Two opposing processes (such as evaporation and condensation) that occur at the same rate and thus produce no *net* change in a system, constitute a dynamic equilibrium. In the case of a liquid enclosed in a chamber, the molecules continuously evaporate and condense, but the amounts of liquid and vapor do not change with time. The pressure exerted by a vapor in dynamic equilibrium with a liquid is the equilibrium vapor pressure of the liquid.

If a liquid is in an *open* container, however, most of the molecules that escape into the vapor phase will *not* collide with the surface of the liquid and return to the liquid phase. Instead, they will diffuse through the gas phase away from the container, and an equilibrium will never be established. Under these conditions, the liquid will continue to evaporate until it has “disappeared.” The speed with which this occurs depends on the vapor pressure of the liquid and the temperature. Volatile liquids have relatively high vapor pressures and tend to evaporate readily; nonvolatile liquids have low vapor pressures and evaporate more slowly. Although the dividing line between volatile and nonvolatile liquids is not clear-cut, as a general guideline, we can say that substances with vapor pressures greater than that of water (Table 11.3.1) are relatively volatile, whereas those with vapor pressures less than that of water are relatively nonvolatile. Thus diethyl ether (ethyl ether), acetone, and gasoline are volatile, but mercury, ethylene glycol, and motor oil are nonvolatile.

The equilibrium vapor pressure of a substance at a particular temperature is a characteristic of the material, like its molecular mass, melting point, and boiling point (Table 11.3.1). It does *not* depend on the amount of liquid as long as at least a tiny amount of liquid is present in equilibrium with the vapor. The equilibrium vapor pressure does, however, depend very strongly on the temperature and the intermolecular forces present, as shown for several substances in Figure 10.4.4. Molecules that can hydrogen bond, such as ethylene glycol, have a much lower equilibrium vapor pressure than those that cannot, such as octane. The nonlinear increase in vapor pressure with increasing temperature is *much* steeper than the increase in pressure expected for an ideal gas over the corresponding temperature range. The temperature dependence is so strong because the vapor pressure depends on the fraction of molecules that have a kinetic energy greater than that needed to escape from the liquid, and this fraction increases exponentially with temperature. As a result, sealed containers of volatile liquids are potential bombs if subjected to large increases in temperature. The gas tanks on automobiles are vented, for example, so that a car won’t explode when parked in the sun. Similarly, the small cans (1–5 gallons) used to transport gasoline are required by law to have a pop-off pressure release.

Figure 11.4.4 The Vapor Pressures of Several Liquids as a Function of Temperature The point at which the vapor pressure curve crosses the $P = 1 \text{ atm}$ line (dashed) is the normal boiling point of the liquid.

Note the Pattern

Volatile substances have low boiling points and relatively weak intermolecular interactions; nonvolatile substances have high boiling points and relatively strong intermolecular interactions.

The exponential rise in vapor pressure with increasing temperature in Figure 11.4.4 allows us to use natural logarithms to express the nonlinear relationship as a linear one. For a review of natural logarithms, refer to Essential Skills 6 in Section 11.9.

$$\ln(P) = \frac{-\Delta H_{vap}}{R} \left(\frac{1}{T} \right) + C \quad (11.4.1)$$

where $\ln P$ is the natural logarithm of the vapor pressure, ΔH_{vap} is the **enthalpy of vaporization**, R is the universal gas constant [$8.314 \text{ J}/(\text{mol}\cdot\text{K})$], T is the temperature in Kelvin, and C is the y -intercept, which is a constant for any given liquid. A plot of $\ln P$ versus the inverse of the absolute temperature ($1/T$) is a straight line with a slope of $-\Delta H_{\text{vap}}/R$. Equation 11.4.1, called the Clausius–Clapeyron equation, can be used to calculate the ΔH_{vap} of a liquid from its measured vapor pressure at two or more temperatures. The simplest way to determine ΔH_{vap} is to measure the vapor pressure of a liquid at two temperatures and insert the values of P and T for these points into Equation 11.4.2, which is derived from the Clausius–Clapeyron equation:

$$\ln\left(\frac{P_2}{P_1}\right) = \frac{-\Delta H_{\text{vap}}}{R} \left(\frac{1}{T_2} - \frac{1}{T_1}\right) \quad (11.4.2)$$

Conversely, if we know ΔH_{vap} and the vapor pressure P_1 at any temperature T_1 , we can use Equation 10.4.2 to calculate the vapor pressure P_2 at any other temperature T_2 , as shown in Example 6.

Example 11.4.1

The experimentally measured vapor pressures of liquid Hg at four temperatures are listed in the following table:

T ($^{\circ}\text{C}$)	80.0	100	120	140
P (torr)	0.0888	0.2729	0.7457	1.845

From these data, calculate the enthalpy of vaporization (ΔH_{vap}) of mercury and predict the vapor pressure of the liquid at 160°C . (Safety note: mercury is highly toxic; when it is spilled, its vapor pressure generates hazardous levels of mercury vapor.)

Given: vapor pressures at four temperatures

Asked for: ΔH_{vap} of mercury and vapor pressure at 160°C

Strategy:

- Use Equation 11.4.2 to obtain ΔH_{vap} directly from two pairs of values in the table, making sure to convert all values to the appropriate units.
- Substitute the calculated value of ΔH_{vap} into Equation 11.4.2 to obtain the unknown pressure (P_2).

Solution:

A The table gives the measured vapor pressures of liquid Hg for four temperatures. Although one way to proceed would be to plot the data using Equation 11.4.1 and find the value of ΔH_{vap} from the slope of the line, an alternative approach is to use Equation 11.4.2 to obtain ΔH_{vap} directly from two pairs of values listed in the table, assuming no errors in our measurement. We therefore select two sets of values from the table and convert the temperatures from degrees Celsius to kelvins because the equation requires absolute temperatures. Substituting the values measured at 80.0°C (T_1) and 120.0°C (T_2) into Equation 11.4.2 gives

$$\ln\left(\frac{0.7457 \text{ Torr}}{0.0888 \text{ Torr}}\right) = \frac{-\Delta H_{\text{vap}}}{8.314 \text{ J/mol}\cdot\text{K}} \left(\frac{1}{(120+273) \text{ K}} - \frac{1}{(80.0+273) \text{ K}}\right) \quad (\text{Chapter 11.4.1})$$

$$\ln(8.398) = \frac{-\Delta H_{\text{vap}}}{8.314 \text{ J/mol}\cdot\text{K}} \left(-2.88 \times 10^{-4} \text{ K}^{-1}\right) \quad (\text{Chapter 11.4.2})$$

$$2.13 = -\Delta H_{\text{vap}} \left(-3.46 \times 10^{-4}\right) \text{ J}^{-1} \cdot \text{mol} \quad (\text{Chapter 11.4.3})$$

$$\Delta H_{\text{vap}} = 61,400 \text{ J/mol} = 61.4 \text{ kJ/mol} \quad (\text{Chapter 11.4.4})$$

B We can now use this value of ΔH_{vap} to calculate the vapor pressure of the liquid (P_2) at 160.0°C (T_2):

$$\ln\left(\frac{P_2}{0.0888 \text{ torr}}\right) = \frac{-61,400 \text{ J/mol}}{8.314 \text{ J/mol}\cdot\text{K}} \left(\frac{1}{(160+273) \text{ K}} - \frac{1}{(80.0+273) \text{ K}}\right) \quad (\text{Chapter 11.4.5})$$

Using the relationship $e^{\ln x} = x$, we have

$$\ln \left(\frac{P_2}{0.0888 \text{ Torr}} \right) = 3.86 \quad (\text{Chapter 11.4.6})$$

$$\frac{P_2}{0.0888 \text{ Torr}} = e^{3.86} = 47.5 \quad (\text{Chapter 11.4.7})$$

$$P_2 = 4.21 \text{ Torr} \quad (\text{Chapter 11.4.8})$$

At 160°C, liquid Hg has a vapor pressure of 4.21 torr, substantially greater than the pressure at 80.0°C, as we would expect.

Exercise

The vapor pressure of liquid nickel at 1606°C is 0.100 torr, whereas at 1805°C, its vapor pressure is 1.000 torr. At what temperature does the liquid have a vapor pressure of 2.500 torr?

Answer: 1896°C

Boiling Points

As the temperature of a liquid increases, the vapor pressure of the liquid increases until it equals the external pressure, or the atmospheric pressure in the case of an open container. Bubbles of vapor begin to form throughout the liquid, and the liquid begins to boil. The temperature at which a liquid boils at exactly 1 atm pressure is the normal boiling point. For water, the normal boiling point is exactly 100°C. The normal boiling points of the other liquids in [Figure 11.4.4](#) are represented by the points at which the vapor pressure curves cross the line corresponding to a pressure of 1 atm. Although we usually cite the normal boiling point of a liquid, the *actual* boiling point depends on the pressure. At a pressure greater than 1 atm, water boils at a temperature greater than 100°C because the increased pressure forces vapor molecules above the surface to condense. Hence the molecules must have greater kinetic energy to escape from the surface. Conversely, at pressures less than 1 atm, water boils below 100°C.

Typical variations in atmospheric pressure at sea level are relatively small, causing only minor changes in the boiling point of water. For example, the highest recorded atmospheric pressure at sea level is 813 mmHg, recorded during a Siberian winter; the lowest sea-level pressure ever measured was 658 mmHg in a Pacific typhoon. At these pressures, the boiling point of water changes minimally, to 102°C and 96°C, respectively. At high altitudes, on the other hand, the dependence of the boiling point of water on pressure becomes significant. [Table 11.4.1](#) lists the boiling points of water at several locations with different altitudes. At an elevation of only 5000 ft, for example, the boiling point of water is already lower than the lowest ever recorded at sea level. The lower boiling point of water has major consequences for cooking everything from soft-boiled eggs (a “three-minute egg” may well take four or more minutes in the Rockies and even longer in the Himalayas) to cakes (cake mixes are often sold with separate high-altitude instructions). Conversely, pressure cookers, which have a seal that allows the pressure inside them to exceed 1 atm, are used to cook food more rapidly by raising the boiling point of water and thus the temperature at which the food is being cooked.

Note the Pattern

As pressure increases, the boiling point of a liquid increases and vice versa.

Table 11.4.1 The Boiling Points of Water at Various Locations on Earth

Place	Altitude above Sea Level (ft)	Atmospheric Pressure (mmHg)	Boiling Point of Water (°C)
Mt. Everest, Nepal/Tibet	29,028	240	70
Bogota, Colombia	11,490	495	88
Denver, Colorado	5280	633	95

Place	Altitude above Sea Level (ft)	Atmospheric Pressure (mmHg)	Boiling Point of Water (°C)
Washington, DC	25	759	100
Dead Sea, Israel/Jordan	-1312	799	101.4

Example 11.4.2

Use [Figure 11.4.4](#) to estimate the following.

- the boiling point of water in a pressure cooker operating at 1000 mmHg
- the pressure required for mercury to boil at 250°C

Given: data in [Figure 11.4.4](#), pressure, and boiling point

Asked for: corresponding boiling point and pressure

Strategy:

- To estimate the boiling point of water at 1000 mmHg, refer to [Figure 10.4.4](#) and find the point where the vapor pressure curve of water intersects the line corresponding to a pressure of 1000 mmHg.
- To estimate the pressure required for mercury to boil at 250°C, find the point where the vapor pressure curve of mercury intersects the line corresponding to a temperature of 250°C.

Solution:

- A** The vapor pressure curve of water intersects the $P = 1000$ mmHg line at about 110°C; this is therefore the boiling point of water at 1000 mmHg.
- B** The vertical line corresponding to 250°C intersects the vapor pressure curve of mercury at $P \approx 75$ mmHg. Hence this is the pressure required for mercury to boil at 250°C.

Exercise

Use the data in [Figure 10.4.4](#) to estimate the following.

- the normal boiling point of ethylene glycol
- the pressure required for diethyl ether to boil at 20°C.

Answer:

- 200°C
- 450 mmHg

Summary

Because the molecules of a liquid are in constant motion and possess a wide range of kinetic energies, at any moment some fraction of them has enough energy to escape from the surface of the liquid to enter the gas or vapor phase. This process, called **vaporization** or **evaporation**, generates a **vapor pressure** above the liquid. Molecules in the gas phase can collide with the liquid surface and reenter the liquid via **condensation**. Eventually, a *steady state* is reached in which the number of molecules evaporating and condensing per unit time is the same, and the system is in a state of **dynamic equilibrium**. Under these conditions, a liquid exhibits a characteristic **equilibrium vapor pressure** that depends only on the temperature. We can express the nonlinear relationship between vapor pressure and temperature as a linear relationship using the **Clausius–Clapeyron equation**. This equation can be used to calculate the enthalpy of vaporization of a liquid from its measured vapor pressure at two or more temperatures. **Volatile liquids** are liquids with high vapor pressures, which tend to evaporate readily from an open container; **nonvolatile liquids** have low vapor pressures. When the vapor pressure equals the external pressure,

bubbles of vapor form within the liquid, and it boils. The temperature at which a substance boils at a pressure of 1 atm is its **normal boiling point**.

Key Takeaways

- The equilibrium vapor pressure of a liquid depends on the temperature and the intermolecular forces present.
- The relationship between pressure, enthalpy of vaporization, and temperature is given by the Clausius-Clapeyron equation.

Key Equations

Clausius–Clapeyron equation

$$\ln(P) = \frac{-\Delta H_{vap}}{R} \left(\frac{1}{T} \right) + C \quad (11.4.1)$$

Using vapor pressure at two temperatures to calculate ΔH_{vap}

$$\ln \left(\frac{P_2}{P_1} \right) = \frac{-\Delta H_{vap}}{R} \left(\frac{1}{T_2} - \frac{1}{T_1} \right) \quad (11.4.2)$$

Conceptual Problems

1. What is the relationship between the boiling point, vapor pressure, and temperature of a substance and atmospheric pressure?
2. What is the difference between a volatile liquid and a nonvolatile liquid? Suppose that two liquid substances have the same molecular mass, but one is volatile and the other is nonvolatile. What differences in the molecular structures of the two substances could account for the differences in volatility?
3. An “old wives’ tale” states that applying ethanol to the wrists of a child with a very high fever will help to reduce the fever because blood vessels in the wrists are close to the skin. Is there a scientific basis for this recommendation? Would water be as effective as ethanol?
4. Why is the air over a strip of grass significantly cooler than the air over a sandy beach only a few feet away?
5. If gasoline is allowed to sit in an open container, it often feels much colder than the surrounding air. Explain this observation. Describe the flow of heat into or out of the system, as well as any transfer of mass that occurs. Would the temperature of a sealed can of gasoline be higher, lower, or the same as that of the open can? Explain your answer.
6. What is the relationship between the vapor pressure of a liquid and
 - a. its temperature?
 - b. the surface area of the liquid?
 - c. the pressure of other gases on the liquid?
 - d. its viscosity?
7. At 25°C, benzene has a vapor pressure of 12.5 kPa, whereas the vapor pressure of acetic acid is 2.1 kPa. Which is more volatile? Based on the intermolecular interactions in the two liquids, explain why acetic acid has the lower vapor pressure.

Numerical Problems

1. Acetylene (C_2H_2), which is used for industrial welding, is transported in pressurized cylinders. Its vapor pressure at various temperatures is given in the following table. Plot the data and use your graph to estimate the vapor pressure of acetylene at 293 K. Then use your graph to determine the value of ΔH_{vap} for acetylene. How much energy is required to vaporize 2.00 g of acetylene at 250 K?

T (K)	145	155	175	200	225	250	300
P (mmHg)	1.3	7.8	32.2	190	579	1370	5093

2. The following table gives the vapor pressure of water at various temperatures. Plot the data and use your graph to estimate the vapor pressure of water at 25°C and at 75°C. What is the vapor pressure of water at 110°C? Use these data to determine the value of ΔH_{vap} for water.

T (°C)	0	10	30	50	60	80	100
P (mmHg)	4.6	9.2	31.8	92.6	150	355	760

3. The ΔH_{vap} of carbon tetrachloride is 29.8 kJ/mol, and its normal boiling point is 76.8°C. What is its boiling point at 0.100 atm?
4. The normal boiling point of sodium is 883°C. If ΔH_{vap} is 97.4 kJ/mol, what is the vapor pressure (in millimeters of mercury) of liquid sodium at 300°C?
5. An unknown liquid has a vapor pressure of 0.860 atm at 63.7°C and a vapor pressure of 0.330 atm at 35.1°C. Use the data in Table 11.5.1 to identify the liquid.
6. An unknown liquid has a boiling point of 75.8°C at 0.910 atm and a boiling point of 57.2°C at 0.430 atm. Use the data in Table 11.5.1 to identify the liquid.
7. If the vapor pressure of a liquid is 0.850 atm at 20°C and 0.897 atm at 25°C, what is the normal boiling point of the liquid?
8. If the vapor pressure of a liquid is 0.799 atm at 99.0°C and 0.842 atm at 111°C, what is the normal boiling point of the liquid?
9. The vapor pressure of liquid SO_2 is 33.4 torr at -63.4°C and 100.0 torr at -47.7°C .
- What is the ΔH_{vap} of SO_2 ?
 - What is its vapor pressure at -24.5°C ?
 - At what temperature is the vapor pressure equal to 220 torr?
10. The vapor pressure of CO_2 at various temperatures is given in the following table:

T (°C)	-120	-110	-100	-90
P (torr)	9.81	34.63	104.81	279.5

- What is ΔH_{vap} over this temperature range?
- What is the vapor pressure of CO_2 at -70°C ?
- At what temperature does CO_2 have a vapor pressure of 310 torr?

Answers

1.

vapor pressure at 273 K is 3050 mmHg; $\Delta H_{\text{vap}} = 18.7$ kJ/mol, 1.44 kJ

-
-
- 12.5°C
-
- $\Delta H_{\text{vap}} = 28.9$ kJ/mol, *n*-hexane
-
- $\Delta H_{\text{vap}} = 7.81$ kJ/mol, 36°C
-
-

Learning Objectives

- To calculate the energy changes that accompany phase changes.

We take advantage of changes between the gas, liquid, and solid states to cool a drink with ice cubes (solid to liquid), cool our bodies by perspiration (liquid to gas), and cool food inside a refrigerator (gas to liquid and vice versa). We use dry ice, which is solid CO_2 , as a refrigerant (solid to gas), and we make artificial snow for skiing and snowboarding by transforming a liquid to a solid. In this section, we examine what happens when any of the three forms of matter is converted to either of the other two. These changes of state are often called phase changes. The six most common phase changes are shown in [Figure 11.5.1](#).

Figure 11.5.1 *The Three Phases of Matter and the Processes That Interconvert Them When the Temperature Is Changed*
Enthalpy changes that accompany phase transitions are indicated by purple and green arrows.

Energy Changes That Accompany Phase Changes

Phase changes are *always* accompanied by a change in the energy of a system. For example, converting a liquid, in which the molecules are close together, to a gas, in which the molecules are, on average, far apart, requires an input of energy (heat) to give the molecules enough kinetic energy to allow them to overcome the intermolecular attractive forces. The stronger the attractive forces, the more energy is needed to overcome them. Solids, which are highly ordered, have the strongest intermolecular interactions, whereas gases, which are very disordered, have the weakest. Thus any transition from a more ordered to a less ordered state (solid to liquid, liquid to gas, or solid to gas) requires an input of energy; it is **endothermic**. Conversely, any transition from a less ordered to a more ordered state (liquid to solid, gas to liquid, or gas to solid) releases energy; it is **exothermic**. The energy change associated with each common phase change is shown in [Figure 11.5.1](#).

In [Chapter 9](#), we defined the enthalpy changes associated with various chemical and physical processes. The melting points and molar **enthalpies of fusion** (ΔH_{fus}), the energy required to convert from a solid to a liquid, a process known as fusion (or melting), as well as the normal boiling points and enthalpies of vaporization (ΔH_{vap}) of selected compounds are listed in [Table 10.5.1](#). The substances with the highest melting points usually have the highest enthalpies of fusion; they tend to be ionic compounds that are

held together by very strong electrostatic interactions. Substances with high boiling points are those with strong intermolecular interactions that must be overcome to convert a liquid to a gas, resulting in high enthalpies of vaporization. The enthalpy of vaporization of a given substance is much greater than its enthalpy of fusion because it takes more energy to completely separate molecules (conversion from a liquid to a gas) than to enable them only to move past one another freely (conversion from a solid to a liquid).

Table 11.5.1 Melting and Boiling Points and Enthalpies of Fusion and Vaporization for Selected Substances

Substance	Melting Point (°C)	ΔH_{fus} (kJ/mol)	Boiling Point (°C)	ΔH_{vap} (kJ/mol)
N ₂	-210.0	0.71	-195.8	5.6
HCl	-114.2	2.00	-85.1	16.2
Br ₂	-7.2	10.6	58.8	30.0
CCl ₄	-22.6	2.56	76.8	29.8
CH ₃ CH ₂ OH (ethanol)	-114.1	4.93	78.3	38.6
CH ₃ (CH ₂) ₄ CH ₃ (<i>n</i> -hexane)	-95.4	13.1	68.7	28.9
H ₂ O	0	6.01	100	40.7
Na	97.8	2.6	883	97.4
NaF	996	33.4	1704	176.1

Note the Pattern

ΔH is positive for any transition from a more ordered to a less ordered state and negative for a transition from a less ordered to a more ordered state.

The direct conversion of a solid to a gas, without an intervening liquid phase, is called sublimation. The amount of energy required to sublime 1 mol of a pure solid is the enthalpy of sublimation (ΔH_{sub}). Common substances that sublime at standard temperature and pressure (STP; 0°C, 1 atm) include CO₂ (dry ice); iodine (Figure 11.5.2); naphthalene, a substance used to protect woolen clothing against moths; and 1,4-dichlorobenzene. As shown in Figure 11.5.1 the enthalpy of sublimation of a substance is the sum of its enthalpies of fusion and vaporization provided all values are at the same T ; this is an application of Hess's law. (For more information about Hess's law, see Section 9.2).

$$\Delta H_{\text{sub}} = \Delta H_{\text{fus}} + \Delta H_{\text{vap}} \quad (11.5.1)$$

Figure 11.5.2 *The Sublimation of Solid Iodine* When solid iodine is heated at ordinary atmospheric pressure, it sublimates. When the I_2 vapor comes in contact with a cold surface, it deposits I_2 crystals.

Fusion, vaporization, and sublimation are endothermic processes; they occur only with the absorption of heat. Anyone who has ever stepped out of a swimming pool on a cool, breezy day has felt the heat loss that accompanies the evaporation of water from the skin. Our bodies use this same phenomenon to maintain a constant temperature: we perspire continuously, even when at rest, losing about 600 mL of water daily by evaporation from the skin. We also lose about 400 mL of water as water vapor in the air we exhale, which also contributes to cooling. Refrigerators and air-conditioners operate on a similar principle: heat is absorbed from the object or area to be cooled and used to vaporize a low-boiling-point liquid, such as ammonia or the chlorofluorocarbons (CFCs) and the hydrofluorocarbons (HFCs) discussed in [Section 7.6](#) in connection with the ozone layer. The vapor is then transported to a different location and compressed, thus releasing and dissipating the heat. Likewise, ice cubes efficiently cool a drink not because of their low temperature but because heat is required to convert ice at 0°C to liquid water at 0°C , as demonstrated later in Example 8.

Temperature Curves

The processes on the right side of [Figure 11.5.1](#)—freezing, condensation, and deposition, which are the reverse of fusion, sublimation, and vaporization—are exothermic. Thus heat pumps that use refrigerants are essentially air-conditioners running in

reverse. Heat from the environment is used to vaporize the refrigerant, which is then condensed to a liquid in coils within a house to provide heat. The energy changes that occur during phase changes can be quantified by using a heating or cooling curve.

Heating Curves

Figure 11.5.3 shows a heating curve, a plot of temperature versus heating time, for a 75 g sample of water. The sample is initially ice at 1 atm and -23°C ; as heat is added, the temperature of the ice increases linearly with time. The slope of the line depends on both the mass of the ice and the specific heat (C_s) of ice, which is the number of joules required to raise the temperature of 1 g of ice by 1°C . As the temperature of the ice increases, the water molecules in the ice crystal absorb more and more energy and vibrate more vigorously. At the melting point, they have enough kinetic energy to overcome attractive forces and move with respect to one another. As more heat is added, the temperature of the system does *not* increase further but remains constant at 0°C until all the ice has melted. Once all the ice has been converted to liquid water, the temperature of the water again begins to increase. Now, however, the temperature increases more slowly than before because the specific heat capacity of water is *greater* than that of ice. When the temperature of the water reaches 100°C , the water begins to boil. Here, too, the temperature remains constant at 100°C until all the water has been converted to steam. At this point, the temperature again begins to rise, but at a *faster* rate than seen in the other phases because the heat capacity of steam is *less* than that of ice or water.

Figure 11.5.3 A Heating Curve for Water This plot of temperature shows what happens to a 75 g sample of ice initially at 1 atm and -23°C as heat is added at a constant rate: A–B: heating solid ice; B–C: melting ice; C–D: heating liquid water; D–E: vaporizing water; E–F: heating steam.

Thus *the temperature of a system does not change during a phase change*. In this example, as long as even a tiny amount of ice is present, the temperature of the system remains at 0°C during the melting process, and as long as even a small amount of liquid water is present, the temperature of the system remains at 100°C during the boiling process. The rate at which heat is added does *not* affect the temperature of the ice/water or water/steam mixture because the added heat is being used exclusively to overcome the attractive forces that hold the more condensed phase together. Many cooks think that food will cook faster if the heat is turned up higher so that the water boils more rapidly. Instead, the pot of water will boil to dryness sooner, but the temperature of the water does not depend on how vigorously it boils.

Note the Pattern

The temperature of a sample does not change during a phase change.

If heat is added at a constant rate, as in Figure 11.5.3, then the length of the horizontal lines, which represents the time during which the temperature does not change, is directly proportional to the magnitude of the enthalpies associated with the phase changes. In Figure 11.5.3, the horizontal line at 100°C is much longer than the line at 0°C because the enthalpy of vaporization of water is several times greater than the enthalpy of fusion.

A superheated liquid is a sample of a liquid at the temperature and pressure at which it should be a gas. Superheated liquids are not stable; the liquid will eventually boil, sometimes violently. The phenomenon of superheating causes “bumping” when a liquid is heated in the laboratory. When a test tube containing water is heated over a Bunsen burner, for example, one portion of the liquid can easily become too hot. When the superheated liquid converts to a gas, it can push or “bump” the rest of the liquid out of the test tube. Placing a stirring rod or a small piece of ceramic (a “boiling chip”) in the test tube allows bubbles of vapor to form on the

surface of the object so the liquid boils instead of becoming superheated. Superheating is the reason a liquid heated in a smooth cup in a microwave oven may not boil until the cup is moved, when the motion of the cup allows bubbles to form.

Cooling Curves

The cooling curve, a plot of temperature versus cooling time, in [Figure 11.5.4](#) plots temperature versus time as a 75 g sample of steam, initially at 1 atm and 200°C, is cooled. Although we might expect the cooling curve to be the mirror image of the heating curve in [Figure 11.5.3](#), the cooling curve is *not* an identical mirror image. As heat is removed from the steam, the temperature falls until it reaches 100°C. At this temperature, the steam begins to condense to liquid water. No further temperature change occurs until all the steam is converted to the liquid; then the temperature again decreases as the water is cooled. We might expect to reach another plateau at 0°C, where the water is converted to ice; in reality, however, this does not always occur. Instead, the temperature often drops below the freezing point for some time, as shown by the little dip in the cooling curve below 0°C. This region corresponds to an unstable form of the liquid, a supercooled liquid. If the liquid is allowed to stand, if cooling is continued, or if a small crystal of the solid phase is added (a seed crystal), the supercooled liquid will convert to a solid, sometimes quite suddenly. As the water freezes, the temperature increases slightly due to the heat evolved during the freezing process and then holds constant at the melting point as the rest of the water freezes. Subsequently, the temperature of the ice decreases again as more heat is removed from the system.

Figure 11.5.4 A Cooling Curve for Water This plot of temperature shows what happens to a 75 g sample of steam initially at 1 atm and 200°C as heat is removed at a constant rate: A–B: cooling steam; B–C: condensing steam; C–D: cooling liquid water to give a supercooled liquid; D–E: warming the liquid as it begins to freeze; E–F: freezing liquid water; F–G: cooling ice.

Supercooling effects have a huge impact on Earth’s climate. For example, supercooling of water droplets in clouds can prevent the clouds from releasing precipitation over regions that are persistently arid as a result. Clouds consist of tiny droplets of water, which in principle should be dense enough to fall as rain. In fact, however, the droplets must aggregate to reach a certain size before they can fall to the ground. Usually a small particle (a *nucleus*) is required for the droplets to aggregate; the nucleus can be a dust particle, an ice crystal, or a particle of silver iodide dispersed in a cloud during *seeding* (a method of inducing rain). Unfortunately, the small droplets of water generally remain as a supercooled liquid down to about -10°C , rather than freezing into ice crystals that are more suitable nuclei for raindrop formation. One approach to producing rainfall from an existing cloud is to cool the water droplets so that they crystallize to provide nuclei around which raindrops can grow. This is best done by dispersing small granules of solid CO_2 (dry ice) into the cloud from an airplane. Solid CO_2 sublimates directly to the gas at pressures of 1 atm or lower, and the enthalpy of sublimation is substantial (25.3 kJ/mol). As the CO_2 sublimates, it absorbs heat from the cloud, often with the desired results.

Example 11.5.1

If a 50.0 g ice cube at 0.0°C is added to 500 mL of tea at 20.0°C , what is the temperature of the tea when the ice cube has just melted? Assume that no heat is transferred to or from the surroundings. The density of water (and iced tea) is 1.00 g/mL over the range 0°C – 20°C , the specific heats of liquid water and ice are $4.184 \text{ J}/(\text{g}\cdot^{\circ}\text{C})$ and $2.062 \text{ J}/(\text{g}\cdot^{\circ}\text{C})$, respectively, and the enthalpy of fusion of ice is 6.01 kJ/mol .

Given: mass, volume, initial temperature, density, specific heats, and ΔH_{fus}

Asked for: final temperature

Strategy:

Substitute the values given into the general equation relating heat gained to heat lost (Equation 9.6.7) to obtain the final temperature of the mixture.

Solution:

Recall from Chapter 9 that when two substances or objects at different temperatures are brought into contact, heat will flow from the warmer one to the cooler. The amount of heat that flows is given by

$$q = mC_s\Delta T$$

where q is heat, m is mass, C_s is the specific heat, and ΔT is the temperature change. Eventually, the temperatures of the two substances will become equal at a value somewhere between their initial temperatures. Calculating the temperature of iced tea after adding an ice cube is slightly more complicated. The general equation relating heat gained and heat lost is still valid, but in this case we also have to take into account the amount of heat required to melt the ice cube from ice at 0.0°C to liquid water at 0.0°C :

$$q_{\text{lost}} = -q_{\text{gained}}$$

$$m_{\text{iced tea}} C_s(\text{H}_2\text{O}) \Delta T_{\text{iced tea}} = -[m_{\text{ice}} C_s(\text{H}_2\text{O}) \Delta T_{\text{ice}}] + m_{\text{ice}} \Delta H_{\text{fus}}(\text{H}_2\text{O})$$

$$500 \text{ g} \left[4.184 \text{ J} / (\text{g} \cdot ^\circ\text{C}) \right] (T_f - 20.0^\circ\text{C}) = -50 \text{ g} \left[4.184 \text{ J} / (\text{g} \cdot ^\circ\text{C}) \right] (T_f - 0.0^\circ\text{C}) - \frac{50.0 \text{ g}}{18.0 \text{ g/mol}} 6.01$$

$$\times 10^3 \text{ J/mol}$$

$$(2090 \text{ J}/^\circ\text{C}) (T_f - 20.0^\circ\text{C}) = -(209 \text{ J}/^\circ\text{C}) T_f - 1.67 \times 10^4 \text{ J}$$

$$2.53 \times 10^4 \text{ J} = (2310 \text{ J}/^\circ\text{C}) T_f$$

$$11.0^\circ\text{C} = T_f$$

Exercise

Suppose you are overtaken by a blizzard while ski touring and you take refuge in a tent. You are thirsty, but you forgot to bring liquid water. You have a choice of eating a few handfuls of snow (say 400 g) at -5.0°C immediately to quench your thirst or setting up your propane stove, melting the snow, and heating the water to body temperature before drinking it. You recall that the survival guide you leafed through at the hotel said something about not eating snow, but you can't remember why—after all, it's just frozen water. To understand the guide's recommendation, calculate the amount of heat that your body will have to supply to bring 400 g of snow at -5.0°C to your body's internal temperature of 37°C . Use the data in Example 8

Answer: 200 kJ (4.1 kJ to bring the ice from -5.0°C to 0.0°C , 133.6 kJ to melt the ice at 0.0°C , and 61.9 kJ to bring the water from 0.0°C to 37°C), which is energy that would not have been expended had you first melted the snow.

Summary

Changes of state are examples of **phase changes**, or *phase transitions*. All phase changes are accompanied by changes in the energy of a system. Changes from a more-ordered state to a less-ordered state (such as a liquid to a gas) are *endothermic*. Changes from a less-ordered state to a more-ordered state (such as a liquid to a solid) are always *exothermic*. The conversion of a solid to a liquid is called **fusion (or melting)**. The energy required to melt 1 mol of a substance is its enthalpy of fusion (ΔH_{fus}). The energy change required to vaporize 1 mol of a substance is the enthalpy of vaporization (ΔH_{vap}). The direct conversion of a solid to a gas is **sublimation**. The amount of energy needed to sublime 1 mol of a substance is its **enthalpy of sublimation (ΔH_{sub})** and is the sum of the enthalpies of fusion and vaporization. Plots of the temperature of a substance versus heat added or versus heating time at a constant rate of heating are called **heating curves**. Heating curves relate

temperature changes to phase transitions. A **superheated liquid**, a liquid at a temperature and pressure at which it should be a gas, is not stable. A **cooling curve** is not exactly the reverse of the heating curve because many liquids do not freeze at the expected temperature. Instead, they form a **supercooled liquid**, a metastable liquid phase that exists below the normal melting point. Supercooled liquids usually crystallize on standing, or adding a **seed crystal** of the same or another substance can induce crystallization.

Key Takeaway

- Fusion, vaporization, and sublimation are endothermic processes, whereas freezing, condensation, and deposition are exothermic processes.

Conceptual Problems

1. In extremely cold climates, snow can disappear with no evidence of its melting. How can this happen? What change(s) in state are taking place? Would you expect this phenomenon to be more common at high or low altitudes? Explain your answer.
2. Why do car manufacturers recommend that an automobile should not be left standing in subzero temperatures if its radiator contains only water? Car manufacturers also warn car owners that they should check the fluid level in a radiator only when the engine is cool. What is the basis for this warning? What is likely to happen if it is ignored?
3. Use Hess's law and a thermochemical cycle to show that, for any solid, the enthalpy of sublimation is equal to the sum of the enthalpy of fusion of the solid and the enthalpy of vaporization of the resulting liquid.
4. Three distinct processes occur when an ice cube at -10°C is used to cool a glass of water at 20°C . What are they? Which causes the greatest temperature change in the water?
5. When frost forms on a piece of glass, crystals of ice are deposited from water vapor in the air. How is this process related to sublimation? Describe the energy changes that take place as the water vapor is converted to frost.
6. What phase changes are involved in each process? Which processes are exothermic, and which are endothermic?
 - a. ice melting
 - b. distillation
 - c. condensation forming on a window
 - d. the use of dry ice to create a cloud for a theatrical production
7. What phase changes are involved in each process? Which processes are exothermic, and which are endothermic?
 - a. evaporation of methanol
 - b. crystallization
 - c. liquefaction of natural gas
 - d. the use of naphthalene crystals to repel moths
8. Why do substances with high enthalpies of fusion tend to have high melting points?
9. Why is the enthalpy of vaporization of a compound invariably much larger than its enthalpy of fusion?
10. What is the opposite of fusion, sublimation, and condensation? Describe the phase change in each pair of opposing processes and state whether each phase change is exothermic or endothermic.
11. Draw a typical heating curve (temperature versus amount of heat added at a constant rate) for conversion of a solid to a liquid and then to a gas. What causes some regions of the plot to have a positive slope? What is happening in the regions of the plot where the curve is horizontal, meaning that the temperature does not change even though heat is being added?
12. If you know the mass of a sample of a substance, how could you use a heating curve to calculate the specific heat of the substance, as well as the change in enthalpy associated with a phase change?
13. Draw the heating curve for a liquid that has been superheated. How does this differ from a normal heating curve for a liquid? Draw the cooling curve for a liquid that has been supercooled. How does this differ from a normal cooling curve for a liquid?

Answers

1. When snow disappears without melting, it must be subliming directly from the solid state to the vapor state. The rate at which this will occur depends solely on the partial pressure of water, not on the total pressure due to other gases. Consequently, altitude (and changes in atmospheric pressure) will not affect the rate of sublimation directly.
- 2.

3. The general equations and enthalpy changes for the changes of state involved in converting a solid to a gas are:

The relationship between these enthalpy changes is shown schematically in the thermochemical cycle below:

4.

5. The formation of frost on a surface is an example of deposition, which is the reverse of sublimation. The change in enthalpy for deposition is equal in magnitude, but opposite in sign, to ΔH_{sub} , which is a positive number: $\Delta H_{sub} = \Delta H_{fus} + \Delta H_{vap}$.

6.

7.

- liquid + heat \rightarrow vapor: endothermic
- liquid \rightarrow solid + heat: exothermic
- gas \rightarrow liquid + heat: exothermic
- solid + heat \rightarrow vapor: endothermic

8.

9. The enthalpy of vaporization is larger than the enthalpy of fusion because vaporization requires the addition of enough energy to disrupt all intermolecular interactions and create a gas in which the molecules move essentially independently. In contrast, fusion requires much less energy, because the intermolecular interactions in a liquid and a solid are similar in magnitude in all condensed phases. Fusion requires only enough energy to overcome the intermolecular interactions that lock molecules in place in a lattice, thereby allowing them to move more freely.

10.

11.

The portions of the curve with a positive slope correspond to heating a single phase, while the horizontal portions of the curve correspond to phase changes. During a phase change, the temperature of the system does not change, because the added heat is melting the solid at its melting point or evaporating the liquid at its boiling point.

12.

13.

A superheated liquid exists temporarily as liquid with a temperature above the normal boiling point of the liquid. When a supercooled liquid boils, the temperature drops as the liquid is converted to vapor.

Conversely, a supercooled liquid exists temporarily as a liquid with a temperature lower than the normal melting point of the solid. As shown below, when a supercooled liquid crystallizes, the temperature increases as the liquid is converted to a solid.

Numerical Problems

- The density of oxygen at 1 atm and various temperatures is given in the following table. Plot the data and use your graph to predict the normal boiling point of oxygen.

T (K)	60	70	80	90	100	120	140
d (mol/L)	40.1	38.6	37.2	35.6	0.123	0.102	0.087

- The density of propane at 1 atm and various temperatures is given in the following table. Plot the data and use your graph to predict the normal boiling point of propane.

T (K)	100	125	150	175	200	225	250	275
d (mol/L)	16.3	15.7	15.0	14.4	13.8	13.2	0.049	0.044

- Draw the cooling curve for a sample of the vapor of a compound that has a melting point of 34°C and a boiling point of 77°C as it is cooled from 100°C to 0°C .
- Propionic acid has a melting point of -20.8°C and a boiling point of 141°C . Draw a heating curve showing the temperature versus time as heat is added at a constant rate to show the behavior of a sample of propionic acid as it is heated from -50°C to its boiling point. What happens above 141°C ?
- A 0.542 g sample of I_2 requires 96.1 J of energy to be converted to vapor. What is the enthalpy of sublimation of I_2 ?
- A 2.0 L sample of gas at 210°C and 0.762 atm condenses to give 1.20 mL of liquid, and 476 J of heat is released during the process. What is the enthalpy of vaporization of the compound?
- One fuel used for jet engines and rockets is aluminum borohydride $[\text{Al}(\text{BH}_4)_3]$, a liquid that readily reacts with water to produce hydrogen. The liquid has a boiling point of 44.5°C . How much energy is needed to vaporize 1.0 kg of aluminum borohydride at 20°C , given a ΔH_{vap} of 30 kJ/mol and a molar heat capacity (C_p) of 194.6 J/(mol·K)?
- How much energy is released when freezing 100.0 g of dimethyl disulfide ($\text{C}_2\text{H}_6\text{S}_2$) initially at 20°C ? Use the following information: melting point = -84.7°C , $\Delta H_{\text{fus}} = 9.19$ kJ/mol, $C_p = 118.1$ J/(mol·K).

The following four problems use the following information (the subscript p indicates measurements taken at constant pressure): $\Delta H_{\text{fus}}(\text{H}_2\text{O}) = 6.01$ kJ/mol, $\Delta H_{\text{vap}}(\text{H}_2\text{O}) = 40.66$ kJ/mol, $C_{p(s)}(\text{crystalline H}_2\text{O}) = 38.02$ J/(mol·K), $C_{p(l)}(\text{liquid H}_2\text{O}) = 75.35$ J/(mol·K), and $C_{p(g)}(\text{H}_2\text{O gas}) = 33.60$ J/(mol·K).

9. How much heat is released in the conversion of 1.00 L of steam at 21.9 atm and 200°C to ice at -6.0°C and 1 atm?
10. How much heat must be applied to convert a 1.00 g piece of ice at -10°C to steam at 120°C ?
11. How many grams of boiling water must be added to a glass with 25.0 g of ice at -3°C to obtain a liquid with a temperature of 45°C ?
12. How many grams of ice at -5.0°C must be added to 150.0 g of water at 22°C to give a final temperature of 15°C ?

Answers

1.

The transition from a liquid to a gaseous phase is accompanied by a drastic decrease in density. According to the data in the table and the plot, the boiling point of liquid oxygen is between 90 and 100 K (actually 90.2 K).

2.

3.

4.

5. 45.0 kJ/mol

6.

7. 488 kJ

8.

9. 32.6 kJ

10.

11. 57 g

Chapter 11.6: Critical Temperature and Pressure

Howard University General Chemistry: An Atoms First Approach

Unit 1: Atomic Theory
Unit 5: States of Matter

Unit 2: Molecular Structure
Unit 6: Kinetics & Equilibria

Unit 3: Stoichiometry
Unit 7: Electro & Thermo Chemistry

Unit 4: Thermochem & Gases
Unit 8: Materials

Learning Objectives

- To know what is meant by the critical temperature and pressure of a liquid.

In [Section 11.1](#), we saw that a combination of high pressure and low temperature allows gases to be liquefied. As we increase the temperature of a gas, liquefaction becomes more and more difficult because higher and higher pressures are required to overcome the increased kinetic energy of the molecules. In fact, for every substance, there is some temperature above which the gas can no longer be liquefied, regardless of pressure. This temperature is the critical temperature (T_c), the highest temperature at which a substance can exist as a liquid. Above the critical temperature, the molecules have too much kinetic energy for the intermolecular attractive forces to hold them together in a separate liquid phase. Instead, the substance forms a single phase that completely occupies the volume of the container. Substances with strong intermolecular forces tend to form a liquid phase over a very large temperature range and therefore have high critical temperatures. Conversely, substances with weak intermolecular interactions have relatively low critical temperatures. Each substance also has a critical pressure (P_c), the minimum pressure needed to liquefy it at the critical temperature. The combination of critical temperature and critical pressure is called the critical point. The critical temperatures and pressures of several common substances are listed in [Table 11.6.1](#).

Note the Pattern

High-boiling-point, nonvolatile liquids have high critical temperatures and vice versa.

Table 11.6.1 Critical Temperatures and Pressures of Some Simple Substances

Substance	T_c (°C)	P_c (atm)
NH ₃	132.4	113.5
CO ₂	31.0	73.8
CH ₃ CH ₂ OH (ethanol)	240.9	61.4
He	-267.96	2.27
Hg	1477	1587
CH ₄	-82.6	46.0
N ₂	-146.9	33.9
H ₂ O	374.0	217.7

Supercritical Fluids

To understand what happens at the critical point, consider the effects of temperature and pressure on the densities of liquids and gases, respectively. As the temperature of a liquid increases, its density decreases. As the pressure of a gas increases, its density

increases. At the critical point, the liquid and gas phases have exactly the same density, and only a single phase exists. This single phase is called a supercritical fluid, which exhibits many of the properties of a gas but has a density more typical of a liquid. For example, the density of water at its critical point ($T = 374^{\circ}\text{C}$, $P = 217.7 \text{ atm}$) is 0.32 g/mL , about one-third that of liquid water at room temperature but much greater than that of water vapor under most conditions. The transition between a liquid/gas mixture and a supercritical phase is demonstrated for a sample of chlorine in [Figure 11.6.1](#). At the critical temperature, the meniscus separating the liquid and gas phases disappears.

Figure 11.6.1 Supercritical fluids Professor Martyn Poliakoff demonstrates supercritical fluids. Below the critical temperature the meniscus between the liquid and gas phases is apparent. At the critical temperature, the meniscus disappears because the density of the vapor is equal to the density of the liquid. Above T_c , a dense homogeneous fluid fills the tube.

In the last few years, supercritical fluids have evolved from laboratory curiosities to substances with important commercial applications. For example, carbon dioxide has a low critical temperature (31°C), a comparatively low critical pressure (73 atm), and low toxicity, making it easy to contain and relatively safe to manipulate. Because many substances are quite soluble in supercritical CO_2 , commercial processes that use it as a solvent are now well established in the oil industry, the food industry, and others. Supercritical CO_2 is pumped into oil wells that are no longer producing much oil to dissolve the residual oil in the underground reservoirs. The less-viscous solution is then pumped to the surface, where the oil can be recovered by evaporation (and recycling) of the CO_2 . In the food, flavor, and fragrance industry, supercritical CO_2 is used to extract components from natural substances for use in perfumes, remove objectionable organic acids from hops prior to making beer, and selectively extract caffeine from whole coffee beans without removing important flavor components. The latter process was patented in 1974, and now virtually all decaffeinated coffee is produced this way. The earlier method used volatile organic solvents such as methylene chloride

(dichloromethane [CH₂Cl₂], boiling point = 40°C), which is difficult to remove completely from the beans and is known to cause cancer in laboratory animals at high doses.

Example 11.6.1

Arrange methanol, *n*-butane, *n*-pentane, and N₂O in order of increasing critical temperatures.

Given: compounds

Asked for: order of increasing critical temperatures

Strategy:

A Identify the intermolecular forces in each molecule and then assess the strengths of those forces.

B Arrange the compounds in order of increasing critical temperatures.

Solution:

A The critical temperature depends on the strength of the intermolecular interactions that hold a substance together as a liquid. In N₂O, a slightly polar substance, weak dipole–dipole interactions and London dispersion forces are important. Butane (C₄H₁₀) and pentane (C₅H₁₂) are larger, nonpolar molecules that exhibit only London dispersion forces. Methanol, in contrast, should have substantial intermolecular hydrogen bonding interactions. Because hydrogen bonds are stronger than the other intermolecular forces, methanol will have the highest T_c . London forces are more important for pentane than for butane because of its larger size, so *n*-pentane will have a higher T_c than *n*-butane. The only remaining question is whether N₂O is polar enough to have stronger intermolecular interactions than pentane or butane. Because the electronegativities of O and N are quite similar, the answer is probably no, so N₂O should have the lowest T_c . **B** We therefore predict the order of increasing critical temperatures as N₂O < *n*-butane < *n*-pentane < methanol. The actual values are N₂O (36.9°C) < *n*-butane (152.0°C) < *n*-pentane (196.9°C) < methanol (239.9°C). This is the same order as their normal boiling points—N₂O (−88.7°C) < *n*-butane (−0.2°C) < *n*-pentane (36.0°C) < methanol (65°C)—because both critical temperature and boiling point depend on the relative strengths of the intermolecular interactions.

Exercise

Arrange ethanol, methanethiol (CH₃SH), ethane, and *n*-hexanol in order of increasing critical temperatures.

Answer: ethane (32.3°C) < methanethiol (196.9°C) < ethanol (240.9°C) < *n*-hexanol (336.9°C)

Molten Salts and Ionic Liquids

Heating a salt to its melting point produces a molten salt. If we heated a sample of solid NaCl to its melting point of 801°C, for example, it would melt to give a stable liquid that conducts electricity. The characteristics of molten salts other than electrical conductivity are their high heat capacity, ability to attain very high temperatures (over 700°C) as a liquid, and utility as solvents because of their relatively low toxicity.

Molten salts have many uses in industry and the laboratory. For example, in solar power towers in the desert of California, mirrors collect and focus sunlight to melt a mixture of sodium nitrite and sodium nitrate. The heat stored in the molten salt is used to produce steam that drives a steam turbine and a generator, thereby producing electricity from the sun for southern California.

Due to their low toxicity and high thermal efficiency, molten salts have also been used in nuclear reactors to enable operation at temperatures greater than 750°C. One prototype reactor tested in the 1950s used a fuel and a coolant consisting of molten fluoride salts, including NaF, ZrF₄, and UF₄. Molten salts are also useful in catalytic processes such as coal gasification, in which carbon and water react at high temperatures to form CO and H₂.

Note the Pattern

Molten salts are good electrical conductors, have a high heat capacity, can maintain a high temperature as a liquid, and are relatively nontoxic.

Although molten salts have proven highly useful, more recently chemists have been studying the characteristics of ionic liquids, ionic substances that are *liquid* at room temperature and pressure. These substances consist of small, symmetrical anions, such as PF_6^- and BF_4^- , combined with larger, asymmetrical organic cations that prevent the formation of a highly organized structure, resulting in a low melting point. By varying the cation and the anion, chemists can tailor the liquid to specific needs, such as using a solvent in a given reaction or extracting specific molecules from a solution. For example, an ionic liquid consisting of a bulky cation and anions that bind metal contaminants such as mercury and cadmium ions can remove those toxic metals from the environment. A similar approach has been applied to removing uranium and americium from water contaminated by nuclear waste.

Note the Pattern

Ionic liquids consist of small, symmetrical anions combined with larger asymmetrical cations, which produce a highly polar substance that is a liquid at room temperature and pressure.

The initial interest in ionic liquids centered on their use as a low-temperature alternative to molten salts in batteries for missiles, nuclear warheads, and space probes. Further research revealed that ionic liquids had other useful properties—for example, some could dissolve the black rubber of discarded tires, allowing it to be recovered for recycling. Others could be used to produce commercially important organic compounds with high molecular mass, such as Styrofoam and Plexiglas, at rates 10 times faster than traditional methods.

Summary

A substance cannot form a liquid above its **critical temperature**, regardless of the applied pressure. Above the critical temperature, the molecules have enough kinetic energy to overcome the intermolecular attractive forces. The minimum pressure needed to liquefy a substance at its critical temperature is its **critical pressure**. The combination of the critical temperature and critical pressure of a substance is its **critical point**. Above the critical temperature and pressure, a substance exists as a dense fluid called a **supercritical fluid**, which resembles a gas in that it completely fills its container but has a density comparable to that of a liquid. A **molten salt** is a salt heated to its melting point, giving a stable liquid that conducts electricity. **Ionic liquids** are ionic substances that are liquids at room temperature. Their disorganized structure results in a low melting point.

Key Takeaway

- The critical temperature and critical pressure of a substance define its critical point, beyond which the substance forms a supercritical fluid.

Conceptual Problems

1. Describe the changes that take place when a liquid is heated above its critical temperature. How does this affect the physical properties?
2. What is meant by the term *critical pressure*? What is the effect of increasing the pressure on a gas to above its critical pressure? Would it make any difference if the temperature of the gas was greater than its critical temperature?
3. Do you expect the physical properties of a supercritical fluid to be more like those of the gas or the liquid phase? Explain. Can an ideal gas form a supercritical fluid? Why or why not?
4. What are the limitations in using supercritical fluids to extract organic materials? What are the advantages?
5. Describe the differences between a molten salt and an ionic liquid. Under what circumstances would an ionic liquid be preferred over a molten salt?

Learning Objectives

- To understand the general features of a phase diagram.

The state exhibited by a given sample of matter depends on the identity, temperature, and pressure of the sample. A phase diagram is a graphic summary of the physical state of a substance as a function of temperature and pressure in a closed system.

A typical phase diagram consists of discrete regions that represent the different phases exhibited by a substance (Figure 11.7.1). Each region corresponds to the range of combinations of temperature and pressure over which that phase is stable. The combination of high pressure and low temperature (upper left of Figure 11.7.1) corresponds to the solid phase, whereas the gas phase is favored at high temperature and low pressure (lower right). The combination of high temperature and high pressure (upper right) corresponds to a supercritical fluid.

Figure 11.7.1 A Typical Phase Diagram for a Substance That Exhibits Three Phases—Solid, Liquid, and Gas—and a Supercritical Region

Note the Pattern

The solid phase is favored at low temperature and high pressure; the gas phase is favored at high temperature and low pressure.

General Features of a Phase Diagram

The lines in a phase diagram correspond to the combinations of temperature and pressure at which two phases can coexist in equilibrium. In Figure 11.7.1 the line that connects points A and D separates the solid and liquid phases and shows how the melting point of a solid varies with pressure. The solid and liquid phases are in equilibrium all along this line; crossing the line horizontally corresponds to melting or freezing. The line that connects points A and B is the vapor pressure curve of the liquid, which we discussed in Section 11.4. It ends at the critical point, beyond which the substance exists as a supercritical fluid. The line that

connects points A and C is the vapor pressure curve of the *solid* phase. Along this line, the solid is in equilibrium with the vapor phase through sublimation and deposition. Finally, point A, where the solid/liquid, liquid/gas, and solid/gas lines intersect, is the triple point; it is the *only* combination of temperature and pressure at which all three phases (solid, liquid, and gas) are in equilibrium and can therefore exist simultaneously. Because no more than three phases can ever coexist, a phase diagram can never have more than three lines intersecting at a single point.

Remember that a phase diagram, such as the one in [Figure 11.7.1](#), is for a single pure substance in a closed system, not for a liquid in an open beaker in contact with air at 1 atm pressure. In practice, however, the conclusions reached about the behavior of a substance in a closed system can usually be extrapolated to an open system without a great deal of error.

The Phase Diagram of Water

[Figure 11.7.2](#) shows the phase diagram of water and illustrates that the triple point of water occurs at 0.01°C and 0.00604 atm (4.59 mmHg). Far more reproducible than the melting point of ice, which depends on the amount of dissolved air and the atmospheric pressure, the triple point (273.16 K) is used to define the absolute (Kelvin) temperature scale. The triple point also represents the lowest pressure at which a liquid phase can exist in equilibrium with the solid or vapor. At pressures less than 0.00604 atm , therefore, ice does not melt to a liquid as the temperature increases; the solid sublimates directly to water vapor. Sublimation of water at low temperature and pressure can be used to “freeze-dry” foods and beverages. The food or beverage is first cooled to subzero temperatures and placed in a container in which the pressure is maintained below 0.00604 atm . Then, as the temperature is increased, the water sublimates, leaving the dehydrated food (such as that used by backpackers or astronauts) or the powdered beverage (as with freeze-dried coffee).

The phase diagram for water illustrated in part (b) in [Figure 11.7.2](#) shows the boundary between ice and water on an expanded scale. The melting curve of ice slopes up and slightly to the left rather than up and to the right as in [Figure 11.7.1](#); that is, the melting point of ice *decreases* with increasing pressure; at 100 MPa (987 atm), ice melts at -9°C . Water behaves this way because it is one of the few known substances for which the crystalline solid is *less dense* than the liquid (others include antimony and bismuth). Increasing the pressure of ice that is in equilibrium with water at 0°C and 1 atm tends to push some of the molecules closer together, thus decreasing the volume of the sample. The decrease in volume (and corresponding increase in density) is smaller for a solid or a liquid than for a gas, but it is sufficient to melt some of the ice.

Figure 11.7.2 *Two Versions of the Phase Diagram of Water (a) In this graph with linear temperature and pressure axes, the boundary between ice and liquid water is almost vertical. (b) This graph with an expanded scale illustrates the decrease in melting point with increasing pressure. (The letters refer to points discussed in Example 10.)*

In part (b) in [Figure 11.7.2](#), point A is located at $P = 1\text{ atm}$ and $T = -1.0^{\circ}\text{C}$, within the solid (ice) region of the phase diagram. As the pressure increases to 150 atm while the temperature remains the same, the line from point A crosses the ice/water boundary to point B, which lies in the liquid water region. Consequently, applying a pressure of 150 atm will melt ice at -1.0°C . We have already indicated that the pressure dependence of the melting point of water is of vital importance. If the solid/liquid boundary in the phase diagram of water were to slant up and to the right rather than to the left, ice would be denser than water, ice cubes would sink, water pipes would not burst when they freeze, and antifreeze would be unnecessary in automobile engines.

The Phase Diagram of Carbon Dioxide

In contrast to the phase diagram of water, the phase diagram of CO_2 ([Figure 11.7.3](#)) has a more typical melting curve, sloping up and to the right. The triple point is -56.6°C and 5.11 atm , which means that liquid CO_2 cannot exist at pressures lower than 5.11 atm . At 1 atm , therefore, solid CO_2 sublimates directly to the vapor while maintaining a temperature of -78.5°C , the normal sublimation temperature. Solid CO_2 is generally known as dry ice because it is a cold solid with no liquid phase observed when it is

warmed. Also notice the critical point at 30.98°C and 72.79 atm. In addition to the uses discussed in [Section 11.6](#), supercritical carbon dioxide is emerging as a natural refrigerant, making it a low carbon (and thus a more environmentally friendly) solution for domestic heat pumps.

Figure 11.7.3 *The Phase Diagram of Carbon Dioxide* Note the critical point, the triple point, and the normal sublimation temperature in this diagram.

Example 11.7.1

Referring to the phase diagram of water in [Figure 11.7.2](#),

1. predict the physical form of a sample of water at 400°C and 150 atm.
2. describe the changes that occur as the sample in part (a) is slowly allowed to cool to -50°C at a constant pressure of 150 atm.

Given: phase diagram, temperature, and pressure

Asked for: physical form and physical changes

Strategy:

A Identify the region of the phase diagram corresponding to the initial conditions and identify the phase that exists in this region.

B Draw a line corresponding to the given pressure. Move along that line in the appropriate direction (in this case cooling) and describe the phase changes.

Solution:

1. **A** Locate the starting point on the phase diagram in part (a) in [Figure 11.7.2](#). The initial conditions correspond to point A, which lies in the region of the phase diagram representing water vapor. Thus water at $T = 400^\circ\text{C}$ and $P = 150$ atm is a gas.
2. **B** Cooling the sample at constant pressure corresponds to moving left along the horizontal line in part (a) in [Figure 11.7.2](#). At about 340°C (point B), we cross the vapor pressure curve, at which point water vapor will begin to condense and the sample will consist of a mixture of vapor and liquid. When all of the vapor has condensed, the temperature drops further, and we enter the region corresponding to liquid water (indicated by point C). Further cooling brings us to the melting curve, the line that separates the liquid and solid phases at a little below 0°C (point D), at which point the sample will consist of a mixture of liquid and solid water (ice). When all of the water has frozen, cooling the sample to -50°C takes us along the horizontal line to point E, which lies within the region corresponding to solid water. At $P = 150$ atm and $T = -50^\circ\text{C}$, therefore, the sample is solid ice.

Exercise

Referring to the phase diagram of water in [Figure 11.7.2](#), predict the physical form of a sample of water at -0.0050°C as the pressure is gradually increased from 1.0 mmHg to 218 atm.

Answer: The sample is initially a gas, condenses to a solid as the pressure increases, and then melts when the pressure is increased further to give a liquid.

Summary

The states of matter exhibited by a substance under different temperatures and pressures can be summarized graphically in a **phase diagram**, which is a plot of pressure versus temperature. Phase diagrams contain discrete regions corresponding to the solid, liquid, and gas phases. The solid and liquid regions are separated by the melting curve of the substance, and the liquid and gas regions are separated by its vapor pressure curve, which ends at the critical point. Within a given region, only a single phase is stable, but along the lines that separate the regions, two phases are in equilibrium at a given temperature and pressure. The lines separating the three phases intersect at a single point, the **triple point**, which is the only combination of temperature and pressure at which all three phases can coexist in equilibrium. Water has an unusual phase diagram: its melting point decreases with increasing pressure because ice is less dense than liquid water. The phase diagram of carbon dioxide shows that liquid carbon dioxide cannot exist at atmospheric pressure. Consequently, solid carbon dioxide sublimates directly to a gas.

Key Takeaway

- A phase diagram is a graphic summary of the physical state of a substance as a function of temperature and pressure in a closed system. It shows the triple point, the critical point, and four regions: solid, liquid, gas, and a supercritical region.

Conceptual Problems

1. A phase diagram is a graphic representation of the stable phase of a substance at any combination of temperature and pressure. What do the lines separating different regions in a phase diagram indicate? What information does the slope of a line in a phase diagram convey about the physical properties of the phases it separates? Can a phase diagram have more than one point where three lines intersect?
2. If the slope of the line corresponding to the solid/liquid boundary in the phase diagram of water were positive rather than negative, what would be the effect on aquatic life during periods of subzero temperatures? Explain your answer.

Answer

1. The lines in a phase diagram represent boundaries between different phases; at any combination of temperature and pressure that lies on a line, two phases are in equilibrium. It is physically impossible for more than three phases to coexist at any combination of temperature and pressure, but in principle there can be more than one triple point in a phase diagram. The slope of the line separating two phases depends upon their relative densities. For example, if the solid–liquid line slopes up and to the *right*, the liquid is less dense than the solid, while if it slopes up and to the *left*, the liquid is denser than the solid.
- 2.

Numerical Problems

1. Naphthalene ($C_{10}H_8$) is the key ingredient in mothballs. It has normal melting and boiling points of $81^\circ C$ and $218^\circ C$, respectively. The triple point of naphthalene is $80^\circ C$ at 1000 Pa. Use these data to construct a phase diagram for naphthalene and label all the regions of your diagram.
2. Argon is an inert gas used in welding. It has normal boiling and freezing points of 87.3 K and 83.8 K, respectively. The triple point of argon is 83.8 K at 0.68 atm. Use these data to construct a phase diagram for argon and label all the regions of your diagram.

Learning Objectives

- To describe the properties of liquid crystals.

When cooled, most liquids undergo a simple phase transition to an ordered crystalline solid, a relatively rigid substance that has a fixed shape and volume. In the phase diagrams for these liquids, there are no regions between the liquid and solid phases. Thousands of substances are known, however, that exhibit one or more phases intermediate between the liquid state, in which the molecules are free to tumble and move past one another, and the solid state, in which the molecules or ions are rigidly locked into place. In these intermediate phases, the molecules have an ordered arrangement and yet can still flow like a liquid. Hence they are called liquid crystals, and their unusual properties have found a wide range of commercial applications. They are used, for example, in the liquid crystal displays (LCDs) in digital watches, calculators, and computer and video displays.

The first documented example of a liquid crystal was reported by the Austrian Frederick Reinitzer in 1888. Reinitzer was studying the properties of a cholesterol derivative, cholesteryl benzoate, and noticed that it behaved strangely as it melted. The white solid first formed a cloudy white liquid phase at 145°C, which reproducibly transformed into a clear liquid at 179°C. The transitions were completely reversible: cooling molten cholesteryl benzoate below 179°C caused the clear liquid to revert to a milky one, which then crystallized at the melting point of 145°C.

In a normal liquid, the molecules possess enough thermal energy to overcome the intermolecular attractive forces and tumble freely. This arrangement of the molecules is described as isotropic, which means that it is equally disordered in all directions. Liquid crystals, in contrast, are anisotropic: their properties depend on the direction in which they are viewed. Hence liquid crystals are not as disordered as a liquid because the molecules have some degree of alignment.

Most substances that exhibit the properties of liquid crystals consist of long, rigid rod- or disk-shaped molecules that are easily polarizable and can orient themselves in one of three different ways, as shown in [Figure 11.8.1](#). In the nematic phase, the molecules are not layered but are pointed in the same direction. As a result, the molecules are free to rotate or slide past one another. In the smectic phase, the molecules maintain the general order of the nematic phase but are also aligned in layers. Several variants of the smectic phase are known, depending on the angle formed between the molecular axes and the planes of molecules. The simplest such structure is the so-called smectic A phase, in which the molecules can rotate about their long axes within a given plane, but they cannot readily slide past one another. In the cholesteric phase, the molecules are directionally oriented and stacked in a helical pattern, with each layer rotated at a slight angle to the ones above and below it. As the degree of molecular ordering increases from the nematic phase to the cholesteric phase, the liquid becomes more opaque, although direct comparisons are somewhat difficult because most compounds form only one of these liquid crystal phases when the solid is melted or the liquid is cooled.

Figure 11.8.1 *The Arrangement of Molecules in the Nematic, Smectic, and Cholesteric Liquid Crystal Phases* In the nematic phase, only the long axes of the molecules are parallel, and the ends are staggered at random intervals. In the smectic phase, the long axes of the molecules are parallel, and the molecules are also arranged in planes. Finally, in the cholesteric phase, the molecules are arranged in layers; each layer is rotated with respect to the ones above and below it to give a spiral structure. The molecular order increases from the nematic phase to the smectic phase to the cholesteric phase, and the phases become increasingly opaque.

Molecules that form liquid crystals tend to be rigid molecules with polar groups that exhibit relatively strong dipole–dipole or dipole–induced dipole interactions, hydrogen bonds, or some combination of both. Some examples of substances that form liquid crystals are listed in [Figure 11.8.2](#) along with their characteristic phase transition temperature ranges. In most cases, the intermolecular interactions are due to the presence of polar or polarizable groups. Aromatic rings and multiple bonds between carbon and nitrogen or oxygen are especially common. Moreover, many liquid crystals are composed of molecules with two similar halves connected by a unit having a multiple bond.

Structure	Liquid Crystal Phase	Liquid Crystalline Temperature Range (°C)
	Nematic	14–28
	Smectic	121–131
	Cholesteric	78–90

Figure 11.8.2 *Structures of Typical Molecules That Form Liquid Crystals* Polar or polarizable groups are indicated in blue.

Because of their anisotropic structures, liquid crystals exhibit unusual optical and electrical properties. The intermolecular forces are rather weak and can be perturbed by an applied electric field. Because the molecules are polar, they interact with an electric field, which causes them to change their orientation slightly. Nematic liquid crystals, for example, tend to be relatively translucent, but many of them become opaque when an electric field is applied and the molecular orientation changes. This behavior is ideal for producing dark images on a light or an opalescent background, and it is used in the LCDs in digital watches; handheld calculators; flat-screen monitors; and car, ship, and aircraft instrumentation. Although each application differs in the details of its construction and operation, the basic principles are similar, as illustrated in [Figure 11.8.3](#).

Note the Pattern

Liquid crystals tend to form from long, rigid molecules with polar groups.

Figure 11.8.3 *Schematic Drawing of an LCD Device, Showing the Various Layers* Applying a voltage to selected segments of the device will produce any of the numbers. The device is a sandwich that contains several very thin layers, consisting of (from top to bottom) a sheet of polarizer to produce polarized light, a transparent electrode, a thin layer of a liquid crystalline substance, a second transparent electrode, a second polarizer, and a screen. Applying an electrical voltage to the liquid crystal changes its orientation slightly, which rotates the plane of the polarized light and makes the area appear dark.

Changes in molecular orientation that are dependent on temperature result in an alteration of the wavelength of reflected light. Changes in reflected light produce a change in color, which can be customized by using either a single type of liquid crystalline material or mixtures. It is therefore possible to build a liquid crystal thermometer that indicates temperature by color (Figure 11.8.4) and to use liquid crystals in heat-sensitive films to detect flaws in electronic board connections where overheating can occur.

Figure 11.8.4 *An Inexpensive Fever Thermometer That Uses Liquid Crystals* Each section contains a liquid crystal sample with a different liquid crystalline range. The section whose liquid crystalline range corresponds to the temperature of the body becomes translucent (here shown in green), indicating the temperature.

We also see the effect of liquid crystals in nature. Iridescent green beetles, known as jewel beetles, change color because of the light-reflecting properties of the cells that make up their external skeletons, not because of light absorption from their pigment. The cells form helices with a structure like those found in cholesteric liquid crystals. When the pitch of the helix is close to the wavelength of visible light, the cells reflect light with wavelengths that lead to brilliant metallic colors. Because a color change occurs depending on a person's angle of view, researchers in New Zealand are studying the beetles to develop a thin material that can be used as a currency security measure. The automobile industry is also interested in exploring such materials for use in paints that would change color at different viewing angles.

With only molecular structure as a guide, one cannot precisely predict which of the various liquid crystalline phases a given compound will actually form. One can, however, identify molecules containing the kinds of structural features that tend to result in liquid crystalline behavior, as demonstrated in Example 11.

Example 11.8.1

Which molecule is most likely to form a liquid crystalline phase as the isotropic liquid is cooled?

1. isooctane (2,2,4-trimethylpentane)
2. ammonium thiocyanate [NH₄(SCN)]
3. *p*-azoxyanisole

4. sodium decanoate {Na[CH₃(CH₂)₈CO₂]}

Given: compounds

Asked for: liquid crystalline behavior

Strategy:

Determine which compounds have a rigid structure and contain polar groups. Those that do are likely to exhibit liquid crystal behavior.

Solution:

1. Isooctane is not long and rigid and contains no polar groups, so it is unlikely to exhibit liquid crystal behavior.
2. Ammonium thiocyanate is ionic, and ionic compounds tend to have high melting points, so it should not form a liquid crystalline phase. In fact, ionic compounds that form liquid crystals are very rare indeed.
3. *p*-Azoxyanisole combines two planar phenyl rings linked through a multiply bonded unit, and it contains polar groups. The combination of a long, rigid shape and polar groups makes it a reasonable candidate for a liquid crystal.
4. Sodium decanoate is the sodium salt of a straight-chain carboxylic acid. The *n*-alkyl chain is long, but it is flexible rather than rigid, so the compound is probably not a liquid crystal.

Exercise

Which compound is least likely to form a liquid crystal phase?

Answer: (b) Biphenyl; although it is rather long and rigid, it lacks any polar substituents.

Summary

Many substances exhibit phases that have properties intermediate between those of a crystalline solid and a normal liquid. These substances, which possess long-range molecular order but still flow like liquids, are called **liquid crystals**. Liquid crystals are typically long, rigid molecules that can interact strongly with one another; they do not have **isotropic** structures, which are completely disordered, but rather have **anisotropic** structures, which exhibit different properties when viewed from different directions. In the **nematic phase**, only the long axes of the molecules are aligned, whereas in the **smectic phase**, the long axes of the molecules are parallel and the molecules are arranged in planes. In the **cholesteric phase**, the molecules are

arranged in planes, but each layer is rotated by a certain amount with respect to those above and below it, giving a helical structure.

Key Takeaway

- Liquid crystals tend to consist of rigid molecules with polar groups, and their anisotropic structures exhibit unusual optical and electrical properties.

Conceptual Problems

1. Describe the common structural features of molecules that form liquid crystals. What kind of intermolecular interactions are most likely to result in a long-chain molecule that exhibits liquid crystalline behavior? Does an electrical field affect these interactions?
2. What is the difference between an *isotropic* liquid and an *anisotropic* liquid? Which is more anisotropic—a cholesteric liquid crystal or a nematic liquid crystal?

Topics

- Natural Logarithms
- Calculations Using Natural Logarithms

Essential Skills 3 in [Section 4.11](#), introduced the common, or base-10, logarithms and showed how to use the properties of exponents to perform logarithmic calculations. In this section, we describe natural logarithms, their relationship to common logarithms, and how to do calculations with them using the same properties of exponents.

Natural Logarithms

Many natural phenomena exhibit an exponential rate of increase or decrease. Population growth is an example of an exponential rate of increase, whereas a runner's performance may show an exponential decline if initial improvements are substantially greater than those that occur at later stages of training. Exponential changes are represented logarithmically by e^x , where e is an irrational number whose value is approximately 2.7183. The *natural logarithm*, abbreviated as \ln , is the power x to which e must be raised to obtain a particular number. The natural logarithm of e is 1 ($\ln e = 1$).

Some important relationships between base-10 logarithms and natural logarithms are as follows:

$$10^{\frac{1}{2.303}} = 10 = e^{2.303}$$

$$\ln e^x = x$$

$$\ln 10 = \ln(e^{2.303}) = 2.303$$

$$\log 10 = \ln e = 1$$

According to these relationships, $\ln 10 = 2.303$ and $\log 10 = 1$. Because multiplying by 1 does not change an equality,

$$\ln 10 = 2.303 \log 10$$

Substituting any value y for 10 gives

$$\ln y = 2.303 \log y$$

Other important relationships are as follows:

$$\log A^x = x \log A$$

$$\ln e^x = x \ln e = x = e^{\ln x}$$

Entering a value x , such as 3.86, into your calculator and pressing the “ln” key gives the value of $\ln x$, which is 1.35 for $x = 3.86$. Conversely, entering the value 1.35 and pressing “ e^x ” key gives an answer of 3.86. On some calculators, pressing [INV] and then [ln

$x]$ is equivalent to pressing $[ex]$. Hence

$$e^{\ln 3.86} = e^{1.35} = 3.86$$

$$\ln(e^{3.86}) = 3.86$$

Skill Builder ES1

Calculate the natural logarithm of each number and express each as a power of the base e .

1. 0.523
2. 1.63

Solution:

1. $\ln(0.523) = -0.648$; $e^{-0.648} = 0.523$
2. $\ln(1.63) = 0.489$; $e^{0.489} = 1.63$

Skill Builder ES2

What number is each value the natural logarithm of?

1. 2.87
2. 0.030
3. -1.39

Solution:

1. $\ln x = 2.87$; $x = e^{2.87} = 17.6 = 18$ to two significant figures
2. $\ln x = 0.030$; $x = e^{0.030} = 1.03 = 1.0$ to two significant figures
3. $\ln x = -1.39$; $x = e^{-1.39} = 0.249 = 0.25$

Calculations with Natural Logarithms

Like common logarithms, natural logarithms use the properties of exponents. We can compare the properties of common and natural logarithms:

Operation	Exponential Form	Logarithm
Multiplication	$(10^a)(10^b) = 10^{a+b}$	$\log(ab) = \log a + \log b$
	$(e^x)(e^y) = e^{x+y}$	$\ln(e^x e^y) = \ln(e^x) + \ln(e^y) = x + y$
Division		$\log\left(\frac{a}{b}\right) = \log a - \log b$
	$\frac{10^a}{10^b} = 10^{a-b}$	$\ln\left(\frac{x}{y}\right) = \ln x - \ln y$
	$\frac{e^a}{e^b} = e^{a-b}$	$\ln\left(\frac{e^x}{e^y}\right) = \ln(e^x) - \ln(e^y) = x - y$

Operation	Exponential Form	Logarithm
Inverse		$\log\left(\frac{1}{a}\right) = -\log(a)$ $\ln\left(\frac{1}{x}\right) = -\ln(x)$

The number of significant figures in a number is the same as the number of digits after the decimal point in its logarithm. For example, the natural logarithm of 18.45 is 2.9151, which means that $e^{2.9151}$ is equal to 18.45.

Skill Builder ES3

Calculate the natural logarithm of each number.

- 22×18.6
- $\frac{0.51}{2.67}$
- 0.079×1.485
- $\frac{20.5}{0.026}$

Solution:

- $\ln(22 \times 18.6) = \ln(22) + \ln(18.6) = 3.09 + 2.923 = 6.01$. Alternatively, $22 \times 18.6 = 410$; $\ln(410) = 6.02$.
- $\ln\left(\frac{0.51}{2.67}\right) = \ln(0.51) - \ln(2.67) = -0.67 - 0.982 = -1.65$. $\ln(0.19) = -1.66$.
- $\ln(0.079 \times 1.485) = \ln(0.079) + \ln(1.485) = -2.54 + 0.395 = -2.15$. Alternatively, $0.079 \times 1.485 = 0.12$; $\ln(0.12) = -2.12$.
- $\ln\left(\frac{20.5}{0.026}\right) = \ln(20.5) - \ln(0.026) = 3.0204 - (-3.65) = 6.67$. $\ln(790) = 6.67$.

The answers obtained using the two methods may differ slightly due to rounding errors.

Skill Builder ES4

Calculate the natural logarithm of each number.

- 34×16.5
- $2.10/0.052$
- 0.402×3.930
- $0.164/10.7$

Solution:

- 6.33
- 3.70
- 0.457
- 4.178

APPLICATION PROBLEMS

Please be sure you are familiar with the topics discussed in Essential Skills 6 (Section 11.9) before proceeding to the Application Problems. Problems marked with a ♦ involve multiple concepts.

- During cold periods, workers in the citrus industry often spray water on orange trees to prevent them from being damaged, even though ice forms on the fruit.
 - Explain the scientific basis for this practice.
 - To illustrate why the production of ice prevents damage to the fruit during cold weather, calculate the heat released by formation of ice from 1000 L of water at 10°C.
- ♦ Relative humidity is the ratio of the actual partial pressure of water in the air to the vapor pressure of water at that temperature (i.e., if the air was completely saturated with water vapor), multiplied by 100 to give a percentage. On a summer day in the Chesapeake, when the temperature was recorded as 35°C, the partial pressure of water was reported to be 33.9 mmHg.
 - The following table gives the vapor pressure of water at various temperatures. Calculate the relative humidity.

T (°C)	0	10	30	50	60	80	100
P (mmHg)	4.6	9.2	31.8	92.6	150	355	760

- Why does it seem “drier” in the winter, even though the relative humidity may be the same as in the summer?
- ♦ Liquids are frequently classified according to their physical properties, such as surface tension, vapor pressure, and boiling point. Such classifications are useful when substitutes are needed for a liquid that might not be available.
 - Draw the structure of methanol, benzene, pentane, toluene, cyclohexane, 1-butanol, trichloroethylene, acetic acid, acetone, and chloroform.
 - Identify the most important kind of intermolecular interaction in each.
 - Sort the compounds into three groups with similar characteristics.
 - If you needed a substitute for trimethylpentane, from which group would you make your selection?
 - ♦ In the process of freeze drying, which is used as a preservation method and to aid in the shipping or storage of fruit and biological samples, a sample is cooled and then placed in a compartment in which a very low pressure is maintained, ≈ 0.01 atm.
 - Explain how this process removes water and “dries” the sample.
 - Identify the phase change that occurs during this process.
 - Using the Clausius–Clapeyron equation, show why it is possible to remove water and still maintain a low temperature at this pressure.
 - ♦ Many industrial processes for preparing compounds use “continuous-flow reactors,” which are chemical reaction vessels in which the reactants are mixed and allowed to react as they flow along a tube. The products are removed at a certain distance from the starting point, when the reaction is nearly complete. The key operating parameters in a continuous-flow reactor are temperature, reactor volume, and reactant flow rate. As an industrial chemist, you think you

have successfully modified a particular process to produce a higher product yield by substituting one reactant for another. The viscosity of the new reactant is, however, greater than that of the initial reactant.

- a. Which of the operating parameters will be most greatly affected by this change?
- b. What other parameter could be changed to compensate for the substitution?
- c. Predict the possible effects on your reactor and your process if you do not compensate for the substitution.

Learning Objectives

- To know the characteristic properties of crystalline and amorphous solids.

With few exceptions, the particles that compose a solid material, whether ionic, molecular, covalent, or metallic, are held in place by strong attractive forces between them. When we discuss solids, therefore, we consider the *positions* of the atoms, molecules, or ions, which are essentially fixed in space, rather than their motions (which are more important in liquids and gases). The constituents of a solid can be arranged in two general ways: they can form a regular repeating three-dimensional structure called a crystal lattice, thus producing a crystalline solid, or they can aggregate with no particular order, in which case they form an amorphous solid (from the Greek *ámorphos*, meaning “shapeless”).

Crystalline solids, or *crystals*, have distinctive internal structures that in turn lead to distinctive flat surfaces, or *faces*. The faces intersect at angles that are characteristic of the substance. When exposed to x-rays, each structure also produces a distinctive pattern that can be used to identify the material (see [Section 12.3](#)). The characteristic angles do not depend on the size of the crystal; they reflect the regular repeating arrangement of the component atoms, molecules, or ions in space. When an ionic crystal is cleaved ([Figure 12.1.1](#)), for example, repulsive interactions cause it to break along fixed planes to produce new faces that intersect at the same angles as those in the original crystal. In a covalent solid such as a cut diamond, the angles at which the faces meet are also not arbitrary but are determined by the arrangement of the carbon atoms in the crystal.

Crystalline faces. The faces of crystals can intersect at right angles, as in galena (PbS) and pyrite (FeS₂), or at other angles, as in quartz.

Figure 12.1.1 *Cleaving a Crystal of an Ionic Compound along a Plane of Ions Deformation of the ionic crystal causes one plane of atoms to slide along another. The resulting repulsive interactions between ions with like charges cause the layers to separate.*

Cleavage surfaces of an amorphous solid. *Obsidian, a volcanic glass with the same chemical composition as granite (typically $KAlSi_3O_8$), tends to have curved, irregular surfaces when cleaved.*

Crystals tend to have relatively sharp, well-defined melting points because all the component atoms, molecules, or ions are the same distance from the same number and type of neighbors; that is, the regularity of the crystalline lattice creates local environments that are the same. Thus the intermolecular forces holding the solid together are uniform, and the same amount of thermal energy is needed to break every interaction simultaneously.

Amorphous solids have two characteristic properties. When cleaved or broken, they produce fragments with irregular, often curved surfaces; and they have poorly defined patterns when exposed to x-rays because their components are not arranged in a regular array. An amorphous, translucent solid is called a glass. Almost any substance can solidify in amorphous form if the liquid phase is cooled rapidly enough. Some solids, however, are intrinsically amorphous, because either their components cannot fit together well enough to form a stable crystalline lattice or they contain impurities that disrupt the lattice. For example, although the chemical composition and the basic structural units of a quartz crystal and quartz glass are the same—both are SiO_2 and both consist of linked SiO_4 tetrahedra—the arrangements of the atoms in space are not. Crystalline quartz contains a highly ordered arrangement of silicon and oxygen atoms, but in quartz glass the atoms are arranged almost randomly. When molten SiO_2 is cooled rapidly (4 K/min), it forms quartz glass, whereas the large, perfect quartz crystals sold in mineral shops have had cooling times of thousands of years. In contrast, aluminum crystallizes much more rapidly. Amorphous aluminum forms only when the liquid is cooled at the extraordinary rate of 4×10^{13} K/s, which prevents the atoms from arranging themselves into a regular array.

In an amorphous solid, the local environment, including both the distances to neighboring units and the numbers of neighbors, varies throughout the material. Different amounts of thermal energy are needed to overcome these different interactions. Consequently, amorphous solids tend to soften slowly over a wide temperature range rather than having a well-defined melting point like a crystalline solid. If an amorphous solid is maintained at a temperature just below its melting point for long periods of time, the component molecules, atoms, or ions can gradually rearrange into a more highly ordered crystalline form.

The lattice of crystalline quartz (SiO_2). *The atoms form a regular arrangement in a structure that consists of linked tetrahedra.*

Note the Pattern

Crystals have sharp, well-defined melting points; amorphous solids do not.

Summary

Solids are characterized by an extended three-dimensional arrangement of atoms, ions, or molecules in which the components are generally locked into their positions. The components can be arranged in a regular repeating three-dimensional array (a **crystal lattice**), which results in a **crystalline solid**, or more or less randomly to produce an **amorphous solid**. Crystalline solids have well-defined edges and faces, diffract x-rays, and tend to have sharp melting points. In contrast, amorphous solids

have irregular or curved surfaces, do not give well-resolved x-ray diffraction patterns, and melt over a wide range of temperatures.

Key Takeaway

- Crystalline solids have regular ordered arrays of components held together by uniform intermolecular forces, whereas the components of amorphous solids are not arranged in regular arrays.

Conceptual Problems

1. Compare the solid and liquid states in terms of
 - a. rigidity of structure.
 - b. long-range order.
 - c. short-range order.
2. How do amorphous solids differ from crystalline solids in each characteristic? Which of the two types of solid is most similar to a liquid?
 - a. rigidity of structure
 - b. long-range order
 - c. short-range order
3. Why is the arrangement of the constituent atoms or molecules more important in determining the properties of a solid than a liquid or a gas?
4. Why are the structures of solids usually described in terms of the positions of the constituent atoms rather than their motion?
5. What physical characteristics distinguish a crystalline solid from an amorphous solid? Describe at least two ways to determine experimentally whether a material is crystalline or amorphous.
6. Explain why each characteristic would or would not favor the formation of an amorphous solid.
 - a. slow cooling of pure molten material
 - b. impurities in the liquid from which the solid is formed
 - c. weak intermolecular attractive forces
7. A student obtained a solid product in a laboratory synthesis. To verify the identity of the solid, she measured its melting point and found that the material melted over a 12°C range. After it had cooled, she measured the melting point of the same sample again and found that this time the solid had a sharp melting point at the temperature that is characteristic of the desired product. Why were the two melting points different? What was responsible for the change in the melting point?

Answers

- 1.
- 2.
3. The arrangement of the atoms or molecules is more important in determining the properties of a solid because of the greater persistent long-range order of solids. Gases and liquids cannot readily be described by the spatial arrangement of their components because rapid molecular motion and rearrangement defines many of the properties of liquids and gases.
- 4.
- 5.
- 6.
7. The initial solid contained the desired compound in an amorphous state, as indicated by the wide temperature range over which melting occurred. Slow cooling of the liquid caused it to crystallize, as evidenced by the sharp second melting point observed at the expected temperature.

Learning Objectives

- To recognize the unit cell of a crystalline solid.
- To calculate the density of a solid given its unit cell.

Because a crystalline solid consists of repeating patterns of its components in three dimensions (a **crystal lattice**), we can represent the entire crystal by drawing the structure of the smallest identical units that, when stacked together, form the crystal. This basic repeating unit is called a unit cell. For example, the unit cell of a sheet of identical postage stamps is a single stamp, and the unit cell of a stack of bricks is a single brick. In this section, we describe the arrangements of atoms in various unit cells.

Unit cells are easiest to visualize in two dimensions. In many cases, more than one unit cell can be used to represent a given structure, as shown for the Escher drawing in the chapter opener and for a two-dimensional crystal lattice in [Figure 12.2.1](#). Usually the smallest unit cell that completely describes the order is chosen. The only requirement for a valid unit cell is that repeating it in space must produce the regular lattice. Thus the unit cell in part (d) in [Figure 12.2.1](#) is not a valid choice because repeating it in space does not produce the desired lattice (there are triangular holes). The concept of unit cells is extended to a three-dimensional lattice in the schematic drawing in [Figure 12.2.2](#).

Figure 12.2.1 Unit Cells in Two Dimensions (a–c) Three two-dimensional lattices illustrate the possible choices of the unit cell. The unit cells differ in their relative locations or orientations within the lattice, but they are all valid choices because repeating them in any direction fills the overall pattern of dots. (d) The triangle is not a valid unit cell because repeating it in space fills only half of the space in the pattern.

Figure 12.2.2 Unit Cells in Three Dimensions These images show (a) a three-dimensional unit cell and (b) the resulting regular three-dimensional lattice.

The Unit Cell

There are seven fundamentally different kinds of unit cells, which differ in the relative lengths of the edges and the angles between them (Figure 12.2.3). Each unit cell has six sides, and each side is a parallelogram. We focus primarily on the cubic unit cells, in which all sides have the same length and all angles are 90° , but the concepts that we introduce also apply to substances whose unit cells are not cubic.

Figure 12.2.3 The General Features of the Seven Basic Unit Cells The lengths of the edges of the unit cells are indicated by a , b , and c , and the angles are defined as follows: α , the angle between b and c ; β , the angle between a and c ; and γ , the angle between a and b .

If the cubic unit cell consists of eight component atoms, molecules, or ions located at the corners of the cube, then it is called simple cubic (part (a) in Figure 12.2.4). If the unit cell also contains an identical component in the center of the cube, then it is body-centered cubic (bcc) (part (b) in Figure 12.2.4). If there are components in the center of each face in addition to those at the corners of the cube, then the unit cell is face-centered cubic (fcc) (part (c) in Figure 12.2.4).

Figure 12.2.4 *The Three Kinds of Cubic Unit Cell* For the three kinds of cubic unit cells, simple cubic (a), body-centered cubic (b), and face-centered cubic (c), there are three representations for each: a ball-and-stick model, a space-filling cutaway model that shows the portion of each atom that lies within the unit cell, and an aggregate of several unit cells.

As indicated in [Figure 12.2.4](#), a solid consists of a large number of unit cells arrayed in three dimensions. Any intensive property of the bulk material, such as its density, must therefore also be related to its unit cell. Because **density** is the mass of substance per unit volume, we can calculate the density of the bulk material from the density of a single unit cell. To do this, we need to know the size of the unit cell (to obtain its volume), the molar mass of its components, and the number of components per unit cell. When we count atoms or ions in a unit cell, however, those lying on a face, an edge, or a corner contribute to more than one unit cell, as shown in [Figure 12.2.4](#). For example, an atom that lies on a face of a unit cell is shared by two adjacent unit cells and is therefore counted as $1/2$ atom per unit cell. Similarly, an atom that lies on the edge of a unit cell is shared by four adjacent unit cells, so it contributes $1/4$ atom to each. An atom at a corner of a unit cell is shared by all eight adjacent unit cells and therefore contributes $1/8$ atom to each. The statement that atoms lying on an edge or a corner of a unit cell count as $1/4$ or $1/8$ atom per unit cell, respectively, is true for all unit cells *except* the hexagonal one, in which three unit cells share each vertical edge and six share each corner ([Figure 12.2.3](#)), leading to values of $1/3$ and $1/6$ atom per unit cell, respectively, for atoms in these positions. In contrast, atoms that lie entirely within a unit cell, such as the atom in the center of a body-centered cubic unit cell, belong to only that one unit cell.

Note the Pattern

For all unit cells except hexagonal, atoms on the faces contribute $1/2$ atom to each unit cell, atoms on the edges contribute $1/4$ atom to each unit cell, and atoms on the corners contribute $1/8$ atom to each unit cell.

Example 12.2.1

Metallic gold has a face-centered cubic unit cell (part (c) in [Figure 12.2.4](#)). How many Au atoms are in each unit cell?

Given: unit cell

Asked for: number of atoms per unit cell

Strategy:

Using [Figure 12.2.4](#), identify the positions of the Au atoms in a face-centered cubic unit cell and then determine how much each Au atom contributes to the unit cell. Add the contributions of all the Au atoms to obtain the total number of Au atoms in a unit cell.

Solution:

As shown in [Figure 12.2.4](#), a face-centered cubic unit cell has eight atoms at the corners of the cube and six atoms on the faces. Because atoms on a face are shared by two unit cells, each counts as $1/2$ atom per unit cell, giving $6 \times 1/2 = 3$ Au atoms per unit cell. Atoms on a corner are shared by eight unit cells and hence contribute only $1/8$ atom per unit cell, giving $8 \times 1/8 = 1$ Au atom per unit cell. The total number of Au atoms in each unit cell is thus $3 + 1 = 4$.

Exercise

Metallic iron has a body-centered cubic unit cell (part (b) in [Figure 12.2.4](#)). How many Fe atoms are in each unit cell?

Answer: two

Now that we know how to count atoms in unit cells, we can use unit cells to calculate the densities of simple compounds. Note, however, that we are assuming a solid consists of a perfect regular array of unit cells, whereas real substances contain impurities and defects that affect many of their bulk properties, including density. Consequently, the results of our calculations will be close but not necessarily identical to the experimentally obtained values.

Example 12.2.2

Calculate the density of metallic iron, which has a body-centered cubic unit cell (part (b) in [Figure 12.2.4](#)) with an edge length of 286.6 pm.

Given: unit cell and edge length

Asked for: density

Strategy:

- Determine the number of iron atoms per unit cell.
- Calculate the mass of iron atoms in the unit cell from the molar mass and Avogadro's number. Then divide the mass by the volume of the cell.

Solution:

A We know from Example 1 that each unit cell of metallic iron contains two Fe atoms.

B The molar mass of iron is 55.85 g/mol. Because density is mass per unit volume, we need to calculate the mass of the iron atoms in the unit cell from the molar mass and Avogadro's number and then divide the mass by the volume of the cell (making sure to use suitable units to get density in g/cm^3):

$$\text{mass of Fe} = (2 \text{ atoms Fe}) \left(\frac{1 \text{ mol}}{6.022 \times 10^{23} \text{ atoms}} \right) \left(\frac{55.85 \text{ g}}{\text{mol}} \right) = 1.855 \times 10^{-22} \text{ g}$$

$$\text{volume} = \left[(286.6 \text{ pm}) \left(\frac{10^{-12} \text{ m}}{\text{pm}} \right) \left(\frac{10^2 \text{ cm}}{\text{m}} \right) \right]^3 = 2.345 \times 10^{-23} \text{ cm}^3$$

$$\text{density} = \frac{1.855 \times 10^{-22} \text{ g}}{2.345 \times 10^{-23} \text{ cm}^3} = 7.880 \text{ g/cm}^3$$

This result compares well with the tabulated experimental value of 7.874 g/cm^3 .

Exercise

Calculate the density of gold, which has a face-centered cubic unit cell (part (c) in [Figure 12.2.4](#)) with an edge length of 407.8 pm.

Answer: 19.29 g/cm^3

Packing of Spheres

Our discussion of the three-dimensional structures of solids has considered only substances in which all the components are identical. As we shall see, such substances can be viewed as consisting of identical spheres packed together in space; the way the components are packed together produces the different unit cells. Most of the substances with structures of this type are metals.

Simple Cubic Structure

The arrangement of the atoms in a solid that has a simple cubic unit cell was shown in part (a) in [Figure 12.2.4](#). Each atom in the lattice has only six nearest neighbors in an octahedral arrangement. Consequently, the simple cubic lattice is an inefficient way to pack atoms together in space: only 52% of the total space is filled by the atoms. The only element that crystallizes in a simple cubic unit cell is polonium. Simple cubic unit cells are, however, common among binary ionic compounds, where each cation is surrounded by six anions and vice versa.

Body-Centered Cubic Structure

The body-centered cubic unit cell is a more efficient way to pack spheres together and is much more common among pure elements. Each atom has eight nearest neighbors in the unit cell, and 68% of the volume is occupied by the atoms. As shown in part (b) in [Figure 12.2.4](#), the body-centered cubic structure consists of a single layer of spheres in contact with each other and aligned so that their centers are at the corners of a square; a second layer of spheres occupies the square-shaped “holes” above the spheres in the first layer. The third layer of spheres occupies the square holes formed by the second layer, so that each lies directly above a sphere in the first layer, and so forth. All the alkali metals, barium, radium, and several of the transition metals have body-centered cubic structures.

The arrangement of atoms in a simple cubic unit cell. Each atom in the lattice has six nearest neighbors in an octahedral arrangement.

Hexagonal Close-Packed and Cubic Close-Packed Structures

The most efficient way to pack spheres is the close-packed arrangement, which has two variants. A single layer of close-packed spheres is shown in part (a) in [Figure 12.2.5](#). Each sphere is surrounded by six others in the same plane to produce a hexagonal arrangement. Above any set of seven spheres are six depressions arranged in a hexagon. In principle, all six sites are the same, and any one of them could be occupied by an atom in the next layer. Actually, however, these six sites can be divided into two sets, labeled B and C in part (a) in [Figure 12.2.5](#). Sites B and C differ because as soon as we place a sphere at a B position, we can no longer place a sphere in any of the three C positions adjacent to A and vice versa.

Figure 12.2.5 Close-Packed Layers of Spheres (a) In this single layer of close-packed spheres, each sphere is surrounded by six others in a hexagonal arrangement. (b) Placing an atom at a B position prohibits placing an atom at any of the adjacent C positions and results in all the atoms in the second layer occupying the B positions. (c) Placing the atoms in the third layer over the atoms at A positions in the first layer gives the hexagonal close-packed structure. Placing the third-layer atoms over the C positions gives the cubic close-packed structure.

If we place the second layer of spheres at the B positions in part (a) in [Figure 12.2.5](#), we obtain the two-layered structure shown in part (b) in [Figure 12.2.5](#). There are now two alternatives for placing the first atom of the third layer: we can place it directly over one of the atoms in the first layer (an A position) or at one of the C positions, corresponding to the positions that we did *not* use for the atoms in the first or second layers (part (c) in [Figure 12.2.5](#)). If we choose the first arrangement and repeat the pattern in succeeding layers, the positions of the atoms alternate from layer to layer in the pattern ABABAB..., resulting in a hexagonal close-packed (hcp) structure (part (a) in [Figure 12.2.6](#)). If we choose the second arrangement and repeat the pattern indefinitely, the positions of the atoms alternate as ABCABC..., giving a cubic close-packed (ccp) structure (part (b) in [Figure 12.2.6](#)). Because the ccp structure contains hexagonally packed layers, it does not look particularly cubic. As shown in part (b) in [Figure 12.2.7](#),

however, simply rotating the structure reveals its cubic nature, which is identical to a fcc structure. The hcp and ccp structures differ only in the way their layers are stacked. Both structures have an overall packing efficiency of 74%, and in both each atom has 12 nearest neighbors (6 in the same plane plus 3 in each of the planes immediately above and below).

Figure 12.2.6 Close-Packed Structures: hcp and ccp The illustrations in (a) show an exploded view, a side view, and a top view of the hcp structure. The simple hexagonal unit cell is outlined in the side and top views. Note the similarity to the hexagonal unit cell shown in Figure 12.2.3. The ccp structure in (b) is shown in an exploded view, a side view, and a rotated view. The rotated view emphasizes the fcc nature of the unit cell (outlined). The line that connects the atoms in the first and fourth layers of the ccp structure is the body diagonal of the cube.

Table 12.2.1 compares the packing efficiency and the number of nearest neighbors for the different cubic and close-packed structures; the number of nearest neighbors is called the coordination number. Most metals have hcp, ccp, or bcc structures, although several metals exhibit both hcp and ccp structures, depending on temperature and pressure.

Table 12.2.1 Properties of the Common Structures of Metals

Structure	Percentage of Space Occupied by Atoms	Coordination Number
simple cubic	52	6
body-centered cubic	68	8
hexagonal close packed	74	12
cubic close packed (identical to face-centered cubic)	74	12

Summary

The smallest repeating unit of a crystal lattice is the **unit cell**. The **simple cubic** unit cell contains only eight atoms, molecules, or ions at the corners of a cube. A **body-centered cubic (bcc)** unit cell contains one additional component in the center of the cube. A **face-centered cubic (fcc)** unit cell contains a component in the center of each face in addition to those at the corners of the cube. Simple cubic and bcc arrangements fill only 52% and 68% of the available space with atoms, respectively. The **hexagonal close-packed (hcp) structure** has an ABABAB... repeating arrangement, and the **cubic close-packed (ccp) structure** has an ABCABC... repeating pattern; the latter is identical to an fcc lattice. The hcp and ccp arrangements fill 74% of the available space and have a **coordination number** of 12 for each atom in the lattice, the number of nearest neighbors. The simple cubic and bcc lattices have coordination numbers of 6 and 8, respectively.

Key Takeaway

- A crystalline solid can be represented by its unit cell, which is the smallest identical unit that when stacked together produces the characteristic three-dimensional structure.

Conceptual Problems

1. Why is it valid to represent the structure of a crystalline solid by the structure of its unit cell? What are the most important constraints in selecting a unit cell?
2. All unit cell structures have six sides. Can crystals of a solid have more than six sides? Explain your answer.
3. Explain how the intensive properties of a material are reflected in the unit cell. Are all the properties of a bulk material the same as those of its unit cell? Explain your answer.
4. The experimentally measured density of a bulk material is slightly *higher* than expected based on the structure of the pure material. Propose two explanations for this observation.
5. The experimentally determined density of a material is *lower* than expected based on the arrangement of the atoms in the unit cell, the formula mass, and the size of the atoms. What conclusion(s) can you draw about the material?
6. Only one element (polonium) crystallizes with a simple cubic unit cell. Why is polonium the only example of an element with this structure?
7. What is meant by the term *coordination number* in the structure of a solid? How does the coordination number depend on the structure of the metal?
8. Arrange the three types of cubic unit cells in order of increasing packing efficiency. What is the difference in packing efficiency between the hcp structure and the ccp structure?
9. The structures of many metals depend on pressure and temperature. Which structure—bcc or hcp—would be more likely in a given metal at very high pressures? Explain your reasoning.
10. A metal has two crystalline phases. The *transition temperature*, the temperature at which one phase is converted to the other, is 95°C at 1 atm and 135°C at 1000 atm. Sketch a phase diagram for this substance. The metal is known to have either a ccp structure or a simple cubic structure. Label the regions in your diagram appropriately and justify your selection for the structure of each phase.

Numerical Problems

1. Metallic rhodium has an fcc unit cell. How many atoms of rhodium does each unit cell contain?
2. Chromium has a structure with two atoms per unit cell. Is the structure of this metal simple cubic, bcc, fcc, or hcp?
3. The density of nickel is 8.908 g/cm³. If the metallic radius of nickel is 125 pm, what is the structure of metallic nickel?
4. The density of tungsten is 19.3 g/cm³. If the metallic radius of tungsten is 139 pm, what is the structure of metallic tungsten?
5. An element has a density of 10.25 g/cm³ and a metallic radius of 136.3 pm. The metal crystallizes in a bcc lattice. Identify the element.
6. A 21.64 g sample of a nonreactive metal is placed in a flask containing 12.00 mL of water; the final volume is 13.81 mL. If the length of the edge of the unit cell is 387 pm and the metallic radius is 137 pm, determine the packing arrangement and identify the element.
7. A sample of an alkali metal that has a bcc unit cell is found to have a mass of 1.000 g and a volume of 1.0298 cm³. When the metal reacts with excess water, the reaction produces 539.29 mL of hydrogen gas at 0.980 atm and 23°C. Identify the metal, determine the unit cell dimensions, and give the approximate size of the atom in picometers.
8. A sample of an alkaline earth metal that has a bcc unit cell is found to have a mass 5.000 g and a volume of 1.392 cm³. Complete reaction with chlorine gas requires 848.3 mL of chlorine gas at 1.050 atm and 25°C. Identify the metal, determine the unit cell dimensions, and give the approximate size of the atom in picometers.
9. Lithium crystallizes in a bcc structure with an edge length of 3.509 Å. Calculate its density. What is the approximate metallic radius of lithium in picometers?
10. Vanadium is used in the manufacture of rust-resistant vanadium steel. It forms bcc crystals with a density of 6.11 g/cm³ at 18.7°C. What is the length of the edge of the unit cell? What is the approximate metallic radius of the vanadium in picometers?
11. A simple cubic cell contains one metal atom with a metallic radius of 100 pm.
 - a. Determine the volume of the atom(s) contained in one unit cell [the volume of a sphere = $\frac{4}{3}\pi r^3$].
 - b. What is the length of one edge of the unit cell? (Hint: there is no empty space between atoms.)
 - c. Calculate the volume of the unit cell.
 - d. Determine the packing efficiency for this structure.
 - e. Use the steps in Problem 11 to calculate the packing efficiency for a bcc unit cell with a metallic radius of 1.00 Å.

Answers

1. four
- 2.
3. fcc
- 4.
5. molybdenum
- 6.
7. sodium, unit cell edge = 428 pm, $r = 185$ pm
- 8.
9. $d = 0.5335 \text{ g/cm}^3$, $r = 151.9$ pm
- 10.
- 11.

Learning Objectives

- To use the cation:anion radius ratio to predict the structures of simple binary compounds.
- To understand how x-rays are diffracted by crystalline solids.

The structures of most binary compounds can be described using the packing schemes we have just discussed for metals. To do so, we generally focus on the arrangement in space of the largest species present. In ionic solids, this generally means the anions, which are usually arranged in a simple cubic, bcc, fcc, or hcp lattice. (For more information about anions, see [Section 4.2](#).) Often, however, the anion lattices are not truly “close packed”; because the cations are large enough to prop them apart somewhat, the anions are not actually in contact with one another. In ionic compounds, the cations usually occupy the “holes” between the anions, thus balancing the negative charge. The ratio of cations to anions within a unit cell is required to achieve electrical neutrality and corresponds to the bulk stoichiometry of the compound.

Common Structures of Binary Compounds

As shown in part (a) in [Figure 12.3.1](#), a simple cubic lattice of anions contains only one kind of hole, located in the center of the unit cell. Because this hole is equidistant from all eight atoms at the corners of the unit cell, it is called a cubic hole. An atom or ion in a cubic hole therefore has a coordination number of 8. Many ionic compounds with relatively large cations and a 1:1 cation:anion ratio have this structure, which is called the cesium chloride structure ([Figure 12.3.2](#)) because CsCl is a common example. Solid-state chemists tend to describe the structures of new compounds in terms of the structure of a well-known reference compound. Hence you will often read statements such as “Compound X possesses the cesium chloride (or sodium chloride, etc.) structure” to describe the structure of compound X. Notice in [Figure 12.3.2](#) that the $z = 0$ and the $z = 1.0$ planes are always the same. This is because the $z = 1.0$ plane of one unit cell becomes the $z = 0$ plane of the succeeding one. The unit cell in CsCl contains a single Cs⁺ ion as well as $8 \times 1/8$ Cl⁻ = 1 Cl⁻ ion, for an overall stoichiometry of CsCl. The cesium chloride structure is most common for ionic substances with relatively large cations, in which the ratio of the radius of the cation to the radius of the anion is in the range shown in [Table 12.3.1](#).

Figure 12.3.1 Holes in Cubic Lattices The three illustrations show (a) the cubic hole that is in the center of a simple cubic lattice of anions, (b) the locations of the octahedral holes in a face-centered cubic lattice of anions, and (c) the locations of the tetrahedral holes in a face-centered cubic lattice of anions.

Figure 12.3.2 The Cesium Chloride Structure The Cs^+ ion occupies the cubic hole in the center of a cube of Cl^- ions. The drawings at the right are horizontal cross-sections through the unit cell at the bottom ($z = 0$) and halfway between the bottom and top ($z = 0.5$). A top cross-section ($z = 1$) is identical to $z = 0$. Such cross-sections often help us visualize the arrangement of atoms or ions in the unit cell more easily.

Table 12.3.2 Relationship between the Cation:Anion Radius Ratio and the Site Occupied by the Cations

Approximate Range of Cation:Anion Radius Ratio	Hole Occupied by Cation	Cation Coordination Number
0.225–0.414	tetrahedral	4
0.414–0.732	octahedral	6
0.732–1.000	cubic	8

Note the Pattern

Very large cations occupy cubic holes, cations of intermediate size occupy octahedral holes, and small cations occupy tetrahedral holes in the anion lattice.

In contrast, a face-centered cubic (fcc) array of atoms or anions contains two types of holes: octahedral holes, one in the center of the unit cell plus a shared one in the middle of each edge (part (b) in [Figure 12.3.1 "Holes in Cubic Lattices"](#)), and tetrahedral holes, located between an atom at a corner and the three atoms at the centers of the adjacent faces (part (c) in [Figure 12.3.1](#)). As shown in [Table 12.3.1](#), the ratio of the radius of the cation to the radius of the anion is the most important determinant of whether cations occupy the cubic holes in a cubic anion lattice or the octahedral or tetrahedral holes in an fcc lattice of anions. Very large cations occupy cubic holes in a cubic anion lattice, cations of intermediate size tend to occupy the octahedral holes in an fcc anion lattice, and relatively small cations tend to occupy the tetrahedral holes in an fcc anion lattice. In general, larger cations have higher coordination numbers than small cations.

The most common structure based on a fcc lattice is the sodium chloride structure ([Figure 12.3.3](#)), which contains an fcc array of Cl^- ions with Na^+ ions in all the octahedral holes. We can understand the sodium chloride structure by recognizing that filling all the octahedral holes in an fcc lattice of Cl^- ions with Na^+ ions gives a total of 4 Cl^- ions (one on each face gives $6 \times 1/2 = 3$ plus one on each corner gives $8 \times 1/8 = 1$, for a total of 4) and 4 Na^+ ions (one on each edge gives $12 \times 1/4 = 3$ plus one in the middle, for a total of 4). The result is an electrically neutral unit cell and a stoichiometry of NaCl. As shown in [Figure 12.3.3](#), the Na^+ ions in the sodium chloride structure also form an fcc lattice. The sodium chloride structure is favored for substances with two atoms or ions in a 1:1 ratio and in which the ratio of the radius of the cation to the radius of the anion is between 0.414 and 0.732. It is observed in many compounds, including MgO and TiC.

Figure 12.3.3 The Sodium Chloride Structure In NaCl, the Na^+ ions occupy the octahedral holes in an fcc lattice of Cl^- ions, resulting in an fcc array of Na^+ ions as well.

The structure shown in [Figure 12.3.4](#) is called the zinc blende structure, from the common name of the mineral ZnS. It results when the cation in a substance with a 1:1 cation:anion ratio is much smaller than the anion (if the cation:anion radius ratio is less than about 0.414). For example, ZnS contains an fcc lattice of S^{2-} ions, and the cation:anion radius ratio is only about 0.40, so we predict that the cation would occupy either a tetrahedral hole or an octahedral hole. In fact, the relatively small Zn^{2+} cations occupy the tetrahedral holes in the lattice. If all 8 tetrahedral holes in the unit cell were occupied by Zn^{2+} ions, however, the unit cell would contain 4 S^{2-} and 8 Zn^{2+} ions, giving a formula of Zn_2S and a net charge of +4 per unit cell. Consequently, the Zn^{2+} ions occupy every other tetrahedral hole, as shown in [Figure 12.3.4](#), giving a total of 4 Zn^{2+} and 4 S^{2-} ions per unit cell and a formula of ZnS. The zinc blende structure results in a coordination number of 4 for each Zn^{2+} ion and a tetrahedral arrangement of the four S^{2-} ions around each Zn^{2+} ion.

Figure 12.3.4 The Zinc Blende Structure Zn^{2+} ions occupy every other tetrahedral hole in the fcc array of S^{2-} ions. Each Zn^{2+} ion is surrounded by four S^{2-} ions in a tetrahedral arrangement.

Example 12.3.1

1. If all the tetrahedral holes in an fcc lattice of anions are occupied by cations, what is the stoichiometry of the resulting compound?
2. Use the ionic radii given in [Figure 3.2.7](#) to identify a plausible oxygen-containing compound with this stoichiometry and structure.

Given: lattice, occupancy of tetrahedral holes, and ionic radii

Asked for: stoichiometry and identity

Strategy:

A Use [Figure 12.3.1](#) to determine the number and location of the tetrahedral holes in an fcc unit cell of anions and place a cation in each.

B Determine the total number of cations and anions in the unit cell; their ratio is the stoichiometry of the compound.

C From the stoichiometry, suggest reasonable charges for the cation and the anion. Use the data in [Figure 3.2.7](#) to identify a cation–anion combination that has a cation:anion radius ratio within a reasonable range.

Solution:

1. **A** [Figure 12.3.1](#) shows that the tetrahedral holes in an fcc unit cell of anions are located entirely within the unit cell, for a total of eight (one near each corner). **B** Because the tetrahedral holes are located entirely within the unit cell, there are eight cations per unit cell. We calculated previously that an fcc unit cell of anions contains a total of four anions per unit cell. The stoichiometry of the compound is therefore M_8Y_4 or, reduced to the smallest whole numbers, M_2Y .
2. **C** The M_2Y stoichiometry is consistent with a lattice composed of M^+ ions and Y^{2-} ions. If the anion is O^{2-} (ionic radius 140 pm), we need a monocation with a radius no larger than about $140 \times 0.414 = 58$ pm to fit into the tetrahedral holes. According to [Figure 3.2.7](#), none of the monocations has such a small radius; therefore, the most

likely possibility is Li^+ at 76 pm. Thus we expect Li_2O to have a structure that is an fcc array of O^{2-} anions with Li^+ cations in all the tetrahedral holes.

Exercise

If only half the octahedral holes in an fcc lattice of anions are filled by cations, what is the stoichiometry of the resulting compound?

Answer: MX_2 ; an example of such a compound is cadmium chloride (CdCl_2), in which the empty cation sites form planes running through the crystal.

We examine only one other structure of the many that are known, the perovskite structure. *Perovskite* is the generic name for oxides with two different kinds of metal and have the general formula $\text{MM}'\text{O}_3$, such as CaTiO_3 . The structure is a body-centered cubic (bcc) array of two metal ions, with one M (Ca in this case) located at the corners of the cube, and the other M' (in this case Ti) in the centers of the cube. The oxides are in the centers of the square faces (part (a) in Figure 12.3.5). The stoichiometry predicted from the unit cell shown in part (a) in Figure 12.3.5 agrees with the general formula; each unit cell contains $8 \times 1/8 = 1$ Ca, 1 Ti, and $6 \times 1/2 = 3$ O atoms. The Ti and Ca atoms have coordination numbers of 6 and 12, respectively. We will return to the perovskite structure when we discuss high-temperature superconductors in Section 12.7.

Figure 12.3.5 *The Perovskite Structure of CaTiO_3* Two equivalent views are shown: (a) a view with the Ti atom at the center and (b) an alternative view with the Ca atom at the center.

X-Ray Diffraction

As you learned in Chapter 2, the wavelengths of x-rays are approximately the same magnitude as the distances between atoms in molecules or ions. Consequently, x-rays are a useful tool for obtaining information about the structures of crystalline substances. In a technique called x-ray diffraction, a beam of x-rays is aimed at a sample of a crystalline material, and the x-rays are diffracted by layers of atoms in the crystalline lattice (part (a) in Figure 12.3.6). When the beam strikes photographic film, it produces an x-ray diffraction pattern, which consists of dark spots on a light background (part (b) in Figure 12.3.6). In 1912, the German physicist Max von Laue (1879–1960; Nobel Prize in Physics, 1914) predicted that x-rays should be diffracted by crystals, and his prediction was rapidly confirmed. Within a year, two British physicists, William Henry Bragg (1862–1942) and his son, William Lawrence Bragg (1890–1972), had worked out the mathematics that allows x-ray diffraction to be used to measure interatomic distances in crystals. The Braggs shared the Nobel Prize in Physics in 1915, when the son was only 25 years old. Virtually everything we know today about the detailed structures of solids and molecules in solids is due to the x-ray diffraction technique.

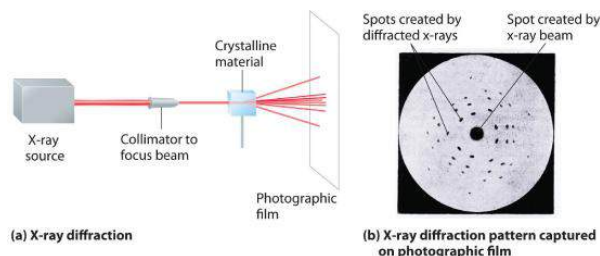

Figure 12.3.6 X-Ray Diffraction These illustrations show (a) a schematic drawing of x-ray diffraction and (b) the x-ray diffraction pattern of a zinc blende crystalline solid captured on photographic film.

Recall from [Chapter 2](#) that two waves that are in phase interfere constructively, thus reinforcing each other and generating a wave with a greater amplitude. In contrast, two waves that are out of phase interfere destructively, effectively canceling each other. When x-rays interact with the components of a crystalline lattice, they are scattered by the electron clouds associated with each atom. As shown in [Figure 12.2.4](#), [Figure 12.2.6](#), and [Figure 12.3.1](#), the atoms in crystalline solids are typically arranged in planes. [Figure 12.3.7](#) illustrates how two adjacent planes of atoms can scatter x-rays in a way that results in constructive interference. If two x-rays that are initially in phase are diffracted by two planes of atoms separated by a distance d , the lower beam travels the extra distance indicated by the lines BC and CD . The *angle of incidence*, designated as θ , is the angle between the x-ray beam and the planes in the crystal. Because $BC = CD = d \sin \theta$, the extra distance that the lower beam in [Figure 12.3.7](#) must travel compared with the upper beam is $2d \sin \theta$. For these two x-rays to arrive at a detector in phase, the extra distance traveled must be an integral multiple n of the wavelength λ :

$$2d \sin \theta = n\lambda \quad (12.3.1)$$

[Equation 12.3.1](#) is the Bragg equation. The structures of crystalline substances with both small molecules and ions or very large biological molecules, with molecular masses in excess of 100,000 amu, can now be determined accurately and routinely using x-ray diffraction and the Bragg equation. [Example 4](#) illustrates how to use the Bragg equation to calculate the distance between planes of atoms in crystals.

Figure 12.3.7 The Reflection of X-Rays from Two Adjacent Planes of Atoms Can Result in Constructive Interference of the X-Rays (a) The x-ray diffracted by the lower layer of atoms must travel a distance that is longer by $2d \sin \theta$ than the distance traveled by the x-ray diffracted by the upper layer of atoms. Only if this distance (BC plus CD) equals an integral number of wavelengths of the x-rays (i.e., only if $\lambda = 2d \sin \theta$) will the x-rays arrive at the detector in phase. (b) In a solid, many different sets of planes of atoms can diffract x-rays. Each has a different interplanar distance and therefore diffracts the x-rays at a different angle θ , which produces a characteristic pattern of spots.

Example 12.3.2

X-rays from a copper x-ray tube ($\lambda = 0.154062$ nm or 154.062 pm) are diffracted at an angle of 10.89° from a sample of crystalline gold. Assuming that $n = 1$, what is the distance between the planes that gives rise to this reflection? Give your answer in angstroms and picometers to four significant figures.

Given: wavelength, diffraction angle, and number of wavelengths

Asked for: distance between planes

Strategy:

Substitute the given values into the Bragg equation and solve to obtain the distance between planes.

Solution:

We are given n , θ , and λ and asked to solve for d , so this is a straightforward application of the Bragg equation. For an answer in angstroms, we do not even have to convert units. Solving the Bragg equation for d gives

$$d = \frac{n\lambda}{2 \sin\theta}$$

and substituting values gives

$$d = \frac{1 \times 0.154062 \text{ nm}}{2 \sin 10.89^\circ} = 0.4077 \text{ nm} = 407.4 \text{ pm}$$

This value corresponds to the edge length of the fcc unit cell of elemental gold.

Exercise

X-rays from a molybdenum x-ray tube ($\lambda = 0.0709300 \text{ nm}$) are diffracted at an angle of 7.11° from a sample of metallic iron. Assuming that $n = 1$, what is the distance between the planes that gives rise to this reflection? Give your answer in angstroms and picometers to three significant figures.

Answer: 0.287 nm or 287 pm (corresponding to the edge length of the bcc unit cell of elemental iron)

Summary

The structures of most binary compounds are dictated by the packing arrangement of the largest species present (the anions), with the smaller species (the cations) occupying appropriately sized holes in the anion lattice. A simple cubic lattice of anions contains a single **cubic hole** in the center of the unit cell. Placing a cation in the cubic hole results in the **cesium chloride structure**, with a 1:1 cation:anion ratio and a coordination number of 8 for both the cation and the anion. An fcc array of atoms or ions contains both **octahedral holes** and **tetrahedral holes**. If the octahedral holes in an fcc lattice of anions are filled with cations, the result is a **sodium chloride structure**. It also has a 1:1 cation:anion ratio, and each ion has a coordination number of 6. Occupation of half the tetrahedral holes by cations results in the **zinc blende structure**, with a 1:1 cation:anion ratio and a coordination number of 4 for the cations. More complex structures are possible if there are more than two kinds of atoms in a solid. One example is the **perovskite structure**, in which the two metal ions form an alternating bcc array with the anions in the centers of the square faces. Because the wavelength of x-ray radiation is comparable to the interatomic distances in most solids, **x-ray diffraction** can be used to provide information about the structures of crystalline solids. X-rays diffracted from different planes of atoms in a solid reinforce one another if they are in phase, which occurs only if the extra distance they travel corresponds to an integral number of wavelengths. This relationship is described by the **Bragg equation**: $2d \sin \theta = n\lambda$.

Key Takeaway

- The ratio of cations to anions within a unit cell produces electrical neutrality and corresponds to the bulk stoichiometry of a compound, the structure of which can be determined using x-ray diffraction.

Key Equation

Bragg equation Equation 12.3.1: $2d \sin \theta = n\lambda$

Conceptual Problems

- Using circles or spheres, sketch a unit cell containing an octahedral hole. Which of the basic structural types possess octahedral holes? If an ion were placed in an octahedral hole, what would its coordination number be?
- Using circles or spheres, sketch a unit cell containing a tetrahedral hole. Which of the basic structural types possess tetrahedral holes? If an ion were placed in a tetrahedral hole, what would its coordination number be?
- How many octahedral holes are there in each unit cell of the sodium chloride structure? Potassium fluoride contains an fcc lattice of F⁻ ions that is identical to the arrangement of Cl⁻ ions in the sodium chloride structure. Do you expect K⁺ ions to occupy the tetrahedral or octahedral holes in the fcc lattice of F⁻ ions?
- The unit cell of cesium chloride consists of a cubic array of chloride ions with a cesium ion in the center. Why then is cesium chloride described as having a simple cubic structure rather than a bcc structure? The unit cell of iron also consists of a cubic array of iron atoms with an iron atom in the center of the cube. Is this a bcc or a simple cubic unit cell? Explain your answer.
- Why are x-rays used to determine the structure of crystalline materials? Could gamma rays also be used to determine crystalline structures? Why or why not?
- X-rays are higher in energy than most other forms of electromagnetic radiation, including visible light. Why can't you use visible light to determine the structure of a crystalline material?
- When x-rays interact with the atoms in a crystal lattice, what relationship between the distances between planes of atoms in the crystal structure and the wavelength of the x-rays results in the scattered x-rays being exactly in phase with one another? What difference in structure between amorphous materials and crystalline materials makes it difficult to determine the structures of amorphous materials by x-ray diffraction?
- It is possible to use different x-ray sources to generate x-rays with different wavelengths. Use the Bragg equation to predict how the diffraction angle would change if a molybdenum x-ray source (x-ray wavelength = 70.93 pm) were used instead of a copper source (x-ray wavelength = 154.1 pm).
- Based on the Bragg equation, if crystal A has larger spacing in its diffraction pattern than crystal B, what conclusion can you draw about the spacing between layers of atoms in A compared with B?

Numerical Problems

- Thallium bromide crystallizes in the cesium chloride structure. This bcc structure contains a Tl⁺ ion in the center of the cube with Br⁻ ions at the corners. Sketch an alternative unit cell for this compound.
- Potassium fluoride has a lattice identical to that of sodium chloride. The potassium ions occupy octahedral holes in an fcc lattice of fluoride ions. Propose an alternative unit cell that can also represent the structure of KF.
- Calcium fluoride is used to fluoridate drinking water to promote dental health. Crystalline CaF₂ ($d = 3.1805 \text{ g/cm}^3$) has a structure in which calcium ions are located at each corner and the middle of each edge of the unit cell, which contains eight fluoride ions per unit cell. The length of the edge of this unit cell is 5.463 Å. Use this information to determine Avogadro's number.
- Zinc and oxygen form a compound that is used as both a semiconductor and a paint pigment. This compound has the following structure:

What is the empirical formula of this compound?

- Here are two representations of the perovskite structure:

Are they identical? What is the empirical formula corresponding to each representation?

- The salt MX₂ has a cubic close-packed (ccp) structure in which all the tetrahedral holes are filled by anions. What is the coordination number of M⁺ of X⁻?
- A compound has a structure based on simple cubic packing of the anions, and the cations occupy half of the cubic holes. What is the empirical formula of this compound? What is the coordination number of the cation?

- Barium and fluoride form a compound that crystallizes in the fluorite structure, in which the fluoride ions occupy all the tetrahedral holes in a ccp array of barium ions. This particular compound is used in embalming fluid. What is its empirical formula?
- Cadmium chloride is used in paints as a yellow pigment. Is the following structure consistent with an empirical formula of CdCl_2 ? If not, what is the empirical formula of the structure shown?

- Use the information in the following table to decide whether the cation will occupy a tetrahedral hole, an octahedral hole, or a cubic hole in each case.

Cation Radius (pm)	Anion Radius (pm)
78.0	132
165	133
81	174

- Calculate the angle of diffraction when x-rays from a copper tube ($\lambda = 154 \text{ pm}$) are diffracted by planes of atoms parallel to the faces of the cubic unit cell for Mg (260 pm), Zn (247 pm), and Ni (216 pm). The length on one edge of the unit cell is given in parentheses; assume first-order diffraction ($n = 1$).
- If x-rays from a copper target ($\lambda = 154 \text{ pm}$) are scattered at an angle of 17.23° by a sample of Mg, what is the distance (in picometers) between the planes responsible for this diffraction? How does this distance compare with that in a sample of Ni for which $\theta = 20.88^\circ$?

Answers

-
-
- $d = 3.1805 \text{ g/cm}^3$; Avogadro's number = $6.023 \times 10^{23} \text{ mol}^{-1}$
-
- Both have same stoichiometry, CaTiO_3
-
- Stoichiometry is MX_2 ; coordination number of cations is 8
-
- No, the structure shown has an empirical formula of Cd_3Cl_8 .
-
-
- Mg: 17.2° , Zn: 18.2° , Ni: 20.9°

Learning Objectives

- To understand the origin and nature of defects in crystals.

The crystal lattices we have described represent an idealized, simplified system that can be used to understand many of the important principles governing the behavior of solids. In contrast, real crystals contain large numbers of defects (typically more than 10^4 per milligram), ranging from variable amounts of impurities to missing or misplaced atoms or ions. These defects occur for three main reasons:

- It is impossible to obtain any substance in 100% pure form. Some impurities are always present.
- Even if a substance were 100% pure, forming a perfect crystal would require cooling the liquid phase infinitely slowly to allow all atoms, ions, or molecules to find their proper positions. Cooling at more realistic rates usually results in one or more components being trapped in the “wrong” place in a lattice or in areas where two lattices that grew separately intersect.
- Applying an external stress to a crystal, such as a hammer blow, can cause microscopic regions of the lattice to move with respect to the rest, thus resulting in imperfect alignment.

In this section, we discuss how defects determine some of the properties of solids. We begin with solids that consist of neutral atoms, specifically metals, and then turn to ionic compounds.

Defects in Metals

Metals can have various types of defects. A point defect is any defect that involves only a single particle (a lattice point) or sometimes a very small set of points. A line defect is restricted to a row of lattice points, and a plane defect involves an entire plane of lattice points in a crystal. A vacancy occurs where an atom is missing from the normal crystalline array; it constitutes a tiny void in the middle of a solid (Figure 12.4.1). We focus primarily on point and plane defects in our discussion because they are encountered most frequently.

Figure 12.4.1 Common Defects in Crystals In this two-dimensional representation of a crystal lattice containing substitutional and interstitial impurities, vacancies, and line defects, a dashed line and arrows indicate the position of the line defect.

Impurities

Impurities can be classified as interstitial or substitutional. An interstitial impurity is usually a smaller atom (typically about 45% smaller than the host) that can fit into the octahedral or tetrahedral holes in the metal lattice (Figure 12.4.1). Steels consist of iron with carbon atoms added as interstitial impurities (Table 12.4.1). The inclusion of one or more transition metals or semimetals can improve the corrosion resistance of steel.

Table 12.4.1 Compositions, Properties, and Uses of Some Types of Steel

Name of Steel	Typical Composition*	Properties	Applications
low-carbon	<0.15% C	soft and ductile	wire
mild carbon	0.15%–0.25% C	malleable and ductile	cables, chains, and nails
high-carbon	0.60%–1.5% C	hard and brittle	knives, cutting tools, drill bits, and springs
stainless	15%–20% Cr, 1%–5% Mn, 5%–10% Ni, 1%–3% Si, 1% C, 0.05% P	corrosion resistant	cutlery, instruments, and marine fittings
invar	36% Ni	low coefficient of thermal expansion	measuring tapes and meter sticks
manganese	10%–20% Mn	hard and wear resistant	armor plate, safes, and rails
high-speed	14%–20% W	retains hardness at high temperatures	high-speed cutting tools
silicon	1%–5% Si	hard, strong, and highly magnetic	magnets in electric motors and transformers

***In addition to enough iron to bring the total percentage up to 100%, most steels contain small amounts of carbon (0.5%–1.5%) and manganese (<2%).**

In contrast, a substitutional impurity is a different atom of about the same size that simply replaces one of the atoms that compose the host lattice (Figure 12.4.1). Substitutional impurities are usually chemically similar to the substance that constitutes the bulk of the sample, and they generally have atomic radii that are within about 15% of the radius of the host. For example, strontium and calcium are chemically similar and have similar radii, and as a result, strontium is a common impurity in crystalline calcium, with the Sr atoms randomly occupying sites normally occupied by Ca.

Note the Pattern

Interstitial impurities are smaller atoms than the host atom, whereas substitutional impurities are usually chemically similar and are similar in size to the host atom.

Dislocations, Deformations, and Work Hardening

Inserting an extra plane of atoms into a crystal lattice produces an edge dislocation. A familiar example of an edge dislocation occurs when an ear of corn contains an extra row of kernels between the other rows (Figure 12.4.2). An edge dislocation in a crystal causes the planes of atoms in the lattice to deform where the extra plane of atoms begins (Figure 12.4.2). The edge dislocation frequently determines whether the entire solid will deform and fail under stress.

Figure 12.4.2 Edge Dislocations Shown are two examples of edge dislocations: (a) an edge dislocation in an ear of corn and (b) a three-dimensional representation of an edge dislocation in a solid, illustrating how an edge dislocation can be viewed as a simple line defect arising from the insertion of an extra set of atoms into the lattice. In both cases, the origin of the edge dislocation is indicated by the symbol \perp

Deformation occurs when a dislocation moves through a crystal. To illustrate the process, suppose you have a heavy rug that is lying a few inches off-center on a nonskid pad. To move the rug to its proper place, you could pick up one end and pull it. Because of the large area of contact between the rug and the pad, however, they will probably move as a unit. Alternatively, you could pick up the rug and try to set it back down exactly where you want it, but that requires a great deal of effort (and probably at least one extra person). An easier solution is to create a small wrinkle at one end of the rug (an edge dislocation) and gradually push the wrinkle across, resulting in a net movement of the rug as a whole (part (a) in [Figure 12.4.3](#)). Moving the wrinkle requires only a small amount of energy because only a small part of the rug is actually moving at any one time. Similarly, in a solid, the contacts between layers are broken in only one place at a time, which facilitates the deformation process.

Figure 12.4.3 The Role of Dislocation in the Motion of One Planar Object across Another (a) Pushing a wrinkle across the rug results in a net movement of the rug with relatively little expenditure of energy because at any given time only a very small amount of the rug is not in contact with the floor. (b) A second intersecting wrinkle prevents movement of the first by “pinning” it.

If the rug we have just described has a *second* wrinkle at a different angle, however, it is very difficult to move the first one where the two wrinkles intersect (part (b) in [Figure 12.4.3](#)); this process is called pinning. Similarly, intersecting dislocations in a solid

prevent them from moving, thereby increasing the mechanical strength of the material. In fact, one of the major goals of materials science is to find ways to pin dislocations to strengthen or harden a material.

Pinning can also be achieved by introducing selected impurities in appropriate amounts. Substitutional impurities that are a mismatch in size to the host prevent dislocations from migrating smoothly along a plane. Generally, the higher the concentration of impurities, the more effectively they block migration, and the stronger the material. For example, bronze, which contains about 20% tin and 80% copper by mass, produces a much harder and sharper weapon than does either pure tin or pure copper. Similarly, pure gold is too soft to make durable jewelry, so most gold jewelry contains 75% (18 carat) or 58% (14 carat) gold by mass, with the remainder consisting of copper, silver, or both.

If an interstitial impurity forms polar covalent bonds to the host atoms, the layers are prevented from sliding past one another, even when only a small amount of the impurity is present. For example, because iron forms polar covalent bonds to carbon, the strongest steels need to contain only about 1% carbon by mass to substantially increase their strength (Table 12.4.1).

Most materials are polycrystalline, which means they consist of many microscopic individual crystals called *grains* that are randomly oriented with respect to one another. The place where two grains intersect is called a grain boundary. The movement of a deformation through a solid tends to stop at a grain boundary. Consequently, controlling the grain size in solids is critical for obtaining desirable mechanical properties; fine-grained materials are usually much stronger than coarse-grained ones.

Work hardening is the introduction of a dense network of dislocations throughout a solid, which makes it very tough and hard. If all the defects in a single 1 cm^3 sample of a work-hardened material were laid end to end, their total length could be 10^6 km ! The legendary blades of the Japanese and Moorish swordsmiths owed much of their strength to repeated work hardening of the steel. As the density of defects increases, however, the metal becomes more brittle (less malleable). For example, bending a paper clip back and forth several times increases its brittleness from work hardening and causes the wire to break.

Grain boundaries. As a polycrystalline material solidifies, grains with irregular shapes form. The interfaces between grains constitute grain boundaries. (Squares represent unit cells within grains.)

Memory Metal

The compound NiTi, popularly known as “memory metal” or nitinol (nickel–titanium Naval Ordnance Laboratory, after the site where it was first prepared), illustrates the importance of deformations. If a straight piece of NiTi wire is wound into a spiral, it will remain in the spiral shape indefinitely, *unless* it is warmed to 50°C – 60°C , at which point it will spontaneously straighten out again. The chemistry behind the temperature-induced change in shape is moderately complex, but for our purposes it is sufficient to know that NiTi can exist in two different solid phases.

The high-temperature phase has the cubic cesium chloride structure, in which a Ti atom is embedded in the center of a cube of Ni atoms (or vice versa). The low-temperature phase has a related but kinked structure, in which one of the angles of the unit cell is no longer 90° . Bending an object made of the low-temperature (kinked) phase creates defects that change the pattern of kinks within the structure. If the object is heated to a temperature greater than about 50°C , the material undergoes a transition to the cubic high-temperature phase, causing the object to return to its original shape. The shape of the object above 50°C is controlled by a complex set of defects and dislocations that can be relaxed or changed only by the thermal motion of the atoms.

Memory metal has many other practical applications, such as its use in temperature-sensitive springs that open and close valves in the automatic transmissions of cars. Because NiTi can also undergo pressure- or tension-induced phase transitions, it is used to make wires for straightening teeth in orthodontic braces and in surgical staples that change shape at body temperature to hold broken bones together

Memory metal. Flexon is a fatigue-resistant alloy of Ti and Ni that is used as a frame for glasses because of its durability and corrosion resistance.

Another flexible, fatigue-resistant alloy composed of titanium and nickel is Flexon. Originally discovered by metallurgists who were creating titanium-based alloys for use in missile heat shields, Flexon is now used as a durable, corrosion-resistant frame for glasses, among other uses.

Example 12.4.1

Because steels with at least 4% chromium are much more corrosion resistant than iron, they are collectively sold as “stainless steel.” Referring to the composition of stainless steel in [Table 12.4.1](#) and, if needed, the atomic radii in [Figure 3.2.7](#), predict which type of impurity is represented by each element in stainless steel, excluding iron, that are present in at least 0.05% by mass.

Given: composition of stainless steel and atomic radii

Asked for: type of impurity

Strategy:

Using the data in [Table 12.4.1](#) and the atomic radii in [Figure 3.2.7](#), determine whether the impurities listed are similar in size to an iron atom. Then determine whether each impurity is chemically similar to Fe. If similar in both size and chemistry, the impurity is likely to be a substitutional impurity. If not, it is likely to be an interstitial impurity.

Solution:

According to [Table 12.4.1](#) stainless steel typically contains about 1% carbon, 1%–5% manganese, 0.05% phosphorus, 1%–3% silicon, 5%–10% nickel, and 15%–20% chromium. The three transition elements (Mn, Ni, and Cr) lie near Fe in the periodic table, so they should be similar to Fe in chemical properties and atomic size (atomic radius = 125 pm). Hence they almost certainly will substitute for iron in the Fe lattice. Carbon is a second-period element that is nonmetallic and much smaller (atomic radius = 77 pm) than iron. Carbon will therefore tend to occupy interstitial sites in the iron lattice. Phosphorus and silicon are chemically quite different from iron (phosphorus is a nonmetal, and silicon is a semimetal), even though they are similar in size (atomic radii of 106 and 111 pm, respectively). Thus they are unlikely to be substitutional impurities in the iron lattice or fit into interstitial sites, but they could aggregate into layers that would constitute plane defects.

Exercise

Consider nitrogen, vanadium, zirconium, and uranium impurities in a sample of titanium metal. Which is most likely to form an interstitial impurity? a substitutional impurity?

Answer: nitrogen; vanadium

Defects in Ionic and Molecular Crystals

All the defects and impurities described for metals are seen in ionic and molecular compounds as well. Because ionic compounds contain both cations and anions rather than only neutral atoms, however, they exhibit additional types of defects that are not possible in metals.

The most straightforward variant is a substitutional impurity in which a cation or an anion is replaced by another of similar charge and size. For example, Br^- can substitute for Cl^- , so tiny amounts of Br^- are usually present in a chloride salt such as CaCl_2 or BaCl_2 . If the substitutional impurity and the host have *different* charges, however, the situation becomes more complicated. Suppose, for example, that Sr^{2+} (ionic radius = 118 pm) substitutes for K^+ (ionic radius = 138 pm) in KCl. Because the ions are approximately the same size, Sr^{2+} should fit nicely into the face-centered cubic (fcc) lattice of KCl. The difference in charge, however, must somehow be compensated for so that electrical neutrality is preserved. The simplest way is for a second K^+ ion to be lost elsewhere in the crystal, producing a vacancy. Thus substitution of K^+ by Sr^{2+} in KCl results in the introduction of *two* defects: a site in which an Sr^{2+} ion occupies a K^+ position and a vacant cation site. Substitutional impurities whose charges do not match the host's are often introduced intentionally to produce compounds with specific properties (see [Section 12.7](#)).

Virtually all the colored gems used in jewelry are due to substitutional impurities in simple oxide structures. For example, $\alpha\text{-Al}_2\text{O}_3$, a hard white solid called *corundum* that is used as an abrasive in fine sandpaper, is the primary component, or *matrix*, of a wide variety of gems. Because many trivalent transition metal ions have ionic radii only a little larger than the radius of Al^{3+} (ionic radius = 53.5 pm), they can replace Al^{3+} in the octahedral holes of the oxide lattice. Substituting small amounts of Cr^{3+} ions (ionic radius = 75 pm) for Al^{3+} gives the deep red color of ruby, and a mixture of impurities (Fe^{2+} , Fe^{3+} , and Ti^{3+}) gives the deep blue of sapphire. True amethyst contains small amounts of Fe^{3+} in an SiO_2 (quartz) matrix. The same metal ion substituted into different mineral lattices can produce very different colors. For example, Fe^{3+} ions are responsible for the yellow color of topaz and the violet color of amethyst. The distinct environments cause differences in *d* orbital energies, enabling the Fe^{3+} ions to absorb light of different frequencies, a topic we describe in more detail in [Chapter 21](#).

Substitutional impurities are also observed in *molecular* crystals if the structure of the impurity is similar to the host, and they can have major effects on the properties of the crystal. Pure anthracene, for example, is an electrical conductor, but the transfer of electrons through the molecule is much slower if the anthracene crystal contains even very small amounts of tetracene despite their strong structural similarities.

The same cation in different environments. An Fe^{3+} substitutional impurity produces substances with strikingly different colors.

If a cation or an anion is simply missing, leaving a vacant site in an ionic crystal, then for the crystal to be electrically neutral, there must be a corresponding vacancy of the ion with the opposite charge somewhere in the crystal. In compounds such as KCl, the charges are equal but opposite, so one anion vacancy is sufficient to compensate for each cation vacancy. In compounds such as CaCl_2 , however, two Cl⁻ anion sites must be vacant to compensate for each missing Ca²⁺ cation. These pairs (or sets) of vacancies are called Schottky defects and are particularly common in simple alkali metal halides such as KCl (part (a) in Figure 12.4.4). Many microwave diodes, which are devices that allow a current to flow in a single direction, are composed of materials with Schottky defects.

Figure 12.4.4 The Two Most Common Defects in Ionic Solids (a) A Schottky defect in KCl shows the missing cation/anion pair. (b) A Frenkel defect in AgI shows a misplaced Ag⁺ cation.

Occasionally one of the ions in an ionic lattice is simply in the wrong position. An example of this phenomenon, called a Frenkel defect, is a cation that occupies a tetrahedral hole rather than an octahedral hole in the anion lattice (part (b) in Figure 12.4.4). Frenkel defects are most common in salts that have a large anion and a relatively small cation. To preserve electrical neutrality, one of the normal cation sites, usually octahedral, must be vacant.

Frenkel defects are particularly common in the silver halides AgCl, AgBr, and AgI, which combine a rather small cation (Ag⁺, ionic radius = 115 pm) with large, polarizable anions. Certain more complex salts with a second cation in addition to Ag⁺ and Br⁻ or I⁻ have so many Ag⁺ ions in tetrahedral holes that they are good electrical conductors in the solid state; hence they are called solid electrolytes. (As you learned in Chapter 8, most ionic compounds do not conduct electricity in the solid state, although they do conduct electricity when molten or dissolved in a solvent that separates the ions, allowing them to migrate in response to an applied electric field.) In response to an applied voltage, the cations in solid electrolytes can diffuse rapidly through the lattice via octahedral holes, creating Frenkel defects as the cations migrate. Sodium–sulfur batteries use a solid Al₂O₃ electrolyte with small amounts of solid Na₂O. Because the electrolyte cannot leak, it cannot cause corrosion, which gives a battery that uses a solid electrolyte a significant advantage over one with a liquid electrolyte.

Example 12.4.2

In a sample of NaCl, one of every 10,000 sites normally occupied by Na⁺ is occupied instead by Ca²⁺. Assuming that all of the Cl⁻ sites are fully occupied, what is the stoichiometry of the sample?

Given: ionic solid and number and type of defect

Asked for: stoichiometry

Strategy:

A Identify the unit cell of the host compound. Compute the stoichiometry if 0.01% of the Na^+ sites are occupied by Ca^{2+} . If the overall charge is greater than 0, then the stoichiometry must be incorrect.

B If incorrect, adjust the stoichiometry of the Na^+ ion to compensate for the additional charge.

Solution:

A Pure NaCl has a 1:1 ratio of Na^+ and Cl^- ions arranged in an fcc lattice (the sodium chloride structure). If all the anion sites are occupied by Cl^- , the negative charge is -1.00 per formula unit. If 0.01% of the Na^+ sites are occupied by Ca^{2+} ions, the cation stoichiometry is $\text{Na}_{0.99}\text{Ca}_{0.01}$. This results in a positive charge of $(0.99)(+1) + (0.01)(+2) = +1.01$ per formula unit, for a net charge in the crystal of $+1.01 + (-1.00) = +0.01$ per formula unit. Because the overall charge is greater than 0, this stoichiometry must be incorrect.

B The most plausible way for the solid to adjust its composition to become electrically neutral is for some of the Na^+ sites to be vacant. If one Na^+ site is vacant for each site that has a Ca^{2+} cation, then the cation stoichiometry is $\text{Na}_{0.98}\text{Ca}_{0.01}$. This results in a positive charge of $(0.98)(+1) + (0.01)(+2) = +1.00$ per formula unit, which exactly neutralizes the negative charge. The stoichiometry of the solid is thus $\text{Na}_{0.98}\text{Ca}_{0.01}\text{Cl}_{1.00}$.

Exercise

In a sample of MgO that has the sodium chloride structure, 0.02% of the Mg^{2+} ions are replaced by Na^+ ions. Assuming that all of the cation sites are fully occupied, what is the stoichiometry of the sample?

Answer: If the formula of the compound is $\text{Mg}_{0.98}\text{Na}_{0.02}\text{O}_{1-x}$, then x must equal 0.01 to preserve electrical neutrality. The formula is thus $\text{Mg}_{0.98}\text{Na}_{0.02}\text{O}_{0.99}$.

Nonstoichiometric Compounds

The law of multiple proportions (see [Chapter 1](#)), states that chemical compounds contain fixed integral ratios of atoms. In fact, nonstoichiometric compounds contain large numbers of defects, usually vacancies, which give rise to stoichiometries that can depart significantly from simple integral ratios *without affecting the fundamental structure of the crystal*. Nonstoichiometric compounds frequently consist of transition metals, lanthanides, and actinides, with polarizable anions such as oxide (O^{2-}) and sulfide (S^{2-}). Some common examples are listed in [Table 12.4.1](#), along with their basic structure type. These compounds are nonstoichiometric because their constituent metals can exist in multiple oxidation states in the solid, which in combination preserve electrical neutrality.

Table 12.4.1 Some Non-stoichiometric Compounds

Compound	Observed Range of x
Oxides*	
Fe_xO	0.85–0.95
Ni_xO	0.97–1.00
TiO_x	0.75–1.45
VO_x	0.9–1.20
NbO_x	0.9–1.04
Sulfides	
Cu_xS	1.77–2.0
Fe_xS	0.80–0.99
ZrS_x	0.9–1.0
*All the oxides listed have the sodium chloride structure.	

One example is iron(II) oxide (ferrous oxide), which produces the black color in clays and is used as an abrasive. Its stoichiometry is *not* FeO because it always contains less than 1.00 Fe per O²⁻ (typically 0.90–0.95). This is possible because Fe can exist in both the +2 and +3 oxidation states. Thus the difference in charge created by a vacant Fe²⁺ site can be balanced by two Fe³⁺ sites that have Fe³⁺ ions instead [$+2 \text{ vacancy} = (3 - 2) + (3 - 2)$]. The crystal lattice is able to accommodate this relatively high fraction of substitutions and vacancies with no significant change in structure.

Note the Pattern

Because a crystal must be electrically neutral, any defect that affects the number or charge of the cations *must be compensated* by a corresponding defect in the number or charge of the anions.

Summary

Real crystals contain large numbers of **defects**. Defects may affect only a single point in the lattice (a **point defect**), a row of lattice points (a **line defect**), or a plane of atoms (a **plane defect**). A point defect can be an atom missing from a site in the crystal (a **vacancy**) or an impurity atom that occupies either a normal lattice site (a **substitutional impurity**) or a hole in the lattice between atoms (an **interstitial impurity**). In an **edge dislocation**, an extra plane of atoms is inserted into part of the crystal lattice. Multiple defects can be introduced into materials so that the presence of one defect prevents the motion of another, in a process called **pinning**. Because defect motion tends to stop at **grain boundaries**, controlling the size of the grains in a material controls its mechanical properties. In addition, a process called **work hardening** introduces defects to toughen metals. **Schottky defects** are a coupled pair of vacancies—one cation and one anion—that maintains electrical neutrality. A **Frenkel defect** is an ion that occupies an incorrect site in the lattice. Cations in such compounds are often able to move rapidly from one site in the crystal to another, resulting in high electrical conductivity in the solid material. Such compounds are called **solid electrolytes**. **Nonstoichiometric compounds** have variable stoichiometries over a given range with no dramatic change in crystal structure. This behavior is due to a large number of vacancies or substitutions of one ion by another ion with a different charge.

Key Takeaway

- Defects determine the behavior of solids, but because ionic compounds contain both cations and anions, they exhibit additional types of defects that are not found in metals.

Conceptual Problems

- How are defects and impurities in a solid related? Can a pure, crystalline compound be free of defects? How can a substitutional impurity produce a vacancy?
- Why does applying a mechanical stress to a covalent solid cause it to fracture? Use an atomic level description to explain why a metal is ductile under conditions that cause a covalent solid to fracture.
- How does work hardening increase the strength of a metal? How does work hardening affect the physical properties of a metal?
- Work-hardened metals and covalent solids such as diamonds are both susceptible to cracking when stressed. Explain how such different materials can both exhibit this property.
- Suppose you want to produce a ductile material with improved properties. Would impurity atoms of similar or dissimilar atomic size be better at maintaining the ductility of a metal? Why? How would introducing an impurity that forms polar covalent bonds with the metal atoms affect the ductility of the metal? Explain your reasoning.
- Substitutional impurities are often used to tune the properties of material. Why are substitutional impurities generally more effective at high concentrations, whereas interstitial impurities are usually effective at low concentrations?
- If an O²⁻ ion (ionic radius = 132 pm) is substituted for an F⁻ ion (ionic radius = 133 pm) in an ionic crystal, what structural changes in the ionic lattice will result?

8. How will the introduction of a metal ion with a different charge as an impurity induce the formation of oxygen vacancies in an ionic metal-oxide crystal?
9. Many nonstoichiometric compounds are transition metal compounds. How can such compounds exist, given that their nonintegral cation:anion ratios apparently contradict one of the basic tenets of Dalton's atomic theory of matter?
10. If you wanted to induce the formation of oxygen vacancies in an ionic crystal, which would you introduce as substitutional impurities—cations with a higher positive charge or a lower positive charge than the cations in the parent structure? Explain your reasoning.

Answers

- 1.
- 2.
- 3.
- 4.
5. Impurity atoms of similar size and with similar chemical properties would be most likely to maintain the ductility of the metal, because they are unlikely to have a large effect on the ease with which one layer of atoms can move past another under mechanical stress. Larger impurity atoms are likely to form "bumps" or kinks that will make it harder for layers of atoms to move across one another. Interstitial atoms that form polar covalent bonds with the metal atoms tend to occupy spaces between the layers; they act as a "glue" that holds layers of metal atoms together, which greatly decreases the ductility.
- 6.
7. Since O^{2-} and F^- are both very similar in size, substitution is possible without disruption of the ionic packing. The difference in charge, however, requires the formation of a vacancy on another F^- site to maintain charge neutrality.
- 8.
9. Most transition metals form at least two cations that differ by only one electron. Consequently, nonstoichiometric compounds containing transition metals can maintain electrical neutrality by gaining electrons to compensate for the absence of anions or the presence of additional metal ions. Conversely, such compounds can lose electrons to compensate for the presence of additional anions or the absence of metal ions. In both cases, the positive charge on the transition metal is adjusted to maintain electrical neutrality.
- 10.

Numerical Problems

1. The ionic radius of K^+ is 133 pm, whereas that of Na^+ is 98 pm. Do you expect K^+ to be a common substitutional impurity in compounds containing Na^+ ? Why or why not?
2. Given Cs (262 pm), Tl (171 pm), and B (88 pm) with their noted atomic radii, which atom is most likely to act as an interstitial impurity in an Sn lattice (Sn atomic radius = 141 pm)? Why?
3. After aluminum, iron is the second most abundant metal in Earth's crust. The silvery-white, ductile metal has a body-centered cubic (bcc) unit cell with an edge length of 286.65 pm.
 - a. Use this information to calculate the density of iron.
 - b. What would the density of iron be if 0.15% of the iron sites were vacant?
 - c. How does the mass of 1.00 cm³ of iron without defects compare with the mass of 1.00 cm³ of iron with 0.15% vacancies?
4. Certain ceramic materials are good electrical conductors due to high mobility of oxide ions resulting from the presence of oxygen vacancies. Zirconia (ZrO_2) can be doped with yttrium by adding Y_2O_3 . If 0.35 g of Y_2O_3 can be incorporated into 25.0 g of ZrO_2 while maintaining the zirconia structure, what is the percentage of oxygen vacancies in the structure?
5. Which of the following ions is most effective at inducing an O^{2-} vacancy in crystal of CaO ? The ionic radii are O^{2-} , 132 pm; Ca^{2+} , 100 pm; Sr^{2+} , 127 pm; F^- , 133 pm; La^{3+} , 104 pm; and K^+ , 133 pm. Explain your reasoning.

Answers

1. No. The potassium is much larger than the sodium ion.
- 2.
- 3.

- a. 7.8744 g/cm^3
 - b. 7.86 g/cm^3
 - c. Without defects, the mass is 0.15% greater.
- 4.
5. The lower charge of K^+ makes it the best candidate for inducing an oxide vacancy, even though its ionic radius is substantially larger than that of Ca^{2+} . Substituting two K^+ ions for two Ca^{2+} ions will decrease the total positive charge by two, and an oxide vacancy will maintain electrical neutrality. For example, if 10% of the Ca^{2+} ions are replaced by K^+ , we can represent the change as going from $\text{Ca}_{20}\text{O}_{20}$ to $\text{K}_2\text{Ca}_{18}\text{O}_{20}$, which has a net charge of +2. Loss of one oxide ion would give a composition of $\text{K}_2\text{Ca}_{18}\text{O}_{19}$, which is electrically neutral.

Learning Objectives

- To understand the correlation between bonding and the properties of solids.

Based on the nature of the forces that hold the component atoms, molecules, or ions together, solids may be formally classified as *ionic*, *molecular*, *covalent (network)*, or *metallic*. The variation in the relative strengths of these four types of interactions correlates nicely with their wide variation in properties.

Ionic Solids

You learned in [Chapter 4](#) that an ionic solid consists of positively and negatively charged ions held together by electrostatic forces. (For more information about ionic solids, see [Section 4.2](#).) The strength of the attractive forces depends on the charge and size of the ions that compose the lattice and determines many of the physical properties of the crystal.

The **lattice energy**, the energy required to separate 1 mol of a crystalline ionic solid into its component ions in the gas phase, is directly proportional to the product of the ionic charges and inversely proportional to the sum of the radii of the ions. For example, NaF and CaO both crystallize in the face-centered cubic (fcc) sodium chloride structure, and the sizes of their component ions are about the same: Na⁺ (102 pm) versus Ca²⁺ (100 pm), and F⁻ (133 pm) versus O²⁻ (140 pm). Because of the higher charge on the ions in CaO, however, the lattice energy of CaO is almost four times greater than that of NaF (3401 kJ/mol versus 923 kJ/mol). The forces that hold Ca and O together in CaO are much stronger than those that hold Na and F together in NaF, so the heat of fusion of CaO is almost twice that of NaF (59 kJ/mol versus 33.4 kJ/mol), and the melting point of CaO is 2927°C versus 996°C for NaF. In both cases, however, the values are large; that is, simple ionic compounds have high melting points and are relatively hard (and brittle) solids.

Molecular Solids

Molecular solids consist of atoms or molecules held to each other by dipole–dipole interactions, London dispersion forces, or hydrogen bonds, or any combination of these, which were discussed in [Chapter 11](#). The arrangement of the molecules in solid benzene is as follows:

The structure of solid benzene. In solid benzene, the molecules are not arranged with their planes parallel to one another but at 90° angles.

Because the intermolecular interactions in a molecular solid are relatively weak compared with ionic and covalent bonds, molecular solids tend to be soft, low melting, and easily vaporized (ΔH_{fus} and ΔH_{vap} are low). For similar substances, the strength of the London dispersion forces increases smoothly with increasing molecular mass. For example, the melting points of benzene (C_6H_6), naphthalene (C_{10}H_8), and anthracene ($\text{C}_{14}\text{H}_{10}$), with one, two, and three fused aromatic rings, are 5.5°C , 80.2°C , and 215°C , respectively. The enthalpies of fusion also increase smoothly within the series: benzene (9.95 kJ/mol) < naphthalene (19.1 kJ/mol) < anthracene (28.8 kJ/mol). If the molecules have shapes that cannot pack together efficiently in the crystal, however, then the melting points and the enthalpies of fusion tend to be unexpectedly low because the molecules are unable to arrange themselves to optimize intermolecular interactions. Thus toluene ($\text{C}_6\text{H}_5\text{CH}_3$) and *m*-xylene [$m\text{-C}_6\text{H}_4(\text{CH}_3)_2$] have melting points of -95°C and -48°C , respectively, which are significantly lower than the melting point of the lighter but more symmetrical analog, benzene.

Self-healing rubber is an example of a molecular solid with the potential for significant commercial applications. The material can stretch, but when snapped into pieces it can bond back together again through reestablishment of its hydrogen-bonding network without showing any sign of weakness. Among other applications, it is being studied for its use in adhesives and bicycle tires that will self-heal.

Covalent Solids

Covalent solids are formed by networks or chains of atoms or molecules held together by covalent bonds. A perfect single crystal of a covalent solid is therefore a single giant molecule. For example, the structure of diamond, shown in part (a) in [Figure 12.5.1](#), consists of sp^3 hybridized carbon atoms, each bonded to four other carbon atoms in a tetrahedral array to create a giant network. The carbon atoms form six-membered rings.

Toluene and m-xylene. The methyl groups attached to the phenyl ring in toluene and m-xylene prevent the rings from packing together as in solid benzene.

Figure 12.5.1 *The Structures of Diamond and Graphite* (a) Diamond consists of sp^3 hybridized carbon atoms, each bonded to four other carbon atoms. The tetrahedral array forms a giant network in which carbon atoms form six-membered rings. (b) These side (left) and top (right) views of the graphite structure show the layers of fused six-membered rings and the arrangement of atoms in alternate layers of graphite. The rings in alternate layers are staggered, such that every other carbon atom in one layer lies directly under (and above) the center of a six-membered ring in an adjacent layer.

The unit cell of diamond can be described as an fcc array of carbon atoms with four additional carbon atoms inserted into four of the tetrahedral holes. It thus has the zinc blende structure described in [Section 12.3](#), except that in zinc blende the atoms that compose the fcc array are sulfur and the atoms in the tetrahedral holes are zinc. Elemental silicon has the same structure, as does silicon carbide (SiC), which has alternating C and Si atoms. The structure of crystalline quartz (SiO_2), shown in [Section 12.1](#), can be viewed as being derived from the structure of silicon by inserting an oxygen atom between each pair of silicon atoms.

All compounds with the diamond and related structures are hard, high-melting-point solids that are not easily deformed. Instead, they tend to shatter when subjected to large stresses, and they usually do not conduct electricity very well. In fact, diamond (melting point = 3500°C at 63.5 atm) is one of the hardest substances known, and silicon carbide (melting point = 2986°C) is used commercially as an abrasive in sandpaper and grinding wheels. It is difficult to deform or melt these and related compounds because strong covalent (C–C or Si–Si) or polar covalent (Si–C or Si–O) bonds must be broken, which requires a large input of energy.

Other covalent solids have very different structures. For example, graphite, the other common allotrope of carbon, has the structure shown in part (b) in [Figure 12.5.1](#). It contains planar networks of six-membered rings of sp^2 hybridized carbon atoms in which each carbon is bonded to three others. This leaves a single electron in an unhybridized $2p_z$ orbital that can be used to form C=C double bonds, resulting in a ring with alternating double and single bonds. Because of its resonance structures, the bonding in graphite is best viewed as consisting of a network of C–C single bonds with one-third of a π bond holding the carbons together, similar to the bonding in benzene.

To completely describe the bonding in graphite, we need a molecular orbital approach similar to the one used for benzene in [Chapter 5](#). In fact, the C–C distance in graphite (141.5 pm) is slightly longer than the distance in benzene (139.5 pm), consistent with a net carbon–carbon bond order of 1.33. In graphite, the two-dimensional planes of carbon atoms are stacked to form a three-dimensional solid; only London dispersion forces hold the layers together. As a result, graphite exhibits properties typical of both covalent and molecular solids. Due to strong covalent bonding within the layers, graphite has a very high melting point, as expected for a covalent solid (it actually sublimates at about 3915°C). It is also very soft; the layers can easily slide past one another because of the weak interlayer interactions. Consequently, graphite is used as a lubricant and as the “lead” in pencils; the friction between graphite and a piece of paper is sufficient to leave a thin layer of carbon on the paper. Graphite is unusual among covalent solids in that its electrical conductivity is very high parallel to the planes of carbon atoms because of delocalized C–C π bonding. Finally, graphite is black because it contains an immense number of alternating double bonds, which results in a very small energy difference between the individual molecular orbitals. Thus light of virtually all wavelengths is absorbed. Diamond, on the other hand, is colorless when pure because it has no delocalized electrons.

[Table 12.5.1](#) compares the strengths of the intermolecular and intramolecular interactions for three covalent solids, showing the comparative weakness of the interlayer interactions.

Table 12.5.1 A Comparison of Intermolecular (ΔH_{sub}) and Intramolecular Interactions

Substance	ΔH_{sub} (kJ/mol)	Average Bond Energy (kJ/mol)
phosphorus (s)	58.98	201
sulfur (s)	64.22	226
iodine (s)	62.42	149

Metallic Solids

Metals are characterized by their ability to reflect light, called luster, their high electrical and thermal conductivity, their high heat capacity, and their malleability and ductility. Every lattice point in a pure metallic element is occupied by an atom of the same metal. The packing efficiency in metallic crystals tends to be high, so the resulting metallic solids are dense, with each atom having as many as 12 nearest neighbors.

Bonding in metallic solids is quite different from the bonding in the other kinds of solids we have discussed. Because all the atoms are the same, there can be no ionic bonding, yet metals always contain too few electrons or valence orbitals to form covalent bonds with each of their neighbors. Instead, the valence electrons are delocalized throughout the crystal, providing a strong cohesive force that holds the metal atoms together.

Note the Pattern

Valence electrons in a metallic solid are delocalized, providing a strong cohesive force that holds the atoms together.

The strength of metallic bonds varies dramatically. For example, cesium melts at 28.4°C, and mercury is a liquid at room temperature, whereas tungsten melts at 3680°C. Metallic bonds tend to be weakest for elements that have nearly empty (as in Cs) or nearly full (Hg) valence subshells, and strongest for elements with approximately half-filled valence shells (as in W). As a result, the melting points of the metals increase to a maximum around group 6 and then decrease again from left to right across the *d* block. Other properties related to the strength of metallic bonds, such as enthalpies of fusion, boiling points, and hardness, have similar periodic trends.

A somewhat oversimplified way to describe the bonding in a metallic crystal is to depict the crystal as consisting of positively charged nuclei in an electron sea ([Figure 12.5.2](#)). In this model, the valence electrons are not tightly bound to any one atom but are distributed uniformly throughout the structure. Very little energy is needed to remove electrons from a solid metal because they are not bound to a single nucleus. When an electrical potential is applied, the electrons can migrate through the solid toward the positive electrode, thus producing high electrical conductivity. The ease with which metals can be deformed under pressure is attributed to the ability of the metal ions to change positions within the electron sea without breaking any specific bonds. The

transfer of energy through the solid by successive collisions between the metal ions also explains the high thermal conductivity of metals. This model does not, however, explain many of the other properties of metals, such as their metallic luster and the observed trends in bond strength as reflected in melting points or enthalpies of fusion. A more complete description of metallic bonding is presented in [Section 12.6](#).

Figure 12.5.2 The Electron-Sea Model of Bonding in Metals Fixed, positively charged metal nuclei from group 1 (a) or group 2 (b) are surrounded by a “sea” of mobile valence electrons. Because a group 2 metal has twice the number of valence electrons as a group 1 metal, it should have a higher melting point.

Substitutional Alloys

An alloy is a mixture of metals with metallic properties that differ from those of its constituent elements. Brass (Cu and Zn in a 2:1 ratio) and bronze (Cu and Sn in a 4:1 ratio) are examples of substitutional alloys, which are metallic solids with large numbers of substitutional impurities. In contrast, small numbers of interstitial impurities, such as carbon in the iron lattice of steel, give an interstitial alloy. Because scientists can combine two or more metals in varying proportions to tailor the properties of a material for particular applications, most of the metallic substances we encounter are actually alloys. Examples include the low-melting-point alloys used in solder (Pb and Sn in a 2:1 ratio) and in fuses and fire sprinklers (Bi, Pb, Sn, and Cd in a 4:2:1:1 ratio).

The compositions of most alloys can vary over wide ranges. In contrast, intermetallic compounds consist of certain metals that combine in only specific proportions. Their compositions are largely determined by the relative sizes of their component atoms and the ratio of the total number of valence electrons to the number of atoms present (the *valence electron density*). The structures and physical properties of intermetallic compounds are frequently quite different from those of their constituent elements, but they may be similar to elements with a similar valence electron density. For example, Cr_3Pt is an intermetallic compound used to coat razor blades advertised as “platinum coated”; it is very hard and dramatically lengthens the useful life of the razor blade. With similar valence electron densities, Cu and PdZn have been found to be virtually identical in their catalytic properties.

Some general properties of the four major classes of solids are summarized in [Table 12.5.2](#).

Table 12.5.2 Properties of the Major Classes of Solids

Ionic Solids	Molecular Solids	Covalent Solids	Metallic Solids
poor conductors of heat and electricity	poor conductors of heat and electricity	poor conductors of heat and electricity*	good conductors of heat and electricity
relatively high melting point	low melting point	high melting point	melting points depend strongly on electron configuration
hard but brittle; shatter under stress	soft	very hard and brittle	easily deformed under stress; ductile and malleable
relatively dense	low density	low density	usually high density

***Many exceptions exist. For example, graphite has a relatively high electrical conductivity within the carbon planes, and diamond has the highest thermal conductivity of any known substance.**

Ionic Solids	Molecular Solids	Covalent Solids	Metallic Solids
dull surface	dull surface	dull surface	lustrous
*Many exceptions exist. For example, graphite has a relatively high electrical conductivity within the carbon planes, and diamond has the highest thermal conductivity of any known substance.			

Note the Pattern

The general order of increasing strength of interactions in a solid is molecular solids < ionic solids \approx metallic solids < covalent solids.

Example 12.5.1

Classify Ge, RbI, $C_6(CH_3)_6$, and Zn as ionic, molecular, covalent, or metallic solids and arrange them in order of increasing melting points.

Given: compounds

Asked for: classification and order of melting points

Strategy:

A Locate the component element(s) in the periodic table. Based on their positions, predict whether each solid is ionic, molecular, covalent, or metallic.

B Arrange the solids in order of increasing melting points based on your classification, beginning with molecular solids.

Solution:

A Germanium lies in the *p* block just under Si, along the diagonal line of semimetallic elements, which suggests that elemental Ge is likely to have the same structure as Si (the diamond structure). Thus Ge is probably a covalent solid. RbI contains a metal from group 1 and a nonmetal from group 17, so it is an ionic solid containing Rb^+ and I^- ions. The compound $C_6(CH_3)_6$ is a hydrocarbon (hexamethylbenzene), which consists of isolated molecules that stack to form a molecular solid with no covalent bonds between them. Zn is a *d*-block element, so it is a metallic solid.

B Arranging these substances in order of increasing melting points is straightforward, with one exception. We expect $C_6(CH_3)_6$ to have the lowest melting point and Ge to have the highest melting point, with RbI somewhere in between. The melting points of metals, however, are difficult to predict based on the models presented thus far. Because Zn has a filled valence shell, it should not have a particularly high melting point, so a reasonable guess is $C_6(CH_3)_6 < Zn \sim RbI < Ge$. The actual melting points are $C_6(CH_3)_6$, 166°C; Zn, 419°C; RbI, 642°C; and Ge, 938°C. This agrees with our prediction.

Exercise

Classify C_{60} , $BaBr_2$, GaAs, and AgZn as ionic, covalent, molecular, or metallic solids and then arrange them in order of increasing melting points.

Answer: C_{60} (molecular) < AgZn (metallic) \sim $BaBr_2$ (ionic) < GaAs (covalent). The actual melting points are C_{60} , about 300°C; AgZn, about 700°C; $BaBr_2$, 856°C; and GaAs, 1238°C.

Summary

The major types of solids are ionic, molecular, covalent, and metallic. **Ionic solids** consist of positively and negatively charged ions held together by electrostatic forces; the strength of the bonding is reflected in the lattice energy. Ionic solids tend to have high melting points and are rather hard. **Molecular solids** are held together by relatively weak forces, such as

dipole–dipole interactions, hydrogen bonds, and London dispersion forces. As a result, they tend to be rather soft and have low melting points, which depend on their molecular structure. **Covalent solids** consist of two- or three-dimensional networks of atoms held together by covalent bonds; they tend to be very hard and have high melting points. **Metallic solids** have unusual properties: in addition to having high thermal and electrical conductivity and being malleable and ductile, they exhibit luster, a shiny surface that reflects light. An **alloy** is a mixture of metals that has bulk metallic properties different from those of its constituent elements. Alloys can be formed by substituting one metal atom for another of similar size in the lattice (**substitutional alloys**), by inserting smaller atoms into holes in the metal lattice (**interstitial alloys**), or by a combination of both. Although the elemental composition of most alloys can vary over wide ranges, certain metals combine in only fixed proportions to form **intermetallic compounds** with unique properties.

Key Takeaway

- Solids can be classified as ionic, molecular, covalent (network), or metallic, where the general order of increasing strength of interactions is molecular < ionic \approx metallic < covalent.

Conceptual Problems

1. Four vials labeled A–D contain sucrose, zinc, quartz, and sodium chloride, although not necessarily in that order. The following table summarizes the results of the series of analyses you have performed on the contents:

	A	B	C	D
Melting Point	high	high	high	low
Thermal Conductivity	poor	poor	good	poor
Electrical Conductivity in Solid State	moderate	poor	high	poor
Electrical Conductivity in Liquid State	high	poor	high	poor
Hardness	hard	hard	soft	soft
Luster	none	none	high	none

Match each vial with its contents.

2. Do ionic solids generally have higher or lower melting points than molecular solids? Why? Do ionic solids generally have higher or lower melting points than covalent solids? Explain your reasoning.
3. The strength of London dispersion forces in molecular solids tends to increase with molecular mass, causing a smooth increase in melting points. Some molecular solids, however, have significantly lower melting points than predicted by their molecular masses. Why?
4. Suppose you want to synthesize a solid that is both heat resistant and a good electrical conductor. What specific types of bonding and molecular interactions would you want in your starting materials?
5. Explain the differences between an interstitial alloy and a substitutional alloy. Given an alloy in which the identity of one metallic element is known, how could you determine whether it is a substitutional alloy or an interstitial alloy?
6. How are intermetallic compounds different from interstitial alloys or substitutional alloys?

Answers

1.
 - a. NaCl, ionic solid
 - b. quartz, covalent solid

- c. zinc, metal
- d. sucrose, molecular solid
- 2.
- 3.
- 4.
5. In a substitutional alloy, the impurity atoms are similar in size and chemical properties to the atoms of the host lattice; consequently, they simply replace some of the metal atoms in the normal lattice and do not greatly perturb the structure and physical properties. In an interstitial alloy, the impurity atoms are generally much smaller, have very different chemical properties, and occupy holes between the larger metal atoms. Because interstitial impurities form covalent bonds to the metal atoms in the host lattice, they tend to have a large effect on the mechanical properties of the metal, making it harder, less ductile, and more brittle. Comparing the mechanical properties of an alloy with those of the parent metal could be used to decide whether the alloy were a substitutional or interstitial alloy.
- 6.

Numerical Problems

1. Will the melting point of lanthanum(III) oxide be higher or lower than that of ferrous bromide? The relevant ionic radii are as follows: La^{3+} , 104 pm; O^{2-} , 132 pm; Fe^{2+} , 83 pm; and Br^{-} , 196 pm. Explain your reasoning.
2. Draw a graph showing the relationship between the electrical conductivity of metallic silver and temperature.
3. Which has the higher melting point? Explain your reasoning in each case.
 - a. Os or Hf
 - b. SnO_2 or ZrO_2
 - c. Al_2O_3 or SiO_2
4. Draw a graph showing the relationship between the electrical conductivity of a typical semiconductor and temperature.

Answer

- 1.
- 2.
3.
 - a. Osmium has a higher melting point, due to more valence electrons for metallic bonding.
 - b. Zirconium oxide has a higher melting point, because it has greater ionic character.
 - c. Aluminum oxide has a higher melting point, again because it has greater ionic character.
- 4.

Learning Objectives

- To describe the electrical properties of a solid using band theory.

To explain the observed properties of metals, a more sophisticated approach is needed than the electron-sea model described in [Section 12.5](#). The molecular orbital theory we used in [Section 6.5](#) to explain the delocalized π bonding in polyatomic ions and molecules such as NO_2^- , ozone, and 1,3-butadiene can be adapted to accommodate the much higher number of atomic orbitals that interact with one another simultaneously in metals.

Band Theory

In a 1 mol sample of a metal, there can be more than 10^{24} orbital interactions to consider. In our molecular orbital description of metals, however, we begin by considering a simple one-dimensional example: a linear arrangement of n metal atoms, each containing a single electron in an s orbital. We use this example to describe an approach to metallic bonding called band theory, which assumes that the valence orbitals of the atoms in a solid interact, generating a set of molecular orbitals that extend throughout the solid.

One-Dimensional Systems

If the distance between the metal atoms is short enough for the orbitals to interact, they produce bonding, antibonding, and nonbonding molecular orbitals. The left portion of [Figure 12.6.1](#) shows the pattern of molecular orbitals that results from the interaction of ns orbitals as n increases from 2 to 5.

Figure 12.6.1 The Molecular Orbital Energy-Level Diagram for a Linear Arrangement of n Atoms, Each of Which Contains a Singly Occupied s Orbital. The far right-hand portion, corresponding to $n = 30$ and $n = \infty$. As n becomes very large, the energy separation between adjacent levels becomes so small that a single continuous band of allowed energy levels results. The lowest-energy molecular orbital corresponds to positive overlap between all the atomic orbitals to give a totally bonding combination, whereas the highest-energy molecular orbital contains a node between each pair of atoms and is thus totally antibonding.

As we saw in [Chapter 6](#), the lowest-energy orbital is the completely bonding molecular orbital, whereas the highest-energy orbital is the completely antibonding molecular orbital. Molecular orbitals of intermediate energy have fewer nodes than the totally antibonding molecular orbital. The energy separation between adjacent orbitals decreases as the number of interacting orbitals increases. For $n = 30$, there are still discrete, well-resolved energy levels, but as n increases from 30 to a number close to

Avogadro's number, the spacing between adjacent energy levels becomes almost infinitely small. The result is essentially a continuum of energy levels, as shown on the right in [Figure 12.6.1](#), each of which corresponds to a particular molecular orbital extending throughout the linear array of metal atoms. The levels that are lowest in energy correspond to mostly bonding combinations of atomic orbitals, those highest in energy correspond to mostly antibonding combinations, and those in the middle correspond to essentially nonbonding combinations.

The continuous set of allowed energy levels shown on the right in [Figure 12.6.1](#) is called an energy band. The difference in energy between the highest and lowest energy levels is the bandwidth and is proportional to the strength of the interaction between orbitals on adjacent atoms: the stronger the interaction, the larger the bandwidth. Because the band contains as many energy levels as molecular orbitals, and the number of molecular orbitals is the same as the number of interacting atomic orbitals, the band in [Figure 12.6.1](#) contains n energy levels corresponding to the combining of s orbitals from n metal atoms. Each of the original s orbitals could contain a maximum of two electrons, so the band can accommodate a total of $2n$ electrons. Recall, however, that each of the metal atoms we started with contained only a single electron in each s orbital, so there are only n electrons to place in the band. Just as with atomic orbitals or molecular orbitals, the electrons occupy the lowest energy levels available. Consequently, only the lower half of the band is filled. This corresponds to filling all of the *bonding* molecular orbitals in the linear array of metal atoms and results in the strongest possible bonding.

Multidimensional Systems

The previous example was a one-dimensional array of atoms that had only s orbitals. To extrapolate to two- or three-dimensional systems and atoms with electrons in p and d orbitals is straightforward in principle, even though in practice the mathematics becomes more complex, and the resulting molecular orbitals are more difficult to visualize. The resulting energy-level diagrams are essentially the same as the diagram of the one-dimensional example in [Figure 12.6.1](#), with the following exception: they contain as many bands as there are different types of interacting orbitals. Because different atomic orbitals interact differently, each band will have a different bandwidth and will be centered at a different energy, corresponding to the energy of the parent atomic orbital of an isolated atom.

Band Gap

Because the $1s$, $2s$, and $2p$ orbitals of a period 3 atom are filled core levels, they do not interact strongly with the corresponding orbitals on adjacent atoms. Hence they form rather narrow bands that are well separated in energy ([Figure 12.6.2](#)). These bands are completely filled (both the bonding and antibonding levels are completely populated), so they do not make a net contribution to bonding in the solid. The energy difference between the highest level of one band and the lowest level of the next is the band gap. It represents a set of forbidden energies that do not correspond to any allowed combinations of atomic orbitals.

Because they extend farther from the nucleus, the valence orbitals of adjacent atoms ($3s$ and $3p$ in [Figure 12.6.2](#)) interact much more strongly with one another than do the filled core levels; as a result, the valence bands have a larger bandwidth. In fact, the bands derived from the $3s$ and $3p$ atomic orbitals are wider than the energy gap between them, so the result is overlapping bands. These have molecular orbitals derived from two or more valence orbitals with similar energies. As the valence band is filled with one, two, or three electrons per atom for Na, Mg, and Al, respectively, the combined band that arises from the overlap of the $3s$ and $3p$ bands is also filling up; it has a total capacity of eight electrons per atom (two electrons for each $3s$ orbital and six electrons for each set of $3p$ orbitals). With Na, therefore, which has one valence electron, the combined valence band is one-eighth filled; with Mg (two valence electrons), it is one-fourth filled; and with Al, it is three-eighths filled, as indicated in [Figure 12.6.2](#). The partially filled valence band is absolutely crucial for explaining metallic behavior because it guarantees that there are unoccupied energy levels at an infinitesimally small energy above the highest occupied level.

Band theory can explain virtually all the properties of metals. Metals conduct electricity, for example, because only a very small amount of energy is required to excite an electron from a filled level to an empty one, where it is free to migrate rapidly throughout the crystal in response to an applied electric field. Similarly, metals have high heat capacities (as you no doubt remember from the last time a doctor or a nurse placed a stethoscope on your skin) because the electrons in the valence band can absorb thermal energy by being excited to the low-lying empty energy levels. Finally, metals are lustrous because light of various wavelengths can be absorbed, causing

Figure 12.6.2 The Band Structures of the Period 3 Metals Na, Mg, and Al The $3s$ and $3p$ valence bands overlap in energy to form a continuous set of energy levels that can hold a maximum of eight electrons per atom.

the valence electrons to be excited into any of the empty energy levels above the highest occupied level. When the electrons decay back to low-lying empty levels, they emit light of different wavelengths. Because electrons can be excited from many different filled levels in a metallic solid and can then decay back to any of many empty levels, light of varying wavelengths is absorbed and reemitted, which results in the characteristic shiny appearance that we associate with metals.

Requirements for Metallic Behavior

For a solid to exhibit metallic behavior, it must have a set of delocalized orbitals forming a band of allowed energy levels, and the resulting band must be only partially filled (10%–90%) with electrons. Without a set of delocalized orbitals, there is no pathway by which electrons can move through the solid.

Note the Pattern

Metallic behavior requires a set of delocalized orbitals and a band of allowed energy levels that is partially occupied.

Band theory explains the correlation between the valence electron configuration of a metal and the strength of metallic bonding. The valence electrons of transition metals occupy either their valence ns , $(n - 1)d$, and np orbitals (with a total capacity of 18 electrons per metal atom) or their ns and $(n - 1)d$ orbitals (a total capacity of 12 electrons per metal atom). These atomic orbitals are close enough in energy that the derived bands overlap, so the valence electrons are not confined to a specific orbital. Metals with 6 to 9 valence electrons (which correspond to groups 6–9) are those most likely to fill the valence bands approximately halfway. Those electrons therefore occupy the highest possible number of bonding levels, while the number of antibonding levels occupied is minimal. Not coincidentally, the elements of these groups exhibit physical properties consistent with the presence of the strongest metallic bonding, such as very high melting points.

Insulators

In contrast to metals, electrical insulators are materials that conduct electricity poorly because their valence bands are full. The energy gap between the highest filled levels and the lowest empty levels is so large that the empty levels are inaccessible: thermal energy cannot excite an electron from a filled level to an empty one. The valence-band structure of diamond, for example, is shown in part (a) in [Figure 12.6.3](#). Because diamond has only 4 bonded neighbors rather than the 6 to 12 typical of metals, the carbon $2s$ and $2p$ orbitals combine to form two bands in the solid, with the one at lower energy representing bonding molecular orbitals and the one at higher energy representing antibonding molecular orbitals. Each band can accommodate four electrons per atom, so only the lower band is occupied. Because the energy gap between the filled band and the empty band is very large (530 kJ/mol), at normal temperatures thermal energy cannot excite electrons from the filled level into the empty band. Thus there is no pathway by which electrons can move through the solid, so diamond has one of the lowest electrical conductivities known.

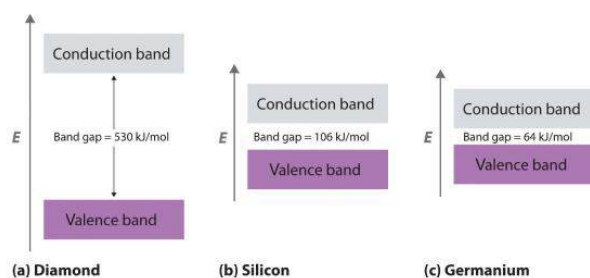

Figure 12.6.3 Energy-Band Diagrams for Diamond, Silicon, and Germanium The band gap gets smaller from C to Ge.

Semiconductors

What if the difference in energy between the highest occupied level and the lowest empty level is intermediate between those of electrical conductors and insulators? This is the case for silicon and germanium, which have the same structure as diamond. Because Si–Si and Ge–Ge bonds are substantially weaker than C–C bonds, the energy gap between the filled and empty bands becomes much smaller as we go down group 14 (part (b) and part (c) of [Figure 12.6.3](#)). (For more information on bond strengths,

see Section 5.5.) Consequently, thermal energy is able to excite a small number of electrons from the filled valence band of Si and Ge into the empty band above it, which is called the conduction band.

Exciting electrons from the filled valence band to the empty conduction band causes an increase in electrical conductivity for two reasons:

1. The electrons in the previously vacant conduction band are free to migrate through the crystal in response to an applied electric field.
2. Excitation of an electron from the valence band produces a “hole” in the valence band that is equivalent to a *positive* charge. The hole in the valence band can migrate through the crystal in the direction opposite that of the electron in the conduction band by means of a “bucket brigade” mechanism in which an adjacent electron fills the hole, thus generating a hole where the second electron had been, and so forth.

Consequently, Si is a much better electrical conductor than diamond, and Ge is even better, although both are still much poorer conductors than a typical metal (Figure 12.6.4). Substances such as Si and Ge that have conductivities between those of metals and insulators are called semiconductors. Many binary compounds of the main group elements exhibit semiconducting behavior similar to that of Si and Ge. For example, gallium arsenide (GaAs) is isoelectronic with Ge and has the same crystalline structure, with alternating Ga and As atoms; not surprisingly, it is also a semiconductor. The electronic structure of semiconductors is compared with the structures of metals and insulators in Figure 12.6.5.

Figure 12.6.5A Comparison of the Key Features of the Band Structures of Metals, Semiconductors, and Insulators. Metallic behavior can arise either from the presence of a single partially filled band or from two overlapping bands (one full and one empty).

Figure 12.6.4 A Logarithmic Scale Illustrating the Enormous Range of Electrical Conductivities of Solids

Temperature and Conductivity

Because thermal energy can excite electrons across the band gap in a semiconductor, increasing the temperature increases the number of electrons that have sufficient kinetic energy to be promoted into the conduction band. The electrical conductivity of a semiconductor therefore increases rapidly with increasing temperature, in contrast to the behavior of a purely metallic crystal. In a metal, as an electron travels through the crystal in response to an applied electrical potential, it cannot travel very far before it encounters and collides with a metal nucleus. The more often such encounters occur, the slower the *net* motion of the electron through the crystal, and the *lower* the conductivity. As the temperature of the solid increases, the metal atoms in the lattice acquire more and more kinetic energy. Because their positions are fixed in the lattice, however, the increased kinetic energy increases only the extent to which they vibrate about their fixed positions. At higher temperatures, therefore, the metal nuclei collide with the mobile electrons more frequently and with greater energy, thus *decreasing* the conductivity. This effect is, however, substantially smaller than the increase in conductivity with temperature exhibited by semiconductors. For example, the conductivity of a tungsten wire decreases by a factor of only about two over the temperature range 750–1500 K, whereas the conductivity of silicon increases approximately 100-fold over the same temperature range. These trends are illustrated in Figure 12.6.6.

Figure 12.6.6 The Temperature Dependence of the Electrical Conductivity of a Metal versus a Semiconductor The conductivity of the metal (tungsten) decreases relatively slowly with increasing temperature, whereas the conductivity of the semiconductor (silicon) increases much more rapidly.

Note the Pattern

The electrical conductivity of a semiconductor *increases* with increasing temperature, whereas the electrical conductivity of a metal *decreases* with increasing temperature.

n- and *p*-Type Semiconductors

Doping is a process used to tune the electrical properties of commercial semiconductors by deliberately introducing small amounts of impurities. If an impurity contains *more* valence electrons than the atoms of the host lattice (e.g., when small amounts of a group 15 atom are introduced into a crystal of a group 14 element), then the doped solid has more electrons available to conduct current than the pure host has. As shown in part (a) in Figure 12.6.7, adding an impurity such as phosphorus to a silicon crystal creates occasional electron-rich sites in the lattice. The electronic energy of these sites lies between those of the filled valence band and the empty conduction band but closer to the conduction band. Because the atoms that were introduced are surrounded by host atoms, and the electrons associated with the impurity are close in energy to the conduction band, those extra electrons are relatively easily excited into the empty conduction band of the host. Such a substance is called an *n*-type semiconductor, with the *n* indicating that the added charge carriers are negative (they are electrons).

Figure 12.6.7 Structures and Band Diagrams of *n*-Type and *p*-Type Semiconductors (a) Doping silicon with a group 15 element results in a new filled level between the valence and conduction bands of the host. (b) Doping silicon with a group 13 element results in a new empty level between the valence and conduction bands of the host. In both cases, the effective band gap is substantially decreased, and the electrical conductivity at a given temperature increases dramatically.

If the impurity atoms contain *fewer* valence electrons than the atoms of the host (e.g., when small amounts of a group 13 atom are introduced into a crystal of a group 14 element), then the doped solid has fewer electrons than the pure host. Perhaps unexpectedly, this also results in *increased* conductivity because the impurity atoms generate holes in the valence band. As shown in part (b) in Figure 12.27 "Structures and Band Diagrams of ", adding an impurity such as gallium to a silicon crystal creates isolated electron-deficient sites in the host lattice. The electronic energy of these empty sites also lies between those of the filled valence band and the empty conduction band of the host but much closer to the filled valence band. It is therefore relatively easy to excite electrons from the valence band of the host to the isolated impurity atoms, thus forming holes in the valence band. This kind of substance is

called a p -type semiconductor, with the p standing for positive charge carrier (i.e., a hole). Holes in what was a filled band are just as effective as electrons in an empty band at conducting electricity.

Note the Pattern

n -Type semiconductors are *negative* charge carriers; the impurity has *more* valence electrons than the host. p -Type semiconductors are *positive* charge carriers; the impurity has *fewer* valence electrons than the host.

The electrical conductivity of a semiconductor is roughly proportional to the number of charge carriers, so doping is a precise way to adjust the conductivity of a semiconductor over a wide range. The entire semiconductor industry is built on methods for preparing samples of Si, Ge, or GaAs doped with precise amounts of desired impurities and assembling silicon chips and other complex devices with junctions between n - and p -type semiconductors in varying numbers and arrangements.

Because silicon does not stand up well to temperatures above approximately 100°C, scientists have been interested in developing semiconductors made from diamonds, a more thermally stable material. A new method has been developed based on vapor deposition, in which a gaseous mixture is heated to a high temperature to produce carbon that then condenses on a diamond kernel. This is the same method now used to create cultured diamonds, which are indistinguishable from natural diamonds. The diamonds are heated to more than 2000°C under high pressure to harden them even further. Doping the diamonds with boron has produced p -type semiconductors, whereas doping them with boron and deuterium achieves n -type behavior. Because of their thermal stability, diamond semiconductors have potential uses as microprocessors in high-voltage applications.

Example 12.6.1

A crystalline solid has the following band structure, with the purple areas representing regions occupied by electrons. The lower band is completely occupied by electrons, and the upper level is about one-third filled with electrons.

1. Predict the electrical properties of this solid.
2. What would happen to the electrical properties if all of the electrons were removed from the upper band? Would you use a chemical oxidant or reductant to effect this change?
3. What would happen to the electrical properties if enough electrons were added to completely fill the upper band? Would you use a chemical oxidant or reductant to effect this change?

Given: band structure

Asked for: variations in electrical properties with conditions

Strategy:

A Based on the occupancy of the lower and upper bands, predict whether the substance will be an electrical conductor. Then predict how its conductivity will change with temperature.

B After all the electrons are removed from the upper band, predict how the band gap would affect the electrical properties of the material. Determine whether you would use a chemical oxidant or reductant to remove electrons from the upper band.

C Predict the effect of a filled upper band on the electrical properties of the solid. Then decide whether you would use an oxidant or a reductant to fill the upper band.

Solution:

1. **A** The material has a partially filled band, which is critical for metallic behavior. The solid will therefore behave like a metal, with high electrical conductivity that decreases slightly with increasing temperature.
2. **B** Removing all of the electrons from the partially filled upper band would create a solid with a filled lower band and an empty upper band, separated by an energy gap. If the band gap is large, the material will be an electrical insulator. If the gap is relatively small, the substance will be a semiconductor whose electrical conductivity increases rapidly with increasing temperature. Removing the electrons would require an oxidant because oxidants accept electrons.
3. **C** Adding enough electrons to completely fill the upper band would produce an electrical insulator. Without another empty band relatively close in energy above the filled band, semiconductor behavior would be impossible. Adding electrons to the solid would require a reductant because reductants are electron donors.

Exercise

A substance has the following band structure, in which the lower band is half-filled with electrons (purple area) and the upper band is empty.

1. Predict the electrical properties of the solid.
2. What would happen to the electrical properties if all of the electrons were removed from the lower band? Would you use a chemical oxidant or reductant to effect this change?
3. What would happen to the electrical properties if enough electrons were added to completely fill the lower band? Would you use a chemical oxidant or reductant to effect this change?

Answer:

1. The solid has a partially filled band, so it has the electrical properties of a conductor.
2. Removing all of the electrons from the lower band would produce an electrical insulator with two empty bands. An oxidant is required.
3. Adding enough electrons to completely fill the lower level would result in an electrical insulator if the energy gap between the upper and lower bands is relatively large, or a semiconductor if the band gap is relatively small. A reductant is required.

