO_2 and its interaction with the ocean. The main gases in the atmosphere, N_2 and O_2, are found in very low concentrations in the ocean since they are nonpolar and generally unreactive. CO_2 is also a nonpolar trace gas, but in contrast, it

can readily react with water to form HCO_3^- and CO_3^{-2}, which are found in great abundance in ocean reserves. Hence the **ocean chemistry of CO_2 determines in large part the levels of atmospheric CO_2**. The coupled reactions of CO_2 are shown below.

$$CO_2(\text{ g, atm}) \leftrightarrow CO_2(\text{aq, ocean}) \tag{32.1.2}$$

$$CO_2(\text{aq, ocean }) + H_2O(\text{I, ocean }) \leftrightarrow H_3O^+(\text{aq}) + HCO_3^-(\text{aq}) \tag{32.1.3}$$

$$H_2O(\text{I}) + HCO_3^-(\text{aq}) \leftrightarrow H_3O^+(\text{aq}) + {CO_3}^{2-}(\text{aq, sparingly soluble }) \tag{32.1.4}$$

This chemistry helps determine the pH of the ocean. Figure 32.1.12 shows atmospheric levels of CO_2 and ocean pH over the last 66 million years.

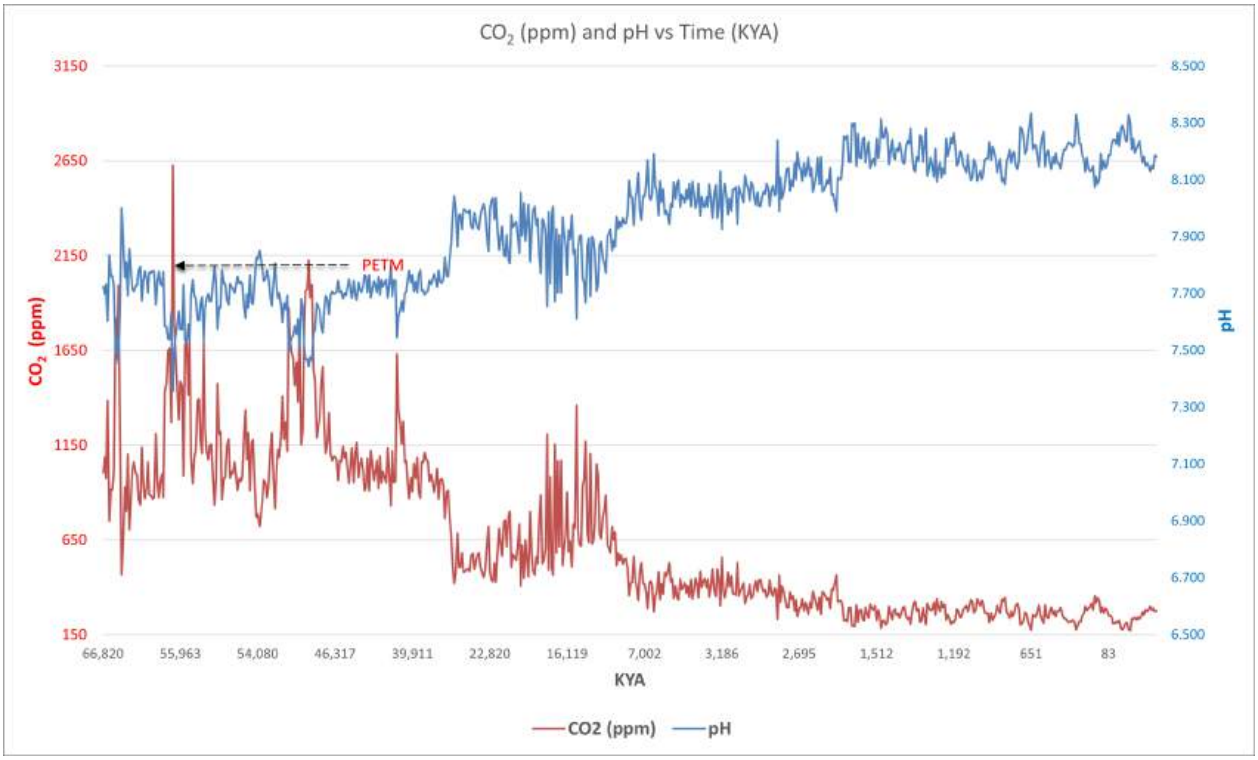

Figure 32.1.12: Atmospheric levels of CO_2 and ocean pH over the last 66 million years

Before the EOT at 34 MYA, atmospheric CO_2 levels were higher and ocean pH levels lower (around 7.7). After the EOT (33 MYA), atmospheric CO_2 is much lower and ocean pH is higher (more basic, 7.9 rising to 8.1). What happened to the CO_2 is a bit unclear. Atmospheric CO_2 decreased by moving into the oceans but wouldn't that have lowered the pH based on the chemical equations presented above? It would have but it turns out that the ocean alkalinity is determined not just by H_3O^+ produced by the equations above, but by the dissolved inorganic carbon ions, HCO_3^- (aq) and CO_3^{2-} (aq), which are conjugate bases. Increased HCO_3^- (aq) and SiO_4^{-2} (aq) from weathering solid carbonates and silicates that entered the oceans would raise the pH of the oceans.

A little review of introductory chemistry helps here.

Let's take bicarbonate, the weak conjugate base of the weak acid carbonic acid. HCO_3^- can act as both an acid and base.

Rx 1: Acts as an acid: HCO_3^- (aq) + H_2O (l) ↔ H_3O^+(aq) + CO_3^{2-} (aq)

$$K_{a2} = \frac{\left[H_3O^+\right]\left[CO_3^{2-}\right]}{\left[HCO_3^-\right]} = 4.7 \times 10^{-11} \tag{32.1.5}$$

Rx 2: Acts as a base: HCO_3^- (aq) + H_2O (l) ↔ H_2CO_3 (aq) + OH^- (aq)

$$K_{b2} = \frac{\left[H_2CO_3\right]\left[OH^-\right]}{\left[HCO_3^-\right]} = 2.2 \times 10^{-8} \tag{32.1.6}$$

The equilibrium constant for the reaction of HCO_3^- as a base is much larger so bicarbonate is a stronger base than acid.

Whatever the mechanism of the CO_2 drawdown, it led to decreasing temperatures in the EOT transition. Increased alkalinity of the ocean would also consume H_3O^+, increasing ocean pH.

A summary of planetary temperatures across geological time is shown in Figure 32.1.13.

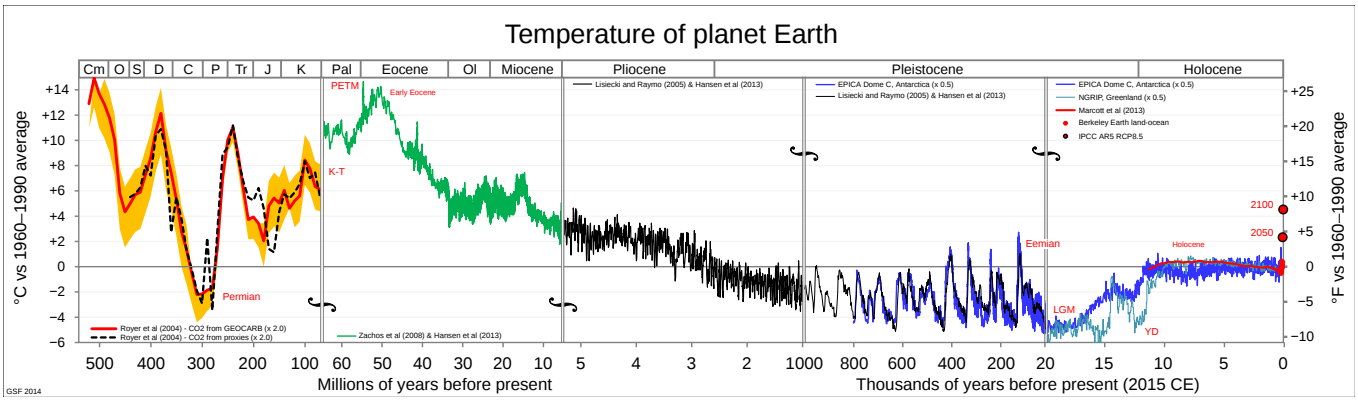

Figure 32.1.13: Temperature of Earth over 500 million years. https://commons.wikimedia.org/wiki/F...alaeotemps.png. (Excel available).
Creative Commons Attribution-Share Alike 3.0 Unported

There are several key features to note. The last time CO_2 was as high as today (415 ppm) was about 3 million years ago. Repetitive cycles of glaciation/deglaciation are obvious in the Pleistocene (2.6 MYA to 11.7KYA).

At around 55 MYA, a spike in temperatures of about 5^0 - 9^0F (or even more) on an already warmer planet occurred over about a 100K year timeframe. This is known as the **Paleocene/Eocene thermal maximum (PETM)**. The poles warmed to near 70 ^{0}F and alligators and palm trees were found there. The warming also led to the spread of tropic rainforests from the equator, allowing the evolution and proliferation of new plant species including flowering plants and an incredible biodiversity of insects, bird,s and animals that relied on them. Flowering plants produce fruits, which helped drive the evolution of mammals and the first true primates, including the tiny Teilhardina magnoliana. It may have resembled the picture below. (https://en.wikipedia.org/wiki/Teilhardina). Bigs eyes and hands would allow them to find fruit in the tropical forests.

The temperature increase was caused by a dramatic spike in CO_2 from deep-sea volcanoes and vents, which also led to a dramatic drop in ocean pH as measured by the loss of deep-sea $CaCO_3$ (chalk). Methane hydrates were also released. These environmental and biosphere changes are visually evident in geological deep-sea sediment records as shown in Figure 32.1.14.

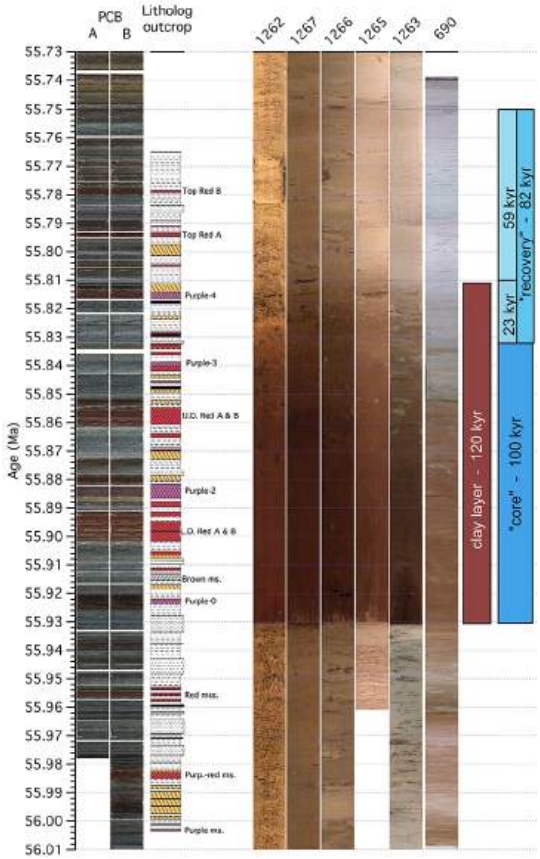

Figure 32.1.14: Overview for the Paleocene–Eocene Thermal Maximum (PETM, 55.5 MYA) data from deep-sea records and the terrestrial Polecat Bench
(PCB) drill core against age. Westerhold et al. Clim. Past, 14, 303–319, 2018. https://doi.org/10.5194/cp-14-303-2018. Creative Commons Attribution 3.0 License

Sediment cores were taken at various sites (1262, 1267, 1266, 1265, 1263, and 690) that are aligned from left to right according to the water depth from deep to shallow. Note at 55.93 million years ago, at the start of the PETM, there was a sharp transition from light brown/gray which is enriched in chalk, to dark brown enriched in clay. Ocean acidification dissolved the chalk. It took over 100,000 years to recover.

This very short time frame is called the **Paleocene/Eocene thermal maximum (PETM**, 55.5 MYA), which shows very quick spikes (on the geological time scale) can and do occur. Approximately 1.5 petagrams (10^{15}) of CO_2 were released annually during the PETM. Now we are releasing about 25 petagram per year. Our present rate of warming is much greater than the rate of warming during the PETM (55.5 MYA). The best candidates for the source of CO_2 release that caused the PETM are volcanoes, the oceans, and the permafrost. In addition, methane hydrates (a solid form of methane found in low- temperature high-pressure waters) might also be another factor.

The PETM and time after allowed for optimal evolution of primates. In fact that time might be called the Age of the Primates (analogous to the Age of the Dinosaurs). Figure 13 shows that the arrival of Oligocene was accompanied by much lower temperatures resulting from CO_2 drawdown. This decimated the habitat for the primates except for in the tropic rainforests. Primates disappeared completely from North America but thrived in Africa. Tectonic forces caused the generation of the African Rift valley, characterized by diverse geology and a less homogenous and more fractured landscape which again provided new challenges but also new habitats for the evolution of primates and the eventual appearance of Homo Sapiens.

This chapter has been divided into two sections. Got to Chapter 01B: Back to the Present and Future of Climate Change to see where we are and where we are headed!

KEY POINTS - BETA VERSION FROM CHAT.OPENAI

1. Climate change is the long-term change in the average weather patterns on Earth.
2. The primary cause of climate change is the burning of fossil fuels, which releases large amounts of greenhouse gases, such as carbon dioxide (CO2), into the atmosphere.
3. Greenhouse gases trap heat in the atmosphere, causing the Earth's temperature to rise. This is known as the greenhouse effect.
4. The most significant contributor to climate change is CO2, which is released when fossil fuels are burned. Other significant contributors include methane, nitrous oxide, and fluorinated gases.
5. Climate change has a wide range of impacts on the Earth's systems, including rising sea levels, changes in precipitation patterns, increased frequency and intensity of extreme weather events, and disruptions to ecosystems.
6. The global temperature has already risen by 1 degree Celsius (1.8 degrees Fahrenheit) since the pre-industrial era, with most of the warming occurring in the last few decades.
7. The Intergovernmental Panel on Climate Change (IPCC) has stated that limiting global warming to 1.5 degrees Celsius (2.7 degrees Fahrenheit) above pre-industrial levels could significantly reduce the risks and impacts of climate change.
8. Reducing greenhouse gas emissions is essential in order to slow or stop climate change. This can be achieved through a combination of actions, such as increasing the use of renewable energy sources, improving energy efficiency, and reducing deforestation.

32.01B: BACK TO THE PRESENT AND FUTURE OF CLIMATE CHANGE

Search Fundamentals of Biochemistry

LEARNING OBJECTIVES

- to demonstrate how climate has changed over geological time through the present
- to explain mechanisms, using knowledge from biology, chemistry, and physics, for climate change
- to show the central role of atmospheric CO_2 as a causative agent of past and present climate change
- to contrast the effects of anthropogenic burning of fossil fuels on climate change with causes of past climate changes
- to address arguments made by climate change skeptics

BACK TO THE RECENT PAST AND PRESENT

Let's return to more recent human history and the anthropogenic forcing of our climate. Figure 32.1.14 shows an interactive graph of atmospheric CO_2 over more recent times. **Zoom into the steep rise in CO_2 starts which around 1760 with the industrial revolution.**

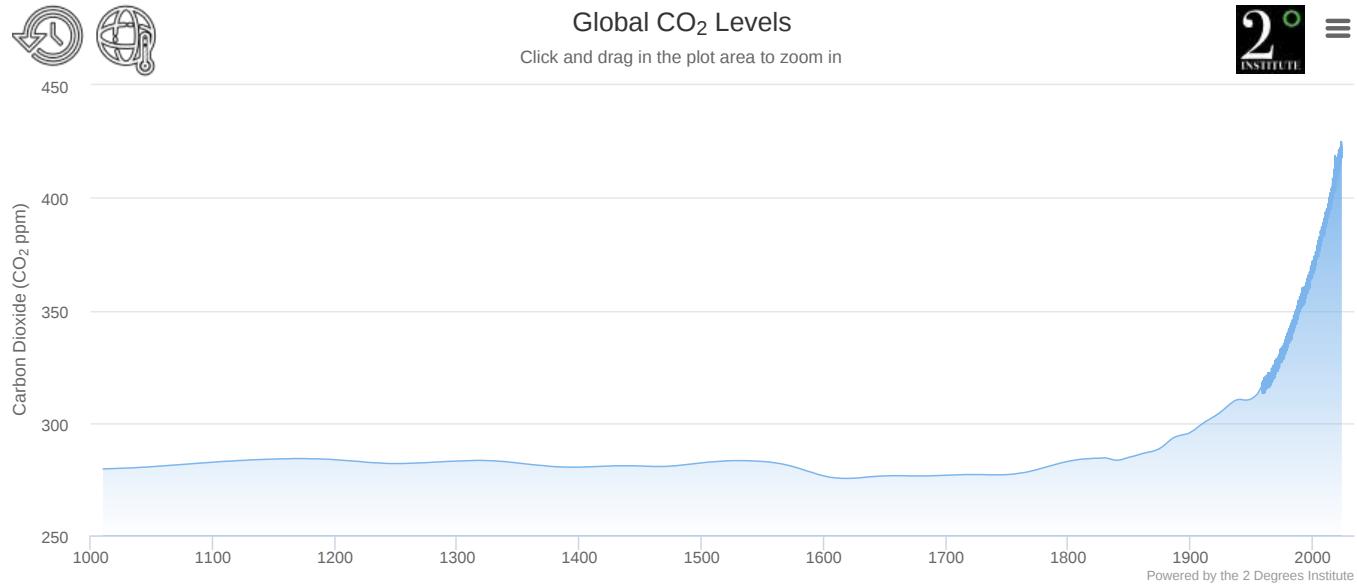

Figure 32.1.15: Interactive graph of atmospheric CO_2 vs time over the last 1000 years. Historical CO_2 record from the Law Dome DE08, DE08-2, and DSS ice cores. Credits: D.M. Etheridge, L.P. Steele, R.L. Langenfelds, R.J. Francey and the Division of Atmospheric Research, CSIRO, Aspendale, Victoria, Australia. 2 Degrees Institute. https://www.2degreesinstitute.org/. Also, https://www.co2levels.org/

Orbital mechanics **cannot** explain the warming of the planet in the brief (in geological terms) times since the industrial revolution. Neither can volcanic activity, changes in solar activity, changes in land use (for example deforestation that slows down photosynthesis and CO_2 removal from the atmosphere), or even aerosols released on burning fossil fuels (which would actually decrease global temperature due to increased reflection of sunlight). Click on Figure 32.1.15 to see an animated explanation of which factors best explains the global temperature increase since 1880. The results are clear: It's us!

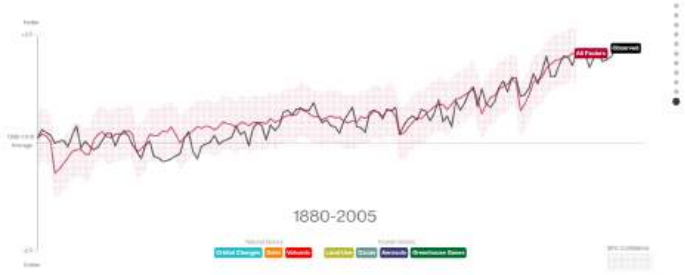

Figure 32.1.15: Factors contributing to global warming based on NASA data and NASA's Goddard Institute for Space Studies (GISS) climate models.

Unfortunately, other greenhouse gases have risen as well since 1975, as shown in Figure 32.1.16.

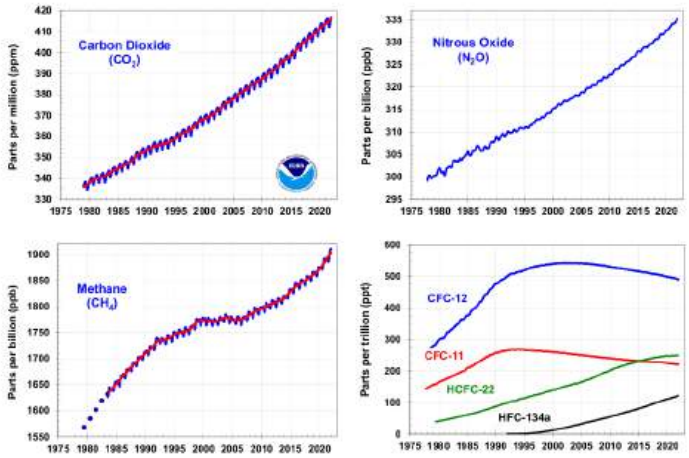

Figure 32.1.16: Rise in greenhouse gases since 1975. https://www.co2.Earth/annual-ghg-index-aggi

Take special note of the zig-zag nature of the CO_2 curve. The curve dips a bit in the summer when CO_2 is actively removed by plants in the Northern hemisphere. Increasing methane now accounts for up to 20% of the warming observed. **Figure 32.1.17 shows as interactive graph a very worrisome rise of atmospheric methane with time.**

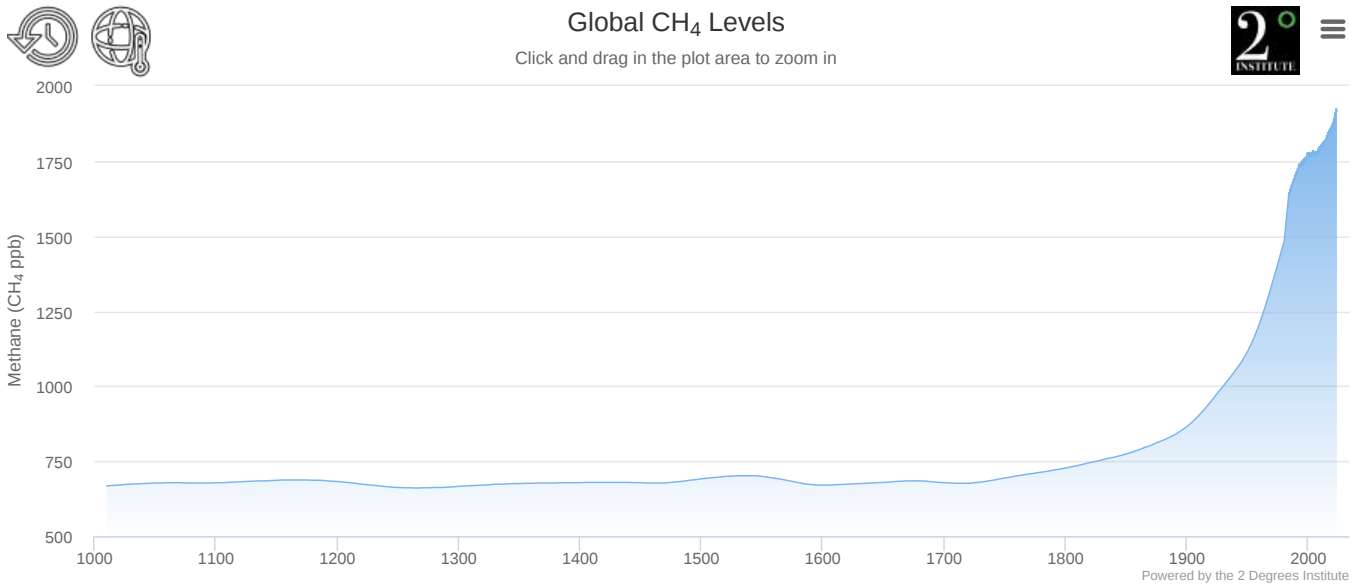

Figure 32.1.17: Interactive graph of atmospheric CH_4 vs time over the last 1000 years. 2 Degrees Institute. https://www.2degreesinstitute.org/

Present-day warming unequivocally is caused by humans' burning of fossil fuels.

PAST CLIMATE ANOMALIES

THE SKEPTIC'S CORNER: CLIMATE CHANGE MISINFORMATION

In recorded human history there have been other times of climate change, so we shouldn't worry about the present time! Look at the Little Ice Ages!

Several dramatic but short-lived (in geological time) climate changes have punctuated recorded human history. Let's look at two, mostly to equip you to address climate skeptics. They also show the sensitivity of our climate to subtle changes.

The Little Ice Ages

Actual and proxy temperature records show a mild period in Europe from around 950-1100 followed by colder weather, especially from 1450 to 1850. The latter period is called the "Little Ice Ages" although there was no significant expansion of the North Hemisphere ice shield. It was especially cold worldwide in 1816 when much of the world experienced a "year without summer". The effect in 1816 has a clear cause, the explosion of the volcano Mount Tambora in Indonesia on April 10, 1815.

But in addition to this identifiable influence in 1816, there was a cool period reported for the northern hemisphere from about 1800 to 1820 that started earlier than the Tambora eruption. Also, a low period of the sun's irradiance, called the Dalton Minimum, occurs from 1790-1860. Proxies for solar activity in the 1600s also show small solar irradiance drops, as we will discuss below. The dip in global average temperatures following the Medieval warm period, is shown in Figure 32.1.18.

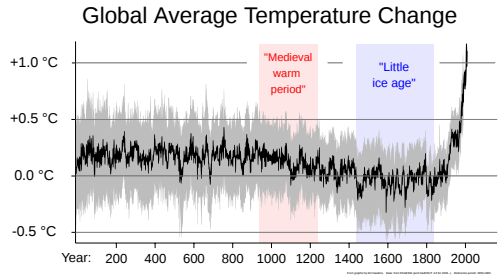

Figure 32.1.18: Dip in global average temperatures following the Medieval warm period, By RCraig09 - Own work, CC BY-SA 4.0, https://commons.wikimedia.org/w/inde...curid=87832845

Modern climate changes have been captured in literature and art. One example is a painting showing "Ice Fairs" on the Thames in London, shown in Figure 32.1.19.

Figure 32.1.19: https://commons.wikimedia.org/wiki/F...enell.jpgdfdfd

Many factors probably contributed to the Little Ice Ages including a drop in solar irradiance. A newer explanation has also been proposed. Marine records show that the water near Greenland and the Nordic seas were warmer, caused by a strengthening of the Atlantic Meridional Overturning Circulation (AMOC). This would have caused the loss of Arctic ice in the late 1300s and 1400s, cooling the water and diluting its salinity, since ice when it crystallized with a tetrahedral hydrogen-bonded coordination of water, excludes salt. This would have collapsed the AMOC and its transfer of heat to the northern waters, leading to rapid and prolonged cooling. An analogous strengthening of the AMOC was observed between 1960 and 1980, which was attributed to a long-duration high-pressure system over Greenland. A similar event might have occurred to kick-start the Little Ice Ages. Tree rings show evidence of higher solar irradiance before the Little Ice Ages, which may be associated with the initial strengthening of the AMOC.

The Little Ice Ages also affected China and may account in part for a crop failure in 1644, the year in which the Ming Dynasty fell. There was also an Arctic hurricane in 1588 that helped destroy the Spanish Armada. The Great Fire in London in 1666 was preceded by a very dry summer that followed an exceptionally cold winter. Food production were severely disrupted, which might have led to significant social change in Europe and elsewhere, much as the Plague in Europe shattered societal and cultural norms.

The explosion of Mount Tambora, in present-day Indonesia, in 1816 greatly exacerbated the effects of cooling. The ash and SO_2 aerosols block solar irradiance, Droughts, floods, cholera epidemics, famine, and migration from Europe to the US and from East to West arose in part from this event.

One of the worst times to be alive: 536

Historians report that in 536 AD, parts of Europe, the Middle East, and Asia experienced 24 hours of darkness for up to 18 months. Summer temperatures plummeted. Famines occurred for a few years after. It snowed in China in the summer. The worst effects were in the Northern Hemisphere but the effects were world-wide. It was probably the most pronounced cooling in the last 2000 years. To make matters worse, a pandemic erupted around 541 that spread from southern Asia to northern Europe. It had a huge effect on the Byzantine Empire and has been called the Justinian (bubonic) Plague after the Byzantine emperor. Crop failures, an expansion of trade, and an influx of rodents derived from the cold temperatures could have led to and also exacerbated the plague.

This second and severe example of cooling was shorter-lived in a geological time frame. Temperatures fell in the summer about 1.5-2.5^{0}C. A "smoking gun" has been linked to this cooling, a volcanic explosion in Iceland. In addition, another eruption occurred in 540, which dropped the temperature another 1.5-2.5^{0}C, and in 547. The combined effects of climate change and the plague led to a significant economic fall in Europe. Signs of airborne lead in the ice in 640, arising from silver mining, suggest a recovery of economic growth. You should ask yourself how the modern world with cope with such an occurrence.

WHAT THE SCIENCE SHOWS

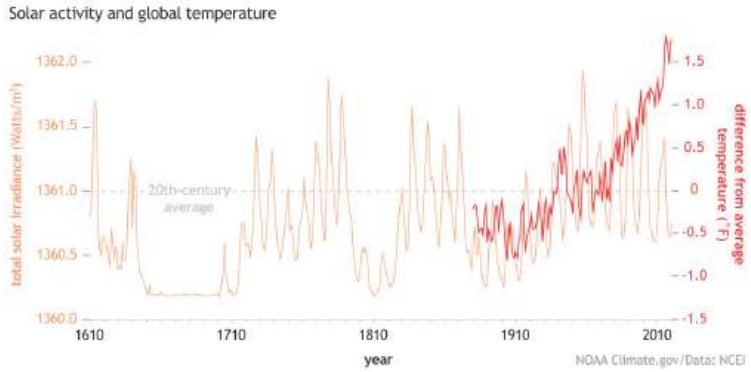
The Little Ice Ages and the climate changes preceding and after the Justinian plague had multiple causes, including volcanic eruptions, small changes in solar irradiance, and changes in the North Atlantic ocean currents and associated weather patterns. These short-term climate changes had disastrous effects on people's lives and the economic health of societies. Predicted future warming arising from CO_2 emitted from fossil fuel use (and other greenhouse causes) would bring far worse immediate and potentially irreversible consequences. It is incumbent on us as people who know the causes of climate change to act with due diligence and speed to avert the worst climate futures.

SOLAR ACTIVITY AND CLIMATE CHANGE

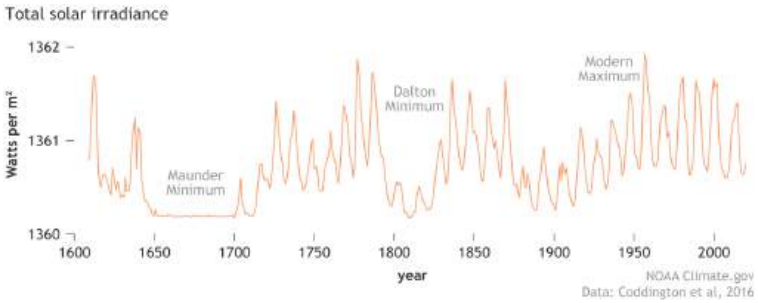
THE SKEPTIC'S CORNER: CLIMATE CHANGE MISINFORMATION

It's not increasing CO_2 that causes any observed increases in temperature. The sun's activity is changing. It always has and always will. There's nothing we can do about it.

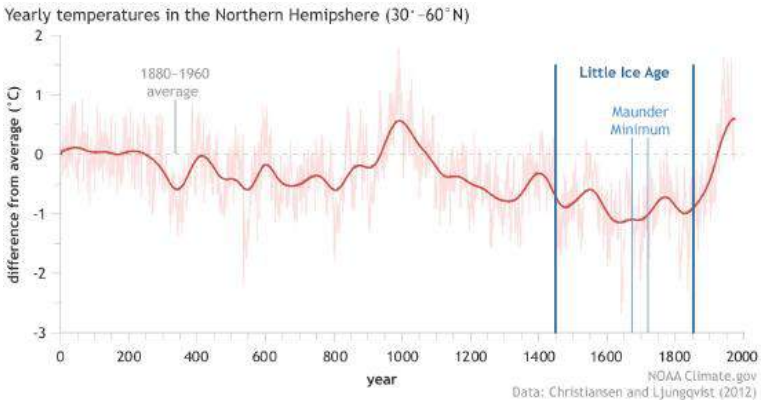
We have discussed how the orbital forcing of the climate kick-started each of the recurring ice ages in the Pleistocene. Some effects of the change in solar activity independent of the sun's orbit have been noted above. Specifically, we have shown that it cannot account for present warming. We present a series of graphs from the NOAA (National Oceanic and Atmospheric Administration) in the collective Figure 32.1.20 below to show the actual change in solar activity over recent times. Comments are shown at the bottom of each graph.



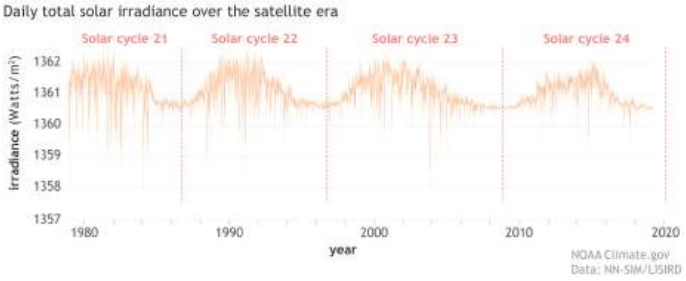
(Above) The maximal % spread from the lowest to the highest is very small. Such a small change shouldn't have such dramatic effects on climate unless it is sustained, as it was from around 1630-1700. Hence this decline in solar activity probably played some part in part of the Little Ice Ages. The regular rise and fall (spikes) are associated with the 11-year sunspot cycle activity. Note that the rise in average temperature since 1910 (shown in red) cannot be accounted for by change sin solar activity



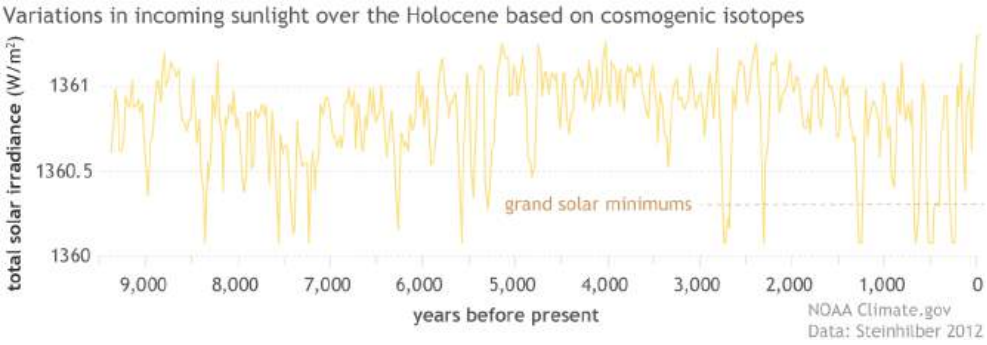
The above graph shows that the irradiance decreased by about 0.06% (although other values have been reported as high as 0.22%) during the Maunder Minimum, which occurred in the Little Ice Ages. The average decrease in terrestrial temperatures was 1.0-2^{0}C.



The graph above shows yearly average temperatures in the Northern Hemisphere. The dark red line shows the average change. Note that the averages are clearly lower in the Little Ice Age with the lowest values and lowest spike temperatures close to and in the Maunder Minimum.



(Above) The 11-year repeat of sunspot activity and resulting solar irradiance is clearly seen in the graphs. In 2020, a low in activity occurred, yet 2020 was the **second warmest year** on record since 1880.



This graph does not show the effects of climate forcing due to orbitals changes. Rather it shows that solar activity has not changed significantly for the 10000 years prior to 0 CE.

Figures 32.1.20: Changing in solar activity in recent geologic time.

This would be true if not for the massive amount of CO_2, approximately 1.5 trillion tons, injected into the atmosphere since the industrial revolution from the use of fossil fuels. Not all of that is still in the atmosphere, of course, but enough to raise CO_2 to levels not seen for 3 million years. Based on the relationship between CO_2 and temperature across the ice ages, science can predict when conditions might exist to initiate and propagate the next ice age. The data arising from these models, illustrated in Figure 32.1.21, show how much incoming solar radiation (insolation) must arrive at the Earth (watts/m^2) to trigger the next ice age.

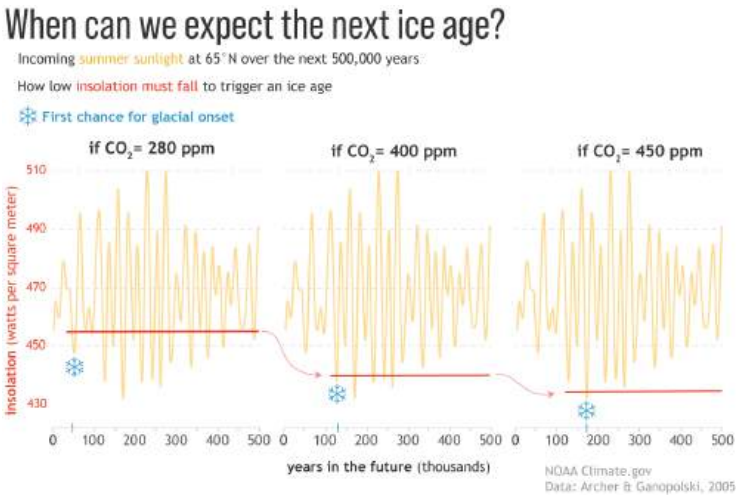


Figure 32.1.21: Incoming solar radiation required to trigger the next ice age.

As shown in the left side of the figure, if CO_2 were 280 ppm (typical of peaks in past interglacial periods), it would take repetitive drops of insolation below the threshold of about 455 watts/m^2 (red line) to start glaciation. As of November 2022, we are at 415 ppm and rising. If it rises to 450 ppm, as it assuredly will in the absence of carbon capture, it would require much less insolation, since the greenhouse effect of the higher CO_2 would warm the atmosphere The right graph shows there is little chance of another ice age in the absence of large and sustained volcanic activity or asteroid impact that would lead to blocking of solar radiation.

WHAT SCIENCE SAYS

Changes in solar irradiance (not changes in Earth's orbital dynamics) **cannot** account for warming since the Industrial Revolution. They have contributed to short-term (on a geological time scale) cooling during the Little Ice Ages.

Summary of Climate Change Causes and Effects Since 900 AC

Figure 32.1.22 shows a great summary of possible contributions to temperature change over the last 1000 years. Note again that present-day warming can only be attributed to greenhouse gases (GHG). One panel shows changes in land use. This has caused a temperature drop since 1800. That effect is caused by deforestation and other land cover changes, which leads to more reflection of incident solar radiation back into space. This effect is increased in the winter if the changed land is snow- covered. Deforestation would also decrease CO_2 capture (photosynthesis) by plants, which would raise the temperature. That component has been added to the GHG panel.

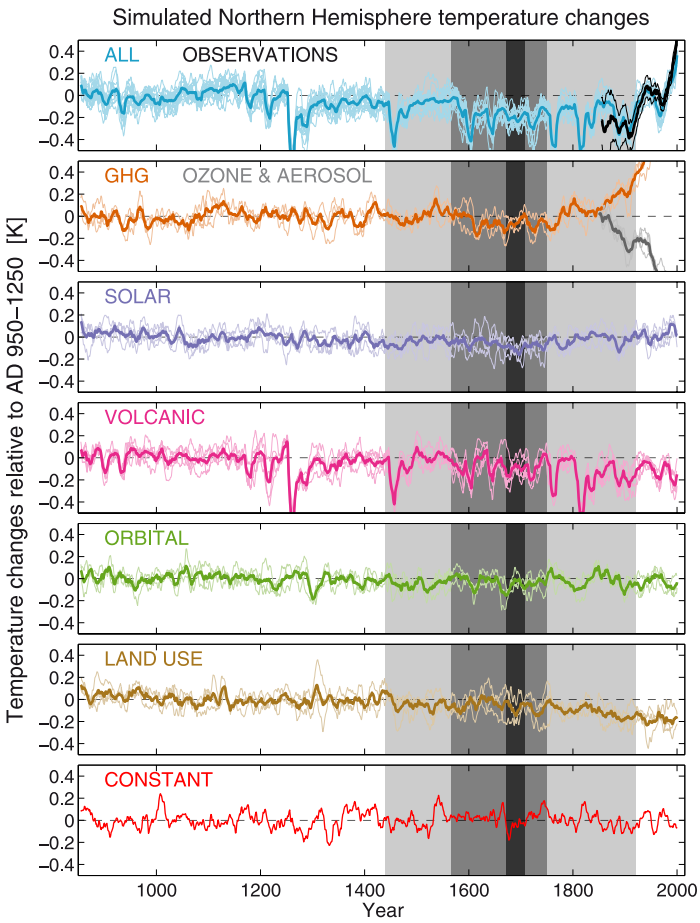

Figure 32.1.22: Simulated northern hemisphere temperature changes, smoothed with an 11 year running mean, relative to the period AD 950–1250. Owens et al. J. Space Weather Space Clim. 2017, 7, https://doi.org/10.1051/swsc/2017034. Creative Commons Attribution License (http://creativecommons.org/licenses/by/4.0).

The black line in the top panel shows the observed instrumental northern hemisphere temperature variations with their associated uncertainties (Morice et al., 2012), which match the simulations well. The bottom panel shows a simulation with no changes to the radiative forcings. This quantifies the magnitude of natural internal variability in the simulations in the absence of changes in forcings. Note periodic dip but short time frame dip in temperature due to volcanic activity. Clearly, warming since the Industrial Revolution is due to emissions from the use of fossil fuels.

CLIMATE JUSTICE: THE EMITTERS AND THE AFFECTED

THE SKEPTIC'S CORNER: CLIMATE CHANGE MISINFORMATION

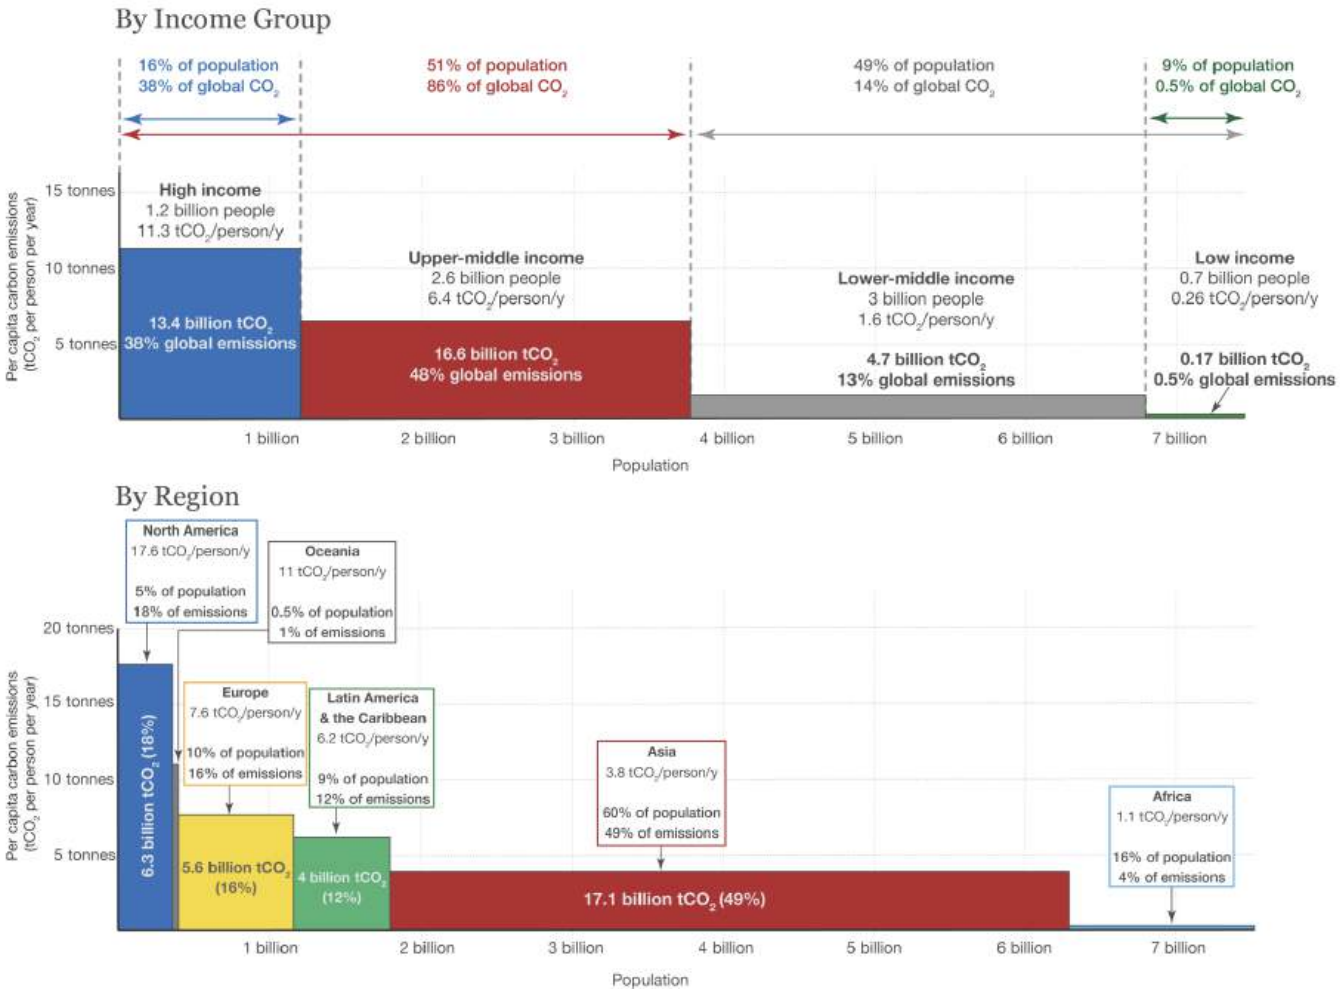
Why should we make changes to reduce fossil fuel emissions when China is the biggest emitter of CO_2!

We present a series of graphs in Figure 32.1.24 below, taken from CO_2 Emissions - Our World in Data to show which countries have emitted the most CO_2 in the past and now. In a just world, those countries which have emitted the most should move swiftly and forcefully not only to decrease emissions but to aid other countries' transitions to clean fuels and to help them with climate change mitigation and adaptation. We don't wish to demonize the fossil fuel industry and those who work in it. The use of fossil fuels, which are high energy, high density, and cheap fuel (because of historically massive subsidies) has lifted millions if not billions out of poverty over time. We had no alternative to fossil fuels until recently. Most did not realize how significantly fossil fuel use would affect our present and future climate and the health of not only humans but the entire biosphere. (Yet there is evidence that.) We can't just stop the use of fossil fuels without inflicting great economic pain on those who can least afford it. In order to help those who are currently suffering and who will suffer most in the future, as well as to help ourselves, our children and out grandchildren, we must move away from the use of fossil fuels as soon as possible.

Above: The dip in total world emissions in 2020 was due to the COVID pandemic. Unfortunately, the rise has resumed. Note that China is now the biggest net emitter but the US and EU emissions are dropping. India is on the rise and if they follow a similar economic path as China, which they need to lift many out of poverty, it will come with a huge cost in CO_2 emission unless they can jumpstart their conversion to clean fuels. The world needs to help.

Above: Although China is the largest net emitter, **the US and Australia are the biggest emitters per person**, although that is dropping.

The US still leads the world in the total amount of CO_2 emitted since the industrial revolution. We also have the greatest GDP. Pakistan suffered tragical flooding, exacerbated by climate change, in 2022. Up to a 1/3 of the country was under water. In a just world, the biggest emitters would aid the rest of the world.



Above: Inequality is clearly evident in this graph as the wealthiest people (high and upper-middle income) collectively contribute 86% of CO_2 emissions

Figure 32.1.24: CO_2 emissions by country and income since the industrial revolution. Our World in Data. Creative Commons BY license.

WHAT SCIENCE SAYS

The United States has emitted the most CO_2 since the beginning of the industrial revolution and the most per capita. China is not even close.

FUTURE PROJECTIONS

We know the science, and we know the consequences if we choose not to act or act in ways insufficient to meet the challenges of climate change. It is one of the most difficult challenges we have faced as a species. It requires sacrifice and united action for the common good. The benefits of our choice are mostly in the future and for future generations.

The Intergovernmental Panel on Climate Change (IPCC), a body composed of leading climate scientists and experts, has defined several different **Relative Concentration Pathways (RCPs)** leading to different emissions and different climate futures. Where we end up depends on economic, social, and political choices. The IPCC initially designated four pathways, RCP 2.6, 4.5, 6, and 8.5, with higher numbers associated with higher temperatures and CO_2 levels. Each assumes a starting value and estimated emissions (which depend on technology, politics, economics, etc). RCP 8.5 assumes extra radiative forces (heat energy/(m^2s)) by 2100 equal to 8.5 J/(s m^2) or 8.5 watts/m^2. This worst-case scenario assumes business as usual with no interventions to reduce our emissions, a totally unlikely scenario given present actions (including the rapid rise of clean energy). The RCP 2.6 scenario assumes that the peak radiative forcing would be 3 watts/m^2 which would decline through very strong governmental and economic actions to 2.5 by 2030-2040. Table 32.1.1 below shows the four RCP scenarios with projected ending CO_2 equivalents (which include other greenhouse gases) and temperature increases.

RCP (W/m^2)	Timeframe	$CO_{2\ atm}$ equivalents (ppm)	Temp increase (°C/°F)	Description
8.5	in 2100	1370	4.9/8.8	rising
6.0	after 2100	850	3/5.4	stabilizing without overshoot
4.5	after 2100	650	2.4/4.3	stabilizing without overshoot
2.6	decline from 3 before 2100	490	1.5/2.7	peak and decline

Translating the projected CO_2 equivalents in the atmosphere into associated temperature increases requires a high-quality value for climate sensitivity (rise in temperate/rise in CO_2). Figure 32.1.25 shows the likely increase in temperatures for the four different scenarios.

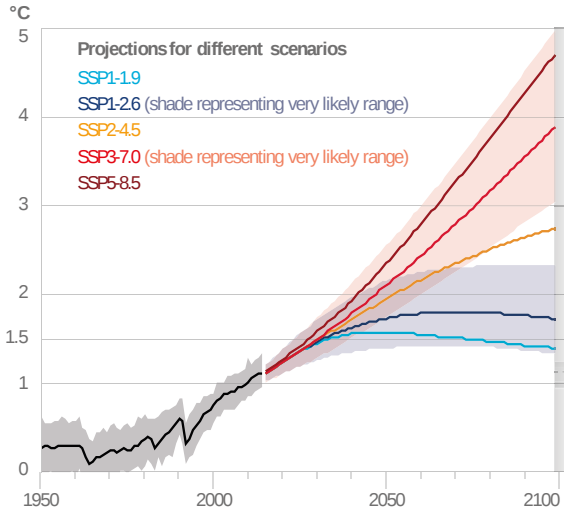


Figure 32.1.25 Projected temperature rises for 4 RCP scenarios. Pörtneret al. *Climate Change 2022: Impacts, Adaptation, and Vulnerability.* Contribution of Working Group II to the Sixth Assessment Report of the Intergovernmental Panel on Climate Change. doi:10.1017/9781009325844.001.

The scenarios in Figure 25 are labeled SSP#-## with the second number ## representing the RCP number. The IPCC 6th report issued in 2021 changed from using RCP scenarios to Shared Socioeconomic Pathways (SSPs) scenarios which are based on possible social and economic developments that would pose different challenges to reduce future temperature increases and hence different strategies for mitigation and adaptation. The SSP scenarios are consistent with the RCP scenarios but use a more enhanced socio-economic and political framework for their construction. The mitigation strategies are based on the RCP forcing levels. The SSP scenarios are described below. They start with SSP1, which leads to a world that has adapted well and moved away from fossil fuels, to SSP5, which assumes a continued and high reliance on fossil fuels.

2023 - NEW CLIMATE SENSITIVITY CALCULATIONS

We mentioned in 31.1A that a new value for climate sensitivity giving a **rise of 4.8 °C (8.6 °F) for a doubling of CO_2** has been determined by Hansen et al (2023). This value has startling implications. If this new value stands, the IPCC/UN call to keep warming to 1.5 ^{0}C above the pre-industrial revolution average is now **impossible**. We are already there or will be there in a few years. It is highly likely that we will not make the changes required to keep warming below 2°C before 2050. The reasons for our inaction are politicians who continue to support the fossil fuel industry and who block significant legislation to act now, religious institutions and leaders who don't make climate action a sacred duty, and the fossil fuel industry that continues to expand fossil fuel exploration and mislead the public as to the causes of climate change and action to address it. Those who say we can't afford to act never mention the much greater cost of inaction!

SSP1: **Sustainability – Taking the Green Road (Low challenges to mitigation and adaptation)**
The world shifts gradually, but pervasively, toward a more sustainable path, emphasizing more inclusive development that respects perceived environmental boundaries. Management of the global commons slowly improves, educational and health investments accelerate the demographic transition, and the emphasis on economic growth shifts toward a broader emphasis on human well-being. Driven by an increasing commitment to achieving development goals, inequality is reduced both across and within countries. Consumption is oriented toward low material growth and lower resource and energy intensity.

SSP2: **Middle of the Road (Medium challenges to mitigation and adaptation)**
The world follows a path in which social, economic, and technological trends do not shift markedly from historical patterns. Development and income growth proceeds unevenly, with some countries making relatively good progress while others fall short of expectations. Global and national institutions work toward but make slow progress in achieving sustainable development goals. Environmental systems experience degradation, although there are some improvements and overall the intensity of resource and energy use declines. Global population growth is moderate and levels off in the second half of the century. Income inequality persists or improves only slowly and challenges to reducing vulnerability to societal and environmental changes remain.

SSP3: **Regional Rivalry – A Rocky Road (High challenges to mitigation and adaptation)**
A resurgent nationalism, concerns about competitiveness and security, and regional conflicts push countries to increasingly focus on domestic or, at most, regional issues. Policies shift over time to become increasingly oriented toward national and regional security issues. Countries focus on achieving energy and food security goals within their own regions at the expense of broader-based development. Investments in education and technological development decline. Economic development is slow, consumption is material-intensive, and inequalities persist or worsen over time. Population growth is low in industrialized and high in developing countries. A low international priority for addressing environmental concerns leads to strong environmental degradation in some regions.

SSP4: **Inequality – A Road Divided (Low challenges to mitigation, high challenges to adaptation)**
Highly unequal investments in human capital, combined with increasing disparities in economic opportunity and political power, lead to increasing inequalities and stratification both across and within countries. Over time, a gap widens between an internationally-connected society that contributes to knowledge- and capital-intensive sectors of the global economy, and a fragmented collection of lower-income, poorly educated societies that work in a labor-intensive, low-tech economy. Social cohesion degrades and conflict and unrest become increasingly common. Technology development is high in the high-tech economy and sectors. The globally connected energy sector diversifies, with investments in both carbon-intensive fuels like coal and unconventional oil, but also low-carbon energy sources. Environmental policies focus on local issues around middle and high income areas.

SSP5: **Fossil-fueled Development – Taking the Highway (High challenges to mitigation, low challenges to adaptation)**
This world places increasing faith in competitive markets, innovation and participatory societies to produce rapid technological progress and development of human capital as the path to sustainable development. Global markets are increasingly integrated. There are also strong investments in health, education, and institutions to enhance human and social capital. At the same time, the push for economic and social development is coupled with the exploitation of abundant fossil fuel resources and the adoption of resource and energy-intensive lifestyles around the world. All these factors lead to rapid growth of the global economy, while global population peaks and declines in the 21st century. Local environmental problems like air pollution are successfully managed. There is faith in the ability to effectively manage social and ecological systems, including by geo-engineering if necessary.

The projected increases in emitted CO_2 (Gigatons/yr) and other greenhouse gases over the next 80 years for each SSP scenario are shown in Figure 32.1.26. The second number in the SSP label is the RCP scenario number based on radiative forcing listed in Table 1 above.

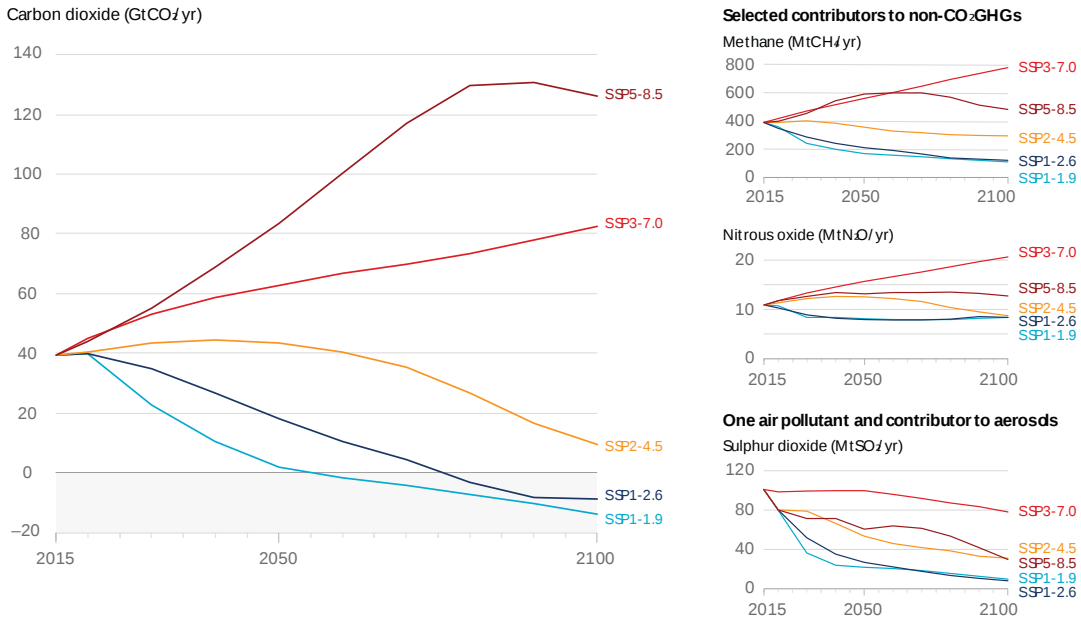

Figure 32.1.26: Projected increases in greenhouse gases under different SSP (RCP) scenarios. Masson-Delmotte et al. Climate Change 2021: The Physical Science Basis. Contribution of Working Group I. to the Sixth Assessment Report of the Intergovernmental Panel on Climate Change. Cambridge University Press, Cambridge, United Kingdom and New York, NY, USA, pp. 3−32, doi:10.1017/9781009157896.001.

Note the welcome decline in SO_2 which causes acid rain as well as aerosols. This shows that under all SSP scenarios, we are moving to clean up our air (in this case reducing SO_2 from burning sulfur-enriched coal or capturing SO_2 before it enters the atmosphere). Paradoxically and unfortunately, decreasing aerosols leads to increasing temperatures due to lower reflectance of incident solar irradiation.

Our final figure, Figure 32.1.27, shows how each greenhouse gas and SO_2 are projected to change in 2081-2100, compared to 1850-1900 levels, for each of the SSP scenarios.

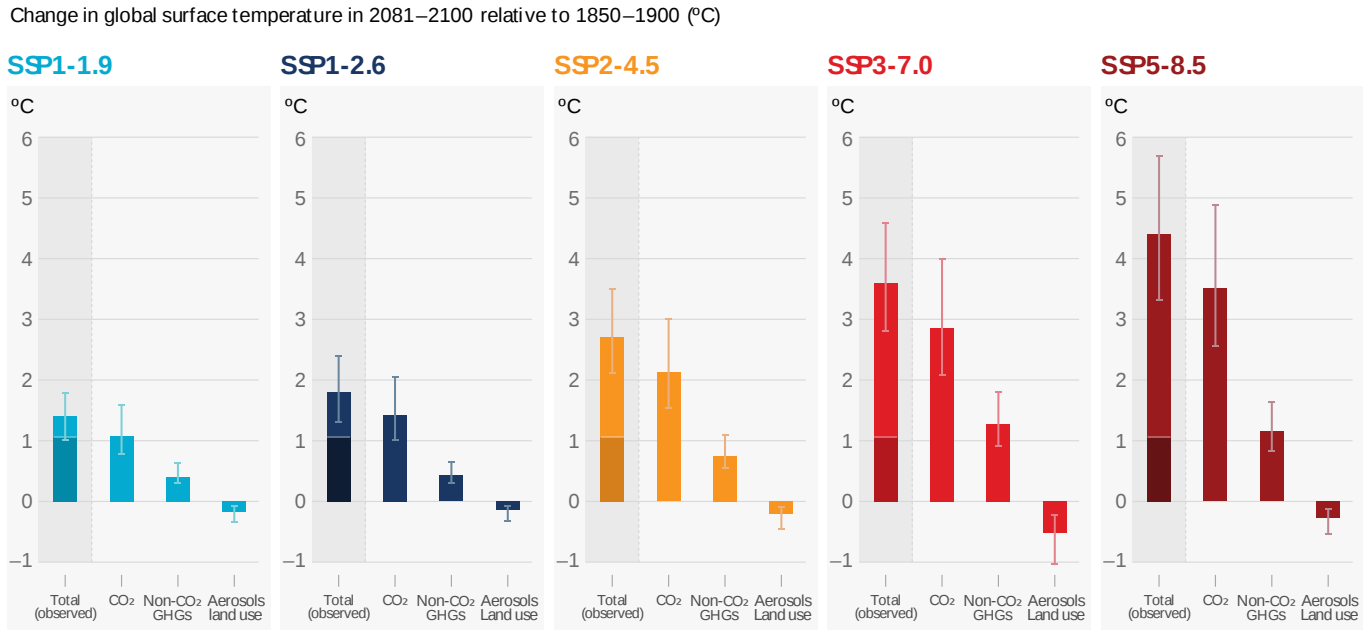

Figure 32.1.26: Projected changes in greenhouse gas es and SO_2 in 2081-2100 compared to 1850-1900 levels for different SSP scenarios. Masson-Delmotte et al, ibid.

We discussed in Chapter 32.1: A that the Earth's Energy Imbalance (EEI) rose from about +0.6 Watts/m^2 in 2000 to +0.9 from around 2005 to 2019, and to +1.0 in around 2021. The trend is unfortunately upward, as shown in Figure 32.1.27.

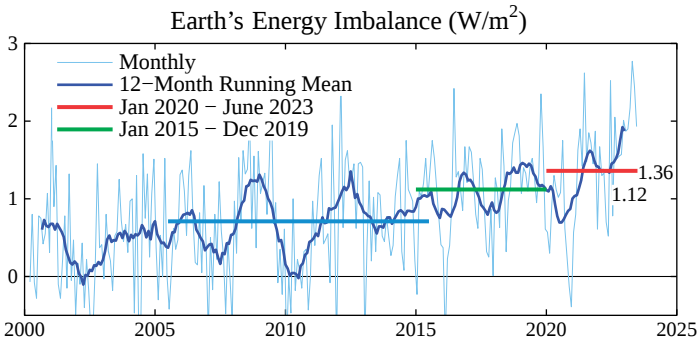

Figure 32.1.27: Earth's Energy Imbalance since 2000. 12-month running-mean of Earth's energy imbalance from CERES satellite data normalized to 0.71W/m2 mean for July 2005–June 2015 (blue bar). James E Hansen, Makiko Sato, Leon Simons, Larissa S Nazarenko, Isabelle Sangha, Pushker Kharecha, James C Zachos, Karina von Schuckmann, Norman G Loeb, Matthew B Osman, Qinjian Jin, George Tselioudis, Eunbi Jeong, Andrew Lacis, Reto Ruedy, Gary Russell, Junji Cao, Jing Li, Global warming in the pipeline, *Oxford Open Climate Change*, Volume 3, Issue 1, 2023, kgad008, https://doi.org/10.1093/oxfclm/kgad008. Creative Commons Attribution License (https://creativecommons.org/licenses/by/4.0/)

The projected value of 1.36 (red bar) for the 2020s bodes poorly for our ability to reverse the effects of climate change. The very large change that started around 2015 probably stems from the **decrease** in atmospheric sulfates (required by legislation) in emissions from ships in the northern Atlantic and Pacific oceans and from coal burning in China. These decreases in atmospheric aerosols, which cause cardiovascular, pulmonary, and cancer, paradoxically increase global warming. Sulfate aerosols reflect solar radiation. They also form clouds which do the same. Both cool the planet. In fact, aerosols that contribute to some of the worst pollution in the world in cities in South Asia have helped keep temperatures there from rising to dangerous levels.

These last two chapter sections clearly show that humans have been engaged in large-scale geoengineering of the planet and its biosphere. It is likely that we will have to devise new methods to bring the temperature of the Earth down. One might be large scale production of salt-aerosols over the oceans that would reflect incident sunlight and increase cloud formation.

As all the data presented in this chapter shows, our climate fate will depend on the choices we make individually and collectively as societies.

KEY POINTS - BETA VERSION FROM CHAT.OPENAI

1. Climate change is the long-term change in the average weather patterns on Earth.
2. The primary cause of climate change is the burning of fossil fuels, which releases large amounts of greenhouse gases, such as carbon dioxide (CO2), into the atmosphere.
3. Greenhouse gases trap heat in the atmosphere, causing the Earth's temperature to rise. This is known as the greenhouse effect.
4. The most significant contributor to climate change is CO2, which is released when fossil fuels are burned. Other significant contributors include methane, nitrous oxide, and fluorinated gases.
5. Climate change has a wide range of impacts on the Earth's systems, including rising sea levels, changes in precipitation patterns, increased frequency and intensity of extreme weather events, and disruptions to ecosystems.
6. The global temperature has already risen by 1 degree Celsius (1.8 degrees Fahrenheit) since the pre-industrial era, with most of the warming occurring in the last few decades.
7. The Intergovernmental Panel on Climate Change (IPCC) has stated that limiting global warming to 1.5 degrees Celsius (2.7 degrees Fahrenheit) above pre-industrial levels could significantly reduce the risks and impacts of climate change.
8. Reducing greenhouse gas emissions is essential in order to slow or stop climate change. This can be achieved through a combination of actions, such as increasing the use of renewable energy sources, improving energy efficiency, and reducing deforestation.

32.2: USE OF ISOTOPE ANALYSIS IN MEASURING CLIMATE CHANGE

Search Fundamentals of Biochemistry

In this chapter section, we will explore how we are able to reconstruct CO_2 and temperature values across millions of years time. It is truly a remarkable, if not awe-inspiring achievement that shows the intellectual rigor and endurance scientists employ to obtain, interpret, and model data. The graphs of CO_2 vs temperature across such a vast swath of time shown in the previous chapter section were obtained through analyses of isotopes of oxygen and carbon found in chemical species in ice and ocean floor sediments. The interpretation of the isotope data requires an understanding of the link between individual and linked chemical and biochemical reactions. So we have to take a deep dive into isotopes and their use.

WHY STUDY ISOTOPE EFFECTS

- Isotopes and their effects, critical in understanding both structure and activity in biochemistry, are key in climate science.
- Both equilibrium and nonequilibrium reactions and processes apply to isotope partitioning into water and biomolecules, in ways similar to linked biochemical reactions and pathways.
- The study and application of isotope effects can integrate and expand learning from previous science courses

In more global terms

- The strength and quality of our data and models that support explanations in biochemistry and climate analyzes must be explored.
- Scientific and ethical rigor in pursuit of knowledge, explanations, and solutions as we pursue complex fields like biochemistry and climate change is essential if we are to place trust in our experts and faith in their findings.

ABSOLUTE AND PROXY MEASUREMENTS FOR CO_2 AND TEMPERATURE

It's simple to see how CO_2 levels over the last 800,000 years have been determined from ice cores since ancient air is actually trapped in bubbles in them. The bubbles can be liberated by melting/shattering and analyzed. However, how can we infer temperature changes or actual temperature from ice core samples and both CO_2 and temperatures from ocean sediment cores? Scientists use "proxies" to determine temperature as modern thermometers and temperature scales were invented only recently (early- and mid-1700s by Fahrenheit and Celsius). These proxies include tree rings, growth bands in coral, pollens found in core samples, and calcite shells from marine organisms found in lake and ocean sediments. The organisms include certain types of algae, phytoplankton like dinoflagellates and diatoms, and foraminferas (single-celled protozoans with shells).

From a more chemical perspective, the analyses of the isotopic compositions of ice, using the isotope ratios of $^{18}O/^{16}O$ in water, and of marine sediments, using the ratio of $^{18}O/^{16}O$ and $^{13}C/^{12}C$ in carbonate-containing shells, have proved critical in determining temperatures back millions of years ago. Even molecules like components of leaf waxes (as we discussed in Chapter 31.1) can be used. Isotope analyses of diatoms (with silicate shells) in lake sediments are also useful.

The analysis of proxies is quite complicated since many factors contribute to the measurement derived from proxy use. Take tree rings as an example. The width of a given ring depends not only on temperature but precipitation. Calibrations for each proxy must be made using alternative data such as rings from a variety of other trees. Proxy data from ice cores go back a few million years, while data from marine sediments back as far as 100 million years ago. Isotope analysis in rocks formed from marine or land sediments can go back billions of years. Proxy data (tree rings) taken from recent times can be compared to actual temperatures measurement from the same time. The calibration relationships can then be used for samples from the past. Alternatively, proxy data can be taken across many different places and temperatures to develop calibration constants, an approach useful for pollen analysis. Organisms could also be cultured in different temperatures, nutrient, and CO_2 conditions to calibrate past data. From a statistical sense, it is best to combine multiple proxies to develop past temperature records. Proxy data sets are available for over 10,000 sites around the world. Figure $32.2.x$ below gives a link to sites compiled by Carbon Brief where databases with information about each study is available.

Figure 32.2.1: Map of over 10,000 proxy data studies and sites. Robert McSweeney and Zeke Hausfather and Tom Prater. https://interactive.carbonbrief.org/...-distant-past/

Most people might care little about climate change millions of years ago. The value in understanding climate change so far in the past is, in part, to build confidence in the data, methods of analysis, and climate model to better understand the relationship between CO_2 and temperature. Some, particularly the PAGES 2k Consortium, focus their attention on the last 2000 years of the Common Era. Figure 32.2.2 shows global mean temperatures obtained from proxy data (yrs 0 - 2000) and direct observations (through the use of thermometer and satellite measurements) since around 1850.

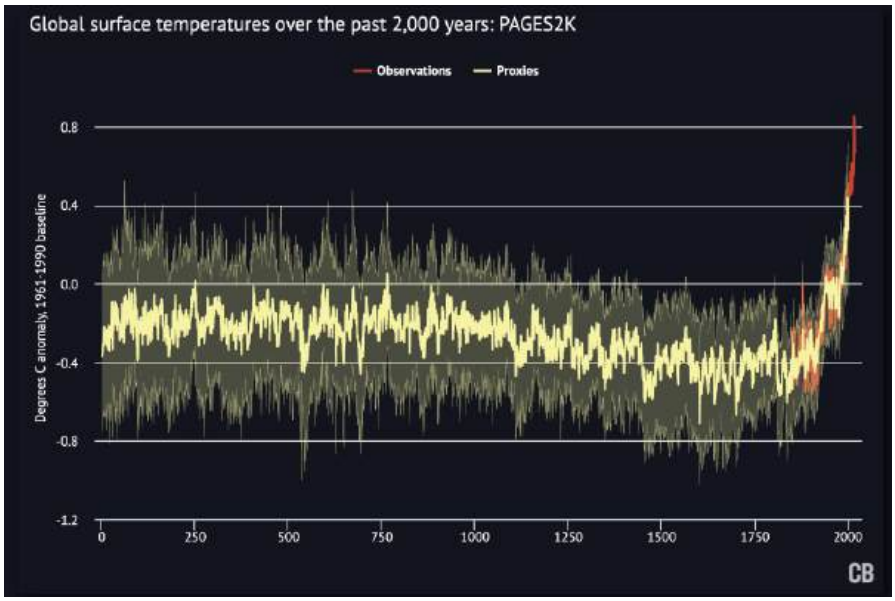

Figure 32.2.2: Global mean surface temperature reconstruction (yellow line) and uncertainties (yellow range) for the years 0-2000 period from the PAGES 2k Consortium along with observations from Cowtan and Way from 1850-2017. Data available in the NOAA Paleoclimate Archive.

Note the overlap of proxy measurements and direct observations of temperatures since around 1850.

OCEAN MICROORGANISMS

Students of biochemistry come from many backgrounds and all do not have a strong biology background. To help with that, and to develop a sense of wonder about the microorganisms that inhabit the oceans and play such a key part in the biosphere, let's look at a few relevant to this chapter. For those with a "chemistry-centric" background, these descriptions are probably new.

Plankton

The word plankton derives from a Greek word meaning drifter or wanderer. There are two main types. One is **zooplankton,** which are not plants, but rather microscopic animals and protozoans. They are heterotrophs that don't synthesize their own food. Most have calcite shells. The other is **phytoplankton,** which are autotrophic plants that use photosynthesis for food production. Hence they are carbon "capturers", which are key players in the carbon cycle in maintaining atmospheric CO_2 and in producing O_2. The phytoplankton broadly include algae

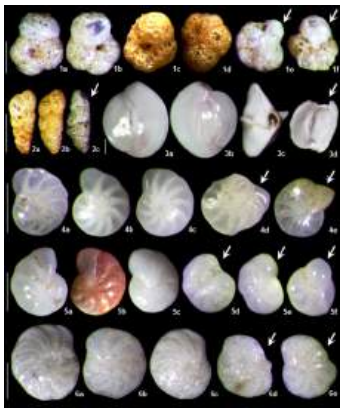
(protists), cyanobacteria (also known as blue-green algae), and dinoflagellates which also fit into other groups. Here are some examples. Also remember that protists are eukaryotic organisms that are not animals, plants, or fungi.

Table 32.2.1 below lists types and examples of plankton.

Type of plankton	Examples
Zooplankton (heterotrophs)	benthic foraminiferans, which live mostly at sea bottoms and in sediment and capture carbon indirectly through the carbon cycle though the use of CO_3^- in their shells. planktonic foraminifera, which live near the surface but are found buried in ocean sediments after their death dinoflagellates that don't photosynthesize are small animals including tiny fish and crustaceans such as krill and jellyfish. radiolarians, single-cell protozoans that have calcium silicate shells
Phytoplankton (autotrophs, primary producers)	diatoms photosynthesizing dinoflagellates blue-green algae which are prokaryotic bacteria green algae, a photosynthetic eukaryotic protist. some foraminifera that live near the surface watera and can photosynthesize

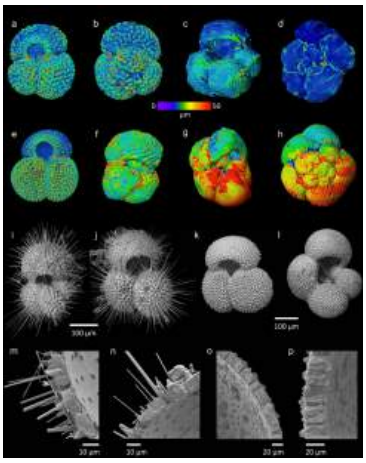
Zooplankton

Existing shells in sea sediments from foraminifera have been critical in dating studies and determining CO_2 and temperatures over millions of years. There are two major types which include benthic foraminifera (which live at the sea bottom and in sediment) and a smaller group of planktonic foraminifera which live near the surface. They are heterotrophs, but some, on ingestion of small autotrophic phytoplankton, can retain and sequester their chloroplasts, which can engage in photosynthesis for a period of time. Figures $32.2.3-5$ below show examples of zooplankton that have been important in climate studies.



Figures 32.2.3 **above: Benthic foraminifera:**

Live mostly at sea bottoms and in sediment); capture carbon indirectly through the carbon cycle through the incorporation of CO_3^- into their shells. Living benthic foraminifera in the Bohai Sea, showing normal specimens and abnormal individuals (indicated by arrows).



Figures 32.2.4 **above: Planktonic foraminifera**

Live near the surface but are found buried in ocean sediments after their death. Phytoplankton

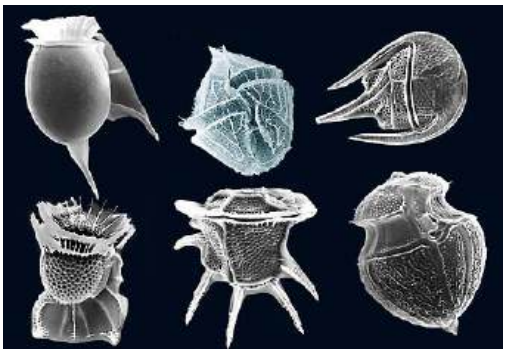
Phytoplankton are microscopic plants, and as such, engage in photosynthesis, capture CO_2, and produce O_2. Hence they are primary autotrophs. We will consider three types, diatoms, photosynthetic dinoflagellates and coccolithophores. Diatoms and photosynthetic dinoflagellates are the major ones and are prey for the zooplankton. They are described in Figures $32.2.6-8$ below.

Figures 32.2.6 **Above: diatoms**

Single-celled eukaryotic algae surrounded by a silica shell (test). These can reach 1 mm in diameter and can form an assortment of shapes. Some can form multicellular chains. They engage in high efficiency photosynthesis and resulting carbohydrate synthesis. They are found in coastal and cold waters with lots of nutrients.



Figures 32.2.7 **Above: photosynthetic dinoflagellates**

Algae with a single shell. They are smaller than diatoms. Most have two flagella for motion. They have a cellulose shell, which degrade on death. Hence, they don't have shells that enter the sediment. Some are nonphotosynthetic and are considered zooplankton.

Figures 32.2.8 **Above: coccolithophores**

Coccolithus pelagicus; coccosphere. These are very small single cell algae, which form interlinked calcium carbonate circulate plates that cover the surface.

Figures 32.2.6 – 8 : Some phytoplankton. Diatoms: https://commons.wikimedia.org/wiki/C...le:Diatom2.jpg; photosynthetic dinoflagellates: https://commons.wikimedia.org/wiki/F...lagellates.jpg; coccolithophores: https://commons.wikimedia.org/wiki/F..._pelagicus.jpg

Along the coast in summer, nutrient-rich upwelling of water occurs which can lead to explosive growth of dinoflagellates, causing the water to become red-gold (often called a red tide). Some species in these blooms produce neurotoxins such as saxitoxin (inhibitor of sodium channels), which can produce paralytic shellfish poisoning if shellfish from the bloom area are eaten, and brevitoxin (stimulate voltage-gated sodium channels in nerve and muscle).

Ice cores from Antarctica and Greenland can extend to over 3.4 km (2.1 miles) in depth and yield direct information on CO_2 and indirect measurements of temperature. The oldest continuous ice core records extend to 130,000 years in Greenland, and 800,000 years in Antarctica. Data going back 2 million years is available using discontinuous cores. Concentrations of trapped CO_2 as a function of time, and the temperature of each layer can be determined. Figure 32.2.9 shows a section of an ice core from the West Antarctic Ice Sheet Divide (WAIS Divide).

Figure 32.2.9: *The dark band in this ice core from the West Antarctic Ice Sheet Divide (WAIS Divide) is a layer of volcanic ash that settled on the ice sheet approximately 21,000 years ago. Credit: Heidi Roop, NSFhttps://icecores.org/about-ice-cores*

The remains of plankton shells described above are found in cores from sea sediments. Analyses of shells, especially from foraminifera, have provided climate data going back tens of millions of years ago. For both ice and ocean sediment cores, isotope analyses have been the key to obtaining CO_2 and temperature data.

ISOTOPE ANALYSES

In analyzing ice and ocean sediment cores, three things are needed: the age of the layer, a direct or indirect measure of the atmospheric CO_2 at the time the layer was deposited, and an indirect measurement of the temperature at the time of deposition. As shown in the figure above, ice core samples have rings, similar to trees, that can be used to count backward in time. The rings get harder to distinguish the further back you go. Figure 3 above shows a visible dark band deposited by volcanoes 21,000 years ago. Ultimately, isotopic analyses of H_2O and CO_2 in ice samples and of carbonates in minerals and deposited microfossils in ocean samples are critical in determining past CO_2 and temperature values.

Most readers are familiar with ^{14}C radioisotope dating and ^{13}C-NMR. Metabolic pathways have been elucidated using ^{2}H (deuterium), ^{3}H (tritium), ^{13}C, and ^{14}C to label specific atoms in substrates and follow their flow into products. These same isotopes have been used in kinetic experiments to determine enzyme reaction mechanisms. We will explore isotopes in some detail in this section.

Use of unstable radioactive isotopes

The use of ^{14}C radioisotope dating is limited in climate analyses given its short half live ($t_{1/2}$ = 5730 years). In contrast to most isotopes made in stellar nucleosynthesis or by the radioactive decay of a precursor radioactive elements to an isotope of another element, ^{14}C is made on a continual basis in the atmosphere when high energy neutrons (n) from solar radiation react with atmospheric nitrogen (N). The neutron kicks out a proton to form ^{14}C as shown in the nuclear reaction below.

$$n + {}^{14}_{7}\mathrm{N} \rightarrow {}^{14}_{6}\mathrm{C} + p \tag{32.2.1}$$

^{14}C becomes oxidized to form $^{14}CO_2$ which can then enter the carbon cycle and enter the organic carbon pool through uptake by photosynthetic organisms and organisms that consume them. It can also form inorganic bicarbonates and carbonates, which could enter into shells.

All living things take in ^{14}C until their death, after which ^{14}C decays through the conversion of a neutron to a proton, a beta particle (electron) and an antineutrino, forming stable ^{14}N. Hence the amount of ^{14}C in dead organisms or their remains diminishes with a $t_{1/2}$ = 5730 years, in a process not affected by temperature or pressure. ^{14}C dating can be used in samples dating back about 55,000 years, a time span representing 9.6 half-lives. Only 0.13% of the original ^{14}C would be left. Data by this method give the age of death of the organism.

Carbon-14 dating depends on the assumption that its amount in the environment is constant, but the burning of fossil fuels and detonation of nuclear weapons has altered its amount (see box below). Changes in solar activity and resulting changes in high-energy neutrons also affect the amount of carbon 14. Also given the relatively short time frame used in ^{14}C dating, differences in CO_2 based on its sequestration and circulation in the oceans are also factors. 61% of the Northern Hemisphere is covered by oceans compared to 81% of the Southern Hemisphere. Books of calibration factors can be used to control for these effects. The calibrations are based on tree rings, lake and ocean sediments, corals and stalagmites data which allows dating back to 55,000 years ago.

NUCLEAR WEAPONS, FOSSIL FUELS AND ^{14}C DATING

In the 1950s up to 1962, nuclear weapons were tested in the air, doubling the amount of ^{14}C in the air. This spike has been taken up into organisms and into the ocean. Also since then, the amount of CO_2 from the burning of fossil fuels has gone up dramatically. This source does not contain ^{14}C as it derives from fossils that long ago decayed. The effects canceled each other in 2021. Since 2021 a lot more CO_2 from fossil fuels has been added so the net effect is now lower levels of ^{14}C equivalent to preindustrial time. It will continue to lessen until well after we stop using fossil fuels. By 2050 the levels might be equivalent to those in the Middle Ages. This, and the human-made stoppage of the next ice age glaciation cycle is yet another warning to us about our effects on the entire biosphere.

The decay of other "unstable" radioactive isotopes is used for dating samples and determining their age of burial:

- ^{39}Ar , an extremely rare isotope ($t_{1/2}$ =269 yr), has been used to date ice cores from the Tibetan Plateau over the last 1,300 years.
- ^{40}K ($t_{1/2}$ =1.25 billion yr) decays to ^{40}Ar (stable), so their ratios can be used to determine how much time has passed since magma solidification into rock, based on rates of diffusion of the resulting stable ^{40}Ar .
- The ratio of $^{26}Al/^{10}Be$ in buried samples is used in dating analyses. The two isotopes are rare and produced in a fixed ratio (6.75/1) when they are formed in surface quartz by solar radiation (much like the formation of ^{14}C). When buried through geological processes, there is no further production of the isotope, but fortunately (for those who measure age of burial), they decay with different half lives ($t_{1/2}$ = 717,000 yr for ^{26}Al and $t_{1/2}$ = 1.39 million yr ^{10}Be)
- The ratios of $^{21}Ne/^{26}Al$ and $^{21}Ne/^{10}Be$ can be used. ^{21}Ne is a stable isotope and these ratios are independent of the $^{26}Al/^{10}Be$ rate.
- Uranium isotopes are widely used in age measures on the long time scale. ^{238}U ($t_{1/2}$ =4.45 billion yr) is converted to ^{206}Pb (stable) and ^{235}U ($t_{1/2}$ =704 million yr) to ^{207}Pb (stable) by parallel decay routes which allow for multiple types of dating measurement.

Use of stable isotopes

Most of the data and graphs of CO_2 and temperature vs time (years ago) presented in Chapter 31.1 were determined by using stable isotopes that do not decay. Much of the data is based on either the ratio of the stable isotope pairs of oxygen ($^{18}O/^{16}O$) or carbon ($^{13}C/^{12}C$) in buried ice or ocean sediment cores. These isotopes have also been used to infer the temperature or temperature change when targets were buried in ice core or ocean sediments. Temperatures at the time of deposition of water in the ice layers are often inferred from $^{18}O/^{16}O$ ratios in the ice layers.

ICE CORE $^{18}O/^{16}O$ ANALYSES

The oceans are huge and generally homogenous reservoirs that can give clues to long-term changes in climate. Short-term climate change would have limited effects on the oceans. The $^{18}O/^{16}O$ ratios in Greenland and Antarctic ice cores have allowed dating and temperature reconstruction over geological time since the ratio is determined by the $^{18}O/^{16}O$ in the liquid oceans at the time of ice formation.

The % natural abundance of ^{18}O (0.205 %) and ^{16}O (99.757 %) gives a ratio of the two isotopes of 0.0021, which is so small that the exact ratio is inconvenient for routine use. Rather, a comparison of the ratios in a target sample vs a universal reference, the **$\delta^{18}O$ value**, is determined using a mass spectrometer. The $\delta^{18}O$ value is calculated by the following equation:

$$\delta^{18}O = \left[\frac{\left(\frac{18}{16}O\right)_{\text{sample}}}{\left(\frac{18}{16}\text{O}\right)_{\text{reference}}} - 1 \right] * 1000 \qquad (32.2.2)$$

Similar δ values are determined for D/H ratios (δ^2H) and for $^{13}C/^{12}C$ ($\delta^{13}C$)

- The reference for $\delta^{18}O$ calculations is the Standard Mean Ocean Water (SMOW or V-SNOW)
- The δ^2D reference value is also based on SMOW or V-SNOW
- The standard for the analogous $\delta^{13}C$ value is the Cretaceous Peedee Belemnite (an extinct order of squid-like cephalopods with an internal cone skeleton) sample from the Peedee belemnite (PDB) formation in South Carolina, USA. This standard is no longer available so an alternative, NBS 19, a carbonate material, is used in a new V-PDB (Vienna-PDB) scale.

Table 32.2.4 shows the ratio of the isotope abundancies in nature and in the references.

Element ratio	Ratio of natural abundance	Reference ratio
$^{18}O/^{16}O$	0.205/99.757 = 0.00205	0.0020052 (SMOW or V-SMOW)
$^{13}C/^{12}C$	1.1/98.9 =0.0111	0.011238 (PDB or V-PDB)
$^{2}H/^{1}H$ (D/H)	0.0156/99.9844 = 0.000156	0.00015576

Note that the ratios of the standards, and likewise of the samples, are small. Also note that in the equation for $\delta^{18}O$, the bracketed term is multiplied by 1000. If multiplied by 100, the value for $\delta^{18}O$ would be a percentage. Instead, it's multiplied by 1000 to convert it to **permill** (per mil or ‰) or parts per thousand (just like percent is parts per 100). Hence 1‰ is 1 part per 1000 or 0.1%.

Equations can be just collections of letters with little intuitive meaning, or they can be deconstructed by the user to make intuitive sense. To help understand this equation, which most readers have likely never encountered, given its importance in climate studies, let's look at 3 sets

of conditions. If ...

- ^{18}O is enriched in the sample compared to the reference, then $(^{18}O/^{16}O)_{sample}/(^{18}O/^{16}O)_{reference}$ is >1, so subtracting 1 from it makes the bracketed term +, along with $\delta^{18}O$;
- ^{18}O in the sample is equal to that in the reference, then $(^{18}O/^{16}O)_{sample}/(^{18}O/^{16}O)_{reference}$ =1, so the bracketed term = 0, and $\delta^{18}O = 0$;
- ^{18}O in depleted in the sample compared to the reference, then $(^{18}O/^{16}O)_{sample}/(^{18}O/^{16}O)_{reference}$ <1, so the bracketed term is -, along with $\delta^{18}O$.

In summary, a sample with a higher $^{18}O/^{16}O$ ratio (enriched in heavier isotope) than the SMOW reference will have a positive (+) δ value. If the $^{18}O/^{16}O$ ratio of the substance is lower (depleted in heavier isotope) than the SMOW reference, the δ value will be negative (-). The δ values of SMOW (O and H isotopes) and PDB (C isotopes) are zero as they are compared to themselves.

Now let's apply this to the analysis of ice and ocean $\delta^{18}O$ values and see how delta values are used as a proxy for temperature or change in temperature at deposition.

The ice shields come from snow which comes from water evaporated from the oceans. Water can have multiple isotopic compositions, but from the % abundancies, the most likely ones are $H_2{}^{16}O$ and $H_2{}^{18}O$, which is heavier than the light form, $H_2{}^{16}O$. $H_2{}^{16}O$ evaporates more readily from the mid-latitudes of the oceans, and when it reaches the poles, condenses to form snow and eventually ice enriched in $H_2{}^{16}O$. Urey showed that the vapor pressure of $H_2{}^{18}O$ is about 1% less that that of $H_2{}^{16}O$ between 46.35°C and 11.25°C.

In addition, the $H_2{}^{18}O$ that evaporates at lower-latitudes is more likely to condense and be removed in rain, leaving the southern oceans enriched in $H_2{}^{18}O$. This effect is actually quite significant as water, in the form of ice, in Greenland and Antarctica has about 5% less $H_2{}^{18}O$ than water at 20^0C from midlatitudes, making the $\delta^{18}O$ for water a proxy for temperature **but even better as measures of ice volume and from that sea levels**.

Now consider the Ice Ages, when oceans were enriched in $H_2{}^{18}O$. On glacial melting of $H_2{}^{16}O$-enriched ice, with the melting flowing into the oceans, the $H_2{}^{18}O$ would get diluted with $H_2{}^{16}O$. At the same time, the salinity of the ocean would decrease since ice condenses without oceans salts. These differences in $H_2{}^{18}O/H_2{}^{16}O$ values in ice core samples are converted to $\delta^{18}O$ values, which can be positive or negative, as shown in Figure 32.2.10.

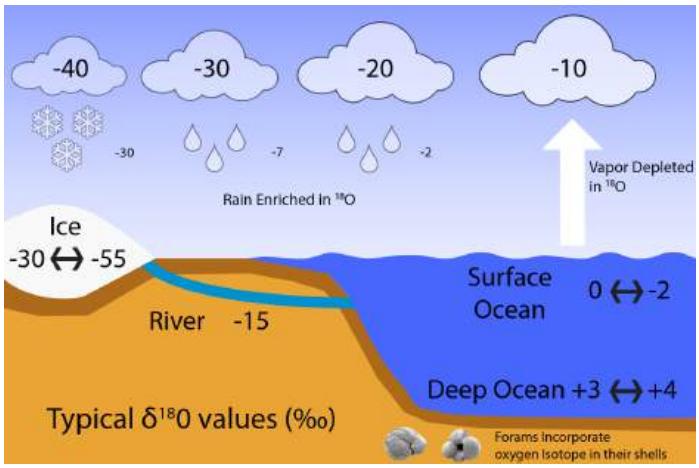


Figure 32.2.10: Typical $\delta^{18}O$ values (in permil). Andreas Schmittner. https://eng.libretexts.org/Bookshelv...A_Paleoclimate

Surface ocean water has $\delta^{18}O$ values of around zero. Due to fractionation during evaporation, less heavy isotopes make it into the air, which leads to negative delta values of around -10 ‰ for the evaporated water vapor. Condensation prefers the heavy isotopes, as described above. In this example, the first precipitation thus has a $\delta^{18}O$ value of about -2 ‰,(more positive than the first vapor). The remaining water vapor will be further depleted in ^{18}O relative to ^{16}O and its $\delta^{18}O$ value become morr negative (-20 ‰). Any subsequent precipitation event further depletes ^{18}O. This process is known as Rayleigh distillation and leads to very low $\delta^{18}O$ values of less than -30 ‰ for snow falling onto ice sheets. Thus, ice has very negative $\delta^{18}O$ of between -30 and -55 ‰. Deep ocean values today are about +3 to +4 ‰. During the last glacial maximum, as more water was locked up in ice sheets, the remaining ocean water became heavier in $\delta^{18}O$ by about 2 ‰. We know this, as we explain below, because foraminifera build their calcium carbonate ($CaCO_3$) shells using the surrounding sea water. Thus they incorporate the oxygen isotopic composition of the water into their shells which are then preserved in the sediments and can be measured in the lab. Bralower and David Bice. https://www.e-education.psu.edu/earth103/node/5. Creative Commons Attribution-NonCommercial-ShareAlike 4.0 International License(link is external).

In summary, in cold conditions, Greenland and Antarctic ice is enriched in ^{16}O since $H_2{}^{16}O$ preferentially evaporates and then condenses and freezes into ice a the poles. In addition, as we will see below, deep sea Foraminifera shells contain more ^{18}O in shells since water is enriched $H_2{}^{18}O$ in cold conditiond, since less evaporates. Hence $\delta^{18}O$ becomes more positive.

OCEAN SEDIMENT CORE $^{18}O/^{16}O$ ANALYSES

In the last section, we looked at $\delta^{18}O$ values in ice core layers and their use as proxies for land and ocean temperatures as more fundamentally as measures of ice volume., which affects sea levels as well as ocean salinity. It's amazing what we can surmise about past climate based on the fact that $H_2{}^{16}O$ evaporates more readily than $H_2{}^{18}O$ and that $H_2{}^{18}O$ that did evaporate condenses at low and mid-latitudes more readily than $H_2{}^{16}O$. These two factors lead to the enrichment of $H_2{}^{16}O$ in polar ice and the enrichment of $H_2{}^{18}O$ in low and mid-latitude ocean water. Remember that evaporation and condensation are physical reactions involving a change in state.

Yet ice cores go back only so far in geological time. To go back further, scientists analyze shells buried in ocean sediments. More specifically, they analyze the isotopic ratio of $^{18}O/^{16}O$ in calcium carbonate (calcite, $CaCO_3$) in buried shells of organisms like Foraminifera. (Calcite is a stable anhydrous form of $CaCO_3$, but under high pressure it can form different calcite phases.) Now we are dealing with a new atom, C, in the carbonates, so the interpretation of $\delta^{18}O$ of buried carbonate depends on many factors compared to than $\delta^{18}O$ values of solid and liquid water. It must include these factors

- the chemical reactions of inorganic carbonate formation (precipitation) and dissolution (compared to the physical reactions of water evaporation and condensation)
- the biological formation of $CaCO_3$ in shells
- an understanding of the carbon cycle
- the temperature at which the $CaCO_3$ was deposited
- the salinity at deposition as the formation of $CaCO_3$ from its ions as the overall ionic strength of the medium in which $CaCO_3$ formed would influence the thermodynamics and kinetics of how the separate ions approach each to form the solid
- equilibrium and kinetic controls of the precipitation reactions.

To truly understand biochemistry, we must include both biological and chemical aspects. Biochemistry requires a synthesis of knowledge from many disciplines, including introductory chemistry (where precipitation reactions were likely covered for the first time) and analytic chemistry (which delves more deeply into precipitation reactions). Hence we don't apologize for bringing back your previous knowledge of precipitation reactions. At the same time, our description of the use of $\delta^{18}O$ values in buried ocean sediments is very simplified.

We need to consider two different reactions to understand $\delta^{18}O$ values in calcite Foraminifera shells. The first describes how ^{18}O gets into CO_3^{2-} in the first place. The second describes seemingly simple reactions for the formation of $CaCO_3$ from its ions.

ENRICHMENT OF $CACO_3$ WITH ^{18}O

The incorporation or **fractionation** of ^{18}O from $H_2{}^{18}O$ into calcite shells can be described most easily by the reaction below.

$$\text{Fractionation Reaction: } (1/3)\ CaC^{16}O_3 + H_2{}^{18}O \rightarrow (1/3)\ CaC^{18}O_3 + H_2{}^{16}O$$

In this reaction, the source of ^{18}O comes from the most abundant and likely sources, $H_2{}^{18}O$. A simplified reaction mechanism is shown in Figure 32.2.11.

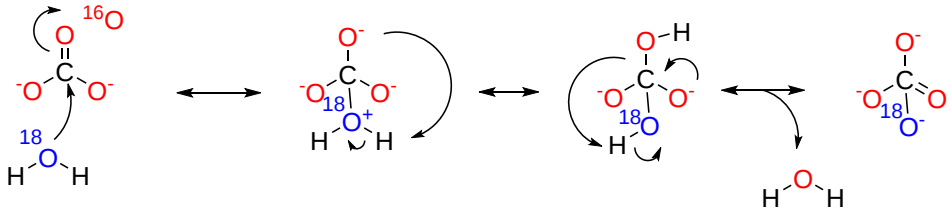

Figure 32.2.11: Incorporation of ^{18}O into carbonate from $H_2{}^{18}O$

More broadly, there would be an exchange of isotopes in the entire **dissolved inorganic pool (DIC)** = $CO_2(aq)$ + H_2CO_3 + HCO_3^- (bicarbonate) + CO_3^{2-} (carbonate) with H_2O.

FORMATION OF $CACO_3$

Two reactions in general describe calcite formation and its growth:

$$Ca^{2+}(aq) + CO_3^{2-}(aq) \leftrightarrow CaCO_3 \tag{32.2.3}$$

and

$$Ca^{2+}(aq) + HCO_3^-(aq) \leftrightarrow CaCO_3 + H^+ \tag{32.2.4}$$

These show the uptake of ^{18}O into $CaCO_3$ should also include a consideration of HCO_3^-.

In a simple and environmentally-controlled in the lab, reaction 2 above can be considered in equilibrium and defined by a K_{sp} value (as you learned in introductory chemistry courses.

In Chapter 4.12, we saw the relationships between K_{eq}, ΔG^0, ΔH^0, DS^0 and temperature. There is an inverse relationship between K_{eq} and temperature.

$$\begin{aligned} \Delta G^0 &= \Delta H^0 - T\Delta S^0 = -RT\ln K_{eq} \\ \ln K_{eq} &= -\frac{\Delta H^0 - T\Delta S^0}{RT} \\ \ln K_{eq} &= -\frac{\Delta H^0}{RT} + \frac{\Delta S^0}{R} \end{aligned} \tag{32.2.5}$$

Assuming that the formation of $CaCO_3$ is in equilibrium, then you would expect that $CaCO_3$ would be enriched in ^{18}O, and have a $+\delta^{18}O$ value. Why? Urey showed that under equilibrium conditions, calcite is enriched in $C^{18}O_3^{2-}$ probably because of lower vibrational energy of the heavier form of carbonate, which favors stabiity and formation of the solid. In addition, the incorporation of ^{18}O is even more pronounced in climatically colder water, which as we have seen, has a $+\delta^{18}O$ value.

Hence in cold periods with large ice shields, $\delta^{18}O$ values from shells of foraminifera living both in the illuminated upper ocean (planktic foraminifera, which engage in photosynthesis) and deep sea benthic foraminifera, are more positive. On ice shield melting, as the $\delta^{18}O$ values of water become more negative, so do the values of $\delta^{18}O$ values of the foraminifera. Benthic foraminifera give a global temperature estimate as deep waters are more homogeneous. Planktic foraminifera $\delta^{18}O$ values are proxies for more local temperatures as they are in a more changing, less mixed environment, and are more affected by evaporation and precipitation.

Yet the formation of $CaCO_3$ in shells in many cases is **not** in equilibrium and is in part determined by the concentration of the reactants, the rate of diffusion of ions into and out of the growing calcite shell, which would also depend on salinity (affecting electrostatic attractions of the ions to the growing crystal), the pH (which affects the ratio of CO_3^{2-} and HCO_3^-) and biological effects (from the mechanism by which shells are formed which at some point may involve HCO_3^- transporters). It also depends on the of transfer of carbonate within the dissolved inorganic carbon pool (DIC). The reaction has been shown to be in equilibrium in some species of foraminifera but not in others.

The term **fractionation** is often used in the isotope and climate literature. Using water as an example, it describes the ratio of heavy to light isotopes of O that partition into the liquid, solid, and gas phases of water. The fractionation factor determines $\delta^{18}O$ value of water. Likewise, there is a fractionation process that determines the partitioning of ^{18}O from water into CO_3^{2-} and $CaCO_3$ during the precipitation of calcite. The fractionation factor α shows how the ratio of the isotopes changes in either a physical (such as a phase transition) or chemical process. It is the factor by which the abundance ratio of two isotopes will change during a chemical reaction or a physical process.

The formation of calcite from HCO_3^- in controlled studies shows that $CaCO_3$ has different oxygen isotope concentrations depending on the initial concentrations of reactants. The size of a shell can also affect the $\delta^{18}O$ of additionally deposited $CaCO_3$. These ideas support the notion that the fractionation of isotopes in $CaCO_3$ occurs through both equilibrium fractionation and kinetic fractionation.

Several different **theoretical "paleotemperature" equations** have been developed to show how temperature T is related to $\delta^{18}O$ in calcite during equilibrium conditions. One theoretical quadratic equation is shown below.

$$\begin{aligned} T &= 16.9 - 4.38\,(\delta_c - A) + 0.10(\delta_c - A)^2 \\ A &= \delta_w - 0.27\% \end{aligned}$$

where T is the temperature in ^oC, δc and δw are the $\delta^{18}O$ of calcite and water, respectively. The 0.27% is just an adjustment factor to convert from the PDB to the VPDB reference values. The equation applies to sea water of normal salinity and freshwater.

A more recent calibration equation for the formation of calcite from HCO_3^- (done with bubbling of the reaction mixture with N_2 for a variety of temperatures) was derived by Kim and O'Neil in 1997. The equation was derived from carefully controlled laboratory studies that apply under equilibrium conditions and is shown below. The Kim and O'Neil equation shows the relationship between the fractionation factor alpha (α) of $^{18}0/^{16}0$ between inorganically precipitated $CaCO_3$ and H_20 as a function of the temperature, and is shown below.

$$1000 \ln \alpha\,(\text{ Calcite- } H_2O) = 18.03\left(10^3 T^{-1}\right) - 32.42 \tag{32.2.6}$$

Alpha is the fractionation factor, and T is in Kelvin. Note: An update of this equation to conform to IUPAC conventions gives 10^3 ln α = 18.04 x 1000 / T - 32.18)

The oxygen isotope fractionation factor alpha between two substances A and B is defined as

$$\alpha = \left({}^{18}O/{}^{16}O\right)_A / \left({}^{18}O/{}^{16}O\right)_B \tag{32.2.7}$$

The left hand side of the equation (1000xlnα) is used for convenience and its relationship to $\delta^{18}O$ values (which are expressed per %o), similar in a way to the use of pKa = -log[K_A] instead of K_A.

Here is an alternative form of the Kim and O'Neil equation expressed in quadratic form.

$$T(^\circ C) = 16.1 - 4.64 \cdot \left(\delta^{18}O_f - \delta^{18}O_w\right) + 0.09 \cdot \left(\delta^{18}O_f - \delta^{18}O_w\right)^2 \tag{32.2.8}$$

A controlled equilibrium study using the cultured foraminifera B. marginata of different sizes at different temperatures was used to develop an experimental equation to compare with the theoretical equations described above. Figure 32.2.12 shows graphs of the empirically-determined equation (nonred lines) vs the theoretical Kim and O'Neil equation (red line).

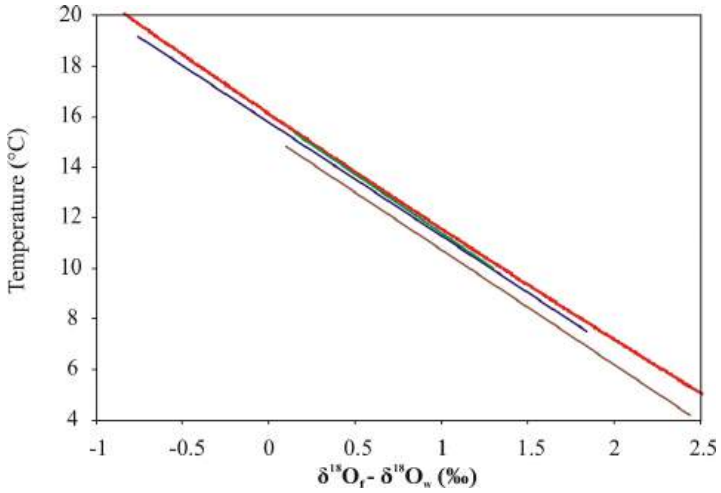

Figure 32.2.12: Comparison of experimental calibration equation with the theoretical equation for equilibrium calcite of Kim and O'Neil (1997). Barras, Christine & Duplessy, J.-C & Geslin, Emmanuelle & Michel, Elisabeth & Jorissen, Frans. (2010). Calibration of δ 18O of cultured benthic foraminiferal calcite as a function of temperature. Biogeosciences. 7. 1349-1356. 10.5194/bg-7-1349-2010. CC Attribution 3.0 License

The brown, blue and green lines represent the calibration equations of cultured B. marginata from ≤ 150, 150–200 and 200–250 µm size fractions, respectively. The quadratic equation derived from Kim and O'Neil (1997) relationship is represented by the red line.

A quick inspection of the empirical equation for different sizes of B. marginata shows the same relationships between T an dδ^{18}O values as shown in Table 32.2.5 below.

	Size fraction	Temperature range	T (°C) = b + a * ($\delta^{18}O_f$-$\delta^{18}O_w$)		R^2
			a	b	
Equation (1)	≤150 µm	4.1-14.7°C	– 4.54 (± 0.14)	15.25 (± 0.17)	0.97
Equation (2)	150-200 µm	7.9-19.3°C	– 4.49 (± 0.13)	15.73 (± 0.14)	0.98
Equation (3)	200-250 µm	10.1-14.7°C	– 4.61 (± 0.37)	16.00 (± 0.33)	0.93
Equation (4)	>250 µm	10.1-14.7°C	– 5.31 (± 0.23)	16.93 (± 0.23)	0.99

Table 32.2.5: Best fit linear plot of temperature T vs ($\delta^{18}O_f$ - $\delta^{18}O_w$) for foraminifera B. marginata vs size, where the subscript f is foraminifera and w is water.

We take this opportunity to reshow the graph that reconstructs changes in planetary temperatures over the last 66+ million years (Figure 32.2.13). The data between 66 MYA and 100,000 years ago (note the change in scale in the x-axis to allow fitting of a large time range in one graph) was obtained, in large part, from δ^{18}O values from deep ocean sediments, while the data from around 100,000 YA to the advent of modern temperature recordings were obtained mostly from δ^{18}O from ice core samples from Antarctica and Greenland. Of course, other temperature proxies, as described above, were important as well.

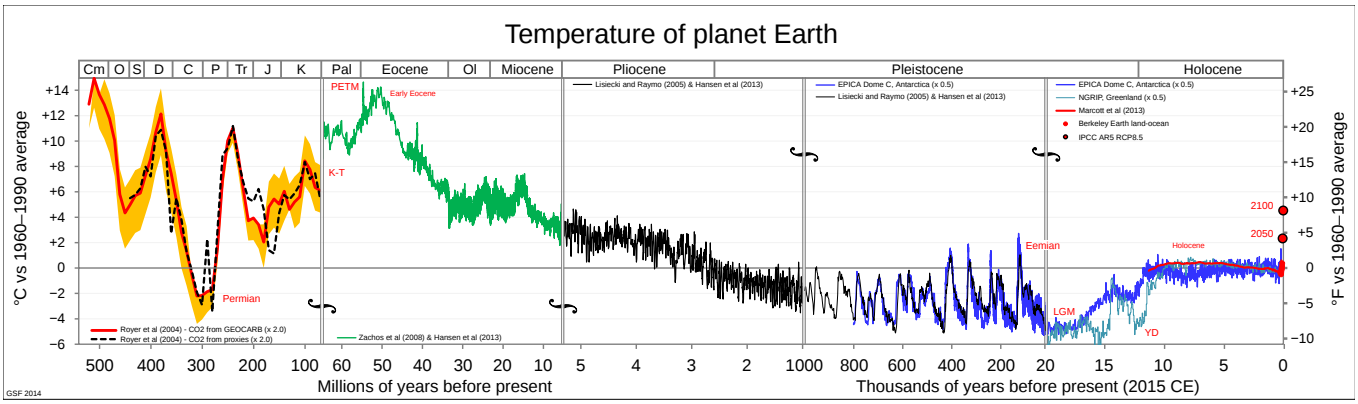

Figure 32.2.13: https://commons.wikimedia.org/wiki/F...alaeotemps.png. (Excel available). Creative Commons Attribution-Share Alike 3.0 Unported

These detailed, but hopefully understandable explanations of the relationship of temperature with $\delta^{18}O$ in foraminifera shells from ocean sediment cores were presented for reasons expressed in the beginning of Chapter 31.2:

- Isotopes and their effects, critical in understanding both structure and activity in biochemistry, are key in climate science.
- Both equilibrium and nonequilibrium reactions and processes apply to isotope partitioning into water and biomolecules, in ways similar to linked biochemical reactions and pathways.
- The study and application of isotope effects can integrate and expand learning from previous science courses

Astute readers will notice that we concentrated on $\delta^{18}O$ values (in water and carbonates) and barely mentioned $\delta^{13}C$ values for carbonate precipitations. We will discuss that in the next chapter section as we consider the carbon cycle.

KEY POINTS - BETA VERSION FROM CHAT.OPENAI

1. Isotope analysis is a technique used to measure the isotopic composition of elements in order to understand the processes and interactions that have occurred in the past, present, and future.
2. Isotopes of carbon, oxygen, and hydrogen can be used to study the effects of climate change on different Earth systems, such as the atmosphere, oceans, and biosphere.
3. Carbon isotopes can be used to study the sources and sinks of CO2 in the atmosphere, and to understand the role of different types of vegetation in the carbon cycle.
4. Oxygen isotopes can be used to study the sources and sinks of water vapor in the atmosphere, and to understand the effects of climate change on precipitation patterns.
5. Hydrogen isotopes can be used to study the sources and sinks of water vapor in the atmosphere and to understand the effects of climate change on the water cycle.
6. Isotope analysis is an important tool for understanding the complex dynamics of the Earth's climate system and for developing effective strategies to mitigate the impacts of climate change.
7. Isotope analysis can provide important information about the Earth's climate and environment and can help scientists understand the causes and impacts of climate change.

32.3: CLIMATE CHANGE - THE CARBON CYCLE AND CARBON CHEMISTRY

Search Fundamentals of Biochemistry

32.3.1: THE CARBON CYCLE

In the last chapter section, we used oxygen isotopes in ice and ocean sediment cores going back millions of years ago to address the history and mechanisms of climate change. We focused on $^{18}\mathbf{O}/^{16}\mathbf{O}$ ratios in $H_2\mathbf{O}$ and in calcite shells ($CaC\mathbf{O}_3$), and their corresponding $\delta^{18}O$ values in ice and sediment cores, to determine CO_2 and temperature over climatic history. Now it's time to talk about the other key atom, **C**, the ratio of $^{13}\mathbf{C}/^{12}\mathbf{C}$ and corresponding $\boldsymbol{\delta}^{\mathbf{13}}\mathbf{C}$ values, not only in $Ca\mathbf{C}O_3$ but also in $\mathbf{C}O_2$ and the organic molecules it transforms into through photosynthesis and the heterotrophic organisms that consume them. $^{13}\mathbf{C}$ partitions not only into inorganic carbon but also into organic molecules throughout life. Hence we need a more detailed understanding of the **carbon cycle**.

The carbon cycle is likely discussed in introductory chapters in biology textbooks, but probably never in chemistry texts. It is fundamental to an understanding of climate, its control and change, and human processes that alter it. Figure 32.3.1 shows a representation of the carbon cycle. Calculated amounts of carbon found in the **lithosphere** (the solid part of the earth), the **atmosphere** (specifically the lower part, the troposphere), and the **hydrosphere** are shown. (The **cryosphere**, the frozen ice found in Greenland and Antarctica, is not shown). The **biosphere** includes part of each of these "spheres" that harbor life. Since life has been shown to exist 10 km down in the crust, we'll refer to the entire region in the diagrams as the biosphere. Figure 1 presents carbon stores in petagrams (10^{15} g) or gigatons of carbon (GtC), as 1 petagram equals 1 billion metric tons (or approximately 1.1 billion US tons).

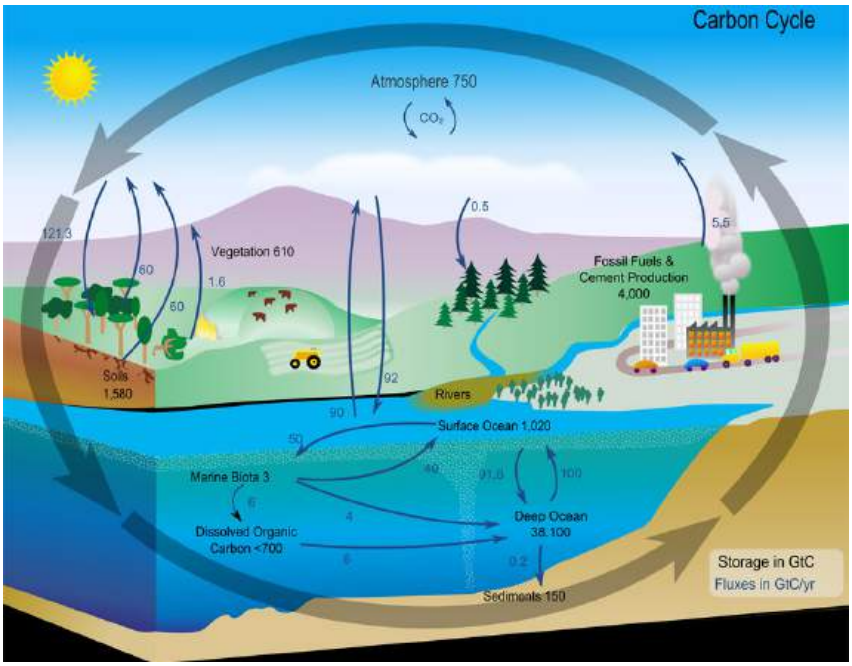

Figure 32.3.1: The carbon cycle. https://commons.wikimedia.org/wiki/F...te_diagram.svg

In addition to the total amount of carbon stored in each region, (GtC), the net changes in carbon per year as it moves into and out of reserves (GtC/yr) are shown in blue arrows with attached numbers.

The exchanges of carbon in the cycle occur at different time scales. Geologically "fast" exchange, on a time scale up to 1000s of years, occurs among the oceans, atmosphere, and land, while a slow exchange (over hundreds of thousands to millions of years) occurs in deep soils, deep ocean sediments, and rocks. We will mostly consider exchanges among the atmosphere, land, and oceans.

CO_2 in the terrestrial biosphere is removed by photosynthesis and returned by respiration by autotrophs like plants, and heterotrophs like microbes that consume soil carbon and plant remains. CO_2 in the atmosphere is also removed by ocean autotrophs like ocean phytoplankton and through partitioning into dissolved inorganic carbons (DIC) molecules like HCO_3^- and CO_3^{2-} into the oceans.

Before we probe some relevant reactions within it, let's look at the big picture and perhaps the most relevant to our climate crisis - the factors causing our increasing CO_2 atm and global warming. To do that, we must put numbers on the cycle to quantify it.

32.3.2: QUANTITATING THE CARBON CYCLE

In Chapter 31.1, we used parts per million (ppm) as a unit for expressing the amount of CO_2 in the atmosphere. Table 32.3.1 below shows how to translate the percentage (parts per 100) for each component gas in the atmosphere (with which you are familiar) into ppm.

Gas	% (parts per 100) in atm	part per million
$\mathbf{N_2}$	78.09	780,900
$\mathbf{O_2}$	20.94	209,400
Ar	0.93	9300
$\mathbf{CO_2}$	0.0415	415

Table 32.3.1: Unit conversion - % to ppm

Climate scientists use ppm instead of concentration (in molecules/m^3) since they wish to know the relative percent or ppm increase with time, which does not depend on temperature and pressure. In contrast, concentration does depend on T and P, as you will remember from the ideal gas law, PV=nRT or n/V=P/RT that you studied in introductory chemistry.

It is important to use dimensional analyses to interconvert units as well. Table 32.3.2 below shows conversion factors to switch between GtC, Gt CO_2, and ppm.

Convert from	to	conversion factor
GtC (Gigatons of carbon)	ppm CO_2	divide by 2.124
GtC (Gigatons of carbon)	PgC (Petgrams of carbon)	multiply by 1
Gt CO_2 (Gigatons of carbon)	GtC (Gigatons of C)	divide by 3.664 = 44.01/12.01)
GtC (Gigatons of carbon)	MtC	multiply by 10000

Table 32.3.2: Unit conversion - GtC and Gt CO_2

To be more technical, atmospheric CO_2 concentrations are expressed in mol fraction of CO_2 in the dry air atmosphere. The ppm for CO_2 is hence µmol CO_2 per mole of dry air.

We have to put numbers on the components of the carbon cycle to quantitatively analyze changes in its components, otherwise, we can't know what is presently happening nor will we be able to predict with some certainty the future. Stoichiometry and reaction kinetics are probably the least liked parts of chemistry for many, but they are critical in understanding climate change We have to apply them on a global scale. Two key terms are important:

Stocks or reserves: How much carbon (mass in Gigatons or petagrams) is stored in given locations in the biosphere. This allows us to understand what % of all carbon stocks are in the ocean, for example. Stocks are usually reported as gigatons of carbon (GtC), not gigatons of carbon dioxide, since many stocks (like fossil fuels) consist of mostly C and H without oxygen. As in stoichiometry calculations in introductory chemistry courses, GtC in the atmosphere can be converted to gigatons of CO_2 by using dimensional analysis.

Fluxes (rates): How much carbon is transferred from one reserve to another per year (Gigatons/yr). Climate scientists are simply applying the Law of Mass Conservation that you learned in introductory chemistry, to the entire biosphere.

Figure 32.3.2 shows the reserves/stock (GtC) for reserves and **decadal (2012-2021) average** fluxes (large and small arrows, GtC/yr) for individual or aggregated stocks.

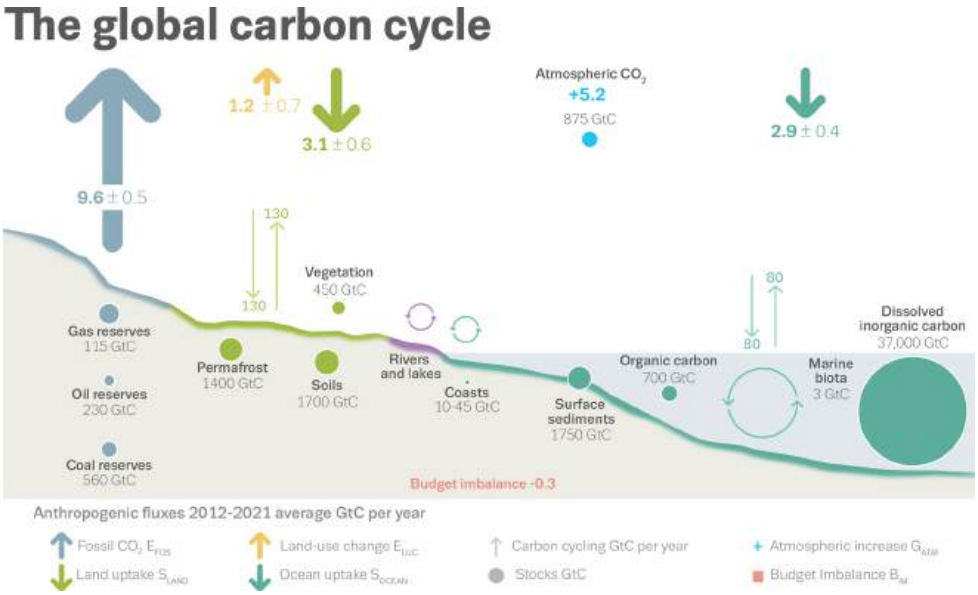

Figure 32.3.2: Schematic representation of the overall perturbation of the global carbon cycle caused by anthropogenic activities **averaged globally for the decade 2012–2021**. E represents emission and S "sink". Earth Syst. Sci. Data, 14, 4811–4900, 2022. https://doi.org/10.5194/essd-14-4811-2022. © Author(s) 2022. This work is distributed under the Creative Commons Attribution 4.0 License.

The abbreviations used are: E_{FOS} (emissions, fossil fuels), E_{LUC} (emissions land use changes - mostly deforestation), S_{LAND} (terrestrial CO_2 sink), S_{OCEAN} (ocean CO_2 sink), G_{ATM} (Growth Rate CO_2 atm), B_{IM} (carbon budget imbalance). Uncertainties are also shown except for the atmospheric CO_2 growth rate which is known precisely and accurately through modern measurements. (It's also the easiest to measure). Human (anthropogenic changes) occurs on top of the carbon cycle.

The upward arrows indicate release into the atmosphere and the downward arrows the absorption in the oceans and land. The thickness of the arrows gives a relative measure of the size of emission or absorption. The thickest arrow and highest value (9.6 GtC/yr) is for the anthropogenic emission of carbon from our use of fossil fuels. Think about that! **Humans are presently the biggest contributor to the carbon cycle**. Before the industrial revolution, human contributions were minimal.

IT'S WORSE THAN THAT!

Figure x above shows that on average, 9.6 GtC/yr was released from fossil fuel use between 2012-2021. The actual flux of anthropogenic carbon release **in 2021 was 9.9 GtC**, equivalent to 36.4 Gt CO_2.

If you add the up arrows and subtract from that sum the down ones, you get +4.8 GtC/yr. This represents the net average increase in GtC in atmosphere CO_2 per year for 2012-2021. That is close to the accurately, and precisely known value of +5.2 GtC/yr increase from the CO_2 we pour into the atmosphere through our use of fossil fuels. Hence the figure above is a bit out of balance (about 0.3 GtC too low - the B_{IM} carbon budget imbalance), but given the difficulty in calculating these values, it is remarkably close to "mass balance" as you learned in introductory chemistry classes. In general, before the industrial revolution, the sum of the fluxes leading to the addition of CO_2 into the atmosphere was equal to the sum of the fluxes that removed it. That is, the system was in a **steady state.** That is no longer the case.

Figure 32.3.3 shows a breakdown of the factors contributing to annual (left) and cumulative (right) fluxes of carbon (GtC/yr), a metric for CO_2 flux, over time since 1850.

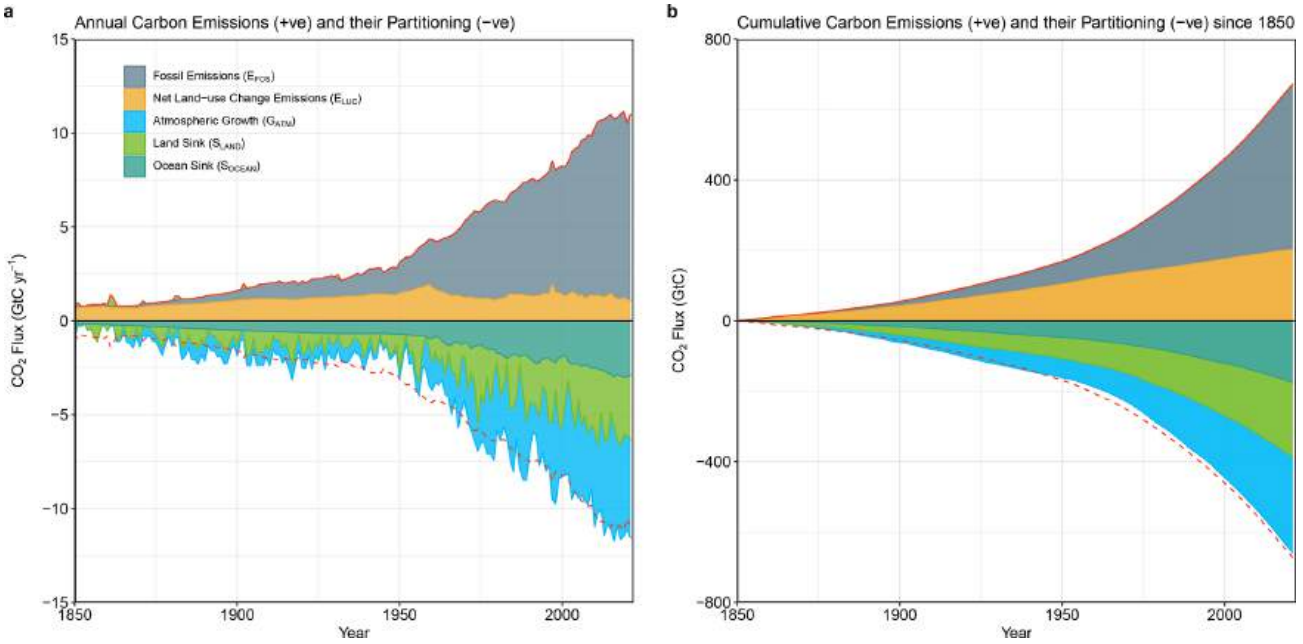

Figure 32.3.3: Combined components of the global carbon budget as a function of time for fossil CO_2 emissions (E_{FOS}, including a small sink from cement carbonation; grey) and emissions from land-use change (E_{LUC}; brown), as well as their partitioning among the atmosphere (G_{ATM}; cyan), ocean (S_{OCEAN}; blue), and land (S_{LAND}; green). Panel **(a)** shows annual estimates of each flux (GtC yr^{-1}, and panel **(b)** shows the cumulative flux (the sum of all prior annual fluxes) since the year 1850. Again, the graph shows GtC not Gt CO_2. . © Author(s), ibid

You might ask why the atmospheric growth in CO_2 (shown in green) is negative. We'll answer that question below.