Summary

Band theory assumes that the valence orbitals of the atoms in a solid interact to generate a set of molecular orbitals that extend throughout the solid; the continuous set of allowed energy levels is an **energy band**. The difference in energy between the highest and lowest allowed levels within a given band is the **bandwidth**, and the difference in energy between the highest level of one band and the lowest level of the band above it is the **band gap**. If the width of adjacent bands is larger than the energy gap between them, **overlapping bands** result, in which molecular orbitals derived from two or more kinds of valence orbitals have similar energies. Metallic properties depend on a partially occupied band corresponding to a set of molecular orbitals that extend throughout the solid to form a band of energy levels. If a solid has a filled valence band with a relatively low-lying empty band above it (a **conduction band**), then electrons can be excited by thermal energy from the filled band into the vacant band where they can then migrate through the crystal, resulting in electrical conductivity. **Electrical insulators** are poor conductors because their valence bands are full. **Semiconductors** have electrical conductivities intermediate between those of insulators and metals. The electrical conductivity of semiconductors increases rapidly with increasing temperature, whereas the electrical conductivity of metals decreases slowly with increasing temperature. The properties of semiconductors can be modified by **doping**, or introducing impurities. Adding an element with more valence electrons than the atoms of the

host populates the conduction band, resulting in an *n*-type semiconductor with increased electrical conductivity. Adding an element with fewer valence electrons than the atoms of the host generates holes in the valence band, resulting in a *p*-type semiconductor that also exhibits increased electrical conductivity.

Key Takeaway

- Bonding in metals and semiconductors can be described using band theory, in which a set of molecular orbitals is generated that extends throughout the solid.

Conceptual Problems

1. Can band theory be applied to metals with two electrons in their valence *s* orbitals? with no electrons in their valence *s* orbitals? Why or why not?
2. Given a sample of a metal with 10^{20} atoms, how does the width of the band arising from *p* orbital interactions compare with the width of the band arising from *s* orbital interactions? from *d* orbital interactions?
3. Diamond has one of the lowest electrical conductivities known. Based on this fact, do you expect diamond to be colored? Why? How do you account for the fact that some diamonds are colored (such as “pink” diamond or “green” diamond)?
4. Why do silver halides, used in the photographic industry, have band gaps typical of semiconducting materials, whereas alkali metal halides have very large band gaps?
5. As the ionic character of a compound increases, does its band gap increase or decrease? Why?
6. Why is silicon, rather than carbon or germanium, used in the semiconductor industry?
7. Carbon is an insulator, and silicon and germanium are semiconductors. Explain the relationship between the valence electron configuration of each element and their band structures. Which will have the higher electrical conductivity at room temperature—silicon or germanium?
8. How does doping affect the electrical conductivity of a semiconductor? Draw the effect of doping on the energy levels of the valence band and the conduction band for both an *n*-type and a *p*-type semiconductor.

Answers

- 1.
- 2.
3. The low electrical conductivity of diamond implies a very large band gap, corresponding to the energy of a photon of ultraviolet light rather than visible light. Consequently, diamond should be colorless. Pink or green diamonds contain small amounts of highly colored impurities that are responsible for their color.
- 4.
5. As the ionic character of a compound increases, the band gap will also increase due to a decrease in orbital overlap. Remember that overlap is greatest for orbitals of the same energy, and that the difference in energy between orbitals on adjacent atoms increases as the difference in electronegativity between the atoms increases. Thus, large differences in electronegativity increase the ionic character, decrease the orbital overlap, and increase the band gap.
- 6.
- 7.
- 8.

Numerical Problems

1. Of Ca, N, B, and Ge, which will convert pure silicon into a *p*-type semiconductor when doping? Explain your reasoning.
2. Of Ga, Si, Br, and P, which will convert pure germanium into an *n*-type semiconductor when doping? Explain your reasoning.

Learning Objectives

- To become familiar with the properties of superconductors.

The phenomenon of superconductivity was discovered by the Danish physicist H. Kamerlingh Onnes (1853–1926; Nobel Prize in Physics, 1913), who found a way to liquefy helium, which boils at 4.2 K and 1 atm pressure. To exploit the very low temperatures made possible by this new cryogenic fluid, he began a systematic study of the properties of metals, especially their electrical properties. Because the electrical resistance of a sample is technically easier to measure than its conductivity, Onnes measured the resistivity of his samples. The resistivity and conductivity of a material are inversely proportional:

$$\text{conductivity} = \frac{1}{\text{resistivity}} \quad (12.7.1)$$

In 1911, Onnes discovered that at about 4 K, the resistivity of metallic mercury (melting point = 234 K) decreased suddenly to essentially zero, rather than continuing to decrease only slowly with decreasing temperature as expected (Figure 12.7.1). He called this phenomenon superconductivity because a resistivity of zero means that an electrical current can flow forever. Onnes soon discovered that many other metallic elements exhibit superconductivity at very low temperatures. Each of these superconductors has a characteristic superconducting transition temperature (T_c) at which its resistivity drops to zero. At temperatures less than their T_c , superconductors also completely expel a magnetic field from their interior (part (a) in Figure 12.7.2). This phenomenon is called the Meissner effect after one of its discoverers, the German physicist Walther Meissner, who described the phenomenon in 1933. Due to the Meissner effect, a superconductor will actually “float” over a magnet, as shown in part (b) in Figure 12.7.2.

Figure 12.7.1 The Temperature Dependence of the Electrical Resistivity of a Normal Metal and a Superconductor The superconducting transition temperature (T_c) is the temperature at which the resistivity of a superconductor drops to zero.

Figure 12.7.2 The Meissner Effect (a) Below its T_c , a superconductor completely expels magnetic lines of force from its interior. (b) In magnetic levitation, a small magnet “floats” over a disk of a high-temperature superconducting material ($\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$) cooled in liquid nitrogen.

BCS Theory

For many years, the phenomenon of superconductivity could not be satisfactorily explained by the laws of conventional physics. In the early 1950s, however, American physicists John Bardeen, Leon Cooper, and John Schrieffer formulated a theory for superconductivity that earned them the Nobel Prize in Physics in 1972. According to the BCS theory (named for the initials of their last names), electrons are able to travel through a solid with zero resistance because of attractive interactions involving two electrons that are at some distance from each other. As one electron moves through the lattice, the surrounding nuclei are attracted to it. The motion of the nuclei can create a transient (short-lived) hole that pulls the second electron in the same direction as the first. The nuclei then return to their original positions to avoid colliding with the second electron as it approaches. The pairs of electrons, called Cooper pairs, migrate through the crystal as a unit. The electrons in Cooper pairs change partners frequently, like dancers in a ballet.

According to the BCS theory, as the temperature of the solid increases, the vibrations of the atoms in the lattice increase continuously, until eventually the electrons cannot avoid colliding with them. The collisions result in the loss of superconductivity at higher temperatures.

The phenomenon of superconductivity suggested many exciting technological applications. For example, using superconducting wires in power cables would result in zero power losses, even over distances of hundreds of miles. Additionally, because superconductors expel magnetic fields, a combination of magnetic rails and superconducting wheels (or vice versa) could be used to produce *magnetic levitation* of, for example, a train over the track, resulting in friction-free transportation.

Unfortunately, for many years the only superconductors known had serious limitations, especially the need for very low temperatures, which required the use of expensive cryogenic fluids such as liquid He. In addition, the superconducting properties of many substances are destroyed by large electrical currents or even moderately large magnetic fields, making them useless for applications in power cables or high-field magnets. The ability of materials such as NbTi, NbSn, Nb₃Si, and Nb₃Ge to tolerate rather high magnetic fields, however, has led to a number of commercial applications of superconductors, including high-field magnets for nuclear magnetic resonance (NMR) spectrometers and magnetic resonance imaging (MRI) instruments in medicine, which, unlike x-rays, can detect small changes in soft tissues in the body.

High-Temperature Superconductors

Because of these limitations, scientists continued to search for materials that exhibited superconductivity at temperatures greater than 77 K (the temperature of liquid nitrogen, the least expensive cryogenic fluid). In 1986, Johannes G. Bednorz and Karl A. Müller, working for IBM in Zurich, showed that certain mixed-metal oxides containing La, Ba, and Cu exhibited superconductivity above 30 K. These compounds had been prepared by French workers as potential solid catalysts some years earlier, but their electrical properties had never been examined at low temperatures. Although initially the scientific community was extremely

skeptical, the compounds were so easy to prepare that the results were confirmed within a few weeks. These high-temperature superconductors earned Bednorz and Müller the Nobel Prize in Physics in 1987. Subsequent research has produced new compounds with related structures that are superconducting at temperatures as high as 135 K. The best known of these was discovered by Paul Chu and Maw-Kuen Wu Jr. and is called the “Chu–Wu phase” or the 1-2-3 superconductor.

The formula for the 1-2-3 superconductor is $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$, where x is about 0.1 for samples that superconduct at about 95 K. If $x \approx 1.0$, giving a formula of $\text{YBa}_2\text{Cu}_3\text{O}_6$, the material is an electrical insulator. The superconducting phase is thus a nonstoichiometric compound, with a fixed ratio of metal atoms but a variable oxygen content. The overall equation for the synthesis of this material is as follows:

If we assume that the superconducting phase is really stoichiometric $\text{YBa}_2\text{Cu}_3\text{O}_7$, then the average oxidation states of O, Y, Ba, and Cu are -2 , $+3$, $+2$, and $+7/3$ respectively. The simplest way to view the average oxidation state of Cu is to assume that two Cu atoms per formula unit are present as Cu^{2+} and one is present as the rather unusual Cu^{3+} . In $\text{YBa}_2\text{Cu}_3\text{O}_6$, the insulating form, the oxidation state of Cu is $+5/3$ so there are two Cu^{2+} and one Cu^{+} per formula unit.

As shown in [Figure 12.7.3](#), the unit cell of the 1-2-3 superconductor is related to the unit cell of the simple perovskite structure (part (b) in [Figure 12.7.3](#)). The only difference between the superconducting and insulating forms of the compound is that an O

atom has been removed from between the Cu^{2+} ions, which destroys the chains of Cu atoms and leaves the Cu in the center of the unit cell as Cu^+ . The chains of Cu atoms are crucial to the formation of the superconducting state.

Figure 12.7.3 The Relationship of the Structure of a Superconductor Consisting of Y-Ba-Cu-O to a Simple Perovskite Structure (a) Stacking three unit cells of the Ca-centered CaTiO_3 perovskite structure (part (b) in [Figure 12.3.5](#)) together with (b) replacement of all Ti atoms by Cu, replacement of Ca in the top and bottom cubes by Ba, and replacement of Ca in the central cube by Y gives a $\text{YBa}_2\text{Cu}_3\text{O}_9$ stoichiometry. (c) The removal of two oxygen atoms per unit cell gives the nominal $\text{YBa}_2\text{Cu}_3\text{O}_7$ stoichiometry of the superconducting material.

[Table 12.7.1](#) lists the ideal compositions of some of the known high-temperature superconductors that have been discovered in recent years. Engineers have learned how to process the brittle polycrystalline 1-2-3 and related compounds into wires, tapes, and films that can carry enormous electrical currents. Commercial applications include their use in infrared sensors and in analog signal processing and microwave devices.

Table 12.7.1 The Composition of Various Superconductors

Compound	T_c (K)
$\text{Ba}(\text{Pb}_{1-x}\text{Bi}_x)\text{O}_3$	13.5
$(\text{La}_{2-x}\text{Sr}_x)\text{CuO}_4$	35
$\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$	95
$\text{Bi}_2(\text{Sr}_{2-x}\text{Ca}_x)\text{CuO}_6^*$	80
$\text{Bi}_2\text{Ca}_2\text{Sr}_2\text{Cu}_3\text{O}_{10}^*$	110
$\text{Tl}_2\text{Ba}_2\text{Ca}_2\text{Cu}_3\text{O}_{10}^*$	125
$\text{HgBa}_2\text{Ca}_2\text{Cu}_3\text{O}_8^*$	133
K_3C_{60}	18
Rb_3C_{60}	30

***Nominal compositions only. Oxygen deficiencies or excesses are common in these compounds.**

Example 12.7.1

Calculate the average oxidation state of Cu in a sample of $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ with $x = 0.5$. How do you expect its structure to differ from those shown in [Figure 12.7.3](#) for $\text{YBa}_2\text{Cu}_3\text{O}_9$ and $\text{YBa}_2\text{Cu}_3\text{O}_7$?

Given: stoichiometry

Asked for: average oxidation state and structure

Strategy:

A Based on the oxidation states of the other component atoms, calculate the average oxidation state of Cu that would make an electrically neutral compound.

B Compare the stoichiometry of the structures shown in [Figure 12.7.3](#) with the stoichiometry of the given compound to predict how the structures differ.

Solution:

A The net negative charge from oxygen is $(7.0 - 0.5)(-2) = -13$, and the sum of the charges on the Y and Ba atoms is $[1 \times (+3)] + [2 \times (+2)] = +7$. This leaves a net charge of -6 per unit cell, which must be compensated for by the three Cu atoms, for a net charge of $$\frac{+6}{3}$ per Cu.$

B The most likely structure would be one in which every other O atom between the Cu atoms in the Cu chains of $\text{YBa}_2\text{Cu}_3\text{O}_7$ has been removed.

Exercise

Calculate the average oxidation state of Cu in a sample of $\text{HgBa}_2\text{Ca}_2\text{Cu}_3\text{O}_8$. Assume that Hg is present as Hg^{2+} .

Answer: +2

Summary

Superconductors are solids that at low temperatures exhibit zero resistance to the flow of electrical current, a phenomenon known as **superconductivity**. The temperature at which the electrical resistance of a substance drops to zero is its **superconducting transition temperature** (T_c). Superconductors also expel a magnetic field from their interior, a phenomenon known as the **Meissner effect**. Superconductivity can be explained by the **BCS theory**, which says that electrons are able to travel through a solid with no resistance because they couple to form pairs of electrons (Cooper pairs). **High-temperature superconductors** have T_c values greater than 30 K.

Key Takeaway

- Superconductivity can be described using the BCS theory, in which Cooper pairs of electrons migrate through the crystal as a unit.

Conceptual Problems

1. Why does the BCS theory predict that superconductivity is not possible at temperatures above approximately 30 K?
2. How does the formation of Cooper pairs lead to superconductivity?

Answer

1. According to BCS theory, the interactions that lead to formation of Cooper pairs of electrons are so weak that they should be disrupted by thermal vibrations of lattice atoms above about 30 K.
- 2.

Learning Objectives

- To understand the differences between synthetic and biological polymers.

Most of the solids discussed so far have been molecules or ions with low molecular masses, ranging from tens to hundreds of atomic mass units. Many of the molecular materials in consumer goods today, however, have very high molecular masses, ranging from thousands to millions of atomic mass units, and are formed from a carefully controlled series of reactions that produce giant molecules called polymers (from the Greek *poly* and *meros*, meaning “many parts”). Polymers are used in corrective eye lenses, plastic containers, clothing and textiles, and medical implant devices, among many other uses. They consist of basic structural units called monomers, which are repeated many times in each molecule. As shown schematically in [Figure 12.8.1](#), polymerization is the process by which monomers are connected into chains or networks by covalent bonds. Polymers can form via a *condensation reaction*, in which two monomer molecules are joined by a new covalent bond and a small molecule such as water is eliminated, or by an *addition reaction*, a variant of a condensation reaction in which the components of a species AB are added to adjacent atoms of a multiple bond. (For more information about condensation and addition reactions, see [Section 7.5](#).) Many people confuse the terms *plastics* and *polymers*. Plastic is the property of a material that allows it to be molded into almost any shape. Although many plastics are polymers, many polymers are not plastics. In this section, we introduce the reactions that produce naturally occurring and synthetic polymers.

Figure 12.8.1 Polymer Formation During a polymerization reaction, a large number of monomers become connected by covalent bonds to form a single long molecule, a polymer.

Note the Pattern

Polymers are formed via condensation or addition reactions.

Naturally Occurring Polymers: Peptides and Proteins

Polymers that occur naturally are crucial components of all organisms and form the fabric of our lives. Hair, silk, skin, feathers, muscle, and connective tissue are all primarily composed of proteins, the most familiar kind of naturally occurring, or biological, polymer. The monomers of many biological polymers are the amino acids each called an *amino acid residue*. The residues are linked together by amide bonds, also called peptide bonds, via a condensation reaction where H_2O is eliminated:

In the above equation, R represents an alkyl or aryl group, or hydrogen, depending on the amino acid. We write the structural formula of the product with the free amino group on the left (the *N-terminus*) and the free carboxylate group on the right (the *C-terminus*). For example, the structural formula for the product formed from the amino acids glycine and valine (glycyl-valine) is as follows:

The most important difference between synthetic and naturally occurring polymers is that the former usually contain very few different monomers, whereas biological polymers can have as many as 20 different kinds of amino acid residues arranged in many different orders. Chains with less than about 50 amino acid residues are called peptides, whereas those with more than about 50 amino acid residues are called proteins. Many proteins are enzymes, which are catalysts that increase the rate of a biological reaction.

Note the Pattern

Synthetic polymers usually contain only a few different monomers, whereas biological polymers can have many kinds of monomers, such as amino acids arranged in different orders.

Many small peptides have potent physiological activities. The *endorphins*, for example, are powerful, naturally occurring painkillers found in the brain. Other important peptides are the hormones vasopressin and oxytocin. Although their structures and amino acid sequences are similar, vasopressin is a blood pressure regulator, whereas oxytocin induces labor in pregnant women and milk production in nursing mothers. Oxytocin was the first biologically active peptide to be prepared in the laboratory by Vincent du Vigneaud (1901–1978), who was awarded the Nobel Prize in Chemistry in 1955.

Synthetic Polymers

Many of the synthetic polymers we use, such as plastics and rubbers, have commercial advantages over naturally occurring polymers because they can be produced inexpensively. Moreover, many synthetic polymers are actually more desirable than their natural counterparts because scientists can select monomer units to tailor the physical properties of the resulting polymer for particular purposes. For example, in many applications, wood has been replaced by plastics that are more durable, lighter, and easier to shape and maintain. Polymers are also increasingly used in engineering applications where weight reduction and corrosion resistance are required. Steel rods used to support concrete structures, for example, are often coated with a polymeric material when the structures are near ocean environments where steel is vulnerable to corrosion (For more information on corrosion, see [Section 19.6](#).) In fact, the use of polymers in engineering applications is a very active area of research.

Probably the best-known example of a synthetic polymer is *nylon* ([Figure 12.8.2](#)). Its monomers are linked by amide bonds (which are called peptide bonds in biological polymers), so its physical properties are similar to those of some proteins because of their common structural unit—the amide group. Nylon is easily drawn into silky fibers that are more than a hundred times longer than they are wide and can be woven into fabrics. Nylon fibers are so light and strong that during World War II, all available nylon was commandeered for use in parachutes, ropes, and other military items. With polymer chains that are fully extended and run parallel to the fiber axis, nylon fibers resist stretching, just like naturally occurring silk fibers, although the structures of nylon and silk are otherwise different. Replacing the flexible $-\text{CH}_2-$ units in nylon by aromatic rings produces a stiffer and stronger polymer, such as

the very strong polymer known as Kevlar. Kevlar fibers are so strong and rigid that they are used in lightweight army helmets, bulletproof vests, and even sailboat and canoe hulls, all of which contain multiple layers of Kevlar fabric.

Figure 12.8.2 The Synthesis of Nylon Nylon is a synthetic condensation polymer created by the reaction of a dicarboxylic acid and a diamine to form amide bonds and water.

Not all synthetic polymers are linked by amide bonds—for example, polyesters contain monomers that are linked by ester bonds. Polyesters are sold under trade names such as Dacron, Kodel, and Fortrel, which are used in clothing, and Mylar, which is used in magnetic tape, helium-filled balloons, and high-tech sails for sailboats. Although the fibers are flexible, properly prepared Mylar films are almost as strong as steel.

A fiberglass mat (left) and a Kevlar vest (right).

Polymers based on skeletons with only carbon are all synthetic. Most of these are formed from ethylene ($\text{CH}_2=\text{CH}_2$), a two-carbon building block, and its derivatives. The relative lengths of the chains and any branches control the properties of polyethylene. For example, higher numbers of branches produce a softer, more flexible, lower-melting-point polymer called low-density polyethylene (LDPE), whereas high-density polyethylene (HDPE) contains few branches. Substances such as glass that melt at relatively low temperatures can also be formed into fibers, producing fiberglass.

Because most synthetic fibers are neither soluble nor low melting, multistep processes are required to manufacture them and form them into objects. Graphite fibers are formed by heating a precursor polymer at high temperatures to decompose it, a process called pyrolysis. The usual precursor for graphite is polyacrylonitrile, better known by its trade name—Orlon. A similar approach is used to prepare fibers of silicon carbide using an organosilicon precursor such as polydimethylsilane $\{[-(\text{CH}_3)_2\text{Si}-]_n\}$. A new type of fiber consisting of carbon nanotubes, hollow cylinders of carbon just one atom thick, is lightweight, strong, and impact resistant. Its performance has been compared to that of Kevlar, and it is being considered for use in body armor, flexible solar panels, and bombproof trash bins, among other uses.

Because there are no good polymer precursors for elemental boron or boron nitride, these fibers have to be prepared by time-consuming and costly indirect methods. Even though boron fibers are about eight times stronger than metallic aluminum and 10% lighter, they are significantly more expensive. Consequently, unless an application requires boron's greater resistance to oxidation, these fibers cannot compete with less costly graphite fibers.

Example 12.8.1

Polyethylene is used in a wide variety of products, including beach balls and the hard plastic bottles used to store solutions in a chemistry laboratory. Which of these products is formed from the more highly branched polyethylene?

Given: type of polymer

Asked for: application

Strategy:

Determine whether the polymer is LDPE, which is used in applications that require flexibility, or HDPE, which is used for its strength and rigidity.

Solution:

A highly branched polymer is less dense and less rigid than a relatively unbranched polymer. Thus hard, strong polyethylene objects such as bottles are made of HDPE with relatively few branches. In contrast, a beach ball must be flexible so it can be inflated. It is therefore made of highly branched LDPE.

Exercise

Which products are manufactured from LDPE and which from HDPE?

1. lawn chair frames
2. rope
3. disposable syringes
4. automobile protective covers

Answer:

1. HDPE
2. LDPE
3. HDPE
4. LDPE

Summary

Polymers are giant molecules that consist of long chains of units called **monomers** connected by covalent bonds. **Polymerization** is the process of linking monomers together to form a polymer. **Plastic** is the property of a material that allows it to be molded. Biological polymers formed from amino acid residues are called **peptides** or **proteins**, depending on their size. **Enzymes** are proteins that catalyze a biological reaction. A particle that is more than a hundred times longer than it is wide is a **fiber**, which can be formed by a high-temperature decomposition reaction called **pyrolysis**.

Key Takeaway

- Polymers are giant molecules formed from addition or condensation reactions and can be classified as either biological or synthetic polymers.

Conceptual Problems

1. How are amino acids and proteins related to monomers and polymers? Draw the general structure of an amide bond linking two amino acid residues.
2. Although proteins and synthetic polymers (such as nylon) both contain amide bonds, different terms are used to describe the two types of polymer. Compare and contrast the terminology used for the
 - a. smallest repeating unit.
 - b. covalent bond connecting the units.

Learning Objectives

- To become familiar with the properties of some contemporary materials.

In addition to polymers, other materials, such as ceramics, high-strength alloys, and composites, play a major role in almost every aspect of our lives. Until relatively recently, steel was used for any application that required an especially strong and durable material, such as bridges, automobiles, airplanes, golf clubs, and tennis rackets. In the last 15 to 20 years, however, graphite or boron fiber golf clubs and tennis rackets have made wood and steel obsolete for these items. Likewise, a modern jet engine now is largely composed of Ti and Ni by weight rather than steel (Table 12.9.1). The percentage of iron in wings and fuselages is similarly low, which indicates the extent to which other materials have supplanted steel. The Chevrolet Corvette introduced in 1953 was considered unusual because its body was constructed of fiberglass, a composite material, rather than steel; by 1992, Jaguar fabricated an all-aluminum limited-edition vehicle. In fact, the current models of many automobiles have engines that are made mostly of aluminum rather than steel. In this section, we describe some of the chemistry behind three classes of contemporary materials: ceramics, superalloys, and composites.

Table 12.9.1 The Approximate Elemental Composition of a Modern Jet Engine

Element	Percentage by Mass
titanium	38
nickel	37
chromium	12
cobalt	6
aluminum	3
niobium	1
tantalum	0.025

Ceramics

A ceramic is any nonmetallic, inorganic solid that is strong enough for use in structural applications. Traditional ceramics, which are based on metal silicates or aluminosilicates, are the materials used to make pottery, china, bricks, and concrete. Modern ceramics contain a much wider range of components and can be classified as either *ceramic oxides*, which are based on metal oxides such as alumina (Al_2O_3), zirconia (ZrO_2), and beryllia (BeO), or *nonoxide ceramics*, which are based on metal carbides such as silicon carbide (carborundum, SiC) and tungsten carbide (WC), or nitrides like silicon nitride (Si_3N_4) and boron nitride (BN).

All modern ceramics are hard, lightweight, and stable at very high temperatures. Unfortunately, however, they are also rather brittle, tending to crack or break under stresses that would cause metals to bend or dent. Thus a major challenge for materials scientists is to take advantage of the desirable properties of ceramics, such as their thermal and oxidative stability, chemical inertness, and toughness, while finding ways to decrease their brittleness to use them in new applications. Few metals can be used in jet engines, for example, because most lose mechanical strength and react with oxygen at the very high operating temperatures inside the engines (approximately 2000°C). In contrast, ceramic oxides such as Al_2O_3 cannot react with oxygen regardless of the temperature because aluminum is already in its highest possible oxidation state (Al^{3+}). Even nonoxide ceramics such as silicon and boron nitrides and silicon carbide are essentially unreactive in air up to about 1500°C . Producing a high-strength ceramic for service use involves a process called sintering, which fuses the grains into a dense and strong material (Figure 12.9.2).

Figure 12.9.2: *Sintering* These photos show the effects of sintering magnesium oxide grains: (a) the microstructure before sintering; (b) the microstructure of the ceramic after sintering for two hours at 1250°C; and (c) the microstructure after sintering for two hours at 1450°C. During the sintering process, the grains fuse, forming a dense and strong material.

Ceramics are hard, lightweight, and able to withstand high temperatures, but they are also brittle.

One of the most widely used raw materials for making ceramics is clay. Clay minerals consist of hydrated alumina (Al_2O_3) and silica (SiO_2) that have a broad range of impurities, including barium, calcium, sodium, potassium, and iron. Although the structures of clay minerals are complicated, they all contain layers of metal atoms linked by oxygen atoms. Water molecules fit between the layers to form a thin film of water. When hydrated, clays can be easily molded, but during high-temperature heat treatment, called *firing*, a dense and strong ceramic is produced.

Because ceramics are so hard, they are easily contaminated by the material used to grind them. In fact, the ceramic often grinds the metal surface of the mill almost as fast as the mill grinds the ceramic! The sol-gel process was developed to address this problem. In this process, a water-soluble precursor species, usually a metal or semimetal alkoxide $[\text{M}(\text{OR})_n]$ undergoes a hydrolysis reaction to form a cloudy aqueous dispersion called a *sol*. The sol contains particles of the metal or semimetal hydroxide $[\text{M}(\text{OH})_n]$, which are typically 1–100 nm in diameter. As the reaction proceeds, molecules of water are eliminated from between the $\text{M}(\text{OH})_n$ units in a condensation reaction, and the particles fuse together, producing oxide bridges, $\text{M}-\text{O}-\text{M}$. Eventually, the particles become linked in a three-dimensional network that causes the solution to form a *gel*, similar to a gelatin dessert. Heating the gel to 200°C–500°C causes more water to be eliminated, thus forming small particles of metal oxide that can be amazingly uniform in size. This chemistry starts with highly pure SiCl_4 and proceeds via the following reactions starting with the alkoxide formation

and then the hydrolysis of the alkoxide

ending with the condensation

Nature uses the same process to create opal gemstones.

Superalloys

Superalloys are high-strength alloys, often with a complex composition, that are used in systems requiring mechanical strength, high surface stability (minimal flaking or pitting), and resistance to high temperatures. The aerospace industry, for example, requires materials that have high strength-to-weight ratios to improve the fuel efficiency of advanced propulsion systems, and these systems must operate safely at temperatures greater than 1000°C.

Superalloys are used in systems requiring mechanical strength, minimal flaking or pitting, and high-temperature resistance.

Although most superalloys are based on nickel, cobalt, or iron, other metals are used as well. Pure nickel or cobalt is relatively easily oxidized, but adding small amounts of other metals (Al, Co, Cr, Mo, Nb, Ti, and W) results in an alloy that has superior properties.

Consequently, most of the internal parts of modern gas turbine jet engines are now made of superalloys based on either nickel (used in blades and disks) or cobalt (used in vanes, combustion chamber liners, and afterburners). The cobalt-based superalloys are not as strong as the nickel-based ones, but they have excellent corrosion resistance at high temperatures.

Other alloys, such as aluminum–lithium and alloys based on titanium, also have applications in the aerospace industry. Because aluminum–lithium alloys are lighter, stiffer, and more resistant to fatigue at high temperatures than aluminum itself, they are used in engine parts and in the metal “skins” that cover wings and bodies. Titanium’s high strength, corrosion resistance, and lightweight properties are equally desirable for applications where minimizing weight is important (as in airplanes). Unfortunately, however, metallic titanium reacts rapidly with air at high temperatures to form TiN and TiO₂. The welding of titanium or any similar processes must therefore be carried out in an argon or inert gas atmosphere, which adds significantly to the cost. Initially, titanium and its alloys were primarily used in military applications, but more recently, they have been used as components of the airframes of commercial planes, in ship structures, and in biological implants.

Composite Materials

Composite materials have at least two distinct components: the matrix (which constitutes the bulk of the material) and fibers or granules that are embedded within the matrix and limit the growth of cracks by pinning defects in the bulk material (Figure 12.9.3). The resulting material is stronger, tougher, stiffer, and more resistant to corrosion than either component alone. Composites are thus the nanometer-scale equivalent of reinforced concrete, in which steel rods greatly increase the mechanical strength of the cement matrix, and are extensively used in the aircraft industry, among others. For example, the Boeing 777 is 9% composites by weight, whereas the newly developed Boeing 787 is 50% composites by weight. Not only does the use of composite materials reduce the weight of the aircraft, and therefore its fuel consumption, but it also allows new design concepts because composites can be molded. Moreover, by using composites in the Boeing 787 multiple functions can be integrated into a single system, such as acoustic damping, thermal regulation, and the electrical system.

Three distinct types of composite material are generally recognized, distinguished by the nature of the matrix. These are polymer-matrix composites, metal-matrix composites, and ceramic-matrix composites.

Figure 12.9.3: Some Possible Arrangements of Fibers in Fiber-Reinforced Composite Materials The arrangements shown range from discontinuous and randomly oriented to continuous and aligned. The fibers limit the growth of cracks by pinning defects within the matrix.

Composites are stronger, tougher, stiffer, and more resistant to corrosion than their components alone.

Fiberglass is a polymer-matrix composite that consists of glass fibers embedded in a polymer, forming tapes that are then arranged in layers impregnated with epoxy. The result is a strong, stiff, lightweight material that is resistant to chemical degradation. It is not strong enough, however, to resist cracking or puncturing on impact. Stronger, stiffer polymer-matrix composites contain fibers of carbon (graphite), boron, or polyamides such as Kevlar. High-tech tennis rackets and golf clubs as well as the skins of modern military aircraft such as the “stealth” F-117A fighters and B-2 bombers are made from both carbon fiber–epoxy and boron fiber–epoxy composites. Compared with metals, these materials are 25%–50% lighter and thus reduce operating costs. Similarly, the space shuttle payload bay doors and panels are made of a carbon fiber–epoxy composite. The structure of the Boeing 787 has been described as essentially one giant macromolecule, where everything is fastened through cross-linked chemical bonds reinforced with carbon fiber.

Metal-matrix composites consist of metals or metal alloys reinforced with fibers. They offer significant advantages for high-temperature applications but pose major manufacturing challenges. For example, obtaining a uniform distribution and alignment of the reinforcing fibers can be difficult, and because organic polymers cannot survive the high temperatures of molten metals, only fibers composed of boron, carbon, or ceramic (such as silicon carbide) can be used. Aluminum alloys reinforced with boron fibers are used in the aerospace industry, where their strength and lightweight properties make up for their relatively high cost. The skins of hypersonic aircraft and structural units in the space shuttle are made of metal-matrix composites.

Ceramic-matrix composites contain ceramic fibers in a ceramic matrix material. A typical example is alumina reinforced with silicon carbide fibers. Combining the two very high-melting-point materials results in a composite that has excellent thermal stability, great strength, and corrosion resistance, while the SiC fibers reduce brittleness and cracking. Consequently, these materials are used in very high-temperature applications, such as the leading edge of wings of hypersonic airplanes and jet engine parts. They are also used in the protective ceramic tiles on the space shuttle, which contain short fibers of pure SiO₂ mixed with fibers of an aluminum–boron–silicate ceramic. These tiles are excellent thermal insulators and extremely light (their density is only about 0.2 g/cm³). Although their surface reaches a temperature of about 1250°C during reentry into Earth's atmosphere, the temperature of the underlying aluminum alloy skin stays below 200°C.

Example *Chapter*12.9.1 :

An engineer is tasked with designing a jet ski hull. What material is most suited to this application? Why?

Given: design objective

Asked for: most suitable material

Strategy:

Determine under what conditions the design will be used. Then decide what type of material is most appropriate.

Solution:

A jet ski hull must be lightweight to maximize speed and fuel efficiency. Because of its use in a marine environment, it must also be resistant to impact and corrosion. A ceramic material provides rigidity but is brittle and therefore tends to break or crack under stress, such as when it impacts waves at high speeds. Superalloys provide strength and stability, but a superalloy is probably too heavy for this application. Depending on the selection of metals, it might not be resistant to corrosion in a marine environment either. Composite materials, however, provide strength, stiffness, and corrosion resistance; they are also lightweight materials. This is not a high-temperature application, so we do not need a metal-matrix composite or a ceramic-matrix composite. The best choice of material is a polymer-matrix composite with Kevlar fibers to increase the strength of the composite on impact.

Exercise *Chapter*12.9.1

In designing a new generation of space shuttle, National Aeronautics and Space Administration (NASA) engineers are considering thermal-protection devices to protect the skin of the craft. Among the materials being considered are titanium- or nickel-based alloys and silicon-carbide ceramic reinforced with carbon fibers. Why are these materials suitable for this application?

Answer: Ti- or Ni-based alloys have a high strength-to-weight ratio, resist corrosion, and are safe at high temperatures. Reinforced ceramic is lightweight; has high thermal and oxidative stability; and is chemically inert, tough, and impact resistant.

Summary

Ceramics are nonmetallic, inorganic solids that are typically strong; they have high melting points but are brittle. The two major classes of modern ceramics are ceramic oxides and nonoxide ceramics, which are composed of nonmetal carbides or nitrides. The production of ceramics generally involves pressing a powder of the material into the desired shape and sintering at a temperature just below its melting point. The necessary fine powders of ceramic oxides with uniformly sized particles can be produced by the **sol-gel process**. **Superalloys** are new metal phases based on cobalt, nickel, or iron that exhibit unusually high temperature stability and resistance to oxidation. **Composite materials** consist of at least two phases: a matrix that constitutes the bulk of the material and fibers or granules that act as a reinforcement. **Polymer-matrix composites** have reinforcing fibers embedded in a polymer matrix. **Metal-matrix composites** have a metal matrix and fibers of boron, graphite, or ceramic. **Ceramic-matrix composites** use reinforcing fibers, usually also ceramic, to make the matrix phase less brittle.

Key Takeaway

- Materials that have contemporary applications include ceramics, high-strength alloys, and composites, whose properties can be modified as needed.

Conceptual Problems

1. Can a compound based on titanium oxide qualify as a ceramic material? Explain your answer.
2. What features make ceramic materials attractive for use under extreme conditions? What are some potential drawbacks of ceramics?
3. How do composite materials differ from the other classes of materials discussed in this chapter? What advantages do composites have versus other materials?
4. How does the matrix control the properties of a composite material? What is the role of an additive in determining the properties of a composite material?

APPLICATION PROBLEMS

Problems marked with a ♦ involve multiple concepts.

- ♦ Cadmium selenide (CdSe) is a semiconductor used in photoconductors and photoelectric cells that conduct electricity when illuminated. In a related process, a CdSe crystal can absorb enough energy to excite electrons from the valence band to the conduction band, and the excited electrons can return to the valence band by emitting light. The relative intensity and peak wavelength of the emitted light in one experiment are shown in the following table:

Relative Intensity (%)	Wavelength (nm)	Temperature (°C)
100	720	23
50	725	45
10	730	75

- Explain why the emitted light shifts to longer wavelength at higher temperatures. (Hint: consider the expansion of the crystal and the resulting changes in orbital interactions when heated.)
 - Why does the relative intensity of the emitted light decrease as the temperature increases?
- A large fraction of electrical energy is currently lost as heat during transmission due to the electrical resistance of transmission wires. How could superconducting technology improve the transmission of electrical power? What are some potential drawbacks of this technology?
 - Light-emitting diodes (LEDs) are semiconductor-based devices that are used in consumer electronics products ranging from digital clocks to fiber-optic telephone transmission lines. The color of the emitted light is determined in part by the band gap of the semiconductor. Electrons can be promoted to the conduction band and return to the valence band by emitting light or by increasing the magnitude of atomic vibrations in the crystal, which increases its temperature. If you wanted to increase the efficiency of an LED display, and thereby the intensity of the emitted light, would you increase or decrease the operating temperature of the LED? Explain your answer.
 - ♦ Strips of pure Au and Al are often used in close proximity to each other on circuit boards. As the boards become warm during use, however, the metals can diffuse, forming a purple alloy known as “the purple plague” between the strips. Because the alloy is electrically conductive, the board short-circuits. A structural analysis of the purple alloy showed that its structure contained a face-centered cubic (fcc) lattice of atoms of one element, with atoms of the other element occupying tetrahedral holes. What type of alloy is this? Which element is most likely to form the fcc lattice? Which element is most likely to occupy the tetrahedral holes? Explain your answers. What is the empirical formula of the “purple plague”?
 - ♦ Glasses are mixtures of oxides, the main component of which is silica (SiO₂). Silica is called the *glass former*, while additives are referred to as *glass modifiers*. The crystalline lattice of the glass former breaks down during heating, producing the random atomic arrangements typical of a liquid. Adding a modifier and cooling the melt rapidly produces a glass. How does the three-dimensional structure of the glass differ from that of the crystalline glass former? Would you expect the melting point of a glass to be higher or lower than that of pure SiO₂? Lead glass, a particular favorite of the Romans, was formed by adding lead oxide as the modifier. Would you expect lead glass to be more or less dense than soda-lime glass formed by adding sodium and potassium salts as modifiers?
 - Many glasses eventually crystallize, rendering them brittle and opaque. Modifying agents such as TiO₂ are frequently added to molten glass to reduce their tendency to crystallize. Why does the addition of small amounts of TiO₂ stabilize the

amorphous structure of glass?

7. ♦ The carbon–carbon bond distances in polyacetylene $(-\text{CH}=\text{CH}-)_n$ alternate between short and long, resulting in the following band structure:

- a. Is polyacetylene a metal, a semiconductor, or an insulator?
- b. Based on its band structure, how would treating polyacetylene with a potent oxidant affect its electrical conductivity?

What would be the effect of treating polyacetylene with small amounts of a powerful reductant? Explain your answers.

8. Enkephalins are pentapeptides, short biopolymers that are synthesized by humans to control pain. Enkephalins bind to certain receptors in brain cells, which are also known to bind morphine and heroin. One enkephalin has the structure tyrosine–glycine–glycine–phenylalanine–methionine. Draw its structure.

9. A polymerization reaction is used to synthesize Saran, a flexible material used in packaging film and seat covers. The monomeric unit for Saran is 1,1-dichloroethylene $(\text{CH}_2=\text{CCl}_2)$, also known as vinylidene chloride. Draw a reasonable structure for the polymer. Why do pieces of Saran “cling” to one another when they are brought in contact?
10. Polymers are often amorphous solids. Like other materials, polymers can also undergo phase changes. For example, many polymers are flexible above a certain temperature, called the *glass-transition temperature* (T_g). Below the glass transition temperature, the polymer becomes hard and brittle. Biomedical devices that replace or augment parts of the human body often contain a wide variety of materials whose properties must be carefully controlled.
- a. Polydimethylsiloxane has a T_g of -123°C , whereas poly(methylmethacrylate) has a T_g of 105°C . Which of these polymers is likely to be used in dentures, and which is likely to be used for soft-tissue replacement?
 - b. If you were designing biomedical devices, which class of biomaterials (alloys, ceramics, or polymers) would you consider for finger joint replacements, eyeball replacements, windpipe replacements, shoulder joint replacements, and bridging bone fractures? Explain your answers.

Learning Objectives

- To understand how enthalpy and entropy changes affect solution formation.

In all solutions, whether gaseous, liquid, or solid, the substance present in the greatest amount is the *solvent*, and the substance or substances present in lesser amounts are the *solute(s)*. The solute does not have to be in the same physical state as the solvent, but the physical state of the solvent usually determines the state of the solution. As long as the solute and solvent combine to give a homogeneous solution, the solute is said to be *soluble* in the solvent. [Table 13.1 "Types of Solutions"](#) lists some common examples of gaseous, liquid, and solid solutions and identifies the physical states of the solute and solvent in each.

Table 13.1 Types of Solutions

Solution	Solute	Solvent	Examples
gas	gas	gas	air, natural gas
liquid	gas	liquid	seltzer water (CO ₂ gas in water)
liquid	liquid	liquid	alcoholic beverage (ethanol in water), gasoline
liquid	solid	liquid	tea, salt water
solid	gas	solid	H ₂ in Pd (used for H ₂ storage)
solid	solid	liquid	mercury in silver or gold (amalgam often used in dentistry)

Forming a Solution

The formation of a solution from a solute and a solvent is a physical process, not a chemical one. That is, both solute and solvent can be recovered in chemically unchanged forms using appropriate separation methods. For example, solid zinc nitrate dissolves in water to form an aqueous solution of zinc nitrate:

Because Zn(NO₃)₂ can be recovered easily by evaporating the water, this is a physical process. In contrast, metallic zinc *appears* to dissolve in aqueous hydrochloric acid. In fact, the two substances undergo a chemical reaction to form an aqueous solution of zinc chloride with evolution of hydrogen gas:

Note the Pattern

Dissolution of a solute in a solvent to form a solution does not involve a chemical transformation.

When the solution evaporates, we do not recover metallic zinc, so we cannot say that metallic zinc is *soluble* in aqueous hydrochloric acid because it is chemically transformed when it dissolves. *The dissolution of a solute in a solvent to form a solution does not involve a chemical transformation.*

Substances that form a single homogeneous phase in all proportions are said to be completely miscible in one another. Ethanol and water are miscible, just as mixtures of gases are miscible. If two substances are essentially insoluble in each other, such as oil and water, they are *immiscible*. Examples of gaseous solutions that we have already discussed include Earth's atmosphere and natural gas .

The Role of Enthalpy in Solution Formation

As we saw in [Chapter 8](#) and [Chapter 9](#) , energy is required to overcome the intermolecular interactions in a solute. This energy can be supplied only by the new interactions that occur in the solution, when each solute particle is surrounded by particles of the solvent in a process called solvation, or hydration when the solvent is water. Thus all of the solute–solute interactions and many of the solvent–solvent interactions must be disrupted for a solution to form. In this section, we describe the role of enthalpy in this process.

Because enthalpy is a state function, we can use the same type of thermochemical cycle described in [Chapter 9](#) to analyze the energetics of solution formation. (For more information about state functions, see [Section 9.2.](#)) The process occurs in three discrete steps, indicated by ΔH_1 , ΔH_2 , and ΔH_3 in [Figure 13.1.1](#). The overall enthalpy change in the formation of the solution (ΔH_{soln}) is the sum of the enthalpy changes in the three steps:

$$\Delta H_{\text{soln}} = \Delta H_1 + \Delta H_2 + \Delta H_3 \quad (13.1.3)$$

When a solvent is added to a solution, steps 1 and 2 are both endothermic because energy is required to overcome the intermolecular interactions in the solvent (ΔH_1) and the solute (ΔH_2). Because ΔH is positive for both steps 1 and 2, the solute–solvent interactions (ΔH_3) must be stronger than the solute–solute and solvent–solvent interactions they replace in order for the dissolution process to be exothermic ($\Delta H_{\text{soln}} < 0$). When the solute is an ionic solid, ΔH_2 corresponds to the lattice energy that must be overcome to form a solution. As you learned in [Chapter 12](#), the higher the charge of the ions in an ionic solid, the higher the lattice energy. Consequently, solids that have very high lattice energies, such as MgO (–3791 kJ/mol), are generally insoluble in all solvents.

Figure 13.1.1 Enthalpy Changes That Accompany the Formation of a Solution

Solvation can be an exothermic or endothermic process depending on the nature of the solute and solvent. In both cases, step 1, separation of the solvent particles, is energetically uphill ($\Delta H_1 > 0$), as is step 2, separation of the solute particles ($\Delta H_2 > 0$). In contrast, energy is released in step 3 ($\Delta H_3 < 0$) because of interactions between the solute and solvent. (a) When ΔH_3 is larger in magnitude than the sum of ΔH_1 and ΔH_2 , the overall process is exothermic ($\Delta H_{\text{soln}} < 0$), as shown in the thermochemical cycle. (b) When ΔH_3 is smaller in magnitude than the sum of ΔH_1 and ΔH_2 , the overall process is endothermic ($\Delta H_{\text{soln}} > 0$).

As you will see in [Chapter 18](#), a positive value for ΔH_{soln} does not mean that a solution will not form. Whether a given process, including formation of a solution, occurs spontaneously depends on whether the *total* energy of the system is lowered as a result. Enthalpy is only one of the contributing factors. A high ΔH_{soln} is usually an indication that the substance is not very soluble. Instant

cold packs used to treat athletic injuries, for example, take advantage of the large positive ΔH_{soln} of ammonium nitrate during dissolution (+25.7 kJ/mol), which produces temperatures less than 0°C (Figure 13.1.2).

Figure 13.1.2 Commercial Cold Packs for Treating Injuries

These packs contain solid NH_4NO_3 and water in separate compartments. When the seal between the compartments is broken, the NH_4NO_3 dissolves in the water. Because ΔH_{soln} for NH_4NO_3 is much greater than zero, heat is absorbed by the cold pack during the dissolution process, producing local temperatures less than 0°C .

Entropy and Solution Formation

The enthalpy change that accompanies a process is important because processes that release substantial amounts of energy tend to occur spontaneously. A second property of any system, its *entropy*, is also important in helping us determine whether a given process occurs spontaneously. We will discuss entropy in more detail in [Chapter 18](#), but for now we can state that entropy(S) is a thermodynamic property of all substances that is proportional to their degree of disorder. A perfect crystal at 0 K, whose atoms are regularly arranged in a perfect lattice and are motionless, is arbitrarily assigned an entropy of zero. In contrast, gases have large positive entropies because their molecules are highly disordered and in constant motion at high speeds.

The formation of a solution disperses molecules, atoms, or ions of one kind throughout a second substance, which generally increases the disorder and results in an increase in the entropy of the system. Thus entropic factors almost always favor formation of a solution. In contrast, a change in enthalpy may or may not favor solution formation. The London dispersion forces that hold cyclohexane and *n*-hexane together in pure liquids, for example, are similar in nature and strength. Consequently, ΔH_{soln} should be approximately zero, as is observed experimentally. Mixing equal amounts of the two liquids, however, produces a solution in which the *n*-hexane and cyclohexane molecules are uniformly distributed over approximately twice the initial volume. In this case, the driving force for solution formation is not a negative ΔH_{soln} but rather the increase in entropy due to the increased disorder in the mixture. *All spontaneous processes with $\Delta H \geq 0$ are characterized by an increase in entropy.* In other cases, such as mixing oil with water, salt with gasoline, or sugar with hexane, the enthalpy of solution is large and positive, and the increase in entropy resulting from solution formation is not enough to overcome it. Thus in these cases a solution does not form.

Note the Pattern

All spontaneous processes with $\Delta H \geq 0$ are characterized by an increase in entropy.

[Table 13.1.2](#) summarizes how enthalpic factors affect solution formation for four general cases. The column on the far right uses the relative magnitudes of the enthalpic contributions to predict whether a solution will form from each of the four. Keep in mind that in each case entropy favors solution formation. In two of the cases the enthalpy of solution is expected to be relatively small and can be either positive or negative. Thus the entropic contribution dominates, and we expect a solution to form readily. In the other two cases the enthalpy of solution is expected to be large and positive. The entropic contribution, though favorable, is usually too small to overcome the unfavorable enthalpy term. Hence we expect that a solution will not form readily.

Table 13.1.2 Relative Changes in Enthalpies for Different Solute–Solvent Combinations*

ΔH_1 (separation of solvent molecules)	ΔH_2 (separation of solute particles)	ΔH_3 (solute–solvent interactions)	ΔH_{soln} ($\Delta H_1 + \Delta H_2 + \Delta H_3$)	Result of Mixing Solute and Solvent [†]
large; positive	large; positive	large; negative	small; positive or negative	solution will usually form
small; positive	large; positive	small; negative	large; positive	solution will not form
large; positive	small; positive	small; negative	large; positive	solution will not form
small; positive	small; positive	small; negative	small; positive or negative	solution will usually form

* ΔH_1 , ΔH_2 , and ΔH_3 refer to the processes indicated in the thermochemical cycle shown in Figure 13.1 "Enthalpy Changes That Accompany the Formation of a Solution".

[†] In all four cases, entropy increases.

In contrast to liquid solutions, the intermolecular interactions in gases are weak (they are considered to be nonexistent in ideal gases). Hence mixing gases is usually a thermally neutral process ($\Delta H_{\text{soln}} \approx 0$), and the entropic factor due to the increase in disorder is dominant (Figure 13.1.3). Consequently, all gases dissolve readily in one another in all proportions to form solutions. We will return to a discussion of enthalpy and entropy in Chapter 18, where we treat their relationship quantitatively.

Figure 13.1.3 Formation of a Solution of Two Gases (top) Pure samples of two different gases are in separate bulbs. (bottom) When the connecting stopcock is opened, diffusion causes the two gases to mix together and form a solution. Even though ΔH_{soln} is zero for the process, the increased entropy of the solution (the increased disorder) versus that of the separate gases favors solution formation.

Example 13.1.1

Considering LiCl, benzoic acid ($\text{C}_6\text{H}_5\text{CO}_2\text{H}$), and naphthalene, which will be most soluble and which will be least soluble in water?

Given: three compounds

Asked for: relative solubilities in water

Strategy:

Assess the relative magnitude of the enthalpy change for each step in the process shown in Figure 13.1.1. Then use Table 13.1.2 to predict the solubility of each compound in water and arrange them in order of decreasing solubility.

Solution:

The first substance, LiCl, is an ionic compound, so a great deal of energy is required to separate its anions and cations and overcome the lattice energy (ΔH_2 is far greater than zero in Equation 13.1.3). Because water is a polar substance, the interactions between both Li^+ and Cl^- ions and water should be favorable and strong. Thus we expect ΔH_3 to be far less than zero, making LiCl soluble in water. In contrast, naphthalene is a nonpolar compound, with only London dispersion forces holding the molecules together in the solid state. We therefore expect ΔH_2 to be small and positive. We also expect the interaction between polar water molecules and nonpolar naphthalene molecules to be weak $\Delta H_3 \approx 0$. Hence we do not expect naphthalene to be very soluble in water, if at all. Benzoic acid has a polar carboxylic acid group and a nonpolar aromatic ring. We therefore expect that the energy required to separate solute molecules (ΔH_2) will be greater than for naphthalene and less than for LiCl. The strength of the interaction of benzoic acid with water should also be intermediate between those of LiCl and naphthalene. Hence benzoic acid is expected to be more soluble in water than naphthalene but less soluble than LiCl. We thus predict LiCl to be the most soluble in water and naphthalene to be the least soluble.

Exercise

Considering ammonium chloride, cyclohexane, and ethylene glycol ($\text{HOCH}_2\text{CH}_2\text{OH}$), which will be most soluble and which will be least soluble in benzene?

Answer: The most soluble is cyclohexane; the least soluble is ammonium chloride.

Summary

Solutions are homogeneous mixtures of two or more substances whose components are uniformly distributed on a microscopic scale. The component present in the greatest amount is the *solvent*, and the components present in lesser amounts are the *solute(s)*. The formation of a solution from a solute and a solvent is a physical process, not a chemical one. Substances that are **miscible**, such as gases, form a single phase in all proportions when mixed. Substances that form separate phases are **immiscible**. **Solvation** is the process in which solute particles are surrounded by solvent molecules. When the solvent is water, the process is called **hydration**. The overall enthalpy change that accompanies the formation of a solution, ΔH_{soln} , is the sum of the enthalpy change for breaking the intermolecular interactions in both the solvent and the solute and the enthalpy change for the formation of new solute–solvent interactions. Exothermic ($\Delta H_{\text{soln}} < 0$) processes favor solution formation. In addition, the change in **entropy**, the degree of disorder of the system, must be considered when predicting whether a solution will form. An increase in entropy (a decrease in order) favors dissolution.

Key Takeaway

- The magnitude of the changes in both enthalpy and entropy must be considered when predicting whether a given solute–solvent combination will spontaneously form a solution.

Conceptual Problems

- Classify each of the following as a heterogeneous mixture or homogeneous mixture. Explain your rationale in each case.
 - aqueous ammonia
 - liquid decongestant
 - vinegar
 - seawater
 - gasoline
 - fog
- Solutions and heterogeneous mixtures are at the extreme ends of the solubility scale. Name one type of mixture that is intermediate on this scale. How are the properties of the mixture you have chosen different from those of a solution or a heterogeneous mixture?
- Classify each process as simple dissolution or a chemical reaction.
 - a naphthalene mothball dissolving in benzene
 - a sample of a common drain cleaner that has a mixture of NaOH crystals and Al chunks dissolving in water to give H₂ gas and an aqueous solution of Na⁺, OH⁻, and Al³⁺ ions
 - an iron ship anchor slowly dissolving in seawater
 - sodium metal dissolving in liquid ammonia
- Classify each process as simple dissolution or a chemical reaction.
 - a sugar cube dissolving in a cup of hot tea
 - SO₃ gas dissolving in water to produce sulfuric acid
 - calcium oxide dissolving in water to produce a basic solution
 - metallic gold dissolving in a small quantity of liquid mercury
- You notice that a gas is evolved as you are dissolving a solid in a liquid. Will you be able to recover your original solid by evaporation? Why or why not?
- Why is heat evolved when sodium hydroxide pellets are dissolved in water? Does this process correspond to simple dissolution or a chemical reaction? Justify your answer.
- Which process(es) is the simple formation of a solution, and which process(es) involves a chemical reaction?
 - mixing an aqueous solution of NaOH with an aqueous solution of HCl
 - bubbling HCl gas through water
 - adding iodine crystals to CCl₄
 - adding sodium metal to ethanol to produce sodium ethoxide (C₂H₅O⁻ Na⁺) and hydrogen gas
- Using thermochemical arguments, explain why some substances that do not form a solution at room temperature will form a solution when heated. Explain why a solution can form even when ΔH_{soln} is positive.
- If you wanted to formulate a new compound that could be used in an instant cold pack, would you select a compound with a positive or negative value of ΔH_{soln} in water? Justify your answer.
- Why is entropy the dominant factor in the formation of solutions of two or more gases? Is it possible for two gases to be immiscible? Why or why not?

Answers

- Homogeneous mixtures: aqueous ammonia, liquid decongestant, vinegar, and gasoline. Heterogeneous mixtures: seawater and fog.
-
-
-
-
-
- All are chemical reactions except dissolving iodine crystals in CCl₄.
-
-

Learning Objectives

- To understand the relationship between solubility and molecular structure.

When a solute dissolves, its individual atoms, molecules, or ions interact with the solvent, become solvated, and are able to diffuse independently throughout the solution (part (a) in [Figure 13.1.1](#)). This is not, however, a unidirectional process. If the molecule or ion happens to collide with the surface of a particle of the undissolved solute, it may adhere to the particle in a process called *crystallization*. Dissolution and crystallization continue as long as excess solid is present, resulting in a *dynamic equilibrium* analogous to the equilibrium that maintains the vapor pressure of a liquid. (For more information about vapor pressure, see [Section 11.4](#)) We can represent these opposing processes as follows:

Although the terms *precipitation* and *crystallization* are both used to describe the separation of solid solute from a solution, *crystallization* refers to the formation of a solid with a well-defined crystalline structure, whereas *precipitation* refers to the formation of any solid phase, often one with very small particles.

Figure 13.2.1 *Dissolution and Precipitation* (a) When a solid is added to a solvent in which it is soluble, solute particles leave the surface of the solid and become solvated by the solvent, initially forming an unsaturated solution. (b) When the maximum possible amount of solute has dissolved, the solution becomes saturated. If excess solute is present, the rate at which solute particles leave the surface of the solid equals the rate at which they return to the surface of the solid. (c) A supersaturated solution can usually be formed from a saturated solution by filtering off the excess solute and lowering the temperature. (d) When a seed crystal of the solute is added to a supersaturated solution, solute particles leave the solution and form a crystalline precipitate.

Factors Affecting Solubility

The maximum amount of a solute that can dissolve in a solvent at a specified temperature and pressure is its solubility. Solubility is often expressed as the mass of solute per volume (g/L) or mass of solute per mass of solvent (g/g), or as the moles of solute per volume (mol/L). Even for very soluble substances, however, there is usually a limit to how much solute can dissolve in a given quantity of solvent. In general, the solubility of a substance depends on not only the energetic factors we have discussed but also the temperature and, for gases, the pressure. At 20°C, for example, 177 g of NaI, 91.2 g of NaBr, 35.9 g of NaCl, and only 4.1 g of NaF dissolve in 100 g of water. At 70°C, however, the solubilities increase to 295 g of NaI, 119 g of NaBr, 37.5 g of NaCl, and 4.8 g of NaF. As you learned in [Chapter 12](#), the lattice energies of the sodium halides increase from NaI to NaF. The fact that the

solubilities decrease as the lattice energy increases suggests that the ΔH_2 term in [Figure 13.1.1](#) dominates for this series of compounds.

A solution with the maximum possible amount of solute is saturated. If a solution contains less than the maximum amount of solute, it is *unsaturated*. When a solution is saturated and excess solute is present, the rate of dissolution is exactly equal to the rate of crystallization (part (b) in [Figure 13.2.1](#)). Using the value just stated, a saturated aqueous solution of NaCl, for example, contains 35.9 g of NaCl per 100 mL of water at 20°C. We can prepare a homogeneous saturated solution by adding excess solute (in this case, greater than 35.9 g of NaCl) to the solvent (water), stirring until the maximum possible amount of solute has dissolved, and then removing undissolved solute by filtration.

Note the Pattern

The solubility of most solids increases with increasing temperature.

Because the solubility of most solids increases with increasing temperature, a saturated solution that was prepared at a higher temperature usually contains more dissolved solute than it would contain at a lower temperature. When the solution is cooled, it can therefore become supersaturated (part (c) in [Figure 13.1.1](#)). Like a supercooled or superheated liquid (see [Chapter 11](#)), a supersaturated solution is unstable. Consequently, adding a small particle of the solute, a seed crystal, will usually cause the excess solute to rapidly precipitate or crystallize, sometimes with spectacular results, as was shown in [Figure 1.3.4](#). The rate of crystallization in [Equation 13.2.1](#) is greater than the rate of dissolution, so crystals or a precipitate form (part (d) in [Figure 13.2.1](#)). In contrast, adding a seed crystal to a saturated solution reestablishes the dynamic equilibrium, and the *net* quantity of dissolved solute no longer changes.

Because crystallization is the reverse of dissolution, a substance that requires an input of heat to form a solution ($\Delta H_{\text{soln}} > 0$) releases that heat when it crystallizes from solution ($\Delta H_{\text{crys}} < 0$). The amount of heat released is proportional to the amount of solute that exceeds its solubility. Two substances that have a positive enthalpy of solution are sodium thiosulfate ($\text{Na}_2\text{S}_2\text{O}_3$) and sodium acetate ($\text{CH}_3\text{CO}_2\text{Na}$), both of which are used in commercial hot packs, small bags of supersaturated solutions used to warm hands (see [Figure 9.5.1](#)).

Interactions in Liquid Solutions

The interactions that determine the solubility of a substance in a liquid depend largely on the chemical nature of the solute (such as whether it is ionic or molecular) rather than on its physical state (solid, liquid, or gas). We will first describe the general case of forming a solution of a molecular species in a liquid solvent and then describe the formation of a solution of an ionic compound.

Solutions of Molecular Substances in Liquids

The London dispersion forces, dipole–dipole interactions, and hydrogen bonds that hold molecules to other molecules are generally weak. Even so, energy is required to disrupt these interactions. As we described in [Section 13.1](#), unless some of that energy is recovered in the formation of new, favorable solute–solvent interactions, the increase in entropy on solution formation is not enough for a solution to form.

For solutions of gases in liquids, we can safely ignore the energy required to separate the solute molecules ($\Delta H_2 = 0$) because the molecules are already separated. Thus we need to consider only the energy required to separate the solvent molecules (ΔH_1) and the energy released by new solute–solvent interactions (ΔH_3). Nonpolar gases such as N_2 , O_2 , and Ar have no dipole moment and cannot engage in dipole–dipole interactions or hydrogen bonding. Consequently, the only way they can interact with a solvent is by means of London dispersion forces, which may be weaker than the solvent–solvent interactions in a polar solvent. It is not surprising, then, that nonpolar gases are most soluble in nonpolar solvents. In this case, ΔH_1 and ΔH_3 are both small and of similar magnitude. In contrast, for a solution of a nonpolar gas in a polar solvent, ΔH_1 is far greater than ΔH_3 . As a result, nonpolar gases are less soluble in polar solvents than in nonpolar solvents. For example, the concentration of N_2 in a saturated solution of N_2 in water, a polar solvent, is only 7.07×10^{-4} M compared with 4.5×10^{-3} M for a saturated solution of N_2 in benzene, a nonpolar solvent.

The solubilities of nonpolar gases in water generally increase as the molecular mass of the gas increases, as shown in [Table 13.2.1](#). This is precisely the trend expected: as the gas molecules become larger, the strength of the solvent–solute interactions due to

London dispersion forces increases, approaching the strength of the solvent–solvent interactions.

Table 13.2.1 Solubilities of Selected Gases in Water at 20°C and 1 atm Pressure

Gas	Solubility (M) $\times 10^{-4}$
He	3.90
Ne	4.65
Ar	15.2
Kr	27.9
Xe	50.2
H ₂	8.06
N ₂	7.07
CO	10.6
O ₂	13.9
N ₂ O	281
CH ₄	15.5

Virtually all common organic liquids, whether polar or not, are miscible. The strengths of the intermolecular attractions are comparable; thus the enthalpy of solution is expected to be small ($\Delta H_{\text{soln}} \approx 0$), and the increase in entropy drives the formation of a solution. If the predominant intermolecular interactions in two liquids are very different from one another, however, they may be immiscible. For example, organic liquids such as benzene, hexane, CCl₄, and CS₂ (S=C=S) are nonpolar and have no ability to act as hydrogen bond donors or acceptors with hydrogen-bonding solvents such as H₂O, HF, and NH₃; hence they are immiscible in these solvents. When shaken with water, they form separate phases or layers separated by an *interface* (Figure 13.5), the region between the two layers. Just because two liquids are immiscible, however, does *not* mean that they are completely insoluble in each other. For example, 188 mg of benzene dissolves in 100 mL of water at 23.5°C. Adding more benzene results in the separation of an upper layer consisting of benzene with a small amount of dissolved water (the solubility of water in benzene is only 178 mg/100 mL of benzene).

Figure 13.2.2 Water is immiscible with with perfluoroheptane (and most halogenated compounds). Because water is less dense than the perfluoroheptane, the water layer floats on top. The goldfish is swimming in the water layer. Figure from [the Wikipedia](#)..

The solubilities of simple alcohols in water are given in Table 13.4 "Solubilities of Straight-Chain Organic Alcohols in Water at 20°C". Only the three lightest alcohols (methanol, ethanol, and *n*-propanol) are completely miscible with water. As the molecular

mass of the alcohol increases, so does the proportion of hydrocarbon in the molecule. Correspondingly, the importance of hydrogen bonding and dipole–dipole interactions in the pure alcohol decreases, while the importance of London dispersion forces increases, which leads to progressively fewer favorable electrostatic interactions with water. Organic liquids such as acetone, ethanol, and tetrahydrofuran are sufficiently polar to be completely miscible with water yet sufficiently nonpolar to be completely miscible with all organic solvents.

Table 13.2.2 Solubilities of Straight-Chain Organic Alcohols in Water at 20°C

Tetrahydrofuran (THF)

Alcohol	Solubility (mol/100 g of H ₂ O)
methanol	completely miscible
ethanol	completely miscible
<i>n</i> -propanol	completely miscible
<i>n</i> -butanol	0.11
<i>n</i> -pentanol	0.030
<i>n</i> -hexanol	0.0058
<i>n</i> -heptanol	0.0008

The same principles govern the solubilities of molecular solids in liquids. For example, elemental sulfur is a solid consisting of cyclic S₈ molecules that have no dipole moment. Because the S₈ rings in solid sulfur are held to other rings by London dispersion forces, elemental sulfur is insoluble in water. It is, however, soluble in nonpolar solvents that have comparable London dispersion forces, such as CS₂ (23 g/100 mL). In contrast, glucose contains five –OH groups that can form hydrogen bonds. Consequently, glucose is very soluble in water (91 g/120 mL of water) but essentially insoluble in nonpolar solvents such as benzene. The structure of one isomer of glucose is shown here.

Low-molecular-mass hydrocarbons with highly electronegative and polarizable halogen atoms, such as chloroform (CHCl₃) and methylene chloride (CH₂Cl₂), have both significant dipole moments and relatively strong London dispersion forces. These hydrocarbons are therefore powerful solvents for a wide range of polar and nonpolar compounds. Naphthalene, which is nonpolar, and phenol (C₆H₅OH), which is polar, are very soluble in chloroform. In contrast, the solubility of ionic compounds is largely determined not by the polarity of the solvent but rather by its *dielectric constant*, a measure of its ability to separate ions in solution, as you will soon see.

D-Glucose

Example 13.2.1

Identify the most important solute–solvent interactions in each solution.

- iodine in benzene
- aniline (C₆H₅NH₂) in dichloromethane (CH₂Cl₂)

Aniline

3. iodine in water

Given: components of solutions

Asked for: predominant solute–solvent interactions

Strategy:

Identify all possible intermolecular interactions for both the solute and the solvent: London dispersion forces, dipole–dipole interactions, or hydrogen bonding. Determine which is likely to be the most important factor in solution formation.

Solution:

1. Benzene and I_2 are both nonpolar molecules. The only possible attractive forces are London dispersion forces.
2. Aniline is a polar molecule with an $-NH_2$ group, which can act as a hydrogen bond donor. Dichloromethane is also polar, but it has no obvious hydrogen bond acceptor. Therefore, the most important interactions between aniline and CH_2Cl_2 are likely to be London interactions.
3. Water is a highly polar molecule that engages in extensive hydrogen bonding, whereas I_2 is a nonpolar molecule that cannot act as a hydrogen bond donor or acceptor. The slight solubility of I_2 in water (1.3×10^{-3} mol/L at $25^\circ C$) is due to London dispersion forces.

Exercise

Identify the most important interactions in each solution:

1. ethylene glycol ($HOCH_2CH_2OH$) in acetone
2. acetonitrile ($CH_3C\equiv N$) in acetone
3. *n*-hexane in benzene

Answer:

1. hydrogen bonding
2. London interactions
3. London dispersion forces

Hydrophilic and Hydrophobic Solutes

A solute can be classified as hydrophilic (literally, “water loving”), meaning that it has an electrostatic attraction to water, or hydrophobic (“water fearing”), meaning that it repels water. A hydrophilic substance is polar and often contains O–H or N–H groups that can form hydrogen bonds to water. For example, glucose with its five O–H groups is hydrophilic. In contrast, a hydrophobic substance may be polar but usually contains C–H bonds that do not interact favorably with water, as is the case with naphthalene and *n*-octane. Hydrophilic substances tend to be very soluble in water and other strongly polar solvents, whereas hydrophobic substances are essentially insoluble in water and soluble in nonpolar solvents such as benzene and cyclohexane.

The difference between hydrophilic and hydrophobic substances has substantial consequences in biological systems. For example, vitamins can be classified as either *fat soluble* or *water soluble*. Fat-soluble vitamins, such as vitamin A, are mostly nonpolar, hydrophobic molecules. As a result, they tend to be absorbed into fatty tissues and stored there. In contrast, water-soluble vitamins, such as vitamin C, are polar, hydrophilic molecules that circulate in the blood and intracellular fluids, which are primarily aqueous. Water-soluble vitamins are therefore excreted much more rapidly from the body and must be replenished in our daily diet. A comparison of the chemical structures of vitamin A and vitamin C quickly reveals why one is hydrophobic and the other hydrophilic.

Because water-soluble vitamins are rapidly excreted, the risk of consuming them in excess is relatively small. Eating a dozen oranges a day is likely to make you tired of oranges long before you suffer any ill effects due to their high vitamin C content. In contrast, fat-soluble vitamins constitute a significant health hazard when consumed in large

amounts. For example, the livers of polar bears and other large animals that live in cold climates contain large amounts of vitamin A, which have occasionally proven fatal to humans who have eaten them.

Example 13.2.2

The following substances are essential components of the human diet:

Using what you know of hydrophilic and hydrophobic solutes, classify each as water soluble or fat soluble and predict which are likely to be required in the diet on a daily basis.

1. arginine
2. pantothenic acid
3. oleic acid

Given: chemical structures

Asked for: classification as water soluble or fat soluble; dietary requirement

Strategy:

Based on the structure of each compound, decide whether it is hydrophilic or hydrophobic. If it is hydrophilic, it is likely to be required on a daily basis.

Solution:

1. Arginine is a highly polar molecule with two positively charged groups and one negatively charged group, all of which can form hydrogen bonds with water. As a result, it is hydrophilic and required in our daily diet.
2. Although pantothenic acid contains a hydrophobic hydrocarbon portion, it also contains several polar functional groups ($-\text{OH}$ and $-\text{CO}_2\text{H}$) that should interact strongly with water. It is therefore likely to be water soluble and required in the diet. (In fact, pantothenic acid is almost always a component of multiple-vitamin tablets.)
3. Oleic acid is a hydrophobic molecule with a single polar group at one end. It should be fat soluble and not required daily.

Exercise

These compounds are consumed by humans: caffeine, acetaminophen, and vitamin D. Identify each as primarily hydrophilic (water soluble) or hydrophobic (fat soluble), and predict whether each is likely to be excreted from the body rapidly or slowly.

Answer: Caffeine and acetaminophen are water soluble and rapidly excreted, whereas vitamin D is fat soluble and slowly excreted.

Solid Solutions

Solutions are not limited to gases and liquids; solid solutions also exist. For example, amalgams are solutions of metals in liquid mercury. Because most metals are soluble in mercury, amalgams are used in gold mining, dentistry, and many other applications. A major difficulty when mining gold is separating very small particles of pure gold from tons of crushed rock. One way to accomplish this is to agitate a suspension of the crushed rock with liquid mercury, which dissolves the gold (as well as any metallic silver that might be present). The very dense liquid gold–mercury amalgam is then isolated and the mercury distilled away.

An alloy is a solid or liquid solution that consists of one or more elements in a metallic matrix. A solid alloy has a single homogeneous phase in which the crystal structure of the solvent remains unchanged by the presence of the solute. Thus the microstructure of the alloy is uniform throughout the sample. Examples are substitutional and interstitial alloys such as brass or solder. (For more information about alloys, see [Section 12.5](#)) Liquid alloys include sodium/potassium and gold/mercury. In contrast, a *partial* alloy solution has two or more phases that can be homogeneous in the distribution of the components, but the microstructures of the two phases are *not* the same. As a liquid solution of lead and tin is cooled, for example, different crystalline phases form at different cooling temperatures. As you learned in [Chapter 12](#), alloys usually have properties that differ from those of the component elements.

Network solids such as diamond, graphite, and SiO_2 are insoluble in all solvents with which they do not react chemically. The covalent bonds that hold the network or lattice together are simply too strong to be broken under normal conditions. They are certainly much stronger than any conceivable combination of intermolecular interactions that might occur in solution. Most metals are insoluble in virtually all solvents for the same reason: the delocalized metallic bonding is much stronger than any favorable metal atom–solvent interactions. Many metals react with solutions such as aqueous acids or bases to produce a solution. However, as we saw in [Section 13.1](#) in these instances the metal undergoes a chemical transformation that cannot be reversed by simply removing the solvent.

Note the Pattern

Solids with very strong intermolecular bonding tend to be insoluble.

Solubilities of Ionic Substances in Liquids

[Table 8.2.1](#) introduced you to guidelines for predicting the solubility of ionic compounds in water. Ionic substances are generally most soluble in polar solvents; the higher the lattice energy, the more polar the solvent must be to overcome the lattice energy and dissolve the substance. Because of its high polarity, water is the most common solvent for ionic compounds. Many ionic compounds are soluble in other polar solvents, however, such as liquid ammonia, liquid hydrogen fluoride, and methanol. Because all these solvents consist of molecules that have relatively large dipole moments, they can interact favorably with the dissolved ions.

The interaction of water with Na^+ and Cl^- ions in an aqueous solution of NaCl is shown whenever you sprinkle salt into water, for example when you are cooking spaghetti. The ion–dipole interactions between Li^+ ions and acetone molecules in a solution of LiCl in acetone are shown in [Figure 13.2.3](#) The energetically favorable Li^+ –acetone interactions make ΔH_3 in [Figure 13.1.1](#) sufficiently negative to overcome the positive ΔH_1 and ΔH_2 . Because the dipole moment of acetone (2.88 D), and thus its polarity, is actually larger than that of water (1.85 D), one might even expect that LiCl would be more soluble in acetone than in water. In fact, the opposite is true: 83 g of LiCl dissolve in 100 mL of water at 20°C, but only about 4.1 g of LiCl dissolve in 100 mL of acetone. This apparent contradiction arises from the fact that the dipole moment is a property of a single molecule in the gas phase. A more useful measure of the ability of a solvent to dissolve ionic compounds is its dielectric constant (ϵ) which is the ability of a bulk substance to decrease the electrostatic forces between two charged particles. By definition, the dielectric constant of a vacuum is 1. In essence, a solvent with a high dielectric constant causes the charged particles to behave as if they have been moved farther apart. At 25°C, the dielectric constant of water is 80.1, one of the highest known, and that of acetone is only 21.0. Hence water is better

+ -

able to decrease the electrostatic attraction between Li^+ and Cl^- ions, so LiCl is more soluble in water than in acetone. This behavior is in contrast to that of molecular substances, for which polarity is the dominant factor governing solubility.

Note the Pattern

A solvent's dielectric constant is the most useful measure of its ability to dissolve ionic compounds. A solvent's polarity is the dominant factor in dissolving molecular substances.

It is also possible to dissolve ionic compounds in organic solvents using crown ethers, cyclic compounds with the general formula $(\text{OCH}_2\text{CH}_2)_n$. Crown ethers are named using both the total number of atoms in the ring and the number of oxygen atoms. Thus 18-crown-6 is an 18-membered ring with six oxygen atoms (part (a) in [Figure 13.2.4](#)). The cavity in the center of the crown ether molecule is lined with oxygen atoms and is large enough to be occupied by a cation, such as K^+ . The cation is stabilized by interacting with lone pairs of electrons on the surrounding oxygen atoms. Thus crown ethers solvate cations inside a hydrophilic cavity, whereas the outer shell, consisting of C–H bonds, is hydrophobic. Crown ethers are useful for dissolving ionic substances such as KMnO_4 in organic solvents such as isopropanol $[(\text{CH}_3)_2\text{CHOH}]$ ([Figure 13.2.4](#)). The availability of crown ethers with cavities of different sizes allows specific cations to be solvated with a high degree of selectivity.

Figure 13.2.4 Crown Ethers and Cryptands (a) The potassium complex of the crown ether 18-crown-6. Note how the cation is nestled within the central cavity of the molecule and interacts with lone pairs of electrons on the oxygen atoms. (b) The potassium complex of 2,2,2-cryptand, showing how the cation is almost hidden by the cryptand. Cryptands solvate cations via lone pairs of electrons on both oxygen and nitrogen atoms.

Figure 13.2.3 Ion–Dipole Interactions in the Solvation of Li^+ Ions by Acetone, a Polar Solvent

Figure 13.2.5. Effect of a Crown Ether on the Solubility of KMnO_4 in Benzene. Normally which is intensely purple, is completely insoluble in benzene which has a relatively low dielectric constant. In the presence of a small amount of crown ether, KMnO_4 dissolves in benzene as shown by the reddish purple color caused by the permanganate ions in solution.

Cryptands²² (from the Greek *kryptós*, meaning “hidden”) are compounds that can completely surround a cation with lone pairs of electrons on oxygen and nitrogen atoms (part (b) in [Figure 13.2.4](#)). The number in the name of the cryptand is the number of oxygen atoms in each strand of the molecule. Like crown ethers, cryptands can be used to prepare solutions of ionic compounds in solvents that are otherwise too nonpolar to dissolve them.

Summary

The **solubility** of a substance is the maximum amount of a solute that can dissolve in a given quantity of solvent; it depends on the chemical nature of both the solute and the solvent and on the temperature and pressure. When a solution contains the maximum amount of solute that can dissolve under a given set of conditions, it is a **saturated solution**. Otherwise, it is *unsaturated*. **Supersaturated solutions**, which contain more dissolved solute than allowed under particular conditions, are not stable; the addition of a **seed crystal**, a small particle of solute, will usually cause the excess solute to crystallize. A system in which crystallization and dissolution occur at the same rate is in *dynamic equilibrium*. The solubility of a substance in a liquid is determined by intermolecular interactions, which also determine whether two liquids are miscible. Solutes can be classified as **hydrophilic** (water loving) or **hydrophobic** (water fearing). Vitamins with hydrophilic structures are water soluble, whereas those with hydrophobic structures are fat soluble. Many metals dissolve in liquid mercury to form **amalgams**. Covalent network solids and most metals are insoluble in nearly all solvents. The solubility of ionic compounds is largely determined by the **dielectric constant (ϵ)** of the solvent, a measure of its ability to decrease the electrostatic forces between charged particles. Solutions of many ionic compounds in organic solvents can be dissolved using **crown ethers**, cyclic polyethers large enough to accommodate a metal ion in the center, or **cryptands**, compounds that completely surround a cation.

Key Takeaway

- The strength of intramolecular bonding determines the solubility of a solute in a given solvent.

Conceptual Problems

- If a compound is only slightly soluble in a particular solvent, what are the relative strengths of the solvent–solvent and solute–solute interactions versus the solute–solvent interactions?
- Predict whether each of the following sets of conditions favors formation of a solution:

Intermolecular Attractive Forces (Solute)	Intermolecular Attractive Forces (Solvent)	ΔH_{soln}
London dispersion	hydrogen bonding	slightly positive
dipole–dipole	hydrogen bonding	very negative
ionic	dipole–dipole	slightly positive
ionic	London dispersion	positive

- Arrange the following liquids in order of increasing solubility in water: *t*-butanol [(CH₃)₃COH], benzene, ammonia, and heptane. Justify your answer.
- Which compound in each pair will be more soluble in water? Explain your reasoning in each case.
 - toluene (C₇H₈) or ethyl ether (C₂H₅OC₂H₅)
 - chloroform (CHCl₃) or acetone (CH₃COCH₃)
 - carbon tetrachloride (CCl₄) or tetrahydrofuran (C₄H₈O)
 - CaCl₂ or CH₂Cl₂
- Which compound in each pair will be more soluble in benzene? Explain your reasoning in each case.
 - cyclohexane or methanol
 - I₂ or MgCl₂
 - methylene chloride (CH₂Cl₂) or acetic acid
- Two water-insoluble compounds—*n*-decylamine [CH₃(CH₂)₉NH₂] and *n*-decane—can be separated by the following procedure: The compounds are dissolved in a solvent such as toluene that is immiscible with water. When adding an aqueous HCl solution to the mixture and stirring vigorously, the HCl reacts with one of the compounds to produce a salt. When the stirring is stopped and the mixture is allowed to stand, two layers are formed. At this point, each layer contains only one of the two original compounds. After the layers are separated, adding aqueous NaOH to the aqueous layer liberates one of the original compounds, which can then be removed by stirring with a second portion of toluene to extract it from the water.
 - Identify the compound that is present in each layer following the addition of HCl. Explain your reasoning.

- b. How can the original compounds be recovered from the toluene solution?
- Bromine and iodine are both soluble in CCl_4 , but bromine is much more soluble. Why?
 - A solution is made by mixing 50.0 mL of liquid A with 75.0 mL of liquid B. Which is the solute, and which is the solvent? Is it valid to assume that the volume of the resulting solution will be 125 mL? Explain your answer.
 - The compounds NaI, NaBr, and NaCl are far more soluble in water than NaF, a substance that is used to fluoridate drinking water. In fact, at 25°C the solubility of NaI is 184 g/100 mL of water, versus only 4.2 g/100 mL of water for NaF. Why is sodium iodide so much more soluble in water? Do you expect KCl to be more soluble or less soluble in water than NaCl?
 - When water is mixed with a solvent with which it is immiscible, the two liquids usually form two separate layers. If the density of the nonaqueous solvent is 1.75 g/mL at room temperature, sketch the appearance of the heterogeneous mixture in a beaker and label which layer is which. If you were not sure of the density and the identity of the other liquid, how might you be able to identify which is the aqueous layer?
 - When two liquids are immiscible, the addition of a third liquid can occasionally be used to induce the formation of a homogeneous solution containing all three.
 - Ethylene glycol ($\text{HOCH}_2\text{CH}_2\text{OH}$) and hexane are immiscible, but adding acetone [$(\text{CH}_3)_2\text{CO}$] produces a homogeneous solution. Why does adding a third solvent produce a homogeneous solution?
 - Methanol and *n*-hexane are immiscible. Which of the following solvents would you add to create a homogeneous solution—water, *n*-butanol, or cyclohexane? Justify your choice.
 - Some proponents of vitamin therapy for combating illness encourage the consumption of large amounts of fat-soluble vitamins. Why can this be dangerous? Would it be as dangerous to consume large amounts of water-soluble vitamins? Why or why not?
 - Why are most metals insoluble in virtually all solvents?
 - Because sodium reacts violently with water, it is difficult to weigh out small quantities of sodium metal for a reaction due to its rapid reaction with small amounts of moisture in the air. Would a Na/Hg amalgam be as sensitive to moisture as metallic sodium? Why or why not? A Na/K alloy is a liquid at room temperature. Will it be more or less sensitive to moisture than solid Na or K?
 - Dental amalgams often contain high concentrations of Hg, which is highly toxic. Why isn't dental amalgam toxic?
 - Arrange 2,2,3-trimethylpentane, 1-propanol, toluene (C_7H_8), and dimethyl sulfoxide [$(\text{CH}_3)_2\text{S}=\text{O}$] in order of increasing dipole moment. Explain your reasoning.
 - Arrange acetone, chloroform, cyclohexane, and 2-butanol in order of increasing dielectric constant. Explain your reasoning.
 - Dissolving a white crystalline compound in ethanol gave a blue solution. Evaporating the ethanol from the solution gave a bluish-crystalline product, which slowly transformed into the original white solid on standing in the air for several days. Explain what happened. How does the mass of the initial bluish solid compare with the mass of the white solid finally recovered?
 - You have been asked to develop a new drug that could be used to bind Fe^{3+} ions in patients who suffer from iron toxicity, allowing the bound iron to be excreted in the urine. Would you consider a crown ether or a cryptand to be a reasonable candidate for such a drug? Explain your answer.
 - Describe two different situations in which fractional crystallization will not work as a separation technique when attempting to isolate a single compound from a mixture.
 - You have been given a mixture of two compounds—A and B—and have been told to isolate pure A. You know that pure A has a lower solubility than pure B and that the solubilities of both A and B increase with temperature. Outline a procedure to isolate pure A. If B had the lower solubility, could you use the same procedure to isolate pure A? Why or why not?

- London dispersion forces increase with increasing atomic mass. Iodine is a solid while bromine is a liquid due to the greater intermolecular interactions between the heavier iodine atoms. Iodine is less soluble than bromine in virtually all solvents

because it requires more energy to separate I_2 molecules than Br_2 molecules.

21. Dissolve the mixture of A and B in a solvent in which they are both soluble when hot and relatively insoluble when cold, filter off any undissolved B, and cool slowly. Pure A should crystallize, while B stays in solution. If B were less soluble, it would be impossible to obtain pure A by this method in a single step, because some of the less soluble compound (B) will always be present in the solid that crystallizes from solution.

Learning Objectives

- To describe the concentration of a solution in the way that is most appropriate for a particular problem or application.

There are several different ways to quantitatively describe the concentration of a solution. For example, molarity was introduced in [Chapter 8](#) as a useful way to describe solution concentrations for reactions that are carried out in solution. Mole fractions, introduced in [Chapter 10](#), are used not only to describe gas concentrations but also to determine the vapor pressures of mixtures of similar liquids. Example 4 reviews the methods for calculating the molarity and mole fraction of a solution when the masses of its components are known.

Example 13.3.1

Commercial vinegar is essentially a solution of acetic acid in water. A bottle of vinegar has 3.78 g of acetic acid per 100.0 g of solution. Assume that the density of the solution is 1.00 g/mL.

- What is its molarity?
- What is its mole fraction?

Given: mass of substance and mass and density of solution

Asked for: molarity and mole fraction

Strategy:

A Calculate the number of moles of acetic acid in the sample. Then calculate the number of liters of solution from its mass and density. Use these results to determine the molarity of the solution.

B Determine the mass of the water in the sample and calculate the number of moles of water. Then determine the mole fraction of acetic acid by dividing the number of moles of acetic acid by the total number of moles of substances in the sample.

Solution:

- A** The molarity is the number of moles of acetic acid per liter of solution. We can calculate the number of moles of acetic acid as its mass divided by its molar mass. The volume of the solution equals its mass divided by its density. The calculations follow:

$$\text{moles } CH_3CO_2H = \frac{3.78 \text{ g } CH_3CO_2H}{60.05 \text{ g/mol}} = 0.0629 \text{ mol}$$

$$\text{volume} = \frac{\text{mass}}{\text{density}} = \frac{100.0 \text{ g solution}}{1.00 \text{ g/mL}} = 100.00 \text{ mL}$$

$$\text{molarity of } CH_3CO_2H = \frac{\text{moles } CH_3CO_2H}{\text{liter solution}} = \frac{0.0629 \text{ mol } CH_3CO_2H}{(100 \text{ mL}) (1L / \text{mL})} = 0.629 \text{ M } CH_3CO_2H$$

- This result makes intuitive sense. If 100.0 g of aqueous solution (equal to 100 mL) contains 3.78 g of acetic acid, then 1 L of solution will contain 37.8 g of acetic acid, which is a little more than 1/2 mole. Keep in mind, though, that the mass and volume of a solution are related by its density; concentrated aqueous solutions often have densities greater than 1.00 g/mL.
- B** To calculate the mole fraction of acetic acid in the solution, we need to know the number of moles of both acetic acid and water. The number of moles of acetic acid is 0.0629 mol, as calculated in part (a). We know that 100.0 g of vinegar contains 3.78 g of acetic acid; hence the solution also contains $(100.0 \text{ g} - 3.78 \text{ g}) = 96.2 \text{ g}$ of water. We have

$$\text{moles } H_2O = \frac{96.2 \text{ g } H_2O}{18.02 \text{ g/mol}} = 5.34 \text{ mol } H_2O$$

The mole fraction X of acetic acid is the ratio of the number of moles of acetic acid to the total number of moles of substances present:

$$X_{CH_3CO_2H} = \frac{\text{moles } CH_3CO_2H}{\text{moles } CH_3CO_2H + \text{moles } H_2O} = \frac{0.0629 \text{ mol}}{0.0629 \text{ mol} + 5.34 \text{ mol}} = 0.0116$$

This answer makes sense, too. There are approximately 100 times as many moles of water as moles of acetic acid, so the ratio should be approximately 0.01.

Exercise

A solution of HCl gas dissolved in water (sold commercially as “muriatic acid,” a solution used to clean masonry surfaces) has 20.22 g of HCl per 100.0 g of solution, and its density is 1.10 g/mL.

- What is its molarity?
- What is its mole fraction?

Answer:

- 6.10 M HCl
- $X_{HCl} = 0.111$

The concentration of a solution can also be described by its molality (m), the number of moles of solute per *kilogram* of solvent:

$$\text{molality } (m) = \frac{(\text{moles solute})}{(\text{kilograms solvent})} \quad (13.3.1)$$

Molality, therefore, has the same numerator as molarity (the number of moles of solute) but a different denominator (kilogram of solvent rather than liter of solution). Molality is independent of temperature, pressure and composition. Since the volume of a solution varies with temperature, pressure and composition, molarity also, if usually only weakly, depends on these three parameters of the solution.

For dilute aqueous solutions, the molality and molarity are nearly the same because dilute solutions are mostly solvent. Thus because the density of water under standard conditions is very close to 1.0 g/mL, the volume of 1.0 kg of H₂O under these conditions is very close to 1.0 L, and a 0.50 M solution of KBr in water, for example, has approximately the same concentration as a 0.50 m solution.

Another common way of describing concentration is as the ratio of the mass of the solute to the total mass of the solution. The result can be expressed as mass percentage, parts per million (ppm), or parts per billion (ppb):

$$\text{mass percentage} = \frac{(\text{mass of solute})}{(\text{mass of solution})} \times 100 \quad (13.3.2)$$

$$\text{parts per million (ppm)} = \frac{(\text{mass of solute})}{(\text{mass of solution})} \times 10^6 \quad (13.3.3)$$

$$\text{parts per billion (ppb)} = \frac{(\text{mass of solute})}{(\text{mass of solution})} \times 10^9 \quad (13.3.4)$$

In the health sciences, the concentration of a solution is typically expressed as parts per thousand (ppt), indicated as a proportion. For example, adrenalin, the hormone produced in high-stress situations, is available in a 1:1000 solution, or one gram of adrenalin per 1000 g of solution.

The labels on bottles of commercial reagents often describe the contents in terms of mass percentage. Sulfuric acid, for example, is sold as a 95% aqueous solution, or 95 g of H₂SO₄ per 100 g of solution. Parts per million and parts per billion are used to describe concentrations of highly dilute solutions. These measurements correspond to milligrams and micrograms of solute per kilogram of solution, respectively. For dilute aqueous solutions, this is equal to milligrams and micrograms of solute per liter of solution (assuming a density of 1.0 g/mL).

Example 13.3.2

Several years ago, millions of bottles of mineral water were contaminated with benzene at ppm levels. This incident received a great deal of attention because the lethal concentration of benzene in rats is 3.8 ppm. A 250 mL sample of mineral water has 13.7 ppm of benzene. Because the contaminated mineral water is a very dilute aqueous solution, we can assume that its density is approximately 1.00 g/mL.

1. What is the molarity of the solution?
2. What is the mass of benzene in the sample?

Given: volume of sample, solute concentration, and density of solution

Asked for: molarity of solute and mass of solute in 250 mL

Strategy:

A Use the concentration of the solute in parts per million to calculate the molarity.

B Use the concentration of the solute in parts per million to calculate the mass of the solute in the specified volume of solution.

Solution:

1. **A** To calculate the molarity of benzene, we need to determine the number of moles of benzene in 1 L of solution. We know that the solution contains 13.7 ppm of benzene. Because 13.7 ppm is equivalent to 13.7 mg/1000 g of solution and the density of the solution is 1.00 g/mL, the solution contains 13.7 mg of benzene per liter (1000 mL). The molarity is therefore

$$\text{molarity} = \frac{\text{moles}}{\text{liter}} = \frac{(12.7 \text{ mg}) \left(1 \text{ g}/1000 \text{ mg}\right) \left(1 \text{ mol}/78.114 \text{ g}\right)}{1000 \text{ mL}} = 1.63 \times 10^{-4} \text{ M}$$

2. **B** We are given that there are 13.7 mg of benzene per 1000 g of solution, which is equal to 13.7 mg/L of solution. Hence the mass of benzene in 250 mL (250 g) of solution is

$$\text{mass of benzene} = \frac{(12.7 \text{ mg benzene}) (250 \text{ mL})}{1000 \text{ mL}} = 3.18 \text{ mg benzene}$$

Exercise

The maximum allowable concentration of lead in drinking water is 9.0 ppb. What is the molarity of Pb²⁺ in a 9.0 ppb aqueous solution? Use your calculated concentration to determine how many grams of Pb²⁺ are in an 8 oz glass of water.

Answer: 4.3×10^{-8} M; 2×10^{-6} g

How do chemists decide which units of concentration to use for a particular application? Although molarity is commonly used to express concentrations for reactions in solution or for titrations, it does have one drawback—molarity is the number of moles of solute divided by the volume of the solution, and the volume of a solution depends on its density, which is a function of temperature. Because volumetric glassware is calibrated at a particular temperature, typically 20°C, the molarity may differ from the original value by several percent if a solution is prepared or used at a significantly different temperature, such as 40°C or 0°C. For many applications this may not be a problem, but for precise work these errors can become important. In contrast, mole fraction, molality, and mass percentage depend on only the masses of the solute and solvent, which are independent of temperature.

Mole fraction is not very useful for experiments that involve quantitative reactions, but it is convenient for calculating the partial pressure of gases in mixtures, as we saw in [Chapter 10](#). As you will learn in [Section 13.5](#), mole fractions are also useful for calculating the vapor pressures of certain types of solutions. Molality is particularly useful for determining how properties such as the freezing or boiling point of a solution vary with solute concentration. Because mass percentage and parts per million or billion are simply different ways of expressing the ratio of the mass of a solute to the mass of the solution, they enable us to express the concentration of a substance even when the molecular mass of the substance is unknown. Units of ppb or ppm are also used to express very low concentrations, such as those of residual impurities in foods or of pollutants in environmental studies.

[Table 13.3.1](#) summarizes the different units of concentration and typical applications for each. When the molar mass of the solute and the density of the solution are known, it becomes relatively easy with practice to convert among the units of concentration we have discussed, as illustrated in [Example 6](#).

Table 13.3.1 Different Units for Expressing the Concentrations of Solutions*

Unit	Definition	Application
molarity (M)	moles of solute/liter of solution (mol/L)	Used for quantitative reactions in solution and titrations; mass and molecular mass of solute and volume of solution are known.
mole fraction (<i>X</i>)	moles of solute/total moles present (mol/mol)	Used for partial pressures of gases and vapor pressures of some solutions; mass and molecular mass of each component are known.
molality (<i>m</i>)	moles of solute/kg of solvent (mol/kg)	Used in determining how colligative properties vary with solute concentration; masses and molecular mass of solute are known.
mass percentage (%)	$[\text{mass of solute (g)}/\text{mass of solution (g)}] \times 100$	Useful when masses are known but molecular masses are unknown.
parts per thousand (ppt)	$[\text{mass of solute}/\text{mass of solution}] \times 10^3$ (g solute/kg solution)	Used in the health sciences, ratio solutions are typically expressed as a proportion, such as 1:1000.
parts per million (ppm)	$[\text{mass of solute}/\text{mass of solution}] \times 10^6$ (mg solute/kg solution)	Used for trace quantities; masses are known but molecular masses may be unknown.
parts per billion (ppb)	$[\text{mass of solute}/\text{mass of solution}] \times 10^9$ (µg solute/kg solution)	Used for trace quantities; masses are known but molecular masses may be unknown.

***The molarity of a solution is temperature dependent, but the other units shown in this table are independent of temperature.**

Example 13.3.3

Vodka is essentially a solution of pure ethanol in water. Typical vodka is sold as “80 proof,” which means that it contains 40.0% ethanol by volume. The density of pure ethanol is 0.789 g/mL at 20°C. If we assume that the volume of the solution is the sum of the volumes of the components (which is not strictly correct), calculate the following for the ethanol in 80-proof vodka.

1. the mass percentage
2. the mole fraction
3. the molarity
4. the molality

Given: volume percent and density

Asked for: mass percentage, mole fraction, molarity, and molality

Strategy:

A Use the density of the solute to calculate the mass of the solute in 100.0 mL of solution. Calculate the mass of water in 100.0 mL of solution.

B Determine the mass percentage of solute by dividing the mass of ethanol by the mass of the solution and multiplying by 100.

C Convert grams of solute and solvent to moles of solute and solvent. Calculate the mole fraction of solute by dividing the moles of solute by the total number of moles of substances present in solution.

D Calculate the molarity of the solution: moles of solute per liter of solution. Determine the molality of the solution by dividing the number of moles of solute by the kilograms of solvent.

Solution:

The key to this problem is to use the density of pure ethanol to determine the mass of ethanol ($\text{CH}_3\text{CH}_2\text{OH}$), abbreviated as EtOH, in a given volume of solution. We can then calculate the number of moles of ethanol and the concentration of ethanol in any of the required units.

A Because we are given a percentage by volume, we assume that we have 100.0 mL of solution. The volume of ethanol will thus be 40.0% of 100.0 mL, or 40.0 mL of ethanol, and the volume of water will be 60.0% of 100.0 mL, or 60.0 mL of water. The mass of ethanol is obtained from its density:

$$\text{mass of EtOH} = (40.0 \text{ mL}) \left(\frac{0.789 \text{ g}}{\text{mL}} \right) = 31.6 \text{ g EtOH}$$

If we assume the density of water is 1.00 g/mL, the mass of water is 60.0 g. We now have all the information we need to calculate the concentration of ethanol in the solution.

B The mass percentage of ethanol is the ratio of the mass of ethanol to the total mass of the solution, expressed as a percentage:

$$\% \text{ EtOH} = \left(\frac{\text{mass EtOH}}{\text{mass of solution}} \right) (100) = \left(\frac{31.6 \text{ g EtOH}}{31.6 \text{ g EtOH} + 60.0 \text{ g H}_2\text{O}} \right) (100) = 34.5 \%$$

C The mole fraction of ethanol is the ratio of the number of moles of ethanol to the total number of moles of substances in the solution. Because 40.0 mL of ethanol has a mass of 31.6 g, we can use the molar mass of ethanol (46.07 g/mol) to determine the number of moles of ethanol in 40.0 mL:

$$\text{moles EtOH} = (31.6 \text{ g EtOH}) \left(\frac{1 \text{ mol}}{46.07 \text{ g EtOH}} \right) = 0.686 \text{ mol EtOH}$$

Similarly, the number of moles of water is

$$\text{moles } H_2O = \left(60.0 \text{ g } \cancel{H_2O} \right) \left(\frac{1 \text{ mol}}{18.02 \text{ g } \cancel{H_2O}} \right) = 3.33 \text{ mol } H_2O$$

The mole fraction of ethanol is thus

$$X_{EtOH} = \left(\frac{0.686 \text{ mol}}{0.686 \text{ mol} + 3.33 \text{ mol}} \right) = 0.171$$

D The molarity of the solution is the number of moles of ethanol per liter of solution. We already know the number of moles of ethanol per 100.0 mL of solution, so the molarity is

$$M_{EtOH} = \left(\frac{0.686 \text{ mol}}{100 \text{ mL}} \right) \left(\frac{1000 \text{ mL}}{L} \right) = 6.86 \text{ M}$$

The molality of the solution is the number of moles of ethanol per kilogram of solvent. Because we know the number of moles of ethanol in 60.0 g of water, the calculation is again straightforward:

$$m_{EtOH} = \left(\frac{0.686 \text{ mol } EtOH}{60.0 \text{ g } H_2O} \right) \left(\frac{1000 \text{ g}}{kg} \right) = \frac{11.4 \text{ mol } EtOH}{kg \text{ } H_2O} = 11.46.86 \text{ m}$$

Exercise

A solution is prepared by mixing 100.0 mL of toluene with 300.0 mL of benzene. The densities of toluene and benzene are 0.867 g/mL and 0.874 g/mL, respectively. Assume that the volume of the solution is the sum of the volumes of the components. Calculate the following for toluene.

1. mass percentage
2. mole fraction
3. molarity
4. molality

Answer:

1. mass percentage toluene = 24.8%
2. $X_{\text{toluene}} = 0.219$
3. 2.35 M toluene
4. 3.59 m toluene

Summary

The **concentration** of a solution is the quantity of solute in a given quantity of solution. It can be expressed in several ways: molarity (moles of solute per liter of solution); *mole fraction*, the ratio of the number of moles of solute to the total number of moles of substances present; **mass percentage**, the ratio of the mass of the solute to the mass of the solution times 100; **parts per thousand (ppt)**, grams of solute per kilogram of solution; **parts per million (ppm)**, milligrams of solute per kilogram of solution; **parts per billion (ppb)**, micrograms of solute per kilogram of solution; and **molality (m)**, the number of moles of solute per kilogram of solvent.

Key Takeaway

- Different units are used to express the concentrations of a solution depending on the application.

Key Equations

molality

Equation 13.3.1:

$$\text{molality } (m) = \frac{(\text{moles solute})}{(\text{kilograms solvent})}$$

mass percentage

Equation 13.3.2:

$$\text{mass percentage} = \frac{(\text{mass of solute})}{(\text{mass of solution})} \times 100$$

parts per million

Equation 13.3.3:

$$\text{parts per million } (ppm) = \frac{(\text{mass of solute})}{(\text{mass of solution})} \times 10^6$$

Equation 13.3.4:

$$\text{parts per billion } (ppb) = \frac{(\text{mass of solute})}{(\text{mass of solution})} \times 10^9$$

Conceptual Problems

1. Does the molality have the same numerical value as the molarity for a highly concentrated aqueous solution of fructose ($\text{C}_6\text{H}_{12}\text{O}_6$) (approximately 3.2 M)? Why or why not?
2. Explain why the molality and molarity of an aqueous solution are not always numerically identical. Will the difference between the two be greater for a dilute or a concentrated solution? Explain your answer.
3. Under what conditions are molality and molarity likely to be equal? Is the difference between the two greater when water is the solvent or when the solvent is not water? Why?
4. What is the key difference between using mole fraction or molality versus molarity to describe the concentration of a solution? Which unit(s) of concentration is most appropriate for experiments that must be carried out at several different temperatures?
5. An experiment that relies on very strict control of the reaction stoichiometry calls for adding 50.0 mL of a 0.95 M solution of A to 225 mL of a 1.01 M solution of B, followed by heating for 1 h at 60°C. To save time, a student decided to heat solution B to 60°C *before* measuring out 225 mL of solution B, transferring it to the flask containing solution A, and proceeding normally. This change in procedure caused the yield of product to be less than usual. How could such an apparently minor change in procedure have resulted in a decrease in the yield?

Numerical Problems

1. Complete the following table for aqueous solutions of the compounds given.

Compound	Molarity (M)	Solution Density (g/mL)	Mole Fraction (X)

Compound	Molarity (M)	Solution Density (g/mL)	Mole Fraction (X)
H ₂ SO ₄	18.0	1.84	7.21×10^{-3}
CH ₃ COOH		1.00	
KOH	3.60	1.16	

2. Complete the following table for each compound given.

Compound	Mass (g)	Volume of Solution (mL)	Molarity (M)
Na ₂ SO ₄	7.80	225	
KNO ₃		125	1.27
NaO ₂ CCH ₃	18.64		0.95

- How would you prepare 100.0 mL of an aqueous solution with 0.40 M KI? a solution with 0.65 M NaCN?
- Calculate the molality of a solution with 775 mg of NaCl in 500.0 g of water. Do you expect the molarity to be the same as the molality? Why or why not?
- What is the molarity of each solution?
 - 12.8 g of glucose (C₆H₁₂O₆) in water, total volume 150.0 mL
 - 9.2 g of Na₃PO₄ in water, total volume 200.0 mL
 - 843 mg of I₂ in EtOH, total volume 150.0 mL
- A medication used to treat abnormal heart rhythms is labeled "Procainamide 0.5 g/250 cc." Express this concentration in parts per thousand.
- Meperidine is a medication used for pain relief. A bottle of meperidine is labeled as 50 mg/mL. Express this concentration in parts per thousand.
- An aqueous solution that is 4.61% NaOH by mass has a density of 1.06 g/mL. Calculate the molarity of the solution, the mole fraction of NaOH, and the molality of the solution.
- A solution of concentrated phosphoric acid contains 85.0% H₃PO₄ by mass and has a density of 1.684 g/mL. Calculate the following.
 - the molarity of the solution
 - the mole fraction of H₃PO₄
 - the molality of the solution
- A solution of commercial concentrated nitric acid is 16 M HNO₃ and has a density of 1.42 g/mL. What is the percentage of HNO₃ in the solution by mass? What is the molality?
- A commercial aqueous ammonia solution contains 28.0% NH₃ by mass and has a density of 0.899 g/mL. Calculate the following.
 - the molarity
 - the mole fraction
- Concentrated, or glacial, acetic acid is pure acetic acid and has a density of 1.053 g/mL. It is widely used in organic syntheses, in the manufacture of rayon and plastics, as a preservative in foods, and occasionally to treat warts. What volume of glacial acetic acid is required to prepare 5.00 L of a 1.75 M solution of acetic acid in ethanol?
- Solutions of sodium carbonate decahydrate, also known as washing soda, are used as skin cleansers. The solubility of this compound in cold water is 21.52 g/100 mL. If a saturated solution has a density of 1.20 g/mL, what is its molarity? What is the mole fraction of sodium carbonate decahydrate in this solution?
- Hydrogen peroxide (H₂O₂) is usually sold over the counter as an aqueous solution that is 3% by mass. Assuming a solution density of 1.01 g/mL, what is the molarity of hydrogen peroxide? What is the molar concentration of a solution that is 30% hydrogen peroxide by mass (density = 1.112 g/mL)? How would you prepare 100.0 mL of a 3% solution from the 30% solution?
- Determine the concentration of a solution with 825 mg of Na₂HPO₄ dissolved in 450.0 mL of H₂O at 20°C in molarity, molality, mole fraction, and parts per million. Assume that the density of the solution is the same as that of water. Which unit

of concentration is most convenient for calculating vapor pressure changes? Why?

16. How many moles of Cl^- are there in 25.0 mL of a 0.15 M CaCl_2 solution?
17. How many moles of Na^+ are there in 25.0 g of a $1.33 \times 10^{-3} \text{ m}$ Na_2HPO_4 solution? What is the sodium concentration of this solution in ppb?
18. How many grams of copper are there in 30.0 mL of a 0.100 M CuSO_4 solution?
19. How many grams of nitrate ion are there in 75.0 g of a $1.75 \times 10^{-3} \text{ m}$ $\text{Pb}(\text{NO}_3)_2$ solution? What is the nitrate concentration of the solution in ppb?
20. How many milliliters of a 0.750 M solution of K_2CrO_4 are required to deliver 250 mg of chromate ion?
21. How many milliliters of a $1.95 \times 10^{-3} \text{ M}$ solution of Ag_3PO_4 are required to deliver 14.0 mg of Ag^+ ?
22. Iron reacts with bromine according to the following equation:

$$2\text{Fe}(\text{s}) + 3\text{Br}_2(\text{aq}) \rightarrow 2\text{FeBr}_3(\text{aq})$$
 How many milliliters of a $5.0 \times 10^{-2} \text{ M}$ solution of bromine in water are required to react completely with 750.0 mg of iron metal?
23. Aluminum reacts with HCl according to the following equation:

$$2\text{Al}(\text{s}) + 6\text{HCl}(\text{aq}) \rightarrow 2\text{AlCl}_3(\text{aq}) + 3\text{H}_2(\text{g})$$
 If 25.0 mL of a solution of HCl in water is required to react completely with 1.05 g of aluminum metal, what is the molarity of the HCl solution?
24. The precipitation of silver chloride is a diagnostic test for the presence of chloride ion. If 25.0 mL of 0.175 M AgNO_3 are required to completely precipitate the chloride ions from 10.0 mL of an NaCl solution, what was the original concentration of NaCl?
25. Barium sulfate is virtually insoluble. If a 10.0 mL solution of 0.333 M $\text{Ba}(\text{NO}_3)_2$ is stirred with 40.0 mL of a 0.100 M Na_2SO_4 , how many grams of barium sulfate will precipitate? Which reactant is present in excess? What is its final concentration?

Answers

1.

Compound	Molarity (M)	Solution Density (g/mL)	Mole Fraction (X)
H_2SO_4	18.0	1.84	0.82
CH_3COOH	0.393	1.00	7.21×10^{-3}
KOH	3.60	1.16	6.33×10^{-2}

2.

3. 100.0 ml of 0.40 M KI: dissolve 6.64 g of KI in enough water to make 100.0 mL of solution; 100.0 ml of 0.65 M NaCN: dissolve 3.18 g of NaCN in enough water to make 100.0 mL of solution.

Learning Objectives

- To understand the relationship among temperature, pressure, and solubility.

Experimentally it is found that the solubility of most compounds depends strongly on temperature and, if a gas, on pressure as well. As we shall see, the ability to manipulate the solubility by changing the temperature and pressure has several important consequences.

Effect of Temperature on the Solubility of Solids

Figure 13.4.1 shows plots of the solubilities of several organic and inorganic compounds in water as a function of temperature. Although the solubility of a solid generally increases with increasing temperature, there is no simple relationship between the structure of a substance and the temperature dependence of its solubility. Many compounds (such as glucose and $\text{CH}_3\text{CO}_2\text{Na}$) exhibit a dramatic increase in solubility with increasing temperature. Others (such as NaCl and K_2SO_4) exhibit little variation, and still others (such as Li_2SO_4) become less soluble with increasing temperature.

Figure 13.4.1 Solubilities of Several Inorganic and Organic Solids in Water as a Function of Temperature Solubility may increase or decrease with temperature; the magnitude of this temperature dependence varies widely among compounds.

Notice in particular the curves for NH_4NO_3 and CaCl_2 . The dissolution of ammonium nitrate in water is endothermic ($\Delta H_{\text{soln}} = +25.7 \text{ kJ/mol}$), whereas the dissolution of calcium chloride is exothermic ($\Delta H_{\text{soln}} = -68.2 \text{ kJ/mol}$), yet Figure 13.4.1 shows that the solubility of both compounds increases sharply with increasing temperature. In fact, the magnitudes of the changes in both enthalpy and entropy for dissolution are temperature dependent. Because the solubility of a compound is ultimately determined by relatively small differences between large numbers, there is generally no good way to predict how the solubility will vary with temperature.

The variation of solubility with temperature has been measured for a wide range of compounds, and the results are published in many standard reference books. Chemists are often able to use this information to separate the components of a mixture by fractional crystallization, the separation of compounds on the basis of their solubilities in a given solvent. For example, if we have a

mixture of 150 g of sodium acetate ($\text{CH}_3\text{CO}_2\text{Na}$) and 50 g of KBr , we can separate the two compounds by dissolving the mixture in 100 g of water at 80°C and then cooling the solution slowly to 0°C . According to the temperature curves in [Figure 13.4.1](#), both compounds dissolve in water at 80°C , and all 50 g of KBr remains in solution at 0°C . Only about 36 g of $\text{CH}_3\text{CO}_2\text{Na}$ are soluble in 100 g of water at 0°C , however, so approximately 114 g ($150\text{ g} - 36\text{ g}$) of $\text{CH}_3\text{CO}_2\text{Na}$ crystallizes out on cooling. The crystals can then be separated by filtration. Thus fractional crystallization allows us to recover about 75% of the original $\text{CH}_3\text{CO}_2\text{Na}$ in essentially pure form in only one step.

Fractional crystallization is a common technique for purifying compounds as diverse as those shown in [Figure 13.4.1](#) and from antibiotics to enzymes. For the technique to work properly, the compound of interest must be more soluble at high temperature than at low temperature, so that lowering the temperature causes it to crystallize out of solution. In addition, the impurities must be *more* soluble than the compound of interest (as was KBr in this example) and preferably present in relatively small amounts.

Effect of Temperature on the Solubility of Gases

The solubility of gases in liquids decreases with increasing temperature, as shown in [Figure 13.4.2](#). Attractive intermolecular interactions in the gas phase are essentially zero for most substances. When a gas dissolves, it does so because its molecules interact with solvent molecules. Because heat is released when these new attractive interactions form, dissolving most gases in liquids is an exothermic process ($\Delta H_{\text{soln}} < 0$). Conversely, adding heat to the solution provides thermal energy that overcomes the attractive forces between the gas and the solvent molecules, thereby decreasing the solubility of the gas. The phenomenon is similar to that involved in the increase in vapor pressure of a pure liquid with increasing temperature, as discussed in [Chapter 11](#). In the case of vapor pressure, however, it is attractive forces between *solvent* molecules that are being overcome by the added thermal energy when the temperature is increased.

The decrease in the solubilities of gases at higher temperatures has both practical and environmental implications. Anyone who routinely boils water in a teapot or electric kettle knows that a white or gray deposit builds up on the inside and must eventually be removed. The same phenomenon occurs on a much larger scale in the giant boilers used to supply hot water or steam for industrial applications, where it is called “boiler scale,” a deposit that can seriously decrease the capacity of hot water pipes ([Figure 13.11](#)). The problem is not a uniquely modern one: aqueducts that were built by the Romans 2000 years ago to carry cold water from alpine regions to warmer, drier regions in southern France were clogged by similar deposits. The chemistry behind the formation of these deposits is moderately complex and will be described in more detail in [Chapter 17](#), but the driving force is the loss of dissolved CO_2 from solution. Hard water contains dissolved Ca^{2+} and HCO_3^- (bicarbonate) ions. Calcium bicarbonate [$\text{Ca}(\text{HCO}_3)_2$] is rather soluble in water, but calcium carbonate (CaCO_3) is quite insoluble. A solution of bicarbonate ions can react to form carbon dioxide, carbonate ion, and water:

Heating the solution decreases the solubility of CO_2 , which escapes into the gas phase above the solution. In the presence of calcium ions, the carbonate ions precipitate as insoluble calcium carbonate, the major component of boiler scale.

In *thermal pollution*, lake or river water that is used to cool an industrial reactor or a power plant is returned to the environment at a higher temperature than normal. Because of the reduced solubility of O_2 at higher temperatures ([Figure 2.4.2](#)), the warmer water contains less dissolved oxygen than the water did when it entered the plant. Fish and other aquatic organisms that need dissolved oxygen to live can literally suffocate if the oxygen concentration of their habitat is too low. Because the warm, oxygen-depleted water is less dense, it tends to float on top of the cooler, denser, more oxygen-rich water in the lake or river, forming a barrier that prevents atmospheric oxygen from dissolving. Eventually even deep lakes can be suffocated if the problem is not corrected. Additionally, most fish and other nonmammalian aquatic organisms are cold-blooded, which means that their body temperature is the same as the temperature of their environment. Temperatures substantially greater than the normal range can lead to severe stress or even death.

Figure 13.4.2 Solubilities of Several Common Gases in Water as a Function of Temperature at Partial Pressure of 1 atm The solubilities of all gases decrease with increasing temperature.

Figure 13.4.3 Boiler Scale in a Water Pipe Calcium carbonate (CaCO_3) deposits in hot water pipes can significantly reduce pipe

Cooling systems for power plants and other facilities must be designed to minimize any adverse effects on the temperatures of surrounding bodies of water.

A similar effect is seen in the rising temperatures of bodies of water such as the Chesapeake Bay, the largest estuary in North America, where global warming has been implicated as the cause. For each 1.5°C that the bay's water warms, the capacity of water to dissolve oxygen decreases by about 1.1%. Many marine species that are at the southern limit of their distributions have shifted their populations farther north. In 2005, the eelgrass, which forms an important nursery habitat for fish and shellfish, disappeared from much of the bay following record high water temperatures. Presumably, decreased oxygen levels decreased populations of clams and other filter feeders, which then decreased light transmission to allow the eelgrass to grow. The complex relationships in ecosystems such as the Chesapeake Bay are especially sensitive to temperature fluctuations that cause a deterioration of habitat quality.

capacity. These deposits, called boiler scale, form when dissolved CO_2 is driven into the gas phase at high temperatures.

Effect of Pressure on the Solubility of Gases: Henry's Law

External pressure has very little effect on the solubility of liquids and solids. In contrast, the solubility of gases increases as the partial pressure of the gas above a solution increases. This point is illustrated in Figure 13.4.4 which shows the effect of increased pressure on the dynamic equilibrium that is established between the dissolved gas molecules in solution and the molecules in the gas phase above the solution. Because the concentration of molecules in the gas phase increases with increasing pressure, the concentration of dissolved gas molecules in the solution at equilibrium is also higher at higher pressures.

Figure 13.4.4 A Model Depicting Why the Solubility of a Gas Increases as the Partial Pressure Increases at Constant Temperature (a) When a gas comes in contact with a pure liquid, some of the gas molecules (purple spheres) collide with the surface of the liquid and dissolve. When the concentration of dissolved gas molecules has increased so that the rate at which gas molecules escape into the gas phase is the same as the rate at which they dissolve, a dynamic equilibrium has been established, as depicted here. This equilibrium is entirely analogous to the one that maintains the vapor pressure of a liquid. (For more information on vapor pressure, see Section 11.3) (b) Increasing the pressure of the gas increases the number of molecules of gas per unit volume, which increases the rate at which gas molecules collide with the surface of the liquid and dissolve. (c) As additional gas molecules dissolve at the higher pressure, the concentration of dissolved gas increases until a new dynamic equilibrium is established.

The relationship between pressure and the solubility of a gas is described quantitatively by Henry's law, which is named for its discoverer, the English physician and chemist, William Henry (1775–1836):

$$C = kP \quad (13.4.2)$$

where C is the concentration of dissolved gas at equilibrium, P is the partial pressure of the gas, and k is the Henry's law constant, which must be determined experimentally for each combination of gas, solvent, and temperature. Although the gas concentration may be expressed in any convenient units, we will use molarity exclusively. The units of the Henry's law constant are therefore $\text{mol}/(\text{L}\cdot\text{atm}) = \text{M}/\text{atm}$. Values of the Henry's law constants for solutions of several gases in water at 20°C are listed in Table 13.4.1.

As the data in Table 13.4.1 demonstrate, the concentration of a dissolved gas in water at a given pressure depends strongly on its physical properties. For a series of related substances, London dispersion forces increase as molecular mass increases. Thus among the elements of group 18, the Henry's law constants increase smoothly from He to Ne to Ar. The table also shows that O_2 is almost twice as soluble as N_2 . Although London dispersion forces are too weak to explain such a large difference, O_2 is paramagnetic and hence more polarizable than N_2 , which explains its high solubility.

Table 13.4.1 Henry's Law Constants for Selected Gases in Water at 20°C

Gas	Henry's Law Constant [mol/(L·atm)] × 10 ⁻⁴
He	3.9
Ne	4.7
Ar	15
H ₂	8.1
N ₂	7.1
O ₂	14
CO ₂	392

Gases that react chemically with water, such as HCl and the other hydrogen halides, H₂S, and NH₃, do not obey Henry's law; all of these gases are much more soluble than predicted by Henry's law. For example, HCl reacts with water to give H⁺(aq) and Cl⁻(aq), *not* dissolved HCl molecules, and its dissociation into ions results in a much higher solubility than expected for a neutral molecule.

Note the Pattern

Gases that react with water do not obey Henry's law.

Henry's law has important applications. For example, bubbles of CO₂ form as soon as a carbonated beverage is opened because the drink was bottled under CO₂ at a pressure greater than 1 atm. When the bottle is opened, the pressure of CO₂ above the solution drops rapidly, and some of the dissolved gas escapes from the solution as bubbles. Henry's law also explains why scuba divers have to be careful to ascend to the surface slowly after a dive if they are breathing compressed air. At the higher pressures under water, more N₂ from the air dissolves in the diver's internal fluids. If the diver ascends too quickly, the rapid pressure change causes small bubbles of N₂ to form throughout the body, a condition known as "the bends." These bubbles can block the flow of blood through the small blood vessels, causing great pain and even proving fatal in some cases.

Due to the low Henry's law constant for O₂ in water, the levels of dissolved oxygen in water are too low to support the energy needs of multicellular organisms, including humans. To increase the O₂ concentration in internal fluids, organisms synthesize highly soluble carrier molecules that bind O₂ reversibly. For example, human red blood cells contain a protein called hemoglobin that specifically binds O₂ and facilitates its transport from the lungs to the tissues, where it is used to oxidize food molecules to provide energy. The concentration of hemoglobin in normal blood is about 2.2 mM, and each hemoglobin molecule can bind four O₂ molecules. Although the concentration of dissolved O₂ in blood serum at 37°C (normal body temperature) is only 0.010 mM, the total dissolved O₂ concentration is 8.8 mM, almost a thousand times greater than would be possible without hemoglobin. Synthetic oxygen carriers based on fluorinated alkanes have been developed for use as an emergency replacement for whole blood. Unlike donated blood, these "blood substitutes" do not require refrigeration and have a long shelf life. Their very high Henry's law constants for O₂ result in dissolved oxygen concentrations comparable to those in normal blood.

Example 13.4.1

The Henry's law constant for O₂ in water at 25°C is 1.27×10^{-3} M/atm, and the mole fraction of O₂ in the atmosphere is 0.21. Calculate the solubility of O₂ in water at 25°C at an atmospheric pressure of 1.00 atm.

Given: Henry's law constant, mole fraction of O₂, and pressure

Asked for: solubility

Strategy:

A Use Dalton's law of partial pressures to calculate the partial pressure of oxygen. (For more information about Dalton's law of partial pressures, see [Section 10.5](#).)

B Use Henry's law to calculate the solubility, expressed as the concentration of dissolved gas.

Solution:

A According to Dalton's law, the partial pressure of O₂ is proportional to the mole fraction of O₂:

$$P_A = X_A P_t = (0.21)(1.00 \text{ atm}) = 0.21 \text{ atm}$$

B From Henry's law, the concentration of dissolved oxygen under these conditions is

$$C_{O_2} = k P_{O_2} \left(1.27 \times 10^{-3} \text{ M/atm} \right) (0.21 \text{ atm}) = 2.7 \times 10^{-4} \text{ M}$$

Exercise

To understand why soft drinks “fizz” and then go “flat” after being opened, calculate the concentration of dissolved CO₂ in a soft drink

1. bottled under a pressure of 5.0 atm of CO₂.
2. in equilibrium with the normal partial pressure of CO₂ in the atmosphere (approximately 3×10^{-4} atm).

The Henry's law constant for CO₂ in water at 25°C is 3.4×10^{-2} M/atm.

Answer:

1. 0.17 M
2. 1×10^{-5} M

Summary

The solubility of most substances depends strongly on the temperature and, in the case of gases, on the pressure. The solubility of most solid or liquid solutes increases with increasing temperature. The components of a mixture can often be separated using **fractional crystallization**, which separates compounds according to their solubilities. The solubility of a gas decreases with increasing temperature. **Henry's law** describes the relationship between the pressure and the solubility of a gas.

Key Takeaway

- The solubility of a solid may increase or decrease with increasing temperature, whereas the solubility of a gas decreases with an increase in temperature and a decrease in pressure.

Conceptual Problems

1. Use the kinetic molecular theory of gases discussed in [Chapter 10](#) to explain why the solubility of virtually all gases in liquids decreases with increasing temperature.
2. An industrial plant uses water from a nearby stream to cool its reactor and returns the water to the stream after use. Over a period of time, dead fish start to appear downstream from the plant, but there is no evidence for any leaks of potentially toxic chemicals into the stream. What other factor might be causing the fish to die?
3. One manufacturer's instructions for setting up an aquarium specify that if boiled water is used, the water must be cooled to room temperature and allowed to stand overnight before fish are added. Why is it necessary for the water to stand?
4. Using a carbonated beverage as an example, discuss the effect of temperature on the “fizz.” How does the “foaminess” of a carbonated beverage differ between Los Angeles, California, and Denver, Colorado?
5. A common laboratory technique for degassing a solvent is to place it in a flask that is sealed to the atmosphere and then evacuate the flask to remove any gases above the liquid. Why is this procedure effective? Why does the temperature of the solvent usually decrease substantially during this process?

Answers

- 1.
- 2.
3. When water is boiled, all of the dissolved oxygen and nitrogen are removed. When the water is cooled to room temperature, it initially contains very little dissolved oxygen. Allowing the water to stand overnight allows oxygen in the air to dissolve, so that the fish will not suffocate.
- 4.
5. Evacuating the flask to remove gases decreases the partial pressure of oxygen above the solution. According to Henry's law, the solubility of any gas decreases as its partial pressure above the solution decreases. Consequently, dissolved oxygen escapes from solution into the gas phase, where it is removed by the vacuum pump. Filling the flask with nitrogen gas and repeating this process several times effectively removes almost all of the dissolved oxygen. The temperature of the solvent decreases because some solvent evaporates as well during this process. The heat that is required to evaporate some of the liquid is initially removed from the rest of the solvent, decreasing its temperature.

Numerical Problems

1. The solubility of CO₂ in water at 0°C and 1 atm is 0.335 g/100 g of H₂O. At 20°C and 1 atm, the solubility of CO₂ in water is 0.169 g/100 g of H₂O.
 - a. What volume of CO₂ would be released by warming 750 g of water saturated with CO₂ from 0°C to 20°C?
 - b. What is the value of the Henry's law constant for CO₂ under each set of conditions?
2. The solubility of O₂ in 100 g of H₂O at varying temperatures and a pressure of 1 atm is given in the following table:

Solubility (g)	Temperature (°C)
0.0069	0
0.0054	10
0.0043	20

- a. What is the value of the Henry's law constant at each temperature?
- b. Does Henry's law constant increase or decrease with increasing temperature?
- c. At what partial pressure of O₂ would the concentration of O₂ in water at 0°C be the same as the concentration in water at 20°C at a partial pressure of 1 atm?
- d. Assuming that air is 20% O₂ by volume, at what atmospheric pressure would the O₂ concentration be the same at 20°C as it is at atmospheric pressure and 0°C?

Answer

1.
 - a. 0.678 L CO₂
 - b. $k_{0^{\circ}\text{C}} = 7.61 \times 10^{-2} \text{ M/atm}$, $k_{20^{\circ}\text{C}} = 3.84 \times 10^{-2} \text{ M/atm}$
- 2.

Learning Objective

- To describe the relationship between solute concentration and the physical properties of a solution.

Many of the physical properties of solutions differ significantly from those of the pure substances discussed in earlier chapters, and these differences have important consequences. For example, the limited temperature range of liquid water (0°C–100°C) severely limits its use. Aqueous solutions have both a lower freezing point and a higher boiling point than pure water. Probably one of the most familiar applications of this phenomenon is the addition of ethylene glycol (“antifreeze”) to the water in an automobile radiator. This solute lowers the freezing point of the water, preventing the engine from cracking in very cold weather from the expansion of pure water on freezing. Antifreeze also enables the cooling system to operate at temperatures greater than 100°C without generating enough pressure to explode.

Changes in the freezing point and boiling point of a solution depend primarily on the *number* of solute particles present rather than the *kind* of particles. Such properties of solutions are called colligative properties (from the Latin *colligatus*, meaning “bound together” as in a quantity). As we will see, the vapor pressure and osmotic pressure of solutions are also colligative properties.

When we determine the number of particles in a solution, it is important to remember that not all solutions with the same molarity contain the same concentration of solute particles. Consider, for example, 0.01 M aqueous solutions of sucrose, NaCl, and CaCl₂. Because sucrose dissolves to give a solution of neutral molecules, the concentration of solute particles in a 0.01 M sucrose solution is 0.01 M. In contrast, both NaCl and CaCl₂ are ionic compounds that dissociate in water to yield solvated ions. As a result, a 0.01 M aqueous solution of NaCl contains 0.01 M Na⁺ ions and 0.01 M Cl⁻ ions, for a total particle concentration of 0.02 M. Similarly, the CaCl₂ solution contains 0.01 M Ca²⁺ ions and 0.02 M Cl⁻ ions, for a total particle concentration of 0.03 M. These values are correct for dilute solutions, where the dissociation of the compounds to form separately solvated ions is complete. At higher concentrations (typically >1 M), especially with salts of small, highly charged ions (such as Mg²⁺ or Al³⁺), or in solutions with less polar solvents, dissociation to give separate ions is often incomplete (see [Figure 13.21 "Ion Pairs"](#)). The sum of the concentrations of the dissolved solute particles dictates the physical properties of a solution. In the following discussion, we must therefore keep the chemical nature of the solute firmly in mind.

Vapor Pressure of Solutions and Raoult's Law

Adding a nonvolatile solute, one whose vapor pressure is too low to measure readily, to a volatile solvent decreases the vapor pressure of the solvent. We can understand this phenomenon qualitatively by examining [Figure 13.5.1](#), which is a schematic diagram of the surface of a solution of glucose in water. In an aqueous solution of glucose, a portion of the surface area is occupied by nonvolatile glucose molecules rather than by volatile water molecules. As a result, fewer water molecules can enter the vapor phase per unit time, even though the surface water molecules have the same kinetic energy distribution as they would in pure water. At the same time, the rate at which water molecules in the vapor phase collide with the surface and reenter the solution is unaffected. The net effect is to shift the dynamic equilibrium between water in the vapor and the liquid phases, decreasing the vapor pressure of the solution compared with the vapor pressure of the pure solvent.

Figure 13.5.1 A Model Depicting Why the Vapor Pressure of a Solution of Glucose Is Less Than the Vapor Pressure of Pure Water (a) When water or any volatile solvent is in a closed container, water molecules move into and out of the liquid phase at the same rate in a dynamic equilibrium. (b) If a nonvolatile solute such as glucose is added, some fraction of the surface area is occupied by solvated solute molecules. As a result, the rate at which water molecules evaporate is decreased, although initially their rate of condensation is unchanged. (c) When the glucose solution reaches equilibrium, the concentration of water molecules in the vapor phase, and hence the vapor pressure, is less than that of pure water.

Figure 13.5.2 shows two beakers, one containing pure water and one containing an aqueous glucose solution, in a sealed chamber. We can view the system as having two competing equilibria: water vapor will condense in both beakers at the same rate, but water molecules will evaporate more slowly from the glucose solution because fewer water molecules are at the surface. Eventually all of the water will evaporate from the beaker containing the liquid with the higher vapor pressure (pure water) and condense in the beaker containing the liquid with the lower vapor pressure (the glucose solution). If the system consisted of only a beaker of water inside a sealed container, equilibrium between the liquid and vapor would be achieved rather rapidly, and the amount of liquid water in the beaker would remain constant.

Figure 13.5.2 Transfer of Water to a Beaker Containing a Glucose Solution (top) One beaker contains an aqueous solution of glucose, and the other contains pure water. If they are placed in a sealed chamber, the lower vapor pressure of water in the glucose solution results in a net transfer of water from the beaker containing pure water to the beaker containing the glucose solution. (bottom) Eventually, all of the water is transferred to the beaker that has the glucose solution.

If the particles of a solute are essentially the same size as those of the solvent and both solute and solvent have roughly equal probabilities of being at the surface of the solution, then the effect of a solute on the vapor pressure of the solvent is proportional to the number of sites occupied by solute particles at the surface of the solution. Doubling the concentration of a given solute causes twice as many surface sites to be occupied by solute molecules, resulting in twice the decrease in vapor pressure. The relationship between solution composition and vapor pressure is therefore

$$P_A = X_A P_A^\circ \quad (13.5.1)$$

where P_A is the vapor pressure of component A of the solution (in this case the solvent), X_A is the mole fraction of A in solution, and P_A° is the vapor pressure of pure A. Equation 13.11 is known as Raoult's law, after the French chemist who developed it. If the solution contains only a single nonvolatile solute (B), then $X_A + X_B = 1$, and we can substitute $X_A = 1 - X_B$ to obtain

$$P_A = (1 - X_B) P_A^\circ = P_A^\circ - X_B P_A^\circ \quad (13.5.2)$$

Rearranging and defining $\Delta P_A = P_A^\circ - P_A$ we obtain a relationship between the decrease in vapor pressure and the mole fraction of nonvolatile solute:

$$P_A^\circ - P_A = \Delta P_A = X_B P_A^\circ \quad (13.5.3)$$

We can solve vapor pressure problems in either of two ways: by using [Equation 13.5.1](#) to calculate the actual vapor pressure above a solution of a nonvolatile solute, or by using [Equation 13.5.3](#) to calculate the decrease in vapor pressure caused by a specified amount of a nonvolatile solute.

Example 13.5.1

Ethylene glycol ($\text{HOCH}_2\text{CH}_2\text{OH}$), the major ingredient in commercial automotive antifreeze, increases the boiling point of radiator fluid by lowering its vapor pressure. At 100°C , the vapor pressure of pure water is 760 mmHg. Calculate the vapor pressure of an aqueous solution containing 30.2% ethylene glycol by mass, a concentration commonly used in climates that do not get extremely cold in winter.

Given: identity of solute, percentage by mass, and vapor pressure of pure solvent

Asked for: vapor pressure of solution

Strategy:

A Calculate the number of moles of ethylene glycol in an arbitrary quantity of water, and then calculate the mole fraction of water.

B Use Raoult's law to calculate the vapor pressure of the solution.

Solution:

A A 30.2% solution of ethylene glycol contains 302 g of ethylene glycol per kilogram of solution; the remainder (698 g) is water. To use Raoult's law to calculate the vapor pressure of the solution, we must know the mole fraction of water. Thus we must first calculate the number of moles of both ethylene glycol (EG) and water present:

$$\text{moles EG} = (302 \text{ g}) \frac{1 \text{ mol}}{62.07 \text{ g}} = 4.87 \text{ mol EG}$$

$$\text{moles H}_2\text{O} = (698 \text{ g}) \frac{1 \text{ mol}}{18.02 \text{ g}} = 38.7 \text{ mol H}_2\text{O}$$

The mole fraction of water is thus

$$X_{\text{H}_2\text{O}} = \frac{38.7 \text{ mol H}_2\text{O}}{38.7 \text{ mol H}_2\text{O} + 4.87 \text{ mol EG}} = 0.888$$

B From Raoult's law ([Equation 13.5.1](#)), the vapor pressure of the solution is

$$P_{\text{H}_2\text{O}} = X_{\text{H}_2\text{O}} P_{\text{H}_2\text{O}}^\circ = (0.888) (760 \text{ Torr}) = 675 \text{ Torr}$$

Alternatively, we could solve this problem by calculating the mole fraction of ethylene glycol and then using [Equation 13.5.3](#) to calculate the resulting decrease in vapor pressure:

$$X_{\text{EG}} = \frac{4.87 \text{ mol EG}}{38.7 \text{ mol H}_2\text{O} + 4.87 \text{ mol EG}} = 0.112$$

$$\Delta P_{\text{H}_2\text{O}} = X_{\text{EG}} P_{\text{H}_2\text{O}}^\circ = (0.112) (760 \text{ Torr}) = 85.1 \text{ Torr}$$

$$P_{\text{H}_2\text{O}} = P_{\text{H}_2\text{O}}^\circ - \Delta P_{\text{H}_2\text{O}} = 760 \text{ Torr} - 85.1 = 675 \text{ Torr}$$

The same result is obtained using either method.

Exercise

Seawater is an approximately 3.0% aqueous solution of NaCl by mass with about 0.5% of other salts by mass. Calculate the decrease in the vapor pressure of water at 25°C caused by this concentration of NaCl, remembering that 1 mol of NaCl produces 2 mol of solute particles. The vapor pressure of pure water at 25°C is 23.8 mmHg.

Answer: 0.45 mmHg. This may seem like a small amount, but it constitutes about a 2% decrease in the vapor pressure of water and accounts in part for the higher humidity in the north-central United States near the Great Lakes, which are freshwater lakes. The decrease therefore has important implications for climate modeling.

Even when a solute is volatile, meaning that it has a measurable vapor pressure, we can still use Raoult's law. In this case, we calculate the vapor pressure of each component separately. The total vapor pressure of the solution (P_T) is the sum of the vapor pressures of the components:

$$P_T = P_A + P_B = X_A P_A^o + X_B P_B^o \quad (13.5.4)$$

Because $X_B = 1 - X_A$ for a two-component system,

$$P_T = X_A P_A^o + (1 - X_A) P_B^o \quad (13.5.5)$$

Thus we need to specify the mole fraction of only one of the components in a two-component system. Consider, for example, the vapor pressure of solutions of benzene and toluene of various compositions. At 20°C, the vapor pressures of pure benzene and toluene are 74.7 and 22.3 mmHg, respectively. The vapor pressure of benzene in a benzene–toluene solution is

$$P_{C_6H_6} = X_{C_6H_6} P_{C_6H_6}^o \quad (13.5.6)$$

and the vapor pressure of toluene in the solution is

$$P_{C_6H_5CH_3} = X_{C_6H_5CH_3} P_{C_6H_5CH_3}^o \quad (13.5.7)$$

Equation 13.5.6 and Equation 13.5.7 are both in the form of the equation for a straight line: $y = mx + b$, where $b = 0$. Plots of the vapor pressures of both components versus the mole fractions are therefore straight lines that pass through the origin, as shown in Figure 13.5.3. Furthermore, a plot of the total vapor pressure of the solution versus the mole fraction is a straight line that represents the sum of the vapor pressures of the pure components. Thus the vapor pressure of the solution is always greater than the vapor pressure of either component.

Figure 13.5.3 Vapor Pressures of Benzene–Toluene Solutions Plots of the vapor pressures of benzene (C_6H_6) and toluene ($C_6H_5CH_3$) versus the mole fractions at 20°C are straight lines. For a solution like this, which approximates an ideal solution, the total vapor pressure of the solution (P) is the sum of the vapor pressures of the components.

A solution of two volatile components that behaves like the solution in Figure 13.5.3 is an ideal solution, which is defined as a solution that obeys Raoult's law. Like an ideal gas, an ideal solution is a hypothetical system whose properties can be described in

terms of a simple model. Mixtures of benzene and toluene approximate an ideal solution because the intermolecular forces in the two pure liquids are almost identical in both kind and magnitude. Consequently, the change in enthalpy on solution formation is essentially zero ($\Delta H_{\text{soln}} \approx 0$), which is one of the defining characteristics of an ideal solution.

Note the Pattern

Ideal solutions and ideal gases are both simple models that ignore intermolecular interactions.

Most real solutions, however, do not obey Raoult's law precisely, just as most real gases do not obey the ideal gas law exactly. Real solutions generally deviate from Raoult's law because the intermolecular interactions between the two components A and B differ. We can distinguish between two general kinds of behavior, depending on whether the intermolecular interactions between molecules A and B are stronger or weaker than the A–A and B–B interactions in the pure components. If the A–B interactions are *stronger* than the A–A and B–B interactions, each component of the solution exhibits a *lower* vapor pressure than expected for an ideal solution, as does the solution as a whole. The favorable A–B interactions effectively stabilize the solution compared with the vapor. This kind of behavior is called a *negative deviation from Raoult's law*. Systems stabilized by hydrogen bonding between two molecules, such as acetone and ethanol, exhibit negative deviations from Raoult's law. Conversely, if the A–B interactions are *weaker* than the A–A and B–B interactions yet the entropy increase is enough to allow the solution to form, both A and B have an increased tendency to escape from the solution into the vapor phase. The result is a *higher* vapor pressure than expected for an ideal solution, producing a *positive deviation from Raoult's law*. In a solution of CCl_4 and methanol, for example, the nonpolar CCl_4 molecules interrupt the extensive hydrogen bonding network in methanol, and the lighter methanol molecules have weaker London dispersion forces than the heavier CCl_4 molecules. Consequently, solutions of CCl_4 and methanol exhibit positive deviations from Raoult's law.

Example 13.5.2

For each system, compare the intermolecular interactions in the pure liquids and in the solution to decide whether the vapor pressure will be greater than that predicted by Raoult's law (positive deviation), approximately equal to that predicted by Raoult's law (an ideal solution), or less than the pressure predicted by Raoult's law (negative deviation).

1. cyclohexane and ethanol
2. methanol and acetone
3. *n*-hexane and isooctane (2,2,4-trimethylpentane)

Given: identity of pure liquids

Asked for: predicted deviation from Raoult's law

Strategy:

Identify whether each liquid is polar or nonpolar, and then predict the type of intermolecular interactions that occur in solution.

Solution:

1. Liquid ethanol contains an extensive hydrogen bonding network, and cyclohexane is nonpolar. Because the cyclohexane molecules cannot interact favorably with the polar ethanol molecules, they will disrupt the hydrogen bonding. Hence the A–B interactions will be weaker than the A–A and B–B interactions, leading to a higher vapor pressure than predicted by Raoult's law (a positive deviation).
2. Methanol contains an extensive hydrogen bonding network, but in this case the polar acetone molecules create A–B interactions that are stronger than the A–A or B–B interactions, leading to a negative enthalpy of solution and a lower vapor pressure than predicted by Raoult's law (a negative deviation).
3. Hexane and isooctane are both nonpolar molecules (isooctane actually has a very small dipole moment, but it is so small that it can be ignored). Hence the predominant intermolecular forces in both liquids are London dispersion

forces. We expect the A–B interactions to be comparable in strength to the A–A and B–B interactions, leading to a vapor pressure in good agreement with that predicted by Raoult’s law (an ideal solution).

Exercise

For each system, compare the intermolecular interactions in the pure liquids with those in the solution to decide whether the vapor pressure will be greater than that predicted by Raoult’s law (positive deviation), approximately equal to that predicted by Raoult’s law (an ideal solution), or less than the pressure predicted by Raoult’s law (negative deviation):

1. benzene and *n*-hexane
2. ethylene glycol and CCl_4
3. acetic acid and *n*-propanol

Answer:

1. approximately equal
2. positive deviation (vapor pressure greater than predicted)
3. negative deviation (vapor pressure less than predicted)

Boiling Point Elevation

Recall from [Chapter 11](#) that the normal boiling point of a substance is the temperature at which the vapor pressure equals 1 atm. If a nonvolatile solute lowers the vapor pressure of a solvent, it must also affect the boiling point. Because the vapor pressure of the solution at a given temperature is *less* than the vapor pressure of the pure solvent, achieving a vapor pressure of 1 atm for the solution requires a *higher* temperature than the normal boiling point of the solvent. Thus *the boiling point of a solution is always greater than that of the pure solvent*. We can see why this must be true by comparing the phase diagram for an aqueous solution with the phase diagram for pure water ([Figure 13.5.4](#)). The vapor pressure of the solution is less than that of pure water *at all temperatures*. Consequently, the liquid–vapor curve for the solution crosses the horizontal line corresponding to $P = 1$ atm at a higher temperature than does the curve for pure water.

Note the Pattern

The boiling point of a solution with a nonvolatile solute is always greater than the boiling point of the pure solvent.

Figure 13.5.4 Phase Diagrams of Pure Water and an Aqueous Solution of a Nonvolatile Solute The vaporization curve for the solution lies below the curve for pure water at all temperatures, which results in an increase in the boiling point and a decrease in

the freezing point of the solution.

The magnitude of the increase in the boiling point is related to the magnitude of the decrease in the vapor pressure. As we have just discussed, the decrease in the vapor pressure is proportional to the concentration of the solute in the solution. Hence the magnitude of the increase in the boiling point must also be proportional to the concentration of the solute (Figure 13.5.5). We can define the boiling point elevation (ΔT_b) as the difference between the boiling points of the solution and the pure solvent:

$$\Delta T_b = T_b - T_b^o \quad (13.5.8)$$

where T_b is the boiling point of the solution and T_b^o is the boiling point of the pure solvent. We can express the relationship between ΔT_b and concentration as follows:

$$\Delta T_b = mK_b \quad (13.5.9)$$

where m is the concentration of the solute expressed in molality, and K_b is the *molal boiling point elevation constant* of the solvent, which has units of $^{\circ}\text{C}/m$. Table 13.7 "Boiling Point Elevation Constants (" lists characteristic K_b values for several commonly used solvents.

Table 13.5.1 Boiling Point Elevation Constants (K_b) and Freezing Point Depression Constants (K_f) for Some Solvents

Figure 13.5.5 Vapor Pressure Decrease and Boiling Point Increase as Functions of the Mole Fraction of a Nonvolatile Solute For relatively dilute solutions, the magnitude of both properties is proportional to the solute concentration.

Solvent	Boiling Point ($^{\circ}\text{C}$)	K_b ($^{\circ}\text{C}/m$)	Freezing Point ($^{\circ}\text{C}$)	K_f ($^{\circ}\text{C}/m$)
acetic acid	117.90	3.22	16.64	3.63
benzene	80.09	2.64	5.49	5.07
<i>d</i> -(+)-camphor	207.4	4.91	178.8	37.8
carbon disulfide	46.2	2.42	-112.1	3.74
carbon tetrachloride	76.8	5.26	-22.62	31.4
chloroform	61.17	3.80	-63.41	4.60
nitrobenzene	210.8	5.24	5.70	6.87
water	100.00	0.51	0.00	1.86

The concentration of the solute is typically expressed as molality rather than mole fraction or molarity for two reasons. First, because the density of a solution changes with temperature, the value of molarity also varies with temperature. If the boiling point depends on the solute concentration, then by definition the system is not maintained at a constant temperature. Second, molality and mole fraction are proportional for relatively dilute solutions, but molality has a larger numerical value (a mole fraction can be only between zero and one). Using molality allows us to eliminate nonsignificant zeros.

According to [Table 13.5.1](#), the molal boiling point elevation constant for water is $0.51^{\circ}\text{C}/m$. Thus a $1.00\ m$ aqueous solution of a nonvolatile molecular solute such as glucose or sucrose will have an increase in boiling point of 0.51°C , to give a boiling point of 100.51°C at $1.00\ \text{atm}$. The increase in the boiling point of a $1.00\ m$ aqueous NaCl solution will be approximately twice as large as that of the glucose or sucrose solution because $1\ \text{mol}$ of NaCl produces $2\ \text{mol}$ of dissolved ions. Hence a $1.00\ m$ NaCl solution will have a boiling point of about 101.02°C .

Example 13.5.3

In Example 8, we calculated that the vapor pressure of a 30.2% aqueous solution of ethylene glycol at 100°C is $85.1\ \text{mmHg}$ less than the vapor pressure of pure water. We stated (without offering proof) that this should result in a higher boiling point for the solution compared with pure water. Now that we have seen why this assertion is correct, calculate the boiling point of the aqueous ethylene glycol solution.

Given: composition of solution

Asked for: boiling point

Strategy:

Calculate the molality of ethylene glycol in the 30.2% solution. Then use [Equation 13.19](#) to calculate the increase in boiling point.

Solution:

From Example 8, we know that a 30.2% solution of ethylene glycol in water contains $302\ \text{g}$ of ethylene glycol ($4.87\ \text{mol}$) per $698\ \text{g}$ of water. The molality of the solution is thus

$$\text{molality of ethylene glycol} = \frac{4.87\ \text{mol}}{698\ \text{gH}_2\text{O}} \frac{1000\ \text{g}}{1\ \text{kg}} = 6.98\ m$$

From [Equation 13.5.9](#), the increase in boiling point is therefore

$$T_b = mK_b = (6.98\ m)(0.51\ ^{\circ}\text{C}/m) = 3.6\ ^{\circ}\text{C}$$

The boiling point of the solution is thus predicted to be 104°C . With a solute concentration of almost $7\ m$, however, the assumption of a dilute solution used to obtain [Equation 13.5.9](#) may not be valid.

Exercise

Assume that a tablespoon ($5.00\ \text{g}$) of NaCl is added to $2.00\ \text{L}$ of water at 20.0°C , which is then brought to a boil to cook spaghetti. At what temperature will the water boil?

Answer: 100.04°C , or 100°C to three significant figures. (Recall that $1\ \text{mol}$ of NaCl produces $2\ \text{mol}$ of dissolved particles. The small increase in temperature means that adding salt to the water used to cook pasta has essentially no effect on the cooking time.)

Freezing Point Depression

The phase diagram in [Figure 13.5.4](#) shows that dissolving a nonvolatile solute in water not only raises the boiling point of the water but also lowers its freezing point. The solid–liquid curve for the solution crosses the line corresponding to $P = 1\ \text{atm}$ at a lower temperature than the curve for pure water.

We can understand this result by imagining that we have a sample of water at the normal freezing point temperature, where there is a dynamic equilibrium between solid and liquid. Water molecules are continuously colliding with the ice surface and entering the solid phase at the same rate that water molecules are leaving the surface of the ice and entering the liquid phase. If we dissolve a nonvolatile solute such as glucose in the liquid, the dissolved glucose molecules will reduce the number of collisions per unit time between water molecules and the ice surface because some of the molecules colliding with the ice will be glucose. Glucose, though, has a very different structure than water, and it cannot fit into the ice lattice. Consequently, the presence of glucose molecules in the solution can only decrease the rate at which water molecules in the liquid collide with the ice surface and solidify. Meanwhile, the rate at which the water molecules leave the surface of the ice and enter the liquid phase is unchanged. The net effect is to cause the ice to melt. The only way to reestablish a dynamic equilibrium between solid and liquid water is to lower the temperature of the system, which decreases the rate at which water molecules leave the surface of the ice crystals until it equals the rate at which water molecules in the solution collide with the ice.

By analogy to our treatment of boiling point elevation, the freezing point depression (ΔT_f) is defined as the difference between the freezing point of the pure solvent and the freezing point of the solution:

$$\Delta T_f = T_f - T_f^\circ \quad (13.5.10)$$

where T_f° is the freezing point of the pure solvent and T_f is the freezing point of the solution. The order of the terms is reversed compared with Equation 13.18 to express the freezing point depression as a positive number. The relationship between ΔT_f and the solute concentration is given by an equation analogous to Equation 13.5.9:

$$\Delta T_f = mK_f \quad (13.5.11)$$

where m is the molality of the solution and K_f is the *molal freezing point depression constant* for the solvent (in units of $^\circ\text{C}/m$). Like K_b , each solvent has a characteristic value of K_f (see Table 13.5.1). Freezing point depression depends on the total number of dissolved nonvolatile solute particles, just as with boiling point elevation. Thus an aqueous NaCl solution has twice as large a freezing point depression as a glucose solution of the same molality.

People who live in cold climates use freezing point depression to their advantage in many ways. For example, salt is used to melt ice and snow on roads and sidewalks, ethylene glycol is added to engine coolant water to prevent an automobile engine from being destroyed, and methanol is added to windshield washer fluid to prevent the fluid from freezing.

Note the Pattern

The decrease in vapor pressure, increase in boiling point, and decrease in freezing point of a solution versus a pure liquid all depend on the total number of dissolved nonvolatile solute particles.

Example 13.5.4

In colder regions of the United States, NaCl or CaCl_2 is often sprinkled on icy roads in winter to melt the ice and make driving safer. Use the data in Figure 13.4.1 to estimate the concentrations of two saturated solutions at 0°C , one of NaCl and one of CaCl_2 , and calculate the freezing points of both solutions to see which salt is likely to be more effective at melting ice.

Given: solubilities of two compounds

Asked for: concentrations and freezing points

Strategy:

A Estimate the solubility of each salt in 100 g of water from Figure 13.4.1. Determine the number of moles of each in 100 g and calculate the molalities.

B Determine the concentrations of the dissolved salts in the solutions. Substitute these values into Equation 13.21 to calculate the freezing point depressions of the solutions.

Solution:

A From [Figure 13.4.1](#), we can estimate the solubilities of NaCl and CaCl₂ to be about 36 g and 60 g, respectively, per 100 g of water at 0°C. The corresponding concentrations in molality are

$$m_{NaCl} = \left(\frac{36 \text{ g NaCl}}{100 \text{ g H}_2\text{O}} \right) \left(\frac{1 \text{ mol NaCl}}{58.44 \text{ g NaCl}} \right) \left(\frac{1000 \text{ g}}{1 \text{ kg}} \right) = 6.2 \text{ m}$$

$$m_{CaCl_2} = \left(\frac{60 \text{ g CaCl}_2}{100 \text{ g H}_2\text{O}} \right) \left(\frac{1 \text{ mol CaCl}_2}{110.98 \text{ g CaCl}_2} \right) \left(\frac{1000 \text{ g}}{1 \text{ kg}} \right) = 5.4 \text{ m}$$

The lower formula mass of NaCl more than compensates for its lower solubility, resulting in a saturated solution that has a slightly higher concentration than CaCl₂.

B Because these salts are ionic compounds that dissociate in water to yield two and three ions per formula unit of NaCl and CaCl₂, respectively, the actual concentrations of the dissolved species in the two saturated solutions are $2 \times 6.2 \text{ m} = 12 \text{ m}$ for NaCl and $3 \times 5.4 \text{ m} = 16 \text{ m}$ for CaCl₂. The resulting freezing point depressions can be calculated using [Equation 13.5.11](#):

$$NaCl : \Delta T_f = mK_f = (12 \text{ m})(1.86 \text{ }^\circ\text{C}/\text{m}) = 22 \text{ }^\circ\text{C}$$

$$CaCl_2 : \Delta T_f = mK_f = (16 \text{ m})(1.86 \text{ }^\circ\text{C}/\text{m}) = 30 \text{ }^\circ\text{C}$$

Because the freezing point of pure water is 0°C, the actual freezing points of the solutions are -22°C and -30°C, respectively. Note that CaCl₂ is substantially more effective at lowering the freezing point of water because its solutions contain three ions per formula unit. In fact, CaCl₂ is the salt usually sold for home use, and it is also often used on highways.

Because the solubilities of both salts decrease with decreasing temperature, the freezing point can be depressed by only a certain amount, regardless of how much salt is spread on an icy road. If the temperature is significantly below the minimum temperature at which one of these salts will cause ice to melt (say -35°C), there is no point in using salt until it gets warmer.

Exercise

Calculate the freezing point of the 30.2% solution of ethylene glycol in water whose vapor pressure and boiling point were calculated in [Example 13.8](#) and [Example 13.10](#).

Answer: -13.0°C

Example 13.5.5

Arrange these aqueous solutions in order of decreasing freezing points: 0.1 m KCl, 0.1 m glucose, 0.1 m SrCl₂, 0.1 m ethylene glycol, 0.1 m benzoic acid, and 0.1 m HCl.

Given: molalities of six solutions

Asked for: relative freezing points

Strategy:

A Identify each solute as a strong, weak, or nonelectrolyte, and use this information to determine the number of solute particles produced.

B Multiply this number by the concentration of the solution to obtain the effective concentration of solute particles. The solution with the highest effective concentration of solute particles has the largest freezing point depression.

Solution:

A Because the molal concentrations of all six solutions are the same, we must focus on which of the substances are strong electrolytes, which are weak electrolytes, and which are nonelectrolytes to determine the actual numbers of particles in

solution. KCl, SrCl₂, and HCl are strong electrolytes, producing two, three, and two ions per formula unit, respectively. Benzoic acid is a weak electrolyte (approximately one particle per molecule), and glucose and ethylene glycol are both nonelectrolytes (one particle per molecule).

B The molalities of the solutions in terms of the total particles of solute are: KCl and HCl, 0.2 *m*; SrCl₂, 0.3 *m*; glucose and ethylene glycol, 0.1 *m*; and benzoic acid, 0.1–0.2 *m*. Because the magnitude of the decrease in freezing point is proportional to the concentration of dissolved particles, the order of freezing points of the solutions is: glucose and ethylene glycol (highest freezing point, smallest freezing point depression) > benzoic acid > HCl = KCl > SrCl₂.

Exercise

Arrange these aqueous solutions in order of increasing freezing points: 0.2 *m* NaCl, 0.3 *m* acetic acid, 0.1 *m* CaCl₂, and 0.2 *m* sucrose.

Answer: 0.2 *m* NaCl (lowest freezing point) < 0.3 *m* acetic acid ≈ 0.1 *m* CaCl₂ < 0.2 *m* sucrose (highest freezing point)

In biological systems, freezing plant and animal tissues produces ice crystals that rip cells apart, causing severe frostbite and degrading the quality of fish or meat. How, then, can living organisms survive in freezing climates, where we might expect that exposure to freezing temperatures would be fatal? Many organisms that live in cold climates are able to survive at temperatures well below freezing by synthesizing their own chemical antifreeze in concentrations that prevent freezing. Such substances are typically small organic molecules with multiple –OH groups analogous to ethylene glycol.

Colligative properties can also be used to determine the molar mass of an unknown compound. One method that can be carried out in the laboratory with minimal equipment is to measure the freezing point of a solution with a known mass of solute. This method is accurate for dilute solutions (≤1% by mass) because changes in the freezing point are usually large enough to measure accurately and precisely. By comparing *K_b* and *K_f* values in [Table 2.5.1](#), we see that changes in the boiling point are smaller than changes in the freezing point for a given solvent. Boiling point elevations are thus more difficult to measure precisely. For this reason, freezing point depression is more commonly used to determine molar mass than is boiling point elevation. Because of its very large value of *K_f* (37.8°C/*m*), *d*-(+)-camphor ([Table 13.5.1](#)) is often used to determine the molar mass of organic compounds by this method.

Example 13.5.6

A 7.08 g sample of elemental sulfur is dissolved in 75.0 g of CS₂ to create a solution whose freezing point is –113.5°C. Use these data to calculate the molar mass of elemental sulfur and thus the formula of the dissolved S_{*n*} molecules (i.e., what is the value of *n*?).

Given: masses of solute and solvent and freezing point

Asked for: molar mass and number of S atoms per molecule

Strategy:

A Use [Equation 13.5.10](#), the measured freezing point of the solution, and the freezing point of CS₂ from [Table 13.5.1](#) to calculate the freezing point depression. Then use [Equation 13.5.11](#) and the value of *K_f* from [Table 13.5.1](#) to calculate the molality of the solution.

B From the calculated molality, determine the number of moles of solute present.

C Use the mass and number of moles of the solute to calculate the molar mass of sulfur in solution. Divide the result by the molar mass of atomic sulfur to obtain *n*, the number of sulfur atoms per mole of dissolved sulfur.

Solution:

A The first step is to calculate the freezing point depression using [Equation 13.5.10](#):

$$\Delta T_f = T_f^\circ - T_f = -112.1\text{ }^\circ\text{C} - (-113.5\text{ }^\circ\text{C}) = 1.4\text{ }^\circ\text{C}$$

Then [Equation 13.5.11](#) gives

$$(m = \frac{\Delta T_f}{K_f} = \frac{1.4 \text{ } ^\circ\text{C}}{3.74 \text{ } ^\circ\text{C/m}} = 0.37 \text{ } m)$$

B The total number of moles of solute present in the solution is

$$\text{moles solute} = \frac{0.37 \text{ mol/kg}}{75 \text{ g}} \frac{1 \text{ kg}}{1000 \text{ g}} = 0.028 \text{ mol}$$

C We now know that 0.708 g of elemental sulfur corresponds to 0.028 mol of solute. The molar mass of dissolved sulfur is thus

$$\text{molar mass} = \frac{7.08 \text{ g}}{0.028 \text{ mol}} = 260 \text{ g/mol}$$

The molar mass of atomic sulfur is 32 g/mol, so there must be $260/32 = 8.1$ sulfur atoms per mole, corresponding to a formula of S_8 .

Exercise

One of the byproducts formed during the synthesis of C_{60} is a deep red solid containing only carbon. A solution of 205 mg of this compound in 10.0 g of CCl_4 has a freezing point of -23.38°C . What are the molar mass and most probable formula of the substance?

Answer: 847 g/mol; C_{70}

Osmotic Pressure

Osmotic pressure is a colligative property of solutions that is observed using a semipermeable membrane, a barrier with pores small enough to allow solvent molecules to pass through but not solute molecules or ions. The net flow of solvent through a semipermeable membrane is called osmosis (from the Greek *osmós*, meaning “push”). The direction of net solvent flow is *always* from the side with the lower concentration of solute to the side with the higher concentration.

Osmosis can be demonstrated using a U-tube like the one shown in [Figure 13.5.6](#), which contains pure water in the left arm and a dilute aqueous solution of glucose in the right arm. A net flow of water through the membrane occurs until the levels in the arms eventually stop changing, which indicates that equilibrium has been reached. The osmotic pressure (Π) of the glucose solution is the difference in the pressure between the two sides, in this case the heights of the two columns. Although the semipermeable membrane allows water molecules to flow through in either direction, the *rate* of flow is not the same in both directions because the concentration of water is not the same in the two arms. The net flow of water through the membrane can be prevented by applying a pressure to the right arm that is equal to the osmotic pressure of the glucose solution.

Figure 13.5.6 Osmotic Pressure (a) A dilute solution of glucose in water is placed in the right arm of a U-tube, and the left arm is filled to the same height with pure water; a semipermeable membrane separates the two arms. Because the flow of pure solvent through the membrane from left to right (from pure water to the solution) is greater than the flow of solvent in the reverse direction, the level of liquid in the right tube rises. (b) At equilibrium, the pressure differential, equal to the osmotic pressure of the solution (Π_{soln}), equalizes the flow rate of solvent in both directions. (c) Applying an external pressure equal to the osmotic pressure of the original glucose solution to the liquid in the right arm reverses the flow of solvent and restores the original situation.

Just as with any other colligative property, the osmotic pressure of a solution depends on the concentration of dissolved solute particles. Osmotic pressure obeys a law that resembles the ideal gas equation:

$$\Pi = \frac{nRT}{V} = MRT \quad (13.5.12)$$

where M is the number of moles of solute per unit volume of solution (i.e., the *molarity* of the solution), R is the ideal gas constant, and T is the absolute temperature. As shown in Example 14, osmotic pressures tend to be quite high, even for rather dilute solutions.

Example 13.5.7

When placed in a concentrated salt solution, certain yeasts are able to produce high internal concentrations of glycerol to counteract the osmotic pressure of the surrounding medium. Suppose that the yeast cells are placed in an aqueous solution containing 4.0% NaCl by mass; the solution density is 1.02 g/mL at 25°C.

1. Calculate the osmotic pressure of a 4.0% aqueous NaCl solution at 25°C.
2. If the normal osmotic pressure inside a yeast cell is 7.3 atm, corresponding to a total concentration of dissolved particles of 0.30 M, what concentration of glycerol must the cells synthesize to exactly balance the external osmotic pressure at 25°C?

Given: concentration, density, and temperature of NaCl solution; internal osmotic pressure of cell

Asked for: osmotic pressure of NaCl solution and concentration of glycerol needed

Strategy:

A Calculate the molarity of the NaCl solution using the formula mass of the solute and the density of the solution. Then calculate the total concentration of dissolved particles.

B Use [Equation 13.5.12](#) to calculate the osmotic pressure of the solution.

C Subtract the normal osmotic pressure of the cells from the osmotic pressure of the salt solution to obtain the additional pressure needed to balance the two. Use [Equation 13.5.12](#) to calculate the molarity of glycerol needed to create this osmotic pressure.

Solution:

1. **A** The solution contains 4.0 g of NaCl per 100 g of solution. Using the formula mass of NaCl (58.44 g/mol) and the density of the solution (1.02 g/mL), we can calculate the molarity:

$$M_{NaCl} = \frac{\text{moles NaCl}}{\text{liter solution}} = \left(\frac{4.0 \text{ g NaCl}}{58.44 \text{ g/mol NaCl}} \right) \left(\frac{1}{100 \text{ g solution}} \right) \left(\frac{1.02 \text{ g solution}}{1.00 \text{ mL solution}} \right) \left(\frac{1000 \text{ mL}}{1 \text{ L}} \right) = 0.70 \text{ M NaCl}$$

Because 1 mol of NaCl produces 2 mol of particles in solution, the total concentration of dissolved particles in the solution is $(2)(0.70 \text{ M}) = 1.4 \text{ M}$.

B Now we can use [Equation 13.5.12](#) to calculate the osmotic pressure of the solution:

$$\Pi = MRT = (1.4 \text{ mol/L})(0.0821 \text{ L} \cdot \text{atm}/\text{K} \cdot \text{mol})(298 \text{ K}) = 34 \text{ atm}$$

2. **C** If the yeast cells are to exactly balance the external osmotic pressure, they must produce enough glycerol to give an additional internal pressure of $(34 \text{ atm} - 7.3 \text{ atm}) = 27 \text{ atm}$. Glycerol is a nonelectrolyte, so we can solve [Equation 13.5.12](#) for the molarity corresponding to this osmotic pressure:

$$M = \frac{\Pi}{RT} = \frac{27 \text{ atm}}{(0.0821 \text{ L} \cdot \text{atm}/\text{K} \cdot \text{mol})(298 \text{ K})} = 1.1 \text{ M glycerol}$$

In solving this problem, we could also have recognized that the only way the osmotic pressures can be the same inside the cells and in the solution is if the concentrations of dissolved particles are the same. We are given that the normal concentration of dissolved particles in the cells is 0.3 M, and we have calculated that

the NaCl solution is effectively 1.4 M in dissolved particles. The yeast cells must therefore synthesize enough glycerol to increase the internal concentration of dissolved particles from 0.3 M to 1.4 M—that is, an additional 1.1 M concentration of glycerol.

Exercise

Assume that the fluids inside a sausage are approximately 0.80 M in dissolved particles due to the salt and sodium nitrite used to prepare them. Calculate the osmotic pressure inside the sausage at 100°C to learn why experienced cooks pierce the semipermeable skin of sausages *before* boiling them.

Answer: 24 atm

Because of the large magnitude of osmotic pressures, osmosis is extraordinarily important in biochemistry, biology, and medicine. Virtually every barrier that separates an organism or cell from its environment acts like a semipermeable membrane, permitting the flow of water but not solutes. The same is true of the compartments inside an organism or cell. Some specialized barriers, such as those in your kidneys, are slightly more permeable and use a related process called dialysis, which permits both water and small molecules to pass through but not large molecules such as proteins.

The same principle has long been used to preserve fruits and their essential vitamins over the long winter. High concentrations of sugar are used in jams and jellies not for sweetness alone but because they greatly increase the osmotic pressure. Thus any bacteria not killed in the cooking process are dehydrated, which keeps them from multiplying in an otherwise rich medium for bacterial growth. A similar process using salt prevents bacteria from growing in ham, bacon, salt pork, salt cod, and other preserved meats. The effect of osmotic pressure is dramatically illustrated in [Figure 13.5.7](#), which shows what happens when red blood cells are placed in a solution whose osmotic pressure is much lower or much higher than the internal pressure of the cells.

Figure 13.5.7 *Effect on Red Blood Cells of the Surrounding Solution's Osmotic Pressure* (a) When red blood cells are placed in a dilute salt solution having the same osmotic pressure as the intracellular fluid, the rate of flow of water into and out of the cells is the same and their shape does not change. (b) When cells are placed in distilled water whose osmotic pressure is less than that of the intracellular fluid, the rate of flow of water into the cells is greater than the rate of flow out of the cells. The cells swell and eventually burst. (c) When cells are placed in a concentrated salt solution with an osmotic pressure greater than that of the intracellular fluid, the rate of flow of water out of the cells is greater than the rate of flow into the cells. The cells shrivel and become so deformed that they cannot function.

In addition to capillary action, trees use osmotic pressure to transport water and other nutrients from the roots to the upper branches. (For more information about capillary action, see [Section 11.3](#).) Evaporation of water from the leaves results in a local increase in the salt concentration, which generates an osmotic pressure that pulls water up the trunk of the tree to the leaves.

Finally, a process called reverse osmosis can be used to produce pure water from seawater. As shown schematically in [Figure 13.5.8](#), applying high pressure to seawater forces water molecules to flow through a semipermeable membrane that separates pure water from the solution, leaving the dissolved salt behind. Large-scale desalination plants that can produce hundreds of thousands of gallons of freshwater per day are common in the desert lands of the Middle East, where they supply a large proportion of the freshwater needed by the population. Similar facilities are now being used to supply freshwater in southern California. Small, hand-operated reverse osmosis units can produce approximately 5 L of freshwater per hour, enough to keep 25 people alive, and are now standard equipment on US Navy lifeboats.

Figure 13.5.8 Desalination of Seawater by Reverse Osmosis (top) When the pressure applied to seawater equals its osmotic pressure (Π_{soln}), there is no net flow of water across the semipermeable membrane. (bottom) The application of pressure greater than the osmotic pressure of seawater forces water molecules to flow through the membrane, leaving behind a concentrated salt solution. In desalination plants, seawater is continuously introduced under pressure and pure water is collected, so the process continues indefinitely.

Colligative Properties of Electrolyte Solutions

Thus far we have assumed that we could simply multiply the molar concentration of a solute by the number of ions per formula unit to obtain the actual concentration of dissolved particles in an electrolyte solution. We have used this simple model to predict such properties as freezing points, melting points, vapor pressure, and osmotic pressure. If this model were perfectly correct, we would expect the freezing point depression of a 0.10 *m* solution of sodium chloride, with 2 mol of ions per mole of NaCl in solution, to be exactly twice that of a 0.10 *m* solution of glucose, with only 1 mol of molecules per mole of glucose in solution. In reality, this is not always the case. Instead, the observed change in freezing points for 0.10 *m* aqueous solutions of NaCl and KCl are significantly less than expected (-0.348°C and -0.344°C , respectively, rather than -0.372°C), which suggests that fewer particles than we expected are present in solution.

The relationship between the actual number of moles of solute added to form a solution and the apparent number as determined by colligative properties is called the van't Hoff factor (*i*) and is defined as follows: Named for Jacobus Hendricus van't Hoff (1852–1911), a Dutch chemistry professor at the University of Amsterdam who won the first Nobel Prize in Chemistry (1901) for his work on thermodynamics and solutions.

$$i = \frac{\text{apparent number of particles in solution}}{\text{number of moles of solute dissolved}} \quad (13.5.13)$$

Note the Pattern

As the solute concentration increases the van't Hoff factor decreases.

The van't Hoff factor is therefore a measure of a deviation from ideal behavior. The lower the van't Hoff factor, the greater the deviation. As the data in [Table 13.5.2](#) show, the van't Hoff factors for ionic compounds are somewhat lower than expected; that is, their solutions apparently contain fewer particles than predicted by the number of ions per formula unit. As the concentration of the solute increases, the van't Hoff factor decreases because ionic compounds generally do not totally dissociate in aqueous solution. Instead, some of the ions exist as ion pairs, a cation and an anion that for a brief time are associated with each other without an intervening shell of water molecules ([Figure 13.5.9](#)). Each of these temporary units behaves like a single dissolved particle until it dissociates. Highly charged ions such as Mg^{2+} , Al^{3+} , SO_4^{2-} , and PO_4^{3-} have a greater tendency to form ion pairs because of their strong electrostatic interactions. The actual number of solvated ions present in a solution can be determined by measuring a colligative property at several solute concentrations.

Table 13.5.2 van't Hoff Factors for 0.0500 M Aqueous Solutions of Selected Compounds at 25°C

Figure 13.21 Ion Pairs In concentrated solutions of electrolytes like NaCl, some of the ions form neutral ion pairs that are not separated by solvent and diffuse as single particles.

Compound	i (measured)	i (ideal)
glucose	1.0	1.0
sucrose	1.0	1.0
NaCl	1.9	2.0
HCl	1.9	2.0
MgCl ₂	2.7	3.0
FeCl ₃	3.4	4.0
Ca(NO ₃) ₂	2.5	3.0
AlCl ₃	3.2	4.0
MgSO ₄	1.4	2.0

Example 13.5.8

A 0.0500 M aqueous solution of FeCl₃ has an osmotic pressure of 4.15 atm at 25°C. Calculate the van't Hoff factor i for the solution.

Given: solute concentration, osmotic pressure, and temperature

Asked for: van't Hoff factor

Strategy:

A Use [Equation 13.22](#) to calculate the expected osmotic pressure of the solution based on the effective concentration of dissolved particles in the solvent.

B Calculate the ratio of the observed osmotic pressure to the expected value. Multiply this number by the number of ions of solute per formula unit, and then use [Equation 13.23](#) to calculate the van't Hoff factor.

Solution:

A If FeCl₃ dissociated completely in aqueous solution, it would produce four ions per formula unit [Fe³⁺ (aq) plus 3Cl⁻ (aq)] for an effective concentration of dissolved particles of $4 \times 0.0500 \text{ M} = 0.200 \text{ M}$. The osmotic pressure would be

$$\Pi = MRT = (0.200 \text{ mol/L})(0.0821 \text{ L} \cdot \text{atm}/\text{K} \cdot \text{mol})(298 \text{ K}) = 4.89 \text{ atm}$$

B The observed osmotic pressure is only 4.15 atm, presumably due to ion pair formation. The ratio of the observed osmotic pressure to the calculated value is $4.15 \text{ atm}/4.89 \text{ atm} = 0.849$, which indicates that the solution contains $(0.849)(4) = 3.40$ particles per mole of FeCl_3 dissolved. Alternatively, we can calculate the observed particle concentration from the osmotic pressure of 4.15 atm:

$$4.15 \text{ atm} = M (0.0821 \text{ L} \cdot \text{atm} / \text{K} \cdot \text{mol}) (298 \text{ K})$$

$$M = 0.170 \text{ mol/L}$$

The ratio of this value to the expected value of 0.200 M is $0.170 \text{ M}/0.200 \text{ M} = 0.850$, which again gives us $(0.850)(4) = 3.40$ particles per mole of FeCl_3 dissolved. From [Equation 13.23](#), the van't Hoff factor for the solution is

$$i = \frac{3.40 \text{ particles observed}}{\text{formula unit } \text{FeCl}_3} = 3.40$$

Exercise

Calculate the van't Hoff factor for a 0.050 m aqueous solution of MgCl_2 that has a measured freezing point of -0.25°C .

Answer: 2.7 (versus an ideal value of 3)

Summary

The **colligative properties** of a solution depend on only the total number of dissolved particles in solution, not on their chemical identity. Colligative properties include vapor pressure, boiling point, freezing point, and osmotic pressure. The addition of a *nonvolatile solute* (one without a measurable vapor pressure) decreases the vapor pressure of the solvent. The vapor pressure of the solution is proportional to the mole fraction of solvent in the solution, a relationship known as **Raoult's law**. Solutions that obey Raoult's law are called **ideal solutions**. Most real solutions exhibit positive or negative deviations from Raoult's law. The **boiling point elevation** (ΔT_b) and **freezing point depression** (ΔT_f) of a solution are defined as the differences between the boiling and freezing points, respectively, of the solution and the pure solvent. Both are proportional to the molality of the solute. When a solution and a pure solvent are separated by a **semipermeable membrane**, a barrier that allows solvent molecules but not solute molecules to pass through, the flow of solvent in opposing directions is unequal and produces an **osmotic pressure**, which is the difference in pressure between the two sides of the membrane. **Osmosis** is the net flow of solvent through such a membrane due to different solute concentrations. **Dialysis** uses a semipermeable membrane with pores that allow only small solute molecules and solvent molecules to pass through. In more concentrated solutions, or in solutions of salts with highly charged ions, the cations and anions can associate to form **ion pairs**, which decreases their effect on the colligative properties of the solution. The extent of ion pair formation is given by the **van't Hoff factor** (i), the ratio of the apparent number of particles in solution to the number predicted by the stoichiometry of the salt.

Key Takeaway

- The total number of nonvolatile solute particles determines the decrease in vapor pressure, increase in boiling point, and decrease in freezing point of a solution versus the pure solvent.

Key Equations

Henry's law

[Equation 13.4.2](#): $C = kP$

Raoult's law

[Equation 13.5.1](#): $P_A = X_A P_A^\circ$

vapor pressure lowering

Equation 13.13: $P_A^o - P_A = \Delta P_A = X_B P_A^o$

vapor pressure of a system containing two volatile components

Equation 13.5.5: $P_T = X_A P_A^o + (1 - X_A) P_B^o$

boiling point elevation

Equation 13.5.9: $\Delta T_b = mK_b$

freezing point depression

Equation 13.5.11: $\Delta T_f = mK_f$

osmotic pressure

Equation 13.5.12: $\Pi = \frac{nRT}{V} = MRT$

van't Hoff factor

Equation 13.5.13: $i = \frac{\text{apparent number of particles in solution}}{\text{number of moles of solute dissolved}}$

Conceptual Problems

1. Why does the vapor pressure of a solvent decrease when adding a nonvolatile solute?
2. Does seawater boil at the same temperature as distilled water? If not, which has the higher boiling point? Explain your answer.
3. Which will be more soluble in benzene—O₂ or HCl? Will H₂S or HCl be more soluble in water? Explain your reasoning in each case.
4. Will the vapor pressure of a solution of hexane and heptane have an ideal vapor pressure curve (i.e., obey Raoult's law)? Explain your answer. What properties of two liquids determine whether a solution of the two will exhibit an ideal behavior?
5. Predict whether the following mixtures will exhibit negative, zero, or positive deviations from Raoult's law. Explain your reasoning in each case.
 - a. carbon tetrachloride and heptane
 - b. methanol and tetrahydrofuran (C₄H₈O)
 - c. acetone [(CH₃)₂C=CO] and dichloromethane
 - d. hexane and methanol
6. Why are deviations from the ideal behavior predicted by Raoult's law more common for solutions of liquids than are deviations from the ideal behavior predicted by the ideal gas law for solutions of gases?
7. Boiling point elevation is proportional to the molal concentration of the solute. Is it also proportional to the molar concentration of the solution? Why or why not?
8. Many packaged foods in sealed bags are cooked by placing the bag in boiling water. How could you reduce the time required to cook the contents of the bag using this cooking method?
9. If the costs per kilogram of ethylene glycol and of ethanol were the same, which would be the more cost-effective antifreeze?
10. Many people get thirsty after eating foods such as ice cream or potato chips that have a high sugar or salt content, respectively. Suggest an explanation for this phenomenon.
11. When two aqueous solutions with identical concentrations are separated by a semipermeable membrane, no net movement of water occurs. What happens when a solute that cannot penetrate the membrane is added to one of the solutions? Why?
12. A solution injected into blood vessels must have an electrolyte concentration nearly identical to that found in blood plasma. Why? What would happen if red blood cells were placed in distilled water? What would happen to red blood cells if they were placed in a solution that had twice the electrolyte concentration of blood plasma?
13. If you were stranded on a desert island, why would drinking seawater lead to an increased rate of dehydration, eventually causing you to die of thirst?

14. What is the relationship between the van't Hoff factor for a compound and its lattice energy?

Numerical Problems

- Hemoglobin is the protein that is responsible for the red color of blood and for transporting oxygen from the lungs to the tissues. A solution with 11.2 mg of hemoglobin per mL has an osmotic pressure of 2.9 mmHg at 5°C. What is the molecular mass of hemoglobin?
- To determine the molar mass of the antifreeze protein from the Arctic right-eye flounder, the osmotic pressure of a solution containing 13.2 mg of protein per mL was measured and found to be 21.2 mmHg at 10°C. What is the molar mass of the protein?
- What is the osmotic pressure at 21.0°C of 13.5 mL of a solution with 1.77 g of sucrose (C₁₂H₂₂O₁₁)?
- A solution of NaNO₃ is generated by dissolving 1.25 g of NaNO₃ in enough water to give a final volume of 25.0 mL. What is the osmotic pressure of this sample at 25.0°C?
- Which would have the lower vapor pressure—an aqueous solution that is 0.12 M in glucose or one that is 0.12 M in CaCl₂? Why?
- What is the total particle concentration expected for each aqueous solution? Which would produce the highest osmotic pressure?
 - 0.35 M KBr
 - 0.11 M MgSO₄
 - 0.26 M MgCl₂
 - 0.24 M glucose (C₆H₁₂O₆)
- The boiling point of an aqueous solution of sodium chloride is 100.37°C. What is the molality of the solution? How many grams of NaCl are present in 125 g of the solution?
- Calculate the boiling point of a solution of sugar prepared by dissolving 8.4 g of glucose (C₆H₁₂O₆) in 250 g of water.
- At 37°C, the vapor pressure of 300.0 g of water was reduced from 0.062 atm to 0.058 atm by the addition of NaBr. How many grams of NaBr were added?
- How many grams of KCl must be added to reduce the vapor pressure of 500.0 g of H₂O from 17.5 mmHg to 16.0 mmHg at 20.0°C?
- How much NaCl would you have to add to 2.0 L of water at a mountain lodge at an elevation of 7350 ft, where the pressure is 0.78 atm and the boiling point of water is 94°C, to get the water to boil at the same temperature as in New Orleans, Louisiana, where the pressure is 1.00 atm?
- You have three solutions with the following compositions: 12.5 g of KCl in 250 mL of water, 12.5 g of glucose in 400 mL of water, and 12.5 g of MgCl₂ in 350 mL of water. Which will have the highest boiling point?
- Assuming the price per kilogram is the same, which is a better salt to use for deicing wintry roads—NaCl or MgCl₂? Why? Would magnesium chloride be an effective deicer at a temperature of -8°C?
- How many grams of KNO₃ must be added to water to produce the same boiling point elevation as a solution of 2.03 g of MgCl₂ in a total volume of 120.0 mL of solution, assuming complete dissociation? If the van't Hoff factor for MgCl₂ at this concentration is 2.73, how much KNO₃ would be needed?
- Calculate the quantity of each compound that would need to be added to lower the freezing point of 500.0 mL of water by 1.0°C: KBr, ethylene glycol, MgBr₂, ethanol. Assume that the density of water is 1.00 g/cm³.
- The melting point depression of biphenyl (melting point = 69.0°C) can be used to determine the molecular mass of organic compounds. A mixture of 100.0 g of biphenyl and 2.67 g of naphthalene (C₁₀H₈) has a melting point of 68.50°C. If a mixture of 1.00 g of an unknown compound with 100.0 g of biphenyl has a melting point of 68.86°C, what is the molar mass of the unknown compound?
- Four solutions of urea in water were prepared, with concentrations of 0.32 *m*, 0.55 *m*, 1.52 *m*, and 3.16 *m*. The freezing points of these solutions were found to be -0.595°C, -1.02°C, -2.72°C, and -5.71°C, respectively. Graphically determine the freezing point depression constant for water. A fifth solution made by dissolving 6.22 g of urea in 250.0 g of water has a freezing point of -0.75°C. Use these data to determine the molar mass of urea.
- The term *osmolality* has been used to describe the total solute concentration of a solution (generally water), where 1 osmole (Osm) is equal to 1 mol of an ideal, nonionizing molecule.
 - What is the osmolality of a 1.5 M solution of glucose? a 1.5 M solution of NaCl? a 1.5 M solution of CaCl₂?
 - What is the relationship between osmolality and the concentration of water?

- c. What would be the direction of flow of water through a semipermeable membrane separating a 0.1 M solution of NaCl and a 0.1 M solution of CaCl₂?
19. At 40°C, the vapor pressures of pure CCl₄ and cyclohexane are 0.2807 atm and 0.2429 atm, respectively. Assuming ideal behavior, what is the vapor pressure of a solution with a CCl₄ mole fraction of 0.475? What is the mole fraction of cyclohexane in the vapor phase? The boiling points of CCl₄ and cyclohexane are 76.8°C and 80.7°C, respectively.
20. A benzene/toluene solution with a mole fraction of benzene of 0.6589 boils at 88°C at 1 atm. The vapor pressures of pure benzene and toluene at this temperature are 1.259 atm and 0.4993 atm, respectively. What is the composition of the vapor above the boiling solution at this temperature?
21. Plot the vapor pressure of the solution versus composition for the system CCl₄-CH₃CN at 45°C, given the following experimental data:

X _{CCl₄} (liquid)	0.035	0.375	0.605	0.961
X _{CCl₄} (vapor)	0.180	0.543	0.594	0.800
Total P (atm)	0.326	0.480	0.488	0.414

Does your diagram show behavior characteristic of an ideal solution? Explain your answer.

Answers 4

- 6.7×10^{-4} amu
-
- 9.24 atm
-
- The CaCl₂ solution will have a lower vapor pressure, because it contains three times as many particles as the glucose solution.
-
- 0.36 m NaCl, 2.6 g NaCl
-
- 60 g NaBr
-
- 700 g NaCl
-
- MgCl₂ produces three particles in solution versus two for NaCl, so the same molal concentration of MgCl₂ will produce a 50% greater freezing point depression than for NaCl. Nonetheless, the molar mass of MgCl₂ is 95.3 g/mol versus 48.45 g/mol for NaCl. Consequently, a solution containing 1 g NaCl per 1000 g H₂O will produce a freezing point depression of 0.064°C versus 0.059°C for a solution containing 1 g MgCl₂ per 1000 g H₂O. Thus, given equal cost per gram, NaCl is more effective. Yes, MgCl₂ would be effective at -8°C; a 1.43 m solution (136 g per 1000 g H₂O) would be required.

Learning Objectives

- To distinguish between true solutions and solutions with aggregate particles.

Suspensions and colloids are two common types of mixtures whose properties are in many ways intermediate between those of true solutions and heterogeneous mixtures. A suspension is a heterogeneous mixture of particles with diameters of about 1 μm (1000 nm) that are distributed throughout a second phase. Common suspensions include paint, blood, and hot chocolate, which are solid particles in a liquid, and aerosol sprays, which are liquid particles in a gas. If the suspension is allowed to stand, the two phases will separate, which is why paints must be thoroughly stirred or shaken before use. A colloid is also a heterogeneous mixture, but the particles of a colloid are typically smaller than those of a suspension, generally in the range of 2 to about 500 nm in diameter. Colloids include fog and clouds (liquid particles in a gas), milk (solid particles in a liquid), and butter (solid particles in a solid). Other colloids are used industrially as catalysts. Unlike in a suspension, the particles in a colloid do not separate into two phases on standing. The only combination of substances that cannot produce a suspension or a colloid is a mixture of two gases because their particles are so small that they always form true solutions. The properties of suspensions, colloids, and solutions are summarized in [Table 13.6.1](#).

Table 13.6.1 Properties of Liquid Solutions, Colloids, and Suspensions

Type of Mixture	Approximate Size of Particles (nm)	Characteristic Properties	Examples
solution	< 2	not filterable; does not separate on standing; does not scatter visible light	air, white wine, gasoline, salt water
colloid	2–500	scatters visible light; translucent or opaque; not filterable; does not separate on standing	smoke, fog, ink, milk, butter, cheese
suspension	500–1000	cloudy or opaque; filterable; separates on standing	muddy water, hot cocoa, blood, paint

Colloids and Suspensions

Colloids were first characterized in about 1860 by Thomas Graham, who also gave us Graham's law of diffusion and effusion. Although some substances, such as starch, gelatin, and glue, appear to dissolve in water to produce solutions, Graham found that they diffuse very slowly or not at all compared with solutions of substances such as salt and sugar. Graham coined the word *colloid* (from the Greek *kólla*, meaning "glue") to describe these substances, as well as the words *sol* and *gel* to describe certain types of colloids in which all of the solvent has been absorbed by the solid particles, thus preventing the mixture from flowing readily, as we see in Jell-O. Two other important types of colloids are aerosols, which are dispersions of solid or liquid particles in a gas, and emulsions, which are dispersions of one liquid in another liquid with which it is immiscible.

Colloids share many properties with solutions. For example, the particles in both are invisible without a powerful microscope, do not settle on standing, and pass through most filters. However, the particles in a colloid scatter a beam of visible light, a phenomenon known as the Tyndall effect. The effect is named after its discoverer, John Tyndall, an English physicist (1820–1893), whereas the particles of a solution do not. The Tyndall effect is responsible for the way the beams from automobile headlights are clearly visible from the side on a foggy night but cannot be seen from the side on a clear night. It is also responsible for the colored rays of light seen in many sunsets, where the sun's light is scattered by water droplets and dust particles high in the atmosphere. An example of the Tyndall effect is shown in [Figure 13.6.1](#)

Although colloids and suspensions can have particles similar in size, the two differ in stability: the particles of a colloid remain dispersed indefinitely unless the temperature or chemical composition of the dispersing medium is changed. The chemical explanation for the stability of colloids depends on whether the colloidal particles are hydrophilic or hydrophobic.

Most proteins, including those responsible for the properties of gelatin and glue, are hydrophilic because their exterior surface is largely covered with polar or charged groups. Starch, a long-branched polymer of glucose molecules, is also hydrophilic. A hydrophilic colloid particle interacts strongly with water, resulting in a shell of tightly bound water molecules that prevents the particles from aggregating when they collide. Heating such a colloid can cause aggregation because the particles collide with greater energy and disrupt the protective shell of solvent. Moreover, heat causes protein structures to unfold, exposing previously buried hydrophobic groups that can now interact with other hydrophobic groups and cause the particles to aggregate and precipitate from solution. When an egg is boiled, for example, the egg white, which is primarily a colloidal suspension of a protein called *albumin*, unfolds and exposes its hydrophobic groups, which aggregate and cause the albumin to precipitate as a white solid.

In some cases, a stable colloid can be transformed to an aggregated suspension by a minor chemical modification. Consider, for example, the behavior of hemoglobin, a major component of red blood cells. Hemoglobin molecules normally form a colloidal suspension inside red blood cells, which typically have a “donut” shape and are easily deformed, allowing them to squeeze through the capillaries to deliver oxygen to tissues. In a common inherited disease called sickle-cell anemia, one of the amino acids in hemoglobin that has a hydrophilic carboxylic acid side chain (glutamate) is replaced by another amino acid that has a hydrophobic side chain (valine, [Figure 9.7.1 5.16](#)). Under some conditions, the abnormal hemoglobin molecules can aggregate to form long, rigid fibers that cause the red blood cells to deform, adopting a characteristic sickle shape that prevents them from passing through the capillaries ([Figure 13.6.2](#)). The reduction in blood flow results in severe cramps, swollen joints, and liver damage. Until recently, many patients with sickle-cell anemia died before the age of 30 from infection, blood clots, or heart or kidney failure, although individuals with the sickle-cell genetic trait are more resistant to malaria than are those with “normal” hemoglobin.

Aggregation and precipitation can also result when the outer, charged layer of a particle is neutralized by ions with the opposite charge. In inland waterways, clay particles, which have a charged surface, form a colloidal suspension. High salt concentrations in seawater neutralize the charge on the particles, causing them to precipitate and form land at the mouths of large rivers, as seen in the satellite view in [Figure 13.6.3](#). Charge neutralization is also an important strategy for precipitating solid particles from gaseous colloids such as smoke, and it is widely used to reduce particulate emissions from power plants that burn fossil fuels.

Emulsions

Emulsions are colloids formed by the dispersion of a hydrophobic liquid in water, thereby bringing two mutually insoluble liquids, such as oil and water, in close contact. Various agents have been developed to stabilize emulsions, the most successful being molecules that combine a relatively long hydrophobic “tail” with a hydrophilic “head”:

Figure 13.6.1 Tyndall Effect, the Scattering of Light by Colloids The glass on the left has dilute colloidal silver, the one on the right tap water. The red laser pointer beam is scattered by the Tyndall effect in the glass on the left.

Figure 13.6.2 Sickle-Cell Anemia The characteristic shape of sickled red blood cells is the result of fibrous aggregation of hemoglobin molecules inside the cell.

Examples of such emulsifying agents include soaps, which are salts of long-chain carboxylic acids, such as sodium stearate⁺ [$\text{CH}_3(\text{CH}_2)_{16}\text{CO}_2\text{Na}$], and detergents, such as sodium dodecyl sulfate [$\text{CH}_3(\text{CH}_2)_{11}\text{OSO}_3\text{Na}$], whose structures are as follows:

Figure 13.6.3 Formation of New Land by the Destabilization of a Colloid Suspension This satellite photograph shows the Mississippi River delta from New Orleans (top) to the Gulf of Mexico (bottom). Where seawater mixes with freshwater from the Mississippi River, colloidal clay particles in the river water precipitate (tan area).

When you wash your laundry, the hydrophobic tails of soaps and detergents interact with hydrophobic particles of dirt or grease through dispersion forces, dissolving in the interior of the hydrophobic particle. The hydrophilic group is then exposed at the surface of the particle, which enables it to interact with water through ion-dipole forces and hydrogen bonding. This causes the particles of dirt or grease to disperse in the wash water and allows them to be removed by rinsing. Similar agents are used in the food industry to stabilize emulsions such as mayonnaise.

A related mechanism allows us to absorb and digest the fats in buttered popcorn and French fries. To solubilize the fats so that they can be absorbed, the gall bladder secretes a fluid called *bile* into the small intestine. Bile contains a variety of *bile salts*, detergent-like molecules that emulsify the fats.

Micelles

Detergents and soaps are surprisingly soluble in water in spite of their hydrophobic tails. The reason for their solubility is that they do not, in fact, form simple solutions. Instead, above a certain concentration they spontaneously form micelles, which are spherical or cylindrical aggregates that minimize contact between the hydrophobic tails and water. In a micelle, only the hydrophilic heads are in direct contact with water, and the hydrophobic tails are in the interior of the aggregate (part (a) in [Figure 13.6.4](#)).

Figure 13.6.4 Micelles and a Phospholipid Bilayer (a) Soaps and detergents, which contain a single hydrophobic tail on each molecule, form spherical micelles with the intertwined tails in the interior and the hydrophilic head groups on the exterior. (b) Phospholipids, which have two hydrophobic tails, tend to form extended double layers in which the hydrophobic tails are sandwiched between the hydrophilic head groups.

A large class of biological molecules called phospholipids consists of detergent-like molecules with a hydrophilic head and two hydrophobic tails, as can be seen in the molecule of phosphatidylcholine. The additional tail results in a cylindrical shape that prevents phospholipids from forming a spherical micelle. Consequently, phospholipids form bilayers, extended sheets consisting of a double layer of molecules. As shown in part (b) in [Figure 13.6.4](#), the hydrophobic tails are in the center of the bilayer, where they are not in contact with water, and the hydrophilic heads are on the two surfaces, in contact with the surrounding aqueous solution.

A cell membrane is essentially a mixture of phospholipids that form a phospholipid bilayer. One definition of a cell is a collection of molecules surrounded by a phospholipid bilayer that is capable of reproducing itself. The simplest cells are bacteria, which consist of only a single compartment surrounded by a single membrane. Animal and plant cells are much more complex, however, and contain many different kinds of compartments, each surrounded by a membrane and able to carry out specialized tasks.

Summary

A **suspension** is a heterogeneous mixture of particles of one substance distributed throughout a second phase; the dispersed particles separate from the dispersing phase on standing. In contrast, the particles in a **colloid** are smaller and do not separate on standing. A colloid can be classified as a **sol**, a dispersion of solid particles in a liquid or solid; a **gel**, a semisolid sol in which all of the liquid phase has been absorbed by the solid particles; an **aerosol**, a dispersion of solid or liquid particles in a gas; or an **emulsion**, a dispersion of one liquid phase in another. A colloid can be distinguished from a true solution by its ability to scatter a beam of light, known as the **Tyndall effect**. Hydrophilic colloids contain an outer shell of groups that interact favorably with water, whereas hydrophobic colloids have an outer surface with little affinity for water. **Emulsions** are prepared by dispersing a hydrophobic liquid in water. In the absence of a dispersed hydrophobic liquid phase, solutions of detergents in water form organized spherical aggregates called **micelles**. **Phospholipids** are a class of detergent-like molecules that have two hydrophobic tails attached to a hydrophilic head. A **bilayer** is a two-dimensional sheet consisting of a double layer of phospholipid molecules arranged tail to tail with a hydrophobic interior and a hydrophilic exterior. **Cells** are collections of molecules that are surrounded by a phospholipid bilayer called a **cell membrane** and are able to reproduce themselves.

Key Takeaway

- Colloids and suspensions are mixtures whose properties are in many ways intermediate between those of true solutions and heterogeneous mixtures.

Conceptual Problems

1. How does a colloid differ from a suspension? Which has a greater effect on solvent properties, such as vapor pressure?
2. Is homogenized milk a colloid or a suspension? Is human plasma a colloid or a suspension? Justify your answers.
3. How would you separate the components of an emulsion of fat dispersed in an aqueous solution of sodium chloride?

APPLICATION PROBLEMS

Problems marked with a ♦ involve multiple concepts.

- ♦ Scuba divers utilize high-pressure gas in their tanks to allow them to breathe under water. At depths as shallow as 100 ft (30 m), the pressure exerted by water is 4.0 atm. At 25°C the values of Henry's law constants for N_2 , O_2 , and He in blood are as follows: $N_2 = 6.5 \times 10^{-4}$ mol/(L·atm), $O_2 = 1.28 \times 10^{-4}$ mol/(L·atm), and $He = 3.7 \times 10^{-4}$ mol/(L·atm).
 - What would be the concentration of nitrogen and oxygen in blood at sea level where the air is 21% oxygen and 79% nitrogen?
 - What would be the concentration of nitrogen and oxygen in blood at a depth of 30 m, assuming that the diver is breathing compressed air?
- ♦ Many modern batteries take advantage of lithium ions dissolved in suitable electrolytes. Typical batteries have lithium concentrations of 0.10 M. Which aqueous solution has the higher concentration of ion pairs: 0.08 M LiCl or 1.4 M LiCl? Why? Does an increase in the number of ion pairs correspond to a higher or lower van't Hoff factor? Batteries rely on a high concentration of unpaired Li⁺ ions. Why is using a more concentrated solution not an ideal strategy in this case?
- Hydrogen sulfide, which is extremely toxic to humans, can be detected at a concentration of 2.0 ppb. At this level, headaches, dizziness, and nausea occur. At higher concentrations, however, the sense of smell is lost, and the lack of warning can result in coma and death can result. What is the concentration of H_2S in milligrams per liter at the detection level? The lethal dose of hydrogen sulfide by inhalation for rats is 7.13×10^{-3} g/L. What is this lethal dose in ppm? The density of air is 1.2929 g/L.
- One class of antibiotics consists of cyclic polyethers that can bind alkali metal cations in aqueous solution. Given the following antibiotics and cation selectivities, what conclusion can you draw regarding the relative sizes of the cavities?

Antibiotic	Cation Selectivity
nigericin	K ⁺ > Rb ⁺ > Na ⁺ > Cs ⁺ > Li ⁺
lasalocid	Ba ²⁺ >> Cs ⁺ > Rb ⁺ , K ⁺ > Na ⁺ , Ca ²⁺ , Mg ²⁺

- Phenylpropanolamine hydrochloride is a common nasal decongestant. An aqueous solution of phenylpropanolamine hydrochloride that is sold commercially as a children's decongestant has a concentration of 6.67×10^{-3} M. If a common dose is 1.0 mL/12 lb of body weight, how many moles of the decongestant should be given to a 26 lb child?
- The "freeze-thaw" method is often used to remove dissolved oxygen from solvents in the laboratory. In this technique, a liquid is placed in a flask that is then sealed to the atmosphere, the liquid is frozen, and the flask is evacuated to remove any gas and solvent vapor in the flask. The connection to the vacuum pump is closed, the liquid is warmed to room temperature and then refrozen, and the process is repeated. Why is this technique effective for degassing a solvent?
- Suppose that, on a planet in a galaxy far, far away, a species has evolved whose biological processes require even more oxygen than we do. The partial pressure of oxygen on this planet, however, is much less than that on Earth. The chemical composition of the "blood" of this species is also different. Do you expect their "blood" to have a higher or lower value of the Henry's law constant for oxygen at standard temperature and pressure? Justify your answer.

8. A car owner who had never taken general chemistry decided that he needed to put some ethylene glycol antifreeze in his car's radiator. After reading the directions on the container, however, he decided that "more must be better." Instead of using the recommended mixture (30% ethylene glycol/70% water), he decided to reverse the amounts and used a 70% ethylene glycol/30% water mixture instead. Serious engine problems developed. Why?
9. The ancient Greeks produced "Attic ware," pottery with a characteristic black and red glaze. To separate smaller clay particles from larger ones, the powdered clay was suspended in water and allowed to settle. This process yielded clay fractions with coarse, medium, and fine particles, and one of these fractions was used for painting. Which size of clay particles forms a suspension, which forms a precipitate, and which forms a colloidal dispersion? Would the colloidal dispersion be better characterized as an emulsion? Why or why not? Which fraction of clay particles was used for painting?
10. The Tyndall effect is often observed in movie theaters, where it makes the beam of light from the projector clearly visible. What conclusions can you draw about the quality of the air in a movie theater where you observe a large Tyndall effect?
11. Aluminum sulfate is the active ingredient in styptic pencils, which can be used to stop bleeding from small cuts. The Al^{3+} ions induce aggregation of colloids in the blood, which facilitates formation of a blood clot. How can Al^{3+} ions induce aggregation of a colloid? What is the probable charge on the colloidal particles in blood?
12. ♦ The liver secretes bile, which is essential for the digestion of fats. As discussed in [Chapter 5 "Energy Changes in Chemical Reactions"](#), fats are biomolecules with long hydrocarbon chains. The globules of fat released by partial digestion of food particles in the stomach and lower intestine are too large to be absorbed by the intestine unless they are emulsified by bile salts, such as glycocholate. Explain why a molecule like glycocholate is effective at creating an aqueous dispersion of fats in the digestive tract.

ANSWERS

1.
 - a. 1 atm: 2.7×10^{-4} M O_2 and 5.1×10^{-4} M N_2
 - b. 4 atm: 1.1×10^{-4} M O_2 and 2.1×10^{-4} M N_2
- 2.
3. 2.6×10^{-6} mg/L, 550 ppm
- 4.
5. 1.4×10^{-5} mol
- 6.
7. To obtain the same concentration of dissolved oxygen in their "blood" at a lower partial pressure of oxygen, the value of the Henry's law constant would have to be higher.
- 8.
9. The large, coarse particles would precipitate, the medium particles would form a suspension, and the fine ones would form a colloid. A colloid consists of solid particles in a liquid medium, so it is not an emulsion, which consists of small particles of one liquid suspended in another liquid. The finest particles would be used for painting.

Learning Objective

- To understand the factors that affect reaction rates.

Although a balanced chemical equation for a reaction describes the quantitative relationships between the amounts of reactants present and the amounts of products that can be formed, it gives us no information about whether or how fast a given reaction will occur. This information is obtained by studying the chemical kinetics of a reaction, which depend on various factors: reactant concentrations, temperature, physical states and surface areas of reactants, and solvent and catalyst properties if either are present. By studying the kinetics of a reaction, chemists gain insights into how to control reaction conditions to achieve a desired outcome.

Concentration Effects

Two substances cannot possibly react with each other unless their constituent particles (molecules, atoms, or ions) come into contact. If there is no contact, the reaction rate will be zero. Conversely, the more reactant particles that collide per unit time, the more often a reaction between them can occur. Consequently, the reaction rate usually increases as the concentration of the reactants increases. One example of this effect is the reaction of sucrose (table sugar) with sulfuric acid, which is shown in [Figure 14.1.1](#).

Figure 14.1.1 The Effect of Concentration on Reaction Rates Mixing sucrose with dilute sulfuric acid in a beaker (a, right) produces a simple solution. Mixing the same amount of sucrose with concentrated sulfuric acid (a, left) results in a dramatic reaction (b) that eventually produces a column of black porous graphite (c) and an intense smell of burning sugar.

Temperature Effects

You learned in [Chapter 10](#) that increasing the temperature of a system increases the average kinetic energy of its constituent particles. As the average kinetic energy increases, the particles move faster, so they collide more frequently per unit time and possess greater energy when they collide. Both of these factors increase the reaction rate. Hence the reaction rate of virtually all reactions increases with increasing temperature. Conversely, the reaction rate of virtually all reactions decreases with decreasing temperature. For example, refrigeration retards the rate of growth of bacteria in foods by decreasing the reaction rates of biochemical reactions that enable bacteria to reproduce. [Figure 14.1.2](#) shows how temperature affects the light emitted by two chemiluminescent light sticks.

Figure 14.1.2 The Effect of Temperature on Reaction Rates At **high** temperature, the reaction that produces light in a chemiluminescent light stick occurs more rapidly, producing more photons of light per unit time. Consequently, the light glows brighter in hot water (left) than in ice water (right).

In systems where more than one reaction is possible, the same reactants can produce different products under different reaction conditions. For example, in the presence of dilute sulfuric acid and at temperatures around 100°C, ethanol is converted to diethyl ether:

At 180°C, however, a completely different reaction occurs, which produces ethylene as the major product:

Phase and Surface Area Effects

When two reactants are in the same fluid phase, their particles collide more frequently than when one or both reactants are solids (or when they are in different fluids that do not mix). If the reactants are uniformly dispersed in a single homogeneous solution, then the number of collisions per unit time depends on concentration and temperature, as we have just seen. If the reaction is heterogeneous, however, the reactants are in two different phases, and collisions between the reactants can occur only at interfaces between phases. The number of collisions between reactants per unit time is substantially reduced relative to the homogeneous case, and, hence, so is the reaction rate. The reaction rate of a heterogeneous reaction depends on the surface area of the more condensed phase.

Automobile engines use surface area effects to increase reaction rates. Gasoline is injected into each cylinder, where it combusts on ignition by a spark from the spark plug. The gasoline is injected in the form of microscopic droplets because in that form it has a much larger surface area and can burn much more rapidly than if it were fed into the cylinder as a stream. Similarly, a pile of finely divided flour burns slowly (or not at all), but spraying finely divided flour into a flame produces a vigorous reaction ([Figure 14.1.3](#)). Similar phenomena are partially responsible for dust explosions that occasionally destroy grain elevators or coal mines.

Learning Objectives

- To determine the reaction rate.
- To understand the meaning of a rate law.

The factors discussed in [Section 14.1](#) affect the reaction rate of a chemical reaction, which may determine whether a desired product is formed. In this section, we will show you how to quantitatively determine the reaction rate.

Reaction Rates

Reaction rates are usually expressed as the concentration of reactant consumed or the concentration of product formed per unit time. The units are thus moles per liter per unit time, written as M/s, M/min, or M/h. To measure reaction rates, chemists initiate the reaction, measure the concentration of the reactant or product at different times as the reaction progresses, perhaps plot the concentration as a function of time on a graph, and then calculate the *change* in the concentration per unit time.

The progress of a simple reaction ($A \rightarrow B$) is shown in [Figure 14.2.1](#) where the beakers are snapshots of the composition of the solution at 10 s intervals. The number of molecules of reactant (A) and product (B) are plotted as a function of time in the graph. Each point in the graph corresponds to one beaker in [Figure 14.2.1](#). The reaction rate is the change in the concentration of either the reactant or the product over a period of time. The concentration of A decreases with time, while the concentration of B increases with time.

Figure 14.2.1 *The Progress of a Simple Reaction ($A \rightarrow B$)* The mixture initially contains only A molecules (purple). With increasing time, the number of A molecules decreases and more B molecules (green) are formed (top). The graph shows the change in the number of A and B molecules in the reaction as a function of time over a 1 min period (bottom).

$$\text{rate} = \frac{\Delta [B]}{\Delta t} = -\frac{\Delta [A]}{\Delta t} \quad (14.2.1)$$

Square brackets indicate molar concentrations, and the capital Greek delta (Δ) means “change in.” Because chemists follow the convention of expressing all reaction rates as positive numbers, however, a negative sign is inserted in front of $\Delta[A]/\Delta t$ to convert

that expression to a positive number. The reaction rate we would calculate for the reaction $A \rightarrow B$ using Equation 14.2.1 would be different for each interval. (This is not true for every reaction, as you will see later.) A much greater change occurs in $[A]$ and $[B]$ during the first 10 s interval, for example, than during the last, which means that the reaction rate is fastest at first. This is consistent with the concentration effects described in Section 14.1 because the concentration of A is greatest at the beginning of the reaction.

Note the Pattern

Reaction rates generally decrease with time as reactant concentrations decrease.

Determining the Reaction Rate of Hydrolysis of Aspirin

We can use Equation 14.2.1 to determine the reaction rate of hydrolysis of aspirin, probably the most commonly used drug in the world. (More than 25,000,000 kg are produced annually worldwide.) Aspirin (acetylsalicylic acid) reacts with water (such as water in body fluids) to give salicylic acid and acetic acid.

Figure 14.2.2 Because salicylic acid is the actual substance that relieves pain and reduces fever and inflammation, a great deal of research has focused on understanding this reaction and the factors that affect its rate. Data for the hydrolysis of a sample of aspirin are in Table 14.2.1 and are shown in the graph in Figure 14.2.3. These data were obtained by removing samples of the reaction mixture at the indicated times and analyzing them for the concentrations of the reactant (aspirin) and one of the products (salicylic acid).

Table 14.2.1 Data for Aspirin Hydrolysis in Aqueous Solution at pH 7.0 and 37°C*

Time (h)	[Aspirin] (M)	[Salicylic Acid] (M)
0	5.55×10^{-3}	0
2.0	5.51×10^{-3}	0.040×10^{-3}
5.0	5.45×10^{-3}	0.10×10^{-3}
10	5.35×10^{-3}	0.20×10^{-3}
20	5.15×10^{-3}	0.40×10^{-3}
30	4.96×10^{-3}	0.59×10^{-3}
40	4.78×10^{-3}	0.77×10^{-3}
50	4.61×10^{-3}	0.94×10^{-3}
100	3.83×10^{-3}	1.72×10^{-3}
200	2.64×10^{-3}	2.91×10^{-3}
300	1.82×10^{-3}	3.73×10^{-3}

*The reaction at pH 7.0 is very slow. It is *much* faster under acidic conditions, such as those found in the stomach.

Figure 14.2.3 The Hydrolysis of Aspirin This graph shows the concentrations of aspirin and salicylic acid as a function of time, based on the hydrolysis data in Table 14.2.1. The time dependence of the concentration of the other product, acetate, is not shown, but based on the stoichiometry of the reaction, it is identical to the data for salicylic acid.

We can calculate the average reaction rate

$$\begin{aligned} \text{rate}_{(t=0-2.0 \text{ h})} &= \frac{[\text{salicylic acid}]_2 - [\text{salicylic acid}]_0}{2.0 \text{ h} - 0.0 \text{ h}} \\ &= \frac{0.040 \times 10^{-3} \text{ M} - 0.000 \text{ M}}{2.0 \text{ h} - 0.0 \text{ h}} = 2 \times 10^{-5} \text{ M/h} \end{aligned}$$

We can also calculate the reaction rate from the concentrations of aspirin at the beginning and the end of the same interval, remembering to insert a negative sign, because its concentration decreases:

$$\begin{aligned} \text{rate}_{(t=0-2.0 \text{ h})} &= \frac{[\text{aspirin}]_2 - [\text{aspirin}]_0}{2.0 \text{ h} - 0.0 \text{ h}} \\ \text{rate}_{(t=0-2.0 \text{ h})} &= \frac{5.51 \times 10^{-3} \text{ M} - 5.55 \times 10^{-3} \text{ M}}{2.0 \text{ h} - 0.0 \text{ h}} = -2.0 \times 10^{-5} \text{ M/h} \end{aligned}$$

If we now calculate the reaction rate during the last interval given in Table 14.2.1 (the interval between 200 h and 300 h after the start of the reaction), we find that the reaction rate is significantly slower than it was during the first interval ($t = 0-2.0 \text{ h}$):

$$\begin{aligned} \text{rate}_{(t=200-300 \text{ h})} &= \frac{[\text{salicylic acid}]_{300} - [\text{salicylic acid}]_{200}}{300 \text{ h} - 200 \text{ h}} \\ &= \frac{3.73 \times 10^{-3} \text{ M} - 2.91 \times 10^{-3} \text{ M}}{100 \text{ h}} = 8.2 \times 10^{-6} \text{ M/h} \end{aligned}$$

(You should verify from the data in Table 14.2.1 that you get the same rate using the concentrations of aspirin measured at 200 h and 300 h.)

Calculating the Reaction Rate of Fermentation of Sucrose

In the preceding example, the stoichiometric coefficients in the balanced chemical equation are the same for all reactants and products; that is, the reactants and products all have the coefficient 1. Let us look at a reaction in which the coefficients are *not* all the same: the fermentation of sucrose to ethanol and carbon dioxide, which we encountered in Chapter 8

The coefficients show us that the reaction produces four molecules of ethanol and four molecules of carbon dioxide for every one molecule of sucrose consumed. As before, we can find the reaction rate by looking at the change in the concentration of any reactant or product. In this particular case, however, a chemist would probably use the concentration of either sucrose or ethanol because gases are usually measured as volumes and, as you learned in Chapter 10, the volume of CO_2 gas formed will depend on the total volume of the solution being studied and the solubility of the gas in the solution, not just the concentration of sucrose. The coefficients in the balanced chemical equation tell us that the reaction rate at which ethanol is formed is always four times faster than the reaction rate at which sucrose is consumed:

$$rate = \frac{\Delta [C_2H_5OH]}{\Delta t} = - \frac{4\Delta [sucrose]}{\Delta t} \quad (14.2.3)$$

The concentration of the reactant—in this case sucrose—*decreases* with increasing time, so the value of $\Delta[sucrose]$ is negative. Consequently, a minus sign is inserted in front of $\Delta[sucrose]$ in Equation 14.2.3 so that the rate of change of the sucrose concentration is expressed as a positive value. Conversely, the ethanol concentration *increases* with increasing time, so its rate of change is automatically expressed as a positive value.

Often the reaction rate is expressed in terms of the reactant or product that has the smallest coefficient in the balanced chemical equation. The smallest coefficient in the sucrose fermentation reaction (Equation 14.2.2) corresponds to sucrose, so the reaction rate is generally defined as follows:

$$rate = - \frac{\Delta [sucrose]}{\Delta t} = \frac{1}{4} \left(\frac{\Delta [C_2H_5OH]}{\Delta t} \right) \quad (14.2.4)$$

Example 14.2.1

Consider the thermal decomposition of gaseous N_2O_5 to NO_2 and O_2 via the following equation:

Write expressions for the reaction rate in terms of the rates of change in the concentrations of the reactant and each product with time.

Given: balanced chemical equation

Asked for: reaction rate expressions

Strategy:

A Choose the species in the equation that has the smallest coefficient. Then write an expression for the rate of change of that species with time.

B For the remaining species in the equation, use molar ratios to obtain equivalent expressions for the reaction rate.

Solution:

A Because O_2 has the smallest coefficient in the balanced chemical equation for the reaction, we define the reaction rate as the rate of change in the concentration of O_2 and write that expression.

B We know from the balanced chemical equation that 2 mol of N_2O_5 must decompose for each 1 mol of O_2 produced and that 4 mol of NO_2 are produced for every 1 mol of O_2 produced. The molar ratios of O_2 to N_2O_5 and to NO_2 are thus 1:2 and 1:4, respectively. This means that we divide the rate of change of $[N_2O_5]$ and $[NO_2]$ by its stoichiometric coefficient to obtain equivalent expressions for the reaction rate. For example, because NO_2 is produced at four times the rate of O_2 , we must divide the rate of production of NO_2 by 4. The reaction rate expressions are as follows:

$$rate = \frac{\Delta [O_2]}{\Delta t} = \frac{\Delta [NO_2]}{4\Delta t} = - \frac{\Delta [N_2O_5]}{2\Delta t}$$

Exercise

The key step in the industrial production of sulfuric acid is the reaction of SO_2 with O_2 to produce SO_3 .

Write expressions for the reaction rate in terms of the rate of change of the concentration of each species.

Answer:

$$rate = - \frac{\Delta [O_2]}{\Delta t} = - \frac{\Delta [SO_2]}{\Delta t} = \frac{\Delta [SO_3]}{2\Delta t}$$

Example 14.2.2

Using the reaction shown in Example 1, calculate the reaction rate from the following data taken at 56°C:

$2\text{N}_2\text{O}_5(\text{g}) \rightarrow 4\text{NO}_2(\text{g}) + \text{O}_2(\text{g})$			
Time (s)	$[\text{N}_2\text{O}_5]$ (M)	$[\text{NO}_2]$ (M)	$[\text{O}_2]$ (M)
240	0.0388	0.0314	0.00792
600	0.0197	0.0699	0.0175

Given: balanced chemical equation and concentrations at specific times

Asked for: reaction rate

Strategy:

A Using the equations in Example 1, subtract the initial concentration of a species from its final concentration and substitute that value into the equation for that species.

B Substitute the value for the time interval into the equation. Make sure your units are consistent.

Solution:

A We are asked to calculate the reaction rate in the interval between $t_1 = 240$ s and $t_2 = 600$ s. From Example 1, we see that we can evaluate the reaction rate using any of three expressions:

$$\text{rate} = \frac{\Delta [\text{O}_2]}{\Delta t} = \frac{\Delta [\text{NO}_2]}{4\Delta t} = -\frac{\Delta [\text{N}_2\text{O}_5]}{2\Delta t}$$

Subtracting the initial concentration from the final concentration of N_2O_5 and inserting the corresponding time interval into the rate expression for N_2O_5 ,

$$\text{rate} = -\frac{\Delta [\text{N}_2\text{O}_5]}{2\Delta t} = -\frac{[\text{N}_2\text{O}_5]_{600} - [\text{N}_2\text{O}_5]_{240}}{2(600 \text{ s} - 240 \text{ s})}$$

B Substituting actual values into the expression,

$$\text{rate} = -\frac{0.0197 \text{ M} - 0.0388 \text{ M}}{2(360 \text{ s})}$$

Similarly, we can use NO_2 to calculate the reaction rate:

$$\text{rate} = -\frac{\Delta [\text{NO}_2]}{4\Delta t} = -\frac{[\text{NO}_2]_{600} - [\text{NO}_2]_{240}}{4(600 \text{ s} - 240 \text{ s})} = \frac{0.0699 \text{ M} - 0.0314 \text{ M}}{4(360)} = 2.67 \times 10^{-5} \text{ M/s}$$

If we allow for experimental error, this is the same rate we obtained using the data for N_2O_5 , as it should be because the reaction rate should be the same no matter which concentration is used. We can also use the data for O_2 :

$$\text{rate} = -\frac{\Delta [\text{O}_2]}{\Delta t} = -\frac{[\text{O}_2]_{600} - [\text{O}_2]_{240}}{(600 \text{ s} - 240 \text{ s})} = \frac{0.0175 \text{ M} - 0.00792 \text{ M}}{360 \text{ s}} = 2.66 \times 10^{-5} \text{ M/s}$$

Again, this is the same value we obtained from the N_2O_5 and NO_2 data. Thus the reaction rate does not depend on which reactant or product is used to measure it.

Exercise

Using the data in the following table, calculate the reaction rate of $\text{SO}_2(\text{g})$ with $\text{O}_2(\text{g})$ to give $\text{SO}_3(\text{g})$.

$2\text{SO}_2(\text{g}) + \text{O}_2(\text{g}) \rightarrow 2\text{SO}_3(\text{g})$			
Time (s)	$[\text{SO}_2]$ (M)	$[\text{O}_2]$ (M)	$[\text{SO}_3]$ (M)

$2\text{SO}_2(\text{g}) + \text{O}_2(\text{g}) \rightarrow 2\text{SO}_3(\text{g})$			
Time (s)	$[\text{SO}_2]$ (M)	$[\text{O}_2]$ (M)	$[\text{SO}_3]$ (M)
300	0.0270	0.0500	0.0072
720	0.0194	0.0462	0.0148

Answer: 9.0×10^{-6} M/s

Instantaneous Rates of Reaction

So far, we have determined average reaction rates over particular intervals of time. We can also determine the instantaneous rate of a reaction, which is the reaction rate at any given point in time. As the period of time used to calculate an average rate of a reaction becomes shorter and shorter, the average rate approaches the instantaneous rate. If you have studied calculus, you may recognize that the instantaneous rate of a reaction at a given time corresponds to the slope of a line tangent to the concentration-versus-time curve at that point—that is, the derivative of concentration with respect to time.

Think of the distinction between the instantaneous and average rates of a reaction as being similar to the distinction between the actual speed of a car at any given time on a trip and the average speed of the car for the entire trip. Although you may travel for a long time at 65 mph on an interstate highway during a long trip, there may be times when you travel only 25 mph in construction zones or 0 mph if you stop for meals or gas. Thus your average speed on the trip may be only 50 mph, whereas your instantaneous speed on the interstate at a given moment may be 65 mph. Whether you are able to stop the car in time to avoid an accident depends on your instantaneous speed, not your average speed. There are important differences between the speed of a car during a trip and the speed of a chemical reaction, however. The speed of a car may vary unpredictably over the length of a trip, and the initial part of a trip is often one of the slowest. In a chemical reaction, the initial interval normally has the fastest rate (though this is not always the case), and the reaction rate generally changes smoothly over time.

In chemical kinetics, we generally focus on one particular instantaneous rate, which is the initial reaction rate, $t = 0$. Initial rates are determined by measuring the reaction rate at various times and then extrapolating a plot of rate versus time to $t = 0$.

Rate Laws

In [Section 14.1](#), you learned that reaction rates generally decrease with time because reactant concentrations decrease as reactants are converted to products. You also learned that reaction rates generally increase when reactant concentrations are increased. We now examine the mathematical expressions called rate laws, which describe the relationships between reactant rates and reactant concentrations. Rate laws are laws as defined in [Chapter 1](#); that is, they are mathematical descriptions of experimentally verifiable data.

Rate laws may be written from either of two different but related perspectives. A differential rate law expresses the reaction rate in terms of *changes* in the concentration of one or more reactants ($\Delta[\text{R}]$) over a specific time interval (Δt). In contrast, an integrated rate law describes the reaction rate in terms of the *initial* concentration ($[\text{R}]_0$) and the *measured* concentration of one or more reactants ($[\text{R}]$) after a given amount of time (t); we will discuss integrated rate laws in [Section 14.3](#). The integrated rate law can be found by using calculus to integrate the differential rate law, although the method of doing so is beyond the scope of this text. *Whether you use a differential rate law or integrated rate law, always make sure that the rate law gives the proper units for the reaction rate, usually moles per liter per second (M/s).*

Reaction Orders

For a reaction with the general equation

the experimentally determined rate law usually has the following form:

$$\text{rate} = k[\text{A}]^m[\text{B}]^n \quad (14.2.6)$$

The *proportionality constant* (k) is called the rate constant, and its value is characteristic of the reaction and the reaction conditions. A given reaction has a particular value of the rate constant under a given set of conditions, such as temperature, pressure, and

solvent; varying the temperature or the solvent usually changes the value of the rate constant. The numerical value of k , however, does *not* change as the reaction progresses under a given set of conditions.

Thus the reaction rate depends on the rate constant for the given set of reaction conditions and the concentration of A and B raised to the powers m and n , respectively. The values of m and n are derived from experimental measurements of the changes in reactant concentrations over time and indicate the reaction order, the degree to which the reaction rate depends on the concentration of each reactant; m and n need not be integers. For example, Equation 14.2.6 tells us that Equation 14.2.5 is m th order in reactant A and n th order in reactant B. It is important to remember that n and m are not related to the stoichiometric coefficients a and b in the balanced chemical equation and must be determined experimentally. The *overall reaction order* is the sum of all the exponents in the rate law: $m + n$.

Note the Pattern

Under a given set of conditions, the value of the rate constant does not change as the reaction progresses.

Although differential rate laws are generally used to describe what is occurring on a molecular level during a reaction, integrated rate laws are used to determine the reaction order and the value of the rate constant from experimental measurements. (We present general forms for integrated rate laws in Section 14.3.) To illustrate how chemists interpret a differential rate law, we turn to the experimentally derived rate law for the hydrolysis of *t*-butyl bromide in 70% aqueous acetone. This reaction produces *t*-butanol according to the following equation:

Combining the rate expression in Equation 14.4 and Equation 14.9 gives us a general expression for the differential rate law:

$$rate = -\frac{\Delta[A]}{\Delta t} = k[A]^m[B]^n \quad (14.2.8)$$

Inserting the identities of the reactants into Equation 14.2.8 gives the following expression for the differential rate law for the reaction:

$$rate = -\frac{\Delta[(CH_3)_3CBr]}{\Delta t} = k[(CH_3)_3CBr]^m[H_2O]^n \quad (14.2.9)$$

Experiments done to determine the rate law for the hydrolysis of *t*-butyl bromide show that the reaction rate is directly proportional to the concentration of $(CH_3)_3CBr$ but is independent of the concentration of water. Thus m and n in Equation 14.12 are 1 and 0, respectively, and

$$rate = k[(CH_3)_3CBr]^1[H_2O]^0 = k[(CH_3)_3CBr] \quad (14.2.10)$$

Because the exponent for the reactant is 1, the reaction is *first order* in $(CH_3)_3CBr$. It is *zeroth order* in water because the exponent for $[H_2O]$ is 0. (Recall that anything raised to the zeroth power equals 1.) Thus the overall reaction order is $1 + 0 = 1$. What the reaction orders tell us in practical terms is that doubling the concentration of $(CH_3)_3CBr$ doubles the reaction rate of the hydrolysis reaction, halving the concentration of $(CH_3)_3CBr$ halves the reaction rate, and so on. Conversely, increasing or decreasing the concentration of water has *no effect* on the reaction rate. (Again, when you work with rate laws, there is no simple correlation between the stoichiometry of the reaction and the rate law. The values of k , m , and n in the rate law *must* be determined experimentally.) Experimental data show that k has the value $5.15 \times 10^{-4} \text{ s}^{-1}$ at 25°C. The rate constant has units of reciprocal seconds (s^{-1}) because the reaction rate is defined in units of concentration per unit time (M/s). The units of a rate constant depend on the rate law for a particular reaction.

Under conditions identical to those for the *t*-butyl bromide reaction, the experimentally derived differential rate law for the hydrolysis of methyl bromide (CH_3Br) is as follows:

$$rate = -\frac{\Delta[CH_3Br]}{\Delta t} = k'[CH_3Br] \quad (14.2.11)$$

This reaction also has an overall reaction order of 1, but the rate constant in Equation 14.2.11 is approximately 10^6 times smaller than that for *t*-butyl bromide. Thus methyl bromide hydrolyzes about 1 million times more slowly than *t*-butyl bromide, and this

information tells chemists how the reactions differ on a molecular level.

Frequently, changes in reaction conditions also produce changes in a rate law. In fact, chemists often change reaction conditions to obtain clues about what is occurring during a reaction. For example, when *t*-butyl bromide is hydrolyzed in an aqueous acetone solution containing OH^- ions rather than in aqueous acetone alone, the differential rate law for the hydrolysis reaction does not change. For methyl bromide, in contrast, the differential rate law becomes $\text{rate} = k''[\text{CH}_3\text{Br}][\text{OH}^-]$, with an overall reaction order of 2. Although the two reactions proceed similarly in neutral solution, they proceed very differently in the presence of a base, which again provides clues as to how the reactions differ on a molecular level.

Note the Pattern

Differential rate laws are generally used to describe what is occurring on a molecular level during a reaction, whereas integrated rate laws are used for determining the reaction order and the value of the rate constant from experimental measurements.

Example 14.2.3

We present three reactions and their experimentally determined differential rate laws. For each reaction, give the *units* of the rate constant, give the reaction *order* with respect to each reactant, give the *overall reaction order*, and predict what happens to the reaction rate when the concentration of the first species in each chemical equation is doubled.

Given: balanced chemical equations and differential rate laws

Asked for: units of rate constant, reaction orders, and effect of doubling reactant concentration

Strategy:

A Express the reaction rate as moles per liter per second [mol/(L·s), or M/s]. Then determine the units of each chemical species in the rate law. Divide the units for the reaction rate by the units for all species in the rate law to obtain the units for the rate constant.

B Identify the exponent of each species in the rate law to determine the reaction order with respect to that species. Sum all exponents to obtain the overall reaction order.

C Use the mathematical relationships as expressed in the rate law to determine the effect of doubling the concentration of a single species on the reaction rate.

Solution:

- A** $[\text{HI}]^2$ will give units of (moles per liter)². For the reaction rate to have units of moles per liter per second, the rate constant must have reciprocal units [1/(M·s)]:

$$\frac{\text{M}}{\text{s}} = k\text{M}^2 \Rightarrow k = \frac{\text{M}/\text{s}}{\text{M}^2} = \frac{1}{\text{M} \cdot \text{s}} = \text{M}^{-1} \text{s}^{-1}$$

B The exponent in the rate law is 2, so the reaction is second order in HI. Because HI is the only reactant and the only species that appears in the rate law, the reaction is also second order overall.

C If the concentration of HI is doubled, the reaction rate will increase from $k[\text{HI}]_0$ to $k(2[\text{HI}])_0 = 4k[\text{HI}]_0$. The reaction rate will therefore quadruple.

2. **A** Because no concentration term appears in the rate law, the rate constant must have M/s units for the reaction rate to have M/s units.

B The rate law tells us that the reaction rate is constant and independent of the N_2O concentration. That is, the reaction is zeroth order in N_2O and zeroth order overall.

C Because the reaction rate is independent of the N_2O concentration, doubling the concentration will have no effect on the reaction rate.

3. **A** The rate law contains only one concentration term raised to the first power. Hence the rate constant must have units of reciprocal seconds (s^{-1}) to have units of moles per liter per second for the reaction rate: $\text{M}\cdot\text{s}^{-1} = \text{M}/\text{s}$.

B The only concentration in the rate law is that of cyclopropane, and its exponent is 1. This means that the reaction is first order in cyclopropane. Cyclopropane is the only species that appears in the rate law, so the reaction is also first order overall.

C Doubling the initial cyclopropane concentration will increase the reaction rate from $k[\text{cyclopropane}]_0$ to $2k[\text{cyclopropane}]_0$. This doubles the reaction rate.

Exercise

Given the following two reactions and their experimentally determined differential rate laws: determine the *units* of the rate constant if time is in seconds, determine the reaction *order* with respect to each reactant, give the *overall reaction order*, and predict what will happen to the reaction rate when the concentration of the first species in each equation is doubled.

Answer:

- s^{-1} ; first order in $\text{CH}_3\text{N}=\text{CH}_3$; first order overall; doubling $[\text{CH}_3\text{N}=\text{CH}_3]$ will double the reaction rate.
- $\text{M}^{-1}\cdot\text{s}^{-1}$; first order in NO_2 , first order in F_2 ; second order overall; doubling $[\text{NO}_2]$ will double the reaction rate.

Summary

Reaction rates are reported either as the **average rate** over a period of time or as the **instantaneous rate** at a single time.

The **rate law** for a reaction is a mathematical relationship between the reaction rate and the concentrations of species in solution. Rate laws can be expressed either as a **differential rate law**, describing the change in reactant or product concentrations as a function of time, or as an **integrated rate law**, describing the actual concentrations of reactants or products as a function of time.

The **rate constant** (k) of a rate law is a constant of proportionality between the reaction rate and the reactant concentration. The power to which a concentration is raised in a rate law indicates the **reaction order**, the degree to which the reaction rate depends on the concentration of a particular reactant.

Key Takeaways

- Reaction rates can be determined over particular time intervals or at a given point in time.
- A rate law describes the relationship between reactant rates and reactant concentrations.

Key Equations

general definition of rate for A → B

$$\text{Equation 14.2.1: } \text{rate} = \frac{\Delta [B]}{\Delta t} = -\frac{\Delta [A]}{\Delta t}$$

general form of rate law when A and B are reactants

Equation 14.2.6:

$$\text{rate} = k[A]^m[B]^n \quad (14.2.6)$$

Conceptual Problems

1. Explain why the reaction rate is generally fastest at early time intervals. For the second-order $A + B \rightarrow C$, what would the plot of the concentration of C versus time look like during the course of the reaction?
2. Explain the differences between a differential rate law and an integrated rate law. What two components do they have in common? Which form is preferred for obtaining a reaction order and a rate constant? Why?
3. Diffusion-controlled reactions have rates that are determined only by the reaction rate at which two reactant molecules can diffuse together. These reactions are rapid, with second-order rate constants typically on the order of $10^{10} \text{ L}/(\text{mol}\cdot\text{s})$. Would you expect the reactions to be faster or slower in solvents that have a low viscosity? Why? Consider the reactions $\text{H}_3\text{O}^+ + \text{OH}^- \rightarrow 2\text{H}_2\text{O}$ and $\text{H}_3\text{O}^+ + \text{N}(\text{CH}_3)_3 \rightarrow \text{H}_2\text{O} + \text{HN}(\text{CH}_3)_3$ in aqueous solution. Which would have the higher rate constant? Why?
4. What information can you get from the reaction order? What correlation does the reaction order have with the stoichiometry of the overall equation?
5. During the hydrolysis reaction $A + \text{H}_2\text{O} \rightarrow B + C$, the concentration of A decreases much more rapidly in a polar solvent than in a nonpolar solvent. How do you expect this effect to be reflected in the overall reaction order?

Answers

1. Reactant concentrations are highest at the beginning of a reaction. The plot of [C] versus t is a curve with a slope that becomes steadily less positive.
- 2.
3. Faster in a less viscous solvent because the rate of diffusion is higher; the $\text{H}_3\text{O}^+ / \text{OH}^-$ reaction is faster due to the decreased relative size of reactants and the higher electrostatic attraction between the reactants.
- 4.
- 5.

Numerical Problems

1. The reaction rate of a particular reaction in which A and B react to make C is as follows:

$$\text{rate} = -\frac{\Delta [A]}{\Delta t} = \frac{1}{2} \frac{\Delta [C]}{\Delta t}$$

Write a reaction equation that is consistent with this rate law. What is the rate expression with respect to time if 2A are converted to 3C?

2. While commuting to work, a person drove for 12 min at 35 mph, then stopped at an intersection for 2 min, continued the commute at 50 mph for 28 min, drove slowly through traffic at 38 mph for 18 min, and then spent 1 min pulling into a parking space at 3 mph. What was the average rate of the commute? What was the instantaneous rate at 13 min? at 28 min?
3. Why do most studies of chemical reactions use the initial rates of reaction to generate a rate law? How is this initial rate determined? Given the following data, what is the reaction order? Estimate.

Time (s)	[A] (M)
120	0.158
240	0.089
360	0.062

4. Predict how the reaction rate will be affected by doubling the concentration of the first species in each equation.
- $C_2H_5I \rightarrow C_2H_4 + HI$: rate = $k[C_2H_5I]$
 - $SO + O_2 \rightarrow SO_2 + O$: rate = $k[SO][O_2]$
 - $2CH_3 \rightarrow C_2H_6$: rate = $k[CH_3]$
 - $ClO \rightarrow Cl + O_2$: rate = k
5. Cleavage of C_2H_6 to produce two $CH_3\cdot$ radicals is a gas-phase reaction that occurs at $700^\circ C$. This reaction is first order, with $k = 5.46 \times 10^{-5} \text{ s}^{-1}$. How long will it take for the reaction to go to 15% completion? to 50% completion?
6. Three chemical processes occur at an altitude of approximately 100 km in Earth's atmosphere.

Write a rate law for each elementary reaction. If the rate law for the overall reaction were found to be rate = $k[N_2][O_2]$, which one of the steps is rate limiting?

7. The oxidation of aqueous iodide by arsenic acid to give I_3^- and arsenous acid proceeds via the following reaction:

Write an expression for the initial rate of decrease of $[I_3^-]$, $-\Delta[I_3^-]/\Delta t$. When the reaction rate of the forward reaction is equal to that of the reverse reaction: $k_f/k_r = [H_3AsO_3][I_3^-]/[H_3AsO_4][I^-]^3[H^+]^2$. Based on this information, what can you say about the nature of the rate-determining steps for the reverse and the forward reactions?

Learning Objective

- To know how to determine the reaction order from experimental data.

In the examples in this text, the exponents in the rate law are almost always the positive integers: 1 and 2 or even 0. Thus the reactions are zeroth, first, or second order in each reactant. The common patterns used to identify the reaction order are described in this section, where we focus on characteristic types of differential and integrated rate laws and how to determine the reaction order from experimental data.

Zerth-Order Reactions

A zeroth-order reaction is one whose rate is independent of concentration; its differential rate law is $rate = k$. We refer to these reactions as zeroth order because we could also write their rate in a form such that the exponent of the reactant in the rate law is 0:

$$rate = -\frac{\Delta[A]}{\Delta t} = -k[reactant]^0 = k(1) = k \quad (14.3.1)$$

Because rate is independent of reactant concentration, a graph of the concentration of any reactant as a function of time is a straight line with a slope of $-k$. The value of k is negative because the concentration of the reactant decreases with time. Conversely, a graph of the concentration of any product as a function of time is a straight line with a slope of k , a positive value.

The integrated rate law for a zeroth-order reaction also produces a straight line and has the general form

$$[A] = [A_0] - kt \quad (14.3.2)$$

where $[A]_0$ is the initial concentration of reactant A. (Equation 14.3.2 has the form of the algebraic equation for a straight line, $y = mx + b$, with $y = [A]$, $mx = -kt$, and $b = [A]_0$.) In a zeroth-order reaction, the rate constant must have the same units as the reaction rate, typically moles per liter per second.

Although it may seem counterintuitive for the reaction rate to be independent of the reactant concentration(s), such reactions are rather common. They occur most often when the reaction rate is determined by available surface area. An example is the decomposition of N_2O on a platinum (Pt) surface to produce N_2 and O_2 , which occurs at temperatures ranging from 200°C to 400°C:

Without a platinum surface, the reaction requires temperatures greater than 700°C, but between 200°C and 400°C, the only factor that determines how rapidly N_2O decomposes is the amount of Pt surface available (not the amount of Pt). As long as there is enough N_2O to react with the entire Pt surface, doubling or quadrupling the N_2O concentration will have no effect on the reaction rate. At very low concentrations of N_2O , where there are not enough molecules present to occupy the entire available Pt surface, the reaction rate is dependent on the N_2O concentration. The reaction rate is as follows:

$$rate = -\frac{1}{2} \left(\frac{\Delta[N_2O]}{\Delta t} \right) = \frac{1}{2} \left(\frac{\Delta[N_2]}{\Delta t} \right) = \frac{\Delta[O_2]}{\Delta t} k[N_2O]^0 = k \quad (14.3.4)$$

The graph of a zeroth-order reaction. The change in concentration of reactant and product with time produces a straight line.

Thus the rate at which N_2O is consumed and the rates at which N_2 and O_2 are produced are independent of concentration. As shown in [Figure 14.3.2](#), the change in the concentrations of all species with time is linear. Most important, the exponent (0) corresponding to the N_2O concentration in the experimentally derived rate law is *not* the same as the reactant's stoichiometric coefficient in the balanced chemical equation (2). For this reaction, as for all others, *the rate law must be determined experimentally*.

Figure 14.3.2 A Zeroth-Order Reaction This graph shows the concentrations of reactants and products versus time for the zeroth-order catalyzed decomposition of N_2O to N_2 and O_2 on a Pt surface. The change in the concentrations of all species with time is linear.

Note the Pattern

If a plot of reactant concentration versus time is linear, then the reaction is zeroth order in that reactant.

A zeroth-order reaction that takes place in the human liver is the oxidation of ethanol (from alcoholic beverages) to acetaldehyde, catalyzed by the enzyme alcohol dehydrogenase. At high ethanol concentrations, this reaction is also a zeroth-order reaction. The overall reaction equation is

where NAD^+ (nicotinamide adenine dinucleotide) and NADH (reduced nicotinamide adenine dinucleotide) are the oxidized and reduced forms, respectively, of a species used by all organisms to transport electrons. When an alcoholic beverage is consumed, the ethanol is rapidly absorbed into the blood. Its concentration then decreases at a constant rate until it reaches zero (part (a) in [Figure 14.3.3](#)). An average 70 kg person typically takes about 2.5 h to oxidize the 15 mL of ethanol contained in a single 12 oz can of beer, a 5 oz glass of wine, or a shot of distilled spirits (such as whiskey or brandy). The actual rate, however, varies a great deal from person to person, depending on body size and the amount of alcohol dehydrogenase in the liver. The reaction rate does not increase if a greater quantity of alcohol is consumed over the same period of time because the reaction rate is determined only by the amount of enzyme present in the liver. Contrary to popular belief, the caffeine in coffee is ineffective at catalyzing the oxidation of ethanol. When the ethanol has been completely oxidized and its concentration drops to essentially zero, the rate of oxidation also drops rapidly (part (b) in [Figure 14.3.3](#)).

Figure 14.3.3 The Catalyzed Oxidation of Ethanol(a) The concentration of ethanol in human blood decreases linearly with time, which is typical of a zeroth-order reaction. (b) The rate at which ethanol is oxidized is constant until the ethanol concentration reaches essentially zero, at which point the reaction rate drops to zero.

These examples illustrate two important points:

1. In a zeroth-order reaction, the reaction rate does not depend on the reactant concentration.
2. A linear change in concentration with time is a clear indication of a zeroth-order reaction.

First-Order Reactions

In a first-order reaction, the reaction rate is directly proportional to the concentration of one of the reactants. First-order reactions often have the general form $A \rightarrow \text{products}$. The differential rate for a first-order reaction is as follows:

$$\text{rate} = -\frac{\Delta[A]}{\Delta t} = k[A]^1 = k[A] \quad (14.3.5)$$

If the concentration of A is doubled, the reaction rate doubles; if the concentration of A is increased by a factor of 10, the reaction rate increases by a factor of 10, and so forth. Because the units of the reaction rate are always moles per liter per second, the units of a first-order rate constant are reciprocal seconds (s^{-1}).

The integrated rate law for a first-order reaction can be written in two different ways: one using exponents and one using logarithms. The exponential form is as follows:

$$\text{rate} = [A] = [A_0] e^{-kt} \quad (14.3.6)$$

where $[A]_0$ is the initial concentration of reactant A at $t = 0$; k is the rate constant; and e is the base of the natural logarithms, which has the value 2.718 to three decimal places. (Essential Skills 6 in [Section 11.9](#), discusses natural logarithms.) Recall that an integrated rate law gives the relationship between reactant concentration and time. [Equation 14.20](#) predicts that the concentration of A will decrease in a smooth exponential curve over time. By taking the natural logarithm of each side of [Equation 14.20](#) and rearranging, we obtain an alternative logarithmic expression of the relationship between the concentration of A and t :

$$\text{rate} = \ln[A] = \ln[A_0] - kt \quad (14.3.7)$$

Because [Equation 14.3.7](#) has the form of the algebraic equation for a straight line, $y = mx + b$, with $y = \ln[A]$ and $b = \ln[A]_0$, a plot of $\ln[A]$ versus t for a first-order reaction should give a straight line with a slope of $-k$ and an intercept of $\ln[A]_0$. Either the differential rate law ([Equation 14.3.5](#)) or the integrated rate law ([Equation 14.3.7](#)) can be used to determine whether a particular reaction is first order.

Figure 14.3.4 Graphs of a first-order reaction. The expected shapes of the curves for plots of reactant concentration versus time (top) and the natural logarithm of reactant concentration versus time (bottom) for a first-order reaction.

First-order reactions are very common. In this chapter, we have already encountered two examples of first-order reactions: the hydrolysis of aspirin (Figure 14.2.1) and the reaction of *t*-butyl bromide with water to give *t*-butanol (Equation 14.7.7). Another reaction that exhibits apparent first-order kinetics is the hydrolysis of the anticancer drug cisplatin.

Cisplatin, the first “inorganic” anticancer drug to be discovered, is unique in its ability to cause complete remission of the relatively rare but deadly cancers of the reproductive organs in young adults. The structures of cisplatin and its hydrolysis product are as follows:

Both platinum compounds have four groups arranged in a square plane around a Pt(II) ion. The reaction shown in Figure 14.11 is important because cisplatin, the form in which the drug is administered, is *not* the form in which the drug is active. Instead, at least one chloride ion must be replaced by water to produce a species that reacts with deoxyribonucleic acid (DNA) to prevent cell division and tumor growth. Consequently, the kinetics of the reaction in Figure 14.11 have been studied extensively to find ways of maximizing the concentration of the active species.

Note the Pattern

If a plot of reactant concentration versus time is not linear but a plot of the natural logarithm of reactant concentration versus time is linear, then the reaction is first order.

The rate law and reaction order of the hydrolysis of cisplatin are determined from experimental data, such as those displayed in Table 14.3.1. The table lists initial rate data for four experiments in which the reaction was run at pH 7.0 and 25°C but with different initial concentrations of cisplatin. Because the reaction rate increases with increasing cisplatin concentration, we know this cannot be a zeroth-order reaction. Comparing Experiments 1 and 2 in Table 14.3.1 shows that the reaction rate doubles [$(1.8 \times 10^{-5} \text{ M/min}) \div (9.0 \times 10^{-6} \text{ M/min}) = 2.0$] when the concentration of cisplatin is doubled (from 0.0060 M to 0.012 M). Similarly, comparing Experiments 1 and 4 shows that the reaction rate increases by a factor of 5 [$(4.5 \times 10^{-5} \text{ M/min}) \div (9.0 \times 10^{-6} \text{ M/min}) = 5.0$] when the concentration of cisplatin is increased by a factor of 5 (from 0.0060 M to 0.030 M). Because the reaction rate is directly proportional to the concentration of the reactant, the exponent of the cisplatin concentration in the rate law must be 1, so the rate law is $\text{rate} = k[\text{cisplatin}]$. Thus the reaction is first order. Knowing this, we can calculate the rate constant using the differential rate law for a first-order reaction and the data in any row of Table 14.3.1. For example, substituting the values for Experiment 3 into Equation 14.19,

$$3.6 \times 10^{-5} \text{ M/min} = k(0.024 \text{ M})$$

$$1.5 \times 10^{-3} \text{ min}^{-1} = k$$

Table 14.3.1 Rates of Hydrolysis of Cisplatin as a Function of Concentration at pH 7.0 and 25°C

Experiment	[Cisplatin] ₀ (M)	Initial Rate (M/min)
1	0.0060	9.0×10^{-6}
2	0.012	1.8×10^{-5}
3	0.024	3.6×10^{-5}
4	0.030	4.5×10^{-5}

Knowing the rate constant for the hydrolysis of cisplatin and the rate constants for subsequent reactions that produce species that are highly toxic enables hospital pharmacists to provide patients with solutions that contain only the desired form of the drug.

Example 14.3.1

At high temperatures, ethyl chloride produces HCl and ethylene by the following reaction:

Using the rate data for the reaction at 650°C presented in the following table, calculate the reaction order with respect to the concentration of ethyl chloride and determine the rate constant for the reaction.

Experiment	$[\text{CH}_3\text{CH}_2\text{Cl}]_0$ (M)	Initial Rate (M/s)
1	0.010	1.6×10^{-8}
2	0.015	2.4×10^{-8}
3	0.030	4.8×10^{-8}
4	0.040	6.4×10^{-8}

Given: balanced chemical equation, initial concentrations of reactant, and initial rates of reaction

Asked for: reaction order and rate constant

Strategy:

A Compare the data from two experiments to determine the effect on the reaction rate of changing the concentration of a species.

B Compare the observed effect with behaviors characteristic of zeroth- and first-order reactions to determine the reaction order. Write the rate law for the reaction.

C Use measured concentrations and rate data from any of the experiments to find the rate constant.

Solution:

The reaction order with respect to ethyl chloride is determined by examining the effect of changes in the ethyl chloride concentration on the reaction rate.

A Comparing Experiments 2 and 3 shows that doubling the concentration doubles the reaction rate, so the reaction rate is proportional to $[\text{CH}_3\text{CH}_2\text{Cl}]$. Similarly, comparing Experiments 1 and 4 shows that quadrupling the concentration quadruples the reaction rate, again indicating that the reaction rate is directly proportional to $[\text{CH}_3\text{CH}_2\text{Cl}]$.

B This behavior is characteristic of a first-order reaction, for which the rate law is $\text{rate} = k[\text{CH}_3\text{CH}_2\text{Cl}]$.

C We can calculate the rate constant (k) using any row in the table. Selecting Experiment 1 gives the following:

$$1.60 \times 10^{-8} \text{ M/s} = k(0.010 \text{ M})$$

$$1.6 \times 10^{-6} \text{ s}^{-1} = k$$

Exercise

Sulfuryl chloride (SO_2Cl_2) decomposes to SO_2 and Cl_2 by the following reaction:

Data for the reaction at 320°C are listed in the following table. Calculate the reaction order with regard to sulfuryl chloride and determine the rate constant for the reaction.

Experiment	$[\text{SO}_2\text{Cl}_2]_0$ (M)	Initial Rate (M/s)
------------	----------------------------------	--------------------

Experiment	$[\text{SO}_2\text{Cl}_2]_0$ (M)	Initial Rate (M/s)
1	0.0050	1.10×10^{-7}
2	0.0075	1.65×10^{-7}
3	0.0100	2.20×10^{-7}
4	0.0125	2.75×10^{-7}

Answer: first order; $k = 2.2 \times 10^{-5} \text{ s}^{-1}$

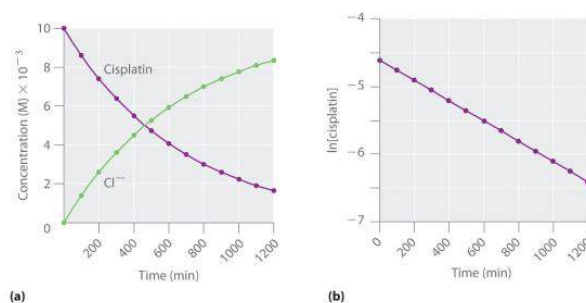

Figure 14.3.5 The Hydrolysis of Cisplatin, a First-Order Reaction These plots show hydrolysis of cisplatin at pH 7.0 and 25°C as (a) the experimentally determined concentrations of cisplatin and chloride ions versus time and (b) the natural logarithm of the cisplatin concentration versus time. The straight line in (b) is expected for a first-order reaction.

We can also use the integrated rate law to determine the reaction rate for the hydrolysis of cisplatin. To do this, we examine the change in the concentration of the reactant or the product as a function of time at a single initial cisplatin concentration. Part (a) in Figure 14.3.5 shows plots for a solution that originally contained 0.0100 M cisplatin and was maintained at pH 7 and 25°C. The concentration of cisplatin decreases smoothly with time, and the concentration of chloride ion increases in a similar way. When we plot the natural logarithm of the concentration of cisplatin versus time, we obtain the plot shown in part (b) in Figure 14.3.5. The straight line is consistent with the behavior of a system that obeys a first-order rate law. We can use any two points on the line to calculate the slope of the line, which gives us the rate constant for the reaction. Thus taking the points from part (a) in Figure 14.3.5 for $t = 100 \text{ min}$ ($[\text{cisplatin}] = 0.0086 \text{ M}$) and $t = 1000 \text{ min}$ ($[\text{cisplatin}] = 0.0022 \text{ M}$),

$$\text{slope} = \frac{\ln[\text{cisplatin}]_{1000} - \ln[\text{cisplatin}]_{100}}{1000 \text{ min} - 100 \text{ min}}$$

$$-k = \frac{\ln 0.0022 - \ln 0.0086}{1000 \text{ min} - 100 \text{ min}} = \frac{-6.12 - (-4.76)}{900 \text{ min}} = -1.51 \times 10^{-3} \text{ min}^{-1}$$

$$k = 1.51 \times 10^{-3} \text{ min}^{-1}$$

The slope is negative because we are calculating the rate of disappearance of cisplatin. Also, the rate constant has units of min^{-1} because the times plotted on the horizontal axes in parts (a) and (b) in Figure 14.3.5 are in minutes rather than seconds.

The reaction order and the magnitude of the rate constant we obtain using the integrated rate law are exactly the same as those we calculated earlier using the differential rate law. This must be true if the experiments were carried out under the same conditions.

Example 14.3.2

Refer back to Example 4. If a sample of ethyl chloride with an initial concentration of 0.0200 M is heated at 650°C, what is the concentration of ethyl chloride after 10 h? How many hours at 650°C must elapse for the concentration to decrease to 0.0050 M? (Recall that we calculated the rate constant for this reaction in Example 4.)

Given: initial concentration, rate constant, and time interval

Asked for: concentration at specified time and time required to obtain particular concentration

Strategy:

A Substitute values for the initial concentration ($[A]_0$) and the calculated rate constant for the reaction (k) into the integrated rate law for a first-order reaction. Calculate the concentration ($[A]$) at the given time t .

B Given a concentration $[A]$, solve the integrated rate law for time t .

Solution:

The exponential form of the integrated rate law for a first-order reaction (Equation 14.3.6) is $[A] = [A]_0 e^{-kt}$.

A Having been given the initial concentration of ethyl chloride ($[A]_0$) and having calculated the rate constant in Example 4 ($k = 1.6 \times 10^{-6} \text{ s}^{-1}$), we can use the rate law to calculate the concentration of the reactant at a given time t . Substituting the known values into the integrated rate law,

$$\begin{aligned} [CH_3CH_2Cl]_{10 \text{ h}} &= [CH_3CH_2Cl]_0 e^{-kt} \\ &= 0.0200 \text{ M} \exp [(-1.6 \times 10^{-6} \text{ s}^{-1})(10 \text{ h})(60 \text{ min/h})(60 \text{ s/min})] \\ &= 0.0189 \text{ M} \end{aligned}$$

We could also have used the logarithmic form of the integrated rate law (Equation 14.3.7):

$$\begin{aligned} \ln[CH_3CH_2Cl]_{10 \text{ h}} &= \ln[CH_3CH_2Cl]_0 - kt \\ &= \ln 0.0200 \text{ M} - (-1.6 \times 10^{-6} \text{ s}^{-1})(10 \text{ h})(60 \text{ min/h})(60 \text{ s/min}) \\ &= -3.912 - -0.0576 = -3.970 \\ [CH_3CH_2Cl]_{10 \text{ h}} &= e^{-3.970} \text{ M} \\ &= 0.0189 \text{ M} \end{aligned}$$

B To calculate the amount of time required to reach a given concentration, we must solve the integrated rate law for t . Equation 14.3.7 gives the following:

$$\begin{aligned} \ln[CH_3CH_2Cl]_t &= \ln[CH_3CH_2Cl]_0 - kt \\ kt &= \ln[CH_3CH_2Cl]_0 - \ln[CH_3CH_2Cl]_t = \ln \frac{[CH_3CH_2Cl]_0}{[CH_3CH_2Cl]_t} \\ t &= \frac{1}{k} \ln \frac{[CH_3CH_2Cl]_0}{[CH_3CH_2Cl]_t} = \frac{1}{1.6 \times 10^{-6} \text{ s}^{-1}} \ln \frac{0.0200 \text{ M}}{0.0050 \text{ M}} \\ t &= \frac{\ln 4.0}{k} = 8.7 \times 10^5 \text{ s} = 240 \text{ h} = 2.4 \times 10^2 \text{ h} \end{aligned}$$

Exercise

In the exercise in Example 4, you found that the decomposition of sulfuryl chloride (SO_2Cl_2) is first order, and you calculated the rate constant at 320°C . Use the form(s) of the integrated rate law to find the amount of SO_2Cl_2 that remains after 20 h if a sample with an original concentration of 0.123 M is heated at 320°C . How long would it take for 90% of the SO_2Cl_2 to decompose?

Answer: 0.0252 M; 29 h

Second-Order Reactions

The simplest kind of second-order reaction is one whose rate is proportional to the square of the concentration of one reactant. These generally have the form $2A \rightarrow \text{products}$. A second kind of second-order reaction has a reaction rate that is proportional to the *product* of the concentrations of two reactants. Such reactions generally have the form $A + B \rightarrow \text{products}$. An example of the former is a *dimerization reaction*, in which two smaller molecules, each called a *monomer*, combine to form a larger molecule (a *dimer*).

The differential rate law for the simplest second-order reaction in which $2A \rightarrow \text{products}$ is as follows:

$$\text{rate} = -\frac{\Delta [A]}{2\Delta t} = k[\text{reactant}]^2 \quad (14.3.8)$$

Consequently, doubling the concentration of A quadruples the reaction rate. For the units of the reaction rate to be moles per liter per second (M/s), the units of a second-order rate constant must be the inverse ($\text{M}^{-1} \cdot \text{s}^{-1}$). Because the units of molarity are expressed as mol/L, the unit of the rate constant can also be written as L(mol·s).

For the reaction $2A \rightarrow \text{products}$, the following integrated rate law describes the concentration of the reactant at a given time:

$$\frac{1}{[A]} = \frac{1}{[A_0]} + kt \quad (14.3.9)$$

Because Equation 14.3.9 has the form of an algebraic equation for a straight line, $y = mx + b$, with $y = 1/[A]$ and $b = 1/[A]_0$, a plot of $1/[A]$ versus t for a simple second-order reaction is a straight line with a slope of k and an intercept of $1/[A]_0$.

Note the Pattern

Second-order reactions generally have the form $2A \rightarrow \text{products}$ or $A + B \rightarrow \text{products}$.

Simple second-order reactions are common. In addition to dimerization reactions, two other examples are the decomposition of NO_2 to NO and O_2 and the decomposition of HI to I_2 and H_2 . Most examples involve simple inorganic molecules, but there are organic examples as well. We can follow the progress of the reaction described in the following paragraph by monitoring the decrease in the intensity of the red color of the reaction mixture.

Many cyclic organic compounds that contain two carbon-carbon double bonds undergo a dimerization reaction to give complex structures. One example is as follows:

For simplicity, we will refer to this reactant and product as “monomer” and “dimer,” respectively. The systematic name of the monomer is 2,5-dimethyl-3,4-diphenylcyclopentadienone. The systematic name of the dimer is the name of the monomer followed by “dimer.” Because the monomers are the same, the general equation for this reaction is $2A \rightarrow \text{product}$. This reaction represents an important class of organic reactions used in the pharmaceutical industry to prepare complex carbon skeletons for the synthesis of drugs. Like the first-order reactions studied previously, it can be analyzed using either the differential rate law (Equation 14.3.8) or the integrated rate law (Equation 14.3.9).

To determine the differential rate law for the reaction, we need data on how the reaction rate varies as a function of monomer concentrations, which are provided in Table 14.3.2. From the data, we see that the reaction rate is not independent of the monomer concentration, so this is not a zeroth-order reaction. We also see that the reaction rate is not proportional to the monomer concentration, so the reaction is not first order. Comparing the data in the second and fourth rows shows that the reaction rate decreases by a factor of 2.8 when the monomer concentration decreases by a factor of 1.7:

$$\frac{5.0 \times 10^{-5} \text{ M/min}}{1.8 \times 10^{-5} \text{ M/min}} = 2.8 \quad \text{and} \quad \frac{3.4 \times 10^{-3} \text{ M/min}}{2.0 \times 10^{-3} \text{ M/min}} = 1.7$$

Table 14.3.2 Rates of Reaction as a Function of Monomer Concentration for an Initial Monomer Concentration of 0.0054 M

Time (min)	[Monomer] (M)	Instantaneous Rate (M/min)
10	0.0044	8.0×10^{-5}
26	0.0034	5.0×10^{-5}
44	0.0027	3.1×10^{-5}
70	0.0020	1.8×10^{-5}
120	0.0014	8.0×10^{-6}

Because $(1.7)^2 = 2.9 \approx 2.8$, the reaction rate is approximately proportional to the square of the monomer concentration.

$$\text{rate} \propto [\text{monomer}]^2$$

This means that the reaction is second order in the monomer. Using Equation 14.3.8 and the data from any row in Table 14.3.2, we can calculate the rate constant. Substituting values at time 10 min, for example, gives the following:

$$\begin{aligned} \text{rate} &= k [A^2] \\ 8.0 \times 10^{-5} \text{ M/min} &= k (4.4 \times 10^{-3} \text{ M})^2 \\ 4.1 \text{ min}^{-1} &= k \end{aligned}$$

We can also determine the reaction order using the integrated rate law. To do so, we use the decrease in the concentration of the monomer as a function of time for a single reaction, plotted in part (a) in Figure 14.3.6. The measurements show that the concentration of the monomer (initially 5.4×10^{-3} M) decreases with increasing time. This graph also shows that the reaction rate decreases smoothly with increasing time. According to the integrated rate law for a second-order reaction, a plot of $1/[\text{monomer}]$ versus t should be a straight line, as shown in part (b) in Figure 14.3.6. Any pair of points on the line can be used to calculate the slope, which is the second-order rate constant. In this example, $k = 4.1 \text{ M}^{-1} \cdot \text{min}^{-1}$, which is consistent with the result obtained using the differential rate equation. Although in this example the stoichiometric coefficient is the same as the reaction order, this is not always the case. *The reaction order must always be determined experimentally.*

Figure 14.3.6 Dimerization of a Monomeric Compound, a Second-Order Reaction These plots correspond to dimerization of the monomer in Figure 14.13 " " as (a) the experimentally determined concentration of monomer versus time and (b) $1/[\text{monomer}]$ versus time. The straight line in (b) is expected for a simple second-order reaction.

For two or more reactions of the same order, the reaction with the largest rate constant is the fastest. Because the units of the rate constants for zeroth-, first-, and second-order reactions are different, however, we cannot compare the magnitudes of rate constants for reactions that have different orders. The differential and integrated rate laws for zeroth-, first-, and second-order reactions and their corresponding graphs are shown in Figure 14.4.2 in Section 14.4.

Example 14.3.3

At high temperatures, nitrogen dioxide decomposes to nitric oxide and oxygen.

Experimental data for the reaction at 300°C and four initial concentrations of NO_2 are listed in the following table:

Experiment	$[\text{NO}_2]_0$ (M)	Initial Rate (M/s)
1	0.015	1.22×10^{-4}
2	0.010	5.40×10^{-5}
3	0.0080	3.46×10^{-5}
4	0.0050	1.35×10^{-5}

Determine the reaction order and the rate constant.

Given: balanced chemical equation, initial concentrations, and initial rates

Asked for: reaction order and rate constant

Strategy:

A From the experiments, compare the changes in the initial reaction rates with the corresponding changes in the initial concentrations. Determine whether the changes are characteristic of zeroth-, first-, or second-order reactions.

B Determine the appropriate rate law. Using this rate law and data from any experiment, solve for the rate constant (k).

Solution:

A We can determine the reaction order with respect to nitrogen dioxide by comparing the changes in NO_2 concentrations with the corresponding reaction rates. Comparing Experiments 2 and 4, for example, shows that doubling the concentration quadruples the reaction rate [$(5.40 \times 10^{-5}) \div (1.35 \times 10^{-5}) = 4.0$], which means that the reaction rate is proportional to $[\text{NO}_2]^2$. Similarly, comparing Experiments 1 and 4 shows that tripling the concentration increases the reaction rate by a factor of 9, again indicating that the reaction rate is proportional to $[\text{NO}_2]^2$. This behavior is characteristic of a second-order reaction.

B We have $\text{rate} = k[\text{NO}_2]^2$. We can calculate the rate constant (k) using data from any experiment in the table. Selecting Experiment 2, for example, gives the following:

$$\begin{aligned} \text{rate} &= k[\text{NO}_2]^2 \\ 5.40 \times 10^{-5} \text{ M/s} &= k(0.010 \text{ M})^2 \\ 0.540 \text{ M}^{-1} \text{ s}^{-1} &= k \end{aligned}$$

Exercise

When the highly reactive species HO_2 forms in the atmosphere, one important reaction that then removes it from the atmosphere is as follows:

The kinetics of this reaction have been studied in the laboratory, and some initial rate data at 25°C are listed in the following table:

Experiment	$[\text{HO}_2]_0$ (M)	Initial Rate (M/s)
1	1.1×10^{-8}	1.7×10^{-7}

Experiment	$[\text{HO}_2]_0$ (M)	Initial Rate (M/s)
2	2.5×10^{-8}	8.8×10^{-7}
3	3.4×10^{-8}	1.6×10^{-6}
4	5.0×10^{-8}	3.5×10^{-6}

Determine the reaction order and the rate constant.

Answer: second order in HO_2 ; $k = 1.4 \times 10^9 \text{ M}^{-1} \cdot \text{s}^{-1}$

Note the Pattern

If a plot of reactant concentration versus time is not linear but a plot of $1/\text{reaction concentration}$ versus time is linear, then the reaction is second order.

Example 14.3.4

If a flask that initially contains 0.056 M NO_2 is heated at 300°C , what will be the concentration of NO_2 after 1.0 h ? How long will it take for the concentration of NO_2 to decrease to 10% of the initial concentration? Use the integrated rate law for a second-order reaction (Equation 14.3.9) and the rate constant calculated in Example 6.

Given: balanced chemical equation, rate constant, time interval, and initial concentration

Asked for: final concentration and time required to reach specified concentration

Strategy:

A Given k , t , and $[\text{A}]_0$, use the integrated rate law for a second-order reaction to calculate $[\text{A}]$.

B Setting $[\text{A}]$ equal to $1/10$ of $[\text{A}]_0$, use the same equation to solve for t .

Solution:

A We know k and $[\text{NO}_2]_0$, and we are asked to determine $[\text{NO}_2]$ at $t = 1 \text{ h}$ (3600 s). Substituting the appropriate values into Equation 14.3.9,

$$\begin{aligned} \frac{1}{[\text{NO}_2]_{3600}} &= \frac{1}{[\text{NO}_2]_0} + kt = \frac{1}{0.056 \text{ M}} + (0.54 \text{ M}^{-1} \text{ s}^{-1})(3600 \text{ s}) \\ &= 2.0 \times 10^{-3} \text{ M}^{-1} \end{aligned}$$

Thus $[\text{NO}_2]_{3600} = 5.1 \times 10^{-4} \text{ M}$.

B In this case, we know k and $[\text{NO}_2]_0$, and we are asked to calculate at what time $[\text{NO}_2] = 0.1[\text{NO}_2]_0 = 0.1(0.056 \text{ M}) = 0.0056 \text{ M}$. To do this, we solve Equation 14.3.9 for t , using the concentrations given.

$$\frac{1}{[\text{NO}_2]_{3600}} - \frac{1}{[\text{NO}_2]_0} = \frac{(1/0.0056 \text{ M}) - (1/0.056 \text{ M})}{0.54 \text{ M}^{-1} \text{ s}^{-1}} = 3.0 \times 10^2 \text{ s} = 5 \text{ min}$$

NO_2 decomposes very rapidly; under these conditions, the reaction is 90% complete in only 5.0 min .

Exercise

In the exercise in Example 6, you calculated the rate constant for the decomposition of HO_2 as $k = 1.4 \times 10^9 \text{ M}^{-1} \cdot \text{s}^{-1}$. This high rate constant means that HO_2 decomposes rapidly under the reaction conditions given in the problem. In fact, the

HO₂ molecule is so reactive that it is virtually impossible to obtain in high concentrations. Given a 0.0010 M sample of HO₂, calculate the concentration of HO₂ that remains after 1.0 h at 25°C. How long will it take for 90% of the HO₂ to decompose? Use the integrated rate law for a second-order reaction (Equation 14.3.9) and the rate constant calculated in the exercise in Example 6.

Answer: 2.0×10^{-13} M; 6.4×10^{-6} s

In addition to the simple second-order reaction and rate law we have just described, another very common second-order reaction has the general form $A + B \rightarrow \text{products}$, in which the reaction is first order in A and first order in B. The differential rate law for this reaction is as follows:

$$\text{rate} = -\frac{\Delta[A]}{\Delta t} = -\frac{\Delta[B]}{\Delta t} = k[A][B] \quad (14.3.10)$$

Because the reaction is first order both in A and in B, it has an overall reaction order of 2. (The integrated rate law for this reaction is rather complex, so we will not describe it.) We can recognize second-order reactions of this sort because the reaction rate is proportional to the concentrations of each reactant. We presented one example at the end of Section 14.2, the reaction of CH₃Br with OH⁻ to produce CH₃OH.

Determining the Rate Law of a Reaction

The number of fundamentally different mechanisms (sets of steps in a reaction) is actually rather small compared to the large number of chemical reactions that can occur. Thus understanding reaction mechanisms can simplify what might seem to be a confusing variety of chemical reactions. The first step in discovering the reaction mechanism is to determine the reaction's rate law. This can be done by designing experiments that measure the concentration(s) of one or more reactants or products as a function of time. For the reaction $A + B \rightarrow \text{products}$, for example, we need to determine k and the exponents m and n in the following equation:

$$\text{rate} = k[A]^m[B]^n \quad (14.3.11)$$

To do this, we might keep the initial concentration of B constant while varying the initial concentration of A and calculating the initial reaction rate. This information would permit us to deduce the reaction order with respect to A. Similarly, we could determine the reaction order with respect to B by studying the initial reaction rate when the initial concentration of A is kept constant while the initial concentration of B is varied. In earlier examples, we determined the reaction order with respect to a given reactant by comparing the different rates obtained when only the concentration of the reactant in question was changed. An alternative way of determining reaction orders is to set up a proportion using the rate laws for two different experiments.

Rate data for a hypothetical reaction of the type $A + B \rightarrow \text{products}$ are given in Table 14.3.3. The general rate law for the reaction is given in Equation 14.3.11. We can obtain m or n directly by using a proportion of the rate laws for two experiments in which the concentration of one reactant is the same, such as Experiments 1 and 3 in Table 14.3.3.

Table 14.3.3 Rate Data for a Hypothetical Reaction of the Form $A + B \rightarrow \text{Products}$

Experiment	[A] (M)	[B] (M)	Initial Rate (M/min)
1	0.50	0.50	8.5×10^{-3}
2	0.75	0.50	19×10^{-3}
3	1.00	0.50	34×10^{-3}
4	0.50	0.75	8.5×10^{-3}
5	0.50	1.00	8.5×10^{-3}

$$\frac{\text{rate}^1}{\text{rate}^3} = \frac{k[A^1]^m[B^1]^n}{k[A^3]^m[B^3]^n}$$

Inserting the appropriate values from Table 14.3.3,

$$\frac{8.5 \times 10^{-3} \text{ M/min}}{34. \times 10^{-3} \text{ M/min}} = \frac{k [0.50 \text{ M}]^m [0.50 \text{ M}]^n}{k [1.00 \text{ M}]^m [0.50 \text{ M}]^n}$$

Because 1.00 to any power is 1, $[1.00 \text{ M}]^m = 1.00 \text{ M}$. We can cancel like terms to give $0.25 = [0.50]^m$, which can also be written as $1/4 = [1/2]^m$. Thus we can conclude that $m = 2$ and that the reaction is second order in A. By selecting two experiments in which the concentration of B is the same, we were able to solve for m .

Conversely, by selecting two experiments in which the concentration of A is the same (e.g., Experiments 5 and 1), we can solve for n .

$$\frac{\text{rate}^1}{\text{rate}^3} = \frac{k[A^1]^m[B^1]^n}{k[A^5]^m[B^5]^n}$$

Substituting the appropriate values from [Table 14.3.3](#),

$$\frac{8.5 \times 10^{-3} \text{ M/min}}{8.5 \times 10^{-3} \text{ M/min}} = \frac{k [0.50 \text{ M}]^m [0.50 \text{ M}]^n}{k [0.50 \text{ M}]^m [1.00 \text{ M}]^n}$$

Canceling leaves $1.0 = [0.50]^n$, which gives $n = 0$; that is, the reaction is zeroth order in B. The experimentally determined rate law is therefore

$$\text{rate} = k[A]^2[B]^0$$

We can now calculate the rate constant by inserting the data from any row of [Table 14.3.3](#) into the experimentally determined rate law and solving for k . Using Experiment 2, we obtain

$$19. \times 10^{-3} \text{ M/min} = k(0.75 \text{ M})^2$$

$$3.4 \times 10^{-2} \text{ M}^{-1}\text{min}^{-1} = k$$

You should verify that using data from any other row of [Table 14.3.3](#) gives the same rate constant. This must be true as long as the experimental conditions, such as temperature and solvent, are the same.

Example 14.3.5

Nitric oxide is produced in the body by several different enzymes and acts as a signal that controls blood pressure, long-term memory, and other critical functions. The major route for removing NO from biological fluids is via reaction with O_2 to give NO_2 , which then reacts rapidly with water to give nitrous acid and nitric acid:

These reactions are important in maintaining steady levels of NO. The following table lists kinetics data for the reaction of NO with O_2 at 25°C:

Determine the rate law for the reaction and calculate the rate constant.

Experiment	$[\text{NO}]_0 \text{ (M)}$	$[\text{O}_2]_0 \text{ (M)}$	Initial Rate (M/s)
1	0.0235	0.0125	7.98×10^{-3}
2	0.0235	0.0250	15.9×10^{-3}
3	0.0470	0.0125	32.0×10^{-3}
4	0.0470	0.0250	63.5×10^{-3}

Given: balanced chemical equation, initial concentrations, and initial rates

Asked for: rate law and rate constant

Strategy:

A Compare the changes in initial concentrations with the corresponding changes in rates of reaction to determine the reaction order for each species. Write the rate law for the reaction.

B Using data from any experiment, substitute appropriate values into the rate law. Solve the rate equation for k .

Solution:

A Comparing Experiments 1 and 2 shows that as $[O_2]$ is doubled₁ at a constant value of $[NO_2]$, the reaction rate approximately doubles. Thus the reaction rate is proportional to $[O_2]$ ₁, so the reaction is first order in O_2 . Comparing Experiments 1 and 3 shows that the reaction rate₂ essentially quadruples when $[NO]$ is doubled and $[O_2]$ is held constant. That is, the reaction rate is proportional to $[NO]$ ₂, which indicates that the reaction is second order in NO . Using these relationships, we can write the rate law for the reaction:

$$rate = k[NO]^2 [O_2]$$

B The data in any row can be used to calculate the rate constant. Using Experiment 1, for example, gives

$$k = \frac{rate}{[NO]^2 [O_2]} = \frac{7.98 \times 10^{-3} \text{ M/s}}{(0.0235 \text{ M})^2 (0.0125 \text{ M})} = 1.16 \times 10^3 \text{ M}^{-2} \text{ s}^{-1}$$

The overall reaction order ($m + n$) is 3, so this is a third-order reaction, a reaction whose rate is determined by three reactants. The units of the rate constant become more complex as the overall reaction order increases.

Exercise

The peroxydisulfate ion ($S_2O_8^{2-}$) is a potent oxidizing agent that reacts rapidly with iodide ion in water:

The following table lists kinetics data for this reaction at 25°C. Determine the rate law and calculate the rate constant.

Experiment	$[S_2O_8^{2-}]_0$ (M)	$[I^-]_0$ (M)	Initial Rate (M/s)
1	0.27	0.38	2.05
2	0.40	0.38	3.06
3	0.40	0.22	1.76

Answer: rate = $k[S_2O_8^{2-}][I^-]$; $k = 20 \text{ M}^{-1} \text{ s}^{-1}$

Summary

The reaction rate of a **zeroth-order reaction** is independent of the concentration of the reactants. The reaction rate of a **first-order reaction** is directly proportional to the concentration of one reactant. The reaction rate of a simple **second-order reaction** is proportional to the square of the concentration of one reactant. Knowing the **rate law** of a reaction gives clues to the **reaction mechanism**.

Key Takeaway

- Either the differential rate law or the integrated rate law can be used to determine the reaction order from experimental data.

Key Equations

zeroth-order reaction

Equation 14.3.1 $rate = -\frac{\Delta[A]}{\Delta t} = k$

Equation 14.3.2: $[A] = [A_0] - kt$

first-order reaction

Equation 14.3.5: $rate = -\frac{\Delta[A]}{\Delta t} = k[A]$

Equation 14.3.6: $[A] = [A_0] e^{-kt}$

Equation 14.3.7: $\ln[A] = \ln[A_0] - kt$

second-order reaction

Equation 14.3.8: $\ln[A] = \ln[A_0] + kt$

Equation 14.3.9: $\frac{1}{[A]} = \frac{1}{[A_0]} + kt$

Conceptual Problems

1. What are the characteristics of a zeroth-order reaction? Experimentally, how would you determine whether a reaction is zeroth order?
2. Predict whether the following reactions are zeroth order and explain your reasoning.
 - a. a substitution reaction of an alcohol with HCl to form an alkyl halide and water
 - b. catalytic hydrogenation of an alkene
 - c. hydrolysis of an alkyl halide to an alcohol
 - d. enzymatic conversion of nitrate to nitrite in a soil bacterium
3. In a first-order reaction, what is the advantage of using the integrated rate law expressed in natural logarithms over the rate law expressed in exponential form?
4. If the reaction rate is directly proportional to the concentration of a reactant, what does this tell you about (a) the reaction order with respect to the reactant and (b) the overall reaction order?
5. The reaction of NO with O₂ is found to be second order with respect to NO and first order with respect to O₂. What is the overall reaction order? What is the effect of doubling the concentration of each reagent on the reaction rate?

Numerical Problems

1. Iodide reduces Fe(III) according to the following reaction:
 $2Fe^{3+}(soln) + 2I^{-}(soln) \rightarrow 2Fe^{2+}(soln) + I_2(soln)$
 Experimentally, it was found that doubling the concentration of Fe(III) doubled the reaction rate, and doubling the iodide concentration increased the reaction rate by a factor of 4. What is the reaction order with respect to each species? What is the overall rate law? What is the overall reaction order?
2. Benzoyl peroxide is a medication used to treat acne. Its rate of thermal decomposition at several concentrations was determined experimentally, and the data were tabulated as follows:

Experiment	[Benzoyl Peroxide] ₀ (M)	Initial Rate (M/s)
------------	-------------------------------------	--------------------

Experiment	[Benzoyl Peroxide] ₀ (M)	Initial Rate (M/s)
1	1.00	2.22×10^{-4}
2	0.70	1.64×10^{-4}
3	0.50	1.12×10^{-4}
4	0.25	0.59×10^{-4}

What is the reaction order with respect to benzoyl peroxide? What is the rate law for this reaction?

3. 1-Bromopropane is a colorless liquid that reacts with $S_2O_3^{2-}$ according to the following reaction:

The reaction is first order in 1-bromopropane and first order in $S_2O_3^{2-}$, with a rate constant of $8.05 \times 10^{-4} \text{ M}^{-1} \text{ s}^{-1}$. If you began a reaction with 40 mmol/100 mL of C_3H_7Br and an equivalent concentration of $S_2O_3^{2-}$, what would the initial reaction rate be? If you were to decrease the concentration of each reactant to 20 mmol/100 mL, what would the initial reaction rate be?

4. The experimental rate law for the reaction $3A + 2B \rightarrow C + D$ was found to be $\Delta[C]/\Delta t = k[A]^2[B]^3$ for an overall reaction that is third order. Because graphical analysis is difficult beyond second-order reactions, explain the procedure for determining the rate law experimentally.

Answers

1. First order in Fe^{3+} ; second order in I^- ; third order overall; rate = $k[Fe^{3+}][I^-]^2$.

2.

3. $1.29 \times 10^{-4} \text{ M/s}$; $3.22 \times 10^{-5} \text{ M/s}$

4.

Unit 4: Thermochem & Gases
Unit 8: Materials

Learning Objective

- To use graphs to analyze the kinetics of a reaction.

In [Section 14.3](#), you learned that the integrated rate law for each common type of reaction (zeroth, first, or second order in a single reactant) can be plotted as a straight line. Using these plots offers an alternative to the methods described for showing how reactant concentration changes with time and determining reaction order.

We will illustrate the use of these graphs by considering the thermal decomposition of NO_2 gas at elevated temperatures, which occurs according to the following reaction:

Experimental data for this reaction at 330°C are listed in [Table 14.4.1](#); they are provided as $[\text{NO}_2]$, $\ln[\text{NO}_2]$, and $1/[\text{NO}_2]$ versus time to correspond to the integrated rate laws for zeroth-, first-, and second-order reactions, respectively. The actual concentrations of NO_2 are plotted versus time in part (a) in [Figure 14.4.1](#). Because the plot of $[\text{NO}_2]$ versus t is not a straight line, we know the reaction is not zeroth order in NO_2 . A plot of $\ln[\text{NO}_2]$ versus t (part (b) in [Figure 14.4.1](#)) shows us that the reaction is not first order in NO_2 because a first-order reaction would give a straight line. Having eliminated zeroth-order and first-order behavior, we construct a plot of $1/[\text{NO}_2]$ versus t (part (c) in [Figure 14.4.1](#)). This plot is a straight line, indicating that the reaction is second order in NO_2 .

Table 14.4.1 Concentration of NO_2 as a Function of Time at 330°C

Time (s)	$[\text{NO}_2]$ (M)	$\ln[\text{NO}_2]$	$1/[\text{NO}_2]$ (M^{-1})
0	1.00×10^{-2}	-4.605	100
60	6.83×10^{-3}	-4.986	146
120	5.18×10^{-3}	-5.263	193
180	4.18×10^{-3}	-5.477	239
240	3.50×10^{-3}	-5.655	286
300	3.01×10^{-3}	-5.806	332
360	2.64×10^{-3}	-5.937	379

Figure 14.4.1 The Decomposition of NO₂ These plots show the decomposition of a sample of NO₂ at 330°C as (a) the concentration of NO₂ versus *t*, (b) the natural logarithm of [NO₂] versus *t*, and (c) 1/[NO₂] versus *t*.

We have just determined the reaction order using data from a single experiment by plotting the concentration of the reactant as a function of time. Because of the characteristic shapes of the lines shown in Figure 14.4.2, the graphs can be used to determine the reaction order of an unknown reaction. In contrast, the method described in Section 14.3 required multiple experiments at different NO₂ concentrations as well as accurate initial rates of reaction, which can be difficult to obtain for rapid reactions.

	Zeroth Order	First Order	Second Order
Differential rate law	Rate = $-\frac{\Delta[A]}{\Delta t} = k$	Rate = $-\frac{\Delta[A]}{\Delta t} = k[A]$	Rate = $-\frac{\Delta[A]}{\Delta t} = k[A]^2$
Concentration vs. time			
Integrated rate law	$[A]_t = [A]_0 - kt$	$[A]_t = [A]_0 e^{-kt}$ or $\ln[A]_t = \ln[A]_0 - kt$	$\frac{1}{[A]_t} = \frac{1}{[A]_0} + kt$
Straight-line plot to determine rate constant			
Relative rate vs. concentration	$\frac{[A]_1}{[A]_2} = \frac{\text{Rate}_1}{\text{Rate}_2}$	$\frac{[A]_1}{[A]_2} = \frac{\text{Rate}_1}{\text{Rate}_2}$	$\frac{[A]_1}{[A]_2} = \sqrt{\frac{\text{Rate}_1}{\text{Rate}_2}}$
Half-life	$t_{1/2} = \frac{[A]_0}{2k}$	$t_{1/2} = \frac{0.693}{k}$	$t_{1/2} = \frac{1}{k[A]_0}$
Units of <i>k</i> , rate constant	M/s	1/s	M ⁻¹ s ⁻¹

Figure 14.4.2 Properties of Reactions That Obey Zeroth-, First-, and Second-Order Rate Laws

Example 14.4.1

Dinitrogen pentoxide (N₂O₅) decomposes to NO₂ and O₂ at relatively low temperatures in the following reaction:

This reaction is carried out in a CCl₄ solution at 45°C. The concentrations of N₂O₅ as a function of time are listed in the following table, together with the natural logarithms and reciprocal N₂O₅ concentrations. Plot a graph of the concentration versus *t*, ln concentration versus *t*, and 1/concentration versus *t* and then determine the rate law and calculate the rate constant.

Time (s)	[N ₂ O ₅] (M)	ln[N ₂ O ₅]	1/[N ₂ O ₅] (M ⁻¹)
0	0.0365	-3.310	27.4
600	0.0274	-3.597	36.5
1200	0.0206	-3.882	48.5
1800	0.0157	-4.154	63.7
2400	0.0117	-4.448	85.5
3000	0.00860	-4.756	116
3600	0.00640	-5.051	156

Given: balanced chemical equation, reaction times, and concentrations

Asked for: graph of data, rate law, and rate constant

Strategy:

A Use the data in the table to separately plot concentration, the natural logarithm of the concentration, and the reciprocal of the concentration (the vertical axis) versus time (the horizontal axis). Compare the graphs with those in [Figure 14.4.2](#) to determine the reaction order.

B Write the rate law for the reaction. Using the appropriate data from the table and the linear graph corresponding to the rate law for the reaction, calculate the slope of the plotted line to obtain the rate constant for the reaction.

Solution:

A Here are plots of [N₂O₅] versus *t*, ln[N₂O₅] versus *t*, and 1/[N₂O₅] versus *t*:

The plot of ln[N₂O₅] versus *t* gives a straight line, whereas the plots of [N₂O₅] versus *t* and 1/[N₂O₅] versus *t* do not. This means that the decomposition of N₂O₅ is first order in [N₂O₅].

B The rate law for the reaction is therefore

$$\text{rate} = k [\text{N}_2\text{O}_5]$$

Calculating the rate constant is straightforward because we know that the slope of the plot of ln[A] versus *t* for a first-order reaction is $-k$. We can calculate the slope using any two points that lie on the line in the plot of ln[N₂O₅] versus *t*. Using the points for *t* = 0 and 3000 s,

$$\text{slope} = \frac{\ln[\text{N}_2\text{O}_5]_{3000} - \ln[\text{N}_2\text{O}_5]_0}{3000 \text{ s} - 0 \text{ s}} = \frac{[-4.756] - [-3.310]}{3000 \text{ s}} = 4.820 \times 10^{-4} \text{ s}^{-1}$$

Thus $k = 4.820 \times 10^{-4} \text{ s}^{-1}$.

Exercise

1,3-Butadiene (CH₂=CH—CH=CH₂; C₄H₆) is a volatile and reactive organic molecule used in the production of rubber. Above room temperature, it reacts slowly to form products. Concentrations of C₄H₆ as a function of time at 326°C are listed in the following table along with ln[C₄H₆] and the reciprocal concentrations. Graph the data as concentration versus *t*, ln concentration versus *t*, and 1/concentration versus *t*. Then determine the reaction order in C₄H₆, the rate law, and the rate constant for the reaction.

Time (s)	$[C_4H_6]$ (M)	$\ln[C_4H_6]$	$1/[C_4H_6]$ (M^{-1})
0	1.72×10^{-2}	-4.063	58.1
900	1.43×10^{-2}	-4.247	69.9
1800	1.23×10^{-2}	-4.398	81.3
3600	9.52×10^{-3}	-4.654	105
6000	7.30×10^{-3}	-4.920	137

Answer:

second order in C_4H_6 ; rate = $k[C_4H_6]^2$; $k = 1.3 \times 10^{-2} M^{-1} \cdot s^{-1}$

Summary

For a zeroth-order reaction, a plot of the concentration of any reactant versus time is a straight line with a slope of $-k$. For a first-order reaction, a plot of the natural logarithm of the concentration of a reactant versus time is a straight line with a slope of $-k$. For a second-order reaction, a plot of the inverse of the concentration of a reactant versus time is a straight line with a slope of k .

Key Takeaway

- Plotting the concentration of a reactant as a function of time produces a graph with a characteristic shape that can be used to identify the reaction order in that reactant.

Conceptual Problems

- Compare first-order differential and integrated rate laws with respect to the following. Is there any information that can be obtained from the integrated rate law that cannot be obtained from the differential rate law?
 - the magnitude of the rate constant
 - the information needed to determine the order
 - the shape of the graphs
- In the single-step, second-order reaction $2A \rightarrow \text{products}$, how would a graph of $[A]$ versus time compare to a plot of $1/[A]$ versus time? Which of these would be the most similar to the same set of graphs for A during the single-step, second-order reaction $A + B \rightarrow \text{products}$? Explain.
- For reactions of the same order, what is the relationship between the magnitude of the rate constant and the reaction rate? If you were comparing reactions with different orders, could the same arguments be made? Why?

Answers

- For a given reaction under particular conditions, the magnitude of the first-order rate constant does not depend on whether a differential rate law or an integrated rate law is used.
 - The differential rate law requires multiple experiments to determine reactant order; the integrated rate law needs only one experiment.

- c. Using the differential rate law, a graph of concentration versus time is a curve with a slope that becomes less negative with time, whereas for the integrated rate law, a graph of $\ln[\text{reactant}]$ versus time gives a straight line with slope = $-k$. The integrated rate law allows you to calculate the concentration of a reactant at any time during the reaction; the differential rate law does not.
- 2.
3. The reaction rate increases as the rate constant increases. We cannot directly compare reaction rates and rate constants for reactions of different orders because they are not mathematically equivalent.

Numerical Problems

1. One method of using graphs to determine reaction order is to use relative rate information. Plotting the log of the relative rate versus log of relative concentration provides information about the reaction. Here is an example of data from a zeroth-order reaction:

Relative [A] (M)	Relative Rate (M/s)
1	1
2	1
3	1

Varying [A] does not alter the reaction rate. Using the relative rates in the table, generate plots of $\log(\text{rate})$ versus $\log(\text{concentration})$ for zeroth-, first- and second-order reactions. What does the slope of each line represent?

2. The table below follows the decomposition of N_2O_5 gas by examining the partial pressure of the gas as a function of time at 45°C . What is the reaction order? What is the rate constant? How long would it take for the pressure to reach 105 mmHg at 45°C ?

Time (s)	Pressure (mmHg)
0	348
400	276
1600	156
3200	69
4800	33

Unit 8: Materials

Learning Objective

- To know how to use half-lives to describe the rates of first-order reactions.

Half-Lives

Another approach to describing reaction rates is based on the time required for the concentration of a reactant to decrease to one-half its initial value. This period of time is called the half-life of the reaction, written as $t_{1/2}$. Thus the half-life of a reaction is the time required for the reactant concentration to decrease from $[A]_0$ to $[A]_0/2$. If two reactions have the same order, the faster reaction will have a shorter half-life, and the slower reaction will have a longer half-life.

The half-life of a first-order reaction under a given set of reaction conditions is a constant. This is not true for zeroth- and second-order reactions. The half-life of a first-order reaction is *independent of the concentration of the reactants*. This becomes evident when we rearrange the integrated rate law for a first-order reaction (Equation 14.3.6) to produce the following equation:

$$\ln \frac{[A]_0}{[A]} = kt \quad (14.5.1)$$

Substituting $[A]_0/2$ for $[A]$ and $t_{1/2}$ for t (to indicate a half-life) into Equation 14.5.1 gives

$$\ln \frac{[A]_0}{[A]_0/2} = \ln 2 = kt_{1/2} \quad (14.5.2)$$

The natural logarithm of 2 (to three decimal places) is 0.693. Substituting this value into the equation, we obtain the expression for the half-life of a first-order reaction:

$$t_{1/2} = \frac{0.693}{k} \quad (14.5.3)$$

Thus, for a first-order reaction, each successive half-life is the same length of time, as shown in Figure 14.5.1 "The Half-Life of a First-Order Reaction", and is independent of $[A]$.

Figure 14.5.1 The Half-Life of a First-Order Reaction This plot shows the concentration of the reactant in a first-order reaction as a function of time and identifies a series of half-lives, intervals in which the reactant concentration decreases by a factor of 2. In a first-order reaction, every half-life is the same length of time.

If we know the rate constant for a first-order reaction, then we can use half-lives to predict how much time is needed for the reaction to reach a certain percent completion.

Number of Half-Lives	Percentage of Reactant Remaining	
1	$\frac{100\%}{2} = 50\%$	$\frac{1}{2}(100\%) = 50\%$
2	$\frac{50\%}{2} = 25\%$	$\frac{1}{2}\left(\frac{1}{2}\right)(100\%) = 25\%$
3	$\frac{25\%}{2} = 12.5\%$	$\frac{1}{2}\left(\frac{1}{2}\right)\left(\frac{1}{2}\right)(100\%) = 12.5\%$
n	$\frac{100\%}{2^n}$	$\left(\frac{1}{2}\right)^n (100\%) = \left(\frac{1}{2}\right)^n \%$

As you can see from this table, the amount of reactant left after n half-lives of a first-order reaction is $(1/2)^n$ times the initial concentration.

Note the Pattern

For a first-order reaction, the concentration of the reactant decreases by a constant with each half-life and is independent of $[A]$.

Example 14.5.1

The anticancer drug cisplatin hydrolyzes in water with a rate constant of $1.5 \times 10^{-3} \text{ min}^{-1}$ at pH 7.0 and 25°C. Calculate the half-life for the hydrolysis reaction under these conditions. If a freshly prepared solution of cisplatin has a concentration of 0.053 M, what will be the concentration of cisplatin after 5 half-lives? after 10 half-lives? What is the percent completion of the reaction after 5 half-lives? after 10 half-lives?

Given: rate constant, initial concentration, and number of half-lives

Asked for: half-life, final concentrations, and percent completion

Strategy:

A Use [Equation 14.5.3](#) to calculate the half-life of the reaction.

B Multiply the initial concentration by 1/2 to the power corresponding to the number of half-lives to obtain the remaining concentrations after those half-lives.

C Subtract the remaining concentration from the initial concentration. Then divide by the initial concentration, multiplying the fraction by 100 to obtain the percent completion.

Solution:

A We can calculate the half-life of the reaction using [Equation 14.5.3](#):

$$t_{1/2} = \frac{0.693}{k} = \frac{0.693}{1.5 \times 10^{-3} \text{ min}^{-1}} = 4.6 \times 10^2 \text{ min}$$

Thus it takes almost 8 h for half of the cisplatin to hydrolyze.

B After 5 half-lives (about 38 h), the remaining concentration of cisplatin will be as follows:

$$\frac{0.053 \text{ M}}{2^5} = \frac{0.053 \text{ M}}{32} = 0.0017 \text{ M}$$

After 10 half-lives (77 h), the remaining concentration of cisplatin will be as follows:

$$\frac{0.053 \text{ M}}{2^{10}} = \frac{0.053 \text{ M}}{1024} = 5.2 \times 10^{-5} \text{ M}$$

C The percent completion after 5 half-lives will be as follows:

$$\text{percent completion} = \frac{(0.053 \text{ M} - 0.0017 \text{ M}) 100}{0.53 \text{ M}} = 97\%$$

The percent completion after 10 half-lives will be as follows:

$$\text{percent completion} = \frac{(0.053 \text{ M} - 5.2 \times 10^{-5} \text{ M}) 100}{0.53 \text{ M}} = 100\%$$

Thus a first-order chemical reaction is 97% complete after 5 half-lives and 100% complete after 10 half-lives.

Exercise

In Example 4 you found that ethyl chloride decomposes to ethylene and HCl in a first-order reaction that has a rate constant of $1.6 \times 10^{-6} \text{ s}^{-1}$ at 650°C . What is the half-life for the reaction under these conditions? If a flask that originally contains 0.077 M ethyl chloride is heated at 650°C , what is the concentration of ethyl chloride after 4 half-lives?

Answer: $4.3 \times 10^5 \text{ s} = 120 \text{ h} = 5.0 \text{ days}$; $4.8 \times 10^{-3} \text{ M}$

Radioactive Decay Rates

As you learned in [Chapter 1](#) radioactivity, or radioactive decay, is the emission of a particle or a photon that results from the spontaneous decomposition of the unstable nucleus of an atom. The rate of radioactive decay is an intrinsic property of each radioactive isotope that is independent of the chemical and physical form of the radioactive isotope. The rate is also independent of temperature. In this section, we will describe radioactive decay rates and how half-lives can be used to monitor radioactive decay processes.

In any sample of a given radioactive substance, the number of atoms of the radioactive isotope must decrease with time as their nuclei decay to nuclei of a more stable isotope. Using N to represent the number of atoms of the radioactive isotope, we can define the rate of decay of the sample, which is also called its activity (A) as the decrease in the number of the radioisotope's nuclei per unit time:

$$A = -\frac{\Delta N}{\Delta t} \quad (14.5.4)$$

Activity is usually measured in *disintegrations per second (dps)* or *disintegrations per minute (dpm)*.

The activity of a sample is directly proportional to the number of atoms of the radioactive isotope in the sample:

$$A = kN \quad (14.5.5)$$

Here, the symbol k is the *radioactive decay constant*, which has units of inverse time (e.g., s^{-1} , yr^{-1}) and a characteristic value for each radioactive isotope. If we combine [Equation 14.5.4](#) and [Equation 14.5.5](#) we obtain the relationship between the number of decays per unit time and the number of atoms of the isotope in a sample:

$$-\frac{\Delta N}{\Delta t} = kN \quad (14.5.6)$$

[Equation 14.5.6](#) is the same as the equation for the reaction rate of a first-order reaction ([Equation 14.3.5](#)), except that it uses numbers of atoms instead of concentrations. In fact, radioactive decay is a first-order process and can be described in terms of either the differential rate law ([Equation 14.4.7](#)) or the integrated rate law:

$$N = N_0 e^{-kt} \quad (14.5.7)$$

$$\ln \frac{N}{N_0} = -kt \quad (14.5.8)$$

Because radioactive decay is a first-order process, the time required for half of the nuclei in any sample of a radioactive isotope to decay is a constant, called the *half-life of the isotope*. The half-life tells us how radioactive an isotope is (the number of decays per unit time); thus it is the most commonly cited property of any radioisotope. For a given number of atoms, isotopes with shorter half-lives decay more rapidly, undergoing a greater number of radioactive decays per unit time than do isotopes with longer half-lives. The half-lives of several isotopes are listed in [Table 14.5.1](#), along with some of their applications.

Table 14.5.1 Half-Lives and Applications of Some Radioactive Isotopes

Radioactive Isotope	Half-Life	Typical Uses
hydrogen-3 (tritium)	12.32 yr	biochemical tracer
carbon-11	20.33 min	positron emission tomography (biomedical imaging)
carbon-14	5.70×10^3 yr	dating of artifacts
sodium-24	14.951 h	cardiovascular system tracer
phosphorus-32	14.26 days	biochemical tracer
potassium-40	1.248×10^9 yr	dating of rocks
iron-59	44.495 days	red blood cell lifetime tracer
cobalt-60	5.2712 yr	radiation therapy for cancer
technetium-99m*	6.006 h	biomedical imaging
iodine-131	8.0207 days	thyroid studies tracer
radium-226	1.600×10^3 yr	radiation therapy for cancer
uranium-238	4.468×10^9 yr	dating of rocks and Earth's crust
americium-241	432.2 yr	smoke detectors

*The *m* denotes metastable, where an excited state nucleus decays to the ground state of the same isotope.

Note the Pattern

Radioactive decay is a first-order process.

Radioisotope Dating Techniques

In our earlier discussion, we used the half-life of a first-order reaction to calculate how long the reaction had been occurring. Because nuclear decay reactions follow first-order kinetics and have a rate constant that is independent of temperature and the chemical or physical environment, we can perform similar calculations using the half-lives of isotopes to estimate the ages of geological and archaeological artifacts. The techniques that have been developed for this application are known as *radioisotope dating* techniques.

The most common method for measuring the age of ancient objects is *carbon-14 dating*. The carbon-14 isotope, created continuously in the upper regions of Earth's atmosphere, reacts with atmospheric oxygen or ozone to form $^{14}\text{CO}_2$. As a result, the CO_2 that plants use as a carbon source for synthesizing organic compounds always includes a certain proportion of $^{14}\text{CO}_2$ molecules as well as nonradioactive $^{12}\text{CO}_2$ and $^{13}\text{CO}_2$. Any animal that eats a plant ingests a mixture of organic compounds that contains approximately the same proportions of carbon isotopes as those in the atmosphere. When the animal or plant dies, the

carbon-14 nuclei in its tissues decay to nitrogen-14 nuclei by a radioactive process known as *beta decay*, which releases low-energy electrons (β particles) that can be detected and measured:

The half-life for this reaction is 5700 ± 30 yr.

The ${}^{14}\text{C}/{}^{12}\text{C}$ ratio in living organisms is 1.3×10^{-12} , with a decay rate of 15 dpm/g of carbon (Figure 14.18 "Radiocarbon Dating"). Comparing the disintegrations per minute per gram of carbon from an archaeological sample with those from a recently living sample enables scientists to estimate the age of the artifact, as illustrated in Example 11. Using this method implicitly assumes that the ${}^{14}\text{CO}_2/{}^{12}\text{CO}_2$ ratio in the atmosphere is constant, which is not strictly correct. Other methods, such as tree-ring dating, have been used to calibrate the dates obtained by radiocarbon dating, and all radiocarbon dates reported are now corrected for minor changes in the ${}^{14}\text{CO}_2/{}^{12}\text{CO}_2$ ratio over time.

Figure 14.5.2 Radiocarbon Dating A plot of the specific activity of ${}^{14}\text{C}$ versus age for a number of archaeological samples shows an inverse linear relationship between ${}^{14}\text{C}$ content (a log scale) and age (a linear scale).

Example 14.5.2

In 1990, the remains of an apparently prehistoric man were found in a melting glacier in the Italian Alps. Analysis of the ${}^{14}\text{C}$ content of samples of wood from his tools gave a decay rate of 8.0 dpm/g carbon. How long ago did the man die?

Given: isotope and final activity

Asked for: elapsed time

Strategy:

A Use Equation 14.5.5 to calculate N_0/N . Then substitute the value for the half-life of ${}^{14}\text{C}$ into Equation 14.5.3 to find the rate constant for the reaction.

B Using the values obtained for N_0/N and the rate constant, solve Equation 14.5.7 to obtain the elapsed time.

Solution:

We know the initial activity from the isotope's identity (15 dpm/g), the final activity (8.0 dpm/g), and the half-life, so we can use the integrated rate law for a first-order nuclear reaction (Equation 14.5.7) to calculate the elapsed time (the amount of time elapsed since the wood for the tools was cut and began to decay).

$$\ln \frac{N}{N_0} = -kt$$

$$\frac{\ln(N_0/N)}{k} = t$$

A From Equation 14.5.5, we know that $A = kN$. We can therefore use the initial and final activities ($A_0 = 15$ dpm and $A = 8.0$ dpm) to calculate N_0/N :

$$\frac{A_0}{A} = \frac{kN_0}{kN} = \frac{N_0}{N} = \frac{15.}{8.0}$$

Now we need only calculate the rate constant for the reaction from its half-life (5730 yr) using Equation 14.5.3:

$$t_{1/2} = \frac{0.693}{k}$$

This equation can be rearranged as follows:

$$k = \frac{0.693}{t_{1/2}} = \frac{0.693}{5730 \text{ yr}} = 1.22 \times 10^{-4} \text{ yr}^{-1}$$

B Substituting into the equation for t ,

$$t = \frac{\ln(N_0/N)}{k} = \frac{\ln(15./8.0)}{1.22 \times 10^{-4} \text{ yr}^{-1}} = 5.2 \times 10^3 \text{ yr}$$

From our calculations, the man died 5200 yr ago.

Exercise

It is believed that humans first arrived in the Western Hemisphere during the last Ice Age, presumably by traveling over an exposed land bridge between Siberia and Alaska. Archaeologists have estimated that this occurred about 11,000 yr ago, but some argue that recent discoveries in several sites in North and South America suggest a much earlier arrival. Analysis of a sample of charcoal from a fire in one such site gave a ^{14}C decay rate of 0.4 dpm/g of carbon. What is the approximate age of the sample?

Answer: 30,000 yr

Summary

The **half-life** of a reaction is the time required for the reactant concentration to decrease to one-half its initial value. The half-life of a first-order reaction is a constant that is related to the rate constant for the reaction: $t_{1/2} = 0.693/k$.

Radioactive decay reactions are first-order reactions. The **rate of decay**, or **activity**, of a sample of a radioactive substance is the decrease in the number of radioactive nuclei per unit time.

Key Takeaways

- The half-life of a first-order reaction is independent of the concentration of the reactants.
- The half-lives of radioactive isotopes can be used to date objects.

Key Equations

half-life of first-order reaction

radioactive decay

Equation 14.5.5: $A = kN$

Conceptual Problems

1. What do chemists mean by the *half-life* of a reaction?
2. If a sample of one isotope undergoes more disintegrations per second than the same number of atoms of another isotope, how do their half-lives compare?

Numerical Problems

1. Half-lives for the reaction $A + B \rightarrow C$ were calculated at three values of $[A]_0$, and $[B]$ was the same in all cases. The data are listed in the following table:

$[A]_0$ (M)	$t_{1/2}$ (s)
0.50	420
0.75	280
1.0	210

Does this reaction follow first-order kinetics? On what do you base your answer?

2. Ethyl-2-nitrobenzoate ($\text{NO}_2\text{C}_6\text{H}_4\text{CO}_2\text{C}_2\text{H}_5$) hydrolyzes under basic conditions. A plot of $[\text{NO}_2\text{C}_6\text{H}_4\text{CO}_2\text{C}_2\text{H}_5]$ versus t was used to calculate $t_{1/2}$, with the following results:

$[\text{NO}_2\text{C}_6\text{H}_4\text{CO}_2\text{C}_2\text{H}_5]$ (M/cm ³)	$t_{1/2}$ (s)
0.050	240
0.040	300
0.030	400

Is this a first-order reaction? Explain your reasoning.

3. Azomethane ($\text{CH}_3\text{N}_2\text{CH}_3$) decomposes at 600 K to C_2H_6 and N_2 . The decomposition is first order in azomethane. Calculate $t_{1/2}$ from the data in the following table:

Time (s)	P _{Azomethane} (atm)
0	8.2×10^{-2}
2000	3.99×10^{-2}
4000	1.94×10^{-2}

How long will it take for the decomposition to be 99.9% complete?

4. The first-order decomposition of hydrogen peroxide has a half-life of 10.7 h at 20°C. What is the rate constant (expressed in s^{-1}) for this reaction? If you started with a solution that was 7.5×10^{-3} M H_2O_2 , what would be the initial rate of decomposition (M/s)? What would be the concentration of H_2O_2 after 3.3 h?

Answers

1. No; the reaction is second order in A because the half-life decreases with increasing reactant concentration according to $t_{1/2} = 1/k[A_0]$.
- 2.
3. $t_{1/2} = 1.92 \times 10^3$ s or 1920 s; 19100 s or 5.32 hrs.
- 4.

Learning Objective

- To determine the individual steps of a simple reaction.

One of the major reasons for studying chemical kinetics is to use measurements of the macroscopic properties of a system, such as the rate of change in the concentration of reactants or products with time, to discover the sequence of events that occur at the molecular level during a reaction. This molecular description is the *mechanism* of the reaction; it describes how individual atoms, ions, or molecules interact to form particular products. The stepwise changes are collectively called the **reaction mechanism**.

In an internal combustion engine, for example, isooctane reacts with oxygen to give carbon dioxide and water:

For this reaction to occur in a single step, 25 dioxygen molecules and 2 isooctane molecules would have to collide simultaneously and be converted to 34 molecules of product, which is very unlikely. It is more likely that a complex series of reactions takes place in a stepwise fashion. Each individual reaction, which is called an elementary reaction, involves one, two, or (rarely) three atoms, molecules, or ions. The overall sequence of elementary reactions is the mechanism of the reaction. *The sum of the individual steps, or elementary reactions, in the mechanism must give the balanced chemical equation for the overall reaction.*

Molecularity and the Rate-Determining Step

To demonstrate how the analysis of elementary reactions helps us determine the overall reaction mechanism, we will examine the much simpler reaction of carbon monoxide with nitrogen dioxide.

From the balanced chemical equation, one might expect the reaction to occur via a collision of one molecule of NO_2 with a molecule of CO that results in the transfer of an oxygen atom from nitrogen to carbon. The experimentally determined rate law for the reaction, however, is as follows:

$$rate = k[NO_2]^2 \quad (14.6.3)$$

The fact that the reaction is second order in $[NO_2]$ and independent of $[CO]$ tells us that it does not occur by the simple collision model outlined previously. If it did, its predicted rate law would be $rate = k[NO_2][CO]$.

The following two-step mechanism is consistent with the rate law if step 1 is much slower than step 2:

According to this mechanism, the overall reaction occurs in two steps, or elementary reactions. Summing steps 1 and 2 and canceling on both sides of the equation gives the overall balanced chemical equation for the reaction. The NO_3 molecule is an intermediate in the reaction, a species that does not appear in the balanced chemical equation for the overall reaction. It is formed as a product of the first step but is consumed in the second step.

Note the Pattern

The sum of the elementary reactions in a reaction mechanism must give the overall balanced chemical equation of the reaction.

Using Molecularity to Describe a Rate Law

The molecularity of an elementary reaction is the number of molecules that collide during that step in the mechanism. If there is only a single reactant molecule in an elementary reaction, that step is designated as *unimolecular*; if there are two reactant molecules, it is *bimolecular*; and if there are three reactant molecules (a relatively rare situation), it is *termolecular*. Elementary reactions that involve the simultaneous collision of more than three molecules are highly improbable and have never been observed experimentally. (To understand why, try to make three or more marbles or pool balls collide with one another simultaneously!)

Writing the rate law for an elementary reaction is straightforward because we know how many molecules must collide simultaneously for the elementary reaction to occur; hence the order of the elementary reaction is the same as its molecularity (Table 14.6.1). In contrast, the rate law for the reaction cannot be determined from the balanced chemical equation for the overall reaction. The general rate law for a unimolecular elementary reaction ($A \rightarrow \text{products}$) is $\text{rate} = k[A]$. For bimolecular reactions, the reaction rate depends on the number of collisions per unit time, which is proportional to the product of the concentrations of the reactants, as shown in Figure 14.6.1. For a bimolecular elementary reaction of the form $A + B \rightarrow \text{products}$, the general rate law is $\text{rate} = k[A][B]$.

Table 14.6.1 Common Types of Elementary Reactions and Their Rate Laws

Elementary Reaction	Molecularity	Rate Law	Reaction Order
$A \rightarrow \text{products}$	unimolecular	$\text{rate} = k[A]$	first
$2A \rightarrow \text{products}$	bimolecular	$\text{rate} = k[A]^2$	second
$A + B \rightarrow \text{products}$	bimolecular	$\text{rate} = k[A][B]$	second
$2A + B \rightarrow \text{products}$	termolecular	$\text{rate} = k[A]^2[B]$	third
$A + B + C \rightarrow \text{products}$	termolecular	$\text{rate} = k[A][B][C]$	third

Figure 14.6.1 The Basis for Writing Rate Laws of Elementary Reactions This diagram illustrates how the number of possible collisions per unit time between two reactant species, A and B, depends on the number of A and B particles present. The number of collisions between A and B particles increases as the product of the number of particles, not as the sum. This is why the rate law for an elementary reaction depends on the product of the concentrations of the species that collide in that step.

Identifying the Rate-Determining Step

Note the important difference between writing rate laws for elementary reactions and the balanced chemical equation of the overall reaction. Because the balanced chemical equation does not necessarily reveal the individual elementary reactions by which the reaction occurs, we *cannot* obtain the rate law for a reaction from the overall balanced chemical equation alone. In fact, it is the rate law for the *slowest* overall reaction, which is the same as the rate law for the slowest step in the reaction mechanism, the rate-determining step, that must give the experimentally determined rate law for the overall reaction. This statement is true if one step is substantially slower than all the others, typically by a factor of 10 or more. If two or more slow steps have comparable rates, the experimentally determined rate laws can become complex. Our discussion is limited to reactions in which one step can be identified as being substantially slower than any other. The reason for this is that any process that occurs through a sequence of

steps can take place no faster than the slowest step in the sequence. In an automotive assembly line, for example, a component cannot be used faster than it is produced. Similarly, blood pressure is regulated by the flow of blood through the smallest passages, the capillaries. Because movement through capillaries constitutes the rate-determining step in blood flow, blood pressure can be regulated by medications that cause the capillaries to contract or dilate. A chemical reaction that occurs via a series of elementary reactions can take place no faster than the slowest step in the series of reactions.

Rate-determining step. The phenomenon of a rate-determining step can be compared to a succession of funnels. The smallest-diameter funnel controls the rate at which the bottle is filled, whether it is the first or the last in the series. Pouring liquid into the first funnel faster than it can drain through the smallest results in an overflow.

Look at the rate laws for each elementary reaction in our example as well as for the overall reaction.

The experimentally determined rate law for the reaction of NO_2 with CO is the same as the predicted rate law for step 1. This tells us that the first elementary reaction is the rate-determining step, so k for the overall reaction must equal k_1 . That is, NO_3 is formed slowly in step 1, but once it is formed, it reacts very rapidly with CO in step 2.

Sometimes chemists are able to propose two or more mechanisms that are consistent with the available data. If a proposed mechanism predicts the wrong experimental rate law, however, the mechanism must be incorrect.

Example 14.6.1

In an alternative mechanism for the reaction of NO_2 with CO , N_2O_4 appears as an intermediate.

Write the rate law for each elementary reaction. Is this mechanism consistent with the experimentally determined rate law ($\text{rate} = k[\text{NO}_2]^2$)?

Given: elementary reactions

Asked for: rate law for each elementary reaction and overall rate law

Strategy:

A Determine the rate law for each elementary reaction in the reaction.

B Determine which rate law corresponds to the experimentally determined rate law for the reaction. This rate law is the one for the rate-determining step.

Solution:

A The rate law for step 1 is $\text{rate} = k_1[\text{NO}_2]^2$; for step 2, it is $\text{rate} = k_2[\text{N}_2\text{O}_4][\text{CO}]$.

B If step 1 is slow (and therefore the rate-determining step), then the overall rate law for the reaction will be the same: $\text{rate} = k_1[\text{NO}_2]^2$. This is the same as the experimentally determined rate law. Hence this mechanism, with N_2O_4 as an intermediate, and the one described previously, with NO_3 as an intermediate, are kinetically indistinguishable. In this case, further experiments are needed to distinguish between them. For example, the researcher could try to detect the proposed intermediates, NO_3 and N_2O_4 , directly.

Exercise A

Iodine monochloride (ICl) reacts with H_2 as follows:

The experimentally determined rate law is $\text{rate} = k[\text{ICl}][\text{H}_2]$. Write a two-step mechanism for this reaction using only bimolecular elementary reactions and show that it is consistent with the experimental rate law. (Hint: HI is an intermediate.)

Answer:

This mechanism is consistent with the experimental rate law if the first step is the rate-determining step.

Exercise B

The reaction between NO and H_2 occurs via a three-step process:

Write the rate law for each elementary reaction, write the balanced chemical equation for the overall reaction, and identify the rate-determining step. Is the rate law for the rate-determining step consistent with the experimentally derived rate law for the overall reaction: $\text{rate} = k[\text{NO}]^2[\text{H}_2]$?

Answer:

- $\text{rate} = k_1[\text{NO}]^2$;
- $\text{rate} = k_2[\text{N}_2\text{O}_2][\text{H}_2]$;
- $\text{rate} = k_3[\text{N}_2\text{O}][\text{H}_2]$;
- $2\text{NO}(g) + 2\text{H}_2(g) \rightarrow \text{N}_2(g) + 2\text{H}_2\text{O}(g)$
- step 2
- Yes, because the rate of formation of $[\text{N}_2\text{O}_2] = k_1[\text{NO}]^2$. Substituting $k_1[\text{NO}]^2$ for $[\text{N}_2\text{O}_2]$ in the rate law for step 2 gives the experimentally derived rate law for the overall chemical reaction, where $k = k_1k_2$.

Chain Reactions

Many reaction mechanisms, like those discussed so far, consist of only two or three elementary reactions. Many others consist of long series of elementary reactions. The most common mechanisms are chain reactions, in which one or more elementary reactions that contain a highly reactive species repeat again and again during the reaction process. Chain reactions occur in fuel combustion,

explosions, the formation of many polymers, and the tissue changes associated with aging. They are also important in the chemistry of the atmosphere.

Chain reactions are described as having three stages. The first is *initiation*, a step that produces one or more reactive intermediates. Often these intermediates are radicals, species that have an unpaired valence electron. In the second stage, *propagation*, reactive intermediates are continuously consumed and regenerated while products are formed. Intermediates are also consumed but not regenerated in the final stage of a chain reaction, *termination*, usually by forming stable products.

Let us look at the reaction of methane with chlorine at elevated temperatures (400°C–450°C), a chain reaction used in industry to manufacture methyl chloride (CH₃Cl), dichloromethane (CH₂Cl₂), chloroform (CHCl₃), and carbon tetrachloride (CCl₄):

Direct chlorination generally produces a mixture of all four carbon-containing products, which must then be separated by distillation. In our discussion, we will examine only the chain reactions that lead to the preparation of CH₃Cl.

In the initiation stage of this reaction, the relatively weak Cl–Cl bond cleaves at temperatures of about 400°C to produce chlorine atoms (Cl·):

During propagation, a chlorine atom removes a hydrogen atom from a methane molecule to give HCl and CH₃·, the methyl radical:

The methyl radical then reacts with a chlorine molecule to form methyl chloride and another chlorine atom, Cl·:

The sum of the propagation reactions is the same as the overall balanced chemical equation for the reaction:

Without a chain-terminating reaction, propagation reactions would continue until either the methane or the chlorine was consumed. Because radical species react rapidly with almost anything, however, including each other, they eventually form neutral compounds, thus terminating the chain reaction in any of three ways:

Here is the overall chain reaction, with the desired product (CH₃Cl) in bold:

<i>Initiation:</i>	Cl ₂ → 2Cl·
<i>Propagation:</i>	Cl· + CH ₄ → CH ₃ · + HCl
	CH ₃ · + Cl ₂ → CH₃Cl + Cl·
<i>Termination:</i>	CH ₃ · + Cl· → CH₃Cl
	CH ₃ · + CH ₃ · → H ₃ CCH ₃
	Cl· + Cl· → Cl ₂

The chain reactions responsible for explosions generally have an additional feature: the existence of one or more *chain branching steps*, in which one radical reacts to produce two or more radicals, each of which can then go on to start a new chain reaction.

Repetition of the branching step has a cascade effect such that a single initiation step generates large numbers of chain reactions. The result is a very rapid reaction or an explosion.

The reaction of H_2 and O_2 , used to propel rockets, is an example of a chain branching reaction:

<i>Initiation:</i>	$\text{H}_2 + \text{O}_2 \rightarrow \text{HO}_2\cdot + \text{H}\cdot$
<i>Propagation:</i>	$\text{HO}_2\cdot + \text{H}_2 \rightarrow \text{H}_2\text{O} + \text{OH}\cdot$
	$\text{OH}\cdot + \text{H}_2 \rightarrow \text{H}_2\text{O} + \text{H}\cdot$
<i>Termination:</i>	$\text{H}\cdot + \text{O}_2 \rightarrow \text{OH}\cdot + \cdot\text{O}\cdot$
	$\cdot\text{O}\cdot + \text{H}_2 \rightarrow \text{OH}\cdot + \text{H}\cdot$

Termination reactions occur when the extraordinarily reactive $\text{H}\cdot$ or $\text{OH}\cdot$ radicals react with a third species. The complexity of a chain reaction makes it unfeasible to write a rate law for the overall reaction.

Summary

A **reaction mechanism** is the microscopic path by which reactants are transformed into products. Each step is an **elementary reaction**. Species that are formed in one step and consumed in another are **intermediates**. Each elementary reaction can be described in terms of its **molecularity**, the number of molecules that collide in that step. The slowest step in a reaction mechanism is the **rate-determining step**. **Chain reactions** consist of three kinds of reactions: initiation, propagation, and termination. Intermediates in chain reactions are often **radicals**, species that have an unpaired valence electron.

Key Takeaway

- A balanced chemical reaction does not necessarily reveal either the individual elementary reactions by which a reaction occurs or its rate law.

Conceptual Problems

1. How does the term *molecularity* relate to elementary reactions? How does it relate to the overall balanced chemical equation?
2. What is the relationship between the reaction order and the molecularity of a reaction? What is the relationship between the reaction order and the balanced chemical equation?
3. When you determine the rate law for a given reaction, why is it valid to assume that the concentration of an intermediate does not change with time during the course of the reaction?
4. If you know the rate law for an overall reaction, how would you determine which elementary reaction is rate determining? If an intermediate is contained in the rate-determining step, how can the experimentally determined rate law for the reaction be derived from this step?
5. Give the rate-determining step for each case.
 - a. Traffic is backed up on a highway because two lanes merge into one.
 - b. Gas flows from a pressurized cylinder fitted with a gas regulator and then is bubbled through a solution.
 - c. A document containing text and graphics is downloaded from the Internet.
6. Before being sent on an assignment, an aging James Bond was sent off to a health farm where part of the program's focus was to purge his body of radicals. Why was this goal considered important to his health?

Numerical Problems

1. Cyclopropane, a mild anesthetic, rearranges to propylene via a collision that produces and destroys an energized species. The important steps in this rearrangement are as follows:

where M is any molecule, including cyclopropane. Only those cyclopropane molecules with sufficient energy (denoted with an asterisk) can rearrange to propylene. Which step determines the rate constant of the overall reaction?

- Above approximately 500 K, the reaction between NO_2 and CO to produce CO_2 and NO follows the second-order rate law $\Delta[\text{CO}_2]/\Delta t = k[\text{NO}_2][\text{CO}]$. At lower temperatures, however, the rate law is $\Delta[\text{CO}_2]/\Delta t = k'[\text{NO}_2]^2$, for which it is known that NO_3 is an intermediate in the mechanism. Propose a complete low-temperature mechanism for the reaction based on this rate law. Which step is the slowest?
- Nitramide (O_2NNH_2) decomposes in aqueous solution to N_2O and H_2O . What is the experimental rate law ($\Delta[\text{N}_2\text{O}]/\Delta t$) for the decomposition of nitramide if the mechanism for the decomposition is as follows?

Assume that the rates of the forward and reverse reactions in the first equation are equal.

- The following reactions are given:

What is the relationship between the relative magnitudes of k_{-1} and k_2 if these reactions have the rate law $\Delta[\text{F}]/\Delta t = k[\text{A}][\text{B}][\text{E}]/[\text{C}]$? How does the magnitude of k_1 compare to that of k_2 ? Under what conditions would you expect the rate law to be $\Delta[\text{F}]/\Delta t = k'[\text{A}][\text{B}]$? Assume that the rates of the forward and reverse reactions in the first equation are equal.

Answers

- The k_2 step is likely to be rate limiting; the rate cannot proceed any faster than the second step.
-
-

$$\text{rate} = k_2 \frac{k_1 [\text{O}_2\text{NNH}_2]}{k_{-1} [\text{H}^+]} = k \frac{[\text{O}_2\text{NNH}_2]}{[\text{H}^+]}$$

Learning Objective

- To understand why and how chemical reactions occur.

In [Section 14.6](#), you saw that it is possible to use kinetics studies of a chemical system, such as the effect of changes in reactant concentrations, to deduce events that occur on a microscopic scale, such as collisions between individual particles. Such studies have led to the *collision model of chemical kinetics*, which is a useful tool for understanding the behavior of reacting chemical species. According to the collision model, a chemical reaction can occur only when the reactant molecules, atoms, or ions collide with more than a certain amount of kinetic energy and in the proper orientation. The collision model explains why, for example, most collisions between molecules do *not* result in a chemical reaction. Nitrogen and oxygen molecules in a single liter of air at room temperature and 1 atm of pressure collide about 10^{30} times per second. If every collision produced two molecules of NO, the atmosphere would have been converted to NO and then NO₂ a long time ago. Instead, in most collisions, the molecules simply bounce off one another without reacting, much as marbles bounce off each other when they collide. The collision model also explains why such chemical reactions occur more rapidly at higher temperatures. For example, the reaction rates of many reactions that occur at room temperature approximately double with a temperature increase of only 10°C. In this section, we will use the collision model to analyze this relationship between temperature and reaction rates.

Activation Energy

In [Chapter 10](#) we discussed the kinetic molecular theory of gases, which showed that the average kinetic energy of the particles of a gas increases with increasing temperature. Because the speed of a particle is proportional to the square root of its kinetic energy, increasing the temperature will also increase the number of collisions between molecules per unit time. What the kinetic molecular theory of gases does not explain is why the reaction rate of most reactions approximately doubles with a 10°C temperature increase. This result is surprisingly large considering that a 10°C increase in the temperature of a gas from 300 K to 310 K increases the kinetic energy of the particles by only about 4%, leading to an increase in molecular speed of only about 2% and a correspondingly small increase in the number of bimolecular collisions per unit time.

The collision model of chemical kinetics explains this behavior by introducing the concept of activation energy (E_a). We will define this concept using the reaction of NO with ozone, which plays an important role in the depletion of ozone in the ozone layer:

Increasing the temperature from 200 K to 350 K causes the rate constant for this particular reaction to increase by a factor of more than 10, whereas the increase in the frequency of bimolecular collisions over this temperature range is only 30%. Thus something other than an increase in the collision rate must be affecting the reaction rate.

The reaction rate, not the rate constant, will vary with concentration. The rate constant, however, does vary with temperature. [Figure 14.7.1](#) shows a plot of the rate constant of the reaction of NO with O₃ at various temperatures. The relationship is not linear but instead resembles the relationships seen in graphs of vapor pressure versus temperature ([Chapter 11](#)) and of conductivity versus temperature ([Chapter 12](#)). In all three cases, the shape of the plots results from a distribution of kinetic energy over a population of particles (electrons in the case of conductivity; molecules in the case of vapor pressure; and molecules, atoms, or ions in the case of reaction rates). Only a fraction of the particles have sufficient energy to overcome an energy barrier.

Figure 14.7.1 Rate Constant versus Temperature for the Reaction of NO with O₃ The nonlinear shape of the curve is caused by a distribution of kinetic energy over a population of molecules. Only a fraction of the particles have enough energy to overcome an energy barrier, but as the temperature is increased, the size of that fraction increases.

In the case of vapor pressure, particles must overcome an energy barrier to escape from the liquid phase to the gas phase. This barrier corresponds to the energy of the intermolecular forces that hold the molecules together in the liquid. In conductivity, the barrier is the energy gap between the filled and empty bands. In chemical reactions, the energy barrier corresponds to the amount of energy the particles must have to react when they collide. This energy threshold, called the activation energy, was first postulated in 1888 by the Swedish chemist Svante Arrhenius (1859–1927; Nobel Prize in Chemistry 1903). It is the minimum amount of energy needed for a reaction to occur. Reacting molecules must have enough energy to overcome electrostatic repulsion, and a minimum amount of energy is required to break chemical bonds so that new ones may be formed. Molecules that collide with less than the threshold energy bounce off one another chemically unchanged, with only their direction of travel and their speed altered by the collision. Molecules that are able to overcome the energy barrier are able to react and form an arrangement of atoms called the activated complex or the transition state of the reaction. The activated complex is *not* a reaction intermediate; it does not last long enough to be detected readily.

Note the Pattern

Any phenomenon that depends on the distribution of thermal energy in a population of particles has a nonlinear temperature dependence.

Graphing Energy Changes during a Reaction

We can graph the energy of a reaction by plotting the potential energy of the system as the reaction progresses. Figure 14.7.2 shows a plot for the NO–O₃ system, in which the vertical axis is potential energy and the horizontal axis is the *reaction coordinate*, which indicates the progress of the reaction with time. The activated complex is shown in brackets with an asterisk. The overall change in potential energy for the reaction (ΔE) is negative, which means that the reaction releases energy. (In this case, ΔE is -200.8 kJ/mol.) To react, however, the molecules must overcome the energy barrier to reaction (E_a is 9.6 kJ/mol). That is, 9.6 kJ/mol must be put into the system as the activation energy. Below this threshold, the particles do not have enough energy for the reaction to occur.

Figure 14.7.2 Energy of the Activated Complex for the NO–O₃ System The diagram shows how the energy of this system varies as the reaction proceeds from reactants to products. Note the initial increase in energy required to form the activated complex.

Part (a) in Figure 14.7.3 illustrates the general situation in which the products have a lower potential energy than the reactants. In contrast, part (b) in Figure 14.22 "Differentiating between " illustrates the case in which the products have a higher potential energy than the reactants, so the overall reaction requires an input of energy; that is, it is energetically uphill, and $\Delta E > 0$. Although the energy changes that result from a reaction can be positive, negative, or even zero, in all cases an energy barrier must be overcome before a reaction can occur. This means that the activation energy is always positive.

Figure 14.7.3 Differentiating between E_a and ΔE The potential energy diagrams for a reaction with (a) $\Delta E < 0$ and (b) $\Delta E > 0$ illustrate the change in the potential energy of the system as reactants are converted to products. E_a is always positive. For a reaction such as the one shown in (b), E_a must be greater than ΔE .

Note the Pattern

For similar reactions under comparable conditions, the one with the smallest E_a will occur most rapidly.

Whereas ΔE is related to the tendency of a reaction to occur spontaneously, E_a gives us information about the reaction rate and how rapidly the reaction rate changes with temperature. (For more information on spontaneous reactions, see Chapter 18.) For two similar reactions under comparable conditions, the reaction with the smallest E_a will occur more rapidly.

Even when the energy of collisions between two reactant species is greater than E_a , however, most collisions do not produce a reaction. The probability of a reaction occurring depends not only on the collision energy but also on the spatial orientation of the molecules when they collide. For NO and O₃ to produce NO₂ and O₂, a terminal oxygen atom of O₃ must collide with the nitrogen atom of NO at an angle that allows O₃ to transfer an oxygen atom to NO to produce NO₂ (Figure 14.7.4). All other collisions produce no reaction. Because fewer than 1% of all possible orientations of NO and O₃ result in a reaction at kinetic energies greater than E_a , most collisions of NO and O₃ are unproductive. The fraction of orientations that result in a reaction is called the steric factor (p), and, in general, its value can range from 0 (no orientations of molecules result in reaction) to 1 (all orientations result in reaction).

Figure 14.7.4 The Effect of Molecular Orientation on the Reaction of NO and O₃ Most collisions of NO and O₃ molecules occur with an incorrect orientation for a reaction to occur. Only those collisions in which the N atom of NO collides with one of the terminal O atoms of O₃ are likely to produce NO₂ and O₂, even if the molecules collide with $E > E_a$.

The Arrhenius Equation

Figure 14.7.5 shows both the kinetic energy distributions and a potential energy diagram for a reaction. The shaded areas show that at the lower temperature (300 K), only a small fraction of molecules collide with kinetic energy greater than E_a ; however, at the higher temperature (500 K) a much larger fraction of molecules collide with kinetic energy greater than E_a . Consequently, the reaction rate is much slower at the lower temperature because only a relatively few molecules collide with enough energy to overcome the potential energy barrier.

Figure 14.7.5 Surmounting the Energy Barrier to a Reaction This chart juxtaposes the energy distributions of lower-temperature (300 K) and higher-temperature (500 K) samples of a gas against the potential energy diagram for a reaction. Only those molecules in the shaded region of the energy distribution curve have $E > E_a$ and are therefore able to cross the energy barrier separating reactants and products. The fraction of molecules with $E > E_a$ is much greater at 500 K than at 300 K, so the reaction will occur much more rapidly at 500 K.

For an A + B elementary reaction, all the factors that affect the reaction rate can be summarized in a single series of relationships:

$$\text{rate} = (\text{collision frequency})(\text{steric factor})(\text{fraction of collisions with } E > E_a)$$

where

$$\text{rate} = k [A] [B] \quad (14.7.2)$$

Arrhenius used these relationships to arrive at an equation that relates the magnitude of the rate constant for a reaction to the temperature, the activation energy, and the constant, A, called the frequency factor:

$$k = Ae^{-E_a/RT} \quad (14.7.3)$$

The frequency factor is used to convert concentrations to collisions per second. Because the frequency of collisions depends on the temperature, A is actually *not* constant. Instead, A increases slightly with temperature as the increased kinetic energy of molecules at higher temperatures causes them to move slightly faster and thus undergo more collisions per unit time. Equation 14.39 is known as the Arrhenius equation and summarizes the collision model of chemical kinetics, where T is the absolute temperature (in K) and R is the ideal gas constant [8.314 J/(K·mol)]. E_a indicates the sensitivity of the reaction to changes in temperature. The reaction rate with a large E_a increases rapidly with increasing temperature, whereas the reaction rate with a smaller E_a increases much more slowly with increasing temperature.

If we know the reaction rate at various temperatures, we can use the Arrhenius equation to calculate the activation energy. Taking the natural logarithm of both sides of Equation 14.7.3,

$$\ln k = \ln A - \frac{E_a}{RT} = \ln A + \left[\left(-\frac{E_a}{R} \right) \left(\frac{1}{T} \right) \right] \quad (14.7.4)$$

Equation 14.40 is the equation of a straight line, $y = mx + b$, where $y = \ln k$ and $x = 1/T$. This means that a plot of $\ln k$ versus $1/T$ is a straight line with a slope of $-E_a/R$ and an intercept of $\ln A$. In fact, we need to measure the reaction rate at only two temperatures to estimate E_a .

Knowing the E_a at one temperature allows us to predict the reaction rate at other temperatures. This is important in cooking and food preservation, for example, as well as in controlling industrial reactions to prevent potential disasters. The procedure for determining E_a from reaction rates measured at several temperatures is illustrated in Example 13.

Example 14.7.1

Many people believe that the rate of a tree cricket's chirping is related to temperature. To see whether this is true, biologists have carried out accurate measurements of the rate of tree cricket chirping (f) as a function of temperature (T). Use the data in the following table, along with the graph of $\ln[\text{chirping rate}]$ versus $1/T$ in Figure 14.7.6 to calculate E_a for the biochemical reaction that controls cricket chirping. Then predict the chirping rate on a very hot evening, when the temperature is 308 K (35°C, or 95°F).

Frequency (f ; chirps/min)	$\ln f$	T (K)	$1/T$ (K)
200	5.30	299	3.34×10^{-3}
179	5.19	298	3.36×10^{-3}
158	5.06	296	3.38×10^{-3}
141	4.95	294	3.40×10^{-3}
126	4.84	293	3.41×10^{-3}
112	4.72	292	3.42×10^{-3}
100	4.61	290	3.45×10^{-3}
89	4.49	289	3.46×10^{-3}
79	4.37	287	3.48×10^{-3}

Given: chirping rate at various temperatures

Asked for: activation energy and chirping rate at specified temperature

Strategy:

A From the plot of $\ln f$ versus $1/T$ in Figure 14.7.6, calculate the slope of the line ($-E_a/R$) and then solve for the activation energy.

B Express Equation 14.7.4 in terms of k_1 and T_1 and then in terms of k_2 and T_2 .

C Subtract the two equations; rearrange the result to describe k_2/k_1 in terms of T_2 and T_1 .

D Using measured data from the table, solve the equation to obtain the ratio k_2/k_1 . Using the value listed in the table for k_1 , solve for k_2 .

Solution:

A If cricket chirping is controlled by a reaction that obeys the Arrhenius equation, then a plot of $\ln f$ versus $1/T$ should give a straight line (Figure 14.7.6). Also, the slope of the plot of $\ln f$ versus $1/T$ should be equal to $-E_a/R$. We can use the two endpoints in Figure 14.7.6 to estimate the slope:

$$\text{slope} = \frac{\Delta \ln f}{\Delta (1/T)} = \frac{5.30 - 4.37}{3.34 \times 10^{-3} \text{ K}^{-1} - 3.48 \times 10^{-3} \text{ K}^{-1}}$$

A computer best-fit line through all the points has a slope of $-6.67 \times 10^3 \text{ K}$, so our estimate is very close. We now use it to solve for the activation energy:

$$E_a = \frac{0.93}{-0.041 \times 10^{-3} \text{ K}^{-1}} = 6.6 \times 10^3 \text{ K}$$

B If the activation energy of a reaction and the rate constant at one temperature are known, then we can calculate the reaction rate at any other temperature. We can use Equation 14.40 to express the known rate constant (k_1) at the first temperature (T_1) as follows:

$$\ln k_1 = \ln A - \frac{E_a}{RT_1}$$

Similarly, we can express the unknown rate constant (k_2) at the second temperature (T_2) as follows:

$$\ln k_2 = \ln A - \frac{E_a}{RT_2}$$

C These two equations contain four known quantities (E_a , T_1 , T_2 , and k_1) and two unknowns (A and k_2). We can eliminate A by subtracting the first equation from the second:

$$\ln k_2 - \ln k_1 = \left(\ln A - \frac{E_a}{RT_2} \right) - \left(\ln A - \frac{E_a}{RT_1} \right) = -\frac{E_a}{RT_2} + \frac{E_a}{RT_1}$$

Then

$$\ln \frac{k_2}{k_1} = -\frac{E_a}{R} \left(\frac{1}{T_1} - \frac{1}{T_2} \right)$$

D To obtain the best prediction of chirping rate at 308 K (T_2), we try to choose for T_1 and k_1 the measured rate constant and corresponding temperature in the data table that is closest to the best-fit line in the graph. Choosing data for $T_1 = 296 \text{ K}$, where $f = 158$, and using the E_a calculated previously,

$$\ln \frac{k_2}{k_1} = -\frac{E_a}{R} \left(\frac{1}{T_1} - \frac{1}{T_2} \right) = \frac{55 \text{ kJ/mol}}{8.314 \text{ J/(K} \cdot \text{mol)}} \left(\frac{1000 \text{ J}}{1 \text{ kJ}} \right) \left(\frac{1}{296 \text{ K}} - \frac{1}{308 \text{ K}} \right) = 0.87$$

Thus $k_{308}/k_{296} = 2.4$ and $k_{308} = (2.4)(158) = 380$, and the chirping rate on a night when the temperature is 308 K is predicted to be 380 chirps per minute.

Exercise

The equation for the decomposition of NO_2 to NO and O_2 is second order in NO_2 :

Data for the reaction rate as a function of temperature are listed in the following table. Calculate E_a for the reaction and the rate constant at 700 K.

T (K)	k ($\text{M}^{-1} \cdot \text{s}^{-1}$)
---------	---

T (K)	k ($M^{-1} \cdot s^{-1}$)
592	522
603	755
627	1700
652	4020
656	5030

Answer: $E_a = 114$ kJ/mol; $k_{700} = 18,600 M^{-1} \cdot s^{-1} = 1.86 \times 10^4 M^{-1} \cdot s^{-1}$.

What E_a results in a doubling of the reaction rate with a 10°C increase in temperature from 20° to 30°C ?

Answer: about 51 kJ/mol

Figure 14.7.6 Graphical Determination of E_a for Tree Cricket Chirping When the natural logarithm of the rate of tree cricket chirping is plotted versus $1/T$, a straight line results. The slope of the line suggests that the chirping rate is controlled by a single reaction with an E_a of 55 kJ/mol.

Summary

A minimum energy (**activation energy**, E_a) is required for a collision between molecules to result in a chemical reaction. Plots of potential energy for a system versus the reaction coordinate show an energy barrier that must be overcome for the reaction to occur. The arrangement of atoms at the highest point of this barrier is the **activated complex**, or **transition state**, of the reaction. At a given temperature, the higher the E_a , the slower the reaction. The fraction of orientations that result in a reaction is the **steric factor**. The **frequency factor**, steric factor, and activation energy are related to the rate constant in the **Arrhenius equation**: $k = A \exp(-E_a/RT)$. A plot of the natural logarithm of k versus $1/T$ is a straight line with a slope of $-E_a/R$.

Key Takeaway

- For a chemical reaction to occur, an energy threshold must be overcome, and the reacting species must also have the correct spatial orientation.

Key Equation

Arrhenius equation

$$k = Ae^{-E_a/RT} \quad (14.7.3)$$

Conceptual Problems

- Although an increase in temperature results in an increase in kinetic energy, this increase in kinetic energy is not sufficient to explain the relationship between temperature and reaction rates. How does the activation energy relate to the chemical kinetics of a reaction? Why does an increase in temperature increase the reaction rate despite the fact that the average kinetic energy is still less than the activation energy?
- For any given reaction, what is the relationship between the activation energy and each of the following?
 - electrostatic repulsions
 - bond formation in the activated complex
 - the nature of the activated complex
- If you are concerned with whether a reaction will occur rapidly, why would you be more interested in knowing the magnitude of the activation energy than the change in potential energy for the reaction?
- The product C in the reaction $A + B \rightarrow C + D$ can be separated easily from the reaction mixture. You have been given pure A and pure B and are told to determine the activation energy for this reaction to determine whether the reaction is suitable for the industrial synthesis of C. How would you do this? Why do you need to know the magnitude of the activation energy to make a decision about feasibility?
- Above E_a , molecules collide with enough energy to overcome the energy barrier for a reaction. Is it possible for a reaction to occur at a temperature less than that needed to reach E_a ? Explain your answer.
- What is the relationship between A , E_a , and T ? How does an increase in A affect the reaction rate?
- Of two highly exothermic reactions with different values of E_a , which would need to be monitored more carefully: the one with the smaller value or the one with the higher value? Why?

Numerical Problems

- What happens to the approximate rate of a reaction when the temperature of the reaction is increased from 20°C to 30°C? What happens to the reaction rate when the temperature is raised to 70°C? For a given reaction at room temperature (20°C), what is the shape of a plot of reaction rate versus temperature as the temperature is increased to 70°C?
- Acetaldehyde, used in silvering mirrors and some perfumes, undergoes a second-order decomposition between 700 and 840 K. From the data in the following table, would you say that acetaldehyde follows the general rule that each 10 K increase in temperature doubles the reaction rate?

T (K)	k ($M^{-1} \cdot s^{-1}$)
720	0.024
740	0.051
760	0.105
800	0.519

- Bromoethane reacts with hydroxide ion in water to produce ethanol. The activation energy for this reaction is 90 kJ/mol. If the reaction rate is 3.6×10^{-4} M/s at 25°C, what would the reaction rate be at the following temperatures?
 - 15°C
 - 30°C
 - 45°C

4. An enzyme-catalyzed reaction has an activation energy of 15 kcal/mol. How would the value of the rate constant differ between 20°C and 30°C? If the enzyme reduced the E_a from 25 kcal/mol to 15 kcal/mol, by what factor has the enzyme increased the reaction rate at each temperature?
5. The data in the following table are the rate constants as a function of temperature for the dimerization of 1,3-butadiene. What is the activation energy for this reaction?

T (K)	k ($M^{-1} \cdot min^{-1}$)
529	1.4
560	3.7
600	25
645	82

6. The reaction rate at 25°C is 1.0×10^{-4} M/s. Increasing the temperature to 75°C causes the reaction rate to increase to 7.0×10^{-4} M/s. Estimate E_a for this process. If E_a were 25 kJ/mol and the reaction rate at 25°C is 1.0×10^{-4} M/s, what would be the reaction rate at 75°C?

Answers

- The reaction rate will approximately double: 20°C to 30°C, the reaction rate increases by about $2^1 = 2$; 20°C to 70°C, the reaction rate increases by about $2^5 = 32$ -fold. A plot of reaction rate versus temperature will give an exponential increase: $rate \propto 2^{\Delta T/10}$.
-
- 1.0×10^{-5} M/s
 - 6.6×10^{-4} M/s
 - 3.5×10^{-4} M/s
-
- 100 kJ/mol

Learning Objective

- To understand how catalysts increase the reaction rate and the selectivity of chemical reactions.

Chapter 7 described catalysts as substances that increase the reaction rate of a chemical reaction without being consumed in the process. A catalyst, therefore, does not appear in the overall stoichiometry of the reaction it catalyzes, but it *must* appear in at least one of the elementary reactions in the mechanism for the catalyzed reaction. The catalyzed pathway has a lower E_a , but the *net* change in energy that results from the reaction (the difference between the energy of the reactants and the energy of the products) is *not* affected by the presence of a catalyst (Figure 14.8.1). Nevertheless, because of its lower E_a , the reaction rate of a catalyzed reaction is faster than the reaction rate of the uncatalyzed reaction at the same temperature. Because a catalyst decreases the height of the energy barrier, its presence increases the reaction rates of *both* the forward *and* the reverse reactions by the same amount. In this section, we will examine the three major classes of catalysts: heterogeneous catalysts, **homogeneous catalysts**, and **enzymes**.

Note the Pattern

A catalyst affects E_a , not ΔE .

Figure 14.8.1 Lowering the Activation Energy of a Reaction by a Catalyst This graph compares potential energy diagrams for a single-step reaction in the presence and absence of a catalyst. The only effect of the catalyst is to lower the activation energy of the reaction. The catalyst does not affect the energy of the reactants or products (and thus does not affect ΔE).

Heterogeneous Catalysis

In heterogeneous catalysis, the catalyst is in a different phase from the reactants. At least one of the reactants interacts with the solid surface in a physical process called *adsorption* in such a way that a chemical bond in the reactant becomes weak and then breaks. *Poisons* are substances that bind irreversibly to catalysts, preventing reactants from adsorbing and thus reducing or destroying the catalyst's efficiency.

An example of heterogeneous catalysis is the interaction of hydrogen gas with the surface of a metal, such as Ni, Pd, or Pt. As shown in part (a) in [Figure 14.8.2](#), the hydrogen–hydrogen bonds break and produce individual adsorbed hydrogen atoms on the surface of the metal. Because the adsorbed atoms can move around on the surface, two hydrogen atoms can collide and form a molecule of hydrogen gas that can then leave the surface in the reverse process, called *desorption*. Adsorbed H atoms on a metal surface are substantially more reactive than a hydrogen molecule. Because the relatively strong H–H bond (dissociation energy = 432 kJ/mol) has already been broken, the energy barrier for most reactions of H_2 is substantially lower on the catalyst surface.

Figure 14.8.2 Hydrogenation of Ethylene on a Heterogeneous Catalyst When a molecule of hydrogen adsorbs to the catalyst surface, the H–H bond breaks, and new M–H bonds are formed. The individual H atoms are more reactive than gaseous H_2 . When a molecule of ethylene interacts with the catalyst surface, it reacts with the H atoms in a stepwise process to eventually produce ethane, which is released.

[Figure 14.8.2](#) shows a process called *hydrogenation*, in which hydrogen atoms are added to the double bond of an alkene, such as ethylene, to give a product that contains C–C single bonds, in this case ethane. Hydrogenation is used in the food industry to convert vegetable oils, which consist of long chains of alkenes, to more commercially valuable solid derivatives that contain alkyl chains. Hydrogenation of some of the double bonds in polyunsaturated vegetable oils, for example, produces margarine, a product with a melting point, texture, and other physical properties similar to those of butter.

Several important examples of industrial heterogeneous catalytic reactions are in [Table 14.8.1](#). Although the mechanisms of these reactions are considerably more complex than the simple hydrogenation reaction described here, they all involve adsorption of the reactants onto a solid catalytic surface, chemical reaction of the adsorbed species (sometimes via a number of intermediate species), and finally desorption of the products from the surface.

Table 14.8.1 Some Commercially Important Reactions that Employ Heterogeneous Catalysts

Commercial Process	Catalyst	Initial Reaction	Final Commercial Product
contact process	V_2O_5 or Pt	$2SO_2 + O_2 \rightarrow 2SO_3$	H_2SO_4
Haber process	Fe, K_2O , Al_2O_3	$N_2 + 3H_2 \rightarrow 2NH_3$	NH_3
Ostwald process	Pt and Rh	$4NH_3 + 5O_2 \rightarrow 4NO + 6H_2O$	HNO_3
water–gas shift reaction	Fe, Cr_2O_3 , or Cu	$CO + H_2O \rightarrow CO_2 + H_2$	H_2 for NH_3 , CH_3OH , and other fuels
steam reforming	Ni	$CH_4 + H_2O \rightarrow CO + 3H_2$	H_2
methanol synthesis	ZnO and Cr_2O_3	$CO + 2H_2 \rightarrow CH_3OH$	CH_3OH
Sohio process	bismuth phosphomolybdate	$CH_2=CHCH_3 + NH_3 + 3/2O_2 \rightarrow CH_2=CHCN + 3H_2O$	$CH_2=CHCN$
catalytic hydrogenation	Ni, Pd, or Pt	$RCH=CHR' + H_2 \rightarrow RCH_2-CH_2R'$	partially hydrogenated oils for margarine, and so forth

Homogeneous Catalysis

In homogeneous catalysis, the catalyst is in the same phase as the reactant(s). The number of collisions between reactants and catalyst is at a maximum because the catalyst is uniformly dispersed throughout the reaction mixture. Many homogeneous catalysts in industry are transition metal compounds (Table 14.8.2), but recovering these expensive catalysts from solution has been a major challenge. As an added barrier to their widespread commercial use, many homogeneous catalysts can be used only at relatively low temperatures, and even then they tend to decompose slowly in solution. Despite these problems, a number of commercially viable processes have been developed in recent years. High-density polyethylene and polypropylene are produced by homogeneous catalysis.

Table 14.8.2 Some Commercially Important Reactions that Employ Homogeneous Catalysts

Commercial Process	Catalyst	Reactants	Final Product
Union Carbide	$[\text{Rh}(\text{CO})_2\text{I}_2]$	$\text{CO} + \text{CH}_3\text{OH}$	$\text{CH}_3\text{CO}_2\text{H}$
hydroperoxide process	Mo(VI) complexes	$\text{CH}_3\text{CH}=\text{CH}_2 + \text{R}-\text{O}-\text{O}-\text{H}$	
hydroformylation	Rh/ PR_3 complexes	$\text{RCH}=\text{CH}_2 + \text{CO} + \text{H}_2$	$\text{RCH}_2\text{CH}_2\text{CHO}$
adiponitrile process	Ni/ PR_3 complexes	$2\text{HCN} + \text{CH}_2=\text{CHCH}=\text{CH}_2$	NCCH ₂ CH ₂ CH ₂ CH ₂ CN used to synthesize nylon
olefin polymerization	$(\text{RC}_5\text{H}_5)_2\text{ZrCl}_2$	$\text{CH}_2=\text{CH}_2$	$-(\text{CH}_2\text{CH}_2-)_n$: high-density polyethylene

Enzymes

Enzymes, catalysts that occur naturally in living organisms, are almost all protein molecules with typical molecular masses of 20,000–100,000 amu. Some are homogeneous catalysts that react in aqueous solution within a cellular compartment of an organism. Others are heterogeneous catalysts embedded within the membranes that separate cells and cellular compartments from their surroundings. The reactant in an enzyme-catalyzed reaction is called a substrate.

Because enzymes can increase reaction rates by enormous factors (up to 10^{17} times the uncatalyzed rate) and tend to be very specific, typically producing only a single product in quantitative yield, they are the focus of active research. At the same time, enzymes are usually expensive to obtain, they often cease functioning at temperatures greater than 37°C, have limited stability in solution, and have such high specificity that they are confined to turning one particular set of reactants into one particular product. This means that separate processes using different enzymes must be developed for chemically similar reactions, which is time-consuming and expensive. Thus far, enzymes have found only limited industrial applications, although they are used as ingredients in laundry detergents, contact lens cleaners, and meat tenderizers. The enzymes in these applications tend to be *proteases*, which are able to cleave the amide bonds that hold amino acids together in proteins. Meat tenderizers, for example, contain a protease called papain, which is isolated from papaya juice. It cleaves some of the long, fibrous protein molecules that make inexpensive cuts of beef tough, producing a piece of meat that is more tender. Some insects, like the bombardier beetle, carry an enzyme capable of catalyzing the decomposition of hydrogen peroxide to water (Figure 14.8.3).

Figure 14.8.3 A Catalytic Defense Mechanism The scalding, foul-smelling spray emitted by this bombardier beetle is produced by the catalytic decomposition of H_2O_2 .

Enzyme inhibitors cause a decrease in the reaction rate of an enzyme-catalyzed reaction by binding to a specific portion of an enzyme and thus slowing or preventing a reaction from occurring. Irreversible inhibitors are therefore the equivalent of poisons in heterogeneous catalysis. One of the oldest and most widely used commercial enzyme inhibitors is aspirin, which selectively inhibits one of the enzymes involved in the synthesis of molecules that trigger inflammation. The design and synthesis of related molecules that are more effective, more selective, and less toxic than aspirin are important objectives of biomedical research.

Summary

Catalysts participate in a chemical reaction and increase its rate. They do not appear in the reaction's net equation and are not consumed during the reaction. Catalysts allow a reaction to proceed via a pathway that has a lower activation energy than the uncatalyzed reaction. In **heterogeneous catalysis**, catalysts provide a surface to which reactants bind in a process of adsorption. In **homogeneous catalysis**, catalysts are in the same phase as the reactants. **Enzymes** are biological catalysts that produce large increases in reaction rates and tend to be specific for certain reactants and products. The reactant in an enzyme-catalyzed reaction is called a **substrate**. **Enzyme inhibitors** cause a decrease in the reaction rate of an enzyme-catalyzed reaction.

Key Takeaway

- Catalysts allow a reaction to proceed via a pathway that has a lower activation energy.

Conceptual Problems

- What effect does a catalyst have on the activation energy of a reaction? What effect does it have on the frequency factor (A)? What effect does it have on the change in potential energy for the reaction?
- How is it possible to affect the product distribution of a reaction by using a catalyst?
- A heterogeneous catalyst works by interacting with a reactant in a process called *adsorption*. What occurs during this process? Explain how this can lower the activation energy.
- What effect does increasing the surface area of a heterogeneous catalyst have on a reaction? Does increasing the surface area affect the activation energy? Explain your answer.
- Identify the differences between a heterogeneous catalyst and a homogeneous catalyst in terms of the following.
 - ease of recovery
 - collision frequency
 - temperature sensitivity
 - cost
- An area of intensive chemical research involves the development of homogeneous catalysts, even though homogeneous catalysts generally have a number of operational difficulties. Propose one or two reasons why a homogeneous catalyst may be preferred.
- Consider the following reaction between cerium(IV) and thallium(I) ions:

$$2\text{Ce}^{4+} + \text{Tl}^+ \rightarrow 2\text{Ce}^{3+} + \text{Tl}^{2+}$$
 This reaction is slow, but Mn^{3+} catalyzes it, as shown in the following mechanism:

$$\text{Ce}^{4+} + \text{Mn}^{3+} \rightarrow \text{Ce}^{3+} + \text{Mn}^{4+}$$

$$\text{Ce}^{4+} + \text{Mn}^+ \rightarrow \text{Ce}^+ + \text{Mn}^{2+}$$

$$\text{Mn}^+ + \text{Tl}^+ \rightarrow \text{Tl}^{\frac{1}{2}+} + \text{Mn}^{\frac{1}{2}+}$$
 In what way does Mn^+ increase the reaction rate?
- The text identifies several factors that limit the industrial applications of enzymes. Still, there is keen interest in understanding how enzymes work for designing catalysts for industrial applications. Why?
- Most enzymes have an optimal pH range; however, care must be taken when determining pH effects on enzyme activity. A decrease in activity could be due to the effects of changes in pH on groups at the catalytic center or to the effects on groups located elsewhere in the enzyme. Both examples are observed in chymotrypsin, a digestive enzyme that is a protease that hydrolyzes polypeptide chains. Explain how a change in pH could affect the catalytic activity due to (a) effects at the catalytic center and (b) effects elsewhere in the enzyme. (*Hint*: remember that enzymes are composed of functional amino acids.)

Answers

- A catalyst lowers the activation energy of a reaction. Some catalysts can also orient the reactants and thereby increase the frequency factor. Catalysts have no effect on the change in potential energy for a reaction.
-

3. In adsorption, a reactant binds tightly to a surface. Because intermolecular interactions between the surface and the reactant weaken or break bonds in the reactant, its reactivity is increased, and the activation energy for a reaction is often decreased.
- 4.
5.
 - a. Heterogeneous catalysts are easier to recover.
 - b. Collision frequency is greater for homogeneous catalysts.
 - c. Homogeneous catalysts are often more sensitive to temperature.
 - d. Homogeneous catalysts are often more expensive.
- 6.
7. The Mn^{2+} ion donates two electrons to Ce^{4+} , one at a time, and then accepts two electrons from Tl^+ . Because Mn can exist in three oxidation states separated by one electron, it is able to couple one-electron and two-electron transfer reactions.
- 8.
- 9.

Numerical Problems

1. At some point during an enzymatic reaction, the concentration of the activated complex, called an enzyme–substrate complex (ES), and other intermediates involved in the reaction is nearly constant. When a single substrate is involved, the reaction can be represented by the following sequence of equations:

This can also be shown as follows:

Using molar concentrations and rate constants, write an expression for the rate of disappearance of the enzyme–substrate complex. Typically, enzyme concentrations are small, and substrate concentrations are high. If you were determining the rate law by varying the substrate concentrations under these conditions, what would be your apparent reaction order?

2. A particular reaction was found to proceed via the following mechanism:

$$\begin{aligned} A + B &\rightarrow C + D \\ 2C &\rightarrow E \\ E + A &\rightarrow 3B + F \end{aligned}$$

What is the overall reaction? Is this reaction catalytic, and if so, what species is the catalyst? Identify the intermediates.
3. A particular reaction has two accessible pathways (A and B), each of which favors conversion of X to a different product (Y and Z, respectively). Under uncatalyzed conditions pathway A is favored, but in the presence of a catalyst pathway B is favored. Pathway B is reversible, whereas pathway A is not. Which product is favored in the presence of a catalyst? without a catalyst? Draw a diagram illustrating what is occurring with and without the catalyst.
4. The kinetics of an enzyme-catalyzed reaction can be analyzed by plotting the reaction rate versus the substrate concentration. This type of analysis is referred to as a Michaelis–Menten treatment. At low substrate concentrations, the plot shows behavior characteristic of first-order kinetics, but at very high substrate concentrations, the behavior shows zeroth-order kinetics. Explain this phenomenon.

Answers

1. $\frac{\Delta(ES)}{\Delta t} = -(k_2 + k_{-1})[ES] + k_1[E][S] + k_{-2}[E][P] \approx 0$; zeroth order in substrate.
- 2.
3. In both cases, the product of pathway A is favored. All of the Z produced in the catalyzed reversible pathway B will eventually be converted to X as X is converted irreversibly to Y by pathway A.

$$Z \xrightleftharpoons{B} X \xrightarrow{A} Y$$
- 4.

APPLICATION PROBLEMS

Problems marked with a ♦ involve multiple concepts.

1. Atmospheric chemistry in the region below the clouds of Venus appears to be dominated by reactions of sulfur and carbon-containing compounds. Included in representative elementary reactions are the following:

For each elementary reaction, write an expression for the net rate of reaction in terms of the concentrations of reactants and products.

2. In acid, nitriles hydrolyze to produce a carboxylic acid and ammonium ion. For example, acetonitrile, a substance used to extract fatty acids from fish liver oils, is hydrolyzed to acetic acid via the following reaction:

Express the reaction rate in terms of changes in the concentrations of each reactant and each product with time.

3. ♦ Ozone production occurs at lower altitudes according to the elementary reaction $\text{O} + \text{O}_2 \rightarrow \text{O}_3$, with an estimated rate of ozone production of 4.86×10^{11} molecules·s⁻¹ worldwide. What is the overall reaction order? If the reaction rate of loss of O_3 due to absorption of UV light (Equation 7.6.3) is 0.89×10^{11} molecules·s⁻¹, and 0.06×10^{11} molecules·s⁻¹ of ozone is transported to other atmospheric regions, is ozone being produced faster than it is being destroyed? Measurements show that ozone concentrations are not increasing rapidly. What conclusion can you draw from these data?
4. ♦ The water in a fishery became polluted when toxic waste was dumped into its pond, causing the fish population to substantially decline. The percentage of fish that survived is recorded in the following table.

Day	1	2	3	4	5
% survival	79	55	38	31	19

What is the reaction order of live fish → dead fish? What is the rate constant? If the fish continue to die at this rate, how many fish will be alive after 10 days?

5. Until 200 yr ago, manufactured iron contained charcoal produced from freshly cut wood that was added during the smelting process. As a result of this practice, older samples of iron can be dated accurately using the carbon-14 method. An archaeologist found a cast iron specimen that she believed dated to the period between 480 and 221 BC in Hunan, China. Radiocarbon dating of the sample indicated a 24% reduction in carbon-14 content. Was the archaeologist correct?
6. ♦ Because of its short half-life, ³²P-labeled compounds must be shipped as quickly as possible so that they can be used as radioactive tags in biological studies. A 50 g sample that contained 0.60% ³²P by mass was shipped at 11 a.m. on Monday morning. The package was delivered to a chemist via an overnight delivery service such that it arrived the next day.
- What would be the mass of ³²P remaining in the sample if he received the package on Tuesday afternoon but was unable to use it until 9 a.m. on Wednesday?
 - What would be the mass of ³²P present in the sample if the shipper had not delivered the sample until Friday afternoon and then it sat on a loading dock until 9 a.m. on Monday morning?
 - The late shipment was used immediately on Monday morning, but the biological samples were not analyzed until Thursday at 5 p.m. What percentage of the sample still consists of ³²P?

7. ♦ Tritium (^3H) is a radioactive isotope that is commonly used to follow biochemical reactions.
- Using the data in [Table 14.5.1](#), calculate the radioactive decay constant (k) for tritium.
 - Use the value of k to determine the mass of tritium that is still present in a 5.00 g sample of NaB_3H_4 that is 17.57 yr old.
8. ♦ L-Aspartic acid is an amino acid found in fossil bone. It can convert to a geometrically different form (D-aspartic acid) at 20°C , with a half-life corresponding to the conversion of L \rightarrow D of 14,000–20,000 yr. If the temperature of an archaeological site is constant, then the extent of the conversion can be used to date fossils. In one such case, archaeologists dated the arrival of humans on the North American continent to be 20,000 yr ago, but the conversion of L-aspartic acid to D-aspartic acid in human fossils indicated that Paleo-Indians were living in California at least 48,000 yr ago. What would be the relative concentrations of the L- and D-forms that produced this result? Carbon-14 has a half-life of approximately 5730 yr. What percentage of the carbon-14 originally present would have been found in the bones?

The technique described is frequently used in conjunction with radiocarbon dating. In cases where the results from the two techniques are in gross disagreement, what information can you get by comparing the two results?

9. ♦ Peroxides are able to initiate the radical polymerization of alkenes. Polyethylene, for example, is a high-molecular-weight polymer used as a film in packaging, as kitchenware, and as tubing. It is produced by heating ethylene at high pressure in the presence of oxygen or peroxide. It is formed by the following radical process:

- Label the steps that correspond to initiation and propagation.
 - Show all available chain-terminating steps.
 - The polymerization of styrene ($\text{C}_6\text{H}_5\text{CH}=\text{CH}_2$) occurs by a similar process to produce polystyrene, which is used as a packaging material. Draw the structure of the polymer that results from five propagation cycles.
10. Lucite and Plexiglas are transparent polymers used as a glass substitute when a plastic material is preferred for safety. The compound used to synthesize Lucite and Plexiglas is methyl methacrylate, which is shown here. During the polymerization reaction, light produces a radical initiator from hydrogen peroxide ($\text{H}_2\text{O}_2 \rightarrow 2\text{HO} \cdot$). Show the mechanism for the polymerization, being sure to include the initiation and propagation steps.

11. ♦ At higher altitudes ozone is converted to O_2 by the reaction $\text{O} + \text{O}_3 \rightarrow 2\text{O}_2$, with a rate constant at 220 K of $6.8 \times 10^{-12} \text{ cm}^3 \cdot \text{molecule}^{-1} \cdot \text{s}^{-1}$.
- What is the overall reaction order?
 - What is E_a for this reaction if $A = 8 \times 10^{-11} \text{ cm}^3 \cdot \text{molecule}^{-1} \cdot \text{s}^{-1}$? If Cl is present, the rate constant at 220 K becomes $3.7 \times 10^{-11} \text{ cm}^3 \cdot \text{molecule}^{-1} \cdot \text{s}^{-1}$, with $A = 4.7 \times 10^{-11} \text{ cm}^3 \cdot \text{molecule}^{-1} \cdot \text{s}^{-1}$.
 - Calculate E_a for the depletion of ozone in the presence of Cl.
 - Show an energy-level diagram for these two processes, clearly labeling reactants, products, and activation energies.
 - If you were an environmental scientist using these data to explain the effects of Cl on ozone concentration, what would be your conclusions?
12. ♦ Nitric acid is produced commercially by the catalytic oxidation of ammonia by air over platinum gauze at approximately 900°C . The following reactions occur:

Why is platinum gauze rather than platinum wire used for the initial reaction? The reaction $4\text{NH}_3(g) + 3\text{O}_2(g) \rightarrow 2\text{N}_2(g) + 6\text{H}_2\text{O}(g)$ has $\Delta H^\circ = -316.6 \text{ kJ/mol}$. What would occur if the catalyst were not present? If the gas leaving the catalyst is not free of NH_3 , the following reaction takes place: $6\text{NO}(g) + 4\text{NH}_3(g) \rightarrow 5\text{N}_2(g) + 6\text{H}_2\text{O}(g)$. If this occurs, what will be the overall reaction?

13. Figure 14.8.2 illustrates the mechanism for the reduction of ethylene on a platinum surface to produce ethane. Industrially important silanes are synthesized using a related mechanism and are used to increase adhesion between layers of glass fiber and between layers of silicone rubber. Predict the products of the following reactions:

14. ♦ In catalysis, if a molecule forms strong bonds to the catalyst, then the catalyst may become poisoned. Experiments on various catalysts showed the following results:
- Fe, Ru, and Os form weak bonds with N_2 ; however, O_2 , alkynes, alkenes, CO, H_2 , and CO_2 interact more strongly.
 - CO_2 and H_2 form weak bonds with a Co or Ni surface.
 - Rh, Pd, Ir, and Pt form weak bonds with H_2 but do not bond with CO_2 .
 - Cu, Ag, and Au form weak bonds with CO and ethylene.
- Explain why Fe was chosen as a catalyst to convert nitrogen and hydrogen to ammonia. Why is Fe more suitable than Ru or Os?
 - Because alkenes generally interact more strongly with metal surfaces than does H_2 , what catalyst would you choose for hydrogenation of an alkene such as ethylene?
 - Although platinum is used in catalytic converters for automobile exhaust, it was not found to be a particularly effective catalyst for the reaction of H_2 with a mixture of carbon monoxide and carbon dioxide to produce methane. Why?
 - If you were interested in developing a catalyst to reversibly bind ethylene, which of the catalysts listed here would you choose?
15. Nonstoichiometric metal oxides can be effective catalysts for oxidation–reduction reactions. One such catalyst is Ni_{1-x}O , found to be effective for converting CO to CO_2 when oxygen is present. Why is it so effective?
16. The chemical reactions in an organism can be controlled by regulating the activity of certain enzymes. Efficient regulation results in an enzyme being active only when it is needed. For example, if a cell needed histidine, the nine enzymes needed to synthesize histidine would all be active. If the cell had adequate histidine, however, those enzymes would be inactive. The following diagram illustrates a situation in which three amino acids (D, F, H) are all synthesized from a common species, A. The numbers above the arrows refer to the enzymes that catalyze each step. Which enzymes would need to be regulated to produce D? F? H?

17. ♦ Because phosphorus-32 is incorporated into deoxyribonucleic acid (DNA), it can be used to detect DNA fragments. Consequently, it is used extensively in biological research, including the Human Genome Project, whose goal was to determine the complete sequence of human DNA. If you were to start with a 20 g sample of phosphorus that contained 10% ^{32}P by mass, converted it into DNA via several chemical steps that had an overall yield of 75% and took 25 days, and then incorporated it into bacteria and allowed them to grow for 5 more days, what mass of ^{32}P would be available for analysis at the end of this time?
18. The enzyme urease contains two atoms of nickel and catalyzes the hydrolysis of urea by the following reaction:
- $$\text{H}_2\text{NC(O)NH}_2 + \text{H}_2\text{O} \rightarrow 2\text{NH}_3 + \text{CO}_2$$
- Urease is one of the most powerful catalysts known. It lowers the activation energy for the hydrolysis of urea from 137 kJ/mol to only 37 kJ/mol. Calculate the ratio of the reaction rate of the catalyzed reaction to the reaction rate of the uncatalyzed reaction at 37°C . Assume that the frequency factor is the same for both reactions.
19. As noted in Section 14.8, the reaction rate for the hydrogenation of ethylene to give ethane can be increased by heterogeneous catalysts such as Pt or Ni:
- $$\text{H}_2(g) + \text{H}_2\text{C}=\text{CH}_2(g) \xrightarrow{\text{Pt, Ni}} \text{H}_3\text{C}-\text{CH}_3(g)$$
- The activation energy for the uncatalyzed reaction is large (188 kJ/mol), so the reaction is very slow at room temperature. In the presence of finely divided metallic Ni, the activation energy is only 84 kJ/mol. Calculate the ratio of the reaction rate of the catalyzed reaction to the reaction rate of the uncatalyzed reaction at 75°C .

ANSWERS

1. $\text{rate} = k_f[\text{SO}_2][\text{CO}] - k_r[\text{SO}][\text{CO}_2]$; $\text{rate} = k_f[\text{SO}][\text{CO}] - k_r[\text{S}][\text{CO}_2]$; $\text{rate} = k_f[\text{SO}][\text{SO}_2] - k_r[\text{S}][\text{SO}_3]$

- 2.
3. The reaction is second order: first order in O and first order in O₃. Ozone is being produced faster than it is being destroyed. If ozone concentrations are not increasing, then either some other reaction must be consuming some of the ozone produced in this reaction or the ozone-producing reaction does not operate at this rate continuously.
- 4.
5. Yes; the object is about 2300 yr old.
- 6.
7. a. $k = 0.0562 \text{ yr}^{-1}$
b. 0.487 g of ³H
- 8.
- 9.
- 10.
11. a. second order, first order in O and first order in O₃;
b. 17 kJ/mol;
c. 0.44 kJ/mol;
d.

e. Cl is a potent catalyst for ozone destruction because there is a large decrease in E_a when Cl is present.

- 12.
- 13.

- 14.
15. Ni_{1-x}O is a nonstoichiometric oxide that contains a fraction of Ni(I) sites. These can react with oxygen to form a Ni(III)-oxide site, which is reduced by CO to give Ni(I) and CO₂.
- 16.
17. 0.35 g of ³²P
- 18.
19. 4.1 × 10¹⁵

Learning Objective

- To understand what is meant by chemical equilibrium.

Chemical equilibrium is a dynamic process that consists of a forward reaction, in which reactants are converted to products, and a reverse reaction, in which products are converted to reactants. At equilibrium, the forward and reverse reactions proceed at equal rates. Consider, for example, a simple system that contains only one reactant and one product, the reversible dissociation of dinitrogen tetroxide (N_2O_4) to nitrogen dioxide (NO_2). You may recall from [Chapter 14](#) that NO_2 is responsible for the brown color we associate with smog. When a sealed tube containing solid N_2O_4 (mp = $-9.3^\circ C$; bp = $21.2^\circ C$) is heated from $-78.4^\circ C$ to $25^\circ C$, the red-brown color of NO_2 appears ([Figure 15.1.1](#)). The reaction can be followed visually because the product (NO_2) is colored, whereas the reactant (N_2O_4) is colorless:

The double arrow indicates that both the forward and reverse reactions are occurring simultaneously; it is read “is in equilibrium with.”

Figure 15.1.1 *The $N_2O_4(g) \rightleftharpoons 2NO_2(g)$ System at Different Temperatures* (left) At dry ice temperature ($-78.4^\circ C$), the system contains essentially pure solid N_2O_4 , which is colorless. (center) As the system is warmed above the melting point of N_2O_4 ($-9.3^\circ C$), the N_2O_4 melts and then evaporates, and some of the vapor dissociates to red-brown NO_2 . (right) Eventually the sample reaches room temperature, and a mixture of gaseous N_2O_4 and NO_2 is present. The composition of the mixture and hence the color do not change further with time: the system has reached equilibrium at the new temperature.

[Figure 15.1.2](#) shows how the composition of this system would vary as a function of time at a constant temperature. If the initial concentration of NO_2 were zero, then it increases as the concentration of N_2O_4 decreases. Eventually the composition of the system

stops changing with time, and chemical equilibrium is achieved. Conversely, if we start with a sample that contains no N_2O_4 but an initial NO_2 concentration twice the initial concentration of N_2O_4 in part (a) in [Figure 15.1.2](#), in accordance with the stoichiometry of the reaction, we reach exactly the same equilibrium composition, as shown in part (b) in [Figure 15.1.2](#). Thus equilibrium can be approached from *either direction* in a chemical reaction.

Figure 15.1.2 The Composition of $\text{N}_2\text{O}_4/\text{NO}_2$ Mixtures as a Function of Time at Room Temperature (a) Initially, this idealized system contains 0.0500 M gaseous N_2O_4 and no gaseous NO_2 . The concentration of N_2O_4 decreases with time as the concentration of NO_2 increases. (b) Initially, this system contains 0.1000 M NO_2 and no N_2O_4 . The concentration of NO_2 decreases with time as the concentration of N_2O_4 increases. In both cases, the final concentrations of the substances are the same: $[\text{N}_2\text{O}_4] = 0.0422 \text{ M}$ and $[\text{NO}_2] = 0.0156 \text{ M}$ at equilibrium.

[Figure 15.1.3](#) shows the forward and reverse reaction rates for a sample that initially contains pure NO_2 . Because the initial concentration of N_2O_4 is zero, the forward reaction rate (dissociation of N_2O_4) is initially zero as well. In contrast, the reverse reaction rate (dimerization of NO_2) is initially very high ($2.0 \times 10^6 \text{ M/s}$), but it decreases rapidly as the concentration of NO_2 decreases. (Recall from [Chapter 14](#) that the reaction rate of the dimerization reaction is expected to decrease rapidly because the reaction is second order in NO_2 : $\text{rate} = k_r[\text{NO}_2]^2$, where k_r is the rate constant for the reverse reaction shown in [Equation 15.1.1](#).) As the concentration of N_2O_4 increases, the rate of dissociation of N_2O_4 increases—but more slowly than the dimerization of NO_2 —because the reaction is only first order in N_2O_4 ($\text{rate} = k_f[\text{N}_2\text{O}_4]$, where k_f is the rate constant for the forward reaction in [Equation 15.1.1](#)). Eventually, the forward and reverse reaction rates become identical, $k_F = k_r$, and the system has reached chemical equilibrium. If the forward and reverse reactions occur at *different* rates, then the system is *not* at equilibrium.

Figure 15.1.3 The Forward and Reverse Reaction Rates as a Function of Time for the $\text{N}_2\text{O}_4(\text{g}) \rightleftharpoons 2\text{NO}_2(\text{g})$ System Shown in Part (b) in [Figure 15.1.2](#)

The rate of dimerization of NO_2 (reverse reaction) decreases rapidly with time, as expected for a second-order reaction. Because the initial concentration of N_2O_4 is zero, the rate of the dissociation reaction (forward reaction) at $t = 0$ is also zero. As the

dimerization reaction proceeds, the N_2O_4 concentration increases, and its rate of dissociation also increases. Eventually the rates of the two reactions are equal: chemical equilibrium has been reached, and the concentrations of N_2O_4 and NO_2 no longer change.

Note the Pattern

At equilibrium, the forward reaction rate is equal to the reverse reaction rate.

Example 15.1.1

The three reaction systems (1, 2, and 3) depicted in the accompanying illustration can all be described by the equation $A \rightleftharpoons 2B$ where the blue circles are A and the purple ovals are B. Each set of panels shows the changing composition of one of the three reaction mixtures as a function of time. Which system took the longest to reach chemical equilibrium?

Given: three reaction systems

Asked for: relative time to reach chemical equilibrium

Strategy:

Compare the concentrations of A and B at different times. The system whose composition takes the longest to stabilize took the longest to reach chemical equilibrium.

Solution:

In systems 1 and 3, the concentration of A decreases from t_0 through t_2 but is the same at both t_2 and t_3 . Thus systems 1 and 3 are at equilibrium by t_3 . In system 2, the concentrations of A and B are still changing between t_2 and t_3 , so system 2 may not yet have reached equilibrium by t_3 . Thus system 2 took the longest to reach chemical equilibrium.

Exercise

In the following illustration, A is represented by blue circles, B by purple squares, and C by orange ovals; the equation for the reaction is $A + B \rightleftharpoons C$. The sets of panels represent the compositions of three reaction mixtures as a function of time. Which, if any, of the systems shown has reached equilibrium?

Answer: system 2

Summary

Chemical equilibrium is a dynamic process consisting of forward and reverse reactions that proceed at equal rates. At equilibrium, the composition of the system no longer changes with time. The composition of an equilibrium mixture is independent of the direction from which equilibrium is approached.

Key Takeaway

- At equilibrium, the forward and reverse reactions of a system proceed at equal rates.

Conceptual Problems

1. What is meant when a reaction is described as “having reached equilibrium”? What does this statement mean regarding the forward and reverse reaction rates? What does this statement mean regarding the concentrations or amounts of the reactants and the products?
2. Is it correct to say that the reaction has “stopped” when it has reached equilibrium? Explain your answer and support it with a specific example.
3. Why is chemical equilibrium described as a dynamic process? Describe this process in the context of a saturated solution of NaCl in water. What is occurring on a microscopic level? What is happening on a macroscopic level?
4. Which of these systems exists in a state of chemical equilibrium?
 - a. oxygen and hemoglobin in the human circulatory system
 - b. iodine crystals in an open beaker
 - c. the combustion of wood
 - d. the amount of ^{14}C in a decomposing organism

Answer

- 1.
- 2.
3. Both forward and reverse reactions occur but at the same rate. Na^+ and Cl^- ions continuously leave the surface of an NaCl crystal to enter solution, while at the same time Na^+ and Cl^- ions in solution precipitate on the surface of the crystal.
- 4.

Learning Objectives

- To know the relationship between the equilibrium constant and the rate constants for the forward and reverse reactions.
- To write an equilibrium constant expression for any reaction.

Because an equilibrium state is achieved when the forward reaction rate equals the reverse reaction rate, under a given set of conditions there must be a relationship between the composition of the system at equilibrium and the kinetics of a reaction (represented by rate constants). We can show this relationship using the system described in [Equation 15.2.1](#), the decomposition of N_2O_4 to NO_2 . Both the forward and reverse reactions for this system consist of a single elementary reaction, so the reaction rates are as follows:

$$\text{forward rate} = k_f[N_2O_4] \quad (15.2.1)$$

and

$$\text{reverse rate} = k_r[NO_2]^2 \quad (15.2.2)$$

At equilibrium, the forward rate equals the reverse rate:

$$k_f[N_2O_4] = k_r[NO_2]^2 \quad (15.2.3)$$

so

$$\frac{k_f}{k_r} = \frac{[NO_2]^2}{[N_2O_4]} \quad (15.2.4)$$

The ratio of the rate constants gives us a new constant, the equilibrium constant (K) which is defined as follows:

$$K = \frac{k_f}{k_r} \quad (15.2.5)$$

Hence there is a fundamental relationship between chemical kinetics and chemical equilibrium: *under a given set of conditions, the composition of the equilibrium mixture is determined by the magnitudes of the rate constants for the forward and the reverse reactions.*

Note the Pattern

The equilibrium constant is equal to the rate constant for the *forward* reaction divided by the rate constant for the *reverse* reaction.

[Table 15.2.1](#) lists the initial and equilibrium concentrations from five different experiments using the reaction system described by [Equation 15.1.1](#). At equilibrium the magnitude of the quantity $[NO_2]^2/[N_2O_4]$ is essentially the same for all five experiments. In fact, no matter what the initial concentrations of NO_2 and N_2O_4 are, at equilibrium the quantity $[NO_2]^2/[N_2O_4]$ will *always* be 6.53

$\pm 0.03 \times 10^{-3}$ at 25°C, which corresponds to the ratio of the rate constants for the forward and reverse reactions. That is, at a given temperature, the equilibrium constant for a reaction always has the same value, even though the specific concentrations of the reactants and products vary depending on their initial concentrations.

Table 15.2.1 Initial and Equilibrium Concentrations for $NO_2 : N_2O_4$ Mixtures at 25°C

Experiment	Initial Concentrations		Concentrations at Equilibrium		$K = [NO_2]^2 / [N_2O_4]$
	$[N_2O_4]$ (M)	$[NO_2]$ (M)	$[N_2O_4]$ (M)	$[NO_2]$ (M)	
1	0.0500	0.0000	0.0417	0.0165	6.54×10^{-3}
2	0.0000	0.1000	0.0417	0.0165	6.54×10^{-3}
3	0.0750	0.0000	0.0647	0.0206	6.56×10^{-3}
4	0.0000	0.0750	0.0304	0.0141	6.54×10^{-3}
5	0.0250	0.0750	0.0532	0.0186	6.50×10^{-3}

Developing an Equilibrium Constant Expression

In 1864, the Norwegian chemists Cato Guldberg (1836–1902) and Peter Waage (1833–1900) carefully measured the compositions of many reaction systems at equilibrium. They discovered that for *any* reversible reaction of the general form

where A and B are reactants, C and D are products, and *a*, *b*, *c*, and *d* are the stoichiometric coefficients in the balanced chemical equation for the reaction, the ratio of the product of the equilibrium concentrations of the products (raised to their coefficients in the balanced chemical equation) to the product of the equilibrium concentrations of the reactants (raised to their coefficients in the balanced chemical equation) is always a constant under a given set of conditions. This relationship is known as the law of mass action $K = \frac{[C]^c [D]^d}{[A]^a [B]^b}$ and can be stated as follows:

$$K = \frac{[C]^c [D]^d}{[A]^a [B]^b} \quad (15.2.7)$$

where K is the equilibrium constant for the reaction. Equation 15.7 is called the equilibrium equation $aA + bB = cC + dD$ $K = \frac{[C]^c [D]^d}{[A]^a [B]^b}$, and the right side of Equation 15.2.7 is called the equilibrium constant expression. The relationship shown in Equation 15.2.7 is true for *any* pair of opposing reactions regardless of the mechanism of the reaction or the number of steps in the mechanism.

The equilibrium constant can vary over a wide range of values. The values of K shown in Table 15.2.2, for example, vary by 60 orders of magnitude. Because products are in the numerator of the equilibrium constant expression and reactants are in the denominator, values of K greater than 10^3 indicate a strong tendency for reactants to form products. In this case, chemists say that equilibrium lies to the right as written, favoring the formation of products. An example is the reaction between H_2 and Cl_2 to produce HCl, which has an equilibrium constant of 1.6×10^{33} at 300 K. Because H_2 is a good reductant and Cl_2 is a good oxidant, the reaction proceeds essentially to completion. In contrast, values of K less than 10^{-3} indicate that the ratio of products to reactants at equilibrium is very small. That is, reactants do not tend to form products readily, and the equilibrium lies to the left as written, favoring the formation of reactants.

Table 15.2.2 Equilibrium Constants for Selected Reactions*

Reaction	Temperature (K)	Equilibrium Constant (K)
$S_{(s)} + O_{2(g)} \rightleftharpoons SO_{2(g)}$	300	4.4×10^{53}
$2H_{2(g)} + O_{2(g)} \rightleftharpoons 2H_2O_{(g)}$	500	2.4×10^{47}
$H_{2(g)} + Cl_{2(g)} \rightleftharpoons 2HCl_{(g)}$	300	1.6×10^{33}

*Equilibrium constants vary with temperature. The K values shown are for systems at the indicated temperatures.