Lastly, let's think about the total cumulative changes in GtC released and absorbed since 1850 (pre-US civil war and before the big release of CO_2 in modern times). Those data are shown in a bar graph in panel A of Figure 32.3.4. The bar graph in the right panel shows the mean decadal averages that are shown in Figure 2 above.

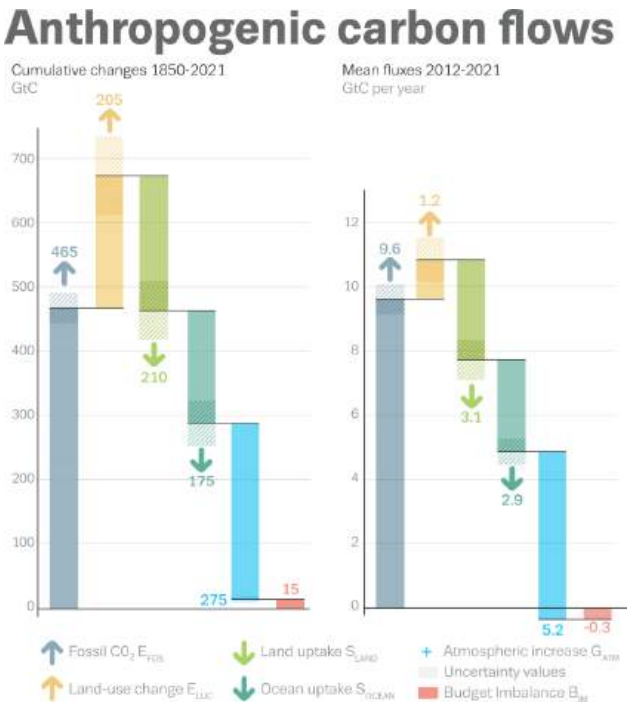

Figure 32.3.4: Total cumulative changes in GtC released and absorbed since 1850 (panel A) and mean decadal fluxes (panel B). E_{FOS} (emissions, fossil fuels), E_{LUC} (emissions land use changes - mostly deforestation), S_{LAND} (terrestrial CO_2 sink), S_{OCEAN} (ocean CO_2 sink), G_{ATM} (Growth Rate CO_2 atm), B_{IM} (carbon budget imbalance). © Author(s), ibid

The positive emission and negative absorption contributions are easy to see in the bar graph. The blue bar represents the net emission of carbon from fossil fuels and fills the gap to complete mass balance as we discussed above. It also explains the negative blue region in Figure 3. Just keep in mind that the blue net flux from fossil fuels is positive.

The cumulative contributions from fossil fuel emissions required to close the gap and fulfill mass balance is is +275 GtC, which when multiplied by the conversion factor (1ppm/2.124 GtC) translates into a 129.5 ppm increase in atmospheric CO_2 over that time. This is very close to independent measurements of a rise of 129.3 ppm (14.7-284.7) over that time.

The data from Figure 32.3.4 has been entered in the first four columns of Table 32.3.3 below.

Source	Subtype	Stock reserves (GtC)	J (Fluxes) GtC/yr (avg 2012/2021) + emission - absorption	$J=k_{app}$[stock]
Atmosphere	-	875		
Buried Fossil Fuels	Coal	560	+9.6	J=+9.6=k[905] k=0.0106
	Oil	230		
	Gas	115		
Terrestrial	Permafrost	1,400	+1.2 (Land use Δ) -3.1 (Land uptake)	J_{use}=+1.2=k_{use}[3550]; k_{use}=0.000338 J_{up}=-3.1=k_{up}[875]; k_{up}=0.00354
	Soil	1,700		
	Vegetation	450		
Oceans	Coasts	10-45	-2.9	J=-2.9=k[875] k=0.00331
	Ocean Surface Sediments	1,750		
	Organic carbon	700		
	Marine Biota	3		
	Dissolve Inorganic Carbon (DIC)	37,000		

We can use this data to develop our own crude computational model predicting future CO_2 emissions using Vcell, the program we used to produce time course (concentration vs time) graphs for both simple and coupled signal transduction reaction pathways.

Vcell can be used to calculate fluxes (J) in reaction pathways, where J is the change in concentrations of a species with time, given the initial concentration or amount of a reactant, and the rate constants affecting its production or removal. If we use the amount of carbon (GtC) in each reservoir in the biosphere and crust as a relative measure of "concentration" and the known fluxes (GtC/yr) for the transfer of carbon to and from the atmosphere as given in Table 3, we could calculate an "apparent rate constant for each flux using this equation:

$J_{stock} = k_{app}$[stock] (where stock is given in GtC).

$$J_{stock} = k_{app}[\text{stock in GtC}] \tag{32.3.1}$$

These "apparent" rate constants are needed to run the Vcell simulation that can reproduce the actual fluxes shown in Figures 2 and 4). The simulation can be run over time

A simple four-term model based on Figures 2 and 4 is shown below. Run the simulation and see how atmospheric CO_2 changes with time. This model is offered only to show how climate models are made and used, and also for fun. The graphs are valid and sound based on the input parameters, but the outputs are based on many assumptions that vastly simplify the model.

The simulation shows CO_2 atm levels peaking at about 982 **GtC** in 51 years (2073) from its average decadal (2011-2021) value of 875. That is an increase of 107 **GtC** over now (50 ppm CO_2 rise from the present 414 to 463 ppm). Over a 50-year period, this gives an average annual rise of 2.14 GtC/yr or about 1 ppm CO_2/yr. A comparison of the predicted atmospheric CO_2 (ppm) levels through 2100 for the IPCC SSP1-2.6 scenario (**blue**) and simple Vcell model (**red**) is shown in Figure 32.3.5.

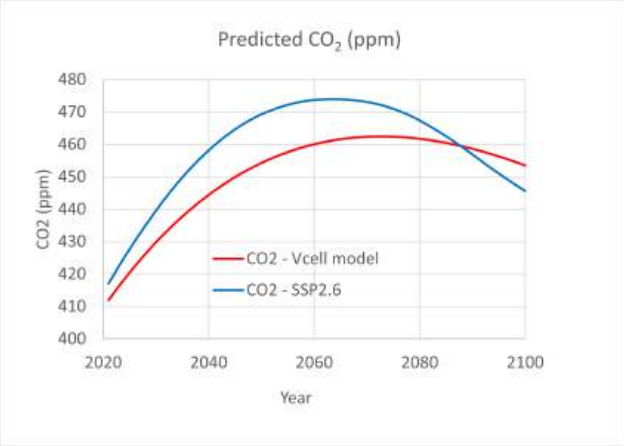

Figure 32.3.5: Predicted atmospheric CO_2 (ppm) for SSP1-2.6 scenario (**blue**) and simple Vcell model (**red**)

SSP1-2.6 data - History: Meinshausen et al. GMD 2017 (https://doi.org/10.5194/gmd-10-2057-2017); Future: Meinshausen et al., GMD, 2020 (https://doi.org/10.5194/gmd-2019-222). https://climateanalytics.org/media/g...-3571-2020.pdf. https://gmd.copernicus.org/articles/13/3571/2020/

However imperfect the Vcell model is (incorrect assumptions, lack of complexity and feedback mechanisms, etc), the results shown above are remarkably close to the projected increases in carbon dioxide in ppm described in IPCC reports for the SSP1-2.6 socioeconomic pathways, shown in the right panel (dark blue line) of Figure 32.3.6. This pathway predicts a rise of approximately 1.8^0 C in average global temperatures.

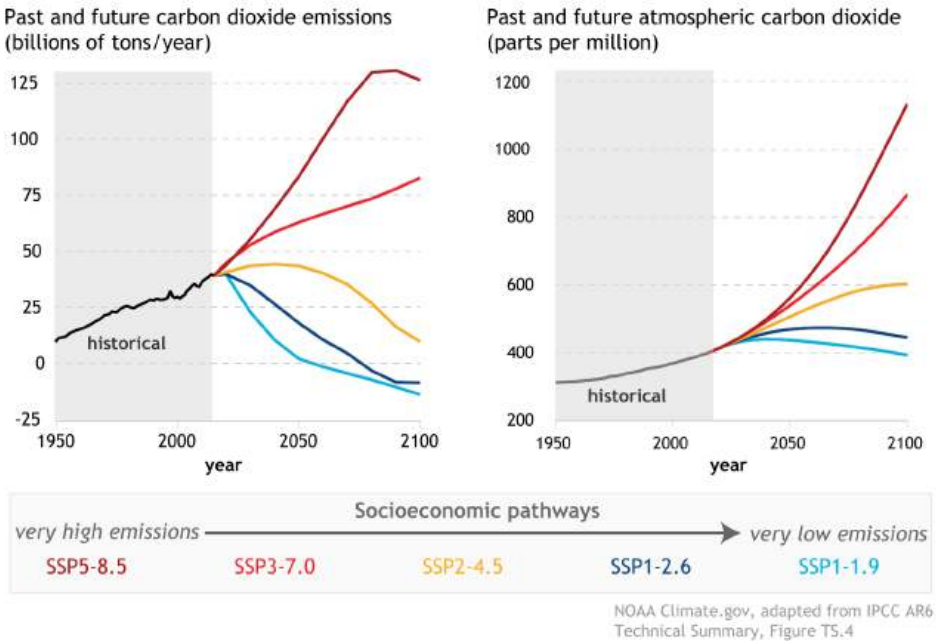

Figure 32.3.6: IPCC, 2021: Summary for Policymakers. In: Climate Change 2021: The Physical Science Basis. Contribution of Working Group I to the Sixth Assessment Report of the Intergovernmental Panel on Climate Change [Masson-Delmotte, V., P. Zhai, A. Pirani, S.L. Connors, C. Péan, S. Berger, N. Caud, Y. Chen, L. Goldfarb, M.I. Gomis, M. Huang, K. Leitzell, E. Lonnoy, J.B.R. Matthews, T.K. Maycock, T. Waterfield, O. Yelekçi, R. Yu, and B. Zhou (eds.)].

Again, remember that the model is based on a ten-year average of CO_2 emissions. Think of all the other assumptions in this model (other than the stock reserves and fluxes) that would give higher or lower values of future CO_2 levels. One major one is that flux values are all held constant to allow calculations of the apparent rate constants for Vcell use. The model depletes much of the fossil fuel reserve. In addition, CO_2 emissions in 2021 were actually 9.9 GtC/yr and going up!

In addition, a change in one parameter can affect the others. For example, the net uptake of atmospheric CO_2 into the land and oceans has increased from 1960-2010, which makes sense given increased CO_2 in the air forcing additional uptake (think LaChatelier's Principle). The oceans have taken up nearly 40% of the CO_2 from fossil fuel use since the industrial revolution. If the rate of uptake decreases (i.e. if we start to saturate the uptake into oceans), CO_2 accumulation in the atmosphere would accelerate. Data also suggest that if we successfully decrease CO_2 in the atmosphere, the oceans would respond by decreasing uptake as well, which would slow the progress in reducing temperatures.

An interesting example relating atmospheric and ocean CO_2 occurred from 1990-2000 when it has been shown that the ocean acted as a weaker sink. This occurred because of a decreasing gradient (the Δ or"effective concentration differences") between atmospheric CO_2 and ocean "CO_2", which decreased the ability of the ocean to act as a sink for CO_2. You can decrease the Δ in two ways:

- decreasing the rate of entry of CO_2 into the atmosphere from fossil fuel use. There indeed was a temporary slowdown in this decade.

- paradoxically, by briefly making the ocean in a shorter term a better sink. This happened in 1991 after the eruption of Mt. Pinatubo, which led to decreased air and ocean temperatures. CO_2 is a nonpolar gas, which has higher solubility in water at lower temperatures (think about soda). This was a short-term and more minor effect than the decreased rate of fossil fuel emissions.

More complex models with more terms for emissions and absorptions of CO_2 can be made. One is shown in Figure 32.3.7. This model adds CO_2 release from the soil through respiration by microorganisms, as well as from plant respiration (CHO to CO2atm). Another term has been added for release by oceans.

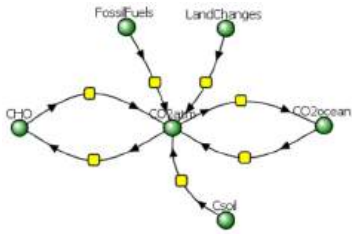

Figure 32.3.7: More complicated Vcell climate model.

Fortunately, we don't have to rely on these simple models to predict future trends in temperature and CO_2. A complex dynamic model simulator that is in accord with many different climate models is available at your fingertips. Developed at MIT and Climate Interactive, and available for free from any web browser, the EN-ROADS program allows users to change sliders for key inputs and see future predicted temperature and CO_2 levels. In accordance with RCP and SSP IPCC pathways that tie future emissions to socio-economic policies (discussed in Chapter 31.1), the program allows users to change variables such as carbon pricing and incentives to move to clean energy in transportation, building and energy supplies sectors. Access the program directly from this page by clicking the Close icon in the program window in Figure 32.3.8 below.

Figure 32.3.8: EN-ROADS global climate simulator

Here is also an external link to the En-Roads global climate simulator (Developed by Climate Interactive, the **MIT Sloan Sustainability Initiative**, and **Ventana Systems**)

Move the interactive sliders and see the effect on greenhouse gas emissions and global temperatures. Here is a link to a one-page tutorial on its use.

THE SKEPTIC'S CORNER: CLIMATE CHANGE MISINFORMATION

We should all be skeptical of models, especially ones that predict changes 80 or more years into the future. We gain confidence in a model if it accurately fits data going back in time and into the future data as well. We mentioned in Chapter 31.1 that oil company scientists knew of the likely climatic effects arising from fossil fuel emissions, but the company executives did not act on their models. Their models were startlingly accurate as shown in Figure 32.3.9 below, which shows their predictions for both CO_2 levels and the associated increases in temperature caused by them.

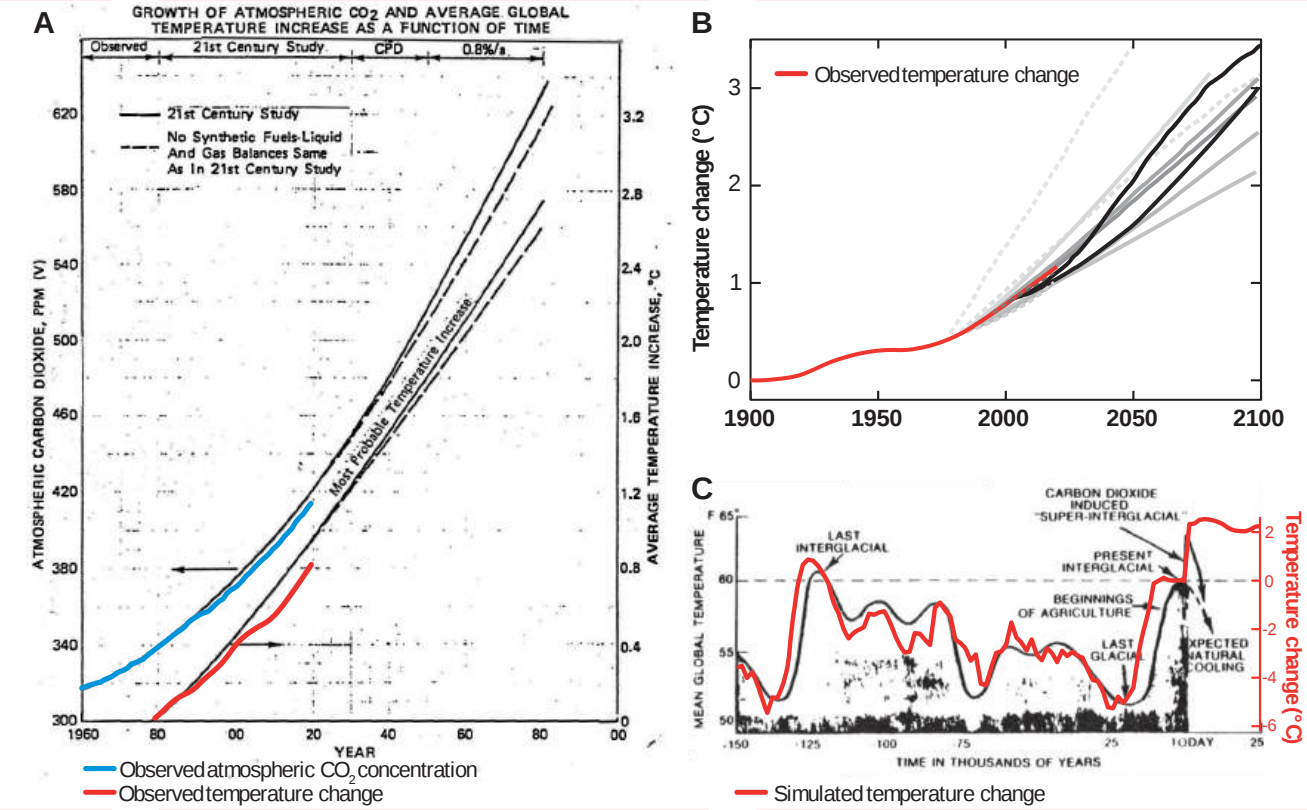

Figure 32.3.9: Historically observed temperature change (red) and atmospheric carbon dioxide concentration (blue) over time, compared against global warming projections reported by ExxonMobil scientists. Supran, G., Rahmstorf, S., and Oreskes, N. Assessing ExxonMobil's global warming projections. Science (2023). https://www.science.org/doi/abs/10.1...cience.abk0063. Reprinted with permission from AAAS. Not for reuse.

Panel (A) shows "Proprietary" 1982 Exxon-modeled projections.

Panel (B) shows a summary of projections in seven internal company memos and five peer-reviewed publications between 1977 and 2003 (gray lines).

Panel (C) shows a 1977 internally reported graph of the global warming "effect of CO2 on an interglacial scale." (A) and (B) display averaged historical temperature observations, whereas the historical temperature record in (C) is a smoothed Earth system model simulation of the last 150,000 years.

As these graphs clearly show, oil companies knew since the late 1970s, over 40 years ago, of the climatic effects of CO_2 emissions. They could even predict the temperatures since the last ice age. In the 70s, solar and wind energy were much more expensive to produce and use than now, but if we had subsidized their development back then as we have done for decades for the fossil fuel industries, our climatic situation now would be much less precarious. Figure 32.3.10 below shows worldwide fossil fuel subsidies in US $billion and in % global GDP from 2015 to 2020 and projections after that.

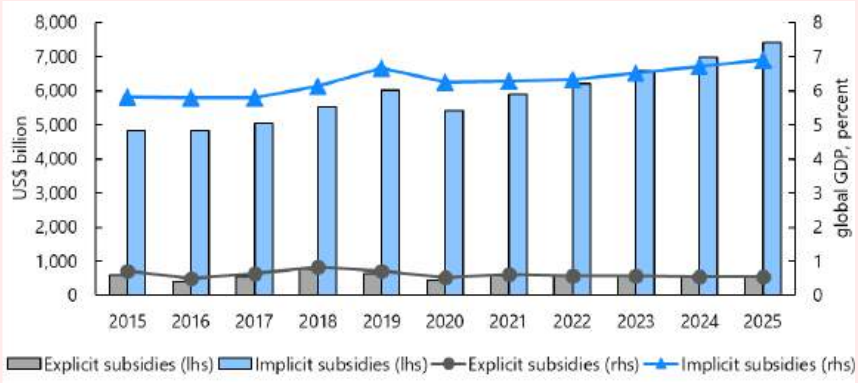

Figure 32.3.10: Worldwide subsidizes in US $billion and in % global GDP. Bar graphs are for US$biillons and the circles and triangles for % global GDP. IMF. ttps://www.imf.org/en/Publications/W...bsidies-466004

The subsidies are broken down into explicit subsidies (tax breaks or direct payments to help fossil fuel companies to fund their uncompensated costs) and implicit ones (undercharging for environmental costs of fossil fuel use that the oil companies don't pay). These latter "hidden" costs are passed down to countries, states, and individuals. In 2020, global subsidies were $5.9 trillion or 6.8% of the world's GDP. The explicit subsidies given to fossil fuel companies, about 8% of the total, amounted to $472 billion just in 2020!

"Company executives chose to publicly denigrate climate models, insist there was no scientific consensus on anthropogenic climate change, and claim the science was highly uncertain when their own scientists were telling them the opposite" (ref). They also propagated the myth that the global climate was actually cooling. This is a powerful and unsettling example of disinformation with enormous consequences.

Now that we have seen the big picture, let's look at how carbon moves through various pools of carbon-containing molecules. We have already discussed photosynthesis in great detail in Chapter 20, so we fill focus our attention more on dissolved inorganic carbons (DIC) including species such as HCO_3^- and CO_3^{2-}. Another view of the carbon cycle that includes weathering of rocks to produce silicates and bicarbonates, and the formation of shells in the ocean from HCO_3^-, CO_3^{2-} and silicates, is shown in Figure 32.3.10.

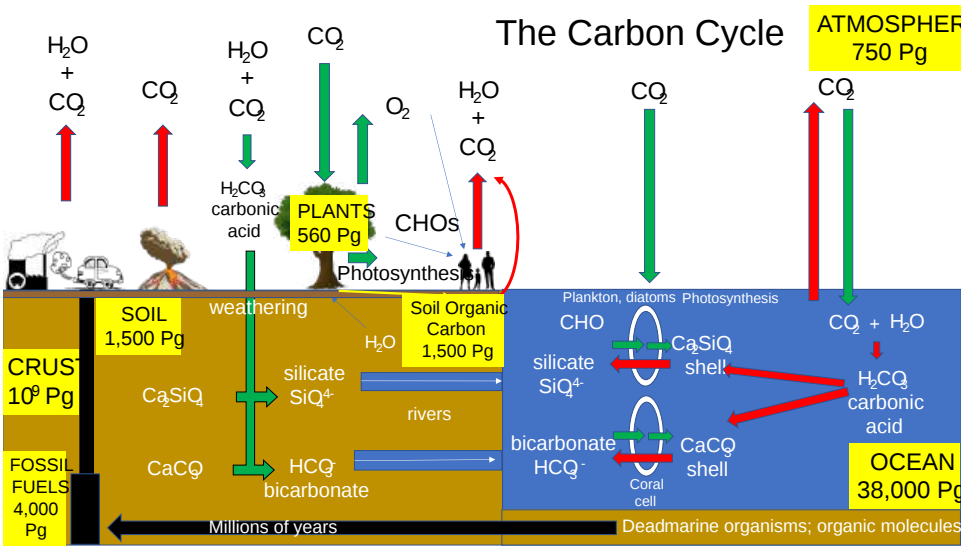

Figure 32.3.10:

Let's focus on the oceans first. The reversible movement of CO_2 from the atmosphere to the oceans, $CO_{2\ atm} \leftrightarrow CO_{2\ ocean}$, depends on the difference in the partial pressures of CO_2 (ΔpCO_2) in the atmosphere and surface waters. The reaction is also driven to the right by the removal of CO_2 (aq) as it forms carbonic acid (H_2CO_3), which then forms bicarbonate (HCO_3^-) and carbonate (CO_3^{2-}). These coupled reactions chemically buffer ocean water, thus regulating ocean pCO_2 and pH.

pCO_2 is not homogenous in ocean surface waters and varies with different conditions of current and temperature. CO_2 can be more readily released from upwellings of nutrient-rich and warm waters, especially in the tropics. In cold Northern waters and also in the Southern Ocean, where water sinks, it is taken up from the atmosphere (again CO_2 is more soluble in cold water).

As we discussed in Chapter 31.1, the **ocean chemistry of CO_2 determines in large part the levels of atmospheric CO_2.** The coupled reactions of CO_2 in the oceans are shown below.

$$CO_2(\text{ g, atm}) \leftrightarrow CO_2(\text{aq, ocean}) \tag{32.3.2}$$

$$CO_2(\text{aq, ocean}) + H_2O(\text{I, ocean}) \leftrightarrow H_3O^+(\text{aq}) + HCO_3^-(\text{aq}) \tag{32.3.3}$$

$$H_2O(\text{I}) + HCO_3^-(\text{aq}) \leftrightarrow H_3O^+(\text{aq}) + {CO_3}^{2-}(\text{aq, sparingly soluble}) \tag{32.3.4}$$

These reactions should be familiar to all chemistry students and were presented previously in Chapter 31.1 and in Chapter 2. A significant contributor to ocean bicarbonate is **weathering** of rocks like limestone. and marble, which are both forms of $CaCO_3$. The relevant reactions are shown below.

$$\begin{aligned} &CaCO_3(\text{ s}) + H_2O \leftrightarrow Ca^{2+}(\text{aq}) + {CO_3}^{2-}(\text{aq}) \\ &{CO_3}^{2-}(\text{aq}) + H_2O \leftrightarrow {HCO_3}^-(\text{aq}) + OH^-(\text{aq}) \end{aligned} \tag{32.3.5}$$

CO_2 is nonpolar and not very soluble in water. Either is CO_3^{2-} in the presence of divalent cations like Ca^{2+}. However HCO_3^- is and can be considered a "soluble" form of carbon. This soluble form from terrestrial weatherings ends up in rivers and eventually enters the ocean. It is also the form of carbonate that is transferred into cells by anion transporters for eventual shell formation. HCO_3^- is also a chief regulator of both blood and ocean pH. Weathering is slow compared to anthropogenic emissions of CO_2 from fossil fuel use, but it is nevertheless a key player in the carbon cycle and the regulation of ocean pH.

The same weathering reactions on silicate rocks lead to the transfer of silicate ions into rivers and then into the ocean, where they can be taken up by diatoms in the formation of $CaSiO_4$ shells. As the oceans take up more CO_2, they become more acidic, which leads to the equivalent of "weathering" of shells of living organisms, leading to their potential death. Silicon is directly underneath carbon in the periodic table so the following simplified reaction is analogous to those we seen with CO_2 and its inorganic ions.

$$H_4SiO_4 = SiO_2 + 2H_2O \tag{32.3.6}$$

H_4SiO_4 is silicic acid.

32.3.3: $^{13}C/^{12}C$ RATIOS IN ICE CORE AND OCEAN SEDIMENTS

We are now in the position to explore how isotopes of carbon can be used for more than radio- ^{14}C dating, which is quite limited in climate studies. ^{13}C, a stable isotope of carbon, however, is extremely useful because C-^{13}C bond dynamics are influenced by it. Reaction rates are affected by the presence of ^{13}C when C-C bonds are made or cleaved. This isotope effect leads to different $^{13}C/^{12}C$ ratios in reactants and products, and hence different $\delta^{13}C$ values.

Isotopes have a long history in the study of biochemical reactions. The k_{cat} and k_{cat}/K_M values for enzyme-catalyzed reactions can be affected if the rate-limiting step involves cleavage or the creation of a C-^{13}C, C-D (deuterium) or C-T (tritium) bond. Substrates labeled with the isotopes have similar transition state energies for the formation/cleavage of a bond involving an isotope, but the ground state vibrational energy for the isotope-substituted atom are proportionately lower, as illustrated in Figure 32.3.11.

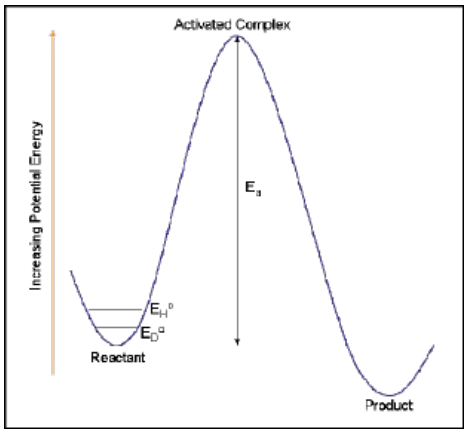

Figure 32.3.11: Kinetic Isotope Effects.

This primary **kinetic isotope effect** leads to higher activation energy for the formation/cleavage of a bond with the isotope. For C-D and C-T bond cleavages that are rate-limiting, the rates are 7X and 16X slower than the cleavage of a C-H bond, respectively. Cleavage or formation of bonds to heavy isotopes of carbon, oxygen, nitrogen, sulfur, and bromine have much smaller isotope effects (between 1.02 and 1.10). The difference in the magnitude of the kinetic isotope effect is directly related to the percentage change in mass. Large effects are seen when hydrogen is replaced with deuterium because the percentage mass change is very large (mass is being doubled). .

Hence the kinetic isotope effect is at play in carbon fixation in photosynthesis, for example. This is evidenced by the observation that the $^{13}C/^{12}C$ ratios are lower in plants than in the atmosphere, showing that $^{12}CO_2$ is preferentially "fixed" in the ribulose bisphosphate carboxylase/oxygenase reaction in plants and other photosynthetic organisms. Also, $^{12}CO_2$, a lighter molecule, has a faster rate of diffusion through the stromata, regulated pores in leaves that facilitate the passage of CO_2, O_2 and H_2O.

In Chapter 31.2, we discussed the use of $\delta^{18}O$ values in ice core and ocean core sediments for measuring past CO_2 and temperatures.

$$\delta^{18}O = \left[\frac{\left(\frac{^{18}O}{^{16}O}\right)_{\text{sample}}}{\left(\frac{^{18}O}{^{16}O}\right)_{\text{reference}}} - 1 \right] * 1000$$

$\delta^{18}O$ values for ice core water samples werer easier to interpret than $\delta^{18}O$ values for $CaCO_3$ sampls, since the deposition of ice is a simple physical process compared to the complexity of the deposition of $CaCO_3$ in ocean sediments, which depends on chemical reactions and nonequilbrium processes (as described in Chapter 31).

Climate scientists can determine and use $\delta^{13}C$ values. An analogous equation for it is shown below.

$$\delta^{13}C = \left[\frac{\left(\frac{13}{12}C\right)_{\text{sample}}}{\left(\frac{13}{12}C\right)_{\text{reference}}} - 1 \right] * 1000$$

As for using $\delta^{18}O$ in carbonate samples, using $\delta^{13}C$ is more difficult as well. The shells of ocean sediment foraminifera were made from dissolved inorganic carbon (DIC) in the ocean at the time so their $\delta^{13}C$ values reflect that. However, shell formation is not a simple equilibrium process since biological shells are formed rapidly so kinetic effects in carbonate and hence isotope fractionation are important. In addition, the biochemistry of shell formation is complicated.

In the open ocean, planktic foraminifera are perhaps the most important marine organism that forms shells given that they produce and export into the ocean about 2.9 Gt $CaCO_3$/yr. Their shells form in a process involving many metastable calcite phases. It starts with a soft template that contains Mg^{2+} and Na^+ ions which play a key role in crystallization. Growth occurs by successive additions of "chambers" to the shell. An F-actin mesh, which forms microtubular structures, leads to the formation of protective envelopes for chamber formation. The layered templates sequester and help control the mineralization of shells and separate bulk sea water for a more intracellular vs extracellular process for biomineralization. Seawater containing minerals becomes vacuolized in a process which for some foraminfera excludes a competing cation, Mg^{2+}. In addition, both Ca^{2+} and HCO_3^- transporters are required. This all combines to form an environment low in Mg^{2+} and supersaturated in Ca^{2+} and CO_3^{2-} for calcite formation. The kinetic fractionation of ^{13}C isotopes into shells is also different than for ^{18}O isotopes since the "pool" of oxygen in the oceans is much greater than carbon. Likewise, the $\delta^{13}C$ is more location-dependent that the $\delta^{18}O$.

Buried organic matter can also be studied. The $\delta^{13}C$ value for buried organic matter depends on primary productivity on land and in the oceans. As mentioned above, autotrophs preferentially take up $^{12}CO_2$. Heterotrophs that eat them also become enriched in ^{12}C. Hence organisms have negative $\delta^{13}C$ values, typically

around −25‰, with the number depending on pathways of incorporation and metabolism. Methane in hydrates in the ocean can be either biogenic, made by methanogens, for example, at low temperatures, or thermogenic, made during high-temperature reactions. Biogenic methane has a $\delta^{13}C$ of around - 60 ‰, while thermogenic methane has a value of around −40‰. Terrestrial plants have different δ^{13} values. $\delta^{13}C$ in C_4 plants range from -16 to −10‰ while for C_3 plants they range from −33 to −24‰.

Changes in $\delta^{13}C$ in ice cores and ocean sediments are used in climate studies. Sometimes it's confusing to understand the cause and effect of the changes. This following explanation for changes in the already negative values of $\delta^{13}C$ might offer help to those with a chemistry-centric view of biochemistry who struggle with mass balance outside of simple chemical equations.

Under climatic conditions, when there is an abundance of **terrestrial** plants that lock in and sequester atmospheric $^{12}CO_2$, the atmosphere becomes depleted in $^{12}CO_2$ and correspondingly enriched in $^{13}CO_2$. Hence primary production (fixing of carbon and anabolic metabolism) by photoplankton in the oceans, under robust growing conditions, would sequester more ^{13}C, causing an **increase in $\delta^{13}C$** (i.e. more positive) values for buried organic and calcite sediments.

During times of mass extinction, when terrestrial plant primary production drops precipitously, the $\delta^{13}C$ becomes more negative with the decrease in primary production and release of plant carbon, leaving more $^{12}CO_2$ in the atmosphere. This drop is called a **negative $\delta^{13}C$ excursion**. When life is robustly favored and carbon is fixed by autotrophs, and the organic carbon resulting from them is eventually buried in sedimentary rocks, the rise in $\delta^{13}C$ is called a positive **$\delta^{13}C$ excursion**.

32.3.3.1: EXAMPLES OF CLIMATIC EVENTS ACCOMPANIED BY CHANGES IN $\Delta^{13}C$.

Late Devonian period

Fossil evidence from the late Devonian, when large terrestrial plants evolved and expanded, is characterized by increases in $\delta^{13}C$.

Paleocene/Eocene Thermal Maximum

We saw in Chapter 31.1 that around 55 MYA, sediment records indicate a spike in temperatures of about 5^0 F occurring over about a 100K year timeframe. This was accompanied by a dramatic spike in CO_2 and a dramatic drop in ocean pH as measured by the loss of deep sea $CaCO_3$ (chalk). This very short time frame is called the Paleocene/Eocene thermal maximum (PETM), which shows very quick spikes (on the geological time scale) can and do occur. Sediment records for this time indicate a large negative $\delta^{13}C$ excursion, consistent with a loss of plants with their preferential uptake of $^{12}CO_2$, leading to an accompanying increase in $^{12}CO_2$ in the atmosphere.

1500-1650 CE

We examined $\delta^{18}O$ values during the Little Ice Ages in Chapter 31.2. What about $\delta^{13}C$ values? CO_2 and $\delta^{13}C$ values from 1000 to 1900 are shown in Figure 32.3.12.

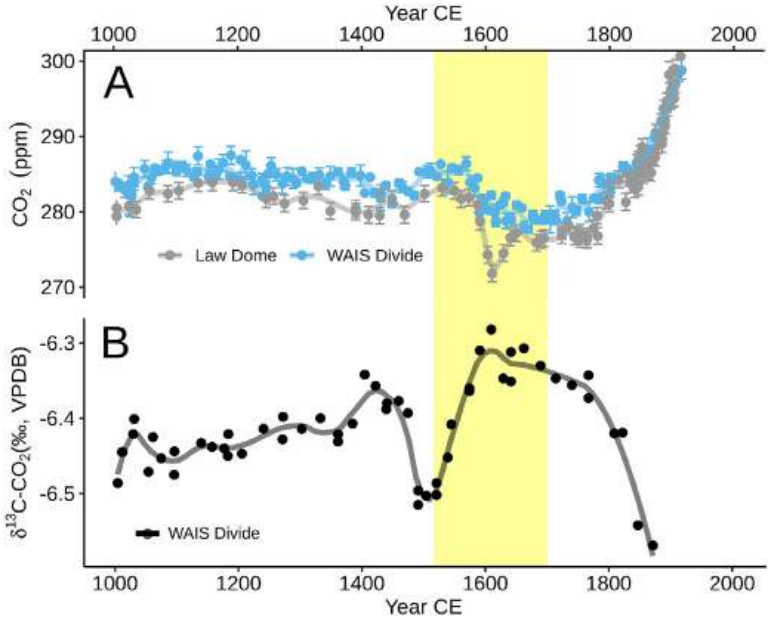

Figure 32.3.12: CO_2 and $\delta^{13}C$ values from 1000 to 1900. Koch et al. Quaternary Science Reviews, 207, 2019, 13-36. https://doi.org/10.1016/j.quascirev.2018.12.004. CC BY license (http://creativecommons.org/licenses/by/4.0/).

Panel (A) shows the CO2 concentrations recorded in two Antarctic ice cores: Law Dome (grey, MacFarling Meure et al., 2006) and West Antarctic Ice Sheet (WAIS) Divide (blue, Ahn et al., 2012).

Panel (B) shows the carbon isotopic ratios recorded in CO2 from the WAIS Divide ice core (black, Bauska et al., 2015) showing an increased terrestrial carbon uptake over the 16th century (B). The yellow box is the span of the major indigenous depopulation event (1520e1700 CE). Loess smoothed lines for visual aid.

Koch et al have strong evidence to suggest that the cooling after 1510 (area in the yellow box in the above figure) was associated with a dip in CO_2 caused by the reforestation of indigenous peoples' land in Meso and South American after epidemics of European disease killed upwards of 90% (around 55 million) of the indigenous peoples. The open and agricultural land reverted back to forests. The diseases included smallpox, measles, influenza, the bubonic plague, and eventually

malaria, diphtheria, typhus and cholera. Domesticated farm animals brought from Europe to the Americans led to most of the disease. Along with the death of so many people was a concomitant return of cleared and agricultural lands (about 56 million hectares or 212,000 mi^2) to forest and plant growth. This may have led to a 7-10 ppm drop in CO_2 in the late 1500s and early 1600s, peaking in 1601 (middle of the yellow box). This decrease in temperature was associated with a small rise (small positive excursion) in the $\delta^{13}C$ values, as $^{12}CO_2$ was preferentially removed from the atmosphere. Global surface air temperatures decreased by around 0.15ºC. This "Great Dying" of Indigenous peoples shows the power of humankind to globally alter climate in calamitous ways, even before the use of fossil fuels. The decrease in $\delta^{13}C$ values before 1500 was unexplained.

1800-the present

$\delta^{13}C$ values can also be used to unequivocally prove that the increase in CO_2 since the industrial revolution is from the burning of fossil fuels, which is of biogenic origin and hence have more negative $\delta^{13}C$ values. Figure 32.3.13 shows atmospheric CO_2 levels in ppm plotted along with $\delta^{13}C$ values. There is a perfect correlation between the rise in atmospheric CO_2 starting with the industrial revolution with the decrease in the $\delta^{13}C$ values over the same time.

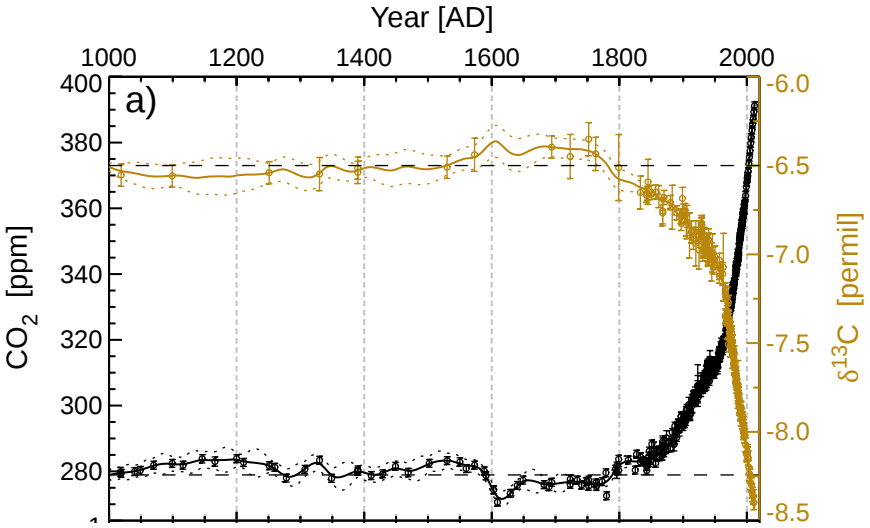

Figure 32.3.13: CO_2 concentration (black circles) and the $\delta^{13}C$ (brown circles) from 1000 to 2010. Rubino et al. Journal of Geophysical Research: Atmospheres. https://doi.org/10.1002/jgrd.50668. With permission (Copyright Clearance Center)

32.3.4: SUMMARY

In the first three sections of Chapter 31 (31.1, 31.2, and this one), we have introduced the basics of climate change, and how climate scientists obtain, analyze and interpret climate data. We emphasized the scientific rigor by which they do that and offered a detailed analysis of the use of isotopes to document past and present changes in climate, Finally, we offered models to predict and mitigate future climate changes. After reading this material, you should be enabled to discuss climate change with others from a sound and valid position. More importantly for this book, you will have a better knowledge base and understanding for the rest of the chapter sections, which will address specific topics in "biochemistry and climate change".

KEY POINTS - BETA VERSION FROM CHAT.OPENAI

1. The carbon cycle is the process by which carbon moves through the Earth's systems, including the atmosphere, oceans, and biosphere.
2. The carbon cycle is driven by the exchange of carbon between different reservoirs, such as the atmosphere, oceans, and living organisms.
3. The main processes involved in the carbon cycle include photosynthesis, respiration, and the formation and weathering of rocks.
4. Human activities, such as burning fossil fuels and deforestation, have significantly increased the amount of carbon dioxide (CO2) in the atmosphere, disrupting the natural balance of the carbon cycle.
5. The increase in atmospheric CO2 is the primary driver of climate change, as it causes the greenhouse effect, trapping heat in the atmosphere and warming the Earth's surface.
6. The ocean also plays a critical role in the carbon cycle, as it acts as a sink for CO2, absorbing about 25% of the CO2 emitted by human activities.
7. The acidification of the ocean caused by the uptake of CO2 is having a significant impact on marine ecosystems, altering the chemistry of seawater and making it more difficult for some organisms to build and maintain their shells and skeletons.
8. Understanding the carbon cycle and carbon chemistry is crucial for understanding the causes and impacts of climate change and for developing strategies to mitigate and adapt to its effects.

32.4: BIOFUELS A - CORN AND SUGAR CANE ETHANOL

32.4.1: INTRODUCTION

The world has a great need for energy. We have invested vast sums of money in finding and using fossil fuels. Fossil fuels seem to be an ideal energy source since they are highly reduced, easily stored, energy-dense, and highly abundant. Yet we now know the immense cost of their use: pollution that shortens lives and climate change. We have dramatically increased our bioethanol production from corn and sugar cane to remove our reliance on fossil fuels for transportation. Ethanol is partially oxidized as it has one oxygen atom in the two-carbon molecule. Hence, the energy released per gram is about 63% (by mass) and 70% (by volume) compared to gasoline. The energy values for various fuels are shown in Table 32.4.1 below, where $\Delta H_c°$ is the standard enthalpy of combustion.

Table 32.4.1: Energy values for a variety of fuelsData source: https://www.engineeringtoolbox.com/s...nt-d_1987.html

Name	Formula	State	-$\Delta H_c°$ *kJ/mol*	-$\Delta H_c°$ *kJ/g or MJ/kg*	-$\Delta H_c°$ *kcal/kg*
Ammonia	NH_3	gas	383	22.48	5369
Butane	C_4H_{10}	gas	2878	49.50	11823
Carbon (graphite)	C	cry	394	32.81	7836
Carbon monoxide	CO	gas	283	10.10	2413
Ethanol	C_2H_6O	liq	1367	29.67	7086
Hydrogen	H_2	gas	286	141.58	33817
Methane	CH_4	gas	891	55.51	13259
Methanol	CH_4O	liq	726	22.65	5410
Naphthalene	$C_{10}H_8$	cry	5157	40.23	9609
Octane	C_8H_{18}	liq	5470	47.87	11434
Propane	C_3H_8	gas	2220	50.33	12021
wood (red oak)				14.8	3540
coal (lignite)				15	3590
coal (anthracite)				27	4060
methyl stearate (biodiesel)	$(CH_3(CH_2)_{16}(CO)CH_3$			40	9560

Nevertheless, ethanol is readily made and is a valuable biofuel. A glance at the table suggests that H_2 would be the best possible fuel, given that it has the highest energy release per gram and contains no carbon. At present, it can't be produced at the scale needed, and it isn't easy to store and transport. The critical infrastructure for its widespread use is lacking. Yet these factors could be solved. We'll explore biohydrogen in a separate chapter section.

In theory production of ethanol from plants at first glance is carbon neutral since each carbon in the ethanol is fixed from atmospheric CO_2 during photosynthesis. Combustion of ethanol then returns the CO_2 to the atmosphere in a net zero emission fashion, as shown in the reaction below.

$$\mathbf{6CO_2}\ (g) + 6H_2O\ (l) \rightarrow C_6H_{12}O_6\ (s) + 6O_2\ \text{(photosynthesis)}$$

$$C_6H_{12}O_6\ (s) \rightarrow 2\ CH_3CH_2OH\ (l) + \mathbf{2CO_2}\ (g)\ \text{(anaerobic ethanol biosynthesis)}$$

$$2CH_3CH_2OH\ (l) + 6O_2 \rightarrow \mathbf{4CO_2}\ (g) + 6H_2O\ (g)\ \text{(combustion of ethanol)}$$

Six CO_2s in, six out! It seems simple but it's not. We'll explain more later. First, let's explore how ethanol is synthesized for its two major uses, drinking and use as a biofuel.

32.4.2: ETHANOL PRODUCTION OVERVIEW

The scale of worldwide ethanol production is quite staggering. Let's first consider the production of ethanol by yeast for alcoholic beverages. About 100 billion US gallons/yr (BGY) of beer, 7 BGY of wine, and 6 BGY of spirits are produced yearly. Assuming beer, wine and spirits are about 5%, 12%, and 40% percent ethanol by volume, respectively, the volume of actual ethanol/year made by yeast in these alcoholic beverages is about 5 BGY (beer), 0.85 BGY (wine) and 2.4 BGY (spirits). This sums to about 8.3 billion gallons of ethanol produced by these microorganisms. Compare this to fuel ethanol production each year, shown in Figure 32.4.1.

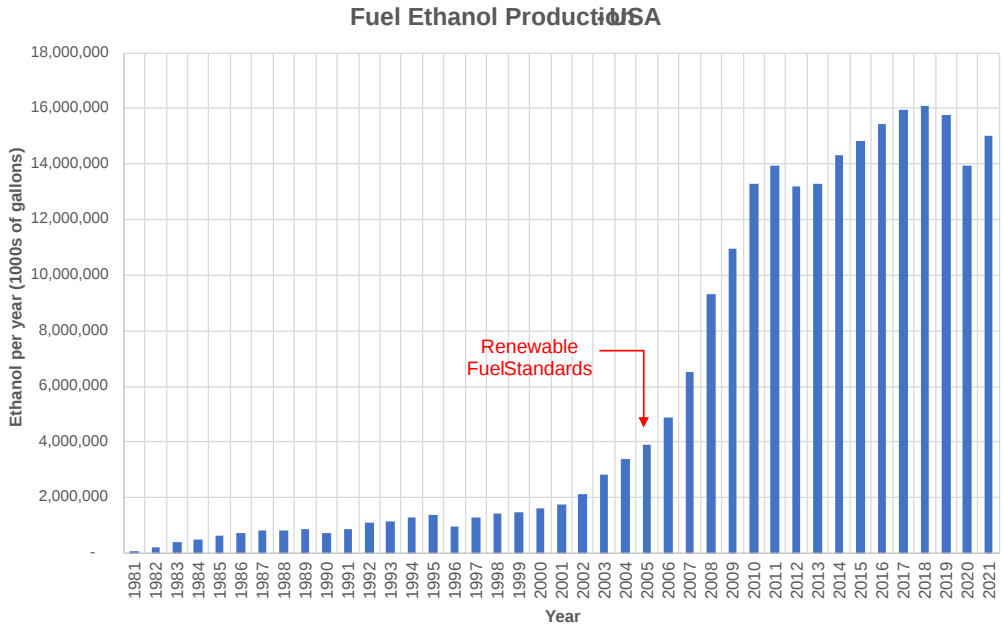

Figure 32.4.1: US Fuel Ethanol Production. Data from **U.S. Bioenergy Statistics**

Note that the y-axis is in units of 1000s gallons of ethanol. Peak US production was in 2018, when 16 billion gallons were produced, about 1/10 of the gasoline used yearly in the US. The year Renewable Fuel Standards (RFS) were introduced in the USA (2005) is also shown. This dip in 2020 is attributed to the COVID pandemic.

Combined, the US and Brazil produce about 85% of fuel ethanol, as shown below in Figure 32.4.2.

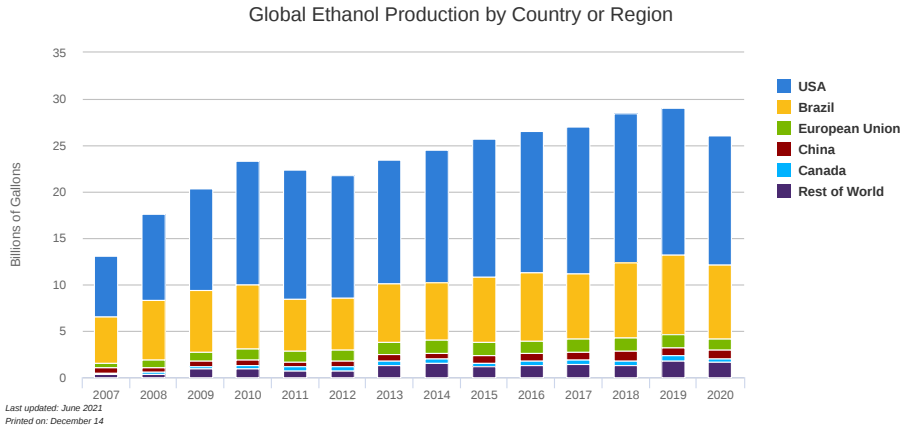

Figure 32.4.2: Fuel ethanol production (billions of gallons or BG) around the world per year. https://afdc.energy.gov/data/10331

Almost all US ethanol is made from corn, while Brazil's primary source is sugar cane.

Since the significant ramp-up of fuel ethanol around 2005, the world now produces 3x the amount of ethanol to drive our outsized vehicles than microorganisms have for our drinking. These statistics show that the world can quickly respond when it meets our needs.

32.4.3: AN OVERVIEW OF ETHANOL BIOSYNTHESIS

Whether ethanol is made for the beverage or biofuel industries, yeast play the major role, as we explored in Chapter 14.2: Fates of Pyruvate under Anaerobic Conditions- Fermentation. Yeast contains all the enzymes necessary to convert glucose (6C), made from various "feedstocks", to pyruvate (3C) through the glycolytic pathway. This is followed by the conversion of pyruvate to ethanol using two key yeast enzymes. First, pyruvate is decarboxylated to acetaldehyde by **pyruvate decarboxylase**, which uses TPP as a cofactor. Acetaldehyde is then reduced to ethanol by **ethanol dehydrogenase**, using NADH as a substrate, in a process that reforms NAD^+, allowing glycolysis to continue. These combined anaerobic reactions, known as fermentation, are shown in Figure 32.4.3.

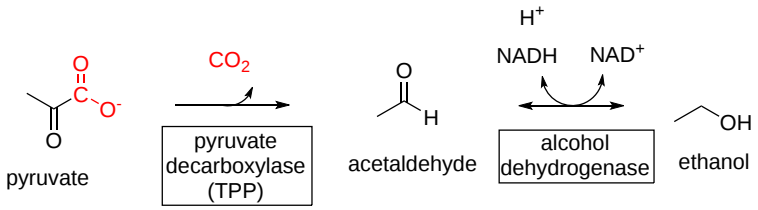

Figure 32.4.3: Summary of Ethanol Fermentation in Yeast

Yeast are facultative (not obligate) anaerobes in that they can produce energy by glycolysis and ethanol fermentation in the absence of oxygen. Of course, in the presence of oxygen, the pyruvate made from glycolysis in yeast is preferentially converted to acetyl-CoA, which enters the citric acid cycle and oxidative phosphorylation pathways to maximize ATP production. Yeast is abundant, so all that is needed is a large source of glucose.

An abundant source of glucose for bioethanol production are plants that contain starch (for example corn) or abundant simple sugars (for example sucrose in sugar cane). Starch, an α (1,4) polymer of glucose with α (1,6) branches, can easily be broken down in an industrial setting with amylases to form glucose. A significant problem with this "first" generation source of glucose is that food crops (corn, and to a lesser degree sugar cane) are used for biofuel consumption instead of for food. "Second" generation sources of glucose are crop and wood waste products that contain cellulose, a β (1,4) polymer of glucose which is found with another carbohydrate polymer lignin. A significant problem with the use of cellulose is the high chemical stability of the β (1,4) glycosidic bond. Fungi and bacteria are sources of β-glycosidases to liberate free glucose from cellulose. "Third" generation sources of glucose use algae, which does not displace cropland for bioethanol production. A "fourth" generation source of glucose are genetically engineered organisms, which might become future sources of bioethanol. Figure 32.4.4 summarizes the different generations of feedstock sources for bioethanol production.

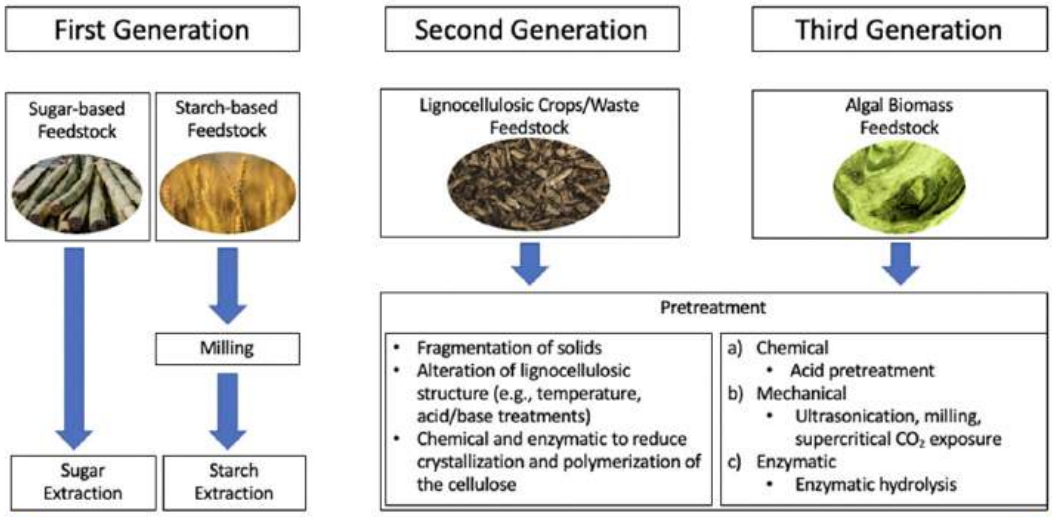

Figure 32.4.4: Generation feedstock sources for bioethanol production. Tse, T.J.; Wiens, D.J.; Reaney, M.J.T. *Fermentation* **2021**, *7*, 268. https://doi.org/10.3390/fermentation7040268. Creative Commons Attribution (CC BY) license (**https://creativecommons.org/licenses/by/4.0/**).

We will discuss the use of first generation sources, corn and sugar cane, which are used to produce most of the world's bioethanol, in this chapter section, and the other two in subsequent sections.

32.4.4: CORN BIOETHANOL

Corn is a significant source of starch, an α (1,4) polymer of glucose with α (1,6) branches. Hence glucosidases are used to hydrolyze starch to glucose. First, the dry corn is ground in a mill, breaking the outer coat of the corn kernel and increasing access to the starch. Heated water is added to form a mash or slurry. Cooking at greater than 85° C helps hydrolyze some glycosidic bonds and lowers the viscosity of the slurry. In the process of liquification, the pH is adjusted to around 6.0. Different **α-amylases** (endoglycosidases) are added, which cleave the α (1,4) glycosidic bonds to produce shorter dextrins (containing branched glucose units not cleaved by alpha-amylases), and α (1,4) linked glucose oligosaccharides of lengths from 2 glucose units (called maltose) up to 7-8. **β-amylase**, an exoamylase, is also used, which successively cleaves maltose units, Glc α (1,4)Glc, from the nonreducing ends of the chains

Alpha-amylases

A mixed-rendered structure of the human pancreatic alpha-amylase is shown below in Figure 32.4.5.

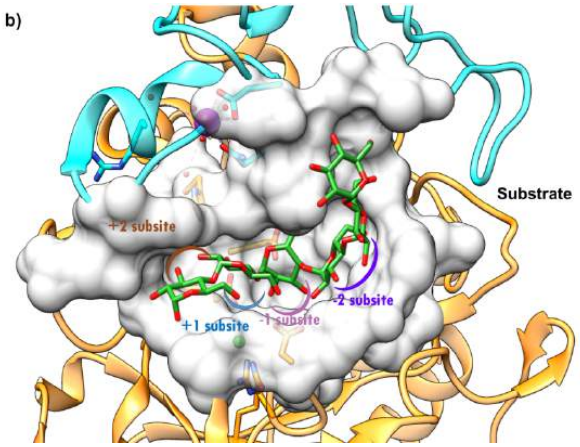

Figure 32.4.5: Surface representation of the active site of HPA (5TD4) *https://pdb101.rcsb.org/global-healt...ha-glucosidase*. CC-BY-4.0 license. Attribution: David S. Goodsell and the RCSB PDB.

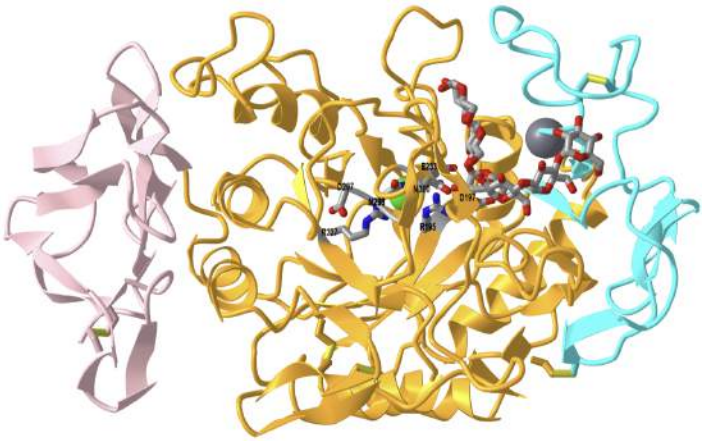
The surface view highlights the deep C-shaped groove into which the substrate, in this case, octaose, is bound. Consistent with substrate numbering for proteases, the starch substrate is numbered ..-2, -1, +1, +2, with cleavage occurring between the -1 and the +1 bound alpha-glucose residues. The protein has three domains (orange, blue, and pink). This particular structure had an active site mutant (Asp300Asn, D300N). The enzyme has bound calcium and chloride ions. Ca^{2+} maintains the necessary structure, while Cl^-, bound in the C domain, is an allosteric activator.

The octaose binding site is between the A and B domains. Asp197, Glu233, and Asp300 are critical catalytic residues, with Asp 197 acting as a nucleophile to produce a glycosylated intermediate, which is hydrolyzed in the next step. Asp197 and Glu233 act as general acids/bases. We will explore in depth similar mechanisms for the action of beta-amylase (below) and cellulase (next chapter section).

Figure 32.4.6 shows an interactive iCn3D model of starch binding sites on the Human pancreatic alpha-amylase D300N variant complexed with an octaose substrate (5TD4)



NCBI iCn3D Figure 32.4.6: Starch binding sites on the Human pancreatic alpha-amylase D300N variant complexed with an octaose substrate (5TD4). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...W29jf4yAc1JEq9

The domains in the enzyme are colored-coded, as in Figure 4. Key active site residues for binding and catalysis are shown as sticks and labeled.

Beta amylase

β-amylase (also called β-1,4-maltosidase) is a key enzyme in the **saccharification** process, in which starch and cellulose are broken down into monosaccharides. β-amylase is abundant in crops (wheat, barley, soybeans, etc.) and other higher plants, as well as bacilli and fungi. It is used in making beer and caramel (malt syrup). As an exo-glycosidase, it cleaves Glc α(1,4) Glc (maltose) units from the nonreducing end of starch. It is called β-amylase since the hydrolysis proceeds with the inversion of configuration at the reducing end of the freed maltose. It can't cleave at α-1,6 branches, so if used alone, this enzyme produces free maltose and large β-limit dextrins. When fruits ripen, the enzyme cleaves starch to produce sweet maltose. It is also used in seed germination.

MALTING

Plants have to sprout, which requires energy and free sugars. Maltose is produced on activation of β-amylase during seed germination and sprouting. Although maltose is less sweet than sucrose and fructose, it is used in hard candies, given its tolerance to the heat needed in candy production. Malting of grains is accomplished by adding water to sprout them, leading to maltose and other sugars forming. This is followed by drying, with the malted grains used as sweeteners in the food industry. Malted grains are used to produce beer, whisky, some baked goods, and drinks. Barley is the most commonly malted grain used in cereals.

Huge amounts of amylases are needed for corn ethanol production, and they must withstand the conditions necessary for the industrial production of ethanol. Much effort has been devoted to finding and characterizing microbial β-amylases. We'll describe one, AmyBa, from *B. aryabhattai*. Figure 32.4.7 shows sequence similarities among various bacterial β-amylases.

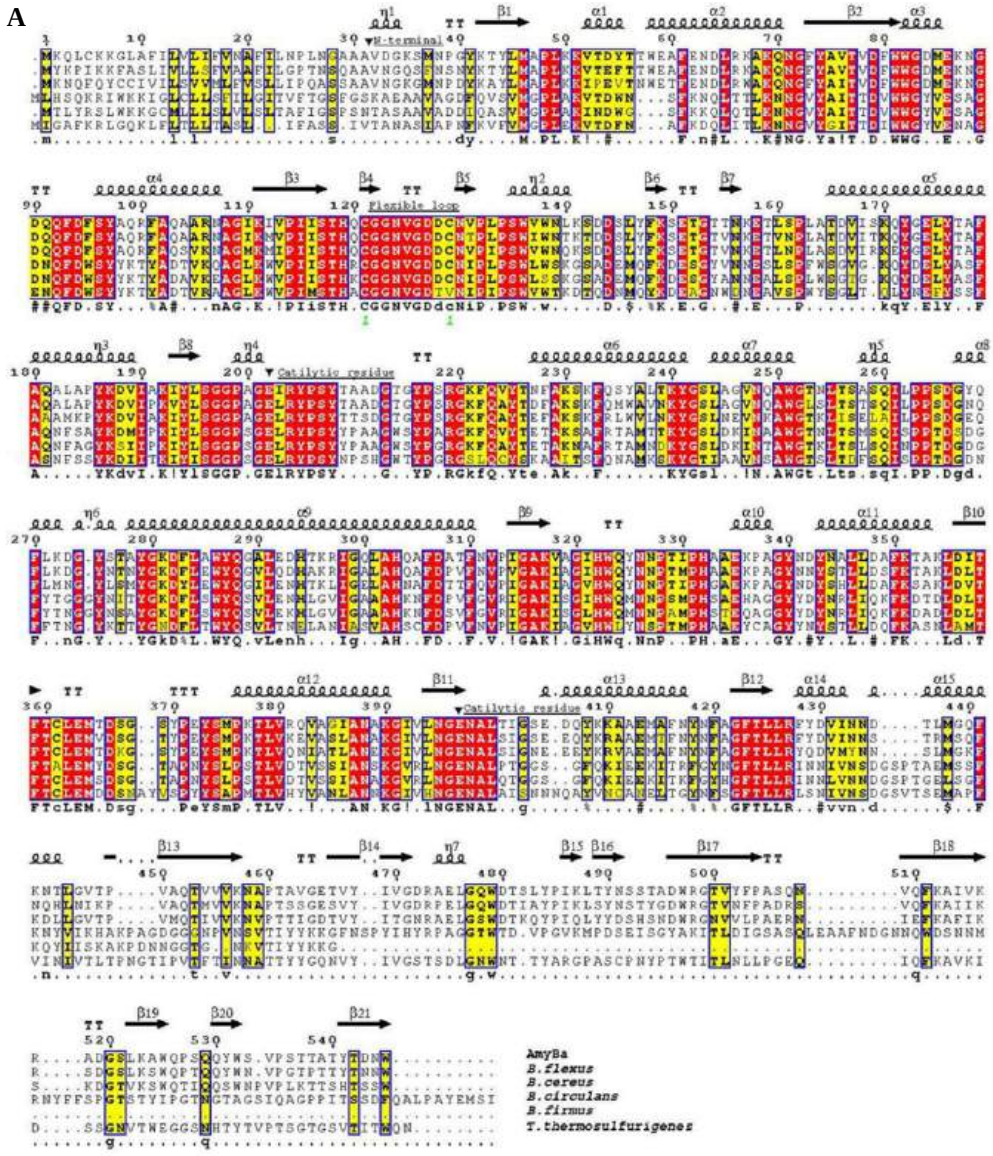


Figure 32.4.7: Sequence and structure analysis of AmyBa. . Duan, X., Zhu, Q., Zhang, X. *et al.* Expression, biochemical and structural characterization of high-specific-activity β-amylase from *Bacillus aryabhattai* GEL-09 for application in starch hydrolysis. *Microb Cell Fact* **20**, 182 (2021). https://doi.org/10.1186/s12934-021-01649-5. Panel A shows multiple sequence alignments of β-amylases. The strictly conserved residues are displayed on a red background, and the highly conserved residues are shown on a yellow background. The secondary structure elements are shown for *B. cereus* β-amylase (PDB ID: 5BCA). The signal-peptide-cleavage site and two catalytic residues (E) are indicated by black triangles (black inverted triangles).

Conservation of the flexible loop motif (HXCGGNVGD) is noted. β-amylase accession numbers are as follows: *B. aryabhattai* (WP_033580731.1), *B. cereus* (P36924.2), *B. flexus* (RIV10038.1), *B. firmus* (P96513.1), *B. circulans* (P06547.1), *T. thermosulfurigenes* (P19584.1).

A comparison of the structures of *B. aryabhattai* β-amylase with soybean β-amylases is shown in Figure 32.4.8.

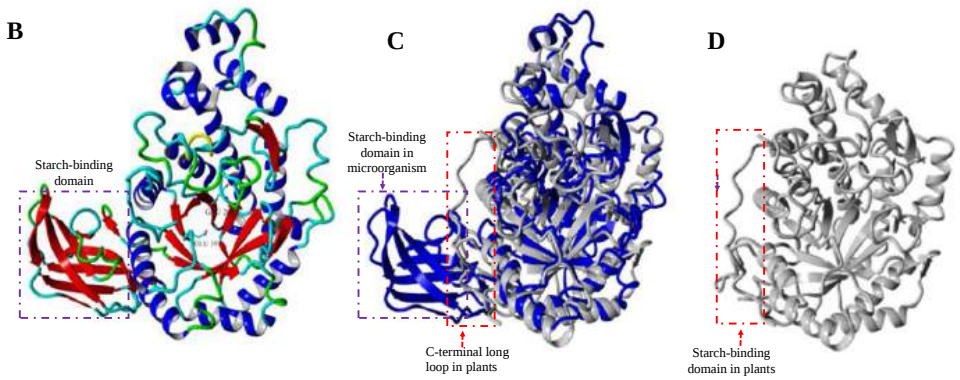

Figure 32.4.8 **B** Three-dimensional molecular model of *B. aryabhattai* β-amylase (AmyBa). **C** Superimposition of AmyBa (Blue) and soybean β-amylases (PDB ID: 1Q6C) (gray) and **D** (PDB ID: 1Q6C) (gray). The C-terminal SBD in microbial β-amylases (box, purple) and the C-terminal loop in plants (box, red). Duan, X, et al., ibid.

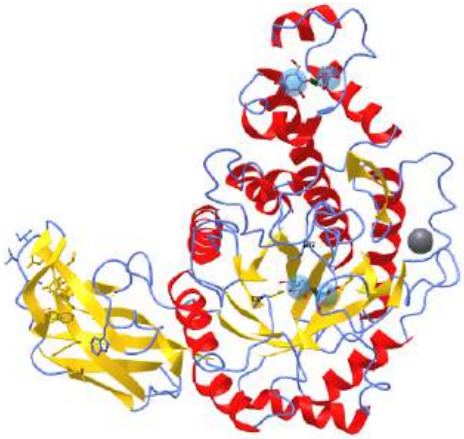
The AmyBa has an additional starch binding domain at the carboxy terminus (Panel B) compared to soybean β-amylases (panel D).

Since no structures of (AmyBa are publically available, we present Figure 32.4.9, which shows an interactive iCn3D model of beta-amylase from Bacillus cereus var. mycoides in complex with maltose (1J0Z)



NCBI iCn3D Figure 32.4.9: Beta-amylase from Bacillus cereus var. mycoides in complex with maltose (1J0Z). (Copyright; author via source).

Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...S2aWbL3z3jPnW8

Similar to alpha-amylase, β-amylase has an N-terminal catalytic domain with a beta-barrel, a connecting second domain, and a third C-terminal domain which is primarily antiparallel β-sheets. Two key catalytic side chains, Glu 172 and Glu 367, are found in the beta-barrel.

In Chapter 20.6, we discussed starch synthesis (not its hydrolysis) in detail. We showed that the reaction, which uses a NDP sugar as a glycan donor, could proceed either with retention or inversion of the anomeric carbon of the donor NDP-sugar. This is illustrated for the reaction of a C1 α-NDP donor monosaccharide with a monosaccharide acceptor to produce the α(1,4) link with retention of configuration or the β(1,4) link with inversion as shown in Figure 32.4.10 below.

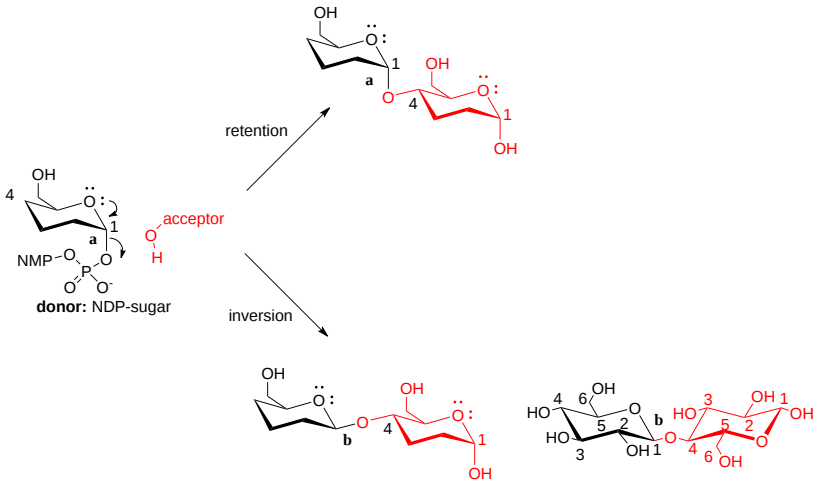


Figure 32.4.10: Reaction of a donor NDP-monosaccharide and an acceptor monosaccharide with retention or inversion of configuration at the anomeric carbon of the donor

The same stereochemical outcomes are possible for the hydrolysis of acetal bonds by glycosyl hydrolases. Alpha-amylases cleave the α (1,4) glycosidic bonds to produce shorter dextrins (containing branched glucose units not cleaved by alpha-amylases), and α (1,4) linked glucose oligosaccharides of lengths from 2 glucose units (maltose) up to 7-8. This reaction hence proceeds with the retention of configuration. In contrast, beta-amylases cleave starch to produce maltose with an inversion of configuration at the anomeric-reducing end of the maltose. We explore the chemistry of retention and inversion more in the next section on cellulase, which cleaves the β (1,4) acetal link in cellulose, but in general, reactions that proceed with inversion react in an S_N2 response, similar to the nucleophilic attack on alkyl halides. For the glycosyl transferases that proceed with inversion, the attacking nucleophile on the acceptor is made more nucleophilic by general base catalysis by a deprotonated glutamic or aspartic acid.

Figure 32.4.11 shows the results of in silicon docking studies of a small glycan, maltotetraose, to AmyBa.

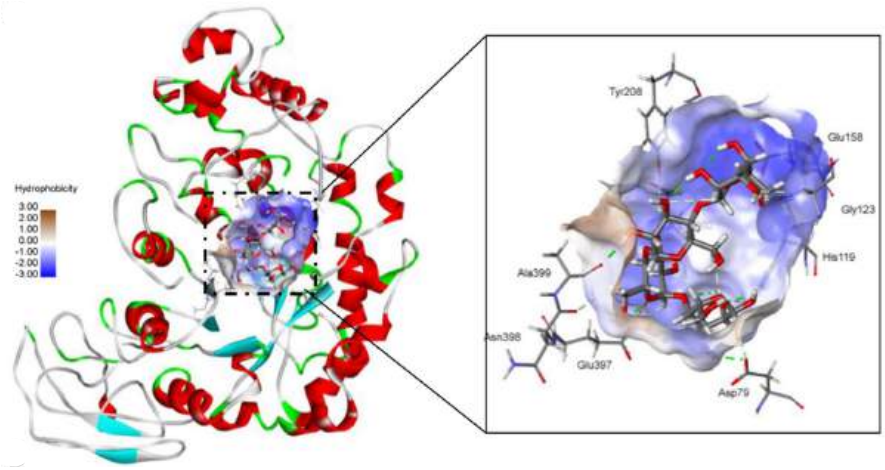

Figure 32.4.11: Molecular docking of AmyBa with maltotetraose. The overall structure and substrate binding pocket analysis of AmyBa are shown.

AmyBa displayed very high amylase activity compared to other microbial β-amylases, and its enzymatic activity was much closer to sweet potato β-amylase. Molecular dynamic and docking programs can be used to calculate binding energies for substrates. The binding energy and enzymatic activities for bacteria and sweet potato β-amylase were highly correlated, suggesting that the extensive interactions of AmyBa and maltotetraose help drive catalysis by using the energy released on binding to lower activation energies for the reaction.

32.4.4.1: SACCHARIFICATION

To enter glycolysis and fermentation, maltose must be converted to the monosaccharide glucose. The conversion of a polysaccharide to its monomers is called saccharification. To complete the conversion of starch to glucose, another enzyme, glucoamylase (also called amyloglucosidase and γ-amylase), is added. It is an exoglucosidase that cleaves both α (1,4) in amylose, amylopectin and maltose and α (1,6) branches, to form free glucose. It is a member of the glycoside hydrolase family 15 in fungi, glycoside hydrolase family 31 of human maltase-glucoamylase, and glycoside hydrolase family 97 of bacterial forms.

32.4.4.2: FERMENTATION

Glucose ($C_6H_{12}O_6$) can now enter the glycolytic pathway and continue to ethanol after conversion of pyruvate to acetaldehyde by pyruvate decarboxylase and final conversion of acetaldehyde to ethanol by alcohol dehydrogenase:

$$C_6H_{12}O_6\,(s) \rightarrow 2\,CH_3CH_2OH\,(l) + 2CO_2\,(g)\ \text{(anaerobic ethanol biosynthesis)}$$

The yeast Saccharomyces cerevisiae catalyzes this entire pathway.

The final fermentation process yields a 12-15% ethanol solution, which is distilled to form a 95% ethanol/5% water azeotrope. The water is removed by adding zeolites (molecular sieves) which can adsorb water but not ethanol.

32.4.4.3: LIFE CYCLE ANALYSIS OF BIOETHANOL: IS IT BETTER THAN FOSSIL FUELS?

We reiterate the promise of bioethanol to address global warming and climate change by presenting again the chemical equations that suggest that its use as a fuel is carbon neutral:

$$6CO_2\,(g) + 6H_2O\,(l) \rightarrow C_6H_{12}O_6\,(s) + 6O_2\ \text{(photosynthesis)}$$

$$C_6H_{12}O_6\,(s) \rightarrow 2\,CH_3CH_2OH\,(l) + 2CO_2\,(g)\ \text{(anaerobic ethanol biosynthesis)}$$

$$2CH_3CH_2OH\,(l) + 6O_2 \rightarrow 4CO_2\,(g) + 6H_2O\,(g)\ \text{(combustion of ethanol)}$$

If only these three equations, this simple model for production and use of corn bioethanol, were the only factors influencing **net** CO_2 emission on bioethanol burning, there would be no controversy about its use. Yet the actual CO_2 emissions depend on many more hidden from view by these simple equations. What is needed is a **life cycle analysis (LCA)** that determines the environmental impact (in this case, net CO_2 emissions) of corn ethanol through every phase of its existence, from cradle to grave, starting with the planting of corn to the combustion of bioethanol for transportation.

All models must be tested. It's easiest to start with the simplest model. If the data fit the model, great, you're done. If not, new, more expansive models must be developed and tested. Those vociferously supporting bioethanol use often use the simple stoichiometry evident in the three equations to state that bioethanol is carbon neutral. Most, however, would want a detailed life cycle analysis (LCA) before jumping to an immediate conclusion.

LCAs are very challenging, and data on a global scale is required. Some measurements at the worldwide scale have significant uncertainties (that don't include CO_2 in the atmosphere, however) and are estimates, at best. A recent study looked at the impact of a specific event, the adoption of the **US Renewable Fuel Standards (RFS)** that regulate biofuels in the US (which produces about half of all the world's biofuels), on CO_2 emission from the significant increase in corn plant and corn ethanol the followed the adoption of the standard. . Using LCA based on a series of economic and environmental metrics, the model shows that bioethanol is not a panacea for CO_2 emissions and may be more detrimental than fossil fuels use for vehicles.

The study calculated the **carbon intensity** changes for corn ethanol that followed after the adoption of the standards. Scientists have used other events that led to immediate changes (9/11) and 1-2 year changes (Covid pandemic) on environmental parameters like CO_2 emissions.

Carbon intensity measures how much energy-related CO_2 is emitted per dollar generated (GDP). Ideally, policies should be implemented that decrease carbon intensity. Green energy derived from both solar and wind is an example. A similar metric is **energy intensity**, the total energy production per GDP, and both are consumption-based values.

Figure 32.4.12 shows carbon intensity per GDP per country over the last 30 years (data from Our World in Data).

Figure 32.4.12: Consumption-based carbon intensity from 1990 to 2018. Our World in Data.

Generally, the world is moving to more efficient energy production, but remember that our energy consumption is still dramatically increasing.

The LCA model showed that the RFS led to these interrelated outcomes. It:

- increased corn prices by 30% and the prices of other crops by 20%
- increased US corn cultivation by 2.8 Mha (8.7%) and total cropland by 2.1 Mha (2.4%) in the years following policy enactment (2008 to 2016). (1 hectare is an area of a square with100 meters sides, equivalent to 10,000 m^2
- increased annual nationwide fertilizer use by 3 to 8%
- increased water quality degradation by 3 to 5%
- increased emissions from domestic land use changes

These all combined to lead to a carbon intensity of corn ethanol that was "no less than gasoline and likely at least 24% higher", according to the study.

The changes in the metric are visually described in Figure 32.4.13.

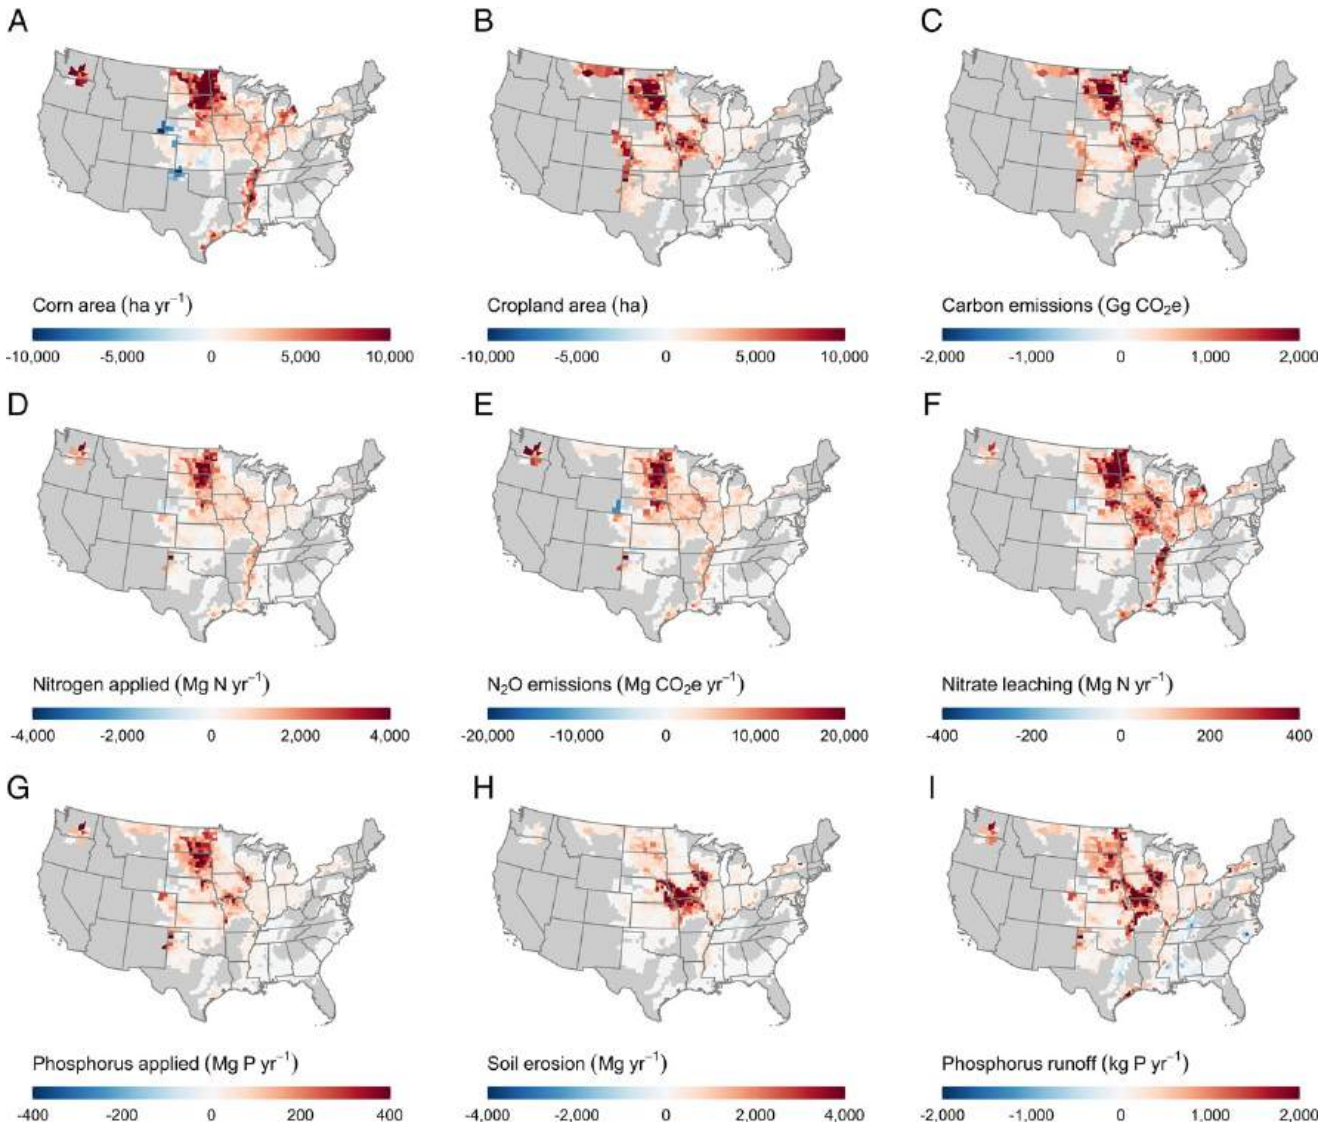

Figure 32.4.13: *Changes due to the RFS. (A) Corn planted area. (B) Cropland area. (C) Carbon emissions. (D) Nitrogen applications. (E) Nitrous oxide emissions. (F) Nitrate leaching. (G) Phosphorus applications. (H) Soil erosion. (I) Phosphorus runoff. Positive numbers indicate an increase due to the RFS. Field-level results were aggregated at the county level for enumeration and visualization.* Tyler J. Lark et al. PNAS. 119, 2022 (https://doi.org/10.1073/pnas.2101084119) Creative Commons Attribution License 4.0 (CC BY).

Land use changes include farming land that was retired or designated for conservation programs. Tilling additional land releases carbon stored in the soil. The increased farming significantly increased fertilizer production, which leads to N_2O emissions. In addition, more of the existing cropland was planted with corn. These finds contrast with a USDA **study** that shows that corn ethanol has a 39% lower corn ethanol intensity than gasoline which was stated to derive from carbon captures from the newly planted crops. However, that study did not account for emissions from land use changes.

LCA can identify aspects of production that lead to the most negative consequences, which for the sake of this chapter is greenhouse gas emissions. For example, the LCA for corn ethanol might improve if the CO_2 released on its production during anaerobic ethanol biosynthesis could be captured. Outcomes would also change if renewable energy sources were used for stages of production that require fossil fuel use.

This rigorous LCA did not address the moral question of using land that could be used to feed people to produce bioethanol for use in our ever-bigger vehicles. In addition, opponents of solar energy installations suggest that solar installs would require so much land that it would remove land for agricultural purposes. What is missing from their argument is the vast amount of land used now for corn ethanol. Farmers planted 90 million acres of corn in 2022 in the US, a land area about 90% the size of the entire state of California. 44% of that corn went to biofuels, and only 12% went to human consumption. In addition, approximately 44% percent was used to feed animals for human consumption, an inefficient and unsustainable use of crop land and resources.

32.4.5: PRODUCTION OF SUCROSE AND BIOETHANOL FROM SUGARCANE

Like corn, sugar cane, a tropical, perennial grass, is used (mainly in Brazil) to produce ethanol. Sugar cane is a C4 plant with a high ability to fix carbon. The fact that it is a perennial and does not need replanting each year makes it a more ideal feedstock than corn for bioethanol production. In 2020, sugar cane was by far the most-produced crop or livestock product in the world (1.87 billion metric tons), followed by corn (1.16 billion metric tons). The production by country for both corn and sugar cane is shown in Figure 32.4.14.

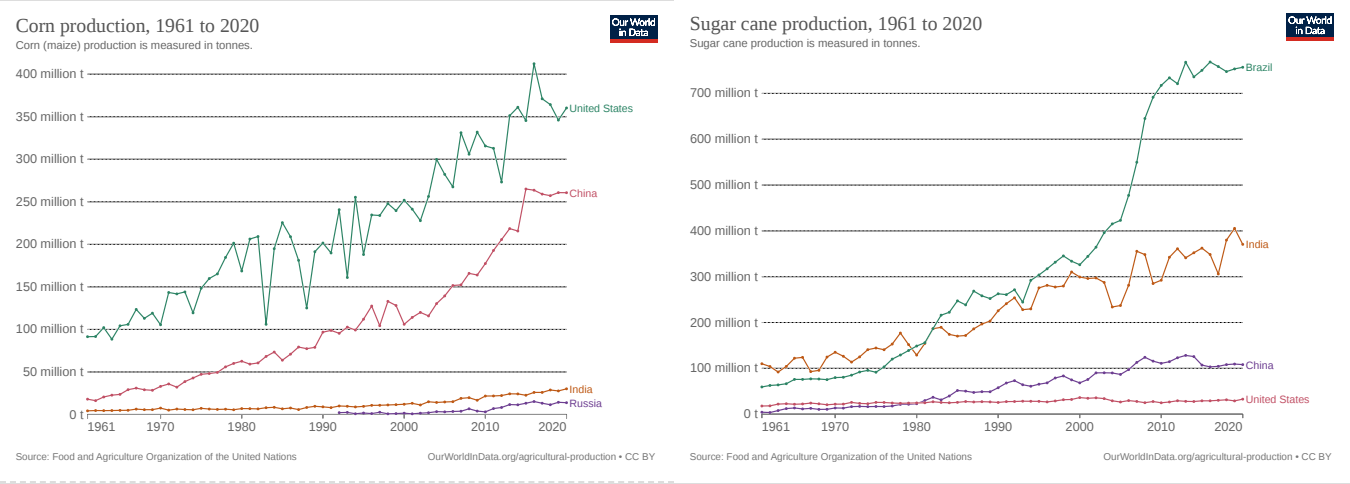

Figure 32.4.14: Corn and sugar cane production by country. Graphs from Our World in Data. https://ourworldindata.org/agricultural-production#

That sugar cane production is so high compared to grain crops that provide nutrition (not just "sweet" calories) might come as a surprise, but it shouldn't, given our addiction to sweet foods.

Sugar cane is often harvested manually in developing countries. It is then cut, milled, and mixed with water to extract the soluble sucrose (table sugar). The sugar cane components during extraction are shown below in Figure 32.4.15.

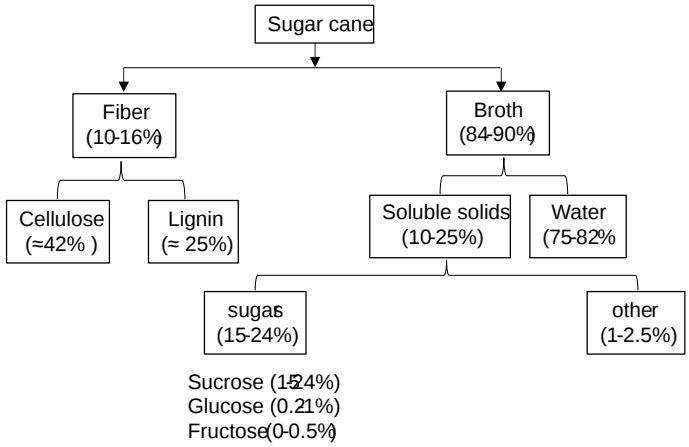

Figure 32.4.15: Components of Sugar Cane (after Larissa Canilha et al. J Biomed Biotechnol. 2012; 2012: 989572. doi: 10.1155/2012/989572

Sucrose is a nonreducing disaccharide (O-α-D-glucopyranosyl-(1,2)-β-D-fructofuranoside). Its structure is shown in Figure 32.4.16.

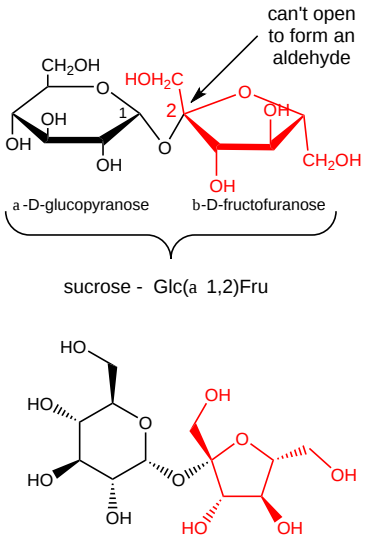

Figure 32.4.16: Structure of fructose

SUCROSE, CARAMEL AND MOLASSES

Sucrose decomposes at 186 °C (367 °F) instead of melting (a feared event for organic chemistry students who wish to record melting temperatures in the lab) to form caramel. Molasses is a very viscous liquid product from refining sugar cane or sugar beets. It is used as a sweetener with its own taste properties, and it's a component of brown sugar as well. On a sweetness scale, if sucrose is assigned a value of 100, fructose is 140, high fructose corn syrup is 120-160, and glucose is 70-80.

For bioethanol production, sucrose is degraded by the enzyme **invertase** to form monomeric glucose and fructose. Invertases are activated on the milling and liquification of the sugar cane, so if sucrose is the desired commercial product, an additional clarification step (heat to 115°C and treat with lime and sulfuric acid) is necessary to prevent hydrolytic cleavage of sucrose.

32.4.6: BIOETHANOL PRODUCTION FROM SUGAR CANE SUCROSE

Bioethanol can be made from either the fibrous lignocellulose remains of the sugar cane, called **bagasse** or from water-soluble sucrose. We will describe the production of cellulosic ethanol from field crop stalks, called stover, and leaves, straw, wood chips, and sawdust (all "waste" biomass), in Chapter 31.5. The same principles apply to bioethanol production from **bagasse**, the solid remains after the juice extraction from sugar cane. (Bagasse is often burned to provide energy for sugar cane processing).

In addition to sugar cane, sugar beets and sweet sorghum, a C4 plant similar to sugar cane, are used to produce bioethanol. As a C4 plant, sweet sorghum is very efficient at producing biomass through photosynthesis. It grows in temperate and tropical climates, has a short growing period, and is resistant to drought and cold. Its stalks have free sugars as well as lignocellulose stocks.

This chapter will focus on bioethanol production from sugar cane sucrose. Again, this is accomplished using yeast (Saccharomyces cerevisiae), which has the enzyme **invertase 2** (**beta-fructofuranosidase 2 or Saccharase**) needed to convert sucrose into sucrose fructose and glucose, which can enter glycolytic and fermentation pathways.

Invertase, shown in 1842 to invert the stereochemistry of sugars, was first isolated from yeast in 1860. It has a secreted glycosylated homooctameric form and an intracellular form, all products of the same gene. It's a member of Family 32 of the glycoside hydrolases. The structure of the Saccharomyces invertase (SInv) octamer structure is shown in Figure 32.4.17 below.

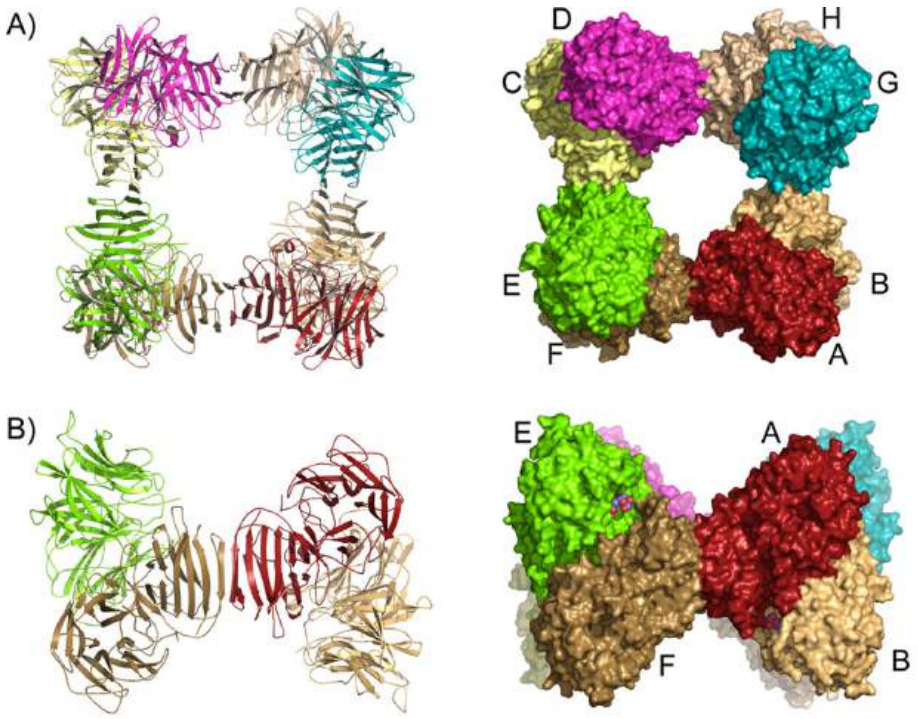

Figure 32.4.17: Structure of octameric SInv. M.Angela Sainz-Polo et al. JBC, 288, 9755-9766 (2013). DOI:https://doi.org/10.1074/jbc.M112.446435. Creative Commons Attribution (CC BY 4.0)

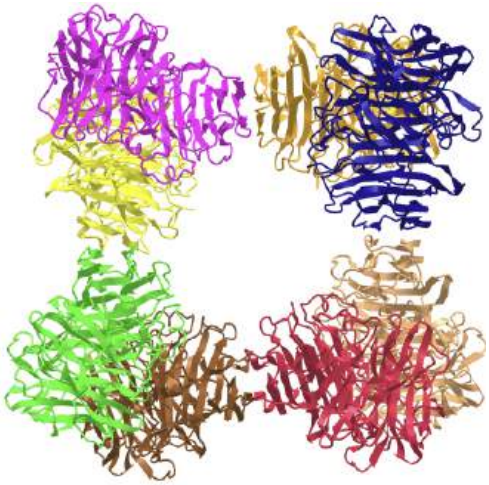
Panel a shows a view of the SInv octamer in ribbon (*left*) and solvent-accessible surface (*right*) representations, showing each subunit in a different color.

Panel *b shows that t*he octamer is rotated 90°, illustrating that it can be best described as a tetramer of two different kinds of dimers, AB/CD and EF/HG, which are compared by superimposing subunit F on subunit B in *c*

Even though all eight subunits in the octamer are identical (58.5K, 512 aa), the quaternary structure of the 8-mer can best be viewed as a tetramer of dimers (i.e. 4 dimers pack to form two packed tetramers giving the octamer). The AB and CD dimers pack in a "closed form" with a narrow active site pocket, allowing a glycan of 3-4 monomers. The EF and GH dimers pack in an "open form" with a wide active site pocket for longer glycans. Of course, our main interest here is in the binding of sucrose.

Figure 32.4.18 shows an interactive iCn3D model of Saccharomyces cerevisiae invertase (4EQV)



NCBI iCn3D Figure 32.4.18: Saccharomyces cerevisiae invertase (4EQV). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...ysQW8YSrvPkus9

The color coding of the subunits is the same as shown in the right top image of Panel A, Figure 16 above.

The GH32 enzymes, including invertase, have a catalytic domain consisting of a 5-bladed β-propeller, with each blade having four antiparallel beta-strands. The blades surround an active site enriched in carboxyl side chains.

The "closed" form active site of the AB and CD dimers has at its base Phe 388 and Phe 296, which provide hydrophobic interactions. The "open" form active site of the EF and GH dimers also has a salt bridge between Asp 45 and Lys 385. These are shown in Figure 32.4.19, along with a bound 1-kestose, which is a trisaccharide"sucrose analog" found in vegetables. It consists of a β-D-fructofuranose connected to β-D-fructofuranosyl and α-D-glucopyranosyl residue at the 1- and 2-positions.

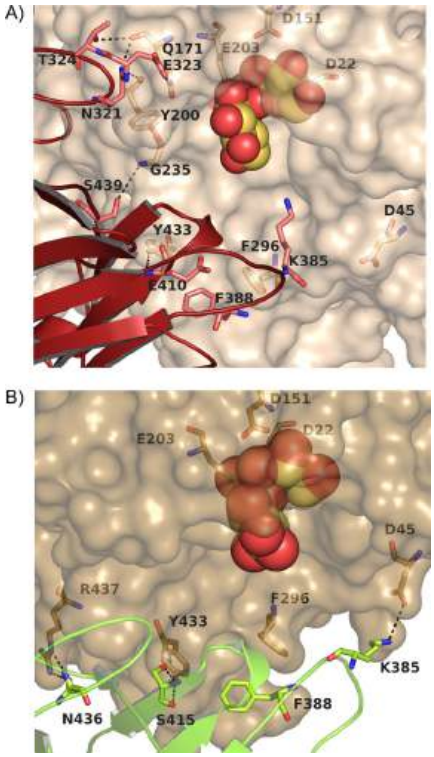


Figure 32.4.19: Dimer interface at the active site. The octameric SInv active site interfaces are detailed, keeping the same color pattern as above with one subunit being shown in ribbon representation for clarity. Angela Sainz-Polo et al. JBC, 288, 9755-9766 (2013). DOI:https://doi.org/10.1074/jbc.M112.446435. Creative Commons Attribution (CC BY 4.0)

Panel A shows that the AB/CD dimers are tightly made by interactions among both their catalytic and β-sandwich domains. Hydrophobic interactions around found at the base of the catalytic pocket through Phe-388 and Phe-296.

Panel *b*, by contrast, shows that the EF/GH dimers interact only through their β-sandwich domains. In addition, the catalytic pocket is also paved by a new salt bridge formed between Asp-45 and Lys-385 from the β-sandwich domain, which lines the cavity. A putative 1-kestose molecule is shown in a spherical representation.

The hydrolysis of sucrose by invertase proceeds with the retention of configuration at the anomeric carbon. An active site Aspartate 22 acts as a nucleophile to form a glycosylated intermediate (fructose-Asp). This is followed by hydrolysis of the intermediate. An active site Glutamate 203 acts as a general acid/base. The fructose could also be transferred to another glycan in a transglycosylation reaction. The hydrophobic side chains Phe-388 and Phe-296 line the base of the active site pocket.

Figure 32.4.20 shows an interactive iCn3D model of the **AB dimer** of Saccharomyces cerevisiae invertase with key active site residues (4EQV)

32.4.7: LIFE CYCLE ANALYSIS OF SUGAR CANE ETHANOL

Does the production of bioethanol from sugar cane lead to lower net CO_2 emissions than bioethanol produced from corn? The answer would depend on if sucrose (first generation) or lignocellulose (second generation) from bagasse is the feedstock.

A recent LCA has been performed on the first-generation (feedstock is sucrose) production of bioethanol from sugar cane in Ecuador. There is a lower cost of production from this sugar-based feedstock, which requires just grinding and the addition of yeast for fermentation. It does not require a saccharification step.

Figure 32.4.22 shows the various stages and processes used to perform LCA on the bioethanol production from sugar cane sucrose. It's presented to show the complexity of such analyses, so look at the detail only if you are especially interested.

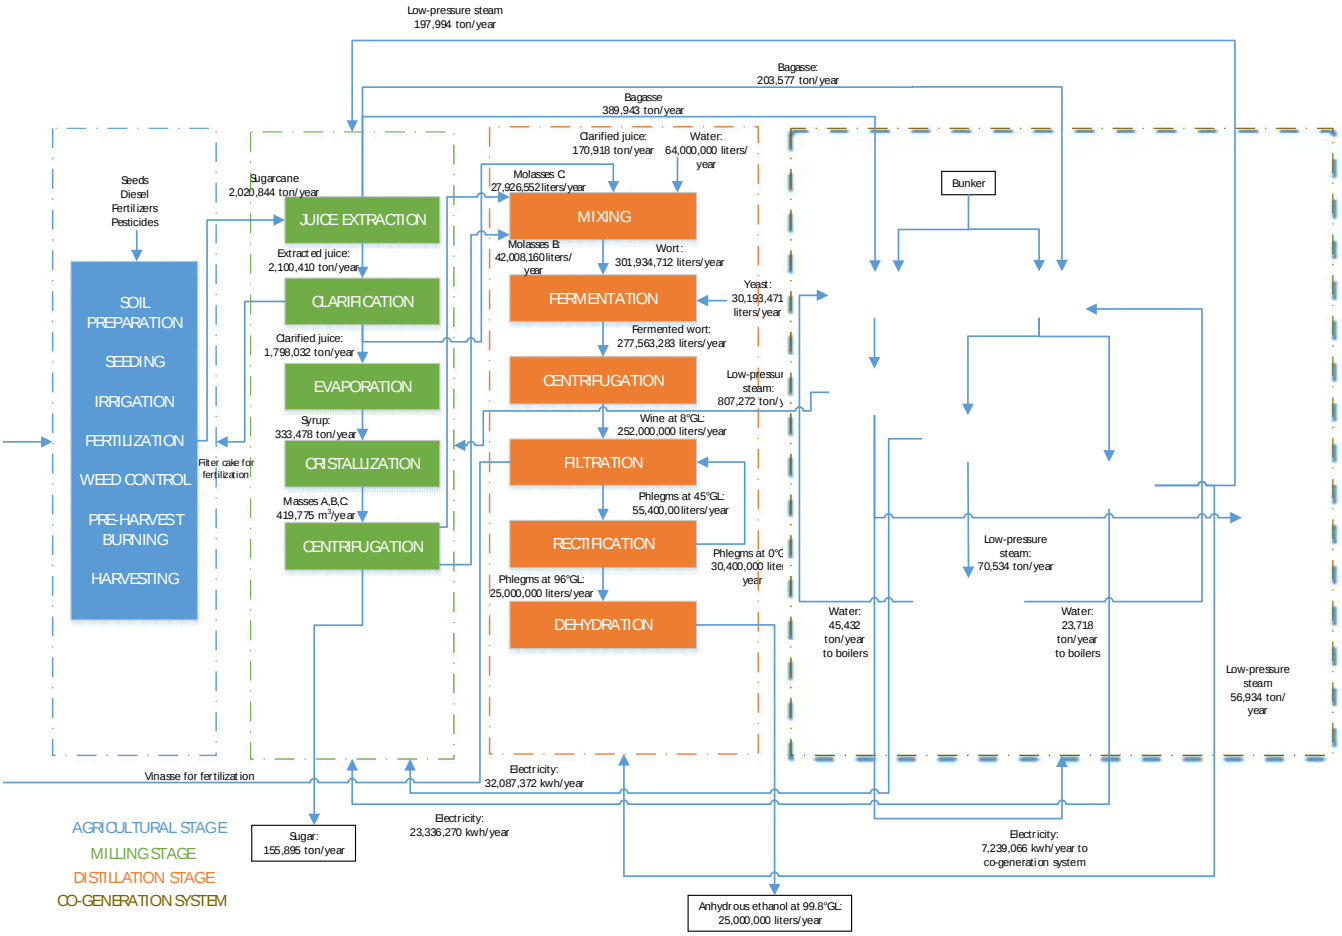

Figure 32.4.22: Anhydrous ethanol life cycle system boundaries and main product flows quantification for year 2018. Arcentales-Bastidas, D.; Silva, C.; Ramirez, A.D. The Environmental Profile of Ethanol Derived from Sugarcane in Ecuador: A Life Cycle Assessment Including the Effect of Cogeneration of Electricity in a Sugar Industrial Complex. *Energies* **2022**, *15*, 5421. https://doi.org/10.3390/en15155421. Creative Commons Attribution (CC BY) license (**https://creativecommons.org/licenses/by/4.0/**)

The study analyzed four stages for analysis, agricultural, milling, distillation and electricity generation (presumably by burning the byproduct bagasse) for impacts. They defined two functional units:

- 1 ton of sugarcane "at the farm gate" for the agricultural stage;
- 1 L of ethanol "at the plant (factory) gate".

The key results are as follows:

- The global warming potential (GWP) impact at the farm gate level was 53.6 kg of carbon dioxide equivalent (kg CO_2 equiv) per ton of sugarcane produced; This arose mostly from N_2O (34%), a potent greenhouse gas released in the process, and diesel fuel used in agricultural machinery (24%).
- The GWP for 1 L of ethanol produced at the plant gate was 0.60 kg CO_2 equiv, with the distillation phase contributing the most.

Before proceeding further, let's explain the key term, **global warming potential (GWP)**, which is widely used in LCA. It adds the contribution of other greenhouse gases like methane (CH_4) and nitrous oxide (N_2O), each of which has unique IR absorption spectra and atmospheric half-lives. The IPCC uses a 100-year time frame for the calculation of the GWP, and uses this formula:

CO_2 Equivalent kg = CO_2 kg + (CH_4 kg x 28) + (N_2O kg x 265)

$$\text{CO}_2 \text{ equivalent kg} = \text{CO}_2 \text{ kg} + (\text{CH}_4 \text{ kg} \times 28) + (\text{N}_2\text{O } kg \times 265) \tag{32.4.1}$$

- CO_2 has GWP of 1 by definition since it is the reference. Its time frame in the atmosphere (100s to 1000 years) doesn't matter since it is the reference.
- CH_4 has a GWP of around 27-30 over 100 years. It reflects its higher IR absorbance but lower lifetime (around 12 years).
- N_2O has a GWP of around 265-273 over a 100-year timescale. N_2O has a lifetime of around 109 years.

The equation can be amended by adding other greenhouse gases released in manufacturing and the use of refrigerants. These include Freon-12 (Dichlorodifluoromethane) (CFC-12, with a lifetime of 100 years and a GWP100 of 10,200, and SF_6 (used in the electricity industry to keep networks running safely and reliably) with a lifetime of 3200 years and GWP00 of 23,500!

NITROUS OXIDE - A POTENT GREENHOUSE GAS BUT NOT A LAUGHING MATTER

N_2O (laughing gas) is an overlooked source of greenhouse gases, but it leads to about 7% of the warming effect of the greenhouse gases with long life-times and a high GWP100. Agricultural practices lead to about 65% of its total emission. It is a component of the soil and atmosphere nitrogen cycle. In soil, its concentration depends on soil microbes that engage in nitrification and denitrification processes. These in turn depend on the amount of fixed nitrogen, oxygen levels and metabolically available carbon sources. The nitrification reaction, which occurs in aerated and moist soils, involves the oxidation of $NH_3 \leftrightarrow NH_4^+$ to NO_2 and NO_3^-, with some N_2O release. The major source of N_2O occurs under anaerobic conditions. These general reactions are shown below.

- Nitrification (aerobic, oxidation): $N_2 \rightarrow (NH_3 \leftrightarrow NH_4^+) \rightarrow NO_2 \rightarrow NO_3^-$
- Denitrification (anaerobic, reduction): $NO_3^- \rightarrow NO_2^- \rightarrow NO \rightarrow N_2O \rightarrow N_2$

In anaerobic sites, NO is an electron receptor during microbial respiration. N_2O is produced when there is excess nitrogen available (past the needs of plants and microorganisms), so excess use of fertilizers and manure increases its production. Nitrifying and denitrifying bacteria are most active in producing N_2O in environments with abundant N relative to assimilatory demands by other microorganisms or plants (Firestone and Davidson, 1989), as is often the case following soil amendment of fertilizers, manure, or crop residues. Physical processing of the soil (such as tillage) also affects N_2O emissions by introducing crop residues in the soil, changing soil particle size and surface area, and by changing the porosity of the soil. All of these affect soil substrate/product availability and their aqueous and gas diffusion rates.

Let's use dimensional analysis from introductory chemistry to convert the GWP from the farm gate/agricultural stage (53.6 kg CO_2 equiv/ton of sugar cane) to kg CO_2 equiv/1L of ethanol (EtOH) so we can add it the GWP from the pant gate, which is expressed in kg CO_2 equiv/L ethanol produced. The dimensional conversion is shown in Table 32.4.2 below.

53.6 kg CO_2 equiv	1 ton SC	1 L Juice	=	0.1 kg CO_2 equiv
1 ton SC	800 L juice	0.7 L EtOH		1 L EtOH produced

Table 32.4.2: Conversion of 53.6 Kg CO_2 equiv/ton of sugar cane from the farm gate (left hand column) to 0.1 Kg CO_2 equiv/1L of ethanol (EtOH).

Now add this to the reported 0.60 kg CO_2 equiv/1 L of ethanol from the plant (factor) gate and you get a total of **0.7 kg CO_2 equiv /1 L ethanol produced**.

Now use dimensional analysis from introductory chemistry to calculate how much CO_2 is actually produced on the combustion of ethanol. That value is calculated in Table 32.4.3 below.

1 L EtOH	1000 mL EtOH	0.789 g EtOH	1 mol EtOH	4 mol CO_2	44 g CO_2	1 kg CO_2	=	1.5 kg CO_2
	1L EtOH	1 mL EtOH	46 g EtOH	2 mol EtOH	1 mol CO_2	1000 g CO_2		1 L EtOH

Table 32.4.3: Total Kg CO_2 produced on combustion of 1 L of ethanol (EtOH)

The promise of bioethanol is that for every 1 C atom used to create it, 1 C atom would be released. We saw that the LCA analysis for corn ethanol in the US did **not** meet that expectation. In the Ecuadorian analysis, it appears that it **did**, since **0.7 kg CO_2 equivalents is required to produce 1 L of bioethanol** from sugar cane, but **1.5 Kg CO_2 is released on its burning**.

The LCA analysis described above reflects just the global warming potential for the use of sugar cane sucrose for bioethanol production. However, bioethanol production from sugar cane juice has other negative impacts as listed in Table 32.4.4 below.

Table 32.4.4: Impact categories included in the LCA

Impact Category	Characterization Factor	Reference Unit
Climate change	Climate change—GWP100	kg CO2eq.
Freshwater eutrophication	Freshwater eutrophication potential—FEP	kg Peq.
Marine eutrophication	Marine eutrophication potential—MEP	kg Neq.
Abiotic depletion	Metal depletion—MDP	kg Feeq.
Photo oxidant formation	Photochemical oxidant formation potential—POFP	kg NMVOCeq.
Particulate matter emissions	Particulate matter formation potential—PMFP	kg PM10eq.
Terrestrial acidification	Terrestrial acidification potential—TAP100	kg SO2eq.

KEY POINTS - BETA VERSION FROM CHAT.OPENAI

1. Biofuels are renewable energy sources derived from biomass, such as plant materials and waste.
2. Corn and sugar cane ethanol are two examples of biofuels that are produced by fermenting the sugars found in these crops.
3. Corn ethanol is typically produced by converting the starch in corn kernels into glucose, which is then fermented to produce ethanol.
4. Sugar cane ethanol is produced by crushing the cane to extract the juice, which is then fermented to produce ethanol.
5. Both corn and sugar cane ethanol are primarily used as a gasoline additive to increase octane and reduce emissions.
6. Corn ethanol is a controversial biofuel because of the high amount of energy used to produce it and the impact on food prices and the environment.
7. Sugar cane ethanol is considered to be a more sustainable biofuel because it is less energy-intensive to produce and can be produced on land not suitable for food crops.
8. However, large scale production of sugar cane ethanol has also been criticized for leading to deforestation, loss of biodiversity and displacement of local communities.
9. Cellulosic ethanol, made from non-food feedstocks like switchgrass or wood chips, is considered to be a more sustainable biofuel alternative to corn and sugar cane ethanol.

32.5: BIOFUELS B - CELLULOSIC ETHANOL

32.5.1: INTRODUCTION

In the last section, we explored how ethanol can be made from corn starch, an α(1,4) polymer of glucose with α(1,6) branches. Its production comes at a cost, however. Recent life cycle studies have shown that compared to fossil fuels, corn ethanol release as much but probably more CO_2 than from fossil fuels. In addition, is it ethically justifiable to remove so much land from food production to produce bioethanol that, at present, is worse than fossil fuels from a climatic perspective?

To address these issues, much work has been done to produce ethanol from cellulose, a β(1,4) polymer of glucose and the most abundant biomolecule in the world. Cellulose from trees, switch grasses, and "waste biomass" are prime sources of cellulose for the production of bioethanol. Waste biomass includes stover (field crop stalks and leaves), straw, wood chips and sawdust. From one ton of corn stover, about 113 gallons of ethanol can be made, close to the 124 gallons produced from corn.

Nature breaks down cellulose routinely using cellulases, enzymes found in bacteria, fungi, protozoans, plants and some animals. Ruminants and even termites obtain cellulases from microbes living within their guts. The fungal-mediated decay of dead trees requires microbial cellulases but think how slow that process is. This stems partly from the very strong β(1,4) glycosidic link connecting glucose monomers in the polymer, which in the absence of a catalyst and at neutral pH, has an estimated half-life of 5 million years. Fossilized plants have been found to have intact cellulose and chitin, a β(1,4) polymer of N-acetylglucosamine. The β(1,4) glycosidic link in cellulose is orders of magnitude more stable than the phosphodiester bond of nucleic acids and the amide link of proteins. They are, however, readily cleaved by glycosidases such as cellulases, which can increase the k_{cat}/K_M over the uncatalyzed rate by up to 10^{17} fold, even in the absence of active site metal ions to facilitate hydrolysis (reference).

Another reason for the slow decay of dead trees is the complex structure of the cell well, and in particular, the presence of a polymer called lignin, which stabilizes the cell wall and adds considerable barriers to the access of cellulose by added glycosidases. .

A final reason for cellulose's extreme stability is the "quaternary" structure of the β(1,4)-linked cellulose strands, which consists of densely packed and intertwined strands of cellulose, which limits solvent (in this case water) accessibility necessary for hydrolysis. In addition, some exposed surface planes of the packed cellulose strands are hydrophobic. This might seem startling, given the polar nature of the glucose subunits of the polymer. Let's review it here now since our goal is present climate change from a biochemical perspective! Some of this material has been presented in previous chapters, but we will reuse it here so this chapter section can stand alone.

32.5.2: A REVIEW: THE PLANT CELL WALL

(See Chapter 7.3 for more details.) There are about 35 different types of plant cells, and each may have a different cell wall depending on the local needs of a given cell. Cells synthesize thin cell wall that extends and stay thin as the cell grows. Figure 32.5.1 shows the primary cell wall of plants. The primary cell wall contains cellulose microfibrils (no surprise) and two other polymers, pectin and hemicellulose. The middle lamella consisting of pectins, is somewhat analogous to the extracellular matrix.

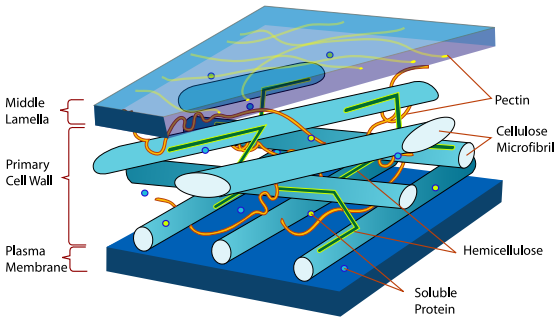

Figure 32.5.1: Primary cell wall of plants. https://commons.wikimedia.org/wiki/F...diagram-en.svg

After cell growth, the cell often synthesizes a secondary cell wall thicker than the first for extra rigidity. Since the enzymatic machinery for its synthesis is in the cytoplasm and the cell membrane, it is deposited between the cell membrane and the primary cell wall, as shown in the animated image in Figure 32.5.2.

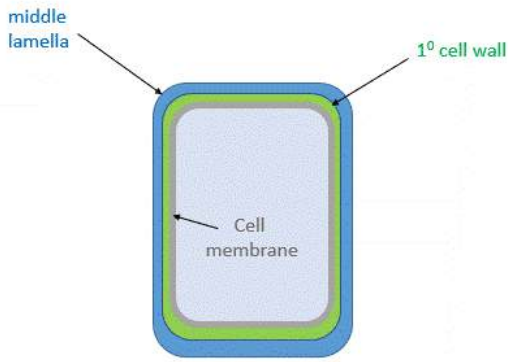

Figure 32.5.2: Primary and secondary cell wall of plants

Figure 32.5.3 shows a structural representation of both the primary and secondary cell wall.

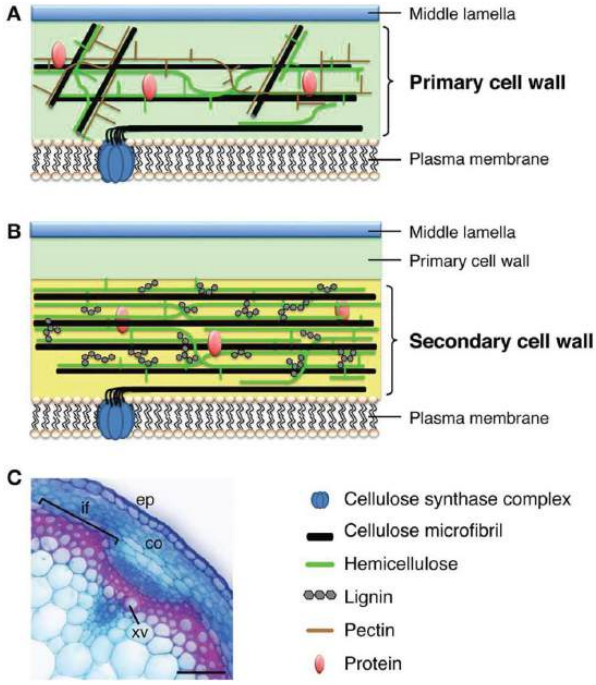

Figure 32.5.3: structural representation of both the primary and secondary cell wall of plants. Nakano Yoshimi et al. Frontiers in Plant Science (6), 288 (2015) https://www.frontiersin.org/article/...015.00288/full. Creative Commons AttributionLicense (CC BY).

The middle lamella, which contains pectins, **lignins** and some proteins, helps "glue together" the primary cell walls of surrounding plants.

Primary Cell Wall:

The main component of the primary plant wall is the homopolymer cellulose (40% -60% mass) in which the glucose monomers are linked β(1→4)-linked into strands that collect into microfibrils through hydrogen bond interactions. Two other groups of polymers, **hemicellulose,** and **pectin,** make up the plant cell wall.

Hemicellulose can make up to 20-40% by the mass These polymers have β(1,4) backbones of glucose, mannose, or xylose (called xyloglucans, xylans, mannans, galactomannans, glucomannans, and galactoglucomanannans along with some β(1,3 and 1,4)-glucans. The most abundant hemicellulose in higher plants higher plants are the xyloglucans and have a cellulose backbone linked at O6 to α-D-xylose. **Pectin** consists of linked galacturonic acids forming homogalacturonans, rhamnogalacturonans, and rhamnogalacturonans II (RGII) [12] [13]. Homogalacturonans (α1→4) linked D-GalA make up more than 50% of the pectin. Figure 32.5.4 shows some of the structures. The are generally branched, shorter than cellulose chains, and can often crystallize.

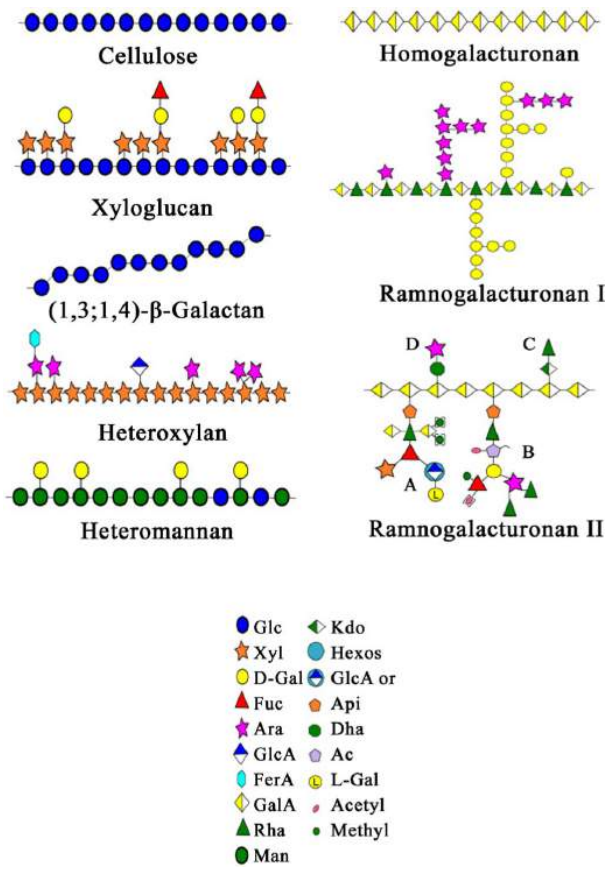

Figure 32.5.4: Variant of the cell wall components of a plant. Costa and Plazanet. Advances in Biological Chemistry 06(03):70-105. DOI: 10.4236/abc.2016.63008. License CC BY 4.0

Secondary Cell Wall

The structure of the secondary cell wall depends on the function and environment of the cell. It contains cellulose fibers, hemicellulose, and a new polymer, **lignin**. It is abundant in xylem vessels and fiber cells of woody plants. It gives the plant extra stability and new functions, including the transport of fluids within the plant through channels. The proportion of cellulose in the secondary cell wall is higher than in the primary cell wall and is less hydrated than in the primary cell wall. Given the relative volume of the secondary and primary cell walls inferred from Fig 2, most of the tree-derived cellulose for bioethanol production comes from the secondary cell wall. Switch grasses, a perennial plant, are also valuable sources of cellulose (**32–45% wt**) and hemicellulose (21–31% wt) but also have significant amounts of lignin (12–28% wt). In summary, the secondary cell wall, formed after the cell stop growing, accounts for most of the carbohydrate biomass of plants.

Glycosidases, mostly α- and β-amylases, are needed to convert corn-derived starch into glucose for fermentation and ethanol production. Likewise, cellulases are needed to degrade cellulose into glucose for cellulosic-ethanol production. However, it is a much more complex process since most of the cellulose is in the secondary cell wall. The lignin barrier in the walls protects cellulose from accessibility to cellulases, even after chemical and thermal pre-processing. In addition, xylans, which can make up 30% of the mass of the secondary cell wall, also inhibit cellulose degradation.

A thermochemical process can convert cellulose to the synthetic gases CO and H_2, which can be used as reactants to form ethanol. We'll discuss the biochemical process using pretreatment and enzymatic hydrolysis to make cellulosic ethanol. Lignin can be recovered and used to provide energy for the industrial-scale synthesis of cellulosic ethanol.

Let's explore the barriers posed by lignin and how they can be surmounted to facilitate access to cellulose and the liberation of glucose for cellulosic ethanol production.

32.5.3: LIGNIN STRUCTURE AND REACTIVITY

Lignins, which can make up to 25% of the biomass weight of secondary walls, are made from phenylalanine derivatives but more directly from cinnamic acid. This derives from is made from phenylalanine which is hydroxylated and converted through other steps to hydroxycinnamic alcohols called monolignols, as shown in Figure 32.5.5. Three typical monomers, p-coumaryl, coniferyl, and sinapyl alcohols, can polymerize into lignins, with their units in the polymer (P) named hydroxyphenyl, guaiacyl and syringly, respectively.