Reaction	Temperature (K)	Equilibrium Constant (K)
$H_{2(g)} + Br_{2(g)} \rightleftharpoons 2HBr_{(g)}$	300	4.1×10^{18}
$2NO_{(g)} + O_{2(g)} \rightleftharpoons 2NO_{2(g)}$	300	4.2×10^{13}
$3H_{2(g)} + N_{2(g)} \rightleftharpoons 2NH_{3(g)}$	300	2.7×10^8
$H_{2(g)} + D_{2(g)} \rightleftharpoons 2HD_{(g)}$	100	1.92
$H_{2(g)} + I_{2(g)} \rightleftharpoons 2HI_{(g)}$	300	2.9×10^{-1}
$I_{2(g)} \rightleftharpoons 2I_{(g)}$	800	4.6×10^{-7}
$Br_{2(g)} \rightleftharpoons 2Br_{(g)}$	1000	4.0×10^{-7}
$Cl_{2(g)} \rightleftharpoons 2Cl_{(g)}$	1000	1.8×10^{-9}
$F_{2(g)} \rightleftharpoons 2F_{(g)}$	500	7.4×10^{-13}

***Equilibrium constants vary with temperature. The K values shown are for systems at the indicated temperatures.**

You will also notice in [Table 15.2.2](#) that equilibrium constants have no units, even though [Equation 15.2.7](#) suggests that the units of concentration might not always cancel because the exponents may vary. In fact, equilibrium constants are calculated using “effective concentrations,” or *activities*, of reactants and products, which are the ratios of the measured concentrations to a standard state of 1 M. As shown in [Equation 15.2.8](#), the units of concentration cancel, which makes *K* unitless as well:

$$\frac{[A]_{measured}}{[A]_{standard\ state}} = \frac{\cancel{M}}{\cancel{M}} = \frac{\frac{mol}{L}}{\frac{mol}{L}} \quad (15.2.8)$$

Many reactions have equilibrium constants between 1000 and 0.001 ($10^3 \geq K \geq 10^{-3}$), neither very large nor very small. At equilibrium, these systems tend to contain significant amounts of both products and reactants, indicating that there is not a strong tendency to form either products from reactants or reactants from products. An example of this type of system is the reaction of gaseous hydrogen and deuterium, a component of high-stability fiber-optic light sources used in ocean studies, to form HD:

The equilibrium constant expression for this reaction is

$$K = \frac{[HD]^2}{[H_2][D_2]} \quad (\text{Chapter 15.2.1})$$

with *K* varying between 1.9 and 4 over a wide temperature range (100–1000 K). Thus an equilibrium mixture of H₂, D₂, and HD contains significant concentrations of both product and reactants.

[Figure 15.2.1](#) summarizes the relationship between the magnitude of *K* and the relative concentrations of reactants and products at equilibrium for a general reaction, written as reactants \rightleftharpoons products. Because there is a direct relationship between the kinetics of a reaction and the equilibrium concentrations of products and reactants ([Equation 15.2.8](#) and [Equation 15.2.7](#)), when $k_f \gg k_r$, *K* is a large number, and the concentration of products at equilibrium predominate. This corresponds to an essentially irreversible reaction. Conversely, when $k_f \ll k_r$, *K* is a very small number, and the reaction produces almost no products as written. Systems for which $k_f \approx k_r$ have significant concentrations of both reactants and products at equilibrium.

Figure 15.2.1 The Relationship between the Composition of the Mixture at Equilibrium and the Magnitude of the Equilibrium Constant The larger the K , the farther the reaction proceeds to the right before equilibrium is reached, and the greater the ratio of products to reactants at equilibrium.

Note the Pattern

A large value of the equilibrium constant K means that products predominate at equilibrium; a small value means that reactants predominate at equilibrium.

Example 15.2.1

Write the equilibrium constant expression for each reaction.

- $N_{2(g)} + 3H_{2(g)} \rightleftharpoons 2NH_{3(g)}$
- $CO_{(g)} + \frac{1}{2}O_{2(g)} \rightleftharpoons CO_{2(g)}$
- $2CO_{2(g)} \rightleftharpoons 2CO_{(g)} + O_{2(g)}$

Given: balanced chemical equations

Asked for: equilibrium constant expressions

Strategy:

Refer to [Equation 15.2.7](#). Place the arithmetic product of the concentrations of the products (raised to their stoichiometric coefficients) in the numerator and the product of the concentrations of the reactants (raised to their stoichiometric coefficients) in the denominator.

Solution:

- The only product is ammonia, which has a coefficient of 2. For the reactants, N_2 has a coefficient of 1 and H_2 has a coefficient of 3. The equilibrium constant expression is as follows:

$$\frac{[NH_3]^2}{[N_2][H_2]^3}$$

- The only product is carbon dioxide, which has a coefficient of 1. The reactants are CO , with a coefficient of 1, and O_2 , with a coefficient of $1/2$. Thus the equilibrium constant expression is as follows:

$$\frac{[CO_2]}{[CO][O_2]^{1/2}}$$

- This reaction is the reverse of the reaction in part b, with all coefficients multiplied by 2 to remove the fractional coefficient for O_2 . The equilibrium constant expression is therefore the inverse of the expression in part b, with all exponents multiplied by 2:

$$\frac{[CO]^2[O_2]}{[CO_2]^2}$$

Exercise

Write the equilibrium constant expression for each reaction.

- $N_2O_{(g)} \rightleftharpoons N_{2(g)} + \frac{1}{2}O_{2(g)}$
- $2C_8H_{18(g)} + 25O_{2(g)} \rightleftharpoons 16CO_{2(g)} + 18H_2O_{(g)}$
- $H_{2(g)} + I_{2(g)} \rightleftharpoons 2HI_{(g)}$

Answer:

- $K = \frac{[N_2][O_2]^{1/2}}{[N_2O]}$
- $K = \frac{[CO_2]^{16}[H_2O]^{18}}{[C_8H_{18}]^2[O_2]^{25}}$
- $K = \frac{[HI]^2}{[H_2][I_2]}$

Example 15.2.2

Predict which systems at equilibrium will (a) contain essentially only products, (b) contain essentially only reactants, and (c) contain appreciable amounts of both products and reactants.

- $H_{2(g)} + I_{2(g)} \rightleftharpoons 2HI_{(g)} \quad K_{(700K)} = 54$
- $2CO_{2(g)} \rightleftharpoons 2CO_{(g)} + O_{2(g)} \quad K_{(1200K)} = 3.1 \times 10^{-18}$
- $PCl_{5(g)} \rightleftharpoons PCl_{3(g)} + Cl_{2(g)} \quad K_{(613K)} = 97$
- $2O_{3(g)} \rightleftharpoons 3O_{2(g)} \quad K_{(298K)} = 5.9 \times 10^{55}$

Given: systems and values of K

Asked for: composition of systems at equilibrium

Strategy:

Use the value of the equilibrium constant to determine whether the equilibrium mixture will contain essentially only products, essentially only reactants, or significant amounts of both.

Solution:

- Only system 4 has $K \gg 10^3$, so at equilibrium it will consist of essentially only products.
- System 2 has $K \ll 10^{-3}$, so the reactants have little tendency to form products under the conditions specified; thus, at equilibrium the system will contain essentially only reactants.
- Both systems 1 and 3 have equilibrium constants in the range $10^3 \geq K \geq 10^{-3}$, indicating that the equilibrium mixtures will contain appreciable amounts of both products and reactants.

Exercise

Hydrogen and nitrogen react to form ammonia according to the following balanced chemical equation:

Values of the equilibrium constant at various temperatures were reported as $K_{25^\circ\text{C}} = 3.3 \times 10^8$, $K_{177^\circ\text{C}} = 2.6 \times 10^3$, and $K_{327^\circ\text{C}} = 4.1$.

- At which temperature would you expect to find the highest proportion of H_2 and N_2 in the equilibrium mixture?
- Assuming that the reaction rates are fast enough so that equilibrium is reached quickly, at what temperature would you design a commercial reactor to operate to maximize the yield of ammonia?

Answer:

1. 327°C, where K is smallest
2. 25°C

Variations in the Form of the Equilibrium Constant Expression

Because equilibrium can be approached from either direction in a chemical reaction, the equilibrium constant expression and thus the magnitude of the equilibrium constant depend on the form in which the chemical reaction is written. For example, if we write the reaction described in [Equation 15.7](#) in reverse, we obtain the following:

The corresponding equilibrium constant K' is as follows:

$$K' = \frac{[A]^a[B]^b}{[C]^c[D]^d} \quad (15.2.11)$$

This expression is the inverse of the expression for the original equilibrium constant, so $K' = 1/K$. That is, when we write a reaction in the reverse direction, the equilibrium constant expression is inverted. For instance, the equilibrium constant for the reaction $N_2O_4 \rightleftharpoons 2NO_2$ is as follows:

$$K = \frac{[NO_2]^2}{[N_2O_4]} \quad (15.2.12)$$

but for the opposite reaction, $2NO_2 \rightleftharpoons N_2O_4$ the equilibrium constant K' is given by the inverse expression:

$$K' = \frac{[N_2O_4]}{[NO_2]^2} \quad (15.2.13)$$

Consider another example, the formation of water: $2H_2(g) + O_2(g) \rightleftharpoons 2H_2O(g)$. Because H_2 is a good reductant and O_2 is a good oxidant, this reaction has a very large equilibrium constant ($K = 2.4 \times 10^{47}$ at 500 K). Consequently, the equilibrium constant for the reverse reaction, the decomposition of water to form O_2 and H_2 , is very small: $K' = 1/K = 1/(2.4 \times 10^{47}) = 4.2 \times 10^{-48}$. As suggested by the very small equilibrium constant, and fortunately for life as we know it, a substantial amount of energy is indeed needed to dissociate water into H_2 and O_2 .

Note the Pattern

The equilibrium constant for a reaction written in reverse is the *inverse* of the equilibrium constant for the reaction as written originally.

Writing an equation in different but chemically equivalent forms also causes both the equilibrium constant expression and the magnitude of the equilibrium constant to be different. For example, we could write the equation for the reaction

as

with the equilibrium constant K'' is as follows:

$$K'' = \frac{[N_2O_4]^{1/2}}{[NO_2]} \quad (15.2.14)$$

The values for K' ([Equation 15.2.13](#)) and K'' are related as follows:

$$K'' = (K')^{1/2} = \sqrt{K'} \quad (15.2.15)$$

In general, if all the coefficients in a balanced chemical equation are subsequently multiplied by n , then the new equilibrium constant is the original equilibrium constant raised to the n th power.

Example 15.2.3

At 745 K, K is 0.118 for the following reaction:

What is the equilibrium constant for each related reaction at 745 K?

- $2NH_{3(g)} \rightleftharpoons N_{2(g)} + 3H_{2(g)}$
- $\frac{1}{2}N_{2(g)} + \frac{3}{2}H_{2(g)} \rightleftharpoons NH_{3(g)}$

Given: balanced equilibrium equation, K at a given temperature, and equations of related reactions

Asked for: values of K for related reactions

Strategy:

Write the equilibrium constant expression for the given reaction and for each related reaction. From these expressions, calculate K for each reaction.

Solution:

The equilibrium constant expression for the given reaction of $N_2(g)$ with $H_2(g)$ to produce $NH_3(g)$ at 745 K is as follows:

$$K = \frac{[NH_3]^2}{[N_2][H_2]^3} = 0.118$$

- This reaction is the reverse of the one given, so its equilibrium constant expression is as follows:

$$K' = \frac{1}{K} = \frac{[N_2][H_2]^3}{[NH_3]^2} = \frac{1}{0.118} = 8.47$$

- In this reaction, the stoichiometric coefficients of the given reaction are divided by 2, so the equilibrium constant is calculated as follows:

$$K'' = \frac{[NH_3]}{[N_2]^{1/2}[H_2]^{3/2}} = K^{1/2} = \sqrt{K} = \sqrt{0.118} = 0.344$$

Exercise

At 527°C, the equilibrium constant for the reaction

is 7.9×10^4 . Calculate the equilibrium constant for the following reaction at the same temperature:

Answer: 3.6×10^{-3}

Equilibrium Constant Expressions for Systems that Contain Gases

For reactions that involve species in solution, the concentrations used in equilibrium calculations are usually expressed in moles/liter. For gases, however, the concentrations are usually expressed in terms of partial pressures rather than molarity, where the standard state is 1 atm of pressure. The symbol K_p is used to denote equilibrium constants calculated from partial pressures. For

the general reaction $aA + bB \rightleftharpoons cC + dD$ in which all the components are gases, we can write the equilibrium constant expression as the ratio of the partial pressures of the products and reactants (each raised to its coefficient in the chemical equation):

$$K_p = \frac{(P_C)^c (P_D)^d}{(P_A)^a (P_B)^b} \quad (15.2.16)$$

Thus K_p for the decomposition of N_2O_4 (Equation 15.1.1) is as follows:

$$K_p = \frac{(P_{NO_2})^2}{P_{N_2O_4}} \quad (15.2.17)$$

Like K , K_p is a unitless quantity because the quantity that is actually used to calculate it is an “effective pressure,” the ratio of the measured pressure to a standard state of 1 bar (approximately 1 atm), which produces a unitless quantity. The “effective pressure” is called the *fugacity*, just as activity is the effective concentration.

Because partial pressures are usually expressed in atmospheres or mmHg, the molar concentration of a gas and its partial pressure do not have the same numerical value. Consequently, the numerical values of K and K_p are usually different. They are, however, related by the ideal gas constant (R) and the temperature (T):

$$K_p = K(RT)^{\Delta n} \quad (15.2.18)$$

where K is the equilibrium constant expressed in units of concentration and Δn is the difference between the numbers of moles of gaseous products and gaseous reactants ($n_p - n_r$). The temperature is expressed as the absolute temperature in kelvins. According to Equation 15.19, $K_p = K$ only if the moles of gaseous products and gaseous reactants are the same (i.e., $\Delta n = 0$). For the decomposition of N_2O_4 , there are 2 mol of gaseous product and 1 mol of gaseous reactant, so $\Delta n = 1$. Thus, for this reaction, $K_p = K(RT) = KRT$.

Example 15.2.4

The equilibrium constant for the reaction of nitrogen and hydrogen to give ammonia is 0.118 at 745 K. The balanced equilibrium equation is as follows:

What is K_p for this reaction at the same temperature?

Given: equilibrium equation, equilibrium constant, and temperature

Asked for: K_p

Strategy:

Use the coefficients in the balanced chemical equation to calculate Δn . Then use Equation 15.19 to calculate K from K_p .

Solution:

This reaction has 2 mol of gaseous product and 4 mol of gaseous reactants, so $\Delta n = (2 - 4) = -2$. We know K , and $T = 745$ K. Thus, from Equation 15.2.15, we have the following:

$$K_p = K(RT)^{-2} = \frac{K}{(RT)^2} = \frac{0.118}{\{[0.08206(L \cdot atm)/(mol \cdot K)][745 K]\}^2} = 3.16 \times 10^{-5}$$

Because K_p is a unitless quantity, the answer is $K_p = 3.16 \times 10^{-5}$.

Exercise

Calculate K_p for the reaction

at 527°C, if $K = 7.9 \times 10^4$ at this temperature.

Answer: $K_p = 1.2 \times 10^5$

Homogeneous and Heterogeneous Equilibria

When the products and reactants of an equilibrium reaction form a single phase, whether gas or liquid, the system is a homogeneous equilibrium. In such situations, the concentrations of the reactants and products can vary over a wide range. In contrast, a system whose reactants, products, or both are in more than one phase is a heterogeneous equilibrium, such as the reaction of a gas with a solid or liquid.

Because the molar concentrations of pure liquids and solids normally do not vary greatly with temperature, their concentrations are treated as constants, which allows us to simplify equilibrium constant expressions that involve pure solids or liquids. The reference states for pure solids and liquids are those forms stable at 1 bar (approximately 1 atm), which are assigned an activity of 1. (Recall from [Chapter 11](#), for example, that the density of water, and thus its volume, changes by only a few percentage points between 0°C and 100°C.)

Consider the following reaction, which is used in the final firing of some types of pottery to produce brilliant metallic glazes:

The glaze is created when metal oxides are reduced to metals by the product, carbon monoxide. The equilibrium constant expression for this reaction is as follows:

$$K = \frac{[CO]^2}{[CO_2][C]} \quad (15.2.20)$$

Because graphite is a solid, however, its molar concentration, determined from its density and molar mass, is essentially constant and has the following value:

$$[C] = \frac{2.26 \text{ g/cm}^3}{12.01 \text{ g/mol}} \times 1000 \text{ cm}^3/\text{L} = 188 \text{ mol/L} = 188 \text{ M} \quad (15.2.21)$$

We can rearrange [Equation 15.2.17](#) so that the constant terms are on one side:

$$K[C] = K(188) = \frac{[CO]^2}{[CO_2]} \quad (15.2.22)$$

Incorporating the constant value of [C] into the equilibrium equation for the reaction in [Equation 15.2.16](#),

$$K' = \frac{[CO]^2}{[CO_2]} \quad (15.2.23)$$

The equilibrium constant for this reaction can also be written in terms of the partial pressures of the gases:

$$K_p = \frac{(P_{CO})^2}{P_{CO_2}} \quad (15.2.24)$$

Incorporating all the constant values into K' or K_p allows us to focus on the substances whose concentrations change during the reaction.

Although the concentrations of pure liquids or solids are not written explicitly in the equilibrium constant expression, these substances must be present in the reaction mixture for chemical equilibrium to occur. Whatever the concentrations of CO and CO₂, the system described in [Equation 15.2.16](#) will reach chemical equilibrium only if a stoichiometric amount of solid carbon or excess solid carbon has been added so that some is still present once the system has reached equilibrium. As shown in [Figure 15.2.2](#), it does not matter whether 1 g or 100 g of solid carbon is present; in either case, the composition of the gaseous components of the system will be the same at equilibrium.

Figure 15.2.2 Effect of the Amount of Solid Present on Equilibrium in a Heterogeneous Solid–Gas System In the system, the equilibrium composition of the gas phase at a given temperature, 1000 K in this case, is the same whether a small amount of solid carbon (left) or a large amount (right) is present.

Example 15.2.5

Write each expression for K , incorporating all constants, and K_p for the following equilibrium reactions.

- $\text{PCl}_3(\text{l}) + \text{Cl}_2(\text{g}) \rightleftharpoons \text{PCl}_5(\text{s})$
- $\text{Fe}_3\text{O}_4(\text{s}) + 4\text{H}_2(\text{g}) \rightleftharpoons 3\text{Fe}(\text{s}) + 4\text{H}_2\text{O}(\text{g})$

Given: balanced equilibrium equations

Asked for: expressions for K and K_p

Strategy:

Find K by writing each equilibrium constant expression as the ratio of the concentrations of the products and reactants, each raised to its coefficient in the chemical equation. Then express K_p as the ratio of the partial pressures of the products and reactants, each also raised to its coefficient in the chemical equation.

Solution:

- This reaction contains a pure solid (PCl_5) and a pure liquid (PCl_3). Their concentrations do not appear in the equilibrium constant expression because they do not change significantly. So

$$K = \frac{1}{[\text{Cl}_2]}$$

and

$$K_p = \frac{1}{P_{\text{Cl}_2}}$$

- This reaction contains two pure solids (Fe_3O_4 and Fe), which do not appear in the equilibrium constant expressions. The two gases do, however, appear in the expressions:

$$K = \frac{[\text{H}_2\text{O}]^4}{[\text{H}_2]^4}$$

Exercise

Write the expressions for K and K_p for the following reactions.

- $\text{CaCO}_3(\text{s}) \rightleftharpoons \text{CaO}(\text{s}) + \text{CO}_2(\text{g})$

Answer:

$$1. K = [CO_2]; \text{ and } K_p = P(CO_2)$$

$$2. K = \frac{[CO_2]^6 [H_2O]^6}{[O_2]^6} \text{ and } K_p = \frac{(P_{CO_2})^6 (P_{H_2O})^6}{(P_{O_2})^6}$$

For reactions carried out in solution, the concentration of the solvent is omitted from the equilibrium constant expression even when the solvent appears in the balanced chemical equation for the reaction. The concentration of the solvent is also typically much greater than the concentration of the reactants or products (recall that pure water is about 55.5 M, and pure ethanol is about 17 M). Consequently, the solvent concentration is essentially constant during chemical reactions, and the solvent is therefore treated as a pure liquid. The equilibrium constant expression for a reaction contains only those species whose concentrations could change significantly during the reaction.

Note the Pattern

The concentrations of pure solids, pure liquids, and solvents are omitted from equilibrium constant expressions because they do not change significantly during reactions when enough is present to reach equilibrium.

Equilibrium Constant Expressions for the Sums of Reactions

Chemists frequently need to know the equilibrium constant for a reaction that has not been previously studied. In such cases, the desired reaction can often be written as the sum of other reactions for which the equilibrium constants are known. The equilibrium constant for the unknown reaction can then be calculated from the tabulated values for the other reactions.

To illustrate this procedure, let's consider the reaction of N_2 with O_2 to give NO_2 . As we stated in [Section 15.1](#), this reaction is an important source of the NO_2 that gives urban smog its typical brown color. The reaction normally occurs in two distinct steps. In the first reaction (1), N_2 reacts with O_2 at the high temperatures inside an internal combustion engine to give NO . The released NO then reacts with additional O_2 to give NO_2 (2). The equilibrium constant for each reaction at 100°C is also given.

- $N_{2(g)} + O_{2(g)} \rightleftharpoons 2NO_{(g)} \quad K_1 = 2.0 \times 10^{-25}$
- $2NO_{(g)} + O_{2(g)} \rightleftharpoons 2NO_{2(g)} \quad K_2 = 6.4 \times 10^9$
- Summing reactions (1) and (2) gives the overall reaction of N_2 with O_2 :
- $N_{2(g)} + 2O_{2(g)} \rightleftharpoons 2NO_{2(g)} \quad K_3 = ?$

The equilibrium constant expressions for the reactions are as follows:

$$K_1 = \frac{[NO]^2}{[N_2][O_2]} \quad K_2 = \frac{[NO_2]^2}{[NO]^2[O_2]} \quad K_3 = \frac{[NO_2]^2}{[N_2][O_2]^2}$$

v

What is the relationship between K_1 , K_2 , and K_3 , all at 100°C ? The expression for K_1 has $[NO]^2$ in the numerator, the expression for K_2 has $[NO]^2$ in the denominator, and $[NO]^2$ does not appear in the expression for K_3 . Multiplying K_1 by K_2 and canceling the $[NO]^2$ terms,

$$K_1 K_2 = \frac{\cancel{[NO]^2}}{[N_2][O_2]} \times \frac{[NO_2]^2}{\cancel{[NO]^2}[O_2]} = \frac{[NO_2]^2}{[N_2][O_2]^2} = K_3$$

Thus the product of the equilibrium constant expressions for K_1 and K_2 is the same as the equilibrium constant expression for K_3 :

$$K_3 = K_1 K_2 = (2.0 \times 10^{-25})(6.4 \times 10^9) = 1.3 \times 10^{-15}$$

The equilibrium constant for a reaction that is the sum of two or more reactions is equal to the product of the equilibrium constants for the individual reactions. In contrast, recall that according to Hess's Law, ΔH for the sum of two or more reactions is the sum of the ΔH values for the individual reactions.

Note the Pattern

To determine K for a reaction that is the sum of two or more reactions, add the reactions but multiply the equilibrium constants.

Example 15.2.6

The following reactions occur at 1200°C:

Calculate the equilibrium constant for the following reaction at the same temperature.

Given: two balanced equilibrium equations, values of K , and an equilibrium equation for the overall reaction

Asked for: equilibrium constant for the overall reaction

Strategy:

Arrange the equations so that their sum produces the overall equation. If an equation had to be reversed, invert the value of K for that equation. Calculate K for the overall equation by multiplying the equilibrium constants for the individual equations.

Solution:

The key to solving this problem is to recognize that reaction 3 is the sum of reactions 1 and 2:

The values for K_1 and K_2 are given, so it is straightforward to calculate K_3 :

$$K_3 = K_1 K_2 = (9.17 \times 10^{-2})(3.3 \times 10^4) = 3.03 \times 10^3$$

Exercise

In the first of two steps in the industrial synthesis of sulfuric acid, elemental sulfur reacts with oxygen to produce sulfur dioxide. In the second step, sulfur dioxide reacts with additional oxygen to form sulfur trioxide. The reaction for each step is shown, as is the value of the corresponding equilibrium constant at 25°C. Calculate the equilibrium constant for the overall reaction at this same temperature.

Answer: $K_3 = 1.1 \times 10^{66}$

Summary

The ratio of the rate constants for the forward and reverse reactions at equilibrium is the **equilibrium constant (K)**, a unitless quantity. The composition of the equilibrium mixture is therefore determined by the magnitudes of the forward and reverse rate constants at equilibrium. Under a given set of conditions, a reaction will always have the same K . For a system at equilibrium, the **law of mass action** relates K to the ratio of the equilibrium concentrations of the products to the concentrations of the reactants raised to their respective powers to match the coefficients in the **equilibrium equation**. The ratio is called the **equilibrium constant expression**. When a reaction is written in the reverse direction, K and the equilibrium constant expression are inverted. For gases, the equilibrium constant expression can be written as the ratio of the partial pressures of the products to the partial pressures of the reactants, each raised to a power matching its coefficient in the chemical equation. An equilibrium constant calculated from partial pressures (K_p) is related to K by the ideal gas constant (R), the temperature (T), and the change in the number of moles of gas during the reaction. An equilibrium system that contains products and reactants in a single phase is a **homogeneous equilibrium**; a system whose reactants, products, or both are in more than one phase is a **heterogeneous equilibrium**. When a reaction can be expressed as the sum of two or more reactions, its equilibrium constant is equal to the product of the equilibrium constants for the individual reactions.

Key Takeaways

- The law of mass action describes a system at equilibrium in terms of the concentrations of the products and the reactants.
- For a system involving one or more gases, either the molar concentrations of the gases or their partial pressures can be used.

Key Equations

Definition of equilibrium constant in terms of forward and reverse rate constants

$$\text{Equation 15.2.5: } K = \frac{k_f}{k_r}$$

Equilibrium constant expression (law of mass action)

$$\text{Equation 15.2.7: } K = \frac{[C]^c [D]^d}{[A]^a [B]^b}$$

Equilibrium constant expression for reactions involving gases using partial pressures

$$\text{Equation 15.2.1617: } K_p = \frac{P_C^c P_D^d}{P_A^a P_B^b}$$

Relationship between K_p and K

$$\text{Equation 15.2.18: } K_p = K(RT)^{\Delta n}$$

Conceptual Problems

1. For an equilibrium reaction, what effect does reversing the reactants and products have on the value of the equilibrium constant?
2. Which of the following equilibria are homogeneous and which are heterogeneous?
 - a. $2HF_{(g)} \rightleftharpoons H_{2(g)} + F_{2(g)}$
 - b. $C_{(s)} + 2H_{2(g)} \rightleftharpoons CH_{4(g)}$
 - c. $H_2C=CH_{2(g)} + H_{2(g)} \rightleftharpoons C_2H_{6(g)}$

- d. $2Hg(l) + O_2(g) \rightleftharpoons 2HgO(s)$
3. Classify each equilibrium system as either homogeneous or heterogeneous.
- $NH_4CO_2NH_2(s) \rightleftharpoons 2NH_3(g) + CO_2(g)$
 - $C(s) + O_2(g) \rightleftharpoons CO_2(g)$
 - $2Mg(s) + O_2(g) \rightleftharpoons 2MgO(s)$
 - $AgCl(s) \rightleftharpoons Ag^+_{(aq)} + Cl^-_{(aq)}$
4. If an equilibrium reaction is endothermic, what happens to the equilibrium constant if the temperature of the reaction is increased? if the temperature is decreased?
5. Industrial production of NO by the reaction $2N_2(g) + O_2(g) \rightleftharpoons 2NO(g)$ is carried out at elevated temperatures to drive the reaction toward the formation of product. After sufficient product has formed, the reaction mixture is quickly cooled. Why?
6. How would you differentiate between a system that has reached chemical equilibrium and one that is reacting so slowly that changes in concentration are difficult to observe?
7. What is the relationship between the equilibrium constant, the concentration of each component of the system, and the rate constants for the forward and reverse reactions?
8. Write the equilibrium constant expressions for K and K_p for each reaction.
- $CO(g) + H_2O(g) \rightleftharpoons CO_2(g) + H_2(g)$
 - $PCl_3(g) + Cl_2(g) \rightleftharpoons PCl_5(g)$
 - $2O_3(g) \rightleftharpoons 3O_2(g)$
9. Write the equilibrium constant expressions for K and K_p as appropriate for each reaction.
- $2NO(g) + O_2(g) \rightleftharpoons 2NO_2(g)$
 - $\frac{1}{2}H_2(g) + I_2(g) \rightleftharpoons HI(g)$
 - cis-stilbene*_(soln) \rightleftharpoons *trans-stilbene*_(soln)
10. Why is it incorrect to state that pure liquids, pure solids, and solvents are not part of an equilibrium constant expression?
11. Write the equilibrium constant expressions for K and K_p for each equilibrium reaction.
- $2S(s) + 3O_2(g) \rightleftharpoons 2SO_3(g)$
 - $C(s) + CO_2(g) \rightleftharpoons 2CO(g)$
 - $2ZnS(s) + 3O_2(g) \rightleftharpoons 2ZnO(s) + 2SO_2(g)$
12. Write the equilibrium constant expressions for K and K_p for each equilibrium reaction.
- $2HgO(s) \rightleftharpoons 2Hg(l) + O_2(g)$
 - $H_2(g) + I_2(s) \rightleftharpoons 2HI(g)$
 - $NH_4CO_2NH_2(s) \rightleftharpoons 2NH_3(g) + CO_2(g)$
13. At room temperature, the equilibrium constant for the reaction $2A(g) \rightleftharpoons B(g)$ is 1. What does this indicate about the concentrations of A and B at equilibrium? Would you expect K and K_p to vary significantly from each other? If so, how would their difference be affected by temperature?
14. For a certain series of reactions, if $[OH^-][HCO_3^-]/[CO_3^{2-}] = K_1$ and $[OH^-][H_2CO_3]/[HCO_3^-] = K_2$, what is the equilibrium constant expression for the overall reaction? Write the overall equilibrium equation.
15. In the equation for an enzymatic reaction, ES represents the complex formed between the substrate S and the enzyme protein E. In the final step of the following oxidation reaction, the product P dissociates from the ESO_2 complex, which regenerates the active enzyme:

Give the overall reaction equation and show that $K = K_1 \times K_2 \times K_3$.

Answers

- The equilibrium constant for the reaction written in reverse: $K' = 1/K$.
-
- Each system is heterogeneous.
-
- Rapid cooling “quenches” the reaction mixture and prevents the system from reverting to the low-temperature equilibrium composition that favors the reactants.
-
- $K = \frac{[C]^c[D]^d}{[A]^a[B]^b}$
-
-

- $K = \frac{[NO_2]^2}{[NO]^2[O_2]} \quad K_p = \frac{(P_{N_2O})^2}{(P_{NO})^2(P_{O_2})}$
- $K = \frac{[HI]}{[H_2]^{1/2}[I_2]^{1/2}} \quad K_p = \frac{P_{HI}}{(P_{H_2})^{1/2}(P_{I_2})^{1/2}}$
- $K = \frac{[\text{trans-stilbene}]}{[\text{cis-stilbene}]}$

10.

11.

- $K = \frac{[SO_3]^2}{[O_2]^3} \quad K_p = \frac{(P_{SO_3})^2}{(P_{O_2})^3}$
- $K = \frac{[CO]^2}{[CO_2]} \quad K_p = \frac{(P_{CO})^2}{P_{CO_2}}$
- $K = \frac{[SO_2]^2}{[O_2]^3} \quad K_p = \frac{(P_{SO_2})^2}{(P_{O_2})^3}$

12.

13. At equilibrium,

$$[A] = \sqrt{B} \text{ and } \Delta n = -1 \text{ so } K_p = K(RT)^{\Delta n} = \frac{K}{RT}$$

the difference increases as T increases.

14.

15.

Numerical Problems

- Explain what each of the following values for K tells you about the relative concentrations of the reactants versus the products in a given equilibrium reaction: $K = 0.892$; $K = 3.25 \times 10^{-11}$; $K = 5.26 \times 10^3$. Are products or reactants favored at equilibrium?
- Write the equilibrium constant expression for each reaction. Are these equilibrium constant expressions equivalent? Explain.
 - $N_2O_{4(g)} \rightleftharpoons 2NO_{2(g)}$
 - $\frac{1}{2}N_2O_{4(g)} \rightleftharpoons NO_{2(g)}$
- Write the equilibrium constant expression for each reaction.
 - $\frac{1}{2}N_{2(g)} + \frac{3}{2}H_{2(g)} \rightleftharpoons NH_{3(g)}$
 - $\frac{1}{3}N_{2(g)} + H_{2(g)} \rightleftharpoons \frac{2}{3}NH_{3(g)}$

How are these two expressions mathematically related to the equilibrium constant expression for

- Write an equilibrium constant expression for each reaction.
 - $C_{(s)} + 2H_2O_{(g)} \rightleftharpoons CO_{2(g)} + 2H_{2(g)}$
 - $SbCl_{3(g)} + Cl_{2(g)} \rightleftharpoons SbCl_{5(g)}$
 - $2O_{3(g)} \rightleftharpoons 3O_{2(g)}$
- Give an equilibrium constant expression for each reaction.

- a. $2NO_{(g)} + O_{2(g)} \rightleftharpoons 2NO_{2(g)}$
 - b. $\frac{1}{2}H_{2(g)} + \frac{1}{2}I_{2(g)} \rightleftharpoons HI_{(g)}$
 - c. $CaCO_{3(s)} + 2HOCl_{(aq)} \rightleftharpoons Ca^{2+}_{(aq)} + 2OCl^{-}_{(aq)} + H_2O_{(l)} + CO_{2(g)}$
6. Calculate K and K_p for each reaction.
 - a. $2NOBr_{(g)} \rightleftharpoons 2NO_{(g)} + Br_{2(g)}$ at 727°C , the equilibrium concentration of NO is 1.29 M , Br_2 is 10.52 M , and $NOBr$ is 0.423 M .
 - b. $C_{(s)} + CO_{2(g)} \rightleftharpoons 2CO_{(g)}$: at 1200 K , a 2.00 L vessel at equilibrium has partial pressures of 93.5 atm CO_2 and 76.8 atm CO , and the vessel contains 3.55 g of carbon.
 7. Calculate K and K_p for each reaction.
 - a. $N_2O_{4(g)} \rightleftharpoons 2NO_{2(g)}$: at the equilibrium temperature of -40°C , a 0.150 M sample of N_2O_4 undergoes a decomposition of 0.456% .
 - b. $CO_{(g)} + 2H_{2(g)} \rightleftharpoons CH_3OH_{(g)}$: an equilibrium is reached at 227°C in a 15.5 L reaction vessel with a total pressure of $6.71 \times 10^{-3}\text{ atm}$. It is found to contain 37.8 g of hydrogen gas, 457.7 g of carbon monoxide, and 7193 g of methanol.
 8. Determine K and K_p (where applicable) for each reaction.
 - a. $2H_2S_{(g)} \rightleftharpoons 2H_{2(g)} + S_{2(g)}$: at 1065°C , an equilibrium mixture consists of $1.00 \times 10^{-3}\text{ M}$ H_2 , $1.20 \times 10^{-3}\text{ M}$ S_2 , and $3.32 \times 10^{-3}\text{ M}$ H_2S .
 - b. $Ba(OH)_{2(s)} \rightleftharpoons 2OH^{-}_{(aq)} + Ba^{2+}_{(aq)}$: at 25°C , a 250 mL beaker contains 0.330 mol of barium hydroxide in equilibrium with 0.0267 mol of barium ions and 0.0534 mol of hydroxide ions.
 9. Determine K and K_p for each reaction.
 - a. $2NOCl_{(g)} \rightleftharpoons 2NO_{(g)} + Cl_{2(g)}$: at 500 K , a 24.3 mM sample of $NOCl$ has decomposed, leaving an equilibrium mixture that contains 72.7% of the original amount of $NOCl$.
 - b. $Cl_{2(g)} + PCl_{3(g)} \rightleftharpoons PCl_{5(g)}$: at 250°C , a 500 mL reaction vessel contains 16.9 g of Cl_2 gas, 0.500 g of PCl_3 , and 10.2 g of PCl_5 at equilibrium.
 10. The equilibrium constant expression for a reaction is $[CO_2]^2/[SO_2]^2[O_2]$. What is the balanced chemical equation for the overall reaction if one of the reactants is $Na_2CO_3(s)$?
 11. The equilibrium constant expression for a reaction is $[NO][H_2O]^{3/2}/[NH_3][O_2]^{5/4}$. What is the balanced chemical equation for the overall reaction?
 12. Given $K = k_f/k_r$, what happens to the magnitude of the equilibrium constant if the reaction rate of the forward reaction is doubled? What happens if the reaction rate of the reverse reaction for the overall reaction is decreased by a factor of 3?
 13. The value of the equilibrium constant for

is 1.08×10^7 at 700°C . What is the value of the equilibrium constant for the following related reactions?

- a. $H_{2(g)} + 12S_{2(g)} \rightleftharpoons H_2S_{(g)}$
- b. $4H_{2(g)} + 2S_{2(g)} \rightleftharpoons 4H_2S_{(g)}$
- c. $H_2S_{(g)} \rightleftharpoons H_{2(g)} + 12S_{2(g)}$

Answers

1. $K = 0.892$: the concentrations of the products and the reactants are approximately equal at equilibrium so neither is favored; $K = 3.25 \times 10^7$: the ratio of the concentration of the products to the reactants at equilibrium is very large so the formation of products is favored; $K = 5.26 \times 10^{-8}$: the ratio of the concentration of the products to the reactants at equilibrium is very small so the formation of products is not favored.

2.

$$3. \quad a. \quad K' = \frac{[NH_3]}{[N_2]^{1/2}[H_2]^{3/2}}$$

$$b. \quad K'' = \frac{[NH_3]^{2/3}}{[N_2]^{1/3}[H_2]} \quad K = \frac{[NH_3]^2}{[N_2][H_2]^3} \quad K' = K^{1/2}, \text{ and } K'' = K^{1/3}$$

4.

$$5. \quad a. \quad K = \frac{[NO_2]^2}{[NO]^2[O_2]}$$

$$b. K = \frac{[HI]}{[H_2]^{1/2}[I_2]^{1/2}}$$

$$c. K = \frac{[Ca^{2+}][OCl^-]^2[PCO_2]}{[HOCl]^2}$$

6.

$$7. a. K = 1.25 \times 10^{-5} \quad K_p = 2.39 \times 10^{-4}$$

$$b. K = 9.43 \quad K_p = 5.60 \times 10^{-3}$$

8.

$$9. a. K = \frac{[Cl_2][NO]^2}{[NOCl]^2} = 4.59 \times 10^{-4} \quad K_p = 1.88 \times 10^{-2}$$

$$b. K = \frac{[PCl_5]}{[PCl_3][Cl_2]} = 28.3 \quad K_p = 0.658$$

10.

11. $NH_3 + \frac{5}{4}O_2 \rightleftharpoons NO + \frac{3}{2}H_2O$, which can also be written as follows:

12.

$$13. a. 3.29 \times 10^{14}$$

$$b. 1.17 \times 10^{-4}$$

$$c. 3.04 \times 10$$

Learning Objective

- To solve quantitative problems involving chemical equilibria.

There are two fundamental kinds of equilibrium problems: (1) those in which we are given the concentrations of the reactants and the products at equilibrium (or, more often, information that allows us to calculate these concentrations), and we are asked to calculate the equilibrium constant for the reaction; and (2) those in which we are given the equilibrium constant and the initial concentrations of reactants, and we are asked to calculate the concentration of one or more substances at equilibrium. In this section, we describe methods for solving both kinds of problems.

Calculating an Equilibrium Constant from Equilibrium Concentrations

We saw in the exercise in Example 6 in Section 15.2 that the equilibrium constant for the decomposition of $\text{CaCO}_3(\text{s})$ to $\text{CaO}(\text{s})$ and $\text{CO}_2(\text{g})$ is $K = [\text{CO}_2]$. At 800°C , the concentration of CO_2 in equilibrium with solid CaCO_3 and CaO is 2.5×10^{-3} M. Thus K at 800°C is 2.5×10^{-3} . (Remember that equilibrium constants are unitless.)

A more complex example of this type of problem is the conversion of *n*-butane, an additive used to increase the volatility of gasoline, to isobutane (2-methylpropane). This reaction can be written as follows:

and the equilibrium constant $K = [\text{isobutane}]/[n\text{-butane}]$. At equilibrium, a mixture of *n*-butane and isobutane at room temperature was found to contain 0.041 M isobutane and 0.016 M *n*-butane. Substituting these concentrations into the equilibrium constant expression,

$$K = \frac{\text{isobutane}}{n\text{-butane}} = \frac{0.041 \cancel{\text{M}}}{0.016 \cancel{\text{M}}} = 2.6 \quad (15.3.2)$$

Thus the equilibrium constant for the reaction as written is 2.6.

Example 15.3.1

The reaction between gaseous sulfur dioxide and oxygen is a key step in the industrial synthesis of sulfuric acid:

A mixture of SO_2 and O_2 was maintained at 800 K until the system reached equilibrium. The equilibrium mixture contained 5.0×10^{-2} M SO_3 , 3.5×10^{-3} M O_2 , and 3.0×10^{-3} M SO_2 . Calculate K and K_p at this temperature.

Given: balanced equilibrium equation and composition of equilibrium mixture

Asked for: equilibrium constant

Strategy:

Write the equilibrium constant expression for the reaction. Then substitute the appropriate equilibrium concentrations into this equation to obtain K .

Solution:

Substituting the appropriate equilibrium concentrations into the equilibrium constant expression,

$$K = \frac{[SO_3]^2}{[SO_2]^2 [O_2]} = \frac{(5.0 \times 10^{-2})^2}{(3.0 \times 10^{-3})^2 (3.5 \times 10^{-3})} = 7.9 \times 10^4$$

To solve for K_p , we use [Equation 15.2.17](#), where $\Delta n = 2 - 3 = -1$:

$$\begin{aligned} K_p &= K(RT)^{\Delta n} \\ &= 7.9 \times 10^4 \left[(0.08206 \text{ L} \cdot \text{atm/mol} \cdot \cancel{K}) (800 \cancel{K}) \right] \\ &= 1.2 \times 10^3 \end{aligned}$$

Exercise

Hydrogen gas and iodine react to form hydrogen iodide via the reaction

A mixture of H_2 and I_2 was maintained at 740 K until the system reached equilibrium. The equilibrium mixture contained 1.37×10^{-2} M HI, 6.47×10^{-3} M H_2 , and 5.94×10^{-4} M I_2 . Calculate K and K_p for this reaction.

Answer: $K = 48.8$; $K_p = 48.8$

Chemists are not often given the concentrations of all the substances, and they are not likely to measure the equilibrium concentrations of all the relevant substances for a particular system. In such cases, we can obtain the equilibrium concentrations from the initial concentrations of the reactants and the balanced chemical equation for the reaction, as long as the equilibrium concentration of one of the substances is known. Example 9 shows one way to do this.

Example 15.3.2

A 1.00 mol sample of NOCl was placed in a 2.00 L reactor and heated to 227°C until the system reached equilibrium. The contents of the reactor were then analyzed and found to contain 0.056 mol of Cl_2 . Calculate K at this temperature. The equation for the decomposition of NOCl to NO and Cl_2 is as follows:

Given: balanced equilibrium equation, amount of reactant, volume, and amount of one product at equilibrium

Asked for: K

Strategy:

A Write the equilibrium constant expression for the reaction. Construct a table showing the initial concentrations, the changes in concentrations, and the final concentrations (as initial concentrations plus changes in concentrations).

B Calculate all possible initial concentrations from the data given and insert them in the table.

C Use the coefficients in the balanced chemical equation to obtain the changes in concentration of all other substances in the reaction. Insert those concentration changes in the table.

D Obtain the final concentrations by summing the columns. Calculate the equilibrium constant for the reaction.

Solution:

A The first step in any such problem is to balance the chemical equation for the reaction (if it is not already balanced) and use it to derive the equilibrium constant expression. In this case, the equation is already balanced, and the equilibrium constant expression is as follows:

$$K = \frac{[NO_2]^2 [Cl_2]}{[NOCl]^2}$$

To obtain the concentrations of NOCl, NO, and Cl₂ at equilibrium, we construct a table showing what is known and what needs to be calculated. We begin by writing the balanced chemical equation at the top of the table, followed by three lines corresponding to the initial concentrations, the changes in concentrations required to get from the initial to the final state, and the final concentrations.

$2NOCl(g) \rightleftharpoons 2NO(g) + Cl_2$			
	[NOCl]	[NO]	[Cl ₂]
initial			
change			
final			

B Initially, the system contains 1.00 mol of NOCl in a 2.00 L container. Thus $[NOCl]_i = 1.00 \text{ mol}/2.00 \text{ L} = 0.500 \text{ M}$. The initial concentrations of NO and Cl₂ are 0 M because initially no products are present. Moreover, we are told that at equilibrium the system contains 0.056 mol of Cl₂ in a 2.00 L container, so $[Cl_2]_f = 0.056 \text{ mol}/2.00 \text{ L} = 0.028 \text{ M}$. We insert these values into the following table:

$2NOCl(g) \rightleftharpoons 2NO(g) + Cl_2$			
	[NOCl]	[NO]	[Cl ₂]
initial	0.500	0	0
change			
final			0.028

C We use the stoichiometric relationships given in the balanced chemical equation to find the change in the concentration of Cl₂, the substance for which initial and final concentrations are known:

$$\Delta[Cl_2] = [0.028 \text{ M (final)} - 0.00 \text{ M (initial)}] = +0.028 \text{ M}$$

According to the coefficients in the balanced chemical equation, 2 mol of NO are produced for every 1 mol of Cl₂, so the change in the NO concentration is as follows:

$$\Delta[NO] = \left(\frac{0.028 \cancel{\text{ mol } Cl_2}}{L} \right) \left(\frac{2 \text{ mol } NO}{1 \cancel{\text{ mol } Cl_2}} \right) = 0.056 \text{ M}$$

Similarly, 2 mol of NOCl are consumed for every 1 mol of Cl₂ produced, so the change in the NOCl concentration is as follows:

$$\Delta[NOCl] = \left(\frac{0.028 \cancel{\text{ mol } Cl_2}}{L} \right) \left(\frac{-2 \text{ mol } NO}{1 \cancel{\text{ mol } Cl_2}} \right) = -0.056 \text{ M}$$

We insert these values into our table:

$2\text{NOCl(g)} \rightleftharpoons 2\text{NO(g)} + \text{Cl}_2$			
	[NOCl]	[NO]	[Cl ₂]
initial	0.500	0	0
change	-0.056	+0.056	+0.028
final			0.028

D We sum the numbers in the [NOCl] and [NO] columns to obtain the final concentrations of NO and NOCl:

$$[\text{NO}]_f = 0.000 \text{ M} + 0.056 \text{ M} = 0.056 \text{ M}$$

$$[\text{NOCl}]_f = 0.500 \text{ M} + (-0.056 \text{ M}) = 0.444 \text{ M}$$

We can now complete the table:

$2\text{NOCl(g)} \rightleftharpoons 2\text{NO(g)} + \text{Cl}_2$			
	[NOCl]	[NO]	[Cl ₂]
initial	0.500	0	0
change	-0.056	+0.056	+0.028
final	0.444	0.056	0.028

We can now calculate the equilibrium constant for the reaction:

$$K = \frac{[\text{NO}_2]^2 [\text{Cl}_2]}{[\text{NOCl}]^2} = \frac{(0.056)^2 (0.028)}{0.444} = 4.5 \times 10^{-4}$$

Exercise

The German chemist Fritz Haber (1868–1934; Nobel Prize in Chemistry 1918) was able to synthesize ammonia (NH₃) by reacting 0.1248 M H₂ and 0.0416 M N₂ at about 500°C. At equilibrium, the mixture contained 0.00272 M NH₃. What is *K* for the reaction N₂ + 3 H₂ ⇌ 2NH₃ at this temperature? What is *K_p*?

Answer: *K* = 0.105; *K_p* = 2.61 × 10⁻⁵

The original laboratory apparatus designed by Fritz Haber and Robert Le Rossignol in 1908 for synthesizing ammonia from its elements. A metal catalyst bed, where ammonia was produced, is in the large cylinder at the left. The Haber-Bosch process used

for the industrial production of ammonia uses essentially the same process and components but on a much larger scale. Unfortunately, Haber's process enabled Germany to prolong World War I when German supplies of nitrogen compounds, which were used for explosives, had been exhausted in 1914.

Calculating Equilibrium Concentrations from the Equilibrium Constant

To describe how to calculate equilibrium concentrations from an equilibrium constant, we first consider a system that contains only a single product and a single reactant, the conversion of *n*-butane to isobutane (Equation 15.26), for which $K = 2.6$ at 25°C . If we begin with a 1.00 M sample of *n*-butane, we can determine the concentration of *n*-butane and isobutane at equilibrium by constructing a table showing what is known and what needs to be calculated, just as we did in Example 9.

<i>n</i>-butane(g) \rightleftharpoons isobutane(g)		
	[<i>n</i>-Butane]	[Isobutane]
initial		
change		
final		

The initial concentrations of the reactant and product are both known: $[\textit{n}\text{-butane}]_i = 1.00\text{ M}$ and $[\textit{isobutane}]_i = 0\text{ M}$. We need to calculate the equilibrium concentrations of both *n*-butane and isobutane. Because it is generally difficult to calculate final concentrations directly, we focus on the *change* in the concentrations of the substances between the initial and the final (equilibrium) conditions. If, for example, we define the change in the concentration of isobutane ($\Delta[\textit{isobutane}]$) as $+x$, then the change in the concentration of *n*-butane is $\Delta[\textit{n}\text{-butane}] = -x$. This is because the balanced chemical equation for the reaction tells us that 1 mol of *n*-butane is consumed for every 1 mol of isobutane produced. We can then express the final concentrations in terms of the initial concentrations and the changes they have undergone.

<i>n</i>-butane(g) \rightleftharpoons isobutane(g)		
	[<i>n</i>-Butane]	[Isobutane]
initial	1.00	0
change	$-x$	$+x$
final	$(1.00 - x)$	$(0 + x) = x$

Substituting the expressions for the final concentrations of *n*-butane and isobutane from the table into the equilibrium equation,

$$K = \frac{[\textit{isobutane}]}{[\textit{n}\text{-butane}]} = \frac{x}{1.00 - x} = 2.6$$

Rearranging and solving for x ,

$$\begin{aligned} x &= 2.6(1.00 - x) = 2.6 - 2.6x \\ x + 2.6x &= 2.6 \\ x &= 0.72 \end{aligned}$$

We obtain the final concentrations by substituting this x value into the expressions for the final concentrations of *n*-butane and isobutane listed in the table:

$$[\textit{n}\text{-butane}]_f = (1.00 - x)\text{ M} = (1.00 - 0.72)\text{ M} = 0.28\text{ M}$$

$$[\textit{isobutane}]_f = (0.00 + x)\text{ M} = (0.00 + 0.72)\text{ M} = 0.72\text{ M}$$

We can check the results by substituting them back into the equilibrium constant expression to see whether they give the same K that we used in the calculation:

$$K = \frac{[\textit{isobutane}]}{[\textit{n-butane}]} = \frac{0.72 \text{ M}}{0.28 \text{ M}} = 2.6$$

This is the same K we were given, so we can be confident of our results.

Example 10 illustrates a common type of equilibrium problem that you are likely to encounter.

Example 15.3.3

The *water-gas shift reaction* is important in several chemical processes, such as the production of H_2 for fuel cells. This reaction can be written as follows:

$K = 0.106$ at 700 K. If a mixture of gases that initially contains 0.0150 M H_2 and 0.0150 M CO_2 is allowed to equilibrate at 700 K, what are the final concentrations of all substances present?

Given: balanced equilibrium equation, K , and initial concentrations

Asked for: final concentrations

Strategy:

A Construct a table showing what is known and what needs to be calculated. Define x as the change in the concentration of one substance. Then use the reaction stoichiometry to express the changes in the concentrations of the other substances in terms of x . From the values in the table, calculate the final concentrations.

B Write the equilibrium equation for the reaction. Substitute appropriate values from the table to obtain x .

C Calculate the final concentrations of all species present. Check your answers by substituting these values into the equilibrium constant expression to obtain K .

Solution:

A The initial concentrations of the reactants are $[\text{H}_2]_i = [\text{CO}_2]_i = 0.0150 \text{ M}$. Just as before, we will focus on the *change* in the concentrations of the various substances between the initial and final states. If we define the change in the concentration of H_2O as x , then $\Delta[\text{H}_2\text{O}] = +x$. We can use the stoichiometry of the reaction to express the changes in the concentrations of the other substances in terms of x . For example, 1 mol of CO is produced for every 1 mol of H_2O , so the change in the CO concentration can be expressed as $\Delta[\text{CO}] = +x$. Similarly, for every 1 mol of H_2O produced, 1 mol each of H_2 and CO_2 are consumed, so the change in the concentration of the reactants is $\Delta[\text{H}_2] = \Delta[\text{CO}_2] = -x$. We enter the values in the following table and calculate the final concentrations.

$\text{H}_2(g) + \text{CO}_2(g) \rightleftharpoons \text{H}_2\text{O}(g) + \text{CO}(g)$				
	$[\text{H}_2]$	$[\text{CO}_2]$	$[\text{H}_2\text{O}]$	$[\text{CO}]$
initial	0.0150	0.0150	0	0
change	$-x$	$-x$	$+x$	$+x$
final	$(0.0150 - x)$	$(0.0150 - x)$	x	x

B We can now use the equilibrium equation and the given K to solve for x :

$$K = \frac{[\text{H}_2\text{O}][\text{CO}]}{[\text{H}_2][\text{CO}_2]} = \frac{(x)(x)}{(0.0150 - x)(0.0150 - x)} = \frac{x^2}{(0.0150 - x)^2} = 0.160$$

We could solve this equation with the quadratic formula, but it is far easier to solve for x by recognizing that the left side of the equation is a perfect square; that is,

$$\frac{x^2}{(0.0150 - x)^2} = \left(\frac{x}{0.0150 - x} \right)^2 = 0.106$$

(The quadratic formula is presented in Essential Skills 7 in [Section 15.7](#).) Taking the square root of the middle and right terms,

$$\frac{x^2}{(0.0150 - x)^2} = (0.106)^{1/2} = 0.326$$

$$x = (0.326)(0.0150) - 0.326x$$

$$1.326x = 0.00489$$

$$x = 0.00369 = 3.69 \times 10^{-3}$$

C The final concentrations of all species in the reaction mixture are as follows:

- $[H_2]_f = [H_2]_i + \Delta[H_2] = (0.0150 - 0.00369) M = 0.0113 M$
- $[CO_2]_f = [CO_2]_i + \Delta[CO_2] = (0.0150 - 0.00369) M = 0.0113 M$
- $[H_2O]_f = [H_2O]_i + \Delta[H_2O] = (0 + 0.00369) M = 0.00369 M$
- $[CO]_f = [CO]_i + \Delta[CO] = (0 + 0.00369) M = 0.00369 M$

We can check our work by inserting the calculated values back into the equilibrium constant expression:

$$K = \frac{[H_2O][CO]}{[H_2][CO_2]} = \frac{(0.00369)^2}{(0.0113)^2} = 0.107$$

To two significant figures, this K is the same as the value given in the problem, so our answer is confirmed.

Exercise

Hydrogen gas reacts with iodine vapor to give hydrogen iodide according to the following chemical equation:

$K = 54$ at 425°C . If $0.172 M H_2$ and I_2 are injected into a reactor and maintained at 425°C until the system equilibrates, what is the final concentration of each substance in the reaction mixture?

Answer: $[HI]_f = 0.270 M$; $[H_2]_f = [I_2]_f = 0.037 M$

In Example 10, the initial concentrations of the reactants were the same, which gave us an equation that was a perfect square and simplified our calculations. Often, however, the initial concentrations of the reactants are not the same, and/or one or more of the products may be present when the reaction starts. Under these conditions, there is usually no way to simplify the problem, and we must determine the equilibrium concentrations with other means. Such a case is described in Example 11.

Example 15.3.4

In the water–gas shift reaction shown in Example 10, a sample containing $0.632 M CO_2$ and $0.570 M H_2$ is allowed to equilibrate at $700 K$. At this temperature, $K = 0.106$. What is the composition of the reaction mixture at equilibrium?

Given: balanced equilibrium equation, concentrations of reactants, and K

Asked for: composition of reaction mixture at equilibrium

Strategy:

A Write the equilibrium equation. Construct a table showing the initial concentrations of all substances in the mixture. Complete the table showing the changes in the concentrations (x) and the final concentrations.

B Write the equilibrium constant expression for the reaction. Substitute the known K value and the final concentrations to solve for x .

C Calculate the final concentration of each substance in the reaction mixture. Check your answers by substituting these values into the equilibrium constant expression to obtain K .

Solution:

A $[CO_2]_i = 0.632\text{ M}$ and $[H_2]_i = 0.570\text{ M}$. Again, x is defined as the change in the concentration of H_2O : $\Delta[H_2O] = +x$. Because 1 mol of CO is produced for every 1 mol of H_2O , the change in the concentration of CO is the same as the change in the concentration of H_2O , so $\Delta[CO] = +x$. Similarly, because 1 mol each of H_2 and CO_2 are consumed for every 1 mol of H_2O produced, $\Delta[H_2] = \Delta[CO_2] = -x$. The final concentrations are the sums of the initial concentrations and the changes in concentrations at equilibrium.

$H_{2(g)} + CO_{2(g)} \rightleftharpoons H_2O_{(g)} + CO_{(g)}$ (Chapter 15.3.1)				
	$[H_2]$	$[CO_2]$	$[H_2O]$	$[CO]$
initial	0.570	0.632	0	0
change	$-x$	$-x$	$+x$	$+x$
final	$(0.570 - x)$	$(0.632 - x)$	x	x

B We can now use the equilibrium equation and the known K value to solve for x :

$$K = \frac{[H_2O][CO]}{[H_2][CO_2]} = \frac{x^2}{(0.570 - x)(0.632 - x)} = 0.106$$

In contrast to Example 10, however, there is no obvious way to simplify this expression. Thus we must expand the expression and multiply both sides by the denominator:

$$x^2 = 0.106(0.360 - 1.20x + x^2)$$

Collecting terms on one side of the equation,

$$0.894x^2 + 0.127x - 0.0382 = 0$$

This equation can be solved using the quadratic formula:

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a} = \frac{-0.127 \pm \sqrt{(0.127)^2 - 4(0.894)(-0.0382)}}{2(0.894)}$$

$$x = 0.148 \text{ and } -0.290$$

Only the answer with the positive value has any physical significance, so $\Delta[H_2O] = \Delta[CO] = +0.148\text{ M}$, and $\Delta[H_2] = \Delta[CO_2] = -0.148\text{ M}$.

C The final concentrations of all species in the reaction mixture are as follows:

- $[H_2]_f = [H_2]_i + \Delta[H_2] = 0.570\text{ M} - 0.148\text{ M} = 0.422\text{ M}$
- $[CO_2]_f = [CO_2]_i + \Delta[CO_2] = 0.632\text{ M} - 0.148\text{ M} = 0.484\text{ M}$
- $[H_2O]_f = [H_2O]_i + \Delta[H_2O] = 0\text{ M} + 0.148\text{ M} = 0.148\text{ M}$
- $[CO]_f = [CO]_i + \Delta[CO] = 0\text{ M} + 0.148\text{ M} = 0.148\text{ M}$

We can check our work by substituting these values into the equilibrium constant expression:

$$K = \frac{[H_2O][CO]}{[H_2][CO_2]} = \frac{(0.148)^2}{(0.422)(0.484)} = 0.107$$

Because K is essentially the same as the value given in the problem, our calculations are confirmed.

Exercise

The exercise in Example 8 showed the reaction of hydrogen and iodine vapor to form hydrogen iodide, for which $K = 54$ at 425°C . If a sample containing 0.200 M H_2 and 0.0450 M I_2 is allowed to equilibrate at 425°C , what is the final concentration of each substance in the reaction mixture?

Answer: $[\text{HI}]_f = 0.0882\text{ M}$; $[\text{H}_2]_f = 0.156\text{ M}$; $[\text{I}_2]_f = 9.2 \times 10^{-4}\text{ M}$

In many situations it is not necessary to solve a quadratic (or higher-order) equation. Most of these cases involve reactions for which the equilibrium constant is either very small ($K \leq 10^{-3}$) or very large ($K \geq 10^3$), which means that the change in the concentration (defined as x) is essentially negligible compared with the initial concentration of a substance. Knowing this simplifies the calculations dramatically, as illustrated in Example 12.

Example 15.3.5

Atmospheric nitrogen and oxygen react to form nitric oxide:

$K_p = 2.0 \times 10^{-31}$ at 25°C . What is the partial pressure of NO in equilibrium with N_2 and O_2 in the atmosphere (at 1 atm, $P\{\text{N}_2\} = 0.78\text{ atm}$ and $P\{\text{O}_2\} = 0.21\text{ atm}$)

Given: balanced equilibrium equation and values of K_p , $P\{\text{O}_2\}$ and $P\{\text{N}_2\}$

Asked for: partial pressure of NO

Strategy:

A Construct a table and enter the initial partial pressures, the changes in the partial pressures that occur during the course of the reaction, and the final partial pressures of all substances.

B Write the equilibrium equation for the reaction. Then substitute values from the table to solve for the change in concentration (x).

C Calculate the partial pressure of NO. Check your answer by substituting values into the equilibrium equation and solving for K .

Solution:

A Because we are given K_p and partial pressures are reported in atmospheres, we will use partial pressures. The initial partial pressure of O_2 is 0.21 atm and that of N_2 is 0.78 atm . If we define the change in the partial pressure of NO as $2x$, then the change in the partial pressure of O_2 and of N_2 is $-x$ because 1 mol each of N_2 and of O_2 is consumed for every 2 mol of NO produced. Each substance has a final partial pressure equal to the sum of the initial pressure and the change in that pressure at equilibrium.

$\text{N}_{2(g)} + \text{O}_{2(g)} \rightleftharpoons 2\text{NO}_{(g)}$ (Chapter 15.3.2)			
	$P\{\text{N}_2\}$	$P\{\text{O}_2\}$	$P\{\text{NO}\}$
initial P	0.78	0.21	0
change in P	$-x$	$-x$	$+2x$
final P	$(0.78 - x)$	$(0.21 - x)$	$2x$

B Substituting these values into the equation for the equilibrium constant,

$$K_p = \frac{(P_{NO})^2}{(P_{N_2})(P_{O_2})} = \frac{(2x)^2}{(0.78 - x)(0.21 - x)} = 2.0 \times 10^{-31}$$

In principle, we could multiply out the terms in the denominator, rearrange, and solve the resulting quadratic equation. In practice, it is far easier to recognize that an equilibrium constant of this magnitude means that the extent of the reaction will be very small; therefore, the x value will be negligible compared with the initial concentrations. If this assumption is correct, then to two significant figures, $(0.78 - x) = 0.78$ and $(0.21 - x) = 0.21$. Substituting these expressions into our original equation,

$$\frac{(2x)^2}{(0.78)(0.21)} = 2.0 \times 10^{-31}$$

$$\frac{4x^2}{0.16} = 2.0 \times 10^{-31}$$

$$x^2 = \frac{0.33 \times 10^{-31}}{4}$$

$$x = 9.1 \times 10^{-17}$$

C Substituting this value of x into our expressions for the final partial pressures of the substances,

- $P_{NO} = 2x \text{ atm} = 1.8 \times 10^{-16} \text{ atm}$
- $P_{N_2} = (0.78 - x) \text{ atm} = 0.78 \text{ atm}$
- $P_{O_2} = (0.21 - x) \text{ atm} = 0.21 \text{ atm}$

From these calculations, we see that our initial assumption regarding x was correct: given two significant figures, 2.0×10^{-16} is certainly negligible compared with 0.78 and 0.21. When can we make such an assumption? As a general rule, if x is less than about 5% of the total, or $10^{-3} > K > 10^{-3}$, then the assumption is justified. Otherwise, we must use the quadratic formula or some other approach. The results we have obtained agree with the general observation that toxic NO, an ingredient of smog, does not form from atmospheric concentrations of N_2 and O_2 to a substantial degree at 25°C. We can verify our results by substituting them into the original equilibrium equation:

$$K_p = \frac{(P_{NO})^2}{(P_{N_2})(P_{O_2})} = \frac{(1.8 \times 10^{-16})^2}{(0.78)(0.21)} = 2.0 \times 10^{-31}$$

The final K_p agrees with the value given at the beginning of this example.

Exercise

Under certain conditions, oxygen will react to form ozone, as shown in the following equation:

$K_p = 2.5 \times 10^{-59}$ at 25°C. What ozone partial pressure is in equilibrium with oxygen in the atmosphere $P(O_2) = 0.21 \text{ atm}$?

Answer: $4.8 \times 10^{-31} \text{ atm}$

Another type of problem that can be simplified by assuming that changes in concentration are negligible is one in which the equilibrium constant is very large ($K \geq 10^3$). A large equilibrium constant implies that the reactants are converted almost entirely to products, so we can assume that the reaction proceeds 100% to completion. When we solve this type of problem, we view the system as equilibrating from the *products* side of the reaction rather than the reactants side. This approach is illustrated in Example 13.

Example 15.3.6

The chemical equation for the reaction of hydrogen with ethylene (C_2H_4) to give ethane (C_2H_6) is as follows:

$K = 9.6 \times 10^{18}$ at 25°C. If a mixture of 0.200 M H_2 and 0.155 M C_2H_4 is maintained at 25°C in the presence of a powdered nickel catalyst, what is the equilibrium concentration of each substance in the mixture?

Given: balanced chemical equation, K , and initial concentrations of reactants

Asked for: equilibrium concentrations

Strategy:

A Construct a table showing initial concentrations, concentrations that would be present if the reaction were to go to completion, changes in concentrations, and final concentrations.

B Write the equilibrium constant expression for the reaction. Then substitute values from the table into the expression to solve for x (the change in concentration).

C Calculate the equilibrium concentrations. Check your answers by substituting these values into the equilibrium equation.

Solution:

A From the magnitude of the equilibrium constant, we see that the reaction goes essentially to completion. Because the initial concentration of ethylene (0.155 M) is less than the concentration of hydrogen (0.200 M), ethylene is the limiting reactant; that is, no more than 0.155 M ethane can be formed from 0.155 M ethylene. If the reaction were to go to completion, the concentration of ethane would be 0.155 M and the concentration of ethylene would be 0 M. Because the concentration of hydrogen is greater than what is needed for complete reaction, the concentration of unreacted hydrogen in the reaction mixture would be $0.200 \text{ M} - 0.155 \text{ M} = 0.045 \text{ M}$. The equilibrium constant for the forward reaction is very large, so the equilibrium constant for the reverse reaction must be very small. The problem then is identical to that in Example 12. If we define $-x$ as the change in the ethane concentration for the reverse reaction, then the change in the ethylene and hydrogen concentrations is $+x$. The final equilibrium concentrations are the sums of the concentrations for the forward and reverse reactions.

	$H_{2(g)} + C_2H_{4(g)} \xrightleftharpoons{Ni} C_2H_{6(g)}$ (Chapter 15.3.3)		
	$[H_2]$	$[C_2H_4]$	$[C_2H_6]$
initial	0.200	0.155	0
assuming 100% reaction	0.045	0	0.155
change	$+x$	$+x$	$-x$
final	$(0.045 + x)$	$(0 + x)$	$(0.155 - x)$

B Substituting values into the equilibrium constant expression,

$$K = \frac{[C_2H_6]}{[H_2][C_2H_4]} = \frac{0.155 - x}{(0.045 + x)x} = 9.6 \times 10^{18}$$

Once again, the magnitude of the equilibrium constant tells us that the equilibrium will lie far to the right as written, so the reverse reaction is negligible. Thus x is likely to be very small compared with either 0.155 M or 0.045 M, and the equation can be simplified [(0.045 + x) = 0.045 and (0.155 - x) = 0.155] as follows:

$$K = \frac{0.155}{0.045x} = 9.6 \times 10^{18}$$

$$x = 3.6 \times 10^{-19}$$

C The small x value indicates that our assumption concerning the reverse reaction is correct, and we can therefore calculate the final concentrations by evaluating the expressions from the last line of the table:

- $[C_2H_6]_f = (0.155 - x) \text{ M} = 0.155 \text{ M}$
- $[C_2H_4]_f = x \text{ M} = 3.6 \times 10^{-19} \text{ M}$
- $[H_2]_f = (0.045 + x) \text{ M} = 0.045 \text{ M}$

We can verify our calculations by substituting the final concentrations into the equilibrium constant expression:

$$K = \frac{[C_2H_6]}{[H_2][C_2H_4]} = \frac{0.155}{(0.045)(3.6 \times 10^{-19})} = 9.6 \times 10^{18}$$

This K value agrees with our initial value at the beginning of the example.

Exercise

Hydrogen reacts with chlorine gas to form hydrogen chloride:

$K_p = 4.0 \times 10^{31}$ at 47°C . If a mixture of $0.257 \text{ M } H_2$ and $0.392 \text{ M } Cl_2$ is allowed to equilibrate at 47°C , what is the equilibrium composition of the mixture?

Answer:

- $[H_2]_f = 4.8 \times 10^{-32} \text{ M}$
- $[Cl_2]_f = 0.135 \text{ M}$
- $[HCl]_f = 0.514 \text{ M}$

Summary

When an equilibrium constant is calculated from equilibrium concentrations, molar concentrations or partial pressures are substituted into the equilibrium constant expression for the reaction. Equilibrium constants can be used to calculate the equilibrium concentrations of reactants and products by using the quantities or concentrations of the reactants, the stoichiometry of the balanced chemical equation for the reaction, and a tabular format to obtain the final concentrations of all species at equilibrium.

Key Takeaway

- Various methods can be used to solve the two fundamental types of equilibrium problems: (1) those in which we calculate the concentrations of reactants and products at equilibrium and (2) those in which we use the equilibrium constant and the initial concentrations of reactants to determine the composition of the equilibrium mixture.

Conceptual Problems

1. Describe how to determine the magnitude of the equilibrium constant for a reaction when not all concentrations of the substances are known.
2. Calculations involving systems with very small or very large equilibrium constants can be dramatically simplified by making certain assumptions about the concentrations of products and reactants. What are these assumptions when K is (a) very large and (b) very small? Illustrate this technique using the system $A + 2B \rightleftharpoons C$ for which you are to calculate the concentration of the product at equilibrium starting with only A and B. Under what circumstances should simplifying assumptions not be used?

Numerical Problems

Please be sure you are familiar with the topics discussed in Essential Skills 7 (Section 15.7) before proceeding to the Numerical Problems.

- In the equilibrium reaction $A + B \rightleftharpoons C$, what happens to K if the concentrations of the reactants are doubled? tripled? Can the same be said about the equilibrium reaction $A \rightleftharpoons B + C$?
- The following table shows the reported values of the equilibrium $P\{O_2\}$ at three temperatures for the reaction $Ag_2O(s) \rightleftharpoons 2Ag(s) + 1/2 O_2(g)$ for which $\Delta H^\circ = 31 \text{ kJ/mol}$. Are these data consistent with what you would expect to occur? Why or why not?

T ($^\circ\text{C}$)	$P(O_2)$ mm Hg
150	182
184	143
191	126

- Given the equilibrium system $N_2O_4(g) \rightleftharpoons 2NO_2(g)$, what happens to K_p if the initial pressure of N_2O_4 is doubled? If K_p is 1.7×10^{-4} at 2300°C , and the system initially contains 100% N_2O_4 at a pressure of 2.6×10^{-2} atm, what is the equilibrium pressure of each component?
- At 430°C , 4.20 mol of HI in a 9.60 L reaction vessel reaches equilibrium according to the following equation: $H_2(g) + I_2(g) \rightleftharpoons 2HI(g)$ At equilibrium, $[H_2] = 0.047 \text{ M}$ and $[HI] = 0.345 \text{ M}$. What are K and K_p for this reaction?
- Methanol, a liquid used as an automobile fuel additive, is commercially produced from carbon monoxide and hydrogen at 300°C according to the following reaction: $CO(g) + 2H_2(g) \rightleftharpoons CH_3OH(g)$ and $K_p = 1.3 \times 10^{-4}$. If 56.0 g of CO is mixed with excess hydrogen in a 250 mL flask at this temperature, and the hydrogen pressure is continuously maintained at 100 atm, what would be the maximum percent yield of methanol? What pressure of hydrogen would be required to obtain a minimum yield of methanol of 95% under these conditions?
- Starting with pure A, if the total equilibrium pressure is 0.969 atm for the reaction $A(s) \rightleftharpoons 2B(g) + C(g)$, what is K_p ?
- The decomposition of ammonium carbamate to NH_3 and CO_2 at 40°C is written as $NH_4CO_2NH_2(s) \rightleftharpoons 2NH_3(g) + CO_2$ If the partial pressure of NH_3 at equilibrium is 0.242 atm, what is the equilibrium partial pressure of CO_2 ? What is the total gas pressure of the system? What is K_p ?
- At 375 K, K_p for the reaction $SO_2Cl_2(g) \rightleftharpoons SO_2(g) + Cl_2(g)$ is 2.4, with pressures expressed in atmospheres. At 303 K, K_p is 2.9×10^{-2} .
 - What is K for the reaction at each temperature?
 - If a sample at 375 K has 0.100 M Cl_2 and 0.200 M SO_2 at equilibrium, what is the concentration of SO_2Cl_2 ?
 - If the sample given in part b is cooled to 303 K, what is the pressure inside the bulb?
- For the gas-phase reaction $aA \rightleftharpoons bB$, show that $K_p = K(RT)^{\Delta n}$ assuming ideal gas behavior.
- For the gas-phase reaction $I_2 \rightleftharpoons 2I$, show that the total pressure is related to the equilibrium pressure by the following equation:

$$P_T = \sqrt{K_p P_{I_2}} + P_{I_2}$$

- Experimental data on the system $Br_2(l) \rightleftharpoons Br_2(aq)$ are given in the following table. Graph $[Br_2]$ versus moles of $Br_2(l)$ present; then write the equilibrium constant expression and determine K .

Grams Br_2 in 100 mL Water	$[Br_2]$ (M)
1.0	0.0626
2.5	0.156
3.0	0.188
4.0	0.219
4.5	0.219

- Data accumulated for the reaction $n\text{-butane}(g) \rightleftharpoons \text{isobutane}(g)$ at equilibrium are shown in the following table. What is the equilibrium constant for this conversion? If 1 mol of $n\text{-butane}$ is allowed to equilibrate under the same reaction conditions, what is the final number of moles of $n\text{-butane}$ and isobutane?

Moles <i>n</i> -butane	Moles Isobutane
0.5	1.25
1.0	2.5
1.50	3.75

13. Solid ammonium carbamate ($\text{NH}_4\text{CO}_2\text{NH}_2$) dissociates completely to ammonia and carbon dioxide when it vaporizes:

At 25°C, the total pressure of the gases in equilibrium with the solid is 0.116 atm. What is the equilibrium partial pressure of each gas? What is K_p ? If the concentration of CO_2 is doubled and then equilibrates to its initial equilibrium partial pressure +x atm, what change in the NH_3 concentration is necessary for the system to restore equilibrium? ₁₀

14. The equilibrium constant for the reaction $\text{COCl}_2(g) \rightleftharpoons \text{CO}(g) + \text{Cl}_2(g)$ is $K_p = 2.2 \times 10^{-10}$ at 100°C. If the initial concentration of COCl_2 is 3.05×10^{-3} M, what is the partial pressure of each gas at equilibrium at 100°C? What assumption can be made to simplify your calculations?
15. Aqueous dilution of IO_4^- results in the following reaction:

and $K = 3.5 \times 10^{-2}$. If you begin with 50 mL of a 0.896 M solution of IO_4^- that is diluted to 250 mL with water, how many moles of H_4IO_6^- are formed at equilibrium?

16. Iodine and bromine react to form IBr , which then sublimates. At 184.4°C, the overall reaction proceeds according to the following equation:

$K_p = 1.2 \times 10^2$. If you begin the reaction with 7.4 g of I_2 vapor and 6.3 g of Br_2 vapor in a 1.00 L container, what is the concentration of $\text{IBr}(g)$ at equilibrium? What is the partial pressure of each gas at equilibrium? What is the total pressure of the system?

17. For the reaction

$K = 1.8 \times 10^{-6}$. If you begin the reaction with 1.0 mol of N_2 , 2.0 mol of H_2 , and sufficient $\text{C}(s)$ in a 2.00 L container, what are the concentrations of N_2 and CH_3NH_2 at equilibrium? What happens to K if the concentration of H_2 is doubled?

Learning Objective

- To predict in which direction a reaction will proceed.

In [Section 15.3](#), we saw that knowing the magnitude of the equilibrium constant under a given set of conditions allows chemists to predict the extent of a reaction. Often, however, chemists must decide whether a system has reached equilibrium or if the composition of the mixture will continue to change with time. In this section, we describe how to quantitatively analyze the composition of a reaction mixture to make this determination.

The Reaction Quotient

To determine whether a system has reached equilibrium, chemists use a quantity called the reaction quotient (Q). The expression for the reaction quotient has precisely the same form as the equilibrium constant expression, except that Q may be derived from a set of values measured at *any* time during the reaction of *any* mixture of the reactants and the products, regardless of whether the system is at equilibrium. Therefore, for the following general reaction:

the reaction quotient is defined as follows:

$$Q = \frac{[C]^c [D]^d}{[A]^a [B]^b} \quad (15.4.1)$$

The reaction quotient Q_p analogous to K_p , can be written for any reaction that involves gases by using the partial pressures of the components.

To understand how information is obtained using a reaction quotient, consider the dissociation of dinitrogen tetroxide to nitrogen dioxide,

for which $K = 4.65 \times 10^{-3}$ at 298 K. We can write Q for this reaction as follows:

$$Q = \frac{[NO_2]^2}{[N_2O_4]} \quad (15.4.2)$$

The following table lists data from three experiments in which samples of the reaction mixture were obtained and analyzed at equivalent time intervals, and the corresponding values of Q were calculated for each. Each experiment begins with different proportions of product and reactant:

Experiment	$[NO_2]$ (M)	$[N_2O_4]$ (M)	$Q = \frac{[NO_2]^2}{[N_2O_4]}$
1	0	0.0400	$\frac{0^2}{0.0400} = 0$
2	0.0600	0	$\frac{(0.0600)^2}{0} = \text{undefined}$

Experiment	[NO ₂] (M)	[N ₂ O ₄] (M)	$Q = \frac{[\text{NO}_2]^2}{[\text{N}_2\text{O}_4]}$
3	0.0200	0.0600	$\frac{(0.0200)^2}{0.0600} = 6.67 \times 10^{-3}$

As these calculations demonstrate, Q can have any numerical value between 0 and infinity (undefined); that is, Q can be greater than, less than, or equal to K .

Comparing the magnitudes of Q and K enables us to determine whether a reaction mixture is already at equilibrium and, if it is not, predict how its composition will change with time to reach equilibrium (i.e., whether the reaction will proceed to the right or to the left as written). All you need to remember is that the composition of a system not at equilibrium will change in a way that makes Q approach K . If $Q = K$, for example, then the system is already at equilibrium, and no further change in the composition of the system will occur unless the conditions are changed. If $Q < K$, then the ratio of the concentrations of products to the concentrations of reactants is *less* than the ratio at equilibrium. Therefore, the reaction will proceed to the right as written, forming products at the expense of reactants. Conversely, if $Q > K$, then the ratio of the concentrations of products to the concentrations of reactants is *greater* than at equilibrium, so the reaction will proceed to the left as written, forming reactants at the expense of products. These points are illustrated graphically in Figure 15.4.1

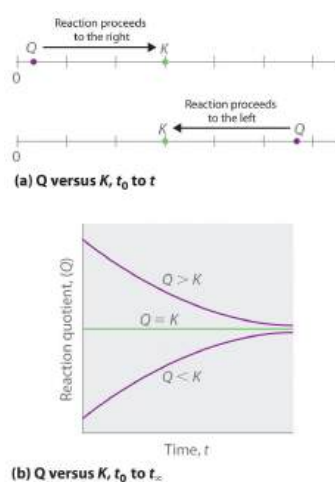

Figure 15.4.1 Two Different Ways of Illustrating How the Composition of a System Will Change Depending on the Relative Values of Q and K (a) Both Q and K are plotted as points along a number line: the system will always react in the way that causes Q to approach K . (b) The change in the composition of a system with time is illustrated for systems with initial values of $Q > K$, $Q < K$, and $Q = K$.

Note the Pattern

If $Q < K$, the reaction will proceed to the right as written. If $Q > K$, the reaction will proceed to the left as written. If $Q = K$, then the system is at equilibrium.

Example 15.4.1

At elevated temperatures, methane (CH₄) reacts with water to produce hydrogen and carbon monoxide in what is known as a *steam-reforming* reaction:

$K = 2.4 \times 10^{-7}$ at 900 K. Huge amounts of hydrogen are produced from natural gas in this way and are then used for the industrial synthesis of ammonia. If 1.2×10^{-2} mol of CH_4 , 8.0×10^{-3} mol of H_2O , 1.6×10^{-3} mol of CO , and 6.0×10^{-3} mol of H_2 are placed in a 2.0 L steel reactor and heated to 900 K, will the reaction be at equilibrium or will it proceed to the right to produce CO and H_2 or to the left to form CH_4 and H_2O ?

Given: balanced chemical equation, K , amounts of reactants and products, and volume

Asked for: direction of reaction

Strategy:

A Calculate the molar concentrations of the reactants and the products.

B Use Equation 15.4.1 to determine Q . Compare Q and K to determine in which direction the reaction will proceed.

Solution:

A We must first find the initial concentrations of the substances present. For example, we have 1.2×10^{-2} mol of CH_4 in a 2.0 L container, so

$$[\text{CH}_4] = \frac{1.2 \times 10^{-2} \text{ mol}}{2.0 \text{ L}} = 6.0 \times 10^{-3} \text{ M}$$

We can calculate the other concentrations in a similar way:

- $[\text{H}_2\text{O}] = 4.0 \times 10^{-3} \text{ M}$,
- $[\text{CO}] = 8.0 \times 10^{-3} \text{ M}$, and
- $[\text{H}_2] = 3.0 \times 10^{-3} \text{ M}$.

B We now compute Q and compare it with K :

$$Q = \frac{[\text{CO}][\text{H}_2]^3}{[\text{CH}_4][\text{H}_2\text{O}]} = \frac{(8.0 \times 10^{-3})(3.0 \times 10^{-3})^3}{(6.0 \times 10^{-3})(4.0 \times 10^{-3})} = 9.0 \times 10^{-6}$$

Because $K = 2.4 \times 10^{-7}$, we see that $Q < K$. Thus the ratio of the concentrations of products to the concentrations of reactants is less than the ratio for an equilibrium mixture. The reaction will therefore proceed to the right as written, forming H_2 and CO at the expense of H_2O and CH_4 .

Exercise

In the water–gas shift reaction introduced in Example 10, carbon monoxide produced by steam-reforming reaction of methane reacts with steam at elevated temperatures to produce more hydrogen:

$K = 0.64$ at 900 K. If 0.010 mol of both CO and H_2O , 0.0080 mol of CO_2 , and 0.012 mol of H_2 are injected into a 4.0 L reactor and heated to 900 K, will the reaction proceed to the left or to the right as written?

Answer: $Q = 0.96$ ($Q > K$), so the reaction will proceed to the left, and CO and H_2O will form.

Predicting the Direction of a Reaction with a Graph

By graphing a few equilibrium concentrations for a system at a given temperature and pressure, we can readily see the range of reactant and product concentrations that correspond to equilibrium conditions, for which $Q = K$. Such a graph allows us to predict what will happen to a reaction when conditions change so that Q no longer equals K , such as when a reactant concentration or a product concentration is increased or decreased.

Lead carbonate decomposes to lead oxide and carbon dioxide according to the following equation:

Because PbCO_3 and PbO are solids, the equilibrium constant is simply $K = [\text{CO}_2]$. At a given temperature, therefore, any system that contains solid PbCO_3 and solid PbO will have exactly the same concentration of CO_2 at equilibrium, regardless of the ratio or the amounts of the solids present. This situation is represented in [Figure 15.4.2](#), which shows a plot of $[\text{CO}_2]$ versus the amount of PbCO_3 added. Initially, the added PbCO_3 decomposes completely to CO_2 because the amount of PbCO_3 is not sufficient to give a CO_2 concentration equal to K . Thus the left portion of the graph represents a system that is *not* at equilibrium because it contains only $\text{CO}_2(\text{g})$ and $\text{PbO}(\text{s})$. In contrast, when just enough PbCO_3 has been added to give $[\text{CO}_2] = K$, the system has reached equilibrium, and adding more PbCO_3 has no effect on the CO_2 concentration: the graph is a horizontal line. Thus any CO_2 concentration that is not on the horizontal line represents a nonequilibrium state, and the system will adjust its composition to achieve equilibrium, provided enough PbCO_3 and PbO are present. For example, the point labeled *A* in [Figure 15.4.2](#) lies above the horizontal line, so it corresponds to a $[\text{CO}_2]$ that is greater than the equilibrium concentration of CO_2 ($Q > K$). To reach equilibrium, the system must decrease $[\text{CO}_2]$, which it can do only by reacting CO_2 with solid PbO to form solid PbCO_3 . Thus the reaction in [Equation 15.4.3](#) will proceed to the left as written, until $[\text{CO}_2] = K$. Conversely, the point labeled *B* in [Figure 15.4.2](#) lies below the horizontal line, so it corresponds to a $[\text{CO}_2]$ that is less than the equilibrium concentration of CO_2 ($Q < K$). To reach equilibrium, the system must increase $[\text{CO}_2]$, which it can do only by decomposing solid PbCO_3 to form CO_2 and solid PbO . The reaction in [Equation 15.4.2](#) will therefore proceed to the right as written, until $[\text{CO}_2] = K$.

Figure 15.4.2 The Concentration of Gaseous CO_2 in a Closed System at Equilibrium as a Function of the Amount of Solid PbCO_3 Added Initially the concentration of $\text{CO}_2(\text{g})$ increases linearly with the amount of solid PbCO_3 added, as PbCO_3 decomposes to $\text{CO}_2(\text{g})$ and solid PbO . Once the CO_2 concentration reaches the value that corresponds to the equilibrium concentration, however, adding more solid PbCO_3 has no effect on $[\text{CO}_2]$, as long as the temperature remains constant.

In contrast, the reduction of cadmium oxide by hydrogen gives metallic cadmium and water vapor:

and the equilibrium constant K is $[\text{H}_2\text{O}]/[\text{H}_2]$. If $[\text{H}_2\text{O}]$ is doubled at equilibrium, then $[\text{H}_2]$ must also be doubled for the system to remain at equilibrium. A plot of $[\text{H}_2\text{O}]$ versus $[\text{H}_2]$ at equilibrium is a straight line with a slope of K ([Figure 15.4.3](#)). Again, only those pairs of concentrations of H_2O and H_2 that lie on the line correspond to equilibrium states. Any point representing a pair of concentrations that does not lie on the line corresponds to a nonequilibrium state. In such cases, the reaction in [Equation 15.4.4](#) will proceed in whichever direction causes the composition of the system to move toward the equilibrium line. For example, point *A* in [Figure 15.4.3](#) lies below the line, indicating that the $[\text{H}_2\text{O}]/[\text{H}_2]$ ratio is less than the ratio of an equilibrium mixture ($Q < K$). Thus the reaction in [Equation 15.4.3](#) will proceed to the right as written, consuming H_2 and producing H_2O , which causes the concentration ratio to move up and to the left toward the equilibrium line. Conversely, point *B* in [Figure 15.4.3](#) lies above the line, indicating that the $[\text{H}_2\text{O}]/[\text{H}_2]$ ratio is greater than the ratio of an equilibrium mixture ($Q > K$). Thus the reaction in [Equation 15.4.3](#) will proceed to the left as written, consuming H_2O and producing H_2 , which causes the concentration ratio to move down and to the right toward the equilibrium line.

Figure 15.4.3 The Concentration of Water Vapor versus the Concentration of Hydrogen for the $\text{CdO}(s) + \text{H}_2(g) \rightleftharpoons \text{Cd}(s) + \text{H}_2\text{O}(g)$ System at Equilibrium For any equilibrium concentration of $\text{H}_2\text{O}(g)$, there is only one equilibrium concentration of $\text{H}_2(g)$. Because the magnitudes of the two concentrations are directly proportional, a large $[\text{H}_2\text{O}]$ at equilibrium requires a large $[\text{H}_2]$ and vice versa. In this case, the slope of the line is equal to K .

In another example, solid ammonium iodide dissociates to gaseous ammonia and hydrogen iodide at elevated temperatures:

For this system, K is equal to the product of the concentrations of the two products: $[\text{NH}_3][\text{HI}]$. If we double the concentration of NH_3 , the concentration of HI must decrease by approximately a factor of 2 to maintain equilibrium, as shown in Figure 15.4.4. As a result, for a given concentration of either HI or NH_3 , only a *single* equilibrium composition that contains equal concentrations of both NH_3 and HI is possible, for which $[\text{NH}_3] = [\text{HI}] = K^{1/2}$. Any point that lies below and to the left of the equilibrium curve (such as point A in Figure 15.4.4) corresponds to $Q < K$, and the reaction in Equation 15.4.4 will therefore proceed to the right as written, causing the composition of the system to move toward the equilibrium line. Conversely, any point that lies above and to the right of the equilibrium curve (such as point B in Figure 15.4.3) corresponds to $Q > K$, and the reaction in Equation 15.4.4 will therefore proceed to the left as written, again causing the composition of the system to move toward the equilibrium line. By graphing equilibrium concentrations for a given system at a given temperature and pressure, we can predict the direction of reaction of that mixture when the system is not at equilibrium.

Figure 15.4.4 The Concentration of $\text{NH}_3(g)$ versus the Concentration of $\text{HI}(g)$ for the $\text{NH}_4\text{I}(s) \rightleftharpoons \text{NH}_3(g) + \text{HI}(g)$ System at Equilibrium Only one equilibrium concentration of $\text{NH}_3(g)$ is possible for any given equilibrium concentration of $\text{HI}(g)$. In this case, the two are inversely proportional. Thus a large $[\text{HI}]$ at equilibrium requires a small $[\text{NH}_3]$ at equilibrium and vice versa.

Le Châtelier's Principle

When a system at equilibrium is perturbed in some way, the effects of the perturbation can be predicted qualitatively using Le Châtelier's principle (named after the French chemist Henri Louis Le Châtelier, 1850–1936). The name is pronounced “Luh SHOT-

lee-ay.” This principle can be stated as follows: *if a stress is applied to a system at equilibrium, the composition of the system will change to counteract the applied stress.* Stress occurs when any change in a system affects the magnitude of Q or K . In [Equation 15.4.4](#), for example, increasing $[\text{NH}_3]$ produces a stress on the system that requires a decrease in $[\text{HI}]$ for the system to return to equilibrium. As a further example, consider esters, which are one of the products of an equilibrium reaction between a carboxylic acid and an alcohol. (For more information on this type of reaction, see [Section 7.5](#).) Esters are responsible for the scents we associate with fruits (such as oranges and bananas), and they are also used as scents in perfumes. Applying a stress to the reaction of a carboxylic acid and an alcohol will change the composition of the system, leading to an increase or a decrease in the amount of ester produced. In [Section 15.5](#) and [Section 15.6](#), we explore how chemists control reactions conditions to affect equilibrium concentrations.

Note the Pattern

In all reactions, if a stress is applied to a system at equilibrium, the composition of the system will change to counteract the applied stress (Le Châtelier’s principle).

Example 15.4.2

Write an equilibrium constant expression for each reaction and use this expression to predict what will happen to the concentration of the substance in bold when the indicated change is made if the system is to maintain equilibrium.

- $2\text{HgO}(\text{s}) \rightleftharpoons 2\text{Hg}(\text{l}) + \mathbf{O}_2(\text{g})$: the amount of HgO is doubled.
- $\text{NH}_4\text{HS}(\text{s}) \rightleftharpoons \mathbf{NH}_3(\text{g}) + \text{H}_2\text{S}(\text{g})$: the concentration of H_2S is tripled.
- $n\text{-butane}(\text{g}) \rightleftharpoons \text{isobutane}(\text{g})$: the concentration of isobutane is halved.

Given: equilibrium systems and changes

Asked for: equilibrium constant expressions and effects of changes

Strategy:

Write the equilibrium constant expression, remembering that pure liquids and solids do not appear in the expression. From this expression, predict the change that must occur to maintain equilibrium when the indicated changes are made.

Solution:

- Because $\text{HgO}(\text{s})$ and $\text{Hg}(\text{l})$ are pure substances, they do not appear in the equilibrium constant expression. Thus, for this reaction, $K = [\text{O}_2]$. The equilibrium concentration of O_2 is a constant and does not depend on the amount of HgO present. Hence adding more HgO will not affect the equilibrium concentration of O_2 , so no compensatory change is necessary.
- NH_4HS does not appear in the equilibrium constant expression because it is a solid. Thus $K = [\text{NH}_3][\text{H}_2\text{S}]$, which means that the concentrations of the products are inversely proportional. If adding H_2S triples the H_2S concentration, for example, then the NH_3 concentration must decrease by about a factor of 3 for the system to remain at equilibrium so that the product of the concentrations equals K .
- For this reaction, $K = [\text{isobutane}]/[n\text{-butane}]$, so halving the concentration of isobutane means that the n -butane concentration must also decrease by about half if the system is to maintain equilibrium.

Exercise

Write an equilibrium constant expression for each reaction. What must happen to the concentration of the substance in bold when the indicated change occurs if the system is to maintain equilibrium?

- $\text{HBr}(\text{g}) + \text{NaH}(\text{s}) \rightleftharpoons \text{NaBr}(\text{s}) + \mathbf{H}_2(\text{g})$: the concentration of HBr is decreased by a factor of 3.
- $6\text{Li}(\text{s}) + \mathbf{N}_2(\text{g}) \rightleftharpoons 2\text{Li}_3\text{N}(\text{s})$: the amount of Li is tripled.
- $\mathbf{SO}_2(\text{g}) + \text{Cl}_2(\text{g}) \rightleftharpoons \text{SO}_2\text{Cl}_2(\text{l})$: the concentration of Cl_2 is doubled.

Answer:

1. $K = [\text{H}_2]/[\text{HBr}]$; $[\text{H}_2]$ must decrease by about a factor of 3.
2. $K = 1/[\text{N}_2]$; solid lithium does not appear in the equilibrium constant expression, so no compensatory change is necessary.
3. $K = 1/[\text{SO}_2][\text{Cl}_2]$; $[\text{SO}_2]$ must decrease by about half.

Summary

The **reaction quotient** (Q or Q_p) has the same form as the equilibrium constant expression, but it is derived from concentrations obtained at any time. When a reaction system is at equilibrium, $Q = K$. Graphs derived by plotting a few equilibrium concentrations for a system at a given temperature and pressure can be used to predict the direction in which a reaction will proceed. Points that do not lie on the line or curve represent nonequilibrium states, and the system will adjust, if it can, to achieve equilibrium. **Le Châtelier's principle** states that if a stress is applied to a system at equilibrium, the composition of the system will adjust to counteract the stress.

Key Takeaway

- The reaction quotient (Q) is used to determine whether a system is at equilibrium and if it is not, to predict the direction of reaction.

Key Equation

Reaction quotient

Equation 15.4.1:

$$Q = \frac{[C]^c [D]^d}{[A]^a [B]^b} \quad (\text{Chapter 15.4.1})$$

Conceptual Problems

1. During a set of experiments, graphs were drawn of [reactants] versus [products] at equilibrium. Using [Figure 15.4.4](#) and [Figure 15.4.4](#) as your guides, sketch the shape of each graph using appropriate labels.
 - a. $\text{H}_2\text{O}_{(l)} \rightleftharpoons \text{H}_2\text{O}_{(g)}$
 - b. $2\text{MgO}_{(s)} \rightleftharpoons 2\text{Mg}_{(s)} + \text{O}_{2(g)}$
 - c. $2\text{O}_3(g) \rightleftharpoons 3\text{O}_2(g)$
 - d. $2\text{PbS}_{(s)} + 3\text{O}_{2(g)} \rightleftharpoons 2\text{PbO}_{(s)} + 2\text{SO}_{2(g)}$
2. Write an equilibrium constant expression for each reaction system. Given the indicated changes, how must the concentration of the species in bold change if the system is to maintain equilibrium?
 - a. $2\text{NaHCO}_3(s) \rightleftharpoons \text{Na}_2\text{CO}_3(s) + \text{CO}_2(g) + \text{H}_2\text{O}(g)$: $[\text{CO}_2]$ is doubled.
 - b. $\text{N}_2\text{F}_4(g) \rightleftharpoons 2\text{NF}_2(g)$: $[\text{NF}_2]$ is decreased by a factor of 2.
 - c. $\text{H}_2(g) + \text{I}_2(g) \rightleftharpoons 2\text{HI}(g)$: $[\text{I}_2]$ is doubled.
3. Write an equilibrium constant expression for each reaction system. Given the indicated changes, how must the concentration of the species in bold change if the system is to maintain equilibrium?
 - a. $\text{CS}_2(g) + 4\text{H}_2(g) \rightleftharpoons \text{CH}_4(g) + 2\text{H}_2\text{S}(g)$: $[\text{CS}_2]$ is doubled.
 - b. $\text{PCl}_5(g) \rightleftharpoons \text{PCl}_3(g) + \text{Cl}_2(g)$: $[\text{Cl}_2]$ is decreased by a factor of 2.
 - c. $4\text{NH}_3(g) + 5\text{O}_2(g) \rightleftharpoons 4\text{NO}(g) + 6\text{H}_2\text{O}(g)$: $[\text{NO}]$ is doubled.

Answer

- 1.
- 2.
3. a. $K = \frac{[CH_4][H_2S]^2}{[CS_2][H_2]^4}$; doubling $[CS_2]$ would require decreasing $[H_2]$ by a factor of $2\sqrt[4]{2} \approx 1.189$.
 b. $K = \frac{[PCl_3]}{[Cl_2][PCl_5]}$; if $[Cl_2]$ is halved, $[PCl_5]$ must also be halved.
 c. $K = \frac{[NO]^4[H_2O]^6}{[NH_3][O_2]^5}$; if $[NO]$ is doubled, $[H_2O]$ is multiplied by $2^{2/3} \approx 1.587$.

Numerical Problems

1. The data in the following table were collected at 450°C for the reaction

P (atm)	Equilibrium Partial Pressure (atm)		
	NH ₃	N ₂	H ₂
30 (equilibrium)	1.740	6.588	21.58
100	15.20	19.17	65.13
600	321.6	56.74	220.8

The reaction equilibrates at a pressure of 30 atm. The pressure on the system is first increased to 100 atm and then to 600 atm. Is the system at equilibrium at each of these higher pressures? If not, in which direction will the reaction proceed to reach equilibrium?

2. For the reaction $2A \rightleftharpoons B + 3C$, K at 200°C is 2.0. A 6.00 L flask was used to carry out the reaction at this temperature. Given the experimental data in the following table, all at 200°C, when the data for each experiment were collected, was the reaction at equilibrium? If it was not at equilibrium, in which direction will the reaction proceed?

Experiment	A	B	C
1	2.50 M	2.50 M	2.50 M
2	1.30 atm	1.75 atm	14.15 atm
3	12.61 mol	18.72 mol	6.51 mol

3. The following two reactions are carried out at 823 K:

- Write the equilibrium expression for each reaction.
 - Calculate the partial pressure of both gaseous components at equilibrium in each reaction if a 1.00 L reaction vessel initially contains 0.316 mol of H₂ or CO plus 0.500 mol CoO.
 - Using the information provided, calculate K_p for the following reaction:

$$H_{2(g)} + CO_{2(g)} \rightleftharpoons CO_{(g)} + H_2O_{(g)}$$
 - Describe the shape of the graphs of [reactants] versus [products] as the amount of CoO changes.
4. Hydrogen iodide (HI)₂ is synthesized via $H_2(g) + I_2(g) \rightleftharpoons 2HI(g)$, for which $K_p = 54.5$ at 425°C. Given a 2.0 L vessel containing 1.12×10^{-2} mol of H₂ and 1.8×10^{-2} mol of I₂ at equilibrium, what is the concentration of HI? Excess hydrogen is added to the vessel so that the vessel now contains 3.64×10^{-2} mol of H₂. Calculate Q and then predict the direction in which the reaction will proceed. What are the new equilibrium concentrations?

Answers

1. Not at equilibrium; in both cases, the sum of the equilibrium partial pressures is *less* than the total pressure, so the reaction will proceed to the right to decrease the pressure.
- 2.
3.
 - a. $K = \frac{[H_2O][H_2]}{[CO_2][CO]}$
 - b. $P_{H_2O} = 21.0 \text{ atm}$; $P_{H_2} = 0.27 \text{ atm}$; $P_{CO_2} = 21.3 \text{ atm}$; $P_{CO} = 0.07 \text{ atm}$
 - c. $K_p = 0.14$
 - d. The amount of CoO has no effect on the shape of a graph of products versus reactants *as long as some solid CoO is present*.
- 4.

Learning Objective

- To predict the effects of stresses on a system at equilibrium.

Chemists use various strategies to increase the yield of the desired products of reactions. When synthesizing an ester, for example, how can a chemist control the reaction conditions to obtain the maximum amount of the desired product? Only three types of stresses can change the composition of an equilibrium mixture: (1) a change in the concentrations (or partial pressures) of the components by adding or removing reactants or products, (2) a change in the total pressure or volume, and (3) a change in the temperature of the system. In this section, we explore how changes in reaction conditions can affect the equilibrium composition of a system. We will explore each of these possibilities in turn.

Changes in Concentration

If we add a small volume of carbon tetrachloride (CCl_4) solvent to a flask containing crystals of iodine, we obtain a saturated solution of I_2 in CCl_4 , along with undissolved crystals:

The system reaches equilibrium, with $K = [\text{I}_2]$. If we add more CCl_4 , thereby diluting the solution, Q is now less than K . Le Châtelier's principle tells us that the system will react to relieve the stress—but how? Adding solvent stressed the system by decreasing the concentration of dissolved I_2 . Hence more crystals will dissolve, thereby increasing the concentration of dissolved I_2 until the system again reaches equilibrium if enough solid I_2 is available (Figure 15.5.1). By adding solvent, we drove the reaction shown in Equation 15.5.1 to the right as written.

Figure 15.5.1 The Concentration of Dissolved I_2 as a Function of Time Following the Addition of More Solvent to a Saturated Solution in Contact with Excess Solid I_2 The concentration of I_2 decreases initially due to dilution but returns to its original value as long as solid I_2 is present.

We encounter a more complex system in the reaction of hydrogen and nitrogen to form ammonia:

The K_p for this reaction is 2.14×10^{-2} at about 540 K. Under one set of equilibrium conditions, the partial pressure of ammonia is $P(NH_3) = 0.454$ atm, that of hydrogen is $P(H_2) = 2.319$ atm, and that of nitrogen is $P(N_2) = 0.773$ atm. If an additional 1 atm of hydrogen is added to the reactor to give $P(H_2) = 3.319$ atm, how will the system respond? Because the stress is an increase in $P(H_2)$ the system must respond in some way that decreases the partial pressure of hydrogen to counteract the stress. The reaction will therefore proceed to the right as written, consuming H_2 and N_2 and forming additional NH_3 . Initially, the partial pressures of H_2 and N_2 will decrease, and the partial pressure of NH_3 will increase until the system eventually reaches a new equilibrium composition, which will have a net increase in $P(H_2)$.

We can confirm that this is indeed what will happen by evaluating Q_p under the new conditions and comparing its value with K_p . The equations used to evaluate K_p and Q_p have the same form: substituting the values after adding hydrogen into the expression for Q_p results in the following:

$$Q_p = \frac{(P_{NH_3})^2}{(P_{N_2})(P_{H_2})^3} = \frac{(0.454)^2}{(0.773)(2.319 + 1.00)^3} = 7.29 \times 10^{-3} \quad (\text{Chapter 15.5.1})$$

Thus $Q_p < K_p$, which tells us that the ratio of products to reactants is less than at equilibrium. To reach equilibrium, the reaction must proceed to the right as written: the partial pressures of the products will increase, and the partial pressures of the reactants will decrease. Q_p will thereby increase until it equals K_p , and the system will once again be at equilibrium. Changes in the partial pressures of the various substances in the reaction mixture (Equation 15.5.2) as a function of time are shown in Figure 15.5.2.

Figure 15.5.2 The Partial Pressures of H_2 , N_2 , and NH_3 as a Function of Time Following the Addition of More H_2 to an Equilibrium Mixture. Some of the added hydrogen is consumed by reacting with nitrogen to produce more ammonia, allowing the system to reach a new equilibrium composition.

We can force a reaction to go essentially to completion, regardless of the magnitude of K , by continually removing one of the products from the reaction mixture. Consider, for example, the *methanation* reaction, in which hydrogen reacts with carbon monoxide to form methane and water:

This reaction is used for the industrial production of methane, whereas the reverse reaction is used for the production of H_2 (Example 14). The expression for Q has the following form:

$$Q = \frac{[CH_4][H_2O]}{[CO][H_2]^3} \quad (15.5.4)$$

Regardless of the magnitude of K , if either H_2O or CH_4 can be removed from the reaction mixture so that $[\text{H}_2\text{O}]$ or $[\text{CH}_4]$ is approximately zero, then $Q \approx 0$. In other words, when product is removed, the system is stressed ($Q \ll K$), and more product will form to counter the stress. Because water (bp = 100°C) is much less volatile than methane, hydrogen, or carbon monoxide (all of which have boiling points below -100°C), passing the gaseous reaction mixture through a cold coil will cause the water vapor to condense to a liquid that can be drawn off. Continuing to remove water from the system forces the reaction to the right as the system attempts to equilibrate, thus enriching the reaction mixture in methane. This technique, referred to as *driving a reaction to completion*, can be used to force a reaction to completion even if K is relatively small. For example, esters are usually synthesized by removing water. The products of the condensation reaction are shown here. In [Chapter 19](#), we will describe the thermodynamic basis for the change in the equilibrium position caused by changes in the concentrations of reaction components.

Example 15.5.1

For each equilibrium system, predict the effect of the indicated stress on the specified quantity.

- $2\text{SO}_2(\text{g}) + \text{O}_2(\text{g}) \rightleftharpoons 2\text{SO}_3(\text{g})$:
 - the effect of removing O_2 on $P(\text{SO}_2)$
 - the effect of removing O_2 on $P(\text{SO}_3)$
- $\text{CaCO}_3(\text{s}) \rightleftharpoons \text{CaO}(\text{s}) + \text{CO}_2(\text{g})$:
 - the effect of removing CO_2 on the amount of CaCO_3 ;
 - the effect of adding CaCO_3 on $P(\text{CO}_2)$

Given: balanced chemical equations and changes

Asked for: effects of indicated stresses

Strategy:

Use Q and K to predict the effect of the stress on each reaction.

Solution:

- Removing O_2 will decrease $P(\text{O}_2)$ thereby decreasing the denominator in the reaction quotient and making $Q_p > K_p$. The reaction will proceed to the left as written, increasing the partial pressures of SO_2 and O_2 until Q_p once again equals K_p .
 - Removing O_2 will decrease $P(\text{O}_2)$ and thus increase Q_p , so the reaction will proceed to the left. The partial pressure of SO_3 will decrease.
- K_p and Q_p are both equal to $P(\text{CO}_2)$.
 - Removing CO_2 from the system causes more CaCO_3 to react to produce CO_2 , which increases $P(\text{CO}_2)$ to the partial pressure required by K_p .
 - Adding (or removing) solid CaCO_3 has no effect on $P(\text{CO}_2)$ because it does not appear in the expression for K_p (or Q_p).

Exercise

For each equilibrium system, predict the effect that the indicated stress will have on the specified quantity.

- $\text{H}_2(\text{g}) + \text{CO}_2(\text{g}) \rightleftharpoons \text{H}_2\text{O}(\text{g}) + \text{CO}(\text{g})$:
 - the effect of adding CO on $[\text{H}_2]$;
 - the effect of adding CO_2 on $[\text{H}_2]$
- $\text{CuO}(\text{s}) + \text{CO}(\text{g}) \rightleftharpoons \text{Cu}(\text{s}) + \text{CO}_2(\text{g})$:
 - the effect of adding CO on the amount of Cu ;
 - the effect of adding CO_2 on $[\text{CO}]$

Answer:

- (1) $[H_2]$ increases; (2) $[H_2]$ decreases.
- (1) the amount of Cu increases; (2) $[CO]$ increases.

Changes in Total Pressure or Volume

Because liquids are relatively incompressible, changing the pressure above a liquid solution has little effect on the concentrations of dissolved substances. Consequently, changes in external pressure have very little effect on equilibrium systems that contain only solids or liquids. In contrast, because gases are highly compressible, their concentrations vary dramatically with pressure. From the ideal gas law, $PV = nRT$, described in [Chapter 10](#), the concentration (C) of a gas is related to its pressure as follows:

$$C = \frac{n}{V} = \frac{P}{RT} \quad (15.5.5)$$

Hence the concentration of any gaseous reactant or product is directly proportional to the applied pressure (P) and inversely proportional to the total volume (V). Consequently, the equilibrium compositions of systems that contain gaseous substances are quite sensitive to changes in pressure, volume, and temperature.

These principles can be illustrated using the reversible dissociation of gaseous N_2O_4 to gaseous NO_2 ([Equation 15.2.1](#)).

The syringe shown in [Figure 15.5.3](#) initially contains an equilibrium mixture of colorless N_2O_4 and red-brown NO_2 . Decreasing the volume by 50% causes the mixture to become darker because all concentrations have doubled. Decreasing the volume also constitutes a stress, however, as we can see by examining the effect of a change in volume on Q . At equilibrium,

$$Q = K = \frac{[NO_2]^2}{[N_2O_4]} \quad (15.5.6a)$$

If the volume is decreased by half, the concentrations of the substances in the mixture are doubled, so the new reaction quotient is as follows:

$$Q = \frac{(2[NO_2]_i)^2}{2[N_2O_4]_i} = \frac{4([NO_2]_i)^2}{2[N_2O_4]_i} = 2K \quad (15.5.6b)$$

Because Q is now greater than K , the system is no longer at equilibrium. The stress can be relieved if the reaction proceeds to the left, consuming 2 mol of NO_2 for every 1 mol of N_2O_4 produced. This will decrease the concentration of NO_2 and increase the concentration of N_2O_4 , causing Q to decrease until it once again equals K . Thus, as shown in part (c) in [Figure 15.5.3](#), the intensity of the brown color due to NO_2 decreases with time following the change in volume.

Figure 15.5.3 The Effect of Changing the Volume (and Thus the Pressure) of an Equilibrium Mixture of N_2O_4 and NO_2 at Constant Temperature(a) The syringe with a total volume of 15 mL contains an equilibrium mixture of N_2O_4 and NO_2 ; the red-brown color is proportional to the NO_2 concentration. (b) If the volume is rapidly decreased by a factor of 2 to 7.5 mL, the initial effect is to double the concentrations of all species present, including NO_2 . Hence the color becomes more intense. (c) With time, the system adjusts its composition in response to the stress as predicted by Le Châtelier's principle, forming colorless N_2O_4 at the expense of red-brown NO_2 , which decreases the intensity of the color of the mixture.

Note the Pattern

Increasing the pressure of a system (or decreasing the volume) favors the side of the reaction that has fewer gaseous molecules and vice versa.

In general, if a balanced chemical equation contains different numbers of gaseous reactant and product molecules, the equilibrium will be sensitive to changes in volume or pressure. Increasing the pressure on a system (or decreasing the volume) will favor the side of the reaction that has fewer gaseous molecules and vice versa.

Example 15.5.2

For each equilibrium system, write the reaction quotient for the system if the pressure is decreased by a factor of 2 (i.e., if the volume is doubled) at constant temperature and then predict the direction of the reaction.

1. $N_{2(g)} + 3H_{2(g)} \rightleftharpoons 2NH_{3(g)}$
2. $C_2H_{2(g)} + C_2H_{6(g)} \rightleftharpoons 2C_2H_{4(g)}$
3. $2NO_{2(g)} \rightleftharpoons 2NO_{(g)} + O_{2(g)}$

Given: balanced chemical equations

Asked for: direction of reaction if pressure is halved

Strategy:

Use Le Châtelier's principle to predict the effect of the stress.

Solution:

1. Two moles of gaseous products are formed from 4 mol of gaseous reactants. Decreasing the pressure will cause the reaction to shift to the left because that side contains the larger number of moles of gas. Thus the pressure increases, counteracting the stress. K for this reaction is $[NH_3]^2/[N_2][H_2]^3$. When the pressure is decreased by a factor of 2, the concentrations are halved, which means that the new reaction quotient is as follows:

$$Q = \frac{[1/2 NH_3]^2}{[1/2 N_2][1/2 H_2]^3} = \frac{1/4 [NH_3]^2}{1/16 [N_2][H_2]^3} = 4K$$

2. Two moles of gaseous products form from 2 mol of gaseous reactants. Decreasing the pressure will have no effect on the equilibrium composition because both sides of the balanced chemical equation have the same number of moles of gas. Here $K = [C_2H_4]^2/[C_2H_2][C_2H_6]$. The new reaction quotient is as follows:

$$Q = \frac{[C_2H_4]^2}{[C_2H_2][C_2H_6]} = \frac{[1/2 C_2H_4]^2}{[1/2 C_2H_2][1/2 C_2H_6]} = \frac{1/4 [C_2H_4]^2}{1/4 [C_2H_2][C_2H_6]} = K$$

3. Three moles of gaseous products are formed from 2 mol of gaseous reactants. Decreasing the pressure will favor the side that contains more moles of gas, so the reaction will shift toward the products to increase the pressure. For this reaction $K = [NO]^2[O_2]/[NO_2]^2$. Under the new reaction conditions the reaction quotient is as follows:

$$Q = \frac{[1/2 NO]^2 [1/2 O_2]}{[1/2 NO_2]^2} = \frac{1/8 [NO]^2 [O_2]}{1/4 [NO_2]^2} = 1/2 K$$

Exercise

For each equilibrium system, write a new reaction quotient for the system if the pressure is increased by a factor of 2 (i.e., if the volume is halved) at constant temperature and then predict the direction in which the reaction will shift.

1. $H_2O_{(g)} + CO_{(g)} \rightleftharpoons H_{2(g)} + CO_{2(g)}$
2. $H_{2(g)} + C_2H_{4(g)} \rightleftharpoons C_2H_{6(g)}$
3. $2SO_{2(g)} + O_{2(g)} \rightleftharpoons 2SO_{3(g)}$

Answer:

1. $Q = K$; no effect
2. $Q = 1/2 K$; to the right
3. $Q = 1/2 K$; to the right

Changes in Temperature

In all the cases we have considered so far, the magnitude of the equilibrium constant, K or K_p , was constant. Changes in temperature can, however, change the value of the equilibrium constant without immediately affecting the reaction quotient ($Q \neq K$). In this case, the system is no longer at equilibrium; the composition of the system will change until Q equals K at the new temperature.

To predict how an equilibrium system will respond to a change in temperature, we must know something about the enthalpy change of the reaction (ΔH_{rxn}). As you learned in [Chapter 9](#), heat is released to the surroundings in an exothermic reaction ($\Delta H_{\text{rxn}} < 0$), and heat is absorbed from the surroundings in an endothermic reaction ($\Delta H_{\text{rxn}} > 0$). We can express these changes in the following way:

- Exothermic ($\Delta H < 0$):

- Endothermic ($\Delta H > 0$):

Thus heat can be thought of as a product in an exothermic reaction and as a reactant in an endothermic reaction. Increasing the temperature of a system corresponds to adding heat. Le Châtelier's principle predicts that an exothermic reaction will shift to the left (toward the reactants) if the temperature of the system is increased (heat is added). Conversely, an endothermic reaction will shift to the right (toward the products) if the temperature of the system is increased. If a reaction is thermochemically neutral ($\Delta H_{\text{rxn}} = 0$), then a change in temperature will not affect the equilibrium composition.

We can examine the effects of temperature on the dissociation of N_2O_4 to NO_2 , for which $\Delta H = +58 \text{ kJ/mol}$. This reaction can be written as follows:

Increasing the temperature (adding heat to the system) is a stress that will drive the reaction to the right, as illustrated in [Figure 15.5.4](#). Thus increasing the temperature increases the ratio of NO_2 to N_2O_4 at equilibrium, which increases K .

Figure 15.5.4 The Effect of Temperature on the Equilibrium between Gaseous N_2O_4 and NO_2 The value of K changes with temperature of the same 99.9% pure $\text{NO}_2/\text{N}_2\text{O}_4$ sealed in an ampoule. From left to right -196°C , 0°C , 23°C , 35°C , 50°C . In the endothermic reaction, the equilibrium position can be shifted by changing the temperature. When heat is added and the temperature increases, the reaction shifts to the right and the flask turns reddish brown due to an increase in NO_2 . When heat is removed and the temperature decreases, the reaction shifts to the left and flask turns colorless due to an increase in N_2O_4 . This demonstrates Le Chatelier's Principle because the equilibrium shifts in the direction that consumes energy. Figure used with permission from Wikipedia.

The effect of increasing the temperature on a system at equilibrium can be summarized as follows: *increasing the temperature increases the magnitude of the equilibrium constant for an endothermic reaction, decreases the equilibrium constant for an exothermic reaction, and has no effect on the equilibrium constant for a thermally neutral reaction.* [Table 15.5.1](#) shows the

temperature dependence of the equilibrium constants for the synthesis of ammonia from hydrogen and nitrogen, which is an exothermic reaction with $\Delta H^\circ = -91.8 \text{ kJ/mol}$. The values of both K and K_p decrease dramatically with increasing temperature, as predicted for an exothermic reaction.

Table 15.5.1 Temperature Dependence of K and K_p for $\text{N}_2(\text{g}) + 3 \text{H}_2(\text{g}) \rightleftharpoons 2 \text{NH}_3(\text{g})$

Temperature (K)	K	K_p
298	3.3×10^8	5.6×10^5
400	3.9×10^4	3.6×10^1
450	2.6×10^3	1.9
500	1.7×10^2	1.0×10^{-1}
550	2.6×10^1	1.3×10^{-2}
600	4.1	1.7×10^{-3}

Note the Pattern

Increasing the temperature causes endothermic reactions to favor products and exothermic reactions to favor reactants.

Example 15.5.3

For each equilibrium reaction, predict the effect of decreasing the temperature:

- $\text{N}_2(\text{g}) + 3\text{H}_2(\text{g}) \rightleftharpoons 2\text{NH}_3(\text{g}) \quad \Delta H_{\text{rxn}} = -91.8 \text{ kJ/mol}$
- $\text{CaCO}_3(\text{s}) \rightleftharpoons \text{CaO}(\text{s}) + \text{CO}_2(\text{g}) \quad \Delta H_{\text{rxn}} = 178 \text{ kJ/mol}$

Given: balanced chemical equations and values of ΔH_{rxn}

Asked for: effects of decreasing temperature

Strategy:

Use Le Châtelier's principle to predict the effect of decreasing the temperature on each reaction.

Solution:

- The formation of NH_3 is exothermic, so we can view heat as one of the products:

- If the temperature of the mixture is decreased, heat (one of the products) is being removed from the system, which causes the equilibrium to shift to the right. Hence the formation of ammonia is favored at lower temperatures.

- The decomposition of calcium carbonate is endothermic, so heat can be viewed as one of the reactants:

If the temperature of the mixture is decreased, heat (one of the reactants) is being removed from the system, which causes the equilibrium to shift to the left. Hence the thermal decomposition of calcium carbonate is less favored at lower temperatures.

Exercise

For each equilibrium system, predict the effect of increasing the temperature on the reaction mixture:

1. $2SO_{2(g)} + O_{2(g)} \rightleftharpoons 2SO_{3(g)}$ with $\Delta H_{rxn} = -198 \text{ kJ/mol}$
2. $N_{2(g)} + O_{2(g)} \rightleftharpoons 2NO_{(g)}$ with $\Delta H_{rxn} = +181 \text{ kJ/mol}$

Answer:

1. Reaction shifts to the left.
2. Reaction shifts to the right.

Summary

Three types of stresses can alter the composition of an equilibrium system: adding or removing reactants or products, changing the total pressure or volume, and changing the temperature of the system. A reaction with an unfavorable equilibrium constant can be driven to completion by continually removing one of the products of the reaction. Equilibria that contain different numbers of gaseous reactant and product molecules are sensitive to changes in volume or pressure; higher pressures favor the side with fewer gaseous molecules. Removing heat from an exothermic reaction favors the formation of products, whereas removing heat from an endothermic reaction favors the formation of reactants.

Key Takeaway

- Equilibria are affected by changes in concentration, total pressure or volume, and temperature.

Conceptual Problems

1. If an equilibrium reaction is endothermic in the forward direction, what is the expected change in the concentration of each component of the system if the temperature of the reaction is increased? If the temperature is decreased?
2. Write the equilibrium equation for the following system:

$$4NH_3(g) + 5O_2(g) \rightleftharpoons 4NO(g) + 6H_2O(g)$$

Would you expect the equilibrium to shift toward the products or reactants with an increase in pressure? Why?
3. The reaction rate approximately doubles for every 10°C rise in temperature. What happens to K ?
4. The formation of $A_2B_2(g)$ via the equilibrium reaction $2AB(g) \rightleftharpoons A_2B_2(g)$ is exothermic. What happens to the ratio k_f/k_r if the temperature is increased? If both temperature and pressure are increased?
5. In each system, predict the effect that the indicated change will have on the specified quantity at equilibrium:
 - a. $H_{2(g)} + I_{2(g)} \rightleftharpoons 2HI_{(g)}$:
 H_2 is removed; what is the effect on $P(I_2)$?
 - b. $2NOBr_{(g)} \rightleftharpoons 2NO_{(g)} + Br_{2(g)}$
 If Br_2 is removed; what is the effect on P_{NOBr} ?
 - c. $2NaHCO_{3(s)} \rightleftharpoons Na_2CO_{3(g)} + CO_{2(g)} + H_2O_{(g)}$
 If CO_2 is removed; what is the effect on $P(NaHCO_3)$?
6. What effect will the indicated change have on the specified quantity at equilibrium?
 - a. $NH_4Cl_{(s)} \rightleftharpoons NH_{3(g)} + HCl_{(g)}$
 If NH_4Cl is increased; what is the effect on P_{HCl} ?
 - b. $2H_2O_{(g)} \rightleftharpoons 2H_{2(g)} + O_{2(g)}$
 If O_2 is added; what is the effect on $P(H_2)$?
 - c. $PCl_{3(g)} + Cl_{2(g)} \rightleftharpoons PCl_{5(g)}$
 If Cl_2 is removed; what is the effect on $P(PCl_5)$?

Numerical Problems

1. For each equilibrium reaction, describe how Q and K change when the pressure is increased, the temperature is increased, the volume of the system is increased, and the concentration(s) of the reactant(s) is increased.
 - a. $A(g) \rightleftharpoons B(g)$ $\Delta H = -20.6 \text{ kJ/mol}$

- b. $2A(g) \rightleftharpoons B(g) \Delta H = -0.3 \text{ kJ/mol}$
 c. $A(g) + B(g) \rightleftharpoons 2C(g) \Delta H = 46 \text{ kJ/mol}$
2. For each equilibrium reaction, describe how Q and K change when the pressure is decreased, the temperature is increased, the volume of the system is decreased, and the concentration(s) of the reactant(s) is increased.
- a. $2A(g) \rightleftharpoons B(g) \Delta H = -80 \text{ kJ/mol}$
 b. $A(g) \rightleftharpoons 2B(g) \Delta H = 0.3 \text{ kJ/mol}$
 c. $2A(g) \rightleftharpoons 2B(g) + C(g) \Delta H = 46 \text{ kJ/mol}$
3. Le Châtelier's principle states that a system will change its composition to counteract stress. For the system $CO(g) + Cl_2(g) \rightleftharpoons COCl_2(g)$, write the equilibrium constant expression K_p . What changes in the values of Q and K would you anticipate when (a) the volume is doubled, (b) the pressure is increased by a factor of 2, and (c) $COCl_2$ is removed from the system?
4. For the equilibrium system $3O_2(g) \rightleftharpoons 2O_3(g)$, $\Delta H^\circ = 284 \text{ kJ}$, write the equilibrium constant expression K_p . What happens to the values of Q and K if the reaction temperature is increased? What happens to these values if both the temperature and pressure are increased?
5. Carbon and oxygen react to form CO_2 gas via $C(s) + O_2(g) \rightleftharpoons CO_2(g)$, for which $K = 1.2 \times 10^{69}$. Would you expect K to increase or decrease if the volume of the system were tripled? Why?
6. The reaction $COCl_2(g) \rightleftharpoons CO(g) + Cl_2(g)$ has $K = 2.2 \times 10^{-10}$ at 100°C . Starting with an initial $P(COCl_2)$ of 1.0 atm, you determine the following values of P_{CO} at three successive time intervals: $6.32 \times 10^{-5} \text{ atm}$, $1.78 \times 10^{-5} \text{ atm}$, and $1.02 \times 10^{-5} \text{ atm}$. Based on these data, in which direction will the reaction proceed after each measurement? If chlorine gas is added to the system, what will be the effect on Q ?
7. The following table lists experimentally determined partial pressures at three temperatures for the reaction $Br_2(g) \rightleftharpoons 2Br(g)$

T (K)	1123	1173	1273
$P(Br_2)$ (atm)	3.000	0.3333	6.755×10^{-2}
$P(Br)$ (atm)	3.477×10^{-2}	2.159×10^{-2}	2.191×10^{-2}

Is this an endothermic or an exothermic reaction? Explain your reasoning.

8. The dissociation of water vapor proceeds according to the following reaction: $H_2O(g) \rightleftharpoons 1/2 O_2(g) + H_2(g)$. At 1300 K, there is 0.0027% dissociation, whereas at 2155 K, the dissociation is 1.18%. Calculate K and K_p . Is this an endothermic reaction or an exothermic reaction? How do the magnitudes of the two equilibria compare? Would increasing the pressure improve the yield of H_2 gas at either temperature? (Hint: assume that the system initially contains 1.00 mol of H_2O in a 1.00 L container.)
9. When 1.33 mol of CO_2 and 1.33 mol of H_2 are mixed in a 0.750 L container and heated to 395°C , they react according to the following equation: $CO_2(g) + H_2(g) \rightleftharpoons CO(g) + H_2O(g)$ If $K = 0.802$, what are the equilibrium concentrations of each component of the equilibrium mixture? What happens to K if H_2O is removed during the course of the reaction?
10. The equilibrium reaction $H_2(g) + Br_2(g) \rightleftharpoons 2HBr(g)$ has $K_p = 2.2 \times 10^4$ at 298 K. If you begin with 2.0 mol of Br_2 and 2.0 mol of H_2 in a 5.0 L container, what is the partial pressure of HBr at equilibrium? What is the partial pressure of H_2 at equilibrium? If H_2 is removed from the system, what is the effect on the partial pressure of Br_2 ?
11. Iron(II) oxide reacts with carbon monoxide according to the following equation: $FeO(s) + CO(g) \rightleftharpoons Fe(s) + CO_2(g)$ At 800°C , $K = 0.34$; at 1000°C , $K = 0.40$.
- a. A 20.0 L container is charged with 800.0 g of CO_2 , 1436 g of FeO , and 1120 g of iron. What are the equilibrium concentrations of all components of the mixture at each temperature?
 b. What are the partial pressures of the gases at each temperature?
 c. If CO were removed, what would be the effect on $P(CO_2)$ at each temperature?
12. The equilibrium constant K for the reaction $C(s) + CO_2(g) \rightleftharpoons 2CO(g)$ is 1.9 at 1000 K and 0.133 at 298 K.
- a. If excess C is allowed to react with 25.0 g of CO_2 in a 3.00 L flask, how many grams of CO are produced at each temperature?
 b. What are the partial pressures of each gas at 298 K? at 1000 K?
 c. Would you expect K to increase or decrease if the pressure were increased at constant temperature and volume?
13. Data for the oxidation of methane, $CH_4(g) + 2O_2(g) \rightleftharpoons CO_2(g) + 2H_2O(g)$, in a closed 5.0 L vessel are listed in the following table. Fill in the blanks and determine the missing values of Q and K (indicated by ?) as the reaction is driven to completion.

	CH ₄	O ₂	CO ₂	H ₂ O	Q	K
initial (moles)	0.45	0.90	0	0	?	
at equilibrium						1.29
add 0.50 mol of methane	0.95				?	
new equilibrium						?
remove water				0	?	
new equilibrium						1.29

Answers

- 1.
- 2.
- 3.

$$K_p = \frac{P(\text{COCl}_2)}{P(\text{CO}) P(\text{Cl}_2)}$$

P

None of the changes would affect K ; (a) Q doubles; (b) Q is halved; Q decreases.

4.

5. K would not change; it does not depend on volume.

6.

7.

8.

9. $[\text{CO}] = [\text{H}_2\text{O}] = 0.839 \text{ M}$, $[\text{CO}_2] = [\text{H}_2] = 0.930 \text{ M}$; no effect on K

10.

- At 800°C, $[\text{CO}] = 0.678 \text{ M}$, $[\text{CO}_2] = 0.231 \text{ M}$; at 1000°C, $[\text{CO}] = 0.645 \text{ M}$, $[\text{CO}_2] = 0.264 \text{ M}$
- At 800°C, $P(\text{CO}) = 59.7 \text{ atm}$, $P(\text{CO}_2) = 20.3 \text{ atm}$; at 1000°C, $P(\text{CO}) = 67.4 \text{ atm}$, $P(\text{CO}_2) = 27.6 \text{ atm}$.
- Removing CO would cause the reaction to shift to the right, causing $P(\text{CO}_2)$ to decrease.

12.

13.

	CH ₄	O ₂	CO ₂	H ₂ O	Q	K
initial (moles)	0.45	0.90	0	0	0	1.29
at equilibrium	0.215	0.43	0.235	0.47	K	1.29
add 0.50 mol of methane	0.715	0.43	0.235	0.47	0.39	1.29

Learning Objective

- To understand different ways to control the products of a reaction.

Whether in the synthetic laboratory or in industrial settings, one of the primary goals of modern chemistry is to control the identity and quantity of the products of chemical reactions. For example, a process aimed at synthesizing ammonia is designed to maximize the amount of ammonia produced using a given amount of energy. Alternatively, other processes may be designed to minimize the creation of undesired products, such as pollutants emitted from an internal combustion engine. To achieve these goals, chemists must consider the competing effects of the reaction conditions that they can control.

One way to obtain a high yield of a desired compound is to make the reaction rate of the desired reaction much faster than the reaction rates of any other possible reactions that might occur in the system. Altering reaction conditions to control reaction rates, thereby obtaining a single product or set of products, is called kinetic control. A second approach, called thermodynamic control, consists of adjusting conditions so that at equilibrium only the desired products are present in significant quantities.

An example of thermodynamic control is the Haber-Bosch process. Karl Bosch (1874–1940) was a German chemical engineer who was responsible for designing the process that took advantage of Fritz Haber's discoveries regarding the $N_2 + H_2/NH_3$ equilibrium to make ammonia synthesis via this route cost-effective. He received the Nobel Prize in Chemistry in 1931 for his work. The industrial process is called either the Haber process or the Haber-Bosch process. used to synthesize ammonia via the following reaction:

with

$$\Delta H_{rxn} = -91.8 \text{ kJ/mol} \quad (15.6.1b)$$

Because the reaction converts 4 mol of gaseous reactants to only 2 mol of gaseous product, Le Châtelier's principle predicts that the formation of NH_3 will be favored when the pressure is increased. The reaction is exothermic, however ($\Delta H_{rxn} = -91.8 \text{ kJ/mol}$), so the equilibrium constant decreases with increasing temperature, which causes an equilibrium mixture to contain only relatively small amounts of ammonia at high temperatures (Figure 15.6.1). Taken together, these considerations suggest that the maximum yield of NH_3 will be obtained if the reaction is carried out at as low a temperature and as high a pressure as possible. Unfortunately, at temperatures less than approximately 300°C , where the equilibrium yield of ammonia would be relatively high, the reaction is too slow to be of any commercial use. The industrial process therefore uses a mixed oxide (Fe_2O_3/K_2O) catalyst that enables the reaction to proceed at a significant rate at temperatures of 400°C – 530°C , where the formation of ammonia is less unfavorable than at higher temperatures.

Figure 15.6.1 Effect of Temperature and Pressure on the Equilibrium Composition of Two Systems that Originally Contained a 3:1 Mixture of Hydrogen and Nitrogen At all temperatures, the total pressure in the systems was initially either 4 atm (purple curves) or 200 atm (green curves). Note the dramatic decrease in the proportion of NH_3 at equilibrium at higher temperatures in both cases, as well as the large increase in the proportion of NH_3 at equilibrium at any temperature for the system at higher pressure (green) versus lower pressure (purple). Commercial plants that use the Haber-Bosch process to synthesize ammonia on an industrial scale operate at temperatures of 400°C – 530°C (indicated by the darker gray band) and total pressures of 130–330 atm.

Because of the low value of the equilibrium constant at high temperatures (e.g., $K = 0.039$ at 800 K), there is no way to produce an equilibrium mixture that contains large proportions of ammonia at high temperatures. We can, however, control the temperature and the pressure while using a catalyst to convert a fraction of the N_2 and H_2 in the reaction mixture to NH_3 , as is done in the Haber-Bosch process. This process also makes use of the fact that the product—ammonia—is less volatile than the reactants. Because NH_3 is a liquid at room temperature at pressures greater than 10 atm, cooling the reaction mixture causes NH_3 to condense from the vapor as liquid ammonia, which is easily separated from unreacted N_2 and H_2 . The unreacted gases are recycled until complete conversion of hydrogen and nitrogen to ammonia is eventually achieved. Figure 15.6.2 is a simplified layout of a Haber-Bosch process plant.

Figure 15.6.2 A Schematic Diagram of an Industrial Plant for the Production of Ammonia via the Haber-Bosch Process A 3:1 mixture of gaseous H_2 and N_2 is compressed to 130–330 atm, heated to 400°C – 530°C , and passed over an $\text{Fe}_2\text{O}_3/\text{K}_2\text{O}$ catalyst, which results in partial conversion to gaseous NH_3 . The resulting mixture of gaseous NH_3 , H_2 , and N_2 is passed through a heat exchanger, which uses the hot gases to prewarm recycled N_2 and H_2 , and a condenser to cool the NH_3 , giving a liquid that is readily separated from unreacted N_2 and H_2 . (Although the normal boiling point of NH_3 is -33°C , the boiling point increases rapidly with increasing pressure, to 20°C at 8.5 atm and 126°C at 100 atm.) The unreacted N_2 and H_2 are recycled to form more NH_3 .

The Sohio acrylonitrile process, in which propene and ammonia react with oxygen to form acrylonitrile, is an example of a kinetically controlled reaction:

Like most oxidation reactions of organic compounds, this reaction is highly exothermic ($\Delta H^\circ = -519 \text{ kJ/mol}$) and has a very large equilibrium constant ($K = 1.2 \times 10^{34}$). Nonetheless, the reaction shown in Equation 15.43 is not the reaction a chemist would expect to occur when propene or ammonia is heated in the presence of oxygen. Competing combustion reactions that produce CO_2 and N_2 from the reactants, such as those shown in Equation 15.6.3 and Equation 15.6.4, are even more exothermic and have even larger equilibrium constants, thereby reducing the yield of the desired product, acrylonitrile:

with

$$\Delta H^\circ = -1926.1 \text{ kJ/mol} \quad (15.6.3b)$$

and

$$K = 4.5 \times 10^{338} \quad (15.6.3c)$$

with

$$\Delta H^\circ = -1359.2 \text{ kJ/mol}, \quad (15.6.4c)$$

and

$$K = 4.4 \times 10^{234} \quad (15.6.4c)$$

In fact, the formation of acrylonitrile in Equation 15.6.2 is accompanied by the release of approximately 760 kJ/mol of heat due to partial combustion of propene during the reaction.

The Sohio process uses a catalyst that selectively accelerates the rate of formation of acrylonitrile without significantly affecting the reaction rates of competing combustion reactions. Consequently, acrylonitrile is formed more rapidly than CO_2 and N_2 under the optimized reaction conditions (approximately 1.5 atm and 450°C). The reaction mixture is rapidly cooled to prevent further oxidation or combustion of acrylonitrile, which is then washed out of the vapor with a liquid water spray. Thus controlling the kinetics of the reaction causes the desired product to be formed under conditions where equilibrium is not established. In industry, this reaction is carried out on an enormous scale. Acrylonitrile is the building block of the polymer called *polyacrylonitrile*, found in all the products referred to collectively as *acrylics*, whose wide range of uses includes the synthesis of fibers woven into clothing and carpets.

Note the Pattern

Controlling the amount of product formed requires that both thermodynamic and kinetic factors be considered.

Example 15.6.1

Recall that methanation is the reaction of hydrogen with carbon monoxide to form methane and water:

This reaction is the reverse of the steam reforming of methane described in Example 14. The reaction is exothermic ($\Delta H^\circ = -206 \text{ kJ/mol}$), with an equilibrium constant at room temperature of $K_p = 7.6 \times 10^{24}$. Unfortunately, however, CO and H_2 do not react at an appreciable rate at room temperature. What conditions would you select to maximize the amount of methane formed per unit time by this reaction?

Given: balanced chemical equation and values of ΔH° and K

Asked for: conditions to maximize yield of product

Strategy:

Consider the effect of changes in temperature and pressure and the addition of an effective catalyst on the reaction rate and equilibrium of the reaction. Determine which combination of reaction conditions will result in the maximum production of methane.

Solution:

The products are highly favored at equilibrium, but the rate at which equilibrium is reached is too slow to be useful. You learned in [Chapter 14](#) that the reaction rate can often be increased dramatically by increasing the temperature of the reactants. Unfortunately, however, because the reaction is quite exothermic, an increase in temperature will shift the equilibrium to the left, causing more reactants to form and relieving the stress on the system by absorbing the added heat. If we increase the temperature too much, the equilibrium will no longer favor methane formation. (In fact, the equilibrium constant for this reaction is very temperature sensitive, decreasing to only 1.9×10^{-3} at 1000°C .) To increase the reaction rate, we can try to find a catalyst that will operate at lower temperatures where equilibrium favors the formation of products. Higher pressures will also favor the formation of products because 4 mol of gaseous reactant are converted to only 2 mol of gaseous product. Very high pressures should not be needed, however, because the equilibrium constant favors the formation of products. Thus optimal conditions for the reaction include carrying it out at temperatures greater than room temperature (but not too high), adding a catalyst, and using pressures greater than atmospheric pressure.

Industrially, catalytic methanation is typically carried out at pressures of 1–100 atm and temperatures of 250°C – 450°C in the presence of a nickel catalyst. (At 425°C , K_p is 3.7×10^{-3} , so the formation of products is still favored.) The synthesis of methane can also be favored by removing either H_2O or CH_4 from the reaction mixture by condensation as they form.

Exercise

As you learned in Example 10, the water–gas shift reaction is as follows:

$K_p = 0.106$ and $\Delta H = 41.2 \text{ kJ/mol}$ at 700 K . What reaction conditions would you use to maximize the yield of carbon monoxide?

Answer: high temperatures to increase the reaction rate and favor product formation, a catalyst to increase the reaction rate, and atmospheric pressure because the equilibrium will not be greatly affected by pressure

Summary

Changing conditions to affect the reaction rates to obtain a single product is called **kinetic control** of the system. In contrast, **thermodynamic control** is adjusting the conditions to ensure that only the desired product or products are present in significant concentrations at equilibrium.

Key Takeaway

- Both kinetic and thermodynamic factors can be used to control reaction products.

Conceptual Problems

1. A reaction mixture will produce either product A or B depending on the reaction pathway. In the absence of a catalyst, product A is formed; in the presence of a catalyst, product B is formed. What conclusions can you draw about the forward and reverse rates of the reaction that produces A versus the reaction that produces B in (a) the absence of a catalyst and (b) the presence of a catalyst?
2. Describe how you would design an experiment to determine the equilibrium constant for the synthesis of ammonia:

The forward reaction is exothermic ($\Delta H^\circ = -91.8$ kJ). What effect would an increase in temperature have on the equilibrium constant?

3. What effect does a catalyst have on each of the following?
 - a. the equilibrium position of a reaction
 - b. the rate at which equilibrium is reached
 - c. the equilibrium constant?
4. How can the ratio Q/K be used to determine in which direction a reaction will proceed to reach equilibrium?
5. Industrial reactions are frequently run under conditions in which competing reactions can occur. Explain how a catalyst can be used to achieve reaction selectivity. Does the ratio Q/K for the selected reaction change in the presence of a catalyst?

Numerical Problems

1. The oxidation of acetylene via $2\text{C}_2\text{H}_2(\text{g}) + 5\text{O}_2(\text{g}) \rightleftharpoons 4\text{CO}_2(\text{g}) + 2\text{H}_2\text{O}(\text{l})$ has $\Delta H^\circ = -2600$ kJ. What strategy would you use with regard to temperature, volume, and pressure to maximize the yield of product?
2. The oxidation of carbon monoxide via $\text{CO}(\text{g}) + 1/2\text{O}_2(\text{g}) \rightleftharpoons \text{CO}_2(\text{g})$ has $\Delta H^\circ = -283$ kJ. If you were interested in maximizing the yield of CO_2 , what general conditions would you select with regard to temperature, pressure, and volume?
3. You are interested in maximizing the product yield of the system $2\text{SO}_2(\text{g}) + \text{O}_2(\text{g}) \rightleftharpoons 2\text{SO}_3(\text{g})$ $K = 280$ and $\Delta H^\circ = -158$ kJ. What general conditions would you select with regard to temperature, pressure, and volume? If SO_2 has an initial concentration of 0.200 M and the amount of O_2 is stoichiometric, what amount of SO_3 is produced at equilibrium?

Answer

1. Use low temperature and high pressure (small volume).
- 2.
- 3.

Learning Objectives

- The quadratic formula

Previous Essential Skills sections introduced many of the mathematical operations you need to solve chemical problems. We now introduce the quadratic formula, a mathematical relationship involving sums of powers in a single variable that you will need to apply to solve some of the problems in this chapter.

The Quadratic Formula

Mathematical expressions that involve a sum of powers in one or more variables (e.g., x) multiplied by coefficients (such as a) are called *polynomials*. Polynomials of a single variable have the general form

$$a_n x^n + \dots + a_2 x^2 + a_1 x + a_0 \quad (15.7.1)$$

The highest power to which the variable in a polynomial is raised is called its *order*. Thus the polynomial shown here is of the n th order. For example, if n were 3, the polynomial would be third order.

A *quadratic equation* is a second-order polynomial equation in a single variable x :

$$ax^2 + bx + c = 0 \quad (15.7.2)$$

According to the fundamental theorem of algebra, a second-order polynomial equation has two solutions—called *roots*—that can be found using a method called *completing the square*. In this method, we solve for x by first adding $-c$ to both sides of the quadratic equation and then divide both sides by a :

$$x^2 + \frac{bx}{a} = -\frac{c}{a} \quad (15.7.3)$$

We can convert the left side of this equation to a perfect square by adding $b^2/4a^2$, which is equal to $(b/2a)^2$:

Left side:

$$x^2 + \frac{b}{a}x + \frac{b^2}{4a^2} = \left(x + \frac{b}{2a}\right)^2 \quad (15.7.4)$$

Having added a value to the left side, we must now add that same value, $b^2/4a^2$, to the right side:

$$\left(x + \frac{b}{2a}\right)^2 = -\frac{c}{a} + \frac{b^2}{4a^2} \quad (15.7.5)$$

The common denominator on the right side is $4a^2$. Rearranging the right side, we obtain the following:

$$\left(x + \frac{b}{2a}\right)^2 = \frac{b^2 - 4ac}{4a^2} \quad (15.7.6)$$

Taking the square root of both sides and solving for x ,

$$x + \frac{b}{2a} = \frac{\pm\sqrt{b^2 - 4ac}}{2a} \quad (15.7.7)$$

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a} \quad (15.7.8)$$

This equation, known as the *quadratic formula*, has two roots:

$$x = \frac{-b + \sqrt{b^2 - 4ac}}{2a} \quad (15.7.9)$$

and

$$x = \frac{-b - \sqrt{b^2 - 4ac}}{2a} \quad (15.7.10)$$

Thus we can obtain the solutions to a quadratic equation by substituting the values of the coefficients (a , b , c) into the quadratic formula.

When you apply the quadratic formula to obtain solutions to a quadratic equation, it is important to remember that one of the two solutions may not make sense or neither may make sense. There may be times, for example, when a negative solution is not reasonable or when both solutions require that a square root be taken of a negative number. In such cases, we simply discard any solution that is unreasonable and only report a solution that is reasonable. Skill Builder ES1 gives you practice using the quadratic formula.

SKILL BUILDER ES1

Use the quadratic formula to solve for x in each equation. Report your answers to three significant figures.

1. $x^2 + 8x - 5 = 0$
2. $2x^2 - 6x + 3 = 0$
3. $3x^2 - 5x - 4 = 6$
4. $2x(-x + 2) + 1 = 0$
5. $3x(2x + 1) - 4 = 5$

Solution:

1. $9x = -8 + 82 - 4(1)(-5)\sqrt{2(1)} = 0.583$ and $x = -8 - 82 - 4(1)(-5)\sqrt{2(1)} = -8.58$
2. $x = -(-6) + (-62) - 4(2)(3)\sqrt{2(2)} = 2.37$ and $x = -(-6) - (-62) - 4(2)(3)\sqrt{2(2)} = 0.634$
3. $x = -(-5) + (-52) - 4(3)(-10)\sqrt{2(3)} = 2.84$ and $x = -(-5) - (-52) - 4(3)(-10)\sqrt{2(3)} = -1.17$
4. $x = -4 + 42 - 4(-2)(1)\sqrt{2(-2)} = -0.225$ and $x = -4 - 42 - 4(-2)(1)\sqrt{2(-2)} = 2.22$
5. $x = -1 + 12 - 4(2)(-3)\sqrt{2(2)} = 1.00$ and $x = -1 - 12 - 4(2)(-3)\sqrt{2(2)} = 1.50$

APPLICATION PROBLEMS

Problems marked with a ♦ involve multiple concepts. 3+

1. ♦ The total concentrations of dissolved Al in a soil sample represent the sum of “free” Al³⁺ and bound forms of Al that are stable enough to be considered definite chemical species. The distribution of aluminum among its possible chemical forms can be described using equilibrium constants such as the following:

$$K_1 = \frac{[\text{AlOH}^+][\text{Al}^{3+}][\text{OH}^-]}{[\text{Al}^{3+}]} = 1.0 \times 10^{-3}$$

$$K_2 = \frac{[\text{AlSO}_4^-][\text{Al}^{3+}][\text{SO}_4^{2-}]}{[\text{Al}^{3+}]} = 1.0 \times 10^{-7}$$

$$K_3 = \frac{[\text{AlF}_2^+][\text{Al}^{3+}][\text{F}^-]}{[\text{Al}^{3+}]} = 1.0 \times 10^{-3}$$

- Write an equilibrium equation for each expression.
 - Which anion has the highest affinity for Al³⁺: OH⁻, SO₄²⁻, or F⁻? Explain your reasoning.
 - A 1.0 M solution of Al³⁺ is mixed with a 1.0 M solution of each of the anions. Which mixture has the lowest Al concentration?
2. Many hydroxy acids form lactones (cyclic esters) that contain a 5- or 6-membered ring. Common hydroxy acids found in nature are glycolic acid, a constituent of cane sugar juice; lactic acid, which has the characteristic odor and taste of sour milk; and citric acid, found in fruit juices. The general reaction for lactone formation can be written as follows:

Use the information in the following table to calculate the equilibrium constant for lactone formation for each hydroxy acid given and determine which ring size is most stable.

Hydroxy Acid Formula	Size of Lactone Ring (atoms)	At Equilibrium	
		Hydroxy Acid (M)	Lactone (M)
HOCH ₂ CH ₂ COOH	4	4.99×10^{-3}	5.00×10^{-5}
HOCH ₂ CH ₂ CH ₂ COOH	5	8.10×10^{-5}	2.19×10^{-4}
HOCH ₂ CH ₂ CH ₂ CH ₂ COOH	6	5.46×10^{-2}	5.40×10^{-9}
HOCH ₂ CH ₂ CH ₂ CH ₂ CH ₂ COOH	7	9.90×10^{-3}	1.00×10^{-4}

3. ♦ Phosphorus pentachloride, an important reagent in organic chemistry for converting alcohols to alkyl chlorides (ROH → RCl), is hydrolyzed in water to form phosphoric acid and hydrogen chloride. In the gaseous state, however, PCl₅ can decompose at 250°C according to PCl₅(g) ⇌ PCl₃(g) + Cl₂(g), for which K = 0.0420.
- Are products or reactants favored in the decomposition of PCl₅(g)?
 - If a 2.00 L flask containing 104.1 g PCl₅ is heated to 250°C, what is the equilibrium concentration of each species in this reaction?

c. What effect would an increase in pressure have on the equilibrium position? Why?

d. If a 1.00×10^3 L vessel containing 2.00×10^3 kg of PCl_3 with a constant chlorine pressure of 2.00 atm is allowed to reach equilibrium, how many kilograms of PCl_5 are produced? What is the percent yield of PCl_5 ?

4. ♦ Carbon disulfide (CS_2) is used in the manufacture of rayon and in electronic vacuum tubes. However, extreme caution must be used when handling CS_2 in its gaseous state because it is extremely toxic and can cause fatal convulsions. Chronic toxicity is marked by psychic disturbances and tremors. CS_2 is used to synthesize H_2S at elevated T via the following reaction:

- a. If the equilibrium concentration of methane in this reaction is 2.5×10^{-2} M and the initial concentration of each reactant is 0.1635 M, what is the concentration of H_2S at equilibrium?
- b. Exposure to CS_2 concentrations greater than 300 ppm for several hours can start to produce adverse effects. After working for several hours in a laboratory that contains large quantities of CS_2 , you notice that the fume hoods were off and there was not enough ventilation to remove any CS_2 vapor. Given the equilibrium $\text{CS}_2(\text{l}) \rightleftharpoons \text{CS}_2(\text{g})$, where $T = 20^\circ\text{C}$ and $K_p = 0.391$, determine whether you are in any danger.
5. ♦ Chloral hydrate, a sedative commonly referred to as “knockout drops,” is in equilibrium with trichloroacetaldehyde in highly concentrated aqueous solutions:

The equilibrium constant for this reaction as written is 3×10^4 . Are the products or the reactants favored? Write an equilibrium expression for this reaction. How could you drive this reaction to completion?

6. Hydrogen cyanide is commercially produced in the United States by the following reaction: $\text{CH}_4(\text{g}) + \text{NH}_3(\text{g}) + 3/2 \text{O}_2(\text{g}) \rightleftharpoons \text{HCN}(\text{g}) + 3\text{H}_2\text{O}(\text{g})$ where HCN is continuously removed from the system. This reaction is carried out at approximately 1100°C in the presence of a catalyst; however, the high temperature causes other reactions to occur. Why is it necessary to run this reaction at such an elevated temperature? Does the presence of the catalyst affect the equilibrium position?
7. ♦ Hemoglobin transports oxygen from the lungs to the capillaries and consists of four subunits, each capable of binding a single molecule of O_2 . In the lungs, $P(\text{O}_2)$ is relatively high (100 mmHg), so hemoglobin becomes nearly saturated with O_2 . In the tissues, however, $P(\text{O}_2)$ is relatively low (40 mmHg), so hemoglobin releases about half of its bound oxygen. Myoglobin, a protein in muscle, resembles a single subunit of hemoglobin. The plots show the percent O_2 saturation versus $P(\text{O}_2)$ for hemoglobin and myoglobin. Based on these plots, which molecule has the higher affinity for oxygen? What advantage does hemoglobin have over myoglobin as the oxygen transporter? Why is it advantageous to have myoglobin in muscle tissue? Use equilibrium to explain why it is more difficult to exercise at high altitudes where the partial pressure of oxygen is lower.

8. ♦ Sodium sulfate is widely used in the recycling industry as well as in the detergent and glass industries. This compound combines with H_2SO_4 via $\text{Na}_2\text{SO}_4(\text{s}) + \text{H}_2\text{SO}_4(\text{g}) \rightleftharpoons 2\text{NaHSO}_4(\text{s})$. Sodium hydrogen sulfate is used as a cleaning agent because it is water soluble and acidic.
- a. Write an expression for K for this reaction.
- b. Relate this equilibrium constant to the equilibrium constant for the related reaction: $2\text{Na}_2\text{SO}_4(\text{s}) + 2\text{H}_2\text{SO}_4(\text{g}) \rightleftharpoons 4\text{NaHSO}_4(\text{s})$
- c. The dissolution of Na_2SO_4 in water produces the equilibrium reaction $\text{SO}_4^{2-}(\text{aq}) + \text{H}_2\text{O}(\text{l}) \rightleftharpoons \text{HSO}_4^-(\text{aq}) + \text{OH}^-(\text{aq})$ with $K = 8.33 \times 10^{-8}$. What is the concentration of OH^- in a solution formed from the dissolution of 1.00 g of sodium sulfate to make 150.0 mL of aqueous solution? Neglect the autoionization of water in your answer.
9. ♦ One of the Venera orbiter satellites measured S_2 concentrations at the surface of Venus. The resulting thermochemical data suggest that S_2 formation at the planet’s surface occurs via the following equilibrium reaction: $4\text{CO}(\text{g}) + 2\text{SO}_2(\text{g}) \rightleftharpoons 4\text{CO}_2(\text{g}) + \text{S}_2(\text{g})$. Write an expression for K for this reaction and then relate this expression to those for the following reactions:
- a. $2\text{CO}(\text{g}) + \text{SO}_2(\text{g}) \rightleftharpoons 2\text{CO}_2(\text{g}) + 1/2 \text{S}_2(\text{g})$
 $\text{CO}(\text{g}) + 1/2 \text{SO}_2(\text{g}) \rightleftharpoons \text{CO}_2(\text{g}) + 1/4 \text{S}_2(\text{g})$

- b. At 450°C, the equilibrium pressure of CO₂ is 85.0 atm, SO₂ is 1.0 atm, CO is 1.0 atm, and S₂ is 3.0 × 10⁻³ atm. What are K and K_p at this temperature? What is the concentration of S₂?
10. ♦ Until the early part of the 20th century, commercial production of sulfuric acid was carried out by the “lead-chamber” process, in which SO₂ was oxidized to H₂SO₄ in a lead-lined room. This process may be summarized by the following sequence of reactions:
- NO(g) + NO₂(g) + 2H₂SO₄(l) ⇌ 2NOHSO₄(s) + H₂O(l) K₁
 - 2NOHSO₄(s) + SO₂(g) + 2H₂O(l) ⇌ 3H₂SO₄(l) + 2NO(g) K₂
- Write the equilibrium constant expressions for reactions 1 and 2 and the sum of the reactions (reaction 3).
 - Show that K₃ = K₁ × K₂.
 - If insufficient water is added in reaction 2 such that the reaction becomes NOHSO₄(s) + 1/2 SO₂(g) + H₂O(l) ⇌ 3/2 H₂SO₄(l) + NO(g) does K₃ still equal K₁ × K₂?
 - Based on part c, write the equilibrium constant expression for K₂.
11. Phosgene (carbon dichloride, COCl₂) is a colorless, highly toxic gas with an odor similar to that of moldy hay. Used as a lethal gas in war, phosgene can be immediately fatal; inhalation can cause either pneumonia or pulmonary edema. For the equilibrium reaction COCl₂(g) ⇌ CO(g) + Cl₂(g) K_p is 0.680 at -10°C. If the initial pressure of COCl₂ is 0.681 atm, what is the partial pressure of each component of this equilibrium system? Is the formation of products or reactant favored in this reaction?
12. ♦ British bituminous coal has a high sulfur content and produces much smoke when burned. In 1952, burning of this coal in London led to elevated levels of smog containing high concentrations of sulfur dioxide, a lung irritant, and more than 4000 people died. Sulfur dioxide emissions can be converted to SO₃ and ultimately to H₂SO₄, which is the cause of acid rain. The initial reaction is 2SO₂(g) + O₂(g) ⇌ 2SO₃(g) for which K_p = 44.
- Given this K_p, are product or reactants favored in this reaction?
 - What is the partial pressure of each species under equilibrium conditions if the initial pressure of each reactant is 0.50 atm?
 - Would an increase in pressure favor the formation of product or reactants? Why?
13. Oxyhemoglobin is the oxygenated form of hemoglobin, the oxygen-carrying pigment of red blood cells. Hemoglobin is built from α and β protein chains. Assembly of the oxygenated (oxy) and deoxygenated (deoxy) β-chains has been studied with the following results:
- $$4\beta(\text{oxy}) \rightleftharpoons \beta_4(\text{oxy}) \quad K = 9.07 \times 10^{15}$$
- $$4\beta(\text{deoxy}) \rightleftharpoons \beta_4(\text{deoxy}) \quad K = 9.20 \times 10^{13}$$
- Is it more likely that hemoglobin β chains assemble in an oxygenated or deoxygenated state? Explain your answer.
14. ♦ Inorganic weathering reactions can turn silicate rocks, such as diopside (CaMgSi₂O₆), to carbonate via the following reaction:
- $$\text{CaMgSi}_2\text{O}_6 + \text{CO}_2(\text{g}) \rightleftharpoons \text{MgSiO}_3(\text{s}) + \text{CaCO}_3(\text{s}) + \text{SiO}_2(\text{s})$$
- Write an expression for the equilibrium constant. Although this reaction occurs on both Earth and Venus, the high surface temperature of Venus causes the reaction to be driven in one direction on that planet. Predict whether high temperatures will drive the reaction to the right or the left and then justify your answer. The estimated partial pressure of carbon dioxide on Venus is 85 atm due to the dense Venusian atmosphere. How does this pressure influence the reaction?
15. Silicon and its inorganic compounds are widely used to manufacture textile glass fibers, cement, ceramic products, and synthetic fillers. Two of the most important industrially utilized silicon halides are SiCl₄ and SiHCl₃, formed by reaction of elemental silicon with HCl at temperatures greater than 300°C:
- $$\text{Si}(\text{s}) + 4\text{HCl}(\text{g}) \rightleftharpoons \text{SiCl}_4(\text{g}) + 2\text{H}_2(\text{g})$$
- $$\text{Si}(\text{s}) + 3\text{HCl}(\text{g}) \rightleftharpoons \text{SiHCl}_3(\text{g}) + \text{H}_2(\text{g})$$
- Which of these two reactions is favored by increasing [HCl]? by decreasing the volume of the system?
16. ♦ The first step in the utilization of glucose in humans is the conversion of glucose to glucose-6-phosphate via the transfer of a phosphate group from ATP (adenosine triphosphate), which produces glucose-6-phosphate and ADP (adenosine diphosphate):
- $$\text{glucose} + \text{ATP} \rightleftharpoons \text{glucose-6-phosphate} + \text{ADP} \quad K = 680 \text{ at } 25^\circ\text{C}$$
- Is the formation of products or reactants favored in this reaction?
 - Would K increase, decrease, or remain the same if the glucose concentration were doubled?
 - If -RT ln K = -RT ln K', what would K be if the temperature were decreased to 0°C?
 - Is the formation of products favored by an increase or a decrease in the temperature of the system?

17. In the presence of O_2 , the carbon atoms of glucose can be fully oxidized to CO_2 with a release of free energy almost 20 times greater than that possible under conditions in which O_2 is not present. In many animal cells, the TCA cycle (tricarboxylic acid cycle) is the second stage in the complete oxidation of glucose. One reaction in the TCA cycle is the conversion of citrate to isocitrate, for which $K = 0.08$ in the forward direction. Speculate why the cycle continues despite this unfavorable value of K . What happens if the citrate concentration increases?
18. ♦ Soil is an open system, subject to natural inputs and outputs that may change its chemical composition. Aqueous-phase, adsorbed, and solid-phase forms of $Al(III)$ are of critical importance in controlling the acidity of soils, although industrial effluents, such as sulfur and nitrogen oxide gases, and fertilizers containing nitrogen can also have a large effect. Dissolution of the mineral gibbsite, which contains Al in the form $Al(OH)_3(s)$, occurs in soil according to the following reaction:

When gibbsite is in a highly crystalline state, $K = 9.35$ for this reaction at 298 K. In the microcrystalline state, $K = 8.11$. Is this change consistent with the increased surface area of the microcrystalline state?

ANSWERS

- 1.
- 2.
3.
 - a. reactant
 - b. $[Cl_2] = [PCl_3] = 0.0836 \text{ M}$; $[PCl_5] = 0.166 \text{ M}$
 - c. increasing pressure favors reactant (PCl_5)
 - d. $1.59 \times 10^{-3} \text{ kg}$; 52.5%
- 4.
5. Products are favored;

$$K = \frac{[\text{chloralhydrate}]}{[Cl_3CHO][H_2O]}$$

high concentrations of water will favor chloral hydrate formation.

- 6.
- 7.
- 8.
9. $K = \frac{[CO_2]^4 [S_2]}{[CO]^4 [SO_2]^2}$
 - a. $K' = \frac{[CO_2]^2 [S_2]^{1/2}}{[CO]^2 [SO_2]} = K^{1/2}$
 - b. $K'' = \frac{[CO_2] [S_2]^{1/4}}{[CO] [SO_2]^{1/2}} = K^{1/4}$
 - c. $K_p = 1.6$; $K = 93$; $[S_2] = 5.1 \times 10^{-10} \text{ M}$
- 10.
11. $P(CO) = P(Cl_2) = 0.421 \text{ atm}$; $P(COCl_2) = 0.260 \text{ atm}$ reactants are slightly favored.
- 12.
- 13.
- 14.
15. Both reactions are favored by increasing $[HCl]$ and decreasing volume.
- 16.
- 17.
- 18.

Learning Objectives

- To understand the autoionization reaction of liquid water.
- To know the relationship among pH, pOH, and pK_w .

As you learned in [Chapter 8](#) and [Chapter 4](#), acids and bases can be defined in several different ways ([Table 16.1.1](#)). Recall that the Arrhenius definition of an acid is a substance that dissociates in water to produce H^+ ions (protons), and an Arrhenius base is a substance that dissociates in water to produce OH^- (hydroxide) ions. According to this view, an acid–base reaction involves the reaction of a proton with a hydroxide ion to form water. Although Brønsted and Lowry defined an acid similarly to Arrhenius by describing an acid as any substance that can *donate* a proton, the Brønsted–Lowry definition of a base is much more general than the Arrhenius definition. In Brønsted–Lowry terms, a base is any substance that can *accept* a proton, so a base is not limited to just a hydroxide ion. This means that for every Brønsted–Lowry acid, there exists a corresponding conjugate base with one fewer proton, as we demonstrated in [Chapter 8](#). Consequently, all Brønsted–Lowry acid–base reactions actually involve *two* conjugate acid–base pairs and the transfer of a *proton* from one substance (the acid) to another (the base). In contrast, the Lewis definition of acids and bases, discussed in [Chapter 8](#), focuses on accepting or donating *pairs of electrons* rather than protons. A Lewis base is an electron-pair donor, and a Lewis acid is an electron-pair acceptor.

Table 16.1.1 Definitions of Acids and Bases

	Acids	Bases
Arrhenius	H^+ donor	OH^- donor
Brønsted–Lowry	H^+ donor	H^+ acceptor
Lewis	electron-pair acceptor	electron-pair donor

Because this chapter deals with acid–base equilibria in *aqueous solution*, our discussion will use primarily the Brønsted–Lowry definitions and nomenclature. Remember, however, that all three definitions are just different ways of looking at the same kind of reaction: a proton is an acid, and the hydroxide ion is a base—no matter which definition you use. In practice, chemists tend to use whichever definition is most helpful to make a particular point or understand a given system. If, for example, we refer to a base as having one or more lone pairs of electrons that can accept a proton, we are simply combining the Lewis and Brønsted–Lowry definitions to emphasize the characteristic properties of a base.

In [Chapter 8](#), we also introduced the acid–base properties of water, its *autoionization reaction*, and the definition of pH. The purpose of this section is to review those concepts and describe them using the concepts of chemical equilibrium developed in [Chapter 15](#).

Acid–Base Properties of Water

The structure of the water molecule, with its polar O–H bonds and two lone pairs of electrons on the oxygen atom, was described in [Chapter 8](#) and [Chapter 4](#), and the structure of liquid water was discussed in [Chapter 13](#). Recall that because of its highly polar structure, liquid water can act as either an acid (by donating a proton to a base) or a base (by using a lone pair of electrons to accept

a proton). For example, when a strong acid such as HCl dissolves in water, it dissociates into chloride ions (Cl^-) and protons (H^+). As you learned in [Chapter 8](#), the proton, in turn, reacts with a water molecule to form the *hydronium ion* (H_3O^+):

In this reaction, HCl is the acid, and water acts as a base by accepting an H^+ ion. The reaction in [Equation 16.1.1](#) is often written in a simpler form by removing H_2O from each side:

In [Equation 16.1.2](#), the hydronium ion is represented by H^+ , although free H^+ ions do not exist in liquid water.

Water can also act as an acid, as shown in [Equation 16.1.3](#). In this equilibrium reaction, H_2O donates a proton to NH_3 , which acts as a base:

Thus water is amphiprotic, meaning that it can behave as either an acid or a base, depending on the nature of the other reactant. Notice that [Equation 16.3](#) is an equilibrium reaction as indicated by the double arrow.

The Ion-Product Constant of Liquid Water

Because water is amphiprotic, one water molecule can react with another to form an OH^- ion and an H_3O^+ ion in an autoionization process:

The equilibrium constant K for this reaction can be written as follows:

$$K = \frac{[\text{H}_3\text{O}^+_{(aq)}][\text{OH}^-_{(aq)}]}{[\text{H}_2\text{O}(l)]^2} \quad (16.1.5)$$

When pure liquid water is in equilibrium with hydronium and hydroxide ions at 25°C , the concentrations of the hydronium ion and the hydroxide ion are equal: $[\text{H}_3\text{O}^+] = [\text{OH}^-] = 1.003 \times 10^{-7} \text{ M}$. Thus the number of dissociated water molecules is very small indeed, approximately 2 ppb. We can calculate $[\text{H}_2\text{O}]$ at 25°C from the density of water at this temperature (0.997 g/mL):

$$[\text{H}_2\text{O}(l)] = \text{mol/L} = (0.997 \text{ g/mL}) \left(\frac{1 \text{ mol}}{18.02 \text{ g}} \right) \left(\frac{1000 \text{ mL}}{L} \right) = 55.3 \text{ M} \quad (16.1.6)$$

With so few water molecules dissociated, the equilibrium of the autoionization reaction ([Equation 16.4](#)) lies far to the left. Consequently, $[\text{H}_2\text{O}]$ is essentially unchanged by the autoionization reaction and can be treated as a constant. Incorporating this constant into the equilibrium expression allows us to rearrange [Equation 16.1.5](#) to define a new equilibrium constant, the ion-product constant of liquid water (K_w)

$$K = \frac{K_w}{[\text{H}_2\text{O}(l)]^2} \quad (16.1.7a)$$

with

$$K_w = [\text{H}_3\text{O}^+_{(aq)}][\text{OH}^-_{(aq)}] = [\text{H}_3\text{O}^+_{(aq)}][\text{OH}^-_{(aq)}] \quad (16.1.7b)$$

Substituting the values for $[\text{H}_3\text{O}^+]$ and $[\text{OH}^-]$ at 25°C into this expression,

$$K_w = (1.003 \times 10^{-7})(1.003 \times 10^{-7}) = 1.006 \times 10^{-14} \quad (16.1.8)$$

Thus, to three significant figures, $K_w = 1.01 \times 10^{-14} \text{ M}$. Like any other equilibrium constant, K_w varies with temperature, ranging from 1.15×10^{-15} at 0°C to 4.99×10^{-14} at 100°C .

In pure water, the concentrations of the hydronium ion and the hydroxide ion are equal, and the solution is therefore neutral. If $[\text{H}_3\text{O}^+] > [\text{OH}^-]$, however, the solution is acidic, whereas if $[\text{H}_3\text{O}^+] < [\text{OH}^-]$, the solution is basic. For an aqueous solution, the H_3O^+ concentration is a quantitative measure of acidity: the higher the H_3O^+ concentration, the more acidic the solution.

Conversely, the higher the OH^- concentration, the more basic the solution. In most situations that you will encounter, the H_3O^+ and OH^- concentrations from the dissociation of water are so small ($1.003 \times 10^{-7} \text{ M}$) that they can be ignored in calculating the H_3O^+ or OH^- concentrations of solutions of acids and bases, but this is not always the case.

The Relationship among pH, pOH, and $\text{p}K_w$

The *pH scale* is a concise way of describing the H_3O^+ concentration and hence the acidity or basicity of a solution. Recall from [Chapter 8](#) that pH and the H^+ (H_3O^+) concentration are related as follows:

$$\text{pH} = -\log_{10}[\text{H}^+(\text{aq})] \quad (16.1.9)$$

$$[\text{H}^+(\text{aq})] = 10^{-\text{pH}} \quad (16.1.10)$$

Because the scale is logarithmic, a pH difference of 1 between two solutions corresponds to a difference of a factor of 10 in their hydronium ion concentrations. (Refer to Essential Skills 3 in [Section 8.11](#), if you need to refresh your memory about how to use logarithms.) Recall also that the pH of a neutral solution is 7.00 ($[\text{H}_3\text{O}^+] = 1.0 \times 10^{-7} \text{ M}$), whereas acidic solutions have $\text{pH} < 7.00$ (corresponding to $[\text{H}_3\text{O}^+] > 1.0 \times 10^{-7}$) and basic solutions have $\text{pH} > 7.00$ (corresponding to $[\text{H}_3\text{O}^+] < 1.0 \times 10^{-7}$).

Similar notation systems are used to describe many other chemical quantities that contain a large negative exponent. For example, chemists use an analogous *pOH scale* to describe the hydroxide ion concentration of a solution. The pOH and $[\text{OH}^-]$ are related as follows:

$$\text{pOH} = -\log_{10}[\text{OH}^-(\text{aq})] \quad (16.1.11)$$

$$[\text{OH}^-(\text{aq})] = 10^{-\text{pOH}} \quad (16.1.12)$$

The constant K_w can also be expressed using this notation, where $\text{p}K_w = -\log K_w$.

Because a neutral solution has $[\text{OH}^-] = 1.0 \times 10^{-7}$, the pOH of a neutral solution is 7.00. Consequently, the sum of the pH and the pOH for a neutral solution at 25°C is $7.00 + 7.00 = 14.00$. We can show that the sum of pH and pOH is equal to 14.00 for any aqueous solution at 25°C by taking the negative logarithm of both sides of [Equation 16.7](#):

$$-\log K_w = -\log([\text{H}_3\text{O}^+(\text{aq})][\text{OH}^-(\text{aq})]) = (-\log[\text{H}_3\text{O}^+(\text{aq})]) + (-\log[\text{OH}^-(\text{aq})]) = \text{pH} + \text{pOH} \quad (16.1.13)$$

Thus at any temperature, $\text{pH} + \text{pOH} = \text{p}K_w$, so at 25°C, where $K_w = 1.0 \times 10^{-14}$, $\text{pH} + \text{pOH} = 14.00$. More generally, the pH of any neutral solution is half of the $\text{p}K_w$ at that temperature. The relationship among pH, pOH, and the acidity or basicity of a solution is summarized graphically in [Figure 16.1.1](#) over the common pH range of 0 to 14. Notice the inverse relationship between the pH and pOH scales.

Note the Pattern

For any neutral solution, $\text{pH} + \text{pOH} = 14.00$ (at 25°C) and $\text{pH} = 14 - \text{pOH}$.

Figure 16.1.1 The Inverse Relationship between the pH and pOH Scales As pH decreases, $[H^+]$ and the acidity increase. As pOH increases, $[OH^-]$ and the basicity decrease. Common substances have pH values that range from extremely acidic to extremely basic.

Example 16.1.1

The K_w for water at 100°C is 4.99×10^{-13} . Calculate pK_w for water at this temperature and the pH and the pOH for a neutral aqueous solution at 100°C . Report pH and pOH values to two decimal places.

Given: K_w

Asked for: pK_w , pH, and pOH

Strategy:

A Calculate pK_w by taking the negative logarithm of K_w .

B For a neutral aqueous solution, $[H_3O^+] = [OH^-]$. Use this relationship and [Equation 16.7](#) to calculate $[H_3O^+]$ and $[OH^-]$. Then determine the pH and the pOH for the solution.

Solution:

A Because pK_w is the negative logarithm of K_w , we can write

$$pK_w = -\log K_w = -\log(4.99 \times 10^{-13}) = 12.302$$

The answer is reasonable: K_w is between 10^{-13} and 10^{-12} , so pK_w must be between 12 and 13.

B [Equation 16.1.7](#) shows that $K_w = [H_3O^+][OH^-]$. Because $[H_3O^+] = [OH^-]$ in a neutral solution, we can let $x = [H_3O^+] = [OH^-]$:

$$K_w = [H_3O^+][OH^-] = (x)(x) = x^2$$

$$x = \sqrt{K_w} = \sqrt{4.99 \times 10^{-13}} = 7.06 \times 10^{-7} \text{ M}$$

Because x is equal to both $[H_3O^+]$ and $[OH^-]$,

$$\text{pH} = \text{pOH} = -\log(7.06 \times 10^{-7}) = 6.15 \text{ (to two decimal places)}$$

We could obtain the same answer more easily (without using logarithms) by using the pK_w . In this case, we know that $pK_w = 12.302$, and from [Equation 16.13](#), we know that $pK_w = \text{pH} + \text{pOH}$. Because $\text{pH} = \text{pOH}$ in a neutral solution, we can use [Equation 16.13](#) directly, setting $\text{pH} = \text{pOH} = y$. Solving to two decimal places we obtain the following:

$$pK_w = \text{pH} + \text{pOH} = y + y = 2y$$

$$y = \frac{pK_w}{2} = \frac{12.302}{2} = 6.15 = \text{pH} = \text{pOH}$$

Exercise

Humans maintain an internal temperature of about 37°C . At this temperature, $K_w = 3.55 \times 10^{-14}$. Calculate pK_w and the pH and the pOH of a neutral solution at 37°C . Report pH and pOH values to two decimal places.

Answer: $pK_w = 13.45$ $\text{pH} = \text{pOH} = 6.73$

Summary

Water is **amphiprotic**: it can act as an acid by donating a proton to a base to form the hydroxide ion, or as a base by accepting a proton from an acid to form the hydronium ion (H_3O^+). The *autoionization* of liquid water produces OH^- and H_3O^+ ions. The equilibrium constant for this reaction is called the **ion-product constant of liquid water** (K_w) and is defined as $K_w = [\text{H}_3\text{O}^+][\text{OH}^-]$. At 25°C , K_w is 1.01×10^{-14} ; hence $\text{pH} + \text{pOH} = \text{p}K_w = 14.00$.

Key Takeaway

- For any neutral solution, $\text{pH} + \text{pOH} = 14.00$ (at 25°C) and $\text{pH} = 1/2 \text{p}K_w$.

Key Equations

Ion-product constant of liquid water

Equation 16.1.7: $K_w = [\text{H}_3\text{O}^+][\text{OH}^-]$

Definition of pH

Equation 16.1.9: $\text{pH} = -\log_{10}[\text{H}^+]$

Equation 16.1.10: $[\text{H}^+] = 10^{-\text{pH}}$

Definition of pOH

Equation 16.1.11: $\text{pOH} = -\log_{10}[\text{OH}^-]$

Equation 16.1.12: $[\text{OH}^-] = 10^{-\text{pOH}}$

Relationship among pH, pOH, and $\text{p}K_w$

Equation 16.1.13: $\text{p}K_w = \text{pH} + \text{pOH}$

Conceptual Problems

- What is the relationship between the value of the equilibrium constant for the autoionization of liquid water and the tabulated value of the ion-product constant of liquid water (K_w)?
- The density of liquid water decreases as the temperature increases from 25°C to 50°C . Will this effect cause K_w to increase or decrease? Why?
- Show that water is amphiprotic by writing balanced chemical equations for the reactions of water with HNO_3 and NH_3 . In which reaction does water act as the acid? In which does it act as the base?
- Write a chemical equation for each of the following.
 - Nitric acid is added to water.
 - Potassium hydroxide is added to water.
 - Calcium hydroxide is added to water.
 - Sulfuric acid is added to water.
- Show that K for the sum of the following reactions is equal to K_w .

Answers

1.
$$K_{\text{auto}} = \frac{[\text{H}_3\text{O}^+][\text{OH}^-]}{[\text{H}_2\text{O}]^2}$$

$$K_w = [H_3O^+][OH^-] = K_{auto}[H_2O]^2$$

2.
3. water is the base:

water is the acid:

4.
5.

Numerical Problems

1. The autoionization of sulfuric acid can be described by the following chemical equation:

At 25°C, $K = 3 \times 10^{-4}$. Write an equilibrium constant expression for $K(H_2SO_4)$ that is analogous to K_w . The density of H_2SO_4 is 1.8 g/cm³ at 25°C. What is the concentration of $H_3SO_4^+$? What fraction of H_2SO_4 is ionized?

2. An aqueous solution of a substance is found to have $[H_3O^+] = 2.48 \times 10^{-4}$ M. Is the solution acidic, neutral, or basic?
3. The pH of a solution is 5.63. What is its pOH? What is the $[OH^-]$? Is the solution acidic or basic?
4. State whether each solution is acidic, neutral, or basic.
- $[H_3O^+] = 8.6 \times 10^{-9}$ M
 - $[H_3O^+] = 3.7 \times 10^{-7}$ M
 - $[H_3O^+] = 2.1 \times 10^{-6}$ M
 - $[H_3O^+] = 1.4 \times 10^{-4}$ M
5. Calculate the pH and the pOH of each solution.
- 0.15 M HBr
 - 0.03 M KOH
 - 2.3×10^{-2} M HNO_3
 - 9.78×10^{-2} M NaOH
 - 0.00017 M HCl
 - 5.78 M HI
6. Calculate the pH and the pOH of each solution.
- 25.0 mL of 2.3×10^{-2} M HCl, diluted to 100 mL
 - 5.0 mL of 1.87 M NaOH, diluted to 125 mL
 - 5.0 mL of 5.98 M HCl added to 100 mL of water
 - 25.0 mL of 3.7 M HNO_3 added to 250 mL of water
 - 35.0 mL of 0.046 M HI added to 500 mL of water
 - 15.0 mL of 0.0087 M KOH added to 250 mL of water.
7. The pH of stomach acid is approximately 1.5. What is the $[H^+]$?
8. Given the pH values in parentheses, what is the $[H^+]$ of each solution?
- household bleach (11.4)
 - milk (6.5)
 - orange juice (3.5)
 - seawater (8.5)
 - tomato juice (4.2)
9. A reaction requires the addition of 250.0 mL of a solution with a pH of 3.50. What mass of HCl (in milligrams) must be dissolved in 250 mL of water to produce a solution with this pH?
10. If you require 333 mL of a pH 12.50 solution, how would you prepare it using a 0.500 M sodium hydroxide stock solution?

Answers

$$1. \quad K_{H_2SO_4} = [H_3SO_4^+][HSO_4^-] = K[H_2SO_4]_2$$

$$[H_3SO_4^+] = 0.3M$$

$[H_3SO_4^+] = 0.3 M$; the fraction ionized is 0.02.

$$2. \quad pOH = 8.37; [OH^-] = 4.3 \times 10^{-9} M; \text{acidic}$$

4.

5. a. pH = 0.82; pOH = 13.18
- b. pH = 12.5; pOH = 1.5
- c. pH = 2.64; pOH = 11.36
- d. pH = 12.990; pOH = 1.010
- e. pH = 3.77; pOH = 10.23
- f. pH = -0.762; pOH = 14.762

6.

Learning Objectives

- To understand the concept of conjugate acid–base pairs.
- To know the relationship between acid or base strength and the magnitude of K_a , K_b , pK_a , and pK_b .
- To understand the leveling effect.

We now turn our attention to acid–base reactions to see how the concepts of chemical equilibrium and equilibrium constants can deepen our understanding of this kind of chemical behavior. We begin with a qualitative description of acid–base equilibria in terms of the Brønsted–Lowry model and then proceed to a quantitative description in [Section 16.4](#).

Conjugate Acid–Base Pairs

In aqueous solutions, acids and bases can be defined in terms of the transfer of a proton from an acid to a base. Thus for every acidic species in an aqueous solution, there exists a species derived from the acid by the loss of a proton. These two species that differ by only a proton constitute a conjugate acid–base pair. For example, in the reaction of HCl with water ([Equation 16.1.1](#)), HCl, the *parent acid*, donates a proton to a water molecule, the *parent base*, thereby forming Cl^- . Thus HCl and Cl^- constitute a conjugate acid–base pair. By convention, we always write a conjugate acid–base pair as the acid followed by its conjugate base. In the reverse reaction, the Cl^- ion in solution acts as a base to accept a proton from H_3O^+ , forming H_2O and HCl. Thus H_3O^+ and H_2O constitute a second conjugate acid–base pair. In general, any acid–base reaction must contain *two* conjugate acid–base pairs, which in this case are HCl/Cl^- and $\text{H}_3\text{O}^+/\text{H}_2\text{O}$.

Note the Pattern

All acid–base reactions contain *two* conjugate acid–base pairs.

Similarly, in the reaction of acetic acid with water, acetic acid donates a proton to water, which acts as the base. In the reverse reaction, H_3O^+ is the acid that donates a proton to the acetate ion, which acts as the base. Once again, we have two conjugate acid–base pairs: the parent acid and its conjugate base ($\text{CH}_3\text{CO}_2\text{H}/\text{CH}_3\text{CO}_2^-$) and the parent base and its conjugate acid ($\text{H}_3\text{O}^+/\text{H}_2\text{O}$).

In the reaction of ammonia with water to give ammonium ions and hydroxide ions (Equation 16.1.3), ammonia acts as a base by accepting a proton from a water molecule, which in this case means that water is acting as an acid. In the reverse reaction, an ammonium ion acts as an acid by donating a proton to a hydroxide ion, and the hydroxide ion acts as a base. The conjugate acid–base pairs for this reaction are $\text{NH}_4^+/\text{NH}_3$ and $\text{H}_2\text{O}/\text{OH}^-$. Some common conjugate acid–base pairs are shown in Figure 16.2.1.

	ACID		BASE
	OH^-	strongest	O^{2-}
	HS^-		S^{2-}
	H_2O		OH^-
	HPO_4^{2-}		PO_4^{3-}
	HCO_3^-		CO_3^{2-}
	NH_4^+		BH_3
	HCN		CN^-
	H_2PO_4^-		HPO_4^{2-}
	HSO_4^-	weak	SO_3^{2-}
	H_2S		HS^-
	H_2CO_3		HCO_3^-
	$\text{C}_6\text{H}_5\text{NH}^+$		$\text{C}_6\text{H}_5\text{N}$
	$\text{CH}_3\text{CO}_2\text{H}$		CH_3CO_2^-
	HF		F^-
	H_2PO_4^-		H_2PO_4^-
	H_2SO_4		HSO_4^-
	HSO_4^-		SO_4^{2-}
	H_2O^+		H_2O
	HNO_3		NO_2^-
	H_2SO_4		HSO_4^-
	HCl		Cl^-
	HBr		Br^-
		weakest	

Relative acid strength increasing ↓ (left column)
Relative base strength increasing ↑ (right column)

Figure 16.2.1 The Relative Strengths of Some Common Conjugate Acid–Base Pairs The strongest acids are at the bottom left, and the strongest bases are at the top right. The conjugate base of a strong acid is a very weak base, and, conversely, the conjugate acid of a strong base is a very weak acid.

Acid–Base Equilibrium Constants: K_a , K_b , pK_a , and pK_b

The magnitude of the equilibrium constant for an ionization reaction can be used to determine the relative strengths of acids and bases. For example, the general equation for the ionization of a weak acid in water, where HA is the parent acid and A^- is its conjugate base, is as follows:

The equilibrium constant for this dissociation is as follows:

$$K = \frac{[H_3O^+][A^-]}{[H_2O][HA]} \quad (16.2.2)$$

As we noted earlier, the concentration of water is essentially constant for all reactions in aqueous solution, so $[H_2O]$ in Equation 16.2.2 can be incorporated into a new quantity, the acid ionization constant (K_a)_A (aq), also called the *acid dissociation constant*:

$$K_a = K[H_2O] = \frac{[H_3O^+][A^-]}{[HA]} \quad (16.2.3)$$

Thus the numerical values of K and K_a differ by the concentration of water (55.3 M). Again, for simplicity, H_3O^+ can be written as H^+ in Equation 16.2.3. Keep in mind, though, that free H^+ does not exist in aqueous solutions and that a proton is transferred to H_2O in all acid ionization reactions to form H_3O^+ . The larger the K_a , the stronger the acid and the higher the H^+ concentration at equilibrium. Like all equilibrium constants, acid–base ionization constants are actually measured in terms of the *activities* of H^+ or OH^- , thus making them unitless. The values of K_a for a number of common acids are given in Table 16.2.1.

Table 16.2.1 Values of K_a , pK_a , K_b , and pK_b for Selected Acids (HA) and Their Conjugate Bases (A^-)

Acid	HA	K_a	pK_a	A^-	K_b	pK_b
hydroiodic acid	HI	2×10^9	-9.3	I^-	5.5×10^{-24}	23.26
sulfuric acid (1)*	H_2SO_4	1×10^2	-2.0	HSO_4^-	1×10^{-16}	16.0
nitric acid	HNO_3	2.3×10^1	-1.37	NO_3^-	4.3×10^{-16}	15.37
hydronium ion	H_3O^+	1.0	0.00	H_2O	1.0×10^{-14}	14.00
sulfuric acid (2)*	HSO_4^-	1.0×10^{-2}	1.99	SO_4^{2-}	9.8×10^{-13}	12.01
hydrofluoric acid	HF	6.3×10^{-4}	3.20	F^-	1.6×10^{-11}	10.80
nitrous acid	HNO_2	5.6×10^{-4}	3.25	NO_2^-	1.8×10^{-11}	10.75
formic acid	HCO_2H	1.78×10^{-4}	3.750	HCO_2^-	5.6×10^{-11}	10.25
benzoic acid	$C_6H_5CO_2H$	6.3×10^{-5}	4.20	$C_6H_5CO_2^-$	1.6×10^{-10}	9.80
acetic acid	CH_3CO_2H	1.7×10^{-5}	4.76	$CH_3CO_2^-$	5.8×10^{-10}	9.24
pyridinium ion	$C_5H_5NH^+$	5.9×10^{-6}	5.23	C_5H_5N	1.7×10^{-9}	8.77
hypochlorous acid	HOCl	4.0×10^{-8}	7.40	OCl^-	2.5×10^{-7}	6.60
hydrocyanic acid	HCN	6.2×10^{-10}	9.21	CN^-	1.6×10^{-5}	4.79
ammonium ion	NH_4^+	5.6×10^{-10}	9.25	NH_3	1.8×10^{-5}	4.75
water	H_2O	1.0×10^{-14}	14.00	OH^-	1.00	0.00
acetylene	C_2H_2	1×10^{-26}	26.0	HC_2^-	1×10^{12}	-12.0
ammonia	NH_3	1×10^{-35}	35.0	NH_2^-	1×10^{21}	-21.0

*The number in parentheses indicates the ionization step referred to for a polyprotic acid.

Weak bases react with water to produce the hydroxide ion, as shown in the following general equation, where B is the parent base and BH^+ is its conjugate acid:

The equilibrium constant for this reaction is the base ionization constant (K_b), also called the *base dissociation constant*:

$$K_b = K[H_2O] = [BH^+][OH^-][B] \quad (16.2.5)$$

Once again, the concentration of water is constant, so it does not appear in the equilibrium constant expression; instead, it is included in the K_b . The larger the K_b , the stronger the base and the higher the OH^- concentration at equilibrium. The values of K_b for a number of common weak bases are given in [Table 16.2.2](#)

Table 16.2.2 Values of K_b , pK_b , K_a , and pK_a for Selected Weak Bases (B) and Their Conjugate Acids (BH^+)

Base	B	K_b	pK_b	BH^+	K_a	pK_a
hydroxide ion	OH^-	1.0	0.00*	H_2O	1.0×10^{-14}	14.00
phosphate ion	PO_4^{3-}	2.1×10^{-2}	1.68	HPO_4^{2-}	4.8×10^{-13}	12.32
dimethylamine	$(CH_3)_2NH$	5.4×10^{-4}	3.27	$(CH_3)_2NH_2^+$	1.9×10^{-11}	10.73
methylamine	CH_3NH_2	4.6×10^{-4}	3.34	$CH_3NH_3^+$	2.2×10^{-11}	10.66
trimethylamine	$(CH_3)_3N$	6.3×10^{-5}	4.20	$(CH_3)_3NH^+$	1.6×10^{-10}	9.80
ammonia	NH_3	1.8×10^{-5}	4.75	NH_4^+	5.6×10^{-10}	9.25
pyridine	C_5H_5N	1.7×10^{-9}	8.77	$C_5H_5NH^+$	5.9×10^{-6}	5.23
aniline	$C_6H_5NH_2$	7.4×10^{-10}	9.13	$C_6H_5NH_3^+$	1.3×10^{-5}	4.87
water	H_2O	1.0×10^{-14}	14.00	H_3O^+	1.0*	0.00

*As in Table 16.2 "Values of ".