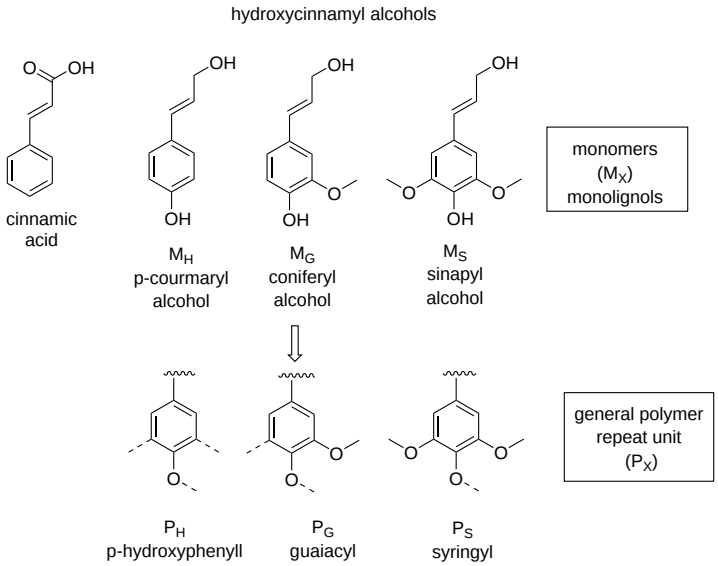

Figure 32.5.5: Monolignols and their polymers

Lignols are activated phenolic compounds, which form phenoxide free radicals (catalyzed by enzymes called peroxidases), which can attack a second lignol to form covalent dimers. Reaction mechanisms for the dimerization of the M_S sinapyl alcohol free radical are shown as an example in Figure 32.5.6.

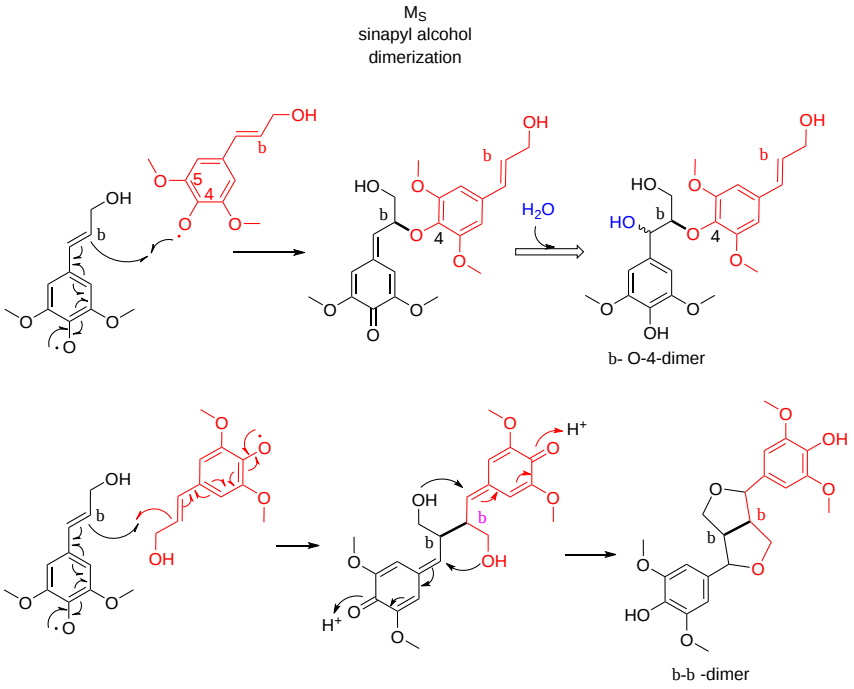

Figure 32.5.6: Dimers of lignols

Now imagine this polymerization continuing through the formation of more phenolic free radicals and coupling at a myriad of sites to form a large covalent lignin polymer. Figure 32.5.7 shows one example of a larger lignin.

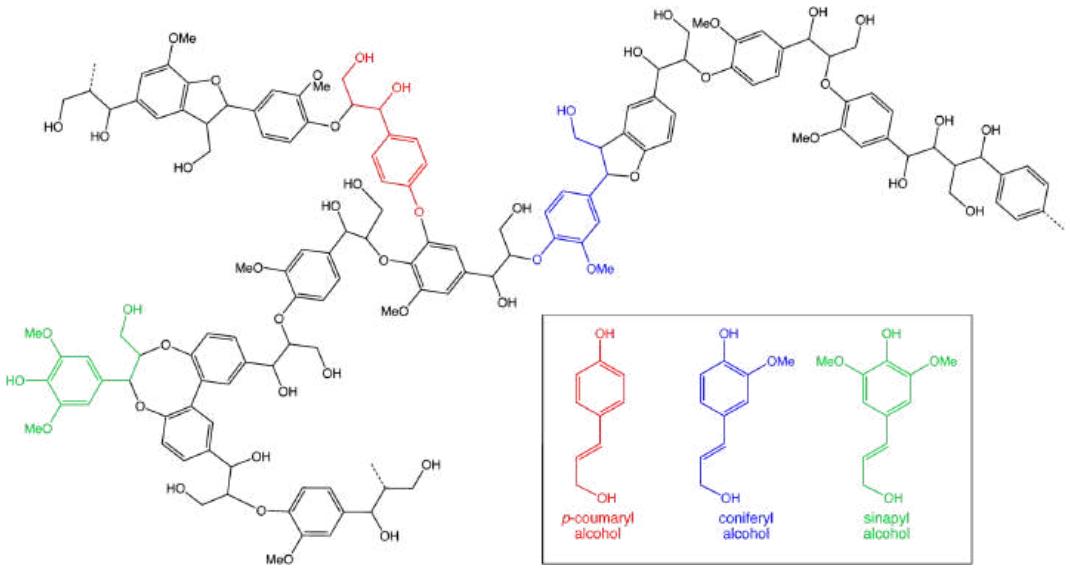

Figure 32.5.7: A larger lignin. https://commons.wikimedia.org/wiki/C...ile:Lignin.png . By Smokefoot - Own work, CC BY-SA 3.0, https://commons.wikimedia.org/w/index.php?curid=16022799

Lignin strengthens the cell wall and further stabilizes the already unreactive cellulose fibers. Let's look at a specific example - using corn stover (CS) as a cellulose source - of how pretreatment of the biomass source with a chemical treatment followed by the addition of a bacterial strain *Pandoraea* sp. B-6 (B-6) isolated from long, narrow strips of bamboo (slips). Bamboo is a type of woody grass that grows rapidly. These bacteria produce two extracellular lignin-degrading enzymes, manganese peroxidase (MnP) and laccase (Lac). Laccase (Lac) is a multi-copper oxidase that uses O_2 as an oxidizing agent in the degradation of the syringyl, guaiacyl and *p*-hydroxyphenyl monomers in lignins. MnP has similar properties. These and other enzymes can lead to the depolymerization of lignin and degradation of lignin-derived aromatic compounds

The adddition of the B-6 bacteria (a source of MnP and Lac) to milled corn stover (CS) did not increase the rate of lignin degradation unless the corn stover was preincubated with a tetrahydrofuran–water (THF–H_2O) with 0.5 wt% sulfuric acid and heated to 150 ºC. This led to the erosion of the corn stover, allowing access to the bacterial enzyme. The untreated and pre-treated CS surface, along with a diagram showing access of Lac and MnP to the lignin, is shown in Figure 32.5.8.

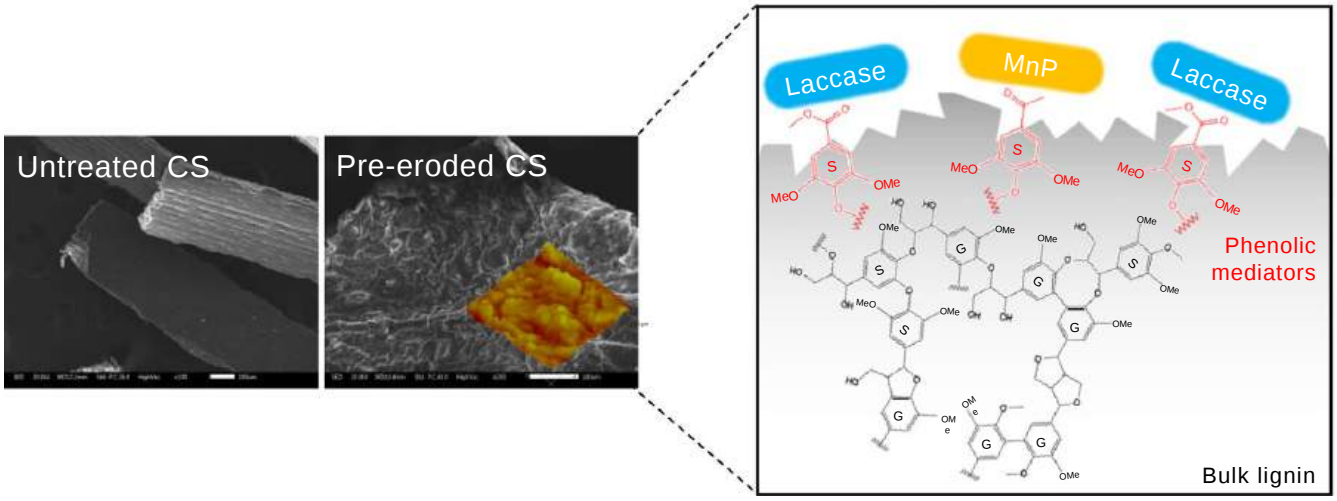

Figure 32.5.8: Untreated and pre-treated CS surface, and Lac and MnP interaction with lignins. Zhuo, S., Yan, X., Liu, D. *et al.* Use of bacteria for improving the lignocellulose biorefinery process: importance of pre-erosion. *Biotechnol Biofuels* **11**, 146 (2018). https://doi.org/10.1186/s13068-018-1...068-018-1146-4. Creative Commons Attribution 4.0 International License (http://creativecommons.org/licenses/by/4.0/)

In addition to restricting access of cellulase to cellulose, cellulase can also nonspecifically adsorb to lignin and its pretreated forms since the lignin derivatives present a more hydrophobic surface that promotes cellulase interactions. Some plant laccases are involved in lignin biosynthesis, whereas in bacteria and fungi, they may be involved in lignin degradation

Of course, fungi, which are prime degraders of dead biomass in forests, are also sources of enzymes for lignin degradation. For example, species of white rot fungi produce manganese peroxidase (MnP), lignin peroxidase (LiP), versatile peroxidase (VP), and laccase (Lac). They work through forming reactive lignin-derived aromatic free radicals (similar to those produced in lignin synthesis), leading to breaking ether bonds, aromatic ring cleavage and removal of methoxy groups from the substrate in a process called delignification. Pretreatment of the biomass increases yields higher amounts of available cellulose. Fungi, however, grow slowly, and the rate of delignification is still low. In addition, they also have hydrolytic enzymes that decrease the yield of cellulose. That is why bacterial sources like B6 are sought for delignification.

As this is a biochemistry textbook, let's explore the structure and function of fungal laccase. The enzyme can bind a large variety of hydroxylated- and methyoxy-aromatic compounds as substrates, so its active site must be adaptable and likely dynamic. Structural analyses, in-silico docking experiments, and molecular dynamics simulations have been performed with the laccase (TvL) from the fungus *Trametes versicolor.*

The enzyme has four copper ions in a T1 Cu site and a tri-nuclear Cu cluster (T2 Cu, T3α Cu and T3β Cu) at a T2/T3 site. As the mechanism involves free radical intermediates with O_2 as an oxidant and substrate, 4 electrons are passed in single electron steps to the T1 Cu, then to the other three coppers, and finally to O_2 to form two water molecules as products. The amino acid side chain ligands for the four copper ions are shown for white rot fungi laccase from Trametes Versicolor in Figure 32.5.9.

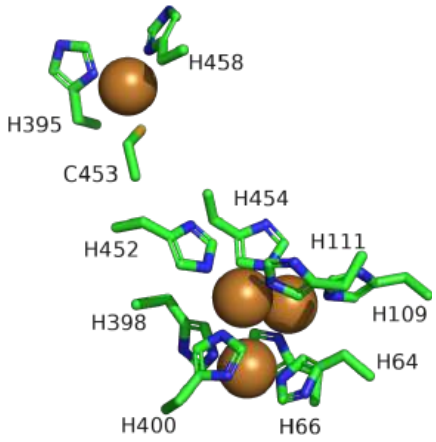

Figure 32.5.9: T1 Cu (top left) and the trinuclear Cu cluster (T2, T3α and T3β) and their ligands for Trametes Versicolor laccase (TvL, pdb: 1GYC)

Fungal laccases are extracellular proteins with about 550 amino acids arranged in three cupredoxin-like, beta-barrel domains. The T1 Cu is close to the surface and is found in domain 3, while the other copper ions are buried at the interface to domains 1 and 3. Figure 32.5.10 shows an interactive iCn3D model of Laccase from the Fungus *Trametes Versicolor* (1GYC)

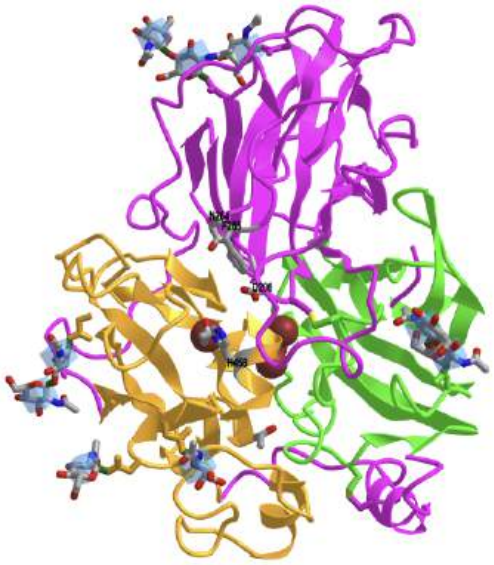

Figure 32.5.10: Laccase from the Fungus Trametes Versicolor (1GYC). (Copyright; author via source).
Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...cSYir86P9nxSW6

Domain 1 is green, domain 2 magenta and domain 3, which contains the single T1 Cu, orange. The protein is glycosylated, as shown in the blue glycan cube cartoons representing N-acetylglucosmine. Key substrate binding and catalytic side chains are shown in sticks and labeled; Asp 206 is a critical residue involved in substrate binding.

The binding interactions of TvL with a wide variety of aromatic substrates are shown schematically in Figure 32.5.11.

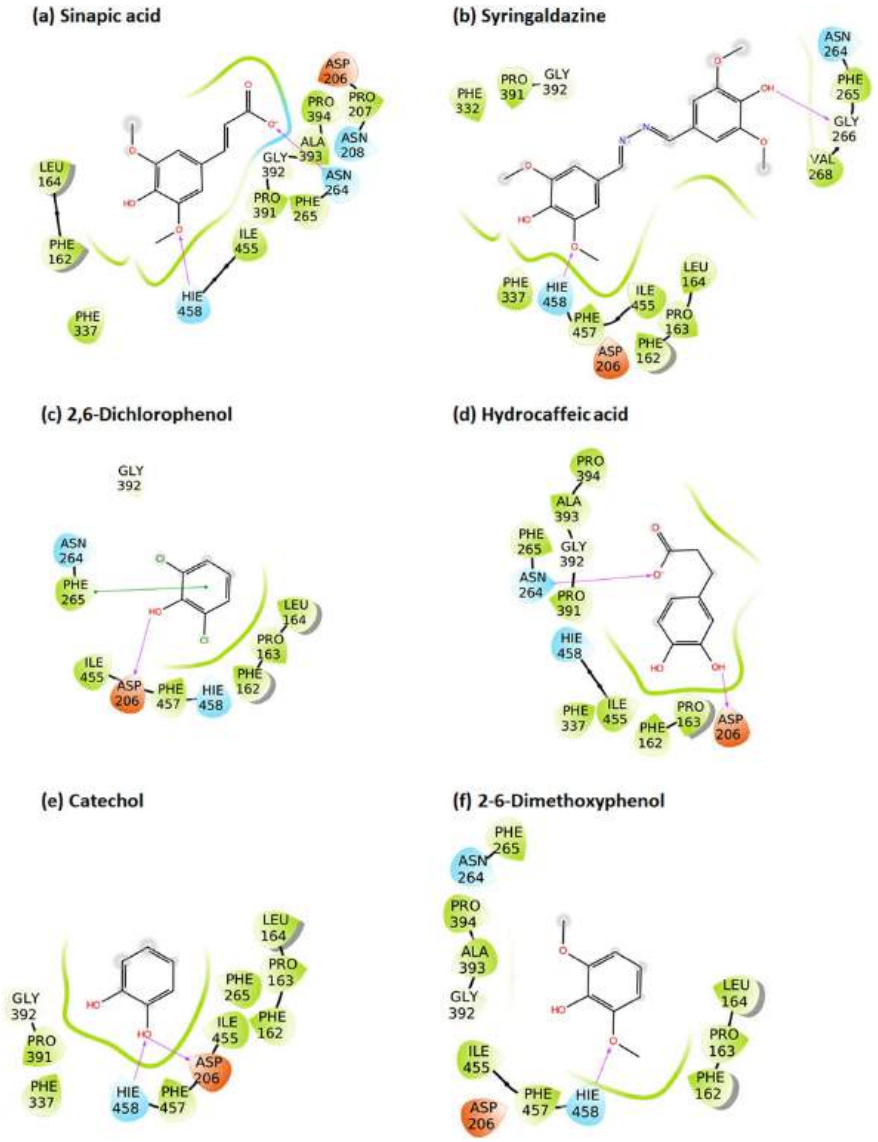

Figure 32.5.11: Binding modes of representative compounds for TvL. Mehra, R., Muschiol, J., Meyer, A.S. *et al.* A structural-chemical explanation of fungal laccase activity. *Sci Rep* **8**, 17285 (2018). https://doi.org/10.1038/s41598-018-35633-8. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/

Most substrates interact with the highly conserved His-458 (blue color, ligand for the Ti Cu)and Asp-206 (orange color) residues and form hydrogen bonds, salt bridges, or π-π stacking interactions with them. Asn-264 (blue) and Phe-265 (green) form important hydrogen bonding and π-π stacking interactions with substrates. The green color highlights nonpolar side chains. Ligands bind near the Ti Cu in domain 3 to initiate electron transfer. The active site of TvL must be dynamic to bind the various-sized ligands shown above. Molecular dynamics simulations, shown in Figure 32.5.12, support this.

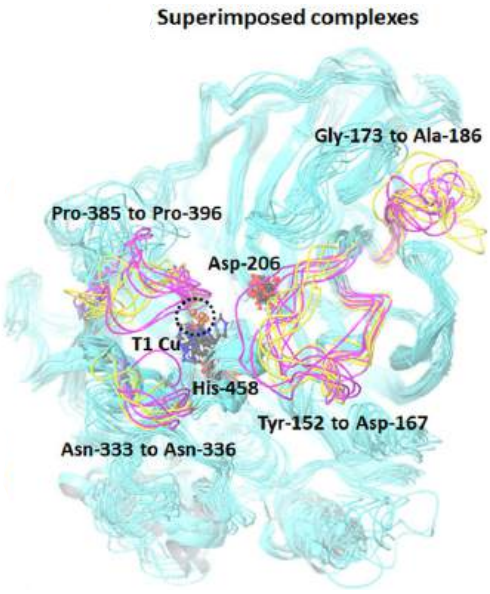

Figure 32.5.12: Display of molecular dynamics simulations showing the loop regions of TvL (magenta colored) and another laccase, CuL (yellow colored), and high levels of fluctuations. Mehra, R., ibid

32.5.4: BREAKING DOWN CELLULOSE

We just explained how the lignin barrier could be degraded so that cellulase can access cellulose. As we described above, that also poses a difficult challenge given the stability of inaccessibility of the glucosidic bonds in cellulose. The inaccessibility of "naked" cellulose fibers stems partly from the tight binding of cellulose strands into crystal lattices. Multiple crystal forms of cellulose, called polymorphs, can form. Plant cellulose has two predominant polymorphs, cellulose Iβ and Iα. Their structures are shown below in Figure 32.5.13.

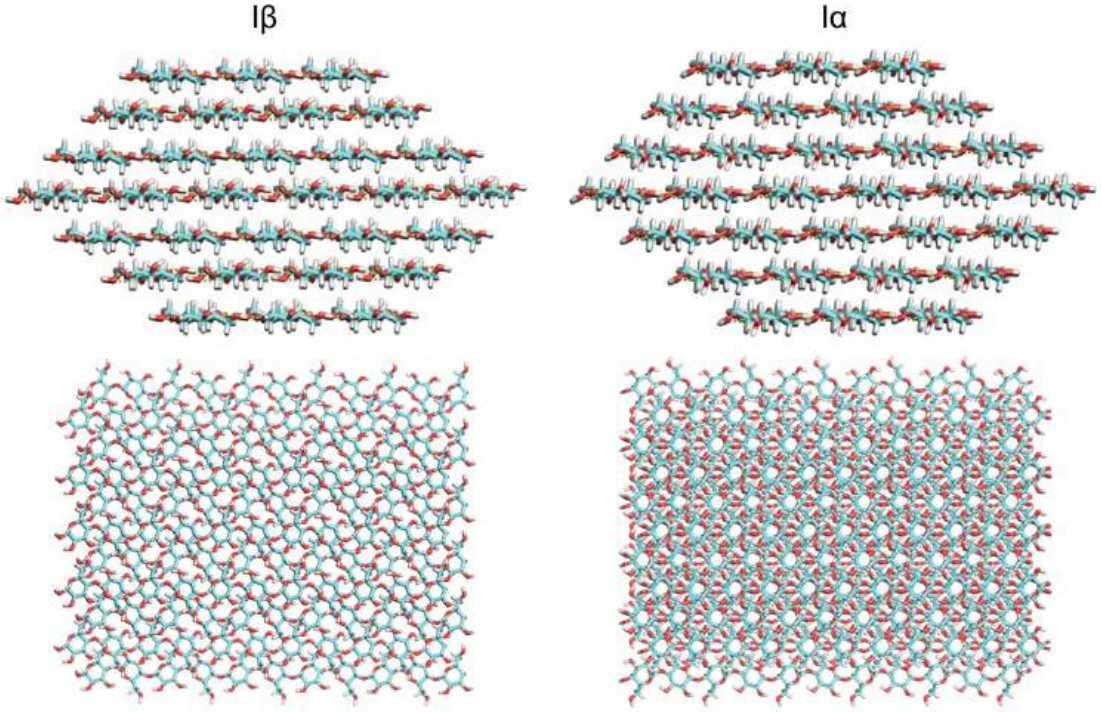

Figure 32.5.13: Natural and synthetic cellulose polymorphs. Christina M. Payne et al. *Chem. Rev.* 2015, 115, 3, 1308–1448 (2015), https://doi.org/10.1021/cr500351c. Open access through a Creative Commons public use license.

They both form hydrogen bonds within a layer, with the main differences resulting from interlayer stacking. There are no hydrogen bonds between layers. You might find that surprising at first glance until you remember that all the OH groups in the lowest energy chair form of the glucose are equatorial, which allows intralayer hydrogen bonding. The interactions between layers predominantly arise from Van der

Waals interactions, specifically induced dipole-induced dipole interactions. The hydrophobic planes, arising from axial H atoms projecting above and above each planar layer of the cellulose fibers, can be readily seen in Figure 32.5.14.

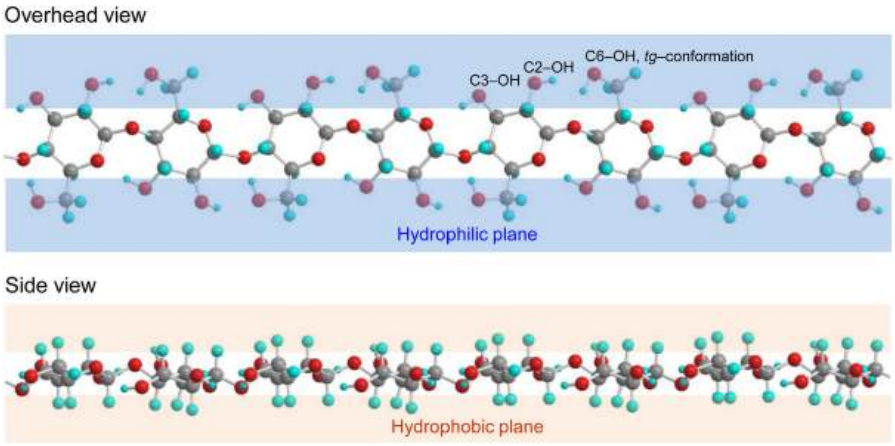

Figure 32.5.14: Hydrophobic planes arising from axial H atoms projecting above and above each planar layer of the cellulose fibers. Akira Isogai et al. Progress in Polymer Science, 86 (2018), https://doi.org/10.1016/j.progpolymsci.2018.07.007. Creative Commons license

Now we can explore the structure of cellulases and how they bind to and cleaves cellulose.

Cellulases, which cleave β(1,4) glycosidic bonds in cellulose, are members of a family of enzymes that go by many names, including **glycosidases**, or more recently, **glycoside hydrolases (GH)**. The Carbohydrate Active Enzymes (CAZypedia) has over 128 glycoside hydrolase (GH) family web pages with enzymes that form hemiacetals on the cleavage of glycosidic bonds. The fungal cellulases that work on cellulose are found in GH families 5, 6, 7, 12 and 45.

There are many types of secreted or cell-surface cellulases, including endoglucanases, exoglucanases (example is cellobiohydrolases (CBHs), and β -glucosidase (BG)). We will focus on **cellobiohydrolases (CBHs)**, the most studied one, which cleaves a 2-glucose unit (cellobiose) from either end of cellulose as it proceeds (processes) along the chain. Fungal and bacterial CBHs can work on crystalline cellulose as well. The resulting cellobiose is further cleaved by β-glucosidases. Ruminants and even termites obtain cellulases from microbes living within their guts. The enzyme has a "tunnel" between two surface loops which interacts with and processively cleaves cellulose.

As mentioned above, fungi are the major degraders of biomass, and are critical in the carbon cycle. Some fungi(brown-rot) use the Fenton reaction (Chapter 13.3) to produce the very reactive hydroxyl free radical (·OH) which causes biomass degradation. Filamentous fungi (like white and soft rot like *T. reesei*) use enzymes. The T. reesei cellulase called cellobiose hydrolase 1 is more recently named *Tr*Cel7A as it is in the GH 7A family.

Cellulase mechanism.

We have previously described the mechanisms of polysaccharide synthesis (Chapter 20.3), so we will discuss in less detail the mechanism of the very similar reaction of cellulose degradation by cellulase. Two general mechanisms are possible, one leading to the retention of configuration at the resulting hemiacetal end of the cellobiose and another that inverts the configuration. These mechanisms are shown in Figure 32.5.15 for glucose in alpha-linkage at the anomeric carbon (not the beta-linkage found in cellulose).

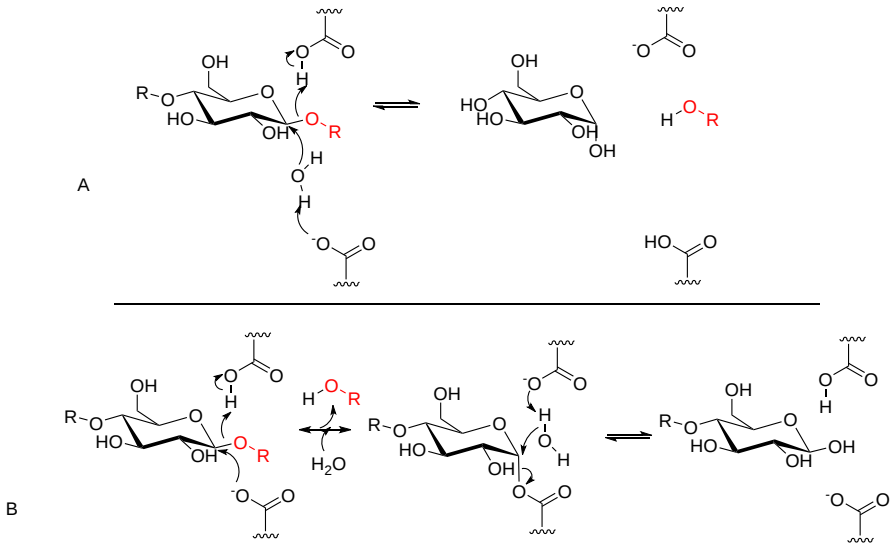

Figure 32.5.15: Two Primary Catalytic Mechanisms of GHs. After Payne et al. *Chem. Rev.* 2015, 115, 3, 1308–1448. https://doi.org/10.1021/cr500351c.

Scheme (A) shows the reaction that inverts the configuration. Water acts as a nucleophile in a S_N2 type of reaction, with catalytic assistance by two proximal carboxylic acid side chains acting as general acids and bases. This results in an inversion of the stereochemistry at the anomeric carbon.

Scheme (B) proceeds with the retention of configuration as two different nucleophilic attacks occur. In the first, an active site carboxylate forms a covalent acetal intermediate with the anomeric carbon. The carboxylate hence acts as a nucleophilic catalyst. Water, acting as a nucleophile, then attacks to form the hemiacetal with the expulsion of the carboxylate leaving group. As we discussed in Chapter 20.3 (section on glycosyl transferases), other variants of these mechanisms would include a S_N1 reaction or one with an oxocarbenium-like transition state.

The CBH1 (family 7) has a long tunnel for binding cellulose. The CBH1 (*Tr*Cel7A) cellulose catalytic site spans at least 9 glucose monomers (n-7, n-6,...,n-1,n+1, n+2) with cleavage typically of a cellobiose from the reducing end (between n-1 and n+1). The structure of the *Tr*Cel7A glycoside hydrolase (cellobiose hydrolase) with a small bound cellulose is shown in Figure 32.5.16.

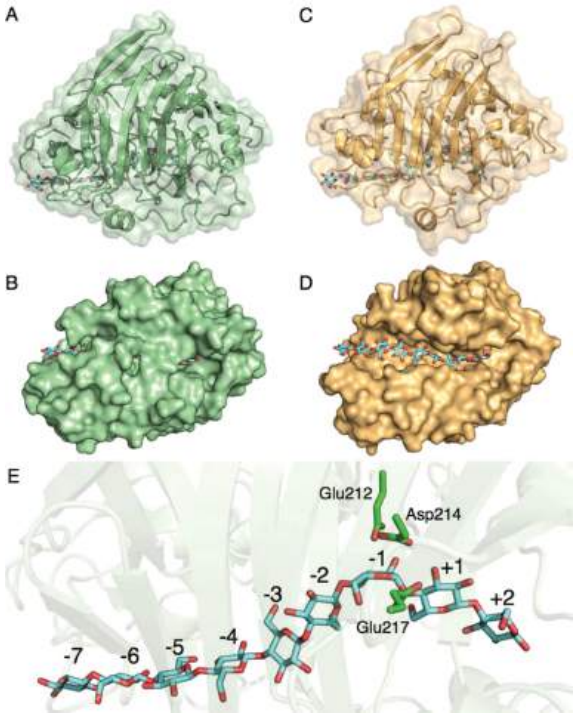

Figure 32.5.16: Crystal structure of the first GH7 CBH and EG. Payne et al. *Chem. Rev.* 2015, 115, 3, 1308–1448. https://doi.org/10.1021/cr500351c Open access through Creative Commons public use license.

The ligand from the *Tr*Cel7A Michaelis complex (PDB code 4C4C (441)) is shown in all panels. (A) CBH *Tr*Cel7A CD (PDB code 1CEL (172)) view from side, exhibiting the β sandwich structure that is characteristic of GH7 enzymes. *Tr*Cel7A was the first GH7 structure solved and is the best-characterized member of GH7. (B) *Tr*Cel7A view from bottom showing the more closed substrate binding "tunnel". (C) EG *F. oxysporum* Cel7B (PDB code 1OVW (174)) view from side. (D) *Fo*Cel7B view from the bottom showing the more open binding "groove". (E) *Tr*Cel7A Michaelis complex (PDB code 4C4C (441)) shows the standard numbering of the substrate binding sites (catalytic residues shown in green for reference). A cellulose chain enters from the −7 site. Hydrolysis occurs between the −1 and +1 sites. The +1/+2 sites are termed the "product sites".

Active site carboxylates (E212, D214, and E217) are shown near the -1/+1 cleavage site in Figure 32.5.17. Glu 217 is covalently attached to the -1 glucose, supporting the retaining mechanism illustrated in Fig 15 above.

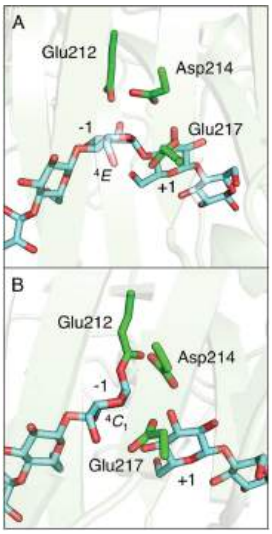

Figure 32.5.17: Michaelis complex and glycosyl-enzyme intermediate of *Tr*Cel7A. Payne et al. ibid.

Panel (A) shows the *Tr*Cel7A Michaelis complex (PDB code 4C4C (441)).

Panel (B) shows a *Tr*Cel7A glycosyl-enzyme intermediate (PDB code 4C4D (441)) with a covalent bond between the nucleophile and the broken cellooligomer chain. There is an approximate 30° rotation of the E217 nucleophile during glycosylation.

Figure 32.5.18 shows a more detailed view of the first step (glycosylation f Glu 217) for the *Hypocrea jecorina* GH Family 7 cellobiohydrolase Cel7A

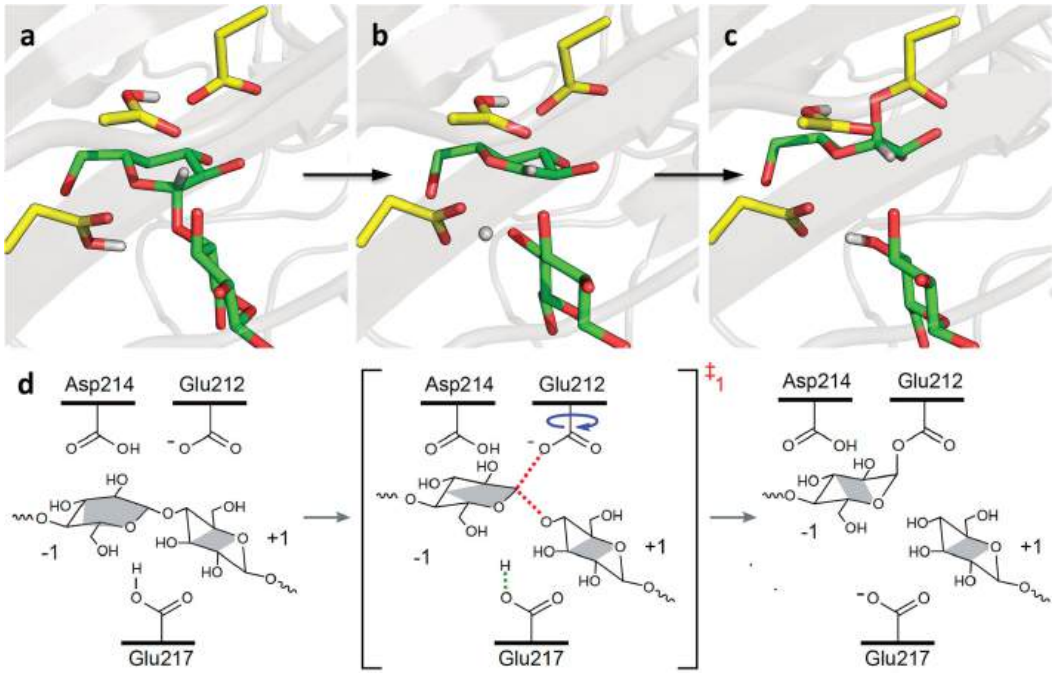

Figure 32.5.18: Figure 2. Glycosylation step for *Hypocrea jecorina* GH Family 7 cellobiohydrolase Cel7A. Knott, Brandon C. et al. - J. Am. Chem. Soc.329 (2013) https://doi.org/10.1021/ja410291u. Open access article published under an ACS AuthorChoice License

Panel (a) shows a snapshot of the reactant the conformation from a representative AS trajectory (with the substrate in green and catalytic residues in yellow) for the glycosylation step. The proton resides on the acid residue, Glu217.

Panel (b) shows a representative snapshot of the transition state. The −1 glucopyranose ring now adopts a different conformation.

Panel (c) shows the product of the glycosylation reaction.

Panel (d) shows a schematic view of the overall glycosylation reaction with the collective variables identified by LM colored at the transition state. The best three-component RC identified by LM includes the forming/breaking bonds involving the anomeric carbon, the breaking bond between Glu217 and its proton, and the orientation of the nucleophile Glu212.

Figure 32.5.19 shows the corresponding deglycosylation (of Glu 217) step.

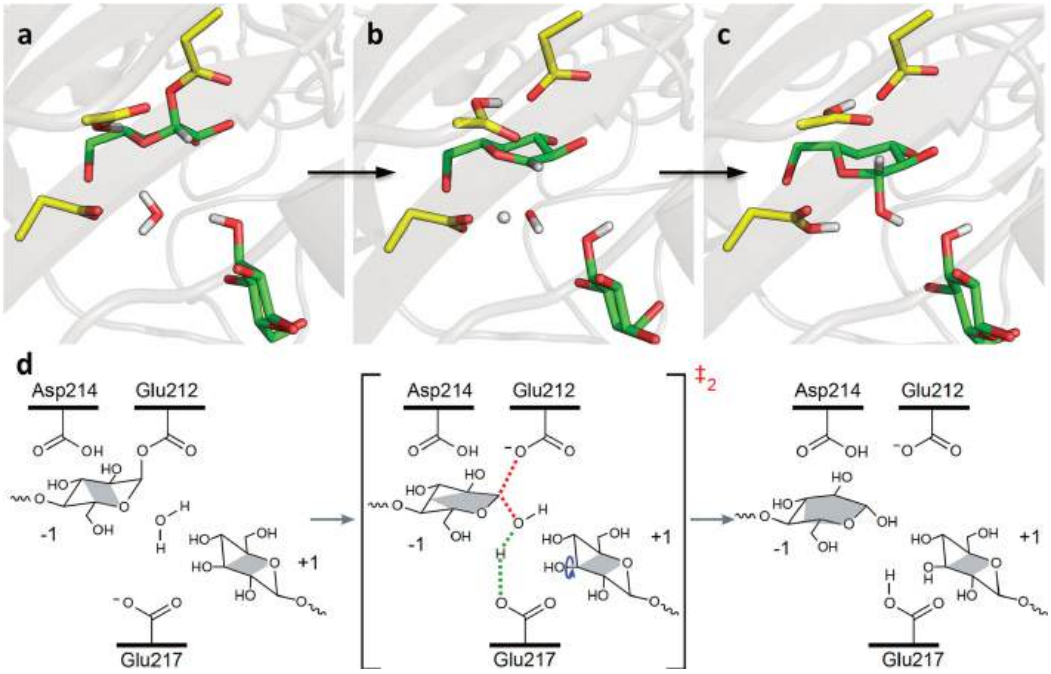

Figure 32.5.19: Figure 4. Deglycosylation step results. Knott, Brandon C. et al, ibid

Panel (a) shows a snapshot of the reactant conformation from a representative AS trajectory (with the substrate in green and catalytic residues in yellow) for the deglycosylation step. The covalent glycosyl–enzyme bond is intact, and the cellobiose product is in primed GEI mode.

Panel (b) shows a representative snapshot of the transition state. Note the distorted conformation of the −1 sugar, as the nucleophilic water molecule is ripped apart.

Panel (c) shows a snapshot of the product in which the glycosyl-enzyme bond has been broken, and the catalytic residues have been regenerated.

Panel (d) shows a schematic view of the overall deglycosylation reaction with the collective variables identified by LM colored at the transition state. The best three-component RC identified by LM includes the forming/breaking bonds involving the anomeric carbon, the forming/breaking bonds involving the transferring proton, and the orientation of the C3 hydroxyl of the +1 sugar.

32.5.5: BINDING OF CELLULASE TO CELLULOSE FIBERS AND LIGNIN

Many glycoside hydrolases contain distinct carbohydrate binding domains/modules (CBD/CBM) and catalytic domains (CD). For example, TrCel7A can be cleaved by the protease papain into a 56K domain with catalytic activity on small substrates but not large cellulose one and a smaller 10K (C terminal) domain that itself is glycosylated and which binds to the hydrophobic surface of cellulose crystals.

Many GHs, in addition, have **linkers** connecting the catalytic domain (CD) and the carbohydrate module (CBM), which add different functions to the enzymes. The linkers vary in size and amino acid sequence. Linkers in fungi tend to be long and N- and O-glycosylated, affecting binding/catalysis. The linkers can also be intrinsically disordered, which adds dynamic complexity to their effects.

The actual cellulose binding site on cellulase has been determined by solution NMR using a synthetic 36 amino acids protein fragment from the C-terminal domain of *Trichoderma reesei* Cel7A (the "carbohydrate binding module or CBM"). The amino acids involved in the binding of cellohexaose (6-mer) were determined by perturbation of the 2D NMR structure on binding cellohexaose. As we mentioned above, cellulase also binds lignin, decreasing their catalytic efficiency towards cellulase. Results of NMR binding studies of the *Tr*Cel7A carbohydrate binding module with cellohexaose and lignins from Japanese cedar (C-MWL) and *Eucalyptus globulus* (E-MWL) are shown in Figure 32.5.20.

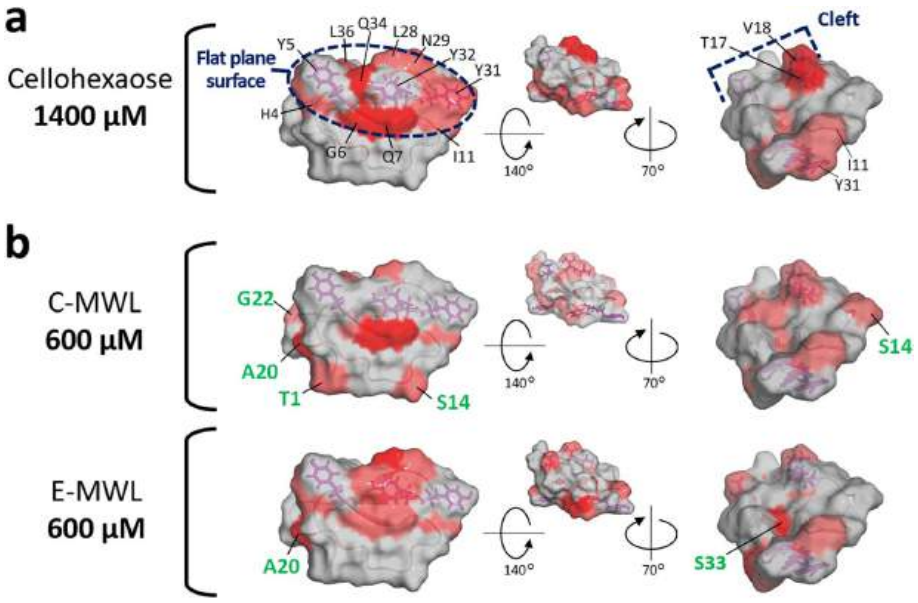

Figure 32.5.20: Comparison of interaction property between cellohexaose and MWLs. Tokunaga, Y., Nagata, T., Suetomi, T. *et al.* NMR Analysis on Molecular Interaction of Lignin with Amino Acid Residues of Carbohydrate-Binding Module from *Trichoderma reesei* Cel7A. *Sci Rep* **9**, 1977 (2019). https://doi.org/10.1038/s41598-018-38410-9. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/.

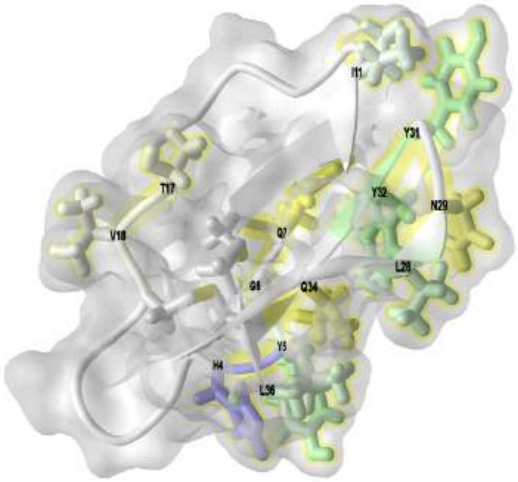
Panel (**a**) shows cellohexaose specifically bound to the flat plane surface and cleft. The flat plane surface is defined by a triplet tyrosine (Y5, Y31, Y32) and H4, G6, Q7, I11, L28, N29, Q34, L36**.**

Panel (**b**) shows both MWLs bound to multiple binding sites, some of which are included in the flat plane surface and cleft even in low concentrations of titrant. These non-specific binding sites are labeled green.

Figure 32.5.21 shows an interactive iCn3D model of the C-terminal cellulose-binding module of cellobiohydrolase I from Trichoderma reesei (2CBH).



NCBI iCn3D Figure 32.5.21: C-terminal cellulose-binding module of cellobiohydrolase I from Trichoderma reesei (2CBH). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...Yva8BVMQCGdUZ7

This synthetic carbohydrate binding module (CBM) from the C-terminal domain of cellobiohydrolase I consists of 36 residues. NMR was used to determine the structure of the CBM. 2D NMR was used to determine the amino acids interacting with cellulose. The interacting side chains are shown as sticks underneath the molecular surface (gray). The side chains are colored according to hydrophobicity, with green followed by yellow being most hydrophobic. The numbering system refers to the 36 amino acid synthetic peptide, not the native protein. This model clearly shows this domain binds to the hydrophobic face of the cellulose microcrystal.

The *Tr*Cel7A CBM has serine and threonine side chains that are glycosylated and affect binding. The interaction of the CBM with the nonpolar cellulose surface is shown in Figure 32.5.22.

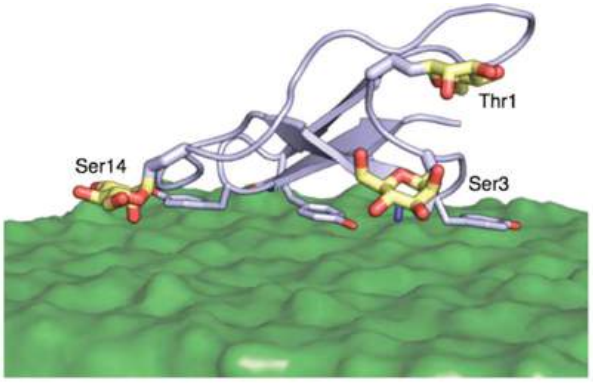


Figure 32.5.22: Glycosylated *Tr*Cel7A CBM on the hydrophobic surface of cellulose. Payne et al., ibid.

Note that the aromatic groups of the triplet tyrosines, Y5, Y31, and Y32 (not labeled), are coplanar with the cellulose surface.

As mentioned above, linkers that connect the C-terminal carbohydrate binding module (CBM) and the catalytic domain (CD) can be of different lengths and sequences and are also N- and O-glycosylated. Figure 32.5.23 shows the interactions of the glycosylated linkers with the cellulose fibers.

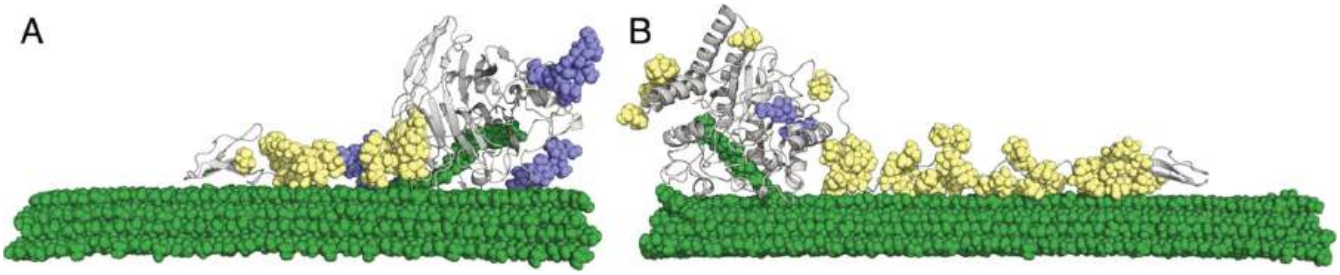

Figure 32.5.23: Molecular snapshots of *Tr*Cel7A and *Tr*Cel6A wherein the linker binds to the cellulose surface from microsecond-long MD simulations. Payne et al., ibid.

These computational predictions of cellulose linkers enhancing binding of CBMs to the cellulose surface were corroborated experimentally via binding isotherm measurements. *N*-glycosylation and *O*-glycosylation are shown in blue and yellow. The glycans attached to the enzyme significantly enhance the binding of cellulase to the cellulose fibers. Payne et al. *Chem. Rev.* 2015, 115, 3, 1308–1448. https://doi.org/10.1021/cr500351c Open access through Creative Commons public use license

A pictorial view of the hydrolytic cleavage of cellobiose from cellulose fibers is shown in Figure 32.5.24.

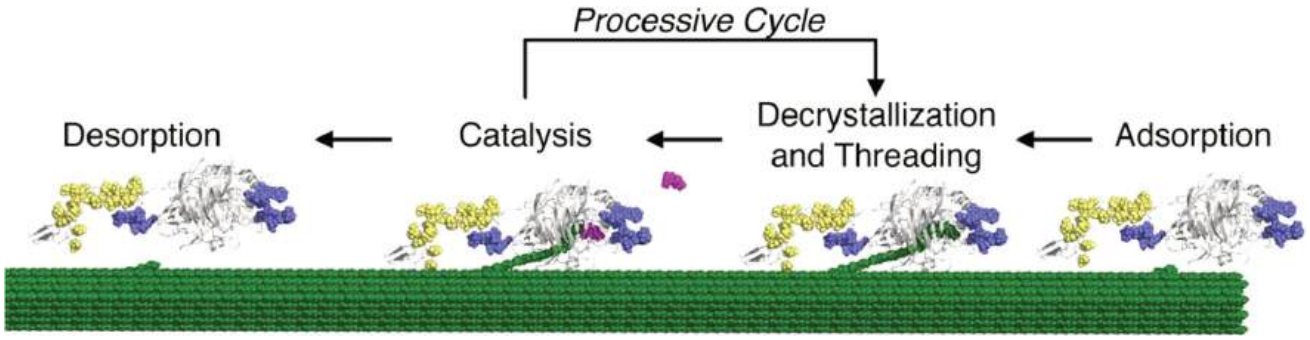

Figure 32.5.24: Complete processive cycle of a GH7 CBH. *Tr*Cel7A is shown with its CD, linker, and CBM in gray "cartoon" representation. Payne et al., ibid.

N-glycosylation and *O*-glycosylation are shown in blue and yellow, respectively. The cellulose surface is green, and the released cellobiose product magenta. Following the CBM and CD adsorption to the substrate and initial chain threading, *Tr*Cel7A processively cleaves cellobiose from a cellulose chain end. The "Processive Cycle" includes chain processivity, hydrolysis, and product expulsion (Figure 35). This processive cycle repeatedly occurs until the enzyme desorbs from the cellulose surface.

Figure 32.5.25 shows an interactive iCn3D model of cellulose bound to cellobiohydrolase I from Trichoderma reesei (7CEL)

KEY POINTS - BETA VERSION FROM CHAT.OPENAI

1. Cellulosic ethanol is a biofuel that is produced from the cellulose, hemicellulose, and lignin in plant material.
2. Unlike first-generation biofuels like corn and sugar cane ethanol, which are produced from sugars and starches, cellulosic ethanol can be produced from a wide range of plant material, including agricultural waste, wood chips, and switchgrass.
3. Cellulosic ethanol is considered a "second-generation" biofuel because it addresses many of the limitations of first-generation biofuels, including the competition with food crops for land and resources.
4. Cellulosic ethanol production involves a two-step process: first, the plant material is broken down into sugars through a process known as pretreatment, and then the sugars are fermented to produce ethanol.
5. The most common pretreatment methods include acid hydrolysis, ammonia fiber expansion, and steam explosion.
6. Cellulosic ethanol has a higher energy balance than first-generation biofuels and lower greenhouse gas emissions, making it a more sustainable option for biofuel production.

7. However, the technology for cellulosic ethanol production is still in the early stages of development, and the cost of production remains high.
8. Research is ongoing to improve the efficiency and cost-effectiveness of cellulosic ethanol production and to find ways to make it a viable alternative to fossil fuels.

32.6: ALGAE - AN INTRODUCTION

Search Fundamentals of Biochemistry

In the previous chapter sections, we discussed bioethanol production from plant starches (first generation) and lignocellulosic plants (second generation) from biomass waste such as stover and sugar cane. Each had its challenges. Now we will consider the third generation production of bioethanol from algae which has significant potential for minimizing damage to the environment. Below in Figure 32.6.1 is a summary of bioethanol production from each generation feedstock.

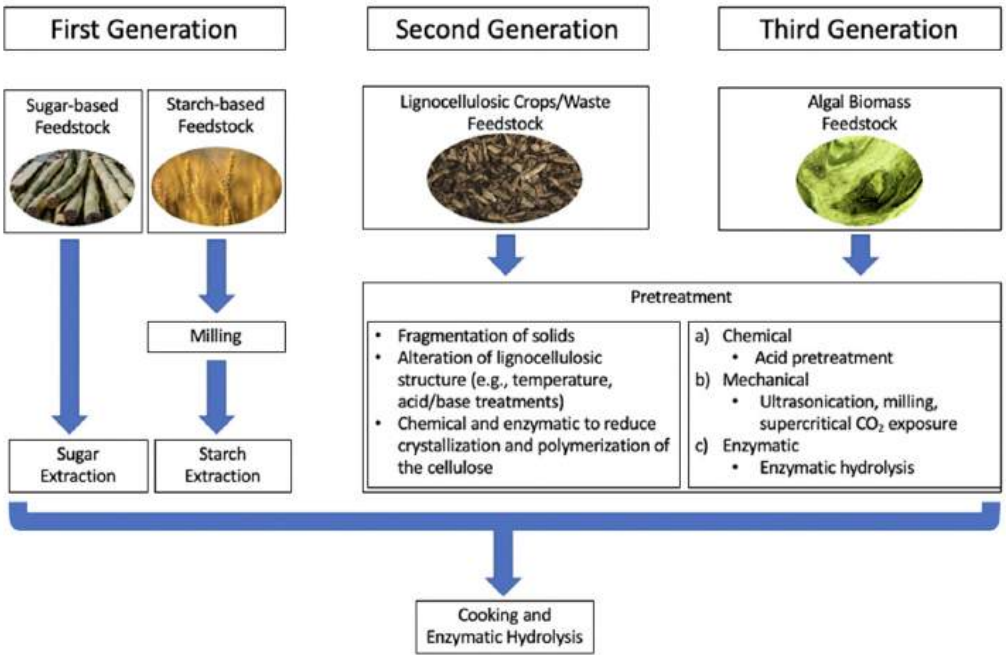

Figure 32.6.x: **Figure 1.** General flowchart of bioethanol production, comparing the pre-fermentation processing of feedstocks for the first three generations of bioethanol production. The blue highlighted area provides an example of a value-added process that can enhance the value of bioethanol production. Tse, T.J.; Wiens, D.J.; Reaney, M.J.T. Production of Bioethanol—A Review of Factors Affecting Ethanol Yield. *Fermentation* **2021**, *7*, 268. https://doi.org/10.3390/fermentation7040268. Creative Commons Attribution (CC BY) license (**https://creativecommons.org/licenses/by/4.0/**)

There are so many types of algae that it can be daunting to read about them. Some are single cells, some can form filaments and colonies, and some are multicellular with different cell types. Some are prokaryotes; some are eukaryotes.

The Algae Database suggests that they are best defined as "oxygenic photosynthesizers other than embryophyte land plants". Naming and classification are generally based on botanical names ending as follows: phyla = -phyta, classes = -phyceae, order = -ales, and family = -aceae. The main groups are blue-green algae (cyanobacteria), rhodophytes, phaeophytes, chlorophytes, euglenophytes, charophytes, diatoms, dinoflagellates, and cryptophytes. To make it more complicated, some animal species have been categorized as algae and have zoological name endings (-zoa, -ea, -ida, -idae). We apologize in advance for any errors and inconsistencies in the description of algae in the chapter section and would ask that you contact us with corrections..

Before we discuss biofuel production from algae, we will review the different algae types (much as we did for zooplankton and phytoplankton). Broadly, algae can be divided into microalgae (seen with a microscope) and macroalgae (seen with the eye). There are almost 170,00 species of algae listed in the Algaebase.

Here is a summary of their properties. They can

- fix carbon and produce food by photosynthesis. As such, they are primary producers.
- be tiny (microalgae) or large and visible (macroalgae, also known as seaweed). Kelp, which can form large underwater forests, is a macroalgae.
- be unicellular, form colonies or filaments, or larger multicellular structures
- attach to objects or float freely.

Some who study algae (phycologists) often consider any organism with chlorophyll but without the stems, roots, leaves, flowers, and vessels of plants to be algae.

The naming and classification of algae are confusing, so let's start with a broad review of their classification.

Life can be divided into domains, kingdoms, phyla, and additional subcategories. Carl Woese proposed three domains, Archaea, Bacteria, and Eukarya, in 1990, based on analyses of ribosomal RNA sequences. These domains are further classified into kingdoms - Archaebacteria, (Eu)bacteria, Protista, Fungi, Plantae, and Animalia. A seventh kingdom was added in 1981 by Thomas Cavalier-Smith, who divided Protista was two kingdoms, Protista (unicellular eukaryotes like some protozoa and some molds) and a new kingdom, Chromista (uni- or multicellular eukaryotes such as algae, diatoms, and some protozoans). Both Protista and Chromista have organisms with chlorophyll, and both also have heterotropic organisms. Newer classifications based on additional biochemical data may yet be proposed. Table 32.6.1 below shows a summary of the domains and kingdoms of life.

Domains and Kingdoms							
Domain	Bacteria	Archaea	Eukarya				
Kingdom	(Eu)bacteria	Archaebacteria	Plantae	Animale	Fungi	Protista	**Chromista**

Table 32.6.1: Domains and kingdoms of life.

All life arose from the **last universal common ancestor, LUCA**, as shown below in Figure 32.6.2.

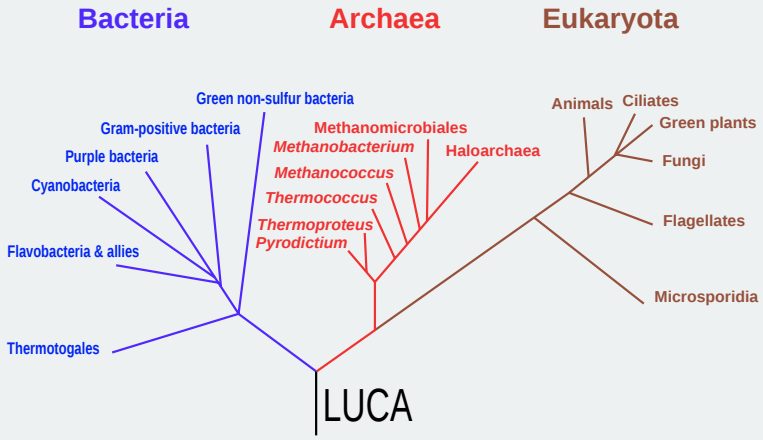

Figure 32.6.2: Phylogenetic tree linking all major groups of living organisms to the LUCAhttps://upload.wikimedia.org/wikiped..._1990_LUCA.svg

Their biological classification of algae (which illustrates how widely spread they are among different domains, kingdoms, and phyla, shown below in Figure 32.6.3

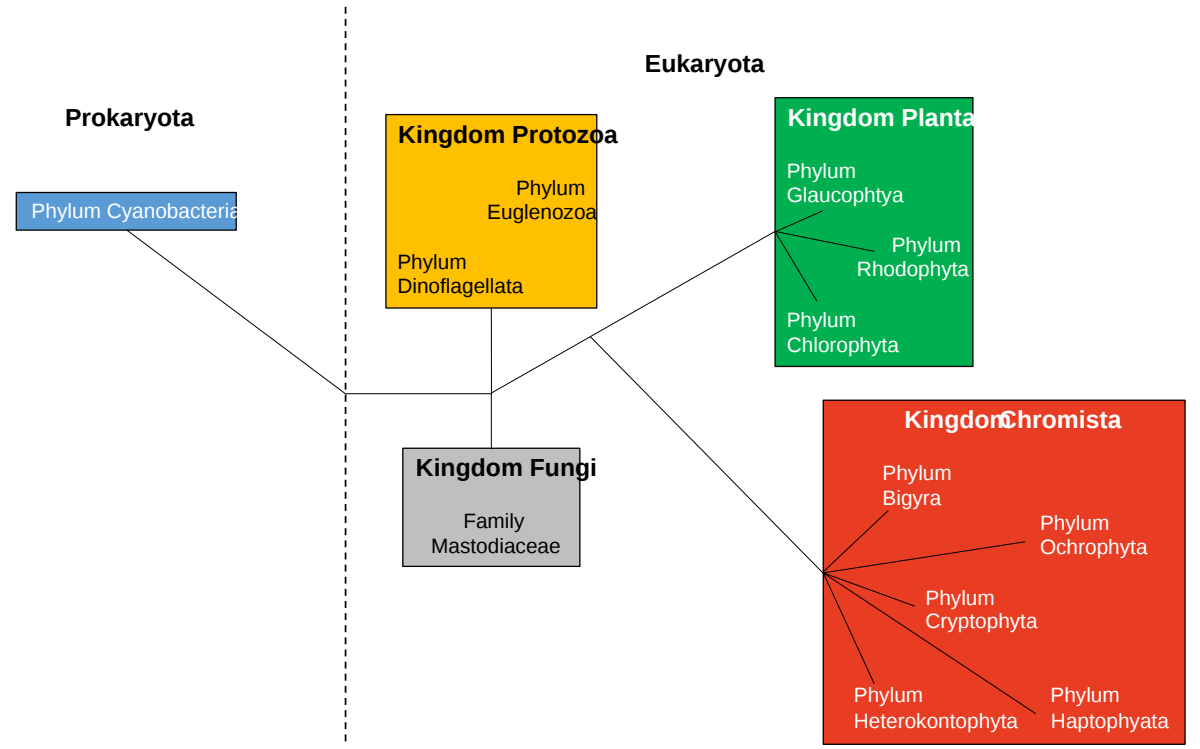

Figure 32.6.3: Distribution of algae among groups in the Tree of Life as recognized by the ITIS and Species 2000 (and ife.org) in 2011. The deep classification of algae is the subject of great debate, and even the higher clades have been discussed and revised recently. Adapted from Verdelho Vieira, V.; Cadoret, J.-P.; Acien, F.G.; Benemann, J. Clarification of Most Relevant Concepts Related to the Microalgae Production Sector. *Processes* **2022**, *10*, 175. https://doi.org/10.3390/pr10010175. Creative Commons Attribution (CC BY) license (**https://creativecommons.org/licenses/by/4.0/**).

32.6.1: MICROALGAE

Microalgae are single-cell organisms that can form filaments and colonies. This group has one prokaryotic member, **cyanobacteria**, also known as **blue-green algae**. As a prokaryote, it does not have mitochondria or chloroplasts. The rest of the microalgae are eukaryotic and include the phyla Chlorophyta, Rhodophyta, Glaucophyta, Cryptophyta, Euglenozoa, Cercozoa, Heterokontophyta, Haptophyta, and Miozoa (Myzozoa). Another simpler organizational system divides microalgae into four categories:

- cyanophyta (blue-green algae/cyanobacteria)
- pyrrophyta (dinoflagellates and cryptomonads, and can be yellowish-green to golden-brown)
- chrysophyta (diatoms, heterokonts and golden brown algae)
- chlorophyta (microscopic green algae). This term also applies to macroalgae (see below).

Green algae are really diverse and are now broken up into two phyla, chlorophyta and charophyta with a combined 17 classes. AlgaeBase dynamic species counts shows that there are about 4,500 species of **Chlorophyta** including those that live on land, in freshwater, and those that are considered macroalgae seaweeds. There are about 2500 species of **Charophyta** that are entirely freshwater.

Within the microalgae are found green, brown, and red algae. (Unfortunately for students of algae, there are also green, brown, and red macroscopic algae as well). Microalgae are much more efficient at photosynthesis than land plants. The diatoms are an example of microalgae and are the precursor of the "fossil" fuel oil deposits. Spirogyra is a unicellular green alga that forms long filaments (colonies) up to 0.1 mm in length, so it loosk like a multicellular organism.

One class of microalgae, green algae, arose when a microbe acquired a cyanobacterium, which allowed photosynthesis. Green algae eventually evolved into higher plants, and a similar process led to red algae. Brown algae and diatoms, dinoflagellates, and euglenoids, other types of algae, arose from the uptake of red or green algae into other eukaryotic host cells.

In general, green microalgae, which absorb red wavelengths, are found on the surface. The red microalgae, which absorb green, and blue wavelengths, are at lower levels. The brown microalgae are generally found in between these water layers. Figure 32.6.x below shows the light penetration spectrum in water.

LIGHT IN THE WATER

The energy of light photons is given by $E=h\nu=hc/\lambda$, where ν if the frequency of the light and λ is the wavelength. As highly energetic x-rays penetrate matter, visible light can penetrate water. Water absorbs incident radiation, with the lower energy, higher wavelength photons of red light absorbed more readily in the top layers while the blue light penetrates farther into the water. The depths of penetration of light in the open ocean (left) and coastal (right) waters are shown in Figure 32.6.4.

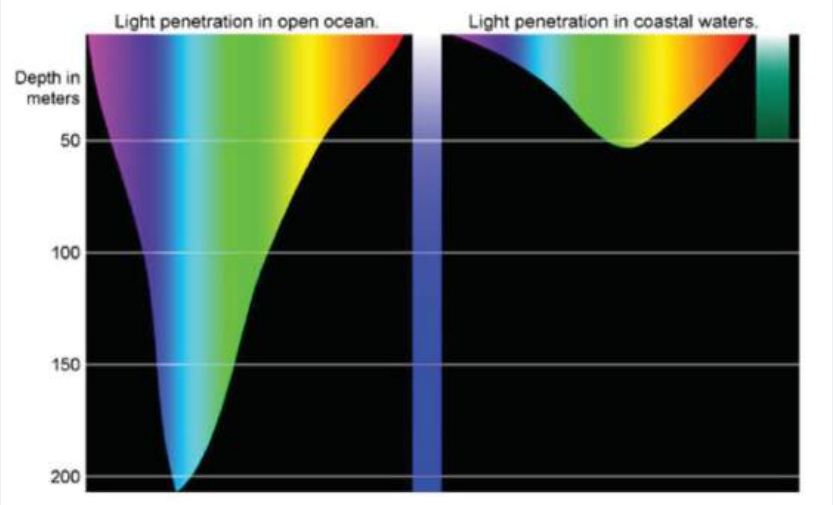

Figure 32.6.4: The light penetration spectrum in water as a function of color. https://oceanexplorer.noaa.gov/edu/m...fact-sheet.pdf

When you are underwater, everything seems blue since red light is preferentially absorbed, leaving photons enriched in blue light reaching our eyes. Blue-enriched light reaches our eyes as it reflects off of objects. Clear water in the open ocean also appears blue since there are fewer particles like phytoplankton from which light scatters back to our eyes. Rayleigh (or elastic light scattering) depends on $1/\lambda^6$, so low wavelength light scatters most from particles. Sunsets and sunrises appear red when light passes through more of the atmosphere and the blue light is scattered from atmospheric particles before reaching our eyes. Coastal waters have more sediment, algae, and microscopic organisms like plankton that can scatter light. These waters appear more green-blue, since red light is significantly absorbed by the microorganisms and blue light is more scattered.

Microalgae exist as single cells or can form multicellular filaments and colonies. They proliferate in the presence of simple nutrients and can produce large amounts of polysaccharides for industrial bioethanol production or fatty acids/triacylglycerols for biodiesel production. They are, as mentioned above, the source of underground oil deposits. Both freshwater (like *Chlorella* and *Haematococcus*) and ocean microalgae (*Dunaliella*, *Phaeodactylum*, and *Tetraselmis)* can be used for the production of biofuels. The cyanobacteria *Spirulina* sp. is commonly used for commercial purposes. It and Synechococcus have large amounts of glycogen that could be used for bioethanol production. Their triacylglycerols are low, so they can't be used for biodiesel (which we will discuss in a future section of the chapter).

Most are familiar with algae blooms in freshwater lakes (and even in saltwater environments). Cyanobacteria (blue-green algae) are the main culprit. Microcystin, a potentially lethal toxin that targets serine/threonine protein phosphatases, is released from some algae blooms. Figure 32.6.5 shows a microalgae bloom in Lake Erie, a shallow freshwater lake polluted with agricultural runoff, making it an excellent site for cyanobacterial blooms.

Figure 32.6.5: Microalgae bloom in Lake Erie, October 2011. https://commons.wikimedia.org/wiki/F..._Lake_Erie.jpg

Red tides are another type of toxic algae blooms that occurs in coastal water. Along US coast they are caused by dinoflagellates and one diatom, both phytoplankton and types of microalgae. Around the Gulf of Mexico, the main cause of red tides is the microalgae *Karenia brevis*. They release large amounts of brevotoxin, a polycyclic ether that binds to and activates voltage-gated Na+ channels in nerve and muscle. Hence it is a potentially deadly neuortoxin. The frequency of red tides is increasing around the world. Two images of red tides are shown in Figure 32.6.6.

Figure 32.6.6: Red Tide. License from Shutterstock

Microalgae are sources of glycan polymers that can be used for bioethanol production; some are excellent candidates for biodiesel fuel, which is made from triacylglycerol reserves. Table 32.6.2 below shows a classification of microalgae and Cyanobacteria along with their characteristic pigments (that impart their distinctive colors) and their energy reserves that could be used for biofuel production.

Phylum	Class	Pigments	Reserve	Habitat
Cyanobacteria	Cyanophyceae	Chl a, β-carotene, flavacene, Echinenone isozea-, zea-, myxo-, oscillaxanthin APC, C-PC, C-PE	Starch (granule) and glycogen	Marine Freshwater Terrestrial
Euglenophyta	Euglenophyceae	Some colorless Chl a, b, diadinoxanthin	Paramylon Ergosterol	Marine Freshwater Terrestrial
Heterokontophyta/ Ochrophyta	Xanthophyceae Eustigmatophyceae	Chl a and c, β-carotene, heteroxanthin, diadinoxanthin (++)	Oil Leucosin Ergosterol	Marine Freshwater Terrestrial
Miozoa	Dinophyceae	Chl a, c, β-carotene, diadinoxanthin, dinoxanthin, peridinins	Starch Lipids	Marine Freshwater
Heterokontophyta/ Ochrophyta	Chrysophycea	Chl a, c, β-carotene, Fuco-, Diato-, diadinoxanthin	Chrysolaminarin Fucosterol Porifasterol	Marine Freshwater
Haptophyta	Coccolithophyceae Pavlovophyceae Rappephyceae	Chl a, c, β-carotdnd, Fuco-, Diato-, diadinoxanthin	Chrysolaminarin Fucosterol Porifasterol	Marine Freshwater
Bacillariophyta (Diatoms)	Bacillariophyceae	Chl a, c, β-carotdnd, Fuco-, Diato-, diadinoxanthin	Chrysolaminarin Oil	Marine Freshwater Terrestrial
Cryptophyta	Cryptophyceae	Chl a, c, Biliproteins, α-carotene, Allo-, Croco-, Monado-xanthin	Starch (granule) Oil Carbohydrates	Marine Freshwater

Table 32.6.2: Classification of microalgae and Cyanobacteria. Hachicha, R.; Elleuch, F.; Ben Hlima, H.; Dubessay, P.; de Baynast, H.; Delattre, C.; Pierre, G.; Hachicha, R.; Abdelkafi, S.; Michaud, P.; Fendri, I. Biomolecules from Microalgae and Cyanobacteria: Applications and Market Survey. *Appl. Sci.* **2022**, *12*, 1924. https://doi.org/10.3390/app12041924. Creative Commons Attribution (CC BY) license (**https://creativecommons.org/licenses/by/4.0/**).

Cyanobacteria and red microalgae store glycogen and floridean starch (a hybrid between starch and glycogen) respectively, while green microalgae accumulate amylopectin-like polysaccharides.

32.6.2: MACROALGAE

As mentioned above, macroalgae, known as seaweeds, do not have **roots**, stems, leaves, or flowers. Kelp in underwater forests appear to have roots, stems and leaves, but they are not plants. They have analogous structures such as holdfast, stipes, and blades which serve the functions of roots, stems and leaves found in plants. As do the microalgae, variants of macroalgae include red (**Rhodophyta**), green (**Chlorophyta,** also a type of microalgae), and brown (**Phaeophyta**) algae. It grows up to 30 times as quickly as land-based groups. In addition, it does not have lignin. They grow much faster than terrestrial plants and can form lots of biomass for commercial processing in much less area than land groups. They can be grown at low cost in sea farms without adding nutrients or pesticides. Hence they are ideal for both food and biofuel production. Brown and red algae have many present commercial uses. They have lots of carbohydrates for potential bioethanol production and triacylglycerols for biodiesel. Their carbohydrate composition includes mannitols and cell wall constituents which could also be used for fermentation. In contrast to present petroleum sources, the biodiesel from macroalgae does not contain sulfur.

Red macroalgae

(some material below for red and green macroalgae from https://bio.libretexts.org/Bookshelv...nd_Green_Algae)

The red algae are almost exclusively marine, and some are unicellular, but most are multicellular. They have true chloroplasts with two membranes (no remnant peptidoglycan) containing chlorophyll. Like the cyanobacteria, they use phycobilins as antenna pigments, **phycoerythrin** (which makes them red), and **phycocyanin**. Red pigment allows the red algae to photosynthesize at deeper depths than the green or brown algae, harnessing more of the blue light waves that penetrate deeper into the water column. Unlike green algae and plants, red algae store carbohydrates as Floridean starch, which has glucose in α(1,4) linkages and occasional α(1,6) linkages, similar to

amylopectin. **Agar**, the base for culturing bacteria and other microorganisms, is extracted from a red alga. Multicellular forms can be filamentous, leafy, sheet-like, coralloid, or even crust-like. Some examples are shown in Figure 32.6.7.

Figure 32.6.7: These images show multicellular red algae, which can range from filamentous (first image) to "leafy" (second image, left) to sheet-like (second image, right). The red color is due to an abundance of the red pigment phycoerythrin, which gives this group reddish chloroplasts. First image by Melissa Ha CC-BY-NC. Second image by Maria Morrow CC-BY-NC. Right image: https://commons.wikimedia.org/wiki/F...ed_algae_3.jpg

Green macroalgae

These algae exhibit great diversity of form and function. Similar to red algae, green algae can be unicellular or multicellular. Many unicellular species form colonies and some green algae exist as large, multinucleate, single cells. Green algae primarily inhabit freshwater and damp soil and are a common component of plankton. They have chloroplasts and the photosynthetic pigments chlorophyll a and b, carotene, and xanthophylls. Examples include *Chlamydomonas*, *Chlorella*, *Pediastrum*, *Netrium*, *Hydrodictyon*, *Acetabularia*, *Ulva*, *and Spirogyra*. Lichens are a symbiotic combination of fungi and green algae.

The nature of the evolutionary relationships between green algae is still debatable. As of 2019, genetic data supports splitting the green algae into two major lineages: **chlorophytes** and **streptophytes**. The green algae exhibit similar features to the land plants, particularly in chloroplast structure. They have chlorophyll a and b, have lost phycobilins but gained carotenoids, and store carbohydrates as **starch inside plastids**. Green algae are an important source of food for many aquatic animals. Two types of green macroalgae are shown in Figure 32.6.8.

Figure 32.6.8:Two types of green macroalgae

left: Figure 5.3.3.125.3.3.12: *Trentepohlia* is a genus of green algae found in terrestrial environments. It forms fluffy orange colonies on trees and is a photobiont in many lichens. One might not know they were looking at a green algae, due to the orange pigmentation. However, green algae have carotenoids. These terrestrial green algae produce an abundance of carotenoids, perhaps for protection from sun damage. Photo by Scott Loarie, CC0.

Right: fresh water green algae. https://upload.wikimedia.org/wikiped...reen_Algae.jpg

Green macroalgal blooms (called green tides) can also occur (just as blooms from the microalgae cyanobacteria). Green tides in the Yellow Sea (between China and Korea) are the largest known. A particularly large one is shown in Figure 32.6.9:

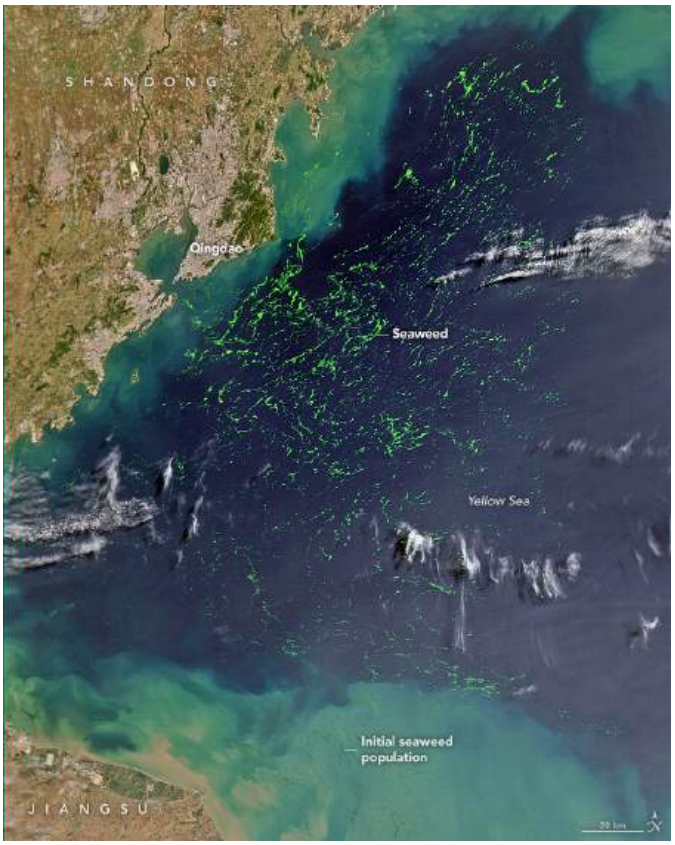

Figure 32.6.9: Green Seaweed in the Yellow Sea , June 2021. https://earthobservatory.nasa.gov/im...the-yellow-sea

This particular green time was from nontoxic green macroalgae, *Ulva prolifera*. It is often called sea lettuce as it is edible. Blooms can affect the local ecosystem and lead to hypoxic zones as they decay.

Brown macroalgae (also known as Kelp)

(some material below for brown macroalgae from https://bio.libretexts.org/Bookshelv...3A_Brown_Algae)

Macroscopic brown algae arose when a heterotrophic eukaryote merged with a unicellular photosynthetic eukaryotic red algae chloroplasts. The red alga degenerated into a chloroplast, this time with four membranes -- the engulfing membrane from the oomycete, the red alga's plasma membrane, and the two membranes of the original chloroplast within the red alga. The chloroplast has lost one of these membranes in many groups derived from secondary endosymbiosis. Figure 32.6.10 shows this secondary endosymbiosis event.

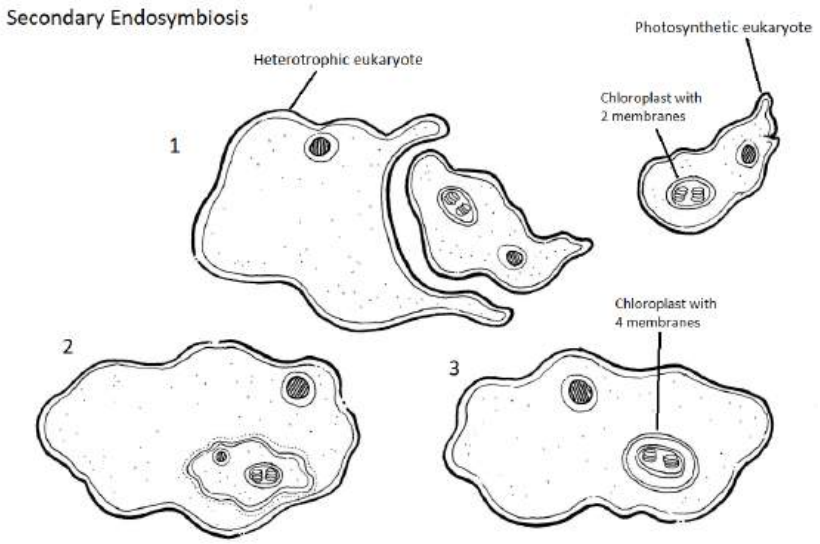

Figure 32.6.10: In the diagram above, we see a unicellular photosynthetic eukaryote with a 2-membrane chloroplast. In step one, this organism is engulfed by a heterotrophic eukaryote. In step two, we see the photosynthetic organism inside the heterotrophic organism. In step three, the original photosynthetic organism has been reduced to a chloroplast with four membranes. Artwork by Nikki Harris CC-BY-NC with added labels by Maria Morrow.

Brown algae are brown due to the large amounts of carotenoids they produce, primarily one called **fucoxanthin**. These organisms are exclusively **multicellular** and can get so large that they require special conductive cells to transport photosynthates from their blades down to the rest of their tissues. These conductive cells are called **trumpet hyphae** and have sieve plates and resemble sieve tubes found in flowering plants.

Much like *Saprolegnia*, the body of an alga is called a thallus because it is not differentiated into specialized tissues. The general morphology of a brown alga includes a **holdfast, stipe, gas bladder**(s), and **blade**(s). Figure 32.6.11 shows a diagram of kelp structure.

32.6.2.1:

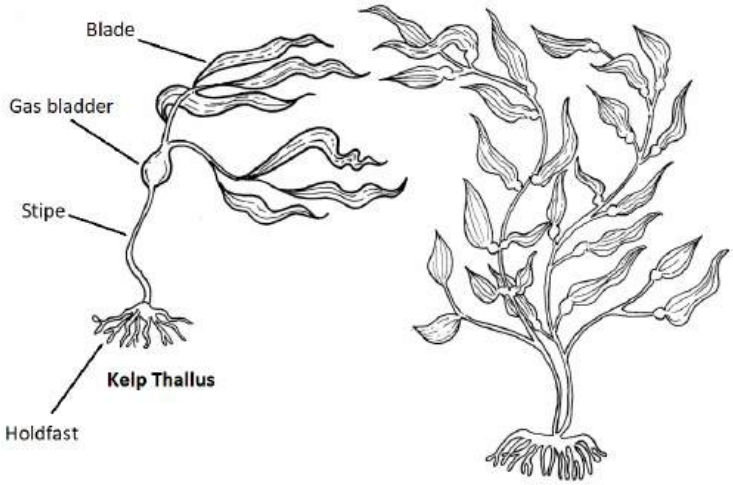

Figure 32.6.11: A diagram of kelp structure. In the diagram above, there are two kelp thalli. The one on the left side is labeled. At the bottom of the thallus is a network of root-like projections that make up the holdfast. The stem-like structure that travels up from the holdfast is the stipe, which terminates in an inflated gas bladder. There are several leaf-like structures attached to the gas bladder. These are blades. The thallus on the right has all these components, but in a slightly different arrangement. Can you find them? Artwork by Nikki Harris CC-BY-NC with added labels by Maria Morrow.

Figure 32.6.12 shows a beautiful image of a kelp forest.

Figure 32.6.12: Kelp forest. https://commons.wikimedia.org/wiki/F...1115735%29.jpg

Figure 32.6.13 shows another type of a brown macroalgae.

Figure 32.6.12: Underwater "roses" of a brown algae Padina pavonica, commonly known as the peacock's tail (Israel). https://commons.wikimedia.org/wiki/F...l_(Israel).jpg

Now we are in a position to discuss algae as a source of biofuels and nutritive foods in the next chapter section.

KEY POINTS - BETA VERSION FROM CHAT.OPENAI

1. Algae are a diverse group of aquatic organisms that range from simple, single-celled organisms to complex, multicellular forms.
2. Algae are photosynthetic organisms and they play a critical role in the Earth's carbon cycle by converting carbon dioxide into oxygen.
3. Algae are found in a wide variety of environments, including freshwater, marine, and terrestrial ecosystems.
4. Algae have been used for a long time as a source of food, medicine and as a fertilizer.
5. Algae are also of great interest as a source of biofuel due to their high growth rates, ability to grow in non-arable land and their ability to produce large amounts of lipids (oils) that can be converted into biofuels.
6. Algae are a valuable resource for the production of biofuels, as they are able to produce large amounts of lipids and carbohydrates that can be converted into biofuels.
7. Algae-based biofuels have the potential to be more sustainable than biofuels produced from terrestrial crops, as they can be grown in non-arable land and do not compete with food crops for resources.
8. Algae can be grown in different systems, including open ponds, closed photobioreactors, and hybrid systems.
9. Algae can be grown using a variety of inputs, such as sunlight, CO2, and nutrients, and can produce a wide range of biofuels, including bioethanol, biodiesel, and biomethane.
10. Algae-based biofuels are still in the early stages of development, and research is ongoing to improve the efficiency and cost-effectiveness of algae cultivation and biofuel production.
11. Algae also have other potential uses, such as for the production of food and feed, as well as for bioremediation and carbon sequestration.

32.7: ALGAE - BIOETHANOL PRODUCTION

Search Fundamentals of Biochemistry

LEARNING OBJECTIVES

- Understand the role that algae play in the production of bioethanol.
- Explore the process of converting algae into bioethanol.
- Learn about the potential benefits and drawbacks of using algae for bioethanol production.
- Evaluate the sustainability of algae-based bioethanol production.
- Analyze the potential of algae as a renewable source of bioethanol and its potential impact on climate change.

Now we are in a position to discuss algae as a source of biofuels and foods. Algae can be used to produce bioethanol from the fermentation of algal polysaccharides (starch, cellulose, and other unique polysaccharides found in them). In addition, triacylglycerols can be converted to biodiesel (which we will discuss in a different chapter). Since we explored bioethanol production from starch and cellulose in previous sections, we'll focus mainly on the unique carbohydrates found in algae and how they can be converted into monomers for glycolytic fermentation by yeast to ethanol.

Both microalgae and macroalgae contain starch reserves (in the cytoplasm and, in some cases, in the chloroplast) and cellulose (in cell walls). They can be grown quickly in aquatic environments, and the key molecules are harvested and processed for use in yeast fermentation by yeast and also by bacteria such as *Zymomonas mobilis* to produce bioethanol. This enzyme can use glucose, fructose, and sucrose as substrates.

STARCH FROM MICROALGAE

Green microalgae have been used as a source of both starch and cellulose. Some species of microalgae have very high starch/glucose composition by mass. Examples include Chlamydomonas reinhaedtil (60%), Chlorococcum humicola (33%), and Chlorella vulgaris (50%). Pretreatment of the microalgae biomass includes liquefaction using alpha-amylases followed by the addition of amyloglucosidase to produce glucose monomers (saccharification) or hydrolysis of glucosidic bonds using acid (sulfuric acid) or base (sodium hydroxide) pretreatment at elevated temperatures.

As discussed previously, starch consists of **amylose**, an unbranched glucose polymer with α(1,4) glucosidic links, and **amylopectin**, which contains α(1,6) branches. Algae starch (for example, in Chlorophyta, Cryptophyta, and Dinophyta) is found in the cytoplasm or chloroplast. A particular type of starch, Floridean (the primary energy storage molecule in the red algae Rhodophyceae), is also found in the cytoplasm. A generic structure of branched starches is shown below in Figure 32.7.1.

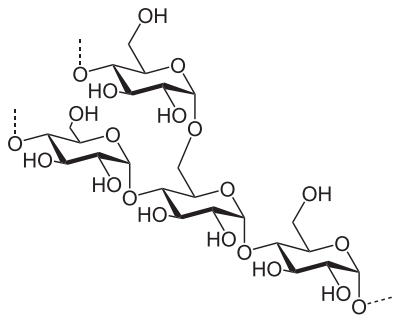

Figure 32.7.1: Branched starches (https://en.wikipedia.org/wiki/Floridean_starch.

Amylopectin has α(1,6) branches every 25-30 glucose units, while animal glycogen, another α(1,4) glucose polymer, has shorter branches every 8-12 glucose units. Floridean starch has branch lengths between these repeat values but is closer to amylopectin. β-amylases can cleave Floridean starch to mainly form glucose and maltose, while mild acid hydrolysis can lead to isomaltose formation.

Other unique glycans are potential sources of glucose for bioethanol production. These are described below.

STARCH-LIKE MOLECULES IN MICROALGAE

Given algae diversity, it should be no surprise that some have alternative, starch-like glycans for their energy reserves that could also be used for bioethanol production.

Laminarin (or Laminaran):

Laminaran is a linear polymer of glucose with β(1,3) glycosidic links with β(1,6)-branches at a ratio of 3:1. It is used for energy storage in brown algae. It can be hydrolyzed by laminarinase, which cleaves β(1,3) glucosidic bonds. It is a linear polysaccharide with a

β(1→3):β(1→6) ratio of 3:1. Its structure is shown in Figure 32.7.2 below.

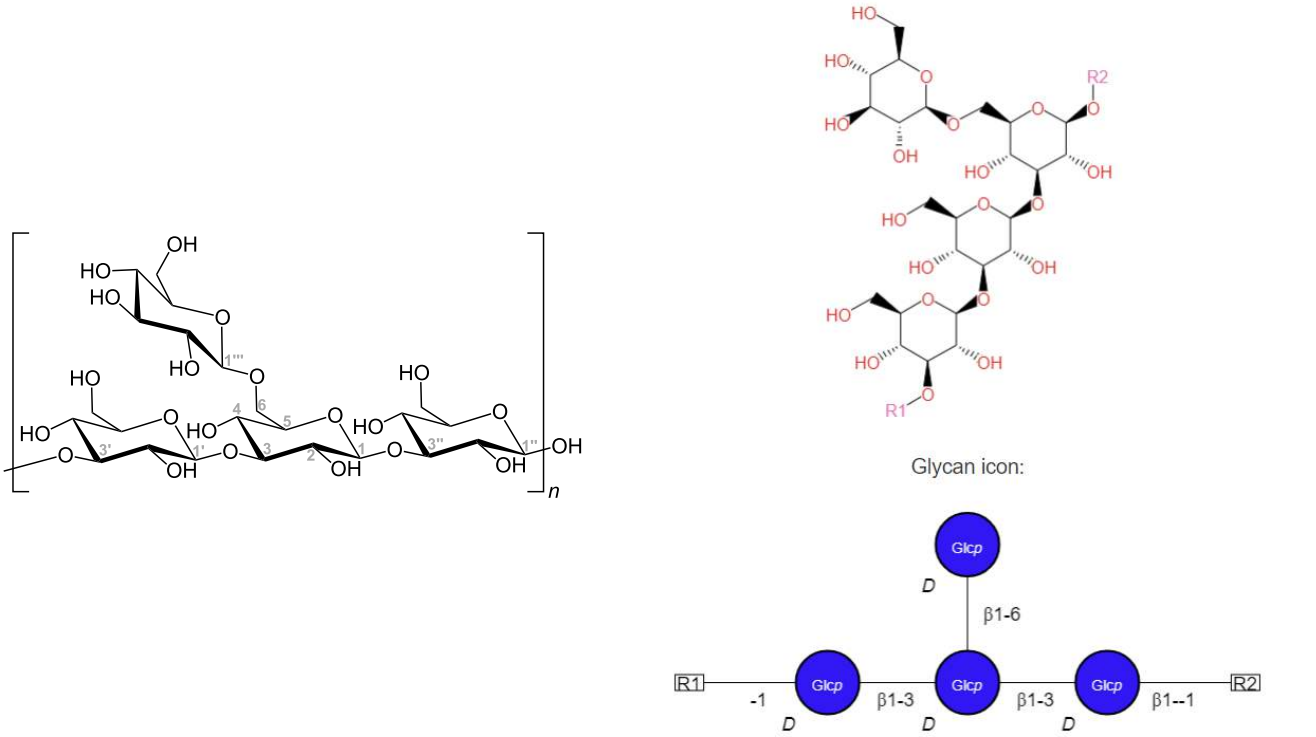

Figure 32.7.2: Structure of laminarin. Left - https://commons.wikimedia.org/wiki/F...ructure_V1.svg; Right - https://biocyc.org/compound?orgid=ME...3602#tab=STRUC

Chrysolaminarin

This glycan is a linear polymer of glucose monomers linked through β(1,3) glycosidic bonds with some β(1,6) linkages. It is found in Haptophyceae, Bacillariophyceae, and Chrysophyceae, which include diatoms. Its generic structure is shown in Figure 32.7.3 below.

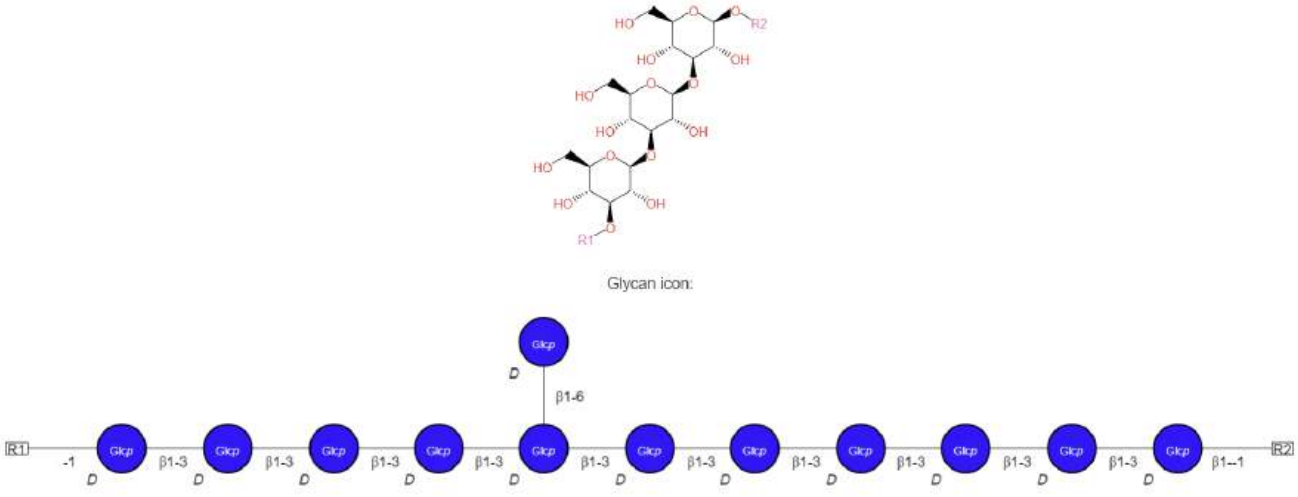

Figure 32.7.3: Structure of Chrysolaminarin. https://metacyc.org/compound?orgid=M...arin#tab=STRUC

The ratio of branching is 11/1, as indicated in the figure. Algae contain enzymes that can cleave the β(1,3) and β(1,4) links, which can be cleaved by acid hydrolysis.

Paramylon

Paramylon is a linear polymer of glucose monomers linked through β(1,3) glycosidic bonds. It is found in Euglenophyceae, Xanthophyceae, and Prymnesiophyta. A β-1,3 glucanase from *Euglena gracilis* (Euglenozoa) cleaves the β(1,3) link. Its structure is shown in Figure 32.7.4 below.

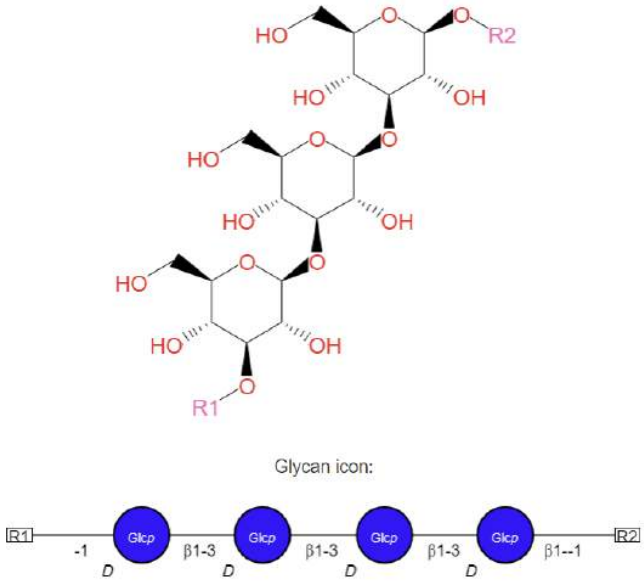

Figure 32.7.4: Paramylon. https://biocyc.org/compound?orgid=ME...ylon#tab=STRUC

ALGAE CELL WALLS

In a previous chapter, we discussed the use of lignocellulosic feedstocks from plant cell walls to produce bioethanol. Both microalgae and macroalgae (red, green, and brown) have cellulose, a β(1,4) glucose polymer, in their cell walls. It is found in Chlorophyta, Dinophyta, Phaeophyta, Prymnesiophyceae, Rhodophyceae, and Xanthophyceae. There is little or much less lignin in algae and apparently none in macroalgae. In addition, there is less hemicellulose. These characteristics make algae excellent candidates for feedstocks for third-generation bioethanol production. There are problems to overcome as well. For example, the cell wall of G*laucocystis nostochinearum* is almost 90% crystalline microfibrils, which adds to its physical and chemical stability. In addition, there are other glycans in some algae's extracellular matrix/cell wall, which can make it difficult to extract and use cellulose. Extracted cellulose can also be used as a feedstock for the chemical industry as well for the synthesis of bioplastics, a topic we will consider in another chapter sections.

Algae cellulose synthesis is performed by membrane-bound cellulose synthase terminal complexes (TCs), with the geometry of the cellulose microfibrils determined by the geometry of the TCs, as shown in Figure 32.7.5. The TCs are arranged in a hexagon with C6 symmetry, and they can form hexameric macrofibrils.

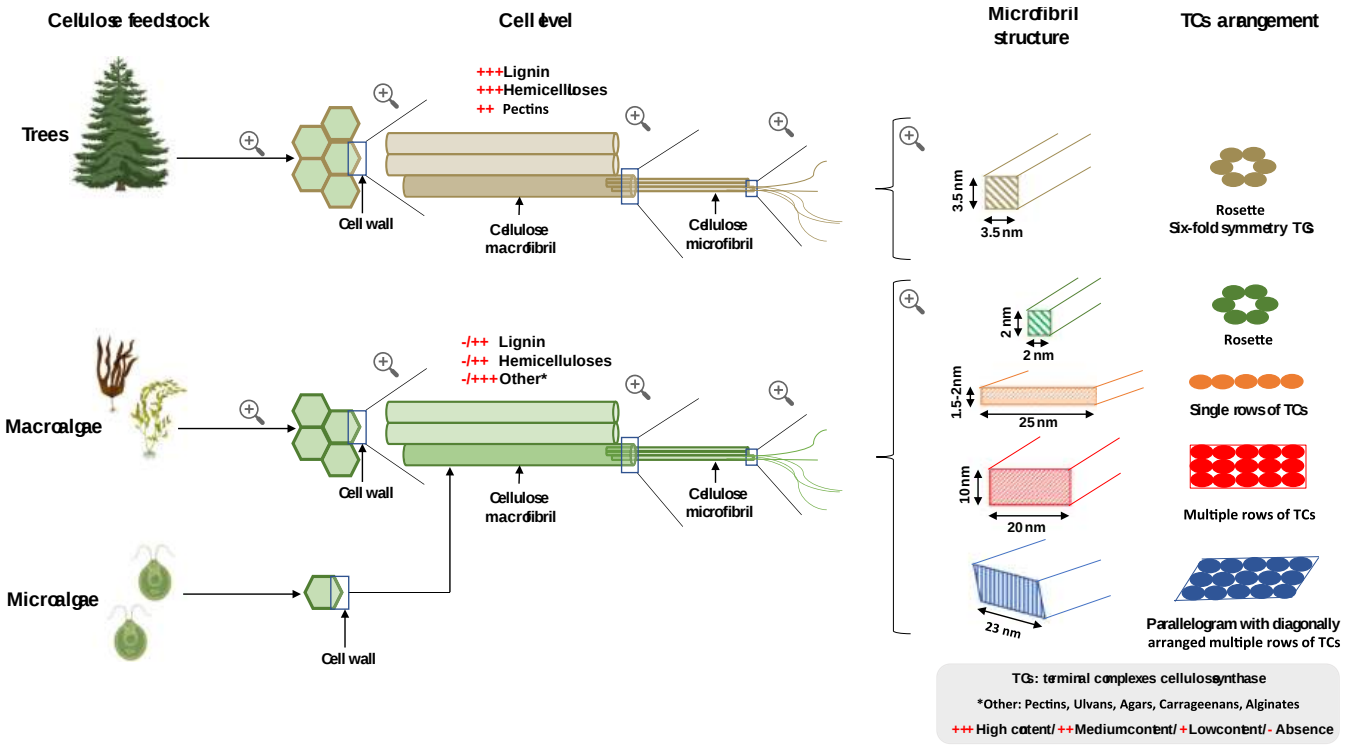

Figure 32.7.5: Organization and morphology of cellulose synthesizing terminal complexes (TCs) in different organisms. Wahlström, N. *et al. Cellulose* **27**, 3707–3725 (2020). https://doi.org/10.1007/s10570-020-03029-5. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/.

Table 32.7.1 below shows the different algae taxa's major polymers in the cell wall and extracellular matrix.

Algal taxa	Crystalline polysaccharides	Hemicelluloses	Matrix polysaccharides
Chlorophyta (green algae)	Cellulose	Xyloglucans, xylans, mannans, glucuronan, (1 → 3)-β-glucan, (1 → 3), (1 → 4)-β-glucan	Ulvans, pectins
Charophyceae (green algae)	Cellulose	Xyloglucans, xylans, mannans, (1 → 3)-β-glucan, (1 → 3),(1 → 4)-β-glucan	Pectins
Phaeophyceae (brown algae)	Cellulose	Sulfated xylofucoglucan, sulfated xylofucoglucuronan, (1 → 3)-β-glucan	Alginates, fucoidans
Rhodophyta (red algae)	Cellulose, (1 → 4)-β-mannan, (1 → 4)-β-xylan, (1 → 3)-β-xylan	Xylans, mannans, glucomannans, sulfated (1 → 3),(1 → 4)-β-glucan, (1 → 3),(1 → 4)-β-xylan	Agars, carrageenans, porphyran
Dinophyta	Cellulose	–	–

Table 32.7.1: Major polymers found in the cell wall and extracellular matrix of different algae taxa. Enio Zanchetta et al., Algal Research, 56 (2021). https://doi.org/10.1016/j.algal.2021.102288.

The percent composition of cellulose, hemicellulose and lignin for bioethanol production is important. Table 32.7.2 shows the % composition of these polymers based on **total dry weight**. (Note: The values for Chlorophyta/Ulvophyceae are highlighted in yellow in both Tables 2 and 3 for convenience of comparision.

Empty Cell	Phylum/class	Strain	Cellulose [%]	Hemicellulose [%]	Lignin [%]

Table 32.7.3: Cellulose, hemicellulose, and lignin content **in the cell wall** of algal feedstock. n.d.: not determined, det.: detected (either directly or indirectly), abs.: absent. Zanchetta et al, ibid.

Note the complete absence of lignin in the cell walls of macroalgae, but the previous table does show some presence in some macroalgae as a whole.

OTHER CELL WALL-ASSOCIATED GLYCANS FOR BIOETHANOL PRODUCTION.

Macroalgae offer an abundant source of other glycans, three of which we describe below. Each requires unique sets of enzymes to convert them to free glucose for fermentation and bioethanol production.

Alginates

These are among the most abundant biopolymers in the world and are the prime carbohydrate in brown seaweeds, where they can reach up to 40% of the dry mass. It is found in the **cell walls** of macroalgae. They are already used for food or other commercial uses. For example, they are used as thickening agents in food and are also used in the textile industries.

The alginate (high in brown algae) is a linear polymer of 1,4-β-D-mannuronic acid (M) and 1,4 α-L-guluronic acid (G) monomers, with stretches (blocks) of pure G, pure M, and mixed MG. Representative structures are shown in Figure 32.7.6 below.

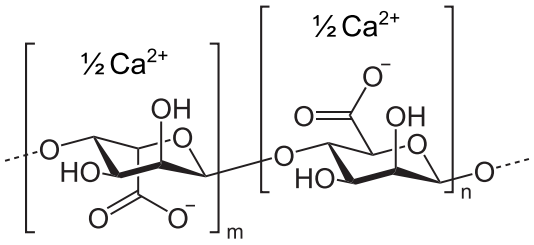

Figure 32.7.6: Left - https://commons.wikimedia.org/wiki/F...e_skeletal.svg; Right - https://biocyc.org/META/NEW-IMAGE?ty...bject=ALGINATE

Agar/Agarose

Agar is abundant in red seaweed. Agar, used in labs, is a mixture of agarose and agaropectin. It acts as a **support for the cell wall** and detaches with boiling. Agarose is a linear polymer of a disaccharide repeating unit of D-galactose and 3,6-anhydro-L-galactopyranose linked by α(1,3) and β(1->4) glycosidic bonds. It has many uses in the laboratory (agarose for chromatography and electrophoresis while agar for cell culture). Its structure is shown in Figure 32.7.7 below.

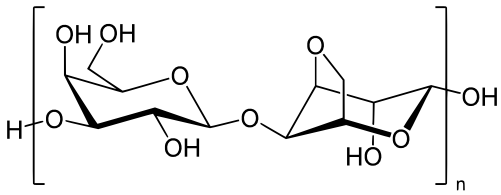

Figure 32.7.7: Agarose. Left - https://commons.wikimedia.org/wiki/F...e_polymere.svg; Right - https://biocyc.org/compound?orgid=ME...oses#tab=STRUC

Carrageenans

These are linear sulfated glycans found **in the cell walls** of red seaweeds (*Rhodophyta*). They have widespread use in the food industry and are used for thickening. They are similar to glycosaminoglycans (GAGs). Their repeating motif is a disaccharide of an α(1,3)-linked D-galactose and a β(1,4)-linked D-galactose. As with GAGs, their degree of sulfation can vary from 15-40%. Different subtypes have a different number of sulfates in the repeating disaccharide unit. For example, the κ form has one, iota (ι) has two, and λ has 3. Representative structures are shown in Figure 32.7.8 below.

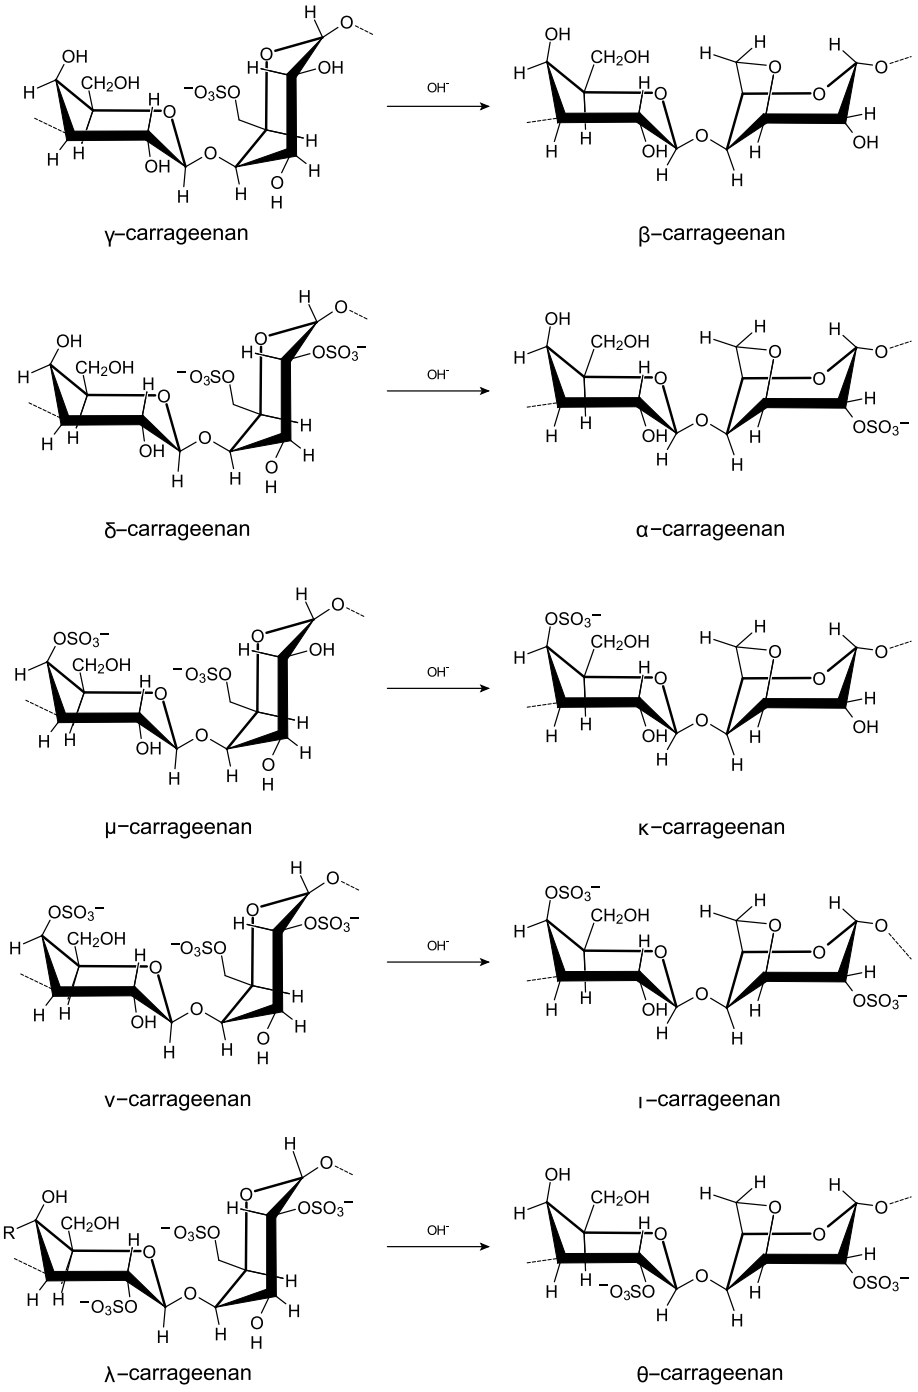

Figure 32.7.8: Carrageenans. https://upload.wikimedia.org/wikiped...enan_types.svg

Variants include the carrageenoses, in which the α(1,3)-linked galactose has a 3,6-anhydro bridge. The carrageenoses are often just called carrageenan. Their structure is shown in Figure 32.7.9.

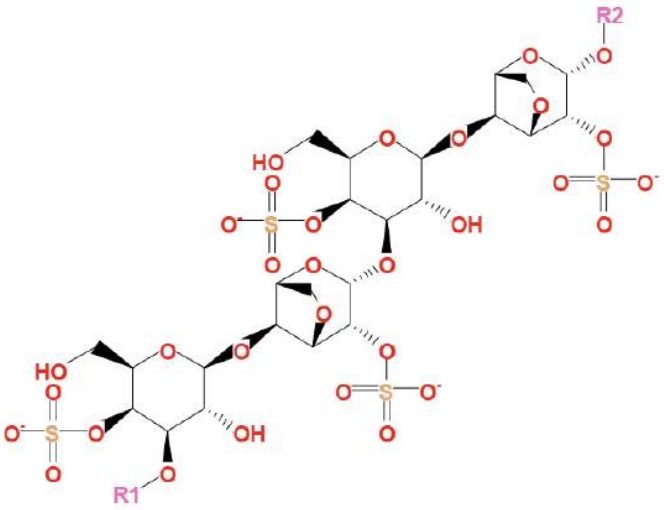

Figure 32.7.9: https://biocyc.org/compound?orgid=ME...enan#tab=STRUC

The 6-anhydro-D-galactose is not fermentable, so microorganisms that can contain enzymes that degrade carrageenan must also be used.

BIOETHANOL PRODUCTION

Now we can put all of this together and make bioethanol from algae. Figure 32.7.10 presents an overview of the entire process.

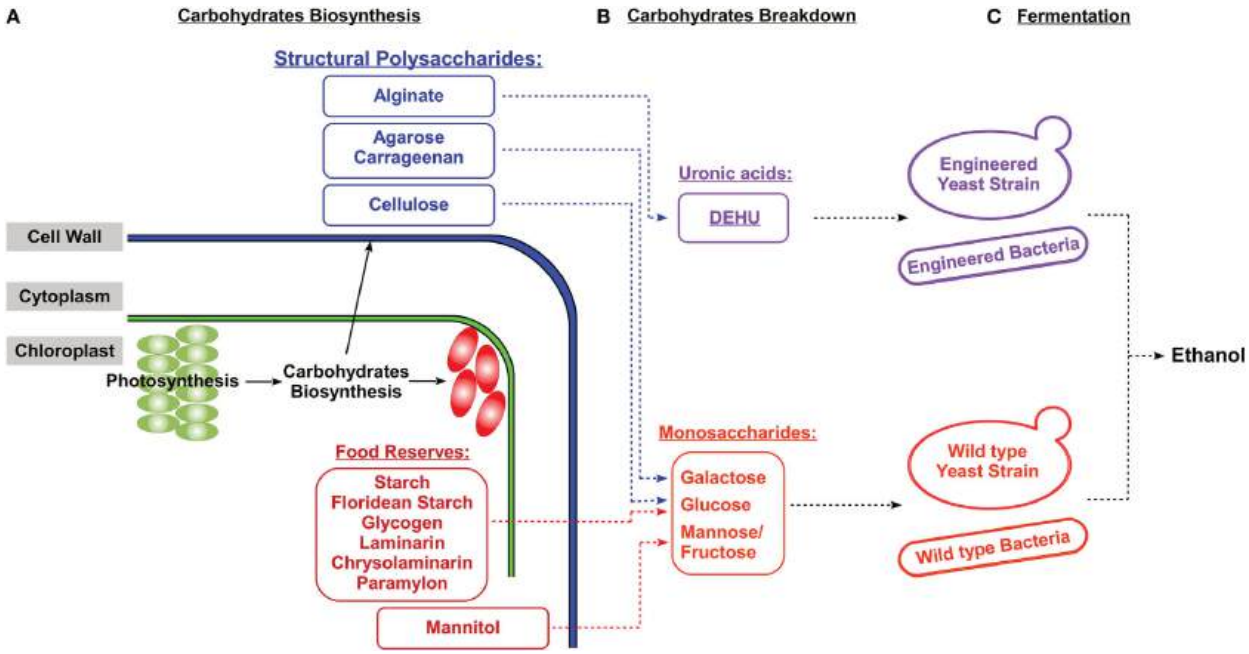

Figure 32.7.10: Overview of ethanol production from major algal carbohydrates. Qusai Al Abdallah et al., Front. Energy Res., 04 November 2016. https://doi.org/10.3389/fenrg.2016.00036. Creative Commons Attribution License (CC BY).

Panel **(A)** shows algae store simple sugars in the form of simple and complex food reserves and as structural polysaccharides.

Panel **(B)** shows how food reserves and structural polysaccharides are degraded into their basic monosaccharides and uronic acids.

Panel **(C)** shows the final fermentation into ethanol using microbial wild-type strains or their genetically engineered counterpartsDEHU, 4-deoxy-l-erythro-5-hexoseulose uronic acid.

Figure 32.7.11 below shows a schematic diagram for converting the algae feedstocks to glucose using key glycan-cleaving enzymes. Note that the colors and shapes are **not** those recommended in the SNFG standard. Those standards show glucose and galactose as blue and yellow circles, respectively.

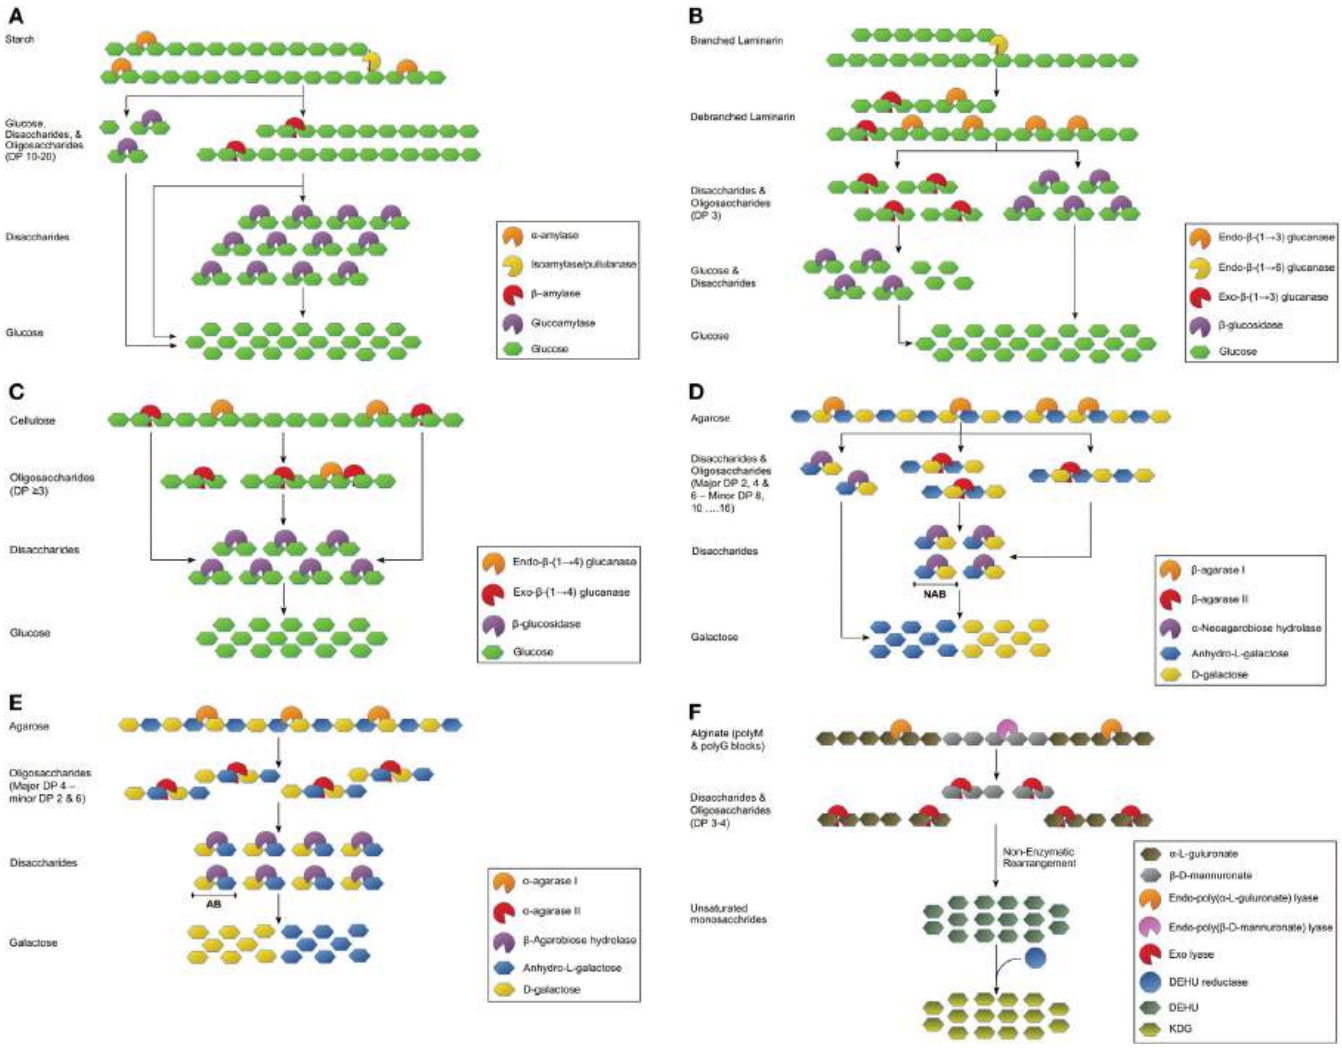

Figure 32.7.11: **SCHEMATIC DIAGRAMS FOR THE ENZYMATIC HYDROLYSIS OF ALGAL POLYSACCHARIDES. DP, degree of polymerization; NAB, neoagarobiose; AB, agarobiose; DEHU, 4-deoxy-l-erythro-5-hexoseulose uronic acid; KDG, 2-keto-3-deoxy-gluconate; M, β-d-mannuronate; G, α-l-guluronaten.

Macroalgae offer enormous advantages for producing food, bioethanol, and intermediates for conversion into bioplastics. Ocean macroalgae don't require irrigation or pesticides, or fertilizers! Figure 32.7.12 below shows rope and raft ocean cultivation of macroalgae.

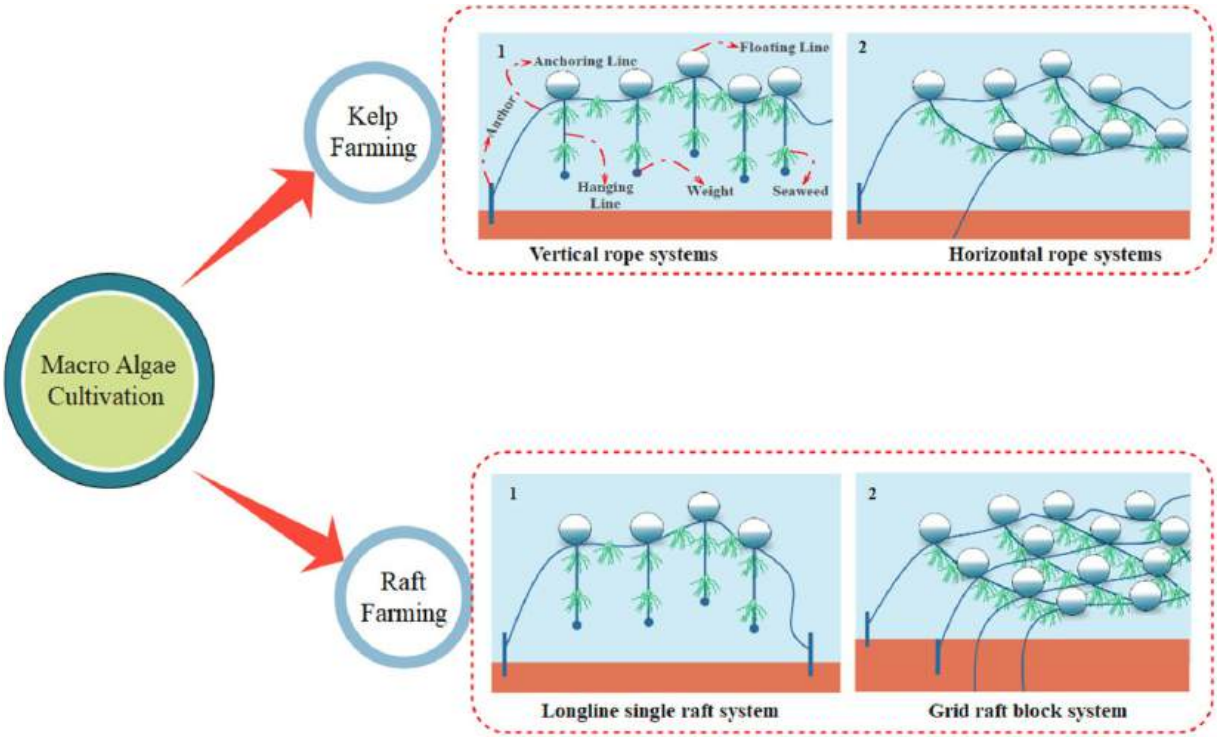

Figure 32.7.12: Macroalgae cultivation systems. Godvin Sharmila V et al. **Bioengineered,** Volume 12, 2021. https://doi.org/10.1080/21655979.2021.1996019. Creative Commons Attribution License (http://creativecommons.org/licenses/by/4.0/)

Figure 32.7.13 below summarizes how macroalgae (as well as microalgae) can be used to produce a variety of biofuels in addition to bioethanol. The algae cell can be chemically processed to produce hydrogen, methane, and syngas for fuels or combusted (as in the use of wood and coal) to provide heat and electricity. Alternatively, the post-harvest algae can be fractionated to produce carbohydrates for alcohol production, straight vegetable oils (SVO - pure triacylglycerols) for fuel, and fatty acid esters (biodiesel). Of course, they can be used directly as food and for food products.