There is a simple relationship between the magnitude of K_a for an acid and K_b for its conjugate base. Consider, for example, the ionization of hydrocyanic acid (HCN) in water to produce an acidic solution, and the reaction of CN^- with water to produce a basic solution:

The equilibrium constant expression for the ionization of HCN is as follows:

$$K_a = \frac{[H^+][CN^-]}{[HCN]} \quad (16.2.8)$$

The corresponding expression for the reaction of cyanide with water is as follows:

$$K_b = \frac{[OH^-][HCN]}{[CN^-]} \quad (16.2.9)$$

If we add [Equation 16.2.8](#) and [Equation 16.2.9](#), we obtain the following (recall from [Chapter 15](#) that the equilibrium constant for the sum of two reactions is the product of the equilibrium constants for the individual reactions):

In this case, the sum of the reactions described by K_a and K_b is the equation for the autoionization of water, and the product of the two equilibrium constants is K_w :

$$K_a K_b = K_w \quad (16.2.10)$$

Thus if we know either K_a for an acid or K_b for its conjugate base, we can calculate the other equilibrium constant for any conjugate acid–base pair.

Just as with pH, pOH, and pK_w , we can use negative logarithms to avoid exponential notation in writing acid and base ionization constants, by defining pK_a as follows:

$$pK_a = -\log_{10} K_a \quad (16.2.11)$$

$$K_a = 10^{-pK_a} \quad (16.2.12)$$

and pK_b as

$$pK_b = -\log_{10} K_b \quad (16.2.13)$$

$$K_b = 10^{-pK_b} \quad (16.2.14)$$

Similarly, [Equation 16.2.10](#), which expresses the relationship between K_a and K_b , can be written in logarithmic form as follows:

$$pK_a + pK_b = pK_w \quad (16.2.15)$$

At 25°C, this becomes

$$pK_a + pK_b = 14.00 \quad (16.2.16)$$

The values of pK_a and pK_b are given for several common acids and bases in [Table 16.2.1](#) and [Table 16.2.2](#), respectively, and a more extensive set of data is provided in [Tables E1](#) and [E2](#). Because of the use of negative logarithms, smaller values of pK_a correspond to larger acid ionization constants and hence stronger acids. For example, nitrous acid (HNO_2), with a pK_a of 3.25, is about a 1000 times stronger acid than hydrocyanic acid (HCN), with a pK_a of 9.21. Conversely, smaller values of pK_b correspond to larger base ionization constants and hence stronger bases.

The relative strengths of some common acids and their conjugate bases are shown graphically in [Figure 16.2.1](#). The conjugate acid–base pairs are listed in order (from top to bottom) of increasing acid strength, which corresponds to decreasing values of pK_a . This order corresponds to decreasing strength of the conjugate base or increasing values of pK_b . At the bottom left of [Figure 16.2 "The Relative Strengths of Some Common Conjugate Acid–Base Pairs"](#) are the common strong acids; at the top right are the most common strong bases. Notice the inverse relationship between the strength of the parent acid and the strength of the conjugate base. Thus the conjugate base of a strong acid is a very weak base, and the conjugate base of a very weak acid is a strong base.

Note the Pattern

The conjugate base of a strong acid is a weak base and vice versa.

We can use the relative strengths of acids and bases to predict the direction of an acid–base reaction by following a single rule: *an acid–base equilibrium always favors the side with the weaker acid and base, as indicated by these arrows:*

In an acid–base reaction, the proton always reacts with the stronger base.

For example, hydrochloric acid is a strong acid that ionizes essentially completely in dilute aqueous solution to produce H_3O^+ and Cl^- ; only negligible amounts of HCl molecules remain undissociated. Hence the ionization equilibrium lies virtually all the way to the right, as represented by a single arrow:

In contrast, acetic acid is a weak acid, and water is a weak base. Consequently, aqueous solutions of acetic acid contain mostly acetic acid molecules in equilibrium with a small concentration of H_3O^+ and acetate ions, and the ionization equilibrium lies far to the left, as represented by these arrows:

Similarly, in the reaction of ammonia with water, the hydroxide ion is a strong base, and ammonia is a weak base, whereas the ammonium ion is a stronger acid than water. Hence this equilibrium also lies to the left:

Note the Pattern

All acid–base equilibria favor the side with the weaker acid and base. Thus the proton is bound to the stronger base.

Example 16.2.1

1. Calculate K_b and pK_b of the butyrate ion ($\text{CH}_3\text{CH}_2\text{CH}_2\text{CO}_2^-$). The pK_a of butyric acid at 25°C is 4.83. Butyric acid is responsible for the foul smell of rancid butter.
2. Calculate K_a and pK_a of the dimethylammonium ion $[(\text{CH}_3)_2\text{NH}_2]^+$. The base ionization constant K_b of dimethylamine $[(\text{CH}_3)_2\text{NH}]$ is 5.4×10^{-4} at 25°C.

Given: pK_a and K_b

Asked for: corresponding K_b and pK_b , K_a and pK_a

Strategy:

The constants K_a and K_b are related as shown in [Equation 16.2.10](#). The pK_a and pK_b for an acid and its conjugate base are related as shown in [Equation 16.2.15](#) and [Equation 16.2.16](#). Use the relationships $pK = -\log K$ and $K = 10^{-pK}$ ([Equation 16.24](#) and [Equation 16.26](#)) to convert between K_a and pK_a or K_b and pK_b .

Solution:

1. We are given the pK_a for butyric acid and asked to calculate the K_b and the pK_b for its conjugate base, the butyrate ion. Because the pK_a value cited is for a temperature of 25°C, we can use [Equation 16.2.16](#): $pK_a + pK_b = pK_w = 14.00$. Substituting the pK_a and solving for the pK_b ,

$$4.83 + pK_b = 14.00$$

$$pK_b = 14.00 - 4.83 = 9.17$$

Because $pK_b = -\log K_b$, K_b is $10^{-9.17} = 6.8 \times 10^{-10}$.

2. In this case, we are given K_b for a base (dimethylamine) and asked to calculate K_a and pK_a for its conjugate acid, the dimethylammonium ion. Because the initial quantity given is K_b rather than pK_b , we can use [Equation 16.23](#): $K_a K_b = K_w$. Substituting the values of K_b and K_w at 25°C and solving for K_a ,

$$K_a(5.4 \times 10^{-4}) = 1.01 \times 10^{-14}$$

$$K_a = 1.9 \times 10^{-11}$$

Because $pK_a = -\log K_a$, we have $pK_a = -\log(1.9 \times 10^{-11}) = 10.72$. We could also have converted K_b to pK_b to obtain the same answer:

$$pK_b = -\log(5.4 \times 10^{-4}) = 3.27$$

$$pK_a + pK_b = 14.00$$

$$pK_a = 10.73$$

$$K_a = 10^{-pK_a} = 10^{-10.73} = 1.9 \times 10^{-11}$$

If we are given any one of these four quantities for an acid or a base (K_a , pK_a , K_b , or pK_b), we can calculate the other three.

Exercise

Lactic acid [$\text{CH}_3\text{CH}(\text{OH})\text{CO}_2\text{H}$] is responsible for the pungent taste and smell of sour milk; it is also thought to produce soreness in fatigued muscles. Its pK_a is 3.86 at 25°C. Calculate K_a for lactic acid and pK_b and K_b for the lactate ion.

Answer: $K_a = 1.4 \times 10^{-4}$ for lactic acid; $pK_b = 10.14$ and $K_b = 7.2 \times 10^{-11}$ for the lactate ion

Solutions of Strong Acids and Bases: The Leveling Effect

You will notice in [Table 16.2.1](#) that acids like H_2SO_4 and HNO_3 lie *above* the hydronium ion, meaning that they have pK_a values less than zero and are stronger acids than the H_3O^+ ion. Recall from [Chapter 8](#) that the acidic proton in virtually all oxoacids is bonded to one of the oxygen atoms of the oxoanion. Thus nitric acid should properly be written as HONO_2 . Unfortunately, however, the formulas of oxoacids are almost always written with hydrogen on the left and oxygen on the right, giving HNO_3 instead. In fact, all six of the common strong acids that we first encountered in [Chapter 8](#) have pK_a values less than zero, which means that they have a greater tendency to lose a proton than does the H_3O^+ ion. Conversely, the conjugate bases of these strong acids are weaker bases than water. Consequently, the proton-transfer equilibria for these strong acids lie far to the right, and adding any of the common strong acids to water results in an essentially stoichiometric reaction of the acid with water to form a solution of the H_3O^+ ion and the conjugate base of the acid.

Although K_a for HI is about 10^8 greater than K_a for HNO_3 , the reaction of either HI or HNO_3 with water gives an essentially stoichiometric solution of H_3O^+ and I^- or NO_3^- . In fact, a 0.1 M aqueous solution of any strong acid actually contains 0.1 M H_3O^+ , regardless of the identity of the strong acid. This phenomenon is called the leveling effect. H_3O^+ : any species that is a stronger acid than the conjugate acid of water (H_3O^+) is leveled to the strength of H_3O^+ in aqueous solution because H_3O^+ is the strongest acid that can exist in equilibrium with water. Consequently, it is impossible to distinguish between the strengths of acids such as HI and HNO_3 in aqueous solution, and an alternative approach must be used to determine their relative acid strengths.

One method is to use a solvent such as anhydrous acetic acid. Because acetic acid is a stronger acid than water, it must also be a weaker base, with a lesser tendency to accept a proton than H_2O . Measurements of the conductivity of 0.1 M solutions of both HI and HNO_3 in acetic acid show that HI is completely dissociated, but HNO_3 is only partially dissociated and behaves like a weak acid *in this solvent*. This result clearly tells us that HI is a stronger acid than HNO_3 . The relative order of acid strengths and approximate K_a and pK_a values for the strong acids at the top of [Table 16.2.1](#) were determined using measurements like this and different nonaqueous solvents.

Note the Pattern

In aqueous solutions, $[\text{H}_3\text{O}^+]$ is the strongest acid and $[\text{OH}^-]$ is the strongest base that can exist in equilibrium with H_2O .

The leveling effect applies to solutions of strong bases as well: In aqueous solution, any base stronger than OH^- is leveled to the strength of OH^- because OH^- is the strongest base that can exist in equilibrium with water. Salts such as K_2O , NaOCH_3 (sodium methoxide), and NaNH_2 (sodamide, or sodium amide), whose anions are the conjugate bases of species that would lie below water in [Table 16.3 "Values of "](#), are all strong bases that react essentially completely (and often violently) with water, accepting a proton to give a solution of OH^- and the corresponding cation:

Other examples that you may encounter are potassium hydride (KH) and organometallic compounds such as methyl lithium (CH₃Li).

Polyprotic Acids and Bases

As you learned in [Chapter 8](#), *polyprotic acids* such as H₂SO₄, H₃PO₄, and H₂CO₃ contain more than one ionizable proton, and the protons are lost in a stepwise manner. The fully protonated species is always the strongest acid because it is easier to remove a proton from a neutral molecule than from a negatively charged ion. Thus acid strength decreases with the loss of subsequent protons, and, correspondingly, the pK_a increases. Consider H₂SO₄, for example:

The equilibrium in the first reaction lies far to the right, consistent with H₂SO₄ being a strong acid. In contrast, in the second reaction, appreciable quantities of both HSO₄⁻ and SO₄²⁻ are present at equilibrium.

Note the Pattern

For a polyprotic acid, acid strength decreases and the pK_a increases with the sequential loss of each proton.

The hydrogen sulfate ion (HSO₄⁻) is both the conjugate base of H₂SO₄ and the conjugate acid of SO₄²⁻. Just like water, HSO₄⁻ can therefore act as *either* an acid or a base, depending on whether the other reactant is a stronger acid or a stronger base. Conversely, the sulfate ion (SO₄²⁻) is a *polyprotic base* that is capable of accepting two protons in a stepwise manner:

Like any other conjugate acid–base pair, the strengths of the conjugate acids and bases are related by pK_a + pK_b = pK_w. Consider, for example, the HSO₄⁻ / SO₄²⁻ conjugate acid–base pair. From [Table 16.2.1](#), we see that the pK_a of HSO₄⁻ is 1.99. Hence the pK_b of SO₄²⁻ is 14.00 – 1.99 = 12.01. Thus sulfate is a rather weak base, whereas OH⁻ is a strong base, so the equilibrium shown above lies to the left. The HSO₄⁻ ion is also a very weak base [pK_a of H₂SO₄ = 2.0, pK_b of HSO₄⁻ = 14 – (–2.0) = 16], which is consistent with what we expect for the conjugate base of a strong acid. Thus the equilibrium also lies almost completely to the left. Once again, equilibrium favors the formation of the weaker acid–base pair.

Example 16.2.2

Predict whether the equilibrium for each reaction lies to the left or the right as written.

- $\text{NH}_4^+(\text{aq}) + \text{PO}_4^{3-}(\text{aq}) \rightleftharpoons \text{NH}_3(\text{aq}) + \text{HPO}_4^{2-}(\text{aq})$
- $\text{CH}_3\text{CH}_2\text{CO}_2\text{H}(\text{aq}) + \text{CN}^-(\text{aq}) \rightleftharpoons \text{CH}_3\text{CH}_2\text{CO}_2^-(\text{aq}) + \text{HCN}(\text{aq})$

Given: balanced chemical equation

Asked for: equilibrium position

Strategy:

Identify the conjugate acid–base pairs in each reaction. Then refer to [Table 16.2.1](#), [Table 16.2.2](#), and [Figure 16.2.1](#) to determine which is the stronger acid and base. Equilibrium always favors the formation of the weaker acid–base pair.

Solution:

1. The conjugate acid–base pairs are NH₄⁺ / NH₃ and HPO₄²⁻ / PO₄³⁻. According to [Table 16.2 "Values of "](#) and [Table 16.3 "Values of "](#), NH₄⁺ is a stronger acid (pK_a = 9.25) than HPO₄²⁻ (pK_a = 12.32), and PO₄³⁻ is a

stronger base ($pK_b = 1.68$) than NH_3 ($pK_b = 4.75$). The equilibrium will therefore lie to the right, favoring the formation of the weaker acid–base pair:

2. The conjugate acid–base pairs are $CH_3CH_2CO_2H/CH_3CH_2CO_2^-$ and HCN/CN^- . According to [Table 16.2.1](#), HCN is a weak acid ($pK_a = 9.21$) and CN^- is a moderately weak base ($pK_b = 4.79$). Propionic acid ($CH_3CH_2CO_2H$) is not listed in [Table 16.2.1](#), however. In a situation like this, the best approach is to look for a similar compound whose acid–base properties *are* listed. For example, propionic acid and acetic acid are identical except for the groups attached to the carbon atom of the carboxylic acid ($-CH_2CH_3$ versus $-CH_3$), so we might expect the two compounds to have similar acid–base properties. In particular, we would expect the pK_a of propionic acid to be similar in magnitude to the pK_a of acetic acid. (In fact, the pK_a of propionic acid is 4.87, compared to 4.76 for acetic acid, which makes propionic acid a slightly weaker acid than acetic acid.) Thus propionic acid should be a significantly stronger acid than HCN . Because the stronger acid forms the weaker conjugate base, we predict that cyanide will be a stronger base than propionate. The equilibrium will therefore lie to the right, favoring the formation of the weaker acid–base pair:

Exercise

Predict whether the equilibrium for each reaction lies to the left or the right as written.

- $H_2O(l) + HS^-(aq) \rightleftharpoons OH^-(aq) + H_2S(aq)$
- $HCO_2^-(aq) + HSO_4^-(aq) \rightleftharpoons HCO_2H(aq) + SO_4^{2-}(aq)$

Answer:

- left
- left

Acid–Base Properties of Solutions of Salts

We can also use the relative strengths of conjugate acid–base pairs to understand the acid–base properties of solutions of salts. In [Chapter 8](#), you learned that a *neutralization reaction* can be defined as the reaction of an acid and a base to produce a salt and water. That is, another cation, such as Na^+ , replaces the proton on the acid. An example is the reaction of CH_3CO_2H , a weak acid, with $NaOH$, a strong base:

Depending on the acid–base properties of its component ions, however, a salt can dissolve in water to produce a neutral solution, a basic solution, or an acidic solution.

When a salt such as $NaCl$ dissolves in water, it produces $Na^+(aq)$ and $Cl^-(aq)$ ions. Using a Lewis approach, the Na^+ ion can be viewed as an acid because it is an electron pair acceptor, although its low charge and relatively large radius make it a very weak acid. The Cl^- ion is the conjugate base of the strong acid HCl , so it has essentially no basic character. Consequently, dissolving $NaCl$ in water has no effect on the pH of a solution, and the solution remains neutral.

Now let's compare this behavior to the behavior of aqueous solutions of potassium cyanide and sodium acetate. Again, the cations (K^+ and Na^+) have essentially no acidic character, but the anions (CN^- and $CH_3CO_2^-$) are weak bases that can react with water because they are the conjugate bases of the weak acids HCN and acetic acid, respectively.

Neither reaction proceeds very far to the right as written because the formation of the weaker acid–base pair is favored. Both HCN and acetic acid are stronger acids than water, and hydroxide is a stronger base than either acetate or cyanide, so in both cases, the equilibrium lies to the left. Nonetheless, each of these reactions generates enough hydroxide ions to produce a basic solution. For example, the pH of a 0.1 M solution of sodium acetate or potassium cyanide at 25°C is 8.8 or 11.1, respectively. From [Table 16.2.2](#) and [Figure 16.2.1](#), we can see that CN^- is a stronger base ($pK_b = 4.79$) than acetate ($pK_b = 9.24$), which is consistent with KCN producing a more basic solution than sodium acetate at the same concentration.

In contrast, the conjugate acid of a weak base should be a weak acid ([Figure 16.2.1](#)). For example, ammonium chloride and pyridinium chloride are salts produced by reacting ammonia and pyridine, respectively, with HCl. As you already know, the chloride ion is such a weak base that it does not react with water. In contrast, the cations of the two salts are weak acids that react with water as follows:

[Figure 16.2.1](#) shows that H_3O^+ is a stronger acid than either NH_4^+ or $C_5H_5NH^+$, and conversely, ammonia and pyridine are both stronger bases than water. The equilibrium will therefore lie far to the left in both cases, favoring the weaker acid–base pair. The H_3O^+ concentration produced by the reactions is great enough, however, to decrease the pH of the solution significantly: the pH of a 0.10 M solution of ammonium chloride or pyridinium chloride at 25°C is 5.13 or 3.12, respectively. This is consistent with the information shown in [Figure 16.2.1](#), indicating that the pyridinium ion is more acidic than the ammonium ion.

What happens with aqueous solutions of a salt such as ammonium acetate, where both the cation *and* the anion can react separately with water to produce an acid and a base, respectively? According to Eq 16.2.25, the ammonium ion will lower the pH, while according to Eq 16.2.24, the acetate ion will raise the pH. This particular case is unusual, in that the cation is as strong an acid as the anion is a base ($pK_a \approx pK_b$). Consequently, the two effects cancel, and the solution remains neutral. With salts in which the cation is a stronger acid than the anion is a base, the final solution has a $pH < 7.00$. Conversely, if the cation is a weaker acid than the anion is a base, the final solution has a $pH > 7.00$.

Solutions of simple salts of metal ions can also be acidic, even though a metal ion cannot donate a proton directly to water to produce H_3O^+ . Instead, a metal ion can act as a Lewis acid and interact with water, a Lewis base, by coordinating to a lone pair of electrons on the oxygen atom to form a hydrated metal ion (part (a) in [Figure 16.2.2](#)), as discussed in [Chapter 8](#). A water molecule coordinated to a metal ion is more acidic than a free water molecule for two reasons. First, repulsive electrostatic interactions between the positively charged metal ion and the partially positively charged hydrogen atoms of the coordinated water molecule make it easier for the coordinated water to lose a proton.

Second, the positive charge on the Al^{3+} ion attracts electron density from the oxygen atoms of the water molecules, which decreases the electron density in the O–H bonds, as shown in part (b) in [Figure 16.2.2](#). With less electron density between the O atoms and the H atoms, the O–H bonds are weaker than in a free H_2O molecule, making it easier to lose a H^+ ion.

Figure 16.2.2 Effect of a Metal Ion on the Acidity of Water(a) Reaction of the metal ion Al^{3+} with water to form the hydrated metal ion is an example of a Lewis acid–base reaction. (b) The positive charge on the aluminum ion attracts electron density from the oxygen atoms, which shifts electron density away from the O–H bonds. The decrease in electron density weakens the O–H bonds in the water molecules and makes it easier for them to lose a proton.

The magnitude of this effect depends on the following two factors (Figure 16.2.3):

1. **The charge on the metal ion.** A divalent ion (M^{2+}) has approximately twice as strong an effect on the electron density in a coordinated water molecule as a monovalent ion (M^+) of the same radius.
2. **The radius of the metal ion.** For metal ions with the same charge, the smaller the ion, the shorter the internuclear distance to the oxygen atom of the water molecule and the greater the effect of the metal on the electron density distribution in the water molecule.

Figure 16.2.3 The Effect of the Charge and Radius of a Metal Ion on the Acidity of a Coordinated Water Molecule The contours show the electron density on the O atoms and the H atoms in both a free water molecule (left) and water molecules coordinated to Na^+ , Mg^{2+} , and Al^{3+} ions. These contour maps demonstrate that the smallest, most highly charged metal ion (Al^{3+}) causes the greatest decrease in electron density of the O–H bonds of the water molecule. Due to this effect, the acidity of hydrated metal ions increases as the charge on the metal ion increases and its radius decreases.

Thus aqueous solutions of small, highly charged metal ions, such as Al^{3+} and Fe^{3+} , are acidic:

The $[\text{Al}(\text{H}_2\text{O})_6]^{3+}$ ion has a $\text{p}K_a$ of 5.0, making it almost as strong an acid as acetic acid. Because of the two factors described previously, the most important parameter for predicting the effect of a metal ion on the acidity of coordinated water molecules is the *charge-to-radius ratio* of the metal ion. A number of pairs of metal ions that lie on a diagonal line in the periodic table, such as Li^+ and Mg^{2+} or Ca^{2+} and Y^{3+} , have different sizes and charges but similar charge-to-radius ratios. As a result, these pairs of metal ions have similar effects on the acidity of coordinated water molecules, and they often exhibit other significant similarities in chemistry as well.

Note the Pattern

Solutions of small, highly charged metal ions in water are acidic.

Reactions such as those discussed in this section, in which a salt reacts with water to give an acidic or basic solution, are often called hydrolysis reactions. Using a separate name for this type of reaction is unfortunate because it suggests that they are somehow different. In fact, hydrolysis reactions are just acid–base reactions in which the acid is a cation or the base is an anion; they obey the same principles and rules as all other acid–base reactions.

Note the Pattern

A hydrolysis reaction is an acid–base reaction.

Example 16.2.3

Predict whether aqueous solutions of these compounds are acidic, basic, or neutral.

1. KNO_3
2. $\text{CrBr}_3 \cdot 6\text{H}_2\text{O}$
3. Na_2SO_4

Given: compound

Asked for: acidity or basicity of aqueous solution

Strategy:

A Assess the acid–base properties of the cation and the anion. If the cation is a weak Lewis acid, it will not affect the pH of the solution. If the cation is the conjugate acid of a weak base or a relatively highly charged metal cation, however, it will react with water to produce an acidic solution.

B If the anion is the conjugate base of a strong acid, it will not affect the pH of the solution. If, however, the anion is the conjugate base of a weak acid, the solution will be basic.

Solution:

1. **A** The K^+ cation has a small positive charge (+1) and a relatively large radius (because it is in the fourth row of the periodic table), so it is a very weak Lewis acid.

B The NO_3^- anion is the conjugate base of a strong acid, so it has essentially no basic character (Table 16.1). Hence neither the cation nor the anion will react with water to produce H^+ or OH^- , and the solution will be neutral.

2. **A** The Cr^{3+} ion is a relatively highly charged metal cation that should behave similarly to the Al^{3+} ion and form the $[\text{Cr}(\text{H}_2\text{O})_6]^{3+}$ complex, which will behave as a weak acid:

B The Br^- anion is a very weak base (it is the conjugate base of the strong acid HBr), so it does not affect the pH of the solution. Hence the solution will be acidic.

3. **A** The Na^+ ion, like the K^+ , is a very weak acid, so it should not affect the acidity of the solution.

B In contrast, SO_4^{2-} is the conjugate base of HSO_4^- , which is a weak acid. Hence the SO_4^{2-} ion will react with water as shown in [Figure 16.6](#) to give a slightly basic solution.

Exercise

Predict whether aqueous solutions of the following are acidic, basic, or neutral.

1. KI
2. $\text{Mg}(\text{ClO}_4)_2$
3. NaHS

Answer:

1. neutral
2. acidic
3. basic (due to the reaction of HS^- with water to form H_2S and OH^-)

Summary

Two species that differ by only a proton constitute a **conjugate acid–base pair**. The magnitude of the equilibrium constant for an ionization reaction can be used to determine the relative strengths of acids and bases. For an aqueous solution of a weak acid, the dissociation constant is called the **acid ionization constant (K_a)**. Similarly, the equilibrium constant for the reaction of a weak base with water is the **base ionization constant (K_b)**. For any conjugate acid–base pair, $K_a K_b = K_w$. Smaller values of $\text{p}K_a$ correspond to larger acid ionization constants and hence stronger acids. Conversely, smaller values of $\text{p}K_b$ correspond to larger base ionization constants and hence stronger bases. At 25°C , $\text{p}K_a + \text{p}K_b = 14.00$. Acid–base reactions always proceed in the direction that produces the weaker acid–base pair. No acid stronger than H_3O^+ and no base stronger than OH^- can exist in aqueous solution, leading to the phenomenon known as the **leveling effect**. Polyprotic acids (and bases) lose (and gain) protons in a stepwise manner, with the fully protonated species being the strongest acid and the fully deprotonated species the strongest base. A salt can dissolve in water to produce a neutral, a basic, or an acidic solution, depending on whether it contains the conjugate base of a weak acid as the anion (A^-), the conjugate acid of a weak base as the cation (BH^+), or both. Salts that contain small, highly charged metal ions produce acidic solutions in water. The reaction of a salt with water to produce an acidic or a basic solution is called a **hydrolysis reaction**.

Key Takeaways

- Acid–base reactions always contain two conjugate acid–base pairs.
- Each acid and each base has an associated ionization constant that corresponds to its acid or base strength.

Key Equations

Acid ionization constant

$$\text{Equation 16.2.13: } K_a = K[\text{H}_2\text{O}] = \frac{[\text{H}_3\text{O}^+][\text{A}^-]}{[\text{HA}]}$$

Base ionization constant

$$\text{Equation 16.2.15: } K_b = K[\text{H}_2\text{O}] = [\text{BH}^+][\text{OH}^-][\text{B}]$$

Relationship between K_a and K_b of a conjugate acid–base pair

$$\text{Equation 16.2.20: } K_a K_b = K_w$$

Definition of $\text{p}K_a$

Equation 16.2.21: $pK_a = -\log_{10} K_a$

Equation 16.2.22: $K_a = 10^{-pK_a}$

Definition of pK_b

Equation 16.2.23: $pK_b = -\log_{10} K_b$

Equation 16.2.25: $K_b = 10^{-pK_b}$

Relationship between pK_a and pK_b of a conjugate acid–base pair

Equation 16.2.25: $pK_a + pK_b = pK_w$

Equation 16.29: $pK_a + pK_b = 14.00$ at 25°C

Conceptual Problems

- Identify the conjugate acid–base pairs in each equilibrium.
 - $\text{HSO}_4^-(\text{aq}) + \text{H}_2\text{O}(\text{l}) \rightleftharpoons \text{SO}_4^{2-}(\text{aq}) + \text{H}_3\text{O}^+(\text{aq})$
 - $\text{C}_3\text{H}_7\text{NO}_2(\text{aq}) + \text{H}_3\text{O}^+(\text{aq}) \rightleftharpoons \text{C}_3\text{H}_8\text{NO}_2^+(\text{aq}) + \text{H}_2\text{O}(\text{l})$
 - $\text{CH}_3\text{CO}_2\text{H}(\text{aq}) + \text{NH}_3(\text{aq}) \rightleftharpoons \text{CH}_3\text{CO}_2^-(\text{aq}) + \text{NH}_4^+(\text{aq})$
 - $\text{SbF}_5(\text{aq}) + 2\text{HF}(\text{aq}) \rightleftharpoons \text{H}_2\text{F}^+(\text{aq}) + \text{SbF}_6^-(\text{aq})$
- Identify the conjugate acid–base pairs in each equilibrium.
 - $\text{HF}(\text{aq}) + \text{H}_2\text{O}(\text{l}) \rightleftharpoons \text{H}_3\text{O}^+(\text{aq}) + \text{F}^-(\text{aq})$
 - $\text{CH}_3\text{CH}_2\text{NH}_2(\text{aq}) + \text{H}_2\text{O}(\text{l}) \rightleftharpoons \text{CH}_3\text{CH}_2\text{NH}_3^+(\text{aq}) + \text{OH}^-(\text{aq})$
 - $\text{C}_3\text{H}_7\text{NO}_2(\text{aq}) + \text{OH}^-(\text{aq}) \rightleftharpoons \text{C}_3\text{H}_6\text{NO}_2^-(\text{aq}) + \text{H}_2\text{O}(\text{l})$
 - $\text{CH}_3\text{CO}_2\text{H}(\text{aq}) + 2\text{HF}(\text{aq}) \rightleftharpoons \text{CH}_3\text{C}(\text{OH})_2^+(\text{aq}) + \text{HF}_2^-(\text{aq})$
- Salts such as NaH contain the hydride ion (H^-). When sodium hydride is added to water, it produces hydrogen gas in a highly vigorous reaction. Write a balanced chemical equation for this reaction and identify the conjugate acid–base pairs.
- Write the expression for K_a for each reaction.
 - $\text{HCO}_3^-(\text{aq}) + \text{H}_2\text{O}(\text{l}) \rightleftharpoons \text{CO}_3^{2-}(\text{aq}) + \text{H}_3\text{O}^+(\text{aq})$
 - formic acid*_(aq) + $\text{H}_2\text{O}(\text{l}) \rightleftharpoons$ *formate*_(aq) + $\text{H}_3\text{O}^+(\text{aq})$
 - $\text{H}_3\text{PO}_4(\text{aq}) + \text{H}_2\text{O}(\text{l}) \rightleftharpoons \text{H}_2\text{PO}_4^-(\text{aq}) + \text{H}_3\text{O}^+(\text{aq})$
- Write an expression for the ionization constant K_b for each reaction.
 - $\text{OCH}_3^-(\text{aq}) + \text{H}_2\text{O}(\text{l}) \rightleftharpoons \text{HOCH}_3(\text{aq}) + \text{OH}^-(\text{aq})$
 - $\text{NH}_2^-(\text{aq}) + \text{H}_2\text{O}(\text{l}) \rightleftharpoons \text{NH}_3(\text{aq}) + \text{OH}^-(\text{aq})$
 - $\text{S}^{2-}(\text{aq}) + \text{H}_2\text{O}(\text{l}) \rightleftharpoons \text{HS}^-(\text{aq}) + \text{OH}^-(\text{aq})$
- Predict whether each equilibrium lies primarily to the left or to the right.
 - $\text{HBr}(\text{aq}) + \text{H}_2\text{O}(\text{l}) \rightleftharpoons \text{H}_3\text{O}^+(\text{aq}) + \text{Br}^-(\text{aq})$
 - $\text{NaNH}(\text{soln}) + \text{NH}_3(\text{l}) \rightleftharpoons \text{H}_2(\text{soln}) + \text{NaNH}_2(\text{soln})$
 - $\text{OCH}_3^-(\text{aq}) + \text{NH}_3(\text{aq}) \rightleftharpoons \text{CH}_3\text{OH}(\text{aq}) + \text{NH}_2^-(\text{aq})$
 - $\text{NH}_3(\text{aq}) + \text{HCl}(\text{aq}) \rightleftharpoons \text{NH}_4^+(\text{aq}) + \text{Cl}^-(\text{aq})$
- Species that are strong bases in water, such as CH_3^- , NH_2^- , and S^{2-} , are leveled to the strength of OH^- , the conjugate base of H_2O . Because their relative base strengths are indistinguishable in water, suggest a method for identifying which is the strongest base. How would you distinguish between the strength of the acids HIO_3 , H_2SO_4 , and HClO_4 ?
- Is it accurate to say that a 2.0 M solution of H_2SO_4 , which contains two acidic protons per molecule, is 4.0 M in H^+ ? Explain your answer.
- The alkalinity of soil is defined by the following equation: $\text{alkalinity} = [\text{HCO}_3^-] + 2[\text{CO}_3^{2-}] + [\text{OH}^-] - [\text{H}^+]$. The source of both HCO_3^- and CO_3^{2-} is H_2CO_3 . Explain why the basicity of soil is defined in this way.
- Why are aqueous solutions of salts such as CaCl_2 neutral? Why is an aqueous solution of NaNH_2 basic?
- Predict whether aqueous solutions of the following are acidic, basic, or neutral.

- Li_3N
 - NaH
 - KBr
 - $\text{C}_2\text{H}_5\text{NH}_3^+ \text{Cl}^-$
12. When each compound is added to water, would you expect the pH of the solution to increase, decrease, or remain the same?
- LiCH_3
 - MgCl_2
 - K_2O
 - $(\text{CH}_3)_2\text{NH}_2^+ \text{Br}^-$
13. Which complex ion would you expect to be more acidic— $\text{Pb}(\text{H}_2\text{O})_4^{2+}$ or $\text{Sn}(\text{H}_2\text{O})_4^{2+}$? Why?
14. Would you expect $\text{Sn}(\text{H}_2\text{O})_4^{2+}$ or $\text{Sn}(\text{H}_2\text{O})_6^{2+}$ to be more acidic? Why?
15. Is it possible to arrange the hydrides LiH , RbH , KH , CsH , and NaH in order of increasing base strength in aqueous solution? Why or why not?

Answer

- $$\overset{\text{acid 1}}{\text{HSO}_4^-}(\text{aq}) + \underset{\text{base 2}}{\text{H}_2\text{O}}(\text{l}) \rightleftharpoons \overset{\text{base 1}}{\text{SO}_4^{2-}}(\text{aq}) + \underset{\text{acid 2}}{\text{H}_3\text{O}^+}(\text{aq})$$
 - $$\underset{\text{base 2}}{\text{C}_3\text{H}_7\text{NO}_2}(\text{aq}) + \overset{\text{acid 1}}{\text{H}_3\text{O}^+}(\text{aq}) \rightleftharpoons \underset{\text{acid 2}}{\text{C}_3\text{H}_8\text{NO}_2^+}(\text{aq}) + \overset{\text{base 1}}{\text{H}_2\text{O}}(\text{l})$$
 - $$\overset{\text{acid 1}}{\text{HOAc}}(\text{aq}) + \underset{\text{base 2}}{\text{NH}_3}(\text{aq}) \rightleftharpoons \overset{\text{base 1}}{\text{CH}_3\text{CO}_2^-}(\text{aq}) + \underset{\text{acid 2}}{\text{NH}_4^+}(\text{aq})$$
 - $$\underset{\text{base 2}}{\text{SbF}_5}(\text{aq}) + \overset{\text{acid 1}}{2\text{HF}}(\text{aq}) \rightleftharpoons \underset{\text{acid 2}}{\text{H}_2\text{F}^+}(\text{aq}) + \overset{\text{base 1}}{\text{SbF}_6^-}(\text{aq})$$

Numerical Problems

- Arrange these acids in order of increasing strength.
 - acid A: $\text{p}K_{\text{a}} = 1.52$
 - acid B: $\text{p}K_{\text{a}} = 6.93$
 - acid C: $\text{p}K_{\text{a}} = 3.86$
 Given solutions with the same initial concentration of each acid, which would have the highest percent ionization?
- Arrange these bases in order of increasing strength:
 - base A: $\text{p}K_{\text{b}} = 13.10$
 - base B: $\text{p}K_{\text{b}} = 8.74$
 - base C: $\text{p}K_{\text{b}} = 11.87$
 Given solutions with the same initial concentration of each base, which would have the highest percent ionization?

3. Calculate the K_a and the pK_a of the conjugate acid of a base with each pK_b value.
 - a. 3.80
 - b. 7.90
 - c. 13.70
 - d. 1.40
 - e. -2.50
4. Benzoic acid is a food preservative with a pK_a of 4.20. Determine the K_b and the pK_b for the benzoate ion.
5. Determine K_a and pK_a of boric acid $[B(OH)_3]$, solutions of which are occasionally used as an eyewash; the pK_b of its conjugate base is 4.80.

Answers

1. acid B < acid C < acid A (strongest)
- 2.
3.
 - a. $K_a = 6.3 \times 10^{-7}$; $pK_a = 10.20$
 - b. $K_a = 7.9 \times 10^{-7}$; $pK_a = 6.10$
 - c. $K_a = 0.50$; $pK_a = 0.30$
 - d. $K_a = 2.5 \times 10^{-17}$; $pK_a = 12.60$
 - e. $K_a = 3.2 \times 10^{-17}$; $pK_a = 16.50$
- 4.
5. $K_a = 6.3 \times 10^{-10}$; $pK_a = 9.20$

Learning Objective

- To understand how molecular structure affects the strength of an acid or base.

We have seen that the strengths of acids and bases vary over many orders of magnitude. In this section, we explore some of the structural and electronic factors that control the acidity or basicity of a molecule.

Bond Strengths

In general, the stronger the A–H or B–H⁺ bond, the less likely the bond is to break to form H⁺ ions and thus the less acidic the substance. This effect can be illustrated using the hydrogen halides:

Relative Acid Strength	HF	<	HCl	<	HBr	<	HI
H–X Bond Energy (kJ/mol)	570		432		366		298
pK _a	3.20		–6.1		–8.9		–9.3

The trend in bond energies is due to a steady decrease in overlap between the 1s orbital of hydrogen and the valence orbital of the halogen atom as the size of the halogen increases. The larger the atom to which H is bonded, the weaker the bond. Thus the bond between H and a large atom in a given family, such as I or Te, is weaker than the bond between H and a smaller atom in the same family, such as F or O. As a result, *acid strengths of binary hydrides increase as we go down a column of the periodic table*. For example, the order of acidity for the binary hydrides of Group 16 is as follows, with pK_a values in parentheses: H₂O (14.00 = pK_w) < H₂S (7.05) < H₂Se (3.89) < H₂Te (2.6).

Stability of the Conjugate Base

Whether we write an acid–base reaction as $AH \rightleftharpoons A^- + H^+$ or as $BH^+ \rightleftharpoons B + H^+$ the conjugate base (A[–] or B) contains one more lone pair of electrons than the parent acid (AH or BH⁺). *Any factor that stabilizes the lone pair on the conjugate base favors dissociation of H⁺ and makes the parent acid a stronger acid*. Let's see how this explains the relative acidity of the binary hydrides of the elements in the second row of the periodic table. The observed order of increasing acidity is the following, with pK_a values in parentheses: CH₄ (~50) << NH₃ (~36) < H₂O (14.00) < HF (3.20).

Consider, for example, the compounds at both ends of this series: methane and hydrogen fluoride. The conjugate base of CH₄ is CH₃[–], and the conjugate base of HF is F[–]. Because fluorine is much more electronegative than carbon, fluorine can better stabilize the negative charge in the F[–] ion than carbon can stabilize the negative charge in the CH₃[–] ion. Consequently, HF has a greater tendency to dissociate to form H⁺ and F[–] than does methane to form H⁺ and CH₃[–], making HF a much stronger acid than CH₄.

The same trend is predicted by analyzing the properties of the conjugate acids. For a series of compounds of the general formula HE, as the electronegativity of E increases, the E–H bond becomes more polar, favoring dissociation to form E[–] and H⁺. Due to

both the increasing stability of the conjugate base and the increasing polarization of the E–H bond in the conjugate acid, *acid strengths of binary hydrides increase as we go from left to right across a row of the periodic table.*

Note the Pattern

Acid strengths of binary hydrides *increase* as we go *down* a column or *from left to right* across a row of the periodic table.

Inductive Effects

Atoms or groups of atoms in a molecule other than those to which H is bonded can induce a change in the distribution of electrons within the molecule. This is called an *inductive effect*, and, much like the coordination of water to a metal ion, it can have a major effect on the acidity or basicity of the molecule. For example, the hypohalous acids (general formula HOX, with X representing a halogen) all have a hydrogen atom bonded to an oxygen atom. In aqueous solution, they all produce the following equilibrium:

The acidities of these acids vary by about three orders of magnitude, however, due to the difference in electronegativity of the halogen atoms:

HOX	Electronegativity of X	p <i>K</i> _a
HOCl	3.0	7.40
HOBr	2.8	8.55
HOI	2.5	10.5

As the electronegativity of X increases, the distribution of electron density within the molecule changes: the electrons are drawn more strongly toward the halogen atom and, in turn, away from the H in the O–H bond, thus weakening the O–H bond and allowing dissociation of hydrogen as H⁺.

The acidity of oxoacids, with the general formula HOXO_{*n*} (*n* = 0–3), depends strongly on the number of terminal oxygen atoms attached to the central atom X. As shown in [Figure 16.3.1](#), the *K*_a values of the oxoacids of chlorine increase by a factor of about 10⁴ to 10⁶ with each oxygen as successive oxygen atoms are added. The increase in acid strength with increasing number of terminal oxygen atoms is due to both an inductive effect and increased stabilization of the conjugate base.

Note the Pattern

Any inductive effect that withdraws electron density from an O–H bond increases the acidity of the compound.

Because oxygen is the second most electronegative element, adding terminal oxygen atoms causes electrons to be drawn away from the O–H bond, making it weaker and thereby increasing the strength of the acid. The colors in [Figure 16.3.1](#) show how the electrostatic potential, a measure of the strength of the interaction of a point charge at any place on the surface of the molecule, changes as the number of terminal oxygen atoms increases. In [Figure 16.3.1](#) and [Figure 16.3.2](#), blue corresponds to low electron densities, while red corresponds to high electron densities. The oxygen atom in the O–H unit becomes steadily less red from HClO to HClO₄ (also written as HOCIO₃), while the H atom becomes steadily bluer, indicating that the electron density on the O–H unit decreases as the number of terminal oxygen atoms increases. The decrease in electron density in the O–H bond weakens it, making it easier to lose hydrogen as H⁺ ions, thereby increasing the strength of the acid.

Figure 16.3.1 The Relationship between the Acid Strengths of the Oxoacids of Chlorine and the Electron Density on the O–H Unit These electrostatic potential maps show how the electron density on the O–H unit decreases as the number of terminal oxygen atoms increases. Blue corresponds to low electron densities, whereas red corresponds to high electron densities.

Source: Chlorine oxoacids pK_a values from J. R. Bowser, *Inorganic Chemistry* (Pacific Grove, CA: Brooks-Cole, 1993).

At least as important, however, is the effect of delocalization of the negative charge in the conjugate base. As shown in [Figure 16.3.2](#), the number of resonance structures that can be written for the oxoanions of chlorine increases as the number of terminal oxygen atoms increases, allowing the single negative charge to be delocalized over successively more oxygen atoms. The electrostatic potential plots in [Figure 16.3.2](#) demonstrate that the electron density on the terminal oxygen atoms decreases steadily as their number increases. The oxygen atom in ClO^- is red, indicating that it is electron rich, and the color of oxygen progressively changes to green in ClO_4^- , indicating that the oxygen atoms are becoming steadily less electron rich through the series. For example, in the perchlorate ion (ClO_4^-), the single negative charge is delocalized over all four oxygen atoms, whereas in the hypochlorite ion (OCl^-), the negative charge is largely localized on a single oxygen atom ([Figure 16.3.2](#)). As a result, the perchlorate ion has no localized negative charge to which a proton can bind. Consequently, the perchlorate anion has a much lower affinity for a proton than does the hypochlorite ion, and perchloric acid is one of the strongest acids known.

Note the Pattern

Electron delocalization in the conjugate base increases acid strength.

Figure 16.3.2 The Relationship between Delocalization of the Negative Charge in the Oxoanions of Chlorine and the Number of Terminal Oxygen Atoms As the number of terminal oxygen atoms increases, the number of resonance structures that can be written for the oxoanions of chlorine also increases, and the single negative charge is delocalized over more oxygen atoms. As these electrostatic potential plots demonstrate, the electron density on the terminal oxygen atoms decreases steadily as their

number increases. As the electron density on the oxygen atoms decreases, so does their affinity for a proton, making the anion less basic. As a result, the parent oxoacid is more acidic.

Similar inductive effects are also responsible for the trend in the acidities of oxoacids that have the same number of oxygen atoms as we go across a row of the periodic table from left to right. For example, H_3PO_4 is a weak acid, H_2SO_4 is a strong acid, and HClO_4 is one of the strongest acids known. The number of terminal oxygen atoms increases steadily across the row, consistent with the observed increase in acidity. In addition, the electronegativity of the central atom increases steadily from P to S to Cl, which causes electrons to be drawn from oxygen to the central atom, weakening the O–H bond and increasing the strength of the oxoacid.

Careful inspection of the data in [Table 16.3.1](#) shows two apparent anomalies: carbonic acid and phosphorous acid. If carbonic acid (H_2CO_3) were a discrete molecule with the structure $(\text{HO})_2\text{C}=\text{O}$, it would have a single terminal oxygen atom and should be comparable in acid strength to phosphoric acid (H_3PO_4), for which $\text{p}K_{\text{a}1} = 2.16$. Instead, the tabulated value of $\text{p}K_{\text{a}1}$ for carbonic acid is 6.35, making it about 10,000 times weaker than expected. As we shall see in [Section 16.6](#), however, H_2CO_3 is only a minor component of the aqueous solutions of CO_2 that are referred to as carbonic acid. Similarly, if phosphorous acid (H_3PO_3) actually had the structure $(\text{HO})_3\text{P}$, it would have no terminal oxygen atoms attached to phosphorous. It would therefore be expected to be about as strong an acid as HOCl ($\text{p}K_{\text{a}} = 7.40$). In fact, the $\text{p}K_{\text{a}1}$ for phosphorous acid is 1.30, and the structure of phosphorous acid is $(\text{HO})_2\text{P}(=\text{O})\text{H}$ with one H atom directly bonded to P and one P=O bond. Thus the $\text{p}K_{\text{a}1}$ for phosphorous acid is similar to that of other oxoacids with one terminal oxygen atom, such as H_3PO_4 . Fortunately, phosphorous acid is the only common oxoacid in which a hydrogen atom is bonded to the central atom rather than oxygen.

Table 16.3.1 Values of $\text{p}K_{\text{a}}$ for Selected Polyprotic Acids and Bases

Polyprotic Acids	Formula	$\text{p}K_{\text{a}1}$	$\text{p}K_{\text{a}2}$	$\text{p}K_{\text{a}3}$
carbonic acid*	" H_2CO_3 "	6.35	10.33	
citric acid	$\text{HO}_2\text{CCH}_2\text{C}(\text{OH})(\text{CO}_2\text{H})\text{CH}_2\text{CO}_2\text{H}$	3.13	4.76	6.40
malonic acid	$\text{HO}_2\text{CCH}_2\text{CO}_2\text{H}$	2.85	5.70	
oxalic acid	$\text{HO}_2\text{CCO}_2\text{H}$	1.25	3.81	
phosphoric acid	H_3PO_4	2.16	7.21	12.32
phosphorous acid	H_3PO_3	1.3	6.70	
succinic acid	$\text{HO}_2\text{CCH}_2\text{CH}_2\text{CO}_2\text{H}$	4.21	5.64	
sulfuric acid	H_2SO_4	-2.0	1.99	
sulfurous acid*	" H_2SO_3 "	1.85	7.21	
<hr/>				
Polyprotic Bases	Formula	$\text{p}K_{\text{b}1}$	$\text{p}K_{\text{b}2}$	
ethylenediamine	$\text{H}_2\text{N}(\text{CH}_2)_2\text{NH}_2$	4.08	7.14	

* H_2CO_3 and H_2SO_3 are at best minor components of aqueous solutions of $\text{CO}_2(\text{g})$ and $\text{SO}_2(\text{g})$, respectively, but such solutions are commonly referred to as containing carbonic acid and sulfurous acid, respectively.

piperazine	$\text{HN}(\text{CH}_2\text{CH}_2)_2\text{NH}$	4.27	8.67
propylenediamine	$\text{H}_2\text{N}(\text{CH}_2)_3\text{NH}_2$	3.45	5.12

*** H_2CO_3 and H_2SO_3 are at best minor components of aqueous solutions of $\text{CO}_2(\text{g})$ and $\text{SO}_2(\text{g})$, respectively, but such solutions are commonly referred to as containing carbonic acid and sulfurous acid, respectively.**

Inductive effects are also observed in organic molecules that contain electronegative substituents. The magnitude of the electron-withdrawing effect depends on both the nature and the number of halogen substituents, as shown by the $\text{p}K_a$ values for several acetic acid derivatives:

$$\text{p}K_a \text{CH}_3\text{CO}_2\text{H} 4.76 < \text{CH}_2\text{ClCO}_2\text{H} 2.87 < \text{CHCl}_2\text{CO}_2\text{H} 1.35 < \text{CCl}_3\text{CO}_2\text{H} 0.66 < \text{CF}_3\text{CO}_2\text{H} 0.52$$

As you might expect, fluorine, which is more electronegative than chlorine, causes a larger effect than chlorine, and the effect of three halogens is greater than the effect of two or one. Notice from these data that inductive effects can be quite large. For instance, replacing the $-\text{CH}_3$ group of acetic acid by a $-\text{CF}_3$ group results in about a 10,000-fold increase in acidity!

Example 16.3.1

Arrange the compounds of each series in order of increasing acid or base strength.

1. sulfuric acid [H_2SO_4 , or $(\text{HO})_2\text{SO}_2$], fluorosulfonic acid (FSO_3H , or FSO_2OH), and sulfurous acid [H_2SO_3 , or $(\text{HO})_2\text{SO}$]
2. ammonia (NH_3), trifluoramine (NF_3), and hydroxylamine (NH_2OH)

The structures are shown here.

Given: series of compounds

Asked for: relative acid or base strengths

Strategy:

Use relative bond strengths, the stability of the conjugate base, and inductive effects to arrange the compounds in order of increasing tendency to ionize in aqueous solution.

Solution:

1. Although both sulfuric acid and sulfurous acid have two $-\text{OH}$ groups, the sulfur atom in sulfuric acid is bonded to two terminal oxygen atoms versus one in sulfurous acid. Because oxygen is highly electronegative, sulfuric acid is the stronger acid because the negative charge on the anion is stabilized by the additional oxygen atom. In comparing sulfuric acid and fluorosulfonic acid, we note that fluorine is more electronegative than oxygen. Thus replacing an $-\text{OH}$ by $-\text{F}$ will remove *more* electron density from the central S atom, which will, in turn, remove electron density from the $\text{S}-\text{OH}$ bond and the $\text{O}-\text{H}$ bond. Because its $\text{O}-\text{H}$ bond is weaker, FSO_3H is a stronger acid than sulfuric acid. The predicted order of acid strengths given here is confirmed by the measured $\text{p}K_a$ values for these acids:

$$pK_a \text{ H}_2\text{SO}_3 \text{ 1.85} < \text{H}_2\text{SO}_4^{-2} < \text{HSO}_3\text{H} \text{ 10} \text{ \notag }$$

2. The structures of both trifluoramine and hydroxylamine are similar to that of ammonia. In trifluoramine, all of the hydrogen atoms in NH_3 are replaced by fluorine atoms, whereas in hydroxylamine, one hydrogen atom is replaced by OH. Replacing the three hydrogen atoms by fluorine will withdraw electron density from N, making the lone electron pair on N less available to bond to an H^+ ion. Thus NF_3 is predicted to be a much weaker base than NH_3 . Similarly, because oxygen is more electronegative than hydrogen, replacing one hydrogen atom in NH_3 by OH will make the amine less basic. Because oxygen is less electronegative than fluorine and only one hydrogen atom is replaced, however, the effect will be smaller. The predicted order of increasing base strength shown here is confirmed by the measured pK_b values:

$$pK_b \text{ NF}_3 \text{ } \ll \text{ NH}_2\text{OH} \text{ 8.06} < \text{ NH}_3 \text{ 4.75}$$

Trifluoramine is such a weak base that it does not react with aqueous solutions of strong acids. Hence its base ionization constant has not been measured.

Exercise

Arrange the compounds of each series in order of

1. decreasing acid strength: H_3PO_4 , $\text{CH}_3\text{PO}_3\text{H}_2$, and HClO_3 .
2. increasing base strength: CH_3S^- , OH^- , and CF_3S^- .

Answer:

1. $\text{HClO}_3 > \text{CH}_3\text{PO}_3\text{H}_2 > \text{H}_3\text{PO}_4$
2. $\text{CF}_3\text{S}^- < \text{CH}_3\text{S}^- < \text{OH}^-$

Summary

The acid–base strength of a molecule depends strongly on its structure. The weaker the A-H or B-H^+ bond, the more likely it is to dissociate to form an H^+ ion. In addition, any factor that stabilizes the lone pair on the conjugate base favors the dissociation of H^+ , making the conjugate acid a stronger acid. Atoms or groups of atoms elsewhere in a molecule can also be important in determining acid or base strength through an *inductive effect*, which can weaken an O-H bond and allow hydrogen to be more easily lost as H^+ ions.

Key Takeaway

- Inductive effects and charge delocalization significantly influence the acidity or basicity of a compound.

Conceptual Problems

1. Section 16.3 presented several factors that affect the relative strengths of acids and bases. For each pair, identify the most important factor in determining which is the stronger acid or base in aqueous solution.
 - a. $\text{CH}_3\text{CCl}_2\text{CH}_2\text{CO}_2\text{H}$ versus $\text{CH}_3\text{CH}_2\text{CH}_2\text{CO}_2\text{H}$
 - b. $\text{CH}_3\text{CO}_2\text{H}$ versus $\text{CH}_3\text{CH}_2\text{OH}$
 - c. HClO versus HBrO
 - d. $\text{CH}_3\text{C}(=\text{O})\text{NH}_2$ versus $\text{CH}_3\text{CH}_2\text{NH}_2$
 - e. H_3AsO_4 versus H_3AsO_3
2. The stability of the conjugate base is an important factor in determining the strength of an acid. Which would you expect to be the stronger acid in aqueous solution— $\text{C}_6\text{H}_5\text{NH}_3^+$ or NH_4^+ ? Justify your reasoning.
3. Explain why H_2Se is a weaker acid than HBr .
4. Arrange the following in order of decreasing acid strength in aqueous solution: H_3PO_4 , $\text{CH}_3\text{PO}_3\text{H}_2$, and HClO_3 .

5. Arrange the following in order of increasing base strength in aqueous solution: CH_3S^- , OH^- , and CF_3S^- .
6. Arrange the following in order of increasing acid strength in aqueous solution: HClO_2 , HNO_2 , and HNO_3 .
7. Do you expect H_2SO_3 or H_2SeO_3 to be the stronger acid? Why?
8. Give a plausible explanation for why CF_3OH is a stronger acid than CH_3OH in aqueous solution. Do you expect $\text{CHCl}_2\text{CH}_2\text{OH}$ to be a stronger or a weaker acid than CH_3OH ? Why?
9. Do you expect Cl_2NH or NH_3 to be the stronger base in aqueous solution? Why?

Answers

- 1.
- 2.
- 3.
- 4.
5. $\text{CF}_3\text{S}^- < \text{CH}_3\text{S}^- < \text{OH}^-$ (strongest base)
- 6.
- 7.
- 8.
9. NH_3 ; Cl atoms withdraw electron density from N in Cl_2NH .

Learning Objective

- To use K_a and K_b values to calculate the percent ionization and the pH of a solution of an acid or a base.

This section presents a quantitative approach to analyzing acid–base equilibria. You will learn how to determine the values of K_a and K_b , how to use K_a or K_b to calculate the percent ionization and the pH of an aqueous solution of an acid or a base, and how to calculate the equilibrium constant for the reaction of an acid with a base from the K_a and K_b of the reactants.

Determining K_a and K_b

The ionization constants K_a and K_b are equilibrium constants that are calculated from experimentally measured concentrations, just like the equilibrium constants discussed in [Chapter 15](#). Before proceeding further, it is important to understand exactly what is meant when we describe the concentration of an aqueous solution of a weak acid or a weak base. Suppose, for example, we have a bottle labeled 1.0 M acetic acid or 1.0 M ammonia. As you learned in [Chapter 8](#), such a solution is usually prepared by dissolving 1.0 mol of acetic acid or ammonia in water and adding enough water to give a final volume of exactly 1.0 L. If, however, we were to list the actual concentrations of all the species present in either solution, we would find that *none* of the values is exactly 1.0 M because a weak acid such as acetic acid or a weak base such as ammonia always reacts with water to some extent. The extent of the reaction depends on the K_a or the K_b , the concentration of the acid or the base, and the temperature. Consequently, only the *total concentration* of both the ionized and unionized species is equal to 1.0 M.

The *analytical concentration* (C) is defined as the *total* concentration of all forms of an acid or a base that are present in solution, regardless of their state of protonation. Thus a “1.0 M” solution of acetic acid has an analytical concentration of 1.0 M, which is the sum of the *actual* concentrations of unionized acetic acid ($\text{CH}_3\text{CO}_2\text{H}$) and the ionized form (CH_3CO_2^-):

$$C_{\text{CH}_3\text{CO}_2\text{H}} = [\text{CH}_3\text{CO}_2\text{H}] + [\text{CH}_3\text{CO}_2^-] \quad (16.4.1)$$

As we shall see shortly, if we know the analytical concentration and the K_a , we can calculate the actual values of $[\text{CH}_3\text{CO}_2\text{H}]$ and $[\text{CH}_3\text{CO}_2^-]$.

The equilibrium equations for the reaction of acetic acid and ammonia with water are as follows:

$$K_a = \frac{[\text{H}^+][\text{CH}_3\text{CO}_2^-]}{[\text{CH}_3\text{CO}_2\text{H}]} \quad (16.4.2)$$

$$K_b = \frac{[\text{NH}_4^+][\text{OH}^-]}{[\text{NH}_3]} \quad (16.4.3)$$

where K_a and K_b are the ionization constants for acetic acid and ammonia, respectively. In addition to the analytical concentration of the acid (or the base), we must have a way to measure the concentration of at least *one* of the species in the equilibrium constant expression to determine the K_a (or the K_b). There are two common ways to obtain the concentrations: (1) measure the electrical conductivity of the solution, which is related to the total concentration of ions present, and (2) measure the pH of the solution, which gives $[\text{H}^+]$ or $[\text{OH}^-]$.

Example 6 and Example 7 illustrate the procedure for determining K_a for a weak acid and K_b for a weak base. In both cases, we will follow the procedure developed in [Chapter 15](#): the analytical concentration of the acid or the base is the *initial* concentration, and the stoichiometry of the reaction with water determines the *change* in concentrations. The *final* concentrations of all species are calculated from the initial concentrations and the changes in the concentrations. Inserting the final concentrations into the equilibrium constant expression enables us to calculate the K_a or the K_b .

Example 16.4.1

Electrical conductivity measurements indicate that 0.42% of the acetic acid molecules in a 1.00 M solution are ionized at 25°C. Calculate K_a and pK_a for acetic acid at this temperature.

Given: analytical concentration and percent ionization

Asked for: K_a and pK_a

Strategy:

A Write the balanced equilibrium equation for the reaction and derive the equilibrium constant expression.

B Use the data given and the stoichiometry of the reaction to construct a table showing the initial concentrations, the changes in concentrations, and the final concentrations for all species in the equilibrium constant expression.

C Substitute the final concentrations into the equilibrium constant expression and calculate the K_a . Take the negative logarithm of K_a to obtain the pK_a .

Solution:

A The balanced equilibrium equation for the dissociation of acetic acid is as follows:

and the equilibrium constant expression is as follows:

$$K_a = \frac{[H^+][CH_3CO_2^-]}{[CH_3CO_2H]} \quad (\text{Chapter 16.4.2})$$

B To calculate the K_a , we need to know the equilibrium concentrations of CH_3CO_2H , $CH_3CO_2^-$, and H^+ . The most direct way to do this is to construct a table that lists the initial concentrations and the changes in concentrations that occur during the reaction to give the final concentrations, using the procedure introduced in [Chapter 15](#). The initial concentration of unionized acetic acid ($[CH_3CO_2H]_i$) is the analytical concentration, 1.00 M, and the initial acetate concentration ($[CH_3CO_2^-]_i$) is zero. The initial concentration of H^+ is not zero, however; $[H^+]_i$ is 1.00×10^{-7} M due to the autoionization of water. The measured percent ionization tells us that 0.42% of the acetic acid molecules are ionized at equilibrium. Consequently, the change in the concentration of acetic acid is $\Delta[CH_3CO_2H] = -(4.2 \times 10^{-3})(1.00 \text{ M}) = -0.0042 \text{ M}$. Conversely, the change in the acetate concentration is $\Delta[CH_3CO_2^-] = +0.0042 \text{ M}$ because every $\frac{1}{2}$ mol of acetic acid that ionizes gives 1 mol of acetate. Because one proton is produced for each acetate ion formed, $\Delta[H^+] = +0.0042 \text{ M}$ as well. These results are summarized in the following table.

$CH_3CO_2H_{(aq)} \rightleftharpoons H_{(aq)}^+ + CH_3CO_2^{-}_{(aq)}$ (Chapter 16.4.3)			
	$[CH_3CO_2H]$	$[H^+]$	$[CH_3CO_2^-]$
initial	1.00	1.00×10^{-7}	0
change	-0.0042	+0.0042	+0.0042
final			

The final concentrations of all species are therefore as follows:

- $[CH_3CO_2H]_f = [CH_3CO_2H]_i + \Delta[CH_3CO_2H] = 1.00\text{ M} + (-0.0042\text{ M}) = 1.00\text{ M}$
- $[CH_3CO_2^-]_f = [CH_3CO_2^-]_i + \Delta[CH_3CO_2^-] = 0\text{ M} + (+0.0042\text{ M}) = 0.0042\text{ M}$
- $[H^+]_f = [H^+]_i + \Delta[H^+] = 1.00 \times 10^{-7}\text{ M} + (+0.0042\text{ M}) = 0.0042\text{ M}$

C We can now calculate K_a by inserting the final concentrations into the equilibrium constant expression:

$$K_a = \frac{[H^+][CH_3CO_2^-]}{[CH_3CO_2H]} = \frac{(0.0042)(0.0042)}{1.00} = 1.8 \times 10^{-5} \quad (\text{Chapter 16.4.4})$$

The pK_a is the negative logarithm of K_a : $pK_a = -\log K_a = -\log(1.8 \times 10^{-5}) = 4.74$.

Exercise

Picric acid is the common name for 2,4,6-trinitrophenol, a derivative of phenol (C_6H_5OH) in which three H atoms are replaced by nitro ($-NO_2$) groups. The presence of the nitro groups removes electron density from the phenyl ring, making picric acid a much stronger acid than phenol ($pK_a = 9.99$). The nitro groups also make picric acid potentially explosive, as you might expect based on its chemical similarity to 2,4,6-trinitrotoluene, better known as TNT. A 0.20 M solution of picric acid is 73% ionized at 25°C. Calculate K_a and pK_a for picric acid.

Answer: $K_a = 0.39$; $pK_a = 0.41$

Example 16.4.2

A 1.0 M aqueous solution of ammonia has a pH of 11.63 at 25°C. Calculate K_b and pK_b for ammonia.

Given: analytical concentration and pH

Asked for: K_b and pK_b

Strategy:

A Write the balanced equilibrium equation for the reaction and derive the equilibrium constant expression.

B Use the data given and the stoichiometry of the reaction to construct a table showing the initial concentrations, the changes in concentrations, and the final concentrations for all species in the equilibrium constant expression.

C Substitute the final concentrations into the equilibrium constant expression and calculate the K_b . Take the negative logarithm of K_b to obtain the pK_b .

Solution:

A The balanced equilibrium equation for the reaction of ammonia with water is as follows:

and the equilibrium constant expression is as follows:

$$K_b = \frac{[NH_4^+][OH^-]}{[NH_3]}$$

Remember that water does not appear in the equilibrium constant expression for K_b .

B To calculate K_b , we need to know the equilibrium concentrations of NH_3 , NH_4^+ , and OH^- . The initial concentration of NH_3 is the analytical concentration, 1.0 M, and the initial concentrations of NH_4^+ and OH^- are 0 M and 1.00×10^{-7} M,

respectively. In this case, we are given the pH of the solution, which allows us to calculate the final concentration of one species (OH^-) directly, rather than the change in concentration. Recall that $\text{p}K_w = \text{pH} + \text{pOH} = 14.00$ at 25°C . Thus $\text{pOH} = 14.00 - \text{pH} = 14.00 - 11.63 = 2.37$, and $[\text{OH}^-]_f = 10^{-2.37} = 4.3 \times 10^{-3} \text{ M}$. Our data thus far are listed in the following table.

$\text{NH}_3(\text{aq}) \rightleftharpoons \text{NH}_4^+(\text{aq}) + \text{OH}^-(\text{aq})$ (Chapter 16.4.5)			
	$[\text{NH}_3]$	$[\text{NH}_4^+]$	$[\text{OH}^-]$
initial	1.0	0	1.00×10^{-7}
change			
final			4.3×10^{-3}

The final $[\text{OH}^-]$ is much greater than the initial $[\text{H}^+]$, so the change in $[\text{OH}^-]$ is as follows:

$$\Delta[\text{OH}^-] = (4.3 \times 10^{-3} \text{ M}) - (1.00 \times 10^{-7} \text{ M}) \approx 4.3 \times 10^{-3} \text{ M}$$

The stoichiometry of the reaction tells us that 1 mol of NH_3 is converted to NH_4^+ for each 1 mol of OH^- formed, so

$$\Delta[\text{NH}_4^+] = +4.3 \times 10^{-3} \text{ M} \text{ and } \Delta[\text{NH}_3] = -4.3 \times 10^{-3} \text{ M}$$

We can now insert these values for the changes in concentrations into the table, which enables us to complete the table.

$\text{H}_2\text{O}(\text{l}) + \text{NH}_3(\text{aq}) \rightleftharpoons \text{NH}_4^+(\text{aq}) + \text{OH}^-(\text{aq})$ (Chapter 16.4.6)			
	$[\text{NH}_3]$	$[\text{NH}_4^+]$	$[\text{OH}^-]$
initial	1.0	0	1.00×10^{-7}
change	-4.3×10^{-3}	$+4.3 \times 10^{-3}$	$+4.3 \times 10^{-3}$
final	1.0	4.3×10^{-3}	4.3×10^{-3}

C Inserting the final concentrations into the equilibrium constant expression gives K_b :

$$K_b = \frac{[\text{NH}_4^+][\text{OH}^-]}{[\text{NH}_3]} = \frac{(4.3 \times 10^{-3})^2}{1.0} = 1.8 \times 10^{-5}$$

and $\text{p}K_b = -\log K_b = 4.74$.

The K_b and the $\text{p}K_b$ for ammonia are almost exactly the same as the K_a and the $\text{p}K_a$ for acetic acid at 25°C . In other words, ammonia is almost exactly as strong a base as acetic acid is an acid. Consequently, the extent of the ionization reaction in an aqueous solution of ammonia at a given concentration is the same as in an aqueous solution of acetic acid at the same concentration.

Exercise

The pH of a 0.050 M solution of pyridine ($\text{C}_6\text{H}_5\text{N}$) is 8.96 at 25°C . Calculate K_b and $\text{p}K_b$ for pyridine.

Answer: $K_b = 1.7 \times 10^{-9}$; $pK_b = 8.77$

Calculating Percent Ionization from K_a or K_b

When carrying out a laboratory analysis, chemists frequently need to know the concentrations of all species in solution. Because the reactivity of a weak acid or a weak base is usually very different from the reactivity of its conjugate base or acid, we often need to know the percent ionization of a solution of an acid or a base to understand a chemical reaction. The percent ionization is defined as follows:

$$\text{percent ionization of acid} = \frac{[H^+]}{C_{HA}} \times 100 \quad (16.4.4)$$

$$\text{percent ionization of base} = \frac{[OH^-]}{C_B} \times 100 \quad (16.4.5)$$

One way to determine the concentrations of species in solutions of weak acids and bases is a variation of the tabular method we used previously to determine K_a and K_b values. As a demonstration, we will calculate the concentrations of all species and the percent ionization in a 0.150 M solution of formic acid at 25°C. The data in [Table E1](#) show that formic acid ($K_a = 1.8 \times 10^{-4}$ at 25°C) is a slightly stronger acid than acetic acid. The equilibrium equation for the ionization of formic acid in water is as follows:

and the equilibrium constant expression for this reaction is as follows:

$$K_a = \frac{[H^+][HCO_2^-]}{[HCO_2H]} \quad (16.4.7)$$

We set the initial concentration of HCO_2H equal to 0.150 M, and that of HCO_2^- is 0 M. The initial concentration of H^+ is 1.00×10^{-7} M due to the autoionization of water. Because the equilibrium constant for the ionization reaction is small, the equilibrium will lie to the left, favoring the unionized form of the acid. Hence we can define x as the amount of formic acid that dissociates.

If the change in $[HCO_2H]$ is $-x$, then the change in $[H^+]$ and $[HCO_2^-]$ is $+x$. The final concentration of each species is the sum of its initial concentration and the change in concentration, as summarized in the following table.

$HCO_2H_{(aq)} \rightleftharpoons H^+_{(aq)} + HCO_2^-_{(aq)}$ (Chapter 16.4.7)			
	$[HCO_2H]$	$[H^+]$	$[HCO_2^-]$
initial	0.150	1.00×10^{-7}	0
change	$-x$	$+x$	$+x$
final	$(0.150 - x)$	$(1.00 \times 10^{-7} + x)$	x

We can calculate x by substituting the final concentrations from the table into the equilibrium constant expression:

$$K_a = \frac{[H^+][HCO_2^-]}{[HCO_2H]} = \frac{(1.00 \times 10^{-7} + x)x}{0.150 - x} \quad (\text{Chapter 16.4.8})$$

Because the ionization constant K_a is small, x is likely to be small compared with the initial concentration of formic acid: $(0.150 - x)$ M \approx 0.150 M. Moreover, $[H^+]$ due to the autoionization of water (1.00×10^{-7} M) is likely to be negligible compared with $[H^+]$ due to the dissociation of formic acid: $(1.00 \times 10^{-7} + x)$ M \approx x M. Inserting these values into the equilibrium constant expression and solving for x ,

$$K_a = \frac{x^2}{0.150} = 1.8 \times 10^{-4} \quad (\text{Chapter 16.4.9})$$

$$x = 5.2 \times 10^{-3} \quad (\text{Chapter 16.4.10})$$

We can now calculate the concentrations of the species present in a 0.150 M formic acid solution by inserting this value of x into the expressions in the last line of the table:

$$[HCO_2H] = (0.150 - x) M = 0.145 M \quad (\text{Chapter 16.4.11})$$

$$[HCO_2^-] = x = 5.2 \times 10^{-3} M \quad (\text{Chapter 16.4.12})$$

$$[H^+] = (1.00 \times 10^{-7} + x) M = 5.2 \times 10^{-3} M \quad (\text{Chapter 16.4.13})$$

Thus the pH of the solution is $-\log(5.2 \times 10^{-3}) = 2.28$. We can also use these concentrations to calculate the fraction of the original acid that is ionized. In this case, the percent ionization is the ratio of $[H^+]$ (or $[HCO_2^-]$) to the analytical concentration, multiplied by 100 to give a percentage:

$$\text{percent ionization} = \frac{[H^+]}{C_{HA}} \times 100 = \frac{5.2 \times 10^{-3} M}{0.150} \times 100 = 3.5\% \quad (\text{Chapter 16.4.14})$$

Always check to make sure that any simplifying assumption was valid. As a general rule of thumb, approximations such as those used here are valid *only* if the quantity being neglected is no more than about 5% of the quantity to which it is being added or from which it is being subtracted. If the quantity that was neglected is much greater than about 5%, then the approximation is probably not valid, and you should go back and solve the problem using the quadratic formula. In the previous demonstration, both simplifying assumptions were justified: the percent ionization is only 3.5%, which is well below the approximately 5% limit, and the $1.00 \times 10^{-7} M [H^+]$ due to the autoionization of water is much, much less than the $5.2 \times 10^{-3} M [H^+]$ due to the ionization of formic acid.

As a general rule, the $[H^+]$ contribution due to the autoionization of water can be ignored as long as the product of the acid or the base ionization constant and the analytical concentration of the acid or the base is at least 10 times greater than the $[H^+]$ or $[OH^-]$ from the autoionization of water—that is, if

$$K_a C_{HA} \geq 10(1.00 \times 10^{-7}) = 1.0 \times 10^{-6} \quad (16.4.8)$$

or

$$K_b C_B \geq 10(1.00 \times 10^{-7}) = 1.0 \times 10^{-6} \quad (16.4.9)$$

By substituting the appropriate values for the formic acid solution into [Equation 16.45](#), we see that the simplifying assumption is valid in this case:

$$K_a C_{HA} = (1.8 \times 10^{-4})(0.150) = 2.7 \times 10^{-5} > 1.0 \times 10^{-6} \quad (16.4.10)$$

Doing this simple calculation before solving this type of problem saves time and allows you to write simplified expressions for the final concentrations of the species present. In practice, it is necessary to include the $[H^+]$ contribution due to the autoionization of water only for extremely dilute solutions of very weak acids or bases.

Example 8 illustrates how the procedure outlined previously can be used to calculate the pH of a solution of a weak base.

Example 16.4.3

Calculate the pH and percent ionization of a 0.225 M solution of ethylamine ($CH_3CH_2NH_2$), which is used in the synthesis of some dyes and medicines. The pK_b of ethylamine is 3.19 at 20°C.

Given: concentration and pK_b

Asked for: pH and percent ionization

Strategy:

A Write the balanced equilibrium equation for the reaction and the equilibrium constant expression. Calculate K_b from pK_b .

B Use Equation 16.4.8 to see whether you can ignore $[H^+]$ due to the autoionization of water. Then use a tabular format to write expressions for the final concentrations of all species in solution. Substitute these values into the equilibrium equation and solve for $[OH^-]$. Use Equation 16.4.5 to calculate the percent ionization.

C Use the relationship $K_w = [OH^-][H^+]$ to obtain $[H^+]$. Then calculate the pH of the solution.

Solution:

A We begin by writing the balanced equilibrium equation for the reaction:

The corresponding equilibrium constant expression is as follows:

$$K_b = \frac{[CH_3CH_2NH_3^+][OH^-]}{[CH_3CH_2NH_2]}$$

From the pK_b , we have $K_b = 10 - 3.19 = 6.5 \times 10^{-4}$.

B To calculate the pH, we need to determine the H^+ concentration. Unfortunately, H^+ does not appear in either the chemical equation or the equilibrium constant expression. However, $[H^+]$ and $[OH^-]$ in an aqueous solution are related by $K_w = [H^+][OH^-]$. Hence if we can determine $[OH^-]$, we can calculate $[H^+]$ and then the pH. The initial concentration of $CH_3CH_2NH_2$ is 0.225 M, and the initial $[OH^-]$ is 1.00×10^{-7} M. Because ethylamine is a weak base, the extent of the reaction will be small, and it makes sense to let x equal the amount of $CH_3CH_2NH_2$ that reacts with water. The change in $[CH_3CH_2NH_2]$ is therefore $-x$, and the change in both $[CH_3CH_2NH_3^+]$ and $[OH^-]$ is $+x$. To see whether the autoionization of water can safely be ignored, we substitute K_b and C_B into Equation 16.4.10:

$$K_b C_B = (6.5 \times 10^{-4})(0.225) = 1.5 \times 10^{-4} > 1.0 \times 10^{-6}$$

Thus the simplifying assumption is valid, and we will not include $[OH^-]$ due to the autoionization of water in our calculations.

$H_2O(l) + CH_3CH_2NH_2(aq) \rightleftharpoons CH_3CH_2NH_3^+(aq) + OH^-(aq)$ (Chapter 16.4.15)			
	$[CH_3CH_2NH_2]$	$[CH_3CH_2NH_3^+]$	$[OH^-]$
initial	0.225	0	1.00×10^{-7}
change	$-x$	$+x$	$+x$
final	$(0.225 - x)$	x	x

Substituting the quantities from the last line of the table into the equilibrium constant expression,

$$K_b = \frac{[CH_3CH_2NH_3^+][OH^-]}{[CH_3CH_2NH_2]} = \frac{(x)(x)}{0.225 - x} = 6.5 \times 10^{-4}$$

As before, we assume the amount of $CH_3CH_2NH_2$ that ionizes is small compared with the initial concentration, so $[CH_3CH_2NH_2]_f = 0.225 - x \approx 0.225$. With this assumption, we can simplify the equilibrium equation and solve for x :

$$K_b = \frac{x^2}{0.225} = 6.5 \times 10^{-4}$$

$$x = 0.012 = [CH_3CH_2NH_3^+]_f = [OH^-]_f$$

The percent ionization is therefore

$$\text{percent ionization} = \frac{[OH^-]}{C_B} \times 100 = \frac{0.012 \text{ M}}{0.225 \text{ M}} \times 100 = 5.4\% \quad (\text{Chapter 16.4.16})$$

which is at the upper limit of the approximately 5% range that can be ignored. The final hydroxide concentration is thus 0.012 M.

C We can now determine the $[H^+]$ using the expression for K_w :

$$K_w = [OH^-][H^+]$$

$$1.01 \times 10^{-14} = (0.012 M)[H^+]$$

$$8.4 \times 10^{-13} M = [H^+]$$

The pH of the solution is $-\log(8.4 \times 10^{-13}) = 12.08$. Alternatively, we could have calculated pOH as $-\log(0.012) = 1.92$ and determined the pH as follows:

$$pH + pOH = pK_w = 14.00$$

$$pH = 14.00 - 1.92 = 12.08$$

The two methods are equivalent.

Exercise

Aromatic amines, in which the nitrogen atom is bonded directly to a phenyl ring ($-C_6H_5$) tend to be much weaker bases than simple alkylamines. For example, aniline ($C_6H_5NH_2$) has a pK_b of 9.13 at 25°C. What is the pH of a 0.050 M solution of aniline?

Answer: 8.78

The previous examples illustrate a key difference between solutions of strong acids and bases and solutions of weak acids and bases. Because strong acids and bases ionize essentially completely in water, the percent ionization is always approximately 100%, regardless of the concentration. In contrast, the percent ionization in solutions of weak acids and bases is small and depends on the analytical concentration of the weak acid or base. As illustrated for benzoic acid in [Figure 16.4.1](#), the percent ionization of a weak acid or a weak base actually *increases* as its analytical concentration decreases. The percent ionization also increases as the magnitude of K_a and K_b increases.

Figure 16.4.1 The Relationship between the Analytical Concentration of a Weak Acid and Percent Ionization As shown here for benzoic acid ($C_6H_5CO_2H$), the percent ionization decreases as the analytical concentration of a weak acid increases.

Unlike the K_a or the K_b , the percent ionization is not a constant for weak acids and bases but depends on *both* the K_a or the K_b and the analytical concentration. Consequently, the procedure in Example 8 must be used to calculate the percent ionization and pH for solutions of weak acids and bases. Example 9 and its corresponding exercise demonstrate that the combination of a dilute solution

and a relatively large K_a or K_b can give a percent ionization much greater than 5%, making it necessary to use the quadratic equation to determine the concentrations of species in solution.

Note the Pattern

The percent ionization in a solution of a weak acid or a weak base *increases* as the analytical concentration *decreases* and as the K_a or the K_b *increases*.

Example 16.4.4

Benzoic acid ($C_6H_5CO_2H$) is used in the food industry as a preservative and medically as an antifungal agent. Its pK_a at $25^\circ C$ is 4.20, making it a somewhat stronger acid than acetic acid. Calculate the percentage of benzoic acid molecules that are ionized in each solution.

1. a 0.0500 M solution
2. a 0.00500 M solution

Given: concentrations and pK_a

Asked for: percent ionization

Strategy:

A Write both the balanced equilibrium equation for the ionization reaction and the equilibrium equation (Equation 16.2.2). Use Equation 16.2.13 to calculate the K_a from the pK_a .

B For both the concentrated solution and the dilute solution, use a tabular format to write expressions for the final concentrations of all species in solution. Substitute these values into the equilibrium equation and solve for $[C_6H_5CO_2^-]_f$ for each solution.

C Use the values of $[C_6H_5CO_2^-]_f$ and Equation 16.4.4 to calculate the percent ionization.

Solution:

A If we abbreviate benzoic acid as $PhCO_2H$ where $Ph = -C_6H_5$, the balanced equilibrium equation for the ionization reaction and the equilibrium equation can be written as follows:

$$K_a = \frac{[H^+][PhCO_2^-]}{[PhCO_2H]}$$

From the pK_a , we have $K_a = 10^{-4.20} = 6.3 \times 10^{-5}$.

1. **B** For the more concentrated solution, we set up our table of initial concentrations, changes in concentrations, and final concentrations:

$PhCO_2H_{(aq)} \rightleftharpoons H_{(aq)}^+ + PhCO_2^-_{(aq)}$ (Chapter 16.4.17)			
	[PhCO ₂ H]	[H ⁺]	[PhCO ₂ ⁻]
initial	0.0500	1.00×10^{-7}	0
change	-x	+x	+x
final	(0.0500 - x)	($1.00 \times 10^{-7} + x$)	x

Inserting the expressions for the final concentrations into the equilibrium equation and making our usual assumptions, that $[PhCO_2^-]$ and $[H^+]$ are negligible due to the autoionization of water,

$$K_a = \frac{[H^+][PhCO_2^-]}{[PhCO_2H]} = \frac{(x)(x)}{0.0500 - x} = \frac{x^2}{0.0500} = 6.3 \times 10^{-5}$$

$$1.8 \times 10^{-3} = x$$

This value is less than 5% of 0.0500, so our simplifying assumption is justified, and $[PhCO_2^-]$ at equilibrium is 1.8×10^{-3} M. We reach the same conclusion using C_{HA} : $K_a C_{HA} = (6.3 \times 10^{-5})(0.0500) = 3.2 \times 10^{-6} > 1.0 \times 10^{-6}$.

C The percent ionized is the ratio of the concentration of $PhCO_2^-$ to the analytical concentration, multiplied by 100:

$$\text{percent ionized} = \frac{[PhCO_2^-]}{C_{PhCO_2H}} \times 100 = \frac{1.8 \times 10^{-3}}{0.0500} \times 100 = 3.6\%$$

Because only 3.6% of the benzoic acid molecules are ionized in a 0.0500 M solution, our simplifying assumptions are confirmed.

2. **B** For the more dilute solution, we proceed in exactly the same manner. Our table of concentrations is therefore as follows:

$PhCO_2H_{(aq)} \rightleftharpoons H^+_{(aq)} + PhCO_2^-_{(aq)}$ (Chapter 16.4.18)			
	$[PhCO_2H]$	$[H^+]$	$[PhCO_2^-]$
initial	0.00500	1.00×10^{-7}	0
change	-x	+x	+x
final	$(0.00500 - x)$	$(1.00 \times 10^{-7} + x)$	x

Inserting the expressions for the final concentrations into the equilibrium equation and making our usual simplifying assumptions,

$$K_a = \frac{[H^+][PhCO_2^-]}{[PhCO_2H]} = \frac{(x)(x)}{0.00500 - x} = \frac{x^2}{0.00500} = 6.3 \times 10^{-5}$$

$$5.6 \times 10^{-4} = x$$

Unfortunately, this number is greater than 10% of 0.00500, so our assumption that the fraction of benzoic acid that is ionized in this solution could be neglected and that $(0.00500 - x) \approx x$ is not valid. Furthermore, we see that $K_a C_{HA} = (6.3 \times 10^{-5})(0.00500) = 3.2 \times 10^{-7} < 1.0 \times 10^{-6}$. Thus the relevant equation is as follows:

$$\frac{x^2}{0.00500 - x} = 6.3 \times 10^{-5}$$

which must be solved using the quadratic formula. Multiplying out the quantities,

$$x^2 = (6.3 \times 10^{-5})(0.00500 - x) = (3.2 \times 10^{-7}) - (6.3 \times 10^{-5})x$$

Rearranging the equation to fit the standard quadratic equation format,

$$x^2 + (6.3 \times 10^{-5})x - (3.2 \times 10^{-7}) = 0$$

This equation can be solved by using the quadratic formula:

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

$$x = \frac{-(6.3 \times 10^{-5}) \pm \sqrt{(6.3 \times 10^{-5})^2 - 4(1)(-3.2 \times 10^{-7})}}{2(1)}$$

$$x = \frac{-(6.3 \times 10^{-5}) \pm (1.1 \times 10^{-3})}{2} = 5.3 \times 10^{-4}$$

or

$$x = -5.9 \times 10^{-4}$$

Because a negative x value corresponds to a negative $[\text{PhCO}_2^-]$, which is not physically meaningful, we use the positive solution: $x = 5.3 \times 10^{-4}$. Thus $[\text{PhCO}_2^-] = 5.3 \times 10^{-4}$ M.

C The percent ionized is therefore

$$\text{percent ionized} = \frac{[\text{PhCO}_2^-]C_{\text{PhCO}_2\text{H}}}{C_{\text{PhCO}_2\text{H}}} \times 100 = \frac{5.3 \times 10^{-4}}{0.00500} \times 100 = 11\%$$

In the more dilute solution ($C = 0.00500$ M), 11% of the benzoic acid molecules are ionized versus only 3.6% in the more concentrated solution ($C = 0.0500$ M). Decreasing the analytical concentration by a factor of 10 results in an approximately threefold increase in the percentage of benzoic acid molecules that are ionized.

Exercise

Lactic acid ($\text{CH}_3\text{CH}(\text{OH})\text{CO}_2\text{H}$) is a weak acid with a $\text{p}K_a$ of 3.86 at 25°C . What percentage of the lactic acid is ionized in each solution?

1. a 0.10 M solution
2. a 0.0020 M solution

Answer:

1. 3.7%
2. 23%

Determining K_{eq} from K_a and K_b

In Section 16.2, you learned how to use K_a and K_b values to qualitatively predict whether reactants or products are favored in an acid–base reaction. Tabulated values of K_a (or $\text{p}K_a$) and K_b (or $\text{p}K_b$), plus the K_w , enable us to quantitatively determine the direction and extent of reaction for a weak acid and a weak base by calculating K for the reaction. To illustrate how to do this, we begin by writing the dissociation equilibria for a weak acid and a weak base and then summing them:

+ -

The overall reaction has H_2O on the left and H^+ and OH^- on the right, which means it involves the autoionization of water ($H_2O \rightleftharpoons H^+ + OH^-$) in addition to the acid–base equilibrium in which we are interested. We can obtain an equation that includes only the acid–base equilibrium by simply adding the equation for the reverse of the autoionization of water ($H^+ + OH^- \rightleftharpoons H_2O$), for which $K = 1/K_w$, to the overall equilibrium in [Equation 16.4.11](#) and canceling:

Thus the equilibrium constant for the reaction of a weak acid with a weak base is the product of the ionization constants of the acid and the base divided by K_w . Example 10 illustrates how to calculate the equilibrium constant for the reaction of a weak acid with a weak base.

Example 16.4.5

Fish tend to spoil rapidly, even when refrigerated. The cause of the resulting “fishy” odor is a mixture of amines, particularly methylamine (CH_3NH_2), a volatile weak base ($pK_b = 3.34$). Fish is often served with a wedge of lemon because lemon juice contains citric acid, a triprotic acid with pK_a values of 3.13, 4.76, and 6.40 that can neutralize amines. Calculate the equilibrium constant for the reaction of excess citric acid with methylamine, assuming that only the first dissociation constant of citric acid is important.

Given: pK_b for base and pK_a for acid

Asked for: K

Strategy:

A Write the balanced equilibrium equation and the equilibrium constant expression for the reaction.

B Convert pK_a and pK_b to K_a and K_b and then use [Equation 16.4.12](#) to calculate K .

Solution:

A If we abbreviate citric acid as $H_3\text{citrate}$, the equilibrium equation for its reaction with methylamine is as follows:

The equilibrium constant expression for this reaction is as follows:

$$K = \frac{[CH_3NH_3^+][H_2\text{citrate}^-]}{[CH_3NH_2][H_3\text{citrate}]}$$

B [Equation 16.49](#) is $K = (K_a K_b)/K_w$. Converting pK_a and pK_b to K_a and K_b gives $K_a = 10^{-3.13} = 7.4 \times 10^{-4}$ for citric acid and $K_b = 10^{-3.34} = 4.6 \times 10^{-4}$ for methylamine. Substituting these values into the equilibrium equation,

$$K = \frac{K_a K_b}{K_w} = \frac{(7.4 \times 10^{-4})(4.6 \times 10^{-4})}{1.01 \times 10^{-14}} = 3.4 \times 10^7$$

The value of pK can also be calculated directly by taking the negative logarithm of both sides of Equation 16.49, which gives

$$\backslash(pK = pK_a + pK_b - pK_w = 3.13 + 3.34 - 14.00 = -7.53 \text{ \notag } \backslash$$

Thus $K = 10^{-(-7.53)} = 3.4 \times 10^7$, in agreement with the earlier value. In either case, the K values show that the reaction of citric acid with the volatile, foul-smelling methylamine lies very far to the right, favoring the formation of a much less volatile salt with no odor. This is one reason a little lemon juice helps make less-than-fresh fish more appetizing.

Exercise

Dilute aqueous ammonia solution, often used as a cleaning agent, is also effective as a deodorizing agent. To see why, calculate the equilibrium constant for the reaction of aqueous ammonia with butyric acid ($\text{CH}_3\text{CH}_2\text{CH}_2\text{CO}_2\text{H}$), a particularly foul-smelling substance associated with the odor of rancid butter and smelly socks. The pK_b of ammonia is 4.75, and the pK_a of butyric acid is 4.83.

Answer: 2.6×10^4

Summary

If the concentration of one or more of the species in a solution of an acid or a base is determined experimentally, K_a and K_b can be calculated, and K_a , pK_a , K_b , and pK_b can be used to quantitatively describe the composition of solutions of acids and bases. The concentrations of all species present in solution can be determined, as can the pH of the solution and the percentage of the acid or base that is ionized. The equilibrium constant for the reaction of a weak acid with a weak base can be calculated from K_a (or pK_a), K_b (or pK_b), and K_w .

Key Takeaway

- For a solution of a weak acid or a weak base, the percent ionization increases as the K_a or the K_b increases and as the analytical concentration decreases.

Key Equations

Percent ionization of acid

$$\text{Equation 16.4.4: } = \frac{[H^+]}{C_{HA}} \times 100$$

Percent ionization of base

$$\text{Equation 16.4.5: } = \frac{[OH^-]}{C_B} \times 100$$

Equilibrium constant for reaction of a weak acid with a weak base

$$\text{Equation 16.4.12: } K = \frac{K_a K_b}{K_w}$$

Conceptual Problems

1. Explain why the analytical concentration (C) of H_2SO_4 is equal to $[\text{H}_2\text{SO}_4] + [\text{HSO}_4^-] + [\text{SO}_4^{2-}]$.
2. Write an expression for the analytical concentration (C) of H_3PO_4 in terms of the concentrations of the species actually present in solution.

- For relatively dilute solutions of a weak acid such as acetic acid ($\text{CH}_3\text{CO}_2\text{H}$), the concentration of undissociated acetic acid in solution is often assumed to be the same as the analytical concentration. Explain why this is a valid practice.
- How does dilution affect the percent ionization of a weak acid or a weak base?
- What is the relationship between the K_a of a weak acid and its percent ionization? Does a compound with a large $\text{p}K_a$ value have a higher or a lower percent ionization than a compound with a small $\text{p}K_a$ value (assuming the same analytical concentration in both cases)? Explain.
- For a dilute solution of a weak acid (HA), show that the pH of the solution can be approximated using the following equation (where C_{HA} is the analytical concentration of the weak acid):

$$\text{pH} = -\log \sqrt{K_a C_{\text{HA}}} \quad (\text{Chapter 16.4.19})$$

Under what conditions is this approximation valid?

Numerical Problems

- The $\text{p}K_a$ of NH_3 is estimated to be 35. Its conjugate base, the amide ion (NH_2^-), can be isolated as an alkali metal salt, such as sodium amide (NaNH_2). Calculate the pH of a solution prepared by adding 0.100 mol of sodium amide to 1.00 L of water. Does the pH differ appreciably from the pH of a NaOH solution of the same concentration? Why or why not?
- Phenol is a topical anesthetic that has been used in throat lozenges to relieve sore throat pain. Describe in detail how you would prepare a 2.00 M solution of phenol ($\text{C}_6\text{H}_5\text{OH}$) in water; then write equations to show all the species present in the solution. What is the equilibrium constant expression for the reaction of phenol with water? Use the information in Table E1 and Table E2 to calculate the pH of the phenol solution.
- Describe in detail how you would prepare a 1.50 M solution of methylamine in water; then write equations to show all the species present in the solution. What is the equilibrium constant expression for the reaction of methylamine with water? Use the information in Table E1 and Table E2 to calculate the pH of the solution.
- A 0.200 M solution of diethylamine, a substance used in insecticides and fungicides, is only 3.9% ionized at 25°C. Write an equation showing the equilibrium reaction and then calculate the $\text{p}K_b$ of diethylamine. What is the $\text{p}K_a$ of its conjugate acid, the diethylammonium ion? What is the equilibrium constant expression for the reaction of diethylammonium chloride with water?
- A 1.00 M solution of fluoroacetic acid ($\text{FCH}_2\text{CO}_2\text{H}$) is 5% dissociated in water. What is the equilibrium constant expression for the dissociation reaction? Calculate the concentration of each species in solution and then calculate the $\text{p}K_a$ of $\text{FCH}_2\text{CO}_2\text{H}$.
- The $\text{p}K_a$ of 3-chlorobutanoic acid ($\text{CH}_3\text{CHClCH}_2\text{CO}_2\text{H}$) is 4.05. What percentage is dissociated in a 1.0 M solution? Do you expect the $\text{p}K_a$ of butanoic acid to be greater than or less than the $\text{p}K_a$ of 3-chlorobutanoic acid? Why?
- The $\text{p}K_a$ of the ethylammonium ion ($\text{C}_2\text{H}_5\text{NH}_3^+$) is 10.64. What percentage of ethylamine is ionized in a 1.00 M solution of ethylamine?
- The $\text{p}K_a$ of $\text{Cl}_3\text{CCO}_2\text{H}$ is 0.64. What is the pH of a 0.580 M solution? What percentage of the $\text{Cl}_3\text{CCO}_2\text{H}$ is dissociated?
- The pH of a 0.150 M solution of aniline hydrochloride ($\text{C}_6\text{H}_5\text{NH}_3^+ \text{Cl}^-$) is 2.70. What is the $\text{p}K_b$ of the conjugate base, aniline ($\text{C}_6\text{H}_5\text{NH}_2$)? Do you expect the $\text{p}K_b$ of $(\text{CH}_3)_2\text{CHNH}_2$ to be greater than or less than the $\text{p}K_b$ of $\text{C}_6\text{H}_5\text{NH}_2$? Why?
- What is the pH of a 0.620 M solution of $\text{CH}_3\text{NH}_3^+ \text{Br}^-$ if the $\text{p}K_b$ of CH_3NH_2 is 10.62?
- The $\text{p}K_b$ of 4-hydroxypyridine is 10.80 at 25°C. What is the pH of a 0.0250 M solution?

- The $\text{p}K_a$ values of formic acid and the methylammonium ion are 3.75 and 10.62, respectively. Calculate K for the following reaction:

- The $\text{p}K_a$ values of butanoic acid and the ammonium ion are 4.82 and 9.24, respectively. Calculate K for the following reaction:

14. Use the information in Tables E1 and E2 to calculate the pH of a 0.0968 M solution of calcium formate.
15. Calculate the pH of a 0.24 M solution of sodium lactate. The pK_a of lactic acid is 3.86.
16. Use the information in Tables E1 and E2 to determine the pH of a solution prepared by dissolving 750.0 mg of methylammonium chloride ($\text{CH}_3\text{NH}_3^+ \text{Cl}^-$) in enough water to make 150.0 mL of solution.
17. Use the information in Tables E1 and E2 to determine the pH of a solution prepared by dissolving 855 mg of sodium nitrite (NaNO_2) in enough water to make 100.0 mL of solution.

Learning Objective

- To calculate the pH at any point in an acid–base titration.

In [Chapter 8](#), you learned that in an acid–base titration, a buret is used to deliver measured volumes of an acid or a base solution of known concentration (the *titrant*) to a flask that contains a solution of a base or an acid, respectively, of unknown concentration (the *unknown*). If the concentration of the titrant is known, then the concentration of the unknown can be determined. The following discussion focuses on the pH changes that occur during an acid–base titration. Plotting the pH of the solution in the flask against the amount of acid or base added produces a titration curve. The shape of the curve provides important information about what is occurring in solution during the titration.

Titrations of Strong Acids and Bases

Part (a) of [Figure 16.5.1](#) shows a plot of the pH as 0.20 M HCl is gradually added to 50.00 mL of pure water. The pH of the sample in the flask is initially 7.00 (as expected for pure water), but it drops very rapidly as HCl is added. Eventually the pH becomes constant at 0.70—a point well beyond its value of 1.00 with the addition of 50.0 mL of HCl (0.70 is the pH of 0.20 M HCl). In contrast, when 0.20 M NaOH is added to 50.00 mL of distilled water, the pH (initially 7.00) climbs very rapidly at first but then more gradually, eventually approaching a limit of 13.30 (the pH of 0.20 M NaOH), again well beyond its value of 13.00 with the addition of 50.0 mL of NaOH as shown in part (b) in [Figure 16.5.1](#). As you can see from these plots, the titration curve for adding a base is the mirror image of the curve for adding an acid.

Figure 16.5.1 Solution pH as a Function of the Volume of a Strong Acid or a Strong Base Added to Distilled Water (a) When 0.20 M HCl is added to 50.0 mL of distilled water, the pH rapidly decreases until it reaches a minimum at the pH of 0.20 M HCl. (b) Conversely, when 0.20 M NaOH is added to 50.0 mL of distilled water, the pH rapidly increases until it reaches a maximum at the pH of 0.20 M NaOH.

Suppose that we now add 0.20 M NaOH to 50.0 mL of a 0.10 M solution of HCl. Because HCl is a strong acid that is completely ionized in water, the initial $[H^+]$ is 0.10 M, and the initial pH is 1.00. Adding NaOH decreases the concentration of H^+ because of the neutralization reaction: $OH^- + H^+ \rightleftharpoons H_2O$ (in part (a) in [Figure 16.5.2](#)). Thus the pH of the solution increases gradually. Near the equivalence point, however, the point at which the number of moles of base (or acid) added equals the number of moles of acid (or base) originally present in the solution, the pH increases much more rapidly because most of the H^+ ions originally present have been consumed. (For more information on titrations and the equivalence point, see [Section 8.9](#).) For the titration of a monoprotic strong acid (HCl) with a *monobasic* strong base (NaOH), we can calculate the volume of base needed to reach the equivalence point from the following relationship:

$$\text{moles of base} = (\text{volume})_b (\text{molarity})_b V_b M_b = \text{moles of acid} = (\text{volume})_a (\text{molarity})_a = V_a M_a \quad (16.5.1)$$

If 0.20 M NaOH is added to 50.0 mL of a 0.10 M solution of HCl, we solve for V_b :

$$V_b(0.20M) = 0.025L = 25mL \quad (\text{Chapter 16.5.1})$$

Figure 16.5.2 The Titration of (a) a Strong Acid with a Strong Base and (b) a Strong Base with a Strong Acid(a) As 0.20 M NaOH is slowly added to 50.0 mL of 0.10 M HCl, the pH increases slowly at first, then increases very rapidly as the equivalence point is approached, and finally increases slowly once more. (b) Conversely, as 0.20 M HCl is slowly added to 50.0 mL of 0.10 M NaOH, the pH decreases slowly at first, then decreases very rapidly as the equivalence point is approached, and finally decreases slowly once more.

At the equivalence point (when 25.0 mL of NaOH solution has been added), the neutralization is complete: only a salt remains in solution (NaCl), and the pH of the solution is 7.00. Adding more NaOH produces a rapid increase in pH, but eventually the pH levels off at a value of about 13.30, the pH of 0.20 M NaOH.

As shown in part (b) in Figure 16.5.2, the titration of 50.0 mL of a 0.10 M solution of NaOH with 0.20 M HCl produces a titration curve that is nearly the mirror image of the titration curve in part (a) in Figure 16.5.2. The pH is initially 13.00, and it slowly decreases as HCl is added. As the equivalence point is approached, the pH drops rapidly before leveling off at a value of about 0.70, the pH of 0.20 M HCl.

The titration of either a strong acid with a strong base or a strong base with a strong acid produces an S-shaped curve. The curve is somewhat asymmetrical because the steady increase in the volume of the solution during the titration causes the solution to become more dilute. Due to the leveling effect, the shape of the curve for a titration involving a strong acid and a strong base depends on *only* the concentrations of the acid and base, *not* their identities.

Note the Pattern

The shape of the titration curve involving a strong acid and a strong base depends only on their concentrations, not their identities.

Example 16.5.1

Calculate the pH of the solution after 24.90 mL of 0.200 M NaOH has been added to 50.00 mL of 0.100 M HCl.

Given: volumes and concentrations of strong base and acid

Asked for: pH

Strategy:

A Calculate the number of millimoles of H^+ and OH^- to determine which, if either, is in excess after the neutralization reaction has occurred. If one species is in excess, calculate the amount that remains after the neutralization reaction.

B Determine the final volume of the solution. Calculate the concentration of the species in excess and convert this value to pH.

Solution:

A Because 0.100 mol/L is equivalent to 0.100 mmol/mL, the number of millimoles of H^+ in 50.00 mL of 0.100 M HCl can be calculated as follows:

$$50.00 \text{ mL} \left(\frac{0.100 \text{ mmol HCl}}{\text{mL}} \right) = 5.00 \text{ mmol HCl} = 5.00 \text{ mmol H}^+$$

The number of millimoles of NaOH added is as follows:

$$24.90 \text{ mL} \left(\frac{0.200 \text{ mmol NaOH}}{\text{mL}} \right) = 4.98 \text{ mmol NaOH} = 4.98 \text{ mmol OH}^-$$

Thus H^+ is in excess. To completely neutralize the acid requires the addition of 5.00 mmol of OH^- to the HCl solution. Because only 4.98 mmol of OH^- has been added, the amount of excess H^+ is $5.00 \text{ mmol} - 4.98 \text{ mmol} = 0.02 \text{ mmol}$ of H^+ .

B The final volume of the solution is 50.00 mL + 24.90 mL = 74.90 mL, so the final concentration of H^+ is as follows:

$$[H^+] = \frac{0.02 \text{ mmol } H^+}{74.90 \text{ mL}} = 3 \times 10^{-4} \text{ M}$$

The pH is $-\log[H^+] = -\log(3 \times 10^{-4}) = 3.5$, which is significantly less than the pH of 7.00 for a neutral solution.

Exercise

Calculate the pH of a solution prepared by adding 40.00 mL of 0.237 M HCl to 75.00 mL of a 0.133 M solution of NaOH.

Answer: 11.6

Titration of Weak Acids and Bases

In contrast to strong acids and bases, the shape of the titration curve for a weak acid or a weak base depends dramatically on the identity of the acid or the base and the corresponding K_a or K_b . As we shall see, the pH also changes much more gradually around the equivalence point in the titration of a weak acid or a weak base. As you learned in Section 16.4, $[H^+]$ of a solution of a weak acid (HA) is *not* equal to the concentration of the acid but depends on both its pK_a and its concentration. Because only a fraction of a weak acid dissociates, $[H^+]$ is less than [HA]. Thus the pH of a solution of a weak acid is greater than the pH of a solution of a strong acid of the same concentration. Part (a) in Figure 16.5.3 shows the titration curve for 50.0 mL of a 0.100 M solution of acetic acid with 0.200 M NaOH superimposed on the curve for the titration of 0.100 M HCl shown in part (a) in Figure 16.5.2. Below the equivalence point, the two curves are very different. Before any base is added, the pH of the acetic acid solution is greater than the pH of the HCl solution, and the pH changes more rapidly during the first part of the titration. Note also that the pH of the acetic acid solution at the equivalence point is greater than 7.00. That is, at the equivalence point, the solution is basic. In addition, the change in pH around the equivalence point is only about half as large as for the HCl titration; the magnitude of the pH change at the equivalence point depends on the pK_a of the acid being titrated. Above the equivalence point, however, the two curves are identical. Once the acid has been neutralized, the pH of the solution is controlled only by the amount of excess NaOH present, regardless of whether the acid is weak or strong.

Note the Pattern

The shape of the titration curve of a weak acid or weak base depends heavily on their identities and the K_a or K_b .

The titration curve in part (a) in Figure 16.5.3 was created by calculating the starting pH of the acetic acid solution before any NaOH is added and then calculating the pH of the solution after adding increasing volumes of NaOH. The procedure is illustrated in the following subsection and Example 12 for three points on the titration curve, using the pK_a of acetic acid (4.76 at 25°C; $K_a = 1.7 \times 10^{-5}$).

Figure 16.5.3 The Titration of (a) a Weak Acid with a Strong Base and (b) a Weak Base with a Strong Acid(a) As 0.200 M NaOH is slowly added to 50.0 mL of 0.100 M acetic acid, the pH increases slowly at first, then increases rapidly as the equivalence point is approached, and then again increases more slowly. The corresponding curve for the titration of 50.0 mL of 0.100 M HCl with 0.200 M NaOH is shown as a dashed line. (b) As 0.200 M HCl is slowly added to 50.0 mL of 0.100 M NH_3 , the pH decreases slowly at first, then decreases rapidly as the equivalence point is approached, and then again decreases more slowly. The corresponding curve for the titration of 50.0 mL of 0.100 M NaOH with 0.200 M HCl is shown as a dashed line.

Calculating the pH of a Solution of a Weak Acid or a Weak Base

As explained [Section 16.4](#), if we know K_a or K_b and the initial concentration of a weak acid or a weak base, we can calculate the pH of a solution of a weak acid or a weak base by setting up a table of initial concentrations, changes in concentrations, and final concentrations. In this situation, the initial concentration of acetic acid is 0.100 M. If we define x as $[H^+]$ due to the dissociation of the acid, then the table of concentrations for the ionization of 0.100 M acetic acid is as follows:

$CH_3CO_2H(aq) \rightleftharpoons H^+(aq) + CH_3CO_2^-(aq)$ (Chapter 16.5.2)			
	$[CH_3CO_2H]$	$[H^+]$	$[CH_3CO_2^-]$
initial	0.100	1.00×10^{-7}	0
change	$-x$	$+x$	$+x$
final	$(0.100 - x)$	x	x

In this and all subsequent examples, we will ignore $[H^+]$ and $[OH^-]$ due to the autoionization of water when calculating the final concentration. However, you should use [Equation 16.4.8](#) and [Equation 16.4.9](#) to check that this assumption is justified.

Inserting the expressions for the final concentrations into the equilibrium equation (and using approximations),

$$K_a = \frac{[H^+][CH_3CO_2^-]}{[CH_3CO_2H]} = \frac{(x)(x)}{0.100 - x} \approx \frac{x^2}{0.100} = 1.74 \times 10^{-5}$$

Solving this equation gives $x = [H^+] = 1.32 \times 10^{-3} M$. Thus the pH of a 0.100 M solution of acetic acid is as follows:

$$pH = -\log(1.32 \times 10^{-3}) = 2.879$$

Calculating the pH during the Titration of a Weak Acid or a Weak Base

Now consider what happens when we add 5.00 mL of 0.200 M NaOH to 50.00 mL of 0.100 M CH_3CO_2H (part (a) in [Figure 16.5.4](#)). Because the neutralization reaction proceeds to completion, all of the OH^- ions added will react with the acetic acid to generate acetate ion and water:

All problems of this type must be solved in two steps: a stoichiometric calculation followed by an equilibrium calculation. In the first step, we use the stoichiometry of the neutralization reaction to calculate the *amounts* of acid and conjugate base present in solution after the neutralization reaction has occurred. In the second step, we use the equilibrium equation ([Equation 16.2.2](#)) to determine $[H^+]$ of the resulting solution.

Step 1: To determine the amount of acid and conjugate base in solution after the neutralization reaction, we calculate the amount of CH_3CO_2H in the original solution and the amount of OH^- in the NaOH solution that was added. The acetic acid solution contained

$$50.00 \text{ mL} (0.100 \text{ mmol}(CH_3CO_2H) / \text{mL}) = 5.00 \text{ mmol}(CH_3CO_2H)$$

The NaOH solution contained

$$5.00 \text{ mL} = 1.00 \text{ mmol} (\text{NaOH})$$

Comparing the amounts shows that CH_3CO_2H is in excess. Because OH^- reacts with CH_3CO_2H in a 1:1 stoichiometry, the amount of excess CH_3CO_2H is as follows:

$$5.00 \text{ mmol } CH_3CO_2H - 1.00 \text{ mmol } OH^- = 4.00 \text{ mmol } CH_3CO_2H$$

Each 1 mmol of OH^- reacts to produce 1 mmol of acetate ion, so the final amount of $CH_3CO_2^-$ is 1.00 mmol.

The stoichiometry of the reaction is summarized in the following table, which shows the numbers of moles of the various species, *not* their concentrations.

$CH_3CO_2H(aq) + OH^-(aq) \rightarrow CH_3CO_2^-(aq) + H_2O(l)$ (Chapter 16.5.3)			
	$[CH_3CO_2H]$	$[OH^-]$	$[CH_3CO_2^-]$
initial	5.00 mmol	1.00 mmol	0 mmol
change	-1.00 mmol	-1.00 mmol	+1.00 mmol

	$CH_3CO_2H(aq)$	$OH^-(aq)$	$CH_3CO_2^-(aq)$	$H_2O(l)$
	$[CH_3CO_2H]$	$[OH^-]$	$[CH_3CO_2^-]$	
final	4.00 mmol	0 mmol	1.00 mmol	

This table gives the initial amount of acetate and the final amount of OH^- ions as 0. Because an aqueous solution of acetic acid always contains at least a small amount of acetate ion in equilibrium with acetic acid, however, the initial acetate concentration is not actually 0. The value can be ignored in this calculation because the amount of $CH_3CO_2^-$ in equilibrium is insignificant compared to the amount of OH^- added. Moreover, due to the autoionization of water, no aqueous solution can contain 0 mmol of OH^- , but the amount of OH^- due to the autoionization of water is insignificant compared to the amount of OH^- added. We use the initial amounts of the reactants to determine the stoichiometry of the reaction and defer a consideration of the equilibrium until the second half of the problem.

Step 2: To calculate $[H^+]$ at equilibrium following the addition of NaOH, we must first calculate $[CH_3CO_2H]$ and $[CH_3CO_2^-]$ using the number of millimoles of each and the total volume of the solution at this point in the titration:

$$\begin{aligned} \text{final volume} &= 50.00 \text{ mL} + 5.00 \text{ mL} = 55.00 \text{ mL} \\ [CH_3CO_2H] &= \frac{4.00 \text{ mmol } CH_3CO_2H}{55.00 \text{ mL}} = 7.27 \times 10^{-2} \text{ M} \\ [CH_3CO_2^-] &= \frac{1.00 \text{ mmol } CH_3CO_2^-}{55.00 \text{ mL}} = 1.82 \times 10^{-2} \text{ M} \end{aligned}$$

Knowing the concentrations of acetic acid and acetate ion at equilibrium and K_a for acetic acid (1.74×10^{-5}), we can use Equation 16.2.2 to calculate $[H^+]$ at equilibrium:

$$\begin{aligned} K_a &= \frac{[CH_3CO_2^-][H^+]}{[CH_3CO_2H]} \\ [H^+] &= \frac{K_a [CH_3CO_2H]}{[CH_3CO_2^-]} = \frac{(1.74 \times 10^{-5})(7.27 \times 10^{-2} \text{ M})}{(1.82 \times 10^{-2})} = 6.95 \times 10^{-5} \text{ M} \end{aligned}$$

Calculating $-\log[H^+]$ gives $pH = -\log(6.95 \times 10^{-5}) = 4.158$.

Comparing the titration curves for HCl and acetic acid in part (a) in Figure 16.5.3, we see that adding the same amount (5.00 mL) of 0.200 M NaOH to 50 mL of a 0.100 M solution of both acids causes a much smaller pH change for HCl (from 1.00 to 1.14) than for acetic acid (2.88 to 4.16). This is consistent with the qualitative description of the shapes of the titration curves at the beginning of this section. In Example 16.5.2, we calculate another point for constructing the titration curve of acetic acid.

Example 16.5.2

What is the pH of the solution after 25.00 mL of 0.200 M NaOH is added to 50.00 mL of 0.100 M acetic acid?

Given: volume and molarity of base and acid

Asked for: pH

Strategy:

- Write the balanced chemical equation for the reaction. Then calculate the initial numbers of millimoles of OH^- and CH_3CO_2H . Determine which species, if either, is present in excess.
- Tabulate the results showing initial numbers, changes, and final numbers of millimoles.
- If excess acetate is present after the reaction with OH^- , write the equation for the reaction of acetate with water. Use a tabular format to obtain the concentrations of all the species present.
- Calculate K_b using the relationship $K_w = K_a K_b$ (Equation 16.2.10). Calculate $[OH^-]$ and use this to calculate the pH of the solution.

Solution:

A Ignoring the spectator ion (Na^+), the equation for this reaction is as follows:

The initial numbers of millimoles of OH^- and CH_3CO_2H are as follows:

$$25.00 \text{ mL} \left(\frac{0.200 \text{ mmol OH}^-}{\text{mL}} \right) = 5.00 \text{ mmol OH}^-$$

$$50.00 \text{ mL} \left(\frac{0.100 \text{ mmol CH}_3\text{CO}_2\text{H}}{\text{mL}} \right) = 5.00 \text{ mmol CH}_3\text{CO}_2\text{H}$$

The number of millimoles of OH^- equals the number of millimoles of $\text{CH}_3\text{CO}_2\text{H}$, so neither species is present in excess.

B Because the number of millimoles of OH^- added corresponds to the number of millimoles of acetic acid in solution, this is the equivalence point. The results of the neutralization reaction can be summarized in tabular form.

$\text{CH}_3\text{CO}_2\text{H}_{(aq)} + \text{OH}^-_{(aq)} \rightleftharpoons \text{CH}_3\text{CO}_2^-_{(aq)} + \text{H}_2\text{O}(l)$			
	$[\text{CH}_3\text{CO}_2\text{H}]$	$[\text{OH}^-]$	$[\text{CH}_3\text{CO}_2^-]$
initial	5.00 mmol	5.00 mmol	0 mmol
final	0 mmol	0 mmol	5.00 mmol
change	-5.00 mmol	-5.00 mmol	+5.00 mmol

C Because the product of the neutralization reaction is a weak base, we must consider the reaction of the weak base *with water* to calculate $[\text{H}^+]$ at equilibrium and thus the final pH of the solution. The initial concentration of acetate is obtained from the neutralization reaction:

$$[\text{CH}_3\text{CO}_2^-] = \frac{5.00 \text{ mmol CH}_3\text{CO}_2^-}{(50.00 + 25.00) \text{ mL}} = 6.67 \times 10^{-2} \text{ M}$$

The equilibrium reaction of acetate with water is as follows:

The equilibrium constant for this reaction is $K_b = K_w/K_a$, where K_a is the acid ionization constant of acetic acid. We therefore define x as $[\text{OH}^-]$ produced by the reaction of acetate with water. Here is the completed table of concentrations:

$\text{H}_2\text{O}(l) + \text{CH}_3\text{CO}_2^-_{(aq)} \rightleftharpoons \text{CH}_3\text{CO}_2\text{H}_{(aq)} + \text{OH}^-_{(aq)}$			
	$[\text{CH}_3\text{CO}_2^-]$	$[\text{CH}_3\text{CO}_2\text{H}]$	$[\text{OH}^-]$
initial	0.0667	0	1.00×10^{-7}
change	-x	+x	+x
final	(0.0667 - x)	x	x

D Substituting the expressions for the final values from this table into [Equation 16.2.5](#),

$$K_b = \frac{[\text{CH}_3\text{CO}_2\text{H}][\text{OH}^-]}{[\text{CH}_3\text{CO}_2^-]} \approx = \frac{x \cdot x}{0.0667 - x} = \frac{x^2}{0.0667}$$

We can obtain K_b by rearranging [Equation 16.2.10](#) and substituting the known values:

$$K_b = \frac{K_w}{K_a} = \frac{1.01 \times 10^{-14}}{1.74 \times 10^{-5}} = 5.80 \times 10^{-10} = \frac{x^2}{0.0667}$$

which we can solve to get $x = 6.22 \times 10^{-6}$. Thus $[\text{OH}^-] = 6.22 \times 10^{-6} \text{ M}$, and the pH of the final solution is 8.794 (part (a) in [Figure 16.5.4](#)). As expected for the titration of a weak acid, the pH at the equivalence point is greater than 7.00 because the product of the titration is a base, the acetate ion, which then reacts with water to produce OH^- .

Exercise

Calculate the pH of a solution prepared by adding 45.0 mL of a 0.213 M HCl solution to 125.0 mL of a 0.150 M solution of ammonia. The $\text{p}K_b$ of ammonia is 4.75 at 25°C.

Answer: 9.23

As shown in part (b) in [Figure 16.5.3](#), the titration curve for NH_3 , a weak base, is the reverse of the titration curve for acetic acid. In particular, the pH at the equivalence point in the titration of a weak base is *less* than 7.00 because the titration produces an acid.

The identity of the weak acid or weak base being titrated strongly affects the shape of the titration curve. [Figure 16.5.4](#) illustrates the shape of titration curves as a function of the $\text{p}K_a$ or the $\text{p}K_b$. As the acid or the base being titrated becomes weaker (its $\text{p}K_a$ or $\text{p}K_b$ becomes larger), the pH change around the equivalence point decreases significantly. With very dilute solutions, the curve becomes so shallow that it can no longer be used to determine the equivalence point.

Figure 16.5.4 Effect of Acid or Base Strength on the Shape of Titration Curves Unlike strong acids or bases, the shape of the titration curve for a weak acid or base depends on the $\text{p}K_a$ or $\text{p}K_b$ of the weak acid or base being titrated. (a) Solution pH as a function of the volume of 1.00 M NaOH added to 10.00 mL of 1.00 M solutions of weak acids with the indicated $\text{p}K_a$ values. (b) Solution pH as a function of the volume of 1.00 M HCl added to 10.00 mL of 1.00 M solutions of weak bases with the indicated $\text{p}K_b$ values. The shapes of the two sets of curves are essentially identical, but one is flipped vertically in relation to the other. Midpoints are indicated for the titration curves corresponding to $\text{p}K_a = 10$ and $\text{p}K_b = 10$.

One point in the titration of a weak acid or a weak base is particularly important: the midpoint of a titration is defined as the point at which exactly enough acid (or base) has been added to neutralize one-half of the acid (or the base) originally present and occurs halfway to the equivalence point. The midpoint is indicated in part (a) in [Figure 16.5.5](#) and part (b) in [Figure 16.5.5](#) for the two shallowest curves. By definition, at the midpoint of the titration of an acid, $[\text{HA}] = [\text{A}^-]$. Recall from [Equation 16.2.2](#) that the ionization constant for a weak acid is as follows:

$$K_a = \frac{[\text{H}_3\text{O}^+][\text{A}^-]}{[\text{HA}]}$$

If $[\text{HA}] = [\text{A}^-]$, this reduces to $K_a = [\text{H}_3\text{O}^+]$. Taking the negative logarithm of both sides,

$$\log K_a = -\log [\text{H}_3\text{O}^+]$$

From the definitions of $\text{p}K_a$ and pH, we see that this is identical to

$$\text{p}K_a = \text{pH}$$

Thus the pH at the midpoint of the titration of a weak acid is equal to the $\text{p}K_a$ of the weak acid, as indicated in part (a) in [Figure 16.5.4](#) for the weakest acid where we see that the midpoint for $\text{p}K_a = 10$ occurs at $\text{pH} = 10$. Titration methods can therefore be used to determine both the concentration *and* the $\text{p}K_a$ (or the $\text{p}K_b$) of a weak acid (or a weak base).

Note the Pattern

The pH at the midpoint of the titration of a weak acid is equal to the $\text{p}K_a$ of the weak acid.

Titration of Polyprotic Acids or Bases

When a strong base is added to a solution of a polyprotic acid, the neutralization reaction occurs in stages. The most acidic group is titrated first, followed by the next most acidic, and so forth. If the $\text{p}K_a$ values are separated by at least three $\text{p}K_a$ units, then the overall titration curve shows well-resolved “steps” corresponding to the titration of each proton. A titration of the triprotic acid H_3PO_4 with NaOH is illustrated in [Figure 16.5.5](#) and shows two well-defined steps: the first midpoint corresponds to $\text{p}K_{a1}$, and the second midpoint corresponds to $\text{p}K_{a2}$. Because HPO_4^{2-} is such a weak acid, $\text{p}K_{a3}$ has such a high value that the third step cannot be resolved using 0.100 M NaOH as the titrant.

Figure 16.5.5 Titration Curve for Phosphoric Acid (H_3PO_4), a Typical Polyprotic Acid The curve for the titration of 25.0 mL of a 0.100 M H_3PO_4 solution with 0.100 M NaOH along with the species in solution at each K_a is shown. Note the two distinct equivalence points corresponding to deprotonation of H_3PO_4 at $pH \approx 4.6$ and $H_2PO_4^-$ at $pH \approx 9.8$. Because HPO_4^{2-} is a very weak acid, the third equivalence point, at $pH \approx 13$, is not well defined.

The titration curve for the reaction of a polyprotic base with a strong acid is the mirror image of the curve shown in Figure 16.5.5 The initial pH is high, but as acid is added, the pH decreases in steps if the successive pK_b values are well separated. Table 16.3.1 lists the ionization constants and pK_a values for some common polyprotic acids and bases.

Example 16.5.3

Calculate the pH of a solution prepared by adding 55.0 mL of a 0.120 M NaOH solution to 100.0 mL of a 0.0510 M solution of oxalic acid (HO_2CCO_2H), a diprotic acid (abbreviated as H_2ox). Oxalic acid, the simplest dicarboxylic acid, is found in rhubarb and many other plants. Rhubarb leaves are toxic because they contain the calcium salt of the fully deprotonated form of oxalic acid, the oxalate ion ($O_2CCO_2^-$, abbreviated ox^{2-}). Oxalate salts are toxic for two reasons. First, oxalate salts of divalent cations such as Ca^{2+} are insoluble at neutral pH but soluble at low pH. As a result, calcium oxalate dissolves in the dilute acid of the stomach, allowing oxalate to be absorbed and transported into cells, where it can react with calcium to form tiny calcium oxalate crystals that damage tissues. Second, oxalate forms stable complexes with metal ions, which can alter the distribution of metal ions in biological fluids.

Given: volume and concentration of acid and base

Asked for: pH

Strategy:

A Calculate the initial millimoles of the acid and the base. Use a tabular format to determine the amounts of all the species in solution.

B Calculate the concentrations of all the species in the final solution. Use Equation 16.2.3 to determine $[H^+]$ and convert this value to pH.

Solution:

A Table 16.3.1 gives the pK_a values of oxalic acid as 1.25 and 3.81. Again we proceed by determining the millimoles of acid and base initially present:

$$100.00 \text{ mL} \left(\frac{0.510 \text{ mmol } H_2ox}{\text{mL}} \right) = 5.10 \text{ mmol } H_2ox$$

$$55.00 \text{ mL} \left(\frac{0.120 \text{ mmol NaOH}}{\text{mL}} \right) = 6.60 \text{ mmol NaOH}$$

The strongest acid (H_2ox) reacts with the base first. This leaves $(6.60 - 5.10) = 1.50$ mmol of OH^- to react with Hox^- , forming ox^{2-} and H_2O . The reactions can be written as follows:

In tabular form,

	H_2ox	OH^-	Hox^-	ox^{2-}
initial	5.10 mmol	6.60 mmol	0 mmol	0 mmol
change (step 1)	-5.10 mmol	-5.10 mmol	+5.10 mmol	0 mmol
final (step 1)	0 mmol	1.50 mmol	5.10 mmol	0 mmol
change (step 2)	—	-1.50 mmol	-1.50 mmol	+1.50 mmol
final	0 mmol	0 mmol	3.60 mmol	1.50 mmol

B The equilibrium between the weak acid (Hox^-) and its conjugate base (ox^{2-}) in the final solution is determined by the magnitude of the second ionization constant, $K_{a2} = 10^{-3.81} = 1.6 \times 10^{-4}$. To calculate the pH of the solution, we need to know $[\text{H}^+]$, which is determined using exactly the same method as in the acetic acid titration in Example 12:

final volume of solution = 100.0 mL + 55.0 mL = 155.0 mL

Thus the concentrations of Hox^- and ox^{2-} are as follows:

$$[\text{Hox}^-] = \frac{3.60 \text{ mmol Hox}^-}{155.0 \text{ mL}} = 2.32 \times 10^{-2} \text{ M}$$

$$[\text{ox}^{2-}] = \frac{1.50 \text{ mmol ox}^{2-}}{155.0 \text{ mL}} = 9.68 \times 10^{-3} \text{ M}$$

We can now calculate $[\text{H}^+]$ at equilibrium using the following equation:

$$K_{a2} = \frac{[\text{ox}^{2-}][\text{H}^+]}{[\text{Hox}^-]}$$

Rearranging this equation and substituting the values for the concentrations of Hox^- and ox^{2-} ,

$$[\text{H}^+] = \frac{K_{a2}[\text{Hox}^-]}{[\text{ox}^{2-}]} = \frac{(1.6 \times 10^{-4})(2.32 \times 10^{-2})}{(9.68 \times 10^{-3})} = 3.7 \times 10^{-4} \text{ M}$$

So

$$\text{pH} = -\log[\text{H}^+] = -\log(3.7 \times 10^{-4}) = 3.43$$

This answer makes chemical sense because the pH is between the first and second pK_a values of oxalic acid, as it must be. We added enough hydroxide ion to completely titrate the first, more acidic proton (which should give us a pH greater than pK_{a1}), but we added only enough to titrate less than half of the second, less acidic proton, with pK_{a2} . If we had added exactly enough hydroxide to completely titrate the first proton plus half of the second, we would be at the midpoint of the second step in the titration, and the pH would be 3.81, equal to pK_{a2} .

Exercise

Piperazine is a diprotic base used to control intestinal parasites (“worms”) in pets and humans. A dog is given 500 mg (5.80 mmol) of piperazine ($\text{pK}_{b1} = 4.27$, $\text{pK}_{b2} = 8.67$). If the dog’s stomach initially contains 100 mL of 0.10 M HCl (pH = 1.00), calculate the pH of the stomach contents after ingestion of the piperazine.

Answer: 4.9 (Video Solution)

Indicators

In practice, most acid–base titrations are not monitored by recording the pH as a function of the amount of the strong acid or base solution used as the titrant. Instead, an acid–base indicator is often used that, if carefully selected, undergoes a dramatic color change at the pH corresponding to the equivalence point of the titration. Indicators are weak acids or bases that exhibit intense colors that vary with pH. The conjugate acid and conjugate base of a good indicator have very different colors so that they can be distinguished easily. Some indicators are colorless in the conjugate acid form but intensely colored when deprotonated (phenolphthalein, for example), which makes them particularly useful.

We can describe the chemistry of indicators by the following general equation:

where the protonated form is designated by HIn and the conjugate base by In^- . The ionization constant for the deprotonation of indicator HIn is as follows:

$$K_{In} = \frac{[H^+][In^-]}{[HIn]} \quad (16.5.4)$$

The pK_{in} (its pK_a) determines the pH at which the indicator changes color.

Many different substances can be used as indicators, depending on the particular reaction to be monitored. For example, red cabbage juice contains a mixture of colored substances that change from deep red at low pH to light blue at intermediate pH to yellow at high pH (Figure 16.22). In all cases, though, a good indicator must have the following properties:

- The color change must be easily detected.
- The color change must be rapid.
- The indicator molecule must not react with the substance being titrated.
- To minimize errors, the indicator should have a pK_{in} that is within one pH unit of the expected pH at the equivalence point of the titration.

Figure 16.5.6 Naturally Occurring Indicators in Red Cabbage Juice

Red cabbage juice contains a mixture of substances whose color depends on the pH. Each solution of red cabbage juice in water, but the pH of the solutions varies from pH = 2.0 (far left) to pH = 11.0 (far right) solution is blue. (From 99 Chemical on YouTube)

Synthetic indicators have been developed that meet these criteria and cover virtually the entire pH range. Figure 16.5.7 shows the approximate pH range over which some common indicators change color and their change in color. In addition, some indicators (such as thymol blue) are polyprotic acids or bases, which change color twice at widely separated pH values.

Figure 16.5.7 Some Common Acid–Base Indicators Approximate colors are shown, along with pK_{in} values and the pH range over which the color changes.

It is important to be aware that an indicator does not change color abruptly at a particular pH value; instead, it actually undergoes a pH titration just like any other acid or base. As the concentration of HIn decreases and the concentration of In^- increases, the color of the solution slowly changes from the characteristic color of HIn to that of In^- . As we will see in Section 16.6, the $[\text{In}^-]/[\text{HIn}]$ ratio changes from 0.1 at a pH one unit below $\text{p}K_{\text{in}}$ to 10 at a pH one unit above $\text{p}K_{\text{in}}$. Thus most indicators change color over a pH range of about two pH units.

We have stated that a good indicator should have a $\text{p}K_{\text{in}}$ value that is close to the expected pH at the equivalence point. For a strong acid–strong base titration, the choice of the indicator is not especially critical due to the very large change in pH that occurs around the equivalence point. In contrast, using the wrong indicator for a titration of a weak acid or a weak base can result in relatively large errors, as illustrated in Figure 16.5.8. This figure shows plots of pH versus volume of base added for the titration of 50.0 mL of a 0.100 M solution of a strong acid (HCl) and a weak acid (acetic acid) with 0.100 M NaOH. The pH ranges over which two common indicators (methyl red, $\text{p}K_{\text{in}} = 5.0$, and phenolphthalein, $\text{p}K_{\text{in}} = 9.5$) change color are also shown. The horizontal bars indicate the pH ranges over which both indicators change color cross the HCl titration curve, where it is almost vertical. Hence both indicators change color when essentially the same volume of NaOH has been added (about 50 mL), which corresponds to the equivalence point. In contrast, the titration of acetic acid will give very different results depending on whether methyl red or phenolphthalein is used as the indicator. Although the pH range over which phenolphthalein changes color is slightly greater than the pH at the equivalence point of the strong acid titration, the error will be negligible due to the slope of this portion of the titration curve. Just as with the HCl titration, the phenolphthalein indicator will turn pink when about 50 mL of NaOH has been added to the acetic acid solution. In contrast, methyl red begins to change from red to yellow around pH 5, which is near the *midpoint* of the acetic acid titration, not the equivalence point. Adding only about 25–30 mL of NaOH will therefore cause the methyl red indicator to change color, resulting in a huge error.

Figure 16.5.8 *Choosing the Correct Indicator for an Acid–Base Titration* The graph shows the results obtained using two indicators (methyl red and phenolphthalein) for the titration of 0.100 M solutions of a strong acid (HCl) and a weak acid (acetic acid) with 0.100 M NaOH. Due to the steepness of the titration curve of a strong acid around the equivalence point, either indicator will rapidly change color at the equivalence point for the titration of the strong acid. In contrast, the $\text{p}K_{\text{in}}$ for methyl red (5.0) is very close to the $\text{p}K_{\text{a}}$ of acetic acid (4.76); the midpoint of the color change for methyl red occurs near the midpoint of the titration, rather than at the equivalence point.

In general, for titrations of strong acids with strong bases (and vice versa), any indicator with a $\text{p}K_{\text{in}}$ between about 4.0 and 10.0 will do. For the titration of a weak acid, however, the pH at the equivalence point is greater than 7.0, so an indicator such as phenolphthalein or thymol blue, with $\text{p}K_{\text{in}} > 7.0$, should be used. Conversely, for the titration of a weak base, where the pH at the equivalence point is less than 7.0, an indicator such as methyl red or bromocresol blue, with $\text{p}K_{\text{in}} < 7.0$, should be used.

The existence of many different indicators with different colors and $\text{p}K_{\text{in}}$ values also provides a convenient way to estimate the pH of a solution without using an expensive electronic pH meter and a fragile pH electrode. Paper or plastic strips impregnated with combinations of indicators are used as “pH paper,” which allows you to estimate the pH of a solution by simply dipping a piece of pH paper into it and comparing the resulting color with the standards printed on the container (Figure 16.25).

Figure 16.5.9 *pH Paper* pH paper contains a set of indicators that change color at different pH values. The approximate pH of a solution can be determined by simply dipping a paper strip into the solution and comparing the color to the standards provided.

Summary

The shape of a **titration curve**, a plot of pH versus the amount of acid or base added, provides important information about what is occurring in solution during a titration. The shapes of titration curves for weak acids and bases depend dramatically on the identity of the compound. The **equivalence point** of an acid–base titration is the point at which exactly enough acid or base has been added to react completely with the other component. The equivalence point in the titration of a strong acid or a strong base occurs at pH 7.0. In titrations of weak acids or weak bases, however, the pH at the equivalence point is greater or less than 7.0, respectively. The pH tends to change more slowly before the equivalence point is reached in titrations of weak acids and weak bases than in titrations of strong acids and strong bases. The pH at the **midpoint**, the point halfway on the titration curve to the equivalence point, is equal to the pK_a of the weak acid or the pK_b of the weak base. Thus titration methods can be used to determine both the concentration *and* the pK_a (or the pK_b) of a weak acid (or a weak base). **Acid–base indicators** are compounds that change color at a particular pH. They are typically weak acids or bases whose changes in color correspond to deprotonation or protonation of the indicator itself.

Key Takeaway

- Plots of acid–base titrations generate titration curves that can be used to calculate the pH, the pOH, the pK_a , and the pK_b of the system.

Conceptual Problems

1. Why is the portion of the titration curve that lies below the equivalence point of a solution of a weak acid displaced upward relative to the titration curve of a strong acid? How are the slopes of the curves different at the equivalence point? Why?
2. Predict whether each solution will be neutral, basic, or acidic at the equivalence point of each titration.
 - a. An aqueous solution of NaOH is titrated with 0.100 M HCl.
 - b. An aqueous solution of ethylamine ($\text{CH}_3\text{CH}_2\text{NH}_2$) is titrated with 0.150 M HNO_3
 - c. An aqueous solution of aniline hydrochloride ($\text{C}_6\text{H}_5\text{NH}_3^+ \text{Cl}^-$) is titrated with 0.050 M KOH.
3. The pK_a values of phenol red, bromophenol blue, and phenolphthalein are 7.4, 4.1, and 9.5, respectively. Which indicator is best suited for each acid–base titration?
 - a. titrating a solution of $\text{Ba}(\text{OH})_2$ with 0.100 M HCl
 - b. titrating a solution of trimethylamine (Me_3N) with 0.150 M HNO_3
 - c. titrating a solution of aniline hydrochloride ($\text{C}_6\text{H}_5\text{NH}_3^+ \text{Cl}^-$) with 0.050 M KOH
4. For the titration of any strong acid with any strong base, the pH at the equivalence point is 7.0. Why is this not usually the case in titrations of weak acids or weak bases?
5. Why are the titration curves for a strong acid with a strong base and a weak acid with a strong base identical in shape above the equivalence points but not below?
6. Describe what is occurring on a molecular level during the titration of a weak acid, such as acetic acid, with a strong base, such as NaOH, at the following points along the titration curve. Which of these points corresponds to $\text{pH} = pK_a$?
 - a. at the beginning of the titration
 - b. at the midpoint of the titration
 - c. at the equivalence point
 - d. when excess titrant has been added
7. On a molecular level, describe what is happening during the titration of a weak base, such as ammonia, with a strong acid, such as HCl, at the following points along the titration curve. Which of these points corresponds to $\text{pOH} = pK_b$?
 - a. at the beginning of the titration
 - b. at the midpoint of the titration
 - c. at the equivalence point
 - d. when excess titrant has been added
8. For the titration of a weak acid with a strong base, use the K_a expression to show that $\text{pH} = pK_a$ at the midpoint of the titration.
9. Chemical indicators can be used to monitor pH rapidly and inexpensively. Nevertheless, electronic methods are generally preferred. Why?
10. Why does adding ammonium chloride to a solution of ammonia in water decrease the pH of the solution?
11. Given the equilibrium system $\text{CH}_3\text{CO}_2\text{H}(\text{aq}) \rightleftharpoons \text{CH}_3\text{CO}_2^-(\text{aq}) + \text{H}^+(\text{aq})$, explain what happens to the position of the equilibrium and the pH in each case.
 - a. Dilute HCl is added.
 - b. Dilute NaOH is added.

- c. Solid sodium acetate is added.
12. Given the equilibrium system $\text{CH}_3\text{NH}_2(\text{aq}) + \text{H}_2\text{O}(\text{l}) \rightleftharpoons \text{CH}_3\text{NH}_3^+(\text{aq}) + \text{OH}^-(\text{aq})$, explain what happens to the position of the equilibrium and the pH in each case.
- Dilute HCl is added.
 - Dilute NaOH is added.
 - Solid $\text{CH}_3\text{NH}_3\text{Cl}$ is added.

Numerical Problems

- Calculate the pH of each solution.
 - A volume of 25.0 mL of 6.09 M HCl is added to 100.0 mL of distilled water
 - A volume of 5.0 mL of 2.55 M NaOH is added to 75.0 mL of distilled water.
- What is the pH of a solution prepared by mixing 50.0 mL of 0.225 M HCl with 100.0 mL of a 0.184 M solution of NaOH?
- What volume of 0.50 M HCl is needed to completely neutralize 25.00 mL of 0.86 M NaOH?
- Calculate the final pH when each pair of solutions is mixed.
 - 100 mL of 0.105 M HCl and 100 mL of 0.115 M sodium acetate
 - 50 mL of 0.10 M HCl and 100 mL of 0.15 M sodium acetate
 - 100 mL of 0.109 M acetic acid and 100 mL of 0.118 M NaOH
 - 100 mL of 0.998 M acetic acid and 50.0 mL of 0.110 M NaOH
- Calculate the final pH when each pair of solutions is mixed.
 - 100 mL of 0.983 M HCl and 100 mL of 0.102 M sodium fluoride
 - 50.0 mL of 0.115 M HCl and 100 mL of 0.109 M sodium fluoride
 - 100 mL of 0.106 M hydrofluoric acid and 50.0 mL of 0.996 M NaOH
 - 100 mL of 0.107 M sodium acetate and 50.0 mL of 0.987 M acetic acid
- Calcium carbonate is a major contributor to the “hardness” of water. The amount of CaCO_3 in a water sample can be determined by titrating the sample with an acid, such as HCl, which produces water and CO_2 . Write a balanced chemical equation for this reaction. Generate a plot of solution pH versus volume of 0.100 M HCl added for the titration of a solution of 250 mg of CaCO_3 in 200.0 mL of water with 0.100 M HCl; assume that the HCl solution is added in 5.00 mL increments. What volume of HCl corresponds to the equivalence point?
- For a titration of 50.0 mL of 0.288 M NaOH, you would like to prepare a 0.200 M HCl solution. The only HCl solution available to you, however, is 12.0 M.
 - How would you prepare 500 mL of a 0.200 M HCl solution?
 - Approximately what volume of your 0.200 M HCl solution is needed to neutralize the NaOH solution?
 - After completing the titration, you find that your “0.200 M” HCl solution is actually 0.187 M. What was the exact volume of titrant used in the neutralization?
- While titrating 50.0 mL of a 0.582 M solution of HCl with a solution labeled “0.500 M KOH,” you overshoot the endpoint. To correct the problem, you add 10.00 mL of the HCl solution to your flask and then carefully continue the titration. The total volume of titrant needed for neutralization is 71.9 mL.
 - What is the actual molarity of your KOH solution?
 - What volume of titrant was needed to neutralize 50.0 mL of the acid?

9. Complete the following table and generate a titration curve showing the pH versus volume of added base for the titration of 50.0 mL of 0.288 M HCl with 0.321 M NaOH. Clearly indicate the equivalence point.

Base Added (mL)	10.0	30.0	40.0	45.0	50.0	55.0	65.0	75.0
pH								

10. The following data were obtained while titrating 25.0 mL of 0.156 M NaOH with a solution labeled "0.202 M HCl." Plot the pH versus volume of titrant added. Then determine the equivalence point from your graph and calculate the exact concentration of your HCl solution.

Volume of HCl (mL)	5	10	15	20	25	30	35
pH	11.46	11.29	10.98	4.40	2.99	2.70	2.52

11. Fill in the data for the titration of 50.0 mL of 0.241 M formic acid with 0.0982 M KOH. The pK_a of formic acid is 3.75. What is the pH of the solution at the equivalence point?

Volume of Base Added (mL)	0	5	10	15	20	25
pH						

12. Glycine hydrochloride, which contains the fully protonated form of the amino acid glycine, has the following structure:

It is a strong electrolyte that completely dissociates in water. Titration with base gives two equivalence points: the first corresponds to the deprotonation of the carboxylic acid group and the second to loss of the proton from the ammonium group. The corresponding equilibrium equations are as follows:

- Given 50.0 mL of solution that is 0.430 M glycine hydrochloride, how many milliliters of 0.150 M KOH are needed to fully deprotonate the carboxylic acid group?
 - How many additional milliliters of KOH are needed to deprotonate the ammonium group?
 - What is the pH of the solution at each equivalence point?
 - How many milliliters of titrant are needed to obtain a solution in which glycine has no net electrical charge? The pH at which a molecule such as glycine has no net charge is its *isoelectric point*. What is the isoelectric point of glycine?
13. What is the pH of a solution prepared by adding 38.2 mL of 0.197 M HCl to 150.0 mL of 0.242 M pyridine? The pK_b of pyridine is 8.77.
14. What is the pH of a solution prepared by adding 40.3 mL of 0.289 M NaOH to 150.0 mL of 0.564 M succinic acid ($HO_2CCH_2CH_2CO_2H$)? (For succinic acid, $pK_{a1} = 4.21$ and $pK_{a2} = 5.64$).
15. Calculate the pH of a 0.15 M solution of malonic acid ($HO_2CCH_2CO_2H$), whose pK_a values are as follows: $pK_{a1} = 2.85$ and $pK_{a2} = 5.70$.

Learning Objectives

- To understand how adding a common ion affects the position of an acid–base equilibrium.
- To know how to use the Henderson-Hasselbalch equation to calculate the pH of a buffer.

Buffers are solutions that maintain a relatively constant pH when an acid or a base is added. They therefore protect, or “buffer,” other molecules in solution from the effects of the added acid or base. Buffers contain either a weak acid (HA) and its conjugate base (A⁻) or a weak base (B) and its conjugate acid (BH⁺), and they are critically important for the proper functioning of biological systems. In fact, every biological fluid is buffered to maintain its physiological pH.

The Common Ion Effect

To understand how buffers work, let’s look first at how the ionization equilibrium of a weak acid is affected by adding either the conjugate base of the acid or a strong acid (a source of H⁺). Le Châtelier’s principle can be used to predict the effect on the equilibrium position of the solution.

A typical buffer used in biochemistry laboratories contains acetic acid and a salt such as sodium acetate. Recall that the dissociation reaction of acetic acid is as follows:

and the equilibrium constant expression is as follows:

$$K_a = \frac{[\text{H}^+][\text{CH}_3\text{CO}_2^-]}{[\text{CH}_3\text{CO}_2\text{H}]} \quad (16.6.2)$$

Sodium acetate (CH₃CO₂Na) is a strong electrolyte that ionizes completely in aqueous solution to produce Na⁺ and CH₃CO₂⁻ ions. If sodium acetate is added to a solution of acetic acid, Le Châtelier’s principle predicts that the equilibrium in Equation 16.6.1 will shift to the left, consuming some of the added CH₃CO₂⁻ and some of the H⁺ ions originally present in solution:

Because Na⁺ is a spectator ion, it has no effect on the position of the equilibrium and can be ignored. The addition of sodium acetate produces a new equilibrium composition, in which [H⁺] is less than the initial value. Because [H⁺] has decreased, the pH will be higher. Thus adding a salt of the conjugate base to a solution of a weak acid increases the pH. This makes sense because sodium acetate is a base, and adding *any* base to a solution of a weak acid should increase the pH.

If we instead add a strong acid such as HCl to the system, [H⁺] increases. Once again the equilibrium is temporarily disturbed, but the excess H⁺ ions react with the conjugate base (CH₃CO₂⁻), whether from the parent acid or sodium acetate, to drive the equilibrium to the left. The net result is a new equilibrium composition that has a lower [CH₃CO₂⁻] than before. In both cases, *only the equilibrium composition has changed; the ionization constant K_a for acetic acid remains the same.* Adding a strong electrolyte that contains one ion in common with a reaction system that is at equilibrium, in this case CH₃CO₂⁻, will therefore shift the equilibrium in the direction that reduces the concentration of the common ion. The shift in equilibrium is called the common ion effect.

Note the Pattern

Adding a common ion to a system at equilibrium affects the equilibrium composition but not the ionization constant.

Example 16.6.1

In Section 16.4, we calculated that a 0.150 M solution of formic acid at 25°C ($pK_a = 3.75$) has a pH of 2.28 and is 3.5% ionized.

1. Is there a change to the pH of the solution if enough solid sodium formate is added to make the final formate concentration 0.100 M (assume that the formic acid concentration does not change)?
2. What percentage of the formic acid is ionized if 0.200 M HCl is added to the system?

Given: solution concentration and pH, pK_a , and percent ionization of acid; final concentration of conjugate base or strong acid added

Asked for: pH and percent ionization of formic acid

Strategy:

A Write a balanced equilibrium equation for the ionization equilibrium of formic acid. Tabulate the initial concentrations, the changes, and the final concentrations.

B Substitute the expressions for the final concentrations into the expression for K_a . Calculate $[H^+]$ and the pH of the solution.

C Construct a table of concentrations for the dissociation of formic acid. To determine the percent ionization, determine the anion concentration, divide it by the initial concentration of formic acid, and multiply the result by 100.

Solution:

1. **A** Because sodium formate is a strong electrolyte, it ionizes completely in solution to give formate and sodium ions. The Na^+ ions are spectator ions, so they can be ignored in the equilibrium equation. Because water is both a much weaker acid than formic acid and a much weaker base than formate, the acid–base properties of the solution are determined solely by the formic acid ionization equilibrium:

The initial concentrations, the changes in concentration that occur as equilibrium is reached, and the final concentrations can be tabulated.

$HCO_2H_{(aq)} \rightleftharpoons HCO_2^-_{(aq)} + H^+_{(aq)}$ (Chapter 16.6.1)			
	[HCO ₂ H]	[H ⁺]	[HCO ₂ ⁻]
initial	0.150	1.00×10^{-7}	0.100
change	-x	+x	+x
final	(0.150 - x)	x	(0.100 + x)

B We substitute the expressions for the final concentrations into the equilibrium constant expression and make our usual simplifying assumptions, so

$$K_a = \frac{[H^+][HCO_2^-]}{[HCO_2H]} = \frac{(x)(0.100 + x)}{0.150 + x} \approx \frac{x(0.100)}{0.150} = 10^{-3.75} = 1.8 \times 10^{-4}$$

Rearranging and solving for x,

$$x = (1.80 \times 10^{-4}) \times \frac{0.150 \text{ M}}{0.200 \text{ M}} = 1.35 \times 10^{-4} = [\text{HCO}_2^-]$$

The value of x is small compared with 0.150 or 0.100 M, so our assumption about the extent of ionization is justified. Moreover, $K_{\text{a}}C_{\text{HA}} = (1.8 \times 10^{-4})(0.150) = 2.7 \times 10^{-5}$, which is greater than 1.0×10^{-5} , so again, our assumption is justified. The final pH is $-\log(2.7 \times 10^{-4}) = 3.57$, compared with the initial value of 2.29. Thus adding a salt containing the conjugate base of the acid has increased the pH of the solution, as we expect based on Le Châtelier's principle; the stress on the system has been relieved by the consumption of H^+ ions, driving the equilibrium to the left.

2. **C** Because HCl is a strong acid, it ionizes completely, and chloride is a spectator ion that can be neglected. Thus the only relevant acid–base equilibrium is again the dissociation of formic acid, and initially the concentration of formate is zero. We can construct a table of initial concentrations, changes in concentration, and final concentrations.

$\text{HCO}_2\text{H}_{(aq)} \rightleftharpoons \text{H}^+_{(aq)} + \text{HCO}_2^-_{(aq)}$ (Chapter 16.6.2)			
	[HCO ₂ H]	[H ⁺]	[HCO ₂ ⁻]
initial	0.150	0.200	0
change	-x	+x	+x
final	(0.150 - x)	(0.200 + x)	x

To calculate the percentage of formic acid that is ionized under these conditions, we have to determine the final $[\text{HCO}_2^-]$. We substitute final concentrations into the equilibrium constant expression and make the usual simplifying assumptions, so

$$K_{\text{a}} = \frac{[\text{H}^+][\text{HCO}_2^-]}{[\text{HCO}_2\text{H}]} = \frac{(0.200 + x)(x)}{0.150 - x} \approx \frac{x(0.200)}{0.150} = 1.80 \times 10^{-4}$$

Rearranging and solving for x ,

$$x = (1.80 \times 10^{-4}) \times \frac{0.150 \text{ M}}{0.200 \text{ M}} = 1.35 \times 10^{-4} = [\text{HCO}_2^-]$$

Once again, our simplifying assumptions are justified. The percent ionization of formic acid is as follows:

$$\text{percent ionization} = \frac{1.35 \times 10^{-4} \text{ M}}{0.150 \text{ M}} \times 100$$

Adding the strong acid to the solution, as shown in the table, decreased the percent ionization of formic acid by a factor of approximately 38 (3.45%/0.0900%). Again, this is consistent with Le Châtelier's principle: adding H^+ ions drives the dissociation equilibrium to the left.

Exercise

As you learned in Example 8, a 0.225 M solution of ethylamine ($\text{CH}_3\text{CH}_2\text{NH}_2$, $\text{p}K_{\text{b}} = 3.19$) has a pH of 12.08 and a percent ionization of 5.4% at 20°C. Calculate the following:

- the pH of the solution if enough solid ethylamine hydrochloride (EtNH_3Cl) is added to make the solution 0.100 M in EtNH_3^+
- the percentage of ethylamine that is ionized if enough solid NaOH is added to the original solution to give a final concentration of 0.050 M NaOH

Answer:

- 11.16
- 1.3%

Now let's suppose we have a buffer solution that contains equimolar concentrations of a weak base (B) and its conjugate acid (BH⁺). The general equation for the ionization of a weak base is as follows:

If the equilibrium constant for the reaction as written in Equation 16.6.3 is small, for example $K_b = 10^{-5}$, then the equilibrium constant for the reverse reaction is very large: $K = 1/K_b = 10^5$. Adding a strong base such as OH⁻ to the solution therefore causes the equilibrium in Equation 16.6.3 to shift to the left, consuming the added OH⁻. As a result, the OH⁻ ion concentration in solution remains relatively constant, and the pH of the solution changes very little. Le Châtelier's principle predicts the same outcome: when the system is stressed by an increase in the OH⁻ ion concentration, the reaction will proceed to the left to counteract the stress.

If the pK_b of the base is 5.0, the pK_a of its conjugate acid is pK_a = pK_w - pK_b = 14.0 - 5.0 = 9.0. Thus the equilibrium constant for ionization of the conjugate acid is even smaller than that for ionization of the base. The ionization reaction for the conjugate acid of a weak base is written as follows:

Again, the equilibrium constant for the reverse of this reaction is very large: $K = 1/K_a = 10^9$. If a strong acid is added, it is neutralized by reaction with the base as the reaction in Equation 16.6.4 shifts to the left. As a result, the H⁺ ion concentration does not increase very much, and the pH changes only slightly. In effect, a buffer solution behaves somewhat like a sponge that can absorb H⁺ and OH⁻ ions, thereby preventing large changes in pH when appreciable amounts of strong acid or base are added to a solution.

Buffers are characterized by the *pH range* over which they can maintain a more or less constant pH and by their buffer capacity, the amount of strong acid or base that can be absorbed before the pH changes significantly. Although the useful pH range of a buffer depends strongly on the chemical properties of the weak acid and weak base used to prepare the buffer (i.e., on *K*), its buffer capacity depends solely on the concentrations of the species in the buffered solution. The more concentrated the buffer solution, the greater its buffer capacity. As illustrated in Figure 16.6.1, when NaOH is added to solutions that contain different concentrations of an acetic acid/sodium acetate buffer, the observed change in the pH of the buffer is inversely proportional to the concentration of the buffer. If the buffer capacity is 10 times larger, then the buffer solution can absorb 10 times more strong acid or base before undergoing a significant change in pH.

Figure 16.6.1 Effect of Buffer Concentration on the Capacity of a Buffer A buffer maintains a relatively constant pH when acid or base is added to a solution. The addition of even tiny volumes of 0.10 M NaOH to 100.0 mL of distilled water results in a very large change in pH. As the concentration of a 50:50 mixture of sodium acetate/acetic acid buffer in the solution is increased from 0.010 M to 1.00 M, the change in the pH produced by the addition of the same volume of NaOH solution decreases steadily. For buffer concentrations of at least 0.500 M, the addition of even 25 mL of the NaOH solution results in only a relatively small change in pH.

Calculating the pH of a Buffer

The pH of a buffer can be calculated from the concentrations of the weak acid and the weak base used to prepare it, the concentration of the conjugate base and conjugate acid, and the pK_a or pK_b of the weak acid or weak base. The procedure is analogous to that used in Example 14 to calculate the pH of a solution containing known concentrations of formic acid and formate.

An alternative method frequently used to calculate the pH of a buffer solution is based on a rearrangement of the equilibrium equation for the dissociation of a weak acid. The simplified ionization reaction is $HA \rightleftharpoons H^+ + A^-$ for which the equilibrium constant expression is as follows:

$$K_a = \frac{[H^+][A^-]}{[HA]} \quad (16.6.5)$$

This equation can be rearranged as follows:

$$[H^+] = K_a \frac{[HA]}{[A^-]} \quad (16.6.6)$$

Taking the logarithm of both sides and multiplying both sides by -1 ,

$$-\log[H^+] = -\log K_a - \log\left(\frac{[HA]}{[A^-]}\right) = -\log K_a + \log\left(\frac{[A^-]}{[HA]}\right) \quad (16.6.7)$$

Replacing the negative logarithms in Equation 16.60,

$$pH = pK_a + \log\left(\frac{[A^-]}{[HA]}\right) \quad (16.6.8)$$

or, more generally,

$$pH = pK_a + \log\left(\frac{[base]}{[acid]}\right) \quad (16.6.9)$$

Equation 16.6.8 and Equation 16.6.9 are both forms of the Henderson-Hasselbalch equation, named after the two early-20th-century chemists who first noticed that this rearranged version of the equilibrium constant expression provides an easy way to calculate the pH of a buffer solution. In general, the validity of the Henderson-Hasselbalch equation may be limited to solutions whose concentrations are at least 100 times greater than their K_a values.

There are three special cases where the Henderson-Hasselbalch equation is easily interpreted without the need for calculations:

1. **[base] = [acid]**. Under these conditions, $[base]/[acid] = 1$ in Equation 16.6.9. Because $\log 1 = 0$, $pH = pK_a$, regardless of the actual concentrations of the acid and base. Recall from Section 16.5 that this corresponds to the midpoint in the titration of a weak acid or a weak base.
2. **[base]/[acid] = 10**. In Equation 16.6.9, because $\log 10 = 1$, $pH = pK_a + 1$.
3. **[base]/[acid] = 100**. In Equation 16.6.9, because $\log 100 = 2$, $pH = pK_a + 2$.

Each time we increase the $[base]/[acid]$ ratio by 10, the pH of the solution increases by 1 pH unit. Conversely, if the $[base]/[acid]$ ratio is 0.1, then $pH = pK_a - 1$. Each additional factor-of-10 decrease in the $[base]/[acid]$ ratio causes the pH to decrease by 1 pH unit.

Note the Pattern

If $[base] = [acid]$ for a buffer, then $pH = pK_a$. Changing this ratio by a factor of 10 either way changes the pH by ± 1 unit.

Example 16.6.2

What is the pH of a solution that contains

1. 0.135 M HCO_2H and 0.215 M HCO_2Na ? (The pK_a of formic acid is 3.75.)
2. 0.0135 M HCO_2H and 0.0215 M HCO_2Na ?

3. 0.119 M pyridine and 0.234 M pyridine hydrochloride? (The pK_b of pyridine is 8.77.)

Given: concentration of acid, conjugate base, and pK_a ; concentration of base, conjugate acid, and pK_b

Asked for: pH

Strategy:

Substitute values into either form of the Henderson-Hasselbalch equation ([Equation 16.61](#) or [Equation 16.62](#)) to calculate the pH.

Solution:

1. According to the Henderson-Hasselbalch equation, the pH of a solution that contains both a weak acid and its conjugate base is $pH = pK_a + \log([A^-]/[HA])$. Inserting the given values into the equation,

$$pH = 3.75 + \log\left(\frac{0.215}{0.135}\right) = 3.75 + \log 1.593 = 3.95$$

This result makes sense because the $[A^-]/[HA]$ ratio is between 1 and 10, so the pH of the buffer must be between the pK_a (3.75) and $pK_a + 1$, or 4.75.

2. This is identical to part (a), except for the concentrations of the acid and the conjugate base, which are 10 times lower. Inserting the concentrations into the Henderson-Hasselbalch equation,

$$pH = 3.75 + \log\left(\frac{0.0215}{0.0135}\right) = 3.75 + \log 1.593 = 3.95$$

This result is identical to the result in part (a), which emphasizes the point that the pH of a buffer depends *only* on the *ratio* of the concentrations of the conjugate base and the acid, *not* on the magnitude of the concentrations. Because the $[A^-]/[HA]$ ratio is the same as in part (a), the pH of the buffer must also be the same (3.95).

3. In this case, we have a weak base, pyridine (Py), and its conjugate acid, the pyridinium ion (HPy^+). We will therefore use [Equation 16.62](#), the more general form of the Henderson-Hasselbalch equation, in which “base” and “acid” refer to the appropriate species of the conjugate acid–base pair. We are given $[base] = [Py] = 0.119$ M and $[acid] = [HPy^+] = 0.234$ M. We also are given $pK_b = 8.77$ for pyridine, but we need pK_a for the pyridinium ion. Recall from [Equation 16.2.10](#) that the pK_b of a weak base and the pK_a of its conjugate acid are related: $pK_a + pK_b = pK_w$. Thus pK_a for the pyridinium ion is $pK_w - pK_b = 14.00 - 8.77 = 5.23$. Substituting this pK_a value into the Henderson-Hasselbalch equation,

$$pH = pK_a + \log\left(\frac{[base]}{[acid]}\right) = 5.23 + \log\left(\frac{0.119}{0.234}\right) = 5.23 - 0.294 = 4.94$$

Once again, this result makes sense: the $[B]/[BH^+]$ ratio is about 1/2, which is between 1 and 0.1, so the final pH must be between the pK_a (5.23) and $pK_a - 1$, or 4.23.

Exercise

What is the pH of a solution that contains

1. 0.333 M benzoic acid and 0.252 M sodium benzoate?
2. 0.050 M trimethylamine and 0.066 M trimethylamine hydrochloride?

The pK_a of benzoic acid is 4.20, and the pK_b of trimethylamine is also 4.20.

Answer:

1. 4.08
2. 9.68

The Henderson-Hasselbalch equation can also be used to calculate the pH of a buffer solution after adding a given amount of strong acid or strong base, as demonstrated in Example 16.

Example 16.6.3

The buffer solution in Example 15 contained 0.135 M HCO_2H and 0.215 M HCO_2Na and had a pH of 3.95.

1. What is the final pH if 5.00 mL of 1.00 M HCl are added to 100 mL of this solution?
2. What is the final pH if 5.00 mL of 1.00 M NaOH are added?

Given: composition and pH of buffer; concentration and volume of added acid or base

Asked for: final pH

Strategy:

A Calculate the amounts of formic acid and formate present in the buffer solution using the procedure from Example 14. Then calculate the amount of acid or base added.

B Construct a table showing the amounts of all species after the neutralization reaction. Use the final volume of the solution to calculate the concentrations of all species. Finally, substitute the appropriate values into the Henderson-Hasselbalch equation (Equation 16.6.9) to obtain the pH.

Solution:

The added HCl (a strong acid) or NaOH (a strong base) will react completely with formate (a weak base) or formic acid (a weak acid), respectively, to give formic acid or formate and water. We must therefore calculate the amounts of formic acid and formate present after the neutralization reaction.

1. **A** We begin by calculating the millimoles of formic acid and formate present in 100 mL of the initial pH 3.95 buffer:

$$100 \text{ mL} \left(\frac{0.135 \text{ mmol HCO}_2\text{H}}{\text{mL}} \right) = 13.5 \text{ mmol HCO}_2\text{H}$$

$$100 \text{ mL} \left(\frac{0.215 \text{ mmol HCO}_2^-}{\text{mL}} \right) = 21.5 \text{ mmol HCO}_2^-$$

The millimoles of H^+ in 5.00 mL of 1.00 M HCl is as follows:

$$5.00 \text{ mL} \left(\frac{1.00 \text{ mmol H}^+}{\text{mL}} \right) = 5.00 \text{ mmol H}^+$$

B Next, we construct a table of initial amounts, changes in amounts, and final amounts:

$\text{HCO}_2^-(\text{aq}) + \text{H}^+(\text{aq}) \rightarrow \text{HCO}_2\text{H}(\text{aq})$			
	$[\text{HCO}_2^-]$	$[\text{H}^+]$	$[\text{HCO}_2\text{H}]$
initial	21.5 mmol	5.00 mmol	13.5 mmol
change	-5.00 mmol	-5.00 mmol	+5.00 mmol
final	16.5 mmol	~0 mmol	18.5 mmol

The final amount of H^+ in solution is given as “~0 mmol.” For the purposes of the stoichiometry calculation, this is essentially true, but remember that the point of the problem is to calculate the final $[\text{H}^+]$ and thus the pH. We now have all the information we need to calculate the pH. We can use either the lengthy procedure of Example 14 or the Henderson–

Hasselbalch equation. Because we have performed *many* equilibrium calculations in this chapter, we'll take the latter approach. The Henderson-Hasselbalch equation requires the concentrations of HCO_2^- and HCO_2H , which can be calculated using the number of millimoles (n) of each and the total volume (V_T). Substituting these values into the Henderson-Hasselbalch equation,

$$pH = pK_a + \log\left(\frac{[\text{HCO}_2^-]}{[\text{HCO}_2\text{H}]}\right) = pK_a + \log\left(\frac{n_{\text{HCO}_2^-}/V_f}{n_{\text{HCO}_2\text{H}}/V_f}\right) = pK_a + \log\left(\frac{n_{\text{HCO}_2^-}}{n_{\text{HCO}_2\text{H}}}\right)$$

Because the total volume appears in both the numerator and denominator, it cancels. We therefore need to use only the ratio of the number of millimoles of the conjugate base to the number of millimoles of the weak acid. So

$$pH = pK_a + \log\left(\frac{n_{\text{HCO}_2^-}}{n_{\text{HCO}_2\text{H}}}\right) = 3.75 + \log\left(\frac{16.5 \text{ mmol}}{18.5 \text{ mmol}}\right) = 3.75 - 0.050 = 3.70$$

Once again, this result makes sense on two levels. First, the addition of HCl has decreased the pH from 3.95, as expected. Second, the ratio of HCO_2^- to HCO_2H is slightly less than 1, so the pH should be between the pK_a and $pK_a - 1$.

1. **A** The procedure for solving this part of the problem is exactly the same as that used in part (a). We have already calculated the numbers of millimoles of formic acid and formate in 100 mL of the initial pH 3.95 buffer: 13.5 mmol of HCO_2H and 21.5 mmol of HCO_2^- . The number of millimoles of OH^- in 5.00 mL of 1.00 M NaOH is as follows:

$$5.00 \text{ mL} \left(\frac{1.00 \text{ mmol } \text{H}^+}{\text{mL}} \right) = 5.00 \text{ mmol } \text{H}^+$$

B With this information, we can construct a table of initial amounts, changes in amounts, and final amounts.

$\text{HCO}_2\text{H}(\text{aq}) + \text{OH}^-(\text{aq}) \rightarrow \text{HCO}_2^-(\text{aq}) + \text{H}_2\text{O}(\text{l})$			
	$[\text{HCO}_2\text{H}]$	$[\text{OH}^-]$	$[\text{HCO}_2^-]$
initial	13.5 mmol	5.00 mmol	21.5 mmol
change	-5.00 mmol	-5.00 mmol	+5.00 mmol
final	8.5 mmol	~0 mmol	26.5 mmol

The final amount of OH^- in solution is not actually zero; this is only approximately true based on the stoichiometric calculation. We can calculate the final pH by inserting the numbers of millimoles of both HCO_2^- and HCO_2H into the simplified Henderson-Hasselbalch expression used in part (a) because the volume cancels:

$$pH = pK_a + \log\left(\frac{n_{\text{HCO}_2^-}}{n_{\text{HCO}_2\text{H}}}\right) = 3.75 + \log\left(\frac{26.5 \text{ mmol}}{8.5 \text{ mmol}}\right) = 3.75 + 0.494 = 4.24$$

Once again, this result makes chemical sense: the pH has increased, as would be expected after adding a strong base, and the final pH is between the pK_a and $pK_a + 1$, as expected for a solution with a $\text{HCO}_2^-/\text{HCO}_2\text{H}$ ratio between 1 and 10.

Exercise

The buffer solution from Example 15 contained 0.119 M pyridine and 0.234 M pyridine hydrochloride and had a pH of 4.94.

1. What is the final pH if 12.0 mL of 1.5 M NaOH are added to 250 mL of this solution?
2. What is the final pH if 12.0 mL of 1.5 M HCl are added?

Answer:

1. 5.30

Note the Pattern

Only the *amounts* (in moles or millimoles) of the acidic and basic components of the buffer are needed to use the Henderson-Hasselbalch equation, *not* their concentrations.

Note the Pattern

The most effective buffers contain equal concentrations of an acid and its conjugate base.

The results obtained in Example 16 and its corresponding exercise demonstrate how little the pH of a well-chosen buffer solution changes despite the addition of a significant quantity of strong acid or strong base. Suppose we had added the same amount of HCl or NaOH solution to 100 mL of an *unbuffered* solution at pH 3.95 (corresponding to 1.1×10^{-4} M HCl). In this case, adding 5.00 mL of 1.00 M HCl would lower the final pH to 1.32 instead of 3.70, whereas adding 5.00 mL of 1.00 M NaOH would raise the final pH to 12.68 rather than 4.24. (Try verifying these values by doing the calculations yourself.) Thus the presence of a buffer significantly increases the ability of a solution to maintain an almost constant pH.

A buffer that contains approximately equal amounts of a weak acid and its conjugate base in solution is equally effective at neutralizing either added base or added acid. This is shown in Figure 16.6.2 for an acetic acid/sodium acetate buffer. Adding a given amount of strong acid shifts the system along the horizontal axis to the left, whereas adding the same amount of strong base shifts the system the same distance to the right. In either case, the change in the ratio of CH_3CO_2^- to $\text{CH}_3\text{CO}_2\text{H}$ from 1:1 reduces the buffer capacity of the solution.

Figure 16.6.2 Distribution Curve Showing the Fraction of Acetic Acid Molecules and Acetate Ions as a Function of pH in a Solution of Acetic Acid The pH range over which the acetic acid/sodium acetate system is an effective buffer (the darker shaded region) corresponds to the region in which appreciable concentrations of both species are present ($\text{pH } 3.76\text{--}5.76$, corresponding to $\text{pH} = \text{p}K_a \pm 1$).

The Relationship between Titrations and Buffers

There is a strong correlation between the effectiveness of a buffer solution and the titration curves discussed in [Section 16.5](#). Consider the schematic titration curve of a weak acid with a strong base shown in [Figure 16.6.3](#). As indicated by the labels, the region around pK_a corresponds to the midpoint of the titration, when approximately half the weak acid has been neutralized. This portion of the titration curve corresponds to a buffer: it exhibits the smallest change in pH per increment of added strong base, as shown by the nearly horizontal nature of the curve in this region. The nearly flat portion of the curve extends only from approximately a pH value of 1 unit less than the pK_a to approximately a pH value of 1 unit greater than the pK_a , which is why buffer solutions usually have a pH that is within ± 1 pH units of the pK_a of the acid component of the buffer.

Figure 16.6.3 The Relationship between Titration Curves and Buffers This schematic plot of pH for the titration of a weak acid with a strong base shows the nearly flat region of the titration curve around the midpoint, which corresponds to the formation of a buffer. At the lower left, the pH of the solution is determined by the equilibrium for dissociation of the weak acid; at the upper right, the pH is determined by the equilibrium for reaction of the conjugate base with water.

In the region of the titration curve at the lower left, before the midpoint, the acid–base properties of the solution are dominated by the equilibrium for dissociation of the weak acid, corresponding to K_a . In the region of the titration curve at the upper right, after the midpoint, the acid–base properties of the solution are dominated by the equilibrium for reaction of the conjugate base of the weak acid with water, corresponding to K_b . However, we can calculate either K_a or K_b from the other because they are related by K_w .

Blood: A Most Important Buffer

Metabolic processes produce large amounts of acids and bases, yet organisms are able to maintain an almost constant internal pH because their fluids contain buffers. This is not to say that the pH is uniform throughout all cells and tissues of a mammal. The internal pH of a red blood cell is about 7.2, but the pH of most other kinds of cells is lower, around 7.0. Even within a single cell, different compartments can have very different pH values. For example, one intracellular compartment in white blood cells has a pH of around 5.0.

Because no single buffer system can effectively maintain a constant pH value over the entire physiological range of approximately pH 5.0 to 7.4, biochemical systems use a set of buffers with overlapping ranges. The most important of these is the $\text{CO}_2/\text{HCO}_3^-$ system, which dominates the buffering action of blood plasma.

The acid–base equilibrium in the $\text{CO}_2/\text{HCO}_3^-$ buffer system is usually written as follows:

with $K_a = 4.5 \times 10^{-7}$ and $pK_a = 6.35$ at 25°C . In fact, [Equation 16.6.10](#) is a grossly oversimplified version of the $\text{CO}_2/\text{HCO}_3^-$ system because a solution of CO_2 in water contains only rather small amounts of H_2CO_3 . Thus [Equation 16.6.10](#) does not allow us to understand how blood is actually buffered, particularly at a physiological temperature of 37°C . As shown in [Equation 16.6.11](#),

CO₂ is in equilibrium with H₂CO₃, but the equilibrium lies far to the left, with an H₂CO₃/CO₂ ratio less than 0.01 under most conditions:

with $K' = 4.0 \times 10^{-3}$ at 37°C. The true pK_a of carbonic acid at 37°C is therefore 3.70, not 6.35, corresponding to a K_a of 2.0×10^{-4} , which makes it a much stronger acid than Equation 16.6.10 suggests. Adding Equation 16.6.10 and Equation 16.6.11 and canceling H₂CO₃ from both sides give the following overall equation for the reaction of CO₂ with water to give a proton and the bicarbonate ion:

with $K' = 4.0 \times 10^{-3}$ (37°C)

with $K_a = 2.0 \times 10^{-4}$ (37°C)

with $K = 8.0 \times 10^{-7}$ (37°C)

The K value for the reaction in Equation 16.6.12 is the product of the true ionization constant for carbonic acid (K_a) and the equilibrium constant (K) for the reaction of CO₂(aq) with water to give carbonic acid. The equilibrium equation for the reaction of CO₂ with water to give bicarbonate and a proton is therefore

$$K = \frac{[H^+][HCO_3^-]}{[CO_2]} = 8.0 \times 10^{-7} \quad (16.6.13)$$

The presence of a gas in the equilibrium constant expression for a buffer is unusual. According to Henry's law, [CO₂] = $kP(\text{CO}_2)$ where k is the Henry's law constant for CO₂, which is 3.0×10^{-5} M/mmHg at 37°C. (For more information about Henry's law, see Section 13.4.) Substituting this expression for [CO₂] in Equation 16.6.13,

$$K = \frac{[H^+][HCO_3^-]}{(3.0 \times 10^{-5} \text{ M/mmHg})(P_{CO_2})} \quad (16.6.14)$$

where $P(\text{CO}_2)$ is in mmHg. Taking the negative logarithm of both sides and rearranging,

$$pH = 6.10 + \log \left(\frac{[HCO_3^-]}{(3.0 \times 10^{-5} \text{ M/mmHg})(P_{CO_2})} \right) \quad (16.6.15)$$

Thus the pH of the solution depends on both the CO₂ pressure over the solution and [HCO₃⁻]. Figure 16.6.4 plots the relationship between pH and [HCO₃⁻] under physiological conditions for several different values of $P(\text{CO}_2)$ with normal pH and [HCO₃⁻] values indicated by the dashed lines.

Figure 16.6.4 Buffering in Blood: pH versus $[\text{HCO}_3^-]$ Curves for Buffers with Different Values of $P(\text{CO}_2)$ Only those combinations of pH and $[\text{HCO}_3^-]$ that lie on a given line are allowed for the particular value of $P(\text{CO}_2)$ indicated. Normal values of blood plasma pH and $[\text{HCO}_3^-]$ are indicated by dashed lines.

According to Equation 16.6.12, adding a strong acid to the $\text{CO}_2/\text{HCO}_3^-$ system causes $[\text{HCO}_3^-]$ to decrease as HCO_3^- is converted to CO_2 . Excess CO_2 is released in the lungs and exhaled into the atmosphere, however, so there is essentially no change in $P(\text{CO}_2)$. Because the change in $[\text{HCO}_3^-]/P(\text{CO}_2)$ is small, Equation 16.6.15 predicts that the change in pH will also be rather small. Conversely, if a strong base is added, the OH^- reacts with CO_2 to form $[\text{HCO}_3^-]$, but CO_2 is replenished by the body, again limiting the change in both $[\text{HCO}_3^-]/P(\text{CO}_2)$ and pH. The $\text{CO}_2/\text{HCO}_3^-$ buffer system is an example of an *open* system, in which the total concentration of the components of the buffer change to keep the pH at a nearly constant value.

If a passenger steps out of an airplane in Denver, Colorado, for example, the lower $P(\text{CO}_2)$ at higher elevations (typically 31 mmHg at an elevation of 2000 m versus 40 mmHg at sea level) causes a shift to a new pH and $[\text{HCO}_3^-]$. The increase in pH and decrease in $[\text{HCO}_3^-]$ in response to the decrease in $P(\text{CO}_2)$ are responsible for the general malaise that many people experience at high altitudes. If their blood pH does not adjust rapidly, the condition can develop into the life-threatening phenomenon known as altitude sickness.

Summary

Buffers are solutions that resist a change in pH after adding an acid or a base. Buffers contain a weak acid (HA) and its conjugate weak base (A^-). Adding a strong electrolyte that contains one ion in common with a reaction system that is at equilibrium shifts the equilibrium in such a way as to reduce the concentration of the common ion. The shift in equilibrium is called the **common ion effect**. Buffers are characterized by their pH range and buffer capacity. The useful pH range of a buffer depends strongly on the chemical properties of the conjugate weak acid–base pair used to prepare the buffer (the K_a or K_b), whereas its **buffer capacity** depends solely on the concentrations of the species in the solution. The pH of a buffer can be calculated using the **Henderson-Hasselbalch equation**, which is valid for solutions whose concentrations are at least 100 times greater than their K_a values. Because no single buffer system can effectively maintain a constant pH value over the physiological range of approximately 5 to 7.4, biochemical systems use a set of buffers with overlapping ranges. The most important of these is the $\text{CO}_2/\text{HCO}_3^-$ system, which dominates the buffering action of blood plasma.

Key Equations

Henderson-Hasselbalch equation

Equation 16.6.8:

$$\text{pH} = \text{p}K_a + \log\left(\frac{[\text{A}^-]}{[\text{HA}]}\right)$$

Equation 16.6.9:

$$\text{pH} = \text{p}K_a + \log\left(\frac{[\text{base}]}{[\text{acid}]}\right)$$

Key Takeaway

- The common ion effect allows solutions to act as buffers, whose pH can be calculated using the Henderson-Hasselbalch equation.

Conceptual Problems

1. Explain why buffers are crucial for the proper functioning of biological systems.
2. What is the role of a buffer in chemistry and biology? Is it correct to say that buffers prevent a change in $[\text{H}_3\text{O}^+]$? Explain your reasoning.
3. Explain why the most effective buffers are those that contain approximately equal amounts of the weak acid and its conjugate base.
4. Which region of the titration curve of a weak acid or a weak base corresponds to the region of the smallest change in pH per amount of added strong acid or strong base?
5. If you were given a solution of sodium acetate, describe two ways you could convert the solution to a buffer.
6. Why are buffers usually used only within approximately one pH unit of the $\text{p}K_a$ or $\text{p}K_b$ of the parent weak acid or base?
7. The titration curve for a monoprotic acid can be divided into four regions: the starting point, the region around the midpoint of the titration, the equivalence point, and the region after the equivalence point. For which region would you use each approach to describe the behavior of the solution?
 - a. a buffer
 - b. a solution of a salt of a weak base
 - c. a solution of a weak acid
 - d. diluting a strong base
8. Which of the following will produce a buffer solution? Explain your reasoning in each case.
 - a. mixing 100 mL of 0.1 M HCl and 100 mL of 0.1 M sodium fluoride
 - b. mixing 50 mL of 0.1 M HCl and 100 mL of 0.1 M sodium fluoride
 - c. mixing 100 mL of 0.1 M hydrofluoric acid and 100 mL of 0.1 M HCl
 - d. mixing 100 mL of 0.1 M hydrofluoric acid and 50 mL of 0.1 M NaOH
 - e. mixing 100 mL of 0.1 M sodium fluoride and 50 mL of 0.1 M NaOH.
9. Which of the following will produce a buffer solution? Explain your reasoning in each case.
 - a. mixing 100 mL of 0.1 M HCl and 100 mL of 0.1 M sodium acetate
 - b. mixing 50 mL of 0.1 M HCl and 100 mL of 0.1 M sodium acetate
 - c. mixing 100 mL of 0.1 M acetic acid and 100 mL of 0.1 M NaOH
 - d. mixing 100 mL of 0.1 M acetic acid and 50 mL of 0.1 M NaOH
 - e. mixing 100 mL of 0.1 M sodium acetate and 50 mL of 0.1 M acetic acid
10. Use the definition of K_b for a weak base to derive the following expression, which is analogous to the Henderson-Hasselbalch equation but for a weak base (B) rather than a weak acid (HA):

$$\text{pOH} = \text{p}K_b - \log\left(\frac{[\text{base}]}{[\text{acid}]}\right) \quad (\text{Chapter 16.6.3})$$

11. Why do biological systems use overlapping buffer systems to maintain a constant pH?
12. The $\text{CO}_2/\text{HCO}_3^-$ buffer system of blood has an effective $\text{p}K_a$ of approximately 6.1, yet the normal pH of blood is 7.4. Why is $\text{CO}_2/\text{HCO}_3^-$ an effective buffer when the $\text{p}K_a$ is more than 1 unit below the pH of blood? What happens to the pH of blood when the CO_2 pressure increases? when the O_2 pressure increases?
13. Carbon dioxide produced during respiration is converted to carbonic acid (H_2CO_3). The $\text{p}K_{a1}$ of carbonic acid is 6.35, and its $\text{p}K_{a2}$ is 10.33. Write the equations corresponding to each pK value and predict the equilibrium position for each reaction.

Numerical Problems

1. Benzenesulfonic acid ($pK_a = 0.70$) is synthesized by treating benzene with concentrated sulfuric acid. Calculate the following:
 - a. the pH of a 0.286 M solution of benzenesulfonic acid
 - b. the pH after adding enough sodium benzenesulfonate to give a final benzenesulfonate concentration of 0.100 M
2. Phenol has a pK_a of 9.99. Calculate the following:
 - a. the pH of a 0.195 M solution
 - b. the percent increase in the concentration of phenol after adding enough solid sodium phenoxide (the sodium salt of the conjugate base) to give a total phenoxide concentration of 0.100 M
3. Salicylic acid is used in the synthesis of acetylsalicylic acid, or aspirin. One gram dissolves in 460 mL of water to create a saturated solution with a pH of 2.40.
 - a. What is the K_a of salicylic acid?
 - b. What is the final pH of a saturated solution that is also 0.238 M in sodium salicylate?
 - c. What is the final pH if 10.00 mL of 0.100 M HCl are added to 150.0 mL of the buffered solution?
 - d. What is the final pH if 10.00 mL of 0.100 M NaOH are added to 150.0 mL of the buffered solution?

4. An intermediate used in the synthesis of perfumes is valeric acid, also called pentanoic acid. The pK_a of pentanoic acid is 4.84 at 25°C.
 - a. What is the pH of a 0.259 M solution of pentanoic acid?
 - b. Sodium pentanoate is added to make a buffered solution. What is the pH of the solution if it is 0.210 M in sodium pentanoate?
 - c. What is the final pH if 8.00 mL of 0.100 M HCl are added to 75.0 mL of the buffered solution?
 - d. What is the final pH if 8.00 mL of 0.100 M NaOH are added to 75.0 mL of the buffered solution?

Answer

- 1.
- 2.
3.
 - a. 1.35×10^{-3}
 - b. 4.03
 - c. 3.88
 - d. 4.30
- 4.

APPLICATION PROBLEMS

Problems marked with a ♦ involve multiple concepts.

- The analytical concentration of lactic acid in blood is generally less than 1.2×10^{-3} M, corresponding to the sum of [lactate] and [lactic acid]. During strenuous exercise, however, oxygen in the muscle tissue is depleted, and overproduction of lactic acid occurs. This leads to a condition known as lactic acidosis, which is characterized by elevated blood lactic acid levels (approximately 5.0×10^{-3} M). The pK_a of lactic acid is 3.86.
 - What is the actual lactic acid concentration under normal physiological conditions?
 - What is the actual lactic acid concentration during lactic acidosis?
- When the internal temperature of a human reaches 105°F, immediate steps must be taken to prevent the person from having convulsions. At this temperature, K_w is approximately 2.94×10^{-14} .
 - Calculate the pK_w and the pH and pOH of a neutral solution at 105°F.
 - Is the pH greater than or less than that calculated in Exercise 1 for a neutral solution at a normal body temperature of 98.6°F?
- ♦ The compound diphenhydramine (DPH) is the active ingredient in a number of over-the-counter antihistamine medications used to treat the runny nose and watery eyes associated with hay fever and other allergies. DPH is a derivative of trimethylamine (one methyl group is replaced by a more complex organic “arm” containing two phenyl rings):

The compound is sold as the water-soluble hydrochloride salt ($DPH^+ Cl^-$). A tablet of diphenhydramine hydrochloride contains 25.0 mg of the active ingredient. Calculate the pH of the solution if two tablets are dissolved in 100 mL of water. The pK_b of diphenhydramine is 5.47, and the formula mass of diphenhydramine hydrochloride is 291.81 amu.

- ♦ Epinephrine, a secondary amine, is used to counter allergic reactions as well as to bring patients out of anesthesia and cardiac arrest. The pK_b of epinephrine is 4.31. What is the percent ionization in a 0.280 M solution? What is the percent ionization after enough solid epinephrine hydrochloride is added to make the final epinephrineH⁺ concentration 0.982 M? What is the final pH of the solution?

5. ♦ Fluoroacetic acid is a poison that has been used by ranchers in the western United States. The ranchers place the poison in the carcasses of dead animals to kill coyotes that feed on them; unfortunately, however, eagles and hawks are also killed in the process. How many milliliters of 0.0953 M Ca(OH)_2 are needed to completely neutralize 50.0 mL of 0.262 M fluoroacetic acid solution ($\text{p}K_a = 2.59$)? What is the initial pH of the solution? What is the pH of the solution at the equivalence point?
6. Accidental ingestion of aspirin (acetylsalicylic acid) is probably the most common cause of childhood poisoning. Initially, salicylates stimulate the portion of the brain that controls breathing, resulting in hyperventilation (excessively intense breathing that lowers the $\text{P}(\text{CO}_2)$ in the lungs). Subsequently, a potentially serious rebound effect occurs, as the salicylates are converted to a weak acid, salicylic acid, in the body. Starting with the normal values of $\text{P}(\text{CO}_2) = 40$ mmHg, $\text{pH} = 7.40$, and $[\text{HCO}_3^-] = 24$ nM, show what happens during the initial phase of respiratory stimulation and the subsequent phase of acid production. Why is the rebound effect dangerous?
7. Emphysema is a disease that reduces the efficiency of breathing. As a result, less CO_2 is exchanged with the atmosphere. What effect will this have on blood pH, $\text{P}(\text{CO}_2)$ and $[\text{HCO}_3^-]$?

ANSWER

Although [Chapter 16](#) focused exclusively on acid–base equilibria in aqueous solutions, equilibrium concepts can also be applied to many other kinds of reactions that occur in aqueous solution. In this chapter, we describe the equilibria involved in the solubility of ionic compounds and the formation of complex ions.

Solubility equilibria involving ionic compounds are important in fields as diverse as medicine, biology, geology, and industrial chemistry. Carefully controlled precipitation reactions of calcium salts, for example, are used by many organisms to produce structural materials, such as bone and the shells that surround mollusks and bird eggs. In contrast, uncontrolled precipitation reactions of calcium salts are partially or wholly responsible for the formation of scale in coffee makers and boilers, “bathtub rings,” and kidney stones, which can be excruciatingly painful. The principles discussed in this chapter will enable you to understand how these apparently diverse phenomena are related. Solubility equilibria are also responsible for the formation of caves and their striking features, such as stalactites and stalagmites, through a long process involving the repeated dissolution and precipitation of calcium carbonate. In addition to all of these phenomena, by the end of this chapter you will understand why barium sulfate is ideally suited for x-ray imaging of the digestive tract, and why soluble complexes of gadolinium can be used for imaging soft tissue and blood vessels using magnetic resonance imaging (MRI), even though most simple salts of both metals are toxic to humans.

Scanning electron micrograph of kettle scale. Hard water is a solution that consists largely of calcium and magnesium carbonate in CO_2 -rich water. When the water is heated, CO_2 gas is released, and the carbonate salts precipitate from solution and produce a solid called scale.

Learning Objective

- To calculate the solubility of an ionic compound from its K_{sp} .

We begin our discussion of solubility and *complexation equilibria*—those associated with the formation of complex ions—by developing quantitative methods for describing dissolution and precipitation reactions of ionic compounds in aqueous solution. Just as with acid–base equilibria, we can describe the concentrations of ions in equilibrium with an ionic solid using an equilibrium constant expression.

The Solubility Product

When a slightly soluble ionic compound is added to water, some of it dissolves to form a solution, establishing an equilibrium between the pure solid and a solution of its ions. For the dissolution of calcium phosphate, one of the two main components of kidney stones, the equilibrium can be written as follows, with the solid salt on the left: As you will discover in [Section 17.4](#) and in more advanced chemistry courses, basic anions, such as S^{2-} , PO_4^{3-} , and CO_3^{2-} , react with water to produce OH^- and the corresponding protonated anion. Consequently, their calculated molarities, assuming no protonation in aqueous solution, are only approximate.

The equilibrium constant for the dissolution of a sparingly soluble salt is the solubility product (K_{sp}) of the salt. Because the concentration of a pure solid such as $Ca_3(PO_4)_2$ is a constant, it does not appear explicitly in the equilibrium constant expression. (For more information on the equilibrium constant expression, see [Section 15.2](#).) The equilibrium constant expression for the dissolution of calcium phosphate is therefore

$$K = \frac{[Ca^{2+}]^3 [PO_4^{3-}]^2}{[Ca_3(PO_4)_2]} \quad (17.1.2a)$$

$$[Ca_3(PO_4)_2]K = K_{sp} = [Ca^{2+}]^3 [PO_4^{3-}]^2 \quad (17.1.2b)$$

At 25°C and pH 7.00, K_{sp} for calcium phosphate is 2.07×10^{-33} , indicating that the concentrations of Ca^{2+} and PO_4^{3-} ions in solution that are in equilibrium with solid calcium phosphate are very low. The values of K_{sp} for some common salts are listed in [Table 17.1.1](#); they show that the magnitude of K_{sp} varies dramatically for different compounds. Although K_{sp} is not a function of pH in [Equation 17.1](#), changes in pH can affect the solubility of a compound, as you will discover in [Section 17.4](#).

Note the Pattern

As with K , the concentration of a pure solid does not appear explicitly in K_{sp} .

Table 17.1.1 Solubility Products for Selected Ionic Substances at 25°C

Solid	Color	K_{sp}	Solid	Color	K_{sp}
-------	-------	----------	-------	-------	----------

Solid	Color	K_{sp}		Solid	Color	K_{sp}
Acetates				Iodides		
$\text{Ca}(\text{O}_2\text{CCH}_3)_2 \cdot 3\text{H}_2\text{O}$	white	4×10^{-3}		Hg_2I_2^*	yellow	5.2×10^{-29}
Bromides				PbI_2	yellow	9.8×10^{-9}

$\text{Fe}(\text{OH})_3$	rust red	2.79×10^{-39}				
*These contain the Hg_2^{2+} ion.						

Solubility products are determined experimentally by directly measuring either the concentration of one of the component ions or the solubility of the compound in a given amount of water. However, whereas solubility is usually expressed in terms of m

mass of solute per 100 mL of solvent, K_{sp} , like K , is defined in terms of the *molar* concentrations of the component ions.

A kidney stone. Kidney stones form from sparingly

soluble calcium salts and are largely composed of $\text{Ca}(\text{O}_2\text{CCO}_2)\cdot\text{H}_2\text{O}$ and $\text{Ca}_3(\text{PO}_4)_2$.

© Thinkstock

Example 17.1.1

Calcium oxalate monohydrate $[\text{Ca}(\text{O}_2\text{CCO}_2)\cdot\text{H}_2\text{O}]$, also written as $\text{CaC}_2\text{O}_4\cdot\text{H}_2\text{O}$ is a sparingly soluble salt that is the other major component of kidney stones [along with $\text{Ca}_3(\text{PO}_4)_2$]. Its solubility in water at 25°C is 7.36×10^{-4} g/100 mL. Calculate its K_{sp} .

Given: solubility in g/100 mL

Asked for: K_{sp}

Strategy:

A Write the balanced dissolution equilibrium and the corresponding solubility product expression.

B Convert the solubility of the salt to moles per liter. From the balanced dissolution equilibrium, determine the equilibrium concentrations of the dissolved solute ions. Substitute these values into the solubility product expression to calculate K_{sp} .