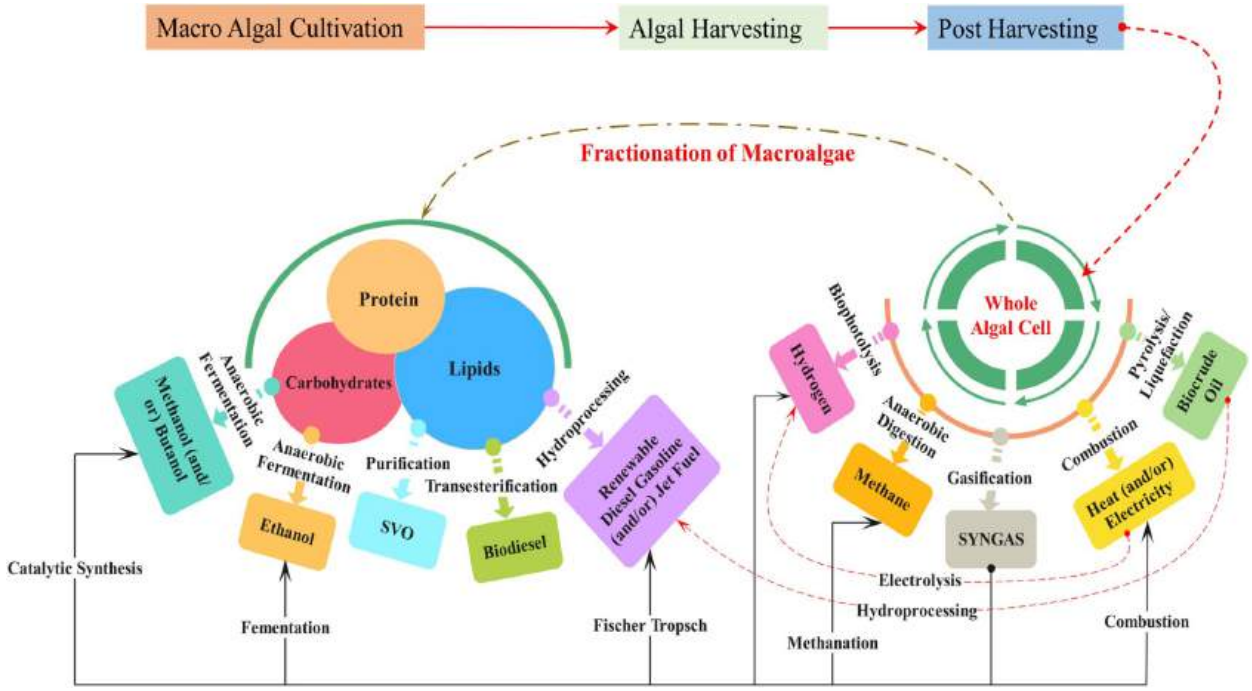

Figure 32.7.13: Macroalgal biofuel refinery. Godvin Sharmila V et al., ibid.

Table 32.7.4 below details the species and methods presently used to produce biofuel from macroalgae.

Type of Biofuel	Species Type	Pretreatment methods or Conversion techniques	Pretreatment or conversion technique conditions	Biofuel Yield or production potential
Biodiesel	*Ulva fasciata*	Catalytic transesterification	Molar ratio of methanol: oil – 9:1; Time – 6 hours; Temperature – 80-100°C	88%
	Chaetomorpha antennina	Transesterification	Chloroform-ethanol solvent- 1:20 (w/v)	2.1 mL/10 $g_{biomass}$
	Gracilaria corticata	Transesterification	Hexane-ether solvent – 1:20 (w/v)	2 mL/10 $g_{biomass}$
	Ulva intestinalis	Transesterification	-	32.3 mg/g dw
	Enteromorpha compressa	Base transesterification	Base – 1% NaOH, Methanol–oil ratio – 9:1, Temperature – 60°CTime – 70 min	90.6%
Bioethanol	*Chaetomorpha linum*	Wet oxidation method	Temperature – 200°C	44 g ethanol/100 g glucan
	Saccharina japonica	Low acid pretreatment	Acid – 0.06% (w/w) sulfuric acidTemperature – 170°CTime – 15 min	6.65 g/L

	Laminaria japonica	Packed tube reactor pyrolysis	Temperature – 500°C	45.8 wt.%
	Undaria pinnatifida	Packed tube reactor pyrolysis	Temperature – 500°C	37.5 wt.%

Table 32.7.4: Biofuel production from macroalgae. Godvin Sharmila V et al., ibid.

We will discuss in another chapter the production of biodiesel from algae.

KEY POINTS - BETA VERSION FROM CHAT.OPENAI

1. Algae can be used to produce bioethanol, a biofuel that is similar to traditional ethanol produced from corn or sugar cane.
2. Algae-based bioethanol production involves the cultivation of algae, followed by the extraction of sugars and the fermentation of these sugars to produce ethanol.
3. Algae have a high growth rate and high sugar content, making them a potential source of bioethanol.
4. The process of bioethanol production from algae is being commercialized, and research is ongoing to improve the efficiency and cost-effectiveness of the process.
5. Algae-based bioethanol production has several advantages over traditional bioethanol production methods, such as the ability to grow algae in non-arable land and the ability to produce bioethanol from CO2 and sunlight.
6. The algae-based bioethanol production process, is considered more sustainable and environmentally friendly than traditional bioethanol production methods, as it does not compete with food crops for resources and consumes CO2 during production.

32.8: BIODIESEL, SYNGAS AND BIOAVIATION FUELS

Search Fundamentals of Biochemistry

Diesel fuel was used in 1900 in an engine designed by Rudolf Diesel. The fuel was peanut oil. That might have worked fine in 1900, but a century later, the demands for diesel fuel are met not by peanut oil, a legume, but by oil. Gasoline (petrol) consists of molecules containing 5-12 carbons compared to diesel at 12-20. Both are obtained through fractional distillation of oil (petroleum). Diesel has a higher boiling and melting point and releases more energy per liter (36.9 vs. 33.7 MJ) than gasoline. Regular gasoline contains about 17% n-alkanes, 32% branched alkanes, 5% cycloalkanes, 2% alkenes (olefins), and 30% aromatics. High octane gas can contain around n- and branched alkanes, with the rest from alkenes. Diesel fuel contains about 75% saturated hydrocarbons and 25% aromatics, including alkylbenzenes and napthalenes. In a diesel engine, ignition occurs on compression of the fuel and air mixture and doesn't require a spark. They use glow plugs which provide heat but not spark.

BIODIESEL

Oils (triacylglycerol) produced from biomass can be converted to diesel fuel. In the following sections, we will discuss the synthesis of gases and liquid fuels from nonpetroleum sources such as biomass through the creation of the synthetic gases H_2 and CO (collectively called syngas) and their condensation into liquid fuels using the Fischer-Tropsch reaction. This section will limit our discussion to using fats to create biodiesel. Triacylglycerols for biodiesel production can come from plants, animals, algae, and even waste oils from the food industry. Because biodiesel fuel is composed of carbon-based molecules (often fatty acid esters) with high melting and boiling point ranges which hamper its utility in cold climates, it is often blended with regular diesel (for example, a 20% **b**lend called **B**20). Still, it can be used at 100% (B100). Biodiesel enriched in unsaturated fatty acids has lower melting points and fewer problems in cold weather.

As will the production of bioethanol from lignocellulosic food stocks, biodiesel production has evolved through multiple generations, as shown in Figure 32.8.1 below.

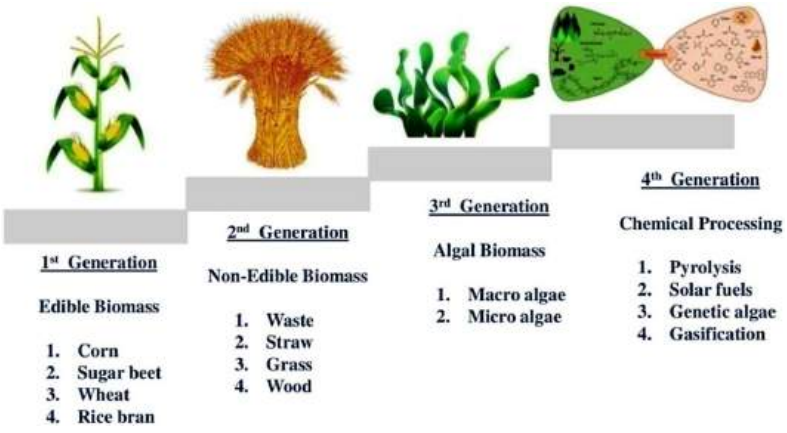

Figure 32.8.1: Palani Vignesh et al., Oil Gas Sci. Technol. – Rev. IFP Energies nouvelles, 76 (2021) 6. DOI: https://doi.org/10.2516/ogst/2020088. Creative Commons Attribution License (https://creativecommons.org/licenses/by/4.0)

Table 32.8.1 below shows the advantages and disadvantages of each generation of biodiesel.

Biodiesel generation	Advantages	Disadvantages
1st generation biodiesel	1. Low emission of greenhouse gas. 2. Easy and low-cost technology for conversion.	1. Yield is inadequate to meet the demand. 2. Causes food shortages. 3. High land footprint.
2nd generation biodiesel	1. Using food waste as a feedstock. 2. Use of non-agricultural land to grow a limited amount of crops.	1. Costly pre-treatment. 2. Sophisticated technology is used to transform biomass into fuel.
3rd generation biodiesel	1. Simple to grow algae. 2. No competition for the use of food crops; wastewater, and seawater can be used.	1. More resource usage for algae cultivation. 2. Low lipid level or biomass accumulation in algae.
4th generation biodiesel	1. High biomass and production yield. 2. More capability to eliminate CO_2.	1. The cost of the bio-reactor is higher. 2. At the early stage of research, a high investment is needed.

Table 32.8.1: Advantages and disadvantages of various biodiesel generations. Palani Vignesh et al., ibid

Triacylglycerol feedstocks for biodiesel are often converted to methyl or ethyl esters through an alcoholysis or transesterification reaction, as shown in Figure 32.8.2 below.

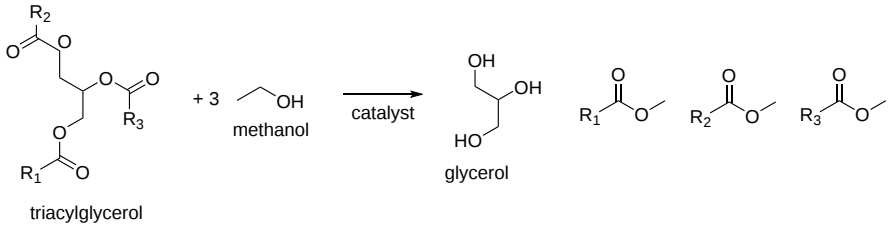

Figure 32.8.2: Methanolysis/transestiferation of triacylglycerol to produce methyl-fatty acid ester for biofuels

This reaction is simply a base-catalyzed cleavage of the ester bonds in the triacylglycerol. Alternatively, vegetable oil can be treated at high pressure and temperature in a hydrogenation reaction to produce a variant called "renewable diesel".

Figure 32.8.3 below shows feedstocks and processing for first-generation biodiesel production.

Feedstock: Processing Method	1st Gen Processing
Waste cooking oil: esterification/transesterification Food crops: extraction/transesterification Organic oils: hydrolysis, distillation Animal fat: hydrolysis, fermentation Bioethanol/butanol: chemical synthesis	
Figure 32.8.3: Feedstocks and processing for first-generation biodiesel production. Palani Vignesh et al., ibid

Figure 32.8.4 below shows feedstocks and processing for second-generation biodiesel production

Feedstock: Processing Method	2nd Gen Processing
Cellulose: advanced fermentation Hemicellulose: hydrolysis Lignin: gasification Tannins: biological synthesis Vegetable oil/animal fats: hydrogenation	
Figure 32.8.4 below shows feedstocks and processing for second-generation biodiesel production. Palani Vignesh et al., ibid

Finally, Figure 32.8.5 below shows the processing steps for 3rd and 4th generation biodiesel from algae.

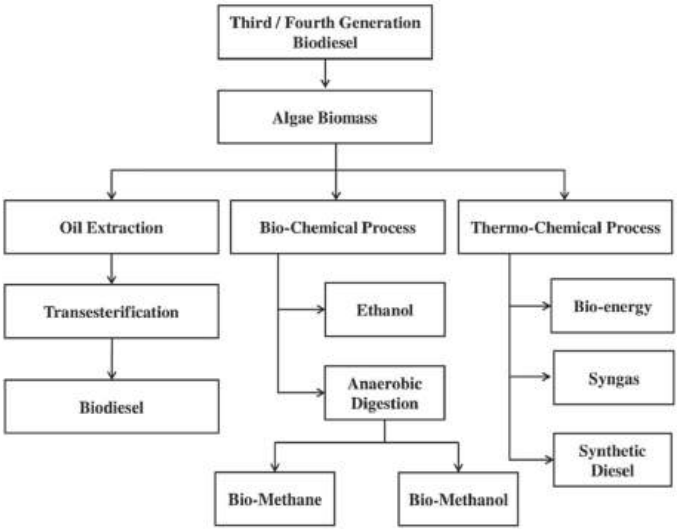

Figure 32.8.5: Processing steps for 3rd and 4th generation biodiesel from algae. Palani Vignesh et al., ibid

Let's consider 3rd and 4th generation biodiesel production using algae. First, algae can be used to produce many different products that can be used for biofuels and chemical feedstocks. These are reviewed in Figure 32.8.6 below.

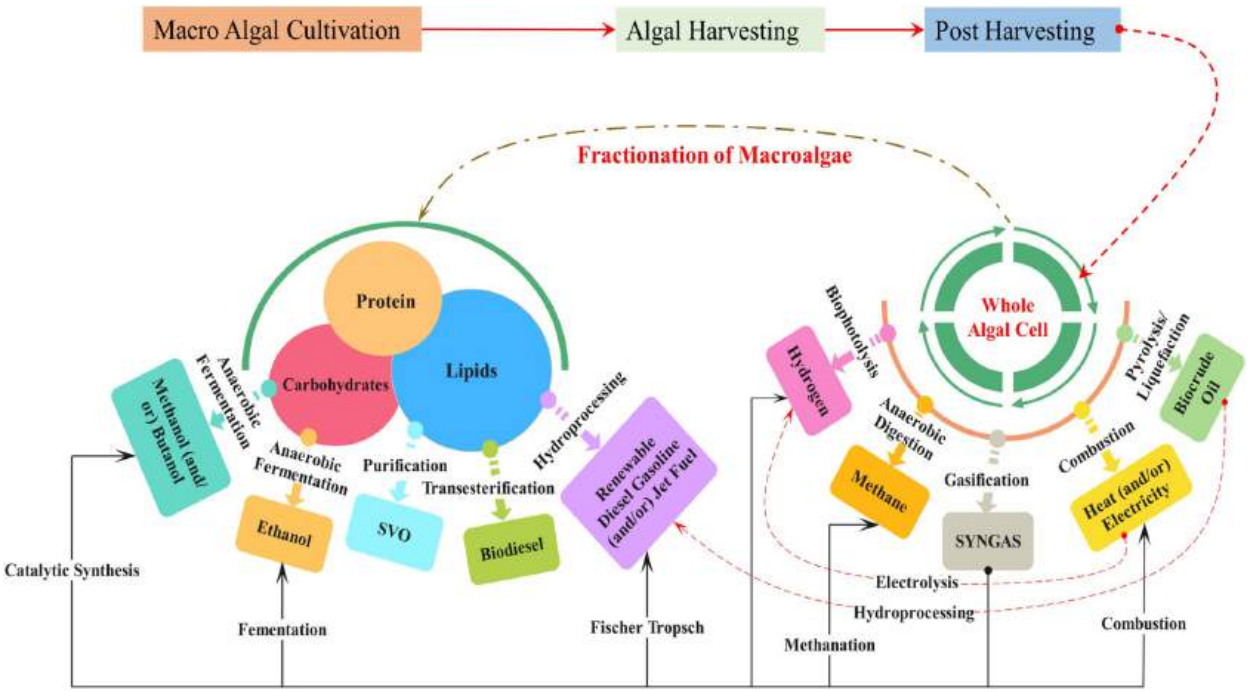

Figure 32.8.6: Macroalgal biofuel refinery; Godvin Sharmila V et al., Bioengineered. 2021 Dec;12(2):9216-9238. doi: 10.1080/21655979.2021.1996019. PMID: 34709971; PMCID: PMC8809944. Creative Commons Attribution License (http://creativecommons.org/licenses/by/4.0/)

To maximize biodiesel production from algae (3rd and 4th generation), steps in the anabolic pathways for fatty acid and triacylglycerol synthesis could be genetically modified. Below is an overview of triacylglycerol synthesis in microalgae in Figure 32.8.7.

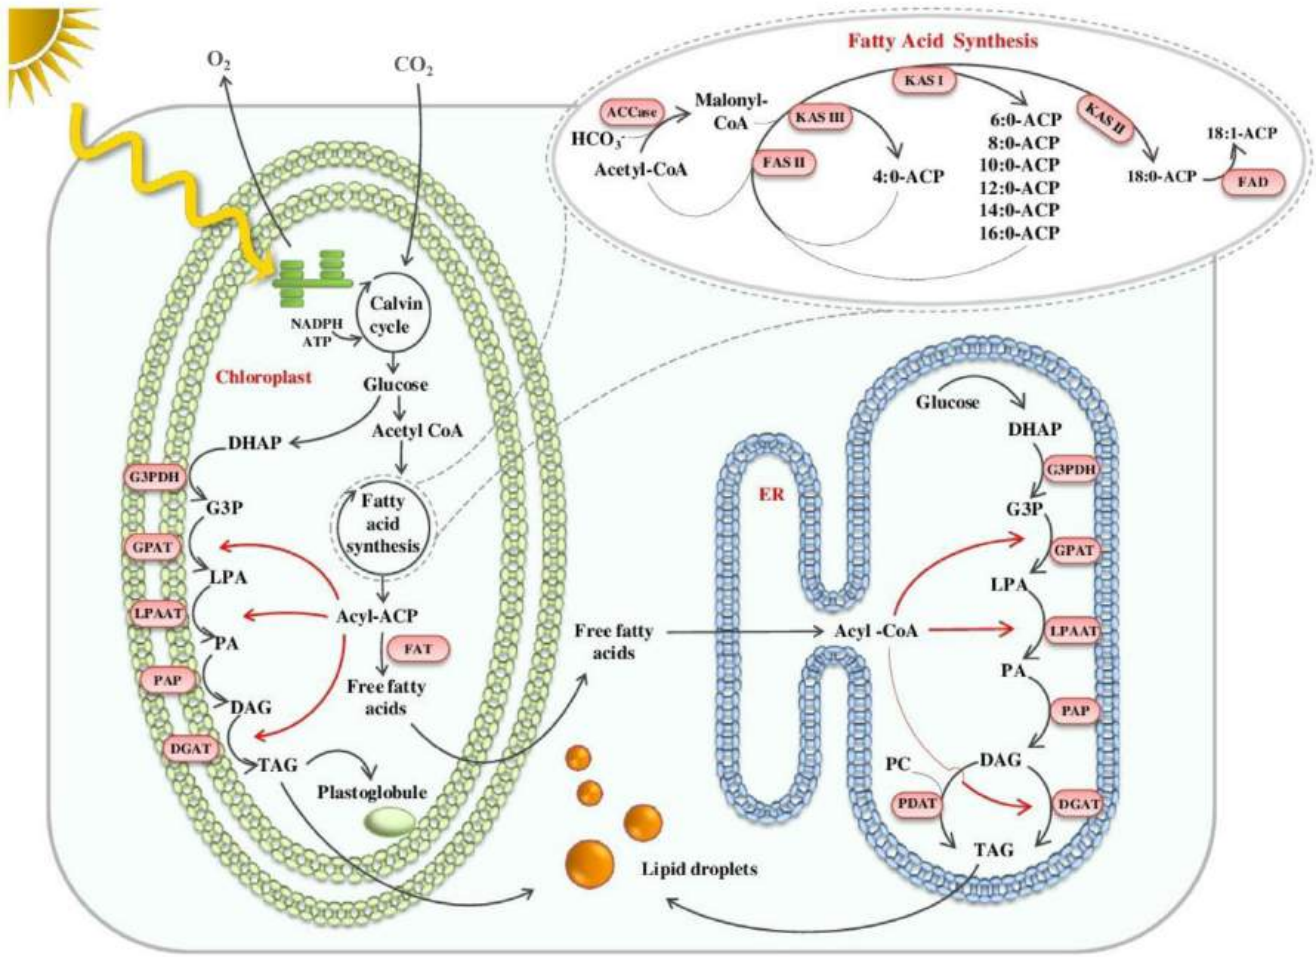

Figure 32.8.7: Schematic illustration of TAG synthesis in microalgae. NADPH; Nicotinamide adenine dinucleotide phosphate; ATP, Adenosine Triphosphate; DHAP, dihydroxyacetone phosphate; G3P/G3pDH, Glyceraldehyde 3-phosphate / G3P dehydrogenase; GPAT, Glycerol 3-phosphate acyltransferase; PA/LPA/LPAAT/PAP, Phosphatidic acid/Lyso-PA/LPA acyltransferase/PA phosphatase; DAG/DGAT, di-Acylglycerol/ DAG acyltransferase; FAT, Fatty acyl-ACP thioesterase; ACP, Acyl-carrier protein; ER, Endoplasmic reticulum; PC, Phosphatidylcholine; PDAT, Phospholipid: DGAT; ACCase, Acetyl-CoA carboxylase; FAS, Fatty acid synthase; KAS, 3-ketoacyl-ACP synthase; FAD, Flavin adenine dinucleotide. Sharma PK, et al. *Front. Mar. Sci.* 5:382, 2018. doi: 10.3389/fmars.2018.00382. .

Each step in the combined pathways are sites for optimization, as shown in Figure 32.8.8 below.

Sharma PK, et al., ibid

Life cycle analyses for 3rd generation biodiesel production indicate they would lead to a net decrease in CO_2 emissions, but most appear incomplete in their analyses.

SYNTHETIC GAS (SYNGAS)

As an alternative to using fossil fuels as an energy stock to power our vehicles and as feedstock for chemical production, what if biomass could produce "gasoline-like" fuel for these purposes? We have already discussed the production of bioethanol from 1st (plant starch), 2nd (lignocellulose) and 3rd (algal) generation feedstocks. It is routinely added to gasoline to upward of 15%. It is also found in E85 (or flex fuel), a gasoline blend containing 50% to 80% ethanol.

Instead of producing ethanol through the fermentation of glucose, wood could be incompletely burned to create **"synthetic gases"** (CO and H_2), called syngas, which could be further burned in vehicles to power them or converted through chemical processes (Fisher-Tropsh reaction) to liquid organic fuels.

Indeed, when fossil fuels were lacking, wood was used to create syngas power vehicles. Up to a million cars were powered by wood gas in Europe during World War II. A bus powered by wood gas (syngas) generated by a gasifier on a trailer is shown in Figure 32.8.9 below.

Figure 32.8.9: Bus power by wood gas c. 1943 in Leeds, England. By Ministry of Information Photo Division Photographer, Smith Norman? - http://media.iwm.org.uk/iwm/mediaLib.../large.jpgThis is photograph D 15675 from the collections of the Imperial War Museums., Public Domain, https://commons.wikimedia.org/w/inde...curid=24364067

The syngas emitted was cleaned up somewhat to remove tars and soot/ash particles by passing through charcoal before entering the vehicle through a tube. Tars with polycyclic aromatic hydrocarbons and methane could be lowered if wood or coals were first converted to char before use in a process called **pyrolysis** (heating to high temperatures in the relative absence of air).

The gases, derived from the incomplete combustion of the wood, have CO and H_2 in various proportions depending on the temperature of burning and the source (wood, coal). A general and very simplified reaction for the incomplete combustion reaction is:

$$\text{Carbon feedstock } + \text{ air } \rightarrow CO + H_2 + CH_4 + CO_2 + H_2O + N_2 \tag{32.8.1}$$

Of course, the reaction is not clean, and many organic side products are produced.

The relative ratios of CO and H_2 produced can be changed by the addition of water in a second reaction called the **water gas shift (WGS) reaction** (as water shifts the ratio of CO to H_2):

$$CO + H_2O \leftrightarrow CO_2 + H_2 \quad (\Delta H = -41.2\ \text{kJ/mol.}) \tag{32.8.2}$$

If run in reverse (rWGS) and at high temperatures, the water shift reaction would be a way to capture carbon. The H_2 could come from the electrolysis of water

$$2H_2O(I) \rightarrow 2H_2(\ g) + O_2(\ g) \quad (\Delta H = 286\ \text{kJ/mol}) \tag{32.8.3}$$

The electrocatalytic reduction of CO_2 and H_2O to produce syngas is shown in 32.8.10.

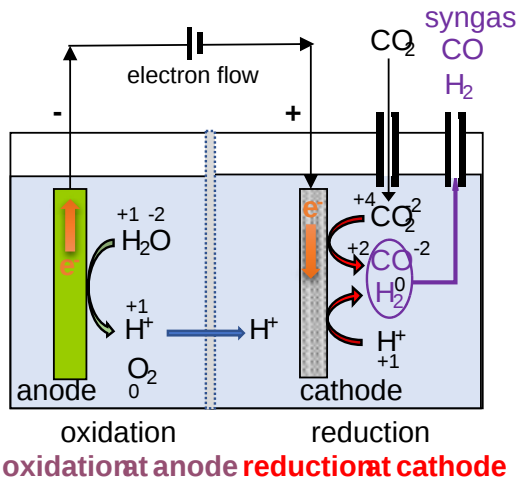

Figure 32.8.10: Syngas Generation by electrocatalytic reduction of CO_2 and H_2O. (after Kang Cheng et al. Advances in Catalysis, 60 (2017). https://doi.org/10.1016/bs.acat.2017.09.003

The oxidation numbers of each element are shown in the diagram. The cathode acts as a catalyst for the reaction. The reaction requires a power source, so this process is greener if electricity derived from green energy sources (wind/solar) is used.

ELECTROCATALYTIC REDUCTION OF CO_2 FOR SMALL MOLECULE FUEL AND CHEMICAL FEEDSTOCKS

Electrocatalytic CO_2 reduction (ECR) offers the potential to capture CO_2 before it is emitted into the air and convert it to small alkanes, alcohols, and acids for fuels (for example, methanol and ethanol) and chemical synthesis (for example, CO and formate). Again this would require a clean source of electricity to power these endergonic reactions. Table 32.8.2 below shows the standard reduction potentials for a variety of half-reactions that could be coupled to form the main ECR products.

Products	Acid		Base	
	Equation	*E*(V)	Equation	*E*(V)
Hydrogen	$2H^+ + 2e^- \rightarrow H_2$	0.000	$2H_2O + 2e^- \rightarrow H_2 + 2OH^-$	−0.828
Carbon monoxide	$CO_2 + 2H^+ + 2e^- \rightarrow CO + H_2O$	−0.104	$CO_2 + H_2O + 2e^- \rightarrow CO + 2OH^-$	−0.932
Methane	$CO_2 + 8H^+ + 8e^- \rightarrow CH_4 + 2H_2O$	0.169	$CO_2 + 6H_2O + 8e^- \rightarrow CH_4 + 8OH^-$	−0.659
Methanol	$CO_2 + 6H^+ + 6e^- \rightarrow CH_3OH + H_2O$	0.016	$CO_2 + 5H_2O + 6e^- \rightarrow CH_3OH + 6OH^-$	−0.812
Formic acid/formate	$CO_2 + 2H^+ + 2e^- \rightarrow HCOOH$	−0.171	$CO_2 + H_2O + 2e^- \rightarrow HCOO^- + OH^-$	−0.639
Ethylene	$2CO_2 + 12H^+ + 12e^- \rightarrow C_2H_4 + 4H_2O$	0.085	$2CO_2 + 8H_2O + 12e^- \rightarrow C_2H_4 + 12OH^-$	−0.743
Ethane	$2CO_2 + 14H^+ + 14e^- \rightarrow C_2H_6 + 4H_2O$	0.144	$2CO_2 + 10H_2O + 14e^- \rightarrow C_2H_6 + 14OH^-$	−0.685
Ethanol	$2CO_2 + 12H^+ + 12e^- \rightarrow CH_3CH_2OH + 3H_2O$	0.084	$2CO_2 + 9H_2O + 12e^- \rightarrow CH_3CH_2OH + 12OH^-$	−0.744
Acetic acid/acetate	$2CO_2 + 8H^+ + 8e^- \rightarrow CH_3COOH + 2H_2O$	0.098	$2CO_2 + 5H_2O + 8e^- \rightarrow CH_3COO^- + 7OH^-$	−0.653
n-Propanol	$3CO_2 + 18H^+ + 18e^- \rightarrow CH_3CH_2CH_2OH + 5H_2O$	0.095	$3CO_2 + 13H_2O + 18e^- \rightarrow CH_3CH_2CH_2OH + 18OH^-$	−0.733

Table 32.8.2: Lei Fan et al. Science Advances. 21 Feb 2020, Vol 6, DOI: 10.1126/sciadv.aay3111. Creative Commons Attribution NonCommercial License 4.0 (CC BY-NC).

The reactions are complex and require CO_2 to adsorb onto the electrocatalytic surface of the cathode. Here is a possible reaction pathway for the conversion of CO_2 to methane:

$$CO_2 \rightarrow *COOH \rightarrow *CO \rightarrow *CHO \rightarrow *CH_2O \rightarrow *CH_3O \rightarrow CH_4 + *O \rightarrow CH_4 + *OH \rightarrow CH_4 + H_2O \qquad (32.8.4)$$

The catalysts employed are heterogeneous (i.e., not solution phase) and are typically organometallic transition metal structures. Possible reaction pathways to produce small CO_2 electrochemical reduction products are shown in Figure 32.8.11 below.

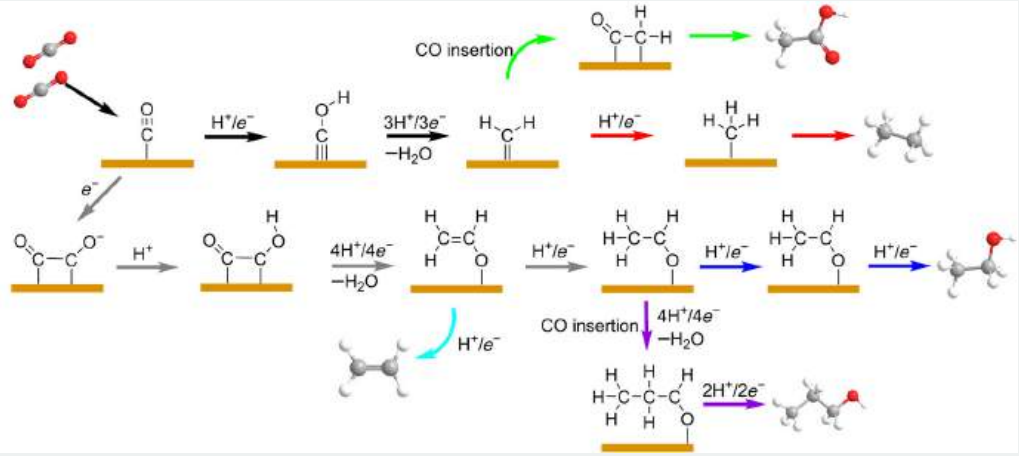

Figure 32.8.11: Possible reaction pathways to produce small CO_2 electrochemical reduction products. Lei Fan et al., ibid

This technology is early in development and will require the development of more robust catalysts and cells before it becomes commercially viable.

The synthesis of syngas (typically described as a mixture of CO, CO_2, and H_2) is widespread now, is used in various processes, and is used to make many products, including hydrocarbons for fuel and oxygen-containing derivatives, including methanol and ethanol. CO and H_2 react in the Fischer-Tropsch reaction (described below) to produce alkanes and alkenes.

$$CO + 2H_2 \rightarrow (CH_2) + H_2O \quad \Delta H = -165\ kJ/mol \tag{32.8.5}$$

where CH_2 is a methylene repeat in longer-chain alkanes.

The CO_2 produced in syngas can be somewhat selectively removed by adsorption onto a CaO catalyst, as shown in Figure 32.8.12 below.

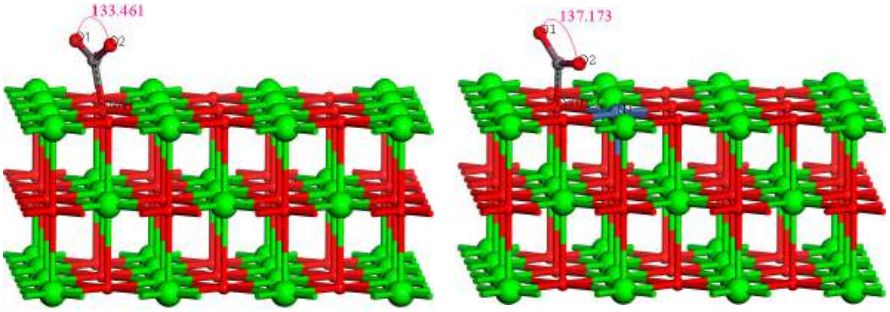

Figure 32.8.12: Adsorption configurations of CO_2 on the surfaces of CaO-based catalysts at 650 °C: (**a**) CO_2 adsorption on CaO (100) surface; (**b**) CO_2 adsorption on 10 wt % Ni/CaO (100) surface. Green, red, gray, and purple balls represent Ca, O, C, and Ni atoms. Zhao, B. et al. *Catalysts* **2019**, *9*, 757. https://doi.org/10.3390/catal9090757. Creative Commons Attribution (CC BY) license (**http://creativecommons.org/licenses/by/4.0/**)

The adsorption energies of CO, CH_4, and H_2 are so small that they have little effect on CO_2 adsorption.

At present, the easiest way to make syngas is to react natural gas (methane) and steam under very high temperatures (up to 1000ºC) over a Ni catalyst (a process called steam reforming). This results in a high H_2/CO ratio of about 3. It can be done with liquified natural gas using Ni-ZrO_2-CeO_2-La_2O_3 catalyst. This process inherently would do little to decrease CO_2 emissions. A **gasification** method converts coal, lignocellulosic biomass, and waste to syngas, with an H_2/CO ratio of <1 for coal and about 0.6-1 for biomass. The electrocatalytic method described above has an H_2/CO ratio of 0-2, depending on the nature of the cathodic catalyst. Syngas can also be made by the partial oxidation of methane. For the subsequent reactions (Fisher-Tropsch), the optimal H_2/CO is about 2. In the gasification of lignocellulosic biomass, the water gas shift (WGS) is used to increase the H_2/CO ratio. This requires lots of water and also produces CO_2 as a product. The water shift reaction use catalysts such as Co–Mo–Al_2O_3, Fe_2O_3–Cr_2O_3, and Cu–ZnO–Al_2O_3) for coal gasification.

Syngas can be used to make small molecule energy and chemical feedstocks, such as ethanol (as well as liquid alkanes and alkenes). Given the many different types of products, it is often essential to selectively make and purify products for commercial use. One method for ethanol production is shown in Figure 32.8.13 below.

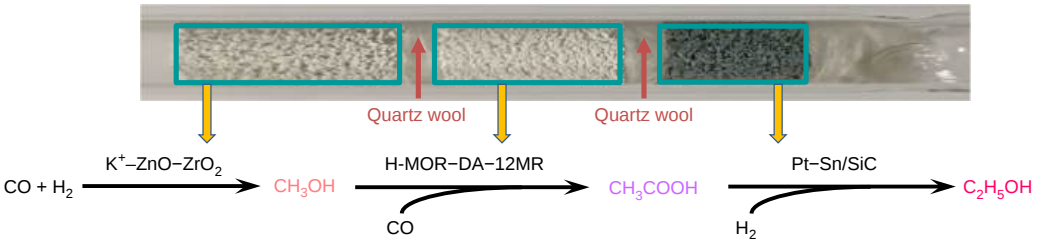

Figure 32.8.13: Conversion of syngas to ethanol proceeds through a tandem mechanism via methanol and acetic acid intermediates using a variety of sequentially positioned catalysts. Kang, J., He, S., Zhou, W. *et al.* Single-pass transformation of syngas into ethanol with high selectivity by triple tandem catalysis. *Nat Commun* **11**, 827 (2020). https://doi.org/10.1038/s41467-020-14672-8. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/.

H-MOR is a zeolite, which is a microporous, crystalline structure made of aluminosilicate.

In a steam reforming reaction, bioethanol could be converted to CO and H_2 as well, as shown in the equation below.

$$C_2H_5OH + H_2O(+ \text{ heat }) \rightarrow 2CO + 4H_2 \tag{32.8.6}$$

Even with the ability to capture CO_2 from the synthesis of syngas, a central issue of concern is whether the production of syngas and syngas-derived fuels and their use is associated with lower net CO_2 emissions. A life cycle analysis would be necessary to determine that.

FISCHER-TROPSCH SYNTHESIS (FTS) OF FUELS

Fischer was head of the Kaiser-Wilhelm Institute for Coal Research in Germany at the start of World War I. Germany had abundant coal but needed oil for the war, so his efforts were redirected toward that end. Fischer and Tropsch developed the water shift reaction discussed above. They deployed new cobalt catalysts to produce oil which ultimately covered 25% of car fuel and 10% of the German military fuel needs in World War II. Large amounts were also made in South African during the Apartheid regime as well.

The Fischer–Tropsch synthesis (FTS) is a polymerization-like reaction that is used to convert gas-to-liquids (GTL), coal-to-liquids (CTL), or biomass-to-liquids (BTL) fuels. It starts with syngas (H_2 and CO) produced from the gasification of coal/biomass or steam reforming/partial oxidation of natural gas), with the ratios of H_2/CO determined by the water-shift reaction. If coal or biomass is used, a cleanup of residual products with heteroatoms and metal ions is necessary. The clean syngas is then passed into a reactor containing the required catalyst to the FTS of fuels. These reaction systems are summarized in Figure 32.8.14.

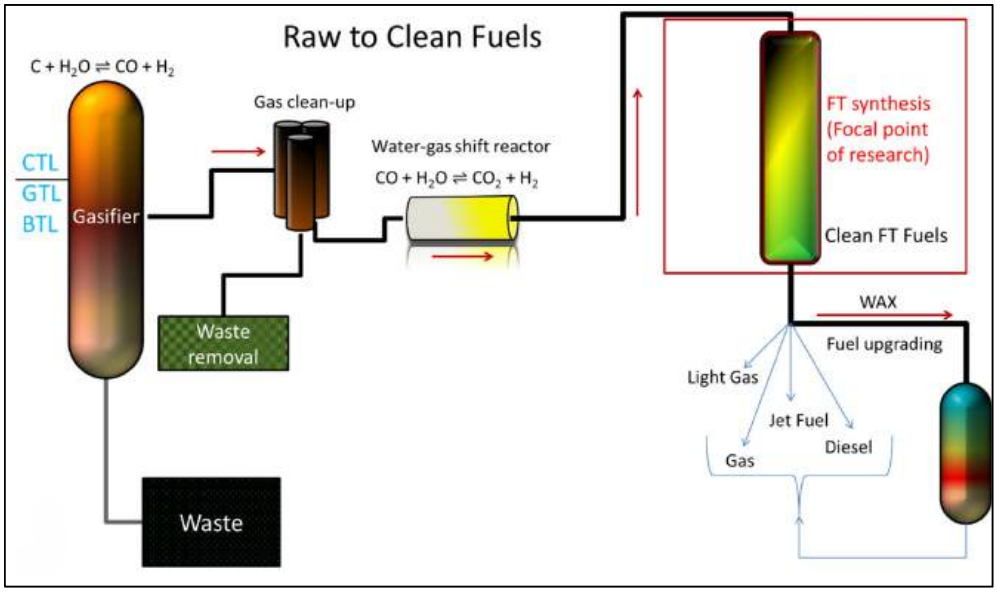

Figure 32.8.14: A simplified diagram of the Coal-to-Liquids (CTL), Gas-to-Liquids (GTL), and Biomass-to-Liquids (BTL) processes. Shafer, W.D.; Gnanamani, M.K.; Graham, U.M.; Yang, J.; Masuku, C.M.; Jacobs, G.; Davis, B.H. Fischer–Tropsch: Product

The FTS reaction is conducted at moderate temperatures and pressure to produce fuels (diesel and jet), lubricants, waxes, and chemical feedstocks. The main representative reactions are given by:

N-alkane production:

$$(2n+1)H_2(g) + nCO(g) \rightarrow C_nH_{2n+2} + nH_2O \quad (32.8.7)$$

Alkene production:

$$(2n)H_2(g) + nCO(g) \rightarrow C_nH_{2n} + nH_2O \quad (32.8.8)$$

The products can have from one carbon (CH_4) to over 70, depending on the catalyst, T, P, and H_2/CO ratio. The FTS is a polymerization reaction, which starts with adsorption of the gas to the catalytic surface, followed by multiple cycles of free radical initiation, propagation, termination, desorption, and reabsorption.

Since this book focuses on structure/function and reaction mechanisms, we would be remiss not to include at least a simplified mechanism for these complex reactions. Several mechanisms have been proposed. Since iron was/is used in the catalyst, and since iron can form iron carbides, Fisher proposed a carbide mechanism. A second enol mechanism has also been proposed. Both are shown in Figure 32.8.15 below.

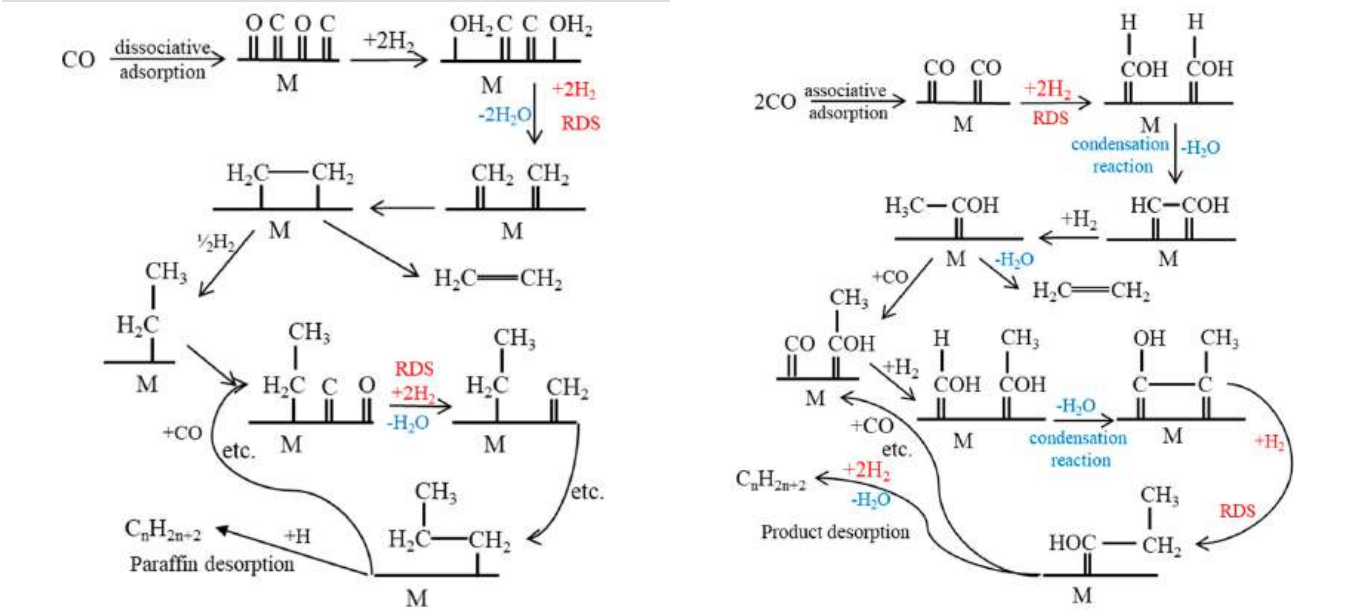

Figure 32.8.15: Proposed mechanisms for the Fischer-Tropsch reaction. Left: A proposed FTS route based on the carbide mechanism; Right: A proposed FTS route based on the enol mechanism. M is the metal surface.

In the carbide mechanism, CO adsorbs on the metal catalyst and dissociates in C and O atoms that cover the surface. These are hydrogenated to form H_2O and CH_2 (methylene), and H_2 adds as the reaction proceeds, as shown.

In the enol mechanism, CO adsorbs without dissociation into atoms. It reacts on the surface to surface-bound H atoms (that arise from the dissociation of adsorbed H_2) to form hydroxymethylene (M-CHOH). This enol grows on condensation with adjacent hydroxymethylenes. The rate-determining step is the hydrogenation of adsorbed CO.

Another proposed mechanism, CO insertion, is shown in Figure 32.8.16

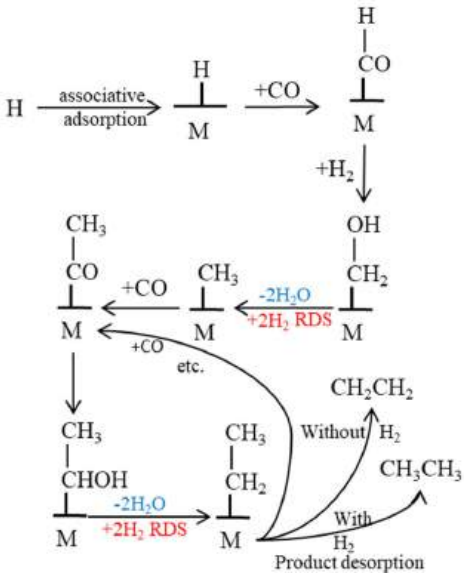

Figure 32.8.16: A proposed FTS route based on the CO insertion mechanism.

CO in this model inserts into a bond from a hydrogen atom to a metal on the catalyst. The rate-limiting step here is the hydrogenation of CO to the CH_2 methylene group. The assumed monomer for this mechanism is simply CO through its insertion into metal-carbon bonds.

Generally, the FTS reaction catalyst has either cobalt or iron ions. The metal catalyst can also be doped with potassium and copper ions and bind silica and alumina. Iron is abundant and cheap and better promotes the water-gas-shift reaction, so it is best for FTS synthesis of fuels from coal and biomass since syngas derived from them have a lower H_2/CO ratio.

CHEMICAL SYNTHESIS OF FOOD

If fuels can be synthesized from nonpetroleum sources and from agricultural waste, why not use the reactions described above (like syn gas production, the Fischer-Tropsch, and electrochemical reduction) to make food, not just fuel? The agricultural sector accounts for about 25% of total greenhouse gas emissions, so it is ripe (no pun intended) for novel ways to produce foodstuffs (think of them as feedstocks for human consumption).

It should be obvious from the chemistry, that the simplest type of food to create from these reactions is fats, and not the more synthetical and stereochemically complicated proteins and carbohydrates. Presently the world relies on palm oil derived from palm trees for fats found in crackers, cookies, breads. and other food products. Typical production of palm oil has been associated with large-scale deforestation of rainforests, with its associated climate and biosphere impacts. Americans consume about 8 kg (17.6 lbs) of palm oil products each year, including products like cosmetics, cleaning products, and waxes. Figure 32.8.17 below shows the scale of palm oil production in the world, which might come as a surprise since we more frequently encounter soybean, sunflower, rapeseed (source of canola oil), and olive oils in our stores.

Figure 32.8.17: Vegetable Oil Product in the World. Our World in Data. https://ourworldindata.org/palm-oil

The general chemical pathways used to chemically synthesize proteins, fat,s and carbohydrates are illustrated in Figure 32.8.18 below. The fat synthesis pathways relevant for this discussion are represented in the central part of the figure.

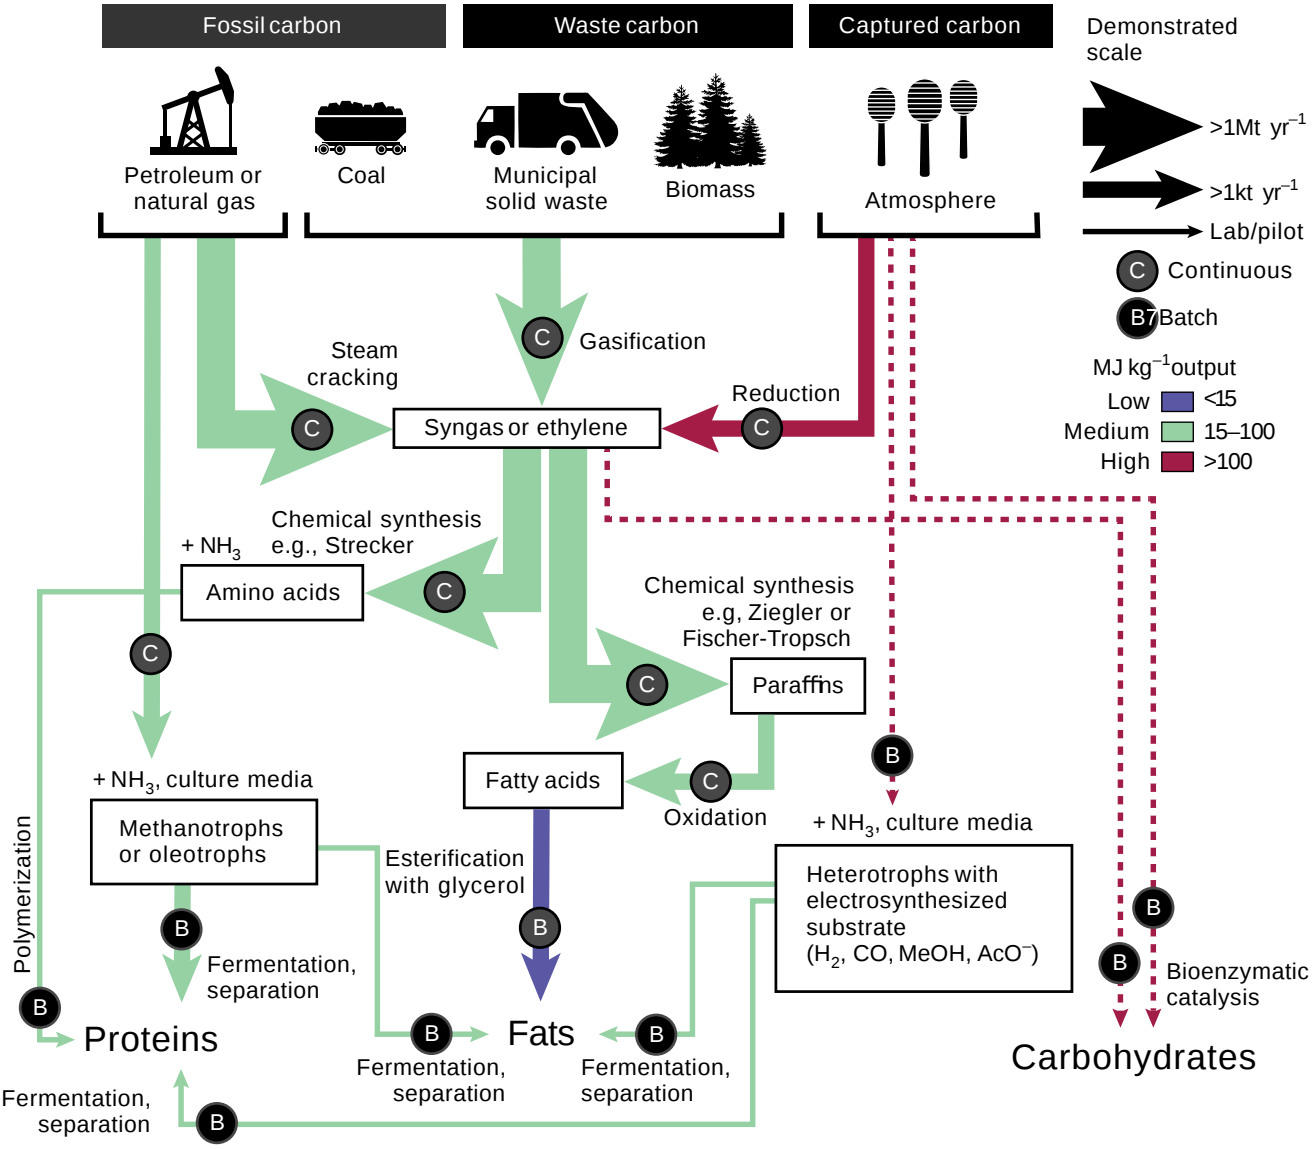

Figure 32.8.18: **Schematic of potential pathways to synthesize food without agriculture.** Davis, S.J., Alexander, K., Moreno-Cruz, J. *et al.* Food without agriculture. *Nat Sustain* (2023). https://doi.org/10.1038/s41893-023-01241-2. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/.

Proteins, fats, and carbohydrates can be synthesized from a range of carbon feedstocks via multiple chemical and biological pathways (arrows). The weight and color of the arrows indicate the scale at which the different processes have been demonstrated and the energy required per mass unit output, respectively. Dashed lines indicate where energy requirements remain highly uncertain. Circular labels on each arrow further indicate whether the process is typically continuous (C) or batched (B). NH_3 is ammonia, H_2 is hydrogen gas, MeOH is methanol, and AcO^- is acetate (agriculturally produced carbon feedstocks are omitted).

It is estimated that the chemical of synthesis of fats could lead to the emission of <0.8 g $CO_{2\ equiv}$/kcal compared to >1.5 g CO_2 equiv/kcal for the present biological synthesis and processing of palm oil in Brazil or Indonesia. This advantage would increase if the CO_2 for the chemical synthesis could be captured from the atmosphere, yielding net 0 emissions.

Figure 32.8.19 shows both land use and energy emissions of $CO_{2\ equiv}$/kcal for agricultural-produced fats (panel a) versus equivalents for chemical-synthesized fats.

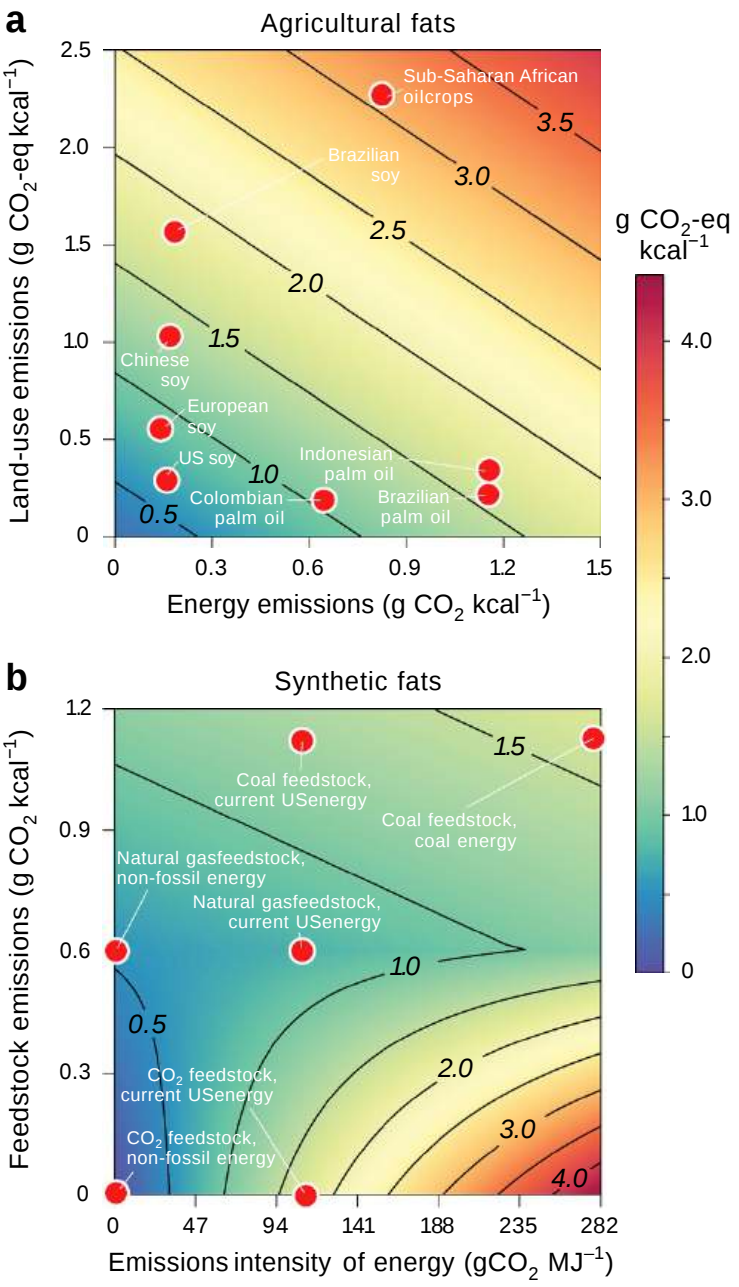

Figure 32.8.19: **Comparison of emissions per calorie of edible fats.** Davis, S.J et al., ibid.

Panels a and **b** show shading and contours show grams of CO_2-equivalent GHG emissions per kilocalorie of edible fat produced by conventional agriculture (Panel **a**) and chemical synthesis (Panel **b**). Agricultural emissions are shown as the sum of land-use emissions (*y*-axis) and energy-related emissions (*x*-axis), and emissions from synthesis are shown as a function of feedstock emissions intensity (*y* axis) and energy emissions intensity. Red circles denote specific estimates based on literature and assumed values. Feedstock emissions include process-related conversion of feedstock to CO_2—for example, during extraction of natural gas, gasification of coal, and the eventual human respiration of fossil feedstock.

BIOAVIATION FUEL

Now we can turn our attention to the production and analysis of bioaviation fuel, which is more like kerosene and diesel fuel than ethanol in its composition. As we saw for bioethanol productions, the feedstocks can be 1st, 2nd and 3rd generation, as shown in Table 32.8.3 below.

First-generation (1-G)	Second-generation (2-G)	Third-generation (3-G)	Fourth-generation (4-G)
• Oil-seed crops: camelina, oil palm, rapeseed, soybean, sunflower, salicornia • Sugar and starchy crops: corn, wheat, sugarcane, sugar beets	• Oil-seed energy crops: jatropha, castor bean • Grass energy crops: switchgrass, miscanthus, Napier grass • Wood energy crops: poplar, willow, eucalyptus • Agricultural and forestry residues: corn stover, sugarcane bagasse, wood harvesting/processing residues • Food and municipal waste: used cooking oil, animal fats, biogenic fraction of municipal solid waste	• Algae: microalgae	• Genetically modified organisms • Non-biological feedstocks: CO2, renewable electricity, water

Table 32.8.3: Feedstocks for bio-aviation fuel production. Doliente SS, Narayan A, Tapia JFD, Samsatli NJ, Zhao Y and Samsatli S (2020) Bio-aviation Fuel: A Comprehensive Review and Analysis of the Supply Chain Components. *Front. Energy Res.* 8:110. doi: 10.3389/fenrg.2020.00110. .

A typical jet aviation fuel (Jet A-1) contains n- and branched-alkanes (often called paraffins) and some alkenes (often called olefins) with 8-16 carbon atoms, cycloalkanes, and aromatics. A comparison of the components of Jet-A1 with a typical bioaviation fuel, Bio-Jet, is shown in Figure 32.8.20 below.

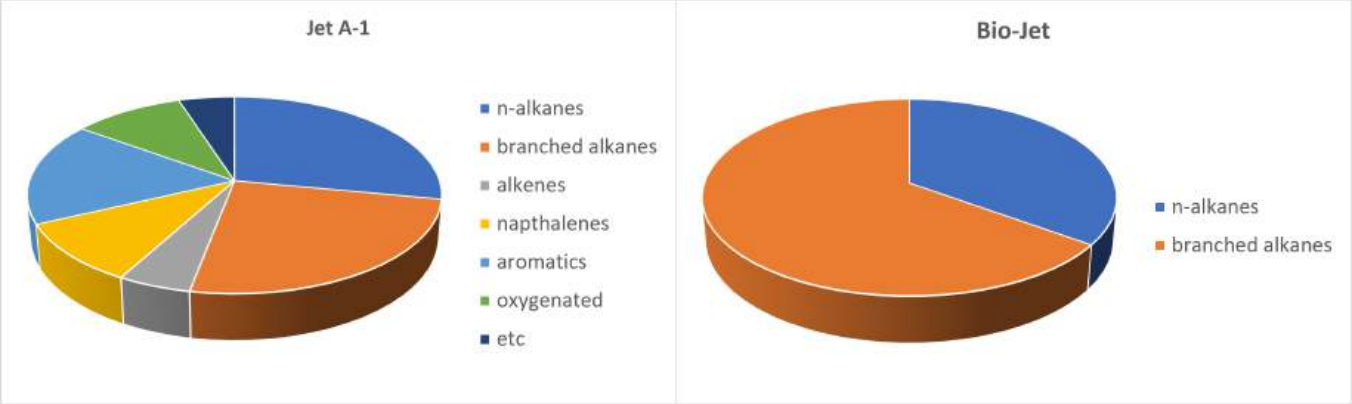

Figure 32.8.20: Molecular-class compositions of (a) Jet A-1 and (b) bio-jet identified by the relative signal area percentage analysis of GC–MS. After Cheon Hyeon Cho, Hee Sun Han, Chae Hoon Sohn, and Jeong Sik Han. *ACS Omega* **2021** *6* (40), 26646-26658. DOI: 10.1021/acsomega.1c04002.

Bioaviation fuel can be made from feedstocks containing triacylglycerol or, most readily using feedstocks shown in Table 2 above to create syngas for use in the Fischer-Tropsch reaction. We've already discussed those reactions above. Instead, let's focus on whether bioaviation fuel, better termed sustainable aviation fuels (SAF), is good for our climate. This presupposes that battery-powered planes and jets are not scalable to our current environmental needs.

LIFE CYCLE ANALYSIS - JET FUEL FROM GRASSES

As expected, the US is the largest user of aviation fuel and causes 25% of aviation CO_2 emissions, as much as all the greenhouse gases emitted through fuel use in Spain. It is estimated that the US will need around 30 billion gallons/per (BGY) of jet fuel in 2040. A biojet fuel industry based on cellulose as a feedstock could theoretically produce that amounts. If the industry costs are estimated at $123 billion, then the cost of the jet fuel would be $4.30/gal. About 60% of the costs would arise from the conversion of biomass to sustainable aviation fuel (SAF), which we described above. Those costs include the building of the biorefineries. Their cost would be distributed over their lifetimes of the plants. The fuel would be derived from syngas from the Fisher-Tropsch reaction, a reasonably mature technology. The costs would be much lower (closer to $1/gal) if the infrastructure costs were not included. These total costs are comparable to the price paid for regular jet fuel (around $2.2/gal in 2021). Consumer costs would not go up 2-fold since fuels are only part of the cost paid by passengers (15-25%)

Consumers' current price for fossil fuel is much less than its actual cost. The present price/gal does not include external costs associated with the use of fossil fuels. These include climate change effects on infrastructure, agriculture, industry, etc., and on human health (mostly from negative health consequences and diseases exacerbated by fossil pollution). We all ultimately pay for these hidden costs resulting from a failed market for pricing fossil fuels. On top of this, the fossil fuel industry has been massively subsidized for decades.

Different prices have been placed on carbon emissions from fossil fuels to resolve this error in the market. The carbon price is based on the number of tons of CO_2 equivalent emitted ($US/ton CO_2e). If a reasonable carbon price is added, biojet fuels made from lignocellulosic stocks through the Fisher-Tropsch reaction would be theoretically competitive with conventional jet fuels made from fossil fuels. The extra added cost for sustainable aviation fuel (SAF) compared to traditional aviation fuel at different prices placed on carbon placed on each are shown in Table 32.8.4 below, assuming an average cost of $2.20/gal for traditional aviation fuel.

Price on carbon ($US/t CO2e)	SAF - Traditional Aviation Fuel ($/gal)
0	+$1.90/gal
$50	+$0.60/gal
$175	$0

If the cost of traditional jet fuel went to $3/gal, as it did in the US in March 2022, SAF and conventional jet fuel would cost the same if a price on carbon of $100/t CO2e were included for both. The actual "social" cost of carbon has been calculated (9/22) to be $175/ton CO_2e.

Other factors other than the cost of carbon should be included in these analyzes. These include the issue of sustainable land use to grow feedstocks for the SAF. A recent analysis shows that it would be possible to produce 30 billion gall/yr of cellulosic SAF by planting 23.2 Mha (Million hectares, about the size of the state of Wyoming) of marginal agricultural lands (about one-third of croplands and 2/3 noncrop lands) in the Midwest with miscanthus, with a net cost of $4.1/gal and assuming a carbon price of a $50/ t CO2e. Miscanthus is a rapidly growing tall perennial grass with a high yield that grows in moderate climates. The life cycle analysis included interactions among atmospheric, land surface, ecosystem, and economic systems. Miscanthus gigantheus is shown below in Figure 32.8.21.

Figure 32.8.21:Miscanthus gigantheus. https://commons.wikimedia.org/wiki/F...us_Bestand.JPG. Creative Commons Attribution-Share Alike 3.0 Unported

Figure 32.8.22 shows some data from the study. Four different scenarios are offered, each represented by bar graphs.

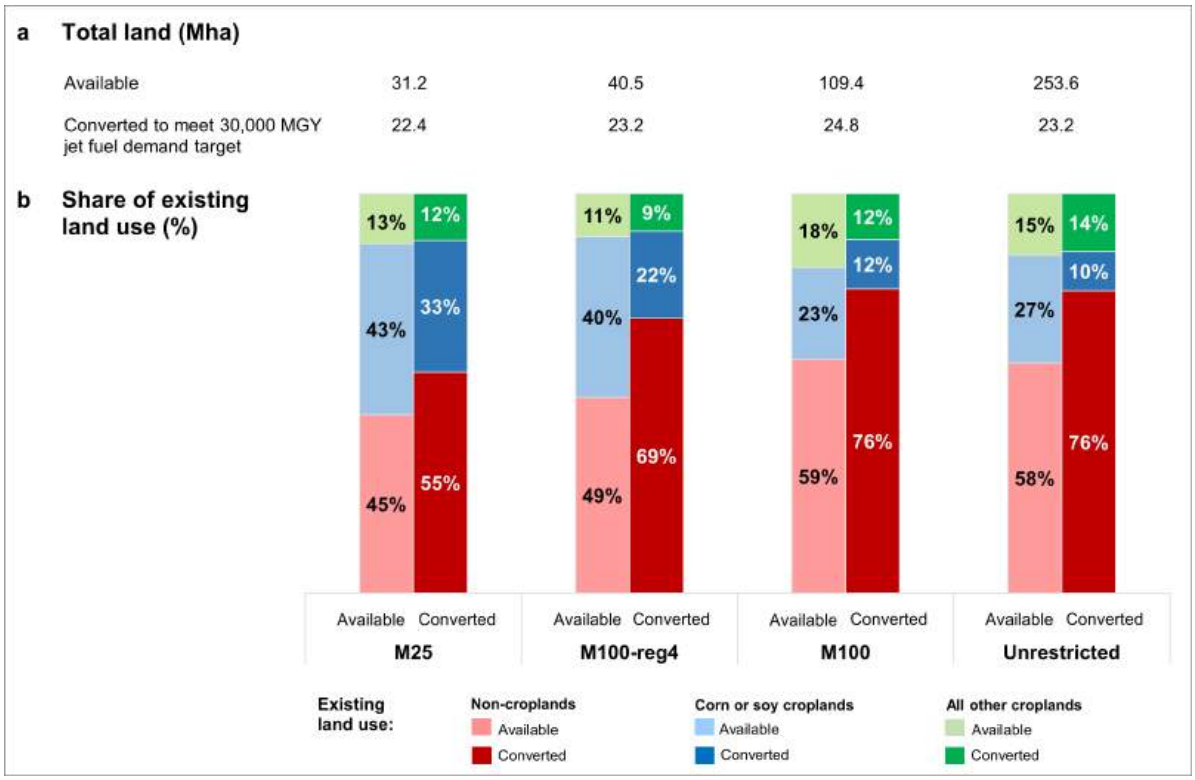

Figure 32.8.22: Land availability and conversion by existing use. Excel data and graph from https://dataverse.harvard.edu/datase...910/DVN/VBFLI2. CC0 1.0 Public Domain.

Four scenarios (left to right) were used to produce 30 MG/yr of SAF using a carbon price of $50/t CO2e.

- M25: only 25% of the marginally useful land was used
- M100-reg4: marginal land bases with the lowest hydrological and climatic risks
- M100: all of the marginally included land was made available
- Unrestricted

Panel (a) shows that in each case, about 23.2 Mha of land was converted to growing miscanthus out of the available land. Pane (b) shows stacked bars showing the percentages of each type of land available and converted for each scenario. The last scenario shows that demand can be made with the lowest % conversion of the marginal lands now used for corn/soybeans and other crops. It would appear that the marginal croplands converted to SAF production would be the same lands diverted to bioethanol production. Nevertheless, it would appear that up to 76% of projected aviation fuel needs could be met by planting marginal cropland and noncrop land for cellulosic SAF production. The study found that using available lands in the Plains was not feasible.

KEY POINTS - BETA VERSION FROM CHAT.OPENAI

1. Biodiesel, syngas and bioaviation fuel are alternative biofuels derived from biomass that can be used to reduce the dependence on fossil fuels.
2. Biodiesel is a liquid fuel that can be used in diesel engines, it is produced by chemically converting vegetable oils or animal fats into a fuel that can be used in place of diesel fuel.
3. Syngas (synthetic gas) is a mixture of hydrogen and carbon monoxide that can be produced from biomass through processes such as gasification. It can be used as a fuel for heat and power generation or further converted into chemicals and liquid fuels.
4. Bioaviation fuel is a form of biofuel that can be used in aviation, it is made from biomass such as algae or woody biomass, it can be blended with traditional jet fuel and can help reduce emissions from airplanes.
5. These biofuels have different advantages and limitations, and their production process is still in the research and development stage.
6. Biodiesel has the advantage of being able to be used in existing diesel engines with little or no modification, it reduces emissions and it is renewable.
7. Syngas has the advantage of being able to be converted into different chemicals and liquid fuels, it has a higher energy content than bioethanol and it can be used for power generation.

8. Bioaviation fuel has the advantage of reducing emissions from airplanes, it can reduce dependence on fossil fuels in the aviation industry and it can be renewable.

32.09: BIOHYDROGEN - AN INTRODUCTION

Search Fundamentals of Biochemistry

32.09.1: H_2 AS A FUEL

Hydrogen gas would be ideal if it could be produced at scale, easily transported and stored, or produced at local sites on demand. The reaction for the "burning" of hydrogen shows that the only greenhouse gas emitted is H_2O.

$$2H_2(\ g) + O_2(\ g) \rightarrow 2H_2O(g) \tag{32.9.1}$$

H_2O comes and goes in our atmosphere in short timescales and does not continually build up, as does CO_2 from burning fossil fuels. The standard heat of combustion (in kJ/g or kcal/kg) for H_2 is far higher than any other fuel, as shown in Table 32.9.1 below, making it an ideal fuel.

Name	Formula	State	$-\Delta H_c°$ *kJ/mol*	$-\Delta H_c°$ *kJ/g or MJ/kg*	$-\Delta H_c°$ *kcal/kg*
Ammonia	NH_3	gas	383	22.48	5369
Butane	C_4H_{10}	gas	2878	49.50	11823
Carbon (graphite)	C	cry	394	32.81	7836
Ethanol	C_2H_6O	liq	1367	29.67	7086
Hydrogen	**H_2**	**gas**	**286**	**141.58**	**33817**
Methane	CH_4	gas	891	55.51	13259
methyl stearate (biodiesel)	$(CH_3(CH_2)_{16}(CO)CH_3$	liq	1764	40	9560
Naphthalene	$C_{10}H_8$	cry	5157	40.23	9609
Octane	C_8H_{18}	liq	5470	47.87	11434
Propane	C_3H_8	gas	2220	50.33	12021
wood (red oak)	-	solid	-	14.8	3540
coal (lignite)	-	solid	-	15	3590
coal (anthracite)	-	solid		27	4060

Table 32.9.1: Energy values for various fuels. Data source: https://www.engineeringtoolbox.com/s...nt-d_1987.html

We won't discuss large-scale H_2 storage or transport, two fundamental engineering problems. Instead, we will focus on the production of "biohydrogen." Of course, the prefix "bio" can mean many things, including the production of H_2 in syngas using cellulose as a feedstock, the electrolysis of water powered by solar/wind energy, and its production by hydrogenases, enzymes found in some microbes.

The fuel industry uses different colors as descriptors of hydrogen based on how it is produced. They are shown in Table 32.9.2.

Color	Method of production
Green	electrolysis of H_2O using solar/wind to generate electricity (expensive at present)
Blue	steam reforming of natural gas (CH_4) with the other product, CO_2 captured and stored (CCS)
Grey	steam reforming of natural gas (CH_4) without CO_2 capture and storage
Black (coal/oil)	gasification to form syngas
Pink (purple/red)	electrolysis powered by nuclear energy, which does not emit CO_2; heat emitted produces steam for blue/gray H_2 production
Turquoise	methane pyrolysis (heat in the absence of O_2) to form H_2 and C
Yellow	electrolysis using solar power without conversion to electricity as the power source.
White	underground H_2 released through fracking

Table 32.9.2: Different "colors" of hydrogen based on production methods

Of course, H_2 in syngas can be produced from biomass, as described in Chapter 32.8, but it is unclear if a hydrogen color has been assigned to it.

At present, the important feedstocks for H_2 production around the world are natural gas (48%), oil (30%), coal (18%), and electrolysis (4%) - mostly all fossil fuels.

32.09.2: METHODS OF PRODUCTION

H_2 production is also classified based on the chemical processes used to produce it. These processes include

1. **Biological** (use of live bacteria and algae cells)
2. **Thermochemical**: (gas and liquid fuel reforming, coal and biomass gasification),

3. **Electrochemical (electrolytic)**: (photothermal, photoelectrolytic, and photobiological)

We will organize this chapter section using these three processes. We will start with Biological (1), followed by Electrochemical/Electrolytic (3), and end with Thermochemical (2). They are summarized in Figure 32.9.1.

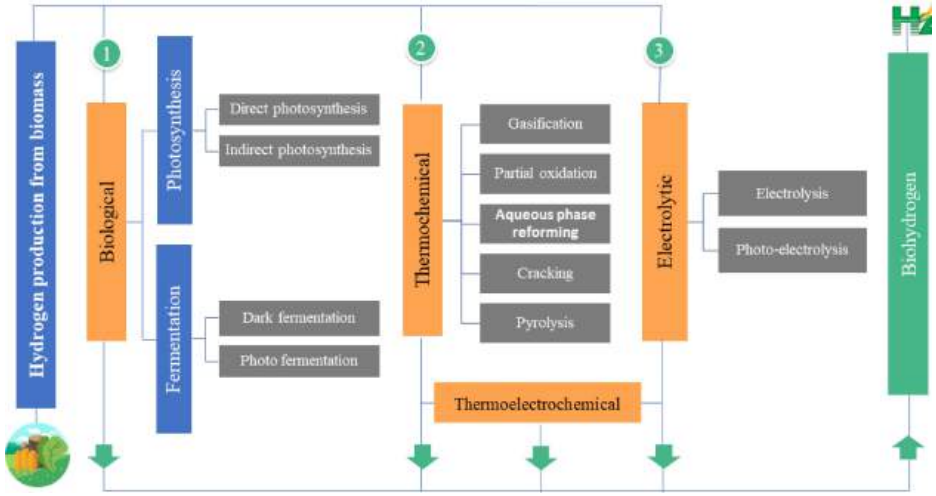

Figure 32.9.1: The main pathways for H_2 production based on biomass. M.G. Eloffy et al., Chemical Engineering Journal Advances, 12 (2022). https://doi.org/10.1016/j.ceja.2022.100410. Creative Commons license

Biomass can be used as the feedstock for all of these methods, so the resulting product can be called biohydrogen. Of course, nonbiological sources of feedstocks are the predominant ones used in thermochemical and electrochemical methods as well, as we discussed in the previous chapter section.

32.09.3: $2H^+ \leftrightarrow H_2$: AN OVERVIEW

We will mostly discuss the production of H_2 as a society energy source. For industry use, it can be used in fuel cells to power spacecraft and cars, as shown in the reaction below.

$$\begin{aligned} O_2 + 4H^+ + 4e^- &\longrightarrow 2H_2O \\ H_2 &\longrightarrow 4H^+ + 4e^- \end{aligned} \qquad (32.9.2)$$

In the next chapter section, we will discuss in great detail the **hydrogenases** that produce and use H_2 in microbes so that this chapter will treat them very generally. However, we need to review the topic.

Use of H_2 as a *source* of electrons for reduction reactions.

Each hydrogen in H_2 has an oxidation number of 0. Each hydrogen can be oxidized to H^+ (oxidation number +1) with the 2 electrons passed on to a substrate/cofactor or a sequential series of substrates with higher and higher standard reduction potentials (better oxidizing agents), leading to the formation of reduced products.

H_2 + $(substrate)_{OX}$ → $2H^+$ + $(product)_{RED}$

This general reaction is analogous to the mitochondrial electron transport chain, in which electrons are passed from a source (NADH) to oxidized forms of acceptors. The general reaction below shows each redox pair in the electron transport chain.

$NADH/NAD^+$ → $FAD/FADH_2$ → UQ/UQH2 → Cyto C_{OX}/Cyto C_{RED} → O_2/H_2O

Some organisms have evolved to produce energy by the oxidation of H_2. This reaction is analogous to those used by photosynthetic organisms to obtain energy through the oxidation of water. In photosystem II, oxygen in H_2O (oxidation number -2) gets oxidized by the oxygen-evolving complex to produce O_2 (oxidation number 0). Some redox pairs, starting with H_2O/O_2, are shown below for photosystem II.

H_2O/O_2 → P680/P680* → $(Plastoquione)_{OX}/(Plastoquione)_{RED}$

The first reaction is endergonic and requires an energy source photons.

Use of H^+ as a *sink* for electrons for oxidation reactions that produce H_2.

H^+ has an oxidation number of +1. Hence it can be reduced to H_2 (oxidation number of 0) as it gains electrons from substrates/cofactors, which get oxidized. This general reaction is shown below.

$2H^+$ + (substrate/cofactor)RED → H_2 + (substrate/cofactor)OX

Many microorganisms can produce H_2 through variants of photosynthesis or through fermentation, both of which provide the two electrons needed. E. Coi has four hydrogenases (Hyd 1, 2, 3, and 4). It forms H_2 through two reactions catalyzed by:

- formate (HCO_2^-) dehydrogenase (FDH): $2HCO_2^- \rightleftharpoons 2CO_2 + 2H^+ + 2e^-$
- hydrogenase (H_2ase): $2H^+ + 2e^- \rightarrow H_2$

The C in formate has an oxidation number of +2 and is oxidized to CO_2, in which the C has an oxidation number of +4.

NOTHING IS SIMPLE: H_2 IS AN INDIRECT GREENHOUSE GAS.

H_2 itself is not a greenhouse gas as it doesn't have any bond vibrations that produce transient dipoles and hence does not absorb in the infrared region of the spectrum. Yet by affecting atmospheric levels of methane, a very potent greenhouse gas, as well as levels of ozone, it can lead to warming. It's not emission from the combustion of H_2 but rather the leakage into the atmosphere of transported and stored H_2 gas that is problematic.

Most of the H_2 that finds its way into the atmosphere diffuses into the soil and is taken up by bacteria. The rest reacts with hydroxy radicals (·OH) in the atmosphere, as shown in the reaction below.

$$H_2 + \cdot OH \rightarrow H_2O + H\cdot \text{ (atomic hydrogen)}$$

The reaction of ·OH with H_2 decreases the hydroxy radical's availability to react with the very potent greenhouse gas methane, CH_4. That reaction is shown below.

$$CH_4 + \cdot OH \rightarrow \cdot CH_3 + H_2O$$

The methyl radical $\cdot CH_3$ reacts rapidly with oxygen to form the methylperoxy radical ($CH_3O_2\cdot$). This eventually forms formaldehyde, a water-soluble molecule that is removed from the atmosphere on precipitation. Hence the reaction of H_2 with ·OH increases the half-live of CH_4 in the atmosphere.

·OH is a key molecule in the troposphere and is considered a methane "sink" that leads to the drawdown of methane. We discussed the extreme reactivity of ·OH in Chapter section's 12.3 and 12.4. It's so reactive that its half-life is in the order of seconds. It is also at very low concentrations of less than 1 part per trillion.

·OH is produced from ozone, O_3, by the following reactions:

$$O_3 + h\nu \text{ (UV)} \rightarrow O_2 + \cdot O$$

$$\cdot O + H_2O \rightarrow 2\ \cdot OH$$

The first reaction is a photolysis, and experiments during a solar eclipse have shown the production of ·OH in the atmosphere shuts down!

Dr. Paul Crutzen, Nobel Prize winner in Chemistry, described ·OH as the "detergent of the atmosphere" since it can react with and oxidize many deleterious trace gases in the troposphere, making them more water-soluble, leading to their elimination from the atmosphere. A main reaction of ·OH is carbon monoxide (CO). It also reacts with volatile organic compounds (VOCs) and NOx (NO + NO_2), which are precursors of tropospheric ozone, a health hazard. Even though dioxygen, which comprises 20% of the atmosphere, is also an excellent oxidizing agent, it is kinetically slow to react.

Very few gases are not oxidized by ·OH. One set includes the refrigerant gases chlorofluorocarbons, which without oxidation by ·OH enter the stratosphere, where they react with stratospheric ozone and reduce its protective effect against dangerous UV light. It does react with hydrochlorofluorocarbons (HCFCs).

Figure 32.9.2 below summarizes the adverse climatic effects of the oxidation of H_2 in the atmosphere.

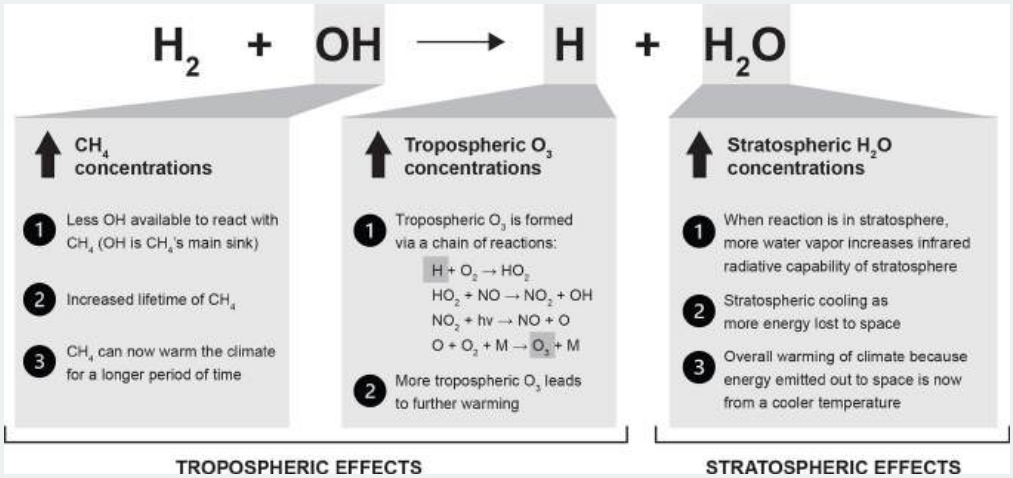

Figure 32.9.2: Effects of hydrogen oxidation on atmospheric greenhouse gas concentrations and warming. I. Ocko and Steven P. HamburgAtmos. Chem. Phys., 22, 9349–9368, 2022. https://doi.org/10.5194/acp-22-9349-2022. Creative Commons Attribution 4.0 License.

Note in the central panel that H· (atomic hydrogen) can start a free radical change reaction to produce tropospheric ozone, O_3, a pollutant that is not only a greenhouse gas but which also causes serious health consequences.

The message is this: Care has to be taken to minimize methane and H_2 leakage during their production and use as fuels.

32.09.4: BIOHYDROGEN FROM MICROALGAE

We will focus most of our attention on the Biological (1) and Electrolytic (3) processes for producing biohydrogen from microalgae. The Biological processes (1) require hydrogenases for H_2 production within cells. The Electrolytic (3) processes use microalgae as a feedstock to provide substrates that other microbes can ferment. These can be combined to increase production. Figure 32.9.3 below summarizes the Biological (1) and Electrolytic (3) metabolic processes that can be used for microalgae H_2 production.

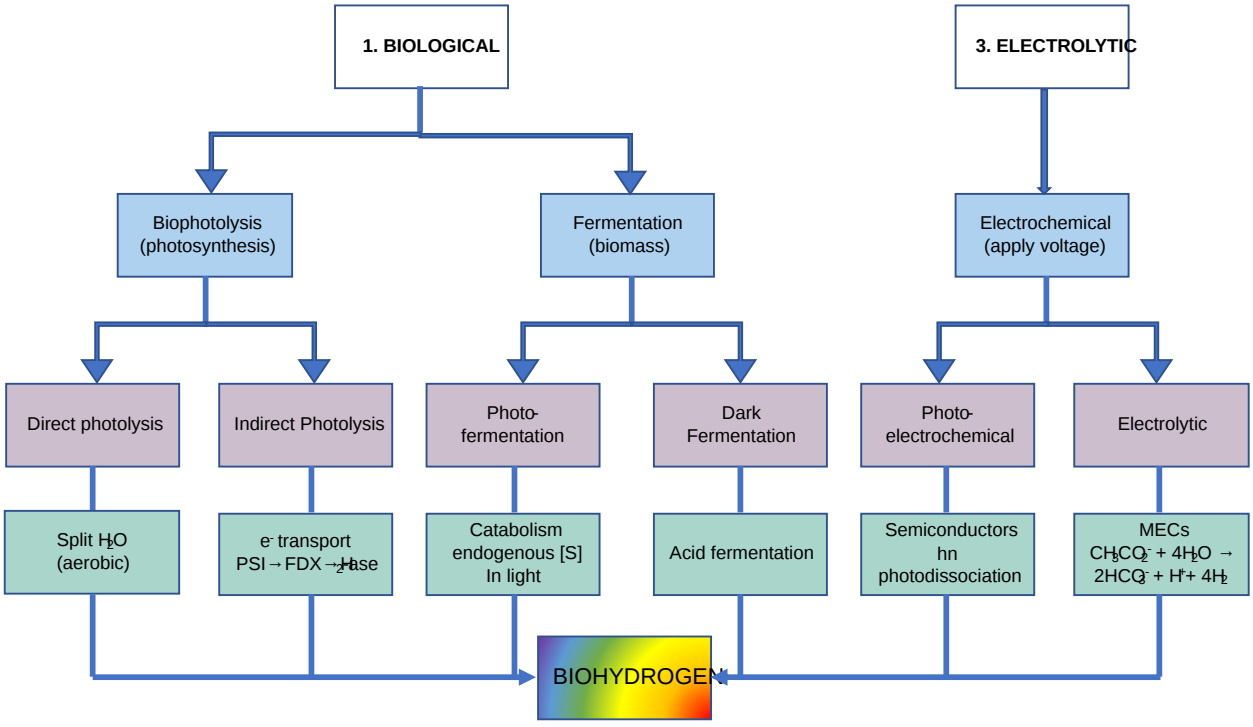

Figure 32.9.3: Metabolic pathways of biohydrogen production by micro-algal biomass. modified from Ahmed SF et al. *Front. Energy Res.* 9:753878. doi: 10.3389/fenrg.2021.753878. Creative Commons Attribution License (CC BY).

These are mainly classified into three categories: i) the photobiological process through which biohydrogen is produced *via* direct and indirect photolysis in the microalgae, ii) fermentation, and iii) the electrochemical process that comprises photoelectrochemical and electrolytic.

32.09.4.1: BIOLOGICAL (1) - BIOPHOTOLYSIS (PHOTOSYNTHESIS)

This consists of two processes, Direct and Indirect Photolysis (photosynthesis). Both use light to drive the ultimate reduction of $2H^+$ to H_2 using hydrogenase or nitrogenase. We will explore the details in the next chapter section. The biophotolysis process is divided into indirect (using electrons from substrates) and direct (using electrons from water). These processes are simplified in Figure 32.9.4.

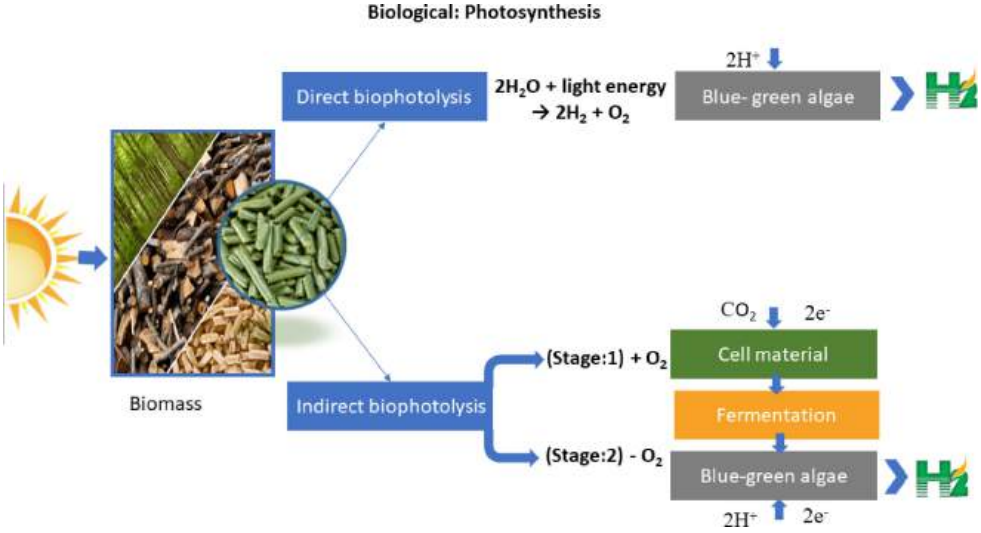

Figure 32.9.4: Schematic diagram for biological (biophotolysis) process. M.G. Eloffy et al.

Direct Biophotolysis (photosynthesis)

In direct biophotolysis (photosynthesis), water molecules are oxidized in Photosystem II, which contains the Oxygen Evolving Complex (OEC). This endergonic process is driven by light. The electrons lost from water are passed through Cytochrome b_6f and Photosystem I to ferredoxin then $NADP^+$, which gets reduced to NADPH (as discussed in Chapter 20). These reactions are illustrated in Figure 32.9.5.

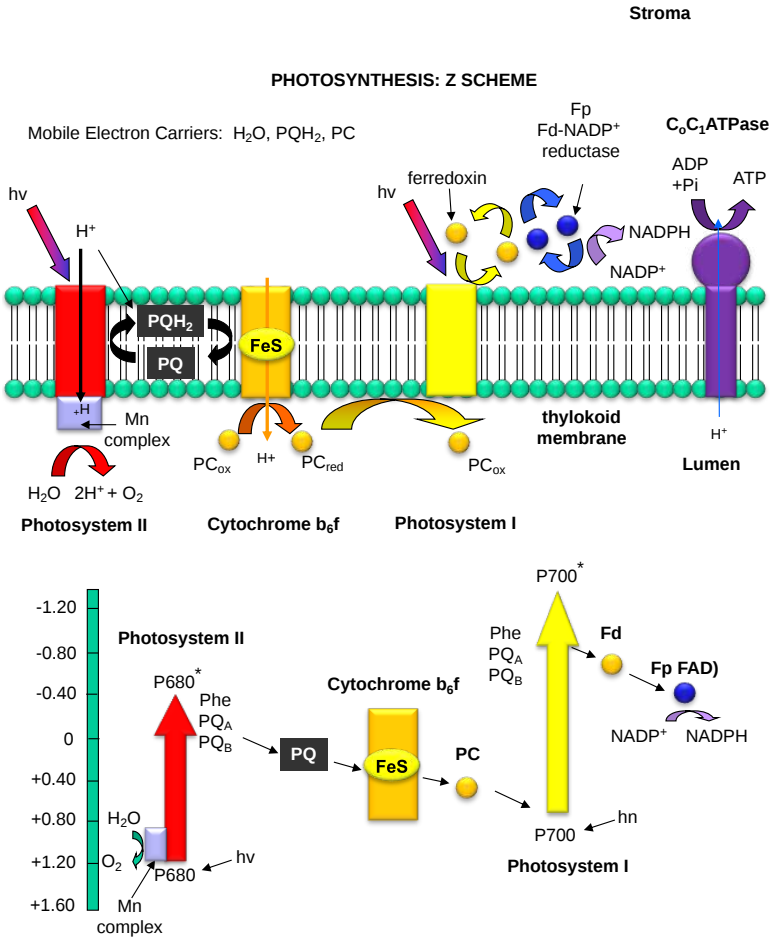

Figure 32.9.5: Light reaction of photosynthesis and associated standard reduction potentials

In direct photolysis, electrons are passed directly from reduced ferredoxin to $2H^+$ in a reaction catalyzed by a hydrogenase, as shown in Figure 32.9.6 below.

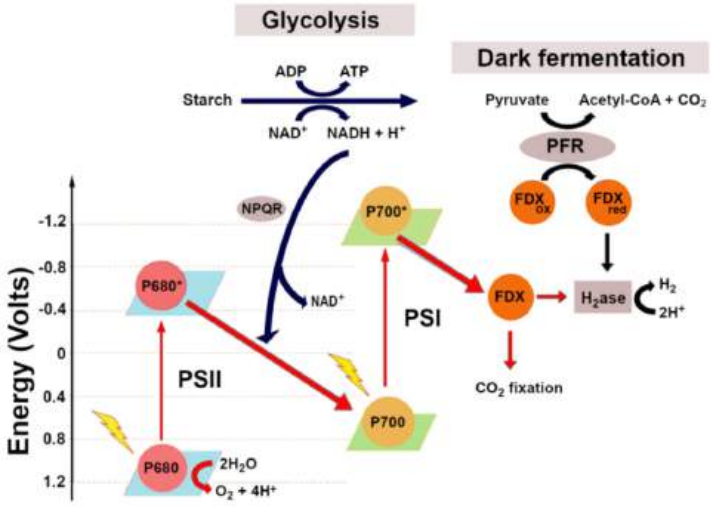

Figure 32.9.6: Metabolic hydrogen production pathways used by *Chlamydomonas reinhartii*.FDX: ferredoxin; H_2ase: hydrogenase; NPQR: NADPH−plastoquinone oxidoreductase; PFR: pyruvate:ferredoxin oxidoreductase; PSI: photosystem I; PSII: photosystem II. Touloupakis, E.; Faraloni, C.; Silva Benavides, A.M.; Torzillo, G. Recent Achievements in Microalgal Photobiological Hydrogen Production. *Energies* **2021**, *14*, 7170. https://doi.org/10.3390/en14217170.

The overall reaction is simplified in the equation below.

$$2H_2O + \text{Light} \rightarrow 2H_2 + O_2 \tag{32.9.3}$$

One problem with direct photolysis is that O2 can damage hydrogenases. Again we will discuss the biochemistry of hydrogenases in great detail in the next chapter section.

Indirect Biophotolysis

This process bypasses the damaging effects of O_2 on hydrogenase by being carried out in the absence of O_2 using fermentation to provide electrons for the hydrogenase reduction of $2H^+$ to H_2. Photosynthesis is required to make the carbohydrates necessary for fermentation. Glucose can then be oxidized anaerobically (in the dark to avoid O_2 formation from photosynthesis) to form pyruvate through the glycolytic pathway. Pyruvate can then be oxidatively decarboxylated through the **pyruvate:ferredoxin oxioreductase (PFR)** as ferredoxin gets reduced. It then passes its electrons on through hydrogenase to produce H_2. The pathway is illustrated in the top/right parts of the above figure and the reaction diagram in Figure 32.9.7 below.

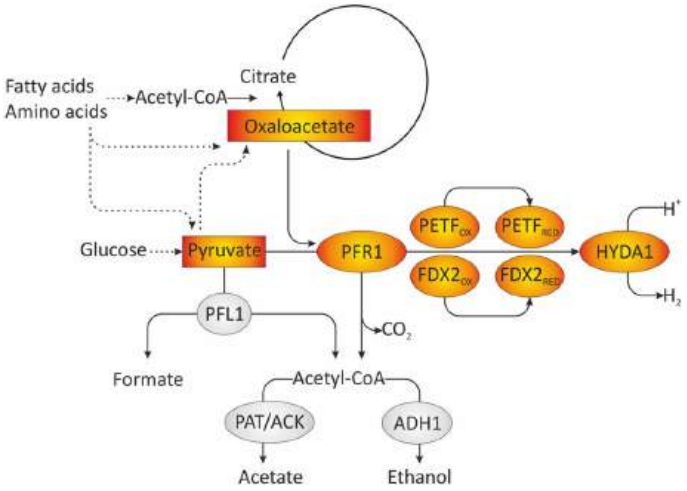

Figure 32.9.7: **Model of fermentative pathways involved in dark anaerobic H_2 production in *C. reinhardtii*.** Proteins are shown as ovals. Photosynthetic ferredoxin (PETF). Jens Noth et al., Journal of Biological Chemistry, 288 (2013). https://doi.org/10.1074/jbc.M112.429985. Creative Commons license.

Glucose and some amino acids can be converted into pyruvate, a substrate for PFR1 in the single-cell algae *C. reinhardtii*. PFR1 converts pyruvate to acetyl-CoA and CO_2 with the electrons used to reduce ferredoxin. The reduced FDX2 passes electrons through hydrogenase (HYDA1) to form H_2.

Another enzyme used to continue fermentation, **pyruvate:formate lyase (PFL1),** converts pyruvate to formate and acetyl-CoA, which can be metabolized further to acetate and ethanol. A shift to pyruvate oxidation to PFR1 occurs if PFL1 is mutated or long term anoxic conditions.

The key enzyme, pyruvate:ferredoxin oxioreductase (PFR), uses thiamine pyrophosphate (TPP) as a cofactor for the oxidative decarboxylation of the α-keto acid pyruvate, as expected. Figure 32.9.8 shows an interactive iCn3D model of the pyruvate ferredoxin oxidoreductase (PFOR) from Desulfocurvibacter africanus in anaerobic conditions (7PLM).

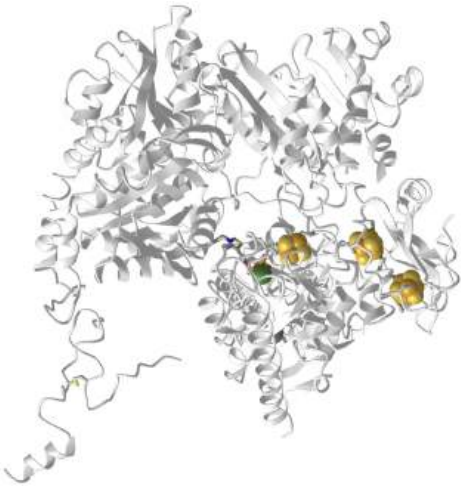

Figure 32.9.8: Pyruvate ferredoxin oxidoreductase (PFOR) from Desulfocurvibacter africanus in anaerobic conditions (7PLM). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...XRFMoVhaoRbW86

PFOR, abbreviated here, is a 267 kDa homodimer containing three [Fe_4S_4] clusters (spacefill) per monomer. Only one monomer is shown, and TPP is shown in sticks.

Again indirect photolysis occurs in the absence of O_2. Light illumination leads to only transient H_2 synthesis. If sulfur is limited in the growth media of the algae, more sustained H_2 production occurs, as the lack of sulfur reduces PSII activity. Hence H_2 production can be maximized by depleting sulfur and minimizing O_2 even in the presence of light. In the absence of O_2, hydrogenase gene expression increases. Nutrient depletion also leads to the production of formate and acetyl-CoA through the enzyme pyruvate:formate lyase (PFL1). This is predominant in *Chlamydomonas* cells in the dark.

The green microalgae *C. reinhardtii* makes most of its H_2 (approximately 90%) using direct photolysis. Commercially, the production of H_2 in indirect photolysis is carried out in a separate sealed bioreactor to avoid O_2. Indirect photolysis is shown in the above figures.

The reactions to this process are as follows :

$$\begin{aligned} 12H_2O + 6CO_2 + h\nu &\rightarrow C_6H_{12}O_6 + 6O_2 \\ C_6H_{12}O_6 + 12H_2O + h\nu &\rightarrow 12H_2 + 6CO_2 \end{aligned} \tag{32.9.4}$$

32.09.4.2: BIOLOGICAL (1) - FERMENTATION

We have just discussed fermentation processes **within living microalgae cells**. Now let's consider fermentation processes using **nonliving biomass feedstocks** supplied to microbes to produce H_2. This offers a significant way to make biohydrogen. A schematic diagram for Biological (1) fermentation is shown below in Figure 32.9.9:

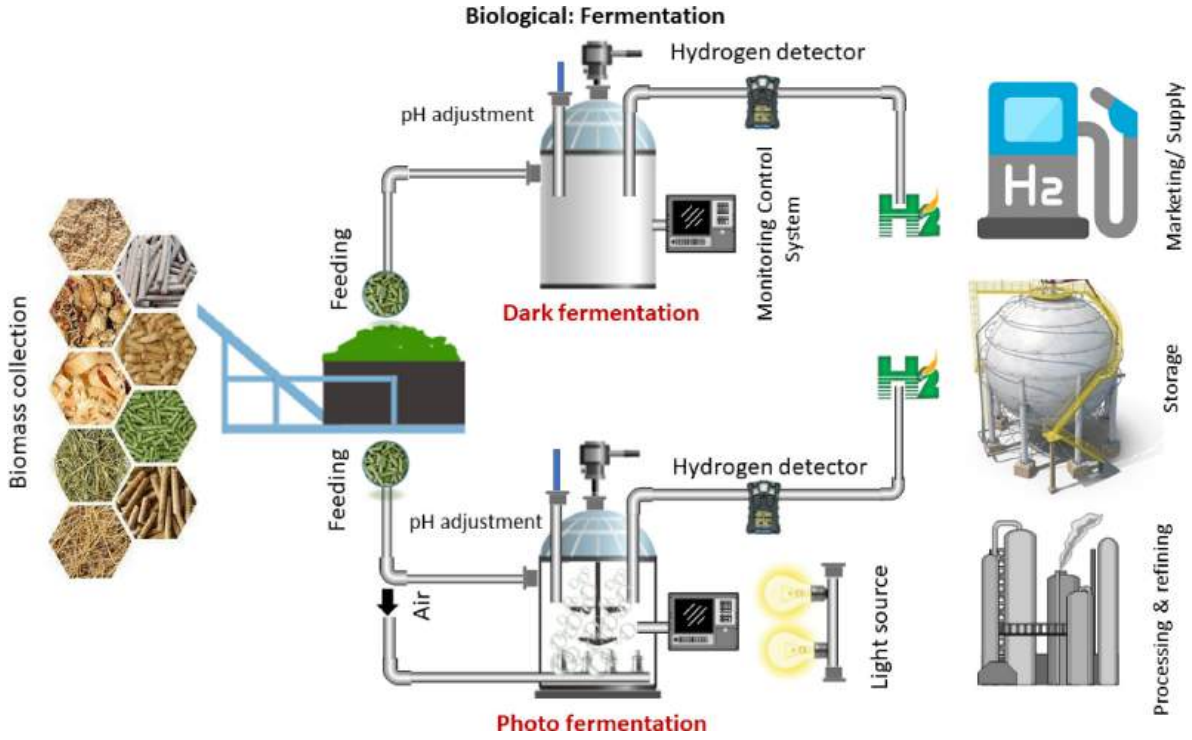

Figure 32.9.9: Schematic diagram for biological (fermentation) process. M.G. Eloffy et al.

Fermentation involves the decomposition of organic biomass to produce CO_2 and H_2. The fermentation process can be separated into photofermentation (light fermentation) and dark fermentation.

Photofermentation

Some photosynthetic bacteria and microalgae use Photofermentation to produce H_2 from organic acids like acetic, butyric, lactic, and succinic acids. Oxidation of the acids produces CO_2 as well as H^+s and e^- for H_2 production. Electrons are transferred through photosystem I and eventually, believe it or not, nitrogenase. It is a fermentation process as the process is anoxic.

Some photosynthetic bacteria, like the purple nonsulfur bacteria, a facultative anoxygenic phototroph, and some microalgae, can produce H_2 using a simplified system that has only one photosystem and uses the enzyme nitrogenase to produce H_2. The photosystem can not generate an oxidizing agent strong enough to oxidize H_2O, but under anaerobic conditions, they can oxidize organic acids and even H_2S to provide electrons from H_2 production. These reactions are shown below in Figure 32.9.10.

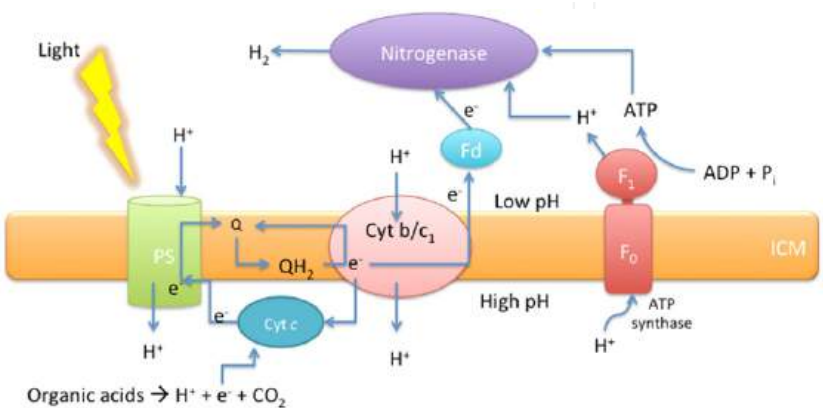

Figure 32.9.10: Photofermentative hydrogen production in PNSB.

Deo, D., Ozgur, E., Eroglu, I., Gunduz, U., & Yucel, M. (2012). Photofermentative Hydrogen Production in Outdoor Conditions. Hydrogen Energy - Challenges and Perspectives. doi: 10.5772/50390. Creative Commons Attribution 3.0 License,

We studied nitrogenase in Chapter x.xx. The net reaction for the fixation of nitrogen is shown below.

$$N_2 + 8H^+ + 8e^- + 16ATP \rightarrow 2NH_3 + H_2 + 16ADP + 16Pi \quad (32.9.5)$$

In this reaction, N_2 is reduced as the N atoms go from a 0 oxidation state to +3 in NH_3. The needed electrons are made from organic acids and fed into the system and eventually go to ferredoxin, which transfers them to protons. The ratio of N_2 to H_2 produced is 1:1, at the expense of 16ATPs per H_2 produced.

The ATP produced by the collapse of the produced proton gradient through FoF1ATPase powers the reaction.

In the absence of N_2, the net reaction becomes

$$2H^+ + 2e^- + 4ATP \rightarrow H_2 + 4ADP + 4Pi \quad (32.9.6)$$

The electrons are still fed into nitrogenase, but in the absence of the substrate N_2, they are used to reduce $2H^+$ to H_2. Note that only 4 ATPs are required per each H_2 produced, a significant energy gain.

ATP produced during photosynthesis would be used for anabolic biosynthesis contributing to biomass, so extra ATP is needed to support H_2 synthesis past that needed for growth. As anabolism is a reductive process (compared to oxidative catabolism), adequate sources of electrons for reduction are required. Multiple pathways need electrons, including CO_2 fixation, N_2 fixation (with associated H_2 production, and organic acids like polyhydroxbutyrate. The bacteria use photosynthesis and the Calvin cycle under photoautotrophic conditions to fix CO_2. When external energy supplies from organic acids are present, the bacteria can become photoheterotropic. Under these conditions, the Calvin cycle is used to maintain redox balance.

Dark Fermentation

We studied this indirectly above section in our discussion of hydrogenases in microalgae. Hydrogenases are induced in dark conditions, and this pathway involved heterotrophic fermentation (anaerobic) in some bacteria and microalgae. Many microbial species are used. Industrial wastewater enriched in organic material can be used as a feedstock.

Feedstock materials are hydrolyzed and subjected to fermentation, during which H_2 can be produced. For example, pyruvate produced by glycolytic fermentation can be oxidatively decarboxylated to acetyl-CoA and CO_2 by pyruvate:ferredoxin oxidoreductase with electrons passed on to ferredoxin and even through hydrogenase to form H_2 (as we described above). Addition H_2-produced steps after fermentation include acetogenesis and methanogenesis. These processes are illustrated in Figure 32.9.11 below.

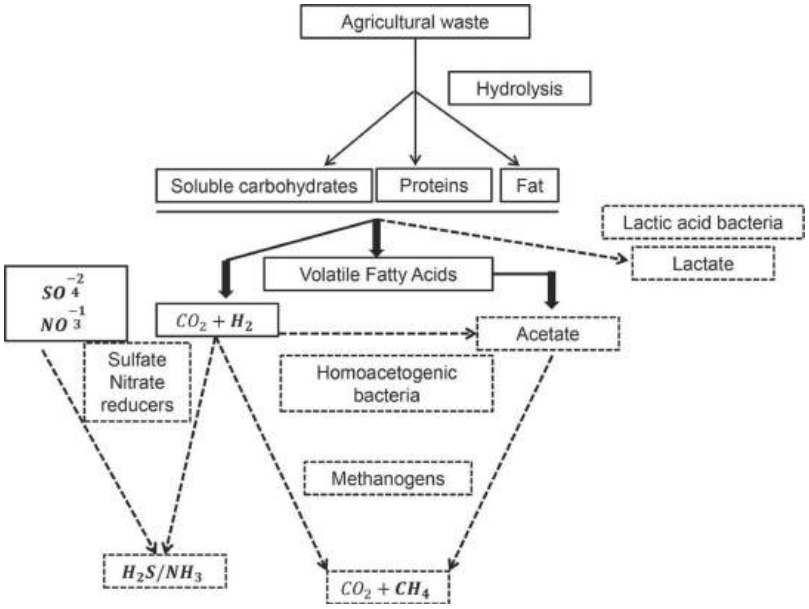

Figure 32.9.11: The steps involved in anaerobic digestion [9]. Rosa, P. R. F., & Silva, E. L. (2017). Review of Continuous Fermentative Hydrogen-Producing Bioreactors from Complex Wastewater. Frontiers in Bioenergy and Biofuels. doi: 10.5772/65548. Creative Commons Attribution 3.0 License

Examples of acidogenic (formation of short carboxylic/fatty acid), acetogenic (formation of acetic acid), and methanogenic (formation of methane) reactions that produce (and a few that consume) H_2 are shown in Table 32.9.3 below.

Acidogenic reactions
$C_6H_{12}O_6 + 2H_2O \rightarrow 2CH_3COOH + 2CO_2 + 4H_2$
$C_6H_{12}O_6 + 2H_2O \rightarrow CH_3CH_2CH_2COOH + 2CO_2 + 2H_2$
Acetogenic reactions
$CO_2 + 4H_2 \rightarrow CH_3COOH + 2H_2O$
$CH_3CHOHCOOH + H2O \rightarrow CH_3COOH + CO_2 + 2H_2$
$CH_3CH_2OH + H2O \rightarrow CH_3COOH + 2H_2$
$CH_3CH_2COOH + 2H_2O \rightarrow CH_3COOH + CO_2 + 3H_2$
$CH_3(CH_2)_2COOH + 2H_2O \rightarrow 2CH_3COOH + 2H_2$
Methanogenic reactions
$4H_2 + CO_2 \rightarrow CH_4 + 2H_2O$
$CH_3COOH \rightarrow CH_4 + CO_2$
$2CH_3(CH_2)_2COOH + 2H_2O + CO_2 \rightarrow 4CH_3COOH + CH_4$

Table 32.9.3: Example of acidogenic, acetogenic, and methanogenic reactions in dark fermentation. Adapted from Rosa, P. R. F., & Silva, E. L., ibid.

We have described a few of the enzymes involved in acidogenic reactions above. Figure 32.9.12 shows a summary of the steps in acidogenesis.

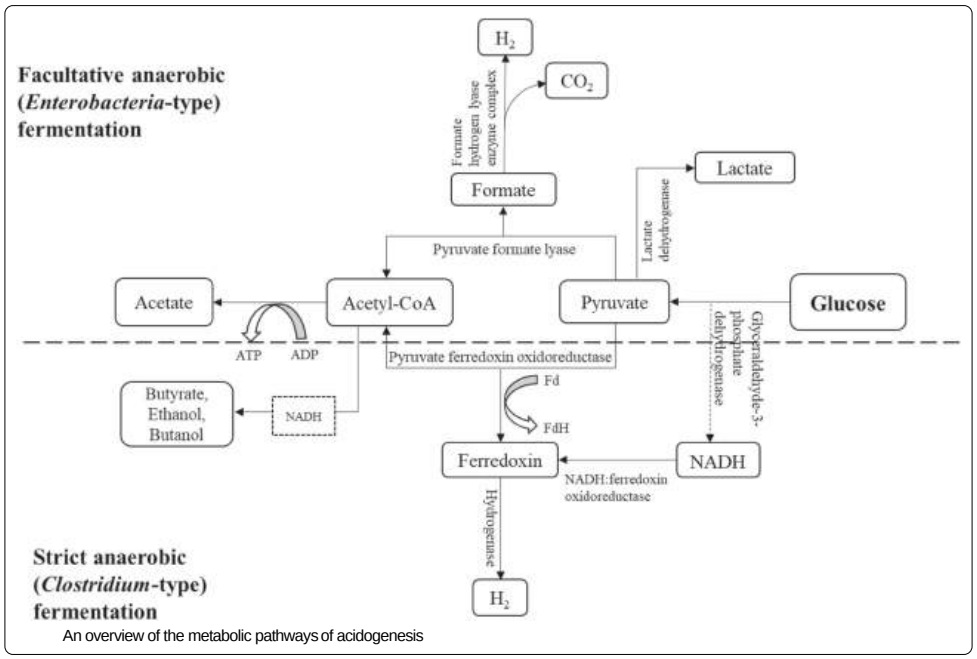

Figure 32.9.12: An overview of the metabolic pathways of acidogenesis. Dzulkarnain, E.L.N., Audu, J.O., Wan Dagang, W.R.Z. *et al.* Microbiomes of biohydrogen production from dark fermentation of industrial wastes: current trends, advanced tools and future outlook. *Bioresour. Bioprocess.* **9**, 16 (2022). https://doi.org/10.1186/s40643-022-00504-8. http://creativecommons.org/licenses/by/4.0/.

A more complex list and summary of dark fermentation reactions are shown in Figure 32.9.13 below.

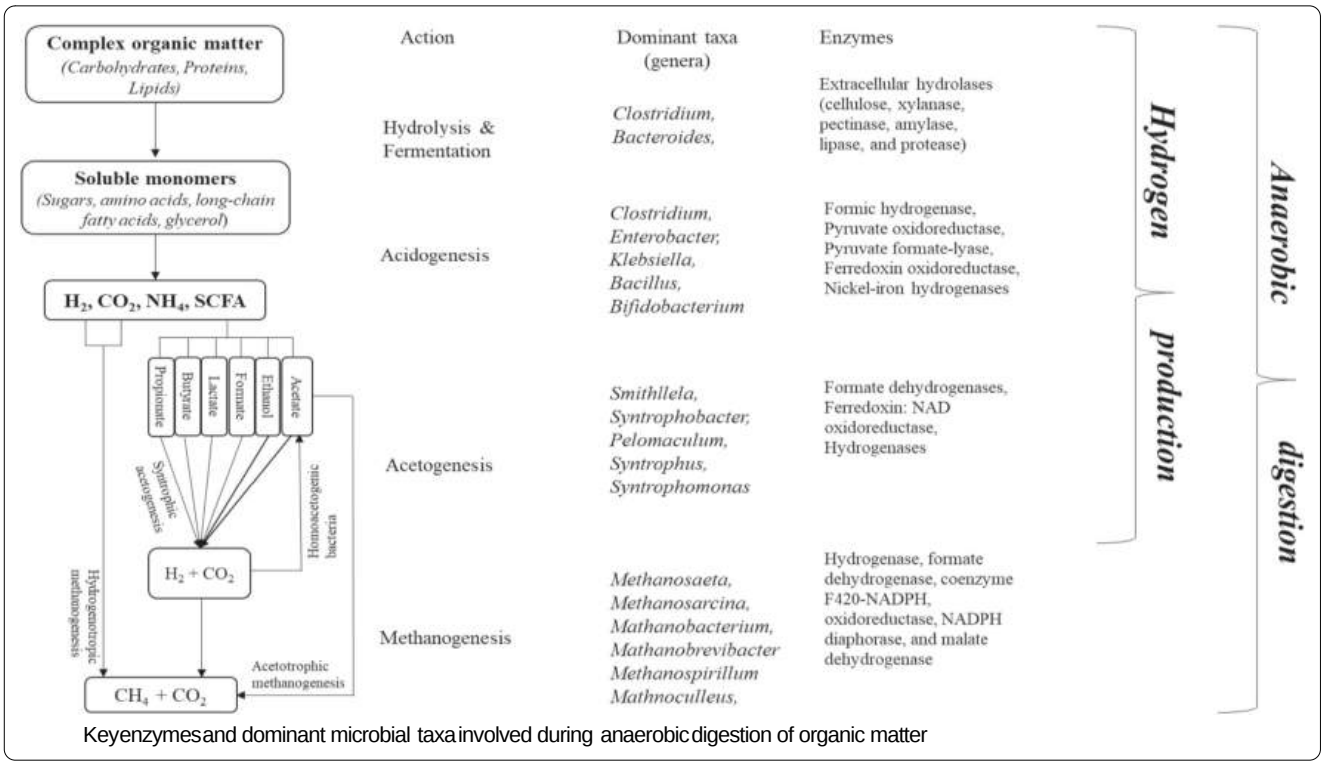

Figure 32.9.13: Key enzymes and dominant microbial taxa involved during anaerobic digestion of organic matter. Dzulkarnain, E.L.N.et al. Ibid.

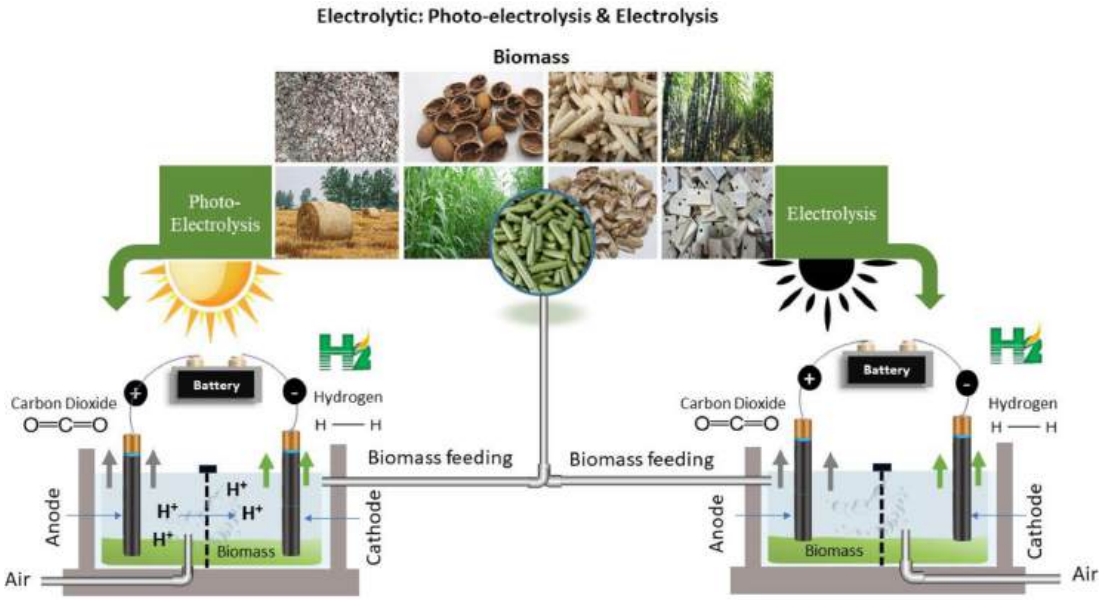
32.09.4.3: ELECTROCHEMICAL/ELECTROLYTIC (3)

Two primary electrochemical/electrolytic methods for H_2 production are photoelectrochemical and electrolytic, as shown in Figure 32.9.14 below.



djfkjdk

Figure 32.9.14: Schematic diagram for the electrochemical process. M.G. Eloffy et al.

Electrolysis

In a microbial electrolytic cell (MEC), microalgae/cyanobacteria use industrially- and metabolically-processed feedstocks to oxidize organic substrates (for example, acetic acid) to CO_2. The released electrons move from the anode (where the oxidation occurs) to the cathode for H^+ reduction to H_2. An external voltage is applied to increase electron flow to the cathode to facilitate the process. This increases the production of H_2 over and above that of just fermentation by microbes in the electrolytic cell. Cyanobacteria and a mix of green microalgae are used, as well as bacteria, which can use dark fermentation (i.e., combining the processes described above).

Photoelectrochemical

Microbial photoelectrochemical cells (PEC) use light-sensitive semiconductor electrodes for water electrolysis. A membrane separates the two electrodes so the protons can be reduced to form H_2. for the separated by a membrane,

32.09.5: 2. THERMOCHEMICAL FROM BIOMASS

We have already explored thermochemical methods to produce syngas (H_2 and CO) and further use in the Fishcer-Tropsch reaction to make small and large molecules for chemical feedstocks and fuels. We also discussed electrochemical methods to produce syngas and other small organic molecules like formate and ethanol from CO_2. Figure 32.9.15 shows a schematic diagram for thermochemical (gasification) processes to produce H_2.

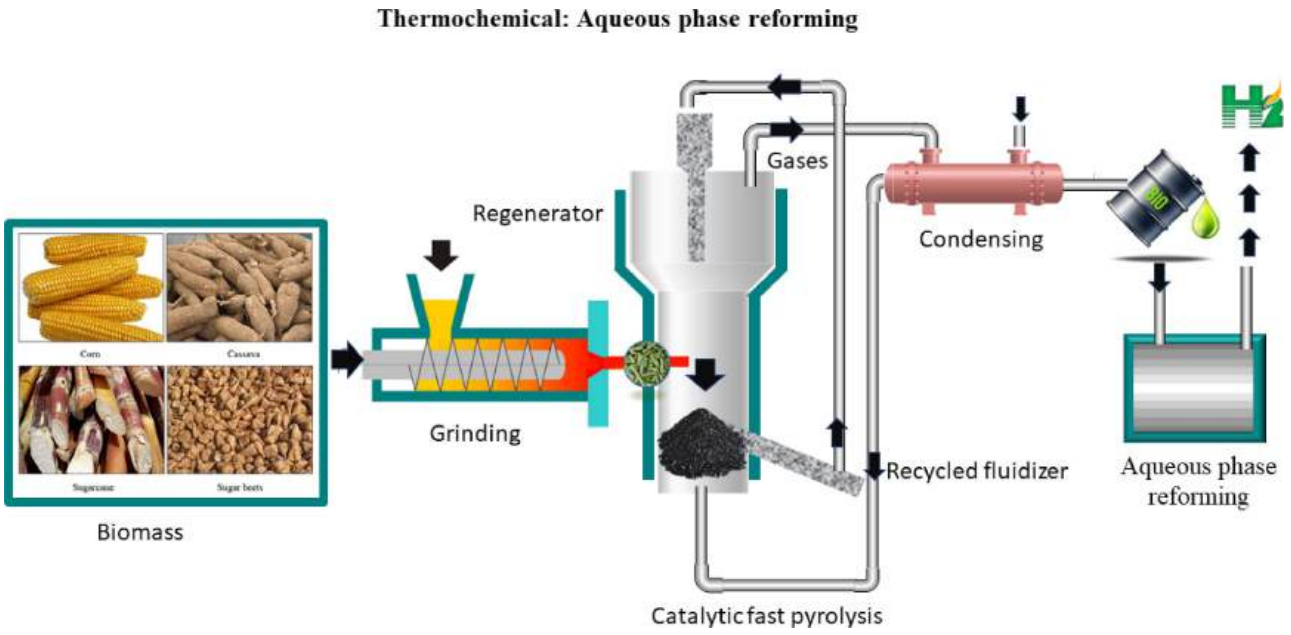


Figure 32.9.15: Schematic diagram for thermochemical (aqueous phase reforming) process. M.G. Eloffy et al.

KEY POINTS - BETA VERSION FROM CHAT.OPENAI

1. Biohydrogen is a form of biofuel that is produced from biomass through a process known as biological hydrogen production.
2. Biological hydrogen production involves the use of microorganisms, such as bacteria and algae, to convert organic matter into hydrogen gas.
3. Biohydrogen has the potential to be a clean, renewable, and sustainable source of energy, as it produces only water when burned and does not produce greenhouse gases.
4. Photosynthetic microorganisms such as algae and cyanobacteria are the most promising organisms for biohydrogen production, they can convert water and CO2 into hydrogen and oxygen through the process of photosynthesis.
5. Fermentative microorganisms such as bacteria and fungi can also be used to produce biohydrogen, they can convert organic materials such as sugars and starches into hydrogen through the process of fermentation.
6. Biohydrogen can be produced through different processes, including dark fermentation, light-driven fermentation, and photo-biological hydrogen production.
7. Dark fermentation is the process of using microorganisms to ferment organic matter in the absence of light to produce hydrogen gas.
8. Light-driven fermentation is the process of using microorganisms to ferment organic matter in the presence of light to produce hydrogen gas.
9. Photo-biological hydrogen production is the process of using algae or photosynthetic bacteria to produce hydrogen gas through photosynthesis.
10. Biohydrogen production is still in the early stages of development and research is ongoing to improve the efficiency and cost-effectiveness of the process.
11. Biohydrogen production from algae is considered more sustainable and environmentally friendly than traditional hydrogen production methods, which are often based on fossil fuels.
12. Biohydrogen has the potential to significantly reduce carbon emissions and to help decarbonize various sectors, including transportation and energy.

32.10: BIOHYDROGEN - HYDROGENASES

Search Fundamentals of Biochemistry

INTRODUCTION

In the last section, we described different ways to produce H_2 and the colors ascribed to them based on the environmental impacts. Many look to the production and use of H_2 to provide energy without releasing CO_2. H_2 can be used in fuel cells to power spacecraft and cars, as shown in the reaction below.

$$\begin{aligned} O_2 + 4H^+ + 4e^- &\longrightarrow 2H_2O \\ H_2 &\longrightarrow 4H^+ + 4e^- \end{aligned} \tag{32.10.1}$$

Cars are already available that run on H_2 considered a zero-emission fuel. These fully electric cars use fuel cells powered by the oxidation of H_2 to produce electrical energy.

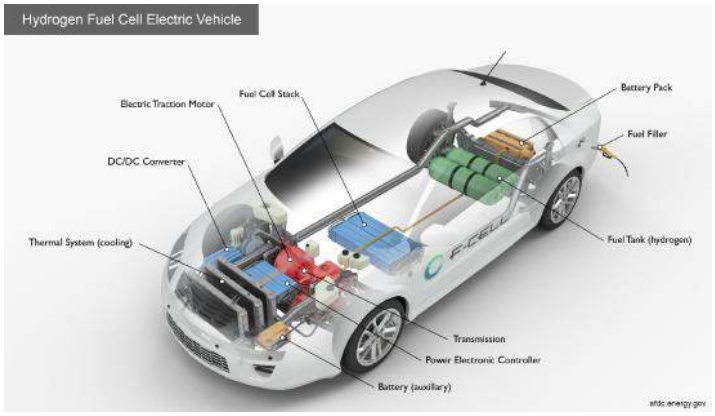

Figure 32.10.1: https://afdc.energy.gov/vehicles/how...tric-cars-work

Given the scale needed, most H_2 is presently derived from the steam reformation of natural gas and the electrolysis of water. From a biochemical perspective, cells have evolved to make H_2 and use H_2 as an energy source. It's unlikely that direct microbial production of H_2 would meet society's energy needs. The 2023 International Energy Agency (IEA) report, "Hydrogen patents for a clean energy future", doesn't mention direct microbial production. However, much can be learned by studying how **hydrogenases (H_2ases, Hyd)**, enzymes that make or use H_2, work. (Don't confuse hydrogenases with dehydrogenases that directly use NAD^+/NADH and FAD/$FADH_2$) for redox reactions. Transition metal active site mimetics can be made as potential catalysts for more industrial-level production of H_2.

Although the reversible formation of H_2 involves the most elemental particles in chemistry, H^+ and e^-, the biological reactions that produce and consume H_2 are complex. Before we proceed, let's see how these reactions are similar to other biochemical reactions and pathways we have already discussed.

Use of H_2 as a *source* of electrons for reduction reactions.

Each hydrogen in H_2 has an oxidation number of 0. Each hydrogen can be oxidized to H^+ (oxidation number +1) with the 2 electrons passed on to a substrate/cofactor or a sequential series of substrates with higher and higher standard reduction potentials (better oxidizing agents), leading to the formation of reduced products.

$$H_2 + (\text{substrate})_{OX} \rightarrow 2H^+ + (\text{product})_{RED}$$

This general reaction is analogous to the mitochondrial electron transport chain, in which electrons are passed from a source (NADH) to oxidized forms of acceptors. The general reaction below shows each redox pair in the electron transport chain.

$$NADH/NAD^+ \rightarrow FAD/FADH_2 \rightarrow UQ/UQH2 \rightarrow \text{Cyto } C_{OX}/\text{Cyto } C_{RED} \rightarrow O_2/H_2O$$

Some organisms have evolved to produce energy by the oxidation of H_2. This is analogous to photosynthetic organisms obtaining energy through the oxidation of water. In photosystem II, oxygen in H_2O (oxidation number -2) gets oxidized by the oxygen-evolving complex to produce O_2 (oxidation number 0). Some redox pairs, starting with H_2O/O_2, are shown below for photosystem II.

$$H_2O/O_2 \rightarrow P680/P680^* \rightarrow (\text{Plastoquione})_{OX}/(\text{Plastoquione})_{RED}$$

The first reaction is endergonic and requires as an energy source photons.

Use of H^+ as a *sink* for electrons for oxidation reactions that produce H_2.

H^+ has an oxidation number of +1. Hence it can be reduced to H_2 (oxidation number of 0) as it gains electrons from substrates/cofactors, which get oxidized. This general reaction is shown below.

$$2H^+ + (\text{substrate/cofactor})RED \rightarrow H_2 + (\text{substrate/cofactor})OX$$

Many microorganisms can produce H_2 through variants of photosynthesis or through fermentation, both of which provide the two electrons needed. E. Coi has four hydrogenases (Hyd 1, 2, 3, and 4). It forms H_2 through two reactions catalyzed by:

- formate (HCO_2^-) dehydrogenase (FDH): $2HCO_2^- \rightleftharpoons 2CO_2 + 2H^+ + 2e^-$
- hydrogenase (H_2ase): $2H^+ + 2e^- \rightarrow H_2$

The C in formate has an oxidation number of +2 and is oxidized to CO_2, in which the C has an oxidation number of +4.

The formate hydrogenlyase (FHL) complex contains both the formate dehydrogenase (FDH) and a hydrogenase (H_2ase) and reversibly interconverts HCO_2^- and H_2. The *E. coli* FHL-1 complex, which makes H_2 using fermentation, is shown below in Figure 32.10.2. The complex can be immobilized on a Macro-mesoporous inverse opal (IO) indium tin oxide (ITO) electrode (IO-IPO) or ITO nanoparticles (NP), which can relay electrons.

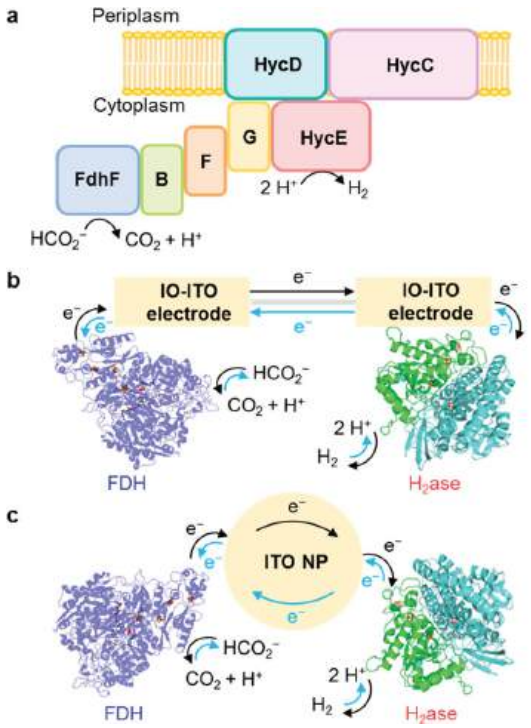

Figure 32.10.2: Katarzyna P. Sokol et al. J. *Am. Chem. Soc.* 2019, 141, 44, 17498–17502. https://doi.org/10.1021/jacs.9b09575. **CC-BY license**

Panel (a) shows the biological *E. coli* FHL-1 complex. FdhF, [Mo]-FDH; B/F/G, Fe–S cluster-containing proteins; HycE, [NiFe]-H_2ase; HycD/C, membrane proteins. (17)

Panel (b) shows a IO-ITO|FDH||IO-ITO|H_2ase cell: IO-ITO|FDH wired to IO-ITO|H_2ase electrode.

Panel (c) shows a FDH–ITO–H_2ase nanoparticle (NP) system with enzymes immobilized onto ITO NP in solution. Species size not drawn to scale.

All you need to synthesize H_2 are 2 protons and 2 electrons (potentially derived from photosynthesis). Let's take a deeper look at the hydrogenase that catalyzes H_2 production.

HYDROGENASES (H_2ASES)

Hydrogenases catalyze the reversible conversion of $2H^+ \rightarrow H_2$. A hydrogenase database, HydDB, a web tool for hydrogenase classification and analysis of sequence, shows their high diversity and metabolic roles. There are three classes of hydrogenases, the **Ni-Fe** (most abundant, primarily for H_2 conversion to $2H^+$), the **Fe-Fe** (highest k_{cat} for H_2 production), and the **single Fe** hydrogenases, as shown in Table 32.10.2 below. We won't discuss the single Fe hydrogenases.

CLASSES AND SUBCLASSES OF HYDROGENASES

[NiFe] Group 1: Respiratory H_2-uptake [NiFe]-hydrogenases		
1a	Periplasmic	Electron input for sulfate, metal and organohalide respiration. [NiFeSe] variants.
1b	Prototypical	Electron input for sulfate, fumarate, metal and nitrate respiration.
1c	Hyb-type	Electron input for fumarate, nitrate and sulfate respiration. Physiologically reversible.
1d	Oxygen-tolerant	Electron input for aerobic respiration and oxygen-tolerant anaerobic respiration.
1e	Isp-type	Electron input primarily for sulfur respiration. Physiologically reversible.
1f	Oxygen-protecting	Unresolved role. May liberate electrons to reduce reactive oxygen species.
1g	Crenarchaeota-type	Electron input primarily for sulfur respiration.
1h	Actinobacteria-type	Electron input for aerobic respiration. Scavenges electrons from atmospheric H_2.
1i	Coriobacteria-type (putative)	Undetermined role. May liberate electrons for anaerobic respiration.
1j	Archaeoglobin-type	Electron input for sulfate respiration[π].
1k	Methanophenazine-reducing	Electron input for methanogenic heterodisulfide respiration.
[NiFe] Group 2: Alternative and sensory uptake [NiFe]-hydrogenases		
2a	Cyanobacteria-type	Electron input for aerobic respiration. Recycles H_2 produced by other cellular processes.
2b	Histidine kinase-linked	H_2 sensing. Activates two-component system controlling hydrogenase expression.
2c	Diguanylate cyclase-linked (putative)	Undetermined role. May sense H_2 and regulate processes through cyclic di-GMP production.
2d	Aquificae-type	Unresolved role. May generate reductant for carbon fixation or have a regulatory role.
2e	Metallosphaera-type (putative)	Undetermined role. May liberate electrons primarily for aerobic respiration.
[NiFe] Group 3: Cofactor-coupled bidirectional [NiFe]-hydrogenases		
3a	F_{420}-coupled	Couples oxidation of H_2 to the reduction of F_{420} during methanogenesis. Physiologically reversible. [NiFeSe] variants.
3b	NADP-coupled	Couples oxidation of NADPH to the evolution of H_2. Physiologically reversible. May have sulfhydrogenase activity.

3c	Heterodisulfide reductase-linked	Bifurcates electrons from H_2 to heterodisulfide and Fd_{ox} in methanogens. [NiFeSe] variants.
3d	NAD-coupled	Interconverts electrons between H_2 and NAD depending on cellular redox state.
	[NiFe] Group 4: Respiratory H_2-evolving [NiFe]-hydrogenases	
4a	Formate hydrogenlyase	Couples formate oxidation to fermentative H_2 evolution. May be H^+-translocating.
4b	Formate-respiring	Respires formate or carbon monoxide using H^+ as electron acceptor. Na^+-translocating via Mrp.
4c	Carbon monoxide-respiring	Respires carbon monoxide using H^+ as electron acceptor. H^+-translocating.
4d	Ferredoxin-coupled, Mrp-linked	Couples Fd_{red} oxidation to H^+ reduction. Na^+-translocating via Mrp complex.
4e	Ferredoxin-coupled, Ech-type	Couples Fd_{red} oxidation to H^+ reduction. Physiologically reversible via H^+/Na^+ translocation.
4f	Formate-coupled (putative)	Undetermined role. May couple formate oxidation to H_2 evolution and H^+ translocation.
4g	Ferredoxin-coupled (putative)	Undetermined role. May couple Fd_{red} oxidation to proton reduction and H^+/Na^+ translocation.
4h	Ferredoxin-coupled, Eha-type	Couples Fd_{red} oxidation to H^+ reduction in anaplerotic processes. H^+/Na^+-translocating.
4i	Ferredoxin-coupled, Ehb-type	Couples Fd_{red} oxidation to H^+ reduction in anabolic processes. H^+/Na^+-translocating.
	[FeFe] Hydrogenases	
A1	Prototypical	Couples ferredoxin oxidation to fermentative or photobiological H_2 evolution.
A2	Glutamate synthase-linked (putative)	Undetermined role. May couple H_2 oxidation to NAD reduction, generating reductant for glutamate synthase.
A3	Bifurcating	Reversibly bifurcates electrons from H_2 to NAD and Fd_{ox} in anaerobic bacteria.
A4	Formate dehydrogenase-linked	Couples formate oxidation to H_2 evolution. Some bifurcate electrons from H_2 to ferredoxin and NADP.
B	Colonic-type (putative)	Undetermined role. May couple Fd_{red} oxidation to fermentative H_2 evolution.
C1	Histidine kinase-linked (putative)	Undetermined role. May sense H_2 and regulate processes via histidine kinases.
C2	Chemotactic (putative)	Undetermined role. May sense H_2 and regulate processes via methyl-accepting chemotaxis proteins.
C3	Phosphatase-linked (putative)	Undetermined role. May sense H_2 and regulate processes via serine/threonine phosphatases.
	[Fe] Hydrogenases	

All	Methenyl-H_4MPT dehydrogenase	Reversibly couples H_2 oxidation to 5,10-methenyltetrahydromethanopterin reduction.

The three main types have different main functions *in general*. The Ni-Fe, Fe-Fe, and Fe H2ases generally oxidize H_2, produce H_2 and promote H^- (hydride) transfer, respectively, as shown in Figure 32.10.3 below.

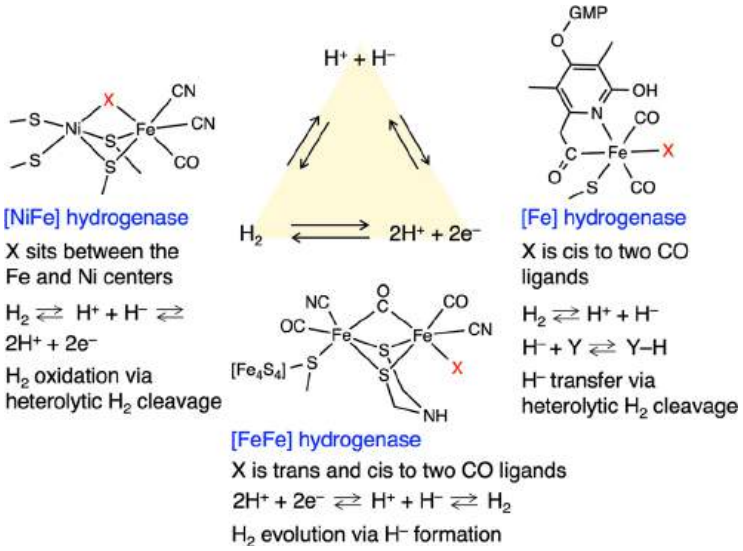

Figure 32.10.3: The active site structures of [NiFe] H_2ases that mainly catalyze H_2 oxidation reactions, [FeFe] H_2ases that mainly catalyze H_2 evolution reactions, and [Fe] H_2ases that catalyze H^- transfer to the substrate via heterolytic H2cleavage. X, possible H_2 active sites; Y, methenyltetrahydromethanopterin; GMP, guanosine monophosphate. Seiji Ogo et al., Science Advances. (2020). DOI: 10.1126/sciadv.aaz81. Creative Commons Attribution-NonCommercial License 4.0 (CC BY-NC).

Much effort has been devoted to making transition state analogs of the active site to act as catalysts for H_2 production for fuel cells. Transition metal catalysts that mimic the structures and activities of the three hydrogenases have been made. Three specific ones are shown below in Figure 32.10.4.

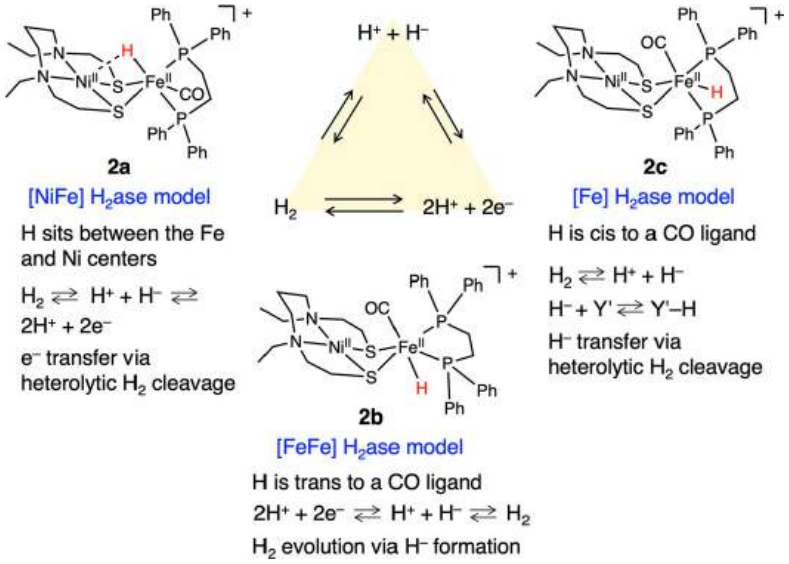

Figure 32.10.4: The differing reactivity of the three isomers. Y′, methylene blue $[MB]^+$.Seiji Ogo et al., ibid.

The ligand containing P and PH is bis(diphenylphosphino)ethane.

First, we will explore the Ni-Fe hydrogenases.

NI-FE H_2ASES (HYD):

We'll discuss two examples of Ni-Fe H_2ases

Group 1a periplasmic (membrane-bound) hydrogenases - MBH

These are used in fuel cells and H_2-producing devices since they can adhere to surfaces that can be useful heterogeneous (not in solution) catalysts. Some also are damaged by O_2. The enzyme consists of a large subunit) found in the periplasm and small subunit, which anchors the protein in the plasma membrane of bacteria. . This enzyme oxidizes H_2: $H_2 \rightarrow 2H^+ + 2e^-$. The electrons enter the bacterial respiratory chain through quinones. The transmembrane part of the small subunit binds cytochrome b, which is involved in electron transfer with the quinones, as we saw in Complex II of mitochondrial electron transport. Some soil bacteria (like *Ralstonia eutropha*,) can use H_2 as their sole energy source. The orientation of a NiFe MBH within a bacterial cell is shown in Figure 32.10.5 below.

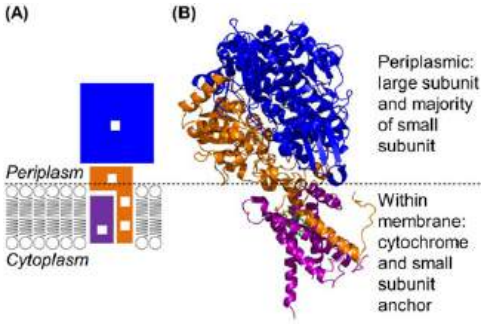

Figure 32.10.5: The orientation of a NiFe MBH within a bacterial cell. Lindsey A. Flanagan* and Alison Parkin. Biochem Soc Trans. 2016 Feb 15; 44(1): 315–328 (2016). doi: 10.1042/BST20150201 Creative Commons Attribution Licence 3.0.

Panel (**A**) shows a cartoon depiction of how a NiFe MBH is located within the cytoplasmic membrane, with white boxes representing the redox active metal centers and blue, orange and purple blocks indicating the large, small and cytochrome subunits, respectively.

Panel (**B**) shows how the *E. coli* hydrogenase-1 large (blue ribbon), small (orange ribbon) and cytochrome (purple ribbon) subunits can interact.

Figure 32.10.6 shows an interactive iCn3D model of the O_2-Tolerant Membrane-Bound Hydrogenase 1 from Escherichia coli in Complex with Its Cognate Cytochrome b (4GD3). The same color coding is used for the subunits as in the above figures.

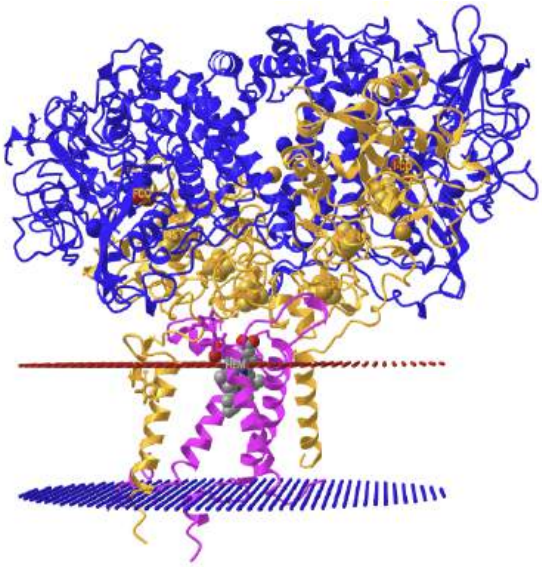

Figure 32.10.6: O_2-Tolerant Membrane-Bound Hydrogenase 1 from Escherichia coli in Complex with Its Cognate Cytochrome b (4GD3). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...9p4CSQRDPM8nL7

The large and small chains of hydrogenase are shown in blue and orange, respectively, while cytochrome b is sown in magenta. Cofactors and key metals are shown in spacefill. F4S is the Fe4-S3 cluster, SF4 is the iron-sulfur cluster, HEM is hemoglobin, FCO is carbonmonoxide-(dicyano) Fe, and Ni is nickel.

The biological (functional) unit consists of two heterodimers. Under low O_2 levels, one dimer can reactivate the other if exposed to O_2. The enzyme is found in the highest concentration during anaerobic fermentation. Remember that E. Coli is a facultative anaerobe and can shift its metabolic pathways to fit conditions. Perhaps its primary role is to reduce O_2 to water and protect enzymes sensitive to it. The function of Cytochrome b may be mostly to anchor the dimeric H_2ase in the membrane.

A bifurcating Ni-Fe H_2ase

These enzymes are more complicated. They oxidize H_2 and move the two electrons through a complicated path that bifurcates electron flow to different substrates/cofactors. They move an electron to a low-potential (i.e. not a great oxidizing agent), high-energy species, which gets reduced in an endergonic process. The other electron simultaneously moves to a high-potential (i.e., great oxidizing agent), low-energy species that also gets reduced in an exergonic process. The overall electron transfer is thermodynamically favorable. An example might prove helpful. NADH ($E^{0'}$ = -280 mV, higher potential) can reduce the protein ferredoxin ($E^{0'}$ = -500 mV, lower potential), which can then pass its electrons in other reactions, including the formation of H_2, CH_4, and NH_3. ATP is not required.

BIFURCATING ENZYMES - WE'VE SEEN ONE BEFORE!

Four classes of bifurcating enzymes that use $FAD/FADH_2$ or $FMN/FMNH_2$ are known. They are optimal since they can participate in either 1 or 2 electron transfers. We will see an example of a Fe-Fe H_2ase further below.

In electron transport, we encountered an electron bifurcating complex in the Q-cycle of Complex III. Reduced ubiquinone (UQH_2, or ubiquinol) is oxidized and the two lost electrons bifurcated to cytochrome C in a high potential pathway and to UQ to reform UQH2, as shown in Figure 32.10.7 below.

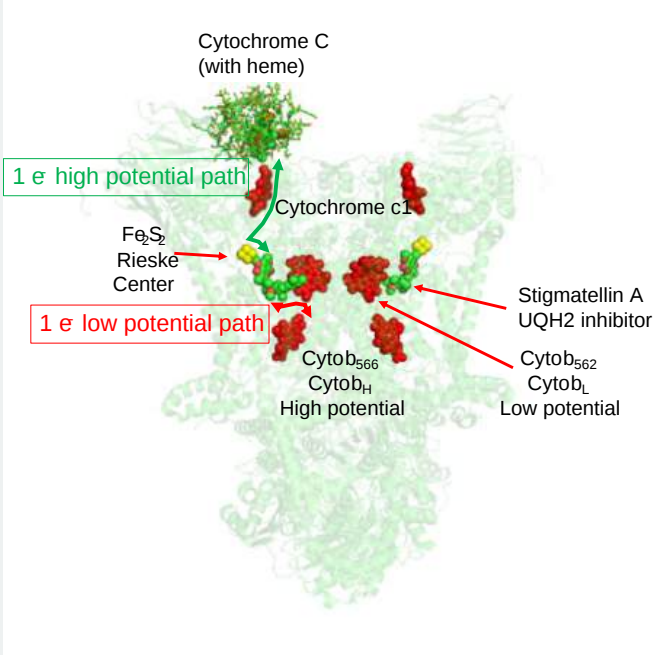

Figure 32.10.7: Electron bifurcation in Complex III

When ubiquinone, UQH "Electron bifurcation was first described in the Q-cycle of the respiratory complex III where the two electrons originating from ubiquinol oxidation are bifurcated via a *high*-potential pathway to cytochrome c, and via a *low*-potential path to reduce ubiquinone to ubiquinol.

One example of a bifurcating Ni-Fe H_2ase is the NiFe-HydABCSL protein from the bacteria *A. mobile*. The general structure of the pentameric form of the functional decamer is shown in Figure 32.10.8 below.

Figure 32.10.8: Structure of the *A. mobile* NiFe-HydABCSL pentamer. XIANG FENG et al. ***SCIENCE ADVANCES.*** 2022. DOI: 10.1126/sciadv.abm7546. Creative Commons Attribution License 4.0 (CC BY). https://creativecommons.org/licenses/by/4.0/

The five subunits are called HydA (Hyd = hydrogenase), HydB, HydC, HydL (large subunit), and HydS (small subunit). Pane (**A**) shows the domain structure of the five subunits. The NiFe-HydB NTD and CTDs are partially flexible, as indicated by dashed outlines. Panel (**B**) shows the subunit organization of the NiFe-Hyd complex and their associated cofactors.

NiFe-HydABCSL hydrogenase can reversibly oxidize H_2 with the two electrons reducing ferredoxin in an endergonic process and reducing NAD in an exergonic process. FMN is surrounded by an FeS cluster and appears to be the center of bifurcation. The reaction is as follows:

- The HydL oxidizes H_2 with two electrons passing through the FeS centers in HydA to HybB.
- The electrons are passed to FMN, where the bound NAD gets reduced.

Figure 32.10.9 jdkfjdkjfdkjff

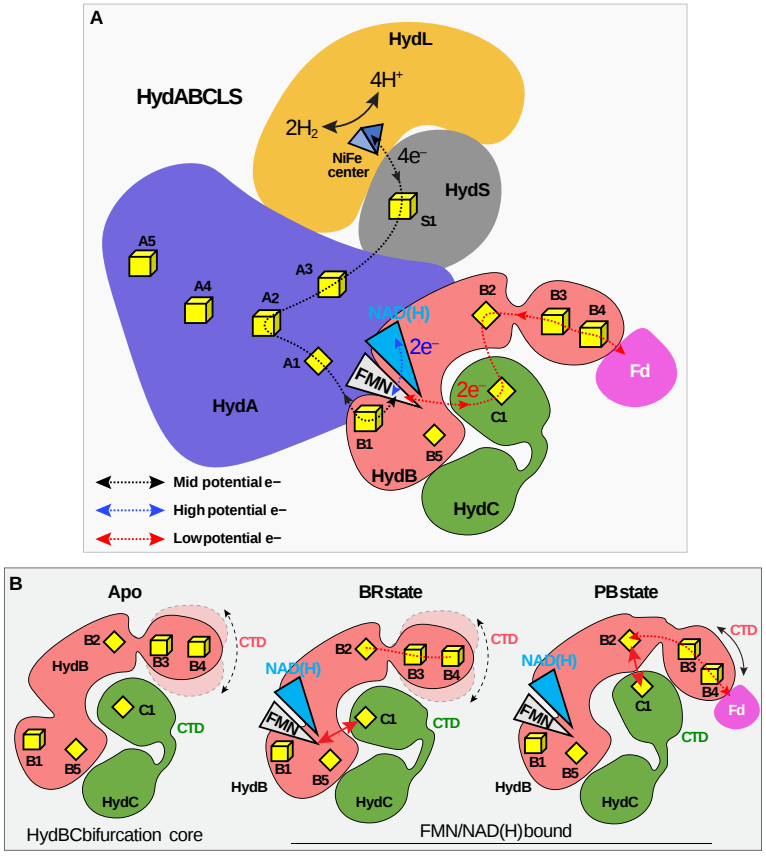

Figure 32.10.9: Proposed mechanism of electron bifurcation/confurcation in *A. mobile* NiFe-HydABCSL.

(**A**) Overall electron transfer pathway, highlighting the three branches of the electron transfer path. The mid-potential path is a black dashed line, the exergonic path is a blue dashed line, and the endergonic path is a red dashed line. (**B**) Conformational changes in the HydBC bifurcation core from the electron bifurcation state (BR state) to the electron transduction state (PB state).

Zoom into the Ni-Fe center catalytic site. The ligands that form coordinate covalent bonds to the Fe are called FCC, or carbon monoxide-(dicyano)-Fe Figure 32.10.12 below. There are also bridging sulfurs between Fe and Ni.

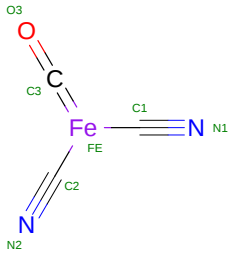

Figure 32.10.12 : Carbonmonoxo-dicyano-Fe and is shown in detail in

FE-FE HYDROGENASES

These enzymes catalyze a variety of reactions as illustrated in Figure 32.10.13 below.

Figure 32.10.13 : [FeFe]-hydrogenases phylogeny and known functions. Morra S. Front Microbiol. 2022 Mar 2;13:853626. doi: 10.3389/fmicb.2022.853626. PMID: 35308355; PMCID: PMC8924675. Creative Commons Attribution License (CC BY)

A phylogenetic tree shows the phylogeny of [FeFe]-hydrogenase sequences from public databases, as previously proposed. Enzymes that have been experimentally characterized are indicated on the tree to show their relative position. The proposed physiological function of each enzyme is also presented, where known. Hyd, hydrogenase subunit; FdhF, formate dehydrogenase subunit; $Fd_{rex/ox}$, reduced/oxidized ferredoxin; $NADH/NAD^+$, reduced/oxidized nicotinamide adenine dinucleotide. They are found in prokaryotic and eukaryotic microorganisms, but not in Archaea.

These are the most active for H_2 production with a k_{cat} around 10,000 s^{-1}. They contain a Fe_2S_2 cluster with CO and CN ligands forming bonds to the iron with the iron ions bridged by a $-SCH_2-NH-CH_2S-$ (aza-dithiolate). A cysteine links the Fe2S2 to a Fe_4S_4 cluster. These two are called the **H-cluster (or $[Fe]_H$**. Within this class are a soluble, monomeric cytoplasmic form, a heterodimeric periplasmic form, and a soluble, monomeric chloroplastic form. This one has a ferredoxin, connecting it to the electron transport chain in photosynthesis. Some in this group using both NADH and ferredoxin are called bifurcating types, as they send two electrons from a donor in two different directions. More on this later.

They contain multiple FeS clusters. The H-cluster consists of a Fe_2S_2 linked to a Fe_4S_4 cluster (cubane-like) by a cysteine. The Fe_2S_2 group has CO and CN ligands, and the two Fe ions of Fe_2S_2 unit are coordinated by an azadithiolato ligand, as shown below in Figure 32.10.14 .

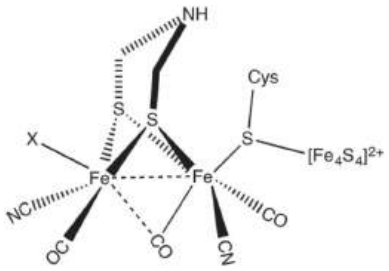

Figure 32.10.14 : Chemical structure of the H-cluster, which is the active site of the [FeFe] hydrogenase enzyme. Rakesh C. Puthenkalathil et al., Phys. Chem. Chem. Phys., 2020, 22, 10447. https://pubs.rsc.org/fa/content/arti.../cp/c9cp06770a. This article is licensed under a Creative Commons Attribution 3.0 Unported Licence

The Fe in the [2Fe2S] cluster is linked to the cubane [4Fe-4S] and has six ligands, so it is saturated. The other Fe has an extra coordination site denoted by X, which can bind H^+ or H_2. The cluster is buried in a hydrophobic catalytic site which helps restrict O_2 access.

As we did for the Fe-Ni H_2ases, we will study two examples of Fe-Fe H_2ases.

Fe-Fe hydrogenase (CpI) from Clostridium pasteurianum

Figure 32.10.15 shows an interactive iCn3D model of the H-Cluster (HC1) of Fe-Fe hydrogenase (CpI) from Clostridium pasteurianum (1FEH).

In this model, the CN ligands are all displayed as CO. The sulfurs are shown in green. Hover over the atoms/ions to identify them. (In iCn3D, choose, **Select, Select on 3D, atom**). The [4Fe-4S] subcluster forms coordinate covalent bonds with four cysteines (300, 355, 499, and 503) with one cysteine (503) forming a bridge to the [2Fe] cluster. The Fe ions in that cluster have an octahedral arrangement of ligands surrounding them. One of the ligands is water (no connecting C atom).

Figure 32.10.16 shows an interactive iCn3D model of the Fe-Fe hydrogenase (CpI) from Clostridium pasteurianum (1FEH)

As we mentioned above, the net reaction is:

$$2H^+ + (\text{substrate/cofactor})RED \rightarrow H_2 + (\text{substrate/cofactor})OX$$

Many microorganisms can produce H_2 through variants of photosynthesis or through fermentation, both of which provide the two electrons needed. E. Coi has four different hydrogenases, (Hyd 1, 2, 3 and 4). It forms H_2 through two reactions catalyzed by:

- formate (HCO_2^-) dehydrogenase: $2HCO_2^- \rightleftharpoons 2CO_2 + 2H^+ + 2e^-$
- hydrogenase 3: $2H^+ + 2e^- \rightarrow H_2$

Figure 32.10.17 below shows a reaction scheme for the production of H_2 linked to photosystem I in the chloroplast of microalgae under anaerobic conditions. It starts with absorption of a photon by P700, which in the excited state transfers an electron to a 4Fe4S cluster in ferredoxin, which then passes an electron to the HC-cluster and then onto H^+.

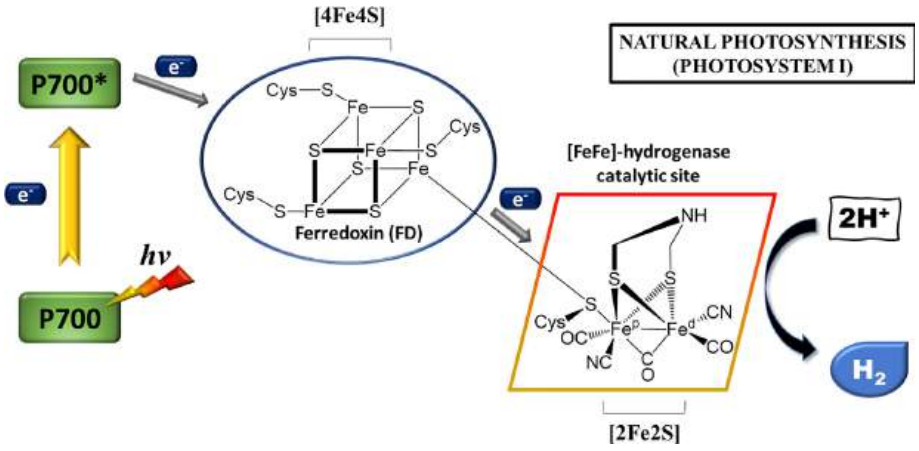

Figure 32.10.17: Schematic representation of electron flow from Photosystem I to an [FeFe]-hydrogenase via a ferredoxin redox mediator (Photosystem I). JuanAmaro-Gahete et al.,Coordination Chemistry Reviews. 448, December 2021. https://doi.org/10.1016/j.ccr.2021.214172. Creative Commons CC-BY

A possible mechanism for the formation of H_2 in the H clusteris shown below in Figure 32.10.18 below.

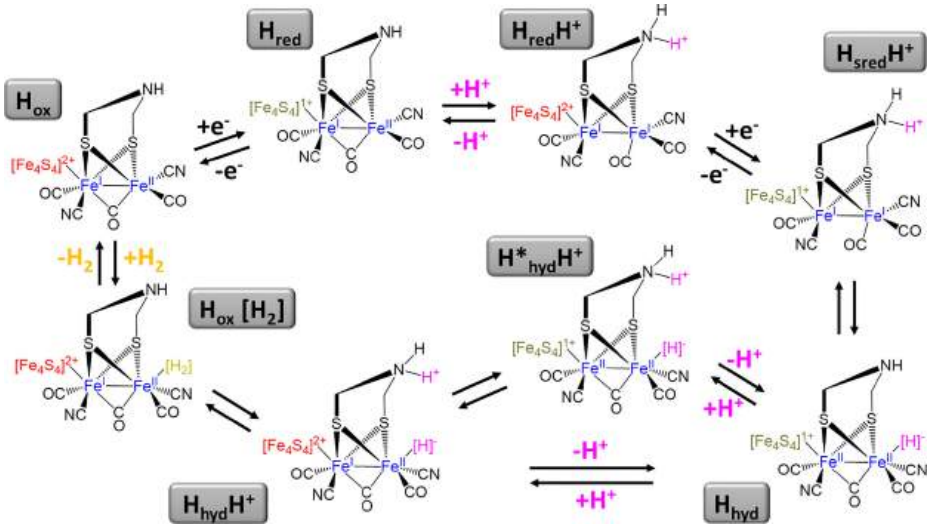

Figure 32.10.18: Proposed mechanistic cycle for hydrogen evolution in the H cluster by [FeFe]-hydrogenase adapted from Lubitz et al. JuanAmaro-Gahete et al., ibid

Start at the top left which shows the resting oxidized state. In the enzyme's most oxidized resting system (H_{ox}), the [4Fe4S] cubane is in a 2 + oxidation state while the catalytic subcluster [2Fe] is a mixed-valence $Fe^{I}Fe^{II}$ state. The first one-electron reduction results in the formation of the H_{red} state, where the [4Fe4S] subcluster is reduced to a 1 + oxidation state. Protonation of the N of aza-propane-1,3-dithiolate ligand (adt-*N*) triggers an intramolecular charge shift to form $H_{red}H^{+}$ in which the [4Fe4S] cubane is in the 2 + state and the [2Fe] subsite reduced to a homovalent $Fe^{I}Fe^{I}$ state. Subsequent one-electron reduction of the subcluster [4Fe4S] gives rise to the "super-reduced" state $H_{sred}H^{+}$. In the next step of the catalytic cycle, an intermediate hydride state [H_{hyd}] is formed by an intramolecular proton shift from the adt-*N* to the distal iron F_d. This process is coupled to an electron rearrangement in the [2Fe] subsite, leading to a formal $Fe^{II}Fe^{II}$ oxidation state. Addition of a second proton coupled to another charge shift from the reduced [4Fe4S] to the [2Fe] subsite either in one or two discrete steps gives rise to [$H_{hyd}H^{+}$] that is characterized by a formal $Fe^{I}Fe^{II}$ oxidation state. At this point, there is an equilibrium between the $H_{hyd}H^{+}$ and $H_{ox}[H_2]$ in which the hydride and the proton are combined into a hydrogen molecule at the distal iron of the system. The catalytic cycle is closed by H_2 release, returning to the initial H_{ox} configuration.

A bifurcating [Fe-Fe] hydrogenase from *Thermotoga maritima* (HydABC)

This enzyme, functionally a heterododecamer, uses NADH as a source of electrons, which passes electrons to FMN, the bifurcation site, with an electron going to oxidized ferredoxin (Fd_{ox}) and another to H^{+}s for reduction to FD_{RED} and H_2. The enzyme consists of a dimer of a trimer of subunits HydA, HydB, and HydC, with dimer $(HydABC)_2$ interacting with another $(HydABC)_2$ to form a heterododecamer, with both halves acting independently. The two trimers (HydABC) in the dimer $(HydABC)_2$ are connected by a [4Fe–4S] cluster. A flexible loop in the B and A chain has a "closed" and "open" bridge conformation with a nearby Zn^{2+} important in the loop conformation.

Figure 32.10.19 below shows the cryo-EM structure of the HydABC tetramer and the arrangement of the redox cofactors.

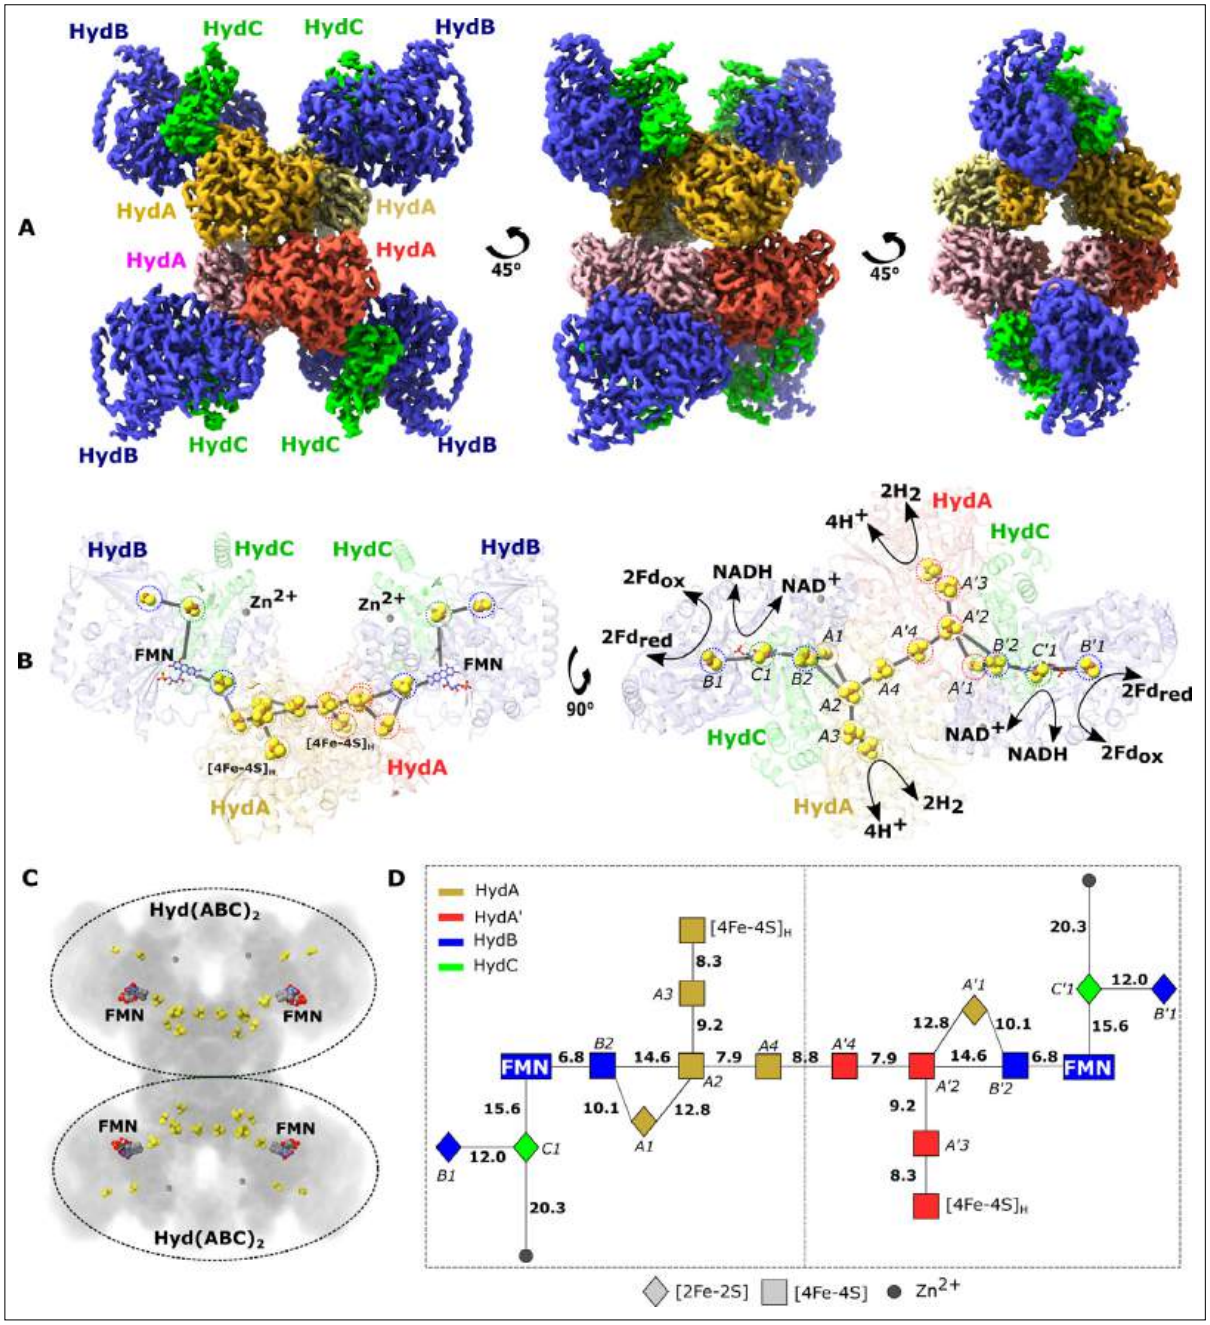

Figure 32.10.19 : Cryo-EM structure of the HydABC tetramer and arrangement of the redox cofactors. Chris Furlan et al. (2022) eLife 11:e79361. https://doi.org/10.7554/eLife.79361. Creative Commons Attribution License

Panel (**A**) shows the unsharpened 2.3 Å map of Hyd(ABC)$_4$ with D2 symmetry enforced, showing a tetramer of HydABC heterotrimers. All four copies of HydB and C are colored blue and green, respectively. The four HydA copies that make up the core of the complex are orange, yellow, pink, and red. The top and bottom halves of the complex are constituted by dimers of HydABC protomers (each HydABC unit is a protomer); the two protomers within the same dimer are strongly interacting, while a weaker interaction is present between the top and bottom dimers.

Panel (**B**) shows the HydABC dimer highlighting the iron–sulfur clusters and flavin mononucleotide (FMN) constituting the electron transfer network.

Panel (**C**) shows the arrangement of redox cofactors within the protein complex, showing two independent identical redox networks (dashed circles); each redox network is composed of iron–sulfur clusters belonging to a Hyd(ABC)$_2$ unit consisting of two strongly interacting HydABC protomers.

Panel (**D**) shows a schematic of the electron transfer network of one of the two identical $Hyd(ABC)_2$ units showing edge-to-edge distances (in Å) between the various cofactors. Note that our structure is of apo-HydABC and contains only the $[4Fe–4S]_H$ subcluster of the H-cluster. The $2H^+/H_2$ interconversion reaction in (**B**) illustrates the site at which this reaction occurs, but this will only occur in the fully assembled H-cluster, including $[2Fe]_H$.

Figure 32.10.20 shows an interactive iCn3D model of the electron-bifurcating [FeFe] hydrogenase from *Thermotoga maritima* (HydABC) (7P5H), using the same colors as the figure above.

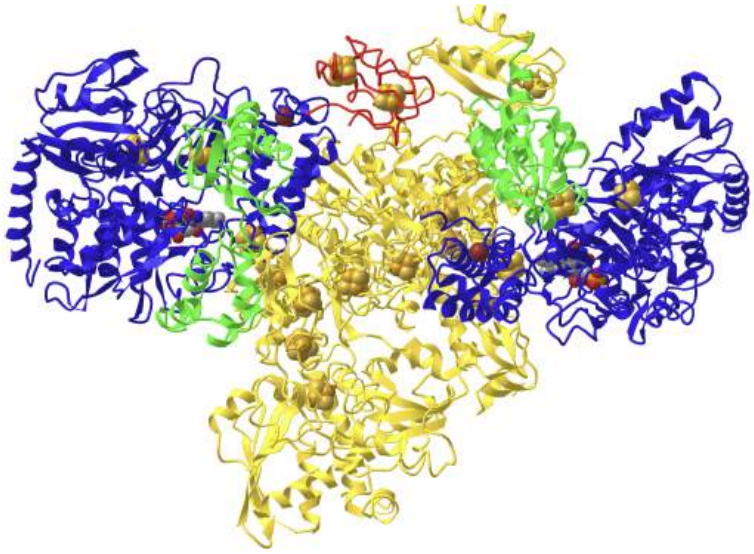

Figure 32.10.20 : electron-bifurcating [FeFe] hydrogenase from *Thermotoga maritima* (HydABC) (**7P5H)**. (Copyright; author via source).

Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...2hwCUnJ9BgwJi8.

Only the dimer $(HydABC)_2$ is shown. The A (gold), B (blue), and C (green) chains are colored as in the previous figure. The conformationally flexible loop at the C-terminal of a B chain in the closed state is shown in red. The gate also includes the C-terminal part of the A subunit near it.

Figure 32.10.21 shows the closed-bridge and open-bridge conformations of HydABC (the closed loop was shown in the model above).

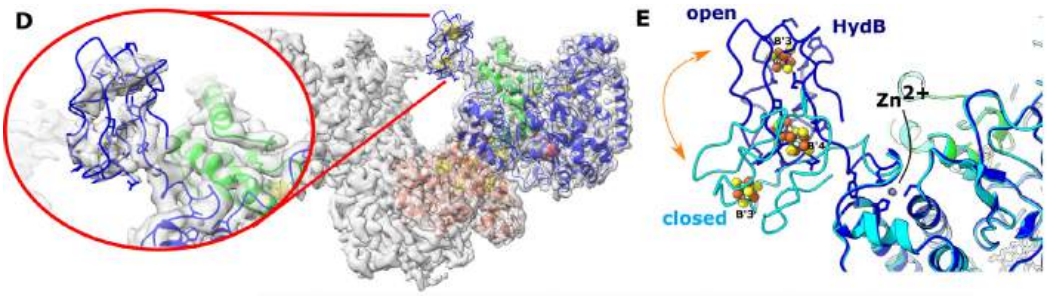

Figure 32.10.21 : closed-bridge and open-bridge conformations of HydABC from *Thermotoga maritime*.

Panel (**D**) shows the HydB bridge domain in the open position and its fitted model. Panel (**E**) shows a Zn^{2+} hinge region and the two possible conformations of the HydB bridge domain, open (blue) and closed (light blue).

The similarities in cofactor arrangement in the *Thermotoga maritime* Hyd A, B and C subunits compared to the Nqo1, Nqo2, and Nquo3 subunits in Complex I from *Thermus thermophilus* (discussed in Chapter 19.1) are shown in Figure 32.10.22 below.

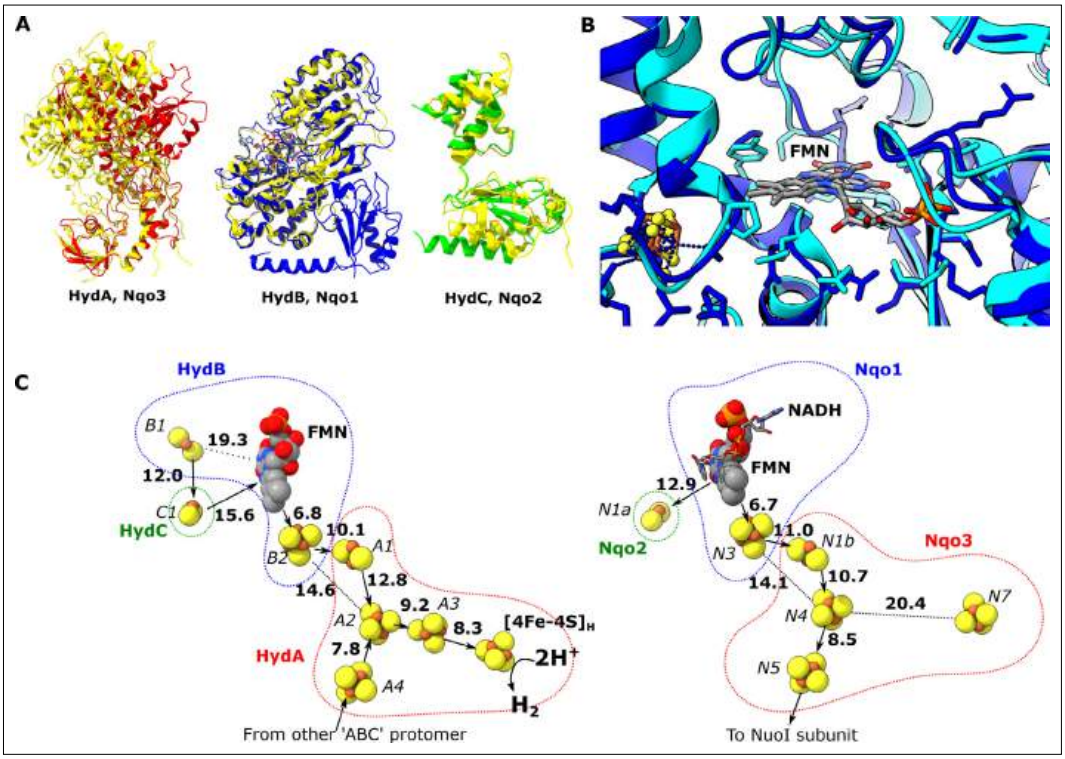

Figure 32.10.22 : Comparison of the HydA, B and C subunits of the electron bifurcating [FeFe] hydrogenase from *Thermotoga maritima* with the Nqo3, 1 and 2 subunits from respiratory complex I from *Thermus thermophilus*.

Panel (**A**) shows the subunits HydA (red), HydB (blues), and HydC (green) overlaid with, respectively, Nqo3, Nqo1, and Nqo2 (all yellow) of complex I from *T. thermophilus* (Gutiérrez-Fernández et al., 2020, PDB: 6ZIY).

Panel (**B**) shows a comparison of the NADH-binding site of the Nqo1 subunit of complex I from *T. thermophilus* (light blue) with the flavin mononucleotide (FMN) site in HydB; the high similarity suggests NADH binds in the proximity of FMN in HydABC similar to complex I.

Panel (**C**) shows an electron transfer network in HydABC compared to complex I from *T. thermophilus* with edge-to-edge distances indicated in bold. The red, blue, and green dotted lines indicate the cofactors present in the HydA (Nqo3), HydB (Nqo1), and HydC (Nqo2) subunits, respectively. Note that our structure is of the apo-HydABC and lacks the $[2Fe]_H$ subcluster of the H-cluster. The $2H^+/H_2$ interconversion reaction in (**C**) illustrates the site at which this reaction occurs, but this will only happen in the fully assembled H-cluster, including $[2Fe]_H$.

Here is a link to a video showing the conformational change observed between the 'Bridge closed forward' (7P8N) and 'Open bridge' (7PN2) classes.

In the video, the HydB C-terminal iron–sulfur cluster domain is colored blue, and the HydA C-terminal iron–sulfur cluster domain is colored orange. The zinc ion (gray sphere) and ligating residues (three cysteine ligands and one histidine) are also shown. The location of the HydA C-terminal domain when the bridge is open is unknown, so it is shown transparently in both states for reference.

The geometric separation of catalytic sites and the bifurcation mechanism **prevents** these thermodynamically favored reactions from happening

- H_2 production from ferredoxin oxidation (in the absence of NADH oxidation)
- NAD^+ reduction by H_2 (in the absence of ferredoxin reduction)
- ferredoxin oxidation by NAD^+

OXYGEN SENSITIVITY OF FE-FE H_2ASES

We have alluded to the fact that Fe-Fe H_2ases can be sensitive to O_2. A possible mechanism involves the interaction of one the Fe ions (Fe_d, the distal Fe) with oxygen, leading to the formation of damaging free radicals. As CO binds more strongly than O_2 to the iron in hemoglobin, its interaction with the H-center can help protect the H_2ases. Sulfides can also afford protection. These mechanisms are illustrated in Figure 32.10.23 :

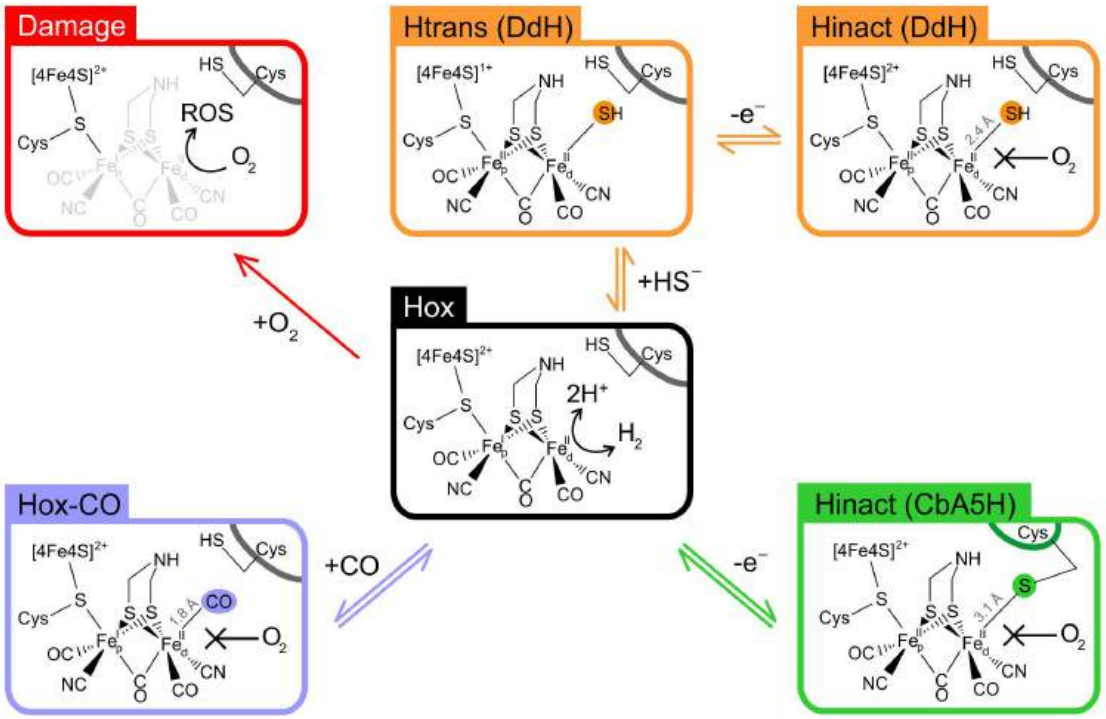

Figure 32.10.23 : Oxygen tolerance strategies in [FeFe]-hydrogenases. Morra S, ibid.

Schematic representation of the H-cluster in the oxidized active state Hox (centre). In the absence of any exogenous protectant, numerous [FeFe]-hydrogenases undergo irreversible inactivation due to H-cluster damage with loss of Fe atoms (red pathway); carbon monoxide acts as a protective agent due to its ability to form Hox-CO, by binding reversibly to the H-cluster at the same site as O_2 (purple pathway); in DdH, a similar mechanism occurs when sulphide binds to the H-cluster forming Hinact, *via* the Htrans intermediate (orange pathway); in CbA5H, a conformational change in the protein structure allows for a conserved cysteine to directly bind to the H-cluster, forming Hinact (green pathway). Fe_p, proximal iron atom; Fe_d, distal iron atom; Cys, cysteine residue.

KEY POINTS - BETA VERSION FROM CHAT.OPENAI

1. Hydrogenases are enzymes that catalyze the reversible conversion of hydrogen gas (H2) to protons and electrons.
2. There are two main types of hydrogenases: [NiFe]-hydrogenases and [FeFe]-hydrogenases.
3. [NiFe]-hydrogenases are found in a variety of microorganisms and mostly used to oxidize H_2.
4. [FeFe]-hydrogenases are mainly used to produce H_2.
5. Hydrogenases play a crucial role in the metabolism of microorganisms, allowing them to produce or consume hydrogen gas as needed.
6. The activity of hydrogenases is regulated by various factors, including the availability of hydrogen and the presence of inhibitors such as oxygen.
7. Research is ongoing to improve the efficiency and cost-effectiveness of hydrogenase-based biohydrogen production and to understand the mechanisms of hydrogenase enzymes to develop more efficient and sustainable ways of producing hydrogen.
8. Genetic engineering techniques can be used to improve hydrogenase activity in microorganisms, and also to increase the tolerance of microorganisms to the toxic effects of H2.

32.11: A WARMER WORLD: TEMPERATURE EFFECTS ON CHEMICAL REACTIONS

Search Fundamentals of Biochemistry

Inspiration for the chapter comes from Biochemical Adaptation by Hochachka and Somero.

Organisms adapt to their environment, with one of the main drivers being temperature. This has occurred over geological time (think of arctic camels 3.4 million years ago!) and space with temperature gradients in terrestrial and aquatic environments. This is evident in the different species that thrive at different mountain heights and ocean depths. Species that can move have advantages in selecting an environment best suited to their thermal needs. Historically, homo sapiens have engaged in seasonal migration, and aquatic species in vertical migrations.

Temperature effects are universal throughout life, and physiology and biochemistry adaptations are ubiquitous. Metabolically-active life can exist from around -15^{o}C to about 121^{o}C (thermal saline springs). Unless greenhouse gas emissions are significantly decreased from present levels, parts of the world will become increasingly uninhabitable due to high temperatures and sea level rise. Estimates for the number of climate refugees range up to 1 billion people by 2050.

Two similar questions arise. Can organisms adapt to increasing temperatures as the climate changes, and are organisms living close to their maximal survivable temperatures?

Before we study the effects of temperature on chemical/biochemical reactions, let's review the basics of thermoregulation. The following classification of organisms by types of thermoregulation is from BioLibre text.

TYPES OF THERMOREGULATION (ECTOTHERMY VS. ENDOTHERMY)

Thermoregulation in organisms runs along a spectrum from endothermy to ectothermy. Endotherms create most of their heat via metabolic processes, and are colloquially referred to as “warm-blooded.” Ectotherms use external sources of temperature to regulate their body temperatures. Ectotherms are colloquially referred to as “cold-blooded” even though their body temperatures often stay within the same temperature ranges as warm-blooded animals.

Ectotherm

An ectotherm, from the Greek (ektós) “outside” and (thermós) “hot,” is an organism in which internal physiological sources of heat are of relatively small or quite negligible importance in controlling body temperature. Since ectotherms rely on environmental heat sources, they can operate at economical metabolic rates. Ectotherms usually live in environments in which temperatures are constant, such as the tropics or ocean. Ectotherms have developed several behavioral thermoregulation mechanisms, such as basking in the sun to increase body temperature or seeking shade to decrease body temperature. The cCommon frog is an ecotherm and regulates its body based on the temperature of the external environment

Endotherms

In contrast to ectotherms, endotherms regulate their own body temperature through internal metabolic processes and usually maintain a narrow range of internal temperatures. Heat is usually generated from the animal’s normal metabolism, but under conditions of excessive cold or low activity, an endotherm generate additional heat by shivering. Many endotherms have a larger number of mitochondria per cell than ectotherms. These mitochondria enables them to generate heat by increasing the rate at which they metabolize fats and sugars. However, endothermic animals must sustain their higher metabolism by eating more food more often. For example, a mouse (endotherm) must consume food every day to sustain high its metabolism, while a snake (ectotherm) may only eat once a month because its metabolism is much lower.

Homeothermy vs. Poikilothermy

Two other descriptors are also used. A **poikilotherm** is an organism whose internal temperature varies considerably. It is the opposite of a **homeotherm**, an organism which maintains thermal homeostasis. Poikilotherm’s internal temperature usually varies with the ambient environmental temperature, and many terrestrial ectotherms are poikilothermic. Poikilothermic animals include many species of fish, amphibians, and reptiles, as well as birds and mammals that lower their metabolism and body temperature as part of hibernation or torpor. Some ectotherms can also be homeotherms. For example, some species of tropical fish inhabit coral reefs that have such stable ambient temperatures that their internal temperature remains constant. Figure 32.11.1 below shows the energy output vs temperature for a homeotherm (mouse) and poikilotherm (lizard).

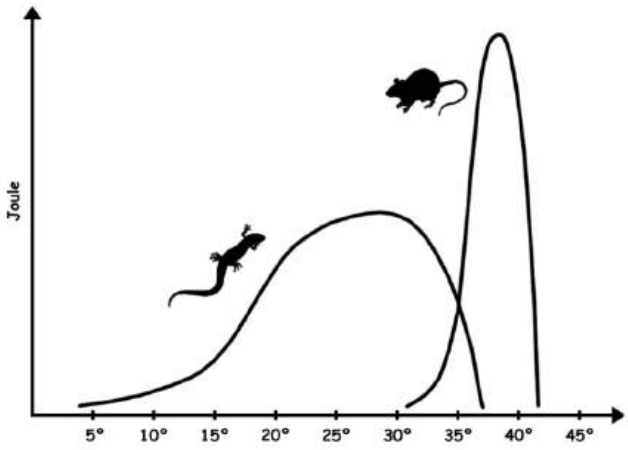

Figure \(\
PageIndex
{1}\):

Homeotherm vs. Poikilotherm: Sustained energy output of an endothermic animal (mammal) and an ectothermic animal (reptile) as a function of core temperature. In this scenario, the mammal is also a homeotherm because it maintains its internal body temperature in a very narrow range. The reptile is also a poikilotherm because it can withstand a large range of temperatures.

Another term is also employed, **heterothermy**, in which the temperature of a homeotherm can vary in different regions of the body (spatially) and also at different times (daily or seasonally as in hibernation). The core body of a homeotherm is usually warmer than the extremities that allow cooling when needed. In hibernation (or sustained torpor), both the body temperature and metabolic rates are decreased.

Means of Heat Transfer

Heat can be exchanged between an animal and its environment through four mechanisms: radiation, evaporation, convection, and conduction. Radiation is the emission of electromagnetic “heat” waves. Heat radiates from the sun and from dry skin the same manner. When a mammal sweats, evaporation removes heat from a surface with a liquid. Convection currents of air remove heat from the surface of dry skin as the air passes over it. Heat can be conducted from one surface to another during direct contact with the surfaces, such as an animal resting on a warm rock.

Key Points

- In response to varying body temperatures, processes such as enzyme production can be modified to acclimate to changes in temperature.
- Endotherms regulate their own internal body temperature, regardless of fluctuating external temperatures, while ectotherms rely on the external environment to regulate their internal body temperature.
- Homeotherms maintain their body temperature within a narrow range, while poikilotherms can tolerate a wide variation in internal body temperature, usually because of environmental variation.
- Heat can be exchanged between the environment and animals via radiation, evaporation, convection, or conduction processes.

Key Terms

- **ectotherm**: An animal that relies on the external environment to regulate its internal body temperature.
- **endotherm**: An animal that regulates its own internal body temperature through metabolic processes.
- **homeotherm**: An animal that maintains a constant internal body temperature, usually within a narrow range of temperatures.
- **poikilotherm**: An animal that varies its internal body temperature within a wide range of temperatures, usually as a result of variation in the environmental temperature.

These terms are diagramed in Figure 32.11.2 below.

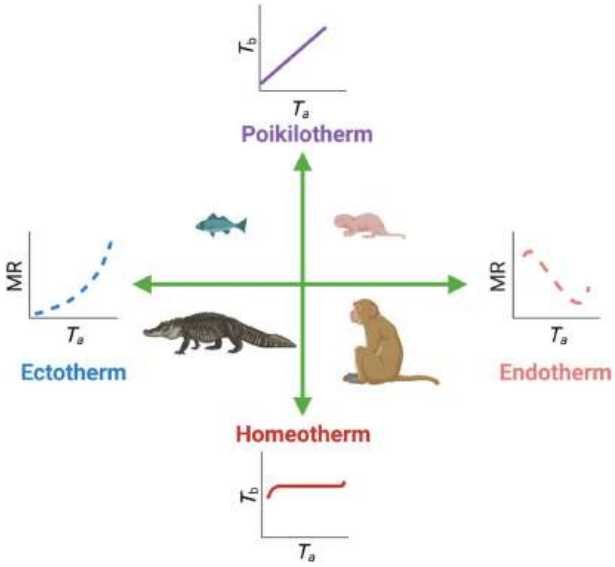

Figure 32.11.2: Thermoregulatory Term. Buffenstein et al., Biol. Rev. (2021), doi: 10.1111/brv.12791. Creative Commons Attribution License

We have discussed in previous chapter sections how temperature can affect macromolecules such as proteins (Chapter 4), nucleic acids (Chapter 9.1) as well as supramolecular assemblies such as membranes (Chapter 10.3). Temperature effects on small molecules and ions (such as salts in the Hofmeister series and glycerol, Chapter 4.9) in the environment that regulate the function/activity of these larger molecules and assemblies are also important. Hence we'll review and discuss the effects of temperature on these key molecular species in the next chapter section. First, we'll delve deeper into the general impact of temperature on chemical and biochemical reactions.

TEMPERATURE EFFECTS ON THE RATES OF CHEMICAL REACTIONS

To understand temperature effects on metabolic processes, let's first review temperature effects on ordinary chemical and biochemical reactions. You may remember the general rule that the rate of a chemical reaction approximately doubles when the temperature is increased 10^o C (10 K). How does that arise? This is generally true in a specific temperature range, as we will see below.

The rates of reactions, either endothermic or exothermic, depend on the activation energy (E_a). The activation energy is required to move from a reactant to the transition state, which then can go on to form product.

The activation energy can be obtained from the Arrhenius equation (that you learned in introductory chemistry), which shows how the rate of an individual chemical reaction depends on temperature.

$$k = Ae^{-E_a/RT} \tag{32.11.1}$$

where k is the rate constant, E_a is the activation energy, E_a/RT is the average kinetic energy, and A is a constant (the "preexponential" factor).

By taking the natural log (ln) of each side and rearranging the equation, you get a "linearized" equation that is easier for most.

$$\ln k = \ln A - \frac{E_a}{RT} \tag{32.11.2}$$

A plot of ln k vs 1/T has a slope = E_a/R, from which the activation energy can be calculated.

An alternative form can be derived:

$$\ln \frac{k_2}{k_1} = \frac{E_a}{R}\left(\frac{1}{T_1} - \frac{1}{T_2}\right) \tag{32.11.3}$$

? A DERIVATION

Here it is!

Derivation

From

$$\ln k_1 = \ln(A) - E_a/RT_1 \tag{32.11.4}$$

solve for lnA

$$\ln(A) = \ln(k_1) + E_a/RT_1 \tag{32.11.5}$$

Substitute into the equation for ln(k_2) gives

$$\ln(k_2) = \ln(k_1) + E_a/RT_1 - E_a/RT_2 \tag{32.11.6}$$

Rearrange to get

$$\ln(k_2) - \ln(k_1) = E_a/RT_1 - E_a/RT_2 \tag{32.11.7}$$

Simplify to get the final equation!

$$\ln\left(\frac{k_2}{k_1}\right) = \frac{E_a}{R}\left(\frac{1}{T_1} - \frac{1}{T_2}\right) \tag{32.11.8}$$

Solving for E_a gives

$$E_a = \frac{R\ln\frac{k_2}{k_1}}{\frac{1}{T_1} - \frac{1}{T_2}} \tag{32.11.9}$$

Let's use this equation to calculate an E_a that will give a doubling of the reaction rate ($k_2/k_1 = 2$) going from T_1 = 295 K (21.9^0 C, 71.3^o F) to T_2 = 305 K (21.9^0 C, 89.3^o F), a 10^{o}C temperature rise.

$$\begin{aligned} E_a &= \frac{(8.314)(\ln 2)}{\frac{1}{295} - \frac{1}{305}} \\ &= \frac{\left(8.314\ \text{J mol}^{-1}\ \text{K}^{-1}\right)(0.693)}{0.00339\ \text{K}^{-1} - 0.00328\ \text{K}^{-1}} \\ &= \frac{5.76\text{Jmol}^{-1}\ \text{K}^{-1}}{\left(0.00011\ \text{K}^{-1}\right)} \\ &= 52,400\text{Jmol}^{-1} = 52.4\ \text{kJ mol}^{-1} \end{aligned} \tag{32.11.10}$$

Hence if a reaction has an activation energy E_a of about 54 kJ/mol, increasing the temperature from 295 to 305^{o}C (i.e, by 10^{o}C) doubles the reaction rate.

Assuming that the activation energy is constant, the rate constants increase with temperature since a larger fraction of the molecules have the energy ($\geq E_a$) necessary to react. This is illustrated in Figure 32.11.3 below.

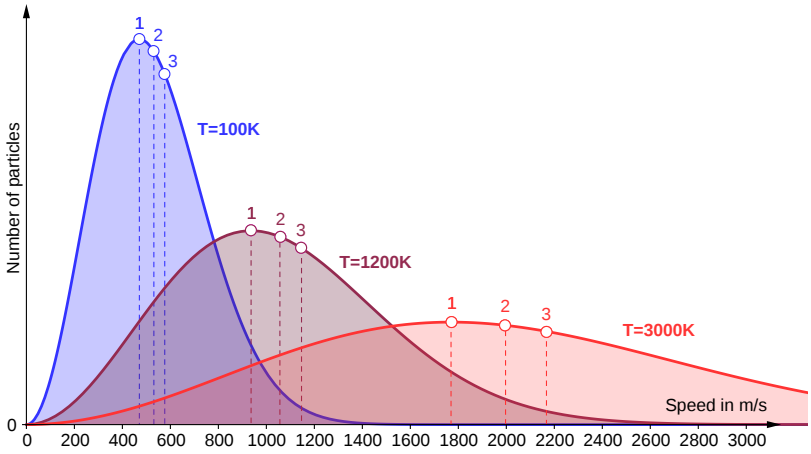

Figure 32.11.3: Plot of a Maxwell-Boltzmann distribution of speeds for different temperatures T=100K, T=1200K, T=5000K. Points along the curve show (1) most likely speed, (2) average speed, and (3) thermal speed (velocity that a particle in a system would have if its kinetic energy were equal to the *average* energy of all the particles of the system). https://commons.wikimedia.org/wiki/F...xis-labels.svg. Creative Commons Attribution-Share Alike 4.0 International license.

Let's look a the brown vertical line around 950 m/s. If we take that as the activation energy, very few molecules in the blue distribution have the required kinetic energy $\geq$ Eact. Ar progressively higher temperatures, great fractions (as measured by the area under the curve to

the right of the dotted line at 950 m/s) have the required energy, hence the rates increase with temperature.

When the **temperature change is 10^oC**, the ratio of the rate constants (or rates), k_2/k_1 is often called **Q_{10}**, the **temperature coefficient** (unitless). Q_{10} is not a constant, since it depends on the two temperatures that differ by 10^0 C (10 K). Hence the Q_{10} value for the 10^0 range from 273-283K is different than the Q_{10} value from 373-383K) . Q_{10} for many reaction is around 2 (doubling of the reaction rate) - 3 (tripling the reaction rate) at physiological temperature . Q_{10} =2 for a given E_a only at one set of temperatures that differ by 10^oC. The variation in Q_{10} values is illustrated in Table 32.11.1 below for a reaction in which E_a = 44.5 kJ/mol. Q_{10} **decreases** from 2 as the temperatures T_1 and T_2=T_1+10^oC increase.

T_1 in K (^oC)	T_2 (K) (^oC)	k_2/k_1 (Q_{10})
273 (- 0.15 ^oC)	283 (9.85 ^oC)^oC	2
373 (99.9 ^oC)	383 (110 ^oC)	1.45
473 (200 ^oC)	483 (210 ^oC)	1.26

Table 32.11.1: Q_{10} = k_2/k_1 values at different temperatures T_1 and T_2 that differ by 10^oC.

We will see how this is important in biological settings in a bit. If Q_{10} = 1, the reaction is independent of temperature, and a Q_{10} <1 shows a reaction that is not functioning. An example might be an enzyme-catalyzed reaction in which the threshold is reached at a higher temperature T_2 = T_1+10, at which the enzymes lose an active conformation and starts to unfold.

The same equation and the Q_{10} parameters apply to enzyme-catalyzed reactions. The activation energies (E_a) for four enzymes involved in the degradation of lignocellulose in the surface soil and subsoil are shown in Table 32.11.2 below. The enzymes include two hydrolases, β-glucosidase (BG) and cellobiohydrolase (CB), which cleave cellulose, and two oxidases, peroxidase (PER) and phenol oxidase (POX), which help degrade lignin. The overall average E_a for these enzymes is about 44.7 kJ/mol, similar to the example used in Table 1 above.

Soil	Type	Ea (kJ/mol)			
		BG	CB	PER	POX
Arctic	surface	35.4	39.4	12.7	81.8
Subarctic	surface	36.5	38.6	21.1	45.7
	subsoil	52.2	41.5	22.4	39.4
Temperate 1	surface	40.9	38	64.9	102
	subsoil	49.4	21.2	28	94.8
Temperate 2	surface	31	43.4	25.4	49.5
	subsoil	40.9	39.9	19.8	47.5
Temperate 3	surface	51.5	53.6	28.8	73.2
	subsoil	58.8	46.7	54.2	29

	subsoil	42.8	43.3	22.8	45.5
Avg		44.9	42.0	33.2	58.9

Table 32.11.2: Activation Energies (E_a, kJ mol^{-1}) for extracellular soil enzymes involved in the degradation of lignocellulose. Adapted from Steinweg JM et al. (2013) PLOS ONE 8(3): e59943. https://doi.org/10.1371/journal.pone.0059943. Creative Commons CC0 public

domain

Q_{10} temperature coefficients are also used to describe biological processes like respiration, speed of neural signal propagation, metabolic rates, etc. Many biological processes are affected by temperature, especially for ectotherms that adjust temperatures to outside environments, including daily and seasonal temperature shifts. Mammals and birds alter metabolic rates with temperature. This is true for hibernating animals.

The Q_{10} **temperature coefficient** can be considered to be the *factor* by which the reaction rates (k or R) increase (factor of 2, 3, 1.5, etc) for each **10-degree** K or C temperature increase. It is given by the following equation:

$$Q_{10} = \left(\frac{k_2}{k_1}\right)^{10^\circ\text{C}/(T_2 - T_1)} \tag{32.11.11}$$

It is also called the **van't Hoff's temperature coefficient**. To help understand Q_{10}, let's consider some examples.

- If T_2-T_1=10^o, then Q_{10} is simply k_2/k_1 for the specified temperature pairs separated by a 10^0 C range (T_1 and T_2=T_1+10). Remember that Q_{10} is not a constant but depends on the temperature pairs and that it goes down with increasing temperature.
- If the temperature range is > 10^0 C, the the measured ratio k_2/k_1 is a factor > 1 x Q_{10}
- If the temperature range is < 10^0 C, the the measured ratio k_2/k_1 is a fraction of Q_{10}

This equation can be converted to

$$k_2 = k_1 Q_{10}^{(T_2 - T_1)/10^\circ\text{C}} \tag{32.11.12}$$

where the rate constant k_2 is related to a "base" rate k_1 at a base temperature of T_1. An interactive graph of the above equation is shown in Figure 32.11.4 below.

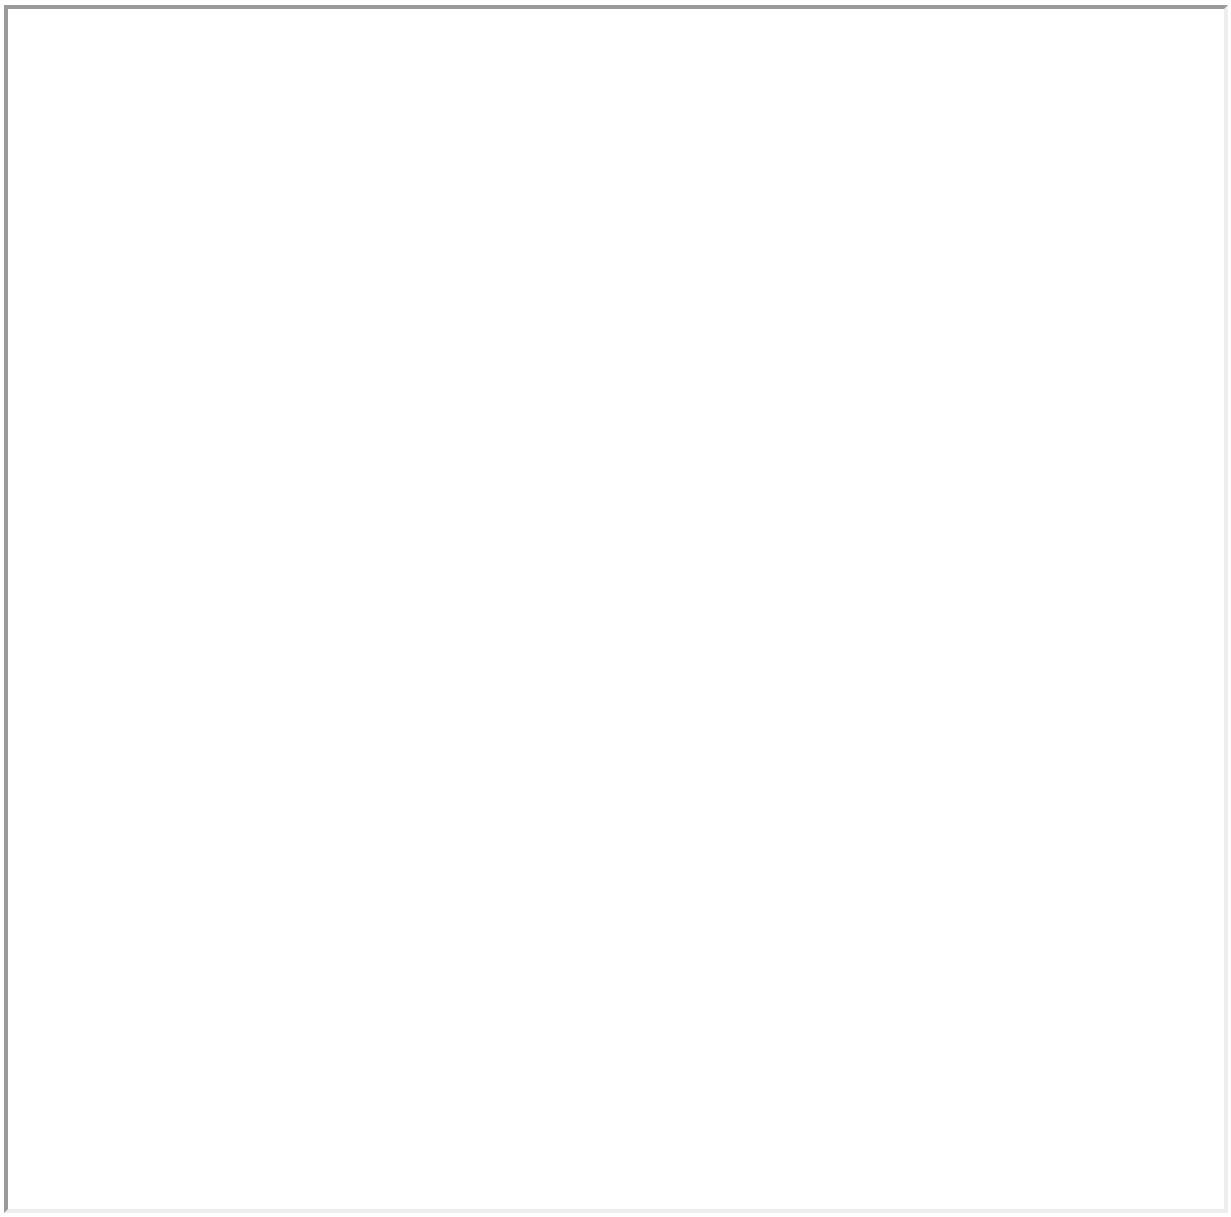

Figure 32.11.4: Interactive graph of k_2 (rate 2) vs. delta T at different base rates k_1.

Change the base rate constant, k_1, at a base temperature of T_1, and Q_{10} coefficient to see how they change k_2.

Note that if Q_{10} =1, k_2 at T_1+10 = k_1 at T_1, the rate is independent of the temperature.

For most biological systems, the Q_{10} value is ~ 2 to 3 under physiological relevant conditions. The ratios of the rates (R_2/R_1) for different Q_{10} values are shown in Figure 32.11.5 below.

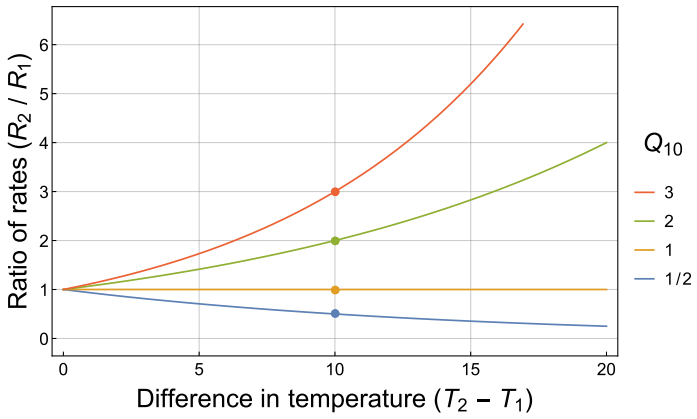

Figure 32.11.5: Idealized graphs showing the dependence on temperature of the rates of chemical reactions and various biological processes for several different Q10 temperature coefficients. The dots on the graph show how the rate change with a temperature difference of 10oC. Wikipedia. https://en.wikipedia.org/wiki/Q10_(t...e_coefficient). CC BY-SA 4.0

Again this hypothetical graph is meant to show the general meaning of Q_{10} values.

The "Q" model has been used to fit complex reaction systems, not just individual reactions. Figure 32.11.6 below shows the daily mean soil respiration rate as a function of soil temperature. In these graphs, the x-axis is Temperature, not ΔT.

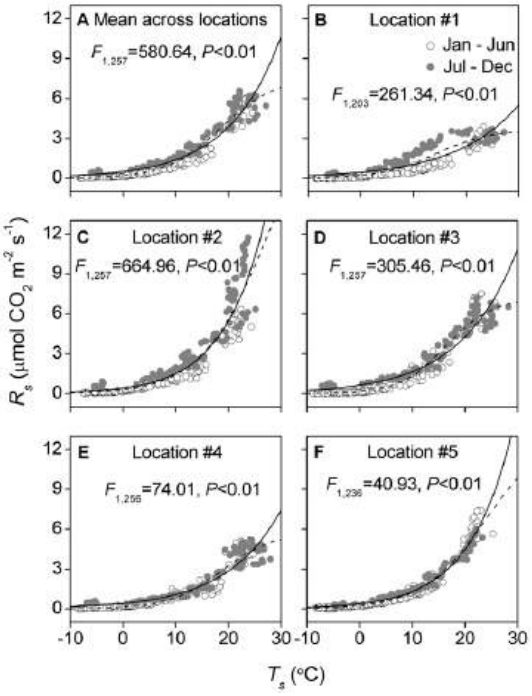

Figure 32.11.6: Relationships between daily mean soil respiration (R_s) and soil temperature (T_s). Jia X et al., PLoS ONE 8(2): e57858. https://doi.org/10.1371/journal.pone.0057858. Creative Commons Attribution License

The soil temperature, T_s, was measured at a 10-cm depth. Open circles are from January to June; closed circles are from July to December. The solid lines use a Q_{10} model, in which the observed R_s vs T_s data are fit with an equation that optimizes the Q_{10} parameter The dashed lines are fitted by a logistic model, which we used in Chapter 5.7 for fitting ELISAs data. R_s is significantly different between the first and second half of the year.

The soil respiration rate, R_s, at 10 cm depth was strongly affected by temperature, with an annual Q_{10} value of 2.76. Daily estimates of Q_{10} averaged 2.04 and decreased with increasing T_s. A study of seagrass showed the Q10 values are affected by plant tissue age and that Q10 varied significantly with the initial temperature and temperature ranges.

The use of Q_{10} values from the Arrhenius equation is based on the assumption that the chemical/biochemical processes are exponential functions of temperature. For complex processes like the decay of organic matter, it would be better to model the whole system by looking at the individual enzymes involved. One problem with using Q_{10} values for very complex systems is the choice of the base temperature value for rate comparisons. The anaerobic decomposition of organic matter is generally a linear function of temperature

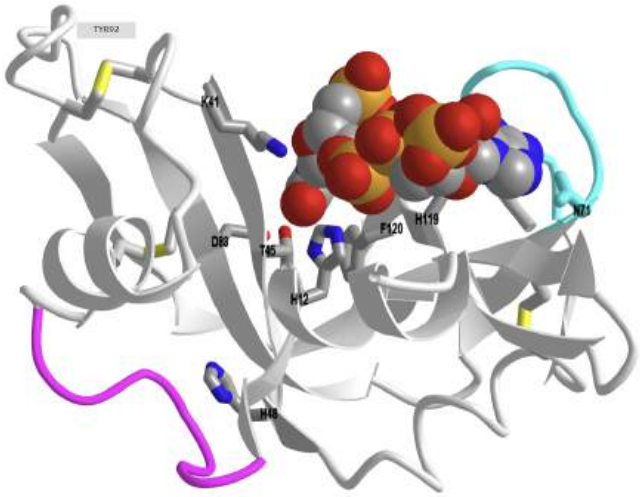
between 5°C and 30°C, which shows that a Q_{10} modeling system is not ideal. A more complex systems biology approach using programs like Vcell and COPASI would be better and less likely to cause errors in predicted CH_4 emissions from the decomposition process, for example.

GETTING BACK TO PROTEINS

In Chapter 6.1 we explored the mechanisms used by enzymes to catalyze chemical reactions. These included general acid/base catalysis, metal ion (electrostatic) catalysis, covalent (nucleophilic) catalysis, and transition state stabilization. Some physical processes included intramolecular catalysis and strain/distortion. The rate-limiting step in enzyme-catalyzed reactions can include actual bond breaking in the substrate, dissociation of product, and conformational change required to facilitate binding, catalysis, and dissociation. A rate-limiting conformational change may occur not in the active site pocket but in nearby loops that modulate the accessibility of reactant to and dissociation of product from the active site. These all may be influenced by temperature, with localized conformational flexibility especially important.

An interesting example of localized conformational changes affecting enzyme activity is RNase A. His 48, 18 Å from the enzyme active site, is involved in the rate-limiting enzymatic step involving product release.

Figure 32.11.7 shows an interactive iCn3D model of bovine pancreatic Ribonuclease A in complex with 3'-phosphothymidine (3'-5')-pyrophosphate adenosine 3'-phosphate (1U1B)



NCBI iCn3D Figure 32.11.7: Bovine pancreatic Ribonuclease A in complex with 3'-phosphothymidine (3'-5')-pyrophosphate adenosine 3'-phosphate (1U1B). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...SnrGYXSVXcLCk6

The substrate is shown in spacefill. The active site side chains and the distal His 48 are shown as sticks and labeled. Two flexible loops, Loop 1 (magenta) near His 48, and Loop 4 (cyan) near the active site are highlighted. On ligand binding, the loops move a few angstroms to make the active site more closed, inhibiting product release. Product release is associated with mobile regions including Loops 1 (20 Å from the active site) and 2. Loop 4, near the active site, is involved in the specificity for purines 5' to the substrate cleavage site. His 48 is conserved in pancreatic RNase A. If mutated to alanine, the k_{cat} decreases greater than 10X, indicating a change in the rate-determining conformational motion. The enzyme is still very active compared to the uncatalyzed reaction. His 48 appears to regulate coupled motions in the protein that are rate-limiting.

Figure 32.11.8 below shows the subtle shift in the conformation of apo-RNase A (magenta, no ligand, 1FS3) to the substrate-bound form (cyan, ligand in sticks), 1U1B). Note the small motion in His 48 shown in sticks at the bottom of the image.

Figure 32.11.8: Conformational changes apo-RNase A (magenta, no ligand, 1FS3) on conversion to the substrate-bound form (cyan, ligand in sticks, 1U1B).

We will explore temperature effects on protein structure and function more in the next chapter section.

32.12: A WARMER WORLD: TEMPERATURE EFFECTS ON PROTEINS

Inspiration for the chapter comes from Biochemical Adaptation by Hochachka and Somero.

INTRODUCTION

In the previous chapter section, we discussed the generalized effects of temperature on chemical/biochemical reactions. The rate for chemical reactions, including enzyme-catalyzed ones, typically increases 2-3 fold (Q_{10} values) with a 10^0 C temperature increase over an organism's typical temperature range. Q_{10} values decrease at higher temperature pairs differing by 10^0 C. At too high a temperature, a protein enzyme destabilizes, and Q_{10} values can fall to less than 1, a sign of potential trouble for an organism subjected to that higher temperature.

As we saw in Chapter 32.11 and will here, two competing processes affect protein enzymes as temperatures increase. They are increased rates for the catalyzed reaction and increased conformational dynamics, which leads to eventual denaturation at high enough temperatures. Hence evolution would presumably select for increased protein stability for organisms adapted to higher temperatures.

For cold-adapted organisms, the rates of catalysis are expected to decrease. Hence evolution might lead to higher k_{cat} values for cold-adapted organisms. However, we saw in Chapter 32.11 that the rate-limiting step for enzyme-catalyzed reactions often involved localized conformational changes, which would be disfavored at colder temperatures. Hence evolution would also select for enzymes that could maintain flexibility at low temperatures. In Chapter 4.9, we discussed low-temperature protein denaturation. Proteins can be destabilized at low temperatures. In this section, we will study how enzymes can adapt to higher temperatures. We won't discuss how proteins adapt to cold since this topic is less relevant for human-caused climate change.

We will follow the approach used throughout this book - that structure mediates function. We will use a lot of enzyme kinetics since kinetic parameters can tell us much about how bound substrate goes to product at high substrate concentrations (k_{cat} or V_M) or low substrate concentrations (k_{cat}/K_M) at different temperatures and for different orthologs of enzymes from species that have adapted to grow at low (psychrophile), medium (mesophile) or high temperatures (thermophiles). We'll next look at the structure of enzymes and which features allow them to adapt to their optimal temperature for growth. Finally, we will look at entire pathways to discern clues as to how they adapt to increased temperatures.

AN OVERVIEW - SOIL ENZYMES

Soil microbes play a key part in the carbon cycle as they can both store and release carbon. Soil temperatures influence this balance between uptake and release of CO_2 into the atmosphere.

SOIL ORGANIC CARBON - SOC

The soil is a sink for carbon and stores about 1500 gigatons [Gt] = 1.5 Pt = 1500 Pg), more than the atmosphere and vegetation combined. SOC derives ultimately from photosynthetic organisms. When they die, their carbon is used by heterotrophs for energy and biosynthesis. Carbon can also be returned to the atmosphere by aerobic oxidation by microorganisms, but this requires O_2, which diminishes rapidly with soil dept. Oxygen levels depend on soil porosity, relative amounts of sand and clay, and hydration. Tilling of soil increases O_2 exposure and hence oxidative respiration of SOC, increasing atmospheric CO_2. No-till farming hence can decrease CO_2 release into the atmosphere. Inorganic carbon from CO_2 (HCO_3^-, and CO_3^{-2}) bind with cations in the soil (mineralization) or is released into the atmosphere as CO_2.

Carbon input into the soil is mostly determined by photosynthesis, which correlates with root mass, and decay, while export is determined by soil microbial (bacteria, fungi, protists, animals) respiration. Microorganisms play a key role in the balance of carbon input and release in the soil and hence are prime determinants of SOC.

SOC is high in northern latitudes since colder temperatures promote lower respiration rates and accumulation of SOC over time. SOC is low in the lush tropics (even given the high photosynthetic rates) because of a high microbial respiration rate at higher temperatures. Deforestation of the lush Amazon Rain Forest will leave soil poor SOC with little to balance CO_2 release from the decomposition of what's left by the abundant soil microorganisms.

About 21 Gt of the 1500 Gt of SOC consists of microbial mass (12 Gt fungi, 7 Gt bacteria and 2 Gt from animals). Fungi hence are key players in soil metabolism. They are involved in the slow decomposition of decaying organic matter and promote the growth of slow-growing organisms like trees. In contrast, bacteria are fast metabolizers, and are found in abundance in grasslands. Northern attitudes have a higher soil microbial mass than in the tropics, but they are less active, allowing great SOC stores.

We often think of enzymes working in an aqueous environment in a test tube or a cell (which is very crowded with other molecules). Figure 32.12.1 below represents the microenvironment of soil enzymes involved in the decomposition of SOC, like cellulose.

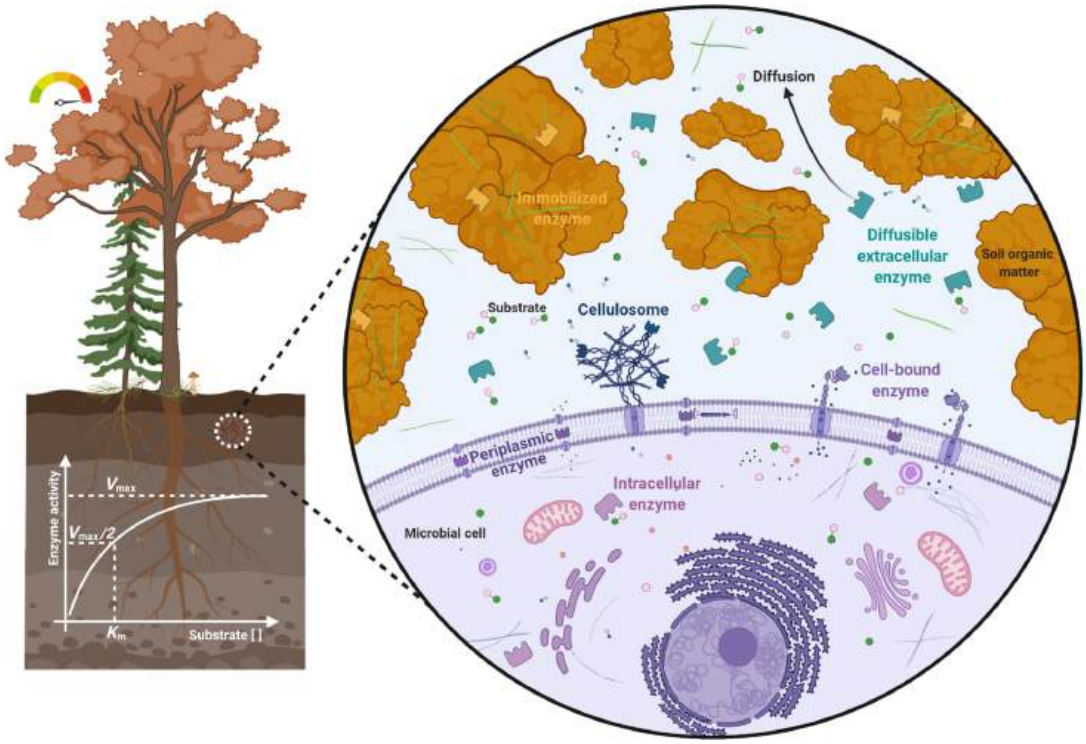


Figure 32.12.1: Location of enzymes in soils and their importance for carbon and nutrient cycling. Fanin, N. et al. (2022). Soil enzymes in response to climate warming: Mechanisms and feedbacks. *Functional Ecology*, 36, 1378– 1395. https://doi.org/10.1111/1365-2435.14027. Permission from John Wiley and Sons and Copyright Clearance Center.

Figure 32.12.2 below give a review and an overview of the effects of increasing temperature on soil enzymes.

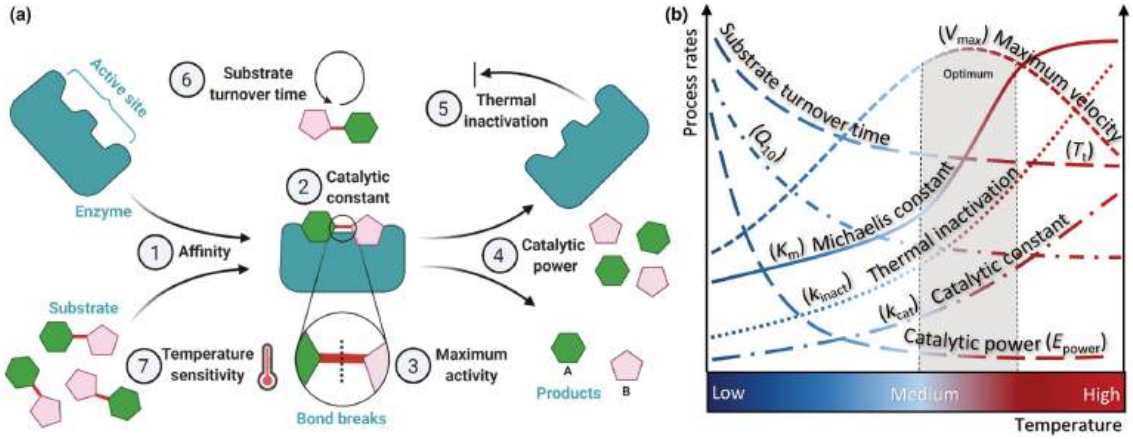

Figure 32.12.2: Effects of temperature at the enzyme scale. Fanin, N. et al., ibid. Permission from John Wiley and Sons and Copyright Clearance Center.

Panel (a) shows the many steps involved in enzyme catalysis that can be affected by temperature changes. Step 1 shows the binding of substrates. The K_M (units M) for the enzyme gives a "measure" of the strength of the interaction (but remember that $K_M = K_D$ - the dissociation constant - only under rapid equilibrium conditions). Step 2 reflects k_{cat}, the "net" rate constant for converting bound substrate to product.

Panel (b) shows how key constants change with increasing temperature. The figure shows that k_{cat} increases with temperature, consistent with the Arrhenius equation, as the temperature coefficient Q_{10} decreases (as discussed in Chapter 12.11). (Remember that Q10 is the *factor* by which the reaction rate, k or R, changes for each **10-degree** K or C temperature increase))The enzyme's thermal inactivation

rate, k_{inact}, also increases with temperature, leading to the bell-shaped V_M curve. K_m, a measure of the apparent K_D of the substrate for the enzymes, increases, reflecting weaker binding. The catalytic power, $E_{power} = k_{cat} / k_{inact}$, also decreases with increasing temperature as the slope of k_{inact} is generally greater than that of k_{cat}. The values for the temperature axis would be different for microbes that grow best at cold temperatures (psychrophilic), moderate temperatures (mesophilic), and high temperatures (thermophilic).

The graphs above represent temperature effects at the enzyme level. The gray rectangle represents the optimal growing conditions, which show that enzymes are poised near V_M for substrate conversion (assuming abundant substrate) but with low catalytic power. Increasing temperatures also have an effect at the microbial community level. These can affect SOC. For example:

- After an increase in the decomposition of SOC at higher temperatures, subsequent decreases in SOC can occur due to the depletion of available substrates (as enzymes are running at V_M) and changes in carbon use among the microbial communities;
- Additional decreases in SOC due to increased oxidation and shifts in the composition of the microbial community occur;
- The levels and types of substrates for enzymes likely change;
- Increased temperatures can lead to increases in microbial community mass, which requires more substrate, but in the long-term metabolic shifts might lead to a decrease of extracellular enzymes and microbial biomass;
- Soil conditions also change with increasing temperatures, which affects biomass by changing substrate availability;
- Increased temperature lead to short-term increases in CO_2 emission due to higher microorganism metabolic rates explained by the Arrhenius equation, but additional effects caused by accompanying changes in the microbial community occur.

Complex mathematical modeling (as we saw using Vcell with metabolic and signal transduction pathways) would be needed to understand the effects of warming on SOC stores and their return to the atmosphere as CO_2.

ENZYME PROPERTIES WITH ALTITUDE - MOUNT KILIMANJARO

It is possible that the loss of SOC with climate change may be mitigated to some extent as the soil microbial community thermally adapts to a lower respiration rate/microbial biomass. As Figure 1 shows, both extracellular and intracellular enzymes must be considered. Extracellular enzymes break down polymers like cellulose into monomers, which are transported into the cell for intracellular respiration and the formation of CO_2 by intracellular enzymes. The extracellular (lytic) and intracellular (oxidative) enzymes might respond differently to higher temperatures. Polymers that are hard to degrade have high activation energies, making soils with higher concentrations of these polymers more sensitive to climate warming (based on the Arrhenius equation).

Changes in the microbial community might include shifts in the fungal/bacterial ratio, causing changes in degradation pathways and the rates of enzyme-catalyzed reactions. At higher temperatures, such changes increase conformational flexibility, which could increase k_{cat} but also decrease the apparent affinity of the enzyme for the substrate, as reflected in increased K_M values. These compensatory effects might leave catalysis unaffected by increasing temperatures.

Studies have been conducted on individual degradative enzymes in soil samples from Mount Kilimanjaro. Enzyme kinetic analyses were done at two different temperatures differing by 10^0 C (10^0 C and 20^0 C), so Q10 values could be evaluated. The soil samples were obtained from different heights on the mountain to allow for the comparison of the kinetic parameters of enzymes from microbes adapted to different heights. All organisms in soil from different heights would experience 10 °C, while those at the highest altitudes (3000 m) would encounter 20^0 C only in the summer. The microbes presumably would have slightly different optimal temperatures for growth, and would likely use different adaptive mechanisms at low and high altitudes. Keep in mind in interpreting the results below that the Q10 value determines the sensitivity of a parameter (v_0, K_M, V_M, etc.) to an increase in the temperature of 10^0 C.

Extracellular enzyme activities in soil from one altitude

The activity of three extracellular enzymes in soil samples were studied: β-1,4-glucosidase (degrades cellulose), N-acetylglucosaminidase (degrades chitin from fungi and peptidoglycans from bacteria), and acid phosphatase. The first two enzymes catalyze "recalcitrant" reactions with higher activation energies. Michaelis-Menten plots for the three enzymes in soil samples taken at one height, 2010 meters (m), are shown in Figure 32.12.3 below. In addition, a plot of glucose conversion to CO_2, an intracellular process, which the authors termed "glucose" mineralization" (probably because they trapped CO_2 using OH^- to form HCO_3^-), is also shown.

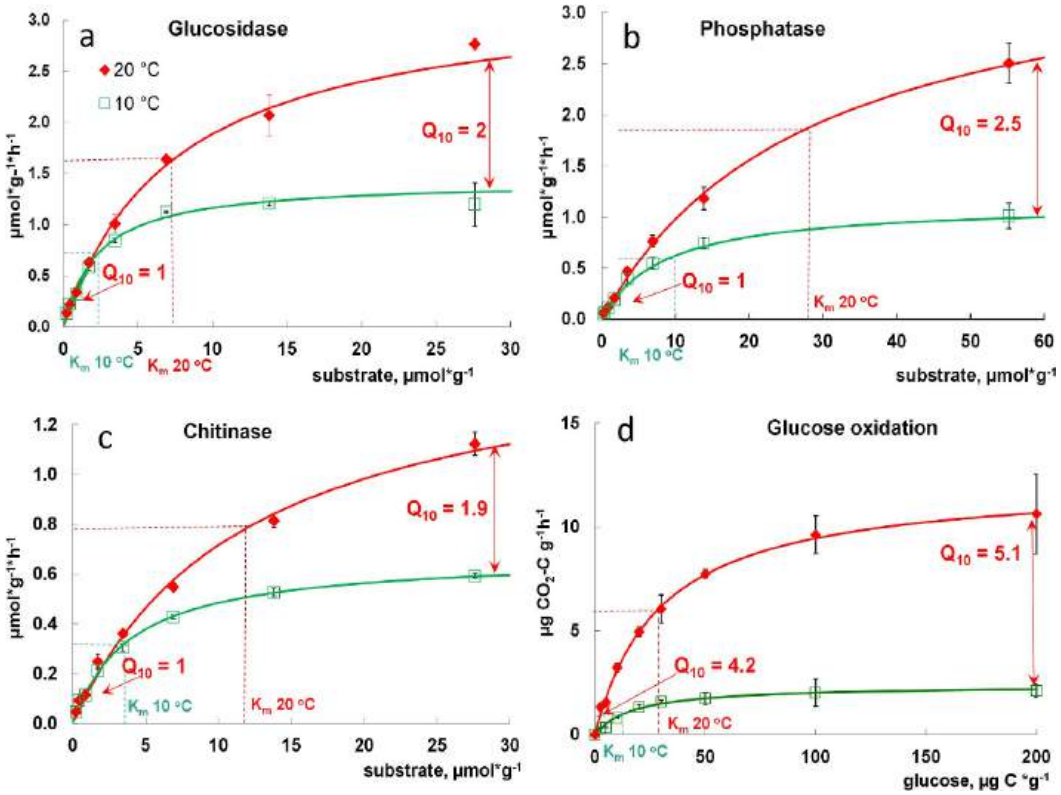

Figure 32.12.3: Rates of reactions mediated by hydrolytic enzymes (**a–c**) and rates of glucose oxidation to CO_2 (**d**) as dependent on substrate concentration at 10 and 20 °C for the site located at 2010 m a.s.l. Symbols – experimental data, lines – approximation by Michaelis–Menten kinetics. The **red** lines indicate assays performed at 20^0 C, while the **green** lines are for assays run at 10^0 C. Blagodatskaya, E. *et al*. Temperature sensitivity and enzymatic mechanisms of soil organic matter decomposition along an altitudinal gradient on Mount Kilimanjaro. *Sci Rep* **6**, 22240 (2016). https://doi.org/10.1038/srep22240. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/

The mineralization rate was determined using trace amounts of ^{14}C-labeled glucose, which if fully oxidized, is converted to $^{14}CO_2$. Given the conditions of the reactions, the added glucose did not cause microbial proliferation. The authors used a fluorophore (4-methylumbelliferone or MUF)-labeled small substrate analogs for cellulose (MUF-β-D-glucopyranoside), chitin (MUF-N-acetyl-β-D-glucosaminide dehydrate) and for acid phosphatase (4-MUF-phosphate). Reactions were carried out in soil samples and valid initial velocities for the reaction were determined. The Km values for the glucose oxidation (mineralization) is **not** a valid K_M value since CO_2 would be produced from the combined actions of the enzymes in glycolysis, pyruvate dehydrogenase and the citric acid cycle. It could be better called an "operational K_M".

For the three enzymes, the K_M at 20 °C was 25–42% larger than the $V_M = k_{cat}E_{T\ at}$ 20 °C, causing $Q_{10}^{KM} > Q_{10}^{VM}$. These compensatory changes canceled any increases in enzyme activity at low substrate concentrations, but not at high ones when the enzyme was saturated. Hence Q10 for the catabolic depolymerization reactions increased with substrate concentration. Note, however, that the rate of intracellular glucose oxidation (mineralization) increased at all substrate concentrations going from 10 to 20 °C and the canceling effect was not detected, even at low substrate levels. The temperature response of monomer oxidation showed a strongly accelerated reaction rate instead of a canceling effect

Extracellular Enzyme activities in soils from different altitudes

Next, kinetic analyses were performed on soil samples from 2010 m (warm-adapted microorganisms) and 3020 m (cold-adapted) on the mountain. Plots of Q10 (**not** v_0 as in Michaelis-Menten plots) vs. substrate for these studies are presented in Figure 32.12.4 below to show the temperature adaption capacities of the enzymes.

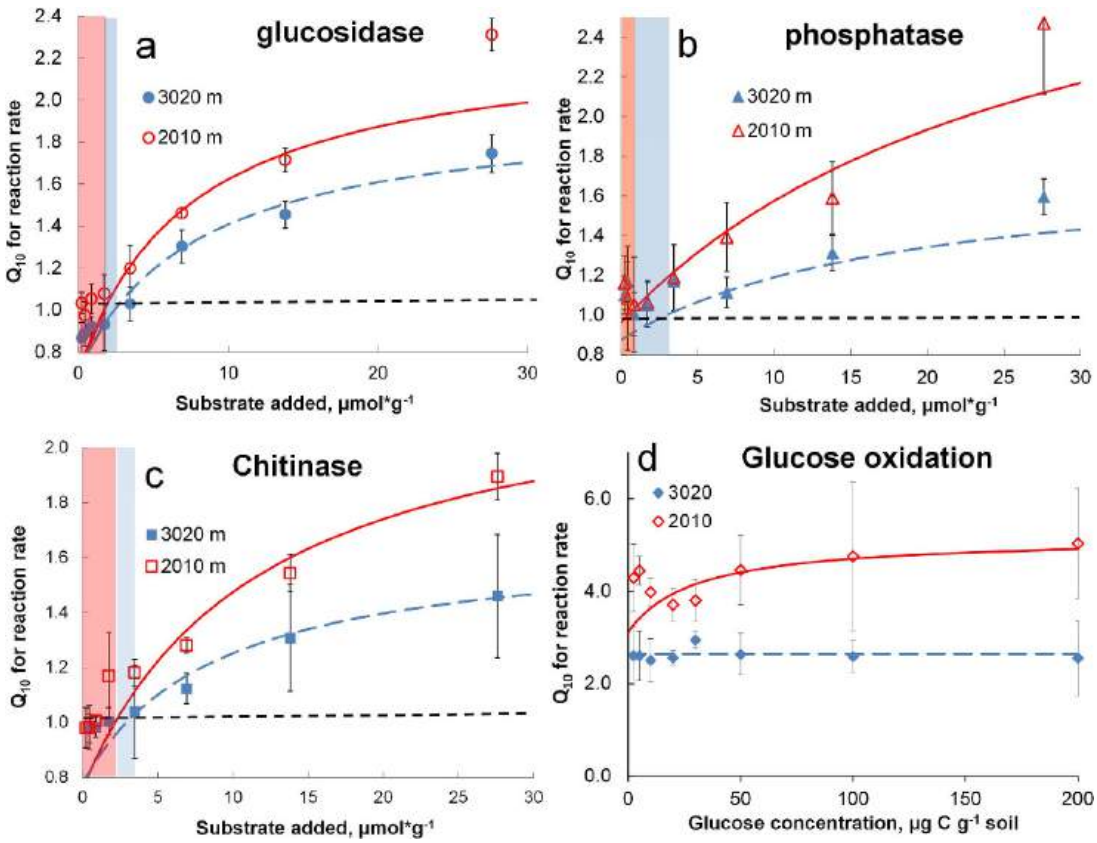

Figure 32.12.4: The Q_{10} values for enzymatic activities (**a–c**) and glucose oxidation to CO_2 (**d**) as dependent on substrate concentration at two altitudes. The blue and red rectangles show the concentration range at which no temperature effects occur (i.e $\leq S_{crit}$) with shading colors corresponding to different altitudes. The Q_{10} values derived from experimental data are shown as symbols. The model simulations based on experimentally obtained parameters of Michaelis–Menten kinetics are shown as curves (**a–c**). For glucose oxidation (**d**) at 3020 m elevation, a non-linear trend was very weakly expressed. Bars show standard deviations of the means (n = 3). Blagodatskaya, E. *et al. ibid.*

The graphs show that Q10 for polymer degradation increased with increasing substrate concentration. The authors defined a substrate concentration threshold (S_{crit}) below which K_M and V_M values canceled, so no increase in rate was seen with increasing temperature based. The width of the rectangles is based on the best-fit dashed **blue** and **red** lines, not the data points. The S_{crit} values were 35–42% larger for the 3020 m (**blue** rectangle) soil samples than at 2010 m (**red** rectangle), even though SOC was lower at that elevation. Q10 values were always lower at $S > S_{crit}$ at higher altitudes. This demonstrates that the enzymes responded less to higher temperatures at higher altitudes (**blue** dots and dashed lower curves), implying that the enzymes at higher latitudes demonstrated significant compensatory changes useful for microorganisms that experience a greater temperature range with larger shifts at these higher altitudes.

Figure 32.12.5 below shows that the Q values generally decrease over a larger range of altitudes for both enzyme activity (panel A) and glucose oxidation (Panel B).

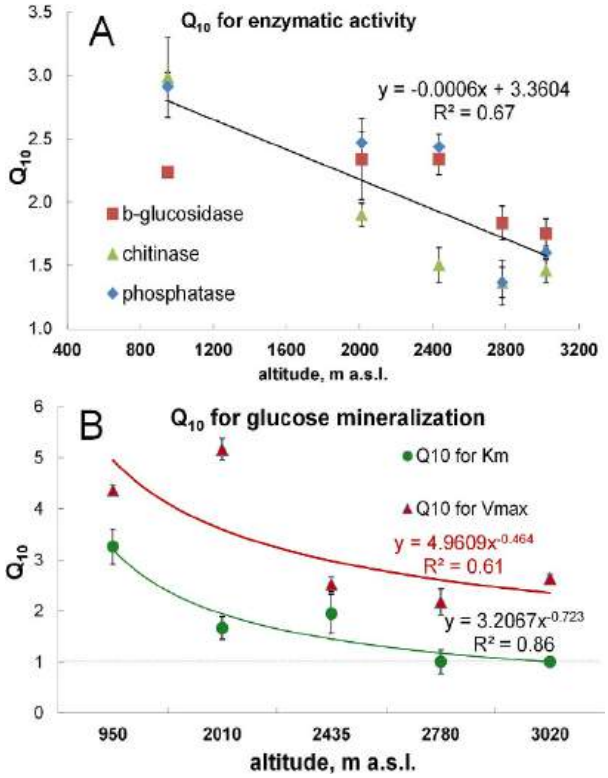

Figure 32.12.5: The $\mathbf{Q_{10}^{total}}$ values for hydrolytic enzyme activity at saturating substrate concentrations (**A**) and the increase in V_{max} and K_m induced by a temperature increase from 10 to 20 °C for ^{14}C-glucose oxidation (**B**) depending on altitude. Symbols – experimentally derived values for $\mathbf{Q_{10}^{total}}$ (**B**), $\mathbf{Q_{10}^{Vmax}}$ and $\mathbf{Q_{10}^{Km}}$ (**A**). Lines are the trend lines obtained by the best fitting of power (**A**) and linear functions (**B**) at P values < 0.05, bars show standard deviations of the means (n = 3). Blagodatskaya, E. *et al. ibid.*

Panel B shows how Q10 values for K_M apparent (**green**) and V_M (**red**) for intracellular glucose oxidation/mineralization both decreased with increasing altitude. Again consider these K_M and V_M values to be operationally defined and apply not to an individual enzyme but in less rigorous way to all the enzymes involved in the intracellular oxidation of glucose to CO_2. Investigators could determine these values only by fitting the kinetic data for CO_2 vs [glucose] to the Michaelis-Menten equation. At altitudes < 2435 m, all showed Q10 K_M values > 1.9, showing that the apparent collective K_M values were very sensitive to temperature increase. This implies the "collective" set of enzymes responsible for intracellular glucose oxidation was more conformational flexible, and higher temperatures caused significant increases in apparent K_M values. However, at high altitudes, the Q10 values for the apparent K_M were about 1, suggesting no temperature effects on the generic structure and apparent K_M values for the enzymes. The high-altitude enzymes were effectively temperature-stable with respect to K_M values. V_M values were more sensitive to increasing temperatures at all altitudes, but little change was seen going from 2435 to 3020 m. This again shows that the enzymes for microorganisms from high altitudes were more strongly adapted to temperature changes, especially at lower substrate concentrations.

The next part can be a bit confusing. The K_M for a given enzyme increases with increasing temperature, as shown in Figure 2. This suggests that the apparent affinity of the given enzyme for substrates decreases, which makes intuitive sense. Figure 32.12.6 shows that the Q10 for K_M (i.e. the sensitivity of K_M to a temperature increase of 10^0 C) decreases with increasing elevation for each enzyme studied.

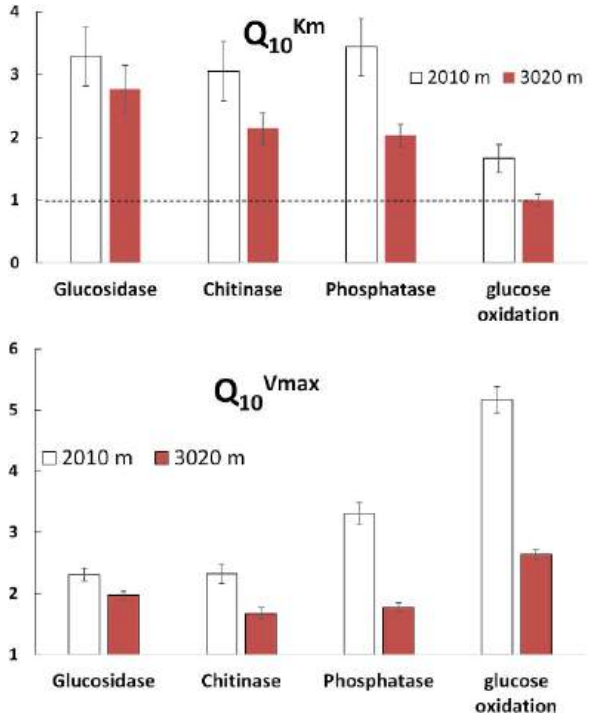

Figure 32.12.6: The values of $\mathbf{Q_{10}^{Km}}$ (**a**) and $\mathbf{Q_{10}^{Vmax}}$ (**b**) for hydrolytic reactions and for reactions of glucose oxidation at low and high altitudes. Bars show standard deviations of the means (n = 3).

The figure shows that both Q_{10}^{Km} and Q_{10}^{Vmax} were lower at high altitudes. Hence the enzymes in organisms from higher altitudes did not respond as strongly to temperature changes. This again suggests that larger compensatory changes are found in enzymes at high latitudes, allowing them to better adapt to the greater temperature range they would experience.

These data suggest that thermal adaptions in the intracellular enzyme are driven more by a large range of temperatures experienced by the organisms and not the mean temperature. Compensatory and canceling changes in K_M and V_M at low substrate concentration led to a higher S_{crit} in cold-adapted organisms.

STRUCTURAL MECHANISMS FOR ENZYME TEMPERATURE ADAPTATION

Structure determines function. A detailed understanding of how proteins, and more directly enzymes, adapt to temperature changes must come from detailed structural analyses that can be correlated to functions such as enzyme catalytic activity. Two approaches have been used to study the structural bases of enzyme temperature adaptation. One involves structural analysis of a single enzyme in organisms adapted to different temperatures. The other involves large computational analyses of databases of protein structure. We'll discuss both. First, let's explore orthologs (in this case, a protein from the same gene in different species) of a single enzyme, **ketosteroid isomerase (KSI),** from mesophilic (grown in moderate temperatures) and thermophilic (grown in warm temperatures) bacteria.

Figure 32.12.7 below shows structural and functional features that document KSIs temperature adaptation through changes in activity and stability. Let's step through each of the panels in order.

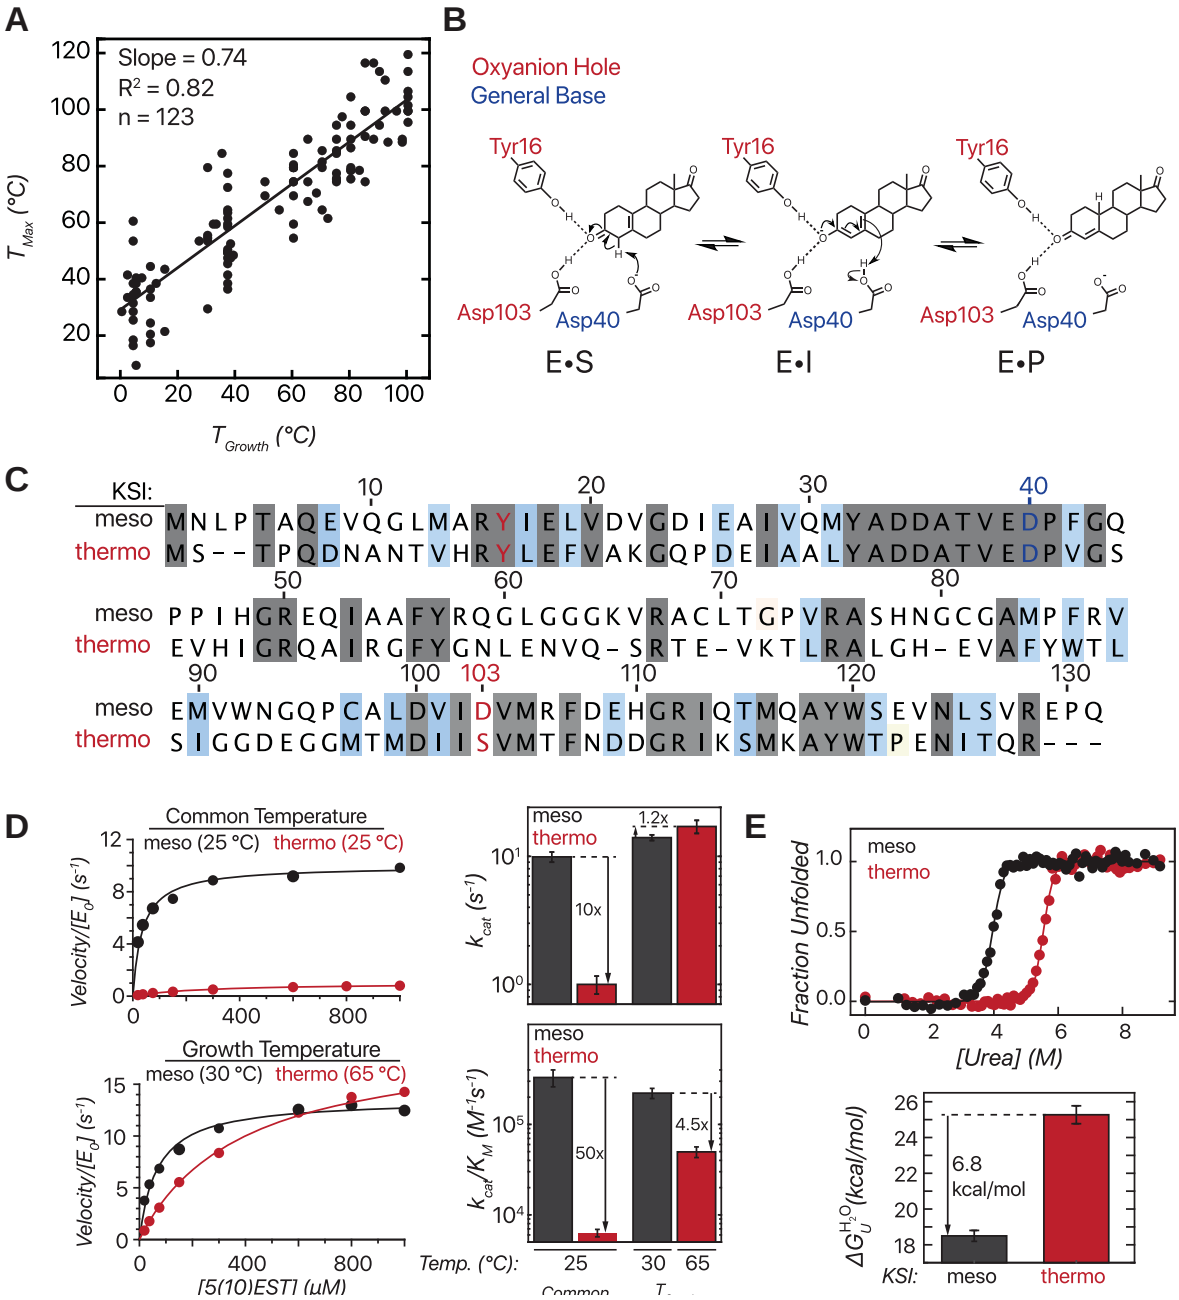

Figure 32.12.7: Enzyme temperature adaptation through changes in activity and stability. Pinney et al., Science, 371. (2021). DOI: 10.1126/science.aay2784. Reprinted with permission of the American Association for the Advancement of Science and Copyright Clearance Center.