Solution:

A We need to write the solubility product expression in terms of the concentrations of the component ions. For calcium oxalate monohydrate, the balanced dissolution equilibrium and the solubility product expression (abbreviating oxalate as ox^{2-}) are as follows:

Neither solid calcium oxalate monohydrate nor water appears in the solubility product expression because their concentrations are essentially constant.

B Next we need to determine $[\text{Ca}^{2+}]$ and $[\text{ox}^{2-}]$ at equilibrium. We can use the mass of calcium oxalate monohydrate that dissolves in 100 mL of water to calculate the number of moles that dissolve in 100 mL of water. From this we can determine the number of moles that dissolve in 1.00 L of water. For dilute solutions, the density of the solution is nearly the same as that of water, so dissolving the salt in 1.00 L of water gives essentially 1.00 L of solution. Because each 1 mol of dissolved calcium oxalate monohydrate dissociates to produce 1 mol of calcium ions and 1 mol of oxalate ions, we can obtain the equilibrium concentrations that must be inserted into the solubility product expression. The number of moles of calcium oxalate monohydrate that dissolve in 100 mL of water is as follows:

$$\frac{7.36 \times 10^{-4} \text{ g}}{146.1 \text{ g/mol}} = 5.04 \times 10^{-6} \text{ mol Ca}(\text{O}_2\text{CCO}_2)\cdot\text{H}_2\text{O}$$

The number of moles of calcium oxalate monohydrate that dissolve in 1.00 L of the saturated solution is as follows:

$$\left(\frac{5.04 \times 10^{-6} \text{ mol Ca}(\text{O}_2\text{CCO}_2)\cdot\text{H}_2\text{O}}{100 \text{ mL}} \right) \left(\frac{1000 \text{ mL}}{1.00 \text{ L}} \right) = 5.04 \times 10^{-5} \text{ mol/L} = 5.04 \times 10^{-5} \text{ M}$$

Because of the stoichiometry of the reaction, the concentration of Ca^{2+} and ox^{2-} ions are both 5.04×10^{-5} M. Inserting these values into the solubility product expression,

$$K_{\text{sp}} = [\text{Ca}^{2+}][\text{ox}^{2-}] = (5.04 \times 10^{-5})(5.04 \times 10^{-5}) = 2.54 \times 10^{-9}$$

In our calculation, we have ignored the reaction of the weakly basic anion with water, which tends to make the actual solubility of many salts greater than the calculated value.

Exercise

One crystalline form of calcium carbonate (CaCO_3) is the mineral sold as “calcite” in mineral and gem shops. The solubility of calcite in water is 0.67 mg/100 mL. Calculate its K_{sp} .

Answer: 4.5×10^{-9}

Note the Pattern

The reaction of weakly basic anions with H_2O tends to make the actual solubility of many salts higher than predicted.

Calcite, a structural material for many organisms, is found in the teeth of sea urchins. The urchins create depressions in limestone that they can settle in by grinding the rock with their teeth. Limestone, however, also consists of calcite, so how can the urchins grind the rock without also grinding their teeth? Researchers have discovered that the teeth are shaped like needles and plates and contain magnesium. The concentration of magnesium increases toward the tip, which contributes to the hardness. Moreover, each tooth is composed of two blocks of the polycrystalline calcite matrix that are interleaved near the tip. This creates a corrugated surface that presumably increases grinding efficiency. Toolmakers are particularly interested in this approach to grinding.

Tabulated values of K_{sp} can also be used to estimate the solubility of a salt with a procedure that is essentially the reverse of the one used in Example 1. In this case, we treat the problem as a typical equilibrium problem and set up a table of initial concentrations, changes in concentration, and final concentrations as we did in Chapter 15, remembering that the concentration of the pure solid is essentially constant.

A crystal of calcite (CaCO_3)

, illustrating the phenomenon of double refraction. When a transparent crystal of calcite is placed over a page, we see two images of the letters.

Example 17.1.2

We saw that the K_{sp} for $\text{Ca}_3(\text{PO}_4)_2$ is 2.07×10^{-33} at 25°C . Calculate the aqueous solubility of $\text{Ca}_3(\text{PO}_4)_2$ in terms of the following:

1. the molarity of ions produced in solution
2. the mass of salt that dissolves in 100 mL of water at 25°C

Given: K_{sp}

Asked for: molar concentration and mass of salt that dissolves in 100 mL of water

Strategy:

A Write the balanced equilibrium equation for the dissolution reaction and construct a table showing the concentrations of the species produced in solution. Insert the appropriate values into the solubility product expression and calculate the molar solubility at 25°C .

B Calculate the mass of solute in 100 mL of solution from the molar solubility of the salt. Assume that the volume of the solution is the same as the volume of the solvent.

Solution:

1. **A** The dissolution equilibrium for $\text{Ca}_3(\text{PO}_4)_2$ (Equation 17.1) is shown in the following table. Because we are starting with distilled water, the initial concentration of both calcium²⁺ and phosphate ions is zero. For every 1 mol of $\text{Ca}_3(\text{PO}_4)_2$ that dissolves, 3 mol of Ca^{2+} and 2 mol of PO_4^{3-} ions are produced in solution. If we let x equal the solubility of $\text{Ca}_3(\text{PO}_4)_2$ in moles per liter, then the change in $[\text{Ca}^{2+}]$ will be $+3x$, and the change in $[\text{PO}_4^{3-}]$ will be $+2x$. We can insert these values into the table.

$\text{Ca}_3(\text{PO}_4)_2(\text{s}) \rightleftharpoons 3\text{Ca}^{2+}(\text{aq}) + 2\text{PO}_4^{3-}(\text{aq})$			
	$\text{Ca}_3(\text{PO}_4)_2$	$[\text{Ca}^{2+}]$	$[\text{PO}_4^{3-}]$
initial	pure solid	0	0
change	—	+3x	+2x
final	pure solid	3x	2x

Although the *amount* of solid $\text{Ca}_3(\text{PO}_4)_2$ changes as some of it dissolves, its *molar concentration* does not change. We now insert the expressions for the equilibrium concentrations of the ions into the solubility product expression (Equation 17.1.2):

$$\begin{aligned} K_{\text{sp}} &= [\text{Ca}^{2+}]^3 [\text{PO}_4^{3-}]^2 = (3x)^3 (2x)^2 \\ 2.07 \times 10^{-33} &= 108x^5 \\ 1.92 \times 10^{-35} &= x^5 \\ 1.14 \times 10^{-7} \text{ M} &= x \end{aligned}$$

This is the molar solubility of calcium phosphate at 25°C. However, the molarity of the ions is 2x and 3x, which means that $[\text{PO}_4^{3-}] = 2.28 \times 10^{-7}$ and $[\text{Ca}^{2+}] = 3.42 \times 10^{-7}$.

2. **B** To find the mass of solute in 100 mL of solution, we assume that the density of this dilute solution is the same as the density of water because of the low solubility of the salt, so that 100 mL of water gives 100 mL of solution. We can then determine the amount of salt that dissolves in 100 mL of water:

$$\left(\frac{1.14 \times 10^{-7} \text{ mol}}{1 \text{ L}} \right) 100 \text{ mL} \left(\frac{1 \text{ L}}{1000 \text{ mL}} \right) \left(\frac{310.18 \text{ g Ca}_3(\text{PO}_4)_2}{1 \text{ mol}} \right) = 3.54 \times 10^{-6} \text{ g Ca}_3(\text{PO}_4)_2$$

Exercise

The solubility product of silver carbonate (Ag_2CO_3) is 8.46×10^{-12} at 25°C. Calculate the following:

- the molarity of a saturated solution
- the mass of silver carbonate that will dissolve in 100 mL of water at this temperature

Answer:

- $1.28 \times 10^{-4} \text{ M}$
- 3.54 mg

The Ion Product

The ion product (Q) of a salt is the product of the concentrations of the ions in solution raised to the same powers as in the solubility product expression. It is analogous to the reaction quotient (Q) discussed for gaseous equilibria in Chapter 15. Whereas K_{sp} describes equilibrium concentrations, the ion product describes concentrations that are *not* necessarily equilibrium concentrations.

Note the Pattern

The ion product Q is analogous to the reaction quotient Q for gaseous equilibria.

As summarized in Figure 17.1.1, there are three possible conditions for an aqueous solution of an ionic solid:

- $Q < K_{\text{sp}}$. The solution is unsaturated, and more of the ionic solid, if available, will dissolve.
- $Q = K_{\text{sp}}$. The solution is saturated and at equilibrium.
- $Q > K_{\text{sp}}$. The solution is supersaturated, and ionic solid will precipitate.

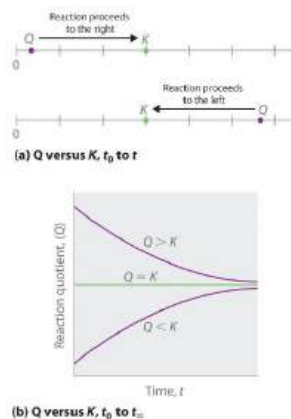

Figure 17.1.1 The Relationship between Q and K_{sp} If Q is less than K_{sp} , the solution is unsaturated and more solid will dissolve until the system reaches equilibrium ($Q = K_{sp}$). If Q is greater than K_{sp} , the solution is supersaturated and solid will precipitate until $Q = K_{sp}$. If $Q = K_{sp}$, the rate of dissolution is equal to the rate of precipitation; the solution is saturated, and no net change in the amount of dissolved solid will occur.

The process of calculating the value of the ion product and comparing it with the magnitude of the solubility product is a straightforward way to determine whether a solution is unsaturated, saturated, or supersaturated. More important, the ion product tells chemists whether a precipitate will form when solutions of two soluble salts are mixed.

Example 17.1.3

We mentioned that barium sulfate is used in medical imaging of the gastrointestinal tract. Its solubility product is 1.08×10^{-10} at 25°C , so it is ideally suited for this purpose because of its low solubility when a “barium milkshake” is consumed by a patient. The pathway of the sparingly soluble salt can be easily monitored by x-rays. Will barium sulfate precipitate if 10.0 mL of 0.0020 M Na_2SO_4 is added to 100 mL of 3.2×10^{-4} M BaCl_2 ? Recall that NaCl is highly soluble in water.

Given: K_{sp} and volumes and concentrations of reactants

Asked for: whether precipitate will form

Strategy:

A Write the balanced equilibrium equation for the precipitation reaction and the expression for K_{sp} .

B Determine the concentrations of all ions in solution when the solutions are mixed and use them to calculate the ion product (Q).

C Compare the values of Q and K_{sp} to decide whether a precipitate will form.

Solution:

A The only slightly soluble salt that can be formed when these two solutions are mixed is BaSO_4 because NaCl is highly soluble. The equation for the precipitation of BaSO_4 is as follows:

The solubility product expression is as follows:

$$K_{sp} = [\text{Ba}^{2+}][\text{SO}_4^{2-}] = 1.08 \times 10^{-10}$$

B To solve this problem, we must first calculate the ion product— $Q = [\text{Ba}^{2+}][\text{SO}_4^{2-}]$ —using the concentrations of the ions that are present after the solutions are mixed and before any reaction occurs. The concentration of Ba^{2+} when the solutions

are mixed is the total number of moles of Ba^{2+} in the original 100 mL of BaCl_2 solution divided by the final volume (100 mL + 10.0 mL = 110 mL):

$$\begin{aligned} \text{moles Ba}^{2+} &= 100 \text{ mL} \left(\frac{1 \text{ L}}{1000 \text{ mL}} \right) \left(\frac{3.2 \times 10^{-4} \text{ mol}}{1 \text{ L}} \right) = 3.2 \times 10^{-5} \text{ mol Ba}^{2+} \\ [\text{Ba}^{2+}] &= \left(\frac{3.2 \times 10^{-5} \text{ mol Ba}^{2+}}{110 \text{ mL}} \right) \left(\frac{1000 \text{ mL}}{1 \text{ L}} \right) = 2.9 \times 10^{-4} \text{ M Ba}^{2+} \end{aligned}$$

Similarly, the concentration of SO_4^{2-} after mixing is the total number of moles of SO_4^{2-} in the original 10.0 mL of Na_2SO_4 solution divided by the final volume (110 mL):

$$\begin{aligned} \text{moles SO}_4^{2-} &= 10.0 \text{ mL} \left(\frac{1 \text{ L}}{1000 \text{ mL}} \right) \left(\frac{0.0020 \text{ mol}}{1 \text{ L}} \right) = 2.0 \times 10^{-5} \text{ mol SO}_4^{2-} \\ [\text{SO}_4^{2-}] &= \left(\frac{2.0 \times 10^{-5} \text{ mol SO}_4^{2-}}{110 \text{ mL}} \right) \left(\frac{1000 \text{ mL}}{1 \text{ L}} \right) = 1.8 \times 10^{-4} \text{ M SO}_4^{2-} \end{aligned}$$

We can now calculate Q :

$$Q = [\text{Ba}^{2+}][\text{SO}_4^{2-}] = (2.9 \times 10^{-4})(1.8 \times 10^{-4}) = 5.2 \times 10^{-8}$$

C We now compare Q with the K_{sp} . If $Q > K_{\text{sp}}$, then BaSO_4 will precipitate, but if $Q < K_{\text{sp}}$, it will not. Because $Q > K_{\text{sp}}$, we predict that BaSO_4 will precipitate when the two solutions are mixed. In fact, BaSO_4 will continue to precipitate until the system reaches equilibrium, which occurs when $[\text{Ba}^{2+}][\text{SO}_4^{2-}] = K_{\text{sp}} = 1.08 \times 10^{-10}$.

Exercise

The solubility product of calcium fluoride (CaF_2) is 3.45×10^{-11} . If 2.0 mL of a 0.10 M solution of NaF is added to 128 mL of a 2.0×10^{-5} M solution of $\text{Ca}(\text{NO}_3)_2$, will CaF_2 precipitate?

Answer: yes ($Q = 4.7 \times 10^{-11} > K_{\text{sp}}$)

The Common Ion Effect and Solubility

The solubility product expression tells us that the equilibrium concentrations of the cation and the anion are inversely related. That is, as the concentration of the anion increases, the maximum concentration of the cation needed for precipitation to occur decreases—and vice versa—so that K_{sp} is constant. Consequently, the solubility of an ionic compound depends on the concentrations of other salts that contain the same ions. This dependency is another example of the common ion effect discussed in [Section 16.6](#): adding a common cation or anion shifts a solubility equilibrium in the direction predicted by Le Châtelier's principle. As a result, *the solubility of any sparingly soluble salt is almost always decreased by the presence of a soluble salt that contains a common ion.* The exceptions generally involve the formation of complex ions, which is discussed in [Section 17.3](#).

Consider, for example, the effect of adding a soluble salt, such as CaCl_2 , to a saturated solution of calcium phosphate $[\text{Ca}_3(\text{PO}_4)_2]$. We have seen that the solubility of $\text{Ca}_3(\text{PO}_4)_2$ in water at 25°C is 1.14×10^{-7} M ($K_{\text{sp}} = 2.07 \times 10^{-33}$). Thus a saturated solution of $\text{Ca}_3(\text{PO}_4)_2$ in water contains $3 \times (1.14 \times 10^{-7} \text{ M}) = 3.42 \times 10^{-7}$ M Ca^{2+} and $2 \times (1.14 \times 10^{-7} \text{ M}) = 2.28 \times 10^{-7}$ M PO_4^{3-} , according to the stoichiometry shown in [Equation 17.1.1](#) (neglecting hydrolysis to form HPO_4^{2-} as described in [Chapter 16](#)). If CaCl_2 is added to a saturated solution of $\text{Ca}_3(\text{PO}_4)_2$, the Ca^{2+} ion concentration will increase such that $[\text{Ca}^{2+}] > 3.42 \times 10^{-7}$ M, making $Q > K_{\text{sp}}$. The only way the system can return to equilibrium is for the reaction in [Equation 17.1.1](#) to proceed to the left, resulting in precipitation of $\text{Ca}_3(\text{PO}_4)_2$. This will decrease the concentration of both Ca^{2+} and PO_4^{3-} until $Q = K_{\text{sp}}$.

Note the Pattern

The common ion effect usually decreases the solubility of a sparingly soluble salt.

Example 17.1.4

Calculate the solubility of calcium phosphate $[\text{Ca}_3(\text{PO}_4)_2]$ in 0.20 M CaCl_2 .

Given: concentration of CaCl_2 solution

Asked for: solubility of $\text{Ca}_3(\text{PO}_4)_2$ in CaCl_2 solution

Strategy:

A Write the balanced equilibrium equation for the dissolution of $\text{Ca}_3(\text{PO}_4)_2$. Tabulate the concentrations of all species produced in solution.

B Substitute the appropriate values into the expression for the solubility product and calculate the solubility of $\text{Ca}_3(\text{PO}_4)_2$.

Solution:

A The balanced equilibrium equation is given in the following table. If we let x equal the solubility of $\text{Ca}_3(\text{PO}_4)_2$ in moles per liter, then the change in $[\text{Ca}^{2+}]$ is once again $+3x$, and the change in $[\text{PO}_4^{3-}]$ is $+2x$. We can insert these values into the table.

$\text{Ca}_3(\text{PO}_4)_2(\text{s}) = 3\text{Ca}^{2+}(\text{aq}) + 2\text{PO}_4^{3-}(\text{aq})$			
	$\text{Ca}_3(\text{PO}_4)_2$	$[\text{Ca}^{2+}]$	$[\text{PO}_4^{3-}]$
initial	pure solid	0.20	0
change	—	$+3x$	$+2x$
final	pure solid	$0.20 + 3x$	$2x$

B The K_{sp} expression is as follows:

$$K_{\text{sp}} = [\text{Ca}^{2+}]^3 [\text{PO}_4^{3-}]^2 = (0.20 + 3x)^3 (2x)^2 = 2.07 \times 10^{-33}$$

Because $\text{Ca}_3(\text{PO}_4)_2$ is a sparingly soluble salt, we can reasonably expect that $x \ll 0.20$. Thus $(0.20 + 3x)$ M is approximately 0.20 M, which simplifies the K_{sp} expression as follows:

$$\begin{aligned} K_{\text{sp}} &= (0.20)^3 (2x)^2 = 2.07 \times 10^{-33} \\ x^2 &= 6.5 \times 10^{-32} && \text{(Chapter 17.1.1)} \\ x &= 2.5 \times 10^{-16} \text{ M} \end{aligned}$$

This value is the solubility of $\text{Ca}_3(\text{PO}_4)_2$ in 0.20 M CaCl_2 at 25°C . It is approximately nine orders of magnitude less than its solubility in pure water, as we would expect based on Le Châtelier's principle. With one exception, this example is identical to Example 2—here the initial $[\text{Ca}^{2+}]$ was 0.20 M rather than 0.

Exercise

Calculate the solubility of silver carbonate in a 0.25 M solution of sodium carbonate. The solubility of silver carbonate in pure water is 8.45×10^{-12} at 25°C .

Answer: 2.9×10^{-6} M (versus 1.3×10^{-4} M in pure water)

Summary

The equilibrium constant for a dissolution reaction, called the **solubility product** (K_{sp}), is a measure of the solubility of a compound. Whereas solubility is usually expressed in terms of *mass* of solute per 100 mL of solvent, K_{sp} is defined in terms of the *molar* concentrations of the component ions. In contrast, the **ion product** (Q) describes concentrations that are not necessarily equilibrium concentrations. Comparing Q and K_{sp} enables us to determine whether a precipitate will form when solutions of two soluble salts are mixed. Adding a common cation or common anion to a solution of a sparingly soluble salt shifts the solubility equilibrium in the direction predicted by Le Châtelier's principle. The solubility of the salt is almost always decreased by the presence of a common ion.

Key Takeaway

- The solubility product (K_{sp}) is used to calculate equilibrium concentrations of the ions in solution, whereas the ion product (Q) describes concentrations that are not necessarily at equilibrium.

Conceptual Problems

- Write an expression for K_{sp} for each salt.
 - AgI
 - CaF₂
 - PbCl₂
 - Ag₂CrO₄
- Some species are not represented in a solubility product expression. Why?
- Describe the differences between Q and K_{sp} .
- How can an ion product be used to determine whether a solution is saturated?
- When using K_{sp} to directly compare the solubilities of compounds, why is it important to compare only the K_{sp} values of salts that have the same stoichiometry?
- Describe the effect of a common ion on the solubility of a salt. Is this effect similar to the common ion effect found in buffers? Explain your answer.
- Explain why the presence of MgCl₂ decreases the molar solubility of the sparingly soluble salt MgCO₃.

Answers

- $K_{sp} = [Ag^{+}][I^{-}]$
 - $K_{sp} = [Ca^{2+}][F^{-}]^2$
 - $K_{sp} = [Pb^{2+}][Cl^{-}]^2$
 - $K_{sp} = [Ag^{+}]^2[CrO_4^{2-}]$
-
-
-
- For a 1:1 salt, the molar solubility is simply $\sqrt{K_{sp}}$; for a 2:1 salt, the molar solubility is $\sqrt[3]{K_{sp}/4}$. Consequently, the magnitudes of K_{sp} can be correlated with molar solubility *only* if the salts have the same stoichiometry.
-
- Because of the common ion effect. Adding a soluble Mg²⁺ salt increases [Mg²⁺] in solution, and Le Châtelier's principle predicts that this will shift the solubility equilibrium of MgCO₃ to the left, decreasing its solubility.

Numerical Problems

- Predict the molar solubility of each compound using the K_{sp} values given in [Table E3](#).
 - Cd(IO₃)₂
 - AgCN
 - HgI₂
- Predict the molar solubility of each compound using the K_{sp} values given.
 - Li₃PO₄: 2.37×10^{-6}
 - Ca(IO₃)₂: 6.47×10^{-10}
 - Y(IO₃)₃: 1.12×10^{-11}
- A student prepared 750 mL of a saturated solution of silver sulfate (Ag₂SO₄). How many grams of Ag₂SO₄ does the solution contain? $K_{sp} = 1.20 \times 10^{-5}$.
- Given the K_{sp} values in [Table 17.1.1](#) and [Table E3](#), predict the molar concentration of each species in a saturated aqueous solution.
 - silver bromide
 - lead oxalate
 - iron(II) carbonate

- d. silver phosphate
e. copper(I) cyanide
5. Given the K_{sp} values in Table 17.1.1 and Table E3, predict the molar concentration of each species in a saturated aqueous solution.
- copper(I) chloride
 - lanthanum(III) iodate
 - magnesium phosphate
 - silver chromate
 - strontium sulfate
6. Silicon dioxide, the most common binary compound of silicon and oxygen, constitutes approximately 60% of Earth's crust. Under certain conditions, this compound can react with water to form silicic acid, which can be written as either H_4SiO_4 or $Si(OH)_4$. Write a balanced chemical equation for the dissolution of SiO_2 in basic solution. Write an equilibrium constant expression for the reaction.
7. The K_{sp} of $Mg(OH)_2$ is 5.61×10^{-12} . If you tried to dissolve 24.0 mg of $Mg(OH)_2$ in 250 mL of water and then filtered the solution and dried the remaining solid, what would you predict to be the mass of the undissolved solid? You discover that only 1.0 mg remains undissolved. Explain the difference between your expected value and the actual value.
8. The K_{sp} of lithium carbonate is 8.15×10^{-4} . If 2.34 g of the salt is stirred with 500 mL of water and any undissolved solid is filtered from the solution and dried, what do you predict to be the mass of the solid? You discover that all of your sample dissolves. Explain the difference between your predicted value and the actual value.
9. You have calculated that 24.6 mg of $BaSO_4$ will dissolve in 1.0 L of water at 25°C. After adding your calculated amount to 1.0 L of water and stirring for several hours, you notice that the solution contains undissolved solid. After carefully filtering the solution and drying the solid, you find that 22.1 mg did not dissolve. According to your measurements, what is the K_{sp} of barium sulfate?
10. In a saturated silver chromate solution, the molar solubility of chromate is 6.54×10^{-5} . What is the K_{sp} ?
11. A saturated lead(II) chloride solution has a chloride concentration of 3.24×10^{-2} mol/L. What is the K_{sp} ?
12. From the solubility data given, calculate K_{sp} for each compound.
- AgI: 2.89×10^{-2} g/100 mL
 - SrF_2 : 1.22×10^{-1} g/100 mL
 - $Pb(OH)_2$: 78 mg/500 mL
 - $BiAsO_4$: 14.4 mg/2.0 L
13. From the solubility data given, calculate K_{sp} for each compound.
- $BaCO_3$: 10.0 mg/500 mL
 - CaF_2 : 3.50 mg/200 mL
 - $Mn(OH)_2$: 6.30×10^{-13} g/300 mL
 - Ag_2S : 1.60×10^{-13} mg/100 mL
14. Given the following solubilities, calculate K_{sp} for each compound.
- $BaCO_3$: 7.00×10^{-5} mol/L
 - CaF_2 : 1.70 mg/100 mL
 - $Pb(IO_3)_2$: 2.30 mg/100 mL
 - SrC_2O_4 : 1.58×10^{-4} mol/L
15. Given the following solubilities, calculate K_{sp} for each compound.
- Ag_2SO_4 : 4.2×10^{-3} g/100 mL
 - $SrSO_4$: 1.5×10^{-2} g/100 mL
 - CdC_2O_4 : 6.0×10^{-2} g/100 mL
 - $Ba(IO_3)_2$: 3.96×10^{-2} g/100 mL
16. The K_{sp} of the phosphate fertilizer $CaHPO_4 \cdot 2H_2O$ is 2.7×10^{-7} at 25°C. What is the molar concentration of a saturated solution? What mass of this compound will dissolve in 3.0 L of water at this temperature?
17. The K_{sp} of zinc carbonate monohydrate is 5.5×10^{-11} at 25°C. What is the molar concentration of a saturated solution? What mass of this compound will dissolve in 2.0 L of water at this temperature?
18. Silver nitrate eye drops were formerly administered to newborn infants to guard against eye infections contracted during birth. Although silver nitrate is highly water soluble, silver sulfate has a K_{sp} of 1.20×10^{-5} at 25°C. If you add 25.0 mL of 0.015 M $AgNO_3$ to 150 mL of 2.8×10^{-2} M Na_2SO_4 , will you get a precipitate? If so, what will its mass be?

19. Use the data in Table E3 to predict whether precipitation will occur when each pair of solutions is mixed.
- 150 mL of 0.142 M $\text{Ba}(\text{NO}_3)_2$ with 200 mL of 0.089 M NaF
 - 250 mL of 0.079 M K_2CrO_4 with 175 mL of 0.087 M CaCl_2
 - 300 mL of 0.109 M MgCl_2 with 230 mL of 0.073 M $\text{Na}_2(\text{C}_2\text{O}_4)$
20. What is the maximum volume of 0.048 M $\text{Pb}(\text{NO}_3)_2$ that can be added to 250 mL of 0.10 M NaSCN before precipitation occurs? $K_{\text{sp}} = 2.0 \times 10^{-6}$ for $\text{Pb}(\text{SCN})_2$.
21. Given 300 mL of a solution that is 0.056 M in lithium nitrate, what mass of solid sodium carbonate can be added before precipitation occurs (assuming that the volume of solution does not change after adding the solid)? $K_{\text{sp}} = 8.15 \times 10^{-4}$ for Li_2CO_3 .
22. Given the information in the following table, calculate the molar solubility of each sparingly soluble salt in 0.95 M MgCl_2 .

Saturated Solution	K_{sp}
$\text{MgCO}_3 \cdot 3\text{H}_2\text{O}$	2.4×10^{-6}
$\text{Mg}(\text{OH})_2$	5.6×10^{-12}
$\text{Mg}_3(\text{PO}_4)_2$	1.04×10^{-24}

Learning Objective

- To understand the factors that determine the solubility of ionic compounds.

The solubility product of an ionic compound describes the concentrations of *ions* in equilibrium with a solid, but what happens if some of the cations become associated with anions rather than being completely surrounded by solvent? Then predictions of the total solubility of the compound based on the assumption that the solute exists solely as discrete ions would differ substantially from the actual solubility, as would predictions of ionic concentrations. In general, four situations explain why the solubility of a compound may be other than expected: ion pair formation, the incomplete dissociation of molecular solutes, the formation of complex ions, and changes in pH. The first two situations are described in this section, the formation of complex ions is discussed in [Section 17.3](#), and changes in pH are discussed in [Section 17.4](#).

Ion-Pair Formation

An ion pair consists of a cation and an anion that are in intimate contact in solution, rather than separated by solvent ([Figure 17.2.1](#)). The ions in an ion pair are held together by the same attractive electrostatic forces that we discussed in [Chapter 4](#) for ionic solids. As a result, the ions in an ion pair migrate as a single unit, whose net charge is the sum of the charges on the ions. In many ways, we can view an ion pair as a species intermediate between the ionic solid (in which each ion participates in many cation–anion interactions that hold the ions in a rigid array) and the completely dissociated ions in solution (where each is fully surrounded by water molecules and free to migrate independently).

Figure 17.2.1 Ion-Pair Formation In an ion pair, the cation and the anion are in intimate contact in solution and migrate as a single unit. They are not completely dissociated and individually surrounded by solvent molecules, as are the hydrated ions, which are free to migrate independently.

As illustrated for calcium sulfate in the following equation, a second equilibrium must be included to describe the solubility of salts that form ion pairs:

The ion pair is represented by the symbols of the individual ions separated by a dot, which indicates that they are associated in solution. The formation of an ion pair is a dynamic process, just like any other equilibrium, so a particular ion pair may exist only briefly before dissociating into the free ions, each of which may later associate briefly with other ions.

Ion-pair formation can have a major effect on the measured solubility of a salt. For example, the measured K_{sp} for calcium sulfate is 4.93×10^{-5} at 25°C. The solubility of CaSO_4 should be 7.02×10^{-3} M if the only equilibrium involved were as follows:

In fact, the experimentally measured solubility of calcium sulfate at 25°C is 1.6×10^{-2} M, almost twice the value predicted from its K_{sp} . The reason for the discrepancy is that the concentration of ion pairs in a saturated CaSO_4 solution is almost as high as the concentration of the hydrated ions. Recall that the magnitude of attractive electrostatic interactions is greatest for small, highly charged ions. Hence ion pair formation is most important for salts that contain M^{2+} and M^{3+} ions, such as Ca^{2+} and La^{3+} , and is relatively unimportant for salts that contain monovalent cations, except for the smallest, Li^+ . We therefore expect a saturated solution of CaSO_4 to contain a high concentration of ion pairs and its solubility to be greater than predicted from its K_{sp} .

Note the Pattern

The formation of ion pairs increases the solubility of a salt.

Incomplete Dissociation

A molecular solute may also be more soluble than predicted by the measured concentrations of ions in solution due to *incomplete dissociation*. This is particularly common with weak organic acids. (For more information about weak organic acids, see [Chapter 16](#).) Although strong acids (HA) dissociate completely into their constituent ions (H^+ and A^-) in water, weak acids such as carboxylic acids do not ($K_{\text{a}} = 1.5 \times 10^{-5}$). However, the molecular (undissociated) form of a weak acid (HA) is often quite soluble in water; for example, acetic acid ($\text{CH}_3\text{CO}_2\text{H}$) is completely miscible with water. Many carboxylic acids, however, have only limited solubility in water, such as benzoic acid ($\text{C}_6\text{H}_5\text{CO}_2\text{H}$), with $K_{\text{a}} = 6.25 \times 10^{-5}$. Just as with calcium sulfate, we need to include an additional equilibrium to describe the solubility of benzoic acid:

In a case like this, measuring only the concentration of the ions grossly underestimates the total concentration of the organic acid in solution. In the case of benzoic acid, for example, the pH of a saturated solution at 25°C is 2.85, corresponding to $[\text{H}^+] = [\text{C}_6\text{H}_5\text{CO}_2^-] = 1.4 \times 10^{-3}$ M. The total concentration of benzoic acid in the solution, however, is 2.8×10^{-2} M. Thus approximately 95% of the benzoic acid in solution is in the form of hydrated neutral molecules— $\text{C}_6\text{H}_5\text{CO}_2\text{H}(\text{aq})$ —and only about 5% is present as the dissociated ions ([Figure 17.2.2](#)).

Note the Pattern

Incomplete dissociation of a molecular solute that is miscible with water can increase the solubility of the solute.

Figure 17.2.2 Incomplete Dissociation of a Molecular Solute In a saturated solution of benzoic acid in water at 25°C, only about 5% of the dissolved benzoic acid molecules are dissociated to form benzoate anions and hydrated protons. The remaining 95% exists in solution in the form of hydrated neutral molecules. (H_2O molecules are omitted for clarity.)

Although ion pairs, such as $Ca^{2+} \cdot SO_4^{2-}$, and undissociated electrolytes, such as $C_6H_5CO_2H$, are both electrically neutral, there is a major difference in the forces responsible for their formation. Simple electrostatic attractive forces between the cation and the anion hold the ion pair together, whereas a polar covalent O–H bond holds together the undissociated electrolyte.

Summary

There are four explanations why the solubility of a compound can differ from the solubility indicated by the concentrations of ions: (1) **ion pair** formation, in which an anion and a cation are in intimate contact in solution and not separated by solvent, (2) the incomplete dissociation of molecular solutes, (3) the formation of complex ions, and (4) changes in pH. An ion pair is held together by electrostatic attractive forces between the cation and the anion, whereas incomplete dissociation results from intramolecular forces, such as polar covalent O–H bonds.

Key Takeaway

- Ion-pair formation, the incomplete dissociation of molecular solutes, the formation of complex ions, and changes in pH all affect solubility.

Conceptual Problems

1. Do you expect the actual molar solubility of $LaPO_4$ to be greater than, the same as, or less than the value calculated from its K_{sp} ? Explain your reasoning.
2. Do you expect the difference between the calculated molar solubility and the actual molar solubility of $Ca_3(PO_4)_2$ to be greater than or less than the difference in the solubilities of $Mg_3(PO_4)_2$? Why?
3. Write chemical equations to describe the interactions in a solution that contains $Mg(OH)_2$, which forms ion pairs, and in one that contains propanoic acid ($CH_3CH_2CO_2H$), which forms a hydrated neutral molecule.
4. Draw representations of $Ca(IO_3)_2$ in solution
 - a. as an ionic solid.
 - b. in the form of ion pairs.
 - c. as discrete ions.

Numerical Problem

1. Ferric phosphate has a molar solubility of 5.44×10^{-16} in 1.82 M Na_3PO_4 . Predict its K_{SP} . The actual K_{SP} is 1.3×10^{-22} . Explain this discrepancy.

Answer

1. 9.90×10^{-16} ; the solubility is much higher than predicted by K_{SP} due to the formation of ion pairs (and/or phosphate complexes) in the sodium phosphate solution.

Learning Objective

- To describe the formation of complex ions quantitatively.

In Chapter 8, you learned that metal ions in aqueous solution are *hydrated*—that is, surrounded by a shell of usually four or six water molecules. A hydrated ion is one kind of a complex ion (or, simply, *complex*), a species formed between a central metal ion and one or more surrounding ligands, molecules or ions that contain at least one lone pair of electrons, such as the $[\text{Al}(\text{H}_2\text{O})_6]^{3+}$ ion in Figure 16.2.22 “Effect of a Metal Ion on the Acidity of Water”.

A complex ion forms from a metal ion and a ligand because of a Lewis acid–base interaction. The positively charged metal ion acts as a Lewis acid, and the ligand, with one or more lone pairs of electrons, acts as a Lewis base. Small, highly charged metal ions, such as Cu^{2+} or Ru^{3+} , have the greatest tendency to act as Lewis acids, and consequently, they have the greatest tendency to form complex ions.

As an example of the formation of complex ions, consider the addition of ammonia to an aqueous solution of the hydrated Cu^{2+} ion $[\text{Cu}(\text{H}_2\text{O})_6]^{2+}$. Because it is a stronger base than H_2O , ammonia replaces the water molecules in the hydrated ion to form the $[\text{Cu}(\text{NH}_3)_4(\text{H}_2\text{O})_2]^{2+}$ ion. Formation of the $[\text{Cu}(\text{NH}_3)_4(\text{H}_2\text{O})_2]^{2+}$ complex is accompanied by a dramatic color change, as shown in Figure 17.3.1. The solution changes from the light blue of $[\text{Cu}(\text{H}_2\text{O})_6]^{2+}$ to the blue-violet characteristic of the $[\text{Cu}(\text{NH}_3)_4(\text{H}_2\text{O})_2]^{2+}$ ion.

Figure 17.3.1 The Formation of Complex Ions An aqueous solution of CuSO_4 consists of hydrated Cu^{2+} ions in the form of pale blue $[\text{Cu}(\text{H}_2\text{O})_6]^{2+}$ (left). The addition of aqueous ammonia to the solution results in the formation of the intensely blue-violet $[\text{Cu}(\text{NH}_3)_4(\text{H}_2\text{O})_2]^{2+}$ ions, usually written as $[\text{Cu}(\text{NH}_3)_4]^{2+}$ ion (right) because ammonia, a stronger base than H_2O , replaces water molecules from the hydrated Cu^{2+} ion.

The Formation Constant

The replacement of water molecules from $[\text{Cu}(\text{H}_2\text{O})_6]^{2+}$ by ammonia occurs in sequential steps. Omitting the water molecules bound to Cu^{2+} for simplicity, we can write the equilibrium reactions as follows:

The sum of the stepwise reactions is the overall equation for the formation of the complex ion: The hydrated Cu^{2+} ion contains six H_2O ligands, but the complex ion that is produced contains only four NH_3 ligands, not six. The reasons for this apparently unusual behavior will be discussed in Chapter 23.

The equilibrium constant for the formation of the complex ion from the hydrated ion is called the formation constant (K_f) $[\text{A}]^a[\text{B}]^b$. The equilibrium constant expression for K_f has the same general form as any other equilibrium constant expression. In this case, the expression is as follows:

$$K_f = \frac{[\text{Cu}(\text{NH}_3)_4]^{2+}}{[\text{Cu}^{2+}][\text{NH}_3]^4} = 2.1 \times 10^{13} = K_1 K_2 K_3 K_4 \tag{17.3.3}$$

Note the Pattern

The formation constant (K_f) has the same general form as any other equilibrium constant expression.

Water, a pure liquid, does not appear explicitly in the equilibrium constant expression, and the hydrated Cu^{2+} (aq) ion is represented as Cu^{2+} for simplicity. As for any equilibrium, the larger the value of the equilibrium constant (in this case, K_f), the more stable the product. With $K_f = 2.1 \times 10^{13}$, the $[\text{Cu}(\text{NH}_3)_4(\text{H}_2\text{O})_2]^{2+}$ complex ion is very stable. The formation constants for some common complex ions are listed in Table 17.3.1.

Table 17.3.1 Formation Constants for Selected Complex Ions in Aqueous Solution*

	Complex Ion	Equilibrium Equation	K_f
Ammonia Complexes	$[\text{Ag}(\text{NH}_3)_2]^+$	$\text{Ag}^+ + 2\text{NH}_3 \rightleftharpoons [\text{Ag}(\text{NH}_3)_2]^+$	1.1×10^7
	$[\text{Cu}(\text{NH}_3)_4]^{2+}$	$\text{Cu}^{2+} + 4\text{NH}_3 \rightleftharpoons [\text{Cu}(\text{NH}_3)_4]^{2+}$	2.1×10^{13}
*Reported values are overall formation constants.			

	Complex Ion	Equilibrium Equation	K_f
Cyanide Complexes	$[\text{Ni}(\text{NH}_3)_6]^{2+}$	$\text{Ni}^{2+} + 6\text{NH}_3 \rightleftharpoons [\text{Ni}(\text{NH}_3)_6]^{2+}$	5.5×10^8
	$[\text{Ag}(\text{CN})_2]^-$	$\text{Ag}^+ + 2\text{CN}^- \rightleftharpoons [\text{Ag}(\text{CN})_2]^-$	1.1×10^{18}
	$[\text{Ni}(\text{CN})_4]^{2-}$	$\text{Ni}^{2+} + 4\text{CN}^- \rightleftharpoons [\text{Ni}(\text{CN})_4]^{2-}$	2.2×10^{31}
	$[\text{Fe}(\text{CN})_6]^{3-}$	$\text{Fe}^{3+} + 6\text{CN}^- \rightleftharpoons [\text{Fe}(\text{CN})_6]^{3-}$	1×10^{42}
Hydroxide Complexes	$[\text{Zn}(\text{OH})_4]^{2-}$	$\text{Zn}^{2+} + 4\text{OH}^- \rightleftharpoons [\text{Zn}(\text{OH})_4]^{2-}$	4.6×10^{17}
	$[\text{Cr}(\text{OH})_4]^-$	$\text{Cr}^{3+} + 4\text{OH}^- \rightleftharpoons [\text{Cr}(\text{OH})_4]^-$	8.0×10^{29}
Halide Complexes	$[\text{HgCl}_4]^{2-}$	$\text{Hg}^{2+} + 4\text{Cl}^- \rightleftharpoons [\text{HgCl}_4]^{2-}$	1.2×10^{15}
	$[\text{CdI}_4]^{2-}$	$\text{Cd}^{2+} + 4\text{I}^- \rightleftharpoons [\text{CdI}_4]^{2-}$	2.6×10^5
	$[\text{AlF}_6]^{3-}$	$\text{Al}^{3+} + 6\text{F}^- \rightleftharpoons [\text{AlF}_6]^{3-}$	6.9×10^{19}
Other Complexes	$[\text{Ag}(\text{S}_2\text{O}_3)_2]^{3-}$	$\text{Ag}^+ + 2\text{S}_2\text{O}_3^{2-} \rightleftharpoons [\text{Ag}(\text{S}_2\text{O}_3)_2]^{3-}$	2.9×10^{13}
	$[\text{Fe}(\text{C}_2\text{O}_4)_3]^{3-}$	$\text{Fe}^{3+} + 3\text{C}_2\text{O}_4^{2-} \rightleftharpoons [\text{Fe}(\text{C}_2\text{O}_4)_3]^{3-}$	2.0×10^{20}

*Reported values are overall formation constants.

Example 17.3.1

If 12.5 g of $\text{Cu}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$ is added to 500 mL of 1.00 M aqueous ammonia, what is the equilibrium concentration of $\text{Cu}^{2+}(\text{aq})$?

Given: mass of Cu^{2+} salt and volume and concentration of ammonia solution

Asked for: equilibrium concentration of $\text{Cu}^{2+}(\text{aq})$

Strategy:

A Calculate the initial concentration of Cu^{2+} due to the addition of copper(II) nitrate hexahydrate. Use the stoichiometry of the reaction shown in Equation 17.3.2 to construct a table showing the initial concentrations, the changes in concentrations, and the final concentrations of all species in solution.

B Substitute the final concentrations into the expression for the formation constant (Equation 17.3.3) to calculate the equilibrium concentration of $\text{Cu}^{2+}(\text{aq})$.

Solution:

Adding an ionic compound that contains Cu^{2+} to an aqueous ammonia solution will result in the formation of $[\text{Cu}(\text{NH}_3)_4]^{2+}(\text{aq})$, as shown in Equation 17.3.2. We assume that the volume change caused by adding solid copper(II) nitrate to aqueous ammonia is negligible.

A The initial concentration of Cu^{2+} from the amount of added copper nitrate prior to any reaction is as follows:

$$12.5 \text{ g Cu}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O} \left(\frac{1 \text{ mol}}{295.65 \text{ g}} \right) \left(\frac{1}{500 \text{ mL}} \right) \left(\frac{1000 \text{ mL}}{1 \text{ L}} \right) = 0.0846 \text{ M}$$

Because the stoichiometry of the reaction is four NH_3 to one Cu^{2+} , the amount of NH_3 required to react completely with the Cu^{2+} is $4(0.0846) = 0.338 \text{ M}$. The concentration of ammonia after complete reaction is $1.00 \text{ M} - 0.338 \text{ M} = 0.66 \text{ M}$. These results are summarized in the first two lines of the following table. Because the equilibrium constant for the reaction is so large (2.1×10^{13}), the equilibrium will lie far to the right. Thus we will assume that the formation of $[\text{Cu}(\text{NH}_3)_4]^{2+}$ in the first step is complete and allow some of it to dissociate into Cu^{2+} and NH_3 until equilibrium has been reached. If we define x as the amount of Cu^{2+} produced by the dissociation reaction, then the stoichiometry of the reaction tells us that the change in the concentration of $[\text{Cu}(\text{NH}_3)_4]^{2+}$ is $-x$, and the change in the concentration of ammonia is $+4x$, as indicated in the table. The final concentrations of all species (in the bottom row of the table) are the sums of the concentrations after complete reaction and the changes in concentrations.

$\text{Cu}^{2+} + 4\text{NH}_3 \rightleftharpoons [\text{Cu}(\text{NH}_3)_4]^{2+}$			
	$[\text{Cu}^{2+}]$	$[\text{NH}_3]$	$[\text{Cu}(\text{NH}_3)_4]^{2+}$
initial	0.0846	1.00	0
after complete reaction	0	0.66	0.0846
change	$+x$	$+4x$	$-x$
final	x	$0.66 + 4x$	$0.0846 - x$

B Substituting the final concentrations into the expression for the formation constant (Equation 17.8) and assuming that $x \ll 0.0846$, which allows us to remove x from the sum and difference,

$$\begin{aligned} K_f &= \frac{[\text{Cu}(\text{NH}_3)_4]^{2+}}{[\text{Cu}^{2+}][\text{NH}_3]^4} = \frac{0.0846 - x}{(x)(0.66 + 4x)^4} \approx \frac{0.0846}{x(0.66)^4} = 2.1 \times 10^{13} \\ x &= 2.1 \times 10^{-14} \end{aligned}$$

The value of x indicates that our assumption was justified. The equilibrium concentration of $\text{Cu}^{2+}(\text{aq})$ in a 1.00 M ammonia solution is therefore $2.1 \times 10^{-14} \text{ M}$.

Exercise

The ferrocyanide ion $[\text{Fe}(\text{CN})_6]^{4-}$ is very stable, with a K_f of 1×10^{35} . Calculate the concentration of cyanide ion in equilibrium with a 0.65 M solution of $\text{K}_4[\text{Fe}(\text{CN})_6]$.

Answer: $2 \times 10^{-6} \text{ M}$

The Effect of the Formation of Complex Ions on Solubility

What happens to the solubility of a sparingly soluble salt if a ligand that forms a stable complex ion is added to the solution? One such example occurs in conventional black-and-white photography, which was discussed briefly in Chapter 8.

Recall that black-and-white photographic film contains light-sensitive microcrystals of AgBr , or mixtures of AgBr and other silver halides. AgBr is a sparingly soluble salt, with a K_{sp} of 5.35×10^{-13} at 25°C. When the shutter of the camera opens, the light from the object being photographed strikes some of the crystals on the film and initiates a photochemical reaction that converts AgBr to black

Ag metal. Well-formed, stable negative images appear in tones of gray, corresponding to the number of grains of AgBr converted, with the areas exposed to the most light being darkest. To fix the image and prevent more AgBr crystals from being converted to Ag metal during processing of the film, the unreacted AgBr on the film is removed using a complexation reaction to dissolve the sparingly soluble salt.

The reaction for the dissolution of silver bromide is as follows:

with

$$K_{sp} = 5.35 \times 10^{-13} \text{ at } 25^\circ \text{C} \quad (17.3.4b)$$

The equilibrium lies far to the left, and the equilibrium concentrations of Ag^+ and Br^- ions are very low (7.31×10^{-7} M). As a result, removing unreacted AgBr from even a single roll of film using pure water would require tens of thousands of liters of water and a great deal of time. Le Châtelier's principle tells us, however, that we can drive the reaction to the right by removing one of the products, which will cause more AgBr to dissolve. Bromide ion is difficult to remove chemically, but silver ion forms a variety of stable two-coordinate complexes with neutral ligands, such as ammonia, or with anionic ligands, such as cyanide or thiosulfate ($\text{S}_2\text{O}_3^{2-}$). In photographic processing, excess AgBr is dissolved using a concentrated solution of sodium thiosulfate.

The reaction of Ag^+ with thiosulfate is as follows:

with

$$K_f = 2.9 \times 10^{13} \quad (17.10b)$$

The magnitude of the equilibrium constant indicates that almost all Ag^+ ions in solution will be immediately complexed by thiosulfate to form $[\text{Ag}(\text{S}_2\text{O}_3)_2]^{3-}$. We can see the effect of thiosulfate on the solubility of AgBr by writing the appropriate reactions and adding them together:

Comparing K with K_{sp} shows that the formation of the complex ion increases the solubility of AgBr by approximately 3×10^{13} . The dramatic increase in solubility combined with the low cost and the low toxicity explains why sodium thiosulfate is almost universally used for developing black-and-white film. If desired, the silver can be recovered from the thiosulfate solution using any of several methods and recycled.

Note the Pattern

If a complex ion has a large K_f , the formation of a complex ion can dramatically increase the solubility of sparingly soluble salts.

Example 17.3.2

Due to the common ion effect, we might expect a salt such as AgCl to be much less soluble in a concentrated solution of KCl than in water. Such an assumption would be incorrect, however, because it ignores the fact that silver ion tends to form a two-coordinate complex with chloride ions (AgCl_2^-). Calculate the solubility of AgCl in each situation:

- in pure water
- in 1.0 M KCl solution, ignoring the formation of any complex ions
- the same solution as in part (b) except taking the formation of complex ions into account, assuming that AgCl_2^- is the only Ag^+ complex that forms in significant concentrations

At 25°C , $K_{sp} = 1.77 \times 10^{-10}$ for AgCl and $K_f = 1.1 \times 10^5$ for AgCl_2^- .

Given: K_{sp} of AgCl, K_f of AgCl_2^- , and KCl concentration

Asked for: solubility of AgCl in water and in KCl solution with and without the formation of complex ions

Strategy:

A Write the solubility product expression for AgCl and calculate the concentration of Ag^+ and Cl^- in water.

B Calculate the concentration of Ag^+ in the KCl solution.

C Write balanced chemical equations for the dissolution of AgCl and for the formation of the AgCl_2^- complex. Add the two equations and calculate the equilibrium constant for the overall equilibrium.

D Write the equilibrium constant expression for the overall reaction. Solve for the concentration of the complex ion.

Solution:

- A** If we let x equal the solubility of AgCl, then at equilibrium $[\text{Ag}^+] = [\text{Cl}^-] = x$ M. Substituting this value into the solubility product expression,

$$K_{sp} = [\text{Ag}^+][\text{Cl}^-] = (x)(x) = x^2 = 1.77 \times 10^{-10}$$

$$x = 1.33 \times 10^{-5}$$

Thus the solubility of AgCl in pure water at 25°C is 1.33×10^{-5} M.

- B** If x equals the solubility of AgCl in the KCl solution, then at equilibrium $[\text{Ag}^+] = x$ M and $[\text{Cl}^-] = (1.0 + x)$ M. Substituting these values into the solubility product expression and assuming that $x \ll 1.0$,

$$K_{sp} = [\text{Ag}^+][\text{Cl}^-] = (x)(1.0 + x) \approx x(1.0) = 1.77 \times 10^{-10} = x$$

If the common ion effect were the only important factor, we would predict that AgCl is approximately five orders of magnitude less soluble in a 1.0 M KCl solution than in water.

3. C To account for the effects of the formation of complex ions, we must first write the equilibrium equations for both the dissolution and the formation of complex ions. Adding the equations corresponding to K_{sp} and K_f gives us an equation that describes the dissolution of AgCl in a KCl solution. The equilibrium constant for the reaction is therefore the product of K_{sp} and K_f :

D If we let x equal the solubility of AgCl in the KCl solution, then at equilibrium $[\text{AgCl}_2]^- = x$ and $[\text{Cl}^-] = 1.0 - x$. Substituting these quantities into the equilibrium constant expression for the net reaction and assuming that $x \ll 1.0$,

$$K = \frac{[\text{AgCl}_2^-]}{[\text{Cl}^-]} = \frac{x}{1.0 - x} \approx 1.9 \times 10^{-5} = x$$

That is, AgCl dissolves in 1.0 M KCl to produce a 1.9×10^{-5} M solution of the $[\text{AgCl}_2]^-$ complex ion. Thus we predict that AgCl has approximately the same solubility in a 1.0 M KCl solution as it does in pure water, which is 10^3 times greater than that predicted based on the common ion effect. (In fact, the measured solubility of AgCl in 1.0 M KCl is almost a factor of 10 *greater* than that in pure water, largely due to the formation of other chloride-containing complexes.)

Exercise

Calculate the solubility of mercury(II) iodide (HgI_2) in each situation:

- pure water
- a 3.0 M solution of NaI, assuming $[\text{HgI}_4]^{2-}$ is the only Hg-containing species present in significant amounts

$$K_{sp} = 2.9 \times 10^{-29} \text{ for } \text{HgI}_2 \text{ and } K_f = 6.8 \times 10^{29} \text{ for } [\text{HgI}_4]^{2-}.$$

Answer:

- 1.9×10^{-10} M
- 1.4 M

Complexing agents, molecules or ions that increase the solubility of metal salts by forming soluble metal complexes, are common components of laundry detergents. Long-chain carboxylic acids, the major components of soaps, form insoluble salts with Ca^{2+} and Mg^{2+} , which are present in high concentrations in “hard” water. The precipitation of these salts produces a bathtub ring and gives a gray tinge to clothing. Adding a complexing agent such as pyrophosphate ($\text{O}_3\text{POPO}_3^-$, or $\text{P}_2\text{O}_7^{4-}$) or triphosphate ($\text{P}_3\text{O}_{10}^{5-}$) to detergents prevents the magnesium and calcium salts from precipitating because the equilibrium constant for complex-ion formation is large:

with

$$K_f = 4 \times 10^4 \quad (17.3.7b)$$

However, phosphates can cause environmental damage by promoting *eutrophication*, the growth of excessive amounts of algae in a body of water, which can eventually lead to large decreases in levels of dissolved oxygen that kill fish and other aquatic organisms. Consequently, many states in the United States have banned the use of phosphate-containing detergents, and France has banned their use beginning in 2007. “Phosphate-free” detergents contain different kinds of complexing agents, such as derivatives of acetic acid or other carboxylic acids. The development of phosphate substitutes is an area of intense research.

Commercial water softeners also use a complexing agent to treat hard water by passing the water over ion-exchange resins, which are complex sodium salts. When water flows over the resin, sodium ion is dissolved, and insoluble salts precipitate onto the resin surface. Water treated in this way has a saltier taste due to the presence of Na^+ , but it contains fewer dissolved minerals.

Another application of complexing agents is found in medicine. Unlike x-rays, magnetic resonance imaging (MRI) can give relatively good images of soft tissues such as internal organs. MRI is based on the magnetic properties of the ^1H nucleus of hydrogen atoms in water, which is a major component of soft tissues. Because the properties of water do not depend very much on whether it is inside a cell or in the blood, it is hard to get detailed images of these tissues that have good contrast. To solve this problem, scientists have developed a class of metal complexes known as “MRI contrast agents.” Injecting an MRI contrast agent into a patient selectively affects the magnetic properties of water in cells of normal tissues, in tumors, or in blood vessels and allows doctors to “see” each of these separately (Figure 17.3.2). One of the most important metal ions for this application is Gd^{3+} , which with seven unpaired electrons is highly paramagnetic. Because $\text{Gd}^{3+}(aq)$ is quite toxic, it must be administered as a very stable complex that does not dissociate in the body and can be excreted intact by the kidneys. The complexing agents used for gadolinium are ligands such as DTPA $^{5-}$ (diethylene triamine pentaacetic acid), whose fully protonated form is shown here.

Figure 17.3.2 An MRI Image of the Heart, Arteries, and Veins When a patient is injected with a paramagnetic metal cation in the form of a stable complex known as an MRI contrast agent, the magnetic properties of water in cells are altered. Because the different environments in different types of cells respond differently, a physician can obtain detailed images of soft tissues.

Summary

A **complex ion** is a species formed between a central metal ion and one or more surrounding **ligands**, molecules or ions that contain at least one lone pair of electrons. Small, highly charged metal ions have the greatest tendency to act as Lewis acids and form complex ions. The equilibrium constant for the formation of the complex ion is the **formation constant (K_f)**. The formation of a complex ion by adding a **complexing agent** increases the solubility of a compound.

Key Takeaway

- The formation of complex ions can substantially increase the solubility of sparingly soluble salts if the complex ion has a large K_f .

Conceptual Problems

- What is the difference between K_{eq} and K_f ?
- Which would you expect to have the greater tendency to form a complex ion: Mg^{2+} or Ba^{2+} ? Why?
- How can a ligand be used to affect the concentration of hydrated metal ions in solution? How is K_{sp} affected? Explain your answer.
- Co(II) forms a complex ion with pyridine (C_5H_5N). Which is the Lewis acid, and which is the Lewis base? Use Lewis electron structures to justify your answer.

Numerical Problems

- Fe(II) forms the complex ion $[Fe(OH)_4]^{2-}$ through equilibrium reactions in which hydroxide replaces water in a stepwise manner. If $\log K_1 = 5.56$, $\log K_2 = 4.21$, $\log K_3 = -0.10$, and $\log K_4 = -1.09$, what is K_f ? Write the equilibrium equation that corresponds to each stepwise equilibrium constant. Do you expect the $[Fe(OH)_4]^{2-}$ complex to be stable? Explain your reasoning.
- Zn(II) forms the complex ion $[Zn(NH_3)_4]^{2+}$ through equilibrium reactions in which ammonia replaces coordinated water molecules in a stepwise manner. If $\log K_1 = 2.37$, $\log K_2 = 2.44$, $\log K_3 = 2.50$, and $\log K_4 = 2.15$, what is the overall K_f ? Write the equilibrium equation that corresponds to each stepwise equilibrium constant. Do you expect the $[Zn(NH_3)_4]^{2+}$ complex to be stable? Explain your reasoning.
- Although thallium has limited commercial applications because it is toxic to humans (10 mg/kg body weight is fatal to children), it is used as a substitute for mercury in industrial switches. The complex ion $[TlBr_6]^{-}$ is highly stable, with $\log K_f = 31.6$. What is the concentration of $Tl(III)(aq)$ in equilibrium with a 1.12 M solution of $Na_3[TlBr_6]$?

Answer

1.

Thus, $K_f = 3.8 \times 10^{33}$. Because $[Fe(OH)_4]^{2-}$ has a very large value of K_f , it should be stable in the presence of excess OH^- .

2.

Learning Objective

- To understand why the solubility of many compounds depends on pH.

The solubility of many compounds depends strongly on the pH of the solution. For example, the anion in many sparingly soluble salts is the conjugate base of a weak acid that may become protonated in solution. In addition, the solubility of simple binary compounds such as oxides and sulfides, both strong bases, is often dependent on pH. In this section, we discuss the relationship between the solubility of these classes of compounds and pH.

The Effect of Acid–Base Equilibriums on the Solubility of Salts

We begin our discussion by examining the effect of pH on the solubility of a representative salt, MA , where A^- is the conjugate base of the weak acid HA . When the salt dissolves in water, the following reaction occurs:

with

$$K_{sp} = [M^+][A^-] \quad (17.4.1b)$$

The anion can also react with water in a hydrolysis reaction:

Because of the reaction described in Equation 17.4.2, the predicted solubility of a sparingly soluble salt that has a basic anion such as S^{2-} , PO_4^{3-} , or CO_3^{2-} is increased, as described in Section 17.1. If instead a strong acid is added to the solution, the added H^+ will react essentially completely with A^- to form HA . This reaction decreases $[A^-]$, which decreases the magnitude of the ion product ($Q = [M^+][A^-]$). According to Le Châtelier's principle, more MA will dissolve until $Q = K_{sp}$. Hence *an acidic pH dramatically increases the solubility of virtually all sparingly soluble salts whose anion is the conjugate base of a weak acid*. In contrast, pH has little to no effect on the solubility of salts whose anion is the conjugate base of a stronger weak acid or a strong acid, respectively (e.g., chlorides, bromides, iodides, and sulfates). For example, the hydroxide salt $Mg(OH)_2$ is relatively insoluble in water:

with

$$K_{sp} = 5.61 \times 10^{-12} \quad (17.4.3b)$$

When acid is added to a saturated solution that contains excess solid $Mg(OH)_2$, the following reaction occurs, removing OH^- from solution:

The overall equation for the reaction of $Mg(OH)_2$ with acid is thus

As more acid is added to a suspension of $\text{Mg}(\text{OH})_2$, the equilibrium shown in [Equation 17.4.6](#) is driven to the right, so more $\text{Mg}(\text{OH})_2$ dissolves.

Such pH-dependent solubility is not restricted to salts that contain anions derived from water. For example, CaF_2 is a sparingly soluble salt:

with

$$K_{sp} = 3.45 \times 10^{-11} \quad (17.4.7b)$$

When strong acid is added to a saturated solution of CaF_2 , the following reaction occurs:

Because the forward reaction decreases the fluoride ion concentration, more CaF_2 dissolves to relieve the stress on the system. The net reaction of CaF_2 with strong acid is thus

Example 7 shows how to calculate the solubility effect of adding a strong acid to a solution of a sparingly soluble salt.

Note the Pattern

Sparingly soluble salts derived from weak acids tend to be more soluble in an acidic solution.

Example 17.4.1

Lead oxalate (PbC_2O_4), lead iodide (PbI_2), and lead sulfate (PbSO_4) are all rather insoluble, with K_{sp} values of 4.8×10^{-10} , 9.8×10^{-8} , and 2.53×10^{-8} , respectively. What effect does adding a strong acid, such as perchloric acid, have on their relative solubilities?

Given: K_{sp} values for three compounds

Asked for: relative solubilities in acid solution

Strategy:

Write the balanced chemical equation for the dissolution of each salt. Because the strongest conjugate base will be most affected by the addition of strong acid, determine the relative solubilities from the relative basicity of the anions.

Solution:

The solubility equilibria for the three salts are as follows:

The addition of a strong acid will have the greatest effect on the solubility of a salt that contains the conjugate base of a weak acid as the anion. Because HI is a strong acid, we predict that adding a strong acid to a saturated solution of PbI_2 will not greatly affect its solubility; the acid will simply dissociate to form H^+ (aq) and the corresponding anion. In contrast, oxalate is the fully deprotonated form of oxalic acid ($\text{HO}_2\text{CCO}_2\text{H}$), which is a weak diprotic acid ($\text{p}K_{a1} = 1.23$ and $\text{p}K_{a2} = 4.19$). Consequently, the oxalate ion has a significant affinity for one proton and a lower affinity for a second proton. Adding a strong acid to a saturated solution of lead oxalate will result in the following reactions:

These reactions will decrease $[C_2O_4^{2-}]$, causing more lead oxalate to dissolve to relieve the stress on the system. The pK_a of HSO_4^- (1.99) is similar in magnitude to the pK_{a1} of oxalic acid, so adding a strong acid to a saturated solution of $PbSO_4$ will result in the following reaction:

Because HSO_4^- has a pK_a of 1.99, this reaction will lie largely to the left as written. Consequently, we predict that the effect of added strong acid on the solubility of $PbSO_4$ will be significantly less than for PbC_2O_4 .

Exercise

Which of the following insoluble salts— $AgCl$, Ag_2CO_3 , Ag_3PO_4 , and/or $AgBr$ —will be substantially more soluble in 1.0 M HNO_3 than in pure water?

Answer: Ag_2CO_3 and Ag_3PO_4

Caves and their associated pinnacles and spires of stone provide one of the most impressive examples of pH-dependent solubility equilibria (part (a) in [Figure 17.6 "The Chemistry of Cave Formation"](#)). Perhaps the most familiar caves are formed from limestone, such as Carlsbad Caverns in New Mexico, Mammoth Cave in Kentucky, and Luray Caverns in Virginia. The primary reactions that are responsible for the formation of limestone caves are as follows:

Figure 17.4.1 The Chemistry of Cave Formation (a) This cave in Campanet, Mallorca, Spain, and its associated formations are examples of pH-dependent solubility equilibria. (b) A cave forms when groundwater containing atmospheric CO_2 , forming an acidic solution, dissolves limestone ($CaCO_3$) in a process that may take tens of thousands of years. As groundwater seeps into a cave, water evaporates from the solution of $CaCO_3$ in CO_2 -rich water, producing a supersaturated solution and a shift in equilibrium that causes precipitation of the $CaCO_3$. The deposited limestone eventually forms stalactites and stalagmites.

Limestone deposits that form caves consist primarily of $CaCO_3$ from the remains of living creatures such as clams and corals, which used it for making structures such as shells. When a saturated solution of $CaCO_3$ in CO_2 -rich water rises toward Earth's surface or is otherwise heated, CO_2 gas is released as the water warms. $CaCO_3$ then precipitates from the solution according to the following equation (part (b) in [Figure 17.4.1](#)):

The forward direction is the same reaction that produces the solid called *scale* in teapots, coffee makers, water heaters, boilers, and other places where hard water is repeatedly heated.

When groundwater-containing atmospheric CO_2 (Equation 17.4.10 and Equation 17.4.11) finds its way into microscopic cracks in the limestone deposits, CaCO_3 dissolves in the acidic solution in the reverse direction of Equation 17.4.13. The cracks gradually enlarge from 10–50 μm to 5–10 mm, a process that can take as long as 10,000 yr. Eventually, after about another 10,000 yr, a cave forms. Groundwater from the surface seeps into the cave and clings to the ceiling, where the water evaporates and causes the equilibrium in Equation 17.4.13 to shift to the right. A circular layer of solid CaCO_3 is deposited, which eventually produces a long, hollow spire of limestone called a *stalactite* that grows down from the ceiling. Below, where the droplets land when they fall from the ceiling, a similar process causes another spire, called a *stalagmite*, to grow up. The same processes that carve out hollows below ground are also at work above ground, in some cases producing fantastically convoluted landscapes like that of Yunnan Province in China (Figure 17.4.2).

Acidic, Basic, and Amphoteric Oxides and Hydroxides

One of the earliest classifications of substances was based on their solubility in acidic versus basic solution, which led to the classification of oxides and hydroxides as being either basic or acidic. Basic oxides and hydroxides either react with water to produce a basic solution or dissolve readily in aqueous acid. Acidic oxides or hydroxides either react with water to produce an acidic solution or are soluble in aqueous base. As shown in Figure 17.4.3, there is a clear correlation between the acidic or the basic character of an oxide and the position of the element combined with oxygen in the periodic table. *Oxides of metallic elements are generally basic oxides, and oxides of nonmetallic elements are acidic oxides.* Compare, for example, the reactions of a typical metal oxide, cesium oxide, and a typical nonmetal oxide, sulfur trioxide, with water:

Cesium oxide reacts with water to produce a basic solution of cesium hydroxide, whereas sulfur trioxide reacts with water to produce a solution of sulfuric acid—very different behaviors indeed!

Figure 17.4.2 Solubility Equilibria in the Formation of Karst Landscapes Landscapes such as the steep limestone pinnacles of the Stone Forest in Yunnan Province, China, are formed from the same process that produces caves and their associated formations.

Note the Pattern

Metal oxides generally react with water to produce basic solutions, whereas nonmetal oxides produce acidic solutions.

The difference in reactivity is due to the difference in bonding in the two kinds of oxides. Because of the low electronegativity of the metals at the far left in the periodic table, their oxides are best viewed as containing discrete M^+ cations and O^{2-} anions. At the other end of the spectrum are nonmetal oxides; due to their higher electronegativities, nonmetals form oxides with covalent bonds to oxygen. Because of the high electronegativity of oxygen, however, the covalent bond between oxygen and the other atom, E, is usually polarized: $\text{E}^{\delta+}-\text{O}^{\delta-}$. The atom E in these oxides acts as a Lewis acid that reacts with the oxygen atom of water to produce an oxoacid. Oxides of metals in high oxidation states also tend to be acidic oxides for the same reason: they contain covalent bonds to oxygen. An example of an acidic metal oxide is MoO_3 , which is insoluble in both water and acid but dissolves in strong base to give solutions of the molybdate ion (MoO_4^{2-}):

	1	2	metal/nonmetal line		13	14	15	16	17
2	Li ₂ O	BeO			B ₂ O ₃	CO ₂	N ₂ O ₃ N ₂ O ₅	O	OF ₂
3	Na ₂ O	MgO			Al ₂ O ₃	SiO ₂	P ₂ O ₃ P ₂ O ₅	SO ₂ SO ₃	Cl ₂ O ₇
4	K ₂ O	CaO			Ga ₂ O ₃	GeO ₂	As ₂ O ₃ As ₂ O ₅	SeO ₂ SeO ₃	Br ₂ O
5	Rb ₂ O	SrO			In ₂ O ₃	SnO ₂	Sb ₂ O ₅	TeO ₃	I ₂ O ₅
6	Cs ₂ O	BaO			Tl ₂ O ₃	PbO ₂	Bi ₂ O ₅	Po	At

■ basic oxide ■ amphoteric oxide ■ acidic oxide

Figure 17.4.3 Classification of the Oxides of the Main Group Elements According to Their Acidic or Basic Character There is a gradual transition from basic oxides to acidic oxides from the lower left to the upper right in the periodic table. Oxides of metallic elements are generally basic oxides, which either react with water to form a basic solution or dissolve in aqueous acid. In contrast, oxides of nonmetallic elements are acidic oxides, which either react with water to form an acidic solution or are soluble in aqueous base. Oxides of intermediate character, called amphoteric oxides, are located along a diagonal line between the two extremes. Amphoteric oxides either dissolve in acid to produce water or dissolve in base to produce a soluble complex ion. (Radioactive elements are not classified.)

As shown in [Figure 17.4.3](#), there is a gradual transition from basic metal oxides to acidic nonmetal oxides as we go from the lower left to the upper right in the periodic table, with a broad diagonal band of oxides of intermediate character separating the two extremes. Many of the oxides of the elements in this diagonal region of the periodic table are soluble in both acidic and basic solutions; consequently, they are called amphoteric oxides (from the Greek *ampho*, meaning “both,” as in amphiprotic, which was defined in [Section 16.1](#)). Amphoteric oxides either dissolve in acid to produce water or dissolve in base to produce a soluble complex. As shown in [Figure 17.4.4](#), for example, mixing the amphoteric oxide $\text{Cr}(\text{OH})_3$ (also written as $\text{Cr}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$) with water gives a muddy, purple-brown suspension. Adding acid causes the $\text{Cr}(\text{OH})_3$ to dissolve to give a bright violet solution of $\text{Cr}^{3+}(\text{aq})$, which contains the $[\text{Cr}(\text{H}_2\text{O})_6]^{3+}$ ion, whereas adding strong base gives a green solution of the $[\text{Cr}(\text{OH})_4]^{-}$ ion. The chemical equations for the reactions are as follows:

Figure 17.4.4 Chromium(III) Hydroxide $[\text{Cr}(\text{OH})_3$ or $\text{Cr}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$] Is an Example of an Amphoteric Oxide All three beakers originally contained a suspension of brownish purple $\text{Cr}(\text{OH})_3(\text{s})$ (center). When concentrated acid (6 M H_2SO_4) was added to the beaker on the left, $\text{Cr}(\text{OH})_3$ dissolved to produce violet $[\text{Cr}(\text{H}_2\text{O})_6]^{3+}$ ions and water. The addition of concentrated base (6 M NaOH) to the beaker on the right caused $\text{Cr}(\text{OH})_3$ to dissolve, producing green $[\text{Cr}(\text{OH})_4]^{-}$ ions.

Example 17.4.2

Aluminum hydroxide, written as either $\text{Al}(\text{OH})_3$ or $\text{Al}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$, is amphoteric. Write chemical equations to describe the dissolution of aluminum hydroxide in (a) acid and (b) base.

Given: amphoteric compound

Asked for: dissolution reactions in acid and base

Strategy:

Using [Equation 17.4.17](#) and [Equation 17.4.18](#) as a guide, write the dissolution reactions in acid and base solutions.

Solution:

1. An acid donates protons to hydroxide to give water and the hydrated metal ion, so aluminum hydroxide, which contains three OH⁻ ions per Al, needs three H⁺ ions:

In aqueous solution, Al³⁺ forms the complex ion [Al(H₂O)₆]³⁺.

2. In basic solution, OH⁻ is added to the compound to produce a soluble and stable poly(hydroxo) complex:

Exercise

Copper(II) hydroxide, written as either Cu(OH)₂ or CuO·H₂O, is amphoteric. Write chemical equations that describe the dissolution of cupric hydroxide both in an acid and in a base.

Answer:

Selective Precipitation Using pH

Many dissolved metal ions can be separated by the selective precipitation of the cations from solution under specific conditions. In this technique, pH is often used to control the concentration of the anion in solution, which controls which cations precipitate.

Note the Pattern

The concentration of anions in solution can often be controlled by adjusting the pH, thereby allowing the selective precipitation of cations.

Suppose, for example, we have a solution that contains 1.0 mM Zn²⁺ and 1.0 mM Cd²⁺ and want to separate the two metals by selective precipitation as the insoluble sulfide salts, ZnS and CdS. The relevant solubility equilibria can be written as follows:

with

$$K_{sp} = 1.6 \times 10^{-24} \quad (17.4.19b)$$

and

with

$$K_{sp} = 8.0 \times 10^{-27} \quad (17.4.20b)$$

Because the S^{2-} ion is quite basic and reacts extensively with water to give HS^- and OH^- , the solubility equilibria are more accurately written as $MS(s) = M^{2+}(aq) + HS^-(aq) + OH^-(aq)$ rather than $MS(s) = M^{2+}(aq) + S^{2-}(aq)$. Here we use the simpler form involving S^{2-} , which is justified because we take the reaction of S^{2-} with water into account later in the solution, arriving at the same answer using either equilibrium equation.

The sulfide concentrations needed to cause ZnS and CdS to precipitate are as follows:

$$K_{sp} = [Zn^{2+}][S^{2-}] \quad (17.4.21a)$$

$$1.6 \times 10^{-24} = (0.0010 M)[S^{2-}] \quad (17.4.21b)$$

$$1.6 \times 10^{-21} M = [S^{2-}] \quad (17.4.21c)$$

and

$$K_{sp} = [Cd^{2+}][S^{2-}] \quad (17.4.22a)$$

$$8.0 \times 10^{-27} = (0.0010 M)[S^{2-}] \quad (17.4.22b)$$

$$8.0 \times 10^{-24} M = [S^{2-}] \quad (17.4.22c)$$

Thus sulfide concentrations between $1.6 \times 10^{-21} M$ and $8.0 \times 10^{-24} M$ will precipitate CdS from solution but not ZnS. How do we obtain such low concentrations of sulfide? A saturated aqueous solution of H_2S contains 0.10 M H_2S at 20°C. The pK_{a1} for H_2S is 6.97, and pK_{a2} corresponding to the formation of $[S^{2-}]$ is 12.90. The equations for these reactions are as follows:

with

$$pK_{a1} = 6.97 \text{ and hence } K_{a1} = 1.1 \times 10^{-7} \quad (17.4.24b)$$

with

$$pK_{a2} = 12.90 \text{ and hence } K_{a2} = 1.3 \times 10^{-13} \quad (17.4.24d)$$

We can show that the concentration of S^{2-} is 1.3×10^{-13} by comparing K_{a1} and K_{a2} and recognizing that the contribution to $[H^+]$ from the dissociation of HS^- is negligible compared with $[H^+]$ from the dissociation of H_2S . Thus substituting 0.10 M in the equation for K_{a1} for the concentration of H_2S , which is essentially constant regardless of the pH, gives the following:

$$K_{a1} = 1.1 \times 10^{-7} = \frac{[H^+][HS^-]}{[H_2S]} = \frac{x^2}{0.10 M} \quad (17.4.5)$$

$$x = 1.1 \times 10^{-4} M = [H^+] = [HS^-]$$

Substituting this value for $[H^+]$ and $[HS^-]$ into the equation for K_{a2} ,

$$K_{a2} = 1.3 \times 10^{-13} = \frac{[H^+][S^{2-}]}{[HS^-]} = \frac{(1.1 \times 10^{-4} M)x}{1.1 \times 10^{-4} M} = x = [S^{2-}]$$

Although $[S^{2-}]$ in an H_2S solution is very low ($1.3 \times 10^{-13} M$), bubbling H_2S through the solution until it is saturated would precipitate both metal ions because the concentration of S^{2-} would then be much greater than $1.6 \times 10^{-21} M$. Thus we must adjust $[S^{2-}]$ to stay within the desired range. The most direct way to do this is to adjust $[H^+]$ by adding acid to the H_2S solution (recall Le Châtelier's principle), thereby driving the equilibrium in Equation 17.4.24a to the left. The overall equation for the dissociation of H_2S is as follows:

Now we can use the equilibrium constant K_f for the overall reaction, which is the product of K_{a1} and K_{a2} , and the concentration of H_2S in a saturated solution to calculate the H^+ concentration needed to produce $[S^{2-}]$ of $1.6 \times 10^{-21} M$:

$$K = K_{a1}K_{a2} = (1.1 \times 10^{-7})(1.3 \times 10^{-13}) = 1.4 \times 10^{-20} = \frac{[\text{H}^+]^2[\text{S}^{2-}]}{[\text{H}_2\text{S}]} \quad (17.4.27)$$

$$[\text{H}^+]^2 = \frac{K[\text{H}_2\text{S}]}{[\text{S}^{2-}]} = \frac{(1.4 \times 10^{-20})(0.10 \text{ M})}{1.6 \times 10^{-21} \text{ M}} = 0.88 \quad (17.4.28)$$

$$[\text{H}^+] = 0.94$$

Thus adding a strong acid such as HCl to make the solution 0.94 M in H^+ will prevent the more soluble ZnS from precipitating while ensuring that the less soluble CdS will precipitate when the solution is saturated with H_2S .

Example 17.4.3

A solution contains 0.010 M Ca^{2+} and 0.010 M La^{3+} . What concentration of HCl is needed to precipitate $\text{La}_2(\text{C}_2\text{O}_4)_3 \cdot 9\text{H}_2\text{O}$ but not $\text{Ca}(\text{C}_2\text{O}_4) \cdot \text{H}_2\text{O}$ if the concentration of oxalic acid is 1.0 M? K_{sp} values are 2.32×10^{-9} for $\text{Ca}(\text{C}_2\text{O}_4)$ and 2.5×10^{-27} for $\text{La}_2(\text{C}_2\text{O}_4)_3$; $\text{p}K_{a1} = 1.25$ and $\text{p}K_{a2} = 3.81$ for oxalic acid.

Given: concentrations of cations, K_{sp} values, and concentration and $\text{p}K_a$ values for oxalic acid

Asked for: concentration of HCl needed for selective precipitation of $\text{La}_2(\text{C}_2\text{O}_4)_3$

Strategy:

A Write each solubility product expression and calculate the oxalate concentration needed for precipitation to occur. Determine the concentration range needed for selective precipitation of $\text{La}_2(\text{C}_2\text{O}_4)_3 \cdot 9\text{H}_2\text{O}$.

B Add the equations for the first and second dissociations of oxalic acid to get an overall equation for the dissociation of oxalic acid to oxalate. Substitute the $[\text{ox}^{2-}]$ needed to precipitate $\text{La}_2(\text{C}_2\text{O}_4)_3 \cdot 9\text{H}_2\text{O}$ into the overall equation for the dissociation of oxalic acid to calculate the required $[\text{H}^+]$.

Solution:

A Because the salts have different stoichiometries, we cannot directly compare the magnitudes of the solubility products. Instead, we must use the equilibrium constant expression for each solubility product to calculate the concentration of oxalate needed for precipitation to occur. Using ox^{2-} for oxalate, we write the solubility product expression for calcium oxalate as follows:

$$K_{sp} = [\text{Ca}^{2+}][\text{ox}^{2-}] = (0.010)[\text{ox}^{2-}] = 2.32 \times 10^{-9}$$

$$[\text{ox}^{2-}] = 2.32 \times 10^{-7} \text{ M}$$

The expression for lanthanum oxalate is as follows:

$$K_{sp} = [\text{La}^{3+}]^2[\text{ox}^{2-}]^3 = (0.010)^2[\text{ox}^{2-}]^3 = 2.5 \times 10^{-27}$$

$$[\text{ox}^{2-}] = 2.9 \times 10^{-8} \text{ M}$$

Thus lanthanum oxalate is less soluble and will selectively precipitate when the oxalate concentration is between $2.9 \times 10^{-8} \text{ M}$ and $2.32 \times 10^{-7} \text{ M}$.

B To prevent Ca^{2+} from precipitating as calcium oxalate, we must add enough H^+ to give a maximum oxalate concentration of $2.32 \times 10^{-7} \text{ M}$. We can calculate the required $[\text{H}^+]$ by using the overall equation for the dissociation of oxalic acid to oxalate:

$$K = K_{a1}K_{a2} = (10^{-1.25})(10^{-3.81}) = 10^{-5.06} = 8.7 \times 10^{-6}$$

Substituting the desired oxalate concentration into the equilibrium constant expression,

$$8.7 \times 10^{-6} = \frac{[\text{H}^+]^2 [\text{ox}^{2-}]}{[\text{HO}_2\text{CCO}_2\text{H}]} = \frac{[\text{H}^+]^2 (2.32 \times 10^{-7})}{1.0}$$

$$[\text{H}^+] = 6.1 \text{ M}$$

Thus adding enough HCl to give $[\text{H}^+] = 6.1 \text{ M}$ will cause only $\text{La}_2(\text{C}_2\text{O}_4)_3 \cdot 9\text{H}_2\text{O}$ to precipitate from the solution.

Exercise

A solution contains 0.015 M Fe^{2+} and 0.015 M Pb^{2+} . What concentration of acid is needed to ensure that Pb^{2+} precipitates as PbS in a saturated solution of H_2S , but Fe^{2+} does not precipitate as FeS ? K_{sp} values are 6.3×10^{-18} for FeS and 8.0×10^{-28} for PbS .

Answer: 0.018 M H^+

Summary

The anion in many sparingly soluble salts is the conjugate base of a weak acid. At low pH, protonation of the anion can dramatically increase the solubility of the salt. Oxides can be classified as acidic oxides or basic oxides. **Acidic oxides** either react with water to give an acidic solution or dissolve in strong base; most acidic oxides are nonmetal oxides or oxides of metals in high oxidation states. **Basic oxides** either react with water to give a basic solution or dissolve in strong acid; most basic oxides are oxides of metallic elements. Oxides or hydroxides that are soluble in both acidic and basic solutions are called **amphoteric oxides**. Most elements whose oxides exhibit amphoteric behavior are located along the diagonal line separating metals and nonmetals in the periodic table. In solutions that contain mixtures of dissolved metal ions, the pH can be used to control the anion concentration needed to selectively precipitate the desired cation.

Key Takeaway

- The anion in sparingly soluble salts is often the conjugate base of a weak acid that may become protonated in solution, so the solubility of simple oxides and sulfides, both strong bases, often depends on pH.

Conceptual Problems

- Which of the following will show the greatest increase in solubility if 1 M HNO_3 is used instead of distilled water? Explain your reasoning.
 - CuCl_2
 - $\text{K}[\text{Pb}(\text{OH})_3]$
 - $\text{Ba}(\text{CH}_3\text{CO}_2)_2$
 - CaCO_3
- Of the compounds $\text{Sn}(\text{CH}_3\text{CO}_2)_2$ and SnS , one is soluble in dilute HCl and the other is soluble only in hot, concentrated HCl. Which is which? Provide a reasonable explanation.
- Where in the periodic table do you expect to find elements that form basic oxides? Where do you expect to find elements that form acidic oxides?
- Because water can autoionize, it reacts with oxides either as a base (as OH^-) or as an acid (as H_3O^+). Do you expect oxides of elements in high oxidation states to be more acidic (reacting with OH^-) or more basic (reacting with H_3O^+) than the corresponding oxides in low oxidation states? Why?
- Given solid samples of CrO , Cr_2O_3 , and CrO_3 , which would you expect to be the most acidic (reacts most readily with OH^-)? Which would be the most basic (reacts most readily with H_3O^+)? Why?
- Which of these elements—Be, B, Al, N, Se, In, Tl, Pb—do you expect to form an amphoteric oxide? Why?

Numerical Problems

1. A 1.0 L solution contains 1.98×10^{-3} M $\text{Al}(\text{NO}_3)_3$. What are $[\text{OH}^-]$ and $[\text{H}_3\text{O}^+]$? What pH is required to precipitate the cation as $\text{Al}(\text{OH})_3$? $K_{\text{sp}} = 1.3 \times 10^{-33}$ and $K_{\text{a}} = 1.05 \times 10^{-5}$ for the hydrated Al^{3+} ion.
2. A 1.0 L solution contains 2.03×10^{-15} M CoCl_2 . What is $[\text{H}^+]$? What pH is required to precipitate the cation as $\text{Co}(\text{OH})_2$? $K_{\text{sp}} = 5.92 \times 10^{-15}$ and $K_{\text{a}} = 1.26 \times 10^{-13}$ for the hydrated Co^{2+} ion.
3. Given 100 mL of a solution that contains 0.80 mM Ag^+ and 0.80 mM Cu^+ , can the two metals be separated by selective precipitation as the insoluble bromide salts by adding 10 mL of an 8.0 mM solution of KBr ? K_{sp} values are 6.27×10^{-13} for CuBr and 5.35×10^{-13} for AgBr . What maximum $[\text{Br}^-]$ will separate the ions?
4. Given 100 mL of a solution that is 1.5 mM in Tl^+ , Zn^{2+} , and Ni^{2+} , which ions can be separated from solution by adding 5.0 mL of a 12.0 mM solution of $\text{Na}_2\text{C}_2\text{O}_4$?

Precipitate	K_{sp}
$\text{Tl}_2\text{C}_2\text{O}_4$	2×10^{-4}
$\text{ZnC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$	1.38×10^{-9}
NiC_2O_4	4×10^{-10}

How many milliliters of 12.0 mM $\text{Na}_2\text{C}_2\text{O}_4$ should be added to separate Tl^+ and Zn^{2+} from Ni^{2+} ?

Answers

1. $[\text{H}^+] = 4.56 \times 10^{-3}$; $[\text{OH}^-] = 2.19 \times 10^{-12}$; pH = 2.94
- 2.
3. No; both metal ions will precipitate; AgBr will precipitate as Br^- is added, and CuBr will begin to precipitate at $[\text{Br}^-] = 8.6 \times 10^{-6}$ M.
- 4.

Learning Objective

- To know how to separate metal ions by selective precipitation.

The composition of relatively complex mixtures of metal ions can be determined using qualitative analysis, a procedure for discovering the *identity* of metal ions present in the mixture (rather than quantitative information about their amounts).

The procedure used to separate and identify more than 20 common metal cations from a single solution consists of selectively precipitating only a few kinds of metal ions at a time under given sets of conditions. Consecutive precipitation steps become progressively *less* selective until almost all of the metal ions are precipitated, as illustrated in Figure 17.5.1.

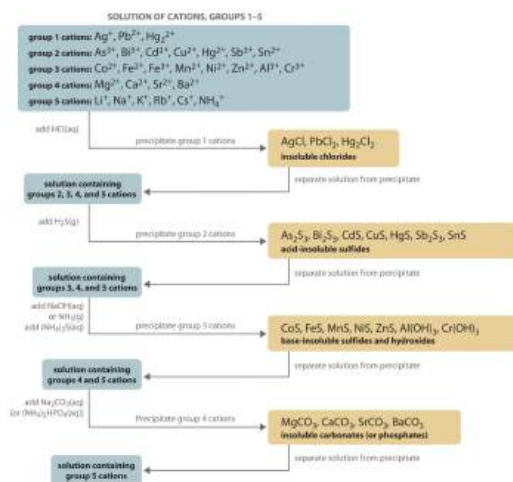

Figure 17.5.1 Steps in a Typical Qualitative Analysis Scheme for a Solution That Contains Several Metal Ions

Group 1: Insoluble Chlorides

Most metal chloride salts are soluble in water; only Ag^+ , Pb^{2+} , and Hg_2^{2+} form chlorides that precipitate from water. Thus the first step in a qualitative analysis is to add about 6 M HCl, thereby causing AgCl , PbCl_2 , and/or Hg_2Cl_2 to precipitate. If no precipitate forms, then these cations are not present in significant amounts. The precipitate can be collected by filtration or centrifugation.

Group 2: Acid-Insoluble Sulfides

Next, the acidic solution is saturated with H_2S gas. Only those metal ions that form very insoluble sulfides, such as As^{3+} , Bi^{3+} , Cd^{2+} , Cu^{2+} , Hg^{2+} , Sb^{3+} , and Sn^{2+} , precipitate as their sulfide salts under these acidic conditions. All others, such as Fe^{2+} and Zn^{2+} , remain in solution. Once again, the precipitates are collected by filtration or centrifugation.

Group 3: Base-Insoluble Sulfides (and Hydroxides)

Ammonia or NaOH is now added to the solution until it is basic, and then $(\text{NH}_4)_2\text{S}$ is added. This treatment removes any remaining cations that form insoluble hydroxides or sulfides. The divalent metal ions Co^{2+} , Fe^{2+} , Mn^{2+} , Ni^{2+} , and Zn^{2+} precipitate as their sulfides, and the trivalent metal ions Al^{3+} and Cr^{3+} precipitate as their hydroxides: $\text{Al}(\text{OH})_3$ and $\text{Cr}(\text{OH})_3$. If the mixture contains Fe^{3+} , sulfide reduces the cation to Fe^{2+} , which precipitates as FeS .

Group 4: Insoluble Carbonates or Phosphates

The next metal ions to be removed from solution are those that form insoluble carbonates and phosphates. When Na_2CO_3 is added to the basic solution that remains after the precipitated metal ions are removed, insoluble carbonates precipitate and are collected. Alternatively, adding $(\text{NH}_4)_2\text{HPO}_4$ causes the same metal ions to precipitate as insoluble phosphates.

Group 5: Alkali Metals

At this point, we have removed all the metal ions that form water-insoluble chlorides, sulfides, carbonates, or phosphates. The only common ions that might remain are any alkali metals (Li^+ , Na^+ , K^+ , Rb^+ , and Cs^+) and ammonium (NH_4^+). We now take a second sample from the *original* solution and add a small amount of NaOH to neutralize the ammonium ion and produce NH_3 . (We cannot use the same sample we used for the first four groups because we added ammonium to that sample in earlier steps.) Any ammonia produced can be detected by either its odor or a litmus paper test. A flame test on another original sample is used to detect sodium, which produces a characteristic bright yellow color. As discussed in [Chapter 2](#), the other alkali metal ions also give characteristic colors in flame tests, which allows them to be identified if only one is present.

Metal ions that precipitate together are separated by various additional techniques, such as forming complex ions, changing the pH of the solution, or increasing the temperature to redissolve some of the solids. For example, the precipitated metal chlorides of group 1 cations, containing Ag^+ , Pb^{2+} , and Hg_2^{2+} , are all quite insoluble in water. Because PbCl_2 is much more soluble in hot water than are the other two chloride salts, however, adding water to the precipitate and heating the resulting slurry will dissolve any PbCl_2 present. Isolating the solution and adding a small amount of Na_2CrO_4 solution to it will produce a bright yellow precipitate of PbCrO_4 if Pb^{2+} was in the original sample ([Figure 17.5.2](#)).

As another example, treating the precipitates from group 1 cations with aqueous ammonia will dissolve any AgCl because Ag^+ forms a stable complex with ammonia: $[\text{Ag}(\text{NH}_3)_2]^+$. In addition, Hg_2Cl_2 disproportionates in ammonia ($2\text{Hg}_2^{2+} \rightarrow \text{Hg} + \text{Hg}^{2+}$) to form a black solid that is a mixture of finely divided metallic mercury and an insoluble mercury(II) compound, which is separated from solution:

Figure 17.5.2 When a small amount of Na_2CrO_4 solution is added to a sample containing Pb^{2+} ions in water, a bright yellow precipitate of PbCrO_4 forms. Image used with permission from Wikipedia.

As another example, treating the precipitates from group 1 cations with aqueous ammonia will dissolve any AgCl because Ag^+ forms a stable complex with ammonia: $[\text{Ag}(\text{NH}_3)_2]^+$. In addition, Hg_2Cl_2 disproportionates in ammonia ($2\text{Hg}_2^{2+} \rightarrow \text{Hg} + \text{Hg}^{2+}$) to form a black solid that is a mixture of finely divided metallic mercury and an insoluble mercury(II) compound, which is separated from solution:

Any silver ion in the solution is then detected by adding HCl, which reverses the reaction and gives a precipitate of white AgCl that slowly darkens when exposed to light:

Similar but slightly more complex reactions are also used to separate and identify the individual components of the other groups.

Summary

In **qualitative analysis**, the identity, not the amount, of metal ions present in a mixture is determined. The technique consists of selectively precipitating only a few kinds of metal ions at a time under given sets of conditions. Consecutive precipitation steps become progressively *less* selective until almost all the metal ions are precipitated. Other additional steps are needed to separate metal ions that precipitate together.

Key Takeaway

- Several common metal cations can be identified in a solution using selective precipitation.

Conceptual Problem

1. Given a solution that contains a mixture of NaCl, CuCl₂, and ZnCl₂, propose a method for separating the metal ions.

17.6 End-of-Chapter Material

APPLICATION PROBLEMS

Problems marked with a ♦ involve multiple concepts.

1. ♦ Gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) is added to soil to enhance plant growth. It dissolves according to the following equation:

- The K_{sp} of gypsum is 3.14×10^{-5} . How much gypsum should you add to your 5.0 L watering can to produce a saturated solution?
 - Gibbsite $[\text{Al}(\text{OH})_3]$ is a component of clay, found in places such as Molokai, Hawaii. It dissolves according to the following equation: $\text{Al}(\text{OH})_3(s) \rightleftharpoons \text{Al}^{3+}(aq) + 3\text{OH}^{-}(aq)$, with a K_{sp} of 1.3×10^{-33} . You are interested in using gypsum to counteract harmful growth effects of Al^{3+} on plants from dissolved gibbsite, and you have found the pH of your soil to be 8.7. What is the apparent concentration of OH^{-} in your soil?
2. Egyptian blue, which is difficult to prepare, is a synthetic pigment developed about 4500 yr ago. It was the only blue pigment identified in a study of stocks of dry pigments found in color merchants' shops in Pompeii. The pigment contains 12.9% calcium carbonate (calcite). A major source of CaCO_3 is limestone, which also contains MgCO_3 . Assuming that the masses of CaCO_3 and MgCO_3 are equal, and that a sample of limestone is dissolved in acidified water to give $[\text{Ca}^{2+}] = [\text{Mg}^{2+}] = 0.010 \text{ M}$ in 5.0 L of solution, would selective precipitation be a viable method for purifying enough CaCO_3 from limestone to produce 1.0 g of pigment? Why? The K_{sp} values are 3.36×10^{-9} for CaCO_3 and 6.8×10^{-10} for MgCO_3 .
3. One method of mining gold is to extract it through the process of cyanidation. Mined ores are milled and treated with aqueous cyanide solution to produce a gold complex ion $\{[\text{Au}(\text{CN})_2]^{-}\}$ that is very stable. Given a sample of AuCl_3 , what is the solubility of AuCl_3 in each situation? The K_{sp} of $\text{AuCl}_3 = 2.0 \times 10^{-25}$; $\log K_f\{[\text{Au}(\text{CN})_2]^{-}\} = 38.3$.
- pure water
 - a 1.68 M solution of NaCN
4. ♦ Almost all barium carbonate is produced synthetically. The compound is used in manufacturing clay tiles and ceramic products as well as in cathode ray tubes and special optical glasses. BaCO_3 is synthesized by allowing barium sulfate to react with coal at 1000°C – 1200°C in a rotary kiln, followed by treatment of a solution of the product with either CO_2 (reaction 1) or Na_2CO_3 (reaction 2). The reactions are as follows:

Barium carbonate has a K_{sp} of 2.58×10^{-9} . The $\text{p}K_{\text{a}}$ for $\text{H}_2\text{S} \rightleftharpoons \text{H}^{+} + \text{HS}^{-}$ is 6.97, and the $\text{p}K_{\text{a}}$ for $\text{HS}^{-} \rightleftharpoons \text{H}^{+} + \text{S}^{2-}$ is 12.90. Given this information, answer the following questions:

- If reaction 1 occurs, what is the pH of the solution if 80.0 g of BaS react with CO_2 in 1.00 L of water?
 - If reaction 2 occurs, how many grams of BaCO_3 are produced by the reaction of 80.0 g of BaS with excess Na_2CO_3 ?
5. A person complaining of chronic indigestion continually consumed antacid tablets containing $\text{Ca}(\text{OH})_2$ over a two-week period. A blood test at the end of this period showed that the person had become anemic. Explain the reactions that caused this test result.
6. Although the commercial production of radium has virtually ceased since artificial radionuclides were discovered to have similar properties and lower costs, commercial radium is still isolated using essentially the same procedure developed by

Marie Curie, as outlined here. Explain what is happening chemically at each step of the purification process. What is precipitate A? What metal ions are present in solution A? What is precipitate B? What metal ions are present in solution B?

7. In a qualitative analysis laboratory, a student initially treated his sample of metal ions with 6 M HNO_3 instead of 6 M HCl , recognizing his mistake only after the acid-insoluble sulfides had been precipitated. He decided to simply add 6 M HCl to the filtrate from which the sulfides had been removed, but he obtained no precipitate. The student therefore concluded that there were no Ag^+ , Hg_2^{2+} , or Pb^{2+} cations in his original sample. Is this conclusion valid?
8. Using qualitative analysis, a student decided to treat her sample with $(\text{NH}_4)_2\text{S}$ solution directly, skipping the HCl and acidic H_2S treatments because she was running out of time. In a sample that contained Ag^+ , Hg_2^{2+} , Cd^{2+} , Sb^{3+} , and Zn^{2+} , which metal ions was she most likely to obtain in the resulting precipitate?

ANSWERS

1. a. $4.3 \times 10^{-6} \text{ g}$
b. $5 \times 10^{-6} \text{ M}$
2. $4.4 \times 10^{-7} \text{ M}$
3. a. $4.4 \times 10^{-7} \text{ M}$
b. 0.84 M
- 4.
- 5.
- 6.
7. No; these cations would precipitate as sulfides.
- 8.

Learning Objectives

- To understand the relationships between work, heat, and energy.
- To become familiar with the concept of PV work.

We begin our discussion of thermodynamics by reviewing some important terms introduced in [Chapter 9](#). First, we need to distinguish between a system and its surroundings. A **system** is that part of the universe in which we are interested, such as a mixture of gases in a glass bulb or a solution of substances in a flask. The **surroundings** are everything else—the rest of the *universe*. We can therefore state the following:

$$\text{system} + \text{surroundings} = \text{universe} \quad (18.1.1)$$

A **closed system**, such as the contents of a sealed jar, cannot exchange matter with its surroundings, whereas an **open system** can; in this case, we can convert a closed system (the jar) to an open system by removing the jar's lid.

In [Chapter 9](#), we also introduced the concept of a state function, a property of a system that depends on only the present state of the system, not its history. Thus a change in a state function depends on only the difference between the initial and final states, not the pathway used to go from one to the other. To help understand the concept of a state function, imagine a person hiking up a mountain ([Figure 18.1.1](#)). If the person is well trained and fit, he or she may be able to climb almost vertically to the top ([path A](#)), whereas another less athletic person may choose a path that winds gradually to the top ([path B](#)). If both hikers start from the same point at the base of the mountain and end up at the same point at the top, their *net change in altitude* will be the same regardless of the path chosen. Hence altitude is a state function. On the other hand, a person may or may not carry a heavy pack and may climb in hot weather or cold. These conditions would influence changes in the hiker's fatigue level, which depends on the path taken and the conditions experienced. Fatigue, therefore, is not a state function. Thermodynamics is generally concerned with state functions and does not deal with how the change between the initial state and final state occurs.

Figure 18.1.1 Altitude Is a State Function. When hiking up a mountain, a person may decide to take [path A](#), which is almost vertical, or [path B](#), which gradually winds up to the top. Regardless of the path taken, the net change in altitude going from the

initial state (bottom of the climb) to the final state (top of the climb) is the same. Thus altitude is a state function.

The Connections among Work, Heat, and Energy

The internal energy (E) of a system is the sum of the potential energy and the kinetic energy of all the components; internal energy is a state function. Although a closed system cannot exchange matter with its surroundings, it can exchange energy with its surroundings in two ways: by doing work or by releasing or absorbing heat—the flow of thermal energy. Work and heat are therefore two distinct ways of changing the internal energy of a system. We defined *work* (w) in Chapter 9 as a force F acting through a distance d :

$$w = Fd \quad (18.1.2)$$

Because work occurs only when an object, such as a person, or a substance, such as water, moves against an opposing force, work requires that a system and its surroundings be connected. In contrast, the flow of *heat*, the transfer of energy due to differences in temperature between two objects, represents a thermal connection between a system and its surroundings. Thus doing work causes a physical displacement, whereas the flow of heat causes a temperature change. The units of work and heat must be the same because both processes result in the transfer of energy. In the SI system, those units are joules (J), the same unit used for energy. There is no difference between an energy change brought about by doing work on a system and an equal energy change brought about by heating it.

The connections among work, heat, and energy were first described by Benjamin Thompson (1753–1814), an American-born scientist who was also known as Count Rumford. While supervising the manufacture of cannons, Rumford recognized the relationship between the amount of work required to drill out a cannon and the temperature of the water used to cool it during the drilling process (Figure 18.1.2). At that time, it was generally thought that heat and work were separate and unrelated phenomena. Hence Rumford's ideas were not widely accepted until many years later, after his findings had been corroborated in other laboratories.

Figure 18.1.2 The Relationship between Heat and Work In the 1780s, an American scientist named Benjamin Thompson, also known as Count Rumford, was hired by the Elector of Bavaria to supervise the manufacture of cannons. During the manufacturing process, teams of horses harnessed to a large-toothed wheel supplied the power needed to drill a hole several inches in diameter straight down the center of a solid brass or bronze cylinder, which was cooled by water. Based on his observations, Rumford became convinced that heat and work are equivalent ways of transferring energy.

PV Work

As we saw in Chapter 9, there are many kinds of work, including mechanical work, electrical work, and work against a gravitational or a magnetic field. Here we will consider only mechanical work, focusing on the work done during changes in the pressure or the volume of a gas. To describe this *pressure–volume work* (PV work), we will use such imaginary oddities as frictionless pistons, which involve no component of resistance, and ideal gases, which have no attractive or repulsive interactions.

Imagine, for example, an ideal gas, confined by a frictionless piston, with internal pressure P_{int} and initial volume V_i (Figure 18.1.3). If $P_{\text{ext}} = P_{\text{int}}$, the system is at equilibrium; the piston does not move, and no work is done. If the external pressure on the piston (P_{ext}) is less than P_{int} , however, then the ideal gas inside the piston will expand, forcing the piston to perform work on its surroundings; that is, the final volume (V_f) will be greater than V_i . If $P_{\text{ext}} > P_{\text{int}}$, then the gas will be compressed, and the surroundings will perform work on the system.

If the piston has cross-sectional area A , the external pressure exerted by the piston is, by definition, the force per unit area: $P_{\text{ext}} = F/A$. The volume of any three-dimensional object with parallel sides (such as a cylinder) is the cross-sectional area times the height ($V = Ah$). Rearranging to give $F = P_{\text{ext}}A$ and defining the distance the piston moves (d) as Δh , we can calculate the magnitude of the work performed by the piston by substituting into Equation 18.1.2:

$$w = Fd = P_{\text{ext}} A \Delta h \quad (18.1.3)$$

The change in the volume of the cylinder (ΔV) as the piston moves a distance d is $\Delta V = A \Delta h$, as shown in Figure 18.1.4. The work performed is thus

$$w = P_{\text{ext}} \Delta V \quad (18.1.4)$$

The units of work obtained using this definition are correct for energy: pressure is force per unit area (newton/m²) and volume has units of cubic meters, so

$$w = \left(\frac{F}{A} \right) \Delta V = \frac{\text{newton}}{\text{m}^2} \times \text{m}^3$$

Figure 18.1.3 PV Work
Using a frictionless piston, if the external pressure is less than P_{int} (a), the ideal gas inside the piston will expand, forcing the piston to perform work on its surroundings. The final volume (V_f) will be greater than V_i . Alternatively, if the external pressure is greater than P_{int} (b), the gas will be compressed, and the surroundings will perform work on the system.

Figure 18.1.4 Work Performed with a Change in Volume The change in the volume (ΔV) of the cylinder housing a piston is $\Delta V = A \Delta h$ as the piston moves. The work performed by the surroundings on the system as the piston moves inward is given by $w = P_{\text{ext}} \Delta V$.

If we use atmospheres for P and liters for V , we obtain units of L·atm for work. These units correspond to units of energy, as shown in the different values of the ideal gas constant R :

$$R = \frac{0.08206 \text{ L} \cdot \text{atm}}{\text{mol} \cdot \text{K}} = \frac{8.314 \text{ J}}{\text{mol} \cdot \text{K}}$$

Thus $0.08206 \text{ L} \cdot \text{atm} = 8.314 \text{ J}$ and $1 \text{ L} \cdot \text{atm} = 101.3 \text{ J}$. (For more information on the ideal gas law, see Chapter 10.)

Whether work is defined as having a positive sign or a negative sign is a matter of convention. In Chapter 9, we defined heat flow from a system to its surroundings as negative. Using that same sign convention, we define work done by a system on its surroundings as having a negative sign because it results in a transfer of energy from a system to its surroundings. This is an arbitrary convention and one that is not universally used. Some engineering disciplines are more interested in the work done on the surroundings than in the work done by the system and therefore use the opposite convention. Because $\Delta V > 0$ for an expansion, Equation 18.4 must be written with a negative sign to describe PV work done by the system as negative:

$$w = P_{\text{ext}} \Delta V \quad (18.1.5)$$

The work done by a gas expanding against an external pressure is therefore negative, corresponding to work done by a system on its surroundings. Conversely, when a gas is compressed by an external pressure, $\Delta V < 0$ and the work is positive because work is being done on a system by its surroundings.

Suppose, for example, that the system under study is a mass of steam heated by the combustion of several hundred pounds of coal and enclosed within a cylinder housing a piston attached to the crankshaft of a large steam engine. The gas is not ideal, and the cylinder is not frictionless. Nonetheless, as steam enters the engine chamber and the expanding gas pushes against the piston, the piston moves, so useful work is performed. In fact, PV work launched the Industrial Revolution of the 19th century and powers the internal combustion engine on which most of us still rely for transportation.

In contrast to internal energy, work is not a state function. We can see this by examining Figure 18.1.5, in which two different, two-step pathways take a gaseous system from an initial state to a final state with corresponding changes in temperature. In pathway A, the volume of a gas is initially increased while its pressure stays constant (step 1); then its pressure is decreased while the volume remains constant (step 2). In pathway B, the order of the steps is reversed. The temperatures, pressures, and volumes of the initial and final states are identical in both cases, but the amount of work done, indicated by the shaded areas in the figure, is substantially different. As we can see, the amount of work done depends on the pathway taken from (V_1, P_1) to (V_2, P_2) , which means that work is not a state function.

Note the Pattern

Internal energy is a state function, whereas work is not.

Figure 18.1.5 Work Is Not a State Function In pathway A, the volume of a gas is initially increased while its pressure stays constant (step 1). Its pressure is then decreased while the volume remains constant (step 2). Pathway B reverses these steps. Although (V_1, P_1) and (V_2, P_2) are identical in both cases, the amount of work done (shaded area) depends on the pathway taken.

Example 18.1.1

A small high-performance internal combustion engine has six cylinders with a total nominal displacement (volume) of 2.40 L and a 10:1 compression ratio (meaning that the volume of each cylinder decreases by a factor of 10 when the piston compresses the air–gas mixture inside the cylinder prior to ignition). How much work in joules is done when a gas in one cylinder of the engine expands at constant temperature against an opposing pressure of 40.0 atm during the engine cycle? Assume that the gas is ideal, the piston is frictionless, and no energy is lost as heat.

Given: final volume, compression ratio, and external pressure

Asked for: work done

Strategy:

A Calculate the final volume of gas in a single cylinder. Then compute the initial volume of gas in a single cylinder from the compression ratio.

B Use [Equation 18.1.5](#) to calculate the work done in liter-atmospheres. Convert from liter-atmospheres to joules.

Solution:

A To calculate the work done, we need to know the initial and final volumes. The final volume is the volume of one of the six cylinders with the piston all the way down: $V_f = 2.40 \text{ L}/6 = 0.400 \text{ L}$. With a 10:1 compression ratio, the volume of the

same cylinder with the piston all the way up is $V_i = 0.400 \text{ L}/10 = 0.0400 \text{ L}$. Work is done by the system on its surroundings, so work is negative.

$$w = -P_{\text{ext}} \Delta V = -(40.0 \text{ atm})(0.400 \text{ L} - 0.0400 \text{ L}) = 14.4 \text{ L} \cdot \text{atm}$$

Converting from liter-atmospheres to joules,

$$w = -P_{\text{ext}} \Delta V = -\left(14.4 \text{ L} \cdot \cancel{\text{atm}}\right) \left[101.3 \text{ J} / \left(\cancel{\text{L} \cdot \text{atm}}\right)\right] = -1.46 \times 10^3 \text{ J}$$

In the following exercise, you will see that the concept of work is not confined to engines and pistons. It is found in other applications as well.

Exercise

Breathing requires work, even if you are unaware of it. The lung volume of a 70 kg man at rest changed from 2200 mL to 2700 mL when he inhaled, while his lungs maintained a pressure of approximately 1.0 atm. How much work in liter-atmospheres and joules was required to take a single breath? During exercise, his lung volume changed from 2200 mL to 5200 mL on each in-breath. How much additional work in joules did he require to take a breath while exercising?

Answer: $-0.500 \text{ L} \cdot \text{atm}$, or -50.7 J ; -304 J ; if he takes a breath every three seconds, this corresponds to 1.4 Calories per minute (1.4 kcal).

Summary

Thermodynamics is the study of the interrelationships among heat, work, and the energy content of a system at equilibrium. The sum of the potential energy and the kinetic energy of all the components of a system is the **internal energy** (E) of the system, which is a **state function**. When the pressure or the volume of a gas is changed, any mechanical work done is called *PV work*. Work done by a system on its surroundings is given a negative value, whereas work done on a system by its surroundings has a positive value.

Key Takeaway

- Internal energy is a state function that is the sum of the potential and kinetic energy of the system, whereas work is not a state function.

Key Equation

Definition of *PV* work

Equation 18.1.5: $w = -P_{\text{ext}} \Delta V$

Conceptual Problems

1. Thermodynamics focuses on the energetics of the reactants and products and provides information about the composition of the reaction system at equilibrium. What information on reaction systems is not provided by thermodynamics?
2. Given a system in which a substance can produce either of two possible products, $A \rightarrow B$ or $A \rightarrow C$, which of the following can be predicted using chemical thermodynamics?
 - a. At equilibrium, the concentration of product C is greater than the concentration of product B.
 - b. Product C forms more quickly than product B.
 - c. The reaction $A \rightarrow C$ is exothermic.
 - d. Low-energy intermediates are formed in the reaction $A \rightarrow B$.
 - e. The reaction $A \rightarrow C$ is spontaneous.

- In what two ways can a closed system exchange energy with its surroundings? Are these two processes path dependent or path independent?
- A microwave oven operates by providing enough energy to rotate water molecules, which produces heat. Can the change in the internal energy of a cup of water heated in a microwave oven be described as a state function? Can the heat produced be described as a state function?

Answers

- Thermodynamics tells us nothing about the rate at which reactants are converted to products.
-
- heat and work; path dependent
-

Numerical Problems

- Calculate the work done in joules in each process.
 - compressing 12.8 L of hydrogen gas at an external pressure of 1.00 atm to 8.4 L at a constant temperature
 - expanding 21.9 L of oxygen gas at an external pressure of 0.71 atm to 23.7 L at a constant temperature
- How much work in joules is done when oxygen is compressed from a volume of 22.8 L and an external pressure of 1.20 atm to 12.0 L at a constant temperature? Was work done by the system or the surroundings?
- Champagne is bottled at a CO_2 pressure of about 5 atm. What is the force on the cork if its cross-sectional area is 2.0 cm^2 ? How much work is done if a 2.0 g cork flies a distance of 8.2 ft straight into the air when the cork is popped? Was work done by the system or the surroundings?
- One mole of water is converted to steam at 1.00 atm pressure and 100°C . Assuming ideal behavior, what is the change in volume when the water is converted from a liquid to a gas? If this transformation took place in a cylinder with a piston, how much work could be done by vaporizing the water at 1.00 atm? Is work done by the system or the surroundings?
- Acceleration due to gravity on the earth's surface is 9.8 m/s^2 . How much work is done by a 175 lb person going over Niagara Falls (approximately 520 ft high) in a barrel that weighs 145 lb?
- Recall that force can be expressed as mass times acceleration ($F = ma$). Acceleration due to gravity on the earth's surface is 9.8 m/s^2 .
 - What is the gravitational force on a person who weighs 52 kg?
 - How much work is done if the person leaps from a burning building out of a window that is 20 m above the ground?
 - If the person lands on a large rescue cushion fitted with a pressure-release valve that maintains an internal pressure of 1.5 atm, how much air is forced out of the cushion?
- A gas is allowed to expand from a volume of 2.3 L to a volume of 5.8 L. During the process, 460 J of heat is transferred from the surroundings to the gas.
 - How much work has been done if the gas expands against a vacuum?
 - How much work has been done if the gas expands against a pressure of 1.3 atm?
 - What is the change in the internal energy of the system?
- One mole of an ideal gas is allowed to expand from an initial volume of 0.62 L to a final volume of 1.00 L at constant temperature against a constant external pressure of 1.0 atm. How much work has been done?

Answers

Learning Objective

- To calculate changes in internal energy.

The relationship between the energy change of a system and that of its surroundings is given by the first law of thermodynamics, which states that the *energy of the universe is constant*. Using [Equation 18.1.1](#), we can express this law mathematically as follows:

$$\Delta E_{univ} = \Delta E_{sys} + \Delta E_{surr} = 0 \quad (18.2.1)$$

$$\Delta E_{sys} = -\Delta E_{surr}$$

where the subscripts *univ*, *sys*, and *surr* refer to the universe, the system, and the surroundings, respectively. Thus the change in energy of a system is identical in magnitude but opposite in sign to the change in energy of its surroundings.

An important factor that determines the outcome of a chemical reaction is the tendency of all systems, chemical or otherwise, to move toward the lowest possible overall energy state. As a brick dropped from a rooftop falls, its potential energy is converted to kinetic energy; when it reaches ground level, it has achieved a state of lower potential energy. Anyone nearby will notice that energy is transferred to the surroundings as the noise of the impact reverberates and the dust rises when the brick hits the ground. Similarly, if a spark ignites a mixture of isooctane and oxygen in an internal combustion engine, carbon dioxide and water form spontaneously, while potential energy (in the form of the relative positions of atoms in the molecules) is released to the surroundings as heat and work. The internal energy content of the CO₂/H₂O product mixture is less than that of the isooctane/O₂ reactant mixture. The two cases differ, however, in the form in which the energy is released to the surroundings. In the case of the falling brick, the energy is transferred as work done on whatever happens to be in the path of the brick; in the case of burning isooctane, the energy can be released as solely heat (if the reaction is carried out in an open container) or as a mixture of heat and work (if the reaction is carried out in the cylinder of an internal combustion engine). Because heat and work are the only two ways in which energy can be transferred between a system and its surroundings, any change in the internal energy of the system is the sum of the heat transferred (*q*) and the work done (*w*):

$$\Delta E_{sys} = q + w \quad (18.2.2)$$

Although *q* and *w* are not state functions on their own, their sum (ΔE_{sys}) is independent of the path taken and is therefore a state function. A major task for the designers of any machine that converts energy to work is to maximize the amount of work obtained and minimize the amount of energy released to the environment as heat. An example is the combustion of coal to produce electricity. Although the maximum amount of energy available from the process is fixed by the energy content of the reactants and the products, the fraction of that energy that can be used to perform useful work is not fixed, as discussed in [Section 18.5](#). Because we focus almost exclusively on the changes in the energy of a system, we will not use “sys” as a subscript unless we need to distinguish explicitly between a system and its surroundings.

Note the Pattern

The tendency of all systems, chemical or otherwise, is to move toward the state with the lowest possible energy.

Note the Pattern

Although q and w are not state functions, their sum (ΔE_{sys}) is independent of the path taken and therefore is a state function.

Example 18.2.1

A sample of an ideal gas in the cylinder of an engine is compressed from 400 mL to 50.0 mL during the compression stroke against a constant pressure of 8.00 atm. At the same time, 140 J of energy is transferred from the gas to the surroundings as heat. What is the total change in the internal energy (ΔE) of the gas in joules?

Given: initial volume, final volume, external pressure, and quantity of energy transferred as heat

Asked for: total change in internal energy

Strategy:

A Determine the sign of q to use in [Equation 18.2.2](#).

B From [Equation 18.1.5](#), calculate w from the values given. Substitute this value into [Equation 18.2.2](#) to calculate ΔE .

Solution:

A From [Equation 18.2.2](#), we know that $\Delta E = q + w$. We are given the magnitude of q (140 J) and need only determine its sign. Because energy is transferred from the system (the gas) to the surroundings, q is negative by convention.

B Because the gas is being compressed, we know that work is being done *on* the system, so w must be positive. From [Equation 18.1.5](#),

$$w = -P_{\text{ext}} \Delta V = - (8.0 \text{ atm}) (0.0500 \text{ L} - 0.400 \text{ L}) \left(\frac{101.3 \text{ J}}{\text{L} \cdot \text{atm}} \right) = 284 \text{ J}$$

Thus

$$\Delta E = q + w = -140 \text{ J} + 284 \text{ J} = 144 \text{ J}$$

In this case, although work is done *on* the gas, increasing its internal energy, heat flows *from* the system *to* the surroundings, decreasing its internal energy by 144 J. The work done and the heat transferred can have opposite signs.

Exercise

A sample of an ideal gas is allowed to expand from an initial volume of 0.200 L to a final volume of 3.50 L against a constant external pressure of 0.995 atm. At the same time, 117 J of heat is transferred from the surroundings to the gas. What is the total change in the internal energy (ΔE) of the gas in joules?

Answer: -216 J

Note the Pattern

By convention, both heat flow and work have a negative sign when energy is transferred from a system to its surroundings and vice versa.

Enthalpy

To further understand the relationship between heat flow (q) and the resulting change in internal energy (ΔE), we can look at two sets of limiting conditions: reactions that occur at constant volume and reactions that occur at constant pressure. We will assume

that PV work is the only kind of work possible for the system, so we can substitute its definition from [Equation 18.1.5](#) into [Equation 18.7](#) to obtain the following:

$$\Delta E = q - p\Delta V \quad (18.2.3)$$

where the subscripts have been deleted.

If the reaction occurs in a closed vessel, the volume of the system is fixed, and ΔV is zero. Under these conditions, the heat flow (often given the symbol q_v to indicate constant volume) must equal ΔE :

$$q_v = \Delta E \quad (18.2.4)$$

constant volume

No PV work can be done, and the change in the internal energy of the system is equal to the amount of heat transferred from the system to the surroundings or vice versa.

Many chemical reactions are not, however, carried out in sealed containers at constant volume but in open containers at a more or less constant pressure of about 1 atm. The heat flow under these conditions is given the symbol q_p to indicate constant pressure. Replacing q in [Equation 18.2.3](#) by q_p and rearranging to solve for q_p ,

$$q_p = \Delta E + P\Delta V \quad (18.2.5)$$

constant pressure

Thus, at constant pressure, the heat flow for any process is equal to the change in the internal energy of the system plus the PV work done, as we stated in [Chapter 9](#).

Because conditions of constant pressure are so important in chemistry, a new state function called enthalpy (H) is defined as $H = E + PV$. At constant pressure, the change in the enthalpy of a system is as follows:

$$\Delta H = \Delta E + \Delta(PV) = \Delta E + P\Delta(V) \quad (18.2.6)$$

Comparing the previous two equations shows that at constant pressure, the change in the enthalpy of a system is equal to the heat flow: $\Delta H = q_p$. This expression is consistent with our definition of enthalpy in [Section 9.1](#), where we stated that enthalpy is the heat absorbed or produced during any process that occurs at constant pressure.

Note the Pattern

At constant pressure, the change in the enthalpy of a system is equal to the heat flow: $\Delta H = q_p$.

Example 18.2.2

The molar enthalpy of fusion for ice at 0.0°C and a pressure of 1.00 atm is 6.01 kJ, and the molar volumes of ice and water at 0°C are 0.0197 L and 0.0180 L, respectively. Calculate ΔH and ΔE for the melting of ice at 0.0°C . (For more information on enthalpy, see [Section 9.2](#).)

Given: enthalpy of fusion for ice, pressure, and molar volumes of ice and water

Asked for: ΔH and ΔE for ice melting at 0.0°C

Strategy:

A Determine the sign of q and set this value equal to ΔH .

B Calculate $\Delta(PV)$ from the information given.

C Determine ΔE by substituting the calculated values into [Equation 18.2.6](#).

Solution:

A Because 6.01 kJ of heat is absorbed from the surroundings when 1 mol of ice melts, $q = +6.01$ kJ. When the process is carried out at constant pressure, $q = q_p = \Delta H = 6.01$ kJ.

B To find ΔE using [Equation 18.2.6](#), we need to calculate $\Delta(PV)$. The process is carried out at a constant pressure of 1.00 atm, so

$$\begin{aligned}\Delta PV &= P\Delta V = P(V_f - V) = (1.00 \text{ atm})(0.0180 \text{ L} - 0.0197 \text{ L}) \\ &= (-1.7 \times 10^{-3} \text{ L} \cdot \text{atm}) (101.3 \text{ J} / \text{L} \cdot \text{atm})\end{aligned}$$

C Substituting the calculated values of ΔH and $P\Delta V$ into [Equation 18.2.6](#),

$$\Delta E = \Delta H - P\Delta V = -6010 \text{ J} - (-0.0017 \text{ J}) = 6010 \text{ J} = 6.01 \text{ kJ}$$

Exercise

At 298 K and 1 atm, the conversion of graphite to diamond requires the input of 1.850 kJ of heat per mole of carbon. The molar volumes of graphite and diamond are 0.00534 L and 0.00342 L, respectively. Calculate ΔH and ΔE for the conversion of C (graphite) to C (diamond) under these conditions.

Answer: $\Delta H = 1.85 \text{ kJ/mol}$; $\Delta E = 1.85 \text{ kJ/mol}$

The Relationship between ΔH and ΔE

If ΔH for a reaction is known, we can use the change in the enthalpy of the system ([Equation 18.2.6](#)) to calculate its change in internal energy. When a reaction involves only solids, liquids, liquid solutions, or any combination of these, the volume does not change appreciably ($\Delta V = 0$). Under these conditions, we can simplify [Equation 18.2.6](#) to $\Delta H = \Delta E$. If gases are involved, however, ΔH and ΔE can differ significantly. We can calculate ΔE from the measured value of ΔH by using the right side of [Equation 18.11](#) together with the ideal gas law, $PV = nRT$. Recognizing that $\Delta(PV) = \Delta(nRT)$, we can rewrite [Equation 18.2.6](#) as follows:

$$\Delta H = \Delta E + \Delta(PV) = \Delta E + \Delta(nRT) \quad (18.2.7)$$

At constant temperature, $\Delta(nRT) = RT\Delta n$, where Δn is the difference between the final and initial numbers of moles of gas. Thus

$$\Delta E = \Delta H - RT\Delta n \quad (18.2.8)$$

For reactions that result in a net production of gas, $\Delta n > 0$, so $\Delta E < \Delta H$. Conversely, endothermic reactions ($\Delta H > 0$) that result in a net consumption of gas have $\Delta n < 0$ and $\Delta E > \Delta H$. The relationship between ΔH and ΔE for systems involving gases is illustrated in Example 4.

Note the Pattern

For reactions that result in a net production of gas, $\Delta E < \Delta H$. For endothermic reactions that result in a net consumption of gas, $\Delta E > \Delta H$.

Example 18.2.3

The combustion of graphite to produce carbon dioxide is described by the equation $\text{C}(\text{graphite, s}) + \text{O}_2(\text{g}) \rightarrow \text{CO}_2(\text{g})$. At 298 K and 1.0 atm, $\Delta H = -393.5 \text{ kJ/mol}$ of graphite for this reaction, and the molar volume of graphite is 0.0053 L. What is ΔE for the reaction?

Given: balanced chemical equation, temperature, pressure, ΔH , and molar volume of reactant

Asked for: ΔE

Strategy:

A Use the balanced chemical equation to calculate the change in the number of moles of gas during the reaction.

B Substitute this value and the data given into [Equation 18.2.8](#) to obtain ΔE .

Solution:

A In this reaction, 1 mol of gas (CO_2) is produced, and 1 mol of gas (O_2) is consumed. Thus $\Delta n = 1 - 1 = 0$.

B Substituting this calculated value and the given values into [Equation 18.2.8](#),

$$\begin{aligned}\Delta E &= \Delta H - RT\Delta n = (-393.5 \text{ kJ/mol}) - [8.314 \text{ J/mol} \cdot \text{K}] (298 \text{ K}) (0) \\ &= (-393.5 \text{ kJ/mol}) - (0 \text{ J/mol}) = -393.5 \text{ kJ}\end{aligned}$$

To understand why only the change in the volume of the gases needs to be considered, notice that the molar volume of graphite is only 0.0053 L. A change in the number of moles of gas corresponds to a volume change of 22.4 L/mol of gas at standard temperature and pressure (STP), so the volume of gas consumed or produced in this case is $(1)(22.4 \text{ L}) = 22.4 \text{ L}$, which is much, much greater than the volume of 1 mol of a solid such as graphite.

Exercise

Calculate ΔE for the conversion of oxygen gas to ozone at 298 K: $3\text{O}_2(\text{g}) \rightarrow 2\text{O}_3(\text{g})$. The value of ΔH for the reaction is 285.4 kJ.

Answer: 288 kJ

As the exercise in Example 4 illustrates, the magnitudes of ΔH and ΔE for reactions that involve gases are generally rather similar, even when there is a net production or consumption of gases.

Summary

The **first law of thermodynamics** states that the energy of the universe is constant. The change in the internal energy of a system is the sum of the heat transferred and the work done. At constant pressure, heat flow (q) and internal energy (E) are related to the system's **enthalpy** (H). The heat flow is equal to the change in the internal energy of the system plus the PV work done. When the volume of a system is constant, changes in its internal energy can be calculated by substituting the ideal gas law into the equation for ΔE .

Key Takeaway

- Enthalpy is a state function, and the change in enthalpy of a system is equal to the sum of the change in the internal energy of the system and the PV work done.

Key Equations

Internal energy change

[Equation 18.2.2](#): $\Delta E_{\text{sys}} = q + w$

Enthalpy change

[Equation 18.2.6](#): $\Delta H = \Delta E + \Delta(PV)$

Relationship between ΔH and ΔE for an ideal gas

[Equation 18.2.8](#): $\Delta E = \Delta H - RT\Delta n$

Conceptual Problems

1. Describe how a swinging pendulum that slows with time illustrates the first law of thermodynamics.
2. When air is pumped into a bicycle tire, the air is compressed. Assuming that the volume is constant, express the change in internal energy in terms of q and w .

3. What is the relationship between enthalpy and internal energy for a reaction that occurs at constant pressure?
4. An intrepid scientist placed an unknown salt in a small amount of water. All the salt dissolved in the water, and the temperature of the solution dropped several degrees.
 - a. What is the sign of the enthalpy change for this reaction?
 - b. Assuming the heat capacity of the solution is the same as that of pure water, how would the scientist calculate the molar enthalpy change?
 - c. Propose an explanation for the decrease in temperature.
5. For years, chemists and physicists focused on enthalpy changes as a way to measure the spontaneity of a reaction. What arguments would you use to convince them not to use this method?
6. What is the relationship between enthalpy and internal energy for a reaction that occurs at constant volume?
7. The *enthalpy of combustion* (ΔH_{comb}) is defined thermodynamically as the enthalpy change for complete oxidation. The complete oxidation of hydrocarbons is represented by the following general equation: $\text{hydrocarbon} + \text{O}_2(\text{g}) \rightarrow \text{CO}_2(\text{g}) + \text{H}_2\text{O}(\text{g})$. Enthalpies of combustion from reactions like this one can be measured experimentally with a high degree of precision. It has been found that the less stable the reactant, the more heat is evolved, so the more negative the value of ΔH_{comb} . In each pair of hydrocarbons, which member do you expect to have the greater (more negative) heat of combustion? Justify your answers.
 - a. cyclopropane or cyclopentane
 - b. butane or 2-methylpropane
 - c. hexane or cyclohexane
8. Using a structural argument, explain why the *trans* isomer of 2-butene is more stable than the *cis* isomer. The enthalpies of formation of *cis*- and *trans*-2-butene are -7.1 kJ/mol and -11.4 kJ/mol , respectively.
9. Using structural arguments, explain why cyclopropane has a positive ΔH_f° (12.7 kJ/mol), whereas cyclopentane has a negative ΔH_f° (-18.4 kJ/mol). (Hint: consider bond angles.)

Answers

- 1.
- 2.
3. At constant pressure, $\Delta H = \Delta E + P\Delta V$.
- 4.
- 5.

- 7.
- 8.
9. With bond angles of 60° , cyclopropane is highly strained, causing it to be less stable than cyclopentane, which has nearly ideal tetrahedral geometry at each carbon atom.

Numerical Problems

1. A block of CO_2 weighing 15 g evaporates in a 5.0 L container at 25°C . How much work has been done if the gas is allowed to expand against an external pressure of 0.98 atm under isothermal conditions? The enthalpy of sublimation of CO_2 is 25.1 kJ/mol . What is the change in internal energy (kJ/mol) for the sublimation of CO_2 under these conditions?
2. Zinc and HCl react according to the following equation:

$$\text{Zn}(\text{s}) + 2\text{HCl}(\text{aq}) \rightarrow \text{Zn}^{2+}(\text{aq}) + 2\text{Cl}^{-}(\text{aq}) + \text{H}_2(\text{g})$$
 When 3.00 g of zinc metal is added to a dilute HCl solution at 1.00 atm and 25°C , and this reaction is allowed to go to completion at constant pressure, 6.99 kJ of heat must be removed to return the final solution to its original temperature. What are the values of q and w , and what is the change in internal energy?
3. Acetylene torches, used industrially to cut and weld metals, reach flame temperatures as high as 3000°C . The combustion reaction is as follows:

$$2\text{C}_2\text{H}_2(\text{g}) + 5\text{O}_2(\text{g}) \rightarrow 4\text{CO}_2(\text{g}) + 2\text{H}_2\text{O}(\text{l}) \quad \Delta H = -2599 \text{ kJ}$$
 Calculate the amount of work done against a pressure of 1.0 atm when 4.0 mol of acetylene are allowed to react with 10 mol of O_2 at 1.0 atm at 20°C . What is the change in internal energy for the reaction?

4. When iron dissolves in 1.00 M aqueous HCl, the products are $\text{FeCl}_2(\text{aq})$ and hydrogen gas. Calculate the work done if 30 g of Fe react with excess hydrochloric acid in a closed vessel at 20°C . How much work is done if the reaction takes place in an open vessel with an external pressure of 1.0 atm?

Answer

1. -350 J ; 8.2 kJ
- 2.
- 3.
- 4.

Learning Objective

- To understand the relationship between internal energy and entropy.

The first law of thermodynamics governs changes in the state function we have called internal energy (E). According to [Section 18.2](#), changes in the internal energy (ΔE) are closely related to changes in the enthalpy (ΔH), which is a measure of the heat flow between a system and its surroundings at constant pressure. You also learned in [Chapter 9](#) that the enthalpy change for a chemical reaction can be calculated using tabulated values of enthalpies of formation. This information, however, does not tell us whether a particular process or reaction will occur spontaneously.

Let's consider a familiar example of spontaneous change. If a hot frying pan that has just been removed from the stove is allowed to come into contact with a cooler object, such as cold water in a sink, heat will flow from the hotter object to the cooler one, in this case usually releasing steam. Eventually both objects will reach the same temperature, at a value between the initial temperatures of the two objects. This transfer of heat from a hot object to a cooler one obeys the first law of thermodynamics: energy is conserved.

Now consider the same process in reverse. Suppose that a hot frying pan in a sink of cold water were to become hotter while the water became cooler. As long as the same amount of thermal energy was gained by the frying pan and lost by the water, the first law of thermodynamics would be satisfied. Yet we all know that such a process cannot occur: heat always flows from a hot object to a cold one, never in the reverse direction. That is, *by itself* the magnitude of the heat flow associated with a process does not predict whether the process will occur spontaneously.

For many years, chemists and physicists tried to identify a single measurable quantity that would enable them to predict whether a particular process or reaction would occur spontaneously. Initially, many of them focused on enthalpy changes and hypothesized that an exothermic process would always be spontaneous. But although it is true that many, if not most, spontaneous processes are exothermic, there are also many spontaneous processes that are *not* exothermic. For example, at a pressure of 1 atm, ice melts spontaneously at temperatures greater than 0°C , yet this is an endothermic process because heat is absorbed. Similarly, many salts (such as NH_4NO_3 , NaCl , and KBr) dissolve spontaneously in water even though they absorb heat from the surroundings as they dissolve (i.e., $\Delta H_{\text{soln}} > 0$). Reactions can also be both spontaneous and highly endothermic, like the reaction of barium hydroxide with ammonium thiocyanate shown in [Figure 18.3.1](#)

Figure 18.3.1 An Endothermic Reaction The reaction of barium hydroxide with ammonium thiocyanate is spontaneous but highly endothermic, so when water is placed on a block of wood under the flask, the highly endothermic reaction that takes place in the flask causes the water to freeze. When water is placed on a block of wood under the flask, the highly endothermic reaction that takes place in the flask causes the water to freeze.

Thus enthalpy is not the only factor that determines whether a process is spontaneous. For example, after a cube of sugar has dissolved in a glass of water so that the sucrose molecules are uniformly dispersed in a dilute solution, they never spontaneously come back together in solution to form a sugar cube. Moreover, the molecules of a gas remain evenly distributed throughout the entire volume of a glass bulb and never spontaneously assemble in only one portion of the available volume. To help explain why these phenomena proceed spontaneously in only one direction requires an additional state function called entropy (S), a thermodynamic property of all substances that is proportional to their degree of disorder. In [Chapter 13](#), we introduced the concept of entropy in relation to solution formation. Here we further explore the nature of this state function and define it mathematically.

Entropy

Chemical and physical changes in a system may be accompanied by either an increase or a decrease in the disorder of the system, corresponding to an increase in entropy ($\Delta S > 0$) or a decrease in entropy ($\Delta S < 0$), respectively. As with any other state function, the change in entropy is defined as the difference between the entropies of the final and initial states: $\Delta S = S_f - S_i$.

When a gas expands into a vacuum, its entropy increases because the increased volume allows for greater atomic or molecular disorder. The greater the number of atoms or molecules in the gas, the greater the disorder. The magnitude of the entropy of a system depends on the number of

microscopic states, or *microstates*, associated with it (in this case, the number of atoms or molecules); that is, the greater the number of microstates, the greater the entropy.

We can illustrate the concepts of microstates and entropy using a deck of playing cards, as shown in [Figure 18.3.2](#). In any new deck, the 52 cards are arranged by four suits, with each suit arranged in descending order. If the cards are shuffled, however, there are approximately 10^{68} different ways they might be arranged, which corresponds to 10^{68} different microscopic states. The entropy of an ordered new deck of cards is therefore low, whereas the entropy of a randomly shuffled deck is high. Card games assign a higher value to a hand that has a low degree of disorder. In games such as five-card poker, only 4 of the 2,598,960 different possible hands, or microstates, contain the highly ordered and valued arrangement of cards called a royal flush, almost 1.1 million hands contain one pair, and more than 1.3 million hands are completely disordered and therefore have no value. Because the last two arrangements are far more probable than the first, the value of a poker hand is inversely proportional to its entropy. For example, a new, unshuffled deck of cards has only a single arrangement, so there is only one microstate. In contrast, a randomly shuffled deck can have any one of approximately 10^{68} different arrangements, which correspond to 10^{68} different microstates.

We can see how to calculate these kinds of probabilities for a chemical system by considering the possible arrangements of a sample of four gas molecules in a two-bulb container ([Figure 18.3.2](#)). There are five possible arrangements: all four molecules in the left bulb (I); three molecules in the left bulb and one in the right bulb (II); two molecules in each bulb (III); one molecule in the left bulb and three molecules in the right bulb (IV); and four molecules in the right bulb (V). If we assign a different color to each molecule to keep track of it for this discussion (remember, however, that in reality the molecules are indistinguishable from one another), we can see that there are 16 different ways the four molecules can be distributed in the bulbs, each corresponding to a particular microstate. As shown in [Figure 18.3.2](#), arrangement I is associated with a single microstate, as is arrangement V, so each arrangement has a probability of 1/16. Arrangements II and IV each have a probability of 4/16 because each can exist in four microstates. Similarly, six different microstates can occur as arrangement III, making the probability of this arrangement 6/16. Thus the arrangement that we would expect to encounter, with half the gas molecules in each bulb, is the *most probable* arrangement. The others are not impossible but simply less likely.

Figure 18.3.2 The Possible Microstates for a Sample of Four Gas Molecules in Two Bulbs of Equal Volume There are 16 different ways to distribute four gas molecules between the bulbs, with each distribution corresponding to a particular microstate. Arrangements I and V each produce a single microstate with a probability of 1/16. This particular arrangement is so improbable that it is likely not observed. Arrangements II and IV each produce four microstates, with a probability of 4/16. Arrangement III, with half the gas molecules in each bulb, has a probability of 6/16. It is the one encompassing the most microstates, so it is the most probable.

Instead of four molecules of gas, let's now consider 1 L of an ideal gas at standard temperature and pressure (STP), which contains 2.69×10^{23} molecules (6.022×10^{23} molecules/22.4 L). If we allow the sample of gas to expand into a second 1 L container, the probability of finding all 2.69×10^{23} molecules in one container and none in the other at any given time is extremely small, approximately 2.69×10^{-47} . The probability of such an occurrence is effectively zero. Although nothing prevents the molecules in the gas sample from occupying only one of the two bulbs, that particular arrangement is so improbable that it is never actually observed. The probability of arrangements with essentially equal numbers of molecules in each bulb is quite high, however, because there are *many* equivalent microstates in which the molecules are distributed equally. Hence a macroscopic sample of a gas occupies all of the space available to it, simply because this is the most probable arrangement.

A disordered system has a greater number of possible microstates than does an ordered system, so it has a higher entropy. This is most clearly seen in the entropy changes that accompany phase transitions, such as solid to liquid or liquid to gas. As you know from [Chapter 11](#), [Chapter 12](#), and [Chapter 13](#), a crystalline solid is composed of an ordered array of molecules, ions, or atoms that occupy fixed positions in a lattice, whereas the molecules in a liquid are free to move and tumble within the volume of the liquid; molecules in a gas have even more freedom to move than those in a liquid. Each degree of motion increases the number of available microstates, resulting in a higher entropy. Thus the entropy of a system must increase during melting ($\Delta S_{\text{fus}} > 0$). Similarly, when a liquid is converted to a vapor, the greater freedom of motion of the molecules in the gas phase means that $\Delta S_{\text{vap}} > 0$. Conversely, the reverse processes (condensing a vapor to form a liquid or freezing a liquid to form a solid) must be accompanied by a decrease in the entropy of the system: $\Delta S < 0$.

Note the Pattern

Entropy (S) is a thermodynamic property of all substances that is proportional to their degree of disorder. The greater the number of possible microstates for a system, the greater the disorder and the higher the entropy.

Experiments show that the magnitude of ΔS_{vap} is 80–90 J/(mol·K) for a wide variety of liquids with different boiling points. However, liquids that have highly ordered structures due to hydrogen bonding or other intermolecular interactions tend to have significantly higher values of ΔS_{vap} . For instance, ΔS_{vap} for water is 102 J/(mol·K). Another process that is accompanied by entropy changes is the formation of a solution. As illustrated in Figure 18.3.3, the formation of a liquid solution from a crystalline solid (the solute) and a liquid solvent is expected to result in an increase in the number of available microstates of the system and hence its entropy. Indeed, dissolving a substance such as NaCl in water disrupts both the ordered crystal lattice of NaCl and the ordered hydrogen-bonded structure of water, leading to an increase in the entropy of the system. At the same time, however, each dissolved Na^+ ion becomes hydrated by an ordered arrangement of at least six water molecules, and the Cl^- ions also cause the water to adopt a particular local structure. Both of these effects *increase* the order of the system, leading to a *decrease* in entropy. The overall entropy change for the formation of a solution therefore depends on the relative magnitudes of these opposing factors. In the case of an NaCl solution, disruption of the crystalline NaCl structure and the hydrogen-bonded interactions in water is quantitatively more important, so $\Delta S_{\text{soln}} > 0$.

Figure 18.3.3 The Effect of Solution Formation on Entropy Dissolving NaCl in water results in an increase in the entropy of the system. Each hydrated ion, however, forms an ordered arrangement with water molecules, which decreases the entropy of the system. The magnitude of the increase is greater than the magnitude of the decrease, so the overall entropy change for the formation of an NaCl solution is positive.

Example 18.3.1

Predict which substance in each pair has the higher entropy and justify your answer.

- 1 mol of $\text{NH}_3(\text{g})$ or 1 mol of $\text{He}(\text{g})$, both at 25°C
- 1 mol of $\text{Pb}(\text{s})$ at 25°C or 1 mol of $\text{Pb}(\text{l})$ at 800°C

Given: amounts of substances and temperature

Asked for: higher entropy

Strategy:

From the number of atoms present and the phase of each substance, predict which has the greater number of available microstates and hence the higher entropy.

Solution:

1. Both substances are gases at 25°C , but one consists of He atoms and the other consists of NH_3 molecules. With four atoms instead of one, the NH_3 molecules have more motions available, leading to a greater number of microstates. Hence we predict that the NH_3 sample will have the higher entropy.
2. The nature of the atomic species is the same in both cases, but the phase is different: one sample is a solid, and one is a liquid. Based on the greater freedom of motion available to atoms in a liquid, we predict that the liquid sample will have the higher entropy.

Exercise

Predict which substance in each pair has the higher entropy and justify your answer.

- 1 mol of $\text{He}(\text{g})$ at 10 K and 1 atm pressure or 1 mol of $\text{He}(\text{g})$ at 250°C and 0.2 atm
- a mixture of 3 mol of $\text{H}_2(\text{g})$ and 1 mol of $\text{N}_2(\text{g})$ at 25°C and 1 atm or a sample of 2 mol of $\text{NH}_3(\text{g})$ at 25°C and 1 atm

Answer:

- 1 mol of $\text{He}(\text{g})$ at 250°C and 0.2 atm (higher temperature and lower pressure indicate greater volume and more microstates)
- a mixture of 3 mol of $\text{H}_2(\text{g})$ and 1 mol of $\text{N}_2(\text{g})$ at 25°C and 1 atm (more molecules of gas are present)

Reversible and Irreversible Changes

Changes in entropy (ΔS), together with changes in enthalpy (ΔH), enable us to predict in which direction a chemical or physical change will occur spontaneously. Before discussing how to do so, however, we must understand the difference between a reversible process and an irreversible one. In a reversible process, every intermediate state between the extremes is an equilibrium state, regardless of the direction of the change. In contrast, an irreversible process is one in which the intermediate states are not equilibrium states, so change occurs spontaneously in only one direction. As a result, *a reversible process can change direction at any time, whereas an irreversible process cannot*. When a gas expands reversibly against an external pressure such as a piston, for example, the expansion can be reversed at any time by reversing the motion of the piston; once the gas is compressed, it can be allowed to expand again, and the process can continue indefinitely. In contrast, the expansion of a gas into a vacuum ($P_{\text{ext}} = 0$) is irreversible because the external pressure is measurably less than the internal pressure of the gas. No equilibrium states exist, and the gas expands irreversibly. When gas escapes from a microscopic hole in a balloon into a vacuum, for example, the process is irreversible; the direction of airflow cannot change.

Because work done during the expansion of a gas depends on the opposing external pressure ($w = P_{\text{ext}}\Delta V$), *work done in a reversible process is always equal to or greater than work done in a corresponding irreversible process*: $w_{\text{rev}} \geq w_{\text{irrev}}$. Whether a process is reversible or irreversible, $\Delta E = q + w$. Because E is a state function, the magnitude of ΔE does *not* depend on reversibility and is independent of the path taken. So

$$\Delta E = q_{\text{rev}} + w_{\text{rev}} = q_{\text{irrev}} + w_{\text{irrev}} \quad (18.3.1)$$

Note the Pattern

Work done in a reversible process is always equal to or greater than work done in a corresponding irreversible process: $w_{\text{rev}} \geq w_{\text{irrev}}$.

In other words, ΔE for a process is the same whether that process is carried out in a reversible manner or an irreversible one. We now return to our earlier definition of entropy, using the magnitude of the heat flow for a reversible process (q_{rev}) to define entropy quantitatively.

The Relationship between Internal Energy and Entropy

Because the quantity of heat transferred (q_{rev}) is directly proportional to the absolute temperature of an object (T) ($q_{\text{rev}} \propto T$), the hotter the object, the greater the amount of heat transferred. Moreover, adding heat to a system increases the kinetic energy of the component atoms and molecules and hence their disorder ($\Delta S \propto q_{\text{rev}}$). Combining these relationships for any reversible process,

$$q_{\text{rev}} = T\Delta S \text{ and } \Delta S = \frac{q_{\text{rev}}}{T} \quad (18.3.2)$$

Because the numerator (q_{rev}) is expressed in units of energy (joules), the units of ΔS are joules/kelvin (J/K). Recognizing that the work done in a reversible process at constant pressure is $w_{\text{rev}} = -P\Delta V$, we can express [Equation 18.14](#) as follows:

$$\Delta E = q_{\text{rev}} + w_{\text{rev}} = T\Delta S - P\Delta V \quad (18.3.3)$$

Thus the change in the internal energy of the system is related to the change in entropy, the absolute temperature, and the PV work done.

To illustrate the use of [Equation 18.3.2](#) and [Equation 18.3.3](#), we consider two reversible processes before turning to an irreversible process. When a sample of an ideal gas is allowed to expand reversibly at constant temperature, heat must be added to the gas during expansion to keep its T constant ([Figure 18.3.4](#)). The internal energy of the gas does not change because the temperature of the gas does not change; that is, $\Delta E = 0$ and $q_{\text{rev}} = -w_{\text{rev}}$. During expansion, $\Delta V > 0$, so the gas performs work on its surroundings: $w_{\text{rev}} = -P\Delta V < 0$. According to [Equation 18.3.16](#), this means that q_{rev} must increase during expansion; that is, the gas must absorb heat from the surroundings during expansion, and the surroundings must give up that same amount of heat. The entropy change of the system is therefore $\Delta S_{\text{sys}} = +q_{\text{rev}}/T$, and the entropy change of the surroundings is $\Delta S_{\text{surr}} = -q_{\text{rev}}/T$. The corresponding change in entropy of the universe is then as follows:

$$\Delta S_{\text{univ}} = \Delta S_{\text{sys}} + \Delta S_{\text{surr}} = \frac{q_{\text{rev}}}{T} + \left(-\frac{q_{\text{rev}}}{T}\right) = 0 \quad (18.3.4)$$

Thus no change in ΔS_{univ} has occurred.

Figure 18.3.4 Expansion of Gas at Constant Temperature In the initial state (top), the temperatures of a gas and the surroundings are the same. During the reversible expansion of the gas, heat must be added to the gas to maintain a constant temperature. Thus the internal energy of the gas does not change, but work is performed on the surroundings. In the final state (bottom), the temperature of the surroundings is lower because the gas has absorbed heat from the surroundings during expansion.

Now consider the reversible melting of a sample of ice at 0°C and 1 atm. The enthalpy of fusion of ice is 6.01 kJ/mol, which means that 6.01 kJ of heat are absorbed reversibly from the surroundings when 1 mol of ice melts at 0°C, as illustrated in [Figure 18.11 "Thermograms Showing That Heat Is Absorbed from the Surroundings When Ice Melts at 0°C"](#). The surroundings constitute a sample of low-density carbon foam that is thermally conductive, and the system is the ice cube that has been placed on it. The direction of heat flow along the resulting temperature gradient is indicated with an arrow. From [Equation 18.3.2](#), we see that the entropy of fusion of ice can be written as follows:

$$\Delta S_{fus} = \frac{q_{rev}}{T} = \frac{\Delta H_{fus}}{T} \quad (18.3.5)$$

Figure 18.3.5 Thermograms Showing That Heat Is Absorbed from the Surroundings When Ice Melts at 0°C By convention, a thermogram shows cold regions in blue, warm regions in red, and thermally intermediate regions in green. When an ice cube (the system, dark blue) is placed on the corner of a square sample of low-density carbon foam with very high thermal conductivity, the temperature of the foam is lowered (going from red to green). As the ice melts, a temperature gradient appears, ranging from warm to very cold. An arrow indicates the direction of heat flow from the surroundings (red and green) to the ice cube. The amount of heat lost by the surroundings is the same as the amount gained by the ice, so the entropy of the universe does not change.

In this case, $\Delta S_{fus} = (6.01 \text{ kJ/mol})/(273 \text{ K}) = 22.0 \text{ J/(mol}\cdot\text{K)} = \Delta S_{sys}$. The amount of heat lost by the surroundings is the same as the amount gained by the ice, so $\Delta S_{surr} = q_{rev}/T = -(6.01 \text{ kJ/mol})/(273 \text{ K}) = -22.0 \text{ J/(mol}\cdot\text{K)}$. Once again, we see that the entropy of the universe does not change:

$$\Delta S_{univ} = \Delta S_{sys} + \Delta S_{surr} = 22.0 \text{ J/(mol}\cdot\text{K)} - 22.0 \text{ J/(mol}\cdot\text{K)} = 0$$

In these two examples of reversible processes, the entropy of the universe is unchanged. This is true of all reversible processes and constitutes part of the second law of thermodynamics: *the entropy of the universe remains constant in a reversible process, whereas the entropy of the universe increases in an irreversible (spontaneous) process.*

Note the Pattern

The entropy of the universe increases during a spontaneous process.

As an example of an irreversible process, consider the entropy changes that accompany the spontaneous and irreversible transfer of heat from a hot object to a cold one, as occurs when lava spewed from a volcano flows into cold ocean water. The cold substance, the water, gains heat ($q > 0$), so the change in the entropy of the water can be written as $\Delta S_{\text{cold}} = q/T_{\text{cold}}$. Similarly, the hot substance, the lava, loses heat ($q < 0$), so its entropy change can be written as $\Delta S_{\text{hot}} = -q/T_{\text{hot}}$, where T_{cold} and T_{hot} are the temperatures of the cold and hot substances, respectively. The total entropy change of the universe accompanying this process is therefore

$$\Delta S_{\text{univ}} = \Delta S_{\text{cold}} + \Delta S_{\text{hot}} = \frac{q}{T_{\text{cold}}} + \left(-\frac{q}{T_{\text{hot}}} \right) \quad (18.3.6)$$

The numerators on the right side of Equation 18.19 are the same in magnitude but opposite in sign. Whether ΔS_{univ} is positive or negative depends on the relative magnitudes of the denominators. By definition, $T_{\text{hot}} > T_{\text{cold}}$, so $-q/T_{\text{hot}}$ must be less than q/T_{cold} , and ΔS_{univ} must be positive. As predicted by the second law of thermodynamics, the entropy of the universe increases during this irreversible process. Any process for which ΔS_{univ} is positive is, by definition, a spontaneous one that will occur as written. Conversely, any process for which ΔS_{univ} approaches zero will not occur spontaneously as written but will occur spontaneously in the reverse direction. We see, therefore, that heat is spontaneously transferred from a hot substance, the lava, to a cold substance, the ocean water. In fact, if the lava is hot enough (e.g., if it is molten), so much heat can be transferred that the water is converted to steam (Figure 18.3.6).

Figure 18.3.6 Spontaneous Transfer of Heat from a Hot Substance to a Cold Substance When molten lava flows into cold ocean water, so much heat is spontaneously transferred to the water that steam is produced.

Example 18.3.2

Tin has two allotropes with different structures. Gray tin (α -tin) has a structure similar to that of diamond, whereas white tin (β -tin) is denser, with a unit cell structure that is based on a rectangular prism. At temperatures greater than 13.2°C , white tin is the more stable phase, but below that temperature, it slowly converts reversibly to the less dense, powdery gray phase. This phenomenon plagued Napoleon's army during his ill-fated invasion of Russia in 1812: the buttons on his soldiers' uniforms were made of tin and disintegrated during the Russian winter, adversely affecting the soldiers' health (and morale). The conversion of white tin to gray tin is exothermic, with $\Delta H = -2.1 \text{ kJ/mol}$ at 13.2°C .

1. What is ΔS for this process?
2. Which is the more highly ordered form of tin—white or gray?

Given: ΔH and temperature

Asked for: ΔS and relative degree of order

Strategy:

Use Equation 18.3.1 to calculate the change in entropy for the reversible phase transition. From the calculated value of ΔS , predict which allotrope has the more highly ordered structure.

Solution:

1. We know from Equation 18.3.2 that the entropy change for any reversible process is the heat transferred (in joules) divided by the temperature at which the process occurs. Because the conversion occurs at constant pressure, and ΔH and ΔE are essentially equal for reactions that involve only solids, we can calculate the change in entropy for the reversible phase transition where $q_{\text{rev}} = \Delta H$. Substituting the given values for ΔH and temperature in kelvins (in this case, $T = 13.2^\circ\text{C} = 286.4 \text{ K}$),

$$\Delta S = \frac{q_{rev}}{T} = \frac{(-2.1 \text{ kJ/mol}) (1000 \text{ J/kJ})}{286.4 \text{ K}} = -7.3 \text{ J/(mol} \cdot \text{K)}$$

2. The fact that $\Delta S < 0$ means that entropy decreases when white tin is converted to gray tin. Thus gray tin must be the more highly ordered structure.

Exercise

Elemental sulfur exists in two forms: an orthorhombic form (S_α), which is stable below 95.3°C, and a monoclinic form (S_β), which is stable above 95.3°C. The conversion of orthorhombic sulfur to monoclinic sulfur is endothermic, with $\Delta H = 0.401 \text{ kJ/mol}$ at 1 atm.

1. What is ΔS for this process?
2. Which is the more highly ordered form of sulfur— S_α or S_β ?

Answer:

1. 1.09 J/(mol·K)
2. S_α

Summary

A measure of the disorder of a system is its **entropy (S)**, a state function whose value increases with an increase in the number of available microstates. A **reversible process** is one for which all intermediate states between extremes are equilibrium states; it can change direction at any time. In contrast, an **irreversible process** occurs in one direction only. The change in entropy of the system or the surroundings is the quantity of heat transferred divided by the temperature. The **second law of thermodynamics** states that in a reversible process, the entropy of the universe is constant, whereas in an irreversible process, such as the transfer of heat from a hot object to a cold object, the entropy of the universe increases.

Key Takeaways

- For a given system, the greater the number of microstates, the higher the entropy.
- During a spontaneous process, the entropy of the universe increases.

Key Equation

Entropy change

Equation 18.3.2: $\Delta S = \frac{q_{rev}}{T}$

Conceptual Problems

1. A Russian space vehicle developed a leak, which resulted in an internal pressure drop from 1 atm to 0.85 atm. Is this an example of a reversible expansion? Has work been done?
2. Which member of each pair do you expect to have a higher entropy? Why?
 - a. solid phenol or liquid phenol
 - b. 1-butanol or butane
 - c. cyclohexane or cyclohexanol
 - d. 1 mol of N_2 mixed with 2 mol of O_2 or 2 mol of NO_2
 - e. 1 mol of O_2 or 1 mol of O_3
 - f. 1 mol of propane at 1 atm or 1 mol of propane at 2 atm
3. Determine whether each process is reversible or irreversible.
 - a. ice melting at 0°C
 - b. salt crystallizing from a saline solution
 - c. evaporation of a liquid in equilibrium with its vapor in a sealed flask
 - d. a neutralization reaction
4. Determine whether each process is reversible or irreversible.
 - a. cooking spaghetti
 - b. the reaction between sodium metal and water
 - c. oxygen uptake by hemoglobin

d. evaporation of water at its boiling point

- Explain why increasing the temperature of a gas increases its entropy. What effect does this have on the internal energy of the gas?
- For a series of related compounds, does ΔS_{vap} increase or decrease with an increase in the strength of intermolecular interactions in the liquid state? Why?
- Is the change in the enthalpy of reaction or the change in entropy of reaction more sensitive to changes in temperature? Explain your reasoning.
- Solid potassium chloride has a highly ordered lattice structure. Do you expect ΔS_{soln} to be greater or less than zero? Why? What opposing factors must be considered in making your prediction?
- Aniline ($\text{C}_6\text{H}_5\text{NH}_2$) is an oily liquid at 25°C that darkens on exposure to air and light. It is used in dyeing fabrics and in staining wood black. One gram of aniline dissolves in 28.6 mL of water, but aniline is completely miscible with ethanol. Do you expect ΔS_{soln} in H_2O to be greater than, less than, or equal to ΔS_{soln} in $\text{CH}_3\text{CH}_2\text{OH}$? Why?

Answers

- No, it is irreversible; no work is done because the external pressure is effectively zero.
-
- reversible
 - irreversible
 - reversible
 - irreversible
-
-
-
-
- Water has a highly ordered, hydrogen-bonded structure that must reorganize to accommodate hydrophobic solutes like aniline. In contrast, we expect that aniline will be able to disperse randomly throughout ethanol, which has a significantly less ordered structure. We therefore predict that ΔS_{soln} in ethanol will be more positive than ΔS_{soln} in water.

Numerical Problems

- Liquid nitrogen, which has a boiling point of -195.79°C , is used as a coolant and as a preservative for biological tissues. Is the entropy of nitrogen higher or lower at -200°C than at -190°C ? Explain your answer. Liquid nitrogen freezes to a white solid at -210.00°C , with an enthalpy of fusion of 0.71 kJ/mol . What is its entropy of fusion? Is freezing biological tissue in liquid nitrogen an example of a reversible process or an irreversible process?
- Using the second law of thermodynamics, explain why heat flows from a hot body to a cold body but not from a cold body to a hot body.
- One test of the spontaneity of a reaction is whether the entropy of the universe increases: $\Delta S_{\text{univ}} > 0$. Using an entropic argument, show that the following reaction is spontaneous at 25°C :

$$4\text{Fe(s)} + 3\text{O}_2\text{(g)} \rightarrow 2\text{Fe}_2\text{O}_3\text{(s)}$$
 Why does the entropy of the universe increase in this reaction even though gaseous molecules, which have a high entropy, are consumed?
- Calculate the missing data in the following table.

Compound	ΔH_{fus} (kJ/mol)	ΔS_{fus} [J/(mol·K)]	Melting Point ($^\circ\text{C}$)
acetic acid	11.7		16.6
CH_3CN	8.2	35.9	
CH_4	0.94		-182.5
CH_3OH		18.2	-97.7
formic acid	12.7	45.1	

Based on this table, can you conclude that entropy is related to the nature of functional groups? Explain your reasoning.

- Calculate the missing data in the following table.

Compound	ΔH_{vap} (kJ/mol)	ΔS_{vap} [J/(mol·K)]	Boiling Point ($^\circ\text{C}$)
hexanoic acid	71.1		105.7
hexane	28.9	85.5	
formic acid		60.7	100.8

Compound	ΔH_{vap} (kJ/mol)	ΔS_{vap} [J/(mol·K)]	Boiling Point (°C)
1-hexanol	44.5		157.5

The text states that the magnitude of ΔS_{vap} tends to be similar for a wide variety of compounds. Based on the values in the table, do you agree?

Learning Objective

- To use thermodynamic cycles to calculate changes in entropy.

The atoms, molecules, or ions that compose a chemical system can undergo several types of molecular motion, including translation, rotation, and vibration (Figure 18.4.1). The greater the molecular motion of a system, the greater the number of possible microstates and the higher the entropy. A perfectly ordered system with only a single microstate available to it would have an entropy of zero. The only system that meets this criterion is a perfect crystal at a temperature of absolute zero (0 K), in which each component atom, molecule, or ion is fixed in place within a crystal lattice and exhibits no motion. Such a state of perfect order (or, conversely, zero disorder) corresponds to zero entropy. In practice, absolute zero is an ideal temperature that is unobtainable, and a perfect single crystal is also an ideal that cannot be achieved. Nonetheless, the combination of these two ideals constitutes the basis for the third law of thermodynamics: *the entropy of any perfectly ordered, crystalline substance at absolute zero is zero.*

Figure 18.4.1 Molecular Motions Vibrational, rotational, and translational motions of a carbon dioxide molecule are illustrated here. Only a perfectly ordered, crystalline substance at absolute zero would exhibit no molecular motion and have zero entropy. In practice, this is an unattainable ideal.

The third law of thermodynamics has two important consequences: it defines the *sign* of the entropy of any substance at temperatures above absolute zero as positive, and it provides a fixed reference point that allows us to measure the *absolute entropy* of any substance at any temperature. In practice, chemists determine the absolute entropy of a substance by measuring the molar heat capacity (C_p) as a function of temperature and then plotting the quantity C_p/T versus T . The *area* under the curve between 0 K and any temperature T is the absolute entropy of the substance at T . In contrast, other thermodynamic properties, such as internal energy and enthalpy, can be evaluated in only *relative* terms, not absolute terms. In this section, we examine two different ways to calculate ΔS for a reaction or a physical change. The first, based on the definition of absolute entropy provided by the third law of thermodynamics, uses tabulated values of absolute entropies of substances. The second, based on the fact that entropy is a state function, uses a thermodynamic cycle similar to those we first encountered in [Chapter 9](#).

Calculating ΔS from Standard Molar Entropy Values

One way of calculating ΔS for a reaction is to use tabulated values of the standard molar entropy (S°), which is the entropy of 1 mol of a substance at a standard temperature of 298 K; the units of S° are J/(mol·K). Unlike enthalpy or internal energy, it is possible to

obtain absolute entropy values by measuring the entropy change that occurs between the reference point of 0 K [corresponding to $S = 0 \text{ J}/(\text{mol}\cdot\text{K})$] and 298 K.

As shown in [Table 18.4.1](#), for substances with approximately the same molar mass and number of atoms, S° values fall in the order $S^\circ(\text{gas}) > S^\circ(\text{liquid}) > S^\circ(\text{solid})$. For instance, S° for liquid water is $70.0 \text{ J}/(\text{mol}\cdot\text{K})$, whereas S° for water vapor is $188.8 \text{ J}/(\text{mol}\cdot\text{K})$. Likewise, S° is $260.7 \text{ J}/(\text{mol}\cdot\text{K})$ for gaseous I_2 and $116.1 \text{ J}/(\text{mol}\cdot\text{K})$ for solid I_2 . This order makes qualitative sense based on the kinds and extents of motion available to atoms and molecules in the three phases. The correlation between physical state and absolute entropy is illustrated in [Figure 18.4.2](#), which is a generalized plot of the entropy of a substance versus temperature.

Table 18.4.2 Standard Molar Entropy Values of Selected Substances at 25°C

Substance	$S^\circ \text{ [J}/(\text{mol}\cdot\text{K})]$
Gases	
He	126.2
H_2	130.7
Ne	146.3
Ar	154.8
Kr	164.1
Xe	169.7
H_2O	188.8
N_2	191.6
O_2	205.2
CO_2	213.8
I_2	260.7
Liquids	
H_2O	70.0
CH_3OH	126.8
Br_2	152.2
$\text{CH}_3\text{CH}_2\text{OH}$	160.7
C_6H_6	173.4
CH_3COCl	200.8
C_6H_{12} (cyclohexane)	204.4
C_8H_{18} (isooctane)	329.3
Solids	
C (diamond)	2.4
C (graphite)	5.7
LiF	35.7
SiO_2 (quartz)	41.5
Ca	41.6
Na	51.3
MgF_2	57.2

Substance	S° [J/(mol·K)]
K	64.7
NaCl	72.1
KCl	82.6
I ₂	116.1

Figure 18.4.2 A Generalized Plot of Entropy versus Temperature for a Single Substance Absolute entropy increases steadily with increasing temperature until the melting point is reached, where it jumps suddenly as the substance undergoes a phase change from a highly ordered solid to a disordered liquid (ΔS_{fus}). The entropy again increases steadily with increasing temperature until the boiling point is reached, where it jumps suddenly as the liquid undergoes a phase change to a highly disordered gas (ΔS_{vap}).

A closer examination of [Table 18.4.1](#) also reveals that substances with similar molecular structures tend to have similar S° values. Among crystalline materials, those with the lowest entropies tend to be rigid crystals composed of small atoms linked by strong, highly directional bonds, such as diamond [$S^\circ = 2.4 \text{ J}/(\text{mol}\cdot\text{K})$]. In contrast, graphite, the softer, less rigid allotrope of carbon, has a higher S° [$5.7 \text{ J}/(\text{mol}\cdot\text{K})$] due to more disorder in the crystal. Soft crystalline substances and those with larger atoms tend to have higher entropies because of increased molecular motion and disorder. Similarly, the absolute entropy of a substance tends to increase with increasing molecular complexity because the number of available microstates increases with molecular complexity. For example, compare the S° values for $\text{CH}_3\text{OH}(\text{l})$ and $\text{CH}_3\text{CH}_2\text{OH}(\text{l})$. Finally, substances with strong hydrogen bonds have lower values of S° , which reflects a more ordered structure.

To calculate ΔS° for a chemical reaction from standard molar entropies, we use the familiar “products minus reactants” rule, in which the absolute entropy of each reactant and product is multiplied by its stoichiometric coefficient in the balanced chemical equation. Example 7 illustrates this procedure for the combustion of the liquid hydrocarbon isooctane (C_8H_{18} ; 2,2,4-trimethylpentane).

Example 18.4.1

Use the data in [Table 18.4.1](#) to calculate ΔS° for the reaction of liquid isooctane with $\text{O}_2(\text{g})$ to give $\text{CO}_2(\text{g})$ and $\text{H}_2\text{O}(\text{g})$ at 298 K.

Given: standard molar entropies, reactants, and products

Asked for: ΔS°

Strategy:

Write the balanced chemical equation for the reaction and identify the appropriate quantities in Table 18.4.1. Subtract the sum of the absolute entropies of the reactants from the sum of the absolute entropies of the products, each multiplied by their appropriate stoichiometric coefficients, to obtain ΔS° for the reaction.

Solution:

The balanced chemical equation for the complete combustion of isooctane (C_8H_{18}) is as follows:

We calculate ΔS° for the reaction using the “products minus reactants” rule, where m and n are the stoichiometric coefficients of each product and each reactant:

$$\begin{aligned} \Delta S_{rxn} &= \sum mS_o(\text{products}) - \sum nS_o(\text{reactants}) \\ &= [8S_o(CO_2) + 9S_o(H_2O)] - \left[S_o(C_8H_{18}) + \frac{25}{2}S_o(O_2) \right] \\ &= \left\{ \left[8 \cancel{\text{mol}} CO_2 \times 213.8 \text{ J} / \left(\cancel{\text{mol}} \cdot K \right) \right] + \left[9 \cancel{\text{mol}} H_2O \times 188.8 \text{ J} / \left(\cancel{\text{mol}} \cdot K \right) \right] \right\} \\ &\quad - \left\{ \left[1 \cancel{\text{mol}} C_8H_{18} \times 329.3 \text{ J} / \left(\cancel{\text{mol}} \cdot K \right) \right] + \left[\frac{25}{2} \cancel{\text{mol}} O_2 \times 205.2 \text{ J} / \left(\cancel{\text{mol}} \cdot K \right) \right] \right\} \\ &= (-515.3 \text{ J/K}) \end{aligned}$$

ΔS° is positive, as expected for a combustion reaction in which one large hydrocarbon molecule is converted to many molecules of gaseous products.

Exercise

Use the data in Table 18.4.1 to calculate ΔS° for the reaction of $H_2(g)$ with liquid benzene (C_6H_6) to give cyclohexane (C_6H_{12}).

Answer: -361.1 J/K

Note the Pattern

Entropy increases with softer, less rigid solids, solids that contain larger atoms, and solids with complex molecular structures.

Note the Pattern

ΔS° for a reaction can be calculated from absolute entropy values using the same “products minus reactants” rule used to calculate ΔH° .

Calculating ΔS from Thermodynamic Cycles

We can also calculate a change in entropy using a thermodynamic cycle. As you learned in Chapter 9, the molar heat capacity (C_p) is the amount of heat needed to raise the temperature of 1 mol of a substance by 1°C at constant pressure. Similarly, C_v is the amount of heat needed to raise the temperature of 1 mol of a substance by 1°C at constant volume. The increase in entropy with increasing temperature in Figure 18.4.2 is approximately proportional to the heat capacity of the substance.

Recall that the entropy change (ΔS) is related to heat flow (q_{rev}) by $\Delta S = q_{\text{rev}}/T$. Because $q_{\text{rev}} = nC_p\Delta T$ at constant pressure or $nC_v\Delta T$ at constant volume, where n is the number of moles of substance present, the change in entropy for a substance whose temperature changes from T_1 to T_2 is as follows:

$$\Delta S = \frac{q_{rev}}{T} = nC_p \frac{\Delta T}{T}$$

As you will discover in more advanced math courses than is required here, it can be shown that this is equal to the following:

$$\Delta S = nC_p \ln \frac{T_2}{T_1} \quad (\text{constant pressure}) \quad (18.4.1)$$

Similarly,

$$\Delta S = nC_v \ln \frac{T_2}{T_1} \quad (\text{constant volume}) \quad (18.4.2)$$

Thus we can use a combination of heat capacity measurements (Equation 18.4.1 or Equation 18.4.2) and experimentally measured values of enthalpies of fusion or vaporization if a phase change is involved (Equation 18.3.X) to calculate the entropy change corresponding to a change in the temperature of a sample.

Figure 18.4.3 Two Forms of Elemental Sulfur and a Thermodynamic Cycle Showing the Transition from One to the Other (a) Orthorhombic sulfur (S_α) has a highly ordered structure in which the S₈ rings are stacked in a “crankshaft” arrangement. Monoclinic sulfur (S_β) is also composed of S₈ rings but has a less-ordered structure. (b) At 368.5 K, S_α undergoes a phase transition to S_β. Although ΔS₃ cannot be measured directly, it can be calculated using the values shown in this thermodynamic cycle.

We can use a thermodynamic cycle to calculate the entropy change when the phase change for a substance such as sulfur cannot be measured directly. As noted in the exercise in Example 6, elemental sulfur exists in two forms (part (a) in Figure 18.4.3): an orthorhombic form with a highly ordered structure (S_α) and a less-ordered monoclinic form (S_β). The orthorhombic (α) form is more stable at room temperature but undergoes a phase transition to the monoclinic (β) form at temperatures greater than 95.3°C (368.5 K). The transition from S_α to S_β can be described by the thermodynamic cycle shown in part (b) in Figure 18.4.3, in which liquid sulfur is an intermediate. The change in entropy that accompanies the conversion of liquid sulfur to S_β (−ΔS_{fus(β)} = ΔS₃ in the cycle) cannot be measured directly. Because entropy is a state function, however, ΔS₃ can be calculated from the overall entropy change (ΔS_t) for the S_α–S_β transition, which equals the sum of the ΔS values for the steps in the thermodynamic cycle, using Equation 18.20 and tabulated thermodynamic parameters (the heat capacities of S_α and S_β, ΔH_{fus(α)}, and the melting point of S_α.)

If we know the melting point of S_α (T_m = 115.2°C = 388.4 K) and ΔS_t for the overall phase transition [calculated to be 1.09 J/(mol·K) in the exercise in Example 6], we can calculate ΔS₃ from the values given in part (b) in Figure 18.4.3 where C_{p(α)} = 22.70 J/mol·K and C_{p(β)} = 24.77 J/mol·K (subscripts on ΔS refer to steps in the cycle)

$$\begin{aligned} \Delta S_t &= \Delta S_1 + \Delta S_2 + \Delta S_3 + \Delta S_4 \\ 1.09 \text{ J}/(\text{mol} \cdot \text{K}) &= C_{p(\alpha)} \ln \frac{T_2}{T_1} + \frac{\Delta H_{fus}}{T_m} + \Delta S_3 + C_{p(\beta)} \ln \frac{T_4}{T_3} \\ &= 22.70 \text{ J}/(\text{mol} \cdot \text{K}) \ln \frac{388.4}{368.5} + \frac{1.722 \text{ kJ}/\text{mol}}{388.4 \text{ K}} \times 1000 \text{ J}/\text{kJ} + \Delta S_3 + 24.77 \text{ J}/(\text{mol} \cdot \text{K}) \ln \frac{368.5}{388.4} \\ &= [1.194 \text{ J}/(\text{mol} \cdot \text{K})] + [4.434 \text{ J}/(\text{mol} \cdot \text{K})] + \Delta S_3 + [-1.303 \text{ J}/(\text{mol} \cdot \text{K})] \end{aligned} \quad (18.4.3)$$

Solving for ΔS₃ gives a value of −3.24 J/(mol·K). As expected for the conversion of a less ordered state (a liquid) to a more ordered one (a crystal), ΔS₃ is negative.

Summary

The **third law of thermodynamics** states that the entropy of any perfectly ordered, crystalline substance at absolute zero is zero. At temperatures greater than absolute zero, entropy has a positive value, which allows us to measure the *absolute entropy* of a substance. Measurements of the heat capacity of a substance and the enthalpies of fusion or vaporization can be used to calculate the changes in entropy that accompany a physical change. The entropy of 1 mol of a substance at a standard temperature of 298 K is its **standard molar entropy** (S°). We can use the “products minus reactants” rule to calculate the standard entropy change (ΔS°) for a reaction using tabulated values of S° for the reactants and the products.

Key Takeaway

- Entropy changes can be calculated using the “products minus reactants” rule or from a combination of heat capacity measurements and measured values of enthalpies of fusion or vaporization.

Key Equations

Temperature dependence of entropy at constant pressure

Equation 18.20: $\Delta S = nC_p \ln \frac{T_2}{T_1}$

Temperature dependence of entropy at constant volume

Equation 18.21: $\Delta S = nC_v \ln \frac{T_2}{T_1}$

Conceptual Problems

- Crystalline MgCl_2 has $S^\circ = 89.63 \text{ J}/(\text{mol}\cdot\text{K})$, whereas aqueous MgCl_2 has $S^\circ = -25.1 \text{ J}/(\text{mol}\cdot\text{K})$. Is this consistent with the third law of thermodynamics? Explain your answer.
- Why is it possible to measure absolute entropies but not absolute enthalpies?
- How many microstates are available to a system at absolute zero? How many are available to a substance in its liquid state?
- Substance A has a higher heat capacity than substance B. Do you expect the absolute entropy of substance A to be less than, similar to, or greater than that of substance B? Why? As the two substances are heated, for which substance do you predict the entropy to increase more rapidly?
- Phase transitions must be considered when calculating entropy changes. Why?

Numerical Problems

- What is the final temperature of water when 5.20 g of ice at 0.0°C are added to 250 mL of water in an insulated thermos at 30.0°C ? The value of ΔH_{fus} for water is $6.01 \text{ kJ}/\text{mol}$, and the heat capacity of liquid water is $75.3 \text{ J}/(\text{mol}\cdot^\circ\text{C})$. What is the entropy change for this process?
- Calculate the change in both enthalpy and entropy when a 3.0 g block of ice melts at 0.0°C [$\Delta H_{\text{fus}}(\text{H}_2\text{O}) = 6.01 \text{ kJ}/\text{mol}$]. For the same block of ice, calculate the entropy change for the system when the ice is warmed from 0.0°C to 25°C . The heat capacity of liquid water over this temperature range is $75.3 \text{ J}/(\text{mol}\cdot^\circ\text{C})$.
- Use the data in [Table 18.4.1](#) and [Table T1](#) to calculate ΔS° for each reaction.
 - $\text{H}_2(\text{g}) + 1/2 \text{O}_2(\text{g}) \rightarrow \text{H}_2\text{O}(\text{l})$
 - $\text{CH}_3\text{OH}(\text{l}) + \text{HCl}(\text{g}) \rightarrow \text{CH}_3\text{Cl}(\text{g}) + \text{H}_2\text{O}(\text{l})$
 - $\text{H}_2(\text{g}) + \text{Br}_2(\text{l}) \rightarrow 2\text{HBr}(\text{g})$
 - $\text{Zn}(\text{s}) + 2\text{HCl}(\text{aq}) \rightarrow \text{ZnCl}_2(\text{s}) + \text{H}_2(\text{g})$
- Calculate the entropy change (J/K) when 4.35 g of liquid bromine are heated from 30.0°C to 50.0°C if the molar heat capacity (C_p) of liquid bromine is $75.1 \text{ kJ}/(\text{mol}\cdot\text{K})$.
- Calculate the molar heat capacity (C_p) of titanium tetrachloride if the change in entropy when a 6.00 g sample of $\text{TiCl}_4(\text{l})$ is heated from 25.0°C to 40.0°C is $0.154 \text{ J}/\text{K}$.

6. When a 1.00 g sample of lead is heated from 298.2 K to just below its melting temperature of 600.5 K, the change in entropy is 0.0891 J/K. Determine the molar heat capacity (C_p) of lead over this temperature range.
7. Phosphorus oxychloride (POCl_3) is a chlorinating agent that is frequently used in organic chemistry to replace oxygen with chlorine. Given $\Delta S_{\text{vap}} = 93.08 \text{ J}/(\text{mol}\cdot\text{K})$ and $\Delta H_{\text{vap}} = 35.2 \text{ kJ}/\text{mol}$, does POCl_3 spontaneously convert from a liquid to a gas at 110°C ? Does it spontaneously crystallize at 0.0°C if $\Delta H_{\text{fus}} = 34.3 \text{ kJ}/\text{mol}$ and $\Delta S_{\text{fus}} = 125 \text{ J}/(\text{mol}\cdot\text{K})$? Using the information provided, what is the melting point of POCl_3 ?
8. A useful reagent for the fluorination of alcohols, carboxylic acids, and carbonyl compounds is selenium tetrafluoride (SeF_4). One must be careful when using this compound, however, because it is known to attack glass (such as the glass of a reaction vessel).
 - a. Is SeF_4 a liquid or a gas at 100°C given that $\Delta H_{\text{vap}} = 46.9 \text{ kJ}/\text{mol}$ and $\Delta S_{\text{vap}} = 124 \text{ J}/(\text{mol}\cdot\text{K})$?
 - b. Determine the boiling point of SeF_4 .
 - c. Would you use SeF_4 for a solution reaction at 0°C if $\Delta H_{\text{fus}} = 46 \text{ kJ}/\text{mol}$ and $\Delta S_{\text{fus}} = 178 \text{ J}/(\text{mol}\cdot\text{K})$?

Answers

1. 27.8°C ; 0.85 J.
- 2.
3.
 - a. $-163.3 \text{ J}/\text{K}$
 - b. $-9.1 \text{ J}/\text{K}$
 - c. $114.5 \text{ J}/\text{K}$
 - d. $-173.2 \text{ J}/\text{K}$
- 4.
5. $25.0 \text{ J}/(\text{mol}\cdot\text{K})$
- 6.
7. yes; yes; 274 K
- 8.

Learning Objective

- To understand the relationship between Gibbs free energy and work.

One of the major goals of chemical thermodynamics is to establish criteria for predicting whether a particular reaction or process will occur spontaneously. We have developed one such criterion, the change in entropy of the universe: if $\Delta S_{\text{univ}} > 0$ for a process or a reaction, then the process will occur spontaneously as written. Conversely, if $\Delta S_{\text{univ}} < 0$, a process cannot occur spontaneously; if $\Delta S_{\text{univ}} = 0$, the system is at equilibrium. The sign of ΔS_{univ} is a universally applicable and infallible indicator of the spontaneity of a reaction. Unfortunately, using ΔS_{univ} requires that we calculate ΔS for *both* a system *and* its surroundings. This is not particularly useful for two reasons: we are normally much more interested in the system than in the surroundings, and it is difficult to make quantitative measurements of the surroundings (i.e., the rest of the universe). A criterion of spontaneity that is based solely on the state functions of a *system* would be much more convenient and is provided by a new state function: the Gibbs free energy.

Gibbs Free Energy and the Direction of Spontaneous Reactions

The Gibbs free energy (G), often called simply *free energy*, was named in honor of J. Willard Gibbs (1838–1903), an American physicist who first developed the concept. It is defined in terms of three other state functions with which you are already familiar: enthalpy, temperature, and entropy:

$$G = H - TS \quad (18.5.1)$$

Because it is a combination of state functions, G is also a state function.

J. Willard Gibbs (1839–1903)

Born in Connecticut, Josiah Willard Gibbs attended Yale, as did his father, a professor of sacred literature at Yale, who was involved in the *Amistad* trial. In 1863, Gibbs was awarded the first engineering doctorate granted in the United States. He was appointed professor of mathematical physics at Yale in 1871, the first such professorship in the United States. His series of papers entitled “On the Equilibrium of Heterogeneous Substances” was the foundation of the field of physical chemistry and is considered one of the great achievements of the 19th century. Gibbs, whose work was translated into French by Le Châtelier, lived with his sister and brother-in-law until his death in 1903, shortly before the inauguration of the Nobel Prizes.

The criterion for predicting spontaneity is based on ΔG , the change in G , at constant temperature and pressure. Although very few chemical reactions actually occur under conditions of constant temperature and pressure, most systems can be brought back to the initial temperature and pressure without significantly affecting the value of thermodynamic state functions such as G . At constant temperature and pressure,

$$\Delta G = \Delta H - T\Delta S \quad (18.5.2)$$

where all thermodynamic quantities are those of the *system*. Recall that at constant pressure, $\Delta H = q$, whether a process is reversible or irreversible, and $T\Delta S = q_{\text{rev}}$. Using these expressions, we can reduce Equation 18.5.2 to $\Delta G = q - q_{\text{rev}}$. Thus ΔG is the difference between the heat released during a process (via a reversible or an irreversible path) and the heat released for the same process

occurring in a reversible manner. Under the special condition in which a process occurs reversibly, $q = q_{\text{rev}}$ and $\Delta G = 0$. As we shall soon see, if ΔG is zero, the system is at equilibrium, and there will be no net change.

What about processes for which $\Delta G \neq 0$? To understand how the sign of ΔG for a *system* determines the direction in which change is spontaneous, we can rewrite Equation 18.3.2 (where $q_p = \Delta H$, Equation 18.2.6) as follows:

$$\Delta S_{\text{surr}} = -\frac{\Delta H_{\text{sys}}}{T} \quad (18.5.3)$$

Thus the entropy change of the *surroundings* is related to the enthalpy change of the *system*. We have stated that for a spontaneous reaction, $\Delta S_{\text{univ}} > 0$, so substituting we obtain

$$\begin{aligned} \Delta S_{\text{univ}} &= \Delta S_{\text{sys}} + \Delta S_{\text{surr}} > 0 \\ &= \Delta S_{\text{sys}} - \frac{\Delta H_{\text{sys}}}{T} > 0 \end{aligned} \quad (18.5.4)$$

Multiplying both sides of the inequality by $-T$ reverses the sign of the inequality; rearranging,

$$\Delta H_{\text{sys}} - T\Delta S_{\text{sys}} < 0$$

which is equal to ΔG (Equation 18.23). We can therefore see that for a spontaneous process, $\Delta G < 0$.

The relationship between the entropy change of the *surroundings* and the heat gained or lost by the *system* provides the key connection between the thermodynamic properties of the system and the change in entropy of the universe. The relationship shown in Equation 18.23 allows us to predict spontaneity by focusing exclusively on the thermodynamic properties and temperature of the system. We predict that highly exothermic processes ($\Delta H \ll 0$) that increase the disorder of a *system* ($\Delta S_{\text{sys}} \gg 0$) would therefore occur spontaneously. An example of such a process is the decomposition of ammonium nitrate fertilizer. (This substance destroyed Texas City, Texas, in 1947; see [Section 7.3](#).) Ammonium nitrate was also used to destroy the Murrah Federal Building in Oklahoma City, Oklahoma, in 1995. For a system at constant temperature and pressure, we can summarize the following results:

- If $\Delta G < 0$, the process occurs spontaneously.
- If $\Delta G = 0$, the system is at equilibrium.
- If $\Delta G > 0$, the process is not spontaneous as written but occurs spontaneously in the reverse direction.

To further understand how the various components of ΔG dictate whether a process occurs spontaneously, we now look at a simple and familiar physical change: the conversion of liquid water to water vapor. If this process is carried out at 1 atm and the normal boiling point of 100.00°C (373.15 K), we can calculate ΔG from the experimentally measured value of ΔH_{vap} (40.657 kJ/mol). For vaporizing 1 mol of water, $\Delta H = 40,657$ J, so the process is highly endothermic. From the definition of ΔS (Equation 18.3.2), we know that for 1 mol of water,

$$\Delta S_{\text{vap}} = \frac{\Delta H_{\text{vap}}}{T_b} = \frac{40,657 \text{ J}}{373.15 \text{ K}} = 108.96 \text{ J/K}$$

Hence there is an increase in the disorder of the system. At the normal boiling point of water,

$$\Delta G_{100^\circ\text{C}} = \Delta H_{100^\circ\text{C}} - T\Delta S_{100^\circ\text{C}} = 40,657 \text{ J} - \left[(373.15 \text{ K}) (108.96 \text{ J/K}) \right] = 0$$

The energy required for vaporization offsets the increase in disorder of the system. Thus $\Delta G = 0$, and the liquid and vapor are in equilibrium, as is true of any liquid at its boiling point under standard conditions. (For more information on standard conditions, see [Chapter 11](#).)

Now suppose we were to superheat 1 mol of liquid water to 110°C. The value of ΔG for the vaporization of 1 mol of water at 110°C, assuming that ΔH and ΔS do not change significantly with temperature, becomes

$$\Delta G_{110^\circ\text{C}} = \Delta H - T\Delta S = 40,657 \text{ J} - \left[(383.15 \text{ K}) (108.96 \text{ J/K}) \right] = -1091 \text{ J}$$

At 110°C, $\Delta G < 0$, and vaporization is predicted to occur spontaneously and irreversibly.

We can also calculate ΔG for the vaporization of 1 mol of water at a temperature below its normal boiling point—for example, 90°C—making the same assumptions:

$$\Delta G_{90^\circ\text{C}} = \Delta H - T\Delta S = 40,657 \text{ J} - \left[(363.15 \text{ K}) (108.96 \text{ J/K}) \right] = 1088 \text{ J}$$

At 90°C, $\Delta G > 0$, and water does not spontaneously convert to water vapor. When using all the digits in the calculator display in carrying out our calculations, $\Delta G_{110^\circ\text{C}} = 1090 \text{ J} = -\Delta G_{90^\circ\text{C}}$, as we would predict. (For more information on using a calculator, see Essential Skills 1 in [Chapter 1](#).)

Note the Pattern

$\Delta G = 0$ only if $\Delta H = T\Delta S$.

We can also calculate the temperature at which liquid water is in equilibrium with water vapor. Inserting the values of ΔH and ΔS into the definition of ΔG ([Equation 18.23](#)), setting $\Delta G = 0$, and solving for T ,

$$0 \text{ J} = 40,657 \text{ J} - T(108.96 \text{ J/K})$$

$$T = 373.15 \text{ K}$$

Thus $\Delta G = 0$ at $T = 373.15 \text{ K}$ and 1 atm, which indicates that liquid water and water vapor are in equilibrium; this temperature is called the *normal boiling point* of water. At temperatures greater than 373.15 K, ΔG is negative, and water evaporates spontaneously and irreversibly. Below 373.15 K, ΔG is positive, and water does not evaporate spontaneously. Instead, water vapor at a temperature less than 373.15 K and 1 atm will spontaneously and irreversibly condense to liquid water. Figure 18.5.1 shows how the ΔH and $T\Delta S$ terms vary with temperature for the vaporization of water. When the two lines cross, $\Delta G = 0$, and $\Delta H = T\Delta S$.

Figure 18.5.1 Temperature Dependence of ΔH and $T\Delta S$ for the Vaporization of Water Both ΔH and $T\Delta S$ are temperature dependent, but the lines have opposite slopes and cross at 373.15 K at 1 atm, where $\Delta H = T\Delta S$. Because $\Delta G = \Delta H - T\Delta S$, at this temperature $\Delta G = 0$, indicating that the liquid and vapor phases are in equilibrium. The normal boiling point of water is therefore 373.15 K. Above the normal boiling point, the $T\Delta S$ term is greater than ΔH , making $\Delta G < 0$; hence, liquid water evaporates spontaneously. Below the normal boiling point, the ΔH term is greater than $T\Delta S$, making $\Delta G > 0$. Thus liquid water does not evaporate spontaneously, but water vapor spontaneously condenses to liquid.

A similar situation arises in the conversion of liquid egg white to a solid when an egg is boiled. The major component of egg white is a protein called albumin, which is held in a compact, ordered structure by a large number of hydrogen bonds. Breaking them requires an input of energy ($\Delta H > 0$), which converts the albumin to a highly disordered structure in which the molecules aggregate as a disorganized solid ($\Delta S > 0$). At temperatures greater than 373 K, the $T\Delta S$ term dominates, and $\Delta G < 0$, so the conversion of a raw egg to a hard-boiled egg is an irreversible and spontaneous process above 373 K.

The Relationship between ΔG and Work

In the previous subsection, we learned that the value of ΔG allows us to predict the spontaneity of a physical or a chemical change. In addition, the magnitude of ΔG for a process provides other important information. The change in free energy (ΔG) is equal to the maximum amount of work that a system can perform on the surroundings while undergoing a spontaneous change (at constant temperature and pressure): $\Delta G = w_{\text{max}}$. To see why this is true, let's look again at the relationships among free energy, enthalpy, and entropy expressed in [Equation 18.5.2](#). We can rearrange this equation as follows:

$$\Delta H = \Delta G + T\Delta S \quad (18.5.5)$$

This equation tells us that when energy is released during an exothermic process ($\Delta H < 0$), such as during the combustion of a fuel, some of that energy can be used to do work ($\Delta G < 0$), while some is used to increase the entropy of the universe ($T\Delta S > 0$). Only if the process occurs infinitely slowly in a perfectly reversible manner will the entropy of the universe be unchanged. (For more information on entropy and reversibility, see [Section 18.4](#)) Because no real system is perfectly reversible, the entropy of the universe increases during all processes that produce energy. As a result, no process that uses stored energy can ever be 100% efficient; that is, ΔH will never equal ΔG because ΔS has a positive value.