Panel (**A**) shows that as the optimal growth temperature for an organism increases, the optimal temperature for selected enzyme activity also increases. Each dot represents a different species with the enzymes broadly chosen across all enzyme commission classes (i.e. the dots do not represent just KSI). There is a strong linear correlation.

Starting with Panel (**B**), we look at KSIs. Panel B shows the mechanism of isomerization of the steroid substrate, 5(10)-estren-3,17-dione [5(10)EST] by KSI. KSI has one of the highest k_{cat} values of enzymes. The reaction changes the position of the C=C double bonds and proceeds through an enolate/oxyanion intermediate (EI) formed after the abstraction of a proton by Asp 40. The transition state, which would have a developing negative charge on the O atom, is stabilized by proximal Tyr 16 and Asp 103 in a developing oxyanion hole.

Panel (**C**) shows the KSI sequences from *P. putida* (a mesoKSI) and *M. hassiacum* (thermoKSI). The sequences are 33% identical, but some key resides (gray) are identical. Similar ones are shown in blue. The thermophilic KSI (thermKSI) has Ser 103 instead of the often conserved Asp 103 in mesophilic organisms (mesoKSI). D103 and S103 are shown in red.

Now let's look at **Panel (D),** which shows the activity (v_0/E_0) vs substrate [5(10)EST], for the meso- and thermophilic enzymes. At a nominal temperature (25^0 C, top left panel), the thermoKSI shows little activity. At their optimal growth temperatures (30^0 C for the mesoKSI and 65^0 C for thermoKSI, bottom left), the thermoKSI has both a higher $V_M=k_{cat}E_0$, and K_M at 65^0 C. The higher K_M is consistent with the idea that K_m values are usually higher at higher temperatures. The derived k_{cat} and k_{cat}/K_M values are shown in the adjacent histogram. Remember that k_{cat} is a measure of how many bound substrate molecules are converted to product per sec (at saturating substrate concentrations). The parameter k_{cat}/K_M is a measure of the effective biomolecular rate constant for product formation at low substrate concentrations ([S] $<<K_M$).

From an evolutionary perspective, early ancestral enzymes probably arose in warmer environments. When the earth cooled, enzymes had to "solve" the problem easily apparent from the Arrhenius equation (the rate of reactions decreases with decreasing temperatures). Hence evolution would lead to structural changes that would facilitate either higher k_{cat} values, lower K_M values, or both, at lower temperatures. We've seen in the examples above that K_M decreases with decreasing temperatures, so evolutionary pressures would more likely lead to increased k_{cat} values. This is consistent with localized changes in protein dynamics as modulators of k_{cat}. The evolutionary pressure to maintain stability would be low since proteins become more stable at lower temperatures.

Now the question arises, how thermally stable are the meso- and thermKSI? Urea denaturation experiments were used to determine the $\Delta G^{0\ H2O}{}_U$ for unfolding of the enzyme, as described in Chapter 4.12. Panel (**E**) shows urea denaturation curves for mesoKSI (black) and thermoKSI (red) monitored by changes in internal tryptophan fluorescence (top) and stabilities extrapolated to 0 M urea ($\Delta G^{H2O}{}_U$) (bottom). The denaturation curve for thermoKSI is significantly shifted to the right. The calculated values for $\Delta G^{0\ H2O}$ unfolding are +18.5 kcal/mol (mesoKSI)and about +25.3 (thermoKSI), a +6.8 kcal/mol difference. These values would be - 18.5 kcal/mol (mesoKSI) and about -25.3 (thermoKSI) for the reverse folding reaction (unfolded ↔ folded transition).

Figure 32.12.8 shows an interactive iCn3D models of the bacterial ketosteroid isomerase from the mesophilic bacteria Pseudomonas Putida (left) and from the thermophilic bacteria Mycobacterium hassiacum (right).

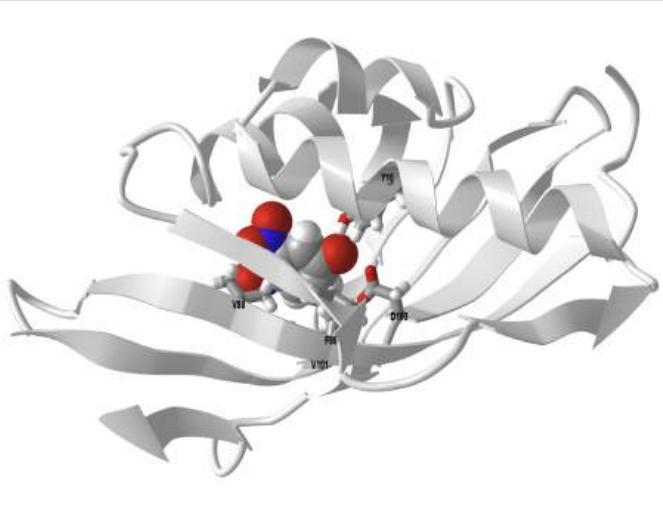

Figure 32.12.8*a*: Mesophilic Ketosteroid Isomerase D40N mutant (monomer) from Pseudomonas Putida (pKSI) bound to 3,4-dinitrophenol (**6C17**). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...kH877KZKPxWsGA

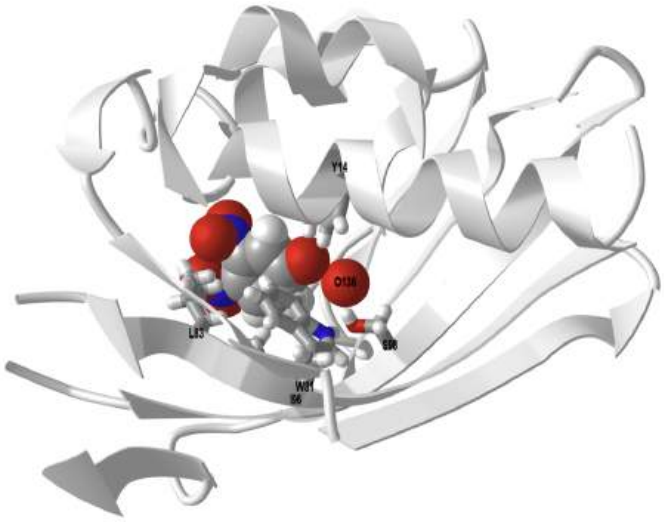

Figure 32.12.8*b*: Thermophilic Ketosteroid Isomerase D38N mutant (monomer) from Mycobacterium hassiacum (mhKSI) bound to 3,4-dinitrophenol (**6P44**). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...YbGw5zr2dRpnK8

Both structures have a bound 3,4-dinitrophenolate, a stable oxyanion and transition state analog. The corresponding active site side chains are shown in color sticks. Just one monomer of the dimer for each protein is shown for clarity. The key active-site residues F86, V88, V101, and **D103** in mesoKSI are replaced by W86, L88, I101, and **S103** in thermoKSI (all very conservative except for D103S). A water molecule forms a bridging hydrogen bond from S103 to the oxyanion in the phenolate.

Figure 32.12.9 below shows the key change in Asp 103 (see the mechanism in Fig. 7B) in mesoKSI to Ser 103 + H_2O in thermoKSI

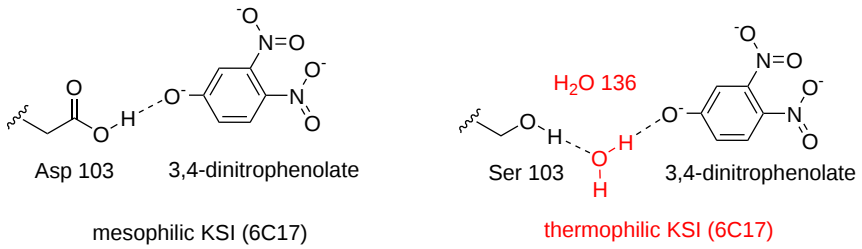

Figure 32.12.9: Change from Asp 103 in mesoKSI to Ser 103 + H_2O in thermoKSI

Asp 103 is initially protonated with a pKa is >9, much higher than in an aqueous solution (3.7). The hydrogen bond from the mesoKSI D103 to the phenolate is stronger than the bridging one from Ser 103 in the thermoKSI. This arises from the increased polarity of the OH on a carboxylic acid (Asp) compared to an alcohol (Ser). In addition, the hydrogen bond distance from the bound water to the phenolate is longer than from Asp 103. Hence the Asp 103 in the thermoKSI improves enzymatic stability. In contrast, at lower temperatures, thermoKSI is less active, but at higher temperature it is more stable. The role of Ser 103 in stabilizing the folded state is shown in Figure 32.12.10 below

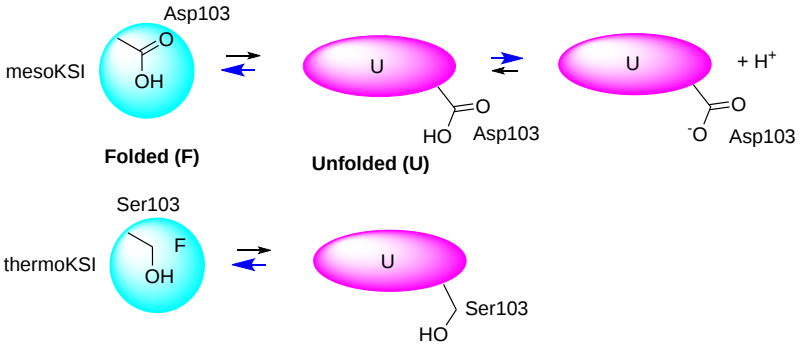

Figure 32.12.10: Roles of Asp 103 and Ser 103 in the folding to unfolding transition of KSI

When mesoKSI unfolds, Asp 103, which is protonated and not accessible to solvent in the native state, becomes solvent exposed on denaturation. Its pka drops, which leads to its deprotonation. This extra deprotonation step stabilizes the unfolded state (pulling the reaction to the right), making thermoKSI less thermally stable. In contrast, Ser 103, on solvent exposure, does not deprotonate, so the unfolded state is not additionally stabilized. Hence Ser 103 leads to greater stability of the folded thermoKSI. The D103/S103 change is found in many KSI from many bacteria.

Here are some additional findings:

- The structures of mesoKSI and thermoKSI are highly similar even though they have only 33% sequence identity. Figure 32.12.11 shows the conformational changes in the monomeric ketosteroid isomerase (KSI) going from the mesophilic enzyme (6C17, cyan) to the thermophilic one (6P44, magenta) enzymes

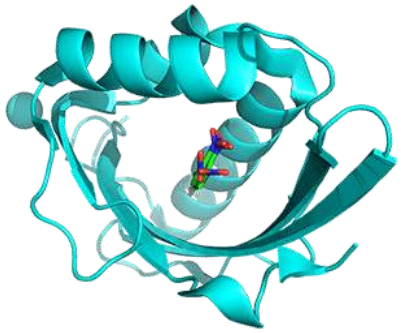

Figure 32.12.11: Conformational changes in the monomeric KSI going from the mesophilic enzyme (6C17, cyan) to the thermophilic one (6P44, magenta) enzyme

- The F86W change in the thermoKSI stabilizes the conformation of S103 to maximize its stabilization of the oxyanion in the oxyanion hole and allows high-temperature activity.
- Other KSI orthologs and mutants show higher enzyme activity if they have D103.

- Changing key residues at 86, 88, and 101 in mesoKSI to those found in the thermoKSI additionally increased the stability of the mesoKSI
- Analysis of 1140 KSIs showed that the fraction containing D103 decreases with increasing growth temperature, and the fraction containing S103 increases.

It appears that the thermal adaption of KSI occurs mostly through one amino acid change (D103S). The change reduces k_{cat} for the mesoKSI 10x at low temperatures but greatly increases stability at high temperatures.

This switch and compensatory changes in activity and stability suggest that protonated Glu and Asp side chains involved in activity might be changed to other amino acids that confer more stability but reduce activity. A conserved and protonated active site Glu is found in glycosidases from high-temperature orthologs. Likewise, a protonated Asp side chain is found in thioredoxin. As a control, a change from a protonated Glu in triosphosphate isomerase distal to the active site to a Gln shows no effect on catalysis and was not found in thermophiles. It should be noted that not all stabilizing mutations decrease activity since many examples are known that don't. 67 protonated Asp and Glu side chains were identified in the PDB, 14 of which were replaced in high-temperature orthologs.

Conservation of chaining pairs of amino acids between mesophilic and thermophilic organisms.

Are there other broadly found changes in amino acids (in addition to Asp/Glu) at each position in a mesophilic protein and its thermophilic ortholog? Computational analysis in 2194 enzyme families in 5582 bacterial species (for a total of 17 million amino acid pairs) were performed to explore this question. Half of all families had an amino acid at a given position which correlated with growth temperature, resulting in almost 160,000 key positions. The results of this study are broadly outlined in Figure 32.12.12 below.

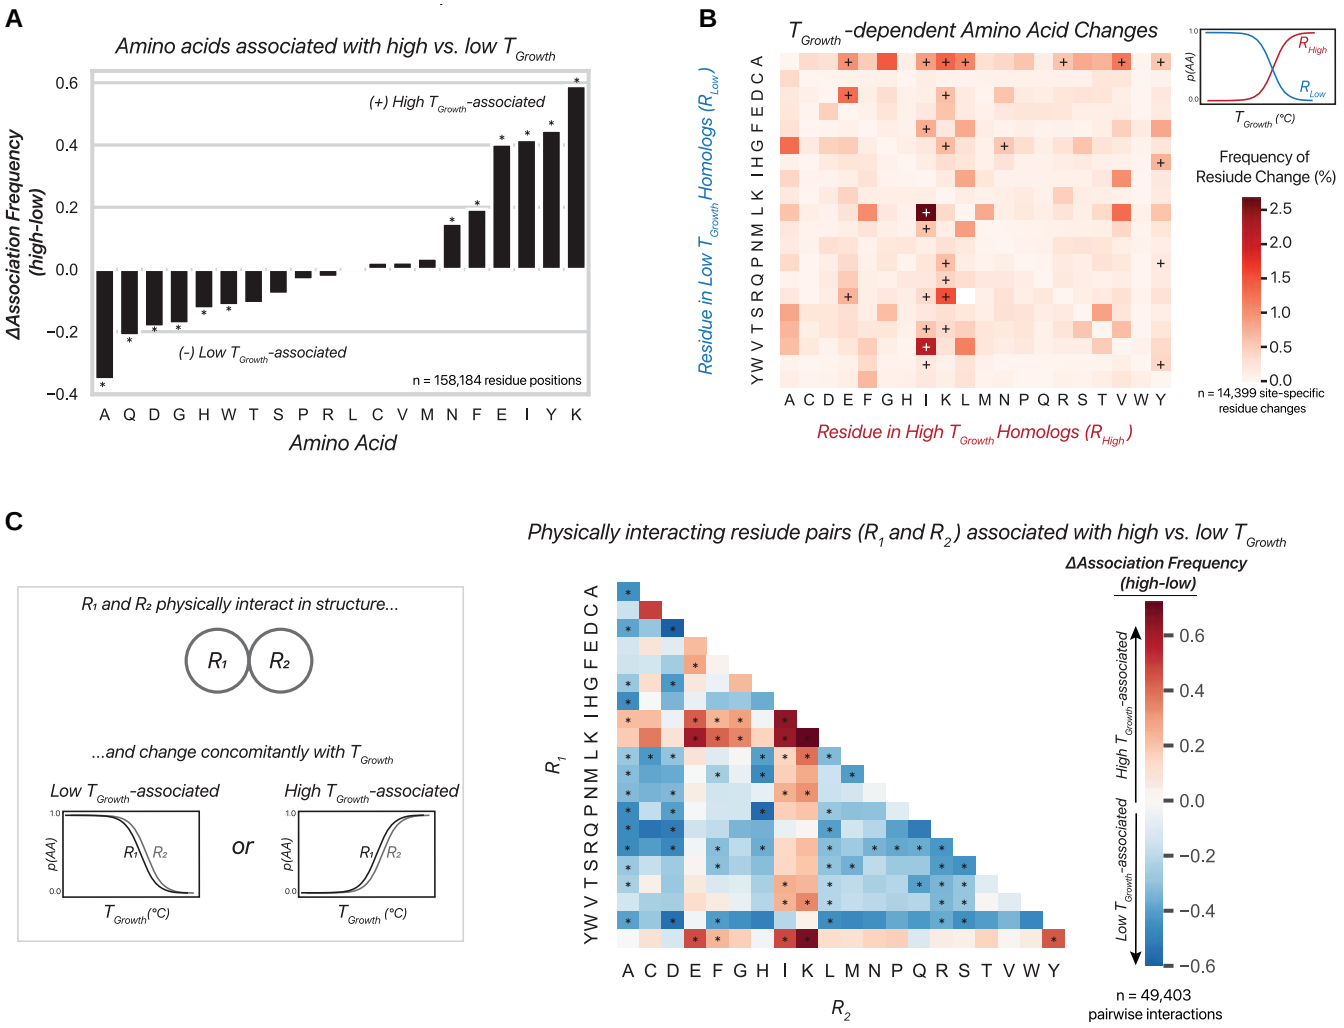

Figure 32.12.12 : Examination of temperature-associated residues and their interactions. Pinney et al., ibid. Reprinted with permission of the American Association for the Advancement of Science and Copyright Clearance Center.

Let's explain each part of this complex figure.

Panel (**A**) - Preferences in the types of amino acids associated with high or low-temperature growth: Panel (**A**) shows the difference in frequency of association of given amino acids with high to low temperatures. Some amino acids were associated with low-temperature growth. These include alanine (A), glutamine (Q), and aspartate (D), as in KSI). Others were associated with high-temperature growth (E, I, Y and K). F

Panel (**B**) - Identities and frequencies of site-specific residue changes across temperature growth conditions: Now let's see how a specific acid changes in going from mesophilic (low T) to thermophilic (high T), which show key temperature-dependent amino acid changes. Panel (**B**) shows the frequency of observed site-specific changes in temperature-associated residues. The "+" indicates that the frequency of a change (such as Leu to Ile) is significant in comparison to the opposite change (Ile to Leu). Indeed the darkest square is from a Leu (at low temperatures) to Ile (at high temperatures change. Other darker squares show these changes occur going from low to high temperature-adapted bacteria: V → I, R → L, and D → E. The specific one found for KSI, D → S, does not stand out, most likely because of the diverse types of enzymes included in the analysis.

Panel (**C**) - Identities and frequencies of physically interacting temperature-associated residue pairs (in a single protein): If one amino acid changes in going from a low to a high-temperature ortholog, it is likely that the original and changed amino acids physically contact different nearby amino acids in their respective protein. Panel (**C**) shows the difference in frequency of association with high vs. low-temperature growth bacterial enzymes for "all possible physically interacting pairs of residues (made up of residues R_1 and R_2) that change concomitantly with *the* growth temperature". The darker blue squares show interacting residue pairs found more often in low-growth temperature enzymes, while darker maroon squares show contacting pairs in high-growth temperature proteins. The asterisk shows pairs are statistically significant.

One of the darkest maroon squares (high-temperature enzymes) shows an Ile-Ile interaction pair. The vertical column above Ile (high growth) in Panel B shows that changes to Ile in high-temperature enzymes occur frequently from 6 different amino acids found in low-temperature enzymes. Ile might be favored over Val to maximize buried hydrophobic surface area. Also, compared to Leu, it has great conformation flexibility and could better pack empty spaces in protein interiors.

A Lys to Glu (K to E) interaction is strongly associated with high-temperature enzymes, while an Arg to Asp (R to D) interaction is strongly associated with the low-temperature enzyme. This implies that simply increasing the number of salt bridges (ion-ion interactions) does not make a protein more thermally adaptable. Lys salt bridges would have greater conformational flexibility than those using Arg. The same applies to Glu compared to Asp. Lys also has the largest hydrophobic surface area, which could enhance hydrophobic packing. Since Arg has hydrogen bond donors requiring more adjacent hydrogen bond acceptors, Arg use might depend more on adjacent amino acids and not just a binary pair.

In summary, these results are more nuanced than previous explanations for high-temperature stability:

- increasing branched chain residues like Ile, Leu, and Val in the packed hydrophobic core. Indeed, as seen in Panel B, the most frequent amino acid change observed are from Leu/Val in low-temperature growth orthologs to Ile in high-temperature growth ones. These are all branched-chain amino acids. They occur 2-3x more frequently than the reverse, Ile in low-temperature growth to Leu/Val in high-temperature growth enzymes. In fact, Panel C shows that Ile preferentially interacts with another Ile in high temperature adapted enzyme. Hence stability is not just improved by substitution with any hydrophobic side chain.
- increasing number of salt bridges (ion-ion interactions) and hydrogen-bonding interaction charged side chains. There are more charge side chains and salt bridged in thermophilic proteins. However, the above data shows a clear preference for Lys in thermophilic proteins as changes from Arg to Lys are common in that group as shown in Panel B. Likewise, Asp to Glu changes from low to high temperature-adapted proteins are 3 times more probably than the reverse. In addition, Panel C shows that interactions between Lys and Glu are most strongly associated with high temperature-adapted proteins, while Arg and asp interactions are most often in low temperature-adapted proteins.

ALLOSTERISM AND THERMAL CHANGES

As we mentioned before, increasing temperature can cause local effects in a protein, instead of large global changes that obviously lead to denaturation at high temperatures. Changes occurring in the active site can clearly affect k_{cat}, K_M, and k_{cat}/K_M. Allosteric effects also occur. The protein imidazole glycerol phosphate synthase (HisFH) is a heterodimer with two active sites, so it is considered a bienzyme. The H subunit is a glutaminase, which cleaves glutamine into glutamine acids and ammonia, which can diffuse through a channel to the active site of the F subunit, the cyclase. The active form of the enzyme occurs only when both substrates are bound resulting on long-range allosteric activations. In particular, the oxyanion hole in the H subunit is formed in the activated form which allows the stabilization of the tetrahedral transition intermediate in the hydrolysis of glutamine.

Figure 32.12.13 shows an interactive iCn3D models of the heterodimeric imidazole glycerol phosphate synthase complex (7AC8)

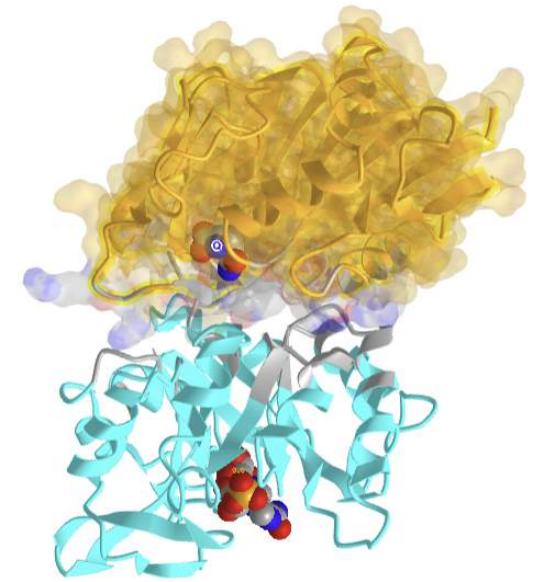

Figure 32.12.13: (Copyright; author via source). Heterodimeric imidazole glycerol phosphate synthase complex (7AC8). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...S5MbiiA9bDvDQ8.

The HisH (glutaminase) subunit is shown in orange with a molecular surface and the bound substrate (spacefill), glutamine. The HisF subunit is shown in cyan with a bound substrate.

An allosteric effector molecule can bind in the active site of His F and induce long-range conformational changes in this HisH active site which increases its activity 5000x. The structures involved are shown in Figure 32.12.14 below.

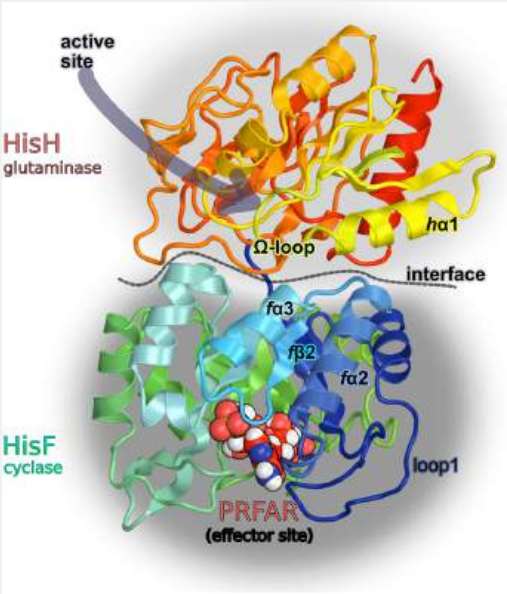

Figure 32.12.14: Imidazole glycerol phosphate synthase (IGPS) from the thermophile *Thermotoga maritima* (*T. maritime*). Maschietto, F., Morzan, U.N., Tofoleanu, F. *et al.* Turning up the heat mimics allosteric signaling in imidazole-glycerol phosphate synthase. *Nat Commun* **14**, 2239 (2023). https://doi.org/10.1038/s41467-023-37956-1. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/.

IThe HisF and HisH subunits are colored respectively in green-to-blue and red-to-yellow gradients, respectively, and separated by a dotted line which marks the interface between HisF and HisH. The labels (*f*α2, *f*α3, *f*β2, loop1, *h*α1, Ω-loop) indicate secondary structure elements that are directly involved in the allosteric regulation.

Molecular dynamics and NMR studies have shown that increases in the temperature lead to conformational changes resembling those that occur on binding of the allosteric effector at room temperature. As the temperature of the apoenzyme (no substrates or effects bound) increases from 30 °C to 50 °C, the dynamics and structure increasingly resemble the state induced by the effector. Increasing

temperatures from climate change are likely to cause subtle conformational and dynamic changes in all proteins with some having negative consequences.

THERMAL DETERMINANTS OF YEAST METABOLISM

With this basic background, we can attempt to understand the thermal determinants for entire metabolic pathways. This has been attempted in the yeast *Saccharomyces cerevisiae*, a eukaryotic organism with optimal growth around ~30 °C, extremely limited growth at 40 °C, and no growth/death at 42 °C.

Mathematical modeling all metabolic pathways in a cell is a daunting task. Accurate concentrations, rate constants, and dissociation constants are needed for all reactions. **Genome-scale metabolic models** (GEM) use a multitude of constants that are experimentally or computationally determined. There are usually significant uncertainties in the parameters used in the model. Bayesian statistics has been used to decrease these uncertainties. In Bayesian statistics, parameters and models are updated with the known values and information. It is similar to machine learning models, which uses data to train the model and refine it.

A Bayesian model for S. cerevisiae was used as it is the most abundantly used organism in industry and has many GEMs. The GEM used was the **enzyme-constrained GEM** (**ecGEM**). It was then further developed into the **enzyme and temperature-constrained GEM** (**etcGEM),** which, in addition, incorporates the temperature dependence of both the concentration of the native enzyme (E_N) and kcat for the enzyme. For each enzyme, the melting point (T_M), the change in heat capacity (ΔCp) for the transition state, and the optimal temperature (T_{opt}) were included. We discussed both (T_M) and the change in heat capacity (ΔCp) for proteins in Chapter 4.9. In addition, another term for **non-growth associated maintenance (NGAM)** of the cells, which is also temperature-dependent, was included. Examples of non-growth associated maintenance include maintaining membrane potential, turgor pressure, normal protein refolding and DNA repair.

The Bayesian models reproduced the datasets well. Using the models, key enzymes that control the flux through metabolic pathways were determined at each temperature. The most rate-limiting enzyme at superoptimal temperature in yeast was squalene epoxidase (ERG1), found in sterol metabolism pathways. Replacing the S. cerevisiae enzyme with one from a thermotolerant yeast strain led to better growth than the wild-type cells.

Figure 32.12.15 below the complexity and extent of the metabolic proteins and pathways of the enzyme-constrained GEM (ecGEM).

Figure \(\PageIndex{15}\): Metabolic proteins and pathways included in the enzyme-constrained GEM. Benjamín J Sánchez et al., Molecular Systems Biology (2017)13:935. https://doi.org/10.15252/msb.20167411. Creative Commons CC BY

(add soon: ecYeast7 model (both constrained and unconstrained; each as.mat,.sbml and.txt files): GitHub (https://github.com/SysBioChalmers/GECKO/tree/v1.0/Models)

Now, let's explore some of the results of the study. Figure 32.12.16 below shows how the temperature dependencies of proteins were incorporated into the enzyme-constrained GEMs.

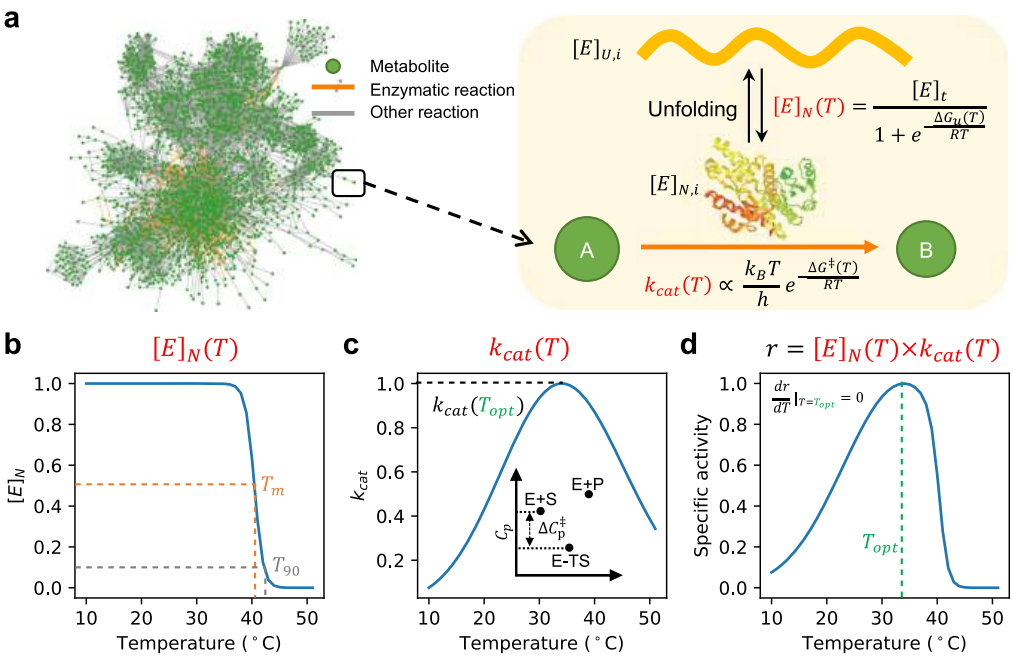

Figure 32.12.16 : **Using Bayesian statistical learning to integrate temperature dependence in enzyme-constrained GEMs.** Li, G et al., *Nat Commun* **12**, 190 (2021). https://doi.org/10.1038/s41467-020-20338-2. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/.

Panel a shows the complexity of the metabolic network used to produce the ecYeast7.6, shown in greater detail in Fig. 13 above, and how E_N and k_{cat} depend on temperature.

Panel b shows how a two-state denaturation model was used. $[E]_N$ is the enzyme concentration in the native state; T_{opt} is the optimal temperature at which the specific activity is maximized; T_m and T_{90} are temperatures at which there is a 50 and 90% probability that an enzyme is in the denatured state, respectively. In Chapter 4.4 we indicated that for a reversible two-state transition, T_M is the temperature at which half of the enzyme is native, and half denatured, giving a K_{eq} for the N ↔ D equilibrium of 1.

Panel c shows how k_{cat} depends on temperature. The insert show how the heat capacity change from E+S to the E-transition state. We have previously seen that the $\Delta C_P > 0$ for protein unfolding, and this $+\Delta C_P$ value is a signature of the hydrophobic and occurs when nonpolar groups become more solvent exposed. We have shown previously that enzymes bind the transition state more tightly than the substrate. This $-\Delta C_P$ is more in line with the latter.

Panel d shows the temperature dependence of enzyme's **specific activity, r**, as a function of temperature, which is determined by E_N (panel B) and k_{cat} (panel C).

Now we can explore the outputs of the ecGEM run with the separate added effects of temperature on NGAM, k_{cat}, and E_N (denaturation). Finally, the combined etcGEM was run. The combined etcGEM was able to produce the observed outcomes in yeast growth. Given that the contributions of each of the three factors, NGAM, k_{cat}, and protein denaturation, to whole-cell growth could be modeled. The outcomes from these models as a function of temperature are shown in Figure 32.12.17. They support the notion that the growth rate of yeast is explained by temperature effects on its enzymes.

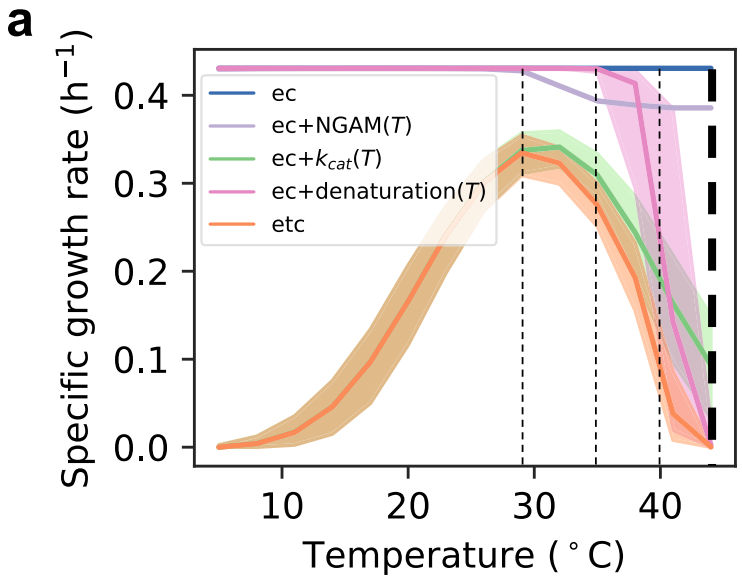

Figure 32.12.17 : **Fig. 3: Yeast growth rate is explained by temperature effects on its enzymes.** Li, G et al., ibid

This figure shows how the temperature dependence of different processes combines to affect the growth rate. EC is the prediction from the enzyme contained GEM, —predictions with the enzyme-constrained model; ec+NGAM includes temperature effects on nongrowth associated maintenance; ec+$k_{cat}(T)$ incorporates the temperature effects on enzyme k_{cat} values; ec+denaturation(T) incorporates the temperature effects on enzyme denaturation. Finally, in the etc model, the enzyme and temperature-constrained model incorporates temperature effects on all three (NGAM, k_{cat} and enzyme denaturation) into ec model. The solid lines indicate median values and shaded areas indicate regions between the 5th and 95th percentiles (n = 100).

Here are some summarized results:

- <29 °C, only temperature-dependent k_{cat} affected the cell growth rate (green line under the orange etc line <29 °C;
- at 29 °C <T < 35 °C, both k_{cat} and NGAM (gray line) determined the growth rate;
- at T > 35 °C, enzyme denaturation at major effects and by 40 °C was dominant,

Figure $32.12.18 d-e$ shows using images how the temperature dependencies of the factors E_N, k_{cat} and r (specific activity) on yeast growth. A phenomenal amount of data is displayed in these images.

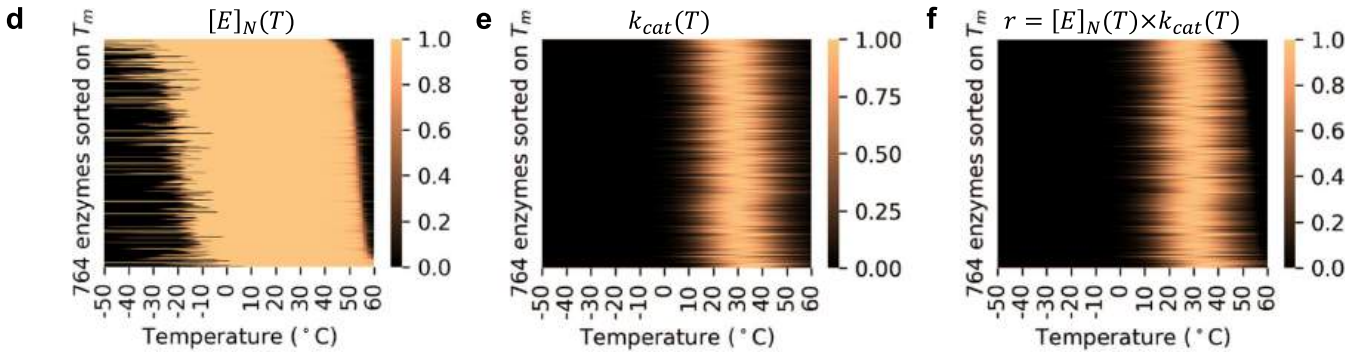

Figure $32.12.18 d-e$: **Fig. 3: Yeast growth rate is explained by temperature effects on its enzymes.** Li, G et al., ibid

Panel d shows the probability that a given enzyme is in the native state. Think of the y-axis as increasing 1 pixel at a time from bottom to top, with each new added pixel representing a different enzyme for a total of 764 enzymes along the y-axis. The x-axis shows with each pixel at a given y-axis if the enzyme is native that temperature

The interface between bright (native) and black (denatured) on the right side of the image shows that some enzymes (top) become unfolded at 40^0C, while some don't unfold until close to 60^0C

Panel e shows normalized k_{cat} values of 764 enzymes at different temperatures. The brightest white pixels show the highest k_{cat} values. The image clearly shows the brightest vertical band at around 30^0C, the optimal growth temperature of yeast.

Panel f shows the normalized specific activities (r) of 764 enzymes at different temperatures. Again the highest specific activity is centered around 30^0C.

Note in Fig. 15d that most enzymes also denature at temperatures < -10 ^{0}C, but cells were not viable under those conditions.

The etcGEM was able to replicate a finding that above 37 °C, yeast cells switch from respiration to partial fermentation accompanied by a larger flux through glycolysis. This occurred because of a decrease in specific activities of enzymes with increasing temperature, which constrains metabolism. In addition, the total protein concentration reaches a limit and can't increase further, which could have increased enzyme activity. Along with an increase in glycolysis, mitochondrial ATP production decreases. Respiration produces more ATP per mole of glucose, but glycolysis/fermentation produces more ATP/protein mass so when protein concentration reaches a maximum, glycolysis is more efficient.

Lastly, the etcGEM was used to find the enzymes whose flux changed most at superoptimal temperatures. (We introduced the flux control coefficient in Chapter 14.3). The results of this modeling are shown in Figure 32.12.19 below.

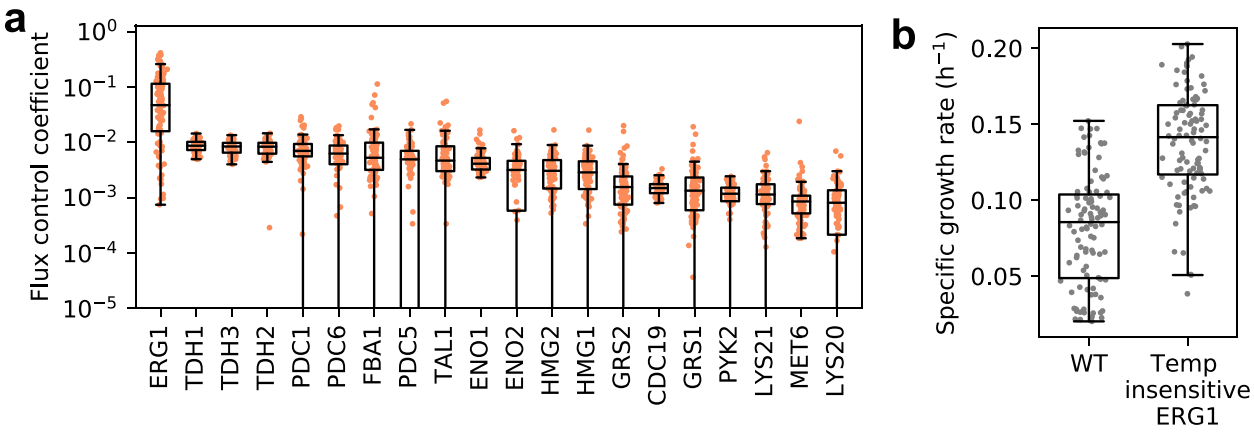

Figure 32.12.19 : Flux control coefficients at superoptimal model for yeast.

One enzyme stands out in Panel a, ERG1, squalene epoxidase, an enzyme involved in sterol oxidation. If the wildt-type enzyme was replaced with a temperature-insensitive ERG1, the specific growth rate increased significantly (over 55%).

WHAT DOES THIS HAVE TO DO WITH CLIMATE CHANGE? LIFE'S THERMAL TOLERANCE AND LIMITS

We've just explored the molecular and metabolic adaptations that allow organisms to thrive at higher temperatures. The question is how quickly present life can adapt to global warming caused by increasing greenhouse gases. Life on the planet will adapt, but the diversity of life forms in the biosphere will change. Five mass extinction have occurred over the last 450 million years up until the present, as shown in Figure 32.12.20 below.

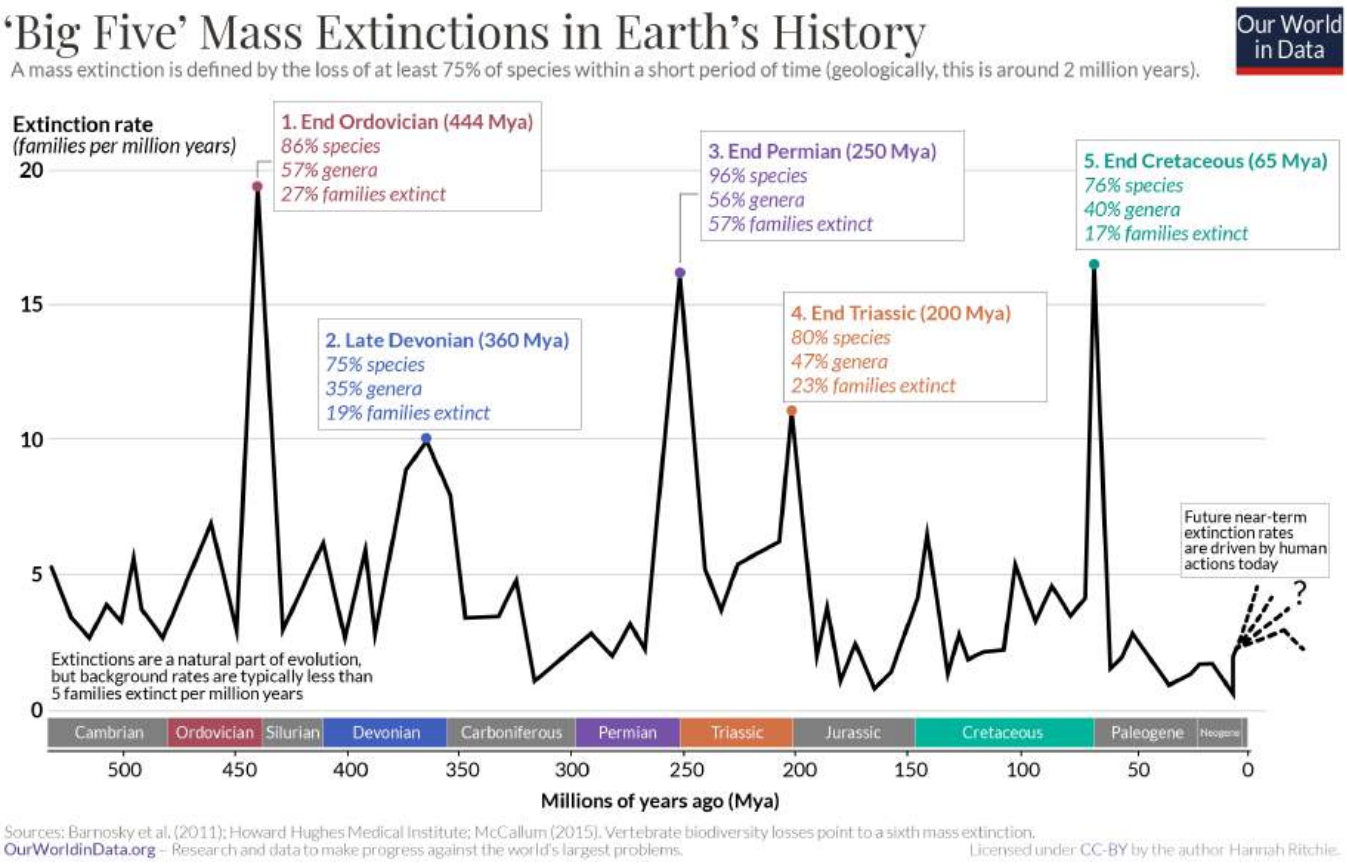

Figure 32.12.20 : Five mass extinction over the last 450 million years. Hannah Ritchie. Our World in Data. https://ourworldindata.org/mass-extinctions. Creative Commons BY license.

Many factors, often interrelated, can contribute to mass extinction. These include volcanism, asteroid impact, climate change, ocean anoxia, and the release of methane from ocean hydrates and permafrost. All are correlated with increased temperatures. as shown in Figure 32.12.21 below. It documents the correlation between temperature changes and the extinction rate for marine animals over the last 450 years. The gray bars highlight the extinction cycle.

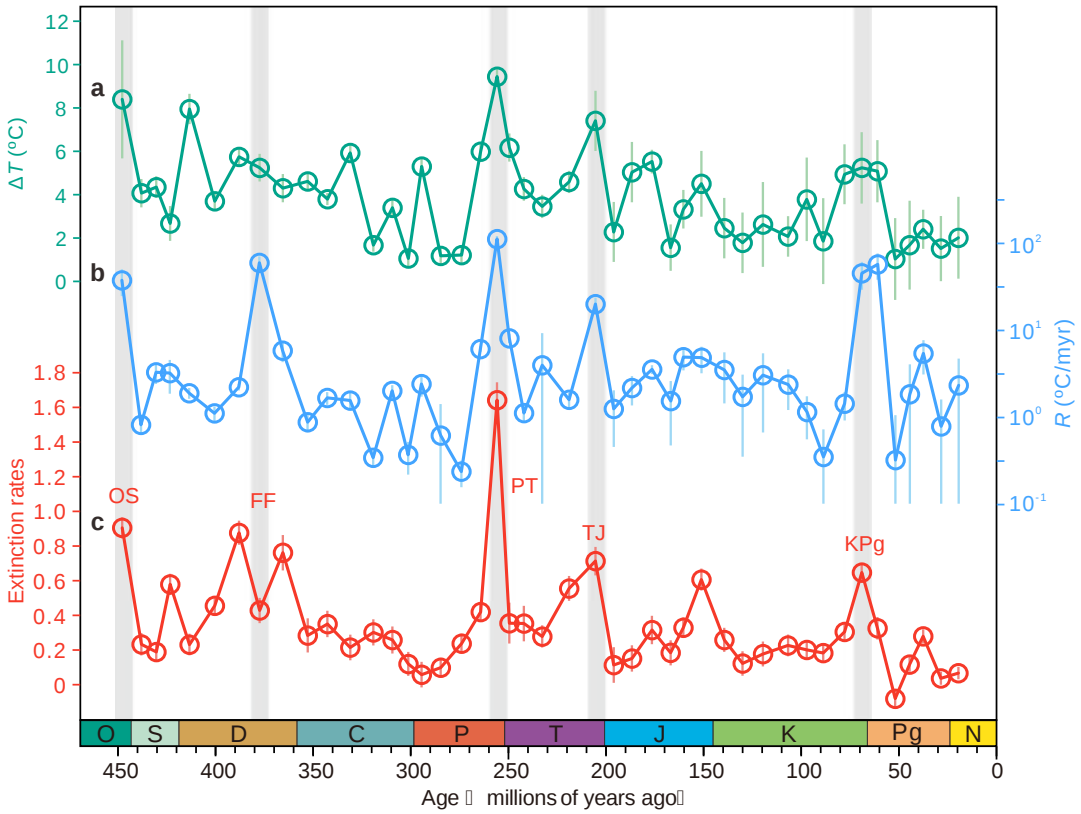

Figure 32.12.21 : **Temperature change and extinction rate over the past 450 million years.** Song, H., Kemp, D.B., Tian, L. *et al. Nat Commun* **12**, 4694 (2021). https://doi.org/10.1038/s41467-021-25019-2. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/.

Pane a shows the largest magnitude of temperature change (Δ*T*, absolute value) in each time interval (bin)

Panel b shows the highest rate (*R*, absolute value) of temperature change in each time bin, defined at the million-year (Myr) scale.

Panel c shows the generic extinction rates of marine animals calculated using gap-filler methods using data from the Paleobiology Database. The Big Five extinctions occurred in the end-Ordovician (OS), Frasnian-Famennian transition (FF), Permian-Triassic transition (PT), Triassic-Jurassic transition (TJ), and Cretaceous-Paleogene transition (KPg). Vertical bars show mean ± 1 x standard deviation (see Methods). O Ordovician, S Silurian, D Devonian, C Carboniferous, P Permian, T Triassic, J Jurassic, K Cretaceous, Pg Paleogene, N Neogene. Dark cyan, blue, and red dots represent Δ*T*, *R*, and extinction rate, respectively.

The authors suggest that a temperature change of >5.2 °C and a rate of >10 °C/Myr would lead to a new extinction rate comparable to the "Big Five". A rise of 5.2 °C is in the upper range (but likely only with human inaction to prevent it) of IPCC projection. The present rate of temperature increase (almost 2 °C/200 years) is unprecedented in at least the last 3 million years. So it appears that we are headed to a 6th mass extinction, caused by a combination of environmental degradation, pollution and climate change created by humans.

Rothamn has suggested that we can tip over into an "official" mass extinction depending on the magnitude and the rate of change in the carbon cycle. If long-scale changes occur too quickly and organisms can't adapt, extinction follows. If the changes occur on a short time scale (as it happening now), the size of the change is a key factor. His analysis suggests that a key factor is anthroprogenic-related increases in ocean CO_2. A threshold of 310 Pg (Gt), which we could reach by 2100, could officially trigger the sixth mass extinction. However, many would argue that we are already in the 6th extinction cycle. For example, of about 30,000 terrestrial vertebrate species, about 1.7% (515 species) are on the verge of extinction (having <1000 individuals). 77 mammal and bird species have lost most of their populations.

When it comes to how organisms will adapt to our present climate change, Hochahka and Somero ask 6 relevant questions:

1. What is the thermal optima and how much change leads to suboptimal or lethal conditions?
2. What mechanisms set upper limits?
3. How close do organisms live to the limits of their thermal tolerance?
4. To what extent can organisms acclimatize to temperature increase?
5. When are genetic changes necessary for survival?
6. Does the acquisition of heat tolerance reduce cold tolerance?

More simply, we can ask if organisms can survive and thrive and at what cost. Humans most assuredly can survive a warming world, but if temperatures become too high, they will not thrive and parts of the world we become inhabitable to them without great economic, social, political, and cultural costs. Some organisms will become extinct. Mass migrations of all species will occur as they seek more habitable environments.

In an evolutionary sense, species occupy environments in which they can survive and adapt. Our climate has been fairly constant since the end of the last ice age, about 12,000 years ago. Climatic changes that make an environment suboptimal depend on how sensitive an organism is and how close it lives to its thermal limits. We have already documented the thermal limits of individual enzymes as well as whole metabolic systems

As you learned in introductory chemistry, multiple linked reactions can only go as fast as their slowest step. An analogous insight is that a chain is only as strong as its weakest link. It may be the membranes, not proteins, are the weakest link with respect to temperature adaptation as higher temperatures alter phases and subphases like rafts with lipid bilayers which in turn can disrupt the activity of membrane proteins. Membrane functions (permeability, endo- and exocytosis, and maintenance of transmembrane potentials) are also very important.

Temperature effects on neural communication in synapses might be key. An interesting example is a particular Antarctic fish, which after long exposures to 4 ^{0}C, dies if temperatures are raised to around 9^{0}C. Synaptic transmission through the acetylcholine receptor is altered as the amount of acetylcholine in the synapse increases and the rate at which it is degraded by acetylcholinesterase decreases.

The lethal temperature for an organism can depend on many factors, including the rate of temperature increase, the length of exposure, previous long-term acclimatization, and for humans, humidity. Humans can't dissipate body heat without sweating if the external temperature is >37^{0}C (average body temperature). If the humidity is high enough, sweating is ineffective in dissipating heat. Since metabolism produces heat, the body temperature can increase past 37^{0}C even if the external temperature is lower. A lethal limit for humans can occur as low as 29^{0}C (84^{0}C) at a relative humidity of 85%. Even now, about 30% of the human population is exposed to lethal thresholds at least 20 days/yr, and this will only grow as temperatures and humidity increase.

Comparisons of similar species (congeneric) that live in intertidal regions (region above the water level at low tide and underwater at high tide) vs. subtidal regions (close to a shore but always submerged) show significant differences. Organisms living in intertidal regions will experience a higher range of temperatures. 19 species of congeneric porcelain crabs exist that inhabit different latitudes and vertical depths in intertidal and subtidal regions. Intertidal crabs that experience a highly variable temperature region are exposed to temperatures much closer to their lethal temperature limit, showing the T_{lethal} - $T_{max\ habitat}$ get smaller. Heart function and neural activity at higher temperatures appear to be weak links in survival. Heat shock protein function is also different in congeners of marine snails. Lethal temperatures appear to be those at which protein synthesis dramatically decreases. Repair to damaged protein is decreased, which limits vertical migration to lower temperatures and can make organisms more susceptible to predation. These effects can occur over a small increase in temperature (a few degrees Celsius). It becomes more important to heed the warnings by the IPCC to limit global average temperature increases to 1.5 to the more likely 2.5^{0}C range.

Laboratory experiments in directed evolution show that an organism's thermal tolerance can be increased, but there are limits. E. Coli can live at a variety of temperatures and experiments to evolve them at 37 ^{0}C (human gut temperature), at 42 ^{0}C (close to their lethal limit), and in an environment with fluctuating temperatures (between 32 ^{0}C - 42 ^{0}C) have been conducted. Over 1000s of generation, the rate of evolution was highest in the 42 ^{0}C group. The group that evolved at fluctuating temperatures was better adapted to both higher and lower temperatures. Under no circumstance did E. Coli evolve into a thermophilic species, which would require novel gene function and not just a small set of mutations that allow for more optimal values of k_{cat} and K_M for enzyme catalysis.

32.13: BIOCHEMISTRY, CLIMATE CHANGE AND HUMAN HEALTH

Search Fundamentals of Biochemistry

32.13.1: INTRODUCTION

Climate change affects human health and of course the health of the biosphere to which we are inextricably linked. Many, including the US CDC, describe the concept of One Health as "a collaborative, multisectoral, and transdisciplinary approach — working at the local, regional, national, and global levels — with the goal of achieving optimal health outcomes recognizing the interconnection between people, animals, plants, and their shared environment."

We all know that pollution from the use of fossil fuels also has severe health consequences independent of effects mediated more directly by climate change. A solution to both is to dramatically decrease the use of fossil fuels and mitigate pollution from their use. People most likely do not understand the extent which climate change and fossil fuel use are linked to human health. If they did, perhaps they would become advocates for climate change action. This section will cover how climate change and fossil fuel use affect aspects of human health and diseases. In this section, we will focus on heat-related illnesses and pulmonary/cardiovascular diseases. We'll tackle climate change, emerging diseases, and pandemics in the next chapter section.

Fossil fuel use and climate change obviously affect other diseases as well, some by indirect means For instance, increases in cancer deaths will occur due to lower availability of health care arising from extreme weather disasters that impact health facilities and peoples' access to them. An increase in cancer deaths occurred during the Covid pandemic since people deferred preventive healthcare treatments as well as cancer surgeries during the pandemic. Allergic illness will increase as growing seasons lengthen and species that cause allergic reactions shift to new growth regions.

32.13.2: HEAT-RELATED ILLNESS

Heat illnesses include heat cramps, heat exhaustion, heat syncope (fainting), and heat stroke, the latter of which can quickly become fatal. Heat affects normal physiology and health. It's estimated that about 1% of all cardiovascular deaths are linked to extreme temperatures. We know that the number of warm days and the number of heat waves has increased with climate change.

Figure 32.13.1 below shows how heat waves have changed in the US in the decades from 960 to 2022 using data from 50 large metropolitan areas. The 2020s is not even a third over but already shows increases in heat waves over the previous decade.

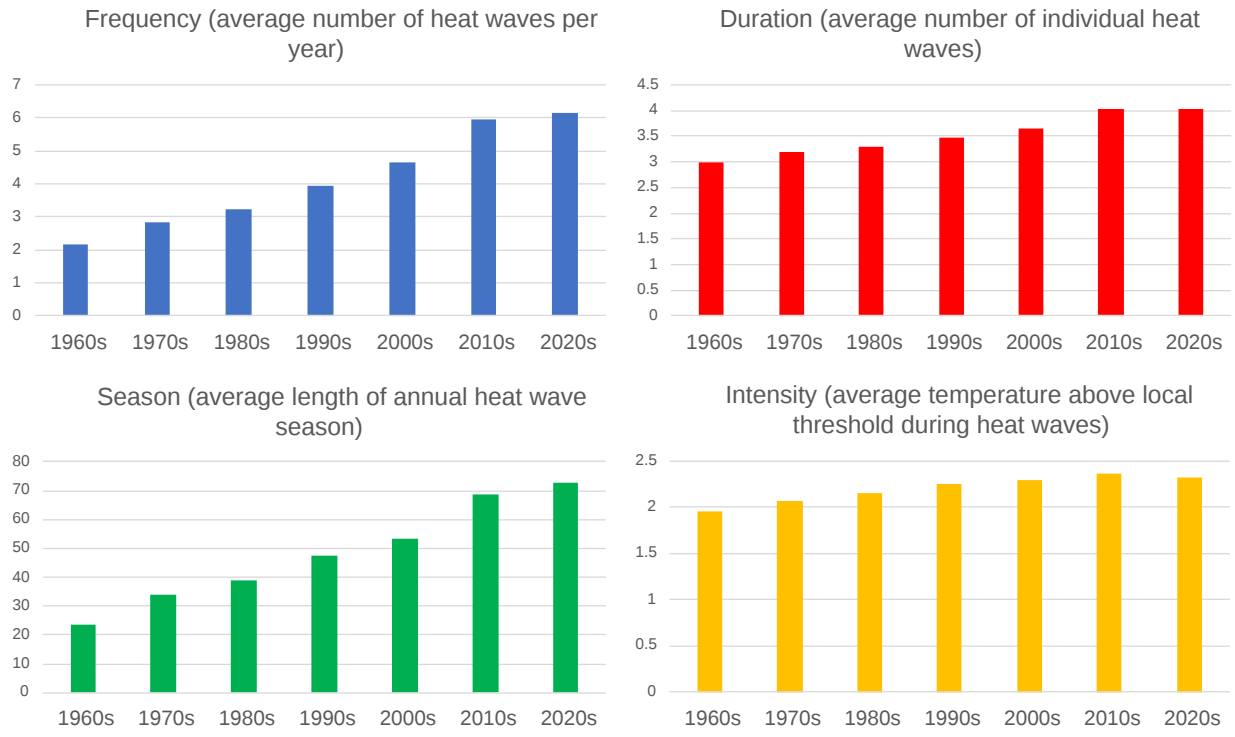

Figure 32.13.1: Climate Change Indicators: Heat Waves. EPA. https://www.epa.gov/climate-indicato...ors-heat-waves. Data source: NOAA (2022)

Many historical heat waves have occurred in recent times. A heat wave in Europe in 2003 caused 15,000 heat-exposure-related deaths in France and 70,000 throughout Europe. On June 28, 2019, France recorded a temperature of 45.9 °C (115 °F). In 2022 China experienced a two-month heat wave and drought, with a record temperature of 45 °C (113 °F) set in Chongqing. The Chicago Heat Wave of 1995, with a maximal temperature of 106 °F, caused by high temperatures and humidity, killed over 500 people. The worst might be the Russian Heat Wave of 2010 when temperatures were 5 °C (9 °F) higher than normal and reached 40 °C (104 °F). Around 55,000 people died.

Figure 32.13.2 shows temperature and excess mortality from the 2022 heat wave in Europe during which 60,000 people died from heat-related causes.

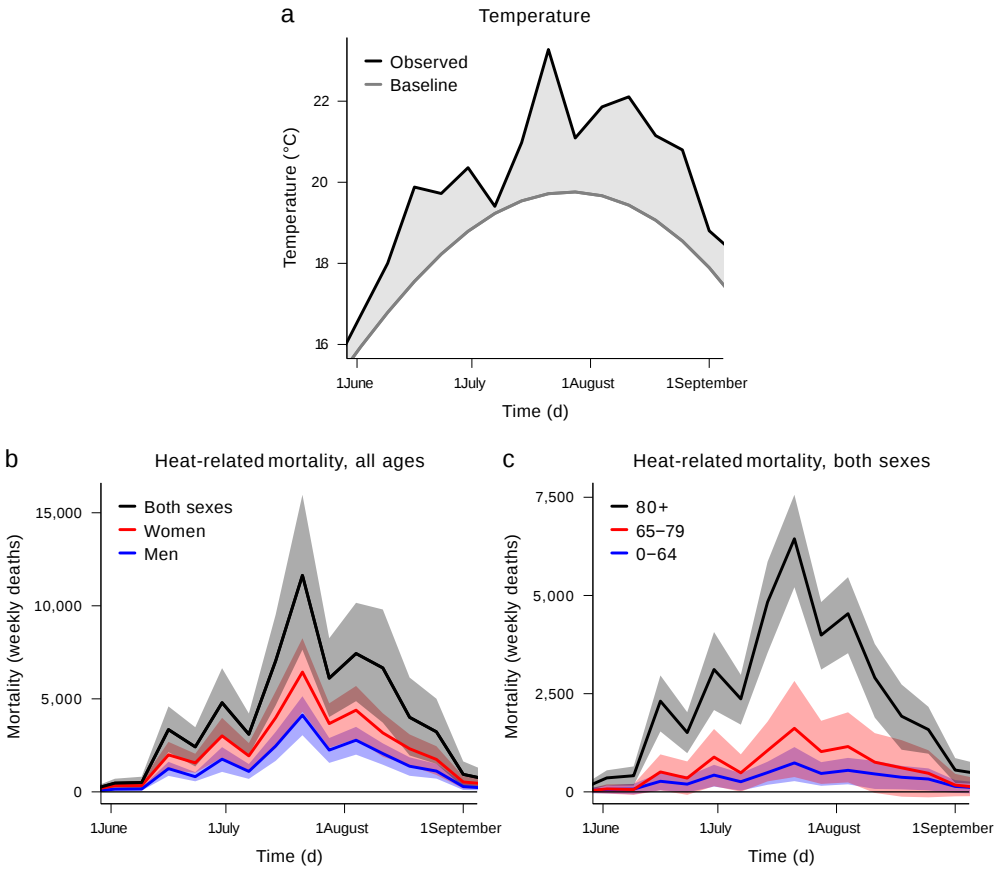

Figure 32.13.2: **Weekly temperature and heat-related mortality numbers in Europe during the summer of 2022.** Ballester, J., Quijal-Zamorano, M., Méndez Turrubiates, R.F. *et al.* Heat-related mortality in Europe during the summer of 2022. *Nat Med* (2023). https://doi.org/10.1038/s41591-023-02419-z. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/

Panel a shows the weekly baseline (gray line) and observed (black line) temperature (°C) averaged over Europe. Temperature anomalies are defined as the difference between observed and baseline temperatures (gray shading). Baseline temperatures were computed as the mean annual cycle of observed temperatures in the reference period 1991–2020.

Panels b and c show weekly heat-related mortality (weekly deaths) aggregated over Europe for the overall population (black), women (red) and men (blue) (**b**) and people aged 0–64 (blue), 65–79 (red) and 80+ (black) years (**c**), together with their 95% CIs (shadings). The numbers for women and men in **b** do not include the United Kingdom; values for the age groups in **c** do not include Germany, Ireland, and the United Kingdom.

Figure 32.13.3 below shows the steady increase in deaths as the average summer temperature in Europe has increased. The outlier in 2022 is shown as a red dot.

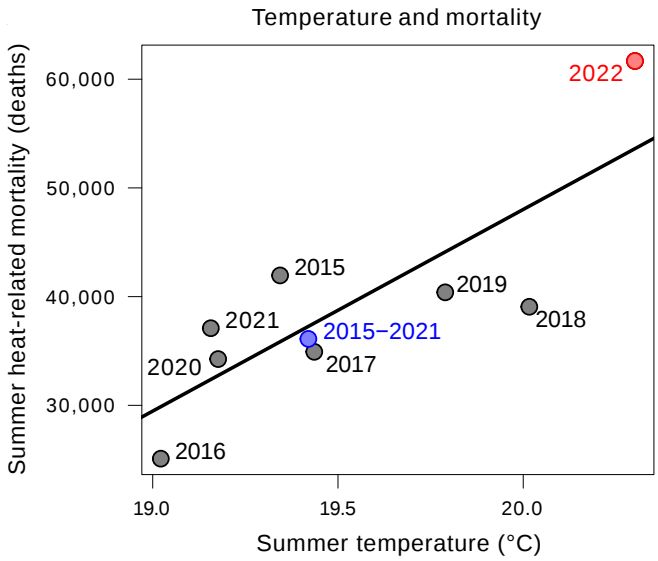

Figure 32.13.3: **The summer of 2022 within the context of rising temperatures in Europe.** Relationship between summer mean temperature (°C) and summer heat-related mortality (summer deaths) in the analyzed European countries. The straight line shows the linear fitting for the 2015–2022 period. Ballester et al., ibid.

In exercise studies under controlled conditions, the heart rate increases and plateaus after a temperature increase, but with further temperature increases, the heart rate increases with plateauing, which is a sign of cardiovascular strain. In humid conditions, cardiovascular strain develops even on slow walking at 34 °C (93.2 °F). Under dry conditions, the strain developed at around 41 °C (106 °F). The strain (as indicated by an increasing heart rate) proceeds by about 20 minutes a rise in core temperature.

With each temperature increase over pre-Industrial Revolution values, the annual probably of heat waves with apparent temperatures of 40 °C/104 °F (dangerous with a high incidence of heat cramps, heat exhaustion, and heat strokes) and 55 °C./131 °F (very dangerous with heat stoke very likely) increases, as shown in Figure 32.13.4 below.

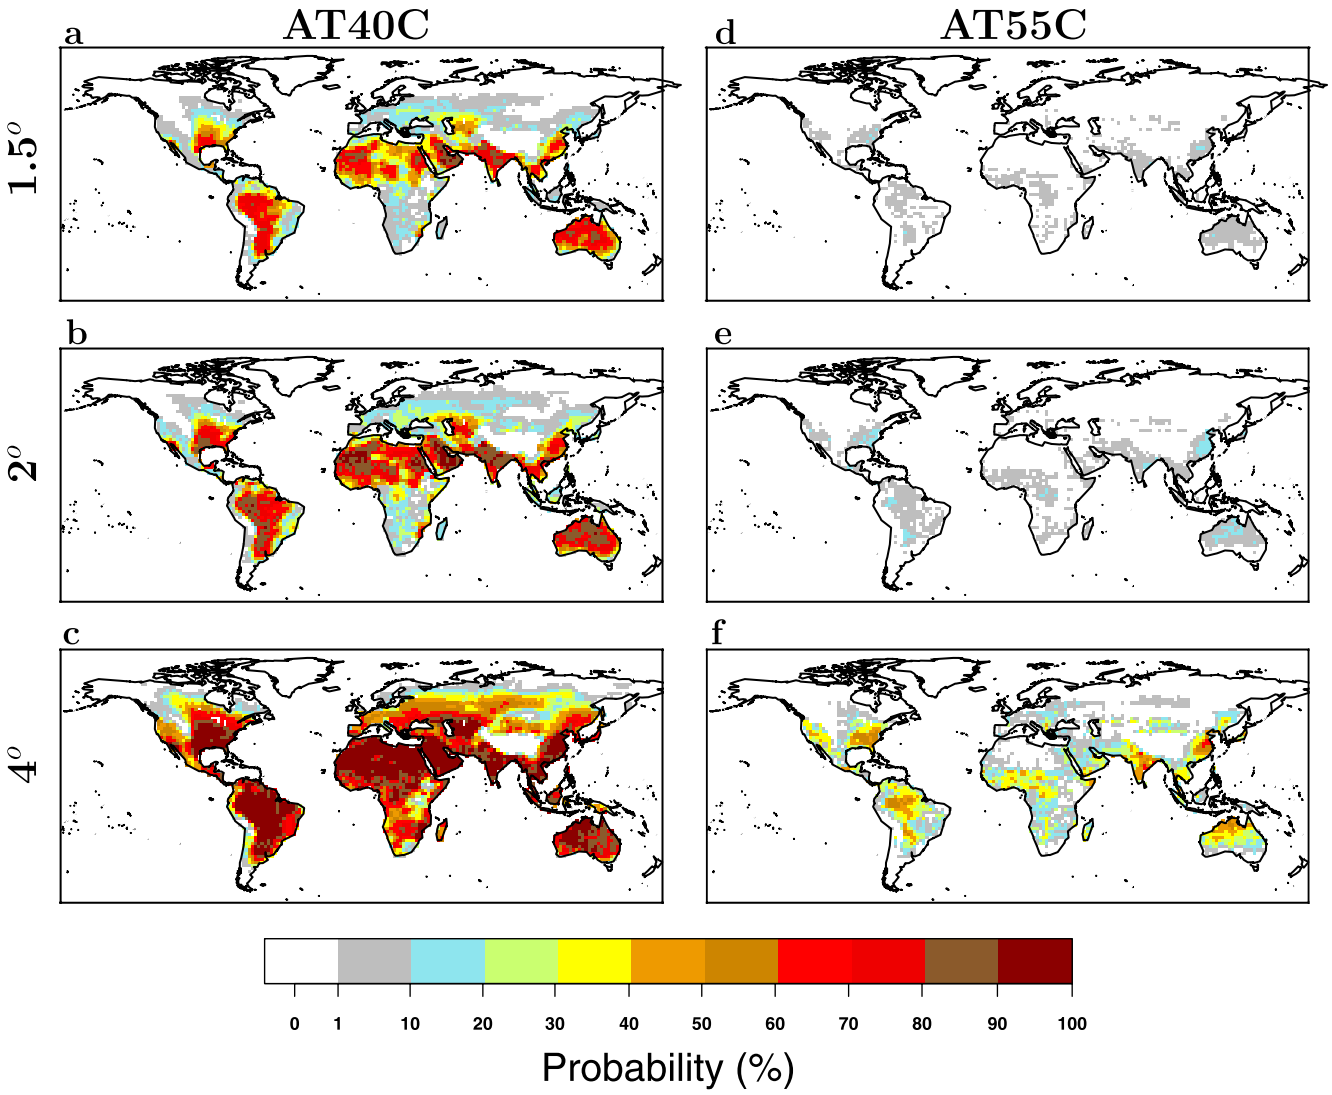

Figure 32.13.4: Annual probability of occurrence of heat waves with apparent temperature (with contributions from humidity) peaks greater than 40 °C and 55 °C. Russo, S., Sillmann, J. & Sterl, A. Humid heat waves at different warming levels. *Sci Rep* **7**, 7477 (2017). https://doi.org/10.1038/s41598-017-07536-7. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/.

Panels (**a**–**c**) show the probability of occurrence of heat waves with $AT_{peak} \geq 40$ (AT40C) calculated at each grid point for all model years with global mean temperature anomaly relative to 1861–1880 at 1.5, 2, and 4 degrees warming (see Fig. 2), respectively.

Panels (**d**–**f**) are similar to panels (**a**–**c**) but show the occurrence of heat waves with $AT_{peak} \geq 55$ (AT55C).

32.13.3: HEAT EXPOSURE AND KIDNEY DISEASE

Cumulative exposure to high effective temperatures caused by sublethal combinations of heat and humidity leads to chronic kidney disease. This is happening with increasing frequency to workers in poor agricultural areas and others who work in such hot conditions in industry and outdoors. This type of kidney disease is not caused by diabetes, hypertension, and other known diseases of the glomeruli. Chronic kidney disease in such workers was noted in El Salvador and elsewhere in Central America. The disease has a high mortality rate. Just in El Salvador, the death from kidney disease is ten times higher than in the US. Initially, the disease was called Mesoamerican nephropathy.

Biochemical correlates of the diseases are yet unclear. Serum creatinine levels are increased, which might affect renal perfusion and lead to kidney damage. The effects might be generally cumulative or from repetitive episodes of exposure. Sugarcane field workers who report nausea, vomiting, headaches, muscle weakness, back pain, and fevers have high levels of creatinine. Kidney biopsies show inflammation and kidney fibrosis.

Similar diseases in other parts of the world that seem to have the same presentation include Sri Lankan nephropathy and Uddanam (in the Indian state of Andhra Pradesh) nephropathy. Some have categorized it as CKDu or Chronic Kidney Disease of Unknown

etiology/Uncertain cause or as chronic kidney disease of non-traditional origin (CKDnt).

Figure 32.13.5 below shows the distribution of kidney disease in the Western Hemisphere in 2019.

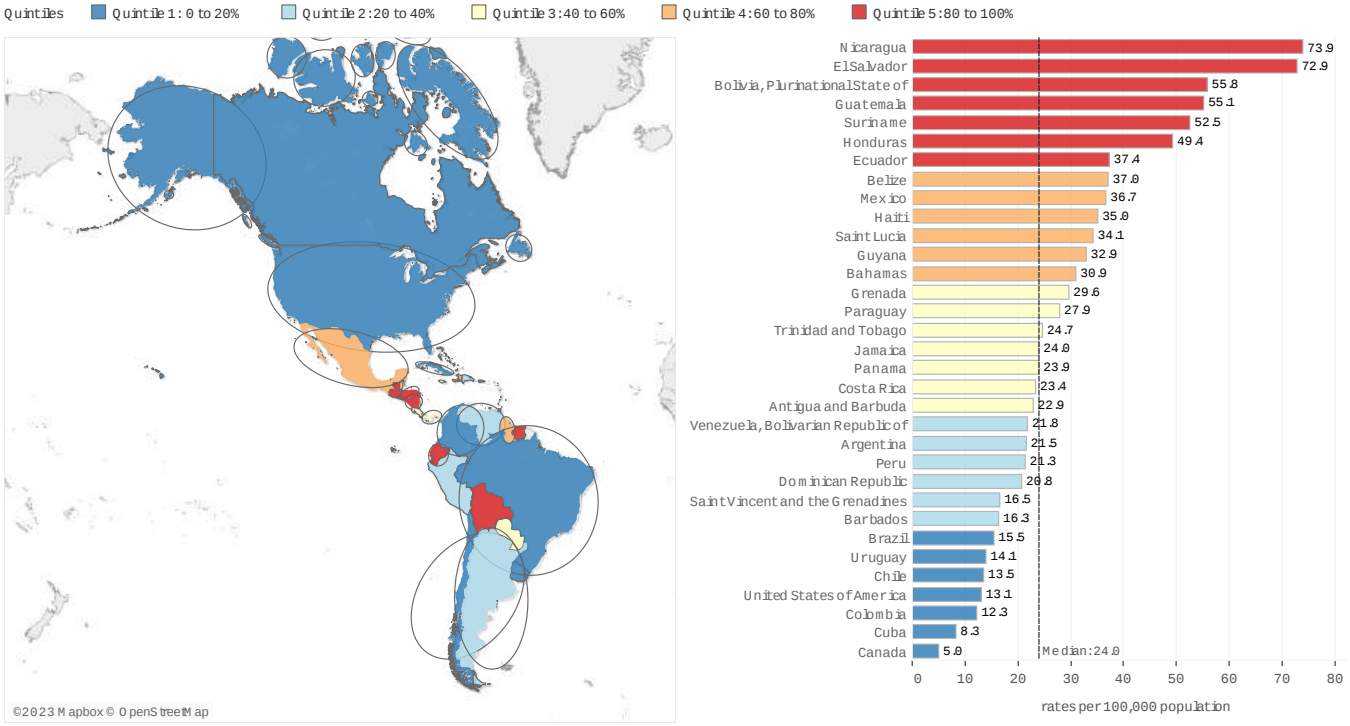

Figure 32.13.5: Burden of Kidney Disease. 2019. Men and Women. Pan American Health Organization/WHO.

Other factors such as increased exposure to herbicides, heavy metals, and microbial agents might also cause or contribute to the disease. However, the disease is most prevalent in the hotter regions of affected countries, as the incidence is lower when workers work at high altitudes. Increased incidence of chronic kidney disease also appears to be occurring in workers in Florida and California.

32.13.4: BIOCHEMICAL MECHANISM FOR HEAT STROKE

The actual biochemical mechanisms of heat stroke effects (circulatory failure, organ injury, uncontrolled clotting, death) are not fully understood. Certainly, cell death plays a major role, but not through the classical apoptotic pathway which depends on the activation of **caspases** (see Chapter 28.14). Rather, cell death occurs through **necroptosis**, a caspase-independent pathway. In necroptosis, an upstream protein kinase **RIPK3** (receptor-interacting serine/threonine protein kinase 1) activates through phosphorylation the effector protein **MLKL** (mixed lineage kinase domain-like protein). Phosphorylated-MLKL then translocates to the cell membrane where it leads to calcium influx and plasma membrane damage in the final "execution" phase of cell necrosis.

The activation of RIPK3 and MLKL through other receptors, including the toll-like receptors (TLR3 and TLR4), and tumor necrosis factor receptor 1 (TNF-R1), is shown in Figure 32.13.6 below.

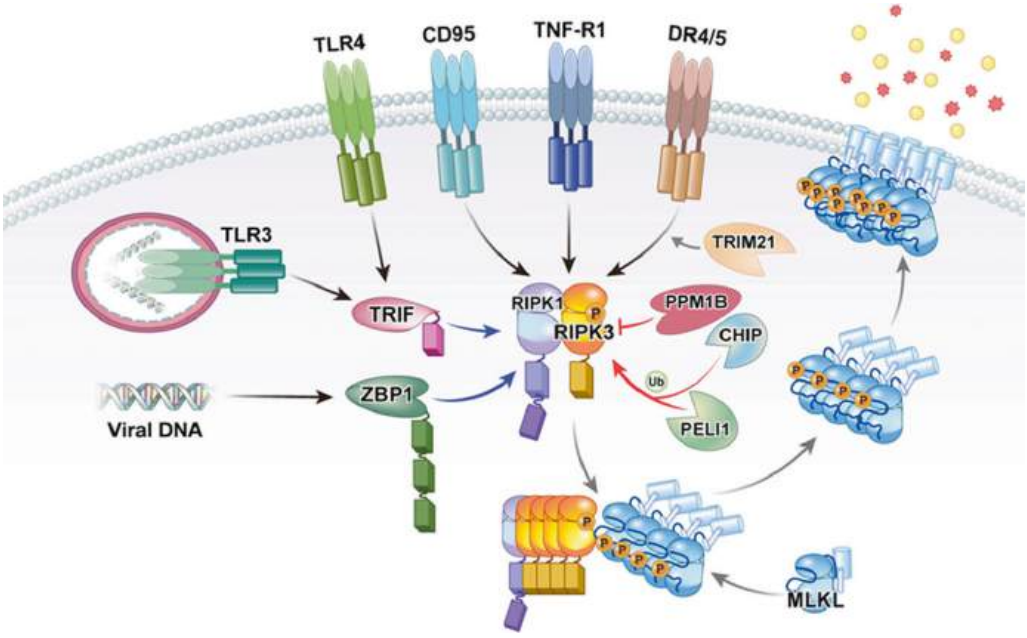

Figure 32.13.6: **Activation of RIPK3 by multiple stimuli.** Morgan MJ, Kim YS. Roles of RIPK3 in necroptosis, cell signaling, and disease. Exp Mol Med. 2022 Oct;54(10):1695-1704. doi: 10.1038/s12276-022-00868-z. Epub 2022 Oct 12. PMID: 36224345; PMCID: PMC9636380. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/

RIPK3 can be activated via various receptors when bound by their respective ligands. These are TNF receptor 1 (TNF-R1), CD95, death receptors (DR4/5), Toll-like receptors (TLR3/4), and Z-DNA-binding protein-1 (ZBP1)/DAI. In the first three of these pathways (but not TLR3/4 or ZBP1), RIPK1 is required and binds to RIPK3 through its receptor-interacting protein homotypic interaction motif (RHIM). In the case of ZBP1, RIPK3 is recruited directly via the ZBP1 RHIM domain, while in the case of TLR3/4, RIPK3 is recruited indirectly via the RHIM domain of TRIF. Once activated, RIPK3 autophosphorylates and then phosphorylates and activates MLKL to induce a conformational change and translocation to the membrane, where membrane permeabilization follows. During this process, post-translational modifications positively and negatively regulate the necroptosis pathway. Two E3 ligases, Pellino-1 (PELI1) and carboxy terminus of HSC70-interacting protein (CHIP), may control the basal threshold of necroptosis. Another E3 ubiquitin ligase, TRIM21, is proposed to be a regulator of necroptotic cell death in response to TRAIL. PPM1B suppresses necroptosis by dephosphorylating RIPK3.

The domain structure and phosphorylation sites on human RIPK3 are shown in Figure 32.13.7 below.

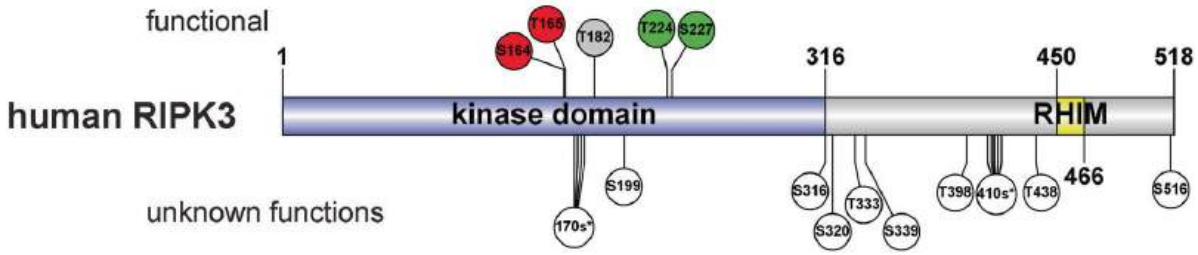

Figure 32.13.7: Meng, Y., Horne, C.R., Samson, A.L. *et al.* Human RIPK3 C-lobe phosphorylation is essential for necroptotic signaling. *Cell Death Dis* **13**, 565 (2022). https://doi.org/10.1038/s41419-022-05009-y. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/

"Schematic of human RIPK3 domain architecture and the phosphorylation sites identified. Phosphorylation sites with proposed functions are shown at the top. pT224 and pS227 positively regulate necroptosis (green) by recruiting MLKL. pS164 and pT165 negatively regulate necroptosis by inhibiting RIPK3 kinase activity (red) [38]. Phosphorylation of T182 (grey) was proposed to promote RIPK3 kinase activity and to recruit PELI1 to mediate proteasomal degradation of RIPK3 [54]. Phosphorylation sites with unknown functions are shown on the bottom (white). Asterisks (*) denotes multiple serine/threonine on the same peptide, as such the exact site of phosphorylation could not be unambiguously identified."

Figure x shows a complex, the **necrosome,** containing multiple activated RIPK3s along with RIPK1. Aggregation of RIPK3 occurs through the **RHIM** (RIP homotypic interaction motifs) domain through the formation of amyloid fibers. The necrosome then phosphorylates

MLKL, which forms oligomers and traffics to the membrane.

Figure x above also shows that an internal sensor protein for viral DNA can also activate RIPK3. That protein is **ZBP1**, or Z-DNA-Binding Protein 1, which also binds Z-RNA. Nuclear Z-RNA can derive from viruses like influenza A, leading to the activation of the same pathway. Cytokine expression then produces a systemic inflammatory response.

In addition to apoptosis and necroptosis, another type of programmed cell death caused by inflammation is called **pyroptosis**. Usually occurring in bacterial-infected macrophages, pyroptosis leads to the activation of intracellular inflammasomes, which then activate inflammatory cytokines through selective proteolysis by caspases. In pyroptosis, proteins called gasdermins are cleaved by caspases and their N-terminals self-associate in the cell membrane to form pores, from which the inflammatory cytokines IL-1β, and IL-18 are released.

A final programmed cell death pathway for virally-infected cells is called PANoptosis, which uses the PANoptosome complex with downstream results not explained by the other three programmed cell death pathways (pyroptosis, apoptosis, and necroptosis) ZBP-1 leads to the activation of RIPK3, caspase-8 (key in the apoptosis pathway) and the NLRP3 inflammasome.

ZBP-1 seems to play a key role in heat stroke. Its concentration increases with heat stress mediated by the heat shock transcription factor 1 (HSF1., which itself is induced by cellular stress. HSF1 induces a heat shock response which causes increased transcription of chaperones and heat shock proteins (HSPs) such as ZBP-1. Deletion/inactivation of ZBP-1, RIPK3, or MLKL and caspase 8 decreases heat stroke. The main role of ZBP-1 in cell death from heat stroke arises from the RIPK3/MLKL pathway and to less extent through cross-talk with the classical apoptosis pathway through caspase 8.

How does ZBP-1 activate cell death during heat stroke without binding to and activating dsDNA or RNA derived from a viral infection? Does ZBP-1 have an endogenous ligand other than viral Z-RNA or Z-DNA? Let's first explore the domain structures of some key proteins in the RIPK3 activation pathway. Figure 1 above shows three key proteins, RIPK1, TRIFF, and ZBP1 that interact with RIPK3. Each of these proteins and RIPK3 have a RHIM domain for protein-protein interactions. Figure 32.13.8 shows the domain structure of our key protein, ZBP-1, the cytosolic Z-DNA/Z-RNA sensor.

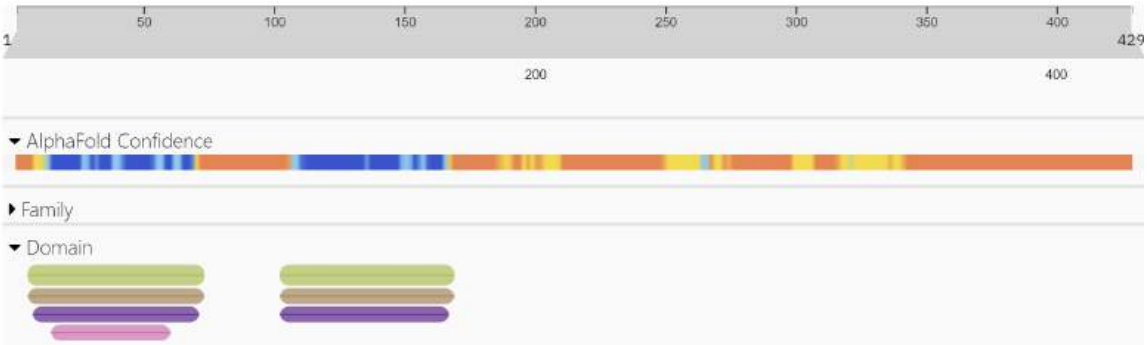

Figure 32.13.8: Domain structure of ZBP-1 (http://www.ebi.ac.uk/interpro/protein/UniProt/Q9H171/)

The green bars in the N-terminal part of the protein are the Z-DNA binding domain. These are also called Zα domains. These regions are the most ordered in the protein, as indicated by the blue in the AlphaFold confidence bar.

Figure 32.13.9 shows an interactive iCn3D models of the AlphaFold-predicted model of human Z-DNA-Binding Protein 1 (ZBP1), (Q9H171)

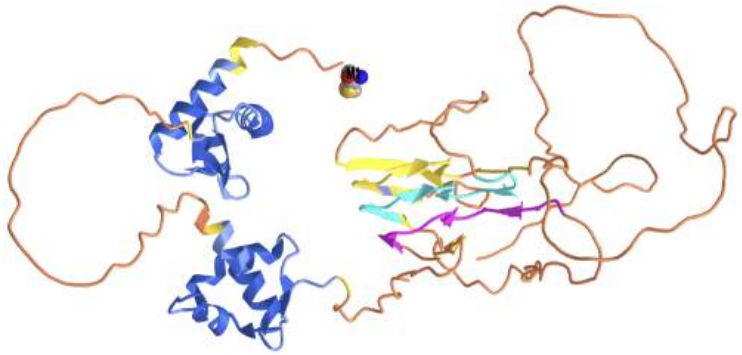

Figure 32.13.9: AlphaFold-predicted model of human Z-DNA-Binding Protein 1 (ZBP1), (Q9H171). (Copyright; author via source).
Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...FMCRhJwHFVb1X7

The spacefill atoms labeled M1 represent the N-terminal methionine of the protein. The two Z-DNA binding domains follow, are well-ordered, and are shown as blue cartoons. Much of the protein can't be predicted as it is most likely intrinsically disordered. Two fairly well-structured motifs, shown in magenta and cyan are the RHIM1 and RHIM2 protein interaction motifs, which can be shown self-

associated through their amyloid-like structures. These motifs allow ZBP1 to bind to other proteins with RHIM motifs and on to cell death through necrosis. The C-terminal domain appears to be involved in signal transduction type I interferon-mediated by DNA.

Figure 32.13.10 shows an interactive iCn3D model of the second Z-DNA binding domain of human DAI (ZBP1) in complex with Z-DNA (3EYI)

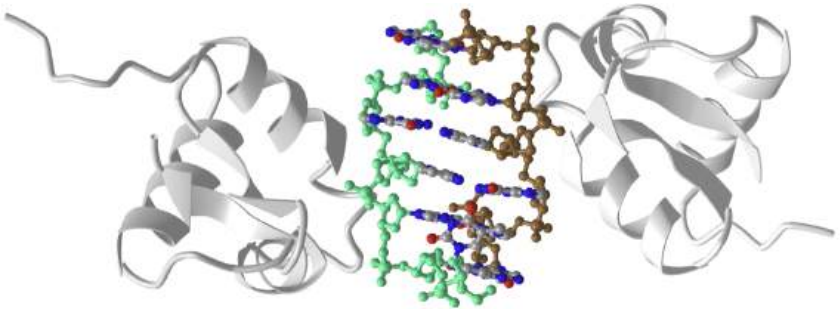

Figure 32.13.10: Second Z-DNA binding domain of human DAI (ZBP1) in complex with Z-DNA (3EYI). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...SLBmo2xqV1WpS6

In the absence of viral DNA or RNA, the Zα domain can bind endogenous ligands. Moreover, it appears that a deficiency in RIPK1 or of the RHIM in RIPK1 also triggers ZBP1 to induce necroptosis and inflammation. and that its Zα domain is required. If nuclear export was stopped, ZBP1 activates nuclear RIPK3 and then necroptosis. This suggests that nuclear ZBP1 interacts with endogenous nuclear Z-nucleic acids, probably Z-RNA from retroelements to activate RIPK3-dependent necroptosis and could lead to some forms of chronic inflammation.

Here are a series of finding on RIPK3-dependent cell death on heat stress in mouse fibroblasts that show that Z-nucleic acid binding to ZBP1 is not required for heat stress effects:

- Heat (43°C for 2 hr) induces phosphorylation of RIPK3 and MLKL within 2 hours, and cleavage of pro-caspases and GSDME in 6 hours but none occurred if RIPK3 was deleted.
- Deletion of ZBP1 but not RIPK1, TRIF, affect heat induce death so so heat stress acts through ZBP1 and RIPK3.
- In mice without ZBP1, the effects of heat stress (clotting, inflammation, organ injury, and death) were prevented.
- Mutations in the RHIM domain, but **not** the Zα domains (made to prevent Z-nucleic acid binding) or in the C-terminal signaling region (to stop signaling) prevented death from heat stress . Hence Z-nucleic acid binding is **not** required but may contribute to cell death from heat stress.
- Heat stress caused the aggregation of a ZBP1-GFP (green fluorescent protein) fusion protein through the RHIM domains of ZBP-1

Hence ZBP1 is an innate pathogen sensor and also an initiator of heat-related death in the absence of pathogens.

32.13.5: HEAT STROKE-INDUCED EPIGENETIC CHANGES

Short of death, heat stroke can also cause long-term health issues. Increasing global temperatures are forcing people to work at more dangerous temperatures and at night to reduce heat exposure. Data suggests that people who have had a heat-related illness are more susceptible to additional heat exposure health consequences. This has been noted in exertional heat illnesses. (such as in athletes). Additional long-term effects on immune regulation have been observed. Epigenetics may play a role in long-term effects such as greater vulnerability to additional heat challenges. Studies show that a single episode of exceptional heat stroke changes DNA methylation patterns in bone marrow-derived monocytes from mice. The monocytes become immunosuppressed allowing for increased microbial disease and reduced heat shock responses. The epigenetic changes are passed onto progeny monocytes which also shows compromised function. The epigenetic changes persist for 30 days or more and we clearly noted in inflammatory cell signaling pathways. This suggests a mechanism for the reduced tolerance to those with previous heat-related illnesses.

32.13.6: CARDIOVASCULAR AND PULMONARY DISEASES

Many factors can cause cancer and lead to mortality. For example, mortalities from cancer can increase due to lower availability of health care arising from extreme weather disasters that impact health facilities and access to them. Early detection of many cancers is key to survival. Instead of discussing climate change links to cancer we will focus on pollution and in particular small particles.

32.13.6.1: PM2.5 PARTICULATE POLLUTION EFFECTS ON CARDIOVASCULAR AND PULMONARY HEALTH

Pollution from the combustion of fossil fuels contributes to many chronic diseases. Here we will focus on one type of pollutant, particulate matter which can be inhaled. These particles can be liquids, solids, or combinations of both. They are classified according to size with common categories including:

- PM10: diameters $\leq$ 10 uM = 10,000 nm;

- PM2.5: fine particles with diameters $\leq$ 2.5 um = 2500 nm
- PM0.1: ultra-fine particles with diameters $\leq$ 0.1 um = 100 nm (also called nanoscopic particulate matter or NPM)

Figure 32.13.11 below shows the relative sizes of PM10 and PM2.5 particles compared to other biological structures.

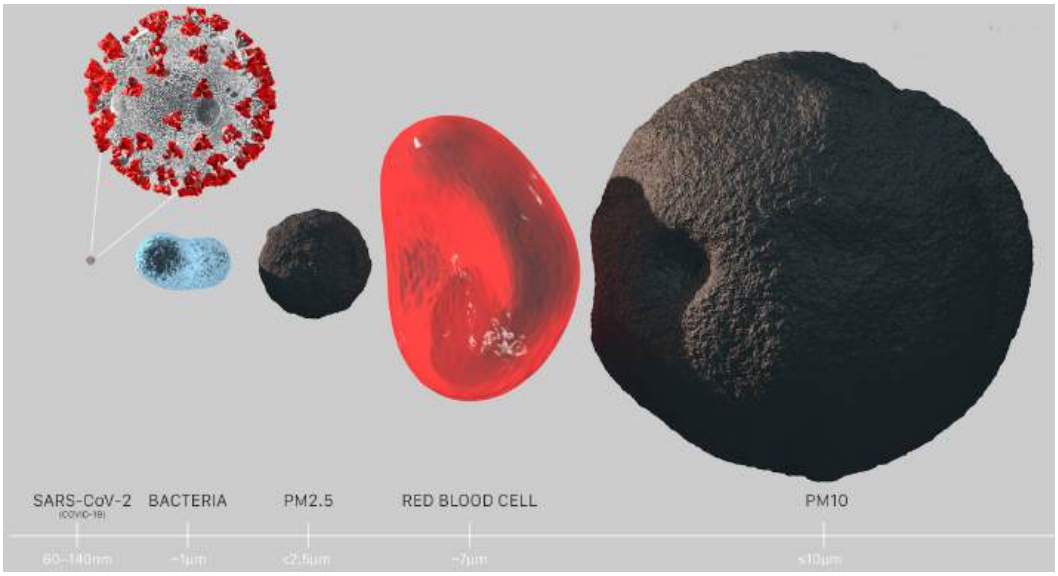

Figure 32.13.11 : Relative sizes of PM particles compared to biological structures. Sotirios Papathanasiou. Particulate Matter (PM2.5) Mega Guide. With Permission. https://seetheair.org/2022/05/16/par...-5-mega-guide/

Figure 32.13.12 below shows the relative sizes of PM0.1 particles compared to a PM2.5 particle.

Figure 32.13.12 : Relative sizes of PM01 particles compared to a PM2.5 particle.Sotirios Papathanasiou, ibid.

32.13.7: COMPOSITION OF PM2.5 PARTICLES

PM2.5 particles obtained by collection from polluted city air can actually be purchased from the National Institute of Standards and Technology (NIST, SRM1648a) and used for experimental studies on living cells. It is typically added to water and a suspension produced through sonication. PM2.5 particles are derived from human sources such as emissions from vehicles and industry, and both human-caused and natural processes such as the burning of biomass, and the release of dust from land. They can also include salts from land and ocean sources.

They arise from the burning of fossil fuels and wear and tear of products such as automobiles (including tires). PM2.5 particles contain mainly black carbon, polycyclic aromatic hydrocarbons (PAH), aryl hydrocarbon, volatile organic compounds (VOCs) as well as minerals,

ions (sulfate, nitrate, ammonium), and general biological materials. The metal composition includes Group 1A (K, Na, Fr), Group 2A (Ca, Mg), Group 3A (Al), transition metals (Al, As, Cr, Fr, Mn, Pb, Ti, Zn), and counter ions Br and Cl. They also contain silicon and silicates. Of course, particles in the air, including dust, also derive from non-anthroprogenic sources. Atmospheric dust is also produced from land by winds and also by volcanic eruptions. In homes, dust has an abundance of dead skin cells. along with pollens, hair, fur, and fibers from clothes and paper. Humans have evolved with particulates in the air, but large increases in their abundance caused by human activities in many parts of the world pose serious health consequences.

In addition, the reaction of pollutants in the atmosphere produces "secondary" pollutants. One, the tropospheric gas ozone (O_3) produced from hydrocarbons and nitrogen oxides, is a known health risk, and its levels are increased in cities on sunny, hot, and humid days. Secondary organic carbon (SOC) is also generated from primary organic carbon, typically volatile organic compounds (VOC) through oxidative photochemical reactions. These VOCs (like m-xylene and 1,2,4-trimethylbenzene) can produce aerosols (larger particles, called secondary organic aerosols by reacting with each other to produce larger structures. Terpenes containing isoprene units like α-pinene and limonene (a monoterpene found in large abundance in fruit peels) are reactants for the products of much larger structures. (See Chapter 10.1 and Chapter 21.6 for a review of isoprene and terpenes). Figure 32.13.13 below shows generalized pathways for the formation of particulate SOCs from smaller terpenes.

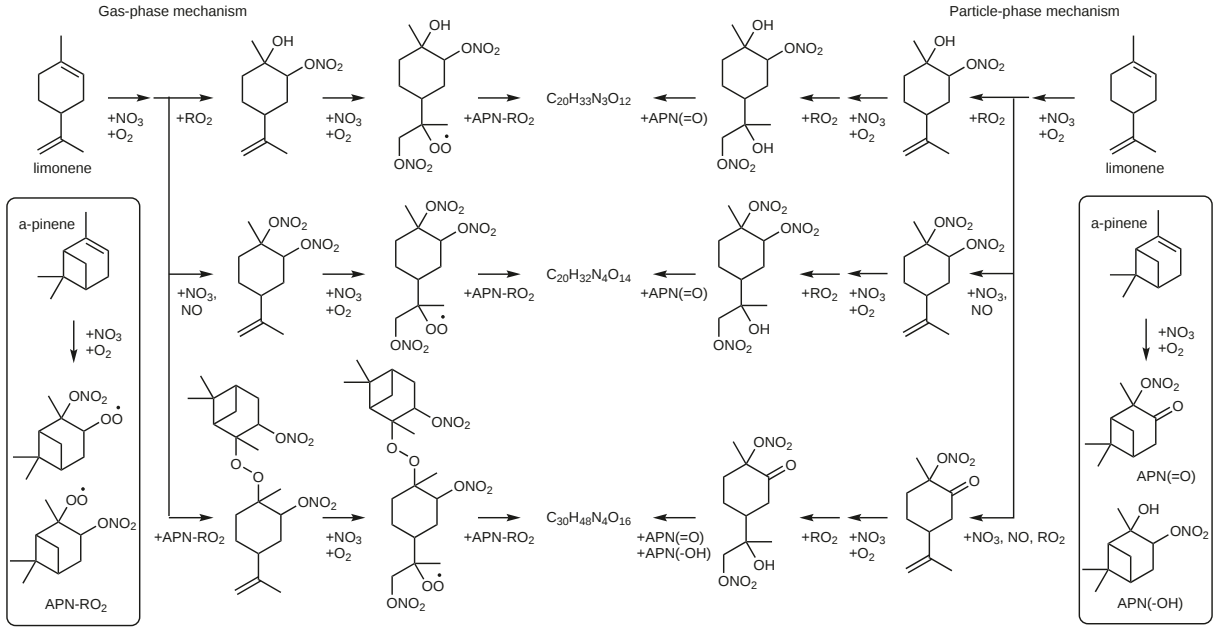

Figure 32.13.13 : **Proposed mechanisms for the formation of $C_{20}H_{33}N_3O_{12}$, $C_{20}H_{32}N_4O_{14}$, and $C_{30}H_{48}N_4O_{16}$ in the simultaneous oxidation (MIX) experiment.** Takeuchi, M., Berkemeier, T., Eris, G. *et al.* Non-linear effects of secondary organic aerosol formation and properties in multi-precursor systems. *Nat Commun* **13**, 7883 (2022). https://doi.org/10.1038/s41467-022-35546-1. Gas-phase mechanism via cross-reactions of α-pinene and limonene peroxy radicals (RO_2·), and particle-phase mechanism via hemiacetal formation involving α-pinene and limonene oxidation products. APN-RO_2, APN(=O), and APN(-OH) represent α-pinene oxidation intermediate (i.e., RO_2·), α-pinene oxidation products with carbonyls, and α-pinene oxidation products with hydroxyl functional groups, respectively.

Figure 32.13.14 below shows the morphology of PM2.5 particles.

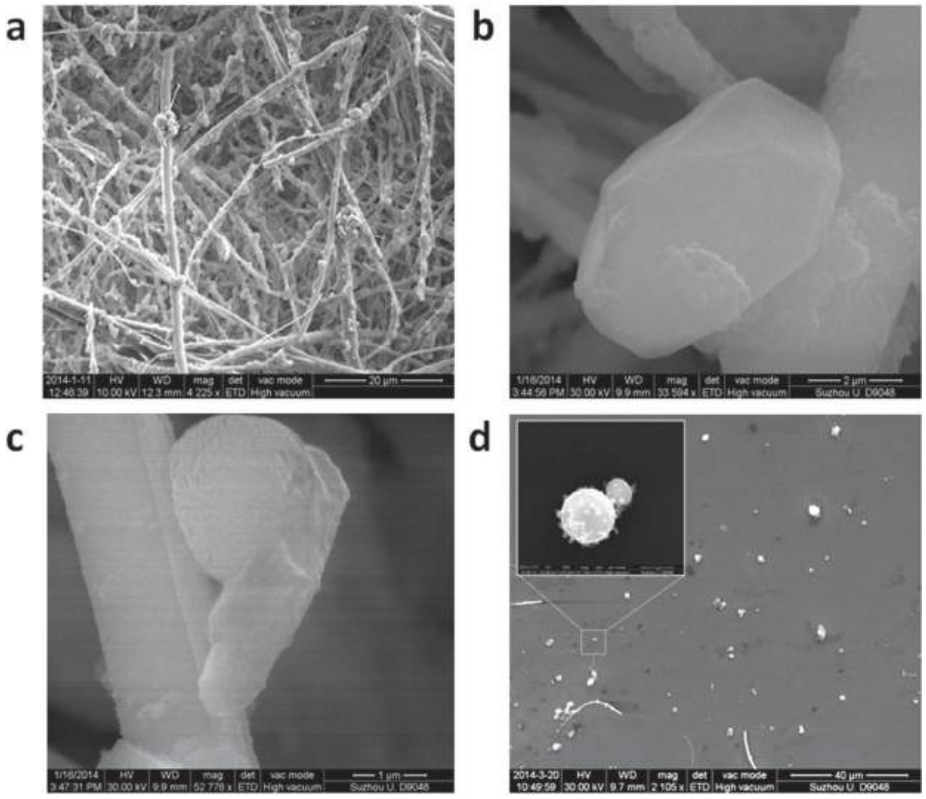

Figure 32.13.14 : Morphology of PM2.5 particles. The scale bars are 20 µm for image (a) 2 µm for image (b) 1 µm for image (c) 40 µm for image (d). Shi, Y., Ji, Y., Sun, H. *et al.* Nanoscale characterization of $PM_{2.5}$ airborne pollutants reveals high adhesiveness and aggregation capability of soot particles. *Sci Rep* **5**, 11232 (2015). https://doi.org/10.1038/srep11232. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/.

Panel (a) shows a large area image of as-collected PM2.5 on the filamentary filter.

Panel (b) and (c) show SEM images of a particle with flat and rough top surface, respectively.

Panel (d) shows a SEM image of the PM2.5 transferred on a Silicon substrate. Inset, zoom-in SEM image of an Iron-rich particle.

Many of the PM2.5 particles have rough surfaces which can deform more easily interact with (i.e. stick to) other particles through noncovalent interactions to produce even larger particles.

Figure 32.13.15 below shows the elemental composition of rough, semi-rough, and flat PM2.5 particles.

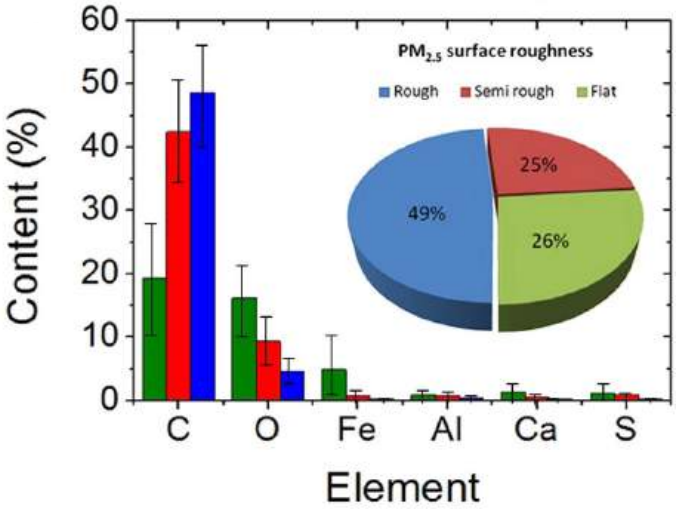

Figure 32.13.15 : EDAX Chemical composition histogram of the particles collected with SEM/EDAX classified by surface roughness; a larger surface roughness (and therefore, stickiness and deformation) are linked to a larger content of Carbon, while particles with a flat

surface (low stickiness and viscosity) are richer in Oxygen and metals. Shi, Y. et al., ibid.

Figure 32.13.16 below shows electron micrographs of actual airborne particles. Most are PM2.5 particles with diameters $\leq$ 2.5 uM = 2500 nm.

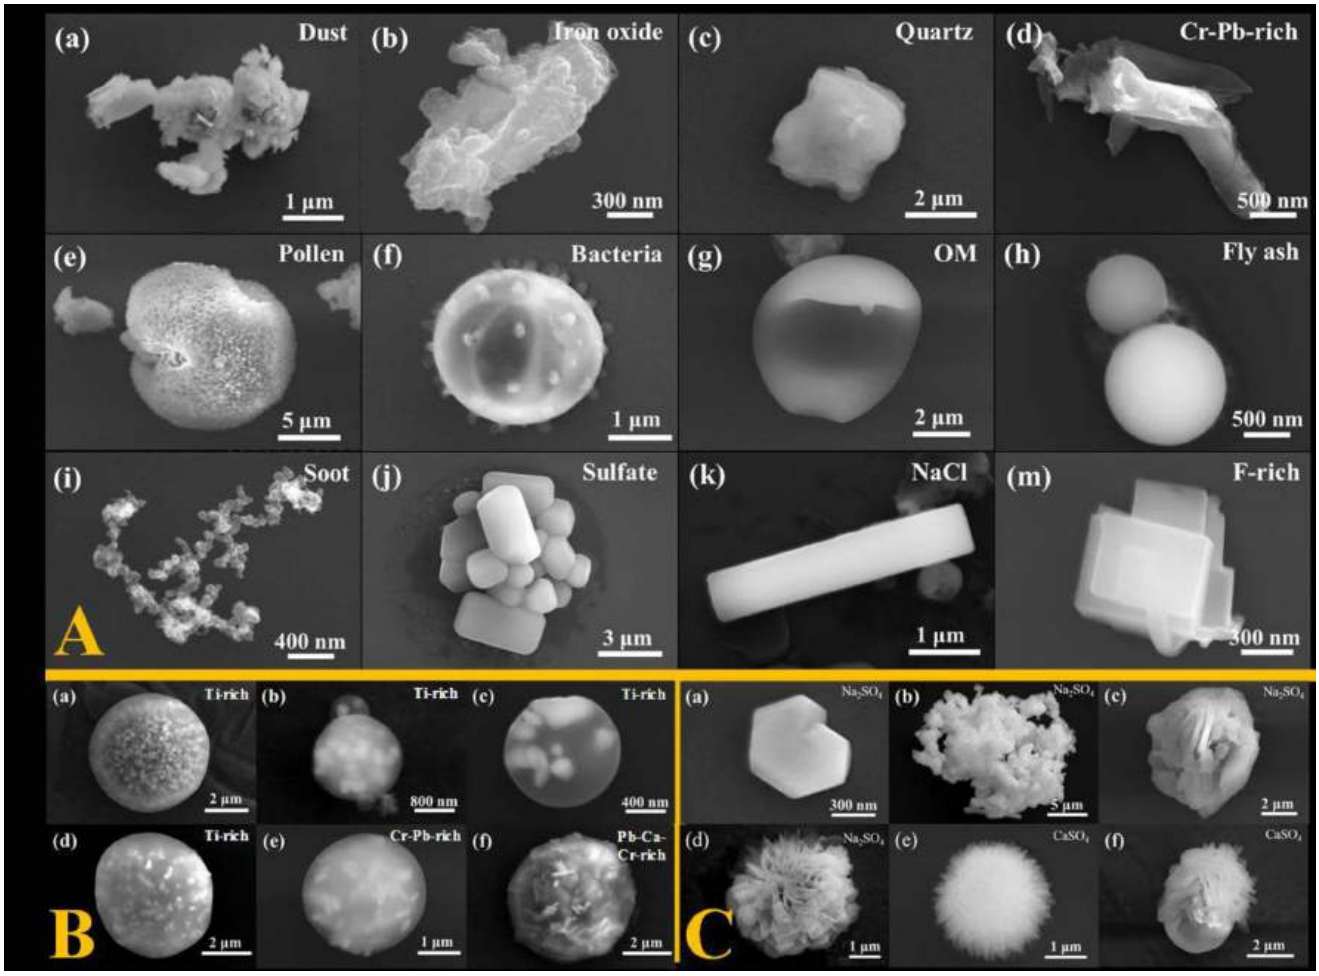

Figure 32.13.16 : A collage of SEM images for airborne particulates. (A) General classification of airborne particulates; (B) particulates with seeds-coating composite morphology; (C) sulfate particulates with different morphologies. Clara Yuan Li et al, Journal of Environmental Protection, Vol.7 No.10, 2016. https://www.scirp.org/journal/paperi...?paperid=71021. Creative Commons Attribution 4.0 International License.

Given their composition and their structures, it doesn't take much thought to realize that the particles must cause significant health effects. Would you want to breath in these particles routinely?

32.13.8: HEALTH EFFECTS OF PM2.5 PARTICLES

PM2.5 particles are associated with just about every type of illness, including cardiovascular and pulmonary diseases, including asthma, as well as cancer. Since they are small, they can easily be inhaled and deposited in lung alveoli from where they can actually enter the bloodstream and be deposited in tissue. Particles up to 240 nm (0.25 uM) can cross the placenta and black carbon particles have been found to cross the placenta. PM2.5 particles can cause inflammation, DNA damage, organelle dysfunction and can also generate free radicals which are most likely involved in these toxic health effects.

THE GREAT LONDON FOG OF 1952

Aerosol particles can even have acute and lethal effects. During The Great London Smog in London in December 1952, around 12,000 people died in two weeks from its effects. Figure 32.13.1 people in the thick smog from that event. The smog consisted of acidified water droplets arising from SO_2 and NO_2 released on burning coal that contains sulfur. This gas can be oxidized to sulfate in

gas-phase reactions probably through the ·OH free radical or in aqueous phase reactions using O_3, peroxides, and NO_2 as reactants/catalysts.

The reaction of SO_2 with NO_2 in aqueous droplets is shown below:

$$SO_2(g) + 2NO_2(g) + 2H_2O(aq) \rightarrow 2H^+(aq) + SO_4^{2-}(aq) + 2HONO(g) \quad (32.13.1)$$

Given the stoichiometry of the reaction with NO_2, the reaction proceeds significantly only in the presence of high NO_2. The reaction is favored under high relative humidity. In large water drops in clouds, the droplets are not very acidic but as water evaporates from the drops, the sulfate concentration and acidity dramatically increase. However, as the acidity increases the rate of oxidation and the solubility decreases.

Major cities in China, including Beijing and Xian, have experienced high levels of haze and particulate matter in the atmosphere until recently. Yet these smogs were not lethal (very acidic) as in London due to the addition of NH_3 in the droplets, which neutralizes the acidic particles. Atmospheric ammonia is derived from large amounts of agricultural fertilizers that get aerosolized and also from vehicles, which produce NH_3 in catalytic converters and from urea used in the catalytic reduction in diesel engines. The relevant production of sulfates in the presence of NH_3 is shown in the equation below.

$$2NH_3(g) + SO_2(g) + 2NO_2(g) + 2H_2O(aq) \rightarrow 2NH_4^+(aq) + SO_4^{2-}(aq) + 2HONO(g) \quad (32.13.2)$$

Figure 32.13.17 below shows a ghostly image of pedestrians in London during the Great Fog.

Figure 32.13.17 : Ghost-like pedestrians making their way through the smog. https://heritagecalling.com/2022/12/...f-london-1952/. Public Domain

The prevailing weather conditions (cold temperatures) increased emissions from coal use. A stalled high pressure system and resulting low winds caused the buildup of stagnant air with increasingly acidic PMs. The appalling death toll led politicians to pass the Clean Air Act in 1954 which over many years led to huge improvements in air quality in London and dramatically reduced negative health effects and deaths. This was a prelude to the Clean Air Act in the US which dramatically improved air quality as well.

High levels of PM2.5s still are prevalent in much of the world, although there have been dramatic decreases in the US. The notable exceptions occur during forest fires that are exacerbated by climate change. In the US, the Air Quaility Index (AQI) is used as an indicator of health risk. It measures the value of 5 pollutants, fine particles (PM2.5 and PM10), ground-level ozone, SO_2, NO_2 and CO. The value of AQI at a given time is determined by which pollutant is highest. In haze produced by smoke, the reported AQI represents PM2.5 particles. AQI values < 50 or below represent good air quality, while an AQI value over 300 represents hazardous air quality. Western forest fires in Oregon in September 2020 lead to an AQI of 611 in Madras, Oregon. Forest fires in Eastern Canada, along with slow-moving weather system, led to PM2.5 levels over 800 (mg/m^3) in New York City on June 7, 2023. No place is immune from PM2.5 particles from wild fires and human-caused pollution.

- AirNow - gives present pollution data, primarily PM2.5 levels, based on US zip codes

The following interactive graphs show the changes in PM2.5 particles over time (from Hannah Ritchie and Max Roser (2019), OurWorldInData.org/outdoor-air-pollution • CC BY. Source: Brauer et al. (2017) via World Bank).

Finally, Figure 32.13.20 below shows the death rate from PM2.5/100,000 people in 2017 in countries around the world.

Figure 32.13.20 : Death rate from PM2.5/100,000 people in 2017 in countries around the world.

32.13.9: MECHANISMS FOR PM2.5 HEALTH EFFECTS

In Chapter 5.4, we discussed how solids such as silica, cholesterol crystals, uric acid crystals, and even aggregated proteins such as prions can be engulfed by monocytes/macrophages (much as they engulf bacteria as part of their immune function) in a process called phagocytosis. The particles are enveloped in plasma bilayer-derived membrane which buds off into the cell. This vesicle merges with a lysosome which gets damaged in the process. They then release ATP into the cytoplasm which acts as a damage signal to activate inflammation.

PM2.5 particles can also be taken up by phagocytosis to produce intracelluar phagosomes. They can also be taken up by pinocytosis, and caveolin and clathrin-mediated endocytosis to form endosomes. These can fuse with lysosomes and mitochondria and induce damage. The heavy metals from PM2.5 particles that are released into the cell also contribute to damage.

Smaller PM2.5 particles of diameter less than 0.1 uM (100 nM), sometimes called **nanoscale particulate matter (NPM)**, offer large surface areas to which proteins can adhere. The adsorbed proteins form a "crown" called a protein **corona**. The corona is actually larger than the NPM. Proteins bounds to the particles include hemoglobin, albumin and fibrinogen. The corona also mediates cellular interactions and participates in the mechanisms that lead to inflammation and cellular dysfunction. As the extracellular matrix includes protein components such as collagen and fibrin, the interaction of PM2.5 with fibrin, has been studied as a model for how the particles might interact with cells. In particular, lung fibroblasts embedded in a 3D matrix of fibrin (i.e. a 3D organotypic culture) were exposed to

NPM with protein coronas, and the effects of the NPM particles on cell proliferation, oxidative stress, etc. were monitored. Figure \(\PageIndex{21}\) below characterizes the interaction of the NPMs with the fibroblast in the 3D culture.

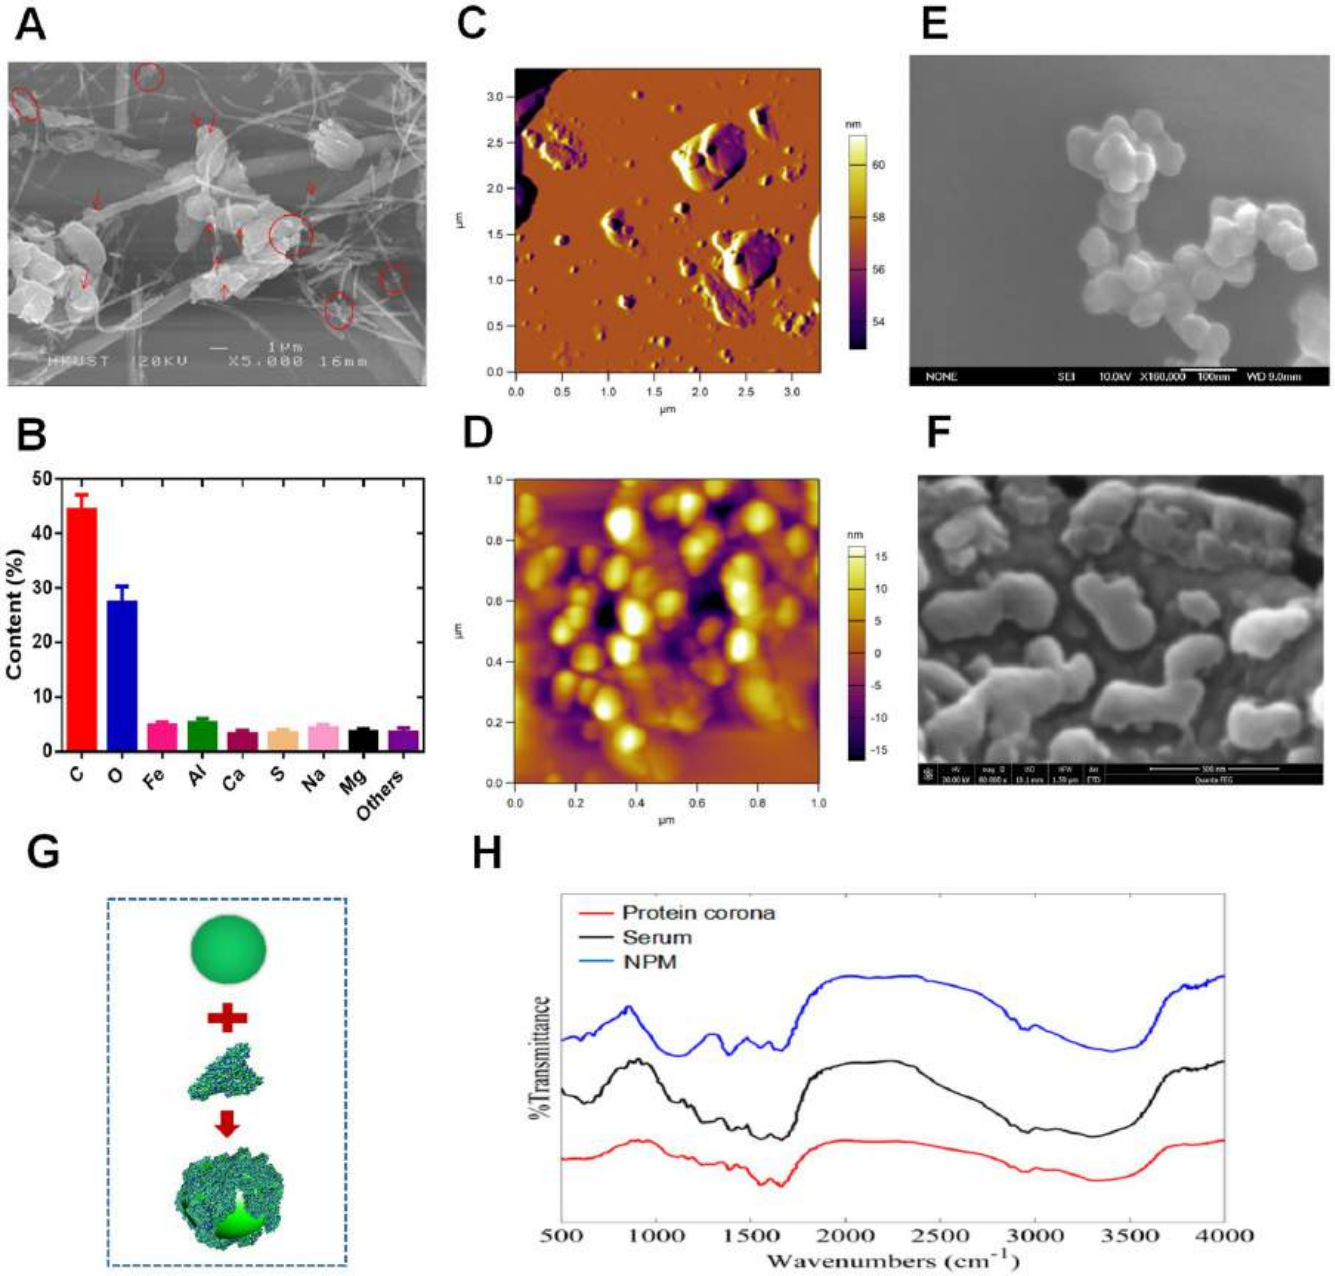

Figure 32.13.21 : Physicochemical characterization of airborne particulate matter. Li, Y., Wang, P., Hu, C. *et al*. Protein corona of airborne nanoscale PM2.5 induces aberrant proliferation of human lung fibroblasts based on a 3D organotypic culture. *Sci Rep* **8**, 1939 (2018). https://doi.org/10.1038/s41598-018-20445-7. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/.

Panel (**A**) shows SEM images of airborne PM2.5 (nanoscale PM2.5 is marked in red).

Panel (**B**) shows a chemical element analysis of PM2.5 by EDX analysis.

Panel (**C**) shows an atomic force microscopy (AFM) image of nanoscale PM2.5 (NPM) from air pollutant samples (scale 3.5 μm).

Panel (**D**) AFM image of airborne NPM from air pollutant samples (scale 1 μm).

Panel (**E**) shows an SEM image of airborne NPM from air pollutant samples.

Panel (**F**) shows an SEM image of an NPM-protein corona.

Panel (**G**) shows a schematic diagram of the biological interaction between NPM and protein.

Panel (**H**) shows a FTIR spectra of NPM, serum, and NPM-protein corona.

The NPM-protein corona particle leads to the proliferation of the 3D-cultured human lung fibroblast cells over and above stimulation of the cells with just NPMs or serum alone. The bigger the size of the corona, the greater the proliferative effect. This is consistent with the extensive fibrosis of the lungs seen after chronic exposure to PM2.5 particles. Reactive oxygen species also increased in the presence of NPM-corona particles. These data suggest that NPM-protein corona are important in PM2.5-induced lung fibrosis and pulmonary disease.

32.13.10: NEURAL EFFECTS OF PMS

PM particles, particularly the ultrafine PM0.1 particles (UFP), can enter the brain, and affect neural function. Exposure to PM2.5 over long periods of time is associated with increased incidence of dementia and Alzheimer's Disease (AD). Four particular components of PMs (SO_4^{2-}, NH_4^+, black carbon, and organic matter) were most associated with a higher risk of dementia and AD. In the US, the first admission to a hospital for Parkinson, AD, and other dementia is "significantly" associated with the average annual mean PM2.5 exposure.

Even low levels of exposure pose risks. Transgenic mice containing mutant forms of human presenilin 1, amyloid precursor protein, and the tau protein, were exposed to subchronic, "real-world" levels of PM2.5 through inhalation for 3 months. Neuronal loss was observed in the cortex but no motor or cognitive impairment was noted. Increased levels of phosphorylated forms of Tau were observed and free radical formation, as evidenced by levels of malondialdehyde (a marker of oxidative stress), was seen in the hippocampus and olfactory centers, consistent with inhalation of PM2.5 through the noise. No abnormal amyloid plaques were observed in this short exposure time.

PMs damage to neurons occur through the generation of reactive oxygen species increased inflammatory responses and organelle damage (all of which are interrelated). Even in skin cells (keratinocytes), exposure to PM2.5 particles led to increased levels of ROS and malondialdehyde, decreased levels of superoxide dismutase, and increased DNA damage. Inflammatory Caspase levels also increased.

Cells have mechanisms to detect and eliminate aberrant species before they led to worse biological effects. One process is **autophagy** which degrades misfolded protein and damaged organelles, processes important for normal neural function. Aberrant autophagy is a key player in the pathogenesis of dementia. A second pathway is **ferroptosis**, a kind of apoptotic pathway, which kills cells that have accumulated large amounts of iron ions, which of course are free radicals themselves. Through the Fenton reaction and others, iron ions can lead to the generation of damaging reactive oxygen species and oxidation of lipids, proteins, and nucleic acids (see Chapter 12.3).

Several key proteins are involved in antioxidant defense and autophagy:

- NRF2 (Nuclear factor erythroid 2-related factor 2): This transcription factor binds to antioxidant response elements (ARE) in front of protective genes.
- Keap1 (Kelch-like ECH-associated protein 1): An adapter program that targets NRF2 for ubiquitination and as such is a sensor for oxidative stress. Under those conditions, electrophilic metabolites lead to post-translational modification of reactive Cys side chains which leads to the inactivation of ubiquitin ligase activity. This increases NRF2 and subsequent transcription of antioxidant genes.
- SQSTM1 aka p62 (Sequestosome-1): This protein bridges autophagosomes and polyubiquitinated proteins (cargo for degradation).

Hence under low oxidative stress, NRF2 are low through its degradation mediated by KEAP1. If SQSTM1 (p62), increases, and reduced autophagy, p62 biding to the NRF2 sites on KEAP1, leading to the release of NRF2, its transfer to the nucleus, and activation of gene transcription of protective genes. These three proteins also protect cells from ferroptosis. In the long term, neural cell death occurs during dementia. Hence apoptosis, necroptosis, and pyroptosis (from activation of the inflammatory response mediators capspase, Gasdermin, and key cytokines like IL-1β and IL-18) do "win out" to eventually kill cells.

Figure 32.13.22 below shows the domain structure of SQSTM1 (panel A) and the signaling process described above.

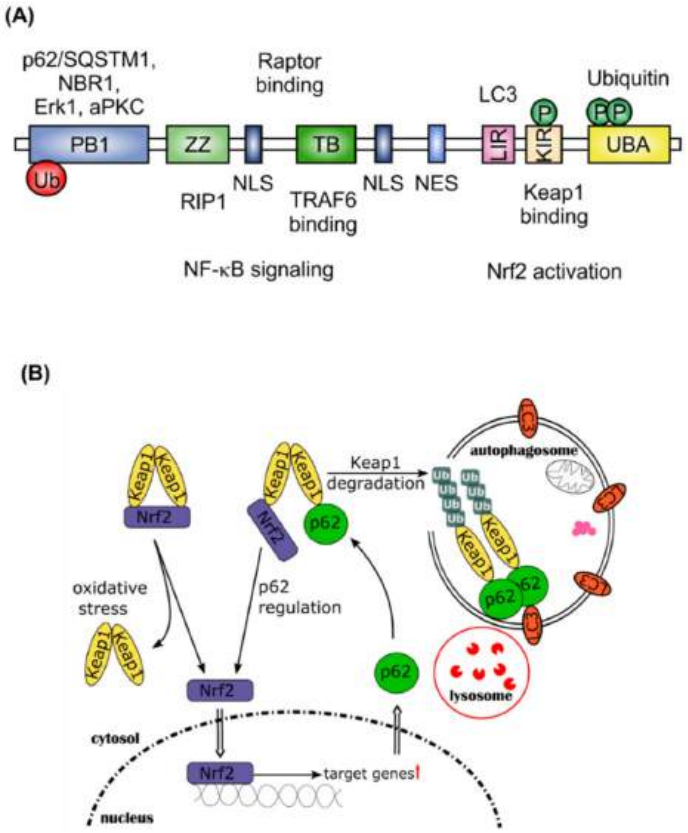

Figure 32.13.22: Positive feedback-loop of Nrf2 activation by *p62/SQSTM1*. Vomund S, Schäfer A, Parnham MJ, Brüne B, von Knethen A. Nrf2, the Master Regulator of Anti-Oxidative Responses. Int J Mol Sci. 2017 Dec 20;18(12):2772. doi: 10.3390/ijms18122772. PMID: 29261130; PMCID: PMC5751370. Creative Commons Attribution (CC BY) license (http://creativecommons.org/licenses/by/4.0/).

Panel (**A**) shows the domain structure of p62/SQSTM1;

Panel (**B**) shows p62/SQSTM1 as an important protein for selective autophagy, as binds to Keap1 and other long-lived proteins and forms polyubiquitinated protein aggregates. Furthermore, it binds to the autophagy marker LC3 within the autophagosome, thereby leading the aggregated proteins into the autophagosome. After fusion with a lysosome, proteins and organelles, such as mitochondria, are degraded within the autophagosome. By binding to Keap1, p62/SQSTM1 stabilizes Nrf2 and enhances its translocation into the nucleus, where Nrf2 activates its target genes (↑ = upregulation of Nrf2 target genes). One of these genes is *p62/SQSTM1*

PM2.5 particles intefer with the protective autophagy and ferroptosis pathways, leading to increased NRF2 activity and expression of antioxidant genes which are beneficial processes to rid cells of aberrant particles and kill damaged cells in normal conditions but not on exposure of neuronal cells to PM2.5 particles.

Lysosomal membrane permeabilization (LMP) as well as mitochondrial and ER damage might be a likely mechanism to initiate ultimate neuronal death on long-term exposure to PM2.5 particles. PM2.5 particles inhibit lysosomal activity and increase their permeability and release to degradative enzymes into the cytoplasm. Ultimately increased or decreased activation of Nrf2 lead to disease states.

32.13.11: PMS AND CANCER

Long-term exposure can also cause lung cancers. This is associated with a conversion of lung cells from normal epithelial to mesenchymal cells (called the EMT transition). Phenotypically, mesenchymal cells can migrate, invade other tissues and cause enhanced production of the extracellular matrix, all hallmarks of tumor cells. This EMT transition is associated with significant changes in cell signaling and the production of transcription factors. These changes are documented in Figure 32.13.23 below and its caption.

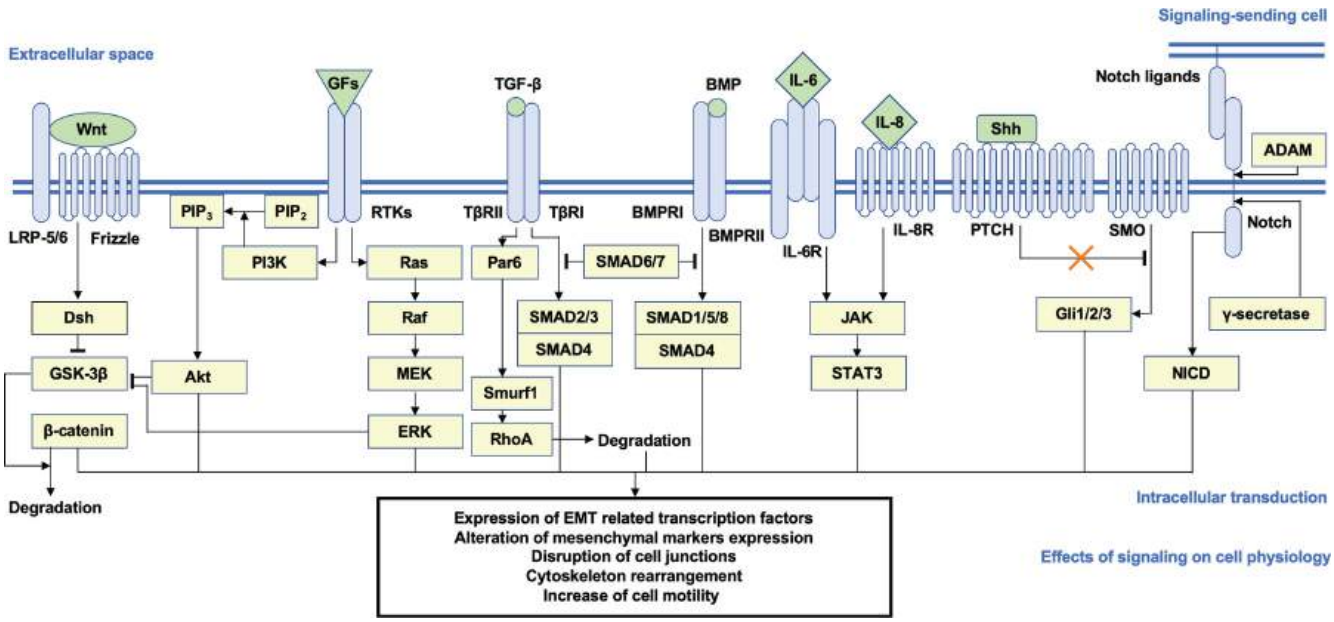

Figure 32.13.23 : Brief schema of the putative signaling transduction mechanisms underlying EMT. Xu et al., **Front. Physiol., 29 November 2019. Sec. Renal Physiology and Pathophysiology.** Volume 10 - 2019 | https://doi.org/10.3389/fphys.2019.01404. **Creative Commons Attribution License (CC BY)**

Activation of the Wnt/β-catenin, PI3K/Akt, Ras/ERK, TGF-β/SMAD2/3, BMP/SMAD1/5/8, JAK/STAT3, Shh, and Notch pathways is highly correlated with EMT. After ligand-receptor binding, intracellular secondary messengers are activated and initiated downstream transduction, which generally induce the nuclear translocation of signaling-specific TFs and the transcriptional regulation of EMT-related genes, such as CDH1 and CDH2, EMT TFs, and mesenchymal markers, accompanied by a series of alterations on cellular physiological or pathological activities (e.g., dysjunction of adherin junctions, cytoskeleton remodeling, and increase of cellular motility). Arrows represent the molecular interactions in which downstream messengers are activated; T shape arrows represent inhibitive molecular interactions. EMT, epithelial-mesenchymal transition; PI3K, phosphoinositide 3-kinase; ERK, extracellular signal-regulated protein kinase; TGF-β, transforming growth factor β; JAK, Janus kinase; Shh, sonic hedgehog; TFs, transcription factors.

PM2.5 particles and their deleterious contents (heavy metal ions, PAHs, etc), as well as ROS generated by them are associated with the changes seen in the EMT transition. These include activation of transforming growth factor β (TGF-β)/SMADs, NF-κB, growth factor (GF)/extracellular signal-regulated protein kinase (ERK), GF/phosphatidylinositol 3-kinase (PI3K)/Akt, wingless/integrated (Wnt)/β-catenin, Notch, Hedgehog, high mobility group box B1 (HMGB1)-receptor for advanced glycation end-products (RAGE), and aryl hydrocarbon receptor (AHR) signaling cascades and to cytoskeleton rearrangement.

32.14: CLIMATE CHANGE, INFECTIOUS DISEASE AND PANDEMICS

Written by Henry Jakubowski

32.14.1: INTRODUCTION

Microorganisms can cause both chronic and acute diseases, both of which if left untreated can lead to death. Infections with the Human Papillomavirus (HPV) can cause cancer of the cervix, vagina, vulva, penis, anus, and throat. Modern vaccines against HPV can prevent over 90% of these cancers. The bacteria H. pylori can, in some people, cause stomach illness (such as severe chronic gastritis and ulcer) which can lead to stomach cancer. The Coxsackie virus, through binding to receptors on cardiac myocytes, can cause heart disease (acute myocarditis and cardiomyopathy), and ultimately death.

Acute microbial diseases that occur immediately after infection can cause epidemics and pandemics (worldwide epidemics). Everyone has experienced the COVID-19 pandemic caused by the SARS-CoV-2 coronavirus. Johns Hopkins estimates as of 3/10/23 (end of their data collection), that there were about 677 million reported cases of Covid-19 and about 6.9 million deaths. The WHO estimates that just for the first two years of the pandemic (2020 and 2021), there were 14.83 million excess deaths globally, 2.74 times more than the number or reported death (5.42 million) from the virus. Machine learning models suggest that there have been closer to 20 million excess death through the end of March 2023, as shown in Figure 32.14.1 below.

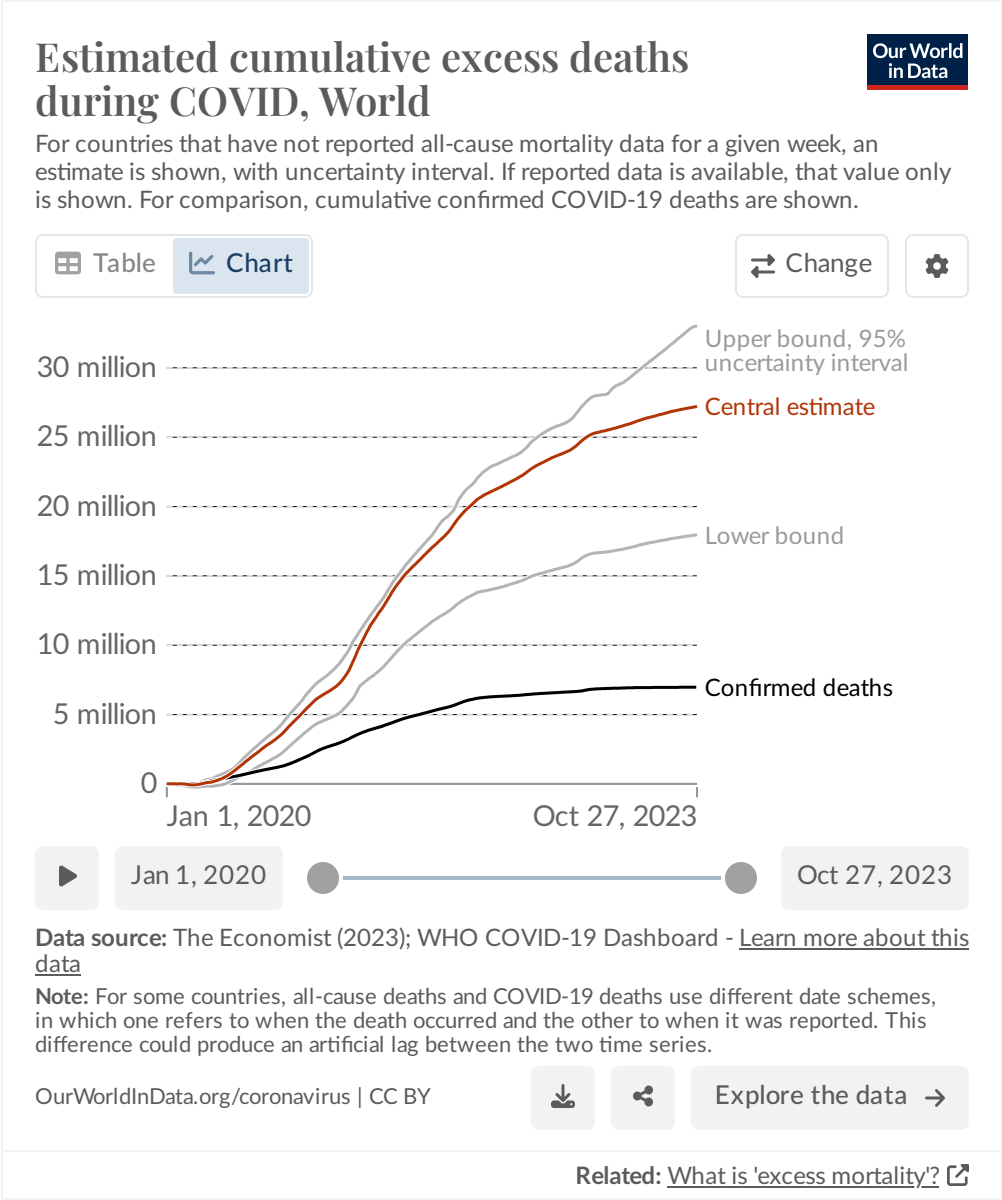

Figure 32.14.1: https://ourworldindata.org/excess-mortality-covid

The data from Johns Hopkins suggest that the average mortality rate was about 1% (deaths/infections). If there have been 20 million cases (based on excess deaths) out of a world population of 8 billion, the mortality rate was close to about 0.25% for the entire world.

Another indicator of the severity of pandemics is a decrease in life expectancy. Figure 32.14.2 below offers an interactive graph that shows the general rise in life expectancies since 1750 punctuated by steep drops.

Figure 32.14.2: Life expectancies since 1750

Note the small drop in 2020 in the United State was caused by the Covid-19 pandemic with some contribution from opioid-associated deaths. The graph is dominated by a stunning decline in 1918 due to the 1918 Flu Pandemic (also historically and inaccurately named the Spanish flu). The large drop in life expectancy in Sweden in 1772-1773 was probably attributed to the Russian plague epidemic of 1770–1772, also known as the Plague of 1771. Figure 32.14.3 below shows a history of pandemics back to the Antonine Plague of 165-180 CE. In viewing the figure, remember that the numbers of deaths are estimates at best, especially for the historically early pandemics.

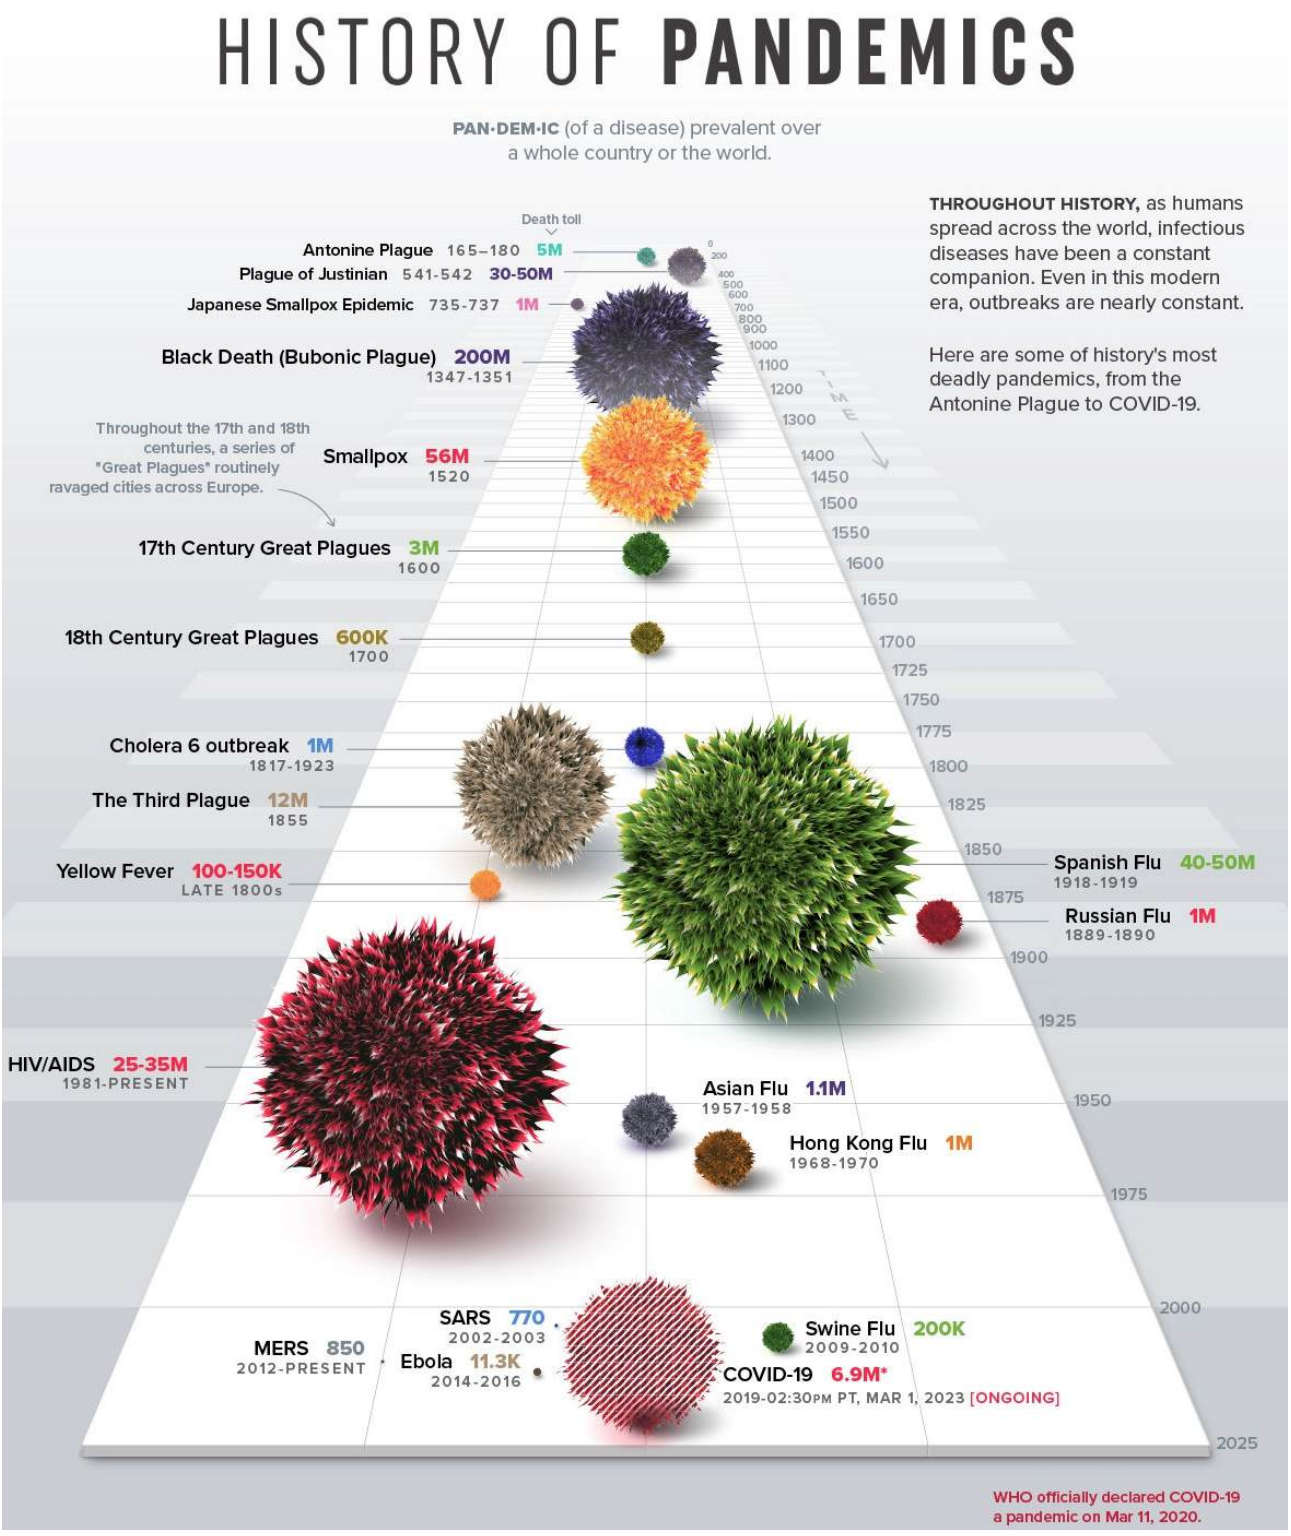

Figure 32.14.3: **Visualizing the History of Pandemics.** Attribution Visual Capitalist. https://www.visualcapitalist.com/his...ics-deadliest/

The graphic misses another key plaque in world history, the Plaque of Athens, which hit the city from around 430 BCE - 427 BCE, during which up to 25% of the city's population died. Smallpox has emerged as a possible candidate for that outbreak.

Figure 32.14.4:

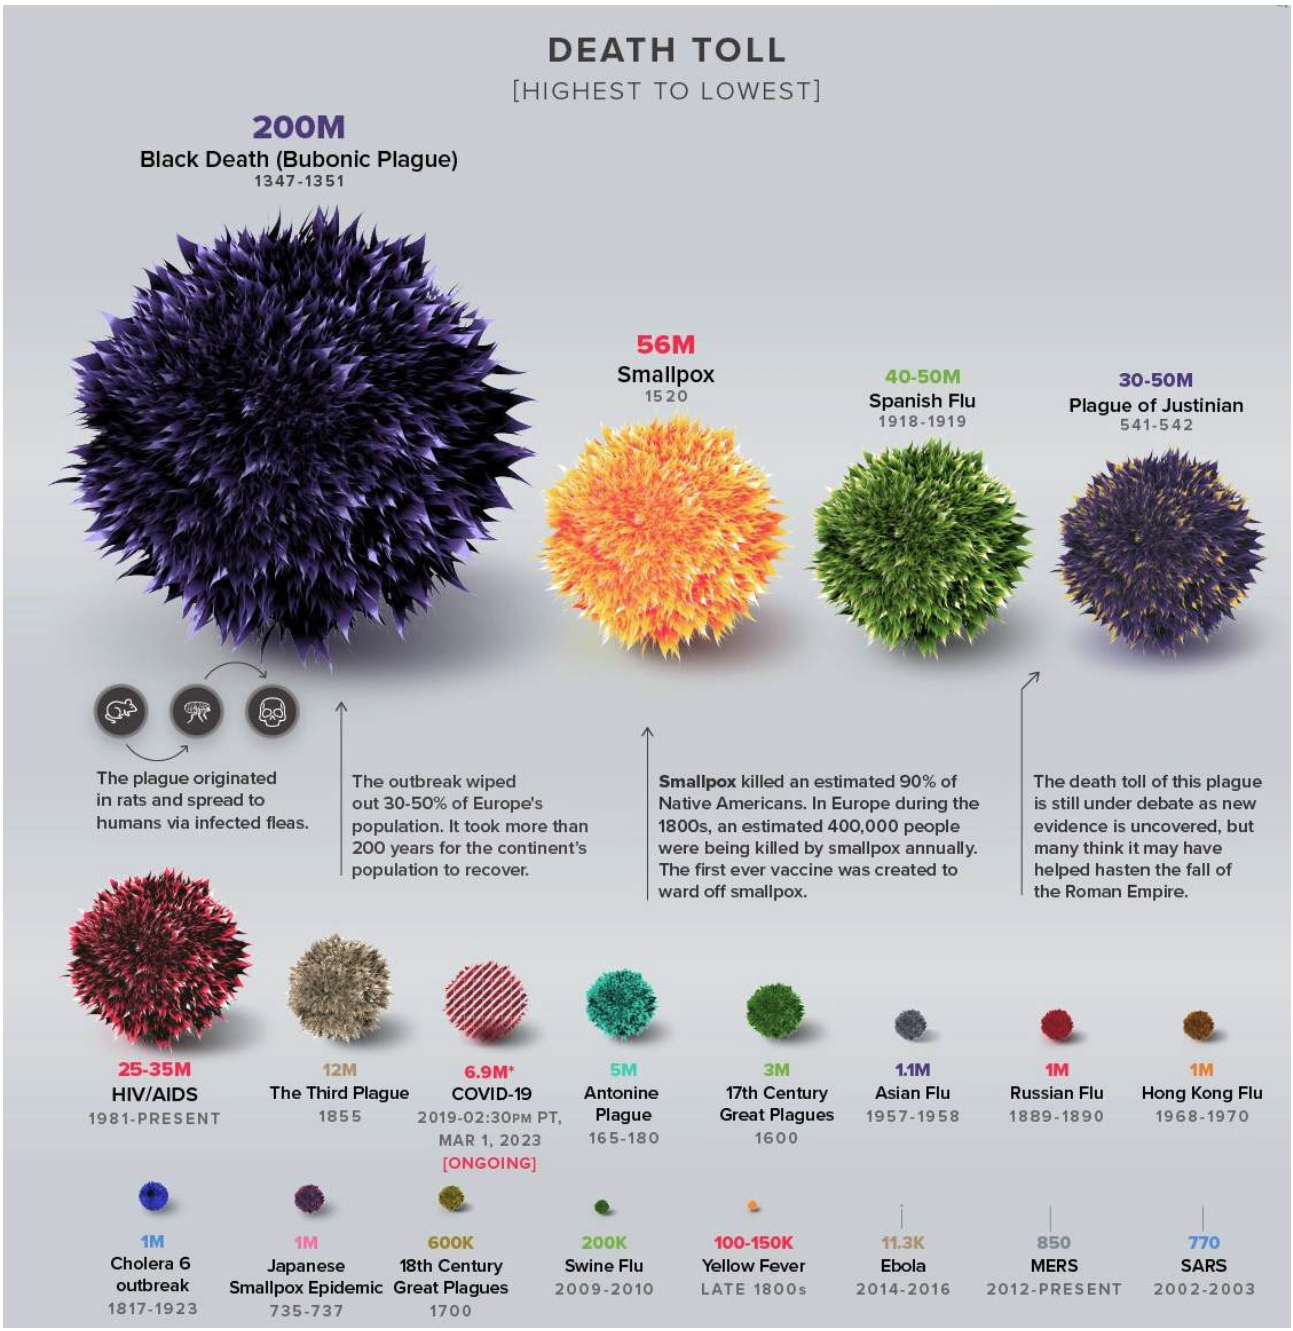

Figure 32.14.4: **Visualizing the History of Pandemics.** Attribution Visual Capitalist. https://www.visualcapitalist.com/his...ics-deadliest/

The **B**lack Death (also called the **B**ubonic Plague) was caused by the **b**acterium, *Yersinia pestis*. Humans usually get the bubonic plague after being **b**itten by a rodent flea that is carrying the plague bacterium or by handling an animal infected with the plague (notice the bold letter **B** to help you remember **B**lack, **B**ubonic, **B**acterium, **B**ite). The Black Death/Bubonic Plagues derives its name from the fact that many had **b**lack tissue from gangrene. Large buboes, and inflammatory swellings of lymphatic glands, especially in the groin or armpit, were common. Another variant caused by Y. pestis is the **Pneumonic Plague**, caused by breathing particles containing Y. pestis into the lungs, which leads to death from pneumonia and its complications. That was more infectious since it could be spread from person to person. Modern antibiotics are used to treat the plague, which still occurs.

Measles: A disease not shown in the figure is measles, which probably has killed upwards of 200 million people throughout time. It emerged from a viral infection, rinderpest, which infects cattle, deer, and buffalo. In 2021 there were 128,000 deaths out of 9 million cases worldwide, even though there is a highly effective vaccine. Vaccinations have decreased since the Covid-19 pandemic. Since it is one of the most infectious viruses known, and one contract leads to life-long immunity, a large population (250,00-500,000) is needed for it to self-sustain. The most recent analysis of historical sequences suggests that it emerge (jumped to humans) around the 6th century BCE, around

the time when cities of high enough population formed to allow its emergence. Measles is caused by an RNA virus, and since RNA is much more labile than DNA, few historical traces of the measles virus are available. The oldest one is from 1911 and it was from this and newer viruses that a phylogenetic RNA tree using a molecular clock model was constructed that led to the 6th century BCE time of emergence. Cities with a critical number of people for sustaining an emergence existed about 300 BCE in North Africa, India, China, Europe, and the Near East. A disease similar to measles was mentioned by Rhazes (Persia, 10th century CE). Past pandemics of unclear etiology could be attributed to measles, but it's difficult to know for sure given the difficulty in differentiating measles from other diseases.

Influenza: The genome of the influenza virus consists of 8 separate segments of ssRNA, much like the human genome resides on 23 different "segmented" chromosomes. Because its genome consists of RNA, past traces of it that point to its origin is lacking. The human influenza virus arose from swine (causing swine flu) and birds (avian flu). Hippocrates wrote of a disease with similar symptoms in 412 BCE. In 1357 an epidemic called “influenza di freddo,” or cold influence, swept Florence, Italy. The influenza RNA genome and transcribed proteins are shown in Figure 32.14.5 below.

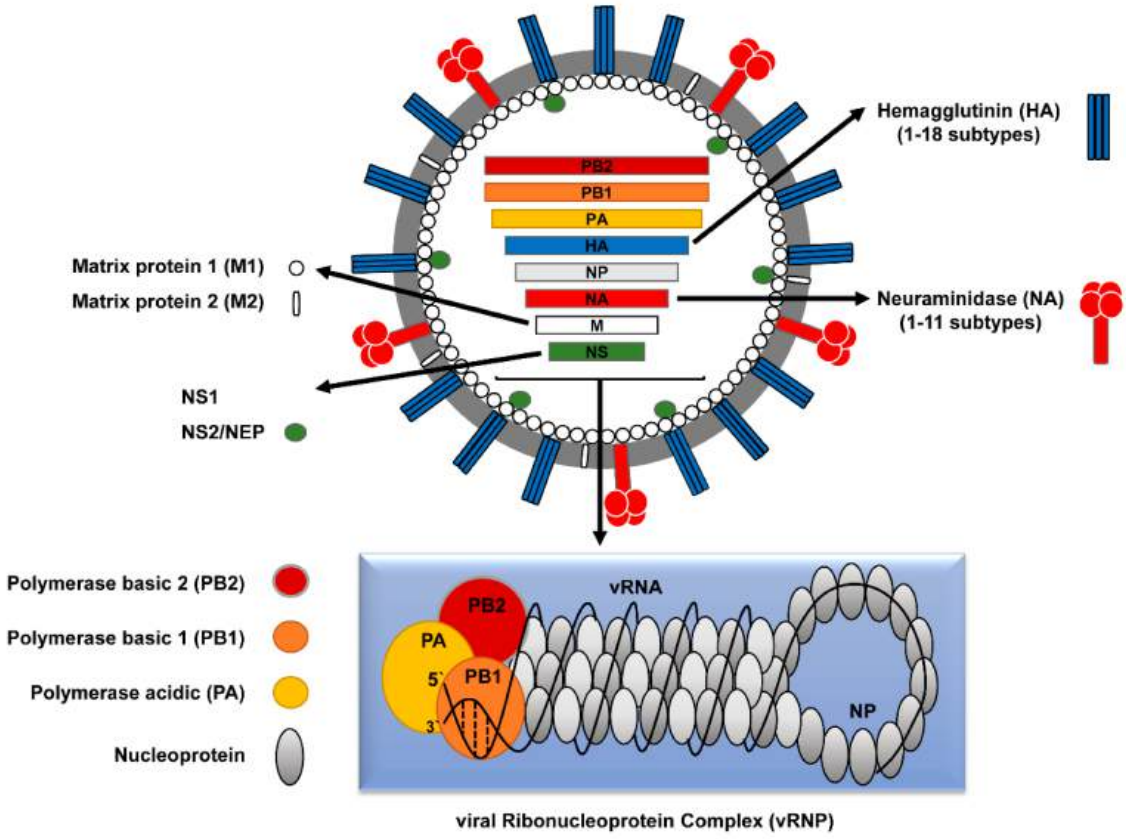

Figure 32.14.5: Influenza RNA genes and their protein products. Ahmed Mostafa, Elsayed M. Abdelwhab, Thomas C. Mettenleiter, and Stephan Pleschka - mdpi.com/1999-4915/10/9/497/htm, CC BY 4.0, https://commons.wikimedia.org/w/inde...curid=92987475

The **hemagglutinin** (H) membrane protein, responsible for viral binding to host cells, and **neuraminidase** (N), required for the exit of newly replicated viruses and hence viral propagation, are especially key in understanding past and future pandemics. There are 18 different subtypes of H and 11 subtypes of N comprising 4 different types of viruses (A-D) with A and B being the most common. The main types in circulation in 2022 were types A (H3N2) and B (H1N1).

Since the genome consists of RNA replicated by a RNA polymerase, which does not have proofreading functions, mutations occur on viral replication. This leads to slow changes in viral protein sequence and structure, called **antigen drift**, and hence to viruses less recognized by the host immune system. This is why new influenza vaccines are formulated each year (through a process that requires growing the virus in eggs).

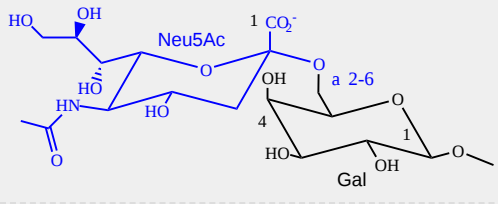
Large-scale pandemics occur through **antigen shifts**. This occurs when an animal such as a pig gets infected with an avian virus, a not unlikely occurrence given the co-farming of these animals in many places in the world. Newly replicated pig viruses could then contain some avian viral segments, which when transmitted to humans could produce lethal disease since they have no immunological memory in the host to produce an immediate immune response. Analyzes show that the horrific 1918 flu pandemic was caused by an avian influenza virus. An ancestral virus from the late 1880s is related to the horse (equine) H7N7 and equine H3N8 as well as to birds, humans, and swine viruses, and was the likely precursor of the 1918 flu virus. This ancestral virus led to a global change in the avian influenza virus which

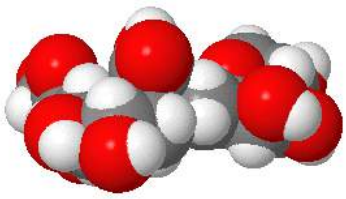
contributed most of the RNA segments to the 1918 pandemic. Smaller pandemics in the last half of the 20th century were likely caused by quick replacements of H3N2 and H1N1 genes leading to evolutionary fitness and ease of transmission. We should be on guard as there is an ongoing, worldwide highly virulent avian flu (H5N1) pandemic in wild birds and domestic poultry that has jumped to some animals, including humans who handle infected birds.

The hemagglutinin protein, homotrimer (3 identical protein subunits), MW 220,000, is the most abundant protein on the viral surface. Only three have adapted to humans in the 20th century, giving pandemic strains H1 (1918), H2 (1957), and H3 (1968). Three recent avian variants (H5, H7, and H9) can jump directly to humans but have low human-to-human transmissibility.

The viral hemagglutinin binds to glycoprotein receptors on human and other animal cells. The receptor binding site on host cells contains a terminal sialic acid (Sia) covalently attached to a galactose. The sialic acid is usually connected through an α(2,3) or α(2,6) link to galactose on N-linked glycoproteins. The viral subtypes found in avian (and equine) influenza bind preferentially to host Sia α(2,3) Gal which predominates in the avian GI tract where viruses replicate. Human influenza binds preferentially to Sia α(2,6) Gal links on human cells. The swine influenza HA binds to both Sia α(2,6) Gal and Sia α(2,3) Gal. The structures of the Sia-Gal disaccharide are shown in Figure 32.14.6 below.

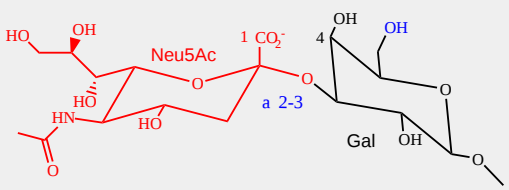
Sia α(2,6) Gal (Human and swine)

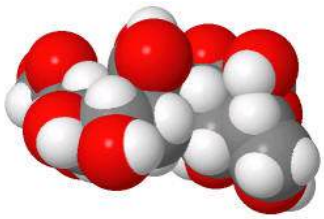




(made with Sweet, with an OH, not AcNH on sialic acid on C5)

Sia α(2,3) Gal (Avian and Swine)





(made with Sweet, with an OH, not AcNH on sialic acid on C5)

Figure 32.14.6: Structures of Sia α(2,6) Gal (human) and Sia α(2,3) Gal Gal (avian/swine)

The H5N1 avian virus is deadly but lacks human-to-human transmissibility. Why? One reason is that it appears to bind deep in the lungs and is not released easily on coughing or sneezing. It appears that cell surface glycoproteins deeper in the respiratory tract have Sia (α2,3) Gal linkages which account for this pathology.

Small changes in the amino acids of the viral hemagglutinin (HA) could change the preference for binding between Sia α(2,6) Gal (predominant human form) and Sia α(2,3) Gal (predominate form in birds) on host cells, and could dramatically affect both human lethality and transmission. Even though it was mostly of avian origin, the predominant 1918 hemagglutinin bound to the human Sia α(2,6) Gal.

Figure 32.14.7 shows an interactive iCn3D model of a H1 1918 hemagglutinin with a human receptor (2WRG), in this case, just the Sia α(2,6) Gal disaccharide from a target N-linked glycoprotein.

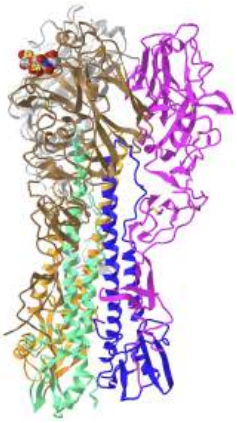


Figure 32.14.7: H1 1918 hemagglutinin with the human receptor - the Sia α(2,6) Gal dissachharide (2WRG). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...svY14r7wmnM1r5

The HAs in each of the 20th-century influenza pandemics, 1918 (H1N1), 1957 (H2N2), and 1968 (H3N2), preferentially bound to the Sia α(2,6) Gal even though the 1918 viruses and presumably the other, arose from avian viruses with a Sia α(2,3) Gal preference.

Figure 32.14.8 shows an interactive iCn3D model of α-2,6-linked sialyl-galactosyl ligand binding to the H1 1918 hemagglutinin (2WRG).

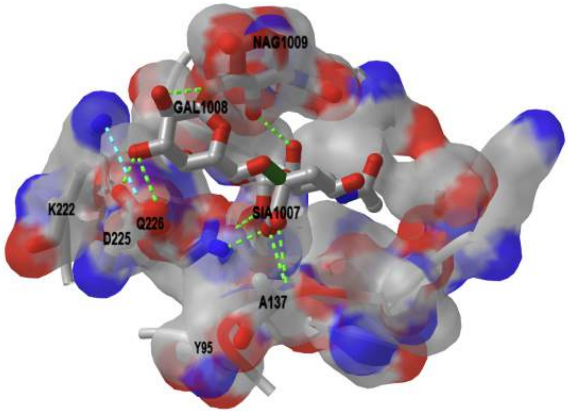

Figure 32.14.8: α-2,6-linked sialyl-galactosyl ligand binding to H1 1918 hemagglutinin (2WRG). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...yNJHQaQQebSuT9

A variant of the 1918 virus, A/South Carolina/1/18 (18H1), also circulated at the time. It contained a single amino acid mutation, D225G. in the HA protein. That variant switched the HA binding specificity on its target from Sia α(2,6) Gal to both Sia α(2,6) Gal and Sia α(2,3) Gal. This change eliminated a salt bridge (ion-ion interaction) between K222 and D225 in the main variant (see the blue-dotted line in the above model). This in turn allowed another key residue, Q226, to bind to the host receptor.

The viral HA in the 2009 human influenza pandemic had K222 and D225, giving it specificity for Sia α(2,6) Gal. Late in that pandemic (as occurred in the 1918 pandemic), a mutated version, D225G, that produced more severe symptoms was isolated. It had also gained dual specificity. Another mutant D225E did not as the salt bridge was maintained and the binding to Sia α(2,6) Gal was actually strengthened. Binding studies showed that the D225G mutants in the HA of both 18H1 and 09H1 viruses bound with higher affinity than the wild-type HAs which likely allowed binding to host glycoproteins deeper in the lung.,

The dissociation constant K_D and the on rate, k_{on}, and off rate, k_{off}, for the 09H1 and 18H1 hemagglutinins and relevant mutants, were determined by surface plasmon resonance spectroscopy (see Chapter 5.2 for a review of SPR). Table 32.14.1 below shows their values.

Hemagluttinin	Sia-Gal link	K_D (μM)	k_{on} (s^{-1})	k_{off} ($M^{-1}s^{-1}$)
09H1	α(2,6)	3.74	319	0.00119
09H1	α(2,3)	nd	nd	nd
09H1 D225G	α(2,6)	0.475	3650	0.00173
09H1 D225G	α(2,3)	2.24	1460	0.00327
18H1	α(2,6)	13.7	125	0.0017
18H1	α(2,3)	nd	nd	nd
18H1 D225G	α(2,6)	8.35	531	0.00444
18H1 D225G	α(2,3)	4.73	984	0.00466

Table 32.14.1: Dissociation and are constants for the interaction of hemagglutinins (H) from the 2009 and 1918 pandemics with Sia-Gal ligands. Adapted from Zhang et al., J Virol. 2013 May;87(10):5949-58. doi: 10.1128/JVI.00545-13. Epub 2013 Mar 20. PMID: 23514882; PMCID: PMC3648181.

It's remarkable how one amino change that can lead from no to strong binding can alter the specificity of a protein for its ligand and human history as well.

32.14.2: SLOWER-ACTING BUT VERY LETHAL MICROBIAL DISEASES HAVE TAKEN A VAST NUMBER OF LIVES

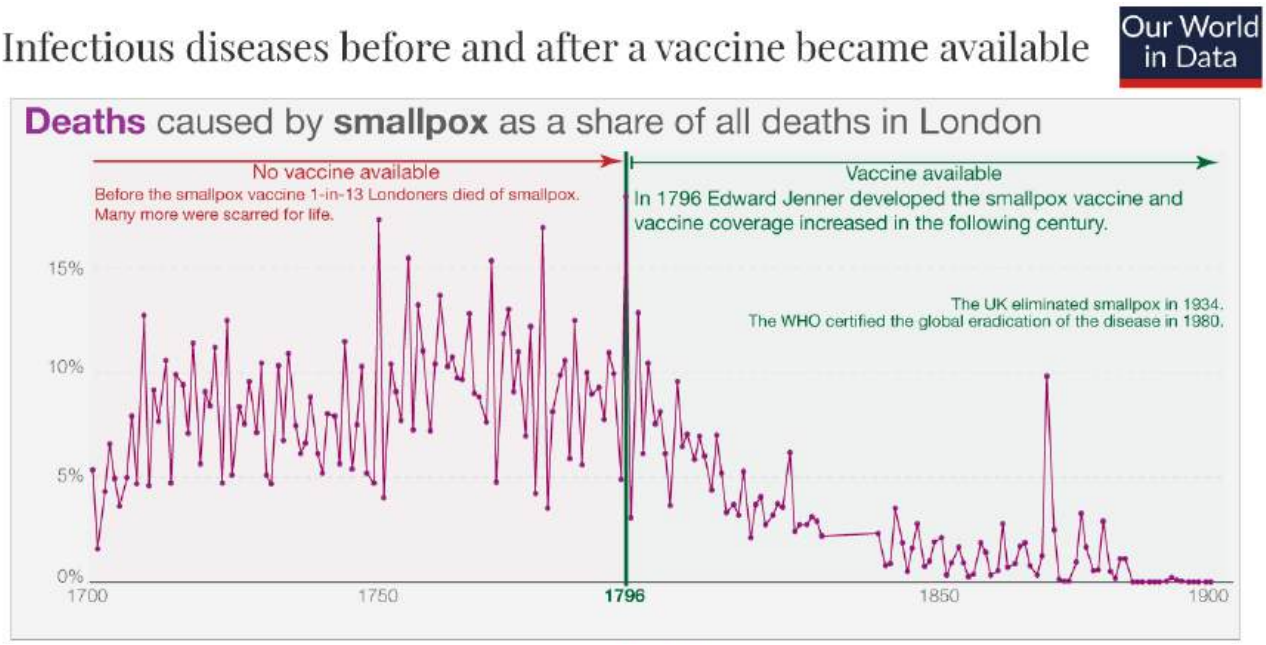
Malaria: Each year there are an estimated 300-500 million cases that result in about 2.7 million death. Most deaths are children under 5 in sub-Saharan Africa. The disease is caused mainly by the female Anopheles mosquito which transmits Plasmodium falciparum and the less lethal *Plasmodium vivax*. In the 100 years of the 20th century between 150-300 million deaths have been attributed to malaria (2-5% of all deaths). It was brought to the new world from Africa by the slave trade of over 7 million Africans, and from Portugal and Spain (the main colonial powers where malaria was endemic. The bacteria probably moved from gorillas to humans long ago in Africa. No effective vaccine has yet been developed to prevent this disease.

Proteins associated with the virus have been found in Egyptian samples from 3200 BCE and there were descriptions of the cyclic fevers associated with malaria in China in 270 BCE. It was also described by Homer (750 BCE), Plato, and Hippocrates in ancient Greece. It probably was first found in Rome around 0-100 ACE. The virus persisted in Europe for 2000 years.

Tuberculosis: This disease is caused by the *Mycobacterium tuberculosis* bacteria and is spread through the breath. Estimates are that up to 1 billion people have died of TB over history. The BCG vaccine is somewhat effective against TB but not often administered given its low prevalence and the availability of antibiotics. Tuberculosis (TB) was called “phthisis” in ancient Greece, and “tabes” in ancient Rome. The modern common ancestor of this bacteria arouse around 6000 years ago and is associated with disease in both the Old and New World.. Older strains were likely found in seals and sea lions. Genetic analysis showed that the modern strain was found in Peru before the arrival of Europeans to the New World. The disease in the Western Hemisphere probably derived from sea mammals which crossed the ocean.

Vaccines against some of our worst infectious disease agents have saved millions of lives. Here are some examples.

Figure 32.14.9:



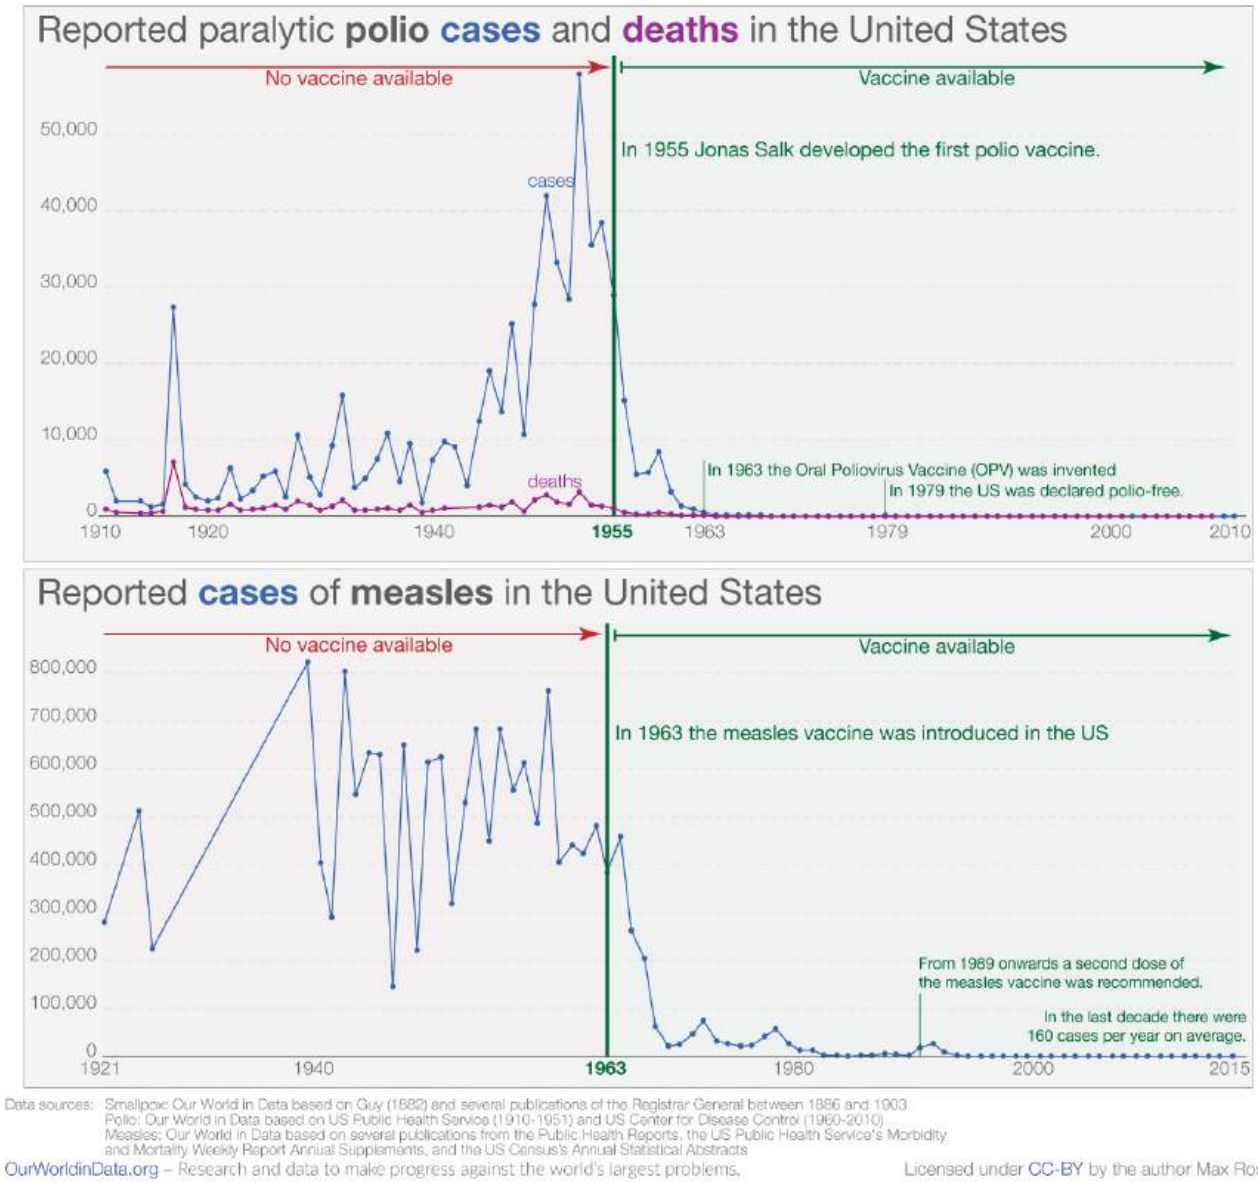


Figure 32.14.9: : https://ourworldindata.org/microbes-...ience-vaccines

Mathematical models show that from 12/20 through 12/22, Covid vaccines prevented over 120 million infections, 18.5 million hospitalizations, and 3.2 million deaths just in the United States. In the first year of the pandemic (12/20-12/21), models show that 14.4 million deaths (and 19.4 million excess deaths) were prevented in the whole world.

EPIDEMICS THAT DECIMATED INDIGENOUS PEOPLES IN THE NEW WORLD

Before Columbus came to the New World, there was no typhoid, flu, smallpox, or measles there. These diseases were present in Eurasia where people lived in increasingly populated areas in close quarters with domesticated animals. They would have developed some immunity over time. Their microbes likely derived from domestic animals before jumping species to humans, much as modern flu can be passed from swine to humans and less regularly but more lethally from birds to humans. Even with the buildup of some immunity, new pandemics were utterly devastating.

Indigenous peoples in the new world were never exposed to these pathogens before the arrival of people from the Ols World. They only utilized llamas for work and not generally for food and milk. Deaths were staggering. It's estimated that 90% of indigenous people died, a far higher proportion than seen even with the Black Plague in Europe. Imagine the loss of culture and civilization that would accompany a decline in the population of central Mexico from 15 million to 1.5 million in the 100 years after 1519.

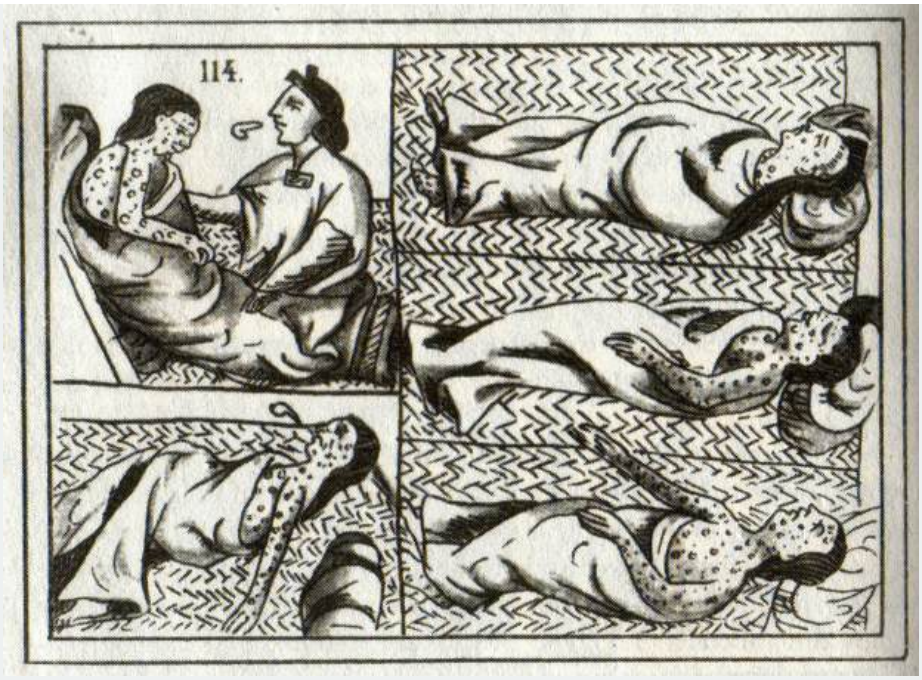

Figure 32.14.10: Sixteenth-century Aztec drawings of victims of smallpox. https://en.wikipedia.org/wiki/Native..._and_epidemics

Social conditions after the initial collapse of the indigenous people in the Americas led to their continued decline, even though they would have gained some immunity. An example is offered by Ostler who describes the health consequences of the Indian Removal Act of 1830, which led to the forced relocation of Native people east of the Mississippi River into "Indian Territory" (Oklahoma and Kansas). As an example, 16,000 Cherokee were expelled and forced to live in camps with few resources, where up to 2000 died of measles, malaria, dysentery, and whooping cough. 1500 more died as they moved west. More died in Oklahoma, leading to a death toll of 25% of the original group.

Cumulative death rates in the COVID-19 pandemic show that Indigenous peoples in the United State still have barriers to optimal health care.

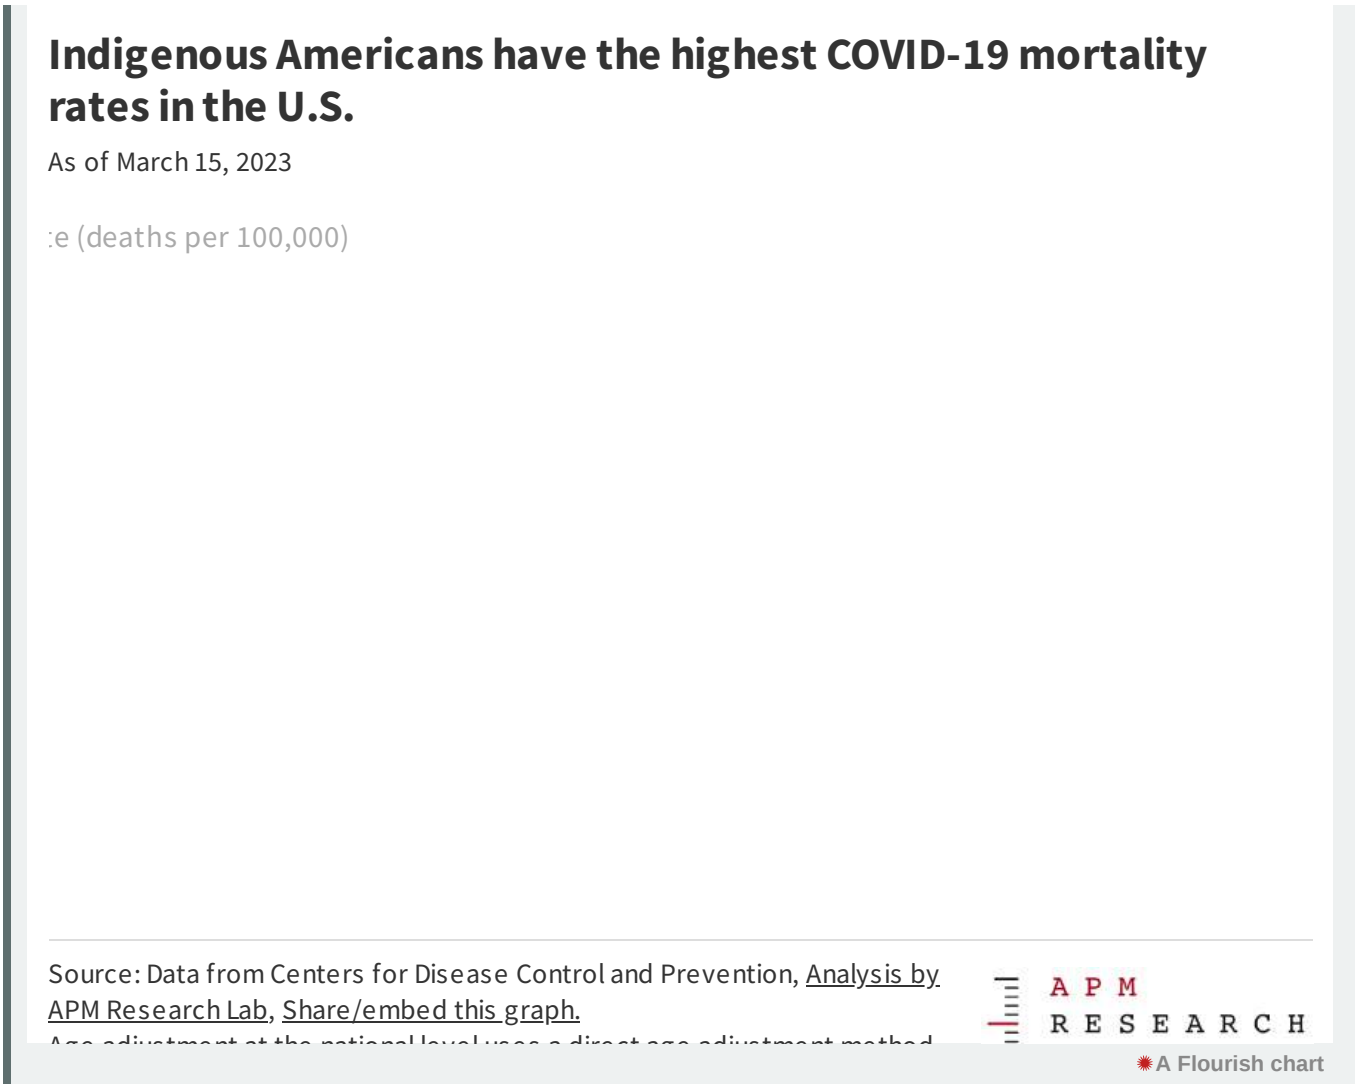

Figure 32.14.11 : Cumulative Deaths and Age-Adjusted Rates per 100,000 in the United States.

32.14.3: INFECTIOUS, EMERGING AND PANDEMIC DISEASES - LINKS TO CLIMATE CHANGE

Our understanding of infectious diseases clearly shows that the great epidemics and pandemics of the world have arisen when microbial pathogens make the jump from animals to humans who have not experienced them before. For example, HIV/AIDS arose when simian immunodeficiency viruses, to which non-human primates were adapted, jumped to humans in central Africa. The best available data suggest that the SARS-CoV-2 virus jumped from bats to animals (raccoon dogs or other animals from Wuhan China live animal markets) and then to humans, although some data suggest the possibility of a lab leak.

A **Zoonotic** disease (**zoonosis,** plural **zoonoses**) is a microbial infectious disease transmitted reversibly between animals and humans. The major types of zoonoses are viral, bacterial, parasitic, mycotic/fungal, rickettsial (obligate intracellular Gram-negative bacteria found in ticks, lice, fleas, mites, chiggers, and mammals), Chlamydial (bacteria that cause STDs), Protozoal or unconventional (such as prions). The ones most prevalent in the US are influenza, Salmonellosis, West Nile virus, Plague, coronaviruses, rabies, Brucellosi, and Lyme disease. **Vector-borne** diseases are caused by bacteria, viruses, and parasites transmitted through bites of **vectors** such as infected arthropods like mosquitoes, ticks, sandflies, and blackflies. The range of arthropod vectors expands with global warming as they are cold-blooded.

Several anthropogenic (human-caused) factors, including climate change, increase the chances of such jumps. These factors, many of which are interrelated include:

- movement of humans into environments where contact with disease-carrying organisms would increase transmission

- biodiversity loss which allows species and their microbes to move into new areas
- land use change (deforestation, farming, etc) that allows the expansion of species and microbes into new areas
- global warming, which encourages the movement of species and their microbes to new areas where human exposure is more likely
- climate change-induced changes in plant life that allow altered distributions of animals and microbes
- climate change-derived changes in precipitation patterns that affect the adaptation of species and their microbes.

Humans affect all of these factors by causing climate change, and land use changes including the expansion of agriculture, urbanization, and the rapid global movement of people, commodities, and other animals. Studies have shown that 58% of human infectious diseases have already worsened with climate change. Another study used databases of mammalian viruses and their host to see which ones might share viruses, an occurrence made much more likely when the species live in the same geographic area. Machine learning was used to model how mammals might share viruses and change their living range in a warming world through 2070. The study found over 4000 viruses could move among 3000 species, greatly enhancing the changes for the exchange of single and multiple viruses among species. Bats (see below) are especially worrisome as they harbor many viruses capable of infecting humans. As bats move habitats due to climate warming, their chances of infecting new species that could then infect humans are greatly increased.

25 years of land use changes in Australia led to altered bat (flying foxes) behavior and to their more permanent presence in agricultural land. This has resulted in viral"spillover" (transmission of a pathogen from a non-human vertebrate to a human) that is driven by periodic food shortages, especially in winters following El Nino weather patterns (characterized by less rain, warmer temperatures, and greater temperature extremes). These changes in bat behavior led to the emergence of the Hendra virus, which infected domestic horses (an intermediate vector), and could pass the virus to humans. The virus does not cause disease in bats but leads to a high mortality rate in horses (75%) and humans (57% based on just four deaths). With climate and land use change, bats persistently spent winters in agricultural lands close to horses. Spillovers occurred more frequently during low food conditions following an El Nino summer.

The Black Death (Second Great Pandemic, 1347-1351), occurred during the Little Ice Age in Europe (1300-1850), which also led to a great famine from 1315-1322. There is a link between the pandemic and climate change, but it's difficult to ascertain the strength of the association. An association exists between periodic warm springs and wet summers in Central Asia (using tree-ring data) and outbreaks of the Plague in Europe about 15 years later. This suggests a continual re-importation of *Yersinia pestis* in Asian rodents into Europe and could explain how long the Plague lasted in Europe.

The presence of the plague in gerbils in Kazakhstan would increase with warm spring and wet summer which increase gerbil and flee populations. This Moran effect (time correlation of two populations of a species with change in environment) is well known in population ecology. When gerbil populations collapse, the flea density of the remaining gerbils increases which also leads them to seek different hosts. The spread across geographic distance would take time. In the case of periodic import of flees to Europe, it has been proposed that the 4000 km from west central Asia to the Black Sea took 10-12 years (around 350km/y) .

PATHOGENS FROM THE NORTH

Most attention has been given to pathogens moving northward from the south as warmer temperatures allow them to thrive in traditionally colder climates. There is growing parallel concern about pathogens moving south from the Arctic as it warms. In fact, the high northern latitudes have experienced the greatest increase in temperature as the planet warms. The Arctic is predicted to be soon ice-free in the summers.

One major concern is that thawing of the permafrost (comprising almost 1/4 of the northern hemisphere that is "permanently" frozen) will allow the release of CO_2 (a metabolic product of microbes in the presence of oxygen) and CH_4 (a metabolic product of Archeal microbes in an anoxic environment) from organic molecules previously found in frozen soils. (A similar concern is the release of "frozen" methane clathrates from a warmer ocean).

An emerging concern is the "activation" of microbes from the permafrost that have been sequestered and dormant for 500,000 years or more. In fact, species like tardigrades, rotifers, and nematodes, that can go dormant and enter a state called **cryptobiosis** in harsh conditions such as freezing and dehydration, can reactivate. Two species of nematodes (roundworms), dating back to 46,000 years ago (based on radioactive dating), the last years of the Pleistocence, were recovered and revived. Periodic reoccurences of anthrax from the release of the Gram-positive bacterium *Bacillus anthracis* spores from permafrost thawed in summers have been reported. In 2016, when average temperatures were significantly elevated (see Figure 32.14.12 below), over 2000 reindeer died (close to a 90% mortality rate) and close to 100 people were hospitalized from an anthrax outbreak in Siberoia. On June 20, 2020, a record temperature of 38 °C (100 °F) in the Russian town of Verkhoyansk was recorded!

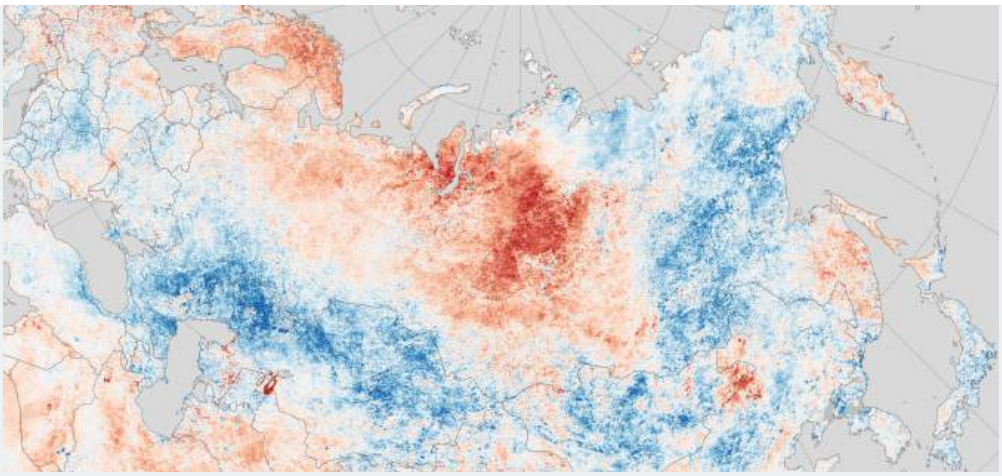

Figure 32.14.12 : Color map showing land surface temperature anomalies from -12 °C (-21.6 °F) (darkest red) to + 12 °C (+21.6 °F) (darkest red) during the week of July 20-27, 1916. https://earthobservatory.nasa.gov/im...n-extreme-year

We also have to worry about emerging viruses that are released from the thawing of the tundra. Just as for the SARS-Covid-2 virus, we would have no immunity to these viruses. Figure 32.14.13 below shows EM pictures of new infectious viruses isolated from seven different ancient Siberian permafrost samples.

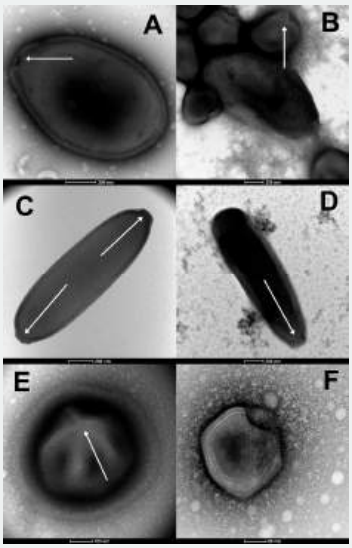

Figure 32.14.13 : Morphological features guiding the preliminary identification of newly isolated viruses (negative staining, TEM). Alempic, J.-M.; Lartigue, A.; Goncharov, A.E.; Grosse, G.; Strauss, J.; Tikhonov, A.N.; Fedorov, A.N.; Poirot, O.; Legendre, M.; Santini, S.; et al. An Update on Eukaryotic Viruses Revived from Ancient Permafrost. *Viruses* **2023**, *15*, 564. https://doi.org/10.3390/v15020564. Panel (**A**) shows large ovoid particle (1000 nm in length) of *Pandoravirus yedoma* (strain Y2) (showing the apex ostiole (white arrowhead) and the thick tegument characteristic of the *Pandoraviridae* family.

Panel (**B**) shows a mixture of *Pandoravirus mammoth* (strain Yana14) oblate particles and of *Megavirus mammoth* (strain Yana14) icosahedral particles exhibiting a “stargate” (white starfish-like structure crowning a vertex, white arrowhead)

Panel (**C**) shows the elongated particle of *Cedratvirus lena* (strain DY0) (1500 nm in length) exhibits two apex cork-like structures (white arrowheads)

Panel (**D**) shows the elongated particle of *Pithovirus mammoth* (1800 nm in length) exhibiting a single apex cork-like structure (white arrowhead).

Panel (**E**) shows the large (770 nm in diameter) “hairy” icosahedral particle of *Megavirus mammoth* (strain Yana14), showing the “stargate” (white arrowhead) characteristic of the *Megavirinae* subfamily

Panel (**F**) shows the smaller icosahedral particle (200 nm in diameter) of *Pacmanvirus lupus* (strain Tums2) typical of asfarviruses/pacmanviruses.

32.14.4: FUNGAL DISEASES

We have concentrated solely on bacteria and viral epidemics/pandemics. We also have to consider fungal outbreaks that affect human health but also the foods that sustain us. We have few medicines that treat fungal infections and no vaccines, so any outbreaks could be quite serious. Most grow optimally between 12-30 ^{0}C (54-86 ^{0}F) so they don't adapt easily to warm blooded animals like humans. Nevertheless, global warming will increase their range and lead to increased thermal tolerance.

Candida auris: This was first found in 2009 in Japan as a cause of an ear infection. It is now found around the world.

***Batrachochytrium dendrobatidis* (*Bd*)**: This affects amphibians and has caused a high loss in amphibian diversity on all continents.

Cryptococcus deuterogattii:, This was typically found in more tropical/subtropical climates but now is also found in western Canada and the Pacific Northwest. It causes infections in people and animals.

Puccinia striiformis: This causes wheat rust which devastates crops and is now moving into warmer areas.

Fusarium graminearum: This causes diseases in wheat and other food crops, especially in warm and wet conditions.

Coccidioides immitis: This fungus, which grows in desert soil, can also spread through severe dust storms that cause fungal spores to be blown over wide regions. An example is the dispersal of *Coccidioides immitis* from Bakersfield, where it was endemic, to Sacramento County, where it wasn't, in 1977. Another example is *Apophysomyces trapeziformis*, which caused disease in 2011 in Joplin, Missouri after a tornado. The fungus actively thrives in wet soils but forms spores in dry conditions These spores can last for decades and cause disease when blown into the air and inhaled. They are associated with a condition called Valley Fever which affects farm workers who spend much time outside. Latino, Asian, and Native American people get Valley Fever at 2-4 times the rate of others.

32.14.5: BATS, VIRUSES, AND CLIMATE CHANGE

We have seen that new infectious diseases arise from pathogen jumps to humans from other species. The more distant the species, the more unlikely humans have encountered the disease and the more likely it could cause severe illness and pandemics. A clear example is the avian flu that led to the 1918 flu pandemic. Yet we also have to worry about zoonoses from pathogen transfer from mammals, including rodents, bats, moles, shrews, monkeys, pigs, camels (a host of the deadly MERS virus), whales, cats, dogs, and seals (a likely source of the original TB virus).

Bats are a key source of zoonotic disease, including Middle East respiratory syndrome (MERS), which has a death rate of around 35%. Bats are the source of the Covid virus MERS-CoV which causes MERS. The virus spreads to people from camels. Severe acute respiratory syndrome (SARS) is another coronaviral disease, caused by the called SARS-associated coronavirus (SARS-CoV) which emerged in China in 2003. It had a death rate of around 12% but it was much higher in older people. Neither of these became lengthy full-blown pandemic, as with the SARS-CoV2 virus, the cause of the COVID-19 pandemic. In addition, viruses from bats include rabies, Ebola, and Marburg viruses, as well as the Nipah and Hendra viruses. Bats are more likely to be infected with zoonotic viruses than rodents.

Why are bat viruses so key in our worst zoonotic diseases? Two features are important. The same viruses that are so virulent to humans do not kill bats. A clue as to the special nature of bats is that they are the only flying mammals. What might protect bats from their own viruses is that their core temperatures are quite elevated during flight, which requires a high metabolic rate. These high temperatures likely prevent these viruses from harming bats but also make the viruses immune to the high-temperature fevers accompanying infection in humans. The average core temperature of flying bats derived from a variety of species was 39.6 ^{0}C or 103.3 ^{0}F. Many pathogens replicate optimally at temperatures less than normal body temperature.

Fevers in humans are regulated by the hypothalamus, mainly through prostaglandin E2 (PGE2). This response is part of the innate immune response and is elicited by most pathogens. PGE_2 binds to the E-prostanoid-3 receptor (EP3), a G protein-coupled receptor in the hypothalmus, which determines the "set point" for body temperature. Hypothalmic PGE_2 is produced from the endocannabinoid 2-arachidonylglycerol by the action of monoacylglycerol lipase, at least in mice stimulated with a bacterial cell wall component (LPS), that stimulates fever production.

Figure 32.14.14 shows an interactive iCn3D model of the human prostaglandin E receptor EP3 bound to prostaglandin E2 (6AK3).

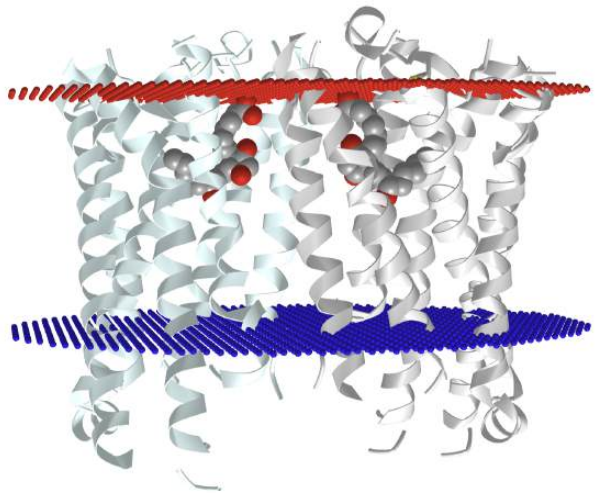

Figure 32.14.14 : Human prostaglandin E receptor EP3 bound to prostaglandin E2 (6AK3).. (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...cCgTGEKu3KoGx9

The model shows a dimer of two, GPCRs each bound to 1 PGE2.

Research suggests that bats have also evolved to have a lower inflammatory response, mediated by the inflammasome (discussed in detail in Chapter 5.4). Here is a short review of the inflammasome modified from that chapter section. It's needed to give readers a more biochemical explanation for immunosuppression in bat cells, a topic critical to understand the role of bats in present and future pandemics.

The inflammasome, part of the innate immune system, is activated by a plethora of pathogens or damaged host molecules. Our innate system immune cells (dendritic cells, macrophages, eosinophils, etc) have receptors that recognize common **pathogen-associated molecular patterns (PAMPs)** such as lipopolysaccharides (LPS) on the surface of bacteria, mannose on bacteria, and yeast, flagellin from bacterial flagella, dsRNA (from viruses) and nonmethylated CpG motifs in bacterial DNA. These antigens are recognized by pattern recognition receptors (PRRs) - specifically the **Toll-like Receptors (TLRs)** 1-10. These include plasma membrane TLRs (TL4 for LPS, TL5 for flagellin, TLR 1, 2 and 6 for membrane and wall components of fungi and bacteria) and intracellular endosomal TLRs (TLR3 for dsRNA, TLR 7 and 8 for ssRNA and TLR9 for dsDNA).

Figure 32.14.15 shows the TLR family, their binding signals, and intracellular adapter proteins used to transmit signals into the cell.

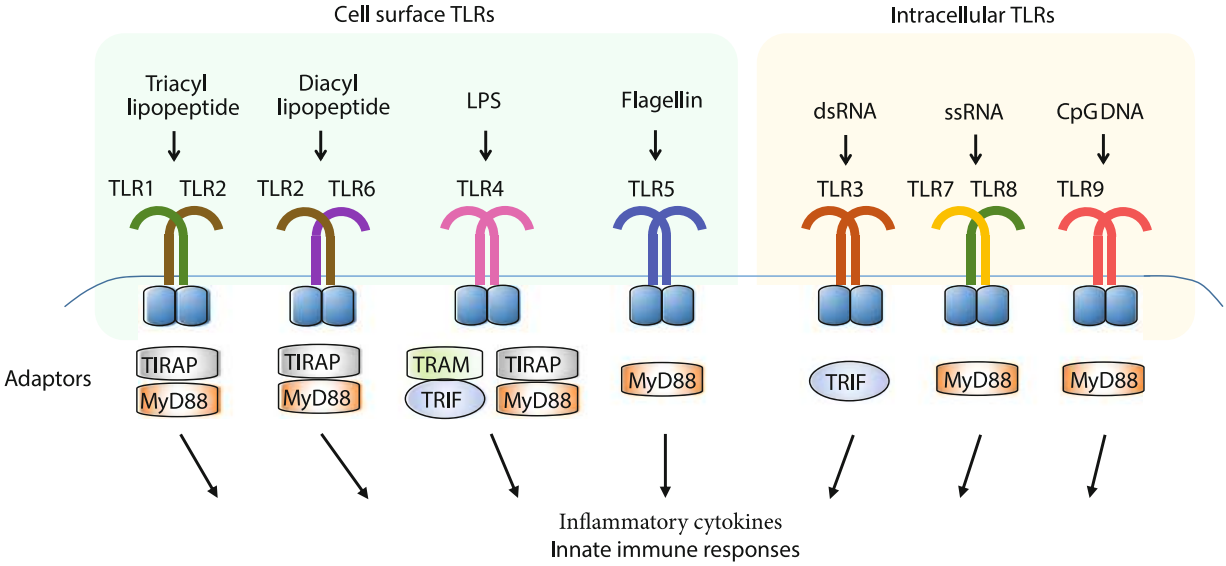

Figure 32.14.15: TLR family, their binding signals, and intracellular adapter proteins Ji-Yoon Noh, Suk Ran Yoon, Tae-Don Kim, Inpyo Choi, Haiyoung Jung, "Toll-Like Receptors in Natural Killer Cells and Their Application for Immunotherapy", *Journal of Immunology Research*, vol. 2020, Article ID 2045860, 9 pages, 2020. https://doi.org/10.1155/2020/2045860. This is an open access article distributed under the Creative Commons Attribution License

Inflammasomes are also activated by **Damage-associated molecular patterns (DAMPs).** These are typically found on molecules released from the cell or intracellular compartments on cellular damage (hence the name DAMP). Many are nuclear or cytoplasmic proteins released

from the cells. These would now find themselves in a more oxidizing environment which would further change their properties. Common DAMP proteins include heat shock proteins, histones and high mobility group proteins (both nuclear), and cytoskeletal proteins. Here are some other common non-protein DAMPS that can be released on cellular damage: ATP, uric acid, heparin sulfate, DNA, and cholesterol crystals. In the wrong location, these can be considered danger signals. They are sometimes referred to as "sterile" signals.

If TLRs recognize PAMPs, what recognizes DAMPs? They are recognized by another type of intracellular pattern recognition receptor (PRR) called **NOD** (Nucleotide-binding **O**ligomerization **D**omain (**NOD**)- **L**ike **R**eceptors or **NLRs**. NLRs also recognize PAMPs. The abbreviation **NLR** also comes from the **N**ucleotide-binding domain (NBD) and **L**eucine-**R**ich repeat (LRR)–containing proteins (**NLR**)s. This family of proteins participates in the formation of a large protein structure called the **inflammasome**. (Sorry about the multiple abbreviations and naming systems!)

As both PAMPs and DAMPs pose dangers, it would make sense that once they recognize their cognate PRRs (TLRs and NLRs, respectively), pathways leading from the occupied receptors might converge in a common effector system for the release of inflammatory cytokines from immune cells. Given that uncontrolled immune effector release from cells in an inflammatory response might be dangerous, it would be sometimes helpful to require two signals to trigger cytokine release from the cell.

Two such inflammatory cytokines are Interleukin 1-β (IL 1-β) and IL-18. Activation of TLRs by a PAMP leads to activation of a potent immune cell transcription factor, NF-kbeta, which leads to transcription of the gene for the precursor of the cytokine, pro-interleukin 1-β. Without a specific proteolytic cleavage, the active cytokine will not be released from the cell.

The protease required for this cleavage is activated by a signal arising when a DAMP activates a NLR, which then through a sequence of interactions leads to the proteolytic activation of another inactive protease, **procaspase 1**, on the **inflammasome**. The activated inflammasome activates procaspase to produce the active protein **caspase** (a cysteine-aspartic protease).

The convergence of the signals from the PAMP activation of a TLR and DAMP activation of a NLD at the inflammasome is shown in Figure 32.14.16 .

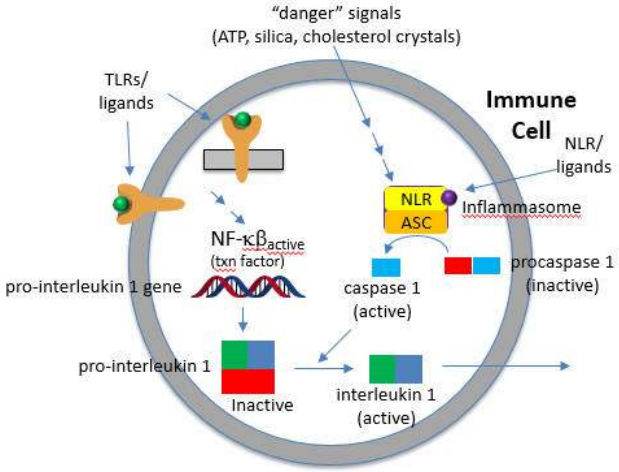

Figure 32.14.16 Signals from PAMP activation of a TLR and DAMP activation of a NLD at the inflammasome

The active cytokine interleukin 1-β helps recruit innate immune cells to the site of infection. It also affects the activity of immune cells in the adaptive immune response (T and B cels). Active IL-18 leads to the increase of another cytokine, interferon-gamma and it also increases the activity of T cells that kill other cells.

Figure 32.14.17 shows an interactive iCn3D model of the NLRP3 double-ring cage, 6-fold (12-mer) (7LFH)

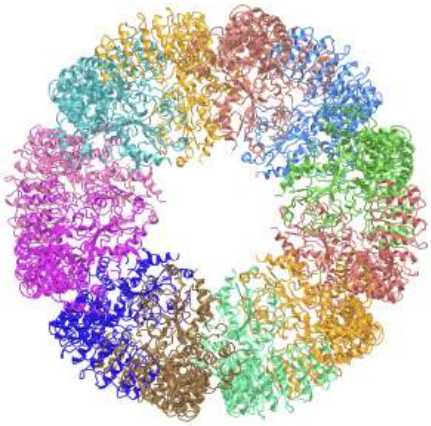

Figure 32.14.17 : NLRP3 double-ring cage, 6-fold (12-mer) (7LFH). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?DEbdkUoBtqRQ9bu59

The full-length mouse NLRP3 consists of 12- to 16-mer organized in a double-ring cage. It is held together by interactions between the leucine-rich repeats (LRR) domains. The pyrin domains are shielded by the structure, so they will not be activated without appropriate signals. The complex is also localized to the membrane. NLRP3 inflammasomes seem to be activated by cellular distress as well as cell exposure to pathogens. It is one of the main responders to a variety of microbial infections.

In summary, two signals are again needed:

Signal 1

The first signals are the bacterial and viral (influenza virus, poliovirus, enterovirus, rhinovirus, human respiratory syncytial virus, etc) PAMPs, which bind to TLRs and lead to the activation of the NFkb transcription factor. This activates not only the transcription of pro-interleukin 1-β and interleukin 18, but also the transcription of the NLRP3 sensor itself.

Signal 2

Signal 2 is delivered by PAMPs and DAMPs indirectly to the sensor NLRP3. This leads to the assembly of the inflammasome. These DAMPs appear to prime the activation of NLRP3 protein and subsequent formation of the active NLRP3 inflammasome. But what activates NLR3P3? After many studies, it became clear that the typical bacterial ligands that would activate TLRs and perhaps NLRs only prime NLRP3 for activation. They don't bind to it directly.

Extracellular ATP is a major activator of NLRP3. Nanoparticles are known to release ATP as well. Most studies show that K^+ efflux from the cell is an early signal.

32.14.6: BACK TO BATS

To survive the viruses they harbor, bats decrease their inflammatory response upstream at the level of PAMP and DAMP recognition, as well as downstream at the level of caspase-1 inhibition. In addition, additional cleavage sites in IL-1β cause its loss through proteolysis. These events decreased inflammasome signaling. That multiple steps are inhibited suggests that they have been selected through evolutionary pressures.

The activation of the bat NLRP3 inflammasome by a "sterile" agent (ATP), as well as 3 RNA viruses is significantly decreased in bat cells compared to responses to these signals in humans and mice cells. The viruses include:

- H1N1 influenza A virus (a negative-sense single-stranded RNA virus known to activate the NLRP3 inflammasome);
- the Melaka virus (a bat-borne zoonotic double-stranded RNA virus);
- MERS-CoV (a positive-sense (+) ssRNA zoonotic virus).

Even though the secretion of interleukin-1β is inhibited in bat cells, viral loads remained high in virally-infected bat cells. The altered NLRP3 activation in bat cells occurs in part through decreasing RNA splicing and an altered LRR domain in NLRP3.

It should be clear that if bat population increases or if they move to new habitats, both events which could be promoted by climate change, humans are at greater risks for bat-derived pandemics. Coronaviruses, with over 3000 species, make up about 1/3 of the bat's viral load. The region comprising southern Yunan (in China, Myanmar and Laos have very high populations of bats and it is from these areas that new bat zoonoses are likely to derive. Models of past climate (in the 1900s) and bat species richness compared to present climatic conditions, along with the knowledge of specific climate conditions necessary to support bat population and diversity, show that the greatest increase in bat species population in the 20th century occurred in SE Asia. Less important sites included regions in Central Africa and some pockets of Central and South America. The region in China, Myanmar, and Laos is likely the location for the origin of the SAR-CoV1 and SARS-CoV2 viruses.

32.15: Pandemic Diseases and Drug Discovery - Under Construction

Under construction - 9/26/23

Written by Valerie Doze (change title to what you want) by clicking pencil icon when hovering over the title.

Headings: Example

On the menu bar, select Normal, Heading 2

You can use Heading 3 for subheadings but adding sub-subheadings gets to look cluttered. For a sub-sub heading just use bold font for the title.

Numbering figures: Example

Figure 32.15.x below shows the reaction of one key carboxylase. x is the figure number you fill in to make them sequential in the document.

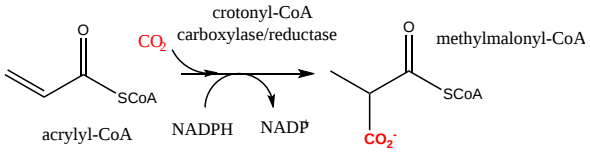

Figure 32.15.x Carboxylase used in the CETCH pathways to fix CO_2

---

iCn3D model: Example (to replace)

Figure 32.15.x shows an interactive iCn3D model of ribulose 1,5-bisphosphate carboxylase/oxygenase from Synechococcus PCC6301 (1RBL). (image is a png screen capture)

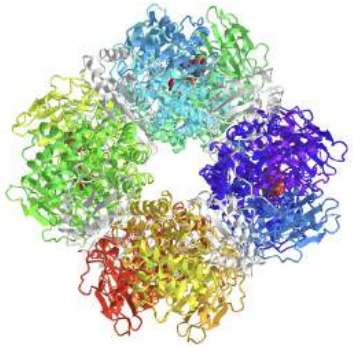

Figure 32.15.x: Ribulose 1,5-bisphosphate carboxylase/oxygenase from Synechococcus PCC6301 (1RBL) (Copyright; author via source). Click the image for a popup or use this external link:

I am sure you will have several to many iCn3D models. I can make them or teach you how to do it. Short but real learning curve. I sometimes use Pymol for some images when I feel that iCn3D doesn't show well.

Figure Types:

- png, jpeg, animated gifs (I can make them for you). Best file type is svg which can be made from PPTX images, ChemDraw, or exporting from other image file types using software like Adobe Illustrator or Affinity Designer
- for svg files, must drag them from a folder on your computer to desired spot in the new section. For other can drag them or use picture icon on menu bar to select and import them from your file.

Incorporate as you like but essential for images et al directly used form a Creative Common CC BY document, for example.

32.16: FIXING CARBON FIXATION

Search Fundamentals of Biochemistry

CARBON FIXATION

Nature has produced many enzymes that can fix atmospheric CO_2, and, of course, everyone knows that photosynthesis is the source of most fixed CO_2 in the biosphere. Plankton, cyanobacteria, algae, and plants are key in removing atmospheric CO_2 through photosynthesis. Yet we can't plant enough trees to reduce CO_2 in the atmosphere in the next decade to avoid some of the worst consequences of anthropogenic climate change. Old-growth trees (mostly gone or under significant stress) are best at removing CO_2. New trees would take decades of growth before their effect on carbon drawdown would be consequential. We also need to fix carbon dioxide not only to decrease atmospheric CO_2 but also to make more food!

A lot of carbon (about 100 petagrams) is sequestered each year in net primary production (fixation of carbon into biomolecules). This is split almost equally between land and ocean organisms. The key enzyme in this process is Rubisco in the C3 (Chapter 20.4) and C4/CAM (Chapter 20.5) pathways. The enzyme is big containing many large subunits and an equivalent number of small ones. A chaperonin is required for folding. It is also a very slow enzyme with a k_{cat} of around 2-10 CO_2/sec. In addition, it can bind another substrate, O_2, and engage in a competing reaction of photorespiration as described in Chapter 20.4.

Figure 32.16.1 shows an interactive iCn3D model of ribulose 1,5-bisphosphate carboxylase/oxygenase from Synechococcus PCC6301 (1RBL)

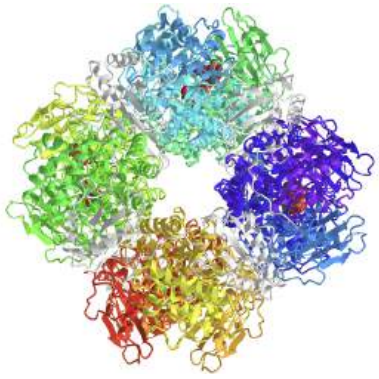

Figure 32.16.1: Ribulose 1,5-bisphosphate carboxylase/oxygenase from Synechococcus PCC6301 (1RBL) (Copyright; author via source). Click the image for a popup or use this external link (long load time): https://structure.ncbi.nlm.nih.gov/i...pxLGgEKR5gCYK8

This structure is a hetero 16-mer of 8 small chains and 8 large chains. The small chains are in gray and the large ones in differing colors. Each large subunit contains a bound reaction intermediate analog 2-carboxyarabinitol 1,5-bisphosphate.

This chapter section will focus on improving and designing new ways to capture carbon dioxide as one way to reduce its concentration in the atmosphere. Don't lose sight of the fact that the best way to deal with anthropogenic climate change is to stop putting CO_2 in the atmosphere from burning fossil fuels.

NATURALLY OCCURRING PATHWAYS TO FIX CARBON

(Much of this immediate section derives from the following reference: Natural carbon fixation. Sulamita Santos et al., Natural carbon fixation and advances in synthetic engineering for redesigning and creating new fixation pathways, Journal of Advanced Research, Volume 47, 2023, Pages 75-92, ISSN 2090-1232, https://doi.org/10.1016/j.jare. Creative Commons license

There are six naturally occurring pathways that fix carbon. These are illustrated in Figure 32.16.2 below.

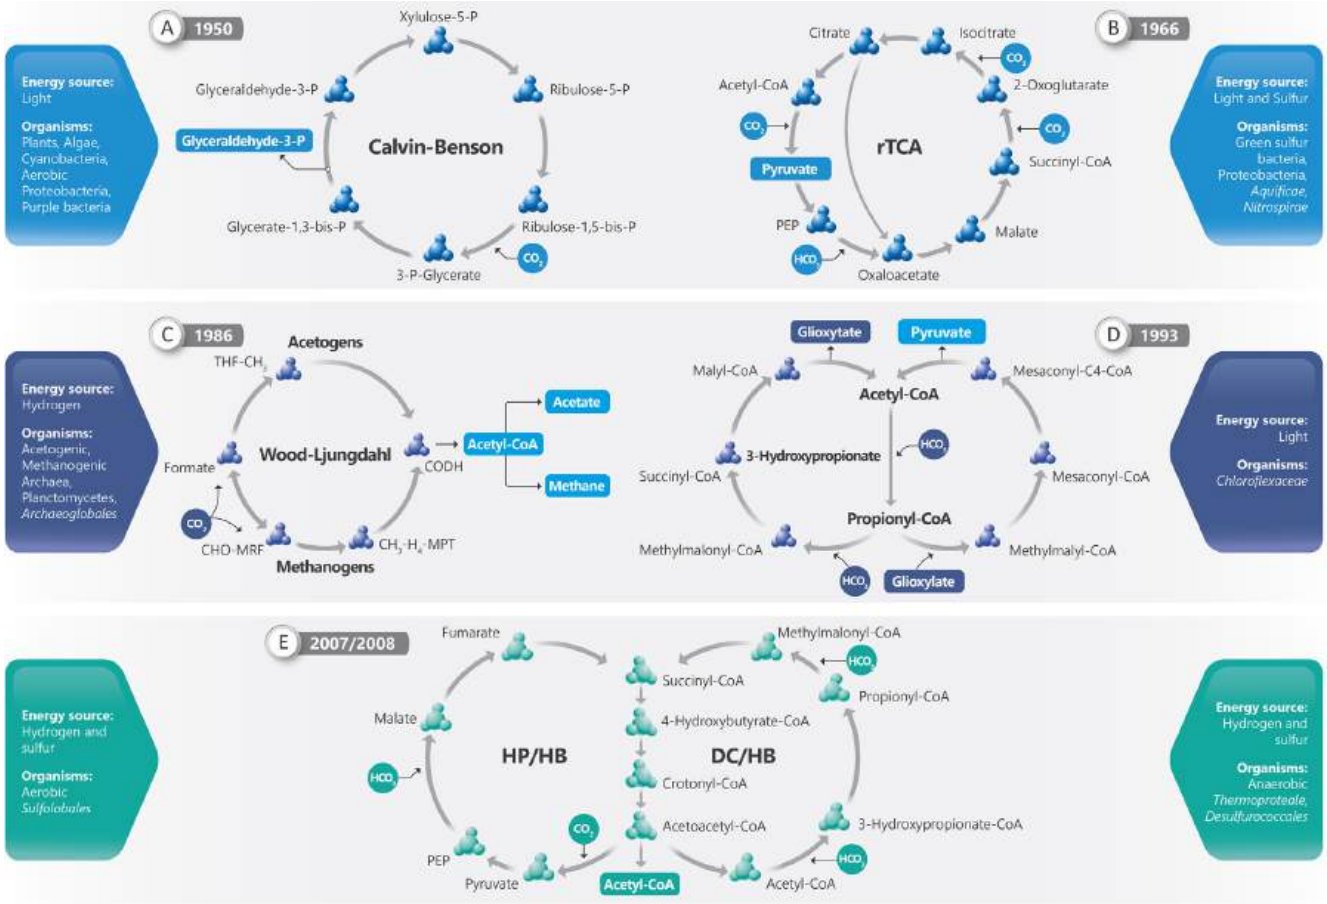

Figure 32.16.2: Natural carbon fixation. Sulamita Santos et al.,ibid.

Panel (A) shows the CBB cycle which we discussed in great detail in Chapter 20.4. Here are the enzymes: ribulose-1,5-bisphosphate carboxylase/oxygenase, 3-phosphoglycerate kinase, glyceraldehyde-3-phosphate dehydrogenase, ribulose-phosphate epimerase.

Panel (B) shows the reverse (reductive)-TCA cycle which we discussed in Chapter 16.4 in the section on the α-ketoacid pathway - A primordial, prebiotic anabolic "TCA-like" pathway. The enzymes include ATP-citrate lyase, malate dehydrogenase, succinyl-CoA synthetase, ferredoxin (Fd)-dependent-2-oxoglutarate synthase, isocitrate dehydrogenase, PEP carboxylase.

Panel (C) shows the Wood–Ljungdahl (or reductive Acetyl-CoA) cycle which we discussed in Chapter 30.1. At the top of the pathway are the acetogens Archaea and at the bottoms are the methanogens Archaea. The enzymes include MPT-methylene tetrahydromethopterin, MFR-methanofuran, THF, tetrahydrofolate.

Panel (D) shows the 3-hydroxypropionate (3HP) cycle. The enzymes include acetyl-CoA carboxylase, propionyl-CoA carboxylase, methylmalonyl-CoA epimerase, succinyl-CoA:(*S*)-malate-CoA transferase, trifunctional (*S*)-malyl-CoA, -methylmalyl-CoA, mesaconyl-CoA transferase, mesaconyl-C4-CoA hydratase.

Panel (E) shows the hydroxypropionate/4-hydroxybutyrate (HP/HB) and the dicarboxylate/4-hydroxybutyrate (DC/HB) cycles. The enzymes include pyruvate synthase, PEP-carboxylase, malate dehydrogenase, fumarate hydratase/reductase, acetyl-CoA/propionyl-CoA carboxylase, 3-hydroxypropionate-CoA ligase/dehydratase, methylmalonyl-CoA mutase, succinyl-CoA reductase, 4-hydroxybutyrate-CoA ligase, crotonyl-CoA hydratase, acetoacetyl-CoA-ketothiolase.

Table 32.16.1 below shows a comparative description of the natural and synthetic carbon fixation pathways.

Pathway	Organisms	Energy Source	Input	Output	Reductants	Key Enzyme
Calvin-Benson (N)	Plants, Algae, Cyanobacteria, Aerobic Proteobacteria, Purple bacteria	Light	3 CO_2, 9 ATP,6 NAD(P)H	Glyceraldehyde-3-phosphate	NAD(P)H	RuBisCO
rTCA (N) *	Green sulfur bacteria, Proteobacteria, Aquificae, Nitrospirae	Light and Sulfur	2 CO_2, 2 ATP,4 NAD(P)H	Pyruvate	NAD(P)H & ferredoxin	2-Oxoglutarate synthase, Isocitrate dehydrogenase
Wood–Ljungdahl (N) *	Acetogenic, Methanogenic Archaea, Planctomycetes, Sulfate. Archaeoglobales,	Hydrogen	2 CO_2, 1 ATP, 4 NAD(P)H	Acetyl-CoA	Ferredoxin	NAD-independent formate dehydrogenase, Acetyl-CoA synthase-CO dehydrogenase
3-HP (N)	Chloroflexaceae	Light	3 HCO , 5 ATP, 5 NAD(P)H	Pyruvate	NAD(P)H	Acetyl-CoA carboxylase, Propionyl-CoA carboxylase
HP/HB (N)	Aerobic Sulfolobales	Hydrogen/sulfur	2 HCO , 4 ATP, 4NAD(P)H	Acetyl-CoA	NAD(P)H	Acetyl-CoA-Propionyl-CoA carboxylase
DC/HB (N) *	Anaerobic Thermoproteale,Desulfurococcales	Hydrogen/sulfur	1 CO_2, 1 HCO , 3ATP, 4 NAD(P)H	Acetyl-CoA	NAD(PH &Ferredoxi	Pyruvate synthase, PEP carboxylase
RHP (CN)	Methanospirillum hungatei	Hydrogen	CO_2, 3 ATP, 2 NAD(P)H	Gluconeogenesis and glycolysis	NAD(P)H	RuBisCO
Natural Reductive Glycine (CD)	Candidatus phosphitivorax, anaerolimiDesulfovibrio desulfuricans	Phosphite	CO_2, ATP, NAD(P), H	Formate/ Pyruvate	NAD(P)H &Ferredoxi	CO_2-reducing formate dehydrogenase(fdhAB)
Reverse Otca (CD)	Desulfurella acetivorans	Hydrogen	CO_2, ATP, NAD(P) H	Acetyl-CoA	Ferredoxin	Citrate synthase
CETCH (S)	Theoretical	–	2 CO_2, 2 ATP, 3 NAD(P)H	Glyoxylate	NAD(P)H	CoA- dependent carboxylase
Reductive Glycine (S)	Demonstrated in E. coli as host	–	CO_2, NADH	Pyruvate	Ferredoxin	Glycine cleavage system
Synthetic malyl-CoA-glycerate (S)	Demonstrated in E. coli and Synechococcus elongatus PCC7942 host	–	CO_2, 3 ATP, 3 NADH	Acetyl-CoA	NAD(P)H	PEP-carboxylase, RuBisCO

Sulamita Santos et al., Natural carbon fixation and advances in synthetic engineering for redesigning and creating new fixation pathways, Journal of Advanced Research,
Volume 47, 2023, Pages 75-92, ISSN 2090-1232, https://doi.org/10.1016/j.jare.

Plants and microorganisms that are photoautotrophic fix CO_2 by the Calvin cycle using NADPH and ATP and produce O_2. Some anerobic photosynthetic bacteria don't produce O_2. In **chemolithoautotrophic** microorganisms, energy sources (i.e. electron donors like H_2, H_2S, sulfur, Fe^{2+}, nitrite and NH_3 found in bedrock - the lithosphere) other than NADPH, ATP and light can be used to drive CO_2 uptake. For **chemoorganotropic** microbes, reduced organic molecules such as sugars and amino acids serve as electron (donor) sources.

Genetic engineering and synthetic biology are now employed to improve preexisting enzymes and to create whole new pathways for carbon capture.

As a simple example, people are trying to engineer carbonic anhydrase, used to convert CO_2 to HCO_3^- for transport to the lung where it is converted back to CO_2 and released. It is a diffusion-controlled enzyme with a k_{cat}/K_M reported as high as 8×10^7 $M^{-1}s^{-1}$, so how can it be made better? One way is to engineer thermal stability into the enzyme. A critical problem for the forward reaction is that the enzyme is readily reversible so bicarbonate, HCO_3^-, is a competitive inhibitor of the forward reaction. In addition, the enzyme can be engineered to be more stable at higher pH to allow product (HCO_3^-) removal by the addition of OH^- in a process of mineralization, as shown in the equation below,

$$HCO_3^- + OH^- \rightarrow CO_3^{2-} + H_2O$$

where the carbonate anion can precipitate in the presence of divalent cations like Ca^{2+}, Mg^{2+} and Fe^{2+}. Here is a link to a Literature-based Guided Assessment on thermoengineering of carbonic anhydrase.

Now let's explore the use of new pathways created by synthetic biology to capture carbon. Some of these pathways are engineered to produce reactants (feedstocks) for biofuels, which we discussed in-depth in previous Chapter 32 sections, and chemical synthesis. We'll

focus on three: the CETCH pathway, the reductive glyoxylate and pyruvate synthesis (rGPS) cycle, and the malyl-CoA-glycerate (MCG) pathway.

CETCH (Crotonyl-CoA-EThylmalonyl-CoA-4Hydorxybutyl-CoA) pathway

To engineer a new pathway, Swander et al identified efficient carboxylases from known ones (acetyl-CoA carboxylase, Rubisco, propionyl-CoA carboxylase, PEP carboxykinase, 2-oxoglutarate carboxylase, and pyruvate carboxylase), all of which we have discussed in previous chapters. They created new pathways, calculated free energy and ATP/NADPH requirements, and then optimized the pathways. They chose CoASH–dependent carboxylases and enoyl-CoA carboxylases/reductases. Figure 32.16.3 below shows the reaction of one key carboxylase.

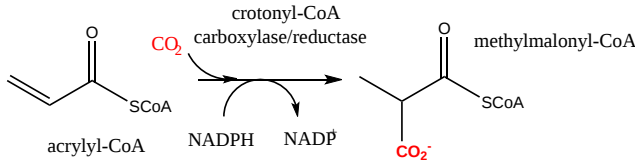

Figure 32.16.3: Carboxylase used in the CETCH pathways to fix CO_2

The pathway was named CETCH (**C**rotonyl-CoA-**ET**hylmalonyl-**C**oA-4**H**ydorxybutyl-CoA) which catalyzes this next reaction in cell lysates (in vitro):

$2CO_2 + 3NAD(P)H + 2ATP + FAD \rightarrow$ glycolate $+ 3NAD(P) + 2ADP + 2P_i + FADH_2$

The rate of CO_2 fixation by the CETCH pathways was similar to the rate of the Calvin cycle rates in cell lysates.

In a more expansive approach, Gleizer used synthetic biology to change E. Coli from a heterotroph to an autotroph in which its biomass (carbon reservoir) came from CO_2. Formate (HCO_2^-) was used as a source of reducing power (electrons) as it was oxidized by an added formate dehydrogenase to produce NADH for the autotropic fixation of CO_2 through the addition of Calvin cycle enzymes. Using isotopically labeled $^{13}CO_2$ to follow carbon flow, after 10 generations and evolution, the cells were completely autotrophic through fixation of CO_2. To accomplish this, they knocked out genes for phosphofructokinase (glycolysis) and glucose-6-phosphate-dehydrogenase (pentose-phosphate pathway) to impair these main metabolic pathways, and added carbonic anhydrase (to interconvert CO_2 and HCO_3^-) as well as Rubisco and phosphoribulokinase. As formate was ultimately converted to CO_2, the net effect was not exactlycarbon neutral but could be if atmospheric CO_2 was used to make formate (for a feedstock) by electrochemical reduction.

Figure 32.16.4 below shows the next reactions in the synthetic E. Coli autotrophs.

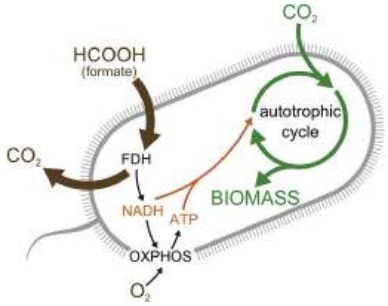

Figure 32.16.4: Schematic Representation of the Engineered Synthetic Chemo-autotrophic *E. coli.* Shmuel Gleizer et al., Conversion of Escherichia coli to Generate All Biomass Carbon from CO2, Cell, 179 (2019). https://doi.org/10.1016/j.cell.2019.11.009. Creative Commons license.

CO_2 (green) is the only carbon source for all the generated biomass. The fixation of CO_2 occurs via an autotrophic carbon assimilation cycle. Formate is oxidized by a recombinant formate dehydrogenase (FDH) to produce CO_2 (brown) and NADH. NADH provides the reducing power to drive carbon fixation and serves as the substrate for ATP generation via oxidative phosphorylation (OXPHOS in black). The formate oxidation arrow is thicker than the CO_2 fixation arrow, indicating a net CO_2 emission even under autotrophic conditions.

Figure 32.16.5 shows that almost 100% of carbon atoms after many generations are labeled with ^{13}C (detected by mass spec analysis) derived from $^{13}CO_2$.

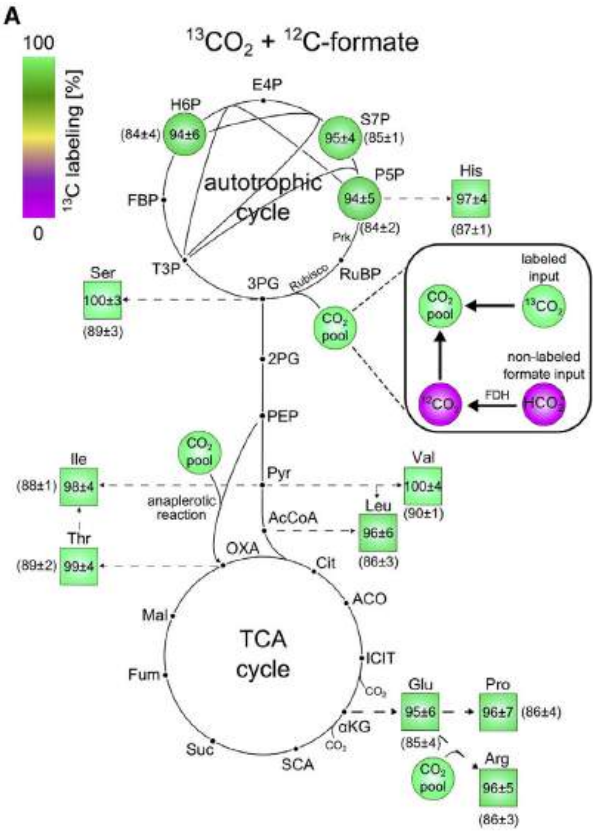

Figure 32.16.5: Isotopic Labeling Experiments Using ^{13}C Show that All Biomass Components Are Generated from CO_2 as the Sole Carbon Source. Gleizer et al., ibid.

(A) Values are based on LC-MS analysis of stable amino acids and sugar-phosphates. The fractional contribution of $^{13}CO_2$ to various protein-bound amino acids and sugar-phosphates of evolved cells grown on $^{13}CO_2$ and naturally labeled formate showed almost full ^{13}C labeling of the biosynthesized amino acids. The numbers reported are the ^{13}C fraction of each metabolite, taking into account the effective $^{13}CO_2$ fraction out of the total inorganic carbon (which decreases due to unlabeled formate oxidation to CO_2). The numbers in parentheses are the uncorrected measured values of the ^{13}C fraction of the metabolites.

Synthetic reductive glyoxylate and pyruvate synthesis (rGPS) cycle and the malyl-CoA-glycerate (MCG) pathways

These pathways were created to synthesize acetyl-CoA, pyruvate, and malate from CO_2 in cell-free systems to free the system from cell growth and regulation requirements, and to make it insensitive to oxygen. These molecules are also intermediates in the created cycle, which could operate continuously for hours at the same or greater rates of CO_2 fixation compared to photosynthesis. The cycle is shown in Figure 32.16.6 below.

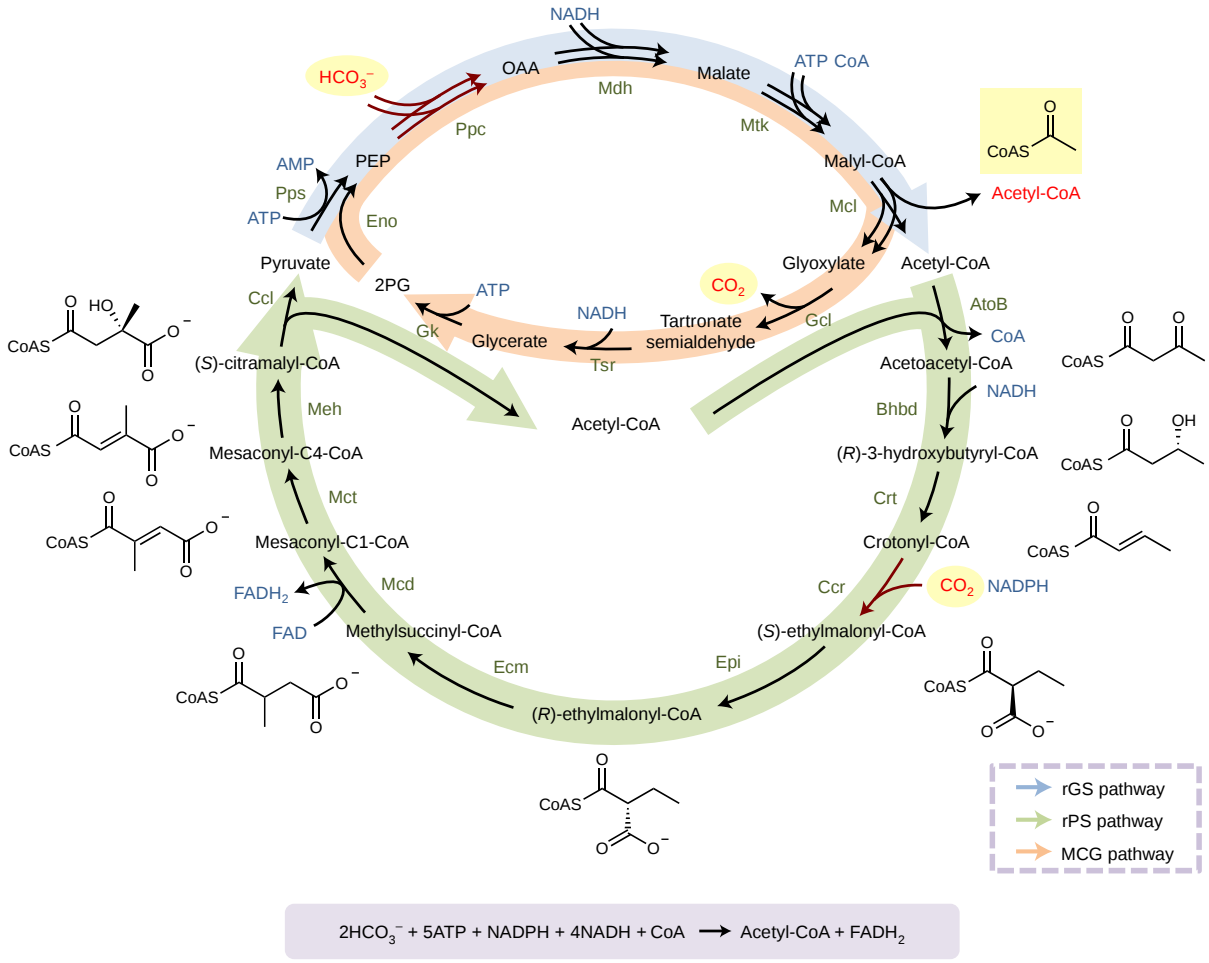

Figure 32.16.6: The rGPS–MCG cycle with acetyl-CoA as the end product. Luo, S., Lin, P.P., Nieh, LY. *et al*. A cell-free self-replenishing CO_2-fixing system. *Nat Catal* **5**, 154–162 (2022). https://doi.org/10.1038/s41929-022-00746-x . The rGPS cycle consists of the reductive glyoxylate sythesis (rGS) pathway (blue) and the reductive pyruvate synthesis (rPS) pathway (green). The malyl-CoA-glycerate (MCG) pathway (orange) consists of the rGS pathway and the glycerate pathway. The red arrow indicates the carboxylation reaction. Gcl, glyoxylate carboligase; Tsr, tartronate semialdehyde reductase; Gk, glycerate 2-kinase; Eno, enolase and 2PG, 2-phospho-d-glycerate

Microbial electrosynthesis from CO_2

We mentioned above that if the formate used in the CETCH pathway could be synthesized through electrochemistry from CO_2, then the pathway would be truly carbon neutral. In fact, new microbial electrochemical methods are being designed to synthesize a variety of small molecules that could serve as feedstocks for chemical synthesis in industry. The carbon in CO_2 has an oxidation number of +4 while the carbon in formic acid has an oxidation number of +2. Hence two electrons must be added by electrochemically to make the CETCH pathway truly carbon neutral. Bigger electrochemical reductants of CO_2 require more electrons. Figure 32.16.7 below shows how key feedstocks could be made electrochemically from CO_2 and how they are usually made in industry.

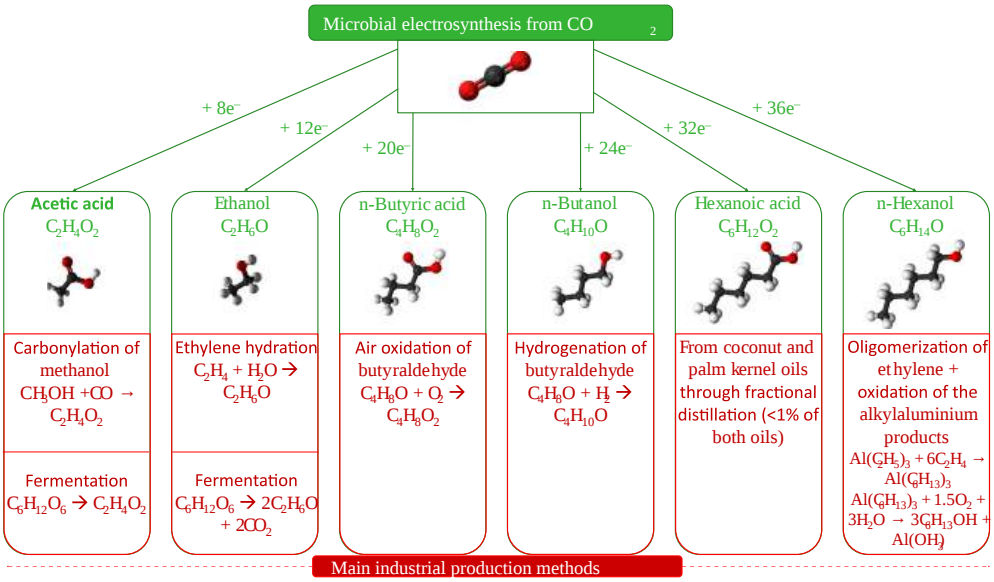

Figure 32.16.7 below. : **Overview of the Main Products Formed from Microbial Electrosynthesis (MES) From CO_2, Along With the Main Industrial Methods to Manufacture These Products.** Jourdin et al., Trends in Biotechnology, April 2021, Vol. 39, No. 4 https://doi.org/10.1016/j.tibtech.2020.10.014. Creative Commons Attribution (CC BY 4.0)

These feedstocks could be made by reductive electrosynthesis using electrons from the oxidation of water though electrolysis. Released electrons (oxidation number of O in water is -2 and 0 in O_2) move to a biocathode to reduce CO_2, as illustrated in Figure 32.16.8 below.

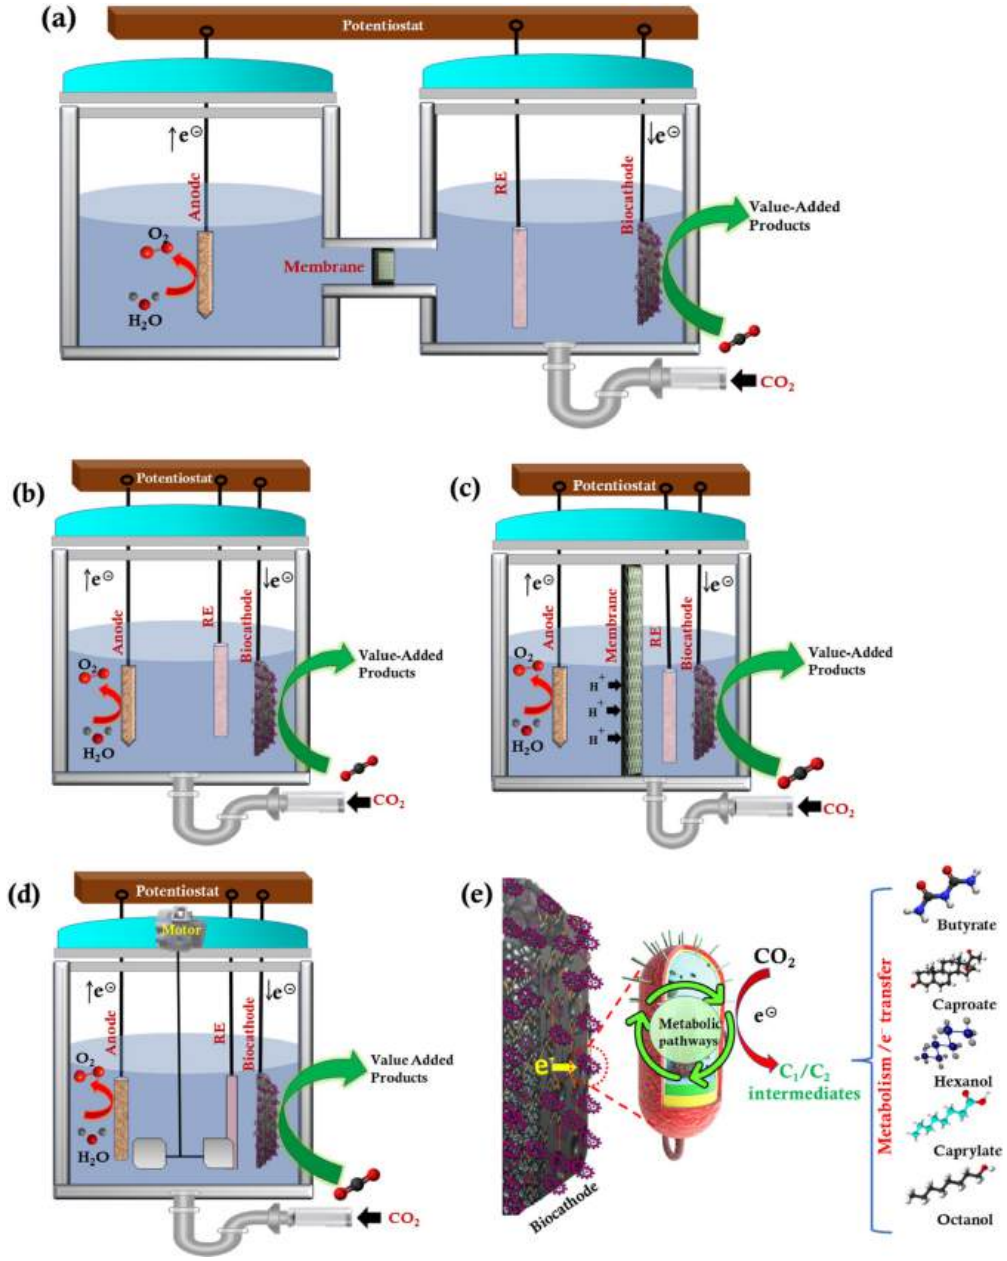

Figure 32.16.8: Reactor configurations for MES-based CO_2 conversion: (a) H-type, (b) single chamber, (c) dual chamber, (d) continuous stirred tank, and (e) schematic of electron transfer mechanism. **G. S. Lekshmi et al., Microbial electrosynthesis: carbonaceous electrode materials for CO_2 conversion.** *Mater. Horiz.*, 2023, **10**, 292-312. DOI: 10.1039/D2MH01178F. The biocathode consists of a biofilm of cells printed onto a graphene, graphite, or carbon nanotube-laden support (all carbonaceous).