One of the major challenges facing engineers is to maximize the efficiency of converting stored energy to useful work or converting one form of energy to another. As indicated in [Table 18.5.1](#) the efficiencies of various energy-converting devices vary widely. For example, an internal combustion engine typically uses only 25%–30% of the energy stored in the hydrocarbon fuel to perform work; the rest of the stored energy is released in an unusable form as heat. In contrast, gas–electric hybrid engines, now used in several models of automobiles, deliver approximately 50% greater fuel efficiency. A large electrical generator is highly efficient (approximately 99%) in converting mechanical to electrical energy, but a typical incandescent light bulb is one of the least efficient devices known (only approximately 5% of the electrical energy is converted to light). In contrast, a mammalian liver cell is a relatively efficient machine and can use fuels such as glucose with an efficiency of 30%–50%.

Table 18.5.1 Approximate Thermodynamic Efficiencies of Various Devices

Device	Energy Conversion	Approximate Efficiency (%)
large electrical generator	mechanical → electrical	99
chemical battery	chemical → electrical	90
home furnace	chemical → heat	65
small electric tool	electrical → mechanical	60
space shuttle engine	chemical → mechanical	50
mammalian liver cell	chemical → chemical	30–50
spinach cell	light → chemical	30
internal combustion engine	chemical → mechanical	25–30
fluorescent light	electrical → light	20
solar cell	light → electricity	10
incandescent light bulb	electricity → light	5
yeast cell	chemical → chemical	2–4

Standard Free-Energy Change

We have seen that there is no way to measure absolute enthalpies, although we can measure *changes* in enthalpy (ΔH) during a chemical reaction. Because enthalpy is one of the components of Gibbs free energy, we are consequently unable to measure absolute free energies; we can measure only changes in free energy. The standard free-energy change (ΔG°) is the change in free energy when one substance or a set of substances in their standard states is converted to one or more other substances, also in their standard states. The standard free-energy change can be calculated from the definition of free energy, if the standard enthalpy and entropy changes are known, using Equation 18.5.6:

$$\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ \quad (18.5.6)$$

If ΔS° and ΔH° for a reaction have the same sign, then the sign of ΔG° depends on the relative magnitudes of the ΔH° and $T\Delta S^\circ$ terms. It is important to recognize that a positive value of ΔG° for a reaction does *not* mean that no products will form if the reactants in their standard states are mixed; it means only that at equilibrium the concentrations of the products will be less than the concentrations of the reactants.

Note the Pattern

A positive ΔG° means that the equilibrium constant is less than 1.

Example 18.5.1

Calculate the standard free-energy change (ΔG°) at 25°C for the reaction $\text{H}_2(\text{g}) + \text{O}_2(\text{g}) \rightleftharpoons \text{H}_2\text{O}_2(\text{l})$. At 25°C, the standard enthalpy change (ΔH°) is -187.78 kJ/mol , and the absolute entropies of the products and reactants are $S^\circ(\text{H}_2\text{O}_2) = 109.6 \text{ J/(mol}\cdot\text{K)}$, $S^\circ(\text{O}_2) = 205.2 \text{ J/(mol}\cdot\text{K)}$, and $S^\circ(\text{H}_2) = 130.7 \text{ J/(mol}\cdot\text{K)}$. Is the reaction spontaneous as written?

Given: balanced chemical equation, ΔH° and S° for reactants and products

Asked for: spontaneity of reaction as written

Strategy:

A Calculate ΔS° from the absolute molar entropy values given.

B Use [Equation 18.5.6](#), the calculated value of ΔS° , and other data given to calculate ΔG° for the reaction. Use the value of ΔG° to determine whether the reaction is spontaneous as written.

Solution:

A To calculate ΔG° for the reaction, we need to know ΔH° , ΔS° , and T . We are given ΔH° , and we know that $T = 298.15 \text{ K}$. We can calculate ΔS° from the absolute molar entropy values provided using the “products minus reactants” rule:

$$\begin{aligned}\Delta S^\circ &= S^\circ(\text{H}_2\text{O}_2) - [S^\circ(\text{O}_2) + S^\circ(\text{H}_2)] \\ &= \left[1 \cancel{\text{ mol}} \text{ H}_2\text{O}_2 \times 109.6 \text{ J} / \left(\cancel{\text{ mol}} \cdot \text{K} \right) \right] \\ &\quad - \left\{ \left[1 \cancel{\text{ mol}} \text{ H}_2 \times 130.7 \text{ J} / \left(\cancel{\text{ mol}} \cdot \text{K} \right) \right] + \left[1 \cancel{\text{ mol}} \text{ O}_2 \times 205.27 \text{ J} / \left(\cancel{\text{ mol}} \cdot \text{K} \right) \right] \right\} \\ &= -226.3 \text{ J/K (per mol H}_2\text{O}_2)\end{aligned}$$

As we might expect for a reaction in which 2 mol of gas is converted to 1 mol of a much more ordered liquid, ΔS° is very negative for this reaction.

B Substituting the appropriate quantities into [Equation 18.5.6](#),

$$\begin{aligned}\Delta G^\circ &= \Delta H^\circ - T\Delta S^\circ = -187.78 \text{ kJ/mol} - (298.15 \cancel{\text{ K}}) \left[-226.3 \cancel{\text{ J}} / \left(\cancel{\text{ mol}} \cdot \cancel{\text{ K}} \right) \times 1 \text{ kJ}/1000 \cancel{\text{ J}} \right] \\ &= -187.78 \text{ kJ/mol} + 67.47 \text{ kJ/mol} = -120.31 \text{ kJ/mol}\end{aligned}$$

The negative value of ΔG° indicates that the reaction is spontaneous as written. Because ΔS° and ΔH° for this reaction have the same sign, the sign of ΔG° depends on the relative magnitudes of the ΔH° and $T\Delta S^\circ$ terms. In this particular case, the enthalpy term dominates, indicating that the strength of the bonds formed in the product more than compensates for the unfavorable ΔS° term and for the energy needed to break bonds in the reactants.

Exercise

Calculate the standard free-energy change (ΔG°) at 25°C for the reaction $2\text{H}_2(\text{g}) + \text{N}_2(\text{g}) \rightleftharpoons \text{N}_2\text{H}_4(\text{l})$. At 25°C, the standard enthalpy change (ΔH°) is 50.6 kJ/mol , and the absolute entropies of the products and reactants are $S^\circ(\text{N}_2\text{H}_4) = 121.2 \text{ J/(mol}\cdot\text{K)}$, $S^\circ(\text{N}_2) = 191.6 \text{ J/(mol}\cdot\text{K)}$, and $S^\circ(\text{H}_2) = 130.7 \text{ J/(mol}\cdot\text{K)}$. Is the reaction spontaneous as written?

Answer: 149.5 kJ/mol ; no

Tabulated values of standard free energies of formation allow chemists to calculate the values of ΔG° for a wide variety of chemical reactions rather than having to measure them in the laboratory. The standard free energy of formation (ΔG_f°) of a compound is the change in free energy that occurs when 1 mol of a substance in its standard state is formed from the component elements in their

standard states. By definition, the standard free energy of formation of an element in its standard state is zero at 298.15 K. One mole of Cl_2 gas at 298.15 K, for example, has $\Delta G_f^\circ = 0$. The standard free energy of formation of a compound can be calculated from the standard enthalpy of formation (ΔH_f°) and the standard entropy of formation (ΔS_f°) using the definition of free energy:

$$\Delta G_f^\circ = \Delta H_f^\circ - T\Delta S_f^\circ \quad (18.5.6)$$

Using standard free energies of formation to calculate the standard free energy of a reaction is analogous to calculating standard enthalpy changes from standard enthalpies of formation using the familiar “products minus reactants” rule:

$$\Delta G_{rxn}^\circ = \sum m\Delta G_f^\circ(\text{products}) - \sum n\Delta G_f^\circ(\text{reactants}) \quad (18.5.7)$$

where m and n are the stoichiometric coefficients of each product and reactant in the balanced chemical equation. A very large negative ΔG° indicates a strong tendency for products to form spontaneously from reactants; *it does not, however, necessarily indicate that the reaction will occur rapidly*. To make this determination, we need to evaluate the kinetics of the reaction. (For more information on chemical kinetics, see [Chapter 14](#).)

Note the Pattern

The ΔG° of a reaction can be calculated from tabulated ΔG_f° values using the “products minus reactants” rule.

Example 18.5.2

Calculate ΔG° for the reaction of isooctane with oxygen gas to give carbon dioxide and water (described in Example 7). Use the following data:

$$\Delta G_f^\circ(\text{isooctane}) = -353.2 \text{ kJ/mol}$$

$$\Delta G_f^\circ(\text{CO}_2) = -394.4 \text{ kJ/mol and}$$

$$\Delta G_f^\circ(\text{H}_2\text{O}) = -237.1 \text{ kJ/mol}$$

Is the reaction spontaneous as written?

Given: balanced chemical equation and values of ΔG_f° for isooctane, CO_2 , and H_2O

Asked for: spontaneity of reaction as written

Strategy:

Use the “products minus reactants” rule to obtain ΔG_{rxn}° , remembering that ΔG_f° for an element in its standard state is zero. From the calculated value, determine whether the reaction is spontaneous as written.

Solution:

From Example 7, we know that the balanced chemical equation for the reaction is as follows: $\text{C}_8\text{H}_{18}(\text{l}) + 25/2 \text{O}_2(\text{g}) \rightarrow 8\text{CO}_2(\text{g}) + 9\text{H}_2\text{O}(\text{l})$. We are given ΔG_f° values for all the products and reactants except $\text{O}_2(\text{g})$. Because oxygen gas is an element in its standard state, $\Delta G_f^\circ(\text{O}_2)$ is zero. Using the “products minus reactants” rule,

$$\Delta G^\circ = \left[8\Delta G_f^\circ(\text{CO}_2) + 9\Delta G_f^\circ(\text{H}_2\text{O}) \right] - \left[1\Delta G_f^\circ(\text{C}_8\text{H}_{18}) + \frac{25}{2}\Delta G_f^\circ(\text{O}_2) \right]$$

Because ΔG° is a large negative number, there is a strong tendency for the spontaneous formation of products from reactants (though not necessarily at a rapid rate). Also notice that the magnitude of ΔG° is largely determined by the ΔG_f° of the stable products: water and carbon dioxide.

Exercise

Calculate ΔG° for the reaction of benzene with hydrogen gas to give cyclohexane using the data

$$\Delta G_f^\circ(\text{benzene}) = 124.5 \text{ kJ/mol and}$$

ΔG_f° (cyclohexane) = 217.3 kJ/mol. Is the reaction spontaneous as written?

Answer: 92.8 kJ; no

Calculated values of ΔG° are extremely useful in predicting whether a reaction will occur spontaneously if the reactants and products are mixed under standard conditions. We should note, however, that very few reactions are actually carried out under standard conditions, and calculated values of ΔG° may not tell us whether a given reaction will occur spontaneously under nonstandard conditions. What determines whether a reaction will occur spontaneously is the free-energy change (ΔG) under the actual experimental conditions, which are usually different from ΔG° . If the ΔH and $T\Delta S$ terms for a reaction have the same sign, for example, then it may be possible to reverse the sign of ΔG by changing the temperature, thereby converting a reaction that is not thermodynamically spontaneous, having $K_{eq} < 1$, to one that is, having a $K_{eq} > 1$, or vice versa. Because ΔH and ΔS usually do not vary greatly with temperature in the absence of a phase change, we can use tabulated values of ΔH° and ΔS° to calculate ΔG° at various temperatures, as long as no phase change occurs over the temperature range being considered.

Note the Pattern

In the absence of a phase change, neither ΔH nor ΔS vary greatly with temperature.

Example 18.5.3

Calculate (a) ΔG° and (b) $\Delta G_{300^\circ\text{C}}$ for the reaction $\text{N}_2(\text{g}) + 3\text{H}_2(\text{g}) \rightleftharpoons 2\text{NH}_3(\text{g})$, assuming that ΔH and ΔS do not change between 25°C and 300°C. Use these data:

$$S^\circ(\text{N}_2) = 191.6 \text{ J}/(\text{mol}\cdot\text{K}),$$

$$S^\circ(\text{H}_2) = 130.7 \text{ J}/(\text{mol}\cdot\text{K}),$$

$$S^\circ(\text{NH}_3) = 192.8 \text{ J}/(\text{mol}\cdot\text{K}), \text{ and}$$

$$\Delta H_f^\circ(\text{NH}_3) = -45.9 \text{ kJ}/\text{mol}.$$

Given: balanced chemical equation, temperatures, S° values, and ΔH_f° for NH_3

Asked for: ΔG° and ΔG at 300°C

Strategy:

A Convert each temperature to kelvins. Then calculate ΔS° for the reaction. Calculate ΔH° for the reaction, recalling that ΔH° for any element in its standard state is zero.

B Substitute the appropriate values into Equation 18.26 to obtain ΔG° for the reaction.

C Assuming that ΔH and ΔS are independent of temperature, substitute values into Equation 18.23 to obtain ΔG for the reaction at 300°C.

Solution:

- A** To calculate ΔG° for the reaction using Equation 18.26, we must know the temperature as well as the values of ΔS° and ΔH° . At standard conditions, the temperature is 25°C, or 298 K. We can calculate ΔS° for the reaction from the absolute molar entropy values given for the reactants and the products using the “products minus reactants” rule:

$$\Delta S_{rxn}^\circ = 2S^\circ(\text{NH}_3) - [S^\circ(\text{N}_2) + 3S^\circ(\text{H}_2)]$$

$$= \left[2 \cancel{\text{mol NH}_3} \times 192.8 \text{ J}/(\cancel{\text{mol}} \cdot \text{K}) \right]$$

$$- \left\{ \left[1 \cancel{\text{mol N}_2} \times 191.6 \text{ J}/(\cancel{\text{mol}} \cdot \text{K}) \right] + \left[3 \cancel{\text{mol H}_2} \times 130.7 \text{ J}/(\cancel{\text{mol}} \cdot \text{K}) \right] \right\}$$

$$= -198.1 \text{ J/K (per mole of } N_2)$$

2. We can also calculate ΔH° for the reaction using the “products minus reactants” rule. The value of $\Delta H_f^\circ(\text{NH}_3)$ is given, and ΔH_f° is zero for both N_2 and H_2 :

$$\begin{aligned} 3. \Delta H_{rxn}^\circ &= 2\Delta H_{rxn}^\circ(\text{NH}_3) - [\Delta H_{rxn}^\circ(\text{N}_2) + 3\Delta H_{rxn}^\circ(\text{H}_2)] \\ &= [2 \times (-45.9 \text{ kJ/mol})] - [(1 \times 0 \text{ kJ/mol}) + 3 \times 0 \text{ kJ/mol}] \\ &= -91.8 \text{ kJ (per mol } N_2) \end{aligned}$$

4. **B** Inserting the appropriate values into [Equation 18.5.6](#),

$$\Delta G_{rxn} = \Delta H^\circ - T\Delta S^\circ = -91.8 \text{ kJ} - (298 \text{ K}) \left(-198.1 \text{ J/K} \right) \left(1 \text{ kJ}/1000 \text{ J} \right) = -32.7 \text{ kJ (per mol } N_2)$$

5. **C** To calculate ΔG for this reaction at 300°C , we assume that ΔH and ΔS are independent of temperature (i.e., $\Delta H_{300^\circ\text{C}} = H^\circ$ and $\Delta S_{300^\circ\text{C}} = \Delta S^\circ$) and insert the appropriate temperature (573 K) into [Equation 18.5.3](#):

$$\begin{aligned} \Delta G_{300^\circ\text{C}} &= \Delta H_{300^\circ\text{C}} - (573 \text{ K}) (\Delta S_{300^\circ\text{C}}) = \Delta H^\circ - (573 \text{ K}) (\Delta S^\circ) \\ &= -91.8 \text{ kJ} - 573 \text{ K} \left(-198 \text{ J/K} \right) \left(1 \text{ kJ}/1000 \text{ J} \right) = -21.7 \text{ kJ (per mol } N_2) \end{aligned}$$

In this example, changing the temperature has a major effect on the thermodynamic spontaneity of the reaction. Under standard conditions, the reaction of nitrogen and hydrogen gas to produce ammonia is thermodynamically spontaneous, but in practice, it is too slow to be useful industrially. Increasing the temperature in an attempt to make this reaction occur more rapidly also changes the thermodynamics by causing the $-T\Delta S^\circ$ term to dominate, and the reaction is no longer spontaneous at high temperatures; that is, its K_{eq} is less than one. This is a classic example of the conflict encountered in real systems between thermodynamics and kinetics, which is often unavoidable.

Exercise

Calculate (a) ΔG° and (b) $\Delta G_{750^\circ\text{C}}$ for the reaction $2\text{NO}(\text{g}) + \text{O}_2(\text{g}) \rightleftharpoons 2\text{NO}_2(\text{g})$, which is important in the formation of urban smog. Assume that ΔH and ΔS do not change between 25.0°C and 750°C and use these data:

$$S^\circ(\text{NO}) = 210.8 \text{ J/(mol}\cdot\text{K)},$$

$$S^\circ(\text{O}_2) = 205.2 \text{ J/(mol}\cdot\text{K)},$$

$$S^\circ(\text{NO}_2) = 240.1 \text{ J/(mol}\cdot\text{K)},$$

$$\Delta H_f^\circ(\text{NO}_2) = 33.2 \text{ kJ/mol, and}$$

$$\Delta H_f^\circ(\text{NO}) = 91.3 \text{ kJ/mol.}$$

Answer

1. $-72.5 \text{ kJ/mol of O}_2$
2. $33.8 \text{ kJ/mol of O}_2$

The effect of temperature on the spontaneity of a reaction, which is an important factor in the design of an experiment or an industrial process, depends on the sign and magnitude of both ΔH° and ΔS° . The temperature at which a given reaction is at equilibrium can be calculated by setting $\Delta G^\circ = 0$ in Equation 18.26, as illustrated in Example 11.

Example 18.5.4

As you saw in Example 10, the reaction of nitrogen and hydrogen gas to produce ammonia is one in which ΔH° and ΔS° are both negative. Such reactions are predicted to be thermodynamically spontaneous at low temperatures but nonspontaneous at

high temperatures. Use the data in Example 10 to calculate the temperature at which this reaction changes from spontaneous to nonspontaneous, assuming that ΔH° and ΔS° are independent of temperature.

Given: ΔH° and ΔS°

Asked for: temperature at which reaction changes from spontaneous to nonspontaneous

Strategy:

Set ΔG° equal to zero in Equation 18.26 and solve for T , the temperature at which the reaction becomes nonspontaneous.

Solution:

In Example 10, we calculated that ΔH° is -91.8 kJ/mol of N_2 and ΔS° is -198.1 J/K per mole of N_2 , corresponding to $\Delta G^\circ = -32.7$ kJ/mol of N_2 at 25°C . Thus the reaction is indeed spontaneous at low temperatures, as expected based on the signs of ΔH° and ΔS° . The temperature at which the reaction becomes nonspontaneous is found by setting ΔG° equal to zero and rearranging Equation 18.26 to solve for T :

$$\begin{aligned}\Delta G^\circ &= \Delta H^\circ - T\Delta S^\circ = 0 \\ \Delta H^\circ &= T\Delta S^\circ \\ T &= \frac{\Delta H^\circ}{\Delta S^\circ} = \frac{(-91.8 \text{ kJ}) \left(\frac{1000 \text{ J}}{\text{kJ}} \right)}{-198.1 \text{ J/K}} = 463 \text{ K}\end{aligned}$$

This is a case in which a chemical engineer is severely limited by thermodynamics. Any attempt to increase the rate of reaction of nitrogen with hydrogen by increasing the temperature will cause reactants to be favored over products above 463 K.

Exercise

As you found in the exercise in Example 10, ΔH° and ΔS° are both negative for the reaction of nitric oxide and oxygen to form nitrogen dioxide. Use those data to calculate the temperature at which this reaction changes from spontaneous to nonspontaneous.

Answer: 792.6 K

Summary

We can predict whether a reaction will occur spontaneously by combining the entropy, enthalpy, and temperature of a system in a new state function called **Gibbs free energy** (G). The change in free energy (ΔG) is the difference between the heat released during a process and the heat released for the same process occurring in a reversible manner. If a system is at equilibrium, $\Delta G = 0$. If the process is spontaneous, $\Delta G < 0$. If the process is not spontaneous as written but is spontaneous in the reverse direction, $\Delta G > 0$. At constant temperature and pressure, ΔG is equal to the maximum amount of work a system can perform on its surroundings while undergoing a spontaneous change. The **standard free-energy change** (ΔG°) is the change in free energy when one substance or a set of substances in their standard states is converted to one or more other substances, also in their standard states. The **standard free energy of formation** (ΔG°_f), is the change in free energy that occurs when 1 mol of a substance in its standard state is formed from the component elements in their standard states. Tabulated values of standard free energies of formation are used to calculate ΔG° for a reaction.

Key Takeaway

- The change in Gibbs free energy, which is based solely on changes in state functions, is the criterion for predicting the spontaneity of a reaction.

Key Equations

Free-energy change

Equation 18.5.2: $\Delta G = \Delta H - T\Delta S$

Standard free-energy change

Equation 18.5.5: $\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ$

Conceptual Problems

- How does each example illustrate the fact that no process is 100% efficient?
 - burning a log to stay warm
 - the respiration of glucose to provide energy
 - burning a candle to provide light
- Neither the change in enthalpy nor the change in entropy is, by itself, sufficient to determine whether a reaction will occur spontaneously. Why?
- If a system is at equilibrium, what must be the relationship between ΔH and ΔS ?
- The equilibrium $2AB \rightleftharpoons A_2B_2$ is exothermic in the forward direction. Which has the higher entropy—the products or the reactants? Why? Which is favored at high temperatures?
- Is ΔG a state function that describes a system or its surroundings? Do its components— ΔH and ΔS —describe a system or its surroundings?
- How can you use ΔG to determine the temperature of a phase transition, such as the boiling point of a liquid or the melting point of a solid?
- Occasionally, an inventor claims to have invented a “perpetual motion” machine, which requires no additional input of energy once the machine has been put into motion. Using your knowledge of thermodynamics, how would you respond to such a claim? Justify your arguments.
- Must the entropy of the universe increase in a spontaneous process? If not, why is no process 100% efficient?
- The reaction of methyl chloride with water produces methanol and hydrogen chloride gas at room temperature, despite the fact that $\Delta H_f^\circ = 7.3$ kcal/mol. Using thermodynamic arguments, propose an explanation as to why methanol forms.

Answer

-
-
-
-
-
-
-
-
- In order for the reaction to occur spontaneously, ΔG for the reaction must be less than zero. In this case, ΔS must be positive, and the $T\Delta S$ term outweighs the positive value of ΔH .

Numerical Problems

- Use the tables in the text to determine whether each reaction is spontaneous under standard conditions. If a reaction is not spontaneous, write the corresponding spontaneous reaction.
 - $H_2(g) + 1/2 O_2(g) \rightarrow H_2O(l)$
 - $2H_2(g) + C_2H_2(g) \rightarrow C_2H_6(g)$
 - $(CH_3)_2O(g) + H_2O(g) \rightarrow 2CH_3OH(l)$
 - $CH_4(g) + H_2O(g) \rightarrow CO(g) + 3H_2(g)$
- Use the tables in the text to determine whether each reaction is spontaneous under standard conditions. If a reaction is not spontaneous, write the corresponding spontaneous reaction.
 - $K_2O_2(s) \rightarrow 2K(s) + O_2(g)$

- b. $\text{PbCO}_3(\text{s}) \rightarrow \text{PbO}(\text{s}) + \text{CO}_2(\text{g})$
 c. $\text{P}_4(\text{s}) + 6\text{H}_2(\text{g}) \rightarrow 4\text{PH}_3(\text{g})$
 d. $2\text{AgCl}(\text{s}) + \text{H}_2\text{S}(\text{g}) \rightarrow \text{Ag}_2\text{S}(\text{s}) + 2\text{HCl}(\text{g})$

3. Nitrogen fixation is the process by which nitrogen in the atmosphere is reduced to NH_3 for use by organisms. Several reactions are associated with this process; three are listed in the following table. Which of these are spontaneous at 25°C ? If a reaction is not spontaneous, at what temperature does it become spontaneous?

Reaction	ΔH°_{298} (kcal/mol)	S°_{298} [cal/(mol-K)]		
(a) $1/2 \text{N}_2 + \text{O}_2 \rightarrow 2\text{NO}_2$	8.0	-14.4		
(b) $1/2 \text{N}_2 + 1/2 \text{O}_2 \rightarrow \text{NO}$	21.6	2.9		
(c) $1/2 \text{N}_2 + 3/2 \text{H}_2 \rightarrow 2\text{NH}_3$	-11.0	-23.7		

4. A student was asked to propose three reactions for the oxidation of carbon or a carbon compound to CO or CO_2 . The reactions are listed in the following table. Are any of these reactions spontaneous at 25°C ? If a reaction does not occur spontaneously at 25°C , at what temperature does it become spontaneous?

Reaction	$\Delta H^\circ_{\text{rxn}}$ (kcal/mol)	S° [cal/(mol-K)]
$\text{C}(\text{s}) + \text{H}_2\text{O}(\text{g}) \rightarrow \text{CO}(\text{g}) + \text{H}_2(\text{g})$	42	32
$\text{CO}(\text{g}) + \text{H}_2\text{O}(\text{g}) \rightarrow \text{CO}_2(\text{g}) + \text{H}_2(\text{g})$	-9.8	-10.1
$\text{CH}_4(\text{g}) + \text{H}_2\text{O}(\text{g}) \rightarrow \text{CO}(\text{g}) + 3\text{H}_2(\text{g})$	49.3	51.3

5. Tungsten trioxide (WO_3) is a dense yellow powder that, because of its bright color, is used as a pigment in oil paints and water colors (although cadmium yellow is more commonly used in artists' paints). Tungsten metal can be isolated by the reaction of WO_3 with H_2 at 1100°C according to the equation $\text{WO}_3(\text{s}) + 3\text{H}_2(\text{g}) \rightarrow \text{W}(\text{s}) + 3\text{H}_2\text{O}(\text{g})$. What is the lowest temperature at which the reaction occurs spontaneously? $\Delta H^\circ = 27.4 \text{ kJ/mol}$ and $\Delta S^\circ = 29.8 \text{ J/K}$.

6. Sulfur trioxide (SO_3) is produced in large quantities in the industrial synthesis of sulfuric acid. Sulfur dioxide is converted to sulfur trioxide by reaction with oxygen gas.

- Write a balanced chemical equation for the reaction of SO_2 with $\text{O}_2(\text{g})$ and determine its ΔG° .
- What is the value of the equilibrium constant at 600°C ?
- If you had to rely on the equilibrium concentrations alone, would you obtain a higher yield of product at 400°C or at 600°C ?

7. Calculate ΔG° for the general reaction $\text{MCO}_3(\text{s}) \rightarrow \text{MO}(\text{s}) + \text{CO}_2(\text{g})$ at 25°C , where M is Mg or Ba. At what temperature does each of these reactions become spontaneous?

Compound	ΔH_f° (kJ/mol)	S° [J/(mol-K)]
MCO₃		
Mg	-1111	65.85
Ba	-1213.0	112.1
MO		
Mg	-601.6	27.0
Ba	-548.0	72.1
CO₂	-393.5	213.8

8. The reaction of aqueous solutions of barium nitrate with sodium iodide is described by the following equation:

You want to determine the absolute entropy of BaI_2 , but that information is not listed in your tables. However, you have been able to obtain the following information:

	$\text{Ba}(\text{NO}_3)_2$	NaI	BaI_2	NaNO_3
ΔH° (kJ/mol)	-952.36	-295.31	-605.4	-447.5
S° [J/(mol·K)]	302.5	170.3		205.4

You know that ΔG° for the reaction at 25°C is 22.64 kJ/mol. What is ΔH° for this reaction? What is S° for BaI_2 ?

Answers

- 237.1 kJ/mol; spontaneous as written
 - 241.9 kJ/mol; spontaneous as written
 - 8.0 kJ/mol; spontaneous in reverse direction.
 - 141.9 kJ/mol; spontaneous in reverse direction.
-
- Not spontaneous at any T
 - Not spontaneous at 25°C ; spontaneous above 7400 K
 - Spontaneous at 25°C
-
- 919 K
-
- MgCO_3 : $\Delta G^\circ = 63$ kJ/mol, spontaneous above 663 K; BaCO_3 : $\Delta G^\circ = 220$ kJ/mol, spontaneous above 1562 K

Learning Objective

- To know the relationship between free energy and the equilibrium constant.

We have identified three criteria for whether a given reaction will occur spontaneously: $\Delta S_{\text{univ}} > 0$, $\Delta G_{\text{sys}} < 0$, and the relative magnitude of the reaction quotient Q versus the equilibrium constant K . (For more information on the reaction quotient and the equilibrium constant, see Chapter 15.) Recall that if $Q < K$, then the reaction proceeds spontaneously to the right as written, resulting in the net conversion of reactants to products. Conversely, if $Q > K$, then the reaction proceeds spontaneously to the left as written, resulting in the net conversion of products to reactants. If $Q = K$, then the system is at equilibrium, and no net reaction occurs. Table 18.6.1 summarizes these criteria and their relative values for spontaneous, nonspontaneous, and equilibrium processes. Because all three criteria are assessing the same thing—the spontaneity of the process—it would be most surprising indeed if they were not related. The relationship between ΔS_{univ} and ΔG_{sys} was described in Section 18.5. In this section, we explore the relationship between the standard free energy of reaction (ΔG°) and the equilibrium constant (K).

Table 18.6.1 Criteria for the Spontaneity of a Process as Written

Spontaneous	Equilibrium	Nonspontaneous*
$\Delta S_{\text{univ}} > 0$	$\Delta S_{\text{univ}} = 0$	$\Delta S_{\text{univ}} < 0$
$\Delta G_{\text{sys}} < 0$	$\Delta G_{\text{sys}} = 0$	$\Delta G_{\text{sys}} > 0$
$Q < K$	$Q = K$	$Q > K$

*Spontaneous in the reverse direction.

Free Energy and the Equilibrium Constant

Because ΔH° and ΔS° determine the magnitude of ΔG° (Equation 18.5.5), and because K is a measure of the ratio of the concentrations of products to the concentrations of reactants, we should be able to express K in terms of ΔG° and vice versa. As you learned in Section 18.5, ΔG is equal to the maximum amount of work a system can perform on its surroundings while undergoing a spontaneous change. For a reversible process that does not involve external work, we can express the change in free energy in terms of volume, pressure, entropy, and temperature, thereby eliminating ΔH from the equation for ΔG . Using higher math, the general relationship can be shown as follows:

$$\Delta G = V\Delta P - S\Delta T \quad (18.6.1)$$

If a reaction is carried out at constant temperature ($\Delta T = 0$), then Equation 18.29 simplifies to

$$\Delta G = V\Delta P \quad (18.6.2)$$

Under normal conditions, the pressure dependence of free energy is not important for solids and liquids because of their small molar volumes. For reactions that involve gases, however, the effect of pressure on free energy is very important. What Equation 18.6.2 tells us is how the free energy changes as the pressure changes at constant temperature.

Assuming ideal gas behavior, we can replace the V in Equation 18.6.2 by nRT/P (where n is the number of moles of gas and R is the ideal gas constant) and express ΔG in terms of the initial and final pressures (P_i and P_f , respectively) as in Equation 18.4.1.

$$\Delta G = \left(\frac{nRT}{P} \right) \Delta P = nRT \frac{\Delta P}{P} = nRT \ln \left(\frac{P_f}{P_i} \right) \quad (18.6.4)$$

To actually show the final step one has to consider infinitesimal changes in both the free energy and the pressure and then integrate both sides of the equation using calculus, which is beyond the scope of this course. If the initial state is the standard state with $P_i = 1$ atm, then the change in free energy of a substance when going from the standard state to any other state with a pressure P can be written as follows:

$$G - G^\circ = nRT \ln P$$

This can be rearranged as follows:

$$G = G^\circ + nRT \ln P \quad (18.6.5)$$

As you will soon discover, Equation 18.6.5 allows us to relate ΔG° and K_p . Any relationship that is true for K_p must also be true for K because K_p and K are simply different ways of expressing the equilibrium constant using different units.

Let's consider the following hypothetical reaction, in which all the reactants and the products are ideal gases and the lowercase letters correspond to the stoichiometric coefficients for the various species:

Because the free-energy change for a reaction is the difference between the sum of the free energies of the products and the reactants, we can write the following expression for ΔG :

$$\Delta G = \sum mG_{\text{products}} - \sum mG_{\text{reactants}} = (cG_C + dG_D) - (aG_A + bG_B) \quad (18.6.7)$$

Substituting Equation 18.6.5 for each term into Equation 18.6.7,

$$\Delta G = [(cG_C + cRT \ln P_C) + (dG_D + dRT \ln P_D)] - [(aG_A + aRT \ln P_A) + (bG_B + bRT \ln P_B)]$$

Combining terms gives the following relationship between ΔG and the reaction quotient Q :

$$\Delta G = \Delta G^\circ + RT \ln \left(\frac{P_C^c P_D^d}{P_A^a P_B^b} \right) = \Delta G^\circ + RT \ln Q \quad (18.6.8)$$

where ΔG° indicates that all reactants and products are in their standard states. In Chapter 15 "Chemical Equilibrium", you learned that for gases $Q = K_p$ at equilibrium, and as you've learned in this chapter, $\Delta G = 0$ for a system at equilibrium. Therefore, we can describe the relationship between ΔG° and K_p for gases as follows:

$$\begin{aligned} 0 &= \Delta G^\circ + RT \ln K_p \\ \Delta G^\circ &= -RT \ln K_p \end{aligned} \quad (18.6.9)$$

If the products and reactants are in their standard states and $\Delta G^\circ < 0$, then $K_p > 1$, and products are favored over reactants. Conversely, if $\Delta G^\circ > 0$, then $K_p < 1$, and reactants are favored over products. If $\Delta G^\circ = 0$, then $K_p = 1$, and neither reactants nor products are favored: the system is at equilibrium.

Note the Pattern

For a spontaneous process under standard conditions, K_{eq} and K_p are greater than 1.

Example 18.6.1

In Example 18.5.3, we calculated that $\Delta G^\circ = -32.7$ kJ/mol of N_2 for the reaction $\text{N}_2(\text{g}) + 3\text{H}_2(\text{g}) \rightleftharpoons 2\text{NH}_3(\text{g})$. This calculation was for the reaction under standard conditions—that is, with all gases present at a partial pressure of 1 atm and a temperature of 25°C. Calculate ΔG for the same reaction under the following nonstandard conditions: $P(\text{N}_2) = 2.00$ atm, $P(\text{H}_2) = 7.00$ atm, $P(\text{NH}_3) = 0.021$ atm, and $T = 100^\circ\text{C}$. Does the reaction favor products or reactants?

Given: balanced chemical equation, partial pressure of each species, temperature, and ΔG°

Asked for: whether products or reactants are favored

Strategy:

A Using the values given and Equation 18.6.8, calculate Q .

B Substitute the values of ΔG° and Q into Equation 18.6.8 to obtain ΔG for the reaction under nonstandard conditions.

Solution:

A The relationship between ΔG° and ΔG under nonstandard conditions is given in Equation 18.6.8. Substituting the partial pressures given, we can calculate Q :

$$Q = \frac{P_{NH_3}^2}{P_{N_2} P_{H_2}^3} = \frac{(0.021)^2}{(2.00)(7.00)^3} = 6.4 \times 10^{-7}$$

B Substituting the values of ΔG° and Q into Equation 18.6.8,

$$\begin{aligned} \Delta G &= \Delta G^\circ + RT \ln Q = -32.7 \text{ kJ} + \left[(8.314 \text{ J/K}) (373 \text{ K}) (1 \text{ kJ}/1000 \text{ J}) \ln (6.4 \times 10^{-7}) \right] \\ &= -32.7 \text{ kJ} + (-44 \text{ kJ}) = -77 \text{ kJ/mol } N_2 \end{aligned}$$

Because $\Delta G < 0$ and $Q < 1.0$, the reaction is spontaneous to the right as written, so products are favored over reactants.

Exercise

Calculate ΔG for the reaction of nitric oxide with oxygen to give nitrogen dioxide under these conditions: $T = 50^\circ\text{C}$, $P(\text{NO}) = 0.0100 \text{ atm}$, $P(\text{O}_2) = 0.200 \text{ atm}$, and $P(\text{NO}_2) = 1.00 \times 10^{-4} \text{ atm}$. The value of ΔG° for this reaction is -72.5 kJ/mol of O_2 . Are products or reactants favored?

Answer: -92.9 kJ/mol of O_2 ; the reaction is spontaneous to the right as written, so products are favored.

Example 18.6.2

Calculate K_p for the reaction of H_2 with N_2 to give NH_3 at 25°C . As calculated in Example 18.5.3, ΔG° for this reaction is -32.7 kJ/mol of N_2 .

Given: balanced chemical equation from Example 10, ΔG° , and temperature

Asked for: K_p

Strategy:

Substitute values for ΔG° and T (in kelvins) into Equation 18.6.9 to calculate K_p , the equilibrium constant for the formation of ammonia.

Solution:

In Example 18.5.3, we used tabulated values of ΔG° to calculate ΔG° for this reaction (-32.7 kJ/mol of N_2). For equilibrium conditions, rearranging Equation 18.6.9,

$$\begin{aligned} \Delta G^\circ &= -RT \ln K_P \\ \frac{-\Delta G^\circ}{RT} &= \ln K_P \end{aligned}$$

Inserting the value of ΔG° and the temperature ($25^\circ\text{C} = 298 \text{ K}$) into this equation,

$$\ln K_P = - \frac{(-32.7 \text{ kJ}) (1000 \text{ J/kJ})}{8.314 \text{ J/K} (298 \text{ K})} = 13.2$$

$$K_P = 5.4 \times 10^5$$

Thus the equilibrium constant for the formation of ammonia at room temperature is favorable. As we saw in [Chapter 15](#), however, the *rate* at which the reaction occurs at room temperature is too slow to be useful.

Exercise

Calculate K_p for the reaction of NO with O_2 to give NO_2 at 25°C . As calculated in the exercise in Example 10, ΔG° for this reaction is -70.5 kJ/mol of O_2 .

Answer: 2.2×10^{12}

Although K_p is defined in terms of the partial pressures of the reactants and the products, the equilibrium constant K is defined in terms of the concentrations of the reactants and the products. We described the relationship between the numerical magnitude of K_p and K in [Chapter 15](#) and showed that they are related:

$$K_P = K(RT)^{\Delta n} \quad (18.6.10)$$

where Δn is the number of moles of gaseous product minus the number of moles of gaseous reactant. For reactions that involve only solutions, liquids, and solids, $\Delta n = 0$, so $K_p = K$. For all reactions that do not involve a change in the number of moles of gas present, the relationship in [Equation 18.36](#) can be written in a more general form:

$$\Delta G^\circ = -RT \ln K \quad (18.6.11)$$

Only when a reaction results in a net production or consumption of gases is it necessary to correct [Equation 18.38](#) for the difference between K_p and K . Although we typically use concentrations or pressures in our equilibrium calculations, recall that equilibrium constants are generally expressed as unitless numbers because of the use of activities or fugacities in precise thermodynamic work. Systems that contain gases at high pressures or concentrated solutions that deviate substantially from ideal behavior require the use of fugacities or activities, respectively.

Combining [Equation 18.26](#) and [Equation 18.6.11](#) provides insight into how the components of ΔG° influence the magnitude of the equilibrium constant:

$$\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ = -RT \ln K \quad (18.6.12)$$

Notice that K becomes larger as ΔS° becomes more positive, indicating that the magnitude of the equilibrium constant is directly influenced by the tendency of a system to move toward maximum disorder. Moreover, K increases as ΔH° decreases. Thus the magnitude of the equilibrium constant is also directly influenced by the tendency of a system to seek the lowest energy state possible.

Note the Pattern

The magnitude of the equilibrium constant is directly influenced by the tendency of a system to move toward maximum disorder and seek the lowest energy state possible.

Temperature Dependence of the Equilibrium Constant

The fact that ΔG° and K are related provides us with another explanation of why equilibrium constants are temperature dependent. This relationship is shown explicitly in [Equation 18.6.12](#), which can be rearranged as follows:

$$\ln K = \frac{\Delta H^\circ}{RT} + \frac{\Delta S^\circ}{R} \quad (18.6.13)$$

Assuming ΔH° and ΔS° are temperature independent, for an exothermic reaction ($\Delta H^\circ < 0$), the magnitude of K decreases with increasing temperature, whereas for an endothermic reaction ($\Delta H^\circ > 0$), the magnitude of K increases with increasing temperature. The quantitative relationship expressed in [Equation 18.6.13](#) agrees with the qualitative predictions made by applying Le Châtelier's principle, which we discussed in [Chapter 15](#). Because heat is produced in an exothermic reaction, adding heat (by increasing the temperature) will shift the equilibrium to the left, favoring the reactants and decreasing the magnitude of K . Conversely, because heat is consumed in an endothermic reaction, adding heat will shift the equilibrium to the right, favoring the products and increasing the magnitude of K . [Equation 18.6.13](#) also shows that the *magnitude* of ΔH° dictates how rapidly K changes as a function of temperature. In contrast, the magnitude and sign of ΔS° affect the magnitude of K but not its temperature dependence.

If we know the value of K at a given temperature and the value of ΔH° for a reaction, we can estimate the value of K at any other temperature, even in the absence of information on ΔS° . Suppose, for example, that K_1 and K_2 are the equilibrium constants for a reaction at temperatures T_1 and T_2 , respectively. Applying [Equation 18.6.13](#) gives the following relationship at each temperature:

$$\ln K_1 = \frac{\Delta H^\circ}{RT_1} + \frac{\Delta S^\circ}{R}$$

$$\ln K_2 = \frac{\Delta H^\circ}{RT_2} + \frac{\Delta S^\circ}{R}$$

Subtracting $\ln K_1$ from $\ln K_2$,

$$\ln K_2 - \ln K_1 = \ln \frac{K_2}{K_1} = \frac{\Delta H^\circ}{R} \left(\frac{1}{T_2} - \frac{1}{T_1} \right) \quad (18.6.13)$$

Thus calculating ΔH° from tabulated enthalpies of formation and measuring the equilibrium constant at one temperature (K_1) allow us to calculate the value of the equilibrium constant at any other temperature (K_2), assuming that ΔH° and ΔS° are independent of temperature.

Example 18.6.3

The equilibrium constant for the formation of NH_3 from H_2 and N_2 at 25°C was calculated to be $K_p = 5.4 \times 10^5$ in [Example 13](#). What is K_p at 500°C ? (Use the data from [Example 10](#).)

Given: balanced chemical equation, ΔH° , initial and final T , and K_p at 25°C

Asked for: K_p at 500°C

Strategy:

Convert the initial and final temperatures to kelvins. Then substitute appropriate values into [Equation 18.41](#) to obtain K_2 , the equilibrium constant at the final temperature.

Solution:

The value of ΔH° for the reaction obtained using Hess's law is -91.8 kJ/mol of N_2 . If we set $T_1 = 25^\circ\text{C} = 298.\text{K}$ and $T_2 = 500^\circ\text{C} = 773 \text{ K}$, then from [Equation 18.6.13](#) we obtain the following:

$$= \frac{(-91.8 \text{ kJ}) (1000 \text{ J/kJ})}{8.314 \text{ J/K}} \left(\frac{1}{298 \text{ K}} - \frac{1}{773 \text{ K}} \right) = -22.8$$

$$\frac{K_2}{K_1} = 1.3 \pm \times 10^{-10}$$

$$K_2 = (5.4 \times 10^5) (1.3 \pm \times 10^{-10}) = 7.0 \times 10^{-5}$$

Thus at 500°C , the equilibrium strongly favors the reactants over the products.

Exercise

In the exercise in [Example 13](#), you calculated $K_p = 2.2 \times 10^{12}$ for the reaction of NO with O_2 to give NO_2 at 25°C . Use the ΔH_f° values in the exercise in [Example 10](#) to calculate K_p for this reaction at 1000°C .

Answer: 5.6×10^{-7}

Summary

For a reversible process that does not involve external work, we can express the change in free energy in terms of volume, pressure, entropy, and temperature. If we assume ideal gas behavior, the ideal gas law allows us to express ΔG in terms of the partial pressures of the reactants and products, which gives us a relationship between ΔG and K_p , the equilibrium constant of a reaction involving gases, or K , the equilibrium constant expressed in terms of concentrations. If $\Delta G^\circ < 0$, then K or $K_p > 1$, and products are favored over reactants. If $\Delta G^\circ > 0$, then K or $K_p < 1$, and reactants are favored over products. If $\Delta G^\circ = 0$, then K or $K_p = 1$, and the system is at equilibrium. We can use the measured equilibrium constant K at one temperature and ΔH° to estimate the equilibrium constant for a reaction at any other temperature.

Key Takeaway

- The change in free energy of a reaction can be expressed in terms of the standard free-energy change and the equilibrium constant K or K_p and indicates whether a reaction will occur spontaneously under a given set of conditions.

Key Equations

Relationship between standard free-energy change and equilibrium constant

Equation 18.6.9: $\Delta G^\circ = -RT \ln K$

Temperature dependence of equilibrium constant

Equation 18.6.11: $\ln K = \frac{-\Delta H^\circ}{RT} + \frac{-\Delta S^\circ}{R}$

Calculation of K at second temperature

Equation 18.6.11: $\ln \frac{K_2}{K_1} = \frac{-\Delta H^\circ}{R} \left(\frac{1}{T_2} - \frac{1}{T_1} \right)$

Conceptual Problems

- Do you expect products or reactants to dominate at equilibrium in a reaction for which ΔG° is equal to
 - 1.4 kJ/mol?
 - 105 kJ/mol?
 - 34 kJ/mol?
- The change in free energy enables us to determine whether a reaction will proceed spontaneously. How is this related to the extent to which a reaction proceeds?
- What happens to the change in free energy of the reaction $\text{N}_2(\text{g}) + 3\text{F}_2(\text{g}) \rightarrow 2\text{NF}_3(\text{g})$ if the pressure is increased while the temperature remains constant? if the temperature is increased at constant pressure? Why are these effects not so important for reactions that involve liquids and solids?
- Compare the expressions for the relationship between the change in free energy of a reaction and its equilibrium constant where the reactants are gases versus liquids. What are the differences between these expressions?

Numerical Problems

- Carbon monoxide, a toxic product from the incomplete combustion of fossil fuels, reacts with water to form CO_2 and H_2 , as shown in the equation $\text{CO}(\text{g}) + \text{H}_2\text{O}(\text{g}) \rightleftharpoons \text{CO}_2(\text{g}) + \text{H}_2(\text{g})$, for which $\Delta H^\circ = -41.0 \text{ kJ/mol}$ and $\Delta S^\circ = -42.3 \text{ J cal}/(\text{mol}\cdot\text{K})$ at

25°C and 1 atm.

- a. What is ΔG° for this reaction?
 - b. What is ΔG if the gases have the following partial pressures: $P(\text{CO}) = 1.3 \text{ atm}$, $P(\text{H}_2\text{O}) = 0.8 \text{ atm}$, $P(\text{CO}_2) = 2.0 \text{ atm}$, and $P(\text{H}_2) = 1.3 \text{ atm}$?
 - c. What is ΔG if the temperature is increased to 150°C assuming no change in pressure?
2. Methane and water react to form carbon monoxide and hydrogen according to the equation $\text{CH}_4(\text{g}) + \text{H}_2\text{O}(\text{g}) \rightleftharpoons \text{CO}(\text{g}) + 3\text{H}_2(\text{g})$
- a. What is the standard free energy change for this reaction?
 - b. What is K_p for this reaction?
 - c. What is the carbon monoxide pressure if 1.3 atm of methane reacts with 0.8 atm of water, producing 1.8 atm of hydrogen gas?
 - d. What is the hydrogen gas pressure if 2.0 atm of methane is allowed to react with 1.1 atm of water?
 - e. At what temperature does the reaction become spontaneous?
3. Calculate the equilibrium constant at 25°C for each equilibrium reaction and comment on the extent of the reaction.
- a. $\text{CCl}_4(\text{g}) + 6 \text{H}_2\text{O}(\text{l}) \rightleftharpoons \text{CO}_2(\text{g}) + 4\text{HCl}(\text{aq})$; $\Delta G^\circ = -377 \text{ kJ/mol}$
 - b. $\text{Xe}(\text{g}) + 2\text{F}_2(\text{g}) \rightleftharpoons \text{XeF}_4(\text{s})$; $\Delta H^\circ = -66.3 \text{ kJ/mol}$, $\Delta S^\circ = -102.3 \text{ J/(mol}\cdot\text{K)}$
 - c. $\text{PCl}_3(\text{g}) + \text{S} \rightleftharpoons \text{PSCl}_3(\text{l})$; $\Delta G_f^\circ(\text{PCl}_3) = -272.4 \text{ kJ/mol}$, $\Delta G_f^\circ(\text{PSCl}_3) = -363.2 \text{ kJ/mol}$
4. Calculate the equilibrium constant at 25°C for each equilibrium reaction and comment on the extent of the reaction.
- a. $2\text{KClO}_3(\text{s}) \rightleftharpoons 2\text{KCl}(\text{s}) + 3\text{O}_2(\text{g})$; $\Delta G^\circ = -225.8 \text{ kJ/mol}$
 - b. $\text{CoCl}_2(\text{s}) + 6 \text{H}_2\text{O}(\text{l}) \rightleftharpoons 6\text{CoCl}_2 \cdot 6 \text{H}_2\text{O}(\text{s})$; $\Delta H_{rxn}^\circ = -352 \text{ kJ/mol}$, $\Delta S_{rxn}^\circ = -899 \text{ J/(mol}\cdot\text{K)}$
 - c. $\text{PCl}_3(\text{g}) + \text{O}_2(\text{g}) \rightleftharpoons 2\text{POCl}_3(\text{g})$; $\Delta G_f^\circ(\text{PCl}_3) = -272.4 \text{ kJ/mol}$, $\Delta G_f^\circ(\text{POCl}_3) = -558.5 \text{ kJ/mol}$
5. The gas-phase decomposition of N_2O_4 to NO_2 is an equilibrium reaction with $K_p = 4.66 \times 10^{-4}$. Calculate the standard free-energy change for the equilibrium reaction between N_2O_4 and NO_2 .
6. The standard free-energy change for the dissolution $\text{K}_4\text{Fe}(\text{CN})_6 \cdot \text{H}_2\text{O}(\text{s}) \rightleftharpoons 4\text{K}^+(\text{aq}) + \text{Fe}(\text{CN})_6^{4-}(\text{aq}) + \text{H}_2\text{O}(\text{l})$ is 26.1 kJ/mol. What is the equilibrium constant for this process at 25°C?
7. Ammonia reacts with water in liquid ammonia solution (am) according to the equation $\text{NH}_3(\text{g}) + \text{H}_2\text{O}(\text{am}) \rightleftharpoons \text{NH}_4^+(\text{am}) + \text{OH}^-(\text{am})$. The change in enthalpy for this reaction is 21 kJ/mol, and $\Delta S^\circ = -303 \text{ J/(mol}\cdot\text{K)}$. What is the equilibrium constant for the reaction at the boiling point of liquid ammonia (-31°C)?
8. At 25°C, a saturated solution of barium carbonate is found to have a concentration of $[\text{Ba}^{2+}] = [\text{CO}_3^{2-}] = 5.08 \times 10^{-5} \text{ M}$. Determine ΔG° for the dissolution of BaCO_3 .
9. Lead phosphates are believed to play a major role in controlling the overall solubility of lead in acidic soils. One of the dissolution reactions is $\text{Pb}_3(\text{PO}_4)_2(\text{s}) + 4\text{H}^+(\text{aq}) \rightleftharpoons 3\text{Pb}^{2+}(\text{aq}) + 2\text{H}_2\text{PO}_4^-(\text{aq})$ for which $\log K = -1.80$. What is ΔG° for this reaction?
10. The conversion of butane to 2-methylpropane is an equilibrium process with $\Delta H^\circ = -2.05 \text{ kcal/mol}$ and $\Delta G^\circ = -0.89 \text{ kcal/mol}$.
- a. What is the change in entropy for this conversion?
 - b. Based on structural arguments, are the sign and magnitude of the entropy change what you would expect? Why?
 - c. What is the equilibrium constant for this reaction?
11. The reaction of $\text{CaCO}_3(\text{s})$ to produce $\text{CaO}(\text{s})$ and $\text{CO}_2(\text{g})$ has an equilibrium constant at 25°C of 2×10^{-23} . Values of ΔH_f° are as follows: CaCO_3 , -1207.6 kJ/mol; CaO , -634.9 kJ/mol; and CO_2 , -393.5 kJ/mol.
- a. What is ΔG° for this reaction?
 - b. What is the equilibrium constant at 900°C?
 - c. What is the partial pressure of $\text{CO}_2(\text{g})$ in equilibrium with CaO and CaCO_3 at this temperature?
 - d. Are reactants or products favored at the lower temperature? at the higher temperature?
12. In acidic soils, dissolved Al^{3+} undergoes a complex formation reaction with SO_4^{2-} to form $[\text{AlSO}_4]^+$. The equilibrium constant at 25°C for the reaction $\text{Al}^{3+}(\text{aq}) + \text{SO}_4^{2-}(\text{aq}) \rightleftharpoons \text{AlSO}_4^+(\text{aq})$ is 1585.
- a. What is ΔG° for this reaction?
 - b. How does this value compare with ΔG° for the reaction $\text{Al}^{3+}(\text{aq}) + \text{F}^-(\text{aq}) \rightleftharpoons \text{AlF}^{2+}(\text{aq})$ for which $K = 10^7$ at 25°C?
 - c. Which is the better ligand to use to trap Al^{3+} from the soil?

Answers

1. a. -28.4 kJ/mol
b. -26.1 kJ/mol
c. -19.9 kJ/mol
- 2.
3. a. 1.21×10^6 ; equilibrium lies far to the right.
b. 1.89×10^{16} ; equilibrium lies to the right.
c. 5.28×10^6 ; equilibrium lies far to the right.
- 4.
5. 13.3 kJ/mol
- 6.
7. 5.1×10^{-21}
- 8.
9. 10.3 kJ/mol
- 10.
11. a. 129.5 kJ/mol
b. 6
c. 6.0 atm
d. Products are favored at high T ; reactants are favored at low T .
- 12.

Learning Objective

- To understand the differences between the information that thermodynamics and kinetics provide about a system.

Because thermodynamics deals with state functions, it can be used to describe the overall properties, behavior, and equilibrium composition of a system. It is *not* concerned with the particular pathway by which physical or chemical changes occur, however, so it cannot address the *rate* at which a particular process will occur. Although thermodynamics provides a significant constraint on what *can* occur during a reaction process, it does not describe the detailed steps of what *actually* occurs on an atomic or a molecular level.

Note the Pattern

Thermodynamics focuses on the energetics of the products and the reactants, whereas kinetics focuses on the pathway from reactants to products.

Table 18.7.1 gives the numerical values of the equilibrium constant (K) that correspond to various approximate values of ΔG° . Note that $\Delta G^\circ \geq +10$ kJ/mol or $\Delta G^\circ \leq -10$ kJ/mol ensures that an equilibrium lies essentially all the way to the left or to the right, respectively, under standard conditions, corresponding to a reactant-to-product ratio of approximately 10,000:1 (or vice versa). Only if ΔG° is quite small (± 10 kJ/mol) are significant amounts of both products and reactants present at equilibrium. Most reactions that we encounter have equilibrium constants substantially greater or less than 1, with the equilibrium strongly favoring either products or reactants. In many cases, we will encounter reactions that are strongly favored by thermodynamics but do not occur at a measurable rate. In contrast, we may encounter reactions that are not thermodynamically favored under standard conditions but nonetheless do occur under certain nonstandard conditions.

Table 18.7.1 The Relationship between K and ΔG° at 25°C

ΔG° (kJ/mol)	K	Physical Significance
500	3×10^{-88}	For all intents and purposes, the reaction does not proceed in the forward direction: only reactants are present at equilibrium.
100	3×10^{-18}	
10	2×10^{-2}	Both forward and reverse reactions occur: significant amounts of both products and reactants are present at equilibrium.
0	1	
-10	60	For all intents and purposes, the forward reaction proceeds to completion: only products are present at equilibrium.
-100	3×10^{17}	
-500	4×10^{87}	

A typical challenge in industrial processes is a reaction that has a large negative value of ΔG° and hence a large value of K but that is too slow to be practically useful. In such cases, mixing the reactants results in only a physical mixture, not a chemical reaction. An example is the reaction of carbon tetrachloride with water to produce carbon dioxide and hydrochloric acid, for which ΔG° is -232 kJ/mol:

The value of K for this reaction is 5×10^{40} at 25°C , yet when CCl_4 and water are shaken vigorously at 25°C , nothing happens: the two immiscible liquids form separate layers, with the denser CCl_4 on the bottom. In comparison, the analogous reaction of SiCl_4 with water to give SiO_2 and HCl , which has a similarly large equilibrium constant, occurs almost explosively. Although the two reactions have comparable thermodynamics, they have very different kinetics!

There are also many reactions for which $\Delta G^\circ \ll 0$ but that do not occur as written because another possible reaction occurs more rapidly. For example, consider the reaction of lead sulfide with hydrogen peroxide. One possible reaction is as follows:

for which ΔG° is -886 kJ/mol and K is 10^{161} . Yet when lead sulfide is mixed with hydrogen peroxide, the ensuing vigorous reaction does *not* produce PbO_2 and SO_2 . Instead, the reaction that actually occurs is as follows:

This reaction has a ΔG° value of -1181 kJ/mol, within the same order of magnitude as the reaction in [Equation 18.7.2](#), but it occurs much more rapidly.

Now consider reactions with $\Delta G^\circ > 0$. Thermodynamically, such reactions do not occur spontaneously under standard conditions. Nonetheless, these reactions can be made to occur under nonstandard conditions. An example is the reduction of chromium(III) chloride by hydrogen gas:

At 25°C , $\Delta G^\circ = 35$ kJ/mol and $K_p = 7 \times 10^{-7}$. However, at 730°C , $\Delta G^\circ = -52$ kJ/mol and $K_p = 5 \times 10^2$; at this elevated temperature, the reaction is a convenient way of preparing chromium(II) chloride in the laboratory. Moreover, removing HCl gas from the system drives the reaction to completion, as predicted by Le Châtelier's principle. Although the reaction is not thermodynamically spontaneous under standard conditions, it becomes spontaneous under nonstandard conditions.

There are also cases in which a compound whose formation appears to be thermodynamically prohibited can be prepared using a different reaction. The reaction for the preparation of chlorine monoxide from its component elements, for example, is as follows:

for which ΔG_f° is 97.9 kJ/mol. The large positive value of ΔG_f° for this reaction indicates that mixtures of chlorine and oxygen do not react to any extent to form Cl_2O . Nonetheless, Cl_2O is easily prepared using the reaction

which has a ΔG° of -22.2 kJ/mol and a K_p of approximately 1×10^4 .

Finally, the ΔG° values for some reactions are so positive that the only way to make them proceed in the desired direction is to supply external energy, often in the form of electricity. Consider, for example, the formation of metallic lithium from molten lithium chloride:

Even at 1000°C , ΔG is very positive (324 kJ/mol), and there is no obvious way to obtain lithium metal using a different reaction. Hence in the industrial preparation of metallic lithium, electrical energy is used to drive the reaction to the right, as described in [Chapter 19](#).

Note the Pattern

A reaction that does not occur under standard conditions can be made to occur under nonstandard conditions, such as by driving the reaction to completion using Le Châtelier's principle or by providing external energy.

Often reactions that are not thermodynamically spontaneous under standard conditions can be made to occur spontaneously if coupled, or connected, in some way to another reaction for which $\Delta G^\circ \ll 0$. Because the overall value of ΔG° for a series of reactions is the sum of the ΔG° values for the individual reactions, virtually any unfavorable reaction can be made to occur by chemically coupling it to a sufficiently favorable reaction or reactions. In the preparation of chlorine monoxide from mercuric oxide and chlorine (Equation 18.7.6), we have already encountered one example of this phenomenon of *coupled reactions*, although we did not describe it as such at the time. We can see how the chemical coupling works if we write Equation 18.7.6 as the sum of three separate reactions:

Comparing the ΔG° values for the three reactions shows that reaction 3 is so energetically favorable that it more than compensates for the other two energetically unfavorable reactions. Hence the overall reaction is indeed thermodynamically spontaneous as written.

Note the Pattern

By coupling reactions, a reaction that is thermodynamically nonspontaneous can be made spontaneous.

Example 18.7.2

Bronze Age metallurgists were accomplished practical chemists who unknowingly used coupled reactions to obtain metals from their ores. Realizing that different ores of the same metal required different treatments, they heated copper oxide ore in the presence of charcoal (carbon) to obtain copper metal, whereas they pumped air into the reaction system if the ore was copper sulfide. Assume that a particular copper ore consists of pure cuprous oxide (Cu_2O). Using the ΔG_f° values given for each, calculate

- ΔG° and K_p for the decomposition of Cu_2O to metallic copper and oxygen gas
 $\Delta G_f^\circ(Cu_2O) = -146.0 \text{ kJ/mol}$
- ΔG° and K_p for the reaction of Cu_2O with carbon to produce metallic copper and carbon monoxide
 $\Delta G_f^\circ(CO) = -137.2 \text{ kJ/mol}$

Given: reactants and products ΔG_f° and K_p values for Cu_2O and CO , and temperature

Asked for: ΔG° and K_p for the formation of metallic copper from Cu_2O in the absence and presence of carbon

Strategy:

A Write the balanced equilibrium equation for each reaction. Using the "products minus reactants" rule, calculate ΔG° for the reaction.

B Substitute appropriate values into [Equation 18.6.9](#) to obtain K_p .

Solution:

1. **A** The chemical equation for the decomposition of cuprous oxide is as follows:

The substances on the right side of this equation are pure elements in their standard states, so their ΔG_f° values are zero. ΔG° for the reaction is therefore

$$\begin{aligned} \Delta G^\circ &= \left[2\Delta G_f^\circ(\text{Cu}) + \frac{1}{2}\Delta G_f^\circ(\text{O}_2) \right] - \Delta G_f^\circ(\text{Cu}_2\text{O}) \\ &= \left[(2 \text{ mol}) (0 \text{ kJ/mol}) + \left(\frac{1}{2} \text{ mol} \right) (0 \text{ kJ/mol}) \right] - (1 \text{ mol}) (-146.0 \text{ kJ/mol}) \\ &= 146 \text{ kJ} \end{aligned}$$

2. **B** Rearranging and substituting the appropriate values into [Equation 18.6.9](#),

$$\ln K_p = -\frac{\Delta G^\circ}{RT} = -\frac{146.0 \text{ kJ} \left(\frac{1000 \text{ J}}{\text{kJ}} \right)}{(8.314 \text{ J/K}) (298.15 \text{ K})} = -58.90$$

3. $K_p = 2.6 \times 10^{-26}$

This is a very small number, indicating that Cu_2O does not spontaneously decompose to a significant extent at room temperature.

4. **A** The O_2 produced in the decomposition of Cu_2O can react with carbon to form CO :

Because ΔG° for this reaction is equal to $<\Delta G_f^\circ$ for CO (-137.2 kJ/mol), it is energetically more feasible to produce metallic copper from cuprous oxide by coupling the two reactions:

B We can find the corresponding value of K_p :

$$\ln K_p = -\frac{\Delta G^\circ}{RT} = -\frac{8.8 \text{ kJ} \left(\frac{1000 \text{ J}}{\text{kJ}} \right)}{(8.314 \text{ J/K}) (298.15 \text{ K})} = -3.6$$

$$K_p = -0.03$$

Although this value is still less than 1, indicating that reactants are favored over products at room temperature, it is about 24 orders of magnitude greater than K_p for the production of copper metal in the absence of carbon. Because both ΔH° and ΔS° are positive for this reaction, it becomes thermodynamically feasible at slightly elevated temperatures (greater than about 80°C). At temperatures of a few hundred degrees Celsius, the reaction occurs spontaneously, proceeding smoothly and rapidly to the right as written and producing metallic copper and carbon monoxide from cuprous oxide and carbon.

Exercise

Use the ΔG_f° values given to calculate ΔG° and K_p for each reaction.

1. the decomposition of cuprous sulfide to copper metal and elemental sulfur
 $\Delta G_f^\circ(\text{Cu}_2\text{S}) = -86.2 \text{ kJ/mol}$
2. the reaction of cuprous sulfide with oxygen gas to produce sulfur dioxide and copper metal
 $\Delta G_f^\circ(\text{SO}_2(\text{g})) = -300.1 \text{ kJ/mol}$

Answer:

1. $\Delta G^\circ = 86.2 \text{ kJ/mol}$; $K_p = 7.90 \times 10^{-16}$
2. $\Delta G^\circ = -213.9 \text{ kJ/mol}$; $K_p = 2.99 \times 10^{37}$

Summary

Thermodynamics describes the overall properties, behavior, and equilibrium composition of a system; kinetics describes the rate at which a particular process will occur and the pathway by which it will occur. Whereas thermodynamics tells us what can occur during a reaction process, kinetics tells us what actually occurs on an atomic or a molecular level. A reaction that is not thermodynamically spontaneous under standard conditions can often be made to occur spontaneously by varying the reaction conditions; using a different reaction to obtain the same product; supplying external energy, such as electricity; or coupling the unfavorable reaction to another reaction for which $\Delta G^\circ \ll 0$.

Key Takeaway

- Thermodynamics describes the overall properties, behavior, and equilibrium composition of a system, whereas kinetics describes the particular pathway by which a physical or a chemical change actually occurs.

Conceptual Problem

1. You are in charge of finding conditions to make the reaction $\text{A}(\text{l}) + \text{B}(\text{l}) \rightarrow \text{C}(\text{l}) + \text{D}(\text{g})$ favorable because it is a critical step in the synthesis of your company's key product. You have calculated that ΔG° for the reaction is negative, yet the ratio of products to reactants is very small. What have you overlooked in your scheme? What can you do to drive the reaction to increase your product yield?

Learning Objective

- To understand the importance of thermodynamics in biochemical systems.

In a thermodynamic sense, a living cell can be viewed as a low-entropy system that is *not* in equilibrium with its surroundings and is capable of replicating itself. A constant input of energy is needed to maintain the cell's highly organized structure, its wide array of precisely folded biomolecules, and its intricate system of thousands of chemical reactions. A cell also needs energy to synthesize complex molecules from simple precursors (e.g., to make proteins from amino acids), create and maintain differences in the concentrations of various substances inside and outside the cell, and do mechanical work (e.g., muscle contraction). In this section, we examine the nature of the energy flow between a cell and its environment as well as some of the chemical strategies cells use to extract energy from their surroundings and store that energy.

Energy Flow between a Cell and Its Surroundings

One implication of the first and second laws of thermodynamics is that any closed system must eventually reach equilibrium. With no external input, a clock will run down, a battery will lose its charge, and a mixture of an aqueous acid and an aqueous base will achieve a uniform intermediate pH value. In contrast, a cell is an open system that can exchange matter with its surroundings as well as absorb energy from its environment in the form of heat or light. Cells use the energy obtained in these ways to maintain the nonequilibrium state that is essential for life.

Because cells are open systems, they cannot be described using the concepts of classical thermodynamics that we have discussed in this chapter, which have focused on reversible processes occurring in closed chemical systems that can exchange energy—but not matter—with their surroundings. Consequently, a relatively new subdiscipline called *nonequilibrium thermodynamics* has been developed to quantitatively describe open systems such as living cells.

Because a cell cannot violate the second law of thermodynamics, the only way it can maintain a low-entropy, nonequilibrium state characterized by a high degree of structural organization is to increase the entropy of its surroundings. A cell releases some of the energy that it obtains from its environment as heat that is transferred to its surroundings, thereby resulting in an increase in S_{Surr} (Figure 18.8.1). As long as ΔS_{Surr} is positive and greater than ΔS_{sys} , the entropy of the universe increases, so the second law of thermodynamics is not violated. Releasing heat to the surroundings is necessary but not sufficient for life: the release of energy must be coupled to processes that increase the degree of order within a cell. For example, a wood fire releases heat to its surroundings, but unless energy from the burning wood is also used to do work, there is no increase in order of any portion of the universe.

Figure 18.8.1 Life and Entropy A living cell is in a low-entropy, nonequilibrium state characterized by a high degree of structural organization. To maintain this state, a cell must release some of the energy it obtains from its environment as heat, thereby increasing S_{surr} sufficiently that the second law of thermodynamics is not violated. In this example, the cell combines smaller components into larger, more ordered structures; the accompanying release of heat increases the entropy of the surrounding environment so that $S_{\text{univ}} > 0$.

Note the Pattern

Any organism in equilibrium with its environment is dead.

Extracting Energy from the Environment

Although organisms employ a wide range of specific strategies to obtain the energy they need to live and reproduce, they can generally be divided into two categories: organisms are either *phototrophs* (from the Greek *photos*, meaning “light,” and *trophos*, meaning “feeder”), whose energy source is sunlight, or *chemotrophs*, whose energy source is chemical compounds, usually obtained by consuming or breaking down other organisms. Phototrophs, such as plants, algae, and photosynthetic bacteria, use the radiant energy of the sun directly, converting water and carbon dioxide to energy-rich organic compounds, whereas chemotrophs, such as animals, fungi, and many nonphotosynthetic bacteria, obtain energy-rich organic compounds from their environment. Regardless of the nature of their energy and carbon sources, all organisms use oxidation–reduction, or redox, reactions to drive the synthesis of complex biomolecules. Organisms that can use only O_2 as the oxidant (a group that includes most animals) are *aerobic organisms* that cannot survive in the absence of O_2 . Many organisms that use other oxidants (such as SO_4^{2-} , NO_3^- , or CO_3^{2-}) or oxidized organic compounds can live only in the absence of O_2 , which is a deadly poison for them; such species are called *anaerobic organisms*.

The fundamental reaction by which all green plants and algae obtain energy from sunlight is photosynthesis, the photochemical reduction of CO_2 to a carbon compound such as glucose. Concurrently, oxygen in water is oxidized to O_2 (recall that $h\nu$ is energy from light):

This reaction is not a spontaneous process as written, so energy from sunlight is used to drive the reaction. Photosynthesis is critical to life on Earth; it produces all the oxygen in our atmosphere.

In many ways, chemotrophs are more diverse than phototrophs because the nature of both the reductant (the nutrient) and the oxidant can vary. The most familiar chemotrophic strategy uses compounds such as glucose as the reductant and molecular oxygen as the oxidant in a process called respiration. The overall reaction of respiration is the reverse of photosynthesis:

An alternative strategy uses fermentation reactions, in which an organic compound is simultaneously oxidized and reduced. Common examples are alcohol fermentation, used in making wine, beer, and bread, and lactic acid fermentation, used in making yogurt:

In these reactions, some of the carbon atoms of glucose are oxidized, while others are reduced. Recall that a reaction in which a single species is both oxidized and reduced is called a *disproportionation* reaction.

The Role of NADH and ATP in Metabolism

Regardless of the identity of the substances from which an organism obtains energy, the energy must be released in very small increments if it is to be useful to the cell. Otherwise, the temperature of the cell would rise to lethal levels. Cells store part of the energy that is released as ATP (adenosine triphosphate), a compound that is the universal energy currency of all living organisms (Figure 18.8.2).

Figure 18.8.2 ATP, the Universal Energy Currency of All Cells The ATP molecule contains a nitrogen-containing base, a sugar, and three phosphate groups, as well as two high-energy phosphoric acid anhydride bonds.

Most organisms use several intermediate species to shuttle electrons between the terminal reductant (such as glucose) and the terminal oxidant (such as O_2). In virtually all cases, an intermediate species oxidizes the energy-rich reduced compound, and the now-reduced intermediate then migrates to another site where it is oxidized. The most important of these electron-carrying intermediates is NAD^+ (nicotinamide adenine dinucleotide; Figure 18.19 "NAD"), whose reduced form, formally containing H , is NADH (reduced nicotinamide adenine dinucleotide). The reduction of NAD^+ to NADH can be written as follows:

Figure 18.8.3 NAD⁺ and Its Reduced Form (NADH) This electron carrier is used by biological systems to transfer electrons from one species to another. The oxidized form (NAD^+) is reduced to NADH by energy-rich nutrients such as glucose, and the reduced form (NADH), is then oxidized to NAD^+ by O_2 during respiration.

Most organisms use NAD^+ to oxidize energy-rich nutrients such as glucose to CO_2 and water; NADH is then oxidized to NAD^+ using an oxidant such as O_2 . During oxidation, a fraction of the energy obtained from the oxidation of the nutrient is stored as ATP. The phosphoric acid anhydride bonds in ATP can then be hydrolyzed by water, releasing energy and forming ADP (adenosine diphosphate). It is through this sequence of reactions that energy from the oxidation of nutrients is made available to cells. Thus

ATP has a central role in metabolism: it is synthesized by the oxidation of nutrients, and its energy is then used by cells to drive synthetic reactions and perform work (Figure 18.8.4).

Figure 18.8.4 The ATP Cycle The high-energy phosphoric acid anhydride bond in ATP stores energy released during the oxidation of nutrients. Hydrolysis of the high-energy bond in ATP releases energy, forming adenosine diphosphate (ADP) and phosphate.

Under standard conditions in biochemical reactions, all reactants are present in aqueous concentrations of 1 M at a pressure of 1 atm. For H^+ , this corresponds to a pH of zero, but very little biochemistry occurs at $pH_7 = 0$. For biochemical reactions, chemists have therefore defined a new standard state in which the H^+ concentration is 1×10^{-7} M (pH 7.0), and all other reactants and products are present in their usual standard-state conditions (1 M or 1 atm). The free-energy change and corresponding equilibrium constant for a reaction under these new standard conditions are denoted by the addition of a prime sign (') to the conventional symbol: $\Delta G^{o'}$ and K' . If protons do not participate in a biological reaction, then $\Delta G^{o'} = \Delta G^o$. Otherwise, the relationship between $\Delta G^{o'}$ and ΔG^o is as follows:

$$\Delta G^{o'} = \Delta G^o + RT \ln(10^{-7})^n \quad (18.8.6)$$

where $\Delta G^{o'}$ and ΔG^o are in kilojoules per mole and n is the number of protons produced in the reaction. At 298 K, this simplifies to

$$\Delta G^{o'} = \Delta G^o - 39.96n \quad (18.8.7)$$

Thus any reaction that involves the release of protons is thermodynamically more favorable at pH 7 than at pH 0.

The chemical equation that corresponds to the hydrolysis of ATP to ADP and phosphate is as follows:

This reaction has a $\Delta G^{o'}$ of -34.54 kJ/mol, but under typical physiological (or biochemical) conditions, the actual value of $\Delta G'$ for the hydrolysis of ATP is about -50 kJ/mol. Organisms use this energy to drive reactions that are energetically uphill, thereby coupling the reactions to the hydrolysis of ATP. One example is found in the biochemical pathway of *glycolysis*, in which the 6-carbon sugar glucose ($C_6H_{12}O_6$) is split into two 3-carbon fragments that are then used as the fuel for the cell. Initially, a phosphate group is added to glucose to form a phosphate ester, glucose-6-phosphate (abbreviated glucose-6-P), in a reaction analogous to that of an alcohol and phosphoric acid:

Due to its electrical charge, the phosphate ester is unable to escape from the cell by diffusing back through the membrane surrounding the cell, ensuring that it remains available for further reactions. For the reaction in Equation 18.57, ΔG^o is 17.8 kJ/mol and K is 7.6×10^{-4} , indicating that the equilibrium lies far to the left. To force this reaction to occur as written, it is coupled to a thermodynamically favorable reaction, the hydrolysis of ATP to ADP:

Thus the formation of glucose-6-phosphate is thermodynamically spontaneous if ATP is used as the source of phosphate.

Note the Pattern

Organisms use energy from the hydrolysis of ATP to drive reactions that are thermodynamically nonspontaneous.

The formation of glucose-6-phosphate is only one of many examples of how cells use ATP to drive an otherwise nonspontaneous biochemical reaction. Under nonstandard physiological conditions, each ATP hydrolyzed actually results in approximately a 10^8 increase in the magnitude of the equilibrium constant, compared with the equilibrium constant of the reaction in the absence of ATP. Thus a reaction in which two ATP molecules are converted to ADP increases K by about 10^{16} , three ATP molecules by 10^{24} , and so forth. Virtually any energetically unfavorable reaction or sequence of reactions can be made to occur spontaneously by coupling it to the hydrolysis of a sufficiently large number of ATP molecules.

Energy Storage in Cells

Although all organisms use ATP as the *immediate* free-energy source in biochemical reactions, ATP is not an efficient form in which to store energy on a long-term basis. If the caloric intake of an average resting adult human were stored as ATP, two-thirds of the body weight would have to consist of ATP. Instead, a typical 70 kg adult human has a total of only about 50 g of both ATP and ADP, and, far from being used for long-term storage, each molecule of ATP is turned over about 860 times per day. The entire ATP supply would be exhausted in less than 2 minutes if it were not continuously regenerated.

How does the body store energy for the eventual production of ATP? Three primary means are as sugars, proteins, and fats. The combustion of sugars and proteins yields about 17 kJ of energy per gram, whereas the combustion of fats yields more than twice as much energy per gram, about 39 kJ/g. Moreover, sugars and proteins are hydrophilic and contain about 2 g of water per gram of fuel, even in very concentrated form. In contrast, fats are hydrophobic and can be stored in essentially anhydrous form. As a result, organisms can store about six times more energy per gram as fats than in any other form. A typical 70 kg adult human has about 170 kJ of energy in the form of glucose circulating in the blood, about 2600 kJ of energy stored in the muscles and liver as glycogen (a polymeric form of glucose), about 100,000 kJ stored in the form of protein (primarily muscle tissue), and almost 500,000 kJ in the form of fats (Figure 18.21). Thus fats constitute by far the greatest energy reserve, while accounting for only about 12 kg of the 70 kg body mass. To store this amount of energy in the form of sugars would require a total body mass of about 144 kg, more than half of which would be sugar.

Figure 18.5 Percentages of Forms of Energy Storage in Adult Humans An average 70 kg adult stores about 6×10^5 kJ of energy in glucose, glycogen, protein, and fats. Fats are the most abundant and most efficient form for storing energy.

Example 18.8.1

Glucose is one form in which the body stores energy.

1. Calculate ΔG° for the respiration of glucose to CO_2 and H_2O using these values of ΔG_f° : -910.4 kJ/mol for glucose, -394.4 kJ/mol for $\text{CO}_2(\text{g})$, and -237.1 kJ/mol for $\text{H}_2\text{O}(\text{l})$.
2. Assuming 50% efficiency in the conversion of the released energy to ATP, how many molecules of ATP can be synthesized by the combustion of one molecule of glucose? At 298.15 K, ΔG° for the hydrolysis of ATP is -34.54 kJ/mol.

Given: balanced chemical equation (Equation 18.50), values of ΔG_f° , conversion efficiency, and ΔG° for hydrolysis of ATP

Asked for: ΔG° for the combustion reaction and the number of molecules of ATP that can be synthesized

Strategy:

A Using the “products minus reactants” rule, calculate $\Delta G_{\text{rxn}}^\circ$ for the respiration reaction.

B Multiply the calculated value of $\Delta G_{\text{rxn}}^\circ$ by the efficiency to obtain the number of kilojoules available for ATP synthesis. Then divide this value by ΔG° for the hydrolysis of ATP to find the maximum number of ATP molecules that can be synthesized.

Solution:

1. **A** Protons are not released or consumed in the reaction, so $\Delta G^\circ = \Delta G^\circ$. We begin by using the balanced chemical equation in Equation 18.50:

From the given values of ΔG_f° (remember that ΔG_f° is zero for an element such as O_2 in its standard state), we can calculate $\Delta G_{\text{rxn}}^\circ$

$$\begin{aligned} \Delta G_{\text{rxn}}^\circ &= \sum m \Delta G_f^\circ (\text{products}) - \sum n \Delta G_f^\circ (\text{reactants}) \\ &= [6(-394.4 \text{ kJ/mol}) + 6(-237.1 \text{ kJ/mol})] - [(910.4 \text{ kJ/mol}) + 0 \text{ kJ/mol}] \\ &= -2879 \text{ kJ/mol of glucose} \end{aligned}$$

2. **B** If we assume that only 50% of the available energy is used, then about 1440 kJ/mol of glucose is available for ATP synthesis. The value of ΔG° for the hydrolysis of ATP under biochemical conditions is -34.54 kJ/mol, so in principle an organism could synthesize

$$\frac{1440 \text{ kJ/mol glucose}}{34.54 \text{ kJ/mol ATP}} = 41.7 \approx 42 \text{ ATP/glucose}$$

Most aerobic organisms actually synthesize about 32 molecules of ATP per molecule of glucose, for an efficiency of about 45%.

Exercise

Some bacteria synthesize methane using the following redox reaction:

1. Calculate ΔG° for this reaction using values of ΔG_f° in Table T1.

2. Calculate how many ATP molecules could be synthesized per mol of CO_2 reduced if the efficiency of the process were 100%.

Answer:

1. $-86.6 \text{ kJ/mol CO}_2$
2. 2.5 ATP/mol CO_2

Summary

A living cell is a system that is not in equilibrium with its surroundings; it requires a constant input of energy to maintain its nonequilibrium state. Cells maintain a low-entropy state by increasing the entropy of their surroundings. *Aerobic organisms* cannot survive in the absence of O_2 , whereas *anaerobic organisms* can live only in the absence of O_2 . Green plants and algae are *phototrophs*, which extract energy from the environment through a process called **photosynthesis**, the photochemical reduction of CO_2 to a reduced carbon compound. Other species, called *chemotrophs*, extract energy from chemical compounds. One of the main processes chemotrophs use to obtain energy is **respiration**, which is the reverse of photosynthesis. Alternatively, some chemotrophs obtain energy by **fermentation**, in which an organic compound is both the oxidant and the reductant. Intermediates used by organisms to shuttle electrons between the reductant and the oxidant include NAD^+ and NADH . Energy from the oxidation of nutrients is made available to cells through the synthesis of ATP, the energy currency of the cell. Its energy is used by cells to synthesize substances through coupled reactions and to perform work. The body stores energy as sugars, protein, or fats before using it to produce ATP.

Conceptual Problem

1. The tricarboxylic acid (TCA) cycle in aerobic organisms is one of four pathways responsible for the stepwise oxidation of organic intermediates. The final reaction in the TCA cycle has $\Delta G^\circ = 29.7 \text{ kJ/mol}$, so it should not occur spontaneously. Suggest an explanation for why this reaction proceeds in the forward direction in living cells.

Answer

1. It is coupled to another reaction that is spontaneous, which drives this reaction forward (Le Châtelier's principle).

APPLICATION PROBLEMS

Problems marked with a ♦ involve multiple concepts.

- Electric utilities have been exploring thermal energy storage as a potentially attractive energy-storage solution for peak use. Thermal energy is extracted as steam and stored in rock, oil, or water for later conversion to electricity via heat exchangers. Which steps involve heat transfer? Which involve work done?
- ♦ During World War II, German scientists developed the first rocket-powered airplane to be flown in combat, the *Messerschmitt 163 Komet*. The *Komet* was powered by the reaction of liquid hydrogen peroxide (H_2O_2) and hydrazine (N_2H_4) as follows:

$$2\text{H}_2\text{O}_2(\text{l}) + \text{N}_2\text{H}_4(\text{l}) \rightarrow \text{N}_2(\text{g}) + 4\text{H}_2\text{O}(\text{g})$$
 - Determine the standard molar enthalpy of reaction.
 - What amount of work can be done by the reaction of 1.00 kg of hydrazine with a stoichiometric amount of hydrogen peroxide at 25°C at a constant pressure of 1.00 atm?
 - What is the change in internal energy under these conditions?
- ♦ During the 1950s, pentaborane-9 was tested as a potential rocket fuel. However, the idea was abandoned when it was discovered that B_2O_3 , the product of the reaction of pentaborane-9 with O_2 , was an abrasive that destroyed rocket nozzles. The reaction is represented by the equation

$$2\text{B}_5\text{H}_9(\text{l}) + 12\text{O}_2(\text{g}) \rightarrow 5\text{B}_2\text{O}_3(\text{s}) + 9\text{H}_2\text{O}(\text{g})$$
 - Determine the standard molar enthalpy of reaction.
 - How much work is done against a pressure of 1.0 atm when 50 lb of fuel are allowed to react with sufficient oxygen to cause the reaction to go to completion at 25°C ?
 - What is ΔE for the reaction?
- ♦ Polar explorers must be particularly careful to keep their clothes from becoming damp because the resulting heat loss could be fatal. If a polar explorer's clothes absorbed 1.0 kg of water and the clothes dried from the polar wind, what would be the heat loss [$\Delta H_{\text{vap}}(\text{H}_2\text{O}) = 44 \text{ kJ/mol}$]? How much glucose must be consumed to make up for this heat loss to prevent death [$\Delta H_{\text{comb}}(\text{glucose}) = -802 \text{ kJ/mol}$]?
- Propane gas is generally preferred to kerosene as a fuel for stoves in the boating industry because kerosene stoves require more maintenance. Propane, however, is much more flammable than kerosene and imposes an added risk because it is denser than air and can collect in the bottom of a boat and ignite. The complete combustion of propane produces CO_2 gas and H_2O vapor and has a value of $\Delta H = -2044 \text{ kJ/mol}$ at 25°C . What is ΔE ?
- The propane in Problem 5 can be produced from the hydrogenation of propene according to the following reaction: $\text{C}_3\text{H}_6(\text{g}) + \text{H}_2(\text{g}) \rightarrow \text{C}_3\text{H}_8(\text{g})$; $\Delta H = -124 \text{ kJ/mol}$. Given that the reaction $\text{H}_2(\text{g}) + 1/2 \text{O}_2(\text{g}) \rightarrow \text{H}_2\text{O}(\text{g})$ has $\Delta H = -241.8 \text{ kJ/mol}$, what is the
 - standard enthalpy of combustion of propene?
 - value of ΔE for the combustion of propene?
- ♦ The anaerobic conversion of sucrose, a sweetening agent, to lactic acid, which is associated with sour milk, can be described as follows:

The combustion of sucrose, however, occurs as follows:

- Which reaction is thermodynamically more favorable—the anaerobic conversion of sucrose to lactic acid or the aerobic oxidation to CO_2 and H_2O ? The values of ΔH_f are as follows: lactic acid, -694.1 kJ/mol; sucrose, -222 kJ/mol; CO_2 , -393.5 kJ/mol; and H_2O , -285.8 kJ/mol.
 - What is ΔE for the combustion of 12.0 g of sucrose at normal body temperature ($37^\circ C$)?
8. Phosphorus exists as several allotropes, the most common being red, black, and white phosphorus. White phosphorus consists of tetrahedral P_4 molecules and melts at $44.15^\circ C$; it is converted to red phosphorus by heating at $400^\circ C$ for several hours. The chemical differences between red and white phosphorus are considerable: white phosphorus burns in air, whereas red phosphorus is stable; white phosphorus is soluble in organic compounds, whereas red phosphorus is not; white phosphorus melts at $44.15^\circ C$, whereas red phosphorus melts at $597^\circ C$. If the enthalpy of fusion of white phosphorus is 0.659 kJ/mol, what is its ΔS ? Black phosphorus is even less reactive than red. Based on this information, which allotrope would you predict to have the highest entropy? the lowest? Why?
9. ♦ Ruby and sapphire have a common mineral name: corundum (Al_2O_3). Although they are crystalline versions of the same compound, the nature of the imperfections determines the identity of the gem. Outline a method for measuring and comparing the entropy of a ruby with the entropy of a sapphire. How would you expect the entropies to compare with the entropy of a perfect corundum crystal?
10. ♦ Tin has two crystalline forms— α and β —represented in the following equilibrium equation:

The earliest known tin artifacts were discovered in Egyptian tombs of the 18th dynasty (1580–1350 BC), although archaeologists are surprised that so few tin objects exist from earlier eras. It has been suggested that many early tin objects were either oxidized to a mixture of stannous and stannic oxides or transformed to powdery, gray tin. Sketch a thermodynamic cycle similar to part (b) in [Figure 18.4.3](#) to show the conversion of liquid tin to gray tin. Then calculate the change in entropy that accompanies the conversion of $Sn(l)$ to α -Sn using the following data: $C_p(\text{white}) = 26.99$, $C_p(\text{gray}) = 25.77$ J/(mol·K), $\Delta H_{fus} = 7.0$ kJ/mol, $\Delta H_{\beta \rightarrow \alpha} = -2.2$ kJ/mol.

11. The reaction of SO_2 with O_2 to produce SO_3 has great industrial significance because SO_3 is converted to H_2SO_4 by reaction with water. Unfortunately, the reaction is also environmentally important because SO_3 from industrial smokestacks is a primary source of acid rain. ΔH for the reaction of SO_2 with O_2 to form SO_3 is -23.49 kJ/mol, and ΔS is -22.66 J/(mol·K). Does this reaction occur spontaneously at $25^\circ C$? Does it occur spontaneously at $800^\circ C$ assuming no change in ΔH and ΔS ? Why is this reaction usually carried out at elevated temperatures?
12. Pollutants from industrial societies pose health risks to individuals from exposure to metals such as lead, mercury, and cadmium. The biological effects of a toxic metal may be reduced by removing it from the system using a chelating agent, which binds to the metal and forms a complex that is eliminated from the system without causing more damage. In designing a suitable chelating agent, one must be careful, however, because some chelating agents form metal complexes that are more toxic than the metal itself. Both methylamine (CH_3NH_2) and ethylenediamine ($H_2NCH_2CH_2NH_2$, abbreviated en) could, in principle, be used to treat heavy metal poisoning. In the case of cadmium, the reactions are as follows:

Based strictly on thermodynamic arguments, which would you choose to administer to a patient suffering from cadmium toxicity? Why? Assume a body temperature of $37^\circ C$.

13. ♦ Explosive reactions often have a large negative enthalpy change and a large positive entropy change, but the reaction must also be kinetically favorable. For example, the following equation represents the reaction between hydrazine, a rocket propellant, and the oxidizer dinitrogen tetroxide:

$$\Delta H^\circ = -249 \text{ kJ/mol}, \quad \Delta S^\circ = 218 \text{ J/(mol} \cdot \text{K)}$$

- How much free energy is produced from this reaction at $25^\circ C$?
- Is the reaction thermodynamically favorable?
- What is K ?
- This reaction requires thermal ignition. Why?

14. ♦ Cesium, a silvery-white metal used in the manufacture of vacuum tubes, is produced industrially by the reaction of CsCl with CaC_2 :

Compare the free energy produced from this reaction at 25°C and at 1227°C , the temperature at which it is normally run, given these values:

$$\Delta H_{298}^\circ = 32.0 \text{ kJ/mol}, \Delta S_{298}^\circ = 8.0 \text{ J/(mol}\cdot\text{K)}; \Delta H_{1500}^\circ = -0.6 \text{ kJ/mol}, \Delta S_{1500}^\circ = 3.6 \text{ J/(mol}\cdot\text{K)}.$$

- If you wanted to minimize energy costs in your production facility by reducing the temperature of the reaction, what is the lowest temperature at which products are favored over reactants (assuming the reaction is kinetically favorable at the lower temperature)? Assume ΔH° and ΔS° vary linearly with temperature.
 - What is the ratio $K_{1500 \text{ K}}/K_{298 \text{ K}}$?
15. Dessicants (drying agents) can often be regenerated by heating, although it is generally not economically worthwhile to do so. A dessicant that is commonly regenerated is $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$:

Regeneration is carried out at 250°C .

- What is ΔG° for this reaction?
 - What is the equilibrium constant at 25°C ?
 - What is the ratio $K_{250^\circ\text{C}}/K_{25^\circ\text{C}}$?
 - What is the equilibrium constant at 250°C ?
 - Is regeneration of $\text{CaSO}_4(s) \cdot 2\text{H}_2\text{O}$ an enthalpy- or entropy-driven process? Explain your answer.
16. The nitrogen triiodide complex with ammonia ($\text{NI}_3 \cdot \text{NH}_3$) is a simple explosive that can be synthesized from common household products. When detonated, it produces N_2 and I_2 . It can be painted on surfaces when wet, but it is shock sensitive when dry (even touching it with a feather can cause an explosion). Do you expect ΔG for the explosion reaction to be positive or negative? Why doesn't $\text{NI}_3 \cdot \text{NH}_3$ explode spontaneously?
17. Adenosine triphosphate (ATP) contains high-energy phosphate bonds that are used in energy metabolism, coupling energy-yielding and energy-requiring processes. Cleaving a phosphate link by hydrolysis (ATP hydrolysis) can be described by the reaction $\text{ATP} + \text{H}_2\text{O} \rightleftharpoons \text{ADP} + \text{P}_i + \text{H}^+$ where P_i symbolizes phosphate. Glycerol and ATP react to form glycerol-3-phosphate, ADP, and H^+ , with an overall $K = 6.61 \times 10^6$ at 37°C . The reaction of glycerol with phosphate to form glycerol-3-phosphate and water has an equilibrium constant of 2.82×10^5 . What is the equilibrium constant for ATP hydrolysis? How much free energy is released from the hydrolysis of ATP?
18. ♦ Consider the biological reduction of molecular nitrogen, for which the following is the minimal reaction stoichiometry under optimal conditions (P_i = phosphate):
- $$8\text{H}^+ + 8\text{e}^- + \text{N}_2 + 16\text{ATP} \rightarrow \text{H}_2 + 2\text{NH}_3 + 16\text{ADP} + 16\text{P}_i$$
- What is the approximate ratio of K_{eq} for this reaction and for the same reaction in the absence of ATP?
 - Given the fact that at pH 7 both the reaction of protons and electrons to give H_2 and the reaction of H_2 with N_2 to give ammonia are thermodynamically spontaneous (i.e., $K \gg 1$), suggest a reason that nitrogen-fixing bacteria use such a large energy input to drive a reaction that is already spontaneous.

ANSWERS

-

In oxidation–reduction (redox) reactions, electrons are transferred from one species (the reductant) to another (the oxidant). This transfer of electrons provides a means for converting chemical energy to electrical energy or vice versa. The study of the relationship between electricity and chemical reactions is called electrochemistry, an area of chemistry we introduced in Chapter 8 and Chapter 9). In this chapter, we describe electrochemical reactions in more depth and explore some of their applications.

In the first three sections, we review redox reactions; describe how they can be used to generate an electrical potential, or *voltage*; and discuss factors that affect the magnitude of the potential. We then explore the relationships among the electrical potential, the change in free energy, and the equilibrium constant for a redox reaction, which are all measures of the thermodynamic driving force for a reaction. Finally, we examine two kinds of applications of electrochemical principles: (1) those in which a spontaneous reaction is used to provide electricity and (2) those in which electrical energy is used to drive a thermodynamically nonspontaneous reaction. By the end of this chapter, you will understand why different kinds of batteries are used in cars, flashlights, cameras, and portable computers; how rechargeable batteries operate; and why corrosion occurs and how to slow—if not prevent—it. You will also discover how metal objects can be plated with silver or chromium for protection; how silver polish removes tarnish; and how to calculate the amount of electricity needed to produce aluminum, chlorine, copper, and sodium on an industrial scale.

A view from the top of the Statue of Liberty, showing the green patina coating the statue. The patina is formed by corrosion of the copper skin of the statue, which forms a thin layer of an insoluble compound that contains copper(II), sulfate, and hydroxide ions.

Learning Objective

- To distinguish between galvanic and electrolytic cells.

In any electrochemical process, electrons flow from one chemical substance to another, driven by an oxidation–reduction (redox) reaction. As we described in Chapter 7, a redox reaction occurs when electrons are transferred from a substance that is oxidized to one that is being reduced. The reductant (a substance that is capable of donating electrons and in the process is oxidized) is the substance that loses electrons and is oxidized in the process; the oxidant (A substance that is capable of accepting electrons and in the process is reduced) is the species that gains electrons and is reduced in the process. The associated potential energy is determined by the potential difference between the valence electrons in atoms of different elements.

Because it is impossible to have a reduction without an oxidation and vice versa, a redox reaction can be described as two half-reactions (reactions that represent either the oxidation half or the reduction half of an oxidation–reduction (redox) reaction), one representing the oxidation process and one the reduction process. For the reaction of zinc with bromine, the overall chemical reaction is as follows:

The half-reactions are as follows:

Each half-reaction is written to show what is actually occurring in the system; Zn is the reductant in this reaction (it loses electrons), and Br₂ is the oxidant (it gains electrons). Adding the two half-reactions gives the overall chemical reaction (Equation 19.1). A redox reaction is balanced when *the number of electrons lost by the reductant equals the number of electrons gained by the oxidant*. Like any balanced chemical equation, the overall process is electrically neutral; that is, the net charge is the same on both sides of the equation.

Note the Pattern

In any redox reaction, the number of electrons lost by the reductant equals the number of electrons gained by the oxidant.

In most of our discussions of chemical reactions, we have assumed that the reactants are in intimate physical contact with one another. Acid–base reactions, for example, are usually carried out with the acid and the base dispersed in a single phase, such as a liquid solution. With redox reactions, however, it is possible to physically separate the oxidation and reduction half-reactions in space, as long as there is a complete circuit, including an external electrical connection, such as a wire, between the two half-reactions. As the reaction progresses, the electrons flow from the reductant to the oxidant over this electrical connection, producing an electric current that can be used to do work. An apparatus that is used to generate electricity from a spontaneous redox reaction or, conversely, that uses electricity to drive a nonspontaneous redox reaction is called an electrochemical cell (an apparatus that generates electricity from a spontaneous oxidation–reduction (redox) reaction or, conversely, uses electricity to drive a nonspontaneous redox reaction).

There are two types of electrochemical cells: galvanic cells and electrolytic cells. A galvanic (voltaic) cell (an electrochemical cell that uses the energy released during a spontaneous oxidation–reduction (redox) reaction (ΔG°) to generate electricity). Galvanic cells are named for the Italian physicist and physician Luigi Galvani (1737–1798), who observed that dissected frog leg muscles twitched when a small electric shock was applied, demonstrating the electrical nature of nerve impulses. uses the energy released during a spontaneous redox reaction ($\Delta G < 0$) to *generate* electricity. This type of electrochemical cell is often called a *voltaic cell* after its inventor, the Italian physicist Alessandro Volta (1745–1827). In contrast, an electrolytic cellAn electrochemical cell that consumes electrical energy from an external source to drive a nonspontaneous (ΔG°) oxidation–reduction (redox) reaction. *consumes* electrical energy from an external source, using it to cause a nonspontaneous redox reaction to occur ($\Delta G > 0$). Both types contain two electrodesA solid metal connected by an electrolyte and an external circuit that provides an electrical connection between systems in an electrochemical cell (galvanic or electrolytic)., which are solid metals connected to an external circuit that provides an electrical connection between the two parts of the system (Figure 19.1.1). The oxidation half-reaction occurs at one electrode (the anodeOne of two electrodes in an electrochemical cell, it is the site of the oxidation half-reaction.), and the reduction half-reaction occurs at the other (the cathodeOne of two electrodes in an electrochemical cell, it is the site of the reduction half-reaction.). When the circuit is closed, electrons flow from the anode to the

cathode. The electrodes are also connected by an *electrolyte*, an ionic substance or solution that allows ions to transfer between the electrode compartments, thereby maintaining the system's electrical neutrality. In this section, we focus on reactions that occur in galvanic cells. We discuss electrolytic cells in Section 19.7.

Figure 19.1.1 Electrochemical Cells A galvanic cell (left) transforms the energy released by a spontaneous redox reaction into electrical energy that can be used to perform work. The oxidative and reductive half-reactions usually occur in separate compartments that are connected by an external electrical circuit; in addition, a second connection that allows ions to flow between the compartments (shown here as a vertical dashed line to represent a porous barrier) is necessary to maintain electrical neutrality. The potential difference between the electrodes (voltage) causes electrons to flow from the reductant to the oxidant through the external circuit, generating an electric current. In an electrolytic cell (right), an external source of electrical energy is used to generate a potential difference between the electrodes that forces electrons to flow, driving a nonspontaneous redox reaction; only a single compartment is employed in most applications. In both kinds of electrochemical cells, the anode is the electrode at which the oxidation half-reaction occurs, and the cathode is the electrode at which the reduction half-reaction occurs.

Galvanic (Voltaic) Cells

To illustrate the basic principles of a galvanic cell, let's consider the reaction of metallic zinc with cupric ion (Cu^{2+}) to give copper metal and Zn^{2+} ion. The balanced chemical equation is as follows:

We can cause this reaction to occur by inserting zinc powder into an aqueous solution of copper(II) sulfate. As the reaction proceeds, the zinc dissolves, and a mass of metallic copper forms (Figure 19.1.2). These changes occur spontaneously, but all the energy released is in the form of heat rather than in a form that can be used to do work.

Figure 19.1.2 The Reaction of Metallic Zinc with Aqueous Copper(II) Ions in a Single Compartment When zinc powder is inserted into a beaker that contains an aqueous solution of copper(II) sulfate, a spontaneous redox reaction occurs: the zinc electrode dissolves to give $\text{Zn}^{2+}(\text{aq})$ ions, while $\text{Cu}^{2+}(\text{aq})$ ions are simultaneously reduced to metallic copper. The reaction occurs so rapidly that the copper is deposited as very fine particles that appear black, rather than the usual reddish color of copper. The reaction demonstration starts at 3:00 in the video, the chemistry of the reaction is discussed in the first three minutes and at the end

This same reaction can be carried out using the galvanic cell illustrated in part (a) in Figure 19.1.3. To assemble the cell, a copper strip is inserted into a beaker that contains a 1 M solution of Cu^{2+} ions, and a zinc strip is inserted into a different beaker that contains a 1 M solution of Zn^{2+} ions. The two metal strips, which serve as electrodes, are connected by a wire, and the compartments are connected by a salt bridge (a U-shaped tube inserted into both solutions of a galvanic cell that contains a concentrated liquid or gelled electrolyte and completes the circuit between the anode and the cathode), a U-shaped tube inserted into both solutions that contains a concentrated liquid or gelled electrolyte. The ions in the salt bridge are selected so that they do not interfere with the electrochemical reaction by being oxidized or reduced themselves or by forming a precipitate or complex; commonly used cations and anions are Na^+ or K^+ and NO_3^- or SO_4^{2-} , respectively. (The ions in the salt bridge do *not* have to be the same as those in the redox couple in either compartment.) When the circuit is closed, a spontaneous reaction occurs: zinc metal is oxidized to Zn^{2+} ions at the zinc electrode (the anode), and Cu^{2+} ions are reduced to Cu metal at the copper electrode (the cathode). As the reaction progresses, the zinc strip dissolves, and the concentration of Zn^{2+} ions in the Zn^{2+} solution increases; simultaneously, the copper strip gains mass, and the concentration of Cu^{2+} ions in the Cu^{2+} solution decreases (part (b) in Figure 19.1.3). Thus we have carried out the same reaction as we did using a single beaker, but this time the oxidative and reductive half-reactions are physically separated from each other. The electrons that are released at the anode flow through the wire, producing an electric current. Galvanic cells therefore transform chemical energy into electrical energy that can then be used to do work.

Figure 19.1.3 The Reaction of Metallic Zinc with Aqueous Copper(II) Ions in a Galvanic Cell (a) A galvanic cell can be constructed by inserting a copper strip into a beaker that contains an aqueous 1 M solution of Cu^{2+} ions and a zinc strip into a different beaker that contains an aqueous 1 M solution of Zn^{2+} ions. The two metal strips are connected by a wire that allows electricity to flow, and the beakers are connected by a salt bridge. When the switch is closed to complete the circuit, the zinc electrode (the anode) is spontaneously oxidized to Zn^{2+} ions in the left compartment, while Cu^{2+} ions are simultaneously reduced to copper metal at the copper electrode (the cathode). (b) As the reaction progresses, the Zn anode loses mass as it dissolves to give $\text{Zn}^{2+}(\text{aq})$ ions, while the Cu cathode gains mass as $\text{Cu}^{2+}(\text{aq})$ ions are reduced to copper metal that is deposited on the cathode.

The electrolyte in the salt bridge serves two purposes: it completes the circuit by carrying electrical charge and maintains electrical neutrality in both solutions by allowing ions to migrate between them. The identity of the salt in a salt bridge is unimportant, as long as the component ions do not react or undergo a redox reaction under the operating conditions of the cell. Without such a connection, the total positive charge in the Zn^{2+} solution would increase as the zinc metal dissolves, and the total positive charge in the Cu^{2+} solution would decrease. The salt bridge allows charges to be neutralized by a flow of anions into the Zn^{2+} solution and a flow of cations into the Cu^{2+} solution. In the absence of a salt bridge or some other similar connection, the reaction would rapidly cease because electrical neutrality could not be maintained.

A galvanic cell. This galvanic cell uses a salt bridge to connect two solutions generating a voltage.

A *voltmeter* can be used to measure the electrical potential between the two compartments. Opening the switch that connects the wires from flowing, so no chemical reaction occurs. With the switch closed, however, the external circuit is completed, and an electric current flows from the anode to the cathode. The potential (E_{cell}) related to the energy needed to move a charged particle in an electric field, it is the difference in electrical potential between two half-reactions and is related to the energy needed to move a charged particle in an electric field. In the cell we have described, the voltmeter indicates a potential of 1.10 V (part (a) in Figure 19.1.3). Because electrons from the oxidation half-reaction are released at the anode, the anode in a galvanic cell is negatively charged. The cathode, which attracts electrons, is positively charged.

Not all electrodes undergo a chemical transformation during a redox reaction. The electrode can be made from an inert, highly conducting metal such as platinum to prevent it from reacting during a redox process, where it does not appear in the overall electrochemical reaction. This phenomenon is illustrated in Example 1.

Note the Pattern

A galvanic (voltaic) cell converts the energy released by a spontaneous chemical reaction to electrical energy. An electrolytic cell consumes electrical energy from an external source to drive a nonspontaneous chemical reaction.

Example 19.1.1

A chemist has constructed a galvanic cell consisting of two beakers. One beaker contains a strip of tin immersed in aqueous sulfuric acid, and the other contains a platinum electrode immersed in aqueous nitric acid. The two solutions are connected by a salt bridge, and the electrodes are connected by a wire. Current begins to flow, and bubbles of a gas appear at the platinum electrode. The spontaneous redox reaction that occurs is described by the following balanced chemical equation:

For this galvanic cell,

1. write the half-reaction that occurs at each electrode.
2. indicate which electrode is the cathode and which is the anode.
3. indicate which electrode is the positive electrode and which is the negative electrode.

Given: galvanic cell and redox reaction

Asked for: half-reactions, identity of anode and cathode, and electrode assignment as positive or negative

Strategy:

A Identify the oxidation half-reaction and the reduction half-reaction. Then identify the anode and cathode from the half-reaction that occurs at each electrode.

B From the direction of electron flow, assign each electrode as either positive or negative.

Solution:

1. **A** In the reduction half-reaction, nitrate is reduced to nitric oxide. (The nitric oxide would then react with oxygen in the air to form NO_2 , with its characteristic red-brown color.) In the oxidation half-reaction, metallic tin is oxidized. The half-reactions corresponding to the actual reactions that occur in the system are as follows:

Thus nitrate is reduced to NO, while the tin electrode is oxidized to Sn^{2+} .

2. Because the reduction reaction occurs at the Pt electrode, it is the cathode. Conversely, the oxidation reaction occurs at the tin electrode, so it is the anode.

3. **B** Electrons flow from the tin electrode through the wire to the platinum electrode, where they transfer to nitrate. The electric circuit is completed by the salt bridge, which permits the diffusion of cations toward the cathode and anions toward the anode. Because electrons flow *from* the tin electrode, it must be electrically negative. In contrast, electrons flow *toward* the Pt electrode, so that electrode must be electrically positive.

Exercise

Consider a simple galvanic cell consisting of two beakers connected by a salt bridge. One beaker contains a solution of MnO_4^- in dilute sulfuric acid and has a Pt electrode. The other beaker contains a solution of Sn^{2+} in dilute sulfuric acid, also with a Pt electrode. When the two electrodes are connected by a wire, current flows and a spontaneous reaction occurs that is described by the following balanced chemical equation:

For this galvanic cell,

1. write the half-reaction that occurs at each electrode.
2. indicate which electrode is the cathode and which is the anode.
3. indicate which electrode is positive and which is negative.

Answer:

1. $\text{MnO}_4^-(\text{aq}) + 8\text{H}^+(\text{aq}) + 5\text{e}^- \rightarrow \text{Mn}^{2+}(\text{aq}) + 4\text{H}_2\text{O}(\text{l})$; $\text{Sn}^{2+}(\text{aq}) \rightarrow \text{Sn}^{4+}(\text{aq}) + 2\text{e}^-$
2. The Pt electrode in the permanganate solution is the cathode; the one in the tin solution is the anode.
3. The cathode (electrode in beaker that contains the permanganate solution) is positive, and the anode (electrode in beaker that contains the tin solution) is negative.

Constructing a Cell Diagram

Because it is somewhat cumbersome to describe any given galvanic cell in words, a more convenient notation has been developed. In this line notation, called a *cell diagram*, the identity of the electrodes and the chemical contents of the compartments are indicated by their chemical formulas, with the anode written on the far left and the cathode on the far right. Phase boundaries are shown by single vertical lines, and the salt bridge, which has two phase boundaries, by a double vertical line. Thus the cell diagram for the Zn/Cu cell shown in part (a) in [Figure 19.1.3](#) is written as follows:

Figure 19.1.4 A cell diagram includes solution concentrations when they are provided.

Galvanic cells can have arrangements other than the examples we have seen so far. For example, the voltage produced by a redox reaction can be measured more accurately using two electrodes immersed in a single beaker containing an electrolyte that completes the circuit. This arrangement reduces errors caused by resistance to the flow of charge at a boundary, called the *junction potential*. One example of this type of galvanic cell is as follows:

This cell diagram does not include a double vertical line representing a salt bridge because there is no salt bridge providing a junction between two dissimilar solutions. Moreover, solution concentrations have not been specified, so they are not included in the cell diagram. The half-reactions and the overall reaction for this cell are as follows:

A single-compartment galvanic cell will initially exhibit the same voltage as a galvanic cell constructed using separate compartments, but it will discharge rapidly because of the direct reaction of the reactant at the anode with the oxidized member of the cathodic redox couple. Consequently, cells of this type are not particularly useful for producing electricity.

Example 19.1.2

Draw a cell diagram for the galvanic cell described in Example 1. The balanced chemical reaction is as follows:

Given: galvanic cell and redox reaction

Asked for: cell diagram

Strategy:

Using the symbols described, write the cell diagram beginning with the oxidation half-reaction on the left.

Solution:

The anode is the tin strip, and the cathode is the Pt electrode. Beginning on the left with the anode, we indicate the phase boundary between the electrode and the tin solution by a vertical bar. The anode compartment is thus $\text{Sn(s)}|\text{Sn}^{2+}(\text{aq})$. We could include $\text{H}_2\text{SO}_4(\text{aq})$ with the contents of the anode compartment, but the sulfate ion (as HSO_4^-) does not participate in the overall reaction, so it does not need to be specifically indicated. The cathode compartment contains aqueous nitric acid, which does participate in the overall reaction, together with the product of the reaction (NO) and the Pt electrode. These are written as $\text{HNO}_3(\text{aq})|\text{NO(g)}|\text{Pt(s)}$, with single vertical bars indicating the phase boundaries. Combining the two compartments and using a double vertical bar to indicate the salt bridge,

The solution concentrations were not specified, so they are not included in this cell diagram.

Exercise

Draw a cell diagram for the following reaction, assuming the concentration of Ag^+ and Mg^{2+} are each 1 M:

Answer: $\text{Mg(s)}|\text{Mg}^{2+}(\text{aq}, 1\text{ M})\|\text{Ag}^+(\text{aq}, 1\text{ M})|\text{Ag(s)}$

Summary

Electrochemistry is the study of the relationship between electricity and chemical reactions. The oxidation–reduction reaction that occurs during an electrochemical process consists of two **half-reactions**, one representing the oxidation process and one the reduction process. The sum of the half-reactions gives the overall chemical reaction. The overall redox reaction is balanced when the number of electrons lost by the **reductant** equals the number of electrons gained by the **oxidant**. An electric current is produced from the flow of electrons from the reductant to the oxidant. An **electrochemical cell** can either generate electricity from a spontaneous redox reaction or consume electricity to drive a nonspontaneous reaction. In a **galvanic (voltaic) cell**, the energy from a spontaneous reaction generates electricity, whereas in an **electrolytic cell**, electrical energy is consumed to drive a nonspontaneous redox reaction. Both types of cells use two **electrodes** that provide an electrical connection between systems that are separated in space. The oxidative half-reaction occurs at the **anode**, and the reductive half-reaction occurs at the **cathode**. A **salt bridge** connects the separated solutions, allowing ions to migrate to either solution to ensure the system's electrical neutrality. A voltmeter is a device that measures the flow of electric current between two half-reactions. The **potential** of a cell, measured in volts, is the energy needed to move a charged particle in an electric field. An electrochemical cell can be described using line notation called a cell diagram, in which vertical lines indicate phase boundaries and the location of the salt bridge. Resistance to the flow of charge at a boundary is called the junction potential.

Key Takeaway

- A galvanic (voltaic) cell uses the energy released during a spontaneous redox reaction to generate electricity, whereas an electrolytic cell consumes electrical energy from an external source to force a reaction to occur.

Conceptual Problems

1. Is $2\text{NaOH(aq)} + \text{H}_2\text{SO}_4(\text{aq}) \rightarrow \text{Na}_2\text{SO}_4(\text{aq}) + 2\text{H}_2\text{O(l)}$ an oxidation–reduction reaction? Why or why not?
2. If two half-reactions are physically separated, how is it possible for a redox reaction to occur? What is the name of the apparatus in which two half-reactions are carried out simultaneously?
3. What is the difference between a galvanic cell and an electrolytic cell? Which would you use to generate electricity?
4. What is the purpose of a salt bridge in a galvanic cell? Is it always necessary to use a salt bridge in a galvanic cell?
5. One criterion for a good salt bridge is that it contains ions that have similar rates of diffusion in aqueous solution, as K^+ and Cl^- ions do. What would happen if the diffusion rates of the anions and cations differed significantly?
6. It is often more accurate to measure the potential of a redox reaction by immersing two electrodes in a single beaker rather than in two beakers. Why?

Answer

- 1.
- 2.
- 3.
- 4.
5. A large difference in cation/anion diffusion rates would increase resistance in the salt bridge and limit electron flow through the circuit.
- 6.

Numerical Problems

1. Copper(I) sulfate forms a bright blue solution in water. If a piece of zinc metal is placed in a beaker of aqueous CuSO_4 solution, the blue color fades with time, the zinc strip begins to erode, and a black solid forms around the zinc strip. What is happening? Write half-reactions to show the chemical changes that are occurring. What will happen if a piece of copper metal is placed in a colorless aqueous solution of ZnCl_2 ?
2. Consider the following spontaneous redox reaction: $\text{NO}_3^-(\text{aq}) + \text{H}^+(\text{aq}) + \text{SO}_3^{2-}(\text{aq}) \rightarrow \text{SO}_4^{2-}(\text{aq}) + \text{HNO}_2(\text{aq})$.
 1. Write the two half-reactions for this overall reaction.
 2. If the reaction is carried out in a galvanic cell using an inert electrode in each compartment, which electrode corresponds to which half-reaction?
 3. Which electrode is negatively charged, and which is positively charged?
3. The reaction $\text{Pb}(\text{s}) + 2\text{VO}^{2+}(\text{aq}) + 4\text{H}^+(\text{aq}) \rightarrow \text{Pb}^{2+}(\text{aq}) + 2\text{V}^{3+}(\text{aq}) + 2\text{H}_2\text{O}(\text{l})$ occurs spontaneously.
 1. Write the two half-reactions for this redox reaction.
 2. If the reaction is carried out in a galvanic cell using an inert electrode in each compartment, which reaction occurs at the cathode and which occurs at the anode?
 3. Which electrode is positively charged, and which is negatively charged?
4. Phenolphthalein is an indicator that turns pink under basic conditions. When an iron nail is placed in a gel that contains $[\text{Fe}(\text{CN})_6]^{3-}$, the gel around the nail begins to turn pink. What is occurring? Write the half-reactions and then write the overall redox reaction.
5. Sulfate is reduced to HS^- in the presence of glucose, which is oxidized to bicarbonate. Write the two half-reactions corresponding to this process. What is the equation for the overall reaction?
6. Write the spontaneous half-reactions and the overall reaction for each proposed cell diagram. State which half-reaction occurs at the anode and which occurs at the cathode.
 1. $\text{Pb}(\text{s}) | \text{PbSO}_4(\text{s}) | \text{SO}_4^{2-}(\text{aq}) || \text{Cu}^{2+}(\text{aq}) | \text{Cu}(\text{s})$
 2. $\text{Hg}(\text{l}) | \text{Hg}_2\text{Cl}_2(\text{s}) | \text{Cl}^-(\text{aq}) || \text{Cd}^{2+}(\text{aq}) | \text{Cd}(\text{s})$
7. For each galvanic cell represented by these cell diagrams, determine the spontaneous half-reactions and the overall reaction. Indicate which reaction occurs at the anode and which occurs at the cathode.
 1. $\text{Zn}(\text{s}) | \text{Zn}^{2+}(\text{aq}) || \text{H}^+(\text{aq}) | \text{H}_2(\text{g}), \text{Pt}(\text{s})$
 2. $\text{Ag}(\text{s}) | \text{AgCl}(\text{s}) | \text{Cl}^-(\text{aq}) || \text{H}^+(\text{aq}) | \text{H}_2(\text{g}) | \text{Pt}(\text{s})$
 3. $\text{Pt}(\text{s}) | \text{H}_2(\text{g}) | \text{H}^+(\text{aq}) || \text{Fe}^{2+}(\text{aq}), \text{Fe}^{3+}(\text{aq}) | \text{Pt}(\text{s})$
8. For each redox reaction, write the half-reactions and draw the cell diagram for a galvanic cell in which the overall reaction occurs spontaneously. Identify each electrode as either positive or negative.
 1. $\text{Ag}(\text{s}) + \text{Fe}^{3+}(\text{aq}) \rightarrow \text{Ag}^+(\text{aq}) + \text{Fe}^{2+}(\text{aq})$
 2. $\text{Fe}^{3+}(\text{aq}) + 1/2\text{H}_2(\text{g}) \rightarrow \text{Fe}^{2+}(\text{aq}) + \text{H}^+(\text{aq})$
9. Write the half-reactions for each overall reaction, decide whether the reaction will occur spontaneously, and construct a cell diagram for a galvanic cell in which a spontaneous reaction will occur.
 1. $2\text{Cl}^-(\text{aq}) + \text{Br}_2(\text{l}) \rightarrow \text{Cl}_2(\text{g}) + 2\text{Br}^-(\text{aq})$
 2. $2\text{NO}_2(\text{g}) + 2\text{OH}^-(\text{aq}) \rightarrow \text{NO}_2^-(\text{aq}) + \text{NO}_3^-(\text{aq}) + \text{H}_2\text{O}(\text{l})$
 3. $2\text{H}_2\text{O}(\text{l}) + 2\text{Cl}^-(\text{aq}) \rightarrow \text{H}_2(\text{g}) + \text{Cl}_2(\text{g}) + 2\text{OH}^-(\text{aq})$
 4. $\text{C}_3\text{H}_8(\text{g}) + 5\text{O}_2(\text{g}) \rightarrow 3\text{CO}_2(\text{g}) + 4\text{H}_2\text{O}(\text{g})$
10. Write the half-reactions for each overall reaction, decide whether the reaction will occur spontaneously, and construct a cell diagram for a galvanic cell in which a spontaneous reaction will occur.
 1. $\text{Co}(\text{s}) + \text{Fe}^{2+}(\text{aq}) \rightarrow \text{Co}^{2+}(\text{aq}) + \text{Fe}(\text{s})$
 2. $\text{O}_2(\text{g}) + 4\text{H}^+(\text{aq}) + 4\text{Fe}^{2+}(\text{aq}) \rightarrow 2\text{H}_2\text{O}(\text{l}) + 4\text{Fe}^{3+}(\text{aq})$
 3. $6\text{Hg}^{2+}(\text{aq}) + 2\text{NO}_3^-(\text{aq}) + 8\text{H}^+ \rightarrow 3\text{Hg}_2^{2+}(\text{aq}) + 2\text{NO}(\text{g}) + 4\text{H}_2\text{O}(\text{l})$
 4. $\text{CH}_4(\text{g}) + 2\text{O}_2(\text{g}) \rightarrow \text{CO}_2(\text{g}) + 2\text{H}_2\text{O}(\text{g})$

Learning Objectives

- To use redox potentials to predict whether a reaction is spontaneous.
- To balance redox reactions using half-reactions.

In a galvanic cell, current is produced when electrons flow externally through the circuit from the anode to the cathode because of a difference in potential energy between the two electrodes in the electrochemical cell. In the Zn/Cu system, the valence electrons in zinc have a substantially higher potential energy than the valence electrons in copper because of shielding of the s electrons of zinc by the electrons in filled d orbitals. (For more information on atomic orbitals, see [Section 2.5](#).) Hence electrons flow spontaneously from zinc to copper(II) ions, forming zinc(II) ions and metallic copper ([Figure 19.2.1](#)). Just like water flowing spontaneously downhill, which can be made to do work by forcing a waterwheel, the flow of electrons from a higher potential energy to a lower one can also be harnessed to perform work.

Figure 19.2.1 Potential Energy Difference in the Zn/Cu System The potential energy of a system consisting of metallic Zn and aqueous Cu^{2+} ions is greater than the potential energy of a system consisting of metallic Cu and aqueous Zn^{2+} ions. Much of this potential energy difference is because the valence electrons of metallic Zn are higher in energy than the valence electrons of metallic Cu. Because the $\text{Zn}(s) + \text{Cu}^{2+}(\text{aq})$ system is higher in energy by 1.10 V than the $\text{Cu}(s) + \text{Zn}^{2+}(\text{aq})$ system, energy is released when electrons are transferred from Zn to Cu^{2+} to form Cu and Zn^{2+} .

Because the potential energy of valence electrons differs greatly from one substance to another, the voltage of a galvanic cell depends partly on the identity of the reacting substances. If we construct a galvanic cell similar to the one in part (a) in [Figure 19.1.3](#) but instead of copper use a strip of cobalt metal and 1 M Co^{2+} in the cathode compartment, the measured voltage is not 1.10 V but 0.51 V. Thus we can conclude that the difference in potential energy between the valence electrons of cobalt and zinc is less than the difference between the valence electrons of copper and zinc by 0.59 V.

The measured potential of a cell also depends strongly on the *concentrations* of the reacting species and the *temperature* of the system. To develop a scale of relative potentials that will allow us to predict the direction of an electrochemical reaction and the magnitude of the driving force for the reaction, the potentials for oxidations and reductions of different substances must be measured under comparable conditions. To do this, chemists use the standard cell potential (E°_{cell}), defined as the potential of a cell measured under standard conditions—that is, with all species in their standard states (1 M for solutions, Concentrated solutions of salts (about 1 M) generally do not exhibit ideal behavior, and the actual standard state corresponds to an *activity* of 1 rather than a concentration of 1 M. Corrections for nonideal behavior are important for precise quantitative work but not for the more qualitative approach that we are taking here. 1 atm for gases, pure solids or pure liquids for other substances) and at a fixed temperature, usually 25°C.

Note the Pattern

Measured redox potentials depend on the potential energy of valence electrons, the concentrations of the species in the reaction, and the temperature of the system.

Measuring Standard Electrode Potentials

It is physically impossible to measure the potential of a single electrode: only the *difference* between the potentials of two electrodes can be measured. (This is analogous to measuring absolute enthalpies or free energies. Recall from [Chapter 18](#) that only *differences* in enthalpy and free energy can be measured.) We can, however, compare the standard cell potentials for two different galvanic cells that have one kind of electrode in common. This allows us to measure the potential difference between two dissimilar electrodes. For example, the measured standard cell potential (E°) for the Zn/Cu system is 1.10 V, whereas E° for the corresponding Zn/Co system is 0.51 V. This implies that the potential difference between the Co and Cu electrodes is $1.10 \text{ V} - 0.51 \text{ V} = 0.59 \text{ V}$. In fact, that is exactly the potential measured under standard conditions if a cell is constructed with the following cell diagram:

This cell diagram corresponds to the oxidation of a cobalt anode and the reduction of Cu^{2+} in solution at the copper cathode.

All tabulated values of *standard electrode potentials* by convention are listed for a reaction written as a reduction, not as an oxidation, to be able to compare standard potentials for different substances. (Standard electrode potentials for various reduction reactions are given in [Table P1](#).) The standard cell potential (E°_{cell}) is therefore the *difference* between the tabulated reduction potentials of the two half-reactions, not their sum:

$$E^\circ_{\text{cell}} = E^\circ_{\text{cathode}} - E^\circ_{\text{anode}} \quad (19.2.2)$$

In contrast, recall that half-reactions are written to show the reduction and oxidation reactions that actually occur in the cell, so the overall cell reaction is written as the *sum* of the two half-reactions. According to [Equation 19.2.1](#), when we know the standard potential for any single half-reaction, we can obtain the value of the standard potential of many other half-reactions by measuring the standard potential of the corresponding cell.

Note the Pattern

The overall cell reaction is the sum of the two half-reactions, but the cell potential is the difference between the reduction potentials: $E^\circ_{\text{cell}} = E^\circ_{\text{cathode}} - E^\circ_{\text{anode}}$.

Although it is impossible to measure the potential of any electrode directly, we can choose a reference electrode whose potential is defined as 0 V under standard conditions. The standard hydrogen electrode (SHE) is universally used for this purpose and is assigned a standard potential of 0 V. It consists of a strip of platinum wire in contact with an aqueous solution containing 1 M H^+ . The $[\text{H}^+]$ in solution is in equilibrium with H_2 gas at a pressure of 1 atm at the Pt-solution interface ([Figure 19.2.2](#)). Protons are reduced or hydrogen molecules are oxidized at the Pt surface according to the following equation:

One especially attractive feature of the SHE is that the Pt metal electrode is not consumed during the reaction.

Figure 19.2.2 The Standard Hydrogen Electrode The SHE consists of platinum wire that is connected to a Pt surface in contact with an aqueous solution containing 1 M H^+ in equilibrium with H_2 gas at a pressure of 1 atm . In the molecular view, the Pt surface catalyzes the oxidation of hydrogen molecules to protons or the reduction of protons to hydrogen gas. (Water is omitted for clarity.) The standard potential of the SHE is arbitrarily assigned a value of 0 V .

Figure 19.2.3 shows a galvanic cell that consists of a SHE in one beaker and a Zn strip in another beaker containing a solution of Zn^{2+} ions. When the circuit is closed, the voltmeter indicates a potential of 0.76 V . The zinc electrode begins to dissolve to form Zn^{2+} , and H^+ ions are reduced to H_2 in the other compartment. Thus the hydrogen electrode is the cathode, and the zinc electrode is the anode. The diagram for this galvanic cell is as follows:

The half-reactions that actually occur in the cell and their corresponding electrode potentials are as follows:

$$E_{\text{cell}}^{\circ} = E_{\text{cathode}}^{\circ} - E_{\text{anode}}^{\circ} = 0.76$$

Figure 19.2.3 Determining a Standard Electrode Potential Using a Standard Hydrogen Electrode The voltmeter shows that the standard cell potential of a galvanic cell consisting of a SHE and a Zn/Zn^{2+} couple is $E_{\text{cell}}^{\circ} = 0.76\text{ V}$. Because the zinc electrode in this cell dissolves spontaneously to form $\text{Zn}^{2+}(aq)$ ions while $\text{H}^+(aq)$ ions are reduced to H_2 at the platinum surface, the standard electrode potential of the Zn^{2+}/Zn couple is -0.76 V .

Although the reaction at the anode is an oxidation, by convention its tabulated E° value is reported as a *reduction* potential. The potential of a half-reaction measured against the SHE under standard conditions is called the standard electrode potential for that

half-reaction. In this example, the standard reduction potential for $\text{Zn}^{2+}(\text{aq}) + 2\text{e}^{-} \rightarrow \text{Zn}(\text{s})$ is -0.76 V , which means that the standard electrode potential for the reaction that occurs at the anode, the *oxidation* of Zn to Zn^{2+} , often called the *Zn/Zn²⁺ redox couple*, or the *Zn/Zn²⁺ couple*, is $-(-0.76\text{ V}) = 0.76\text{ V}$. We must therefore subtract E°_{anode} from $E^{\circ}_{\text{cathode}}$ to obtain E°_{cell} : $0 - (-0.76\text{ V}) = 0.76\text{ V}$.

Because electrical potential is the energy needed to move a charged particle in an electric field, standard electrode potentials for half-reactions are intensive properties and do not depend on the amount of substance involved. Consequently, *E^o values are independent of the stoichiometric coefficients for the half-reaction*, and, most important, the coefficients used to produce a balanced overall reaction do not affect the value of the cell potential.

Note the Pattern

E^o values do not depend on the stoichiometric coefficients for a half-reaction.

To measure the potential of the Cu/Cu^{2+} couple, we can construct a galvanic cell analogous to the one shown in [Figure 19.2.3](#) but containing a Cu/Cu^{2+} couple in the sample compartment instead of Zn/Zn^{2+} . When we close the circuit this time, the measured potential for the cell is negative (-0.34 V) rather than positive. The negative value of E°_{cell} indicates that the direction of spontaneous electron flow is the opposite of that for the Zn/Zn^{2+} couple. Hence the reactions that occur spontaneously, indicated by a positive E°_{cell} , are the reduction of Cu^{2+} to Cu at the copper electrode. The copper electrode gains mass as the reaction proceeds, and H_2 is oxidized to H^{+} at the platinum electrode. In this cell, the copper strip is the *cathode*, and the hydrogen electrode is the *anode*. The cell diagram therefore is written with the SHE on the left and the Cu^{2+}/Cu couple on the right:

The half-cell reactions and potentials of the spontaneous reaction are as follows:

$$E^{\circ}_{\text{cell}} = E^{\circ}_{\text{cathode}} - E^{\circ}_{\text{anode}} = 0.34$$

Thus the standard electrode potential for the Cu^{2+}/Cu couple is 0.34 V .

Balancing Redox Reactions Using the Half-Reaction Method

In [Chapter 8](#), we described a method for balancing redox reactions using oxidation numbers. Oxidation numbers were assigned to each atom in a redox reaction to identify any changes in the oxidation states. Here we present an alternative approach to balancing redox reactions, the half-reaction method, in which the overall redox reaction is divided into an oxidation half-reaction and a reduction half-reaction, each balanced for mass and charge. This method more closely reflects the events that take place in an electrochemical cell, where the two half-reactions may be physically separated from each other.

We can illustrate how to balance a redox reaction using half-reactions with the reaction that occurs when Drano, a commercial solid drain cleaner, is poured into a clogged drain. Drano contains a mixture of sodium hydroxide and powdered aluminum, which in solution reacts to produce hydrogen gas:

In this reaction, $\text{Al}(\text{s})$ is oxidized to Al^{3+} , and H^{+} in water is reduced to H_2 gas, which bubbles through the solution, agitating it and breaking up the clogs.

The overall redox reaction is composed of a reduction half-reaction and an oxidation half-reaction. From the standard electrode potentials listed in [Table P1](#), we find the corresponding half-reactions that describe the reduction of H^{+} ions in water to H_2 and the oxidation of Al to Al^{3+} in basic solution:

The half-reactions chosen must exactly reflect the reaction conditions, such as the basic conditions shown here. Moreover, the physical states of the reactants and the products must be identical to those given in the overall reaction, whether gaseous, liquid, solid, or in solution.

In [Equation 19.2.13](#), two H^+ ions gain one electron each in the reduction; in [Equation 19.2.14](#), the aluminum atom loses three electrons in the oxidation. The charges are balanced by multiplying the reduction half-reaction ([Equation 19.2.13](#)) by 3 and the oxidation half-reaction ([Equation 19.2.14](#)) by 2 to give the same number of electrons in both half-reactions:

Simplifying by canceling substances that appear on both sides of the equation,

We have a -2 charge on the left side of the equation and a -2 charge on the right side. Thus the charges are balanced, but we must also check that atoms are balanced:

The atoms also balance, so [Equation 19.2.18](#) is a balanced chemical equation for the redox reaction depicted in [Equation 19.20](#).

Note the Pattern

The half-reaction method requires that half-reactions exactly reflect reaction conditions, and the physical states of the reactants and the products must be identical to those in the overall reaction.

We can also balance a redox reaction by first balancing the atoms in each half-reaction and then balancing the charges. With this alternative method, we do not need to use the half-reactions listed in [Table P1](#) but instead focus on the atoms whose oxidation states change, as illustrated in the following steps:

Step 1: Write the reduction half-reaction and the oxidation half-reaction.

For the reaction shown in [Equation 19.2.13](#), hydrogen is reduced from H^+ in OH^- to H_2 , and aluminum is oxidized from Al^0 to Al^{3+} :

Step 2: Balance the atoms by balancing elements other than O and H. Then balance O atoms by adding H_2O and balance H atoms by adding H^+ .

Elements other than O and H in the previous two equations are balanced as written, so we proceed with balancing the O atoms. We can do this by adding water to the appropriate side of each half-reaction:

Balancing H atoms by adding H^+ , we obtain the following:

We have now balanced the atoms in each half-reaction, but the charges are not balanced.

Step 3: Balance the charges in each half-reaction by adding electrons.

Two electrons are gained in the reduction of H^+ ions to H_2 , and three electrons are lost during the oxidation of Al^0 to Al^{3+} :

Step 4: Multiply the reductive and oxidative half-reactions by appropriate integers to obtain the same number of electrons in both half-reactions.

In this case, we multiply [Equation 19.2.26](#) (the reductive half-reaction) by 3 and [Equation 19.2.27](#) (the oxidative half-reaction) by 2 to obtain the same number of electrons in both half-reactions:

Step 5: Add the two half-reactions and cancel substances that appear on both sides of the equation.

Adding and, in this case, canceling $8H^+$, $3H_2O$, and $6e^-$,

We have three OH^- and one H^+ on the left side. Neutralizing the H^+ gives us a total of $5H_2O + H_2O = 6H_2O$ and leaves $2OH^-$ on the left side:

Step 6: Check to make sure that all atoms and charges are balanced.

[Equation 19.2.31](#) is identical to [Equation 19.2.18](#), obtained using the first method, so the charges and numbers of atoms on each side of the equation balance.

Figure 19.2.4 The Reaction of Dichromate with Iodide The reaction of a yellow solution of sodium dichromate with a colorless solution of sodium iodide produces a deep amber solution that contains a green $Cr^{3+}(aq)$ complex and brown $I_2(aq)$ ions.

Example 19.2.1

In acidic solution, the redox reaction of dichromate ion ($Cr_2O_7^{2-}$) and iodide (I^-) can be monitored visually. The yellow dichromate solution reacts with the colorless iodide solution to produce a solution that is deep amber due to the presence of a green $Cr^{3+}(aq)$ complex and brown $I_2(aq)$ ions ([Figure 19.2.4](#)):

Balance this equation using half-reactions.

Given: redox reaction and [Table P1](#)

Asked for: balanced chemical equation using half-reactions

Strategy:

Follow the steps to balance the redox reaction using the half-reaction method.

Solution:

From the standard electrode potentials listed in [Table P1](#), we find the half-reactions corresponding to the overall reaction:

Balancing the number of electrons by multiplying the oxidation reaction by 3,

oxidation: $6I^{-}(aq) \rightarrow 3I_2(aq) + 6e^{-}$

Adding the two half-reactions and canceling electrons,

We must now check to make sure the charges and atoms on each side of the equation balance:

The charges and atoms balance, so our equation is balanced.

We can also use the alternative procedure, which does not require the half-reactions listed in [Table P1](#).

Step 1: Chromium is reduced from Cr^{6+} in $Cr_2O_7^{2-}$ to Cr^{3+} , and I^{-} ions are oxidized to I_2 . Dividing the reaction into two half-reactions,

Step 2: Balancing the atoms other than oxygen and hydrogen,

We now balance the O atoms by adding H_2O —in this case, to the right side of the reduction half-reaction. Because the oxidation half-reaction does not contain oxygen, it can be ignored in this step.

Next we balance the H atoms by adding H^{+} to the left side of the reduction half-reaction. Again, we can ignore the oxidation half-reaction.

Step 3: We must now add electrons to balance the charges. The reduction half-reaction ($2Cr^{6+}$ to $2Cr^{3+}$) has a +12 charge on the left and a +6 charge on the right, so six electrons are needed to balance the charge. The oxidation half-reaction ($2I^{-}$ to I_2) has a -2 charge on the left side and a 0 charge on the right, so it needs two electrons to balance the charge:

Step 4: To have the same number of electrons in both half-reactions, we must multiply the oxidation half-reaction by 3:

Step 5: Adding the two half-reactions and canceling substances that appear in both reactions,

Step 6: This is the same equation we obtained using the first method. Thus the charges and atoms on each side of the equation balance.

Exercise

Copper is commonly found as the mineral covellite (CuS). The first step in extracting the copper is to dissolve the mineral in nitric acid (HNO_3), which oxidizes sulfide to sulfate and reduces nitric acid to NO :

Balance this equation using the half-reaction method.

Answer: $3\text{CuS}(s) + 8\text{HNO}_3 \rightarrow 8\text{NO}(g) + 3\text{CuSO}_4 + 4\text{H}_2\text{O}(l)$

Calculating Standard Cell Potentials

The standard cell potential for a redox reaction (E°_{cell}) is a measure of the tendency of reactants in their standard states to form products in their standard states; consequently, it is a measure of the driving force for the reaction, which earlier we called *voltage*. We can use the two standard electrode potentials we found earlier to calculate the standard potential for the Zn/Cu cell represented by the following cell diagram:

We know the values of E°_{anode} for the reduction of Zn^{2+} and E°_{cathode} for the reduction of Cu^{2+} , so we can calculate E°_{cell} :

$$E_{\text{cell}} = E^\circ_{\text{cathode}} - E_{\text{anode}} = 1.10 \text{ V}$$

This is the same value that is observed experimentally. If the value of E°_{cell} is positive, the reaction will occur spontaneously as written. If the value of E°_{cell} is negative, then the reaction is not spontaneous, and it will not occur as written under standard conditions; it will, however, proceed spontaneously in the opposite direction. As we shall see in [Section 19.7](#), this does not mean that the reaction cannot be made to occur at all under standard conditions. With a sufficient input of electrical energy, virtually any reaction can be forced to occur. Example 4 and its corresponding exercise illustrate how we can use measured cell potentials to calculate standard potentials for redox couples.

Note the Pattern

A positive E°_{cell} means that the reaction will occur spontaneously as written. A negative E°_{cell} means that the reaction will proceed spontaneously in the opposite direction.

Example 19.2.2

A galvanic cell with a measured standard cell potential of 0.27 V is constructed using two beakers connected by a salt bridge. One beaker contains a strip of gallium metal immersed in a 1 M solution of GaCl_3 , and the other contains a piece of nickel immersed in a 1 M solution of NiCl_2 . The half-reactions that occur when the compartments are connected are as follows:

If the potential for the oxidation of Ga to Ga^{3+} is 0.55 V under standard conditions, what is the potential for the oxidation of Ni to Ni^{2+} ?

Given: galvanic cell, half-reactions, standard cell potential, and potential for the oxidation half-reaction under standard conditions

Asked for: standard electrode potential of reaction occurring at the cathode

Strategy:

A Write the equation for the half-reaction that occurs at the anode along with the value of the standard electrode potential for the half-reaction.

B Use [Equation 19.2.2](#) to calculate the standard electrode potential for the half-reaction that occurs at the cathode. Then reverse the sign to obtain the potential for the corresponding oxidation half-reaction under standard conditions.

Solution:

A We have been given the potential for the oxidation of Ga to Ga^{3+} under standard conditions, but to report the standard electrode potential, we must reverse the sign. For the reduction reaction $\text{Ga}^{3+}(\text{aq}) + 3\text{e}^{-} \rightarrow \text{Ga}(\text{s})$, $E^{\circ}_{\text{anode}} = -0.55 \text{ V}$.

B Using the value given for E°_{cell} and the calculated value of E°_{anode} , we can calculate the standard potential for the reduction of Ni^{2+} to Ni from [Equation 19.2.2](#):

$$\begin{aligned} E_{\text{cell}} &= E^{\circ}_{\text{cathode}} - E_{\text{anode}} \\ 0.27 \text{ V} &= E^{\circ}_{\text{cathode}} - (-0.55 \text{ V}) \\ E^{\circ}_{\text{cathode}} &= -0.28 \text{ V} \end{aligned}$$

This is the standard electrode potential for the reaction $\text{Ni}^{2+}(\text{aq}) + 2\text{e}^{-} \rightarrow \text{Ni}(\text{s})$. Because we are asked for the potential for the *oxidation* of Ni to Ni^{2+} under standard conditions, we must reverse the sign of $E^{\circ}_{\text{cathode}}$. Thus $E^{\circ} = -(-0.28 \text{ V}) = 0.28 \text{ V}$ for the oxidation. With three electrons consumed in the reduction and two produced in the oxidation, the overall reaction is not balanced. Recall, however, that standard potentials are *independent* of stoichiometry.

Exercise

A galvanic cell is constructed with one compartment that contains a mercury electrode immersed in a 1 M aqueous solution of mercuric acetate $[\text{Hg}(\text{CH}_3\text{CO}_2)_2]$ and one compartment that contains a strip of magnesium immersed in a 1 M aqueous solution of MgCl_2 . When the compartments are connected, a potential of 3.22 V is measured and the following half-reactions occur:

If the potential for the oxidation of Mg to Mg^{2+} is 2.37 V under standard conditions, what is the standard electrode potential for the reaction that occurs at the anode?

Answer: 0.85 V

Reference Electrodes and Measuring Concentrations

When using a galvanic cell to measure the concentration of a substance, we are generally interested in the potential of only one of the electrodes of the cell, the so-called indicator electrode, whose potential is related to the concentration of the substance being measured. To ensure that any change in the measured potential of the cell is due to only the substance being analyzed, the potential of the other electrode, the reference electrode, must be constant. You are already familiar with one example of a reference electrode: the SHE. The potential of a reference electrode must be unaffected by the properties of the solution, and if possible, it should be physically isolated from the solution of interest. To measure the potential of a solution, we select a reference electrode and an appropriate indicator electrode. Whether reduction or oxidation of the substance being analyzed occurs depends on the potential of the half-reaction for the substance of interest (the sample) and the potential of the reference electrode.

Note the Pattern

The potential of any reference electrode should not be affected by the properties of the solution to be analyzed, and it should also be physically isolated.

There are many possible choices of reference electrode other than the SHE. The SHE requires a constant flow of highly flammable hydrogen gas, which makes it inconvenient to use. Consequently, two other electrodes are commonly chosen as reference electrodes. One is the silver–silver chloride electrode, which consists of a silver wire coated with a very thin layer of AgCl that is dipped into a chloride ion solution with a fixed concentration. The cell diagram and reduction half-reaction are as follows:

If a saturated solution of KCl is used as the chloride solution, the potential of the silver–silver chloride electrode is 0.197 V versus the SHE. That is, 0.197 V must be subtracted from the measured value to obtain the standard electrode potential measured against the SHE.

A second common reference electrode is the saturated calomel electrode (SCE), which has the same general form as the silver–silver chloride electrode. The SCE consists of a platinum wire inserted into a moist paste of liquid mercury (Hg_2Cl_2 ; called *calomel* in the old chemical literature) and KCl. This interior cell is surrounded by an aqueous KCl solution, which acts as a salt bridge between the interior cell and the exterior solution (part (a) in Figure 19.2.5). Although it sounds and looks complex, this cell is actually easy to prepare and maintain, and its potential is highly reproducible. The SCE cell diagram and corresponding half-reaction are as follows:

Figure 19.2.5 Three Common Types of Electrodes: (a) The SCE is a reference electrode that consists of a platinum wire inserted into a moist paste of liquid mercury (calomel; Hg_2Cl_2) and KCl. The interior cell is surrounded by an aqueous KCl solution, which acts as a salt bridge between the interior cell and the exterior solution. (b) In a glass electrode, an internal Ag/AgCl electrode is immersed in a 1 M HCl solution that is separated from the sample solution by a very thin glass membrane. The potential of the electrode depends on the H^+ ion concentration of the sample. (c) The potential of an ion-selective electrode depends on the concentration of only a single ionic species in solution.

At 25°C, the potential of the SCE is 0.2415 V versus the SHE, which means that 0.2415 V must be subtracted from the potential versus an SCE to obtain the standard electrode potential.

One of the most common uses of electrochemistry is to measure the H^+ ion concentration of a solution. A glass electrode is generally used for this purpose, in which an internal Ag/AgCl electrode is immersed in a 0.10 M HCl solution that is separated from the solution by a very thin glass membrane (part (b) in Figure 19.2.5). The glass membrane absorbs protons, which affects the measured potential. The extent of the adsorption on the inner side is fixed because $[H^+]$ is fixed inside the electrode, but the adsorption of protons on the outer surface depends on the pH of the solution. The potential of the glass electrode depends on $[H^+]$ as follows (recall that $pH = -\log[H^+]$):

$$E_{glass} = E' + (0.0591 V \times \log[H^+]) = E' - 0.0591 V \times pH \quad (19.2.39)$$

The voltage E' is a constant that depends on the exact construction of the electrode. Although it can be measured, in practice, a glass electrode is *calibrated*; that is, it is inserted into a solution of known pH, and the display on the pH meter is adjusted to the known value. Once the electrode is properly calibrated, it can be placed in a solution and used to determine an unknown pH.

Ion-selective electrodes are used to measure the concentration of a particular species in solution; they are designed so that their potential depends on only the concentration of the desired species (part (c) in Figure 19.2.5). These electrodes usually contain an internal reference electrode that is connected by a solution of an electrolyte to a crystalline inorganic material or a membrane, which acts as the sensor. For example, one type of ion-selective electrode uses a single crystal of Eu-doped LaF_3 as the inorganic material. When fluoride ions in solution diffuse to the surface of the solid, the potential of the electrode changes, resulting in a so-called *fluoride electrode*. Similar electrodes are used to measure the concentrations of other species in solution. Some of the species

whose concentrations can be determined in aqueous solution using ion-selective electrodes and similar devices are listed in [Table 19.2.1](#).

Table 19.2.1 Some Species Whose Aqueous Concentrations Can Be Measured Using Electrochemical Methods

Species	Type of Sample
H ⁺	laboratory samples, blood, soil, and ground and surface water
NH ₃ /NH ₄ ⁺	wastewater and runoff water
K ⁺	blood, wine, and soil
CO ₂ /HCO ₃ ⁻	blood and groundwater
F ⁻	groundwater, drinking water, and soil
Br ⁻	grains and plant extracts
I ⁻	milk and pharmaceuticals
NO ₃ ⁻	groundwater, drinking water, soil, and fertilizer

Summary

The flow of electrons in an electrochemical cell depends on the identity of the reacting substances, the difference in the potential energy of their valence electrons, and their concentrations. The potential of the cell under standard conditions (1 M for solutions, 1 atm for gases, pure solids or liquids for other substances) and at a fixed temperature (25°C) is called the **standard cell potential** (E°_{cell}). Only the *difference* between the potentials of two electrodes can be measured. By convention, all tabulated values of *standard electrode potentials* are listed as standard reduction potentials. The overall cell potential is the reduction potential of the reductive half-reaction minus the reduction potential of the oxidative half-reaction ($E^\circ_{\text{cell}} = E^\circ_{\text{cathode}} - E^\circ_{\text{anode}}$). The potential of the **standard hydrogen electrode (SHE)** is defined as 0 V under standard conditions. The potential of a half-reaction measured against the SHE under standard conditions is called its **standard electrode potential**. The standard cell potential is a measure of the driving force for a given redox reaction. All E° values are independent of the stoichiometric coefficients for the half-reaction. Redox reactions can be balanced using the half-reaction method, in which the overall redox reaction is divided into an oxidation half-reaction and a reduction half-reaction, each balanced for mass and charge. The half-reactions selected from tabulated lists must exactly reflect reaction conditions. In an alternative method, the atoms in each half-reaction are balanced, and then the charges are balanced. Whenever a half-reaction is reversed, the sign of E° corresponding to that reaction must also be reversed. If E°_{cell} is positive, the reaction will occur spontaneously under standard conditions. If E°_{cell} is negative, then the reaction is not spontaneous under standard conditions, although it will proceed spontaneously in the opposite direction. The potential of an **indicator electrode** is related to the concentration of the substance being measured, whereas the potential of the **reference electrode** is held constant. Whether reduction or oxidation occurs depends on the potential of the sample versus the potential of the reference electrode. In addition to the SHE, other reference electrodes are the **silver–silver chloride electrode**; the **saturated calomel electrode (SCE)**; the **glass electrode**, which is commonly used to measure pH; and **ion-selective electrodes**, which depend on the concentration of a single ionic species in solution. Differences in potential between the SHE and other reference electrodes must be included when calculating values for E° .

Key Takeaways

- Redox reactions can be balanced using the half-reaction method.
- The standard cell potential is a measure of the driving force for the reaction.

Key Equation

Standard cell potential

Equation 19.2.2: $E^\circ_{\text{cell}} = E^\circ_{\text{cathode}} - E^\circ_{\text{anode}}$

Conceptual Problems

- Is a hydrogen electrode chemically inert? What is the major disadvantage to using a hydrogen electrode?
- List two factors that affect the measured potential of an electrochemical cell and explain their impact on the measurements.
- What is the relationship between electron flow and the potential energy of valence electrons? If the valence electrons of substance A have a higher potential energy than those of substance B, what is the direction of electron flow between them in a galvanic cell?
- If the components of a galvanic cell include aluminum and bromine, what is the predicted direction of electron flow? Why?
- Write a cell diagram representing a cell that contains the Ni/Ni²⁺ couple in one compartment and the SHE in the other compartment. What are the values of E°_{cathode} , E°_{anode} , and E°_{cell} ?
- Explain why E° values are independent of the stoichiometric coefficients in the corresponding half-reaction.
- Identify the oxidants and the reductants in each redox reaction.
 - $\text{Cr}(s) + \text{Ni}^{2+}(aq) \rightarrow \text{Cr}^{3+}(aq) + \text{Ni}(s)$
 - $\text{Cl}_2(g) + \text{Sn}^{2+}(aq) \rightarrow 2\text{Cl}^-(aq) + \text{Sn}^{4+}(aq)$
 - $\text{H}_3\text{AsO}_4(aq) + 8\text{H}^+(aq) + 4\text{Zn}(s) \rightarrow \text{AsH}_3(g) + 4\text{H}_2\text{O}(l) + 4\text{Zn}^{2+}(aq)$
 - $2\text{NO}_2(g) + 2\text{OH}^-(aq) \rightarrow \text{NO}_2^-(aq) + \text{NO}_3^-(aq) + \text{H}_2\text{O}(l)$
- Identify the oxidants and the reductants in each redox reaction.
 - $\text{Br}_2(l) + 2\text{I}^-(aq) \rightarrow 2\text{Br}^-(aq) + \text{I}_2(s)$
 - $\text{Cu}^+(aq) + 2\text{Ag}(s) \rightarrow \text{Cu}(s) + 2\text{Ag}^+(aq)$
 - $\text{H}^+(aq) + 2\text{MnO}_4^-(aq) + 5\text{H}_2\text{SO}_3(aq) \rightarrow 2\text{Mn}^{2+}(aq) + 3\text{H}_2\text{O}(l) + 5\text{HSO}_4^-(aq)$
 - $\text{IO}_3^-(aq) + 5\text{I}^-(aq) + 6\text{H}^+(aq) \rightarrow 3\text{I}_2(s) + 3\text{H}_2\text{O}(l)$
- All reference electrodes must conform to certain requirements. List the requirements and explain their significance.
- For each application, describe the reference electrode you would use and explain why. In each case, how would the measured potential compare with the corresponding E° ?
 - measuring the potential of a Cl⁻/Cl₂ couple
 - measuring the pH of a solution
 - measuring the potential of a MnO₄⁻/Mn²⁺ couple

Numerical Problems

- Draw the cell diagram for a galvanic cell with an SHE and a copper electrode that carries out this overall reaction:

$$\text{H}_2(\text{g}) + \text{Cu}^{2+}(\text{aq}) \rightarrow 2\text{H}^{+}(\text{aq}) + \text{Cu}(\text{s})$$
- Draw the cell diagram for a galvanic cell with an SHE and a zinc electrode that carries out this overall reaction:

$$\text{Zn}(\text{s}) + 2\text{H}^{+}(\text{aq}) \rightarrow \text{Zn}^{2+}(\text{aq}) + \text{H}_2(\text{g})$$
- Balance each reaction and calculate the standard electrode potential for each. Be sure to include the physical state of each product and reactant.
 - $\text{Cl}_2(\text{g}) + \text{H}_2(\text{g}) \rightarrow 2\text{Cl}^{-}(\text{aq}) + 2\text{H}^{+}(\text{aq})$
 - $\text{Br}_2(\text{aq}) + \text{Fe}^{2+}(\text{aq}) \rightarrow 2\text{Br}^{-}(\text{aq}) + \text{Fe}^{3+}(\text{aq})$
 - $\text{Fe}^{2+}(\text{aq}) + \text{Cd}(\text{s}) \rightarrow \text{Fe}(\text{s}) + \text{Cd}^{2+}(\text{aq})$
- Balance each reaction and calculate the standard reduction potential for each. Be sure to include the physical state of each product and reactant.
 - $\text{Cu}^{+}(\text{aq}) + \text{Ag}^{+}(\text{aq}) \rightarrow \text{Cu}^{2+}(\text{aq}) + \text{Ag}(\text{s})$
 - $\text{Sn}(\text{s}) + \text{Fe}^{2+}(\text{aq}) \rightarrow \text{Sn}^{2+}(\text{aq}) + \text{Fe}(\text{s})$
 - $\text{Mg}(\text{s}) + \text{Br}_2(\text{l}) \rightarrow 2\text{Br}^{-}(\text{aq}) + \text{Mg}^{2+}(\text{aq})$
- Write a balanced chemical equation for each redox reaction.
 - $\text{H}_2\text{PO}_2^{-}(\text{aq}) + \text{SbO}_2^{-}(\text{aq}) \rightarrow \text{HPO}_3^{2-}(\text{aq}) + \text{Sb}(\text{s})$ in basic solution
 - $\text{HNO}_2(\text{aq}) + \text{I}_2(\text{aq}) \rightarrow \text{NO}(\text{g}) + \text{I}_2(\text{s})$ in acidic solution
 - $\text{N}_2\text{O}(\text{g}) + \text{ClO}^{-}(\text{aq}) \rightarrow \text{Cl}^{-}(\text{aq}) + \text{NO}_2^{-}(\text{aq})$ in basic solution
 - $\text{Br}_2(\text{l}) \rightarrow \text{Br}^{-}(\text{aq}) + \text{BrO}_3^{-}(\text{aq})$ in basic solution
 - $\text{Cl}(\text{CH}_2)_2\text{OH}(\text{aq}) + \text{K}_2\text{Cr}_2\text{O}_7(\text{aq}) \rightarrow \text{ClCH}_2\text{CO}_2\text{H}(\text{aq}) + \text{Cr}^{3+}(\text{aq})$ in acidic solution
- Write a balanced chemical equation for each redox reaction.
 - $\text{I}^{-}(\text{aq}) + \text{HClO}_2(\text{aq}) \rightarrow \text{IO}_3^{-}(\text{aq}) + \text{Cl}_2(\text{g})$ in acidic solution
 - $\text{Cr}^{3+}(\text{aq}) + \text{O}_2(\text{g}) \rightarrow \text{Cr}^{6+}(\text{aq}) + \text{H}_2\text{O}(\text{l})$ in acidic solution
 - $\text{CrO}_2^{-}(\text{aq}) + \text{ClO}^{-}(\text{aq}) \rightarrow \text{CrO}_4^{2-}(\text{aq}) + \text{Cl}^{-}(\text{aq})$ in basic solution
 - $\text{S}(\text{s}) + \text{HNO}_2(\text{aq}) \rightarrow \text{H}_2\text{SO}_3(\text{aq}) + \text{N}_2\text{O}(\text{g})$ in acidic solution
 - $\text{F}(\text{CH}_2)_2\text{OH}(\text{aq}) + \text{K}_2\text{Cr}_2\text{O}_7(\text{aq}) \rightarrow \text{FCH}_2\text{CO}_2\text{H}(\text{aq}) + \text{Cr}^{3+}(\text{aq})$ in acidic solution
- The standard cell potential for the oxidation of Pb to Pb^{2+} with the concomitant reduction of Cu^{2+} to Cu is 0.39 V. You know that E° for the Pb^{2+}/Pb couple is -0.13 V. What is E° for the Cu^{2+}/Cu couple?
- You have built a galvanic cell similar to the one in [Figure 19.2.3](#) using an iron nail, a solution of FeCl_2 , and an SHE. When the cell is connected, you notice that the iron nail begins to corrode. What else do you observe? Under standard conditions, what is E_{cell} ?
- Carbon is used to reduce iron ore to metallic iron. The overall reaction is as follows:

$$2\text{Fe}_2\text{O}_3 \cdot x\text{H}_2\text{O}(\text{s}) + 3\text{C}(\text{s}) \rightarrow 4\text{Fe}(\text{l}) + 3\text{CO}_2(\text{g}) + 2x\text{H}_2\text{O}(\text{g})$$
 Write the two half-reactions for this overall reaction.
- Will each reaction occur spontaneously under standard conditions?
 - $\text{Cu}(\text{s}) + 2\text{H}^{+}(\text{aq}) \rightarrow \text{Cu}^{2+}(\text{aq}) + \text{H}_2(\text{g})$
 - $\text{Zn}^{2+}(\text{aq}) + \text{Pb}(\text{s}) \rightarrow \text{Zn}(\text{s}) + \text{Pb}^{2+}(\text{aq})$
- Each reaction takes place in acidic solution. Balance each reaction and then determine whether it occurs spontaneously as written under standard conditions.
 - $\text{Se}(\text{s}) + \text{Br}_2(\text{l}) \rightarrow \text{H}_2\text{SeO}_3(\text{aq}) + \text{Br}^{-}(\text{aq})$
 - $\text{NO}_3^{-}(\text{aq}) + \text{S}(\text{s}) \rightarrow \text{HNO}_2(\text{aq}) + \text{H}_2\text{SO}_3(\text{aq})$
 - $\text{Fe}^{2+}(\text{aq}) + \text{Cr}^{3+}(\text{aq}) \rightarrow \text{Fe}^{3+}(\text{aq}) + \text{Cr}_2\text{O}_7^{2-}(\text{aq})$
- Calculate E°_{cell} and ΔG° for the redox reaction represented by the cell diagram $\text{Pt}(\text{s}) | \text{Cl}_2(\text{g}, 1 \text{ atm}) || \text{ZnCl}_2(\text{aq}, 1 \text{ M}) | \text{Zn}(\text{s})$. Will this reaction occur spontaneously?
- If you place Zn-coated (galvanized) tacks in a glass and add an aqueous solution of iodine, the brown color of the iodine solution fades to a pale yellow. What has happened? Write the two half-reactions and the overall balanced chemical equation for this reaction. What is E°_{cell} ?
- Your lab partner wants to recover solid silver from silver chloride by using a 1.0 M solution of HCl and 1 atm H_2 under standard conditions. Will this plan work?

Answers

1. $\text{Pt(s)} | \text{H}_2(\text{g}, 1 \text{ atm}) | \text{H}^+(\text{aq}, 1\text{M}) || \text{Cu}^{2+}(\text{aq}) | \text{Cu(s)}$

Learning Objective

- To know how to predict the relative strengths of various oxidants and reductants.

We can use the procedure described in [Section 19.2](#) to measure the standard potentials for a wide variety of chemical substances, some of which are listed in [Table 19.3.1](#) ([Table P1](#) contains a more extensive listing.) These data allow us to compare the oxidative and reductive strengths of a variety of substances. The half-reaction for the standard hydrogen electrode (SHE) lies more than halfway down the list in [Table 19.3.1](#). All reactants that lie *above* the SHE in the table are stronger oxidants than H⁺, and all those that lie below the SHE are weaker. The strongest oxidant in the table is F₂, with a standard electrode potential of 2.87 V. This high value is consistent with the high electronegativity of fluorine and tells us that fluorine has a stronger tendency to accept electrons (it is a stronger oxidant) than any other element.

Table 19.3.1 Standard Potentials for Selected Reduction Half-Reactions at 25°C

Half-Reaction	E° (V)
$F_2(g) + 2e^- \rightarrow 2F^-(aq)$	2.87
$H_2O_2(aq) + 2H^+(aq) + 2e^- \rightarrow 2H_2O(l)$	1.78
$Ce^{4+}(aq) + e^- \rightarrow Ce^{3+}(aq)$	1.72
$PbO_2(s) + HSO_4^-(aq) + 3H^+(aq) + 2e^- \rightarrow PbSO_4(s) + 2H_2O(l)$	1.69
$Cl_2(g) + 2e^- \rightarrow 2Cl^-(aq)$	1.36
$Cr_2O_7^{2-}(aq) + 14H^+(aq) + 6e^- \rightarrow 2Cr^{3+}(aq) + 7H_2O(l)$	1.23
$O_2(g) + 4H^+(aq) + 4e^- \rightarrow 2H_2O(l)$	1.23
$MnO_2(s) + 4H^+(aq) + 2e^- \rightarrow Mn^{2+}(aq) + 2H_2O(l)$	1.22
$Br_2(aq) + 2e^- \rightarrow 2Br^-(aq)$	1.09
$NO_3^-(aq) + 3H^+(aq) + 2e^- \rightarrow HNO_2(aq) + H_2O(l)$	0.93
$Ag^+(aq) + e^- \rightarrow Ag(s)$	0.80
$Fe^{3+}(aq) + e^- \rightarrow Fe^{2+}(aq)$	0.77
$H_2SeO_3(aq) + 4H^+ + 4e^- \rightarrow Se(s) + 3H_2O(l)$	0.74
$O_2(g) + 2H^+(aq) + 2e^- \rightarrow H_2O_2(aq)$	0.70
$MnO_4^-(aq) + 2H_2O(l) + 3e^- \rightarrow MnO_2(s) + 4OH^-(aq)$	0.60
$MnO_4^{2-}(aq) + 2H_2O(l) + 2e^- \rightarrow MnO_2(s) + 4OH^-(aq)$	0.60
$I_2(s) + 2e^- \rightarrow 2I^-(aq)$	0.54

Half-Reaction	E° (V)
$\text{H}_2\text{SO}_3(\text{aq}) + 4\text{H}^+(\text{aq}) + 4\text{e}^- \rightarrow \text{S}(\text{s}) + 3\text{H}_2\text{O}(\text{l})$	0.45
$\text{O}_2(\text{g}) + 2\text{H}_2\text{O}(\text{l}) + 4\text{e}^- \rightarrow 4\text{OH}^-(\text{aq})$	0.40
$\text{Cu}^{2+}(\text{aq}) + 2\text{e}^- \rightarrow \text{Cu}(\text{s})$	0.34
$\text{AgCl}(\text{s}) + \text{e}^- \rightarrow \text{Ag}(\text{s}) + \text{Cl}^-(\text{aq})$	0.22
$\text{Cu}^{2+}(\text{aq}) + \text{e}^- \rightarrow \text{Cu}^+(\text{aq})$	0.15
$\text{Sn}^{4+}(\text{aq}) + 2\text{e}^- \rightarrow \text{Sn}^{2+}(\text{aq})$	0.15
$2\text{H}^+(\text{aq}) + 2\text{e}^- \rightarrow \text{H}_2(\text{g})$	0.00
$\text{Sn}^{2+}(\text{aq}) + 2\text{e}^- \rightarrow \text{Sn}(\text{s})$	-0.14
$2\text{SO}_4^{2-}(\text{aq}) + 4\text{H}^+(\text{aq}) + 2\text{e}^- \rightarrow \text{S}_2\text{O}_6^{2-}(\text{aq}) + 2\text{H}_2\text{O}(\text{l})$	-0.22
$\text{Ni}^{2+}(\text{aq}) + 2\text{e}^- \rightarrow \text{Ni}(\text{s})$	-0.26
$\text{PbSO}_4(\text{s}) + 2\text{e}^- \rightarrow \text{Pb}(\text{s}) + \text{SO}_4^{2-}(\text{aq})$	-0.36
$\text{Cd}^{2+}(\text{aq}) + 2\text{e}^- \rightarrow \text{Cd}(\text{s})$	-0.40
$\text{Cr}^{3+}(\text{aq}) + \text{e}^- \rightarrow \text{Cr}^{2+}(\text{aq})$	-0.41
$\text{Fe}^{2+}(\text{aq}) + 2\text{e}^- \rightarrow \text{Fe}(\text{s})$	-0.45
$\text{Ag}_2\text{S}(\text{s}) + 2\text{e}^- \rightarrow 2\text{Ag}(\text{s}) + \text{S}^{2-}(\text{aq})$	-0.69
$\text{Zn}^{2+}(\text{aq}) + 2\text{e}^- \rightarrow \text{Zn}(\text{s})$	-0.76
$\text{Al}^{3+}(\text{aq}) + 3\text{e}^- \rightarrow \text{Al}(\text{s})$	-1.662
$\text{Be}^{2+}(\text{aq}) + 2\text{e}^- \rightarrow \text{Be}(\text{s})$	-1.85
$\text{Li}^+(\text{aq}) + \text{e}^- \rightarrow \text{Li}(\text{s})$	-3.04

Similarly, all species in [Table 19.3.1](#) that lie *below* H_2 are stronger reductants than H_2 , and those that lie above H_2 are weaker. The strongest reductant in the table is thus metallic lithium, with a standard electrode potential of -3.04 V. This fact might be surprising because cesium, not lithium, is the least electronegative element. The apparent anomaly can be explained by the fact that electrode potentials are measured in aqueous solution, where intermolecular interactions are important, whereas ionization potentials and electron affinities are measured in the gas phase. Due to its small size, the Li^+ ion is stabilized in aqueous solution by strong electrostatic interactions with the negative dipole end of water molecules. These interactions result in a significantly greater $\Delta H_{\text{hydration}}$ for Li^+ compared with Cs^+ . Lithium metal is therefore the strongest reductant (most easily oxidized) of the alkali metals in aqueous solution.

Note the Pattern

Species in [Table 19.3.1](#) that lie below H_2 are stronger reductants (more easily oxidized) than H_2 . Species that lie above H_2 are stronger oxidants.

Because the half-reactions shown in [Table 19.3.1](#) are arranged in order of their E° values, we can use the table to quickly predict the relative strengths of various oxidants and reductants. Any species on the left side of a half-reaction will spontaneously oxidize any species on the right side of another half-reaction that lies *below* it in the table. Conversely, any species on the right side of a half-reaction will spontaneously reduce any species on the left side of another half-reaction that lies *above* it in the table. We can use these generalizations to predict the spontaneity of a wide variety of redox reactions ($E^\circ_{\text{cell}} > 0$), as illustrated in Example 5.

Example 19.3.1

The black tarnish that forms on silver objects is primarily Ag_2S . The half-reaction for reversing the tarnishing process is as follows:

1. Referring to [Table 19.3.1](#), predict which species— $\text{H}_2\text{O}_2(\text{aq})$, $\text{Zn}(\text{s})$, $\text{I}^-(\text{aq})$, $\text{Sn}^{2+}(\text{aq})$ —can reduce Ag_2S to Ag under standard conditions.
2. Of these species— $\text{H}_2\text{O}_2(\text{aq})$, $\text{Zn}(\text{s})$, $\text{I}^-(\text{aq})$, $\text{Sn}^{2+}(\text{aq})$, identify which is the strongest reducing agent in aqueous solution and thus the best candidate for a commercial product.
3. From the data in [Table 19.3.1](#), suggest an alternative reducing agent that is readily available, inexpensive, and possibly more effective at removing tarnish.

Given: reduction half-reaction, standard electrode potential, and list of possible reductants

Asked for: reductants for Ag_2S , strongest reductant, and potential reducing agent for removing tarnish

Strategy:

A From their positions in [Table 19.3.1](#), decide which species can reduce Ag_2S . Determine which species is the strongest reductant.

B Use [Table 19.3.1](#) to identify a reductant for Ag_2S that is a common household product.

Solution:

We can solve the problem in one of two ways: (1) compare the relative positions of the four possible reductants with that of the $\text{Ag}_2\text{S}/\text{Ag}$ couple in [Table 19.3.1](#) or (2) compare E° for each species with E° for the $\text{Ag}_2\text{S}/\text{Ag}$ couple (-0.69 V).

1. **A** The species in [Table 19.3.1](#) are arranged from top to bottom in order of increasing reducing strength. Of the four species given in the problem, $\text{I}^-(\text{aq})$, $\text{Sn}^{2+}(\text{aq})$, and $\text{H}_2\text{O}_2(\text{aq})$ lie above Ag_2S , and one [$\text{Zn}(\text{s})$] lies below it. We can therefore conclude that $\text{Zn}(\text{s})$ can reduce $\text{Ag}_2\text{S}(\text{s})$ under standard conditions, whereas $\text{I}^-(\text{aq})$, $\text{Sn}^{2+}(\text{aq})$, and $\text{H}_2\text{O}_2(\text{aq})$ cannot. $\text{Sn}^{2+}(\text{aq})$ and $\text{H}_2\text{O}_2(\text{aq})$ appear twice in the table: on the left side (oxidant) in one half-reaction and on the right side (reductant) in another.
2. The strongest reductant is $\text{Zn}(\text{s})$, the species on the right side of the half-reaction that lies closer to the bottom of [Table 19.3.1](#) than the half-reactions involving $\text{I}^-(\text{aq})$, $\text{Sn}^{2+}(\text{aq})$, and $\text{H}_2\text{O}_2(\text{aq})$. (Commercial products that use a piece of zinc are often marketed as a “miracle product” for removing tarnish from silver. All that is required is to add warm water and salt for electrical conductivity.)
3. **B** Of the reductants that lie below $\text{Zn}(\text{s})$ in [Table 19.3.1](#), and therefore are stronger reductants, only one is commonly available in household products: $\text{Al}(\text{s})$, which is sold as aluminum foil for wrapping foods.

Exercise

Refer to [Table 19.3.1](#) to predict

1. which species— $\text{Sn}^{4+}(\text{aq})$, $\text{Cl}^-(\text{aq})$, $\text{Ag}^+(\text{aq})$, $\text{Cr}^{3+}(\text{aq})$, and/or $\text{H}_2\text{O}_2(\text{aq})$ —can oxidize $\text{MnO}_2(\text{s})$ to MnO_4^- under standard conditions.

2. which species— $\text{Sn}^{2+}(\text{aq})$, $\text{Cl}^{-}(\text{aq})$, $\text{Ag}^{+}(\text{aq})$, $\text{Cr}^{3+}(\text{aq})$, and/or $\text{H}_2\text{O}_2(\text{aq})$ —is the strongest oxidizing agent in aqueous solution.

Answer:

1. $\text{Ag}^{+}(\text{aq})$; $\text{H}_2\text{O}_2(\text{aq})$
2. $\text{H}_2\text{O}_2(\text{aq})$

Example 19.3.2

Use the data in [Table 19.3.1](#) to determine whether each reaction is likely to occur spontaneously under standard conditions:

1. $\text{Sn}(\text{s}) + \text{Be}^{2+}(\text{aq}) \rightarrow \text{Sn}^{2+}(\text{aq}) + \text{Be}(\text{s})$
2. $\text{MnO}_2(\text{s}) + \text{H}_2\text{O}_2(\text{aq}) + 2\text{H}^{+}(\text{aq}) \rightarrow \text{O}_2(\text{g}) + \text{Mn}^{2+}(\text{aq}) + 2\text{H}_2\text{O}(\text{l})$

Given: redox reaction and list of standard electrode potentials ([Table 19.3.1](#))

Asked for: reaction spontaneity

Strategy:

A Identify the half-reactions in each equation. Using [Table 19.3.1](#), determine the standard potentials for the half-reactions in the appropriate direction.

B Use [Equation 19.2.2](#) to calculate the standard cell potential for the overall reaction. From this value, determine whether the overall reaction is spontaneous.

Solution:

1. **A** Metallic tin is oxidized to $\text{Sn}^{2+}(\text{aq})$, and $\text{Be}^{2+}(\text{aq})$ is reduced to elemental beryllium. We can find the standard electrode potentials for the latter (reduction) half-reaction (-1.85 V) and for the former (oxidation) half-reaction (-0.14 V) directly from [Table 19.3.1](#).

B Adding the two half-reactions gives the overall reaction:

The standard cell potential is quite negative, so the reaction will *not* occur spontaneously as written. That is, metallic tin cannot be used to reduce Be^{2+} to beryllium metal under standard conditions. Instead, the reverse process, the reduction of stannous ions (Sn^{2+}) by metallic beryllium, which has a positive value of E_{cell}° , will occur spontaneously.

2. **A** MnO_2 is the oxidant (Mn^{4+} is reduced to Mn^{2+}), while H_2O_2 is the reductant (O^{2-} is oxidized to O_2). We can obtain the standard electrode potentials for the reduction and oxidation half-reactions directly from [Table 19.2 "Standard Potentials for Selected Reduction Half-Reactions at 25°C"](#).

B The two half-reactions and their corresponding potentials are as follows:

The standard potential for the reaction is positive, indicating that under standard conditions, it will occur spontaneously as written. Hydrogen peroxide will reduce MnO_2 , and oxygen gas will evolve from the

solution.

Exercise

Use the data in [Table 19.3.2](#) to determine whether each reaction is likely to occur spontaneously under standard conditions:

- $2\text{Ce}^{4+}(\text{aq}) + 2\text{Cl}^{-}(\text{aq}) \rightarrow 2\text{Ce}^{3+}(\text{aq}) + \text{Cl}_2(\text{g})$
- $4\text{MnO}_2(\text{s}) + 3\text{O}_2(\text{g}) + 4\text{OH}^{-}(\text{aq}) \rightarrow 4\text{MnO}_4^{-}(\text{aq}) + 2\text{H}_2\text{O}$

Answer:

- spontaneous ($E^{\circ}_{\text{cell}} = 0.36 \text{ V}$)
- nonspontaneous ($E^{\circ}_{\text{cell}} = -0.20 \text{ V}$)

Although the sign of E°_{cell} tells us whether a particular redox reaction will occur spontaneously under standard conditions, it does not tell us to what *extent* the reaction proceeds, and it does not tell us what will happen under nonstandard conditions. To answer these questions requires a more quantitative understanding of the relationship between electrochemical cell potential and chemical thermodynamics, as described in [Section 19.4](#).

Summary

The oxidative and reductive strengths of a variety of substances can be compared using standard electrode potentials. Apparent anomalies can be explained by the fact that electrode potentials are measured in aqueous solution, which allows for strong intermolecular electrostatic interactions, and not in the gas phase.

Key Takeaway

- The relative strengths of various oxidants and reductants can be predicted using E° values.

Conceptual Problems

- The order of electrode potentials cannot always be predicted by ionization potentials and electron affinities. Why? Do you expect sodium metal to have a higher or a lower electrode potential than predicted from its ionization potential? What is its approximate electrode potential?
- Without referring to tabulated data, of $\text{Br}_2/\text{Br}^{-}$, Ca^{2+}/Ca , O_2/OH^{-} , and Al^{3+}/Al , which would you expect to have the *least* negative electrode potential and which the *most* negative? Why?
- Because of the sulfur-containing amino acids present in egg whites, eating eggs with a silver fork will tarnish the fork. As a chemist, you have all kinds of interesting cleaning products in your cabinet, including a 1 M solution of oxalic acid ($\text{H}_2\text{C}_2\text{O}_4$). Would you choose this solution to clean the fork that you have tarnished from eating scrambled eggs?
- The electrode potential for the reaction $\text{Cu}^{2+}(\text{aq}) + 2\text{e}^{-} \rightarrow \text{Cu}(\text{s})$ is 0.34 V under standard conditions. Is the potential for the oxidation of 0.5 mol of Cu equal to $-0.34/2 \text{ V}$? Explain your answer.

Answer

-
-
- No; $E^{\circ} = -0.691 \text{ V}$ for $\text{Ag}_2\text{S}(\text{s}) + 2\text{e}^{-} \rightarrow 2\text{Ag}(\text{s}) + \text{S}^{2-}(\text{aq})$, which is too negative for Ag_2S to be spontaneously reduced by oxalic acid [$E^{\circ} = 0.49 \text{ V}$ for $2\text{CO}_2(\text{g}) + 2\text{H}^{+}(\text{aq}) + 2\text{e}^{-} \rightarrow \text{H}_2\text{C}_2\text{O}_4(\text{aq})$]

Learning Objectives

- To understand the relationship between cell potential and the equilibrium constant.
- To use cell potentials to calculate solution concentrations.

Changes in reaction conditions can have a tremendous effect on the course of a redox reaction. For example, under standard conditions, the reaction of Co(s) with Ni²⁺(aq) to form Ni(s) and Co²⁺(aq) occurs spontaneously, but if we reduce the concentration of Ni²⁺ by a factor of 100, so that [Ni²⁺] is 0.01 M, then the reverse reaction occurs spontaneously instead. The relationship between voltage and concentration is one of the factors that must be understood to predict whether a reaction will be spontaneous.

The Relationship between Cell Potential and Free Energy

Electrochemical cells convert chemical energy to electrical energy and vice versa. The total amount of energy produced by an electrochemical cell, and thus the amount of energy available to do electrical work, depends on both the cell potential and the total number of electrons that are transferred from the reductant to the oxidant during the course of a reaction. The resulting electric current is measured in coulombs (C), an SI unit that measures the number of electrons passing a given point in 1 s. A coulomb relates energy (in joules) to electrical potential (in volts). Electric current is measured in amperes (A); 1 A is defined as the flow of 1 C/s past a given point (1 C = 1 A·s):

$$\frac{1 \text{ J}}{1 \text{ V}} = 1 \text{ C} = 1 \text{ A} \cdot \text{s} \quad (19.4.1)$$

In chemical reactions, however, we need to relate the coulomb to the charge on a *mole* of electrons. Multiplying the charge on the electron by Avogadro's number gives us the charge on 1 mol of electrons, which is called the faraday (F), named after the English physicist and chemist Michael Faraday (1791–1867):

$$F = (1.60218 \times 10^{-19} \text{ C}) \frac{6.02214 \times 10^{23}}{1 \text{ mole}} \quad (19.4.2)$$

$$F = 9.64855 \times 10^4 \text{ C/mole} \approx 96,486 \text{ C/(mol } e^-)$$

The total charge transferred from the reductant to the oxidant is therefore nF , where n is the number of moles of electrons.

Michael Faraday (1791–1867)

Faraday was a British physicist and chemist who was arguably one of the greatest experimental scientists in history. The son of a blacksmith, Faraday was self-educated and became an apprentice bookbinder at age 14 before turning to science. His experiments in electricity and magnetism made electricity a routine tool in science and led to both the electric motor and the electric generator. He discovered the phenomenon of electrolysis and laid the foundations of electrochemistry. In fact, most of the specialized terms introduced in this chapter (electrode, anode, cathode, and so forth) are due to Faraday. In addition, he discovered benzene and invented the system of oxidation state numbers that we use today. Faraday is probably best known for "The Chemical History of a Candle," a series of public lectures on the chemistry and physics of flames.

The maximum amount of work that can be produced by an electrochemical cell (w_{\max}) is equal to the product of the cell potential (E_{cell}) and the total charge transferred during the reaction (nF):

$$w_{\max} = nFE_{\text{cell}} \quad (19.4.3)$$

Work is expressed as a negative number because work is being done *by* a system (an electrochemical cell with a positive potential) *on* its surroundings.

As you learned in [Chapter 18](#), the change in free energy (ΔG) is also a measure of the maximum amount of work that can be performed during a chemical process ($\Delta G = w_{\max}$). Consequently, there must be a relationship between the potential of an electrochemical cell and ΔG , the most important thermodynamic quantity discussed in [Chapter 18](#). This relationship is as follows:

$$\Delta G = -nFE_{\text{cell}} \quad (19.4.4)$$

A spontaneous redox reaction is therefore characterized by a *negative* value of ΔG and a *positive* value of E_{cell} , consistent with our earlier discussions. When both reactants and products are in their standard states, the relationship between ΔG° and E°_{cell} is as follows:

$$\Delta G^\circ = -nFE^\circ_{\text{cell}} \quad (19.4.5)$$

Note the Pattern

A spontaneous redox reaction is characterized by a negative value of ΔG° , which corresponds to a positive value of E°_{cell} .

Example 19.4.1

Suppose you want to prepare elemental bromine from bromide using the dichromate ion as an oxidant. Using the data in [Table 19.3.1](#), calculate the free-energy change (ΔG°) for this redox reaction under standard conditions. Is the reaction spontaneous?

Given: redox reaction

Asked for: ΔG° for the reaction and spontaneity

Strategy:

A From the relevant half-reactions and the corresponding values of E° , write the overall reaction and calculate E°_{cell} using [Equation 19.2.2](#).

B Determine the number of electrons transferred in the overall reaction. Then use [Equation 19.4.5](#) to calculate ΔG° . If ΔG° is negative, then the reaction is spontaneous.

Solution:

A As always, the first step is to write the relevant half-reactions and use them to obtain the overall reaction and the magnitude of E° . From [Table 19.3.1](#), we can find the reduction and oxidation half-reactions and corresponding E° values:

To obtain the overall balanced chemical equation, we must multiply both sides of the oxidation half-reaction by 3 to obtain the same number of electrons as in the reduction half-reaction, remembering that the magnitude of E° is not affected:

B We can now calculate ΔG° using [Equation 19.4.10](#). Because six electrons are transferred in the overall reaction, the value of n is 6:

$$\Delta G^\circ = -nFE_{cell}^\circ = (6 \cancel{\text{mol}}) \left(96,468 \text{ J} / (\cancel{\text{V}} \cdot \cancel{\text{mol}}) \right) (0.14 \cancel{\text{V}})$$

$$= -8.1 \times 10^4 \text{ J}$$

$$= -81 \text{ kJ/mol } Cr_2O_7$$

Thus ΔG° is -81 kJ for the reaction as written, and the reaction is spontaneous.

Exercise

Use the data in [Table 19.3.1](#) to calculate ΔG° for the reduction of ferric ion by iodide:

Is the reaction spontaneous?

Answer: $-44 \text{ kJ/mol } I_2$; yes

Potentials for the Sums of Half-Reactions

Although [Table 19.3.1](#) and [Table P1](#) list several half-reactions, many more are known. When the standard potential for a half-reaction is not available, we can use relationships between standard potentials and free energy to obtain the potential of any other half-reaction that can be written as the sum of two or more half-reactions whose standard potentials are available. For example, the potential for the reduction of $Fe^{3+}(aq)$ to $Fe(s)$ is not listed in the table, but two related reductions are given:

Although the sum of these two half-reactions gives the desired half-reaction, we cannot simply add the potentials of two reductive half-reactions to obtain the potential of a third reductive half-reaction *because E° is not a state function*. However, because ΔG° is a state function, the sum of the ΔG° values for the individual reactions gives us ΔG° for the overall reaction, which is proportional to *both* the potential *and* the number of electrons (n) transferred. To obtain the value of E° for the overall half-reaction, we first must add the values of $\Delta G^\circ (= -nFE^\circ)$ for each individual half-reaction to obtain ΔG° for the overall half-reaction:

Solving the last expression for ΔG° for the overall half-reaction,

$$\Delta G^\circ = F[(-0.77 \text{ V}) + (-2)(-0.457 \text{ V})] = F(0.13 \text{ V}) \quad (19.4.9)$$

Three electrons ($n = 3$) are transferred in the overall reaction ([Equation 19.4.15](#)), so substituting into [Equation 19.4.10](#) and solving for E° gives the following:

$$\Delta G^\circ = -nFE_{cell}^\circ$$

$$F(0.13 \text{ V}) = -3FE_{cell}^\circ$$

$$E_{cell}^\circ = -\frac{0.13 \text{ V}}{3} = -0.043 \text{ V}$$

This value of E° is very different from the value that is obtained by simply adding the potentials for the two half-reactions (0.32 V) and even has the opposite sign.

Note the Pattern

Values of E° for half-reactions cannot be added to give E° for the sum of the half-reactions; only values of $\Delta G^\circ = -nFE_{cell}^\circ$ for half-reactions can be added.

The Relationship between Cell Potential and the Equilibrium Constant

We can use the relationship between ΔG° and the equilibrium constant K , defined in [Chapter 18](#), to obtain a relationship between E°_{cell} and K . Recall that for a general reaction of the type $aA + bB \rightarrow cC + dD$, the standard free-energy change and the equilibrium constant are related by the following equation:

$$\Delta G^\circ = -RT \ln K \quad (19.4.10)$$

Given the relationship between the standard free-energy change and the standard cell potential ([Equation 19.4.9](#)), we can write

$$-nF E^\circ_{\text{cell}} = -RT \ln K \quad (19.4.11)$$

Rearranging this equation,

$$E^\circ_{\text{cell}} = \left(\frac{RT}{nF} \right) \ln K \quad (19.4.12)$$

For $T = 298 \text{ K}$, [Equation 19.4.12](#) can be simplified as follows:

$$E^\circ_{\text{cell}} = \left(\frac{RT}{nF} \right) \ln K = \left[\frac{8.314 \text{ J/(mol} \cdot \text{K)} (298 \text{ K})}{n [96,486 \text{ J/(V} \cdot \text{mol)}]} \right] 2.303 \log K = \left(\frac{0.0591}{n} \right) \log K \quad (19.4.13)$$

Thus E°_{cell} is directly proportional to the logarithm of the equilibrium constant. This means that large equilibrium constants correspond to large positive values of E°_{cell} and vice versa.

Example 19.4.2

Use the data in [Table 19.3.1](#) to calculate the equilibrium constant for the reaction of metallic lead with PbO_2 in the presence of sulfate ions to give PbSO_4 under standard conditions. (This reaction occurs when a car battery is discharged.) Report your answer to two significant figures.

Given: redox reaction

Asked for: K

Strategy:

A Write the relevant half-reactions and potentials. From these, obtain the overall reaction and E°_{cell} .

B Determine the number of electrons transferred in the overall reaction. Use [Equation 19.4.13](#) to solve for $\log K$ and then K .

Solution:

A The relevant half-reactions and potentials from [Table 19.3.1](#) are as follows:

B Two electrons are transferred in the overall reaction, so $n = 2$. Solving [Equation 19.4.13](#) for $\log K$ and inserting the values of n and E° ,

$$\ln K = \frac{nE^\circ}{0.0591 \text{ V}} = \frac{2 (2.05 \text{ V})}{0.0591 \text{ V}} = 69.37$$

$$K = 2.3 \times 10^{69}$$

Thus the equilibrium lies far to the right, favoring a discharged battery (as anyone who has ever tried unsuccessfully to start a car after letting it sit for a long time will know).

Exercise

Use the data in [Table 19.3.1](#) to calculate the equilibrium constant for the reaction of $\text{Sn}^{2+}(\text{aq})$ with oxygen to produce $\text{Sn}^{4+}(\text{aq})$ and water under standard conditions. Report your answer to two significant figures. The reaction is as follows:

Answer: 1.2×10^{73}

[Figure 19.4.1](#) summarizes the relationships that we have developed based on properties of the *system*—that is, based on the equilibrium constant, standard free-energy change, and standard cell potential—and the criteria for spontaneity ($\Delta G^\circ < 0$). Unfortunately, these criteria apply only to systems in which all reactants and products are present in their standard states, a situation that is seldom encountered in the real world. A more generally useful relationship between cell potential and reactant and product concentrations, as we are about to see, uses the relationship between ΔG and the reaction quotient Q developed in [Chapter 18](#).

Figure 19.4.1 The Relationships among Criteria for Thermodynamic Spontaneity The three properties of a system that can be used to predict the spontaneity of a redox reaction under standard conditions are K , ΔG° , and E°_{cell} . If we know the value of one of these quantities, then these relationships enable us to calculate the value of the other two. The signs of ΔG° and E°_{cell} and the magnitude of K determine the direction of spontaneous reaction under standard conditions.

The Effect of Concentration on Cell Potential: The Nernst Equation

Recall from [Chapter 18](#) that the *actual* free-energy change for a reaction under nonstandard conditions, ΔG , is given as follows:

$$\Delta G = \Delta G^\circ + RT \ln Q \quad (19.4.14)$$

We also know that $\Delta G = -nFE_{\text{cell}}$ and $\Delta G^\circ = -nFE^\circ_{\text{cell}}$. Substituting these expressions into [Equation 19.4.14](#), we obtain

$$-nFE_{\text{cell}} = -nFE^\circ_{\text{cell}} + RT \ln Q \quad (19.4.15)$$

Dividing both sides of this equation by $-nF$,

$$E_{\text{cell}} = E^\circ_{\text{cell}} - \frac{RT}{nF} \ln Q \quad (19.4.16)$$

[Equation 19.4.16](#) is called the Nernst equation, after the German physicist and chemist Walter Nernst (1864–1941), who first derived it. The Nernst equation is arguably the most important relationship in electrochemistry. When a redox reaction is at equilibrium ($\Delta G = 0$), [Equation 19.4.16](#) reduces to [Equation 19.4.12](#) because $Q = K$, and there is no net transfer of electrons (i.e., $E_{\text{cell}} = 0$).

Substituting the values of the constants into [Equation 19.4.16](#) with $T = 298 \text{ K}$ and converting to base-10 logarithms give the relationship of the actual cell potential (E_{cell}), the standard cell potential (E°_{cell}), and the reactant and product concentrations at room temperature (contained in Q):

$$E_{\text{cell}} = E^\circ_{\text{cell}} - \frac{0.0591 \text{ V}}{n} \log Q \quad (19.4.17)$$

Note the Pattern

The Nernst equation can be used to determine the value of E_{cell} , and thus the direction of spontaneous reaction, for any redox reaction under any conditions.

Equation 19.4.17 allows us to calculate the potential associated with any electrochemical cell at 298 K for any combination of reactant and product concentrations under any conditions. We can therefore determine the spontaneous direction of any redox reaction under any conditions, as long as we have tabulated values for the relevant standard electrode potentials. Notice in **Equation 19.4.17** that the cell potential changes by $0.0591/n$ V for each 10-fold change in the value of Q because $\log 10 = 1$.