32.17: FIXING NITROGEN FIXATION

Search Fundamentals of Biochemistry

NITROGEN FIXATION

We spent most of Chapter 22.1 discussing the biochemistry of nitrogenase which fixes the stable molecule N_2 to form NH_3/NH_4^+. It's a very complicated reaction conducted by symbiotic microbes (prokaryotes) that fix N_2 for plants. The world uses the Haber-Bosch process to produce over 100 million metric tons of nitrogen fertilizer that supports half of the world's population's food supply. Only about half of the ammonium added to soil is taken up by plants. The rest is released into waterways or used by microbes, which can produce from it the potent greenhouse gas nitrous oxide (N_2O). It has a 300x greater effect than CO_2 based on weight. The oxidation number of N in NH_3 is -3 and in N_2O it is +1 showing that the NH_3 can be oxidatively metabolized for energy production by the microbes. Also, excess NH_4^+ goes into waterways and leads to eutrophication, the overproduction of algae and plankton, which depletes O_2 from the waters and kills other organisms.

N_2O emissions have increased dramatically since 1850, as shown in the interactive graph from Our World in Data in Figure 32.17.9 below.

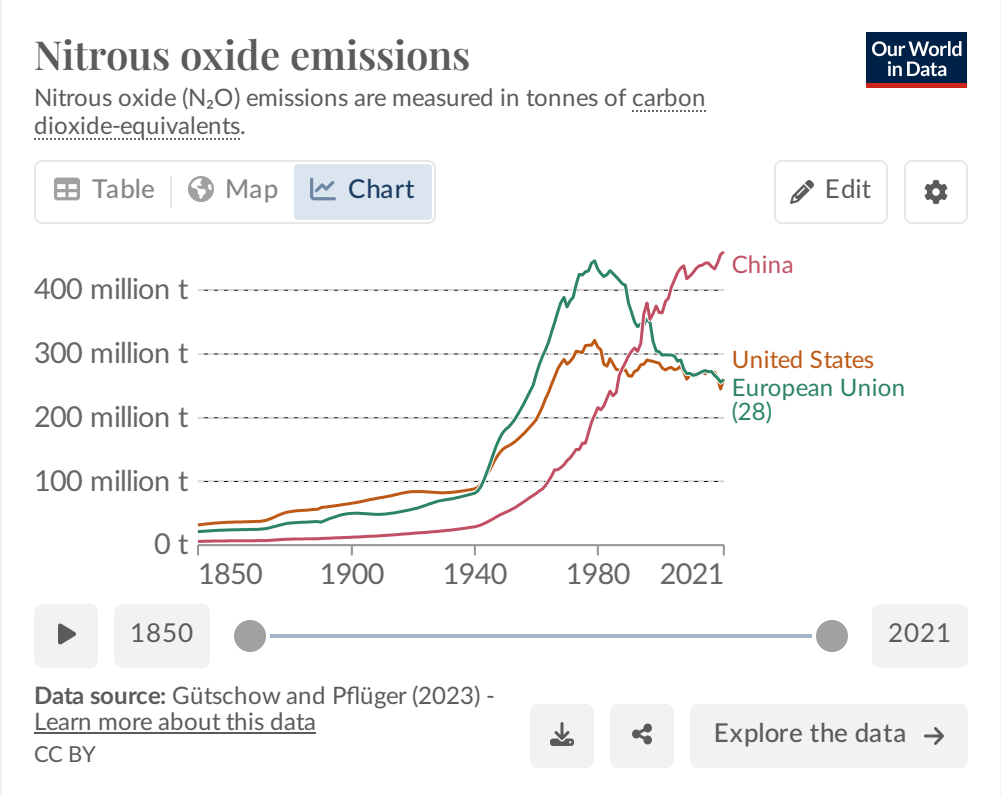

Figure 32.17.9: Our World in Data. https://ourworldindata.org/grapher/n...ions?tab=chart

So what can we do to "fix" nitrogen fixation to reduce our reliance on the Haber process and its collateral climate effects? Perhaps we could use mutagenesis to make nitrogenase a better and more efficient enzyme. That would prove very difficult given the complexity of both the enzyme and the mechanism of N_2 conversion to NH_3 that requires many metal ion cofactors. A better alternative would be to express nitrogenase in plants so they could synthesize their own nitrogen fertilizer!

Genes of Nitrogen Fixation

The catalytic nitrogenase enzyme complex is encoded by three genes:

- nifH gene for the subunit **Nitrogenase iron protein 1** (also called Nitrogenase component II, and Nitrogenase reductase). It is a homodimer that binds one [4Fe-4S] cluster per dimer.
- nifD gene for the subunit **Nitrogenase molybdenum-iron protein alpha chain** (also called Dinitrogenase and Nitrogenase component I). It catalyzes the key enzymatic reactions along with its partner nifK as part of a heterodimer. It binds one [8Fe-7S] cluster per heterodimer with nifK and binds 1 [7Fe-Mo-9S-C-homocitryl] cluster per subunit.
- nifK gene for the subunit **Nitrogenase molybdenum-iron protein beta chain** (also called Dinitrogenase and Nitrogenase component I). With its partner nifD, it catalyzes the key enzymatic reactions as part of a heterodimer with nifD. It binds one [8Fe-7S] cluster per

heterodimer with nifD and binds 1 [7Fe-Mo-9S-C-homocitryl] cluster per subunit.

The nitrogenase enzyme complex has regulatory proteins as well:

- nifA - **Nif-specific regulatory protein** required for activation of most nif operons. It senses N_2. If there is insufficient quantities of N_2, the protein NtrC activates NifA expression which activates the rest of the genes.
- nifB - **FeMo cofactor biosynthesis protein NifB** (also called FeMo-cofactor maturase NifB, Nitrogenase cofactor maturase NifB, and radical SAM assemblase NifB).
- nifL - **Nitrogen fixation regulatory protein** required for the inhibition of NifA activity (i.e. nitrogenase formation) in response to oxygen and low level of fixed nitrogen.
- nifE - **Periplasmic [NiFe] hydrogenase small subunit**.
- NifM - a possible peptidyl prolyl *cis-trans* isomerase (i.e. a protein chaperone) which helps in the folding of NifH.

Figure 32.17.10 below shows a summary of these gene products.

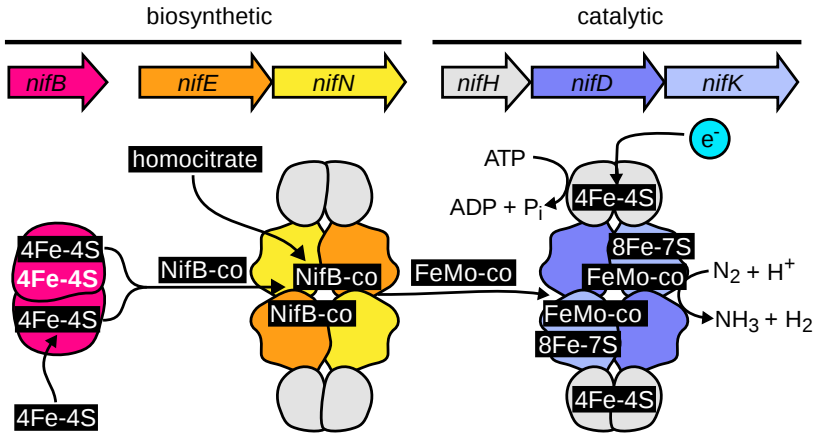

Figure 32.17.10 : Minimum set of *nif* genes essential for nitrogen fixation with molybdenum-iron nitrogenase. EMILY M. BENNETT et al., ***BIODESIGN RESEARCH.*** 10 Jan 2023, Vol 5, https://spj.science.org/doi/10.34133/bdr.0005 . Creative Commons Attribution License 4.0 (CC BY 4.0).https://doi.org/10.34133/bdr.0005

The stoichiometry depicted has not been adjusted. NifB contains one catalytic cluster (shown in white) and 2 substrate [4Fe-4S] clusters that react to produce the NifB cofactor. NifEN matures the NifB cofactor producing the FeMo cofactor. The molybdenum-iron (MoFe) nitrogenase (NifHDK) contains the FeMo cofactor at its active site. Electron donors transfer single electrons to the [4Fe-4S] cluster at the interface of the NifH homodimer. Electrons are moved from the [4Fe-4S] cluster into the active site of nitrogenase using energy produced by ATP hydrolysis by NifH. A minimum of 8 electrons are used to reduce each molecule of N_2.

It would be especially important to express nitrogenase in the main cereal food crops (rice, corn, and wheat) which get their nitrogen from soil microbes (in contrast to legumes, which contain nitrogen-fixing bacteria in nodules in their roots). It's a daunting task given the complexity of the protein complex, its metal cofactors, their inhibition by O_2, and the multiple genes required for nitrogenase regulation. Ideally, the relevant gene clusters could be moved into a chlorplast which is evolutionarily derived from bacteria so the gene regulation system might be more suitable. It also has low O_2 levels at night. However, O_2 is produced in chloroplasts, which is problematic given the sensitivity of nitrogenase to O2.

Using synthetic biology, *Saccharomyces cerevisiae* has been engineered to express the NifDK nitrogenase tetrameric protein in their mitochondria (after post-translational import). Yeast is a model organism and tools have been developed for synthetic biology experiments using yeast, so much can be learned that could apply to other eukaryotic organisms like plants. Mitochondria have high O_2 consumption (as opposed to production as in the chloroplast) and the ability to synthesize bacterial-type iron–sulfur clusters. The Nif gene clusters were engineered into the XV chromosome as shown in Figure 32.17.11 below.

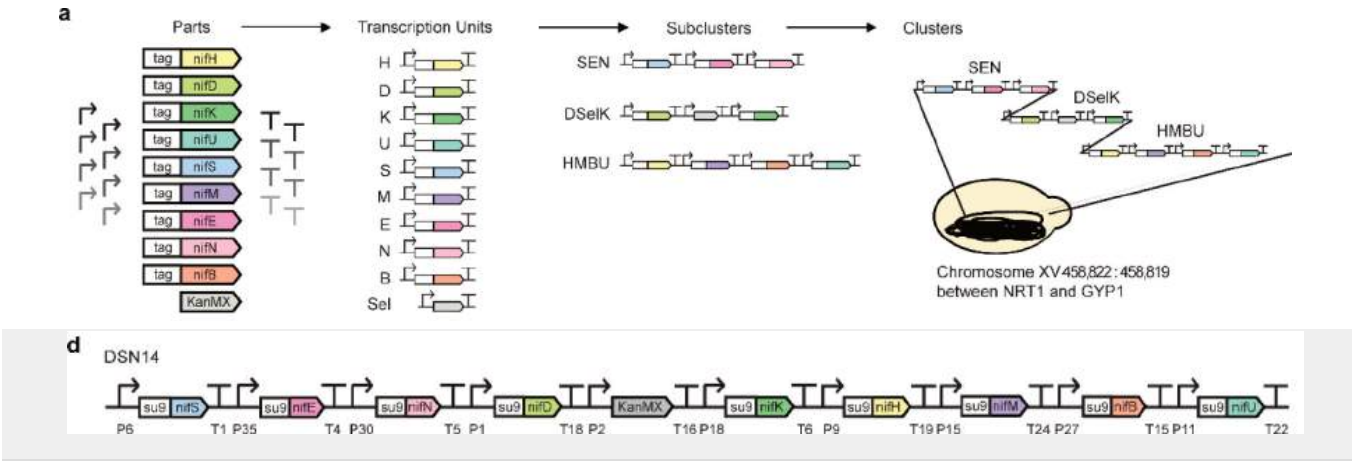

Figure 32.17.11 : nif gene assembly in yeast. *Buren et al., ACS Synth. Biol.* 2017, 6, 6, 1043–1055. https://doi.org/10.1021/acssynbio.6b00371. **CC-BY license**

Panel (a) shows the assembly strategy for transcription units, subclusters, and full clusters inserted by homologous recombination in the genome of *S. cerevisiae*. Panel (d) shows a disgram of *nif* gene organization in DSN14, a strain of *S. cerevisiae.*

Nitrogenase activity has also been functionally expressed in transgenic rice containing the NifH with a [4Fe-4S] cluster from *Hydrogenobacter thermophilus* and NifM (a peptidyl prolyl *cis-trans* isomerase from *Azotobacter vinelandii)* which helps NifH fold. They were correctly targeted to the mitochondria which again minimizes O_2 oxidative damage to the metal ion cofactors. The purified protein was able to transfer electrons to the MoFe protein (NfiDK dimer) but did so poorly. It also assisted in the assembly of the FeMo cofactor. However, the [4Fe-4S] cluster occupancy in the protein was poor. However purified protein was also able to reduce acetylene, HC≡CH (an alternative substrate similar to N≡N) after the addition of purified NifDK.

Many steps have to be optimized to create a functional nitrogenase in plants like rice, corn, and wheat. For example, mitochondrial-expressed NifD is readily cleaved by a mitochondria endoprotease. Some NifD subunits are more resistant to proteolysis and a single amino acid change (Y100Q) leads to enhanced stability on the protein. AI will likely be extremely useful in maximizing the expression of nitrogen in crop plants.

SYNTHETIC BIOLOGY TO EXPRESS NITROGENASE IN BACTERIA

Bacteria can express nitrogenase that can fix atmospheric N_2 but they won't work with the critical cereal crops unless the bacteria can interact with roots in the "rhizosphere", the layers of dirt intimately in contact with roots. This life in this area is often called the **holobiont**, which consists of the plant host and all species interacting with it in a symbiotic relationship. The metabolism in the holobiont is complex. For example, plant carbohydrates are used by other organisms in the holobiont. It's similar in a way to the gut biome, which consists of an ecosystem of human and microbial cells.

Bacteria have now been engineered that express nitrogenase AND interact with corn roots to fix N_2. The cells are derivatives of γ-proteobacterium (KV137), found on corns roots and which can fix N_2. They have been engineered to turn nitrogenase genes on when N_2 fixation is needed. The engineered bacteria is added to liquid fertilizer, reducing the need for chemical fertilizer by 25 lb/acre) and at the same time increasing yields. This bacterial-based fertilizer does not wash into waterways with its concomitant negative environmental effects. Likewise, no N_2O is produced on microbial metabolism of excess fertilizers, which decreases the release of this potent greenhouse gas. In 2021 it was used on 3 million acres of corn.

One problem with the use of biological N_2 microbes in agricultural settings is that high levels of chemical fertilizers can effectively inhibit microbial N_2 fixation, which is regulated (as mentioned above) to shut down if nitrogen is bioavailable. Still, bacteria that fix N_2 can produce up to 10% of the nitrogen requirement. Genetic engineering is needed to overcome this inhibition. Such bacteria are **diazotrophs** as they can fix N_2 and grow without exogenous sources of N_2. Rhizobia are one example. which can fix N_2 in the nodules of legumes. The diazotroph isolated from corn roots and mentioned above, Kv137, was gene-edited to produce a modified strain (Kv137-1036) that fixes N_2 without inhibition by applied nitrogen fertilizers.

The Kv137 strain has nifA and nifL genes and proteins which, as described above, regulate the expression of nitrogenase based on the need for nitrogen. These two genes are on one operon under the control of a single promoter. nifL was replaced with another promoter which removes the down-regulation of nifA since no nifL was present. This allowed the expression and activity of nitrogen even in the presence of exogenous fertilizer.

Figure 32.17.12 below shows that Kv137-1036 strain (red dots) does colonize corn roots.

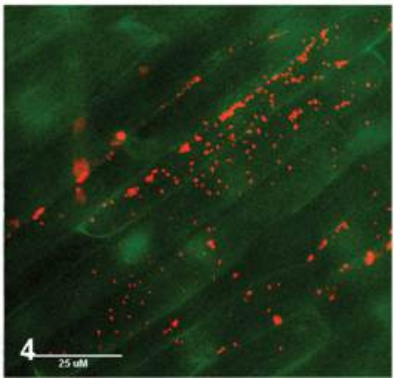

Figure 32.17.12 : Commercial efficacy of strain Kv137-1036 - Colonization of corn roots by microbes (red) after germination. 32.18: TURNING TREES INTO PLEXIGLASS - SYNTHETIC BIOLOGY FOR PRODUCTION OF GREEN FOODS AND PRODUCTS

INTRODUCTION

Manufacturing of any kind is energy-consuming and environmentally damaging and contributes to climate change through the release of CO_2 and other pollutants. A manufactured item has a lifetime after which it must be disposed of in a fashion that often involves little recycling. A circular economy in which a used product is always recycled for further use if done well, would be highly beneficial for the environment.

Synthetic biology as a field seeks to genetically alter and redesign organisms to produce traditional or novel products in more sustainable ways with less energy input and polluting output. Although it is a nascent field, well-known products are binding produced through its use. We will explore several products made through synthetic biology as well as several in which novel cells themselves are the products.

PRODUCTS FROM CELLS

Burgers by Impossible Foods

Agriculture has literally transformed the planet. About 50% of all land (other than deserts and ice shields and comprising an area equal to the Americas) is used for agriculture and most of that is for animal production. In the US, about 10% of all greenhouse gases derive from the agricultural sector. Similar estimates are made for global greenhouse gas emissions from the production of food, which include agriculture, land use change, and supply chain emissions (transport, packaging, food processing, retail, cooking, and waste).

Estimates show that wild mammals comprise only about 6% of the total mass of all mammals (including people, livestock, and pets) on the planet). In a parallel finding, the mass of "stuff" (plastics, metals, asphalt, concrete, etc) created by humans now exceeds the entire biomass of the planet!

Most of agricultural land is used to produce meat and milk for human consumption. Collectively, cattle by far require the most land use, as shown in the interactive graph of Our World In Data in Figure 32.18.1 below, which shows how many square meters are required to produce 1000 kcals (1000 cal in the dietary sense) of food from each food type listed. The graph is similar when the measure is land use per 100 grams of protein produced.

Figure 32.18.1: Land use of foods/1000 kcals. https://ourworldindata.org/land-use-diets

The number of animals slaughtered **each day** in the world is unbelievably high, as shown in Table 32.18.1 below.

cows	goats	sheep	pigs	ducks	chickens	fish
900,00	1.4 million	1.7 million	3.8 million	11.8 million	202 million	100's of millions

Table 32.18.1: Animals slaughtered each day for food. Max Roser (2023) - "How many animals get slaughtered every day?" Published online at OurWorldInData.org. Retrieved from: 'https://ourworldindata.org/how-many-...ered-every-day' [Online Resource]

If you consider greenhouse gas emissions all aspects of food products through the entire food chain, the number approached 25%. Other factors contributing to the emission of greenhouse gases and the environmental impact of food production are shown in Figure 32.18.2 below.

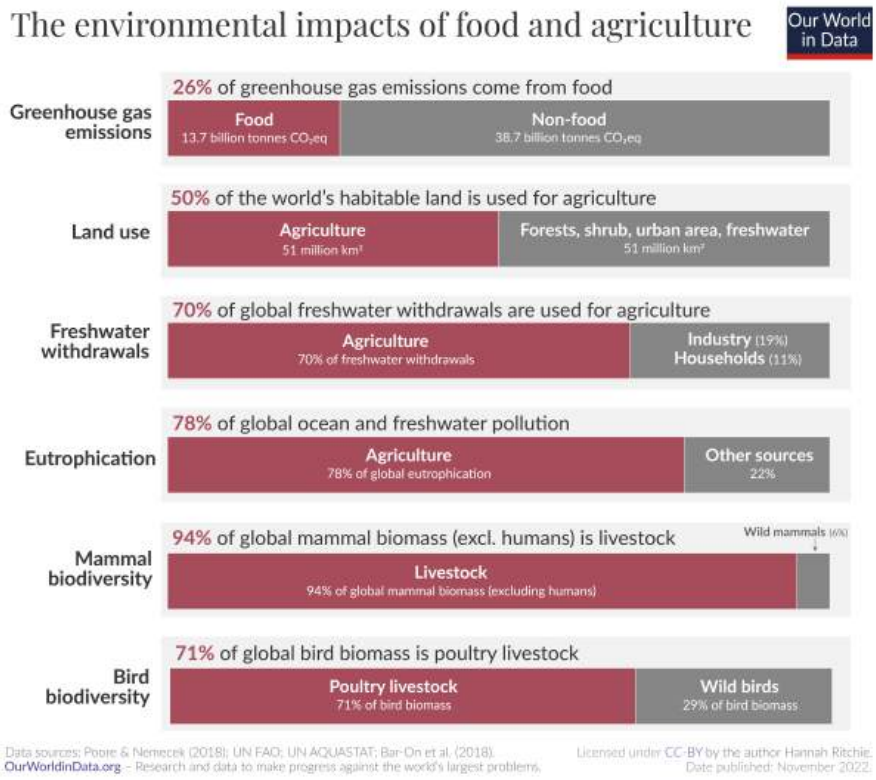

Figure 32.18.2: Environmental impact of food and agriculture

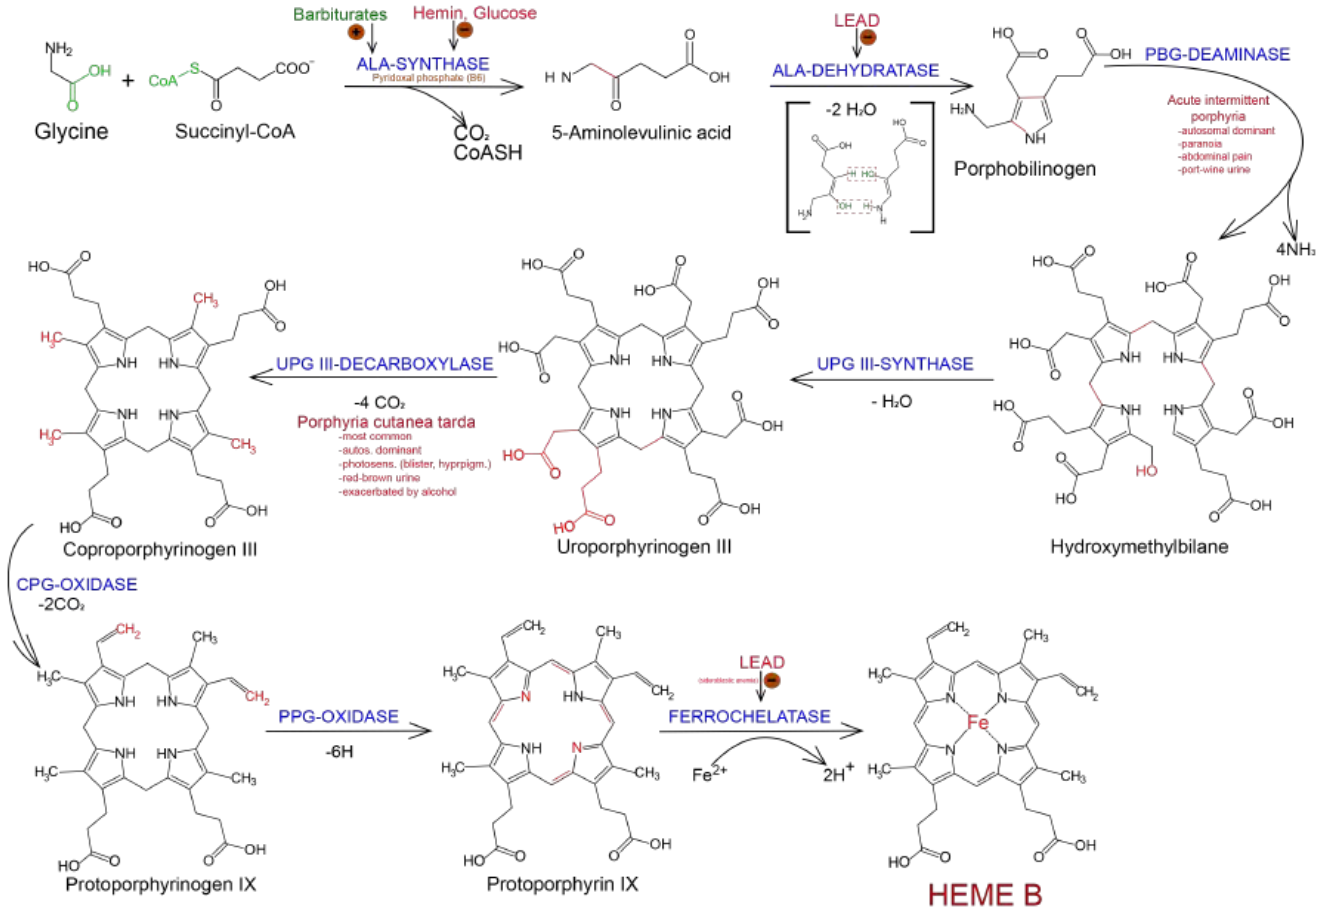
Making plant-based foods that taste more like meat, if people would eat them, could have a large effect on greenhouse gas emissions and climate change. One example is the Impossible Burgers and other similar meats from Impossible Foods. They have soy **leghemoglobin**, a monomeric heme-binding protein found in root nodules in legumes, to give the appearance and taste of blood in meat. As a single-chain heme-binding protein, it has a high affinity of O_2, similar to animal myoglobin. The high affinity derives from very high on-rates for binding O_2 (almost diffusion-controlled at around $2x10^8$ s^{-1}, and an off rate of around 20 s^{-1}. This high affinity keeps O_2 bound which would otherwise inhibit nitrogenase and nitrogen fixation by root-associated microbes. The heme is important for positive tastes when we eat red meat. Plant-based burgers containing leghemoglobin require much less land and lead to far lower greenhouse gas emissions.

Figure 32.18.3 shows an interactive iCn3D model of the alignment of sperm whale myoglobin (1MBO) and soy leghemoglobin (1BIN).

NCBI iCn3D Figure 32.18.3: Alignment of sperm whale myoglobin (1MBO, cyan) and soy leghemoglobin (1BIN, magenta). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...4pUi1S6qFtGn4A

The leghemoglobin in the Impossible burgers is produced in yeast so it can be scaled up easily. To produce leghemoglobin in yeast, large amounts of heme are required, which is also produced in the engineered cells on the introduction of the appropriate genes. The heme synthesis pathways (described in Chapter 22.3) for C4 (humans, animals, fungi, and purple non-sulfur phototrophic bacteria top) and C5

(archaea, plants, and other bacteria) for heme synthesis are shown in Figure 32.18.4 below. The succinyl-CoA is derived from the citric acid cycle.



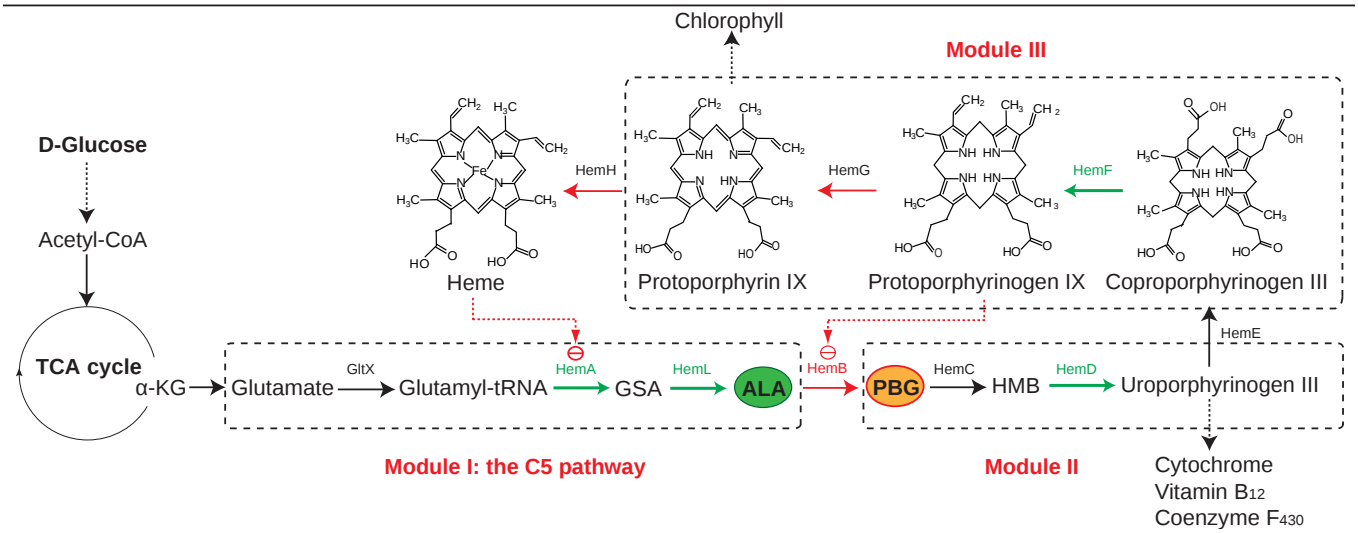


Figure 32.18.4: Top - heme synthesis pathway for C4 (humans, animals, fungi, and purple non-sulfur phototrophic bacteria top). Bottom - heme synthesis pathway for C5 (archaea, plants, and other bacteria). Heme biosynthetic pathway. Wikimedia Commonsile: Heme-Synthesis-Chemical-Details-Mirror (top) and Heme pathway in *E. coli*. Zhang, J., Kang, Z., Chen, J. *et al.* Optimization of the heme biosynthesis pathway for the production of 5-aminolevulinic acid in *Escherichia coli*. *Sci Rep* **5,** 8584 (2015). https://doi.org/10.1038/srep08584. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/ (bottom).

Note that both succinyl-CoA (C4 pathway) and α-ketoglutarate (C5 pathway) are derived from the citric acid cycle. The key precursor 5-aminolevulinate, ALA needs to be elevated, through engineering of the C4 or C5 pathways with the C5 pathways generally producing more ALA in engineered E. Coli.

Leghemoglobin from soy (species name Glycine max) can also be synthesized in the methylotrophic (uses methanol as a sole carbon source) yeast Pichia pastoris which is often used for recombinant protein expression. Three groups of enzymes are needed"

- (group 1: porphobilinogen synthase (PBGS)
- group 2: uroporphyrinogen III synthase (UROS), uroporphyrinogen III decarboxylase (UROD), coproporphyrinogen III oxidase (CPO)
- group 3: Ala synthase (ALAS), protoporphyrinogen oxidase (PPO), and ferrochelatase (FECH)

Transcription of these genes in P. pastoris can be controlled by the use of the methanol-induced alcohol oxidase (AOX1) promoter, which is often used to achieve high expression of recombinant proteins. Hence when the cells also contain two copies of leghemoglobin along with the rest of the genes, high levels of the protein were made.

A more detailed representation of the heme synthesis pathway is shown in Figure 32.18.5 below.

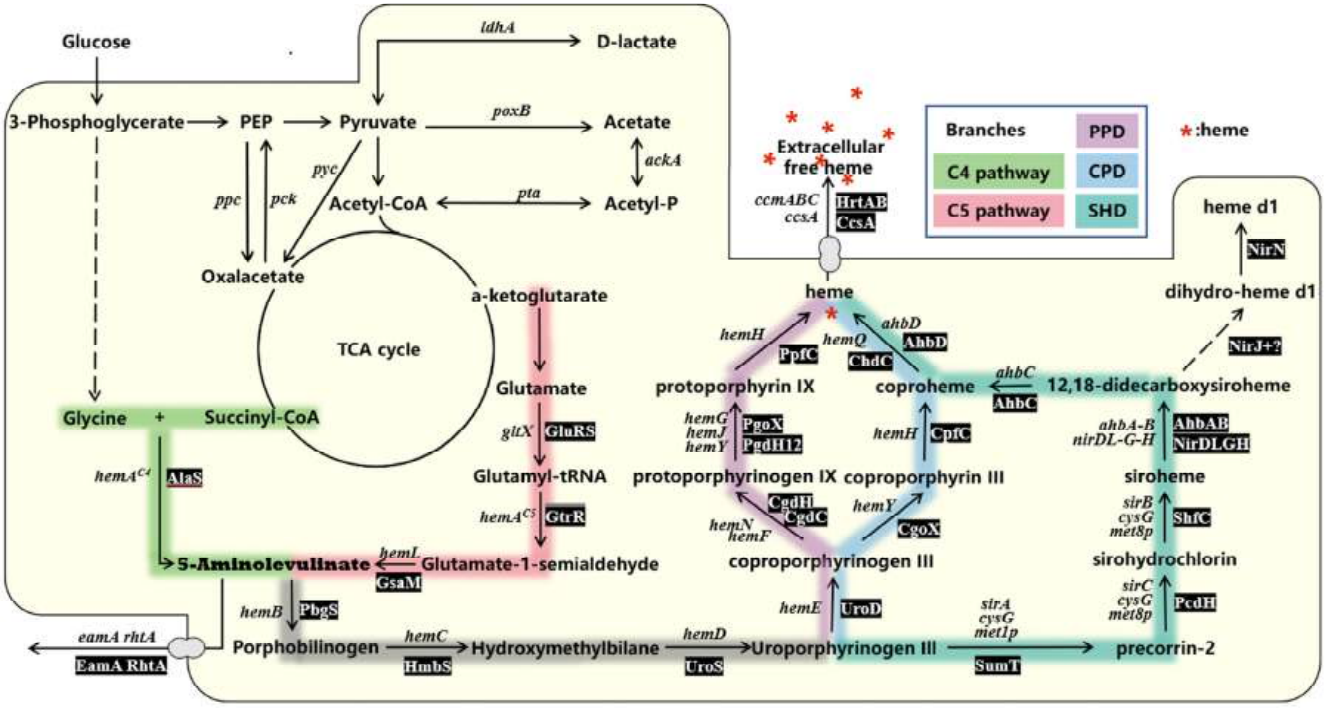

Figure 32.18.5: The biosynthetic pathway of heme. Su, H.; Chen, X.; Chen, S.; Guo, M.; Liu, H. Applications of the Whole-Cell System in the Efficient Biosynthesis of Heme. *Int. J. Mol. Sci.* **2023**, *24*, 8384. https://doi.org/10.3390/ijms24098384. Creative Commons Attribution (CC BY) license (**https://creativecommons.org/licenses/by/4.0/**)

The two biosynthetic pathways of 5-aminolevulinic acid (bolded to indicate its importance) are shown in green (C4 pathway) and red (C5 pathway). The three downstream synthetic pathways of heme are marked with blue (CPD), indigo (SHD) and purple (PPD). Solid lines indicate single reactions, and dashed lines indicate more than two reactions. The names of genes encoding the individual enzymes are in italics and some reactions have alternative genes. The abbreviations of the corresponding enzymes are shown in the grey rectangle. See **Table 1** for a list of names and abbreviations for heme synthesis enzymes

Figure 32.18.6 below complements this figure and shows the synthetic biology strategies to enhance heme production.

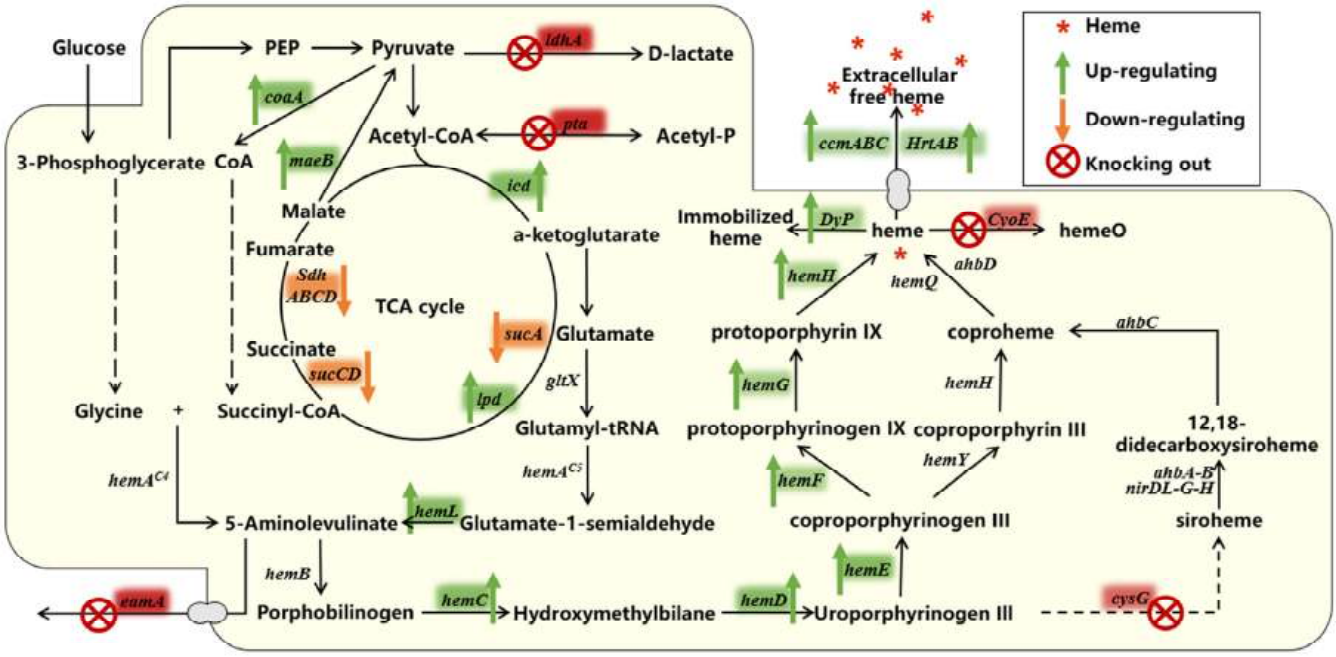

Figure 32.18.6: Synthetic biology strategies to enhance heme production. Green, orange, and red color blocks indicate genes that need to be up-regulated, down-regulated, and knocked out, respectively. Su, H. et al., ibid.

Computational tools such as AI can help the design of new pathways and novel enzymes to enhance production. It is becoming easier to transfer large pathways into yeast as well.

OTHER FOOD PRODUCTS FROM MICROBES AND SUSTAINABLE PLANTS

Significant effort is being devoted to growing meat in cell culture in the lab. This is a nascent field and has to overcome many problems, including consumer resistance to eating lab-created meat. At present meat grown in tissue culture is very expensive. Three key steps in growing meat are finding the best cells to grow, finding the nutrient conditions to maximize their growth, and adjusting conditions to make the lab meat taste like meat.

Muscle stem cells have been used as they can multiply many times, but these have growth limits. Alternatively, immortal cells, such as those derived from chicken fibroblasts, could be used. They can also be converted to fat cells. Yet they could accrue mutations with possible, but unlikely health consequences. Animal cells grown in culture often use fetal cow serum for its rich composition of growth factors and nutrients. However, it is very expensive and has ethical concerns as well since it's derived from animals. Synthetic growth medium can be used but it is also expensive. Whether lab-grown meat can overcome high costs and consumer resistance will determine its potential as a meat substitute.

More simply, people can use more peas, soy, grains, and nuts in their diet (i.e. being a vegan or vegetarian is the best approach to reducing your carbon footprint). Soy products have an extensive history of use as a source of protein but contain potential allergens (especially important in babies who use soy formulas) and isoflavones, which mimic human estrogen derivatives. Pea-based protein infant formulas are an increasing-used substitute.

Expressed recombinant proteins made in genetically modified bacteria and yeast are also becoming more popular. Examples (other than leghemogloblin) include the production in the fungus Trichoderma reesei of β-lactoglobulin, a cow whey protein, for dairy and animal-free milk products. The genetically-modified yeast Pichia pastoris has also been engineered to make milk casein proteins, egg-white proteins, muscle myoglobin, and human breast milk proteins. Enzymes used in the manufacture of cheese (derived from calves' stomachs) can be replaced by chymosin made in yeast. Production is linked to fermentation for many of these proteins. Filamentous proteins that have a texture similar to chicken fiber can be made through fermentation in the filamentous fungi Fusarium venenatumin. Macroalgae like seaweeds can provide high-protein food and have long been used in many cultures. Kelp farming can help not only provide protein but also capture carbon. Finally, insects, long eaten in many cultures, could become more climate-friendly source of protein.

If humans are in search of nonanimal sources of protein to fight climate change, why not produce and eat the most abundant protein in the biosphere, Rubisco? New products derived from the duckweed plant (genus Lemna) are coming to market. Figure 32.18.7:

Figure 32.18.7: Duckweed (and a frog). https://commons.wikimedia.org/wiki/F...7678481%29.jpg

Duckweed is high in nutrients, fast-growing, and a great source of Rubisco. It can be grown in aquaculture and does not require farmable land. It contains up to 50% protein. After harvesting, the plants are filtered, milled, and dried, which are all very simple technologies. Proteins, the most abundant being Rubisco, are then extracted. It can be used in baked goods and as meat and dairy substitutes. It is equal to eggs and meat in supplying all the essential amino acids required by humans.

GENETIC MANUFACTURING OF INDUSTRIAL FEEDSTOCKS

Let's look at one example in which synthetic biology and computational techniques are used to create products such as plexiglass from a biological source of acrylates. Acrylates are esters of acrylic acid (typically made from propylene) synthesized by reacting it with alcohols like methanol. Life cycle analyses show that almost 4000 kg CO_2 are produced per metric ton of acrylic acid made. To reduce the climate effect, biological feedstocks like glycerol and 3-hydroxypropanoic acid can be used, but large-scale supplies are needed. Figure 32.18.8 shows an overview of acrylate production fossil and biological feedstocks.

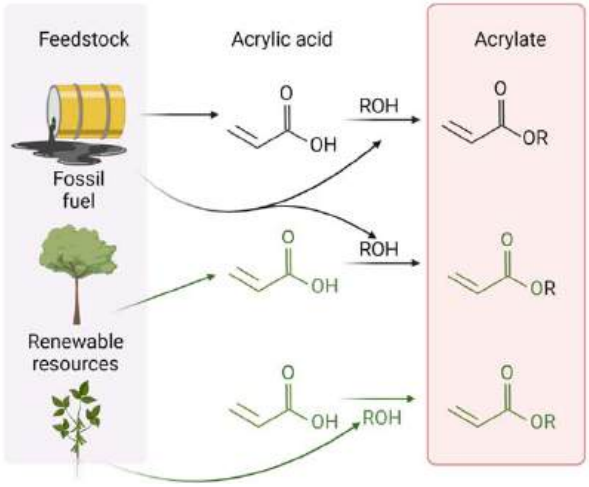

Figure 32.18.8: Production pathway of acrylates using fossil fuel and renewable resources. Souza, L.R.d.; Whitfield, B.; Al-Tabbaa, A. Biobased Acrylate Shells for Microcapsules Used in Self-Healing of Cementitious Materials. *Sustainability* **2022**, *14*, 13556. https://doi.org/10.3390/su142013556. Creative Commons Attribution (CC BY) license (**https://creativecommons.org/licenses/by/4.0/**)

When the alcohol is methanol, the final product is methylacrylate (MA). The structure of the cyclic acrylate monomer feedstock used to polymerize plexiglass (lucite) is methylene-butyrolactone, (MBL)whose structure is shown in Figure 32.18.9 below.

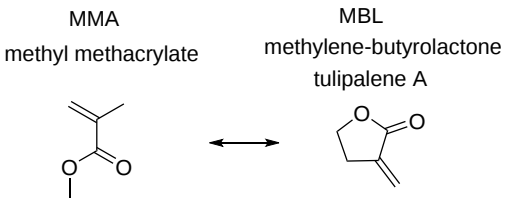

Figure 32.18.9: Structure of methyl methacrylate and its lactone (a cyclic ester)

Methyl methacrylate can undergo a free radical polymerization in the presence of an initiator (In·), as shown below in Figure 32.18.10.

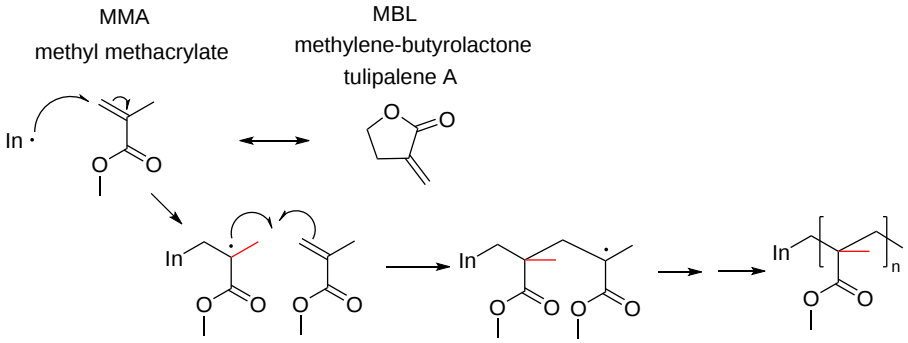

Figure 32.18.10: Mechanism of free radical polymerization of MMA

This reaction can form large polymers like plexiglass. The market for acrylic acid, the feedstock for plexiglass, is estimated to reach 12 million metric tons by 2030.

MBL, the lactone of MMA, is made in tulips from pathways that are not completely elucidated. It can also be used as a feedstock for the polymerization of plexiglass. Figure 32.18.11 shows the polymerization products from MMA and MBL.

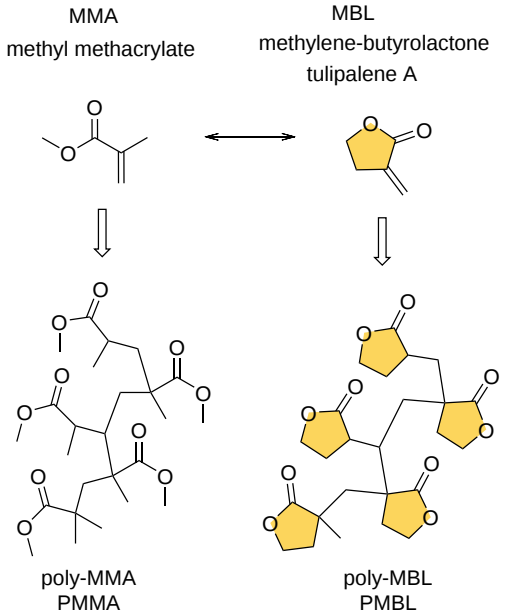

Figure 32.18.11: Structure of poly-MMA and poly-MBL

Using synthetic biology and advanced computational methods, plexiglass can now be made from biological sources instead of fossil fuels. To accomplish this, Azerda has designed synthetic pathways from millions of potential metabolic pathways (using a software package called Scylax™), and intelligently redesigned key enzymes to maximize their catalytic potential for the synthesis of MBL (using the software Archytas™). They used high-throughput DNA and protein analyses to maximize expression. Finally, they engineered expression strains and downstream purification processes to maximize the final output of MBL. In summary, the key steps in the process were:

- identifying a pathway from millions of reactions in databases of pathways that could produce MBL from simple sugars through a fermentation process;
- engineering pathway enzymes to greatly increase catalytic efficiency and decrease inhibition;

- producing test quantities of the products in cell strains;
- scaling up production to levels needed for purification and reactions of the MBL
- purifying sufficient amounts of MBL from large fermentation broths
- making the desired product (plexiglass, for example) from the feedstock.

Strains of bacteria, yeast, and filamentous fungi were modified to meet the above criteria. The ultimate substrate for the process was a lignocellulosic hydrolysate, so in the end the process converts trees to plexiglass (incredible to think about)! Of course, it is also amazing that CO_2 from the air, water, and minerals/ions from the soil can become a tree!

Starting with just a detectable level of product, the process was continually improved and scaled to eventually yield 5 g/L of broth, which is getting close to the 20 g/L required for commercial viability. Figure 32.18.12 below shows plexiglass created from the lignocellulosic stock!

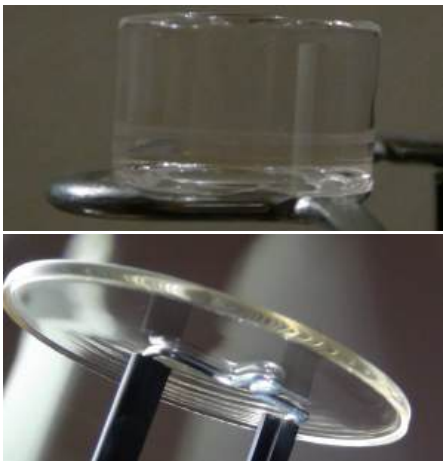

Figure 32.18.12: Plexiglass made from biosourced MBL.

Table 32.18.2 below compares the key physical properties of the polymers from Arzeda's PMBL compared to literature values for fossil-fuel-based PMBL and for PMMA.

Property	Measure	Lit PMBL	Arzeda PMBL	PMMA
Thermal	Glass transition pt T_g (^oC)	194-195	195	105
Mechanical	Elasticity (mPa)	1999/3439	5972	2855
	Tensile strength (mPa)	36.7/62.7	72.7	70
	Elongation at break	1.3%.6.5%	1.3%	2.5
Optical	Light transmission	NA	>88%	92%
Solvent resistance	toluene, 30 days, 20^oC	NA	Pass	Fail

Arthur Sikora Lipid rafts

Exercise 1

What kinds of lipids are found in a eukaryotic cell membrane under normal conditions?

Here is a Hint if you need one

Answer

Glycerophospholipids, sphingolipids, sterols and fatty acids.

Authored by Arthur Sikora. Last update: 6/5/2023

Date of origin

1: Introduction

Lipid rafts are formed and dissipated over time. They are regions where specific lipids are enriched, frequently resulting in protein aggregation as well

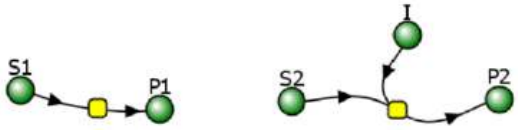
VCell MODEL

No inhibition (left) and Uncompetitive Inhibition (right)



Note that the Vcell reaction diagram is the same as for competitive and uncompetive inhibition. It doesn't explicitly show that the mixed inhibitor binds to both free and substrate-bound enzymes. Those interactions are addressed in the mathematical equations for mixed inhibition.

Initial values No Inhibition

Name	Description	Global	
J	reaction rate	☐	$\frac{Vmax \cdot S1}{(Km + S1)}$
Km	Km (1/2 max)	☐	5.0
Vmax	max reaction rate	☐	10.0
S1	Species Concentration	☑	Variable

Initial values With Uncompetitive Inhibitor

Name	Description	Global	
J	reaction rate	☐	$\frac{Vmax \cdot S2}{(Km \cdot (1.0 + \frac{I}{Kc}) + S2 \cdot (1.0 + \frac{I}{Ki}))}$
Km	user defined	☐	5.0

BIOMOLVIZ

Promoting Molecular Visualization Literacy

The BMV framework is used with permission from BioMolViz.Org

Copy the appropriate row when assigning a theme, goal, and objective to a designated iCn3D or other biomolecular visualization assessment

Atomic Geometry (AG)		Three-atom and four-atom (dihedral) angles, metal size and metal-ligand geometries, steric clashes

AG1. Students can describe the ideal geometry for a given atom within a molecule and deviations from the ideal geometry due to neighboring interactions.

AG1.01 Students can identify atomic geometry/hybridization for a given atom. (Novice)

AG1.02 Students can measure bond angles for a given atom. (Novice)

AG1.03 Students can identify deviations from the ideal bond angles. (Amateur)

AG1.04 Students can explain deviations from the ideal bond angles due to local effects. (Amateur, Expert)

AG1.05 Students can predict the effect of deviations from ideal bond angles on the structure and function of a macromolecule. (Expert)

AG1.06 Students can identify the geometric features of bonds (e.g., peptide bond, glycosidic, phosphoester).

AG2. Students can compare and contrast different structural conformations with regard to energy, the addition of substituents, and the impact on the structure/function of a macromolecule.

AG2.01 Students can describe different conformations that a structure can adopt using visualization tools. (Amateur)

AG2.02 Students can describe different conformations of atoms about a bond using visualization tools. (Novice)

AG2.03 Students can distinguish energetically favorable and unfavorable conformations that a structure can adopt. (Amateur)

AG2.04 Students can predict the effect of a given substituent on the structure and function of a macromolecule (e.g., substituent on a carbohydrate/ligand, R groups/rotamers, phosphorylation, methylation of nucleic acids, post-translational modifications). (Expert)

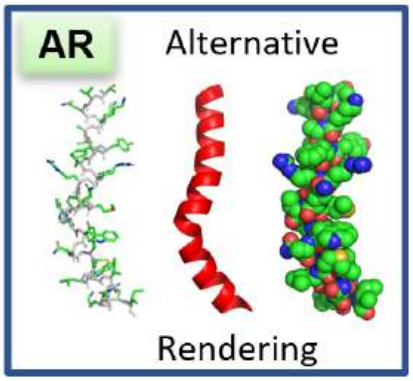
AG3. Students can describe dihedral/torsion angles in biomolecules.

AG3.01 Students can identify a dihedral/torsion angle in a three-dimensional representation of a molecule. (Novice)

AG3.02 Students can identify the planes between which a dihedral/torsion angle exists within a three-dimensional representation of a macromolecule. (Novice)

AG3.03 Students can identify phi, psi, and omega torsion/dihedral angles in a three-dimensional representation of a protein. (Amateur)

Alternate Renderings (AR)



Rendering of a macromolecular structure such as a protein or nucleic acid structure in various ways from the simplest possible way (connections between alpha carbons) to illustration of secondary structure (ribbons) to surface rendering and space filling.

AR1. Students can interpret or create molecular images that convey features such as secondary structure, CPK coloring, and active sites.

AR1.01 Students can manipulate rendered structures to illustrate molecular properties. (Novice)

AR1.02 REMOVED (integrated with SF2.02)

AR1.03 Students can describe or label structural differences among multiple structures. (Amateur, Expert)

AR1.04 Students can infer information from rendering a structure in different ways. (Novice, Amateur, Expert)

AR1.05 Students can create renderings that distinguish secondary structural features. (Novice)

AR1.06 Students can create an information rich rendering of a structure that depicts structural features found in the literature. (Amateur)

AR1.07 Students can create an information rich rendering of a structure containing ligands, covalent modifications, and noncanonical amino acids or nucleotides. (Amateur, Expert)

AR1.08 Students can use molecular visualization to tell a story about a macromolecular structure. (Expert)

AR1.09 REMOVED (integrated with MI1.02)

AR1.10 Students can convert textbook images of small molecules into 3D representations in a molecular visualization program. (Amateur)

AR2. Students can choose the best rendering of a macromolecule to use in a given situation.

AR2.01 Students can recognize that a cartoon rendering is a summary of the detail in a line rendering. (Novice, Amateur)

AR2.02 Students can describe the atoms and their representations in different renderings (e.g., coloring, showing hydrogens/double bonds). (Novice)

AR2.03 Students can identify or create a suitable rendering, or combination of renderings, for a specific purpose (e.g., a surface rendering overlaid with a cartoon to highlight the van der Waals surface alongside secondary structure, or active site sticks shown over a cartoon). (Novice, Amateur)

AR2.04 Students can identify the limitations in various renderings of molecular structures. (Amateur)

AR2.05 Students can understand the level of detail of different molecular representations. (Novice, Amateur, Expert)

AR2.06 Students can transition comfortably between equivalent 2D and 3D renderings of biomolecules. (Novice, Amateur, Expert)

AR2.07 Students can use and interpret color in the context of macromolecules to clarify and/or highlight features (e.g., coloring amino acids differently by property, different molecules uniquely in a complex, protein chains, secondary structure).

(Novice)

Construction and Annotation (CA)		Ability to build macromolecular models, either physical or computerized, and, where possible, add commentary, either written or verbal, to tell a molecular story.

CA1. Students can compose information-rich renderings of macromolecule-ligand interactions.

CA1.01 Students can construct and annotate a model of a macromolecule bound to a ligand. (Amateur)

CA1.02 Students can construct a model of a macromolecule bound to a ligand and identify the types of molecular interactions. (Amateur)

CA1.03 Students can construct a model of a macromolecule bound to a ligand and assess the importance of molecular interactions. (Expert)

CA1.04 Students can produce a model of a macromolecule based on a known structure of a related macromolecule. (Amateur, Expert)

CA2. Students can compose a rendering to predict the cellular location of a protein (e.g., extracellular, membrane associated, or cytoplasmic) based on the properties and orientations of functional groups.

CA2.01 Students can design a rendering that conveys properties such as polarity, charge, secondary structure, etc. to suggest the cellular location of a macromolecule. (Amateur)

CA2.02 Students can create protein images with colored polar/nonpolar residues to determine whether they fold with a hydrophobic core. (Amateur)

CA2.03 Students can create images to display polar/nonpolar residues and propose a role for the protein and/or how it interacts with its environment - and that the predictions would be plausible based on the protein. (Amateur)

CA2.04 Students can make accurate predictions of the location/function of the protein that incorporates additional protein features, such as transmembrane helices, apparent docking surfaces, etc. (Expert)

Ligands and Modifications (LM)		Metals and metal clusters, additions such as glycosylation, phosphorylation, lipid attachment, methylation etc.

LM1. Students can identify ligands and modified building blocks (e.g., hydroxyproline, aminosaccharides, modified nucleobase) within a rendered structure.

LM1.01 Students can use the annotation associated with a pdb file to identify and locate ligands and modified building blocks in a given biomolecule. (Amateur)

LM1.02 Students can visually identify non-protein chemical components in a given rendered structure. (Amateur)

LM1.03 Students can distinguish between nucleic acid and ligands (e.g., metal ions) in a given nucleic acid superstructure. (Amateur)

LM1.04 Students can explain how a ligand in a given rendered structure associates with the biomolecule (e.g., covalent interaction with residue X). (Amateur)

LM1.05 Students can locate/identify ligands and modified building blocks in unannotated structures and describe their role. (Expert)

LM2. Students can describe the impact of a ligand or modified building block on the structure/function of a macromolecule.

LM2.01 Students can look at a given rendered structure and describe how the presence of a specific ligand or modified building block alters the structure of that biomolecule. (Amateur)

LM2.02 Students can explain how the removal of a particular ligand or modified building block would alter the structure of a given biomolecule. (Expert)

LM2.03 Students can use molecular visualization tools to predict how a specified ligand or modified building block contributes to the function of a given protein. (Amateur, Expert)

LM2.04 Students can predict how a ligand or modified building block contributes to the function of a protein for which the structure has been newly solved. (Expert)

Macromolecular Assemblies (MA)		Polypeptides, oligosaccharides, and nucleic acid and lipid superstructures (e.g. protein–nucleic acid complexes, lipid membrane-associated proteins)

MA1. Students can describe various macromolecular assemblies.

MA1.01 Students can identify individual biomolecules in a macromolecular assembly. (Novice, Amateur, Expert)

MA1.02 Students can describe functions of individual biomolecules within a macromolecular assembly. (Novice, Amateur, Expert)

MA1.03 Students recognize the various lipid ultrastructures (e.g., micelles, bicelles, vesicles, and lipid bilayers) in a 3D structure. (Novice)

MA2. Students can compose information-rich renderings of macromolecular assemblies.

MA2.01 Students can render a macromolecular assembly to highlight individual structures. (Amateur)

MA2.02 Students can render a macromolecular assembly to illustrate structural features (e.g., binding interfaces, symmetry, tertiary structure, etc.). (Novice, Amateur, Expert)

Macromolecular Building Blocks (MB)		Recognition of native amino acids, nucleotides, sugars, and other biomonomer units/building blocks. Understanding of their physical and chemical properties, particularly regarding functional groups.

MB1. Students can identify individual building blocks of biological polymers.

MB1.01 Given a rendered structure of a biological polymer, students can identify the ends of a biological polymer. (Novice, Amateur, Expert)

MB1.02 Given a rendered structure, students can divide the polymer into its individual building blocks. (Novice)

MB1.03 Given a rendered structure, students can identify the individual building blocks. (Novice)

MB2. Students can describe the contributions different individual building blocks make in determining the 3-D shape of the polymer.

MB2.01 Students can describe the physical/chemical properties of an individual building block/functional group in a rendered structure of a polymer. (Amateur)

MB2.02 Students can describe the significance of the location of individual building blocks within the 3D structure of a polymer (protein, carbohydrate, or nucleic acid). (Novice, Amateur, Expert)

MB2.03 Students can identify physical/chemical properties of individual building blocks/functional groups in different local environments. (Amateur)

MB2.04 Using a visualized structure, students can identify stereochemistry (e.g., in carbohydrate, lipid, and protein structures). (Amateur)

MB2.05 Students can modify/mutate a building block to change the 3D structure of a polymer (protein, carbohydrate, or nucleic acid). (Amateur, Expert)

Molecular Dynamics (MD)		Animated motion simulating conformational changes involved in ligand binding or catalysis, or other molecular motion/dynamics.

MD1. Students can describe the impact of the dynamic motion of a biomolecule on its function.

MD1.01 Students can recognize that biological molecules have different conformations. (Novice, Amateur)

MD1.02 Students can correlate molecular movement with function. (Novice, Amateur, Expert)

MD2. Students can predict limits to macromolecular movement.

MD2.01 Students can locate potential regions of flexibility and inflexibility in the structure of a biomolecule. (Novice, Amateur)

MD2.02 Students can recognize acceptable/unacceptable movement within a macromolecule by determining whether the movement is within allowable bond angles. (Expert)

MD2.03 Students can recognize acceptable/unacceptable movement within a macromolecule by determining whether the movement results in steric hindrance. (Amateur)

MD2.04 Students can recognize acceptable/unacceptable movement within a macromolecule by considering the atomic packing constraints. (Expert)

Molecular Interactions (MI)		Covalent and noncovalent bonding governing ligand binding and subunit-subunit interactions.

MI1. Students can predict the existence of an interaction using structural and environmental information (e.g. bond lengths, charges, pH, dielectric constant).

MI1.01 Students can distinguish between covalent and noncovalent interactions. (Novice)

MI1.02 Students can identify different noncovalent interactions (e.g., hydrogen bonds, ionic interactions, van der Waals contacts, induced dipole) given a 3D structure. (Amateur)

MI1.03 Students can predict whether a functional group (region) would be a hydrogen bond donor or acceptor. (Amateur)

MI1.04 Students can render the 3D structure of a biomolecule so as to demonstrate the ionic interactions and/or charge distribution of the different non-covalent interactions. (Amateur)

MI1.05 As it relates to a particular rendered structure, students can rank the relative strengths of covalent and noncovalent interactions. (Amateur)

MI2. Students can evaluate the effect of the local environment on various molecular interactions.

MI2.01 Students can identify regions of a biomolecule that are exposed to or shielded from solvent. (Novice)

MI2.02 Students can identify other molecules in the local environment (e.g., solvent, salt ions, metals, detergents, other small molecules) that impact a molecular interaction of interest. (Novice)

MI2.03 Students can predict the impact of other molecules in the local environment (e.g., solvent, salt ions, metals, detergents, other small molecules) on a molecular interaction of interest. (Amateur)

MI2.04 Students can predict the pKa of an ionizable group based on the influence of its local three-dimensional environment. (Amateur)

MI2.05 Students can propose a change to the local environment that would yield a desired change in a molecular interaction. (Expert)

MI2.06 Using molecular visualization tools, students can determine which intermolecular force is most critical to stabilizing a given interaction. (Expert)

Symmetry/ Asymmetry Recognition (SA)		Recognition of symmetry elements within both single chain and multi-chain macromolecules.

SA1. Students can identify symmetric or asymmetric features in rendered molecules.

SA1.01 Students can identify symmetric features in a rendered molecule (shown in fixed orientation). (Novice)

SA1.02 Students can rotate a single macromolecule, multi-chain macromolecules (e.g., homo- or heteromers), complexes of macromolecules, and supramolecular assemblies to identify axes of symmetry. (Amateur)

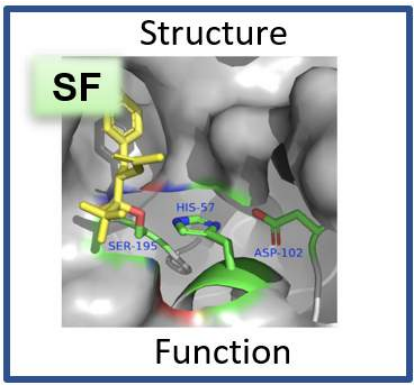
SA1.03 Students can identify symmetric and asymmetric features in rendered molecules after coloring a given rendered molecule to reveal structural features (charge, hydrophobicity, etc.). (Amateur)

SA2. Students can hypothesize the functional significance of symmetry or asymmetry in rendered molecules.

SA2.01 Students can explain the functional significance of rotational axes of symmetry (or asymmetry) in a given rendered molecule. (Novice, Amateur, Expert)

SA2.02 Students can predict functional significance of symmetry (or asymmetry) in a given rendered molecule. (Amateur, Expert)

Structure-Function Relationship (SF)



Active/binding sites, microenvironments, nucleophiles, redox centers, etc. (please also see LM2.03)

SF1. Students can evaluate biomolecular interaction sites using molecular visualization tools.

SF1.01 Students can identify functionally relevant cofactors, ligands or substrates associated with a macromolecule and describe their role (e.g., an active site magnesium ion). (Amateur, Expert)

SF1.02 Students recognize that the size and shape of the ligand must match the size and shape of the binding site. (Novice, Amateur)

SF1.03 Students recognize that the polarity or electrostatic potential of a surface complements that of the ligand or substrate. (Novice, Amateur)

SF1.04 Students recognize that the hydrophobicity of a surface complements that of the ligand or substrate. (Novice, Amateur)

SF1.05 REMOVED (integrated with SF1.03)

SF1.06 Students can use docking software to predict how the surface properties of a macromolecule guide and allow the binding of a ligand or substrate. (Amateur)

SF2. Using molecular visualization, students can predict the function of biomolecules.

SF2.01 Students can recognize structurally related molecules. (Novice)

SF2.02 Students can superimpose structurally related molecules. (Novice, Amateur)

SF2.03 Students can identify functionally relevant features of a macromolecule (e.g., an active site cysteine, a functional loop). (Amateur)

SF2.04 Students can predict molecular function given a binding site. (Amateur, Expert)

SF3. Using molecular visualization, students can predict the function of an altered macromolecule.

SF3.01 Students can structurally alter a macromolecule. (Novice)

SF3.02 Students can propose structural alterations to test interactions in a macromolecule. (Amateur)

SF3.03 Students can predict the impact of a structural alteration on the function of a macromolecule. (Amateur, Expert)

Structural Model Skepticism (SK)		Recognition of the limitations of models to describe the structure of macromolecules.

SK1. Students can critique the limitations of a structural model of a macromolecule.

SK1.01 Students can explain that the pdb file is a model based on data and that, as a model, it has limitations. (Novice, Amateur)

SK1.02 Students associate resolution with reliability of atom positions. (Amateur)

SK1.03 Students can identify building blocks (for example, amino acid side chains) whose orientation in a biopolymer is uncertain. (Expert)

SK1.04 Students can evaluate the flexibility/disorder of various regions of a macromolecular structure. (Novice, Amateur, Expert)

SK1.05 Students can reconcile inconsistent numbering of individual building blocks among species and structure files. (Novice)

SK1.06 Students can utilize a Ramachandran plot/steric clashes to interpret the validity of a structure. (Amateur, Expert)

SK1.07 Students can describe the limitations of a macromolecule-ligand docking simulation. (Amateur, Expert)

SK2. Students can evaluate the quality of 3D models including features that are open to alternate interpretations based on molecular visualization and PDB flat files.

SK2.01 Students can evaluate a crystal structure for crystal packing effects. (Novice, Amateur, Expert)

SK2.02 Students can resolve differences between the asymmetric unit and the functional biological assembly. (Expert)

SK2.03 Students can differentiate functional ligands (with biological/biochemistry role) from nonfunctional ligands (most solvents, salts, ions, and crystallization agents). (Novice, Amateur, Expert)

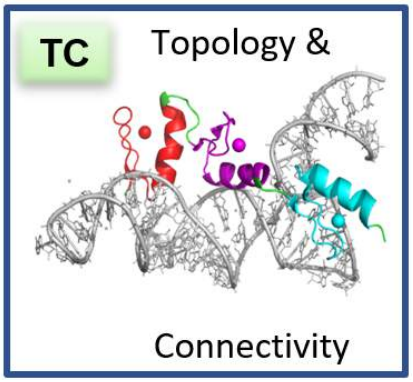
SK3. Students can discuss the value of experimentally altering a biomolecule to facilitate structure determination.

SK3.01 Students can identify non-native structural features. (Amateur)

SK3.02 Students can propose molecular modifications to facilitate structure determination. (Amateur, Expert)

SK3.03 Students can propose a purpose for the introduction of non-native structural features to facilitate structure determination. (Amateur, Expert)

Topology and Connectivity (TC)



Following the chain direction through the molecule, translating between 2D topology mapping and 3D rendering.

TC1. Students can describe or illustrate the linkages between building blocks within a macromolecule.

TC1.01 Students can trace the backbone of a macromolecule in three dimensions. (Novice, Amateur)

TC1.02 Students can use appropriate terms to describe the linkages/bonds/interactions that join individual building blocks together in a macromolecule or macromolecular assembly. (Novice, Amateur)

TC1.03 Given a virtual model of individual building blocks, students can predict the types of linkages/bonds/interactions that are possible or favorable. (Amateur)

TC1.04 Given individual building blocks, students can appropriately connect them to create a biological polymer (e.g., drawing carbohydrate linkages, a small peptide). (Amateur, Expert)

TC2. Students can describe the overall shape and common motifs within a 3D macromolecular structure.

TC2.01 Using molecular visualization software, students can describe the three-dimensional structure of a macromolecule, including overall shape and common structural motifs. (Novice, Amateur, Expert)

TC2.02 Students can identify common domains/motifs within a macromolecule. (Amateur, Expert)

TC2.03 Students can identify connectivity features between domains or subunits in a macromolecular structure. (Amateur)

TC2.04 Students can identify interactions between domains or subunits in a macromolecular structure. (Amateur, Expert)

TC2.05 Students can describe how domains/motifs in a macromolecule work together to achieve a concerted function in the cell. (Amateur, Expert)

TC2.06 Students can identify the levels of protein structure (e.g., parse a tertiary/quaternary structure into a series of secondary structures/motifs) and the ways in which they are connected from a three-dimensional structure. (Novice, Amateur, Expert)

TC3. Students can explain how any given biomolecular interaction site can be made by a variety of topologies.

TC3.01 Students can recognize that the groups that comprise a functional site only require proper arrangement in three-dimensional space rather than a particular order or position in the linear sequence. (Amateur)

TC3.02 Students can recognize similarities and differences in two similar - but not identical - three dimensional structures. (Amateur)

TC3.03 Students can describe dissimilar portions of homologous proteins as arising from genetic insertions/deletions/rearrangements. (Amateur)

? Exercise 1

What mutations to specific amino acid residues could be introduced to strengthen contacts between the upper and lower C-spine?

Answer

Mutations to create a greater extent of interaction or a stronger class of interaction are necessary to strengthen intramolecular contacts.

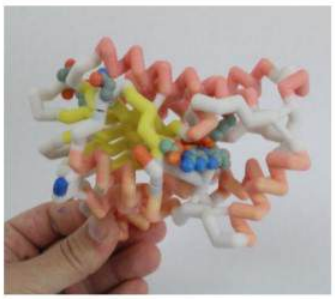
Example 1: Mutation of a small hydrophobic amino acid to a bulky hydrophobic or aromatic amino acid can be used to bridge the gap.

Example 2: Mutation to introduce a new hydrogen bond, salt bridge, or disulfide bond can be used to create a new link between these sections of the hydrophobic core.

Emily Schmitt Sepiapterin Reductase-Beery Twins Story

? Exercise 1

Which mutation was contributed by the mother that affected the Sepiapterian reductase (SPR) in the Beery Twins situation?



Answer

a) early stop of the protein (Lys to termination) Lys251X

b) Arg 150 Gly

c) there was no mutation from the mother that caused the disease

d) Lys 250 Glu

Here is a hint if you need one

Helena-Test

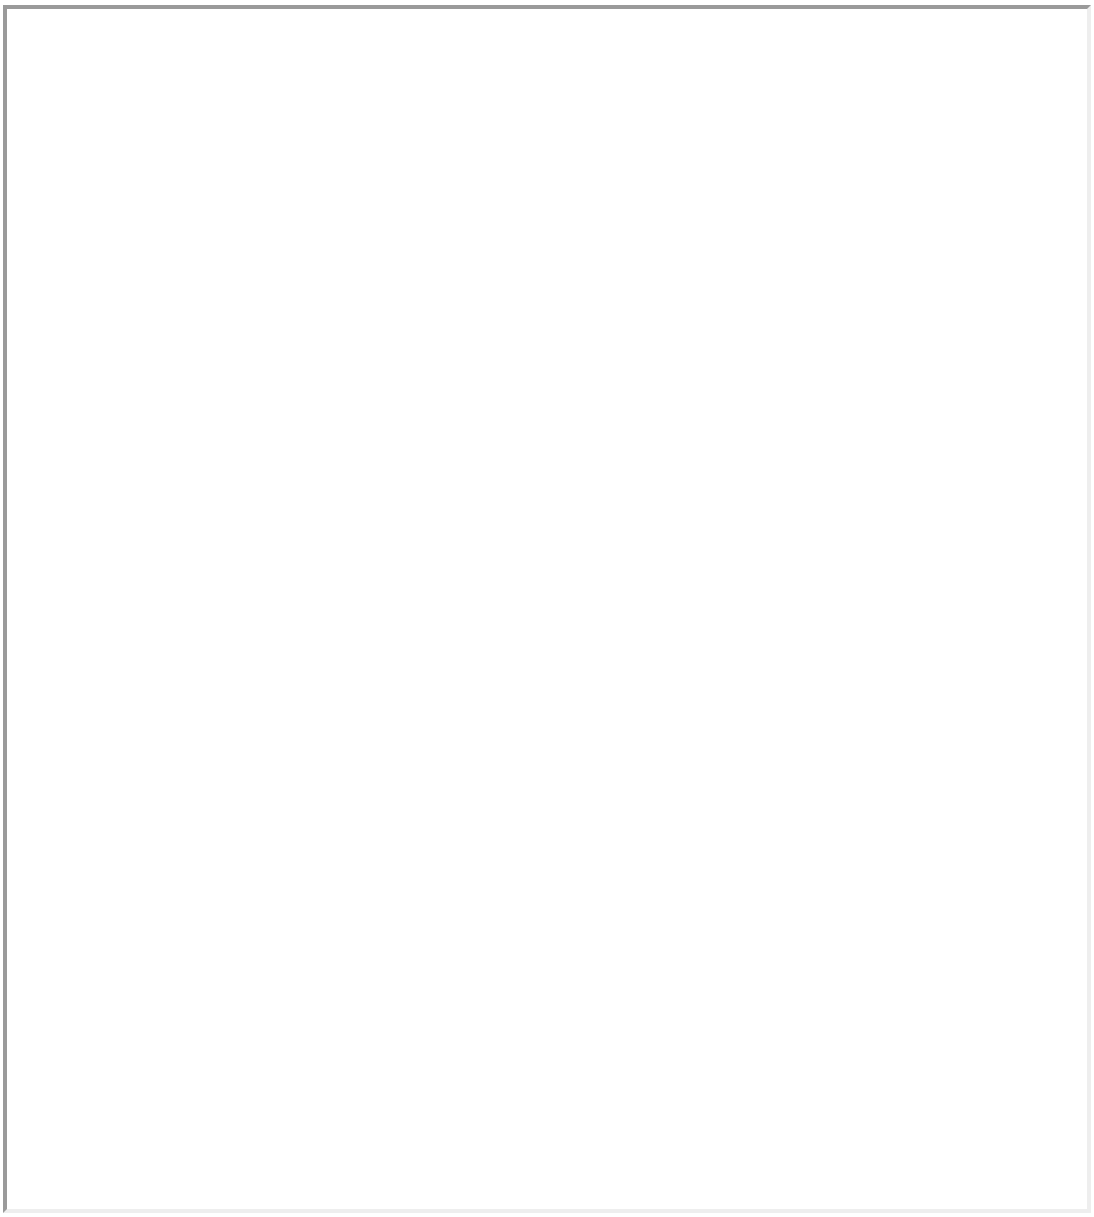
Exercise 1

Degradation of amino acids yields compounds that are common intermediates in the major metabolic pathways. Explain the distinction between glucogenic and ketogenic amino acids in terms of their metabolic fates.

Answer

Glucogenic amino acids are those which can be catabolized into pyruvate, oxaloacetate, a-ketoglutarate , fumarate, or succinyl-CoA, and thus can serve as glucose precursors.

Ketogenic amino acids are catabolized to Acetyl-CoA or acetoacetate, and thus can serve as precursors for fatty acids or ketone bodies.



Here is a hint if you need it.

Reversible Competitive inhibition occurs when substrate (S) and inhibitor (I) both bind to the same site on the enzyme. In effect, they compete for the active site and bind in a mutually exclusive fashion. This is illustrated in the chemical equations and molecular cartoons shown in Figure 1.

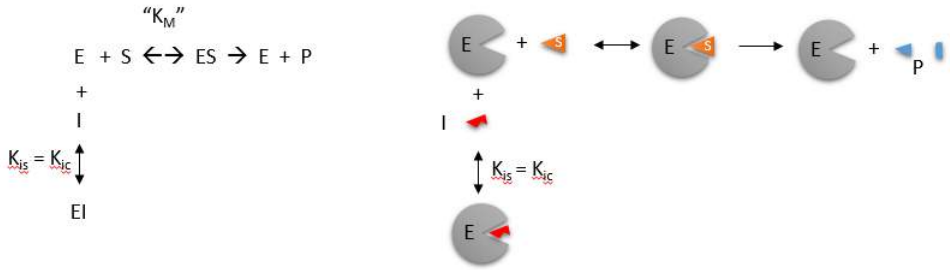

Figure 1: Competitive Inhibition

$$v_0 = \frac{V_M S}{K_M\left(1+\frac{I}{Kis}\right)+S} \tag{1}$$

There is another type of inhibition that would give the same kinetic data. If S and I bound to different sites, and S bound to E and produced a conformational change in E such that I could not bind (and vice versa), then the binding of S and I would be mutually exclusive. This is called allosteric competitive inhibition. Inhibition studies are usually done at several fixed and non-saturating concentrations of I and varying S concentrations.

The key kinetic parameters to understand are V_M and K_M. Let us assume for ease of equation derivation that I binds reversibly, and with rapid equilibrium to E, with a dissociation constant K_{IS}. The "s" in the subscript "is" indicates that the slope of the 1/v vs 1/S Lineweaver-Burk plot changes while the y-intercept stays constant. K_{IS} is also named K_{IC} where the subscript "c" stands for competitive inhibition constant.

A look at the top mechanism shows that even in the presence of I, as S increases to infinity, all E is converted to ES. That is, there is no free E to which I could bind. Now, remember that $V_M = k_{cat}E_0$. Under these conditions, ES = E_0; hence v = V_M. V_M is not changed. However, the apparent K_M, K_{Mapp}, will change. We can use LaChatelier's principle to understand this. If I binds to E alone and not ES, it will shift the equilibrium of E + S → ES to the left. This would increase the K_{Mapp} (i.e. it would appear that the affinity of E and S has decreased.). The double reciprocal plot (Lineweaver-Burk plot) offers a great way to visualize the inhibition as shown in Figure 2.

$$v_0 = \frac{V_M S}{K_M\left(1+\frac{I}{Kis}\right)+S}$$

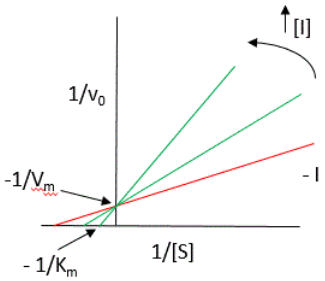

Figure 2: Competitive Inhibition: Lineweaver-Burk plots

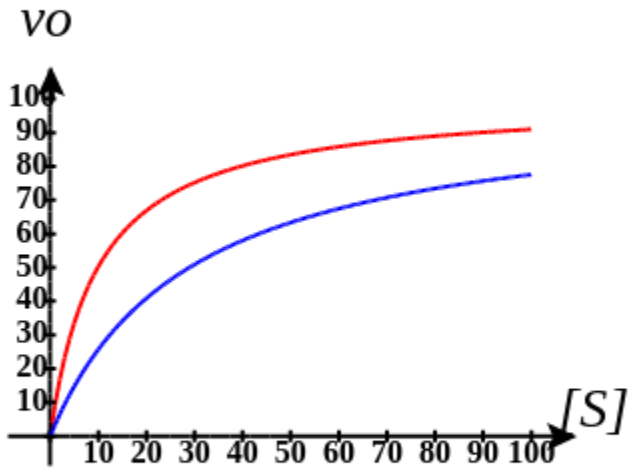
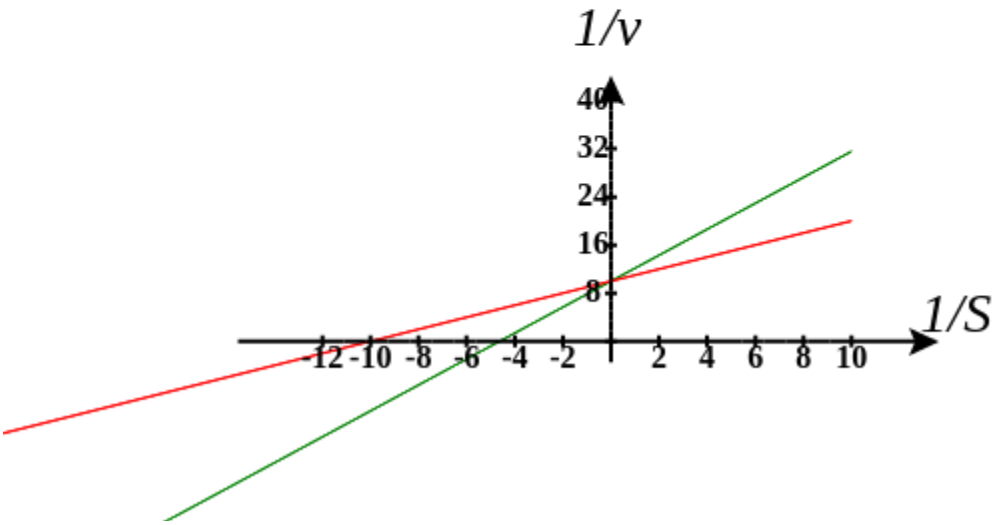
In the presence of I, V_M does not change, but K_M appears to increase. Therefore, $1/K_M$, the x-intercept on the plot will get smaller, and closer to 0. Therefore the plots will consist of a series of lines, with the same y-intercept ($1/V_M$), and the x-intercepts ($-1/K_M$) closer and closer to 0 as I increases. These intersecting plots are the hallmark of competitive inhibition.

Here is an interactive graph showing v_0 vs [S] for competitive inhibition with Vm and Km both set to 100. Change the sliders for [I] and Kis and see the effect on the graph.



Here is the interactive graphs showing $1/v_0$ vs 1/[S] for competitive inhibition, with Vm and Km both set to 10.

Competitive Inhibition



Note that in the first three inhibition models discussed in this section, the Lineweaver-Burk plots are linear in the presence and absence of an inhibitor. This suggests that plots of v vs S in each case would be hyperbolic and conform to the usual form of the Michaelis Menton equation, each with potentially different apparent V_M and K_M values.

An equation for v_0 in the presence of a competitive inhibitor is shown in the above figure. The only change compared to the equation for the initial velocity in the absence of the inhibitor is that the K_M term is multiplied by the factor $1+I/K_{is}$. Hence $K_{Mapp} = K_M(1+I/Kis)$. This shows that the apparent K_M does increase as we predicted. K_{IS} is the inhibitor dissociation constant in which the inhibitor affects the slope of the double reciprocal plot.

If the data were plotted as v_0 vs log S, the plots would be sigmoidal, as we saw for plots of ML vs log L in Chapter 5B. In the case of a competitive inhibitor, the plot of v_0 vs log S in the presence of different fixed concentrations of inhibitor would consist of a series of sigmoidal curves, each with the same V_M, but with different apparent K_M values (where $K_{Mapp} = K_M(1+I/K_{is})$, progressively shifted to the right. Enzyme kinetic data is rarely plotted this way. These plots are mostly used for simple binding data for the M + L ↔ ML equilibrium, in the presence of different inhibitor concentrations.

Reconsider our discussion of the simple binding equilibrium, M + L ↔ ML. For fractional saturation Y vs a log L graphs, we considered three examples:

1. $L = 0.01\ K_D$ (i.e. $L << K_D$), which implies that $K_D = 100L$. Then $Y = L/[K_D+L] = L/[100L + L] \approx 1/100$. This implies that irrespective of the actual [L], if $L = 0.01\ K_D$, then $Y \approx 0.01$.
2. $L = 100\ K_D$ (i.e. $L >> K_D$), which implies that $K_D = L/100$. Then $Y = L/[K_D+L] = L/[(L/100) + L] = 100L/101L \approx 1$. This implies that irrespective of the actual [L], if L = 100 Kd, then Y ≈1.
3. $L = K_D$, then Y = 0.5

These scenarios show that if L varies over 4 orders of magnitude ($0.01K_D < K_D < 100K_D$), or, in log terms, from $-2 + \log K_D < \log K_D < 2 + \log Kd$), irrespective of the magnitude of the K_D, that Y varies from approximately 0 - 1.

In other words, Y varies from 0-1 when L varies from log K_D by +2. Hence, plots of Y vs log L for a series of binding reactions of increasingly higher K_D (lower affinity) would reveal a series of identical sigmoidal curves shifted progressively to the right, as shown below in Figure 3.

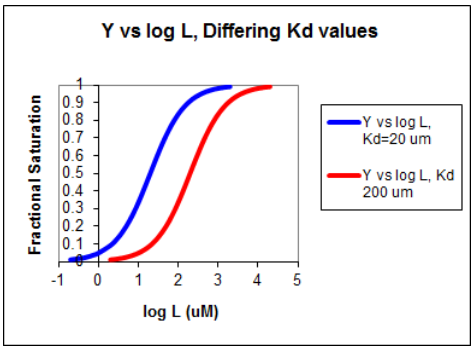


Figure 3: Plot of fractional saturation Y vs log L for two different K_D values.

The same would be true of v_0 vs S in the presence of different concentrations of a competitive inhibitor, for initial flux, Jo vs ligand outside, in the presence of a competitive inhibitor, or ML vs L (or Y vs L) in the presence of a competitive inhibitor.

In many ways plots of v_0 vs lnS are easier to visually interpret than plots of v_0 vs S . As noted for simple binding plots, textbook illustrations of hyperbolas are often misdrawn, showing curves that level off too quickly as a function of [S] as compared to plots of v_0 vs lnS, in which it is easy to see if saturation has been achieved. In addition, as the curves above show, multiple complete plots of v_0 vs lnS at varying fixed inhibitor concentrations or for variant enzyme forms (different isoforms, site-specific mutants) over a broad range of lnS can be made which facilitates comparisons of the experimental kinetics under these different conditions. This is especially true if Km values differ widely.

Now that you are more familiar with binding and enzyme kinetics curves, in the presence and absence of inhibitors, you should be able to apply the above analysis to inhibition curves where the binding or the initial velocity is plotted at varying competitive inhibitor concentrations at different fixed nonsaturating concentrations of ligand or substrate. Consider the activity of an enzyme. Let's say that at some reasonable concentration of substrate (not infinite), the enzyme is approximately 100% active. If a competitive inhibitor is added, the activity of the enzyme decreases until at saturating (infinite) I, no activity would remain. Graphs showing this are shown below in Figure 4.

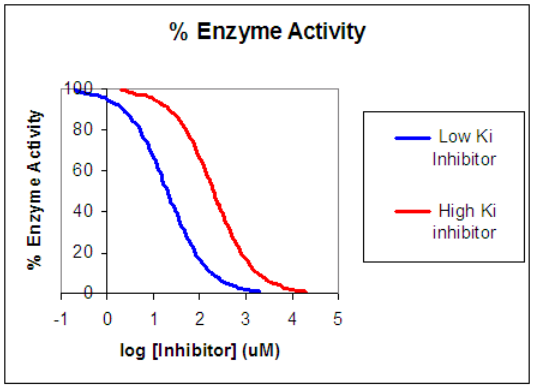

Figure 4: Inhibition of Enzyme Activity - % Activity vs log [Inhibitor]

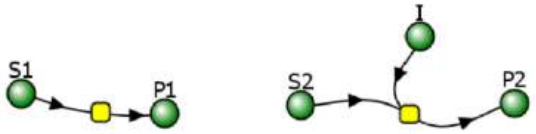
2.1: Progress Curves for Competitive Inhibition

In the previous section, we explored how important progress curve (Product vs time) analyses are in understanding both uncatalyzed and enzyme-catalyzed reactions. We are aware of no textbooks which cover progress curves for enzyme inhibition. Yet progress curves are what most investigators record and analyze to determine initial rates v_0 and to calculate V_M, K_M and inhibition constants, as described above. We will use Vcell to produce progress curves for reversibly inhibited enzyme-catalyzed reactions.

VCell MODEL

Competitive Inhibition with constant [I]:

No inhibition (left) and competitive inhibition (right)



Initial conditions for no inhibition

Name	Description	Global	
J	reaction rate	☐	$\frac{Vmax \cdot S1}{(Km + S1)}$
Km	Km (1/2 max)	☐	5.0
Vmax	max reaction rate	☐	10.0
S1	Species Concentration	☑	Variable

Initial conditions for competitive inhibition

Name	Description	Global	
J	reaction rate	☐	$\frac{Vmax \cdot S2}{(Km + S2 + \frac{Km \cdot I}{Ki})}$
Km	user defined	☐	5.0
Vmax	user defined	☐	10.0
Ki	user defined	☐	5.0
S2	Species Concentration	☑	Variable
I	Species Concentration	☑	Variable

I is fixed for each simulation (as it is not converted to a product) but can be changed in the simulation below.

Select Load [model name] below

Load NoInhib_CompInhib_MM_I

Select **Start** to begin the simulation.

Select **Plot** to change Y axis min/max, then **Reset** and **Play** | Select **Slider** to change which constants are displayed. For this model, select Vm, Km, Ki and I | Select **About** for software information.

Move the sliders to change the constants and see changes in the displayed graph in real-time.

Time course model made using Virtual Cell (Vcell), **The Center for Cell Analysis & Modeling**, at **UConn Health**. Funded by NIH/NIGMS (R24 GM137787); Web simulation software (miniSidewinder) from Bartholomew Jardine and Herbert M. Sauro, University of Washington. Funded by NIH/NIGMS (RO1-GM123032-04)

The graphs from your initial run show the concentrations of S, P and I as a function of time for just the initial conditions shown above. In typical initial rate laboratory analyzes, of competitive inhibition, at least three sets of reactions are run with the same varying substrate concentrations and different fixed concentrations of inhibitor. In the analyses above, [I] is fixed at 5 uM.

Conduct a series of run at different values of I. Vary the K_I, the dissociation constant for the EI complex, as follows:

- I << K_I, the dissociation constant for the EI complex
- I >> K_I, the dissociation constant for the EI complex. Then download the data and determine the initial rate for each of the initial conditions.

Figure 5 shows an interactive iCn3D model of human low molecular weight phosphotyrosyl phosphatase bound to a competitive inhibitor (5PNT)

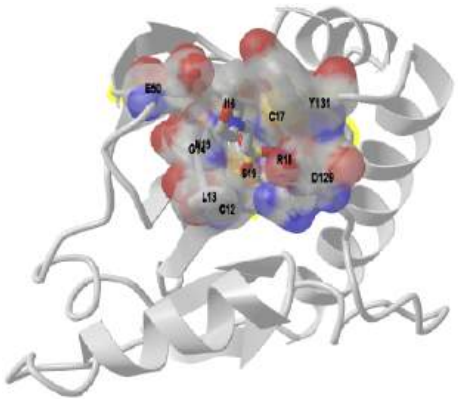


Figure 5: Human low molecular weight phosphotyrosyl phosphatase bound to a competitive inhibitor (5PNT). (Copyright; author via source).
Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...XsEacG2tixDDi9

The competitive inhibitor, the deprotonated form of 2-(N-morpholino)-ethanesulfonic acid (MES), is actually the conjugate base of the weak acid (pKa = 6.15) of a commonly used component of a buffered solution. It is shown in color sticks with the negatively charged sulfonate sitting at the bottom of the active site pocket. The amino acids comprising the active site binding pocket are shown as color sticks underneath the transparent colored surface of the binding pocket. The normal substrates for the enzyme are proteins phosphorylated on tyrosine side chains so the sulfonate is a mimic of the negatively charged phosphate group of the phosphoprotein target.

2.2: Two specials cases of competition inhibition

Product Inhibition

Let's look at an enzyme that converts reactant S to product P. Since P arises from S, they may have structural similarities. For example, what if GTP was the reactant and GDP was a product? If so, then P might also bind in the active site and inhibit the conversion of S to P. This is called **product inhibition**. It probably occurs in most enzymes, and when it does occur it will start bending downward the beginning part of the progress curve for P formation. If the product binds very tightly, it might cause a significant underestimation of the initial velocity (v_0) or flux (J_0) of the enzyme. Let's use Vcell to explore product inhibition. The model will explore two reactions:

- E + R ↔ ER → E + Q (no product inhibition)
- E + S ↔ ES → E + P (with product inhibition)

Note that the chemical equation above does not explicitly show the product P binding the enzyme to form an EP complex. An actual reaction diagram showing the inhibition of an enzyme by an inhibitor I and by the product P is shown in Figure 6 below.

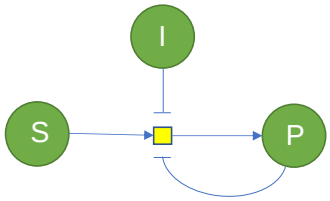

Figure 6: reaction diagram showing inhibition of an enzyme by an inhibitor I and by the product P

Vcell uses much simpler diagrams since it is most often used for modeling whole pathways or even entire cells. In the simpler Vcell reaction diagrams, the inhibitor is typically not shown since the inhibition is built into the equation for the enzyme, represented by the node or yellow square in the figure above.

Let's now explore product inhibition in Vcell. R and Q are the reactant and product, respectively, in the reaction *without* product inhibition. S and P are used for the reaction *with* product P inhibition.

VCell MODEL

Irreversible MM Kinetics - Without (left rx 1) and With (right, rx 2) Product Inhibition

Initial Conditions: No product inhibition

Name	Description	Global

Select Load [model name] below

Load ProdInhib_NoProdInhib

Select **Start** to begin the simulation.

Select **Plot** to change Y axis min/max, then **Reset** and **Play** | Select **Slider** to change which constants are displayed | Select **About** for software information.

Move the sliders to change the constants and see changes in the displayed graph in real-time.

Time course model made using Virtual Cell (Vcell), **The Center for Cell Analysis & Modeling**, at **UConn Health**. Funded by NIH/NIGMS (R24 GM137787); Web simulation software (miniSidewinder) from Bartholomew Jardine and Herbert M. Sauro, University of Washington. Funded by NIH/NIGMS (RO1-GM123032-04)

Inhibition by a competing substrate - the specificity constant

In the previous chapter, the specificity constant was defined as k_{cat}/K_M which we also described as the second-order rate constant associated with the bimolecular reaction of E and S when S << K_M. It also describes how good an enzyme is in differentiating between different substrates. If an enzyme encounters two different substrates, one can be considered to be a competitive inhibitor of the other. The following equation gives the ratio of initial velocities for two competing substrates at the same concentration is equal to the ratio of their k_{cat}/K_M values.

$$\frac{v_A}{v_B} = \frac{\frac{k_{cat\,A}}{K_A}A}{\frac{k_{cat\,B}}{K_B}B} \tag{2}$$

A derivation of the specificity constant for an enzyme with competing substrates

Here it is!

Derivation

$$v_A = \frac{V_A A}{K_A\left(1+\frac{B}{K_B}\right)+A} \quad v_B = \frac{V_B B}{K_B\left(1+\frac{A}{K_A}\right)+B} \tag{3}$$

$$\frac{v_A}{v_B} = \frac{\frac{V_A A}{K_A\left(1+\frac{B}{K_B}\right)+A}}{\frac{V_B B}{K_B\left(1+\frac{A}{K_A}\right)+B}} = \frac{\frac{V_A A}{K_A+\frac{K_A B}{K_B}+A}}{\frac{V_B B}{K_B+\frac{K_B A}{K_A}+B}} \tag{4}$$

Now in the above equation:

multiple the top half of the right-hand expression by

$$\frac{\frac{1}{K_A}}{\frac{1}{K_A}} \tag{5}$$

multiple the bottom half of the right-hand expression by

$$\frac{\frac{1}{K_B}}{\frac{1}{K_B}} \tag{6}$$

replace V_A with $k_{catA}E_0$ and V_B with $k_{catB}E_0$

This gives the following expression for v_A/v_B:

$$\frac{v_A}{v_B} = \frac{\frac{k_{catA}}{K_A}A}{\frac{k_{catB}}{K_B}B} \tag{7}$$

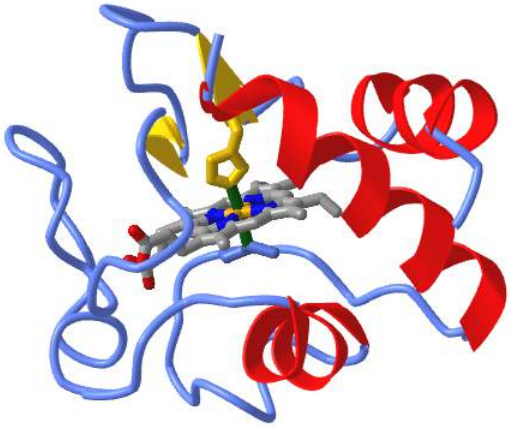
[ADD VCELL/SBML SIMULATION - REUSE]

*your text before and after insert as needed

3: New Heading

Figure x is an interactive iCn3D model of **[2B4Z cytochrome c]**



INSERT PNG ( ) OF YOUR iCn3D MODEL

Figure 6: [2B4Z]. Click the image for a popup or use this external link: [https://bio.libretexts.org/Learning_..._iCn3Ds_Helena]. (Copyright; author via source). iCn3D model made by [Helena Prieto]

Inserting an iCn3D model into a FOB Chapter section

(If you need a refresher, here is a link to an iCn3D workshop tutorial presented by BioMolViz at the BMB 2023 in Seattle, WA on March 25, 2023.)

A. Creating an iCn3D model in FOB

1. Open iCn3D, input a PDB code, and do the following:

   - **Color, Secondary, Sheets in Yellow**
   - **Style, Background, Transparent**
   - **File, Share Link**
   - Copy the Original URL with commands

2. Follow these instructions but use your code (open a new Word document for your code).

Here is a sample code for 1XWW:

> https://www.ncbi.nlm.nih.gov/Structu...0&command=load mmdb 1xww | parameters &mmdbid=1xww&bu=1; set thickness | linerad 0.1 | coilrad 0.3 | stickrad 0.4 | crosslinkrad 0.4 | tracerad 0.1 | ribbonthick 0.2 | proteinwidth 1.3 | nucleotidewidth 0.8 | ballscale 0.3; set background transparent; color secondary structure yellow|||{"factor":"1.000","mouseChange":{"x":"0.000","y":"0.000"},"quaternion":{"_x":"-0.006542","_y":"0.8578","_z":"-0.04771","_w":"0.5117"}}

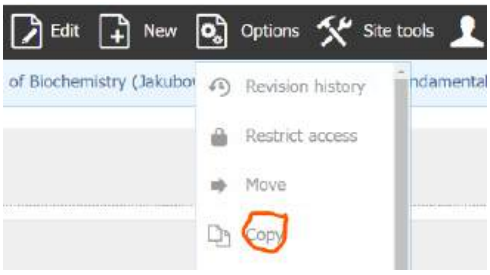
2. Copy all of the code ***BEFORE*** the ||| and paste it in a Word document. Then add the 3 small **red codes** in the example below, and add them in the corresponding positions in your sample code. It will be helpful to color the newly added code red to make sure it is correct. It will look like this but your code will replace the back code below.

> **template('EmbediCn3D/iCn3D',{config: '{"fullURL":** "https://www.ncbi.nlm.nih.gov/Structu...30430&v=3.25.0**&closepopup=1**&command=load mmdb 1xww | parameters &mmdbid=1xww&bu=1; set thickness | linerad 0.1 | coilrad 0.3 | stickrad 0.4 | crosslinkrad 0.4 | tracerad 0.1 | ribbonthick 0.2 | proteinwidth 1.3 | nucleotidewidth 0.8 | ballscale 0.3; set background transparent; color secondary structure yellow**"}'})**

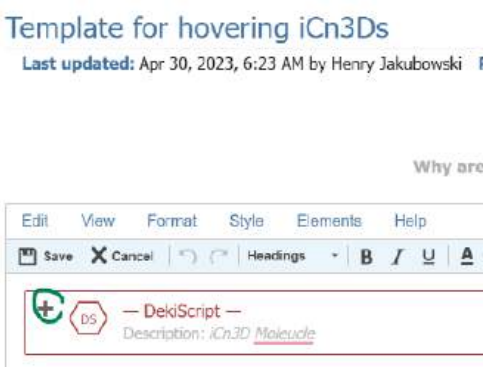
3. Now go to this page in a new window to create your own iCn3D page for FOB

4. Open the file **Template for Your Own Separate iCn3D Page**

5. **You must make a copy of this file**. From the top menu bar click **Options, Copy,** and give the file a name derived from the PDB web page. For example Human Low Molecular Weight Protein Phosphatase (1XWW). Don't overnight the original file with your new name.



6. Then from the top menu bar for your new file select **Edit**. Click the + button (green circle) on the DekiScript box.



7. Paste your entire modified URL code from your Word document (with the 3 inserted red codes) into the DekiScript box.

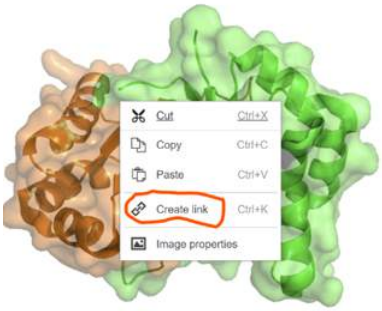
8. Choose the Save just above the DekiScript box and you should see a small version of the molecule in a workable iCn3D window.

B. Inserting your iCn3D model into your Chapter 33 Section

1. Open your Chapter 33 section and click **Edit**

2. Place your cursor on a new line where you would like to place the model to appear.

3. Go to this page in a new window, select Edit in the menu bar, and copy the material between the two horizontal lines into the desired location in your Chapter 33 section.

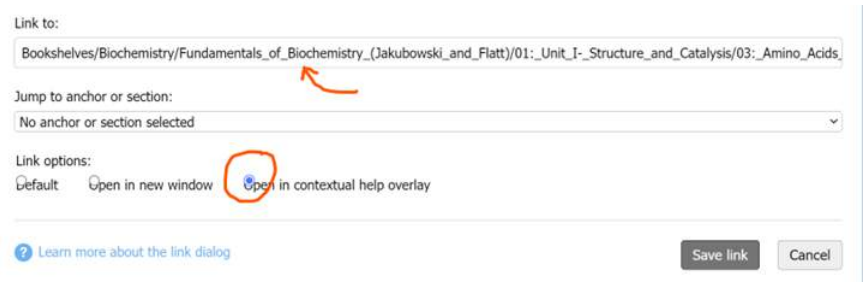


4. Take a screen snip showing the molecule in the iCn3D modeling window. Save it to your computer. Then insert the image in you Chapter 33 section where the text reads: INSERT PNG (just a screen snip) OF YOUR iCn3D MODEL. Use the top menu bar picture icon to select the file or drag the file from your computer into your section page.

5. Complete the captions for the image and make sure to include the PDB ID in your text as well as the iCn3D short link.

6. To make a hovering iCn3D model with a full menu within your chapter section (and not just from the external iCn3D short link), right-click the image you inserted in Step 4, and select **Create Link** (see image below).

7. Delete the link shown (red arrow) and replace it with the URL from the LibreText iCn3D file you just made in Part A above. Make sure that you choose **Open in contextual help overlay.**



8. Save the link.

Inserting an interactive mathematic graph into FOB

1. Navigate to this page in a new window
2. Select and view the graph of interest
3. Navigate to your Chapter 33 section and select Edit from the top menu bar
4. Move the cursor to the location you wish to insert the graph
5. From the top menu bar select **Elements, Content Reuse**
6. Navigate through the folder tree to get to the page with the interactive mathematical models:

    Home

        Learning Objects

            Visualization and Simulations

                Interactive Figures

                    Interactive Biochemistry Graphs

7. Click the file name for the model of interest to insert.
8. Save the page.

Inserting a mathematical simulation (SBML) into a FOB

1. Navigate to this page in a new window
2. Select and view the graph of interest
3. Navigate to your Chapter 33 section and select Edit from the top menu bar
4. Move the cursor to the location you wish to insert the graph
5. From the top menu bar select **Elements, Content Reuse**
6. Navigate through the folder tree to get to the page with the interactive mathematical models:

    Home

        Learning Objects

            Visualization and Simulations

                Progress Curve Analysis

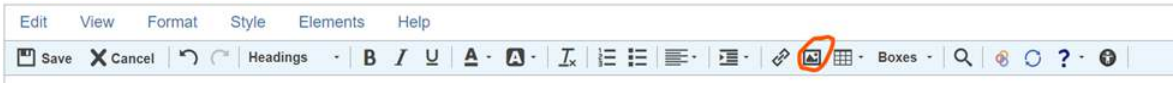
                    SBML Computational Models

7. Click the file name for the model of interest to insert.
8. Save the page.

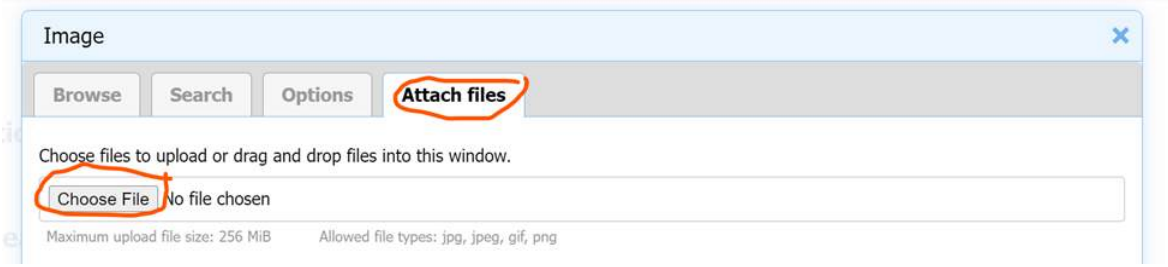
Insert an Image into FOB

Inserting an image into FOB

1. Do a Google search for an image with Creative Commons permission for reuse. The optimal permission category is CC BY.
2. Make a copy and save it to your computer.
3. Open your Chapter 33.x Libretext file and select **Edit** in the top menu bar
4. Navigate to ADD IMAGE, remove these words but leave the cursor there
5. From the Editing menu bar, select **Elements, Templates,** and from the drop-down Template:FigureCenterCenter.
6. Click on the Copy/Paste Placeholder image and **delete** it.
7. Recenter the cursor centered above the automatic figure legend, click the Image icon from the menu bar.



8. Select the Attach Files tab, followed by Choose File, and navigate to the image you wish to upload.



9. Select Save Image, and the image will appear centered above the caption.
10. Change the placeholder text in the caption to one of your choosing.

Insert a question with hidden answer and floating hint

Example 1

Which elements can form hydrogen bonds?

Solution

fluorine, oxygen, or nitrogen

Exercise 1

Can phosphorus form hydrogen bonds?

Here is a hint if you need one!

Answer

No. Phosphorus and hydrogen have almost equal values of electronegativity.

Box Question with floating Hint

1. On your Chapter 33 page, click Edit.
2. From the menu bar that appears, select Elements, Templates
3. From the dropdown menu select Box: Exercise. The following box will appear

Exercise

Example 1

Add example text here. Which elements can form hydrogen bonds?

Solution

Add example text here. **fluorine, oxygen, or nitrogen**

1

Add exercises text here. Can phosphorus form hydrogen bonds?

Answer

No. Phosphorus and hydrogen have equal values of electronegativity.

4. Edit the Box Exercise as shown below by clicking in the text areas and replacing the text with your own. You can add an image by scrolling to the bottom of this page and selecting **Attach a file**.

A question 1

Which does **NOT** describe sodium dodecyl sulfate (SDS). SDS ....

1. readily forms bilayers
2. readily form micelles
3. is a single-chain amphiphile
4. has (a) unsaturated acyl chain(s)

Here is a hint if you need one!

Answer

It does not readily form a bilayer since it is a single-chain amphiphile. Instead, it forms micelles.

5. The hint in this example is a file that has been uploaded (see the list of attached files below). Right-click on the SDS.png file below and choose **Copy the link address**. Then double-click the word "hint" in the above box to highlight it, choose the link icon from the top menu bar, and paste the link into the Link To box after replacing the default link in the box. Under link options, select **Open in Contextual Help Overlay** to get the hint to float above the page.

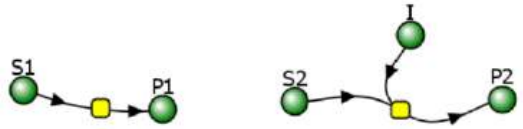
No inhibition (left) and Uncompetitive Inhibition (right)



Note that the Vcell reaction diagram is the same as for competitive and uncompetive inhibition. It doesn't explicitly show that the mixed inhibitor binds to both free and substrate-bound enzymes. Those interactions are addressed in the mathematical equations for mixed inhibition.

Initial values No Inhibition

Name	Description	Global	
J	reaction rate	☐	$\frac{Vmax \cdot S1}{(Km + S1)}$
Km	Km (1/2 max)	☐	5.0
Vmax	max reaction rate	☐	10.0
S1	Species Concentration	☑	Variable

Initial values With Uncompetitive Inhibitor

Name	Description	Global	
J	reaction rate	☐	$\frac{Vmax \cdot S2}{(Km \cdot (1.0 + \frac{I}{Kc}) + S2 \cdot (1.0 + \frac{I}{Ki}))}$
Km	user defined	☐	5.0
Vmax	user defined	☐	10.0
Kc	user defined	☐	1.0
Ki	user defined	☐	1.0
S2	Species Concentration	☑	Variable
I	Species Concentration	☑	Variable

I is fixed for each simulation (as it is not converted to a product) but can be changed in the simulation below.

Select Load [model name] below

Load NoInhib_MIXEDInhib_MM

Select **Start** to begin the simulation.

Select **Plot** to change Y axis min/max, then **Reset** and **Play** | Select **Slider** to change which constants are displayed | Select **About** for software information.

Move the sliders to change the constants and see changes in the displayed graph in real-time.

Time course model made using Virtual Cell (Vcell), **The Center for Cell Analysis & Modeling**, at **UConn Health**. Funded by NIH/NIGMS (R24 GM137787); Web simulation software (miniSidewinder) from Bartholomew Jardine and Herbert M. Sauro, University of Washington. Funded by NIH/NIGMS (RO1-GM123032-04)

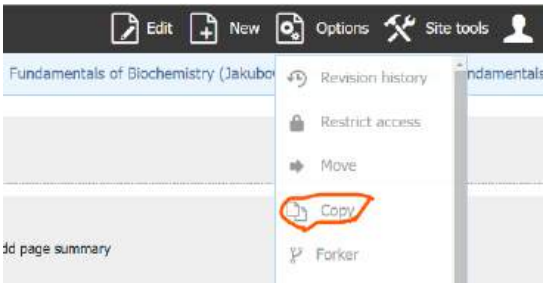
Add what you want

Make your own Chapter 33.x Section

Make Your Own Chapter 33.x Section

1. Navigate to this page in a new window
2. Open the file named **Template to Copy**
3. On the top menu bar select Options, Copy



4. Add a page title with this format: FirstName LastName Short Descriptive Title and then chose Copy Page.

5. Editing a webpage is generally intuitive. Once you click the Edit button on the top left-hand side of the page, editing icons will appear, similar to a word processing program. The icons on the top menu bar next to the indent icon allow you to: create a link, add a picture directly, add a table, and search (magnifying glass).

Make Your Own Customized FOB: Assemble and Remix a Custom Book (Short Version)

A. Introduction

Remixes are texts created from existing OER content. Constructing Remixes on the LibreTexts platform is facilitated by the OER Remixer tool. The title of the Remix often starts with the campus acronym (e.g., the Chemistry 110A remix at the University of California is "UCD: Chem 110A Introductory Quantum Mechanics")

If using the OER Remixer to build a large textbook, it is advisable to construct a Remixing Map in a spreadsheet including to organize the sections you'll include. This content will be an effective Table of Contents. For this exercise, we'll make a remix with just 3 chapter sections from 3 different chapters so no spreadsheet is needed.

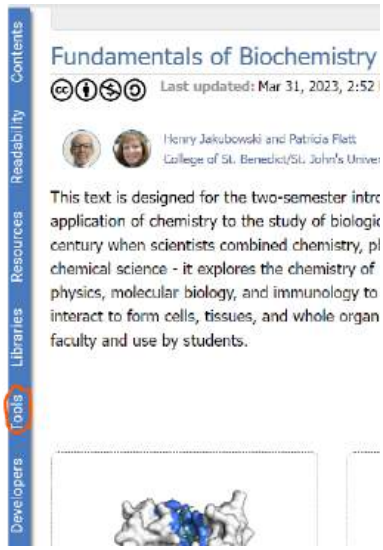
We'll use these chapter sections:

- Vol 1 – Chapter 6.5: Enzymatic Reaction Mechanisms (written by Henry and KP)
- Vol 2 – Chapter 14.5: Metabolism and Signaling: The Steady State, Adaptation and Homeostasis
- Vol 4 – Chapter 32.12: A Warmer World – Temperature Effects on Proteins

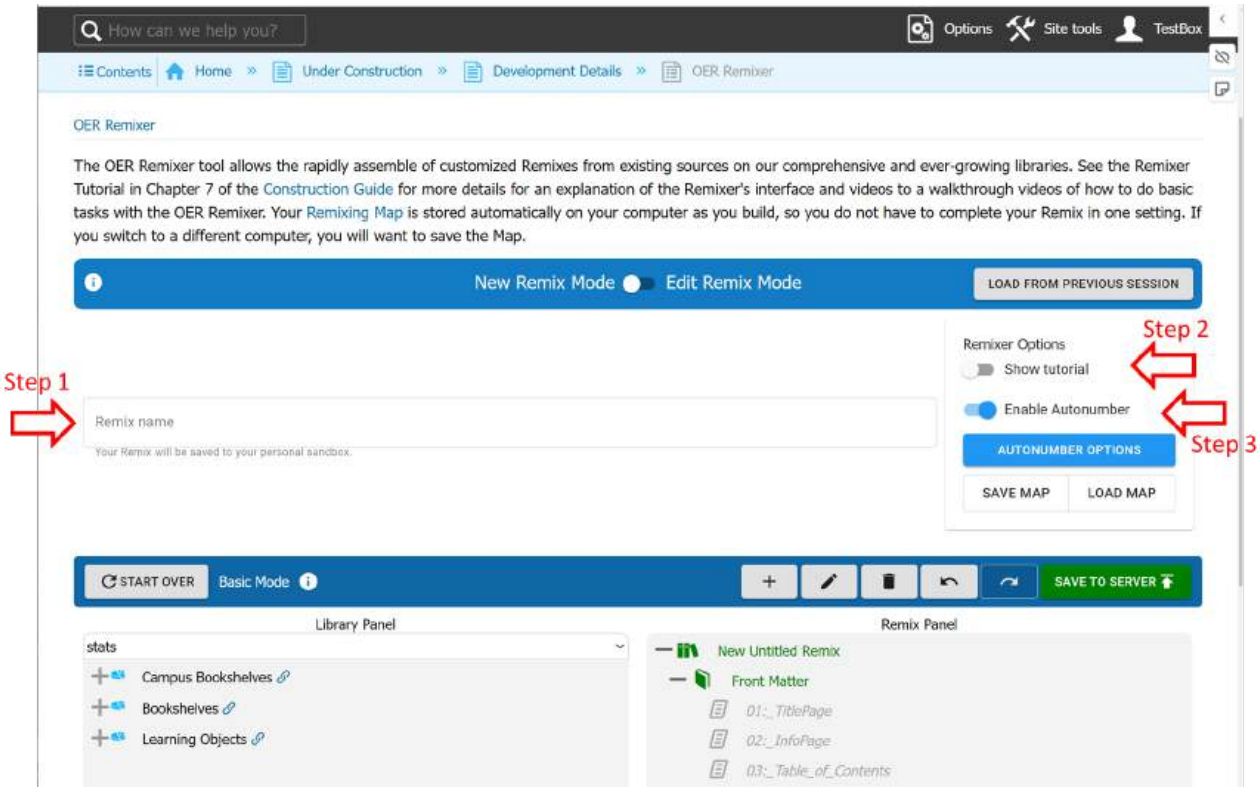
(Note: you could add content from any LibreText book as well.)

Instructions

1. Go to the main FOB page
2. An author with permission can see a blue vertical icon bar on the left side of the page.

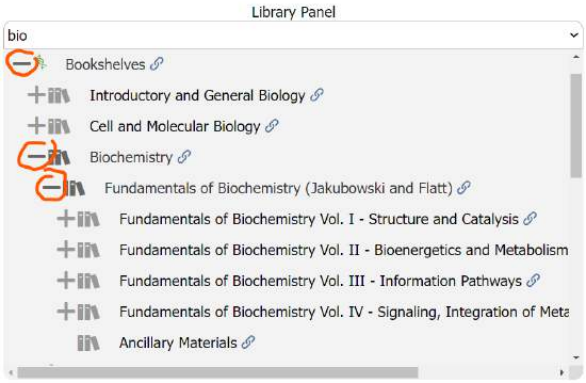


3. Select **Tools** and from the right side menu choose **OER Remixer**.
4. Complete the step indicated in the figure below



- ***Step 1:*** *Enter the name you want for your custom book (typically your name and the name of the class) in the box labeled "LibreText name" (Step 1 in Figure 7.3.57.3.5). Ex: Henry Jakubowski_TrialRemixFOB_1*
- ***For Step 2 and Step 3:*** *Accept the default*

5. In the left "Library Panel": Click the + by the bookshelves and continue to see Vol I, II, and IV (see image right). Keep expanding the list until you see Chapter 6 (Vol 1), then Chapter 14 (Vol 2), and finally Chapter 32 (Vol 4)

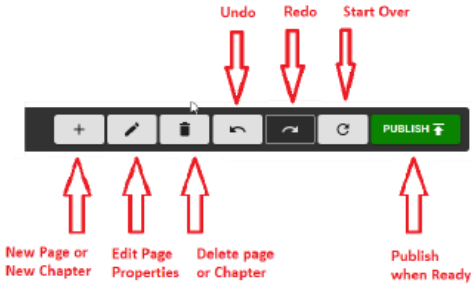


6. Insert the entire Chapter 6 by selecting it and dragging and dropping it to the right panel. Position it by moving it to the correct position (you will see a little blue line indicating the position)

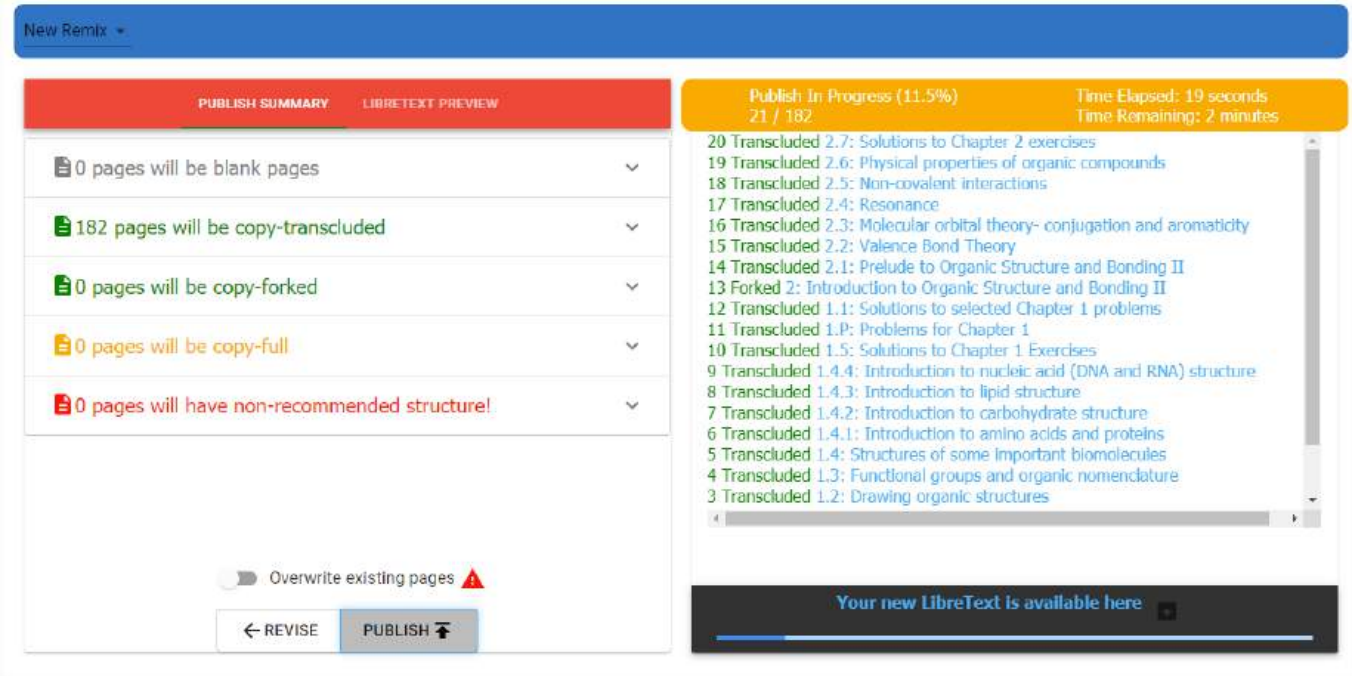
7. Repeat and move the entire Chapt 14 and Chapter 32.

8. Now expand the moved Chapters in the panel. Select the section you do **NOT** want and click the delete icon (recycle bin) in the menu bar in the right panel. Continue deleting until each Chapter has just the desired section.

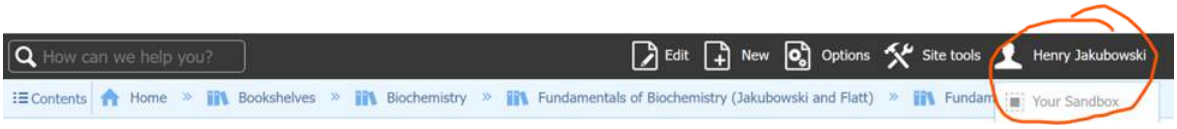
9. Select the Publish button (see image below)



10. In the next window select Publish again and wait until the remix is complete. Click the "Your new LibreText is available here to see your custom book (which is your Sandbox).



11. Your sandbox can be seen by clicking in your name on any LibreText page when you have logged in as shown below



B. Making a PDF

You can easily make a PDF of a chapter. For example, navigate to Chapter 14 and select PDF then Chapter and follow prompts.

? Question 1 1

Which does **NOT** describe sodium dodecyl sulfate (SDS). SDS ....

1. readily forms bilayers
2. readily form micelles
3. is a single-chain amphiphile
4. has (a) unsaturated acyl chain(s)

Here is a hint if you need one!

Answer

1. readily forms bilayers.