Example 19.4.3

In the exercise in Example 6, you determined that the following reaction proceeds spontaneously under standard conditions because $E^{\circ}_{\text{cell}} > 0$ (which you now know means that $\Delta G^{\circ} < 0$):

Calculate E for this reaction under the following nonstandard conditions and determine whether it will occur spontaneously: $[\text{Ce}^{4+}] = 0.013$ M, $[\text{Ce}^{3+}] = 0.60$ M, $[\text{Cl}^{-}] = 0.0030$ M, $P_{\text{Cl}_2} = 1.0$ atm, and $T = 25^{\circ}\text{C}$.

Given: balanced redox reaction, standard cell potential, and nonstandard conditions

Asked for: cell potential

Strategy:

Determine the number of electrons transferred during the redox process. Then use the Nernst equation to find the cell potential under the nonstandard conditions.

Solution:

We can use the information given and the Nernst equation to calculate E_{cell} . Moreover, because the temperature is 25°C (298 K), we can use **Equation 19.4.17** instead of 19.46. The overall reaction involves the net transfer of two electrons:

so $n = 2$. Substituting the concentrations given in the problem, the partial pressure of Cl_2 , and the value of E°_{cell} into **Equation 19.4.17**,

$$\begin{aligned} E_{\text{cell}} &= E^{\circ}_{\text{cell}} - \frac{0.0591 \text{ V}}{n} \log Q \\ &= 0.25 \text{ V} - \frac{0.0591 \text{ V}}{2} \log n \left(\frac{[\text{Ce}^{3+}]^2 P_{\text{Cl}_2}}{[\text{Ce}^{4+}]^2 [\text{Cl}^{-}]^2} \right) \\ &= 0.25 \text{ V} - [(0.0296 \text{ V})(8.37)] = 0.00 \text{ V} \end{aligned}$$

Thus the reaction will *not* occur spontaneously under these conditions (because $E = 0$ V and $\Delta G = 0$). The composition specified is that of an equilibrium mixture.

Exercise

In the exercise in Example 6, you determined that molecular oxygen will not oxidize MnO_2 to permanganate via the reaction

Calculate E_{cell} for the reaction under the following nonstandard conditions and decide whether the reaction will occur spontaneously: pH 10, $P(\text{O}_2) = 0.20 \text{ atm}$, $[\text{MNO}_4^-] = 1.0 \times 10^{-4} \text{ M}$, and $T = 25^\circ\text{C}$.

Answer: $E_{\text{cell}} = -0.22 \text{ V}$; the reaction will not occur spontaneously.

Applying the Nernst equation to a simple electrochemical cell such as the Zn/Cu cell discussed in Section 19.2 allows us to see how the cell voltage varies as the reaction progresses and the concentrations of the dissolved ions change. Recall that the overall reaction for this cell is as follows:

The reaction quotient is therefore $Q = \frac{[\text{Zn}^{2+}]}{[\text{Cu}^{2+}]}$. Suppose that the cell initially contains 1.0 M Cu^{2+} and $1.0 \times 10^{-6} \text{ M Zn}^{2+}$. The initial voltage measured when the cell is connected can then be calculated from Equation 19.4.17:

$$E_{\text{cell}} = E_{\text{cell}}^{\circ} - \frac{0.0591 \text{ V}}{n} \log \frac{[\text{Zn}^{2+}]}{[\text{Cu}^{2+}]} \quad (19.4.19)$$

$$E_{\text{cell}} = 1.10 \text{ V} - \frac{0.0591 \text{ V}}{2} \log \frac{1.0 \times 10^{-6}}{1.0} = 1.28 \text{ V}$$

Thus the initial voltage is *greater* than E_{cell}° because $Q < 1$. As the reaction proceeds, $[\text{Zn}^{2+}]$ in the anode compartment increases as the zinc electrode dissolves, while $[\text{Cu}^{2+}]$ in the cathode compartment decreases as metallic copper is deposited on the electrode. During this process, the ratio $Q = \frac{[\text{Zn}^{2+}]}{[\text{Cu}^{2+}]}$ steadily increases, and the cell voltage therefore steadily decreases. Eventually, $[\text{Zn}^{2+}] = [\text{Cu}^{2+}]$, so $Q = 1$ and $E_{\text{cell}} = E_{\text{cell}}^{\circ}$. Beyond this point, $[\text{Zn}^{2+}]$ will continue to increase in the anode compartment, and $[\text{Cu}^{2+}]$ will continue to decrease in the cathode compartment. Thus the value of Q will increase further, leading to a further decrease in E_{cell} . When the concentrations in the two compartments are the opposite of the initial concentrations (i.e., 1.0 M Zn^{2+} and $1.0 \times 10^{-6} \text{ M Cu}^{2+}$), $Q = 1.0 \times 10^6$, and the cell potential will be reduced to 0.92 V .

The variation of E_{cell} with $\log Q$ over this range is linear with a slope of $-0.0591/n$, as illustrated in Figure 19.4.2. As the reaction proceeds still further, Q continues to increase, and E_{cell} continues to decrease. If neither of the electrodes dissolves completely, thereby breaking the electrical circuit, the cell voltage will eventually reach zero. This is the situation that occurs when a battery is "dead." The value of Q when $E_{\text{cell}} = 0$ is calculated as follows:

$$E_{\text{cell}} = E_{\text{cell}}^{\circ} - \frac{0.0591 \text{ V}}{n} \log Q = 0 \quad (19.4.20)$$

$$E_{\text{cell}}^{\circ} = \frac{0.0591 \text{ V}}{n} \log Q$$

$$\log Q = \frac{E_{\text{cell}}^{\circ} n}{0.0591 \text{ V}} = \frac{(1.10 \text{ V})(2)}{0.0591 \text{ V}} = 37.23$$

$$Q = 10^{37.23} = 1.7 \times 10^{37}$$

Figure 19.4.2 The Variation of E_{cell} with $\log Q$ for a Zn/Cu Cell Initially, $\log Q < 0$, and the voltage of the cell is greater than E_{cell}° . As the reaction progresses, $\log Q$ increases, and E_{cell} decreases. When $[\text{Zn}^{2+}] = [\text{Cu}^{2+}]$, $\log Q = 0$ and $E_{\text{cell}} = E_{\text{cell}}^{\circ} = 1.10 \text{ V}$. As long as the electrical circuit remains intact, the reaction will continue, and $\log Q$ will increase until $Q = K$ and the cell voltage reaches zero. At this point, the system will have reached equilibrium.

Recall that at equilibrium, $Q = K$. Thus the equilibrium constant for the reaction of Zn metal with Cu^{2+} to give Cu metal and Zn^{2+} is 1.7×10^{37} at 25°C .

Concentration Cells

A voltage can also be generated by constructing an electrochemical cell in which each compartment contains the same redox active solution but at different concentrations. The voltage is produced as the concentrations equilibrate. Suppose, for example, we have a cell with 0.010 M AgNO_3 in one compartment and 1.0 M AgNO_3 in the other. The cell diagram and corresponding half-reactions are as follows:

As the reaction progresses, the concentration of Ag^+ will increase in the left (oxidation) compartment as the silver electrode dissolves, while the Ag^+ concentration in the right (reduction) compartment decreases as the electrode in that compartment gains mass. The total mass of $\text{Ag}(s)$ in the cell will remain constant, however. We can calculate the potential of the cell using the Nernst equation, inserting 0 for E°_{cell} because $E^\circ_{\text{cathode}} = -E^\circ_{\text{anode}}$:

$$E_{\text{cell}} = E^\circ_{\text{cell}} - \frac{0.0591\text{ V}}{n} \log Q = 0 - \left(\frac{0.0591\text{ V}}{1} \right) \log \frac{0.010}{1.0} = 0.12 \quad (19.4.25)$$

An electrochemical cell of this type, in which the anode and cathode compartments are identical except for the concentration of a reactant, is called a concentration cell. As the reaction proceeds, the difference between the concentrations of Ag^+ in the two compartments will decrease, as will E_{cell} . Finally, when the concentration of Ag^+ is the same in both compartments, equilibrium will have been reached, and the measured potential difference between the two compartments will be zero ($E_{\text{cell}} = 0$).

Example 19.4.4

Calculate the voltage in a galvanic cell that contains a manganese electrode immersed in a 2.0 M solution of MnCl_2 as the cathode, and a manganese electrode immersed in a $5.2 \times 10^{-2}\text{ M}$ solution of MnSO_4 as the anode ($T = 25^\circ\text{C}$).

Given: galvanic cell, identities of the electrodes, and solution concentrations

Asked for: voltage

Strategy:

A Write the overall reaction that occurs in the cell.

B Determine the number of electrons transferred.

$$E_{\text{cell}} = E^\circ_{\text{cell}} - \frac{0.0591\text{ V}}{n} \log Q = 0 - \left(\frac{0.0591\text{ V}}{2} \right) \log \frac{5.2 \times 10^{-2}}{2.0} = 0.047$$

ed. Substitute this value into the Nernst equation to calculate the voltage.

Solution:

A This is a concentration cell, in which the electrode compartments contain the same redox active substance but at different concentrations. The anions (Cl^- and SO_4^{2-}) do not participate in the reaction, so their identity is not important. The overall reaction is as follows:

B For the reduction of $\text{Mn}^{2+}(aq)$ to $\text{Mn}(s)$, $n = 2$. We substitute this value and the given Mn^{2+} concentrations into [Equation 19.4.17](#):

Thus manganese will dissolve from the electrode in the compartment that contains the more dilute solution and will be deposited on the electrode in the compartment that contains the more concentrated solution.

Exercise

Suppose we construct a galvanic cell by placing two identical platinum electrodes in two beakers that are connected by a salt bridge. One beaker contains 1.0 M HCl, and the other a 0.010 M solution of Na₂SO₄ at pH 7.00. Both cells are in contact with the atmosphere, with P(O₂) = 0.20 atm. If the relevant electrochemical reaction in both compartments is the four-electron reduction of oxygen to water, O₂(g) + 4H⁺(aq) + 4e⁻ → 2H₂O(l), what will be the potential when the circuit is closed?

Answer: 0.41 V

Using Cell Potentials to Measure Solubility Products

Because voltages are relatively easy to measure accurately using a voltmeter, electrochemical methods provide a convenient way to determine the concentrations of very dilute solutions and the solubility products (K_{sp}) of sparingly soluble substances. As you learned in [Chapter 17](#), solubility products can be very small, with values of less than or equal to 10^{-30} . Equilibrium constants of this magnitude are virtually impossible to measure accurately by direct methods, so we must use alternative methods that are more sensitive, such as electrochemical methods.

To understand how an electrochemical cell is used to measure a solubility product, consider the cell shown in [Figure 19.4.3](#), which is designed to measure the solubility product of silver chloride: $K_{sp} = [Ag^+][Cl^-]$. In one compartment, the cell contains a silver wire inserted into a 1.0 M solution of Ag⁺; the other compartment contains a silver wire inserted into a 1.0 M Cl⁻ solution saturated with AgCl. In this system, the Ag⁺ ion concentration in the first compartment equals K_{sp} . We can see this by dividing both sides of the equation for K_{sp} by [Cl⁻] and substituting: $[Ag^+] = K_{sp}/[Cl^-] = K_{sp}/1.0 = K_{sp}$. The overall cell reaction is as follows:

Thus the voltage of the concentration cell due to the difference in [Ag⁺] between the two cells is as follows:

$$E_{cell} = 0 - \left(\frac{0.0591 \text{ V}}{1} \right) \log \left(\frac{[Ag^+]_{dilute}}{[Ag^+]_{concentrated}} \right) = -0.0591 \text{ V} \log \left(\frac{K_{sp}}{1.0} \right) = -0.0591 \text{ V} \quad (19.4.26)$$

Figure 19.4.3. A Galvanic Cell for Measuring the Solubility Product of AgCl One compartment contains a silver wire inserted into a 1.0 M solution of Ag⁺, and the other compartment contains a silver wire inserted into a 1.0 M Cl⁻ solution saturated with AgCl. The potential due to the difference in [Ag⁺] between the two cells can be used to determine K_{sp} .

By closing the circuit, we can measure the potential caused by the difference in [Ag⁺] in the two cells. In this case, the experimentally measured voltage of the concentration cell at 25°C is 0.580 V. Solving [Equation 19.4.26](#) for K_{sp} ,

$$\log K_{sp} = \frac{-E_{cell}}{0.0591 \text{ V}} = \frac{-0.580 \text{ V}}{0.0591 \text{ V}} = -9.81 \quad (19.4.27)$$

$$K_{sp} = 1.5 \times 10^{-10}$$

Thus a single potential measurement can provide the information we need to determine the value of the solubility product of a sparingly soluble salt.

Example 19.4.5

To measure the solubility product of lead(II) sulfate (PbSO_4) at 25°C , you construct a galvanic cell like the one shown in Figure 19.4.3, which contains a 1.0 M solution of a very soluble Pb^{2+} salt [lead(II) acetate trihydrate] in one compartment that is connected by a salt bridge to a 1.0 M solution of Na_2SO_4 saturated with PbSO_4 in the other. You then insert a Pb electrode into each compartment and close the circuit. Your voltmeter shows a voltage of 230 mV. What is K_{sp} for PbSO_4 ? Report your answer to two significant figures.

Given: galvanic cell, solution concentrations, electrodes, and voltage

Asked for: K_{sp}

Strategy:

A From the information given, write the equation for K_{sp} . Express this equation in terms of the concentration of Pb^{2+} .

B Determine the number of electrons transferred in the electrochemical reaction. Substitute the appropriate values into Equation 19.4.26 and solve for K_{sp} .

Solution:

A You have constructed a concentration cell, with one compartment containing a 1.0 M solution of Pb^{2+} and the other containing a dilute solution of Pb^{2+} in 1.0 M Na_2SO_4 . As for any concentration cell, the voltage between the two compartments can be calculated using the Nernst equation. The first step is to relate the concentration of Pb^{2+} in the dilute solution to K_{sp} :

$$[\text{Pb}^{2+}] [\text{SO}_4^{2-}] = K_{sp} \quad (\text{Chapter 19.4.1})$$

$$[\text{Pb}^{2+}] = \frac{K_{sp}}{[\text{SO}_4^{2-}]} = \frac{K_{sp}}{1.0 \text{ M}} = K_{sp} \quad (\text{Chapter 19.4.2})$$

B The reduction of Pb^{2+} to Pb is a two-electron process and proceeds according to the following reaction:

so

$$E_{\text{cell}} = E_{\text{cell}}^{\circ} - \frac{0.0591 \text{ V}}{n} \log Q =$$

$$0.230 \text{ V} = 0 - \left(\frac{0.0591 \text{ V}}{2} \right) \log \left(\frac{[\text{Pb}^{2+}]_{\text{dilute}}}{[\text{Pb}^{2+}]_{\text{concentrated}}} \right) = -0.0296 \text{ V} \log \left(\frac{K_{sp}}{1.0} \right)$$

$$-7.77 = \log K_{sp}$$

$$1.7 \times 10^{-8} = K_{sp}$$

Exercise

A concentration cell similar to the one described in Example 11 contains a 1.0 M solution of lanthanum nitrate [$\text{La}(\text{NO}_3)_3$] in one compartment and a 1.0 M solution of sodium fluoride saturated with LaF_3 in the other. A metallic La strip is inserted into each compartment, and the circuit is closed. The measured potential is 0.32 V. What is the K_{sp} for LaF_3 ? Report your answer to two significant figures.

Answer: 5.7×10^{-17}

Using Cell Potentials to Measure Concentrations

Another use for the Nernst equation is to calculate the concentration of a species given a measured potential and the concentrations of all the other species. We saw an example of this in Example 11, in which the experimental conditions were defined in such a way that the concentration of the metal ion was equal to K_{sp} . Potential measurements can be used to obtain the concentrations of dissolved species under other conditions as well, which explains the widespread use of electrochemical cells in many analytical devices. Perhaps the most common application is in the determination of $[H^+]$ using a pH meter, as illustrated in Example 12.

Example 19.4.6

Suppose a galvanic cell is constructed with a standard Zn/Zn²⁺ couple in one compartment and a modified hydrogen electrode in the second compartment (Figure 19.4.3). The pressure of hydrogen gas is 1.0 atm, but $[H^+]$ in the second compartment is unknown. The cell diagram is as follows:

What is the pH of the solution in the second compartment if the measured potential in the cell is 0.26 V at 25°C?

Given: galvanic cell, cell diagram, and cell potential

Asked for: pH of the solution

Strategy:

A Write the overall cell reaction.

B Substitute appropriate values into the Nernst equation and solve for $-\log[H^+]$ to obtain the pH.

Solution:

A Under standard conditions, the overall reaction that occurs is the reduction of protons by zinc to give H₂ (note that Zn lies below H₂ in Table 19.3.1):

B By substituting the given values into the simplified Nernst equation (Equation 19.64), we can calculate $[H^+]$ under nonstandard conditions:

$$E_{\text{cell}} = E_{\text{cell}}^o - \frac{0.0591 \text{ V}}{n} \log \left(\frac{[\text{Zn}^{2+}][\text{P}_{\text{H}_2}]}{[\text{H}^+]^2} \right)$$

$$0.26 \text{ V} = 0.76 \text{ V} - \left(\frac{0.0591 \text{ V}}{2} \right) \log \left(\frac{(1.0)(1.0)}{[\text{H}^+]^2} \right) = -0.0296 \text{ V} \log \left(\frac{K_{sp}}{1.0} \right)$$

$$16.9 = \log \left(\frac{1}{[\text{H}^+]^2} \right) = \log[\text{H}^+]^{-2} = -2 \log[\text{H}^+]$$

$$8.46 = -\log[\text{H}^+]$$

$$8.5 = \text{pH}$$

Thus the potential of a galvanic cell can be used to measure the pH of a solution.

Exercise

Suppose you work for an environmental laboratory and you want to use an electrochemical method to measure the concentration of Pb²⁺ in groundwater. You construct a galvanic cell using a standard oxygen electrode in one compartment ($E^{\circ}_{\text{cathode}} = 1.23 \text{ V}$). The other compartment contains a strip of lead in a sample of groundwater to which you have added sufficient acetic acid, a weak organic acid, to ensure electrical conductivity. The cell diagram is as follows”

2+ +

$\text{Pb(s)} \mid \text{Pb}^{2+}(\text{aq}, ? \text{ M}) \parallel \text{H}^+(\text{aq}, 1.0 \text{ M}) \mid \text{O}_2(\text{g}, 1.0 \text{ atm}) \mid \text{Pt(s)}$

When the circuit is closed, the cell has a measured potential of 1.62 V. Use [Table 19.7.1](#) and [Table T1](#) to determine the concentration of Pb^{2+} in the groundwater.

Answer: $1.2 \times 10^{-9} \text{ M}$

Summary

A **coulomb (C)** relates electrical potential, expressed in volts, and energy, expressed in joules. The current generated from a redox reaction is measured in **amperes (A)**, where 1 A is defined as the flow of 1 C/s past a given point. The **faraday (F)** is Avogadro's number multiplied by the charge on an electron and corresponds to the charge on 1 mol of electrons. The product of the cell potential and the total charge is the maximum amount of energy available to do work, which is related to the change in free energy that occurs during the chemical process. Adding together the ΔG values for the half-reactions gives ΔG for the overall reaction, which is proportional to *both* the potential *and* the number of electrons (n) transferred. Spontaneous redox reactions have a negative ΔG and therefore a positive E_{cell} . Because the equilibrium constant K is related to ΔG , E°_{cell} and K are also related. Large equilibrium constants correspond to large positive values of E° . The **Nernst equation** allows us to determine the spontaneous direction of any redox reaction under any reaction conditions from values of the relevant standard electrode potentials. **Concentration cells** consist of anode and cathode compartments that are identical except for the concentrations of the reactant. Because $\Delta G = 0$ at equilibrium, the measured potential of a concentration cell is zero at equilibrium (the concentrations are equal). A galvanic cell can also be used to measure the solubility product of a sparingly soluble substance and calculate the concentration of a species given a measured potential and the concentrations of all the other species.

Key Takeaway

- The Nernst equation can be used to determine the direction of spontaneous reaction for any redox reaction in aqueous solution.

Key Equations

Charge on a mole of electrons (faraday)

Equation 19.4.2: $F \approx 96,486 \text{ J}/(\text{V}\cdot\text{mol})$

Maximum work from an electrochemical cell

Equation 19.4.3: $w_{\text{max}} = -nFE_{\text{cell}}$

Relationship between ΔG° and ΔE°

Equation 19.4.5: $\Delta G^{\circ} = -nFE^{\circ}_{\text{cell}}$

Relationship between ΔG° and K for a redox reaction

Equation 19.4.10: $\Delta G^{\circ} = -RT \ln K$

Relationship between ΔE° and K for a redox reaction at 25°C

Equation 19.4.12: $E^{\circ}_{\text{cell}} = \left(\frac{RT}{nF}\right) \ln K$

Equation 19.4.13: $E^{\circ}_{\text{cell}} = \left(\frac{0.0591}{n}\right) \log K$

Relationship between ΔG° and Q

Equation 19.4.14: $\Delta G = \Delta G^\circ + RT \ln Q$

Relationship between E_{cell} and Q at 25°C

$$\text{EQUATION 19.4.17: } E_{\text{cell}} = E_{\text{cell}}^\circ - \frac{0.0591 \text{ V}}{F} \ln Q$$

Conceptual Problems

1. State whether you agree or disagree with this reasoning and explain your answer: Standard electrode potentials arise from the number of electrons transferred. The greater the number of electrons transferred, the greater the measured potential difference. If 1 mol of a substance produces 0.76 V when 2 mol of electrons are transferred—as in $\text{Zn(s)} \rightarrow \text{Zn}^{2+}(\text{aq}) + 2\text{e}^-$ —then 0.5 mol of the substance will produce 0.76/2 V because only 1 mol of electrons is transferred.
2. What is the relationship between the *measured cell potential* and the *total charge* that passes through a cell? Which of these is dependent on concentration? Which is dependent on the identity of the oxidant or the reductant? Which is dependent on the number of electrons transferred?
3. In the equation $w_{\text{max}} = -nFE_{\text{cell}}^\circ$, which quantities are extensive properties and which are intensive properties?
4. For any spontaneous redox reaction, E is positive. Use thermodynamic arguments to explain why this is true.
5. State whether you agree or disagree with this statement and explain your answer: Electrochemical methods are especially useful in determining the reversibility or irreversibility of reactions that take place in a cell.
6. Although the sum of two half-reactions gives another half-reaction, the sum of the potentials of the two half-reactions cannot be used to obtain the potential of the net half-reaction. Why? When does the sum of two half-reactions correspond to the overall reaction? Why?
7. Occasionally, you will find high-quality electronic equipment that has its electronic components plated in gold. What is the advantage of this?
8. Blood analyzers, which measure pH, $P(\text{CO}_2)$ and $P(\text{O}_2)$ are frequently used in clinical emergencies. For example, blood $P(\text{CO}_2)$ is measured with a pH electrode covered with a plastic membrane that is permeable to CO_2 . Based on your knowledge of how electrodes function, explain how such an electrode might work. Hint: $\text{CO}_2(\text{g}) + \text{H}_2\text{O}(\text{l}) \rightarrow \text{HCO}_3^-(\text{aq}) + \text{H}^+(\text{aq})$.
9. Concentration cells contain the same species in solution in two different compartments. Explain what produces a voltage in a concentration cell. When does $V = 0$ in such a cell?
10. Describe how an electrochemical cell can be used to measure the solubility of a sparingly soluble salt.

Answers

- 1.
- 2.
3. extensive: w_{max} and n ; intensive: E_{cell}°
- 4.
- 5.
- 6.
7. Gold is highly resistant to corrosion because of its very positive reduction potential.
- 8.
- 9.
- 10.

Numerical Problems

1. The chemical equation for the combustion of butane is as follows:

This reaction has $\Delta H^\circ = -2877 \text{ kJ/mol}$. Calculate E°_{cell} and then determine ΔG° . Is this a spontaneous process? What is the change in entropy that accompanies this process at 298 K?

- How many electrons are transferred during the reaction $\text{Pb(s)} + \text{Hg}_2\text{Cl}_2\text{(s)} \rightarrow \text{PbCl}_2\text{(aq)} + 2\text{Hg(l)}$? What is the standard cell potential? Is the oxidation of Pb by Hg_2Cl_2 spontaneous? Calculate ΔG° for this reaction.
- For the cell represented as $\text{Al(s)} | \text{Al}^{3+}(\text{aq}) || \text{Sn}^{2+}(\text{aq}), \text{Sn}^{4+}(\text{aq}) | \text{Pt(s)}$, how many electrons are transferred in the redox reaction? What is the standard cell potential? Is this a spontaneous process? What is ΔG° ?
- Explain why the sum of the potentials for the half-reactions $\text{Sn}^{4+}(\text{aq}) + 2\text{e}^- \rightarrow \text{Sn}^{2+}(\text{aq})$ and $\text{Sn}^{2+}(\text{aq}) + 2\text{e}^- \rightarrow \text{Sn(s)}$ does not equal the potential for the reaction $\text{Sn}^{4+}(\text{aq}) + 4\text{e}^- \rightarrow \text{Sn(s)}$. What is the net cell potential? Compare the values of ΔG° for the sum of the potentials and the actual net cell potential.
- Based on Table 19.3.1 and Table P1, do you agree with the proposed potentials for the following half-reactions? Why or why not?
 - $\text{Cu}^{2+}(\text{aq}) + 2\text{e}^- \rightarrow \text{Cu(s)}, E^\circ = 0.68 \text{ V}$
 - $\text{Ce}^{4+}(\text{aq}) + 4\text{e}^- \rightarrow \text{Ce(s)}, E^\circ = -0.62 \text{ V}$
- For each reaction, calculate E°_{cell} and then determine ΔG° . Indicate whether each reaction is spontaneous.
 - $2\text{Na(s)} + 2\text{H}_2\text{O(l)} \rightarrow 2\text{NaOH(aq)} + \text{H}_2\text{(g)}$
 - $\text{K}_2\text{S}_2\text{O}_8\text{(aq)} + \text{I}_2\text{(s)} \rightarrow 2\text{KI(aq)} + 2\text{K}_2\text{SO}_4\text{(aq)}$
 - $\text{Sn(s)} + \text{CuSO}_4\text{(aq)} \rightarrow \text{Cu(s)} + \text{SnSO}_4\text{(aq)}$
- What is the standard change in free energy for the reaction between Ca^{2+} and Na(s) to give Ca(s) and Na^+ ? Do the sign and magnitude of ΔG° agree with what you would expect based on the positions of these elements in the periodic table? Why or why not?
- In acidic solution, permanganate (MnO_4^-) oxidizes Cl^- to chlorine gas, and MnO_4^- is reduced to $\text{Mn}^{2+}(\text{aq})$.
 - Write the balanced chemical equation for this reaction.
 - Determine E°_{cell} .
 - Calculate the equilibrium constant.
- Potentiometric titrations are an efficient method for determining the endpoint of a redox titration. In such a titration, the potential of the solution is monitored as measured volumes of an oxidant or a reductant are added. Data for a typical titration, the potentiometric titration of Fe(II) with a 0.1 M solution of Ce(IV), are given in the following table. The starting potential has been arbitrarily set equal to zero because it is the *change* in potential with the addition of the oxidant that is important.

Titrant (mL)	E (mV)
2.00	50
6.00	100
9.00	255
10.00	960
11.00	1325
12.00	1625
14.00	1875

- Write the balanced chemical equation for the oxidation of Fe^{2+} by Ce^{4+} .
 - Plot the data and then locate the endpoint.
 - How many millimoles of Fe^{2+} did the solution being titrated originally contain?
- The standard electrode potential (E°) for the half-reaction $\text{Ni}^{2+}(\text{aq}) + 2\text{e}^- \rightarrow \text{Ni(s)}$ is -0.257 V . What pH is needed for this reaction to take place in the presence of 1.00 atm $\text{H}_2\text{(g)}$ as the reductant if $[\text{Ni}^{2+}]$ is 1.00 M?
 - The reduction of Mn(VII) to Mn(s) by $\text{H}_2\text{(g)}$ proceeds in five steps that can be readily followed by changes in the color of the solution. Here is the redox chemistry:
 - $\text{MnO}_4^-(\text{aq}) + \text{e}^- \rightarrow \text{MnO}_4^{2-}(\text{aq}); E^\circ = +0.56 \text{ V}$ (purple \rightarrow dark green)
 - $\text{MnO}_4^{2-}(\text{aq}) + 2\text{e}^- + 4\text{H}^+(\text{aq}) \rightarrow \text{MnO}_2\text{(s)}; E^\circ = +2.26 \text{ V}$ (dark green \rightarrow dark brown solid)
 - $\text{MnO}_2\text{(s)} + \text{e}^- + 4\text{H}^+(\text{aq}) \rightarrow \text{Mn}^{3+}(\text{aq}); E^\circ = +0.95 \text{ V}$ (dark brown solid \rightarrow red-violet)
 - $\text{Mn}^{3+}(\text{aq}) + \text{e}^- \rightarrow \text{Mn}^{2+}(\text{aq}); E^\circ = +1.51 \text{ V}$ (red-violet \rightarrow pale pink)
 - $\text{Mn}^{2+}(\text{aq}) + 2\text{e}^- \rightarrow \text{Mn(s)}; E^\circ = -1.18 \text{ V}$ (pale pink \rightarrow colorless)

- a. Is the reduction of MnO_4^- to $\text{Mn}^{2+}(\text{aq})$ by $\text{H}_2(\text{g})$ spontaneous under standard conditions? What is E°_{cell} ?
- b. Is the reduction of $\text{Mn}^{2+}(\text{aq})$ to $\text{Mn}(\text{s})$ by $\text{H}_2(\text{g})$ spontaneous under standard conditions? What is E°_{cell} ?
12. $\text{Mn}^{3+}(\text{aq})$ can disproportionate (both oxidize and reduce itself) by means of the following half-reactions:
- $$\text{Mn}^{3+}(\text{aq}) + \text{e}^- \rightarrow \text{Mn}^{2+}(\text{aq}); E^\circ = +1.51 \text{ V}$$
- $$\text{Mn}^{3+}(\text{aq}) + 2\text{H}_2\text{O}(\text{l}) \rightarrow \text{MnO}_2(\text{s}) + 4\text{H}^+(\text{aq}) + \text{e}^-; E^\circ = +0.95 \text{ V}$$
- a. What is E° for the disproportionation reaction?
- b. Is disproportionation more or less thermodynamically favored at low pH than at pH 7.0? Explain your answer.
- c. How could you prevent the disproportionation reaction from occurring?
13. For the reduction of oxygen to water, $E^\circ = 1.23 \text{ V}$. What is the potential for this half-reaction at pH 7.00? What is the potential in a 0.85 M solution of NaOH?
14. The biological molecule abbreviated as NADH (reduced nicotinamide adenine dinucleotide) can be formed by reduction of NAD (nicotinamide adenine dinucleotide) via the half-reaction $\text{NAD}^+ + \text{H}^+ + 2\text{e}^- \rightarrow \text{NADH}; E^\circ = -0.32 \text{ V}$.
- a. Would NADH be able to reduce acetate to pyruvate?
- b. Would NADH be able to reduce pyruvate to lactate?
- c. What potential is needed to convert acetate to lactate?
- $$\text{acetate} + \text{CO}_2 + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{pyruvate} + \text{H}_2\text{O}; E^\circ = +0.70 \text{ V}$$
- $$\text{pyruvate} + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{lactate}; E^\circ = -0.185 \text{ V}$$
15. Given the following biologically relevant half-reactions, will FAD (flavin adenine dinucleotide), a molecule used to transfer electrons whose reduced form is FADH_2 , be an effective oxidant for the conversion of acetaldehyde to acetate at pH 4.00?
- $$\text{acetate} + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{acetaldehyde} + \text{H}_2\text{O}; E^\circ = -0.58 \text{ V}$$
- $$\text{FAD} + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{FADH}_2; E^\circ = -0.18 \text{ V}$$
16. Ideally, any half-reaction with $E^\circ > 1.23 \text{ V}$ will oxidize water as a result of the half-reaction $\text{O}_2(\text{g}) + 4\text{H}^+(\text{aq}) + 4\text{e}^- \rightarrow 2\text{H}_2\text{O}(\text{l})$.
- a. Will FeO_4^{2-} oxidize water if the half-reaction for the reduction of $\text{Fe(VI)} \rightarrow \text{Fe(III)}$ is $\text{FeO}_4^{2-}(\text{aq}) + 8\text{H}^+(\text{aq}) + 3\text{e}^- \rightarrow \text{Fe}^{3+}(\text{aq}) + 4\text{H}_2\text{O}; E^\circ = 1.9 \text{ V}$?
- b. What is the highest pH at which this reaction will proceed spontaneously if $[\text{Fe}^{3+}] = [\text{FeO}_4^{2-}] = 1.0 \text{ M}$ and $P_{\text{O}_2} = 1.0 \text{ atm}$?
17. Under acidic conditions, ideally any half-reaction with $E^\circ > 1.23 \text{ V}$ will oxidize water via the reaction $\text{O}_2(\text{g}) + 4\text{H}^+(\text{aq}) + 4\text{e}^- \rightarrow 2\text{H}_2\text{O}(\text{l})$.
- a. Will aqueous acidic KMnO_4 evolve oxygen with the formation of MnO_2 ?
- b. At pH 14.00, what is E° for the oxidation of water by aqueous KMnO_4 (1 M) with the formation of MnO_2 ?
- c. At pH 14.00, will water be oxidized if you are trying to form MnO_2 from MnO_4^- via the reaction $2\text{MnO}_4^-(\text{aq}) + 2\text{H}_2\text{O}(\text{l}) \rightarrow 2\text{MnO}_2(\text{s}) + \text{O}_2(\text{g}) + 4\text{OH}^-(\text{aq})$?
18. Complexing agents can bind to metals and result in the net stabilization of the complexed species. What is the net thermodynamic stabilization energy that results from using CN^- as a complexing agent for $\text{Mn}^{3+}/\text{Mn}^{2+}$?
- $$\text{Mn}^{3+}(\text{aq}) + \text{e}^- \rightarrow \text{Mn}^{2+}(\text{aq}); E^\circ = +1.51 \text{ V}$$
- $$\text{Mn}(\text{CN})_6^{3-}(\text{aq}) + \text{e}^- \rightarrow \text{Mn}(\text{CN})_6^{4-}(\text{aq}); E^\circ = -0.24 \text{ V}$$
19. You have constructed a cell with zinc and lead amalgam electrodes described by the cell diagram $\text{Zn}(\text{Hg})(\text{s}) | \text{Zn}(\text{NO}_3)_2(\text{aq}) || \text{Pb}(\text{NO}_3)_2(\text{aq}) | \text{Pb}(\text{Hg})(\text{s})$. If you vary the concentration of $\text{Zn}(\text{NO}_3)_2$ and measure the potential at different concentrations, you obtain the following data:

$\text{Zn}(\text{NO}_3)_2 \text{ (M)}$	$E_{\text{cell}} \text{ (V)}$
0.0005	0.7398
0.002	0.7221

Zn(NO ₃) ₂ (M)	E _{cell} (V)
0.01	0.7014

- Write the half-reactions that occur in this cell.
 - What is the overall redox reaction?
 - What is E°_{cell} ? What is ΔG° for the overall reaction?
 - What is the equilibrium constant for this redox reaction?
20. Hydrogen gas reduces Ni²⁺ according to the following reaction: $\text{Ni}^{2+}(\text{aq}) + \text{H}_2(\text{g}) \rightarrow \text{Ni}(\text{s}) + 2\text{H}^+(\text{aq})$; $E^\circ_{\text{cell}} = -0.25 \text{ V}$; $\Delta H = 54 \text{ kJ/mol}$.
- What is K for this redox reaction?
 - Is this reaction likely to occur?
 - What conditions can be changed to increase the likelihood that the reaction will occur as written?
 - Is the reaction more likely to occur at higher or lower pH?
21. The silver–silver bromide electrode has a standard potential of 0.07133 V. What is K_{sp} of AgBr?

Learning Objective

- To learn how commercial galvanic cells work.

Because galvanic cells can be self-contained and portable, they can be used as batteries and fuel cells. A battery (storage cell) is a galvanic cell (or a series of galvanic cells) that contains all the reactants needed to produce electricity. In contrast, a fuel cell is a galvanic cell that requires a constant external supply of one or more reactants to generate electricity. In this section, we describe the chemistry behind some of the more common types of batteries and fuel cells.

Batteries

There are two basic kinds of batteries: *disposable*, or *primary*, batteries, in which the electrode reactions are effectively irreversible and which cannot be recharged; and *rechargeable*, or *secondary*, batteries, which form an insoluble product that adheres to the electrodes. These batteries can be recharged by applying an electrical potential in the reverse direction. The recharging process temporarily converts a rechargeable battery from a galvanic cell to an electrolytic cell.

Batteries are cleverly engineered devices that are based on the same fundamental laws as galvanic cells. The major difference between batteries and the galvanic cells we have previously described is that commercial batteries use solids or pastes rather than solutions as reactants to maximize the electrical output per unit mass. The use of highly concentrated or solid reactants has another beneficial effect: the concentrations of the reactants and the products do not change greatly as the battery is discharged; consequently, the output voltage remains remarkably constant during the discharge process. This behavior is in contrast to that of the Zn/Cu cell, whose output decreases logarithmically as the reaction proceeds (Figure 19.4.3). When a battery consists of more than one galvanic cell, the cells are usually connected in series—that is, with the positive (+) terminal of one cell connected to the negative (–) terminal of the next, and so forth. The overall voltage of the battery is therefore the sum of the voltages of the individual cells.

Leclanché Dry Cell

The dry cell, by far the most common type of battery, is used in flashlights, electronic devices such as the Walkman and Game Boy, and many other devices. Although the dry cell was patented in 1866 by the French chemist Georges Leclanché and more than 5 billion such cells are sold every year, the details of its electrode chemistry are still not completely understood. In spite of its name, the Leclanché dry cell is actually a “wet cell”: the electrolyte is an acidic water-based paste containing MnO_2 , NH_4Cl , ZnCl_2 , graphite, and starch (part (a) in Figure 19.5.1). The half-reactions at the anode and the cathode can be summarized as follows:

The Zn^{2+} ions formed by the oxidation of $\text{Zn}(s)$ at the anode react with NH_3 formed at the cathode and Cl^- ions present in solution, so the overall cell reaction is as follows:

The dry cell produces about 1.55 V and is inexpensive to manufacture. It is not, however, very efficient in producing electrical energy because only the relatively small fraction of the MnO_2 that is near the cathode is actually reduced and only a small fraction of the zinc anode is actually consumed as the cell discharges. In addition, dry cells have a limited shelf life because the Zn anode reacts spontaneously with NH_4Cl in the electrolyte, causing the case to corrode and allowing the contents to leak out.

The alkaline battery is essentially a Leclanché cell adapted to operate under alkaline, or basic, conditions. The half-reactions that occur in an alkaline battery are as follows:

This battery also produces about 1.5 V, but it has a longer shelf life and more constant output voltage as the cell is discharged than the Leclanché dry cell. Although the alkaline battery is more expensive to produce than the Leclanché dry cell, the improved performance makes this battery more cost-effective.

Button Batteries

Although some of the small *button* batteries used to power watches, calculators, and cameras are miniature alkaline cells, most are based on a completely different chemistry. In these batteries, the anode is a zinc–mercury amalgam rather than pure zinc, and the cathode uses either HgO or Ag₂O as the oxidant rather than MnO₂ (part (b) in [Figure 19.13 "Three Kinds of Primary \(Nonrechargeable\) Batteries"](#)). The cathode and overall reactions and cell output for these two types of button batteries are as follows:

The major advantages of the mercury and silver cells are their reliability and their high output-to-mass ratio. These factors make them ideal for applications where small size is crucial, as in cameras and hearing aids. The disadvantages are the expense and the environmental problems caused by the disposal of heavy metals, such as Hg and Ag.

Lithium–Iodine Battery

None of the batteries described above is actually “dry.” They all contain small amounts of liquid water, which adds significant mass and causes potential corrosion problems. Consequently, substantial effort has been expended to develop water-free batteries.

One of the few commercially successful water-free batteries is the lithium–iodine battery. The anode is lithium metal, and the cathode is a solid complex of I₂. Separating them is a layer of solid LiI, which acts as the electrolyte by allowing the diffusion of Li⁺ ions. The electrode reactions are as follows:

As shown in part (c) in [Figure 19.5.1](#), a typical lithium–iodine battery consists of two cells separated by a nickel metal mesh that collects charge from the anode. Because of the high internal resistance caused by the solid electrolyte, only a low current can be drawn. Nonetheless, such batteries have proven to be long-lived (up to 10 yr) and reliable. They are therefore used in applications where frequent replacement is difficult or undesirable, such as in cardiac pacemakers and other medical implants and in computers for memory protection. These batteries are also used in security transmitters and smoke alarms. Other batteries based on lithium anodes and solid electrolytes are under development, using TiS₂, for example, for the cathode.

Cardiac pacemaker. An x-ray of a patient showing the location and size of a pacemaker powered by a lithium–iodine battery.

Figure 19.5.1 Three Kinds of Primary (Nonrechargeable) Batteries (a) A Leclanché dry cell is actually a “wet cell,” in which the electrolyte is an acidic water-based paste containing MnO_2 , NH_4Cl , ZnCl_2 , graphite, and starch. Though inexpensive to manufacture, the cell is not very efficient in producing electrical energy and has a limited shelf life. (b) In a button battery, the anode is a zinc–mercury amalgam, and the cathode can be either HgO (shown here) or Ag_2O as the oxidant. Button batteries are reliable and have a high output-to-mass ratio, which allows them to be used in applications such as calculators and watches, where their small size is crucial. (c) A lithium–iodine battery consists of two cells separated by a metallic nickel mesh that collects charge from the anodes. The anode is lithium metal, and the cathode is a solid complex of I_2 . The electrolyte is a layer of solid LiI that allows Li^+ ions to diffuse from the cathode to the anode. Although this type of battery produces only a relatively small current, it is highly reliable and long-lived.

Dry cells, button batteries, and lithium–iodine batteries are disposable and cannot be recharged once they are discharged. Rechargeable batteries, in contrast, offer significant economic and environmental advantages because they can be recharged and discharged numerous times. As a result, manufacturing and disposal costs drop dramatically for a given number of hours of battery usage. Two common rechargeable batteries are the nickel–cadmium battery and the lead–acid battery, which we describe next.

Nickel–Cadmium (NiCad) Battery

The nickel–cadmium, or *NiCad*, battery is used in small electrical appliances and devices like drills, portable vacuum cleaners, and AM/FM digital tuners. It is a water-based cell with a cadmium anode and a highly oxidized nickel cathode that is usually described as the nickel(III) oxo-hydroxide, $\text{NiO}(\text{OH})$. As shown in Figure 19.5.2, the design maximizes the surface area of the electrodes and minimizes the distance between them, which decreases internal resistance and makes a rather high discharge current possible.

Figure 19.5.2 The Nickel–Cadmium (NiCad) Battery, a Rechargeable Battery NiCad batteries contain a cadmium anode and a highly oxidized nickel cathode. This design maximizes the surface area of the electrodes and minimizes the distance between them, which gives the battery both a high discharge current and a high capacity.

The electrode reactions during the discharge of a NiCad battery are as follows:

Because the products of the discharge half-reactions are solids that adhere to the electrodes [$\text{Cd}(\text{OH})_2$ and $2\text{Ni}(\text{OH})_2$], the overall reaction is readily reversed when the cell is recharged. Although NiCad cells are lightweight, rechargeable, and high capacity, they have certain disadvantages. For example, they tend to lose capacity quickly if not allowed to discharge fully before recharging, they do not store well for long periods when fully charged, and they present significant environmental and disposal problems because of the toxicity of cadmium.

A variation on the NiCad battery is the nickel–metal hydride battery (NiMH) used in hybrid automobiles, wireless communication devices, and mobile computing. The overall chemical equation for this type of battery is as follows:

The NiMH battery has a 30%–40% improvement in capacity over the NiCad battery; it is more environmentally friendly so storage, transportation, and disposal are not subject to environmental control; and it is not as sensitive to recharging memory. It is, however, subject to a 50% greater self-discharge rate, a limited service life, and higher maintenance, and it is more expensive than the NiCad battery.

Lead–Acid (Lead Storage) Battery

The lead–acid battery is used to provide the starting power in virtually every automobile and marine engine on the market. Marine and car batteries typically consist of multiple cells connected in series. The total voltage generated by the battery is the potential per cell (E°_{cell}) times the number of cells. As shown in [Figure 19.5.3](#), the anode of each cell in a lead storage battery is a plate or grid of spongy lead metal, and the cathode is a similar grid containing powdered lead dioxide (PbO_2). The electrolyte is usually an approximately 37% solution (by mass) of sulfuric acid in water, with a density of 1.28 g/mL (about 4.5 M H_2SO_4). Because the redox active species are solids, there is no need to separate the electrodes. The electrode reactions in each cell during discharge are as follows:

Figure 19.5.3 One Cell of a Lead–Acid Battery The anodes in each cell of a rechargeable battery are plates or grids of lead containing spongy lead metal, while the cathodes are similar grids containing powdered lead dioxide (PbO_2). The electrolyte is an aqueous solution of sulfuric acid. The value of E° for such a cell is about 2 V. Connecting three such cells in series produces a 6 V battery, whereas a typical 12 V car battery contains six cells in series. When treated properly, this type of high-capacity battery can be discharged and recharged many times over.

As the cell is discharged, a powder of $PbSO_4$ forms on the electrodes. Moreover, sulfuric acid is consumed and water is produced, decreasing the density of the electrolyte and providing a convenient way of monitoring the status of a battery by simply measuring the density of the electrolyte.

When an external voltage in excess of 2.04 V per cell is applied to a lead–acid battery, the electrode reactions reverse, and $PbSO_4$ is converted back to metallic lead and PbO_2 . If the battery is recharged too vigorously, however, electrolysis of water can occur, resulting in the evolution of potentially explosive hydrogen gas. (For more information on electrolysis, see [Section 19.7](#).) The gas bubbles formed in this way can dislodge some of the $PbSO_4$ or PbO_2 particles from the grids, allowing them to fall to the bottom of the cell, where they can build up and cause an internal short circuit. Thus the recharging process must be carefully monitored to optimize the life of the battery. With proper care, however, a lead–acid battery can be discharged and recharged thousands of times. In automobiles, the alternator supplies the electric current that causes the discharge reaction to reverse.

Fuel Cells

A fuel cell is a galvanic cell that requires a constant external supply of reactants because the products of the reaction are continuously removed. Unlike a battery, it does not store chemical or electrical energy; a fuel cell allows electrical energy to be extracted directly from a chemical reaction. In principle, this should be a more efficient process than, for example, burning the fuel to drive an internal combustion engine that turns a generator, which is typically less than 40% efficient, and in fact, the efficiency of a fuel cell is generally between 40% and 60%. Unfortunately, significant cost and reliability problems have hindered the wide-scale adoption of fuel cells. In practice, their use has been restricted to applications in which mass may be a significant cost factor, such as US manned space vehicles.

These space vehicles use a hydrogen/oxygen fuel cell that requires a continuous input of $H_2(g)$ and $O_2(g)$, as illustrated in [Figure 19.5.4](#). The electrode reactions are as follows:

Figure 19.5.4 A Hydrogen Fuel Cell Produces Electrical Energy Directly from a Chemical Reaction Hydrogen is oxidized to protons at the anode, and the electrons are transferred through an external circuit to the cathode, where oxygen is reduced and combines with H^+ to form water. A solid electrolyte allows the protons to diffuse from the anode to the cathode. Although fuel cells are an essentially pollution-free means of obtaining electrical energy, their expense and technological complexity have thus far limited their applications.

The overall reaction represents an essentially pollution-free conversion of hydrogen and oxygen to water, which in space vehicles is then collected and used. Although this type of fuel cell should produce 1.23 V under standard conditions, in practice the device achieves only about 0.9 V. One of the major barriers to achieving greater efficiency is the fact that the four-electron reduction of $O_2(g)$ at the cathode is intrinsically rather slow, which limits current that can be achieved. All major automobile manufacturers have major research programs involving fuel cells: one of the most important goals is the development of a better catalyst for the reduction of O_2 .

Summary

A **battery** is a contained unit that produces electricity, whereas a **fuel cell** is a galvanic cell that requires a constant external supply of one or more reactants to generate electricity. One type of battery is the **Leclanché dry cell**, which contains an electrolyte in an acidic water-based paste. This battery is called an **alkaline battery** when adapted to operate under alkaline conditions. Button batteries have a high output-to-mass ratio; **lithium–iodine batteries** consist of a solid electrolyte; the **nickel–cadmium (NiCad)** battery is rechargeable; and the **lead–acid battery**, which is also rechargeable, does not require the electrodes to be in separate compartments. A fuel cell requires an external supply of reactants as the products of the reaction are continuously removed. In a fuel cell, energy is not stored; electrical energy is provided by a chemical reaction.

Key Takeaway

- Commercial batteries are galvanic cells that use solids or pastes as reactants to maximize the electrical output per unit mass.

Conceptual Problems

- What advantage is there to using an alkaline battery rather than a Leclanché dry cell?
- Why does the density of the fluid in lead–acid batteries drop when the battery is discharged?
- What type of battery would you use for each application and why?
 - powering an electric motor scooter
 - a backup battery for a smartphone
 - powering an iPod
- Why are galvanic cells used as batteries and fuel cells? What is the difference between a battery and a fuel cell? What is the advantage to using highly concentrated or solid reactants in a battery?

Answer

-
-
- lead storage battery
 - lithium–iodine battery
 - NiCad, NiMH, or lithium ion battery (rechargeable)
-

Numerical Problem

- This reaction is characteristic of a lead storage battery:

If you have a battery with an electrolyte that has a density of 1.15 g/cm^3 and contains 30.0% sulfuric acid by mass, is the potential greater than or less than that of the standard cell?

Answer

- $[\text{H}_2\text{SO}_4] = 3.52 \text{ M}$; $E > E^\circ$

Learning Objective

- To understand the process of corrosion.

Corrosion is a galvanic process by which metals deteriorate through oxidation—usually but not always to their oxides. For example, when exposed to air, iron rusts, silver tarnishes, and copper and brass acquire a bluish-green surface called a *patina*. Of the various metals subject to corrosion, iron is by far the most important commercially. An estimated \$100 billion per year is spent in the United States alone to replace iron-containing objects destroyed by corrosion. Consequently, the development of methods for protecting metal surfaces from corrosion constitutes a very active area of industrial research. In this section, we describe some of the chemical and electrochemical processes responsible for corrosion. We also examine the chemical basis for some common methods for preventing corrosion and treating corroded metals.

Note the Pattern

Corrosion is a galvanic process.

Under ambient conditions, the oxidation of most metals is thermodynamically spontaneous, with the notable exception of gold and platinum. Hence it is actually somewhat surprising that any metals are useful at all in Earth's moist, oxygen-rich atmosphere. Some metals, however, are resistant to corrosion for kinetic reasons. For example, aluminum in soft-drink cans and airplanes is protected by a thin coating of metal oxide that forms on the surface of the metal and acts as an impenetrable barrier that prevents further destruction. Aluminum cans also have a thin plastic layer to prevent reaction of the oxide with acid in the soft drink. Chromium, magnesium, and nickel also form protective oxide films. Stainless steels are remarkably resistant to corrosion because they usually contain a significant proportion of chromium, nickel, or both.

In contrast to these metals, when iron corrodes, it forms a red-brown hydrated metal oxide ($\text{Fe}_2\text{O}_3 \cdot x\text{H}_2\text{O}$), commonly known as *rust*, that does not provide a tight protective film (Figure 19.17). Instead, the rust continually flakes off to expose a fresh metal surface vulnerable to reaction with oxygen and water. Because both oxygen and water are required for rust to form, an iron nail immersed in deoxygenated water will not rust—even over a period of several weeks. Similarly, a nail immersed in an organic solvent such as kerosene or mineral oil saturated with oxygen will not rust because of the absence of water.

2+

Figure 19.6.1 Rust, the Result of Corrosion of Metallic Iron Iron is oxidized to $Fe^{2+}(aq)$ at an anodic site on the surface of the iron, which is often an impurity or a lattice defect. Oxygen is reduced to water at a different site on the surface of the iron, which acts as the cathode. Electrons are transferred from the anode to the cathode through the electrically conductive metal. Water is a solvent for the Fe^{2+} that is produced initially and acts as a salt bridge. Rust ($Fe_2O_3 \cdot xH_2O$) is formed by the subsequent oxidation of Fe^{2+} by atmospheric oxygen.

In the corrosion process, iron metal acts as the anode in a galvanic cell and is oxidized to Fe^{2+} ; oxygen is reduced to water at the cathode. The relevant reactions are as follows:

The Fe^{2+} ions produced in the initial reaction are then oxidized by atmospheric oxygen to produce the insoluble hydrated oxide containing Fe^{3+} , as represented in the following equation:

The sign and magnitude of E° for the corrosion process (Equation 19.6.3) indicate that there is a strong driving force for the oxidation of iron by O_2 under standard conditions (1 M H⁺). Under neutral conditions, the driving force is somewhat less but still appreciable ($E = 1.25 \text{ V}$ at pH 7.0). Normally, the reaction of atmospheric CO_2 with water to form H^+ and HCO_3^- provides a low enough pH to enhance the reaction rate, as does acid rain. Automobile manufacturers spend a great deal of time and money developing paints that adhere tightly to the car's metal surface to prevent oxygenated water, acid, and salt from coming into contact with the underlying metal. Unfortunately, even the best paint is subject to scratching or denting, and the electrochemical nature of the corrosion process means that two scratches relatively remote from each other can operate together as anode and cathode, leading to sudden mechanical failure (Figure 19.6.2).

Figure 19.6.2 Small Scratches in a Protective Paint Coating Can Lead to the Rapid Corrosion of Iron Holes in a protective coating allow oxygen to be reduced at the surface with the greater exposure to air (the cathode), while metallic iron is oxidized to $Fe^{2+}(aq)$ at the less exposed site (the anode). Rust is formed when $Fe^{2+}(aq)$ diffuses to a location where it can react with atmospheric oxygen, which is often remote from the anode. The electrochemical interaction between cathodic and anodic sites can cause a large pit to form under a painted surface, eventually resulting in sudden failure with little visible warning that corrosion has occurred.

One of the most common techniques used to prevent the corrosion of iron is applying a protective coating of another metal that is more difficult to oxidize. Faucets and some external parts of automobiles, for example, are often coated with a thin layer of chromium using an electrolytic process that will be discussed in Section 19.7. With the increased use of polymeric materials in cars, however, the use of chrome-plated steel has diminished in recent years. Similarly, the “tin cans” that hold soups and other

foods are actually made of steel coated with a thin layer of tin. Neither chromium nor tin is intrinsically resistant to corrosion, but both form protective oxide coatings.

As with a protective paint, scratching a protective metal coating will allow corrosion to occur. In this case, however, the presence of the second metal can actually increase the rate at which Fe is more easily oxidized than Sn. As a result, the more corrosion-resistant metal (in this case, tin) accelerates the corrosion of iron by acting as the cathode and providing a large surface area for the reduction of oxygen (Figure 19.6.3). This process is seen in some older homes where copper and iron pipes have been directly connected to each other. The less easily oxidized copper acts as the cathode, causing iron to dissolve rapidly near the connection and occasionally resulting in a catastrophic plumbing failure.

Figure 19.6.3 Galvanic Corrosion If iron is in contact with a more corrosion-resistant metal such as tin, copper, or lead, the other metal can act as a large cathode that greatly increases the rate of reduction of oxygen. Because the reduction of oxygen is coupled to the oxidation of iron, this can result in a dramatic increase in the rate at which iron is oxidized at the anode. Galvanic corrosion is likely to occur whenever two dissimilar metals are connected directly, allowing electrons to be transferred from one to the other.

One way to avoid these problems is to use a more easily oxidized metal to protect iron from corrosion. In this approach, called *cathodic protection*, a more reactive metal such as Zn ($E^\circ = -0.76 \text{ V}$ for $\text{Zn}^{2+} + 2\text{e}^{-} \rightarrow \text{Zn}$) becomes the anode, and iron becomes the cathode. This prevents oxidation of the iron and protects the iron object from corrosion. The reactions that occur under these conditions are as follows:

The more reactive metal reacts with oxygen and will eventually dissolve, “sacrificing” itself to protect the iron object. Cathodic protection is the principle underlying *galvanized steel*, which is steel protected by a thin layer of zinc. Galvanized steel is used in objects ranging from nails to garbage cans. In a similar strategy, sacrificial electrodes using magnesium, for example, are used to protect underground tanks or pipes (Figure 19.20). Replacing the sacrificial electrodes is more cost-effective than replacing the iron objects they are protecting.

Figure 19.6.4 The Use of a Sacrificial Electrode to Protect Against Corrosion Connecting a magnesium rod to an underground steel pipeline protects the pipeline from corrosion. Because magnesium ($E^\circ = -2.37 \text{ V}$) is much more easily oxidized than iron ($E^\circ = -0.45 \text{ V}$), the Mg rod acts as the anode in a galvanic cell. The pipeline is therefore forced to act as the cathode at which oxygen is reduced. The soil between the anode and the cathode acts as a salt bridge that completes the electrical circuit and maintains electrical neutrality. As $\text{Mg}(\text{s})$ is oxidized to Mg^{2+} at the anode, anions in the soil, such as nitrate, diffuse toward the anode to neutralize the positive charge. Simultaneously, cations in the soil, such as H^{+} or NH_4^{+} , diffuse toward the cathode, where they

replenish the protons that are consumed as oxygen is reduced. A similar strategy uses many miles of somewhat less reactive zinc wire to protect the Alaska oil pipeline.

Example 19.6.1

Suppose an old wooden sailboat, held together with iron screws, has a bronze propeller (recall that bronze is an alloy of copper containing about 7%–10% tin).

1. If the boat is immersed in seawater, what corrosion reaction will occur? What is E°_{cell} ?
2. How could you prevent this corrosion from occurring?

Given: identity of metals

Asked for: corrosion reaction, E°_{cell} , and preventive measures

Strategy:

A Write the reactions that occur at the anode and the cathode. From these, write the overall cell reaction and calculate E°_{cell} .

B Based on the relative redox activity of various substances, suggest possible preventive measures.

Solution:

1. **A** According to [Table 19.3.1](#), both copper and tin are less active metals than iron (i.e., they have higher positive values of E° than iron). Thus if tin or copper is brought into electrical contact by seawater with iron in the presence of oxygen, corrosion will occur. We therefore anticipate that the bronze propeller will act as the cathode at which O_2 is reduced, and the iron screws will act as anodes at which iron dissolves:

Over time, the iron screws will dissolve, and the boat will fall apart.

2. **B** Possible ways to prevent corrosion, in order of decreasing cost and inconvenience, are as follows: disassembling the boat and rebuilding it with bronze screws; removing the boat from the water and storing it in a dry place; or attaching an inexpensive piece of zinc metal to the propeller shaft to act as a sacrificial electrode and replacing it once or twice a year. Because zinc is a more active metal than iron, it will act as the sacrificial anode in the electrochemical cell and dissolve ([Equation 19.102](#)).

Exercise

Suppose the water pipes leading into your house are made of lead, while the rest of the plumbing in your house is iron. To eliminate the possibility of lead poisoning, you call a plumber to replace the lead pipes. He quotes you a very low price if he can use up his existing supply of copper pipe to do the job.

1. Do you accept his proposal?
2. What else should you have the plumber do while at your home?

Answer:

1. Not unless you plan to sell the house very soon because the Cu/Fe pipe joints will lead to rapid corrosion.
2. Any existing Pb/Fe joints should be examined carefully for corrosion of the iron pipes due to the Pb–Fe junction; the less active Pb will have served as the cathode for the reduction of O_2 , promoting oxidation of the more active Fe nearby.

Summary

The deterioration of metals through oxidation is a galvanic process called **corrosion**. Protective coatings consist of a second metal that is more difficult to oxidize than the metal being protected. Alternatively, a more easily oxidized metal can be applied to a metal surface, thus providing cathodic protection of the surface. A thin layer of zinc protects galvanized steel. **Sacrificial electrodes** can also be attached to an object to protect it.

Key Takeaway

- Corrosion is a galvanic process that can be prevented using cathodic protection.

Conceptual Problems

1. Do you expect a bent nail to corrode more or less rapidly than a straight nail? Why?
2. What does it mean when a metal is described as being coated with a sacrificial layer? Is this different from galvanic protection?
3. Why is it important for automobile manufacturers to apply paint to the metal surface of a car? Why is this process particularly important for vehicles in northern climates, where salt is used on icy roads?

Answer

- 1.
- 2.
3. Paint keeps oxygen and water from coming into direct contact with the metal, which prevents corrosion. Paint is more necessary because salt is an electrolyte that increases the conductivity of water and facilitates the flow of electric current between anodic and cathodic sites.

Learning Objective

- To understand electrolysis and describe it quantitatively.

In this chapter, we have described various galvanic cells in which a spontaneous chemical reaction is used to generate electrical energy. In an electrolytic cell, however, the opposite process, called electrolysis, occurs: an external voltage is applied to drive a nonspontaneous reaction (Figure 19.1.1). In this section, we look at how electrolytic cells are constructed and explore some of their many commercial applications.

Note the Pattern

In an electrolytic cell, an external voltage is applied to drive a nonspontaneous reaction. Electrolytic Cells

If we construct an electrochemical cell in which one electrode is copper metal immersed in a 1 M Cu^{2+} solution and the other electrode is cadmium metal immersed in a 1 M Cd^{2+} solution and then close the circuit, the potential difference between the two compartments will be 0.74 V. The cadmium electrode will begin to dissolve (Cd is oxidized to Cd^{2+}) and is the anode, while metallic copper will be deposited on the copper electrode (Cu^{2+} is reduced to Cu), which is the cathode (part (a) in Figure 19.7.19). The overall reaction is as follows:

This reaction is thermodynamically spontaneous as written (

$$\Delta G^\circ = nFE^\circ_{\text{cell}} = (2 \text{ mole } e^-) \left[96,486 \text{ J} / \left(\cancel{\text{V}} \cdot \cancel{\text{mol}} \right) \right] (0.74 \text{ V}) = -140 \text{ kJ/mol} \quad (19.7.2)$$

In this direction, the system is acting as a galvanic cell.

Figure 19.7.1 An Applied Voltage Can Reverse the Flow of Electrons in a Galvanic Cd/Cu Cell (a) When compartments that contain a Cd electrode immersed in 1 M $\text{Cd}^{2+}(aq)$ and a Cu electrode immersed in 1 M $\text{Cu}^{2+}(aq)$ are connected to create a galvanic cell, Cd(s) is spontaneously oxidized to $\text{Cd}^{2+}(aq)$ at the anode, and $\text{Cu}^{2+}(aq)$ is spontaneously reduced to Cu(s) at the cathode. The potential of the galvanic cell is 0.74 V. (b) Applying an external potential greater than 0.74 V in the reverse direction forces electrons to flow from the Cu electrode [which is now the anode, at which metallic Cu(s) is oxidized to $\text{Cu}^{2+}(aq)$] and into

the Cd electrode [which is now the cathode, at which $Cd^{2+}(aq)$ is reduced to $Cd(s)$]. The anode in an electrolytic cell is positive because electrons are flowing from it, whereas the cathode is negative because electrons are flowing into it.

The reverse reaction, the reduction of Cd^{2+} by Cu, is thermodynamically nonspontaneous and will occur only with an *input* of 140 kJ. We can force the reaction to proceed in the reverse direction by applying an electrical potential greater than 0.74 V from an external power supply. The applied voltage forces electrons through the circuit in the reverse direction, converting a galvanic cell to an electrolytic cell. Thus the copper electrode is now the anode (Cu is oxidized), and the cadmium electrode is now the cathode (Cd^{2+} is reduced) (part (b) in [Figure 19.21 "An Applied Voltage Can Reverse the Flow of Electrons in a Galvanic Cd/Cu Cell"](#)). The signs of the cathode and the anode have switched to reflect the flow of electrons in the circuit. The half-reactions that occur at the cathode and the anode are as follows:

Because $E_{\text{cell}}^{\circ} < 0$, the overall reaction—the reduction of Cd^{2+} by Cu—clearly cannot occur spontaneously and proceeds only when sufficient electrical energy is applied. The differences between galvanic and electrolytic cells are summarized in [Table 19.7.1](#).

Table 19.7.1 Comparison of Galvanic and Electrolytic Cells

Property	Galvanic Cell	Electrolytic Cell
ΔG	< 0	> 0
E_{cell}	> 0	< 0
Electrode Process		
anode	oxidation	oxidation
cathode	reduction	reduction
Sign of Electrode		
anode	–	+
cathode	+	–

Electrolytic Reactions

At sufficiently high temperatures, ionic solids melt to form liquids that conduct electricity extremely well due to the high concentrations of ions. If two inert electrodes are inserted into molten NaCl, for example, and an electrical potential is applied, Cl[–] is oxidized at the anode, and Na⁺ is reduced at the cathode. The overall reaction is as follows:

This is the reverse of the formation of NaCl from its elements. The product of the reduction reaction is *liquid* sodium because the melting point of sodium metal is 97.8°C, well below that of NaCl (801°C). Approximately 20,000 tons of sodium metal are produced commercially in the United States each year by the electrolysis of molten NaCl in a *Downs cell* ([Figure 19.7.2](#)). In this specialized cell, CaCl₂ (melting point = 772°C) is first added to the NaCl to lower the melting point of the mixture to about 600°C, thereby lowering operating costs.

Figure 19.7.2 A Downs Cell for the Electrolysis of Molten NaCl The electrolysis of a molten mixture of NaCl and CaCl₂ results in the formation of elemental sodium and chlorine gas. Because sodium is a liquid under these conditions and liquid sodium is less dense than molten sodium chloride, the sodium floats to the top of the melt and is collected in concentric capped iron cylinders surrounding the cathode. Gaseous chlorine collects in the inverted cone over the anode. An iron screen separating the cathode and anode compartments ensures that the molten sodium and gaseous chlorine do not come into contact.

Similarly, in the *Hall–Heroult process* used to produce aluminum commercially, a molten mixture of about 5% aluminum oxide (Al₂O₃; melting point = 2054°C) and 95% cryolite (Na₃AlF₆; melting point = 1012°C) is electrolyzed at about 1000°C, producing molten aluminum at the cathode and CO₂ gas at the carbon anode. The overall reaction is as follows:

Oxide ions react with oxidized carbon at the anode, producing CO₂(g).

There are two important points to make about these two commercial processes and about the electrolysis of molten salts in general.

1. The electrode potentials for molten salts are likely to be very different from the standard cell potentials listed in [Table 19.3.1](#) and [Table P1](#), which are compiled for the reduction of the hydrated ions in aqueous solutions under standard conditions.
2. Using a mixed salt system means there is a possibility of competition between different electrolytic reactions. When a mixture of NaCl and CaCl₂ is electrolyzed, Cl⁻ is oxidized because it is the only anion present, but either Na⁺ or Ca²⁺ can be reduced. Conversely, in the Hall–Heroult process, only one cation is present that can be reduced (Al³⁺), but there are three species that can be oxidized: C, O²⁻, and F⁻.

In the Hall–Heroult process, C is oxidized instead of O²⁻ or F⁻ because oxygen and fluorine are more electronegative than carbon, which means that C is a weaker oxidant than either O₂ or F₂. Similarly, in the Downs cell, we might expect electrolysis of a NaCl/CaCl₂ mixture to produce calcium rather than sodium because Na is slightly less electronegative than Ca ($\chi = 0.93$ versus 1.00, respectively), making Na easier to oxidize and, conversely, Na⁺ more difficult to reduce. In fact, the reduction of Na⁺ to Na is the observed reaction. In cases where the electronegativities of two species are similar, other factors, such as the formation of complex ions, become important and may determine the outcome.

Example 19.7.1

If a molten mixture of MgCl₂ and KBr is electrolyzed, what products will form at the cathode and the anode, respectively?

Given: identity of salts

Asked for: electrolysis products

Strategy:

A List all the possible reduction and oxidation products. Based on the electronegativity values shown in [Figure 3.3.9](#), determine which species will be reduced and which species will be oxidized.

B Identify the products that will form at each electrode.

Solution:

A The possible reduction products are Mg and K, and the possible oxidation products are Cl₂ and Br₂. Because Mg is more electronegative than K ($\chi = 1.31$ versus 0.82), it is likely that Mg will be reduced rather than K. Because Cl is more electronegative than Br (3.16 versus 2.96), Cl₂ is a stronger oxidant than Br₂.

B Electrolysis will therefore produce Br₂ at the anode and Mg at the cathode.

Exercise

Predict the products if a molten mixture of AlBr₃ and LiF is electrolyzed.

Answer: Br₂ and Al

Electrolysis can also be used to drive the thermodynamically nonspontaneous decomposition of water into its constituent elements: H₂ and O₂. However, because pure water is a very poor electrical conductor, a small amount of an ionic solute (such as H₂SO₄ or Na₂SO₄) must first be added to increase its electrical conductivity. Inserting inert electrodes into the solution and applying a voltage between them will result in the rapid evolution of bubbles of H₂ and O₂ (Figure 19.7.3). The reactions that occur are as follows:

Figure 19.7.3 The Electrolysis of Water Applying an external potential of about 1.7–1.9 V to two inert electrodes immersed in an aqueous solution of an electrolyte such as H₂SO₄ or Na₂SO₄ drives the thermodynamically nonspontaneous decomposition of water into H₂ at the cathode and O₂ at the anode.

For a system that contains an electrolyte such as Na₂SO₄, which has a negligible effect on the ionization equilibrium of liquid water, the pH of the solution will be 7.00 and $[\text{H}^+] = [\text{OH}^-] = 1.0 \times 10^{-7}$. Assuming that $P(\text{O}_2) = P(\text{H}_2) = 1 \text{ atm}$, we can use the standard potentials and Equation 19.4.17 to calculate E for the overall reaction:

$$E_{\text{cell}} = E_{\text{cell}}^{\circ} - \left(\frac{0.0591 \text{ V}}{n} \right) \log \left(P_{\text{O}_2} P_{\text{H}_2}^2 \right) \quad (19.7.11)$$

$$E_{\text{cell}} = -1.23 \text{ V} - \left(\frac{0.0591 \text{ V}}{4} \right) \log (1) = -1.23 \text{ V}$$

Thus E_{cell} is -1.23 V , which is the value of E_{cell}° if the reaction is carried out in the presence of 1 M H^+ rather than at pH 7.0.

In practice, a voltage about 0.4–0.6 V greater than the calculated value is needed to electrolyze water. This added voltage, called an overvoltage, represents the additional driving force required to overcome barriers such as the large activation energy for the

formation of a gas at a metal surface. Overvoltages are needed in all electrolytic processes, which explain why, for example, approximately 14 V must be applied to recharge the 12 V battery in your car.

In general, any metal that does *not* react readily with water to produce hydrogen can be produced by the electrolytic reduction of an aqueous solution that contains the metal cation. The *p*-block metals and most of the transition metals are in this category, but metals in high oxidation states, which form oxoanions, cannot be reduced to the metal by simple electrolysis. Active metals, such as aluminum and those of groups 1 and 2, react so readily with water that they can be prepared only by the electrolysis of molten salts. Similarly, any nonmetallic element that does not readily oxidize water to O₂ can be prepared by the electrolytic oxidation of an aqueous solution that contains an appropriate anion. In practice, among the nonmetals, only F₂ cannot be prepared using this method. Oxoanions of nonmetals in their highest oxidation states, such as NO₃⁻, SO₄²⁻, PO₄³⁻, are usually difficult to reduce electrochemically and usually behave like spectator ions that remain in solution during electrolysis.

Note the Pattern

In general, any metal that does not react readily with water to produce hydrogen can be produced by the electrolytic reduction of an aqueous solution that contains the metal cation.

Electroplating

In a process called electroplating, a layer of a second metal is deposited on the metal electrode that acts as the cathode during electrolysis. Electroplating is used to enhance the appearance of metal objects and protect them from corrosion. Examples of electroplating include the chromium layer found on many bathroom fixtures or (in earlier days) on the bumpers and hubcaps of cars, as well as the thin layer of precious metal that coats silver-plated dinnerware or jewelry. In all cases, the basic concept is the same. A schematic view of an apparatus for electroplating silverware and a photograph of a commercial electroplating cell are shown in Figure 19.7.4.

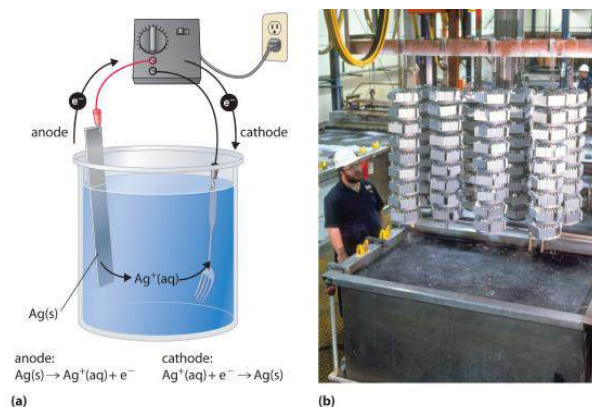

Figure 19.7.4 Electroplating (a) Electroplating uses an electrolytic cell in which the object to be plated, such as a fork, is immersed in a solution of the metal to be deposited. The object being plated acts as the cathode, on which the desired metal is deposited in a thin layer, while the anode usually consists of the metal that is being deposited (in this case, silver) that maintains the solution concentration as it dissolves. (b) In this commercial electroplating apparatus, a large number of objects can be plated simultaneously by lowering the rack into the Ag⁺ solution and applying the correct potential.

The half-reactions in electroplating a fork, for example, with silver are as follows:

The overall reaction is the transfer of silver metal from one electrode (a silver bar acting as the anode) to another (a fork acting as the cathode). Because $E^{\circ}_{\text{cell}} = 0 \text{ V}$, it takes only a small applied voltage to drive the electroplating process. In practice, various other

substances may be added to the plating solution to control its electrical conductivity and regulate the concentration of free metal ions, thus ensuring a smooth, even coating.

Quantitative Considerations

If we know the stoichiometry of an electrolysis reaction, the amount of current passed, and the length of time, we can calculate the amount of material consumed or produced in a reaction. Conversely, we can use stoichiometry to determine the combination of current and time needed to produce a given amount of material.

The quantity of material that is oxidized or reduced at an electrode during an electrochemical reaction is determined by the stoichiometry of the reaction and the amount of charge that is transferred. For example, in the reaction $\text{Ag}^+(\text{aq}) + \text{e}^- \rightarrow \text{Ag}(\text{s})$, 1 mol of electrons reduces 1 mol of Ag^+ to Ag metal. In contrast, in the reaction $\text{Cu}^{2+}(\text{aq}) + 2\text{e}^- \rightarrow \text{Cu}(\text{s})$, 1 mol of electrons reduces only 0.5 mol of Cu^{2+} to Cu metal. Recall that the charge on 1 mol of electrons is 1 faraday (1 F), which is equal to 96,486 C. We can therefore calculate the number of moles of electrons transferred when a known current is passed through a cell for a given period of time. The total charge (C) transferred is the product of the current (A) and the time (t , in seconds):

$$C = A \times t \quad (19.7.14)$$

The stoichiometry of the reaction and the total charge transferred enable us to calculate the amount of product formed during an electrolysis reaction or the amount of metal deposited in an electroplating process.

For example, if a current of 0.60 A passes through an aqueous solution of CuSO_4 for 6.0 min, the total number of coulombs of charge that passes through the cell is as follows:

$$\text{charge} = (0.60 \text{ A}) (6.0 \text{ min}) (60 \text{ s/min}) = 220 \text{ A} \cdot \text{s} \quad (19.7.15)$$

The number of moles of electrons transferred to Cu^{2+} is therefore

$$\text{moles } \text{e}^- = \frac{220 \cancel{\text{C}}}{96,486 \cancel{\text{C/mol}}} = 2.3 \times 10^{-3} \text{ mol } \text{e}^- \quad (19.7.16)$$

Because two electrons are required to reduce a single Cu^{2+} ion, the total number of moles of Cu produced is half the number of moles of electrons transferred, or 1.2×10^{-3} mol. This corresponds to 76 mg of Cu. In commercial electrorefining processes, much higher currents (greater than or equal to 50,000 A) are used, corresponding to approximately 0.5 F/s , and reaction times are on the order of 3–4 weeks.

Example 19.7.2

A silver-plated spoon typically contains about 2.00 g of Ag. If 12.0 h are required to achieve the desired thickness of the Ag coating, what is the average current per spoon that must flow during the electroplating process, assuming an efficiency of 100%?

Given: mass of metal, time, and efficiency

Asked for: current required

Strategy:

A Calculate the number of moles of metal corresponding to the given mass transferred.

B Write the reaction and determine the number of moles of electrons required for the electroplating process.

C Use the definition of the faraday to calculate the number of coulombs required. Then convert coulombs to current in amperes.

Solution:

A We must first determine the number of moles of Ag corresponding to 2.00 g of Ag:

$$\text{moles Ag} = \frac{2.0 \text{ g}}{107.868 \text{ g/mol}} = 1.85 \times 10^{-2} \text{ mol Ag}$$

B The reduction reaction is $\text{Ag}^+(\text{aq}) + \text{e}^- \rightarrow \text{Ag}(\text{s})$, so 1 mol of electrons produces 1 mol of silver.

C Using the definition of the faraday,

$$\text{Coulombs} = (1.85 \times 10^{-2} \text{ mol}) (96,486 \text{ C/mol}) = 1.78 \times 10^3 \text{ C}$$

The current in amperes needed to deliver this amount of charge in 12.0 h is therefore

$$\begin{aligned} \text{amperes} &= \frac{1.78 \times 10^3 \text{ C}}{(12.0 \text{ h}) (60 \text{ min/h}) (60 \text{ s/min})} \\ &= 4.12 \times 10^{-2} \text{ C/s} = 4.12 \times 10^{-2} \text{ A} \end{aligned}$$

Because the electroplating process is usually much less than 100% efficient (typical values are closer to 30%), the actual current necessary is greater than 0.1 A.

Exercise

A typical aluminum soft-drink can weighs about 29 g. How much time is needed to produce this amount of Al(s) in the Hall–Heroult process, using a current of 15 A to reduce a molten $\text{Al}_2\text{O}_3/\text{Na}_3\text{AlF}_6$ mixture?

Answer: 5.8 h

Summary

In **electrolysis**, an external voltage is applied to drive a nonspontaneous reaction. A Downs cell is used to produce sodium metal from a mixture of salts, and the Hall–Heroult process is used to produce aluminum commercially. Electrolysis can also be used to produce H_2 and O_2 from water. In practice, an additional voltage, called an **overvoltage**, must be applied to overcome factors such as a large activation energy and a junction potential. **Electroplating** is the process by which a second metal is deposited on a metal surface, thereby enhancing an object's appearance or providing protection from corrosion. The amount of material consumed or produced in a reaction can be calculated from the stoichiometry of an electrolysis reaction, the amount of current passed, and the duration of the electrolytic reaction.

Key Takeaways

- In electrolysis, an external voltage is applied to drive a nonspontaneous reaction.
- The quantity of material oxidized or reduced can be calculated from the stoichiometry of the reaction and the amount of charge transferred.

Key Equation

Relationship of charge, current and time

Equation 19.116: $C = A \times t$

Conceptual Problems

1. Why might an electrochemical reaction that is thermodynamically favored require an overvoltage to occur?
2. How could you use an electrolytic cell to make quantitative comparisons of the strengths of various oxidants and reductants?
3. Why are mixtures of molten salts, rather than a pure salt, generally used during electrolysis?

4. Two solutions, one containing $\text{Fe}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$ and the other containing the same molar concentration of $\text{Fe}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$, were electrolyzed under identical conditions. Which solution produced the most metal? Justify your answer.

Numerical Problems

- The electrolysis of molten salts is frequently used in industry to obtain pure metals. How many grams of metal are deposited from these salts for each mole of electrons?
 - AlCl_3
 - MgCl_2
 - FeCl_3
- Electrolysis is the most direct way of recovering a metal from its ores. However, the $\text{Na}^+(\text{aq})/\text{Na}(\text{s})$, $\text{Mg}^{2+}(\text{aq})/\text{Mg}(\text{s})$, and $\text{Al}^{3+}(\text{aq})/\text{Al}(\text{s})$ couples all have standard electrode potentials (E°) more negative than the reduction potential of water at pH 7.0 (-0.42 V), indicating that these metals can never be obtained by electrolysis of aqueous solutions of their salts. Why? What reaction would occur instead?
- What volume of chlorine gas at standard temperature and pressure is evolved when a solution of MgCl_2 is electrolyzed using a current of 12.4 A for 1.0 h?
- What mass of copper metal is deposited if a 5.12 A current is passed through a $\text{Cu}(\text{NO}_3)_2$ solution for 1.5 h.
- What mass of PbO_2 is reduced when a current of 5.0 A is withdrawn over a period of 2.0 h from a lead storage battery?
- Electrolysis of $\text{Cr}^{3+}(\text{aq})$ produces $\text{Cr}^{2+}(\text{aq})$. If you had 500 mL of a 0.15 M solution of $\text{Cr}^{3+}(\text{aq})$, how long would it take to reduce the Cr^{3+} to Cr^{2+} using a 0.158 A current?
- Predict the products obtained at each electrode when aqueous solutions of the following are electrolyzed.
 - AgNO_3
 - RbI
- Predict the products obtained at each electrode when aqueous solutions of the following are electrolyzed.
 - MgBr_2
 - $\text{Hg}(\text{CH}_3\text{CO}_2)_2$
 - $\text{Al}_2(\text{SO}_4)_3$

Unit 8: Materials

APPLICATION PROBLEMS

Problems marked with a ♦ involve multiple concepts.

- The percent efficiency of a fuel cell is defined as $\Delta G^\circ/\Delta H^\circ \times 100$. If hydrogen gas were distributed for domestic and industrial use from a central electrolysis facility, the gas could be piped to consumers much as methane is piped today. Conventional nuclear power stations have an efficiency of 25%–30%. Use tabulated data to calculate the efficiency of a fuel cell in which the reaction $\text{H}_2(\text{g}) + 1/2\text{O}_2(\text{g}) \rightarrow \text{H}_2\text{O}(\text{g})$ occurs under standard conditions.
- ♦ You are about to run an organic reaction and need a strong oxidant. Although you have BrO_3^- at your disposal, you prefer to use MnO_4^- . You notice you also have MnO_2 in the lab.
 - Predict whether you will be able to synthesize MnO_4^- using the materials available to you.
 - Write the overall reaction for the synthesis of MnO_4^- .
 - What is ΔG° for this reaction?
 - What is the equilibrium constant?
- It is possible to construct a galvanic cell using amalgams as electrodes, each containing different concentrations of the same metal. One example is the $\text{Pb}(\text{Hg})(a_1) | \text{PbSO}_4(\text{soln}) | \text{Pb}(\text{Hg})(a_2)$ cell, in which a_1 and a_2 represent the concentrations of lead in the amalgams. No chemical change occurs; rather, the reaction transfers lead from one amalgam to the other, thus altering the Pb concentration in both amalgams. Write an equation for E for such a cell.
- ♦ The oldest known metallurgical artifacts are beads made from alloys of copper, produced in Egypt, Mesopotamia, and the Indus Valley around 3000 BC. To determine the copper content of alloys such as brass, a brass sample is dissolved in nitric acid to obtain $\text{Cu}^{2+}(\text{aq})$, and then the pH is adjusted to 7.0. Excess KI is used to reduce the Cu^{2+} to Cu^+ with concomitant oxidation of I^- to I_2 . The iodine that is produced is then titrated with thiosulfate solution to determine the amount of Cu^{2+} in the original solution. The following reactions are involved in the procedure:
 - $\text{Cu}^{2+}(\text{aq}) + \text{I}^-(\text{aq}) + \text{e}^- \rightarrow \text{Cu}^+(\text{s}); E^\circ = 0.86 \text{ V}$
 - $\text{S}_4\text{O}_6^{2-}(\text{aq}) + 2\text{e}^- \rightarrow 2\text{S}_2\text{O}_3^{2-}(\text{aq}); E^\circ = 0.08 \text{ V}$
 - $\text{NO}_3^-(\text{aq}) + 2\text{H}^+(\text{aq}) + 2\text{e}^- \rightarrow \text{NO}_2(\text{aq}) + \text{H}_2\text{O}(\text{l}); E^\circ = 0.94 \text{ V}$
 - $\text{I}_2(\text{s}) + 2\text{e}^- \rightarrow 2\text{I}^-(\text{aq}); E^\circ = 0.54 \text{ V}$
 - Write a balanced chemical equation for the reaction between nitric acid and $\text{Cu}(\text{s})$.
 - What is E°_{cell} for this reaction?
 - What is E°_{cell} for the reaction between thiosulfate and iodine?
 - When the pH of the copper(II) solution is adjusted to 7.0, what is E for reduction of nitrate?
 - Why is it necessary to adjust the pH of the copper(II) solution before adding KI?
 - Use tabulated data to explain why rust (Fe_2O_3) is a contaminant that renders this method useless in determining Cu concentrations.
- The biological electron transport chain provides for an orderly, stepwise transfer of electrons. Both NADH (reduced nicotinamide adenine dinucleotide) and FADH_2 (reduced flavin adenine dinucleotide) are energy-rich molecules that liberate a large amount of energy during oxidation. Free energy released during the transfer of electrons from either of these molecules to oxygen drives the synthesis of ATP (adenosine triphosphate) formed during respiratory metabolism. The reactions are as follows:

The standard potential (E°) for a biological process is defined at pH = 7.0.

- What is E°_{cell} for each reaction?
 - What is the reduction potential of NAD^+ at pH 7.0?
 - What is the reduction potential of FAD at pH 7.0?
6. While working at a nuclear reactor site, you have been put in charge of reprocessing spent nuclear fuel elements. Your specific task is to reduce Pu(VI) to elemental Pu without reducing U(VI) to elemental U . You have the following information at your disposal:

Use tabulated data to decide what reductant will accomplish your task in an acidic solution containing 1.0 M concentrations of both UO_2^{2+} and PuO_2^{2+} .

7. Stainless steels typically contain 11% Cr and are resistant to corrosion because of the formation of an oxide layer that can be approximately described as FeCr_2O_4 , where the iron is Fe(II). The protective layer forms when Cr(II) is oxidized to Cr(III) and Fe is oxidized to Fe(III). Explain how this film prevents the corrosion of Fe to rust, which has the formula Fe_2O_3 .
8. ♦ Ion-selective electrodes are powerful tools for measuring specific concentrations of ions in solution. For example, they are used to measure iodide in milk, copper-ion levels in drinking water, fluoride concentrations in toothpastes, and the silver-ion concentration in photographic emulsions and spent fixing solutions. Describe how ion-selective electrodes work and then propose a design for an ion-selective electrode that can be used for measuring water hardness (Ca^{2+} , Mg^{2+}) in water-conditioning systems.
9. ♦ Enzymes are proteins that catalyze a specific reaction with a high degree of specificity. An example is the hydrolysis of urea by urease:

An enzyme electrode for measuring urea concentrations can be made by coating the surface of a glass electrode with a gel that contains urease.

- Explain what occurs when the electrode is placed in contact with a solution that contains urea.
 - What species diffuses through the gel?
 - What would be an effective reference electrode?
10. Gas-sensing electrodes can be constructed using a combination electrode that is surrounded by a gas-permeable membrane. For example, to measure CO_2 , a pH electrode and a reference electrode are placed in solution on the “inner” side of a CO_2 -permeable membrane, and the sample solution is placed on the “external” side. As CO_2 diffuses through the membrane, the pH of the internal solution changes due to the reaction $\text{CO}_2(\text{g}) + \text{H}_2\text{O}(\text{l}) \rightarrow \text{HCO}_3^-(\text{aq}) + \text{H}^+(\text{aq})$. Thus the pH of the internal solution varies directly with the CO_2 pressure in the external sample. Ammonia electrodes operate in the same manner. Describe an electrode that would test for ammonia levels in seawater.
11. US submarines that are not nuclear powered use a combination of batteries and diesel engines for their power. When submerged, they are battery driven; when on the surface, they are diesel driven. Why are batteries not used when submarines are on the surface?
12. List some practical considerations in designing a battery to power an electric car.
13. ♦ It is possible to run a digital clock using the power supplied by two potatoes. The clock is connected to two wires: one is attached to a copper plate, and the other is attached to a zinc plate. Each plate is pushed into a different potato; when a wire connects the two potatoes, the clock begins to run as if it were connected to a battery.
- Draw a cell diagram of the potato clock.
 - Explain why the clock runs.
14. ♦ The silver–zinc battery has the highest energy density of any rechargeable battery available today. Its use is presently limited to military applications, primarily in portable communications, aerospace, and torpedo-propulsion systems. The disadvantages of these cells are their limited life (they typically last no more than about 2 yr) and their high cost, which restricts their use to situations in which cost is only a minor factor. The generally accepted equations representing this type of battery are as follows:

- Write the overall cell reaction and calculate E°_{cell} .
- If the cell is 75% efficient, what is the maximum amount of work that can be generated from this type of battery?

- c. Use tabulated data to calculate the maximum work that can be generated by a lead storage cell. If a silver–zinc battery is operating at 100% efficiency, how do the two batteries compare?
15. All metals used in boats and ships are subject to corrosion, particularly when the vessels are operated in salt water, which is a good electrolyte. Based on the data in the following table, where potentials are measured using a glass electrode, explain why
- iron or steel should not be used in bolts in a lead ballast keel.
 - ordinary brass should not be used as a structural fastening, particularly below the waterline.
 - an aluminum hull should not be painted with a copper-based antifouling paint.
 - magnesium sacrificial anodes are preferred over zinc when a vessel is kept in fresh water.
 - Monel (an alloy that contains mostly nickel and copper) is preferred over stainless steel for freshwater tanks.

Metal	E versus Ag/AgCl (V)
titanium	0.02
Monel [Ni(Cu)]	-0.06
Ni(Al) bronze	-0.16
lead	-0.20
manganese bronze	-0.29
brass	-0.30
copper	-0.31
tin	-0.31
stainless steel	-0.49
aluminum	-0.87
zinc	-1.00
magnesium	-1.60

16. Parents often coat a baby's first shoes with copper to preserve them for posterity. A conducting powder, such as graphite, is rubbed on the shoe, and then copper is electroplated on the shoe. How much copper is deposited on a shoe if the electrolytic process is run for 60 min at 1.2 A from a 1.0 M solution of CuSO_4 ?
17. Before 1886, metallic aluminum was so rare that a bar of it was displayed next to the Crown Jewels at the Paris Exposition of 1855. Today, aluminum is obtained commercially from aluminum oxide by the Hall–Heroult process, an electrolytic process that uses molten Al_2O_3 and cryolite (Na_3AlF_6). As the operation proceeds, molten Al sinks to the bottom of the cell. The overall reaction is $2\text{Al}_2\text{O}_3(\text{l}) + 3\text{C}(\text{s}) \rightarrow 4\text{Al}(\text{l}) + 3\text{CO}_2(\text{g})$; however, the process is only approximately 90% efficient.
- Why is cryolite added to the Al_2O_3 ?
 - How much aluminum is deposited if electrodeposition occurs for 24 h at 1.8 A?
18. ♦ One of the most important electrolytic processes used in industry is the electrolytic reduction of acrylonitrile (CH_2CHCN) to adiponitrile [$\text{NC}(\text{CH}_2)_4\text{CN}$]. The product is then hydrogenated to hexamethylenediamine [$\text{H}_2\text{N}(\text{CH}_2)_6\text{NH}_2$], a key component of one form of nylon. Using this process, Monsanto produces about 200,000 metric tons of adiponitrile annually. The cathode reaction in the electrochemical cell is as follows:

$$2\text{CH}_2\text{CHCN} + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{NC}(\text{CH}_2)_4\text{CN}$$
The cost of electricity makes this an expensive process. Calculate the total number of kilowatt-hours of electricity used by Monsanto each year in this process, assuming a continuous applied potential of 5.0 V and an electrochemical efficiency of 50%. (One kilowatt-hour equals 3.6×10^3 kJ.)
19. ♦ Compact discs (CDs) are manufactured by electroplating. Information is stored on a CD master in a pattern of “pits” (depressions, which correspond to an audio track) and “lands” (the raised areas between depressions). A laser beam cuts the pits into a plastic or glass material. The material is cleaned, sprayed with $[\text{Ag}(\text{NH}_3)_2]^+$, and then washed with a formaldehyde solution that reduces the complex and leaves a thin silver coating. Nickel is electrodeposited on the disk and then peeled away to produce a master disk, which is used to stamp copies.
- Write the half-reactions that correspond to the electrodeposition reaction.

- b. If a CD has a radius of 12 cm and an interior hole with a diameter of 2.5 cm, how long does it take to deposit a 50 μm layer of nickel on one side of the CD using a 1.0 M solution of NiSO_4 and a current of 0.80 A?
20. \blacklozenge Calculate the total amount of energy consumed in the electrolysis reaction used to make the 16×10^6 metric tons of aluminum produced annually worldwide, assuming a continuous applied potential of 5.0 V and an efficiency of 50%. Express your answer in kilojoules and in kilowatt-hours. (See Problem 19 for the conversion between kilowatt-hours and kilojoules.)

In previous chapters, we used the principles of chemical bonding, thermodynamics, and kinetics to provide a conceptual framework for understanding the chemistry of the elements. Beginning in [Chapter 21 "Periodic Trends and the "](#), we use the periodic table to guide our discussion of the properties and reactions of the elements and the synthesis and uses of some of their commercially important compounds. We begin this chapter with a review of periodic trends as an introduction, and then we describe the chemistry of hydrogen and the other *s*-block elements. In [Chapter 22 "The "](#), we consider the chemistry of the *p*-block elements; [Chapter 23 "The "](#) presents the transition metals, in which the *d*-subshell is being filled. In this chapter, you will learn why potassium chloride is used as a substitute for sodium chloride in a low-sodium diet, why cesium is used as a photosensor, why the heating elements in electric ranges are coated with magnesium oxide, and why exposure to a radioactive isotope of strontium is more dangerous for children than for adults.

Flame tests. Heating a compound results in the formation of its component atoms in electronically excited states. When an excited atom decays to the ground state, it emits light. Each element emits light at characteristic frequencies. Flame tests are used to identify many elements based on the color of the light they emit in the visible region of the electromagnetic spectrum. As shown here, sodium compounds produce an intense yellow light, whereas

compounds produce a crimson color.

Unit 5: States of Matter

Unit 2: Molecular Structure
Unit 6: Kinetics & Equilibria

Unit 3: Stoichiometry
Unit 7: Electro & Thermo Chemistry

Unit 4: Thermochem & Gases
Unit 8: Materials

Learning Objectives

- To know important periodic trends in several atomic properties.

As we begin our summary of periodic trends, recall from [Chapter 3](#) that the single most important unifying principle in understanding the chemistry of the elements is the systematic increase in atomic number, accompanied by the orderly filling of atomic orbitals by electrons, which leads to periodicity in such properties as atomic and ionic size, ionization energy, electronegativity, and electron affinity. The same factors also lead to periodicity in valence electron configurations, which for each group results in similarities in oxidation states and the formation of compounds with common stoichiometries.

The most important periodic trends in atomic properties are summarized in [Figure 20.1.1](#). Recall from [Chapter 3](#) that these trends are based on periodic variations in a single fundamental property, the effective nuclear charge (Z_{eff}), which increases from left to right and from top to bottom in the periodic table.

The orange diagonal line in [Figure 20.1.1](#) separates the metals (to the left of the line) from the nonmetals (to the right of the line). Because metals have relatively low electronegativities, they tend to lose electrons in chemical reactions to elements that have relatively high electronegativities, forming compounds in which they have positive oxidation states. Conversely, nonmetals have high electronegativities, and they therefore tend to gain electrons in chemical reactions to form compounds in which they have negative oxidation states. The semimetals lie along the diagonal line dividing metals and nonmetals. It is not surprising that they tend to exhibit properties and reactivities intermediate between those of metals and nonmetals. Because the elements of groups 13, 14, and 15 span the diagonal line separating metals and nonmetals, their chemistry is more complex than predicted based solely on their valence electron configurations.

Figure 20.1.1 Summary of Periodic Trends in Atomic Properties Ionization energies, the magnitude of electron affinities, and electronegativities generally increase from left to right and from bottom to top. In contrast, atomic size decreases from left to right and from bottom to top. Consequently, the elements in the upper right of the periodic table are the smallest and most electronegative; the elements in the bottom left are the largest and least electronegative. The semimetals lie along the diagonal line separating the metals from the nonmetals and exhibit intermediate properties.

Unique Chemistry of the Lightest Elements

The chemistry of the second-period element of each group ($n = 2$: Li, Be, B, C, N, O, and F) differs in many important respects from that of the heavier members, or *congeners*, of the group. Consequently, the elements of the third period ($n = 3$: Na, Mg, Al, Si, P, S, and Cl) are generally more representative of the group to which they belong. The anomalous chemistry of second-period elements results from three important characteristics: small radii, energetically unavailable d orbitals, and a tendency to form pi (π) bonds with other atoms.

Note the Pattern

In contrast to the chemistry of the second-period elements, the chemistry of the third-period elements is more representative of the chemistry of the respective group.

Due to their small radii, second-period elements have electron affinities that are less negative than would be predicted from general periodic trends. When an electron is added to such a small atom, increased electron–electron repulsions tend to destabilize the anion. Moreover, the small sizes of these elements prevent them from forming compounds in which they have more than four nearest neighbors. Thus BF_3 forms only the four-coordinate, tetrahedral BF_4^- ion, whereas under the same conditions AlF_3 forms the six-coordinate, octahedral AlF_6^{3-} ion. Because of the smaller atomic size, simple binary ionic compounds of second-period elements also have more covalent character than the corresponding compounds formed from their heavier congeners. The very small cations derived from second-period elements have a high charge-to-radius ratio and can therefore polarize the filled valence shell of an anion. As such, the bonding in such compounds has a significant covalent component, giving the compounds properties that can differ significantly from those expected for simple ionic compounds. As an example, LiCl , which is partially covalent in character, is much more soluble than NaCl in solvents with a relatively low dielectric constant, such as ethanol ($\epsilon = 25.3$ versus 80.1 for H_2O).

Because d orbitals are never occupied for principal quantum numbers less than 3, the valence electrons of second-period elements occupy $2s$ and $2p$ orbitals only. The energy of the $3d$ orbitals far exceeds the energy of the $2s$ and $2p$ orbitals, so using them in bonding is energetically prohibitive. Consequently, electron configurations with more than four electron pairs around a central, second-period element are simply not observed. You may recall from [Chapter 6](#) that the role of d orbitals in bonding in main group compounds with coordination numbers of 5 or higher remains somewhat controversial. In fact, theoretical descriptions of the bonding in molecules such as SF_6 have been published without mentioning the participation of d orbitals on sulfur. Arguments based on d -orbital availability and on the small size of the central atom, however, predict that coordination numbers greater than 4 are unusual for the elements of the second period, which is in agreement with experimental results.

One of the most dramatic differences between the lightest main group elements and their heavier congeners is the tendency of the second-period elements to form species that contain multiple bonds. For example, N is just above P in group 15: N_2 contains an $\text{N}\equiv\text{N}$ bond, but each phosphorus atom in tetrahedral P_4 forms three P–P bonds. This difference in behavior reflects the fact that within the same group of the periodic table, the relative energies of the π bond and the sigma (σ) bond differ. A C=C bond, for example, is approximately 80% stronger than a C–C bond. In contrast, an Si=Si bond, with less p -orbital overlap between the valence orbitals of the bonded atoms because of the larger atomic size, is only about 40% stronger than an Si–Si bond. Consequently, compounds that contain both multiple and single C to C bonds are common for carbon, but compounds that contain only sigma Si–Si bonds are more energetically favorable for silicon and the other third-period elements.

Another important trend to note in main group chemistry is the chemical similarity between the lightest element of one group and the element immediately below and to the right of it in the next group, a phenomenon known as the *diagonal effect* ([Figure 20.1.2](#)). There are, for example, significant similarities between the chemistry of Li and Mg, Be and Al, and B and Si. Both BeCl_2 and AlCl_3 have substantial covalent character, so they are somewhat soluble in nonpolar organic solvents. In contrast, although Mg and Be are in the same group, MgCl_2 behaves like a typical *ionic halide* due to the lower electronegativity and larger size of magnesium.

	1	2	13	14
2	Li	Be	B	C
3	Na	Mg	Al	Si

Figure 20.1.2 The Diagonal Effect The properties of the lightest element in a group are often more similar to those of the element below and to the right in the periodic table. For instance, the chemistry of lithium is more similar to that of magnesium in group 2 than it is to the chemistry of sodium, the next member in group 1.

The Inert-Pair Effect

The inert-pair effect refers to the empirical observation that the heavier elements of groups 13–17 often have oxidation states that are lower by 2 than the maximum predicted for their group. For example, although an oxidation state of +3 is common for group 13 elements, the heaviest element in group 13, thallium (Tl), is more likely to form compounds in which it has a +1 oxidation state. There appear to be two major reasons for the inert-pair effect: increasing ionization energies and decreasing bond strengths.

Note the Pattern

In moving down a group in the p -block, increasing ionization energies and decreasing bond strengths result in an inert-pair effect.

The ionization energies increase because filled $(n - 1)d$ or $(n - 2)f$ subshells are relatively poor at shielding electrons in ns orbitals. Thus the two electrons in the ns subshell experience an unusually high effective nuclear charge, so they are strongly attracted to the nucleus, reducing their participation in bonding. It is therefore substantially more difficult than expected to remove these ns^2 electrons, as shown in Table 20.1.1 (by the difference between the first ionization energies of thallium and aluminum). Because Tl is less likely than Al to lose its two ns^2 electrons, its most common oxidation state is +1 rather than +3.

Table 20.1.1 Ionization Energies (I) and Average M–Cl Bond Energies for the Group 13 Elements

Element	Electron Configuration	I_1 (kJ/mol)	$I_1 + I_2 + I_3$ (kJ/mol)	Average M–Cl Bond Energy (kJ/mol)
B	[He] $2s^2 2p^1$	801	6828	536
Al	[Ne] $3s^2 3p^1$	578	5139	494
Ga	[Ar] $3d^{10} 4s^2 4p^1$	579	5521	481
In	[Kr] $4d^{10} 5s^2 5p^1$	558	5083	439
Tl	[Xe] $4f^{14} 5d^{10} 6s^2 6p^1$	589	5439	373

Source of data: John A. Dean, Lange's Handbook of Chemistry, 15th ed. (New York: McGraw-Hill, 1999).

Going down a group, the atoms generally became larger, and the overlap between the valence orbitals of the bonded atoms decreases. Consequently, bond strengths tend to decrease down a column. As shown by the M–Cl bond energies listed in Table 21.1, the strength of the bond between a group 13 atom and a chlorine atom decreases by more than 30% from B to Tl. Similar decreases are observed for the atoms of groups 14 and 15.

The net effect of these two factors—increasing ionization energies and decreasing bond strengths—is that in going down a group in the p -block, the additional energy released by forming two additional bonds eventually is not great enough to compensate for the

additional energy required to remove the two ns^2 electrons.

Example 20.1.1

Based on the positions of the group 13 elements in the periodic table and the general trends outlined in this section,

1. classify these elements as metals, semimetals, or nonmetals.
2. predict which element forms the most stable compounds in the +1 oxidation state.
3. predict which element differs the most from the others in its chemistry.
4. predict which element of another group will exhibit chemistry most similar to that of Al.

Given: positions of elements in the periodic table

Asked for: classification, oxidation-state stability, and chemical reactivity

Strategy:

From the position of the diagonal line in the periodic table separating metals and nonmetals, classify the group 13 elements. Then use the trends discussed in this section to compare their relative stabilities and chemical reactivities.

Solution:

1. Group 13 spans the diagonal line separating the metals from the nonmetals. Although Al and B both lie on the diagonal line, only B is a semimetal; the heavier elements are metals.
2. All five elements in group 13 have an $ns^2 np^1$ valence electron configuration, so they are expected to form ions with a +3 charge from the loss of all valence electrons. The inert-pair effect should be most important for the heaviest element (Tl), so it is most likely to form compounds in an oxidation state that is lower by 2. Thus the +1 oxidation state is predicted to be most important for thallium.
3. Among the main group elements, the lightest member of each group exhibits unique chemistry because of its small size resulting in a high concentration of charge, energetically unavailable d orbitals, and a tendency to form multiple bonds. In group 13, we predict that the chemistry of boron will be quite different from that of its heavier congeners.
4. Within the s and p blocks, similarities between elements in different groups are most marked between the lightest member of one group and the element of the next group immediately below and to the right of it. These elements exhibit similar electronegativities and charge-to-radius ratios. Because Al is the second member of group 13, we predict that its chemistry will be most similar to that of Be, the lightest member of group 2.

Exercise

Based on the positions of the group 14 elements C, Si, Ge, Sn, and Pb in the periodic table and the general trends outlined in this section,

1. classify these elements as metals, semimetals, or nonmetals.
2. predict which element forms the most stable compounds in the +2 oxidation state.
3. predict which element differs the most from the others in its chemistry.
4. predict which element of group 14 will be chemically most similar to a group 15 element.

Answer:

1. nonmetal: C; semimetals: Si and Ge; metals: Sn and Pb
2. Pb is most stable as M^{2+} .
3. C is most different.
4. C and P are most similar in chemistry.

Summary

The most important unifying principle in describing the chemistry of the elements is that the systematic increase in atomic number and the orderly filling of atomic orbitals lead to periodic trends in atomic properties. The most fundamental property leading to periodic variations is the **effective nuclear charge (Z_{eff})**. Because of the position of the diagonal line separating metals and nonmetals in the periodic table, the chemistry of groups 13, 14, and 15 is relatively complex. The second-period elements ($n = 2$) in each group exhibit unique chemistry compared with their heavier congeners because of their smaller radii, energetically unavailable d orbitals, and greater ability to form π bonds with other atoms. Increasing ionization energies and decreasing bond strengths lead to the **inert-pair effect**, which causes the heaviest elements of groups 13–17 to have a stable oxidation state that is lower by 2 than the maximum predicted for their respective groups.

Key Takeaway

- The chemistry of the third-period element in a group is most representative of the chemistry of the group because the chemistry of the second-period elements is dominated by their small radii, energetically unavailable d orbitals, and tendency to form π bonds with other atoms.

Conceptual Problems

- List three physical properties that are important in describing the behavior of the main group elements.
- Arrange K, Cs, Sr, Ca, Ba, and Li in order of
 - increasing ionization energy.
 - increasing atomic size.
 - increasing electronegativity.
- Arrange Rb, H, Be, Na, Cs, and Ca in order of
 - decreasing atomic size.
 - decreasing magnitude of electron affinity.
- Which periodic trends are affected by Z_{eff} ? Based on the positions of the elements in the periodic table, which element would you expect to have the highest Z_{eff} ? the lowest Z_{eff} ?
- Compare the properties of the metals and nonmetals with regard to their electronegativities and preferred oxidation states.
- Of Ca, Br, Li, N, Zr, Ar, Sr, and S, which elements have a greater tendency to form positive ions than negative ions?
- Arrange As, O, Ca, Sn, Be, and Sb in order of decreasing metallic character.
- Give three reasons the chemistry of the second-period elements is generally not representative of their groups as a whole.
- Compare the second-period elements and their heavier congeners with regard to
 - magnitude of electron affinity.
 - coordination number.
 - the solubility of the halides in nonpolar solvents.
- The heavier main group elements tend to form extended sigma-bonded structures rather than multiple bonds to other atoms. Give a reasonable explanation for this tendency.
- What is the diagonal effect? How does it explain the similarity in chemistry between, for example, boron and silicon?
- Although many of the properties of the second- and third-period elements in a group are quite different, one property is similar. Which one?
- Two elements are effective additives to solid rocket propellant: beryllium and one other element that has similar chemistry. Based on the position of beryllium in the periodic table, identify the second element. $2+$
- Give two reasons for the inert-pair effect. How would this phenomenon explain why Sn $2+$ is a better reducing agent than Pb $2+$?
- Explain the following trend in electron affinities: Al (-41.8 kJ/mol), Si (-134.1 kJ/mol), P (-72.0 kJ/mol), and S (-200.4 kJ/mol).
- Using orbital energy arguments, explain why electron configurations with more than four electron pairs around the central atom are not observed for second-period elements.

Answers

- 1.
- 2.
3. a. $\text{Cs} > \text{Rb} > \text{Ca} > \text{Na} > \text{Be} > \text{H}$
b. $\text{H} > \text{Na} > \text{Rb} > \text{Cs} > \text{Ca} > \text{Be}$
- 4.
- 5.
- 6.
7. $\text{Ca} > \text{Be} > \text{Sn} > \text{Sb} > \text{As} > \text{O}$
- 8.
- 9.
- 10.
- 11.
- 12.
13. aluminum
- 14.
15. The magnitude of electron affinity increases from left to right in a period due to the increase in Z_{eff} ; P has a lower electron affinity than expected due to its half-filled $3p$ shell, which requires the added electron to enter an already occupied $3p$ orbital.
- 16.

Structure and Reactivity

1. The following table lists the valences, coordination numbers, and ionic radii for a series of cations. Which would you substitute for K^+ in a crystalline lattice? Explain your answer.

Metal	Charge	Coordination Number	Ionic Radius (pm)
Li	+1	4	76
Na	+1	6	102
K	+1	6	138
Mg	+2	6	72
Ca	+2	6	100
Sr	+2	6	118

Answer

1. Sr^{2+} ; it is the ion with the radius closest to that of K^+ .

Chapter 20.2: The Chemistry of Hydrogen

Howard University General Chemistry: An Atoms First Approach

Unit 1: Atomic Theory
Unit 5: States of Matter

Unit 2: Molecular Structure
Unit 6: Kinetics & Equilibria

Unit 3: Stoichiometry
Unit 7: Electro & Thermo Chemistry

Unit 4: Thermochem & Gases
Unit 8: Materials

Learning Objectives

- To describe the physical and chemical properties of hydrogen and predict its reactivity.

We now turn from an overview of periodic trends to a discussion of the s-block elements, first by focusing on hydrogen, whose chemistry is sufficiently distinct and important to be discussed in a category of its own. Most versions of the periodic table place hydrogen in the upper left corner immediately above lithium, implying that hydrogen, with a $1s^1$ electron configuration, is a member of group 1. In fact, the chemistry of hydrogen does *not* greatly resemble that of the metals of group 1. Indeed, some versions of the periodic table place hydrogen above fluorine in group 17 because the addition of a single electron to a hydrogen atom completes its valence shell.

Note the Pattern

Although hydrogen has an ns^1 electron configuration, its chemistry does not resemble that of the metals of group 1.

Isotopes of Hydrogen

Hydrogen, the most abundant element in the universe, is the ultimate source of all other elements by the process of nuclear fusion. (For more information on nuclear fusion, see [Chapter 24](#)). [Table 20.2.1](#) compares the three isotopes of hydrogen, all of which contain one proton and one electron per atom. The most common isotope is protium (^1_1H or H), followed by deuterium (^2_1H or D), which has an additional neutron. The rarest isotope of hydrogen is tritium (^3_1H or T), which is produced in the upper atmosphere by a nuclear reaction when cosmic rays strike nitrogen and other atoms; it is then washed into the oceans by rainfall. Tritium is radioactive, decaying to ^3_2He with a half-life of only 12.32 years. Consequently, the atmosphere and oceans contain only a very low, steady-state level of tritium. The term *hydrogen* and the symbol H normally refer to the naturally occurring mixture of the three isotopes.

Table 20.2.1 The Isotopes of Hydrogen

	Protium	Deuterium	Tritium
symbol	$>^1_1\text{H}$	^2_1H	^3_1H
neutrons	0	1	2
mass (amu)	1.00783	2.0140	3.01605
abundance (%)	99.9885	0.0115	$\sim 10^{-17}$
half-life (years)	—	—	12.32
boiling point of X_2 (K)	20.28	23.67	25
melting point/boiling point of X_2O ($^\circ\text{C}$)	0.0/100.0	3.8/101.4	4.5/?

The different masses of the three isotopes of hydrogen cause them to have different physical properties. Thus H_2 , D_2 , and T_2 differ in their melting points, boiling points, densities, and heats of fusion and vaporization. In 1931, Harold Urey and coworkers discovered deuterium by slowly evaporating several liters of liquid hydrogen until a volume of about 1 mL remained. When that remaining liquid was vaporized and its emission spectrum examined, they observed new absorption lines in addition to those previously identified as originating from hydrogen. The natural abundance of tritium, in contrast, is so low that it could not be detected by similar experiments; it was first prepared in 1934 by a nuclear reaction.

Harold Urey (1893–1981)

Urey won the Nobel Prize in Chemistry in 1934 for his discovery of deuterium (${}^2\text{H}$). Urey was born and educated in rural Indiana. After earning a BS in zoology from the University of Montana in 1917, Urey changed career directions. He earned his PhD in chemistry at Berkeley with G. N. Lewis (of Lewis electron structure fame) and subsequently worked with Niels Bohr in Copenhagen. During World War II, Urey was the director of war research for the Atom Bomb Project at Columbia University. In later years, his research focused on the evolution of life. In 1953, he and his graduate student, Stanley Miller, showed that organic compounds, including amino acids, could be formed by passing an electric discharge through a mixture of compounds thought to be present in the atmosphere of primitive Earth.

Because the normal boiling point of D_2O is 101.4°C (compared to 100.0°C for H_2O), evaporation or fractional distillation can be used to increase the concentration of deuterium in a sample of water by the selective removal of the more volatile H_2O . Thus bodies of water that have no outlet, such as the Great Salt Lake and the Dead Sea, which maintain their level solely by evaporation, have significantly higher concentrations of deuterated water than does lake or seawater with at least one outlet. A more efficient way to obtain water highly enriched in deuterium is by prolonged electrolysis of an aqueous solution. Because a deuteron (D^+) has twice the mass of a proton (H^+), it diffuses more slowly toward the electrode surface. Consequently, the gas evolved at the cathode is enriched in H, the species that diffuses more rapidly, favoring the formation of H_2 over D_2 or HD. Meanwhile, the solution becomes enriched in deuterium. Deuterium-rich water is called *heavy water* because the density of D_2O (1.1044 g/cm^3 at 25°C) is greater than that of H_2O (0.99978 g/cm^3). Heavy water was an important constituent of early nuclear reactors. (For more information on nuclear reactors, see [Chapter 23](#))

Because deuterons diffuse so much more slowly, D_2O will not support life and is actually toxic if administered to mammals in large amounts. The rate-limiting step in many important reactions catalyzed by enzymes involves proton transfer. The transfer of D^+ is so slow compared with that of H^+ because bonds to D break more slowly than those to H, so the delicate balance of reactions in the cell is disrupted. Nonetheless, deuterium and tritium are important research tools for biochemists. By incorporating these isotopes into specific positions in selected molecules, where they act as labels, or *tracers*, biochemists can follow the path of a molecule through an organism or a cell. Tracers can also be used to provide information about the mechanism of enzymatic reactions.

Bonding in Hydrogen and Hydrogen-Containing Compounds

The $1s^1$ electron configuration of hydrogen indicates a single valence electron. Because the $1s$ orbital has a maximum capacity of two electrons, hydrogen can form compounds with other elements in three ways ([Figure 20.2.1](#)):

- Losing its electron to form a proton (H^+) with an empty $1s$ orbital.** The proton is a Lewis acid that can accept a pair of electrons from another atom to form an electron-pair bond. In the acid–base reactions discussed in [Chapter 16](#), for example, the proton always binds to a lone pair of electrons on an atom in another molecule to form a polar covalent bond. If the lone pair of electrons belongs to an oxygen atom of a water molecule, the result is the hydronium ion (H_3O^+).
- Accepting an electron to form a hydride ion (H^-), which has a filled $1s^2$ orbital.** Hydrogen reacts with relatively electropositive metals, such as the alkali metals (group 1) and alkaline earth metals (group 2), to form *ionic hydrides*, which contain metal cations and H^- ions.
- Sharing its electron with an electron on another atom to form an electron-pair bond.** With a half-filled $1s^1$ orbital, the hydrogen atom can interact with singly occupied orbitals on other atoms to form either a covalent or a polar covalent electron-pair bond, depending on the electronegativity of the other atom.

Figure 20.2.1 Three Types of Bonding in Compounds of Hydrogen Because of its $1s^1$ electron configuration and the fact that the $1s$ orbital can accommodate no more than two electrons, hydrogen can (a) bond to other elements by losing an electron to form a proton, which can accept a pair of electrons from a more electronegative atom to form a polar covalent bond; (b) gain an electron from an electropositive metal to form a hydride ion, resulting in an ionic hydride; or (c) share its half-filled $1s$ orbital with a half-filled orbital on another atom to form a covalent or a polar covalent electron-pair bond.

Hydrogen can also act as a bridge between two atoms. One familiar example is the hydrogen bond, an electrostatic interaction between a hydrogen bonded to an electronegative atom and an atom that has one or more lone pairs of electrons (Figure 20.2.2). An example of this kind of interaction is the hydrogen bonding network found in water (Figure 11.2.6). Hydrogen can also form a three-center bond (or electron-deficient bond), in which a hydride bridges two electropositive atoms. Compounds that contain hydrogen bonded to boron and similar elements often have this type of bonding. The B–H–B units found in boron hydrides cannot be described in terms of localized electron-pair bonds. Because the H atom in the middle of such a unit can accommodate a maximum of only two electrons in its $1s$ orbital, the B–H–B unit can be described as containing a hydride that interacts simultaneously with empty sp^3 orbitals on two boron atoms (Figure 20.2.3). In these bonds, only two bonding electrons are used to hold three atoms together, making them electron-deficient bonds. You encountered a similar phenomenon in the discussion of π bonding in ozone and the nitrite ion in Section 6.6. Recall that in both these cases, we used the presence of two electrons in a π molecular orbital extending over three atoms to explain the fact that the two O–O bond distances in ozone and the two N–O bond distances in nitrite are the same, which otherwise can be explained only by the use of resonance structures.

Figure 20.2.2 The Hydrogen Bond The covalent bond between hydrogen and a very electronegative element, such as nitrogen, oxygen, or fluorine, is highly polar. The resulting partial positive charge on H allows it to interact with a lone pair of electrons on another atom to form a hydrogen bond, which is typically a linear arrangement of the three atoms, with the hydrogen atom placed asymmetrically between the two heavier atoms.

Figure 20.2.3 A Three-Center Bond Uses Two Electrons to Link Three Atom In the B–H–B unit shown, a hydride, with a filled $1s$ orbital, interacts simultaneously with empty sp^3 hybrids on the boron atoms of two BH_3 units to give three molecular orbitals. The two bonding electrons occupy the lowest-energy (σ) bonding orbital, thereby holding all three atoms together.

Note the Pattern

Hydrogen can lose its electron to form H^+ , accept an electron to form H^- , share its electron, hydrogen bond, or form a three-center bond.

Synthesis, Reactions, and Compounds of Hydrogen

The first known preparation of elemental hydrogen was in 1671, when Robert Boyle dissolved iron in dilute acid and obtained a colorless, odorless, gaseous product. Hydrogen was finally identified as an element in 1766, when Henry Cavendish showed that water was the sole product of the reaction of the gas with oxygen. The explosive properties of mixtures of hydrogen with air were not discovered until early in the 18th century; they partially caused the spectacular explosion of the hydrogen-filled dirigible *Hindenburg* in 1937 (Figure 20.2.4). Due to its extremely low molecular mass, hydrogen gas is difficult to condense to a liquid (boiling point = 20.3 K), and solid hydrogen has one of the lowest melting points known (13.8 K).

The most common way to produce small amounts of highly pure hydrogen gas in the laboratory was discovered by Boyle: reacting an active metal (M), such as iron, magnesium, or zinc, with dilute acid:

Hydrogen gas can also be generated by reacting metals such as aluminum or zinc with a strong base:

Solid commercial drain cleaners such as Drano use this reaction to generate gas bubbles that help break up clogs in a drainpipe. (For more information on redox reactions like that of Drano, see Section 19.2.) Hydrogen gas is also produced by reacting ionic hydrides with water. Because ionic hydrides are expensive, however, this reaction is generally used for only specialized purposes, such as producing HD gas by reacting a hydride with D_2O :

On an industrial scale, H_2 is produced from methane by means of *catalytic steam reforming*, a method used to convert hydrocarbons to a mixture of CO and H_2 known as *synthesis gas*, or *syngas*. (For more information on steam reforming, see Section 14.8) The process is carried out at elevated temperatures (800°C) in the presence of a nickel catalyst:

Most of the elements in the periodic table form binary compounds with hydrogen, which are collectively referred to as *hydrides*. Binary hydrides in turn can be classified in one of three ways, each with its own characteristic properties. *Covalent hydrides* contain hydrogen bonded to another atom via a covalent bond or a polar covalent bond. Covalent hydrides are usually molecular substances that are relatively volatile and have low melting points. *Ionic hydrides* contain the hydride ion as the anion with cations derived from electropositive metals. Like most ionic compounds, they are typically nonvolatile solids that contain three-dimensional lattices of cations and anions. Unlike most ionic compounds, however, they often decompose to $H_2(g)$ and the parent metal after heating. *Metallic hydrides* are formed by hydrogen and less electropositive metals such as the transition metals. The properties of metallic hydrides are usually similar to those of the parent metal. Consequently, metallic hydrides are best viewed as metals that contain many hydrogen atoms present as interstitial impurities.

Figure 20.2.4 The Explosive Properties of Hydrogen
When mixed with air and ignited by a spark, hydrogen gas can explode. The photograph shows the German dirigible *Hindenburg* on fire at Lakehurst, New Jersey, in 1937, after its hydrogen compartment was accidentally ignited as a consequence of an electrical discharge that caused the dirigible's flammable skin to catch fire.

Note the Pattern

Covalent hydrides are relatively volatile and have low melting points; ionic hydrides are generally nonvolatile solids in a lattice framework.

Summary

The three isotopes of hydrogen—**protium** (^1H or **H**), **deuterium** (^2H or **D**), and **tritium** (^3H or **T**)—have different physical properties. Deuterium and tritium can be used as *tracers*, substances that enable biochemists to follow the path of a molecule through an organism or a cell. Hydrogen can form compounds that contain a proton (H^+), a **hydride ion** (H^-), an electron-pair bond to H, a **hydrogen bond**, or a **three-center bond (or electron-deficient bond)**, in which two electrons are shared between three atoms. Hydrogen gas can be generated by reacting an active metal with dilute acid, reacting Al or Zn with a strong base, or industrially by *catalytic steam reforming*, which produces *synthesis gas*, or *syngas*.

Key Takeaway

- Hydrogen can lose an electron to form a proton, gain an electron to form a hydride ion, or form a covalent bond or polar covalent electron-pair bond.

Conceptual Problems

- Some periodic tables include hydrogen as a group 1 element, whereas other periodic tables include it as a group 17 element. Refer to the properties of hydrogen to propose an explanation for its placement in each group. In each case, give one property of hydrogen that would exclude it from groups 1 and 17.
- If there were a planet where the abundances of D_2O and H_2O were reversed and life had evolved to adjust to this difference, what would be the effects of consuming large amounts of H_2O ?
- Describe the bonding in a hydrogen bond and the central B–H bond in B_2H_7^- . Why are compounds containing isolated protons unknown?
- With which elements does hydrogen form ionic hydrides? covalent hydrides? metallic hydrides? Which of these types of hydrides can behave like acids?
- Indicate which elements are likely to form ionic, covalent, or metallic hydrides and explain your reasoning:
 - Sr
 - Si
 - O
 - Li
 - B
 - Be
 - Pd
 - Al
- Which has the higher ionization energy—H or H^- ? Why?
- The electronegativities of hydrogen, fluorine, and iodine are 2.20, 3.98, and 2.66, respectively. Why, then, is HI a stronger acid than HF?
- If H_2O were a linear molecule, would the density of ice be less than or greater than that of liquid water? Explain your answer.
- In addition to ion–dipole attractions, hydrogen bonding is important in solid crystalline hydrates, such as $\text{Na}_4\text{XeO}_6 \cdot 8\text{H}_2\text{O}$. Based on this statement, explain why anhydrous Na_4XeO_6 does not exist.

Answers

- H has one electron in an s orbital, like the group 1 metals, but it is also one electron short of a filled principal shell, like the group 17 elements. Unlike the alkali metals, hydrogen is not a metal. Unlike the halogens, elemental hydrogen is not a potent oxidant.
-
-
-
- ionic; it is an alkaline earth metal.

- b. covalent; it is a semimetal.
 - c. covalent; it is a nonmetal.

9. Hydrogen bonding with waters of hydration will partially neutralize the negative charge on the terminal oxygen atoms on the XeO_6^{4-} ion, which stabilizes the solid.

Structure and Reactivity

- One of the largest uses of methane is to produce syngas, which is a source of hydrogen for converting nitrogen to ammonia. Write a complete equation for formation of syngas from methane and carbon dioxide. Calculate ΔG° for this reaction at 298 K and determine the temperature at which the reaction becomes spontaneous.
- An alternative method of producing hydrogen is the water-gas shift reaction:

$$\text{CO(g)} + \text{H}_2\text{O(g)} \rightarrow \text{CO}_2\text{(g)} + \text{H}_2\text{(g)}$$
 Use [Standard Thermodynamic Quantities](#) to calculate ΔG° for this reaction at 298 K and determine the temperature at which the reaction changes from spontaneous to nonspontaneous (or vice versa).
- Predict the products of each reaction at 25°C and then balance each chemical equation.
 - $\text{CsH(s)} + \text{D}_2\text{O(l)} \rightarrow$
 - $\text{CH}_3\text{CO}_2\text{H(l)} + \text{D}_2\text{O(l)} \rightarrow$
 - $\text{H}_3\text{PO}_4\text{(aq)} + \text{D}_2\text{O(l)} \rightarrow$
 - $\text{NH}_2\text{CH}_2\text{CO}_2\text{H(s)} + \text{D}_2\text{O(l)} \rightarrow$
 - $\text{NH}_4\text{Cl(s)} + \text{D}_2\text{O(l)} \rightarrow$
- Using heavy water (D_2O) as the source of deuterium, how could you conveniently prepare
 - D_2SO_4 ?
 - LiD ?
- What are the products of reacting NaH with D_2O ? Do you expect the same products from reacting NaD and H_2O ? Explain your answer.
- A 2.50 g sample of zinc metal reacts with 100.0 mL of 0.150 M HCl . What volume of H_2 (in liters) is produced at 23°C and 729 mmHg?
- A chemical reaction requires 16.8 L of H_2 gas at standard temperature and pressure. How many grams of magnesium metal are needed to produce this amount of hydrogen gas?
- Seawater contains 3.5% dissolved salts by mass and has an average density of 1.026 g/mL. The volume of the ocean is estimated to be 1.35×10^{21} L. Using the data in [Table 19.2.1](#), calculate the total mass of deuterium in the ocean.
- From the data in [Table 19.2.1](#), determine the molarity of DOH in water. Do you expect the molarity of D_2O in water to be similar? Why or why not?
- From the data in [Table 19.2.1](#) calculate how many liters of water you would have to evaporate to obtain 1.0 mL of TOD (tritium-oxygen-deuterium). The density of TOD is 1.159 g/mL.

Learning Objectives

- To describe how the alkali metals are isolated.
- To be familiar with the reactions, compounds, and complexes of the alkali metals.

The alkali metals are so reactive that they are never found in nature in elemental form. Although some of their ores are abundant, isolating them from their ores is somewhat difficult. For these reasons, the group 1 elements were unknown until the early 19th century, when Sir Humphry Davy first prepared sodium (Na) and potassium (K) by passing an electric current through molten alkalis. (The ashes produced by the combustion of wood are largely composed of potassium and sodium carbonate.) Lithium (Li) was discovered 10 years later when the Swedish chemist Johan Arfwedson was studying the composition of a new Brazilian mineral. Cesium (Cs) and rubidium (Rb) were not discovered until the 1860s, when Robert Bunsen conducted a systematic search for new elements. Known to chemistry students as the inventor of the Bunsen burner, Bunsen's spectroscopic studies of ores showed sky blue and deep red emission lines that he attributed to two new elements, Cs and Rb, respectively. Francium (Fr) is found in only trace amounts in nature, so our knowledge of its chemistry is limited. All the isotopes of Fr have very short half-lives, in contrast to the other elements in group 1.

Sir Humphry Davy (1778–1829)

Davy was born in Penzance, Cornwall, England. He was a bit of a wild man in the laboratory, often smelling and tasting the products of his experiments, which almost certainly shortened his life. He discovered the physiological effects that cause nitrous oxide to be called “laughing gas” (and became addicted to it!), and he almost lost his eyesight in an explosion of nitrogen trichloride (NCl₃), which he was the first to prepare. Davy was one of the first to recognize the utility of Alessandro Volta's “electric piles” (batteries). By connecting several “piles” in series and inserting electrodes into molten salts of the alkali metals and alkaline earth metals, he was able to isolate six previously unknown elements as pure metals: sodium, potassium, calcium, strontium, barium, and magnesium. He also discovered boron and was the first to prepare phosphine (PH₃) and hydrogen telluride (H₂Te), both of which are highly toxic.

Robert Wilhelm Bunsen (1811–1899)

Bunsen was born and educated in Göttingen, Germany. His early work dealt with organic arsenic compounds, whose highly toxic nature and explosive tendencies almost killed him and did cost him an eye. He designed the Bunsen burner, a reliable gas burner, and used it and emission spectra to discover cesium (named for its blue line) and rubidium (named for its red line).

Preparation of the Alkali Metals

Because the alkali metals are among the most potent reductants known, obtaining them in pure form requires a considerable input of energy. Pure lithium and sodium for example, are typically prepared by the electrolytic reduction of molten chlorides:

In practice, CaCl₂ is mixed with LiCl to lower the melting point of the lithium salt. The electrolysis is carried out in an argon atmosphere rather than the nitrogen atmosphere typically used for substances that are highly reactive with O₂ and water because Li reacts with nitrogen gas to form lithium nitride (Li₃N). Metallic sodium is produced by the electrolysis of a molten mixture of NaCl and CaCl₂. In contrast, potassium is produced commercially from the reduction of KCl by Na, followed by the fractional distillation of K(g). Although rubidium and cesium can also be produced by electrolysis, they are usually obtained by reacting their hydroxide salts with a reductant such as Mg:

Massive deposits of essentially pure NaCl and KCl are found in nature and are the major sources of sodium and potassium. The other alkali metals are found in low concentrations in a wide variety of minerals, but ores that contain high concentrations of these elements are relatively rare. No concentrated sources of rubidium are known, for example, even though it is the 16th most abundant element on Earth. Rubidium is obtained commercially by isolating the 2%–4% of Rb present as an impurity in micas, minerals that are composed of sheets of complex hydrated potassium–aluminum silicates.

Alkali metals are recovered from silicate ores in a multistep process that takes advantage of the pH-dependent solubility of selected salts of each metal ion. The steps in this process are *leaching*, which uses sulfuric acid to dissolve the desired alkali metal ion and Al^{3+} from the ore; *basic precipitation* to remove Al^{3+} from the mixture as $\text{Al}(\text{OH})_3$; *selective precipitation* of the insoluble alkali metal carbonate; *dissolution* of the salt again in hydrochloric acid; and isolation of the metal by *evaporation* and *electrolysis*. Figure 20.3.1 illustrates the isolation of liquid lithium from a lithium silicate ore by this process.

Figure 20.3.1 Isolating Lithium from Spodumene, a Lithium Silicate Ore The key steps are acid leaching, basic precipitation of aluminum hydroxide, selective precipitation of insoluble lithium carbonate, conversion to lithium chloride, evaporation, and electrolysis. The other alkali metals and the alkaline earth metals are recovered from their ores by similar processes.

General Properties of the Alkali Metals

Various properties of the group 1 elements are summarized in Table 20.3.1. In keeping with overall periodic trends, the atomic and ionic radii increase smoothly from Li to Cs, and the first ionization energies decrease as the atoms become larger. As a result of their low first ionization energies, the alkali metals have an overwhelming tendency to form ionic compounds where they have a +1 charge. All the alkali metals have relatively high electron affinities because the addition of an electron produces an anion (M^-) with an ns^2 electron configuration. The densities of the elements generally increase from Li to Cs, reflecting another common trend: because the atomic masses of the elements increase more rapidly than the atomic volumes as you go down a group, the densest elements are near the bottom of the periodic table. An unusual trend in the group 1 elements is the smooth decrease in the melting and boiling points from Li to Cs. As a result, Cs (melting point = 28.5°C) is one of only three metals (the others are Ga and Hg) that are liquids at body temperature (37°C).

Table 20.3.1 Selected Properties of the Group 1 Elements

	Lithium	Sodium	Potassium	Rubidium	Cesium	Francium
atomic symbol	Li	Na	K	Rb	Cs	Fr
atomic number	3	11	19	37	55	87
atomic mass	6.94	22.99	39.10	85.47	132.91	223
valence electron configuration	$2s^1$	$3s^1$	$4s^1$	$5s^1$	$6s^1$	$7s^1$
melting point/boiling point (°C)	180.5/1342	97.8/883	63.5/759	39.3/688	28.5/671	27/—

*The values cited are for four-coordinate ions except for Rb^+ and Cs^+ , whose values are given for the six-coordinate ion.

	Lithium	Sodium	Potassium	Rubidium	Cesium	Francium
density (g/cm ³) at 25°C	0.534	0.97	0.89	1.53	1.93	—
atomic radius (pm)	167	190	243	265	298	—

type of oxide	basic	basic	basic	basic	basic	—
product of reaction with N ₂	Li ₃ N	none	none	none	none	—
product of reaction with X ₂	LiX	NaX	KX	RbX	CsX	—
product of reaction with H ₂	LiH	NaH	KH	RbH	CsH	—

*The values cited are for four-coordinate ions except for Rb⁺ and Cs⁺, whose values are given for the six-coordinate ion.

The standard reduction potentials (E°) of the alkali metals do not follow the trend based on ionization energies. (For more information on reduction potentials, see [Chapter 19](#)). Unexpectedly, lithium is the strongest reductant, and sodium is the weakest ([Table 20.3.1](#)). Because Li⁺ is much smaller than the other alkali metal cations, its hydration energy is the highest. The high hydration energy of Li⁺ more than compensates for its higher ionization energy, making lithium metal the strongest reductant in aqueous solution. This apparent anomaly is an example of how the physical or the chemical behaviors of the elements in a group are often determined by the subtle interplay of opposing periodic trends.

Reactions and Compounds of the Alkali Metals

All alkali metals are electropositive elements with an ns^1 valence electron configuration, forming the monocation (M^+) by losing the single valence electron. Because removing a second electron would require breaking into the $(n-1)$ closed shell, which is energetically prohibitive, the chemistry of the alkali metals is largely that of ionic compounds that contain M^+ ions. However, as we discuss later, the lighter group 1 elements also form a series of organometallic compounds that contain polar covalent M–C bonds.

All the alkali metals react vigorously with the halogens (group 17) to form the corresponding ionic halides, where X is a halogen:

Similarly, the alkali metals react with the heavier chalcogens (sulfur, selenium, and tellurium in group 16) to produce metal chalcogenides, where Y is S, Se, or Te:

Sodium and potassium reacting with sulfur

When excess chalcogen is used, a variety of products can be obtained that contain chains of chalcogen atoms, such as the sodium polysulfides (Na_2S_n , where $n = 2-6$). For example, Na_2S_3 contains the S_3^{2-} ion, which is V shaped with an S–S–S angle of about 103°. The one-electron oxidation product of the trisulfide ion (S_3^-) is responsible for the intense blue color of the gemstones lapis lazuli and blue ultramarine ([Figure 20.3.2](#)).

Figure 20.3.2 The Trisulfide Anion Is Responsible for the Deep Blue Color of Some Gemstones (a) The rich blue color of lapis lazuli is due to small amounts of the normally unstable S_3^- anion. (b) The aluminosilicate cages of the minerals (zeolites) that make up the matrix of blue ultramarine stabilize the reactive anion; excess Na^+ ions in the structure balance the negative charges on the zeolite framework and the S_3^- anion.

Reacting the alkali metals with oxygen, the lightest element in group 16, is more complex, and the stoichiometry of the product depends on both the metal:oxygen ratio and the size of the metal atom. For instance, when alkali metals burn in air, the observed products are Li_2O (white), Na_2O_2 (pale yellow), KO_2 (orange), RbO_2 (brown), and CsO_2 (orange). Only Li_2O has the stoichiometry expected for a substance that contains two M^+ cations and one O^{2-} ion. In contrast, Na_2O_2 contains the O_2^{2-} (peroxide) anion plus two Na^+ cations. The other three salts, with stoichiometry MO_2 , contain the M^+ cation and the O_2^- (superoxide) ion. Because O^- is the smallest of the three oxygen anions, it forms a stable ionic lattice with the smallest alkali metal cation (Li^+). In contrast, the larger alkali metals—potassium, rubidium, and cesium—react with oxygen in air to give the metal superoxides. Because the Na^+ cation is intermediate in size, sodium reacts with oxygen to form a compound with an intermediate stoichiometry: sodium peroxide. Under specific reaction conditions, however, it is possible to prepare the oxide, peroxide, and superoxide salts of all five alkali metals, except for lithium superoxide (LiO_2).

A crystal of spodumene ($LiAlSi_2O_6$). This mineral is one of the most important lithium ores.

Note the Pattern

The chemistry of the alkali metals is largely that of ionic compounds containing the M^+ ions.

The alkali metal peroxides and superoxides are potent oxidants that react, often vigorously, with a wide variety of reducing agents, such as charcoal or aluminum metal. For example, Na_2O_2 is used industrially for bleaching paper, wood pulp, and fabrics such as linen and cotton. In submarines, Na_2O_2 and KO_2 are used to purify and regenerate the air by removing the CO_2 produced by respiration and replacing it with O_2 . Both compounds react with CO_2 in a redox reaction in which O_2^{2-} or O_2^- is simultaneously oxidized and reduced, producing the metal carbonate and O_2 :

The presence of water vapor, the other product of respiration, makes KO_2 even more effective at removing CO_2 because potassium bicarbonate, rather than potassium carbonate, is formed:

Notice that 4 mol of CO_2 are removed in this reaction, rather than 2 mol in [Equation 20.3.6](#)

Lithium, the lightest alkali metal, is the only one that reacts with atmospheric nitrogen, forming lithium nitride (Li_3N). Lattice energies again explain why the larger alkali metals such as potassium do not form nitrides: packing three large K^+ cations around a single relatively small anion is energetically unfavorable. In contrast, all the alkali metals react with the larger group 15 elements phosphorus and arsenic to form metal phosphides and arsenides (where Z is P or As):

Note the Pattern

Because of lattice energies, only lithium forms a stable oxide and nitride.

The alkali metals react with all group 14 elements, but the compositions and properties of the products vary significantly. For example, reaction with the heavier group 14 elements gives materials that contain polyatomic anions and three-dimensional cage structures, such as K_4Si_4 whose structure is shown here. In contrast, lithium and sodium are oxidized by carbon to produce a compound with the stoichiometry M_2C_2 (where M is Li or Na):

The same compounds can be obtained by reacting the metal with acetylene (C_2H_2). In this reaction, the metal is again oxidized, and hydrogen is reduced:

The three-dimensional cage structure of the Si_4^{4-} ion in the ionic compound K_4Si_4 . The Si_4^{4-} ion is isoelectronic and isostructural with the P_4 molecule.

The acetylide ion (C_2^{2-}), formally derived from acetylene by the loss of both hydrogens as protons, is a very strong base. Reacting acetylide salts with water produces acetylene and $MOH(aq)$.

The heavier alkali metals (K, Rb, and Cs) also react with carbon in the form of graphite. Instead of disrupting the hexagonal sheets of carbon atoms, however, the metals insert themselves *between* the sheets of carbon atoms to give new substances called graphite intercalation compounds (part (a) in Figure 20.3.3). The stoichiometries of these compounds include MC_{60} and MC_{48} , which are black/gray; MC_{36} and MC_{24} , which are blue; and MC_8 , which is bronze (part (b) in Figure 20.3.3). The remarkably high electrical conductivity of these compounds (about 200 times greater than graphite) is attributed to a net transfer of the valence electron of the alkali metal to the graphite layers to produce, for example, $K^+C_8^-$.

Figure 20.3.3 Graphite Intercalation Compounds Reacting graphite with alkali metals such as K, Rb, and Cs results in partial reduction of the graphite and insertion of layers of alkali metal cations between sets of n layers of carbon atoms. (a) In KC_8 , layers of K^+ ions are inserted between every pair of carbon layers, giving $n = 1$. (b) The stoichiometry and color of intercalation compounds depend on the number of layers of carbon atoms (n) between each layer of intercalated metal atoms. This schematic diagram illustrates the most common structures that have been observed.

All the alkali metals react directly with gaseous hydrogen at elevated temperatures to produce ionic hydrides (M^+H^-):

All are also capable of reducing water to produce hydrogen gas:

Although lithium reacts rather slowly with water, sodium reacts quite vigorously (Figure 20.3.4), and the heavier alkali metals (K, Rb, and Cs) react so vigorously that they invariably explode. This trend, which is not consistent with the relative magnitudes of the reduction potentials of the elements, serves as another example of the complex interplay of different forces and phenomena—in this case, kinetics and thermodynamics. Although the driving force for the reaction is greatest for lithium, the heavier metals have lower melting points. The heat liberated by the reaction causes them to melt, and the larger surface area of the liquid metal in contact with water greatly accelerates the reaction rate.

Figure 20.3.4 Reacting Sodium (aq) ion and hydrogen gas, with

most elements in groups 1 and 2, sodium reacts violently with water. The products are the Na^+ explosive when mixed with air.

Alkali metal cations are found in a wide variety of ionic compounds. In general, any alkali metal salt can be prepared by reacting the alkali metal hydroxide with an acid:

Hydroxides of alkali metals also can react with organic compounds that contain an acidic hydrogen to produce a salt. An example is the preparation of sodium acetate (CH_3CO_2Na) by reacting sodium hydroxide and acetic acid:

Soap is a mixture of the sodium and potassium salts of naturally occurring carboxylic acids, such as palmitic acid [$CH_3(CH_2)_{14}CO_2H$] and stearic acid [$CH_3(CH_2)_{16}CO_2H$]. Lithium salts, such as lithium stearate [$CH_3(CH_2)_{14}CO_2Li$], are used as additives in motor oils and greases.

Complexes of the Alkali Metals

Because of their low positive charge (+1) and relatively large ionic radii, alkali metal cations have only a weak tendency to react with simple Lewis bases to form metal complexes like those discussed in Section 17.3. Complex formation is most significant for the smallest cation (Li^+) and decreases with increasing radius. In aqueous solution, for example, Li^+ forms the tetrahedral $[Li(H_2O)_4]^+$ complex. In contrast, the larger alkali metal cations form octahedral $[M(H_2O)_6]^+$ complexes. Complex formation is primarily due to the electrostatic interaction of the metal cation with polar water molecules. Because of their high affinity for water, anhydrous salts that contain Li^+ and Na^+ ions (such as Na_2SO_4) are often used as *drying agents*. These compounds absorb trace amounts of water from nonaqueous solutions to form hydrated salts, which are then easily removed from the solution by filtration.

The tetrahedral $[Li(H_2O)_4]^+$ and octahedral $[Rb(H_2O)_6]^+$ complexes. The Li^+ ion is so small that it can accommodate only four water molecules around it, but the larger alkali metal cations tend to bind six water molecules.

Note the Pattern

Because of their low positive charge (+1) and relatively large ionic radii, alkali metal cations have only a weak tendency to form complexes with simple Lewis bases.

Electrostatic interactions also allow alkali metal ions to form complexes with certain cyclic polyethers and related compounds, such as crown ethers and cryptands. As discussed in Chapter 13, crown ethers are cyclic polyethers that contain four or more oxygen atoms separated by two or three carbon atoms. All crown ethers have a central cavity that can accommodate a metal ion coordinated to the ring of oxygen atoms, and crown ethers with rings of different sizes prefer to bind metal ions that fit into the cavity. For example, 14-crown-4, with the smallest cavity that can accommodate a metal ion, has the highest affinity for Li^+ , whereas 18-crown-6 forms the strongest complexes with K^+ (part (a) in Figure 13.2.4).

Cryptands are more nearly spherical analogues of crown ethers and are even more powerful and selective complexing agents. Cryptands consist of three chains containing oxygen that are connected by two nitrogen atoms (part (b) in Figure 13.2.4). They can completely surround (encapsulate) a metal ion of the appropriate size, coordinating to the metal by a lone pair of electrons on each O atom and the two N atoms. Like crown ethers, cryptands with different cavity sizes are highly selective for metal ions of particular sizes. Crown ethers and cryptands are often used to dissolve simple inorganic salts such as $KMnO_4$ in nonpolar organic solvents (Figure 12.2.5).

Liquid Ammonia Solutions

A remarkable feature of the alkali metals is their ability to dissolve reversibly in liquid ammonia. Just as in their reactions with water, reacting alkali metals with liquid ammonia eventually produces hydrogen gas and the metal salt of the conjugate base of the solvent—in this case, the *amide* ion (NH_2^-) rather than hydroxide:

where the (am) designation refers to an ammonia solution, analogous to (aq) used to indicate aqueous solutions. Without a catalyst, the reaction in Equation 20.3.16 tends to be rather slow. In many cases, the alkali metal amide salt (MNH_2) is not very soluble in liquid ammonia and precipitates, but when dissolved, very concentrated solutions of the alkali metal are produced. One mole of Cs metal, for example, will dissolve in as little as 53 mL (40 g) of liquid ammonia. The pure metal is easily recovered when the ammonia evaporates.

Figure 20.3.5 Alkali Metal–Liquid Ammonia Solutions Most metals are insoluble in virtually all solvents, but the alkali metals (and the heavier transition metals) dissolve readily in liquid ammonia to form solvated metal cations and solvated electrons.

Most metals are insoluble in virtually all solvents, but the alkali metals (and the heavier transition metals) dissolve readily in liquid ammonia to form solvated metal cations and solvated electrons, giving the solution a deep blue color.

Solutions of alkali metals in liquid ammonia are intensely colored and good conductors of electricity due to the presence of *solvated electrons* (e^- , NH_3), which are not attached to single atoms. A solvated electron is loosely associated with a cavity in the ammonia solvent that is stabilized by hydrogen bonds. Alkali metal–liquid ammonia solutions of about 3 M or less are deep blue (Figure 20.3.5) and conduct electricity about 10 times better than an aqueous NaCl solution because of the high mobility of the solvated electrons. As the concentration of the metal increases above 3 M, the color changes to metallic bronze or gold, and the conductivity increases to a value comparable with that of the pure liquid metals.

In addition to solvated electrons, solutions of alkali metals in liquid ammonia contain the metal cation (M^+), the neutral metal atom (M), metal dimers (M_2), and the metal anion (M^-). The anion is formed by adding an electron to the singly occupied ns valence orbital of the metal atom. Even in the absence of a catalyst, these solutions are not very stable and eventually decompose to the thermodynamically favored products: M NH_2 and hydrogen gas (Equation 20.3.16). Nonetheless, the solvated electron is a potent reductant that is often used in synthetic chemistry.

Solvated electrons. The presence of solvated electrons (e^- , NH_3) in solutions of alkali metals in liquid ammonia is indicated by the intense color of the solution and its electrical conductivity.

Organometallic Compounds of the Group 1 Elements

Compounds that contain a metal covalently bonded to a carbon atom of an organic species are called organometallic compounds. The properties and reactivities of organometallic compounds differ greatly from those of either the metallic or organic components. Because of its small size, lithium, for example, forms an extensive series of covalent organolithium compounds, such as methyllithium (LiCH_3), which are by far the most stable and best-known group 1 organometallic compounds. These volatile, low-melting-point solids or liquids can be sublimed or distilled at relatively low temperatures and are soluble in nonpolar solvents. Like organic compounds, the molten solids do not conduct electricity to any significant degree. Organolithium compounds have a tendency to form oligomers with the formula $(\text{RLi})_n$, where R represents the organic component. For example, in both the solid state and solution, methyllithium exists as a tetramer with the structure shown in Figure 19.3.6, where each triangular face of the Li_4 tetrahedron is bridged by the carbon atom of a methyl group. Effectively, the carbon atom of each CH_3 group is using a single pair of electrons in an sp hybrid lobe to bridge *three* lithium atoms, making this an example of two-electron, *four-center* bonding. Clearly, such a structure, in which each carbon atom is apparently bonded to *six* other atoms, cannot be explained using any of the electron-pair bonding schemes discussed in Chapter 4 and Chapter 5. Molecular orbital theory can explain the bonding in methyllithium, but the description is beyond the scope of this text.

Figure 20.3.6 The Tetrameric Structure of Methyllithium Methyllithium is not an ionic compound; it exists as tetrameric $(\text{CH}_3\text{Li})_4$ molecules. The structure consists of a tetrahedral arrangement of four lithium atoms, with the carbon atom of a methyl group located above the middle of each triangular face of the tetrahedron. The carbon atoms thus bridge three lithium atoms to form four-center, two-electron bonds.

Note the Pattern

The properties and reactivities of organometallic compounds differ greatly from those of either the metallic or organic components.

Organosodium and organopotassium compounds are more ionic than organolithium compounds. They contain discrete M^+ and R^- ions and are insoluble or only sparingly soluble in nonpolar solvents.

Uses of the Alkali Metals

Because sodium remains liquid over a wide temperature range (97.8–883°C), it is used as a coolant in specialized high-temperature applications, such as nuclear reactors and the exhaust valves in high-performance sports car engines. Cesium, because of its low ionization energy, is used in

photosensors in automatic doors, toilets, burglar alarms, and other electronic devices. In these devices, cesium is ionized by a beam of visible light, thereby producing a small electric current; blocking the light interrupts the electric current and triggers a response.

Compounds of sodium and potassium are produced on a huge scale in industry. Each year, the top 50 industrial compounds include NaOH, used in a wide variety of industrial processes; Na_2CO_3 , used in the manufacture of glass; K_2O , used in porcelain glazes; and Na_4SiO_4 , used in detergents.

Several other alkali metal compounds are also important. For example, Li_2CO_3 is one of the most effective treatments available for manic depression or bipolar disorder. It appears to modulate or dampen the effect on the brain of changes in the level of neurotransmitters, which are biochemical substances responsible for transmitting nerve impulses between neurons. Consequently, patients who take “lithium” do not exhibit the extreme mood swings that characterize this disorder.

Example 20.3.1

For each application, choose the more appropriate substance based on the properties and reactivities of the alkali metals and their compounds. Explain your choice in each case.

1. For a reaction that requires a strong base in a solution of tetrahydrofuran (THF), would you use LiOH or CsOH?
2. To extinguish a fire caused by burning lithium metal, would you use water, CO_2 , N_2 gas, or sand (SiO_2)?
3. Both LiNO_3 and CsNO_3 are highly soluble in acetone (2-propanone). Which of these alkali metal salts would you use to precipitate I^- from an acetone solution?

Given: application and selected alkali metals

Asked for: appropriate metal for each application

Strategy:

Use the properties and reactivities discussed in this section to determine which alkali metal is most suitable for the indicated application.

Solution:

1. Both LiOH and CsOH are ionic compounds that contain the hydroxide anion. Li^+ , however, is much smaller than Cs^+ , so the Li^+ cation will be more effectively solvated by the oxygen of THF with its lone pairs of electrons. This difference will have two effects: (1) LiOH is likely to be much more soluble than CsOH in the nonpolar solvent, which could be a significant advantage, and (2) the solvated Li^+ ions are less likely to form tight ion pairs with the OH^- ions in the relatively nonpolar solution, making the OH^- more basic and thus more reactive. Thus LiOH is the better choice.
2. Lithium is a potent reductant that reacts with water to form LiOH and H_2 gas, so adding a source of hydrogen such as water to a lithium fire is likely to produce an explosion. Lithium also reacts with oxygen and nitrogen in the air to form Li_2O and Li_3N , respectively, so we would not expect nitrogen to extinguish a lithium fire. Because CO_2 is a gaseous molecule that contains carbon in its highest accessible oxidation state (+4), adding CO_2 to a strong reductant such as Li should result in a vigorous redox reaction. Thus water, N_2 , and CO_2 are all unsuitable choices for extinguishing a lithium fire. In contrast, sand is primarily SiO_2 , which is a network solid that is not readily reduced. Smothering a lithium fire with sand is therefore the best choice.
3. The salt with the smaller cation has the higher lattice energy, and high lattice energies tend to decrease the solubility of a salt. (For more information on lattice energies, see [Chapter 4](#)) However, the solvation energy of the cation is also important in determining solubility, and small cations tend to have higher solvation energies. Recall from [Chapter 13](#) that high solvation energies tend to increase the solubility of ionic substances. Thus CsI should be the least soluble of the alkali metal iodides, and LiI the most soluble. Consequently, CsNO_3 is the better choice.

Exercise

Indicate which of the alternative alkali metals or their compounds given is more appropriate for each application.

1. drying agent for an organic solvent— Li_2SO_4 or Rb_2SO_4
2. removing trace amounts of N_2 from highly purified Ar gas—Li, K, or Cs
3. reacting with an alkyl halide (formula RX) to prepare an organometallic compound (formula MR)—Li or K

Answer:

1. Li_2SO_4
2. Li
3. Li

Example 20.3.2

Predict the products of each reaction and then balance each chemical equation.

1. $\text{Na(s)} + \text{O}_2\text{(g)} \rightarrow$
2. $\text{Li}_2\text{O(s)} + \text{H}_2\text{O(l)} \rightarrow$
3. $\text{K(s)} + \text{CH}_3\text{OH(l)} \rightarrow$
4. $\text{Li(s)} + \text{CH}_3\text{Cl(l)} \rightarrow$
5. $\text{Li}_3\text{N(s)} + \text{KCl(s)} \rightarrow$

Given: reactants

Asked for: products and balanced chemical equation

Strategy:

A Determine whether one of the reactants is an oxidant or a reductant or a strong acid or a strong base. If so, a redox reaction or an acid–base reaction is likely to occur. Identify the products of the reaction.

B If a reaction is predicted to occur, balance the chemical equation.

Solution:

1. **A** Sodium is a reductant, and oxygen is an oxidant, so a redox reaction is most likely. We expect an electron to be transferred from Na (thus forming Na^+) to O_2 . We now need to determine whether the reduced product is a superoxide (O_2^-), peroxide (O_2^{2-}), or oxide (O^{2-}). Under normal reaction conditions, the product of the reaction of an alkali metal with oxygen depends on the identity of the metal. Because of differences in lattice energy, Li produces the oxide (Li_2O), the heavier metals (K, Rb, Cs) produce the superoxide (MO_2), and Na produces the peroxide (Na_2O_2).

B The balanced chemical equation is $2\text{Na(s)} + \text{O}_2\text{(g)} \rightarrow \text{Na}_2\text{O}_2\text{(s)}$.

2. **A** Li_2O is an ionic salt that contains the oxide ion (O^{2-}), which is the completely deprotonated form of water and thus is expected to be a strong base. The other reactant, water, is both a weak acid and a weak base, so we can predict that an acid–base reaction will occur.

B The balanced chemical equation is $\text{Li}_2\text{O(s)} + \text{H}_2\text{O(l)} \rightarrow 2\text{LiOH(aq)}$.

3. **A** Potassium is a reductant, whereas methanol is both a weak acid and a weak base (similar to water). A weak acid produces H^+ , which can act as an oxidant by accepting an electron to form $1/2 \text{H}_2$. This reaction, therefore, is an acid dissociation that is driven to completion by a reduction of the protons as they are released.

B The balanced chemical equation is as follows: $\text{K(s)} + \text{CH}_3\text{OH(l)} \rightarrow 1/2 \text{H}_2\text{(g)} + \text{CH}_3\text{OK(l)}$

4. **A** One of the reactants is an alkali metal, a potent reductant, and the other is an alkyl halide. Any compound that contains a carbon–halogen bond can, in principle, be reduced, releasing a halide ion and forming an organometallic compound. That outcome seems likely in this case because organolithium compounds are among the most stable organometallic compounds known.

B Two moles of lithium are required to balance the equation: $2\text{Li(s)} + \text{CH}_3\text{Cl(l)} \rightarrow \text{LiCl(s)} + \text{CH}_3\text{Li(soln)}$.

5. **A** Lithium nitride and potassium chloride are largely ionic compounds. The nitride ion (N^{3-}) is a very strong base because it is the fully deprotonated form of ammonia, a weak acid. An acid–base reaction requires an acid as well as a base, however, and KCl is not acidic. What about a redox reaction? Both substances contain ions that have closed-shell valence electron configurations. The nitride ion could act as a reductant by donating electrons to an oxidant and forming N_2 . KCl is not an oxidant, however, and a redox reaction requires an oxidant as well as a reductant.

B We conclude that the two substances will not react with each other.

Exercise

Predict the products of each reaction and balance each chemical equation.

1. $\text{K(s)} + \text{N}_2\text{(g)} \rightarrow$
2. $\text{Li}_3\text{N(s)} + \text{H}_2\text{O(l)} \rightarrow$
3. $\text{Na(s)} + (\text{CH}_3)_2\text{NH(soln)} \rightarrow$
4. $\text{C}_6\text{H}_5\text{Li(soln)} + \text{D}_2\text{O(l)} \rightarrow$
5. $\text{CH}_3\text{CH}_2\text{Cl(soln)} + 2\text{Li} \rightarrow$

Answer:

1. no reaction
2. $\text{Li}_3\text{N(s)} + 3\text{H}_2\text{O(l)} \rightarrow \text{NH}_3\text{(aq)} + 3\text{LiOH(aq)}$

- $\text{Na(s)} + (\text{CH}_3)_2\text{NH(soln)} \rightarrow 1/2 \text{H}_2(\text{g}) + \text{Na}[(\text{CH}_3)_2\text{N}](\text{soln})$
- $\text{C}_6\text{H}_5\text{Li(soln)} + \text{D}_2\text{O(l)} \rightarrow \text{C}_6\text{H}_5\text{D(l)} + \text{LiOD(soln)}$
- $\text{CH}_3\text{CH}_2\text{Cl(soln)} + 2\text{Li} \rightarrow \text{CH}_3\text{CH}_2\text{Li(soln)} + \text{LiCl(soln)}$

Summary

The first alkali metals to be isolated (Na and K) were obtained by passing an electric current through molten potassium and sodium carbonates. The alkali metals are among the most potent reductants known; most can be isolated by electrolysis of their molten salts or, in the case of rubidium and cesium, by reacting their hydroxide salts with a reductant. They can also be recovered from their silicate ores using a multistep process. Lithium, the strongest reductant, and sodium, the weakest, are examples of the physical and chemical effects of opposing periodic trends. The alkali metals react with halogens (group 17) to form ionic halides; the heavier chalcogens (group 16) to produce metal chalcogenides; and oxygen to form compounds, whose stoichiometry depends on the size of the metal atom. The peroxides and superoxides are potent oxidants. The only alkali metal to react with atmospheric nitrogen is lithium. Heavier alkali metals react with graphite to form **graphite intercalation compounds**, substances in which metal atoms are inserted between the sheets of carbon atoms. With heavier group 14 elements, alkali metals react to give polyatomic anions with three-dimensional cage structures. All alkali metals react with hydrogen at high temperatures to produce the corresponding hydrides, and all reduce water to produce hydrogen gas. Alkali metal salts are prepared by reacting a metal hydroxide with an acid, followed by evaporation of the water. Both Li and Na salts are used as *drying agents*, compounds that are used to absorb water. Complexing agents such as **crown ethers** and **cryptands** can accommodate alkali metal ions of the appropriate size. Alkali metals can also react with liquid ammonia to form solutions that slowly decompose to give hydrogen gas and the metal salt of the *amide* ion (NH_2^-). These solutions, which contain unstable solvated electrons loosely associated with a cavity in the solvent, are intensely colored, good conductors of electricity, and excellent reductants. Alkali metals can react with organic compounds that contain an acidic proton to produce salts. They can also form **organometallic compounds**, which have properties that differ from those of their metallic and organic components.

Key Takeaways

- The alkali metals are potent reductants whose chemistry is largely that of ionic compounds containing the M^+ ion.
- Alkali metals have only a weak tendency to form complexes with simple Lewis bases.

Conceptual Problems

- Which of the group 1 elements reacts least readily with oxygen? Which is most likely to form a hydrated, crystalline salt? Explain your answers.
- The alkali metals have a significant electron affinity, corresponding to the addition of an electron to give the M^- anion. Why, then, do they commonly lose the ns electron to form the M^+ cation rather than gaining an electron to form M^- ?
- Lithium is a far stronger reductant than sodium; cesium is almost as strong as lithium, which does not agree with the expected periodic trend. What two opposing properties explain this apparent anomaly? Is the same anomaly found among the alkaline earth metals?
- Explain why the ionic character of LiCl is less than that of NaCl. Based on periodic trends, would you expect the ionic character of BeCl_2 to be greater or less than that of LiCl? Why?
- Alkali metals and carbon form intercalation compounds with extremely high electrical conductivity. Is this conductivity through the layers or along the layers? Explain your answer.
- Electrolysis is often used to isolate the lighter alkali metals from their molten halides. Why are halides used rather than the oxides or carbonates, which are easier to isolate? With this in mind, what is the purpose of adding calcium chloride to the alkali metal halide?
- The only alkali metal that reacts with oxygen to give a compound with the expected stoichiometry is lithium, which gives Li_2O . In contrast, sodium reacts with oxygen to give Na_2O_2 , and the heavier alkali metals form superoxides. Explain the difference in the stoichiometries of these products.
- Classify aqueous solutions of Li_2O , Na_2O , and CsO_2 as acidic, basic, or amphoteric.
- Although methanol is relatively unreactive, it can be converted to a synthetically more useful form by reaction with LiH. Predict the products of reacting methanol with LiH. Describe the visual changes you would expect to see during this reaction.
- Lithium reacts with atmospheric nitrogen to form lithium nitride (Li_3N). Why do the other alkali metals not form analogous nitrides? Explain why all the alkali metals react with arsenic to form the corresponding arsenides (M_3As).

Structure and Reactivity

- Write a balanced chemical equation to describe each reaction.
 - the electrolysis of fused (melted) sodium chloride
 - the thermal decomposition of KClO_3
 - the preparation of hydrogen fluoride from calcium fluoride and sulfuric acid

- d. the oxidation of sodium metal by oxygen
2. What products are formed at the anode and the cathode during electrolysis of
- molten lithium hydride?
 - molten lithium chloride?
 - aqueous sodium fluoride?
- Write the corresponding half-reactions for each reaction.
3. Sodium metal is prepared by electrolysis of molten NaCl. If 25.0 g of chlorine gas are produced in the electrolysis of the molten salt using 9.6 A (C/s) of current, how many hours were required for the reaction? What mass of sodium was produced?
4. Sodium peroxide can remove CO₂ from the air and replace it with oxygen according to the following unbalanced chemical equation:
- $$\text{Na}_2\text{O}_2(\text{s}) + \text{CO}_2(\text{g}) \rightarrow \text{Na}_2\text{CO}_3(\text{s}) + \text{O}_2(\text{g})$$
- Balance the chemical equation.
 - Identify each oxidation and reduction half-reaction.
 - Assuming complete reaction, what will be the pressure inside a sealed 1.50 L container after reacting excess sodium peroxide with carbon dioxide that was initially at 0.133 atm and 37°C?
5. Predict the products of each chemical reaction and then balance each chemical equation.
- $\text{K}(\text{s}) + \text{CH}_3\text{CH}_2\text{OH}(\text{l}) \rightarrow$
 - $\text{Na}(\text{s}) + \text{CH}_3\text{CO}_2\text{H}(\text{l}) \rightarrow$
 - $\text{NH}_4\text{Cl}(\text{s}) + \text{Li}(\text{s}) \rightarrow$
 - $(\text{CH}_3)_2\text{NH}(\text{l}) + \text{K}(\text{s}) \rightarrow$
6. Predict the products of each reaction.
- an alkyl chloride with lithium metal
 - rubidium with oxygen
7. A 655 mg sample of graphite was allowed to react with potassium metal, and 744 mg of product was isolated. What is the stoichiometry of the product?
8. Perchloric acid, which is used as a reagent in a number of chemical reactions, is typically neutralized before disposal. When a novice chemist accidentally used K₂CO₃ to neutralize perchloric acid, a large mass of KClO₄ ($K_{\text{sp}} = 1.05 \times 10^{-2}$) precipitated from solution. What mass of potassium ion is present in 1.00 L of a saturated solution of KClO₄?
9. A key step in the isolation of the alkali metals from their ores is selective precipitation. For example, lithium is separated from sodium and potassium by precipitation of Li₂CO₃ ($K_{\text{sp}} = 8.15 \times 10^{-4}$). If 500.0 mL of a 0.275 M solution of Na₂CO₃ are added to 500.0 mL of a 0.536 M lithium hydroxide solution, what mass of Li₂CO₃ will precipitate (assuming no further reactions occur)? What mass of lithium will remain in solution?

Answer

-
-
-
-
-
-
-
-
- 5.54 g Li₂CO₃; 0.82 g Li

Chapter 20.4: The Alkaline Earth Metals (Group 2)

Howard University General Chemistry: An Atoms First Approach

Unit 1: Atomic Theory
Unit 5: States of Matter

Unit 2: Molecular Structure
Unit 6: Kinetics & Equilibria

Unit 3: Stoichiometry
Unit 7: Electro & Thermo Chemistry

Unit 4: Thermochem & Gases
Unit 8: Materials

Learning Objectives

- To describe how to isolate the alkaline earth metals.
- To be familiar with the reactions, compounds, and complexes of the alkaline earth metals.

Like the alkali metals, the alkaline earth metals are so reactive that they are never found in elemental form in nature. Because they form +2 ions that have very negative reduction potentials, large amounts of energy are needed to isolate them from their ores. Four of the six group 2 elements—magnesium (Mg), calcium (Ca), strontium (Sr), and barium (Ba)—were first isolated in the early 19th century by Sir Humphry Davy, using a technique similar to the one he used to obtain the first alkali metals. In contrast to the alkali metals, however, compounds of the alkaline earth metals had been recognized as unique for many centuries. In fact, the name *alkali* comes from the Arabic *al-qili*, meaning “ashes,” which were known to neutralize acids. Medieval alchemists found that a portion of the ashes would melt on heating, and these substances were later identified as the carbonates of sodium and potassium (M_2CO_3). The ashes that did not melt (but did dissolve in acid), originally called alkaline earths, were subsequently identified as the alkaline earth oxides (MO). In 1808, Davy was able to obtain pure samples of Mg, Ca, Sr, and Ba by electrolysis of their chlorides or oxides.

Beryllium (Be), the lightest alkaline earth metal, was first obtained in 1828 by Friedrich Wöhler in Germany and simultaneously by Antoine Bussy in France. The method used by both men was reduction of the chloride by the potent “new” reductant, potassium:

Radium was discovered in 1898 by Pierre and Marie Curie, who processed tons of residue from uranium mines to obtain about 120 mg of almost pure $RaCl_2$. Marie Curie was awarded the Nobel Prize in Chemistry in 1911 for its discovery. Because of its low abundance and high radioactivity however, radium has few uses and will not be discussed further.

Preparation of the Alkaline Earth Metals

The alkaline earth metals are produced for industrial use by electrolytic reduction of their molten chlorides, as indicated in this equation for calcium:

The group 2 metal chlorides are obtained from a variety of sources. For example, $BeCl_2$ is produced by reacting HCl with beryllia (BeO), which is obtained from the semiprecious stone *beryl* [$Be_3Al_2(SiO_3)_6$].

Chemical reductants can also be used to obtain the group 2 elements. For example, magnesium is produced on a large scale by heating a form of limestone called *dolomite* ($CaCO_3 \cdot MgCO_3$) with an inexpensive iron/silicon alloy at 1150°C . Initially CO_2 is released, leaving behind a mixture of CaO and MgO ; Mg^{2+} is then reduced:

An early source of magnesium was an ore called *magnesite* ($MgCO_3$) from the district of northern Greece called Magnesia. Strontium was obtained from *strontianite* ($SrCO_3$) found in a lead mine in the town of Strontian in Scotland. The alkaline earth metals are somewhat easier to isolate from

A crystal of beryl. Beryl is a gemstone and an important source of beryllium.

their ores, as compared to the alkali metals, because their carbonate and some sulfate and hydroxide salts are insoluble.

General Properties of the Alkaline Earth Metals

Several important properties of the alkaline earth metals are summarized in [Table 20.4.1](#). Although many of these properties are similar to those of the alkali metals ([Table 20.3.1](#)), certain key differences are attributable to the differences in the valence electron configurations of the two groups (ns^2 for the alkaline earth metals versus ns^1 for the alkali metals).

A crystal of strontianite.
Both strontianite, one of the most important strontium ores, and strontium are named after the town of Strontian, Scotland, the location of one of the first mines for strontium ores.

Table 20.4.1 Selected Properties of the Group 2 Elements

	Beryllium	Magnesium	Calcium	Strontium	Barium	Radium
atomic symbol	Be	Mg	Ca	Sr	Ba	Ra
atomic number	4	12	20	38	56	88
atomic mass	9.01	24.31	40.08	87.62	137.33	226

	Beryllium	Magnesium	Calcium	Strontium	Barium	Radium
type of oxide	amphoteric	weakly basic	basic	basic	basic	—
product of reaction with N ₂	none	Mg ₃ N ₂	Ca ₃ N ₂	Sr ₃ N ₂	Ba ₃ N ₂	—
product of reaction with X ₂	BeX ₂	MgX ₂	CaX ₂	SrX ₂	BaX ₂	—
product of reaction with H ₂	none	MgH ₂	CaH ₂	SrH ₂	BaH ₂	—
*The values cited are for six-coordinate ions except for Be ²⁺ , for which the value for the four-coordinate ion is given.						

As with the alkali metals, the atomic and ionic radii of the alkaline earth metals increase smoothly from Be to Ba₂, and the ionization energies decrease. As we would expect, the first ionization energy of an alkaline earth metal, with an ns^2 valence electron configuration, is always significantly greater than that of the alkali metal immediately preceding it. The group 2 elements do exhibit some anomalies, however. For example, the density of Ca is less than that of Be and Mg, the two lightest members of the group, and Mg has the lowest melting and boiling points. In contrast to the alkali metals, the heaviest alkaline earth metal (Ba) is the strongest reductant, and the lightest (Be) is the weakest. The standard electrode potentials of Ca and Sr are not very different from that of Ba, indicating that the opposing trends in ionization energies and hydration energies are of roughly equal importance.

One major difference between the group 1 and group 2 elements is their electron affinities. With their half-filled ns orbitals, the alkali metals have a significant affinity for an additional electron. In contrast, the alkaline earth metals generally have little or no tendency to accept an additional electron because their ns valence orbitals are already full; an added electron would have to occupy one of the vacant np orbitals, which are much higher in energy.

Reactions and Compounds of the Alkaline Earth Metals

With their low first and second ionization energies, the group 2 elements almost exclusively form ionic compounds that contain M²⁺ ions. As expected, however, the lightest element (Be), with its higher ionization energy and small size, forms compounds that are largely covalent, as discussed in [Section 20.1](#). Some compounds of Mg²⁺ also have significant covalent character. Hence organometallic compounds like those discussed for Li in group 1 are also important for Be and Mg in group 2.

Note the Pattern

The group 2 elements almost exclusively form ionic compounds containing M²⁺ ions.

Note the Pattern

Because of their higher ionization energy and small size, both Be and Mg form organometallic compounds.

All alkaline earth metals react vigorously with the halogens (group 17) to form the corresponding halides (MX₂). Except for the beryllium halides, these compounds are all primarily ionic in nature, containing the M²⁺ cation and two X⁻ anions. The beryllium halides, with properties more typical of covalent compounds, have a polymeric halide-bridged structure in the solid state, as shown for BeCl₂. These compounds are volatile, producing vapors that contain the linear X–Be–X molecules predicted by the valence-shell electron-pair repulsion (VSEPR) model. (For more information on the VSEPR model, see [Chapter 6](#).) As expected for compounds with only four valence electrons around the central atom, the beryllium halides are potent Lewis acids. They react readily with Lewis bases, such as ethers, to form tetrahedral adducts in which the central beryllium is surrounded by an octet of electrons:

Solid beryllium chloride (BeCl₂). The solid has a polymeric, halide-bridged structure.

The reactions of the alkaline earth metals with oxygen are less complex than those of the alkali metals. All group 2 elements except barium react directly with oxygen to form the simple oxide MO. Barium forms barium peroxide (BaO₂) because the larger O₂²⁻ ion is better able to separate the large Ba²⁺ ions in the crystal lattice. In practice, only BeO is prepared by direct reaction with oxygen, and this reaction requires finely divided Be and high temperatures because Be is relatively inert. The other alkaline earth oxides are usually prepared by the thermal decomposition of carbonate salts:

The reactions of the alkaline earth metals with the heavier chalcogens (Y) are similar to those of the alkali metals. When the reactants are present in a 1:1 ratio, the binary chalcogenides (MY) are formed; at lower M:Y ratios, salts containing polychalcogenide ions (Y_n²⁻) are formed.

In the reverse of Equation 20.4.5, the oxides of Ca, Sr, and Ba react with CO₂ to regenerate the carbonate. Except for BeO, which has significant covalent character and is therefore amphoteric, all the alkaline earth oxides are basic. Thus they react with water to form the hydroxides—M(OH)₂:

and they dissolve in aqueous acid. Hydroxides of the lighter alkaline earth metals are insoluble in water, but their solubility increases as the atomic number of the metal increases. Because BeO and MgO are much more inert than the other group 2 oxides, they are used as refractory materials in applications involving high temperatures and mechanical stress. For example, MgO (melting point = 2825°C) is used to coat the heating elements in electric ranges.

The carbonates of the alkaline earth metals also react with aqueous acid to give CO₂ and H₂O:

The reaction in Equation 20.4.7 is the basis of antacids that contain MCO₃, which is used to neutralize excess stomach acid.

The trend in the reactivities of the alkaline earth metals with nitrogen is the opposite of that observed for the alkali metals. Only the lightest element (Be) does *not* react readily with N₂ to form the nitride (M₃N₂), although finely divided Be will react at high temperatures. The higher lattice energy due to the highly charged M²⁺ and N³⁻ ions is apparently sufficient to overcome the chemical inertness of the N₂ molecule, with its N≡N bond. Similarly, all the alkaline earth metals react with the heavier group 15 elements to form binary compounds such as phosphides and arsenides with the general formula M₃Z₂.

Note the Pattern

Higher lattice energies cause the alkaline earth metals to be more reactive than the alkali metals toward group 15 elements.

When heated, all alkaline earth metals, except for beryllium, react directly with carbon to form ionic carbides with the general formula MC₂. The most important alkaline earth carbide is calcium carbide (CaC₂), which reacts readily with water to produce acetylene. For many years, this reaction was the primary source of acetylene for welding and lamps on miners' helmets. In contrast, beryllium reacts with elemental carbon to form Be₂C, which formally contains the C⁴⁻ ion (although the compound is covalent). Consistent with this formulation, reaction of Be₂C with water or aqueous acid produces methane:

Beryllium does not react with hydrogen except at high temperatures (1500°C), although BeH₂ can be prepared at lower temperatures by an indirect route. All the heavier alkaline earth metals (Mg through Ba) react directly with hydrogen to produce the

binary hydrides (MH_2). The hydrides of the heavier alkaline earth metals are ionic, but both BeH_2 and MgH_2 have polymeric structures that reflect significant covalent character. All alkaline earth hydrides are good reducing agents that react rapidly with water or aqueous acid to produce hydrogen gas:

Like the alkali metals, the heavier alkaline earth metals are sufficiently electropositive to dissolve in liquid ammonia. In this case, however, two solvated electrons are formed per metal atom, and no equilibria involving metal dimers or metal anions are known. Also, like the alkali metals, the alkaline earth metals form a wide variety of simple ionic salts with oxoanions, such as carbonate, sulfate, and nitrate. The nitrate salts tend to be soluble, but the carbonates and sulfates of the heavier alkaline earth metals are quite insoluble because of the higher lattice energy due to the doubly charged cation and anion. The solubility of the carbonates and the sulfates decreases rapidly down the group because hydration energies decrease with increasing cation size.

Note the Pattern

The solubility of alkaline earth carbonate and sulfates decrease down the group because the hydration energies decrease.

Complexes of the Alkaline Earth Metals

Because of their higher positive charge (+2) and smaller ionic radii, the alkaline earth metals have a much greater tendency to form complexes with Lewis bases than do the alkali metals. This tendency is most important for the lightest cation (Be^{2+}) and decreases rapidly with the increasing radius of the metal ion.

Note the Pattern

The alkaline earth metals have a substantially greater tendency to form complexes with Lewis bases than do the alkali metals.

The chemistry of Be^{2+} is dominated by its behavior as a Lewis acid, forming complexes with Lewis bases that produce an octet of electrons around beryllium. For example, Be^{2+} salts dissolve in water to form acidic solutions that contain the tetrahedral $[Be(H_2O)_4]^{2+}$ ion. Because of its high charge-to-radius ratio, the Be^{2+} ion polarizes coordinated water molecules, thereby increasing their acidity:

Similarly, in the presence of a strong base, beryllium and its salts form the tetrahedral hydroxo complex: $[Be(OH)_4]^{2-}$. Hence beryllium oxide is amphoteric. Beryllium also forms a very stable tetrahedral fluoride complex: $[BeF_4]^{2-}$. Recall that beryllium halides behave like Lewis acids by forming adducts with Lewis bases ([Equation 20.4.4](#)).

The heavier alkaline earth metals also form complexes, but usually with a coordination number of 6 or higher. Complex formation is most important for the smaller cations (Mg^{2+} and Ca^{2+}). Thus aqueous solutions of Mg^{2+} contain the octahedral $[Mg(H_2O)_6]^{2+}$ ion. Like the alkali metals, the alkaline earth metals form complexes with neutral cyclic ligands like the crown ethers and cryptands discussed in [Section 20.3](#).

Organometallic Compounds Containing Group 2 Elements

Like the alkali metals, the lightest alkaline earth metals (Be and Mg) form the most covalent-like bonds with carbon, and they form the most stable organometallic compounds. Organometallic compounds of magnesium with the formula $RMgX$, where R is an alkyl or aryl group and X is a halogen, are universally called *Grignard reagents*, after Victor Grignard (1871–1935), the French chemist who discovered them. (For more information on the Grignard reagents, see [Section 23.5](#).) Grignard reagents can be used to synthesize various organic compounds, such as alcohols, aldehydes, ketones, carboxylic acids, esters, thiols, and amines.

Uses of the Alkaline Earth Metals

Elemental magnesium is the only alkaline earth metal that is produced on a large scale (about 5×10^5 tn per year). Its low density (1.74 g/cm³ compared with 7.87 g/cm³ for iron and 2.70 g/cm³ for aluminum) makes it an important component of the lightweight

metal alloys used in aircraft frames and aircraft and automobile engine parts (Figure 20.4.1). Most commercial aluminum actually contains about 5% magnesium to improve its corrosion resistance and mechanical properties. Elemental magnesium also serves as an inexpensive and powerful reductant for the production of a number of metals, including titanium, zirconium, uranium, and even beryllium, as shown in the following equation:

The only other alkaline earth that is widely used as the metal is beryllium, which is extremely toxic. Ingestion of beryllium or exposure to beryllium-containing dust causes a syndrome called *berylliosis*, characterized by severe inflammation of the respiratory tract or other tissues. A small percentage of beryllium dramatically increases the strength of copper or nickel alloys, which are used in nonmagnetic, nonsparking tools (such as wrenches and screwdrivers), camera springs, and electrical contacts. The low atomic number of beryllium gives it a very low tendency to absorb x-rays and makes it uniquely suited for applications involving radioactivity. Both elemental Be and BeO, which is a high-temperature ceramic, are used in nuclear reactors, and the windows on all x-ray tubes and sources are made of beryllium foil.

Millions of tons of calcium compounds are used every year. As discussed in earlier chapters, $CaCl_2$ is used as “road salt” to lower the freezing point of water on roads in cold temperatures. In addition, $CaCO_3$ is a major component of cement and an ingredient in many commercial antacids. “Quicklime” (CaO), produced by heating $CaCO_3$ (Equation 20.4.5), is used in the steel industry to remove oxide impurities, make many kinds of glass, and neutralize acidic soil. Other applications of group 2 compounds described in earlier chapters include the medical use of $BaSO_4$ in “barium milkshakes” for identifying digestive problems by x-rays and the use of various alkaline earth compounds to produce the brilliant colors seen in fireworks.

Figure 20.4.1 Magnesium Alloys Are Lightweight and Corrosion Resistant Because magnesium is about five times lighter than steel and 50% lighter than aluminum, it was long considered the “material of the future,” as shown in this 1950 concept Buick LeSabre sports car made almost entirely of magnesium and aluminum alloys. Modern aluminum alloys usually contain about 5% magnesium to improve their corrosion resistance and mechanical properties.

Example 20.4.1

For each application, choose the most appropriate substance based on the properties and reactivities of the alkaline earth metals and their compounds. Explain your choice in each case. Use any tables you need in making your decision, such as K_{sp} values (Table 16.1.1), lattice energies (Table 4.2.1), and band-gap energies (hyperphysics).

1. To neutralize excess stomach acid that causes indigestion, would you use $BeCO_3$, $CaCO_3$, or $BaCO_3$?
2. To remove CO_2 from the atmosphere in a space capsule, would you use MgO , CaO , or BaO ?
3. As a component of the alloy in an automotive spark plug electrode, would you use Be, Ca, or Ba?

Given: application and selected alkaline earth metals

Asked for: most appropriate substance for each application

Strategy:

Based on the discussion in this section and any relevant information elsewhere in this book, determine which substance is most appropriate for the indicated use.

Solution:

1. All the alkaline earth carbonates will neutralize an acidic solution by Equation 20.4.5. Because beryllium and its salts are toxic, however, $BeCO_3$ cannot be used as an antacid. Of the remaining choices, $CaCO_3$ is somewhat more soluble than $BaCO_3$ (according to the K_{sp} values in Table 16.1.1), suggesting that it will act more rapidly. Moreover, the

formula mass of CaCO_3 is 100.1 amu, whereas that of BaCO_3 is almost twice as large. Therefore, neutralizing a given amount of acid would require twice the mass of BaCO_3 compared with CaCO_3 . Furthermore, reaction of BaCO_3 with acid produces a solution containing Ba^{2+} ions, which are toxic. (Ba^{2+} is a stimulant that can cause ventricular fibrillation of the heart.) Finally, CaCO_3 is produced on a vast scale, so CaCO_3 is likely to be significantly less expensive than any barium compound. Consequently, CaCO_3 is the best choice for an antacid.

- This application involves reacting CO_2 with an alkaline earth oxide to form the carbonate, which is the reverse of the thermal decomposition reaction in which MCO_3 decomposes to CO_2 and the metal oxide MO (Equation 20.4.5). Owing to their higher lattice energies, the smallest alkaline earth metals should form the most stable oxides. (For more information on lattice energies, see Chapter 4.) Hence their carbonates should decompose at the lowest temperatures, as is observed (BeCO_3 decomposes at 100°C ; BaCO_3 at 1360°C). If the carbonate with the smallest alkaline earth metal decomposes most readily, we would expect the reverse reaction (formation of a carbonate) to occur most readily with the largest metal cation (Ba^{2+}). Hence BaO is the best choice.
- The alloy in a spark plug electrode must release electrons and promote their flow across the gap between the electrodes at high temperatures. (For more information on solid electrolytes, see Section 12.5.) Of the three metals listed, Ba has the lowest ionization energy and thus releases electrons most readily. Heating a barium-containing alloy to high temperatures will cause some ionization to occur, providing the initial step in forming a spark.

Exercise

Which of the indicated alkaline earth metals or their compounds is most appropriate for each application?

- drying agent for removing water from the atmosphere— CaCl_2 , MgSO_4 , or BaF_2
- removal of scale deposits (largely CaCO_3) in water pipes— $\text{HCl}(\text{aq})$ or $\text{H}_2\text{SO}_4(\text{aq})$
- removal of traces of N_2 from purified argon gas—Be, Ca, or Ba

Answer:

- MgSO_4
- HCl
- Ba

Example 20.4.2

Predict the products of each reaction and then balance each chemical equation.

- $\text{CaO}(\text{s}) + \text{HCl}(\text{g}) \rightarrow$
- $\text{MgO}(\text{s}) + \text{excess OH}^-(\text{aq}) \rightarrow$
- $\text{CaH}_2(\text{s}) + \text{TiO}_2(\text{s}) + \Delta \rightarrow$

Given: reactants

Asked for: products and balanced chemical equation

Strategy:

Follow the procedure given in Example 3 to predict the products of each reaction and then balance each chemical equation.

Solution:

- A** Gaseous HCl is an acid, and CaO is a basic oxide that contains the O^{2-} ion. This is therefore an acid–base reaction that produces CaCl_2 and H_2O .

B The balanced chemical equation is $\text{CaO}(\text{s}) + 2\text{HCl}(\text{g}) \rightarrow \text{CaCl}_2(\text{aq}) + \text{H}_2\text{O}(\text{l})$.
- A** Magnesium oxide is a basic oxide, so it can either react with water to give a basic solution or dissolve in an acidic solution. Hydroxide ion is also a base. Because we have two bases but no acid, an acid–base

reaction is impossible. A redox reaction is not likely because MgO is neither a good oxidant nor a good reductant.

B We conclude that no reaction occurs.

3. **A** Because CaH_2 contains the hydride ion (H^-), it is a good reductant. It is also a strong base because H^- ions can react with H^+ ions to form H_2 . Titanium oxide (TiO_2) is a metal oxide that contains the metal in its highest oxidation state (+4 for a group 4 metal); it can act as an oxidant by accepting electrons. We therefore predict that a redox reaction will occur, in which H^- is oxidized and Ti^{4+} is reduced. The most probable reduction product is metallic titanium, but what is the oxidation product? Oxygen must appear in the products, and both CaO and H_2O are stable compounds. The +1 oxidation state of hydrogen in H_2O is a sign that an oxidation has occurred ($2\text{H}^- \rightarrow 2\text{H}^+ + 4e^-$).

B The balanced chemical equation is $\text{CaH}_2(\text{s}) + \text{TiO}_2(\text{s}) + \Delta \rightarrow \text{Ti}(\text{s}) + \text{CaO}(\text{s}) + \text{H}_2\text{O}(\text{l})$
We could also write the products as $\text{Ti}(\text{s}) + \text{Ca}(\text{OH})_2(\text{s})$.

Exercise

Predict the products of each reaction and then balance each chemical equation.

- $\text{BeCl}_2(\text{s}) + \text{Mg}(\text{s}) + \Delta \rightarrow$
- $\text{BaCl}_2(\text{aq}) + \text{Na}_2\text{SO}_4(\text{aq}) \rightarrow$
- $\text{BeO}(\text{s}) + \text{OH}^-(\text{aq}) + \text{H}_2\text{O}(\text{l}) \rightarrow$

Answer:

- $\text{BeCl}_2(\text{s}) + \text{Mg}(\text{s}) + \Delta \rightarrow \text{Be}(\text{s}) + \text{MgCl}_2(\text{s})$
- $\text{BaCl}_2(\text{aq}) + \text{Na}_2\text{SO}_4(\text{aq}) \rightarrow \text{BaSO}_4(\text{s}) + 2\text{NaCl}(\text{aq})$
- $\text{BeO}(\text{s}) + 2\text{OH}^-(\text{aq}) + \text{H}_2\text{O}(\text{l}) \rightarrow [\text{Be}(\text{OH})_4]^{2-}(\text{aq})$

Summary

Pure samples of most of the alkaline earth metals can be obtained by electrolysis of the chlorides or oxides. Beryllium was first obtained by the reduction of its chloride; radium chloride, which is radioactive, was obtained through a series of reactions and separations. In contrast to the alkali metals, the alkaline earth metals generally have little or no affinity for an added electron. All alkaline earth metals react with the halogens to produce the corresponding halides, with oxygen to form the oxide (except for barium, which forms the peroxide), and with the heavier chalcogens to form chalcogenides or polychalcogenide ions. All oxides except BeO react with CO_2 to form carbonates, which in turn react with acid to produce CO_2 and H_2O . Except for Be, all the alkaline earth metals react with N_2 to form nitrides, and all react with carbon and hydrogen to form carbides and hydrides. Alkaline earth metals dissolve in liquid ammonia to give solutions that contain two solvated electrons per metal atom. The alkaline earth metals have a greater tendency than the alkali metals to form complexes with crown ethers, cryptands, and other Lewis bases. The most important alkaline earth organometallic compounds are *Grignard reagents* (RMgX), which are used to synthesize organic compounds.

Key Takeaway

- Group 2 elements almost exclusively form ionic compounds containing the M^{2+} ion, they are more reactive toward group 15 elements, and they have a greater tendency to form complexes with Lewis bases than do the alkali metals.

Conceptual Problems

- The electronegativities of Li and Sr are nearly identical (0.98 versus 0.95, respectively). Given their positions in the periodic table, how do you account for this?
- Arrange Na, Ba, Cs, and Li in order of increasing Z_{eff} .

- Do you expect the melting point of NaCl to be greater than, equal to, or less than that of MgCl₂? Why?
- Which of the group 2 elements would you expect to form primarily ionic rather than covalent organometallic compounds? Explain your reasoning.
- Explain why beryllium forms compounds that are best regarded as covalent in nature, whereas the other elements in group 2 generally form ionic compounds.
- Why is the trend in the reactions of the alkaline earth metals with nitrogen the reverse of the trend seen for the alkali metals?
- Is the bonding in the alkaline earth hydrides primarily ionic or covalent in nature? Explain your answer. Given the type of bonding, do you expect the lighter or heavier alkaline earth metals to be better reducing agents?
- Using arguments based on ionic size, charge, and chemical reactivity, explain why beryllium oxide is amphoteric. What element do you expect to be most similar to beryllium in its reactivity? Why?
- Explain why the solubility of the carbonates and sulfates of the alkaline earth metals decreases with increasing cation size.
- Beryllium oxide is amphoteric, magnesium oxide is weakly basic, and calcium oxide is very basic. Explain how this trend is related to the ionic character of the oxides.
- Do you expect the ΔH_f° of CaH₂ to be greater than, the same as, or less than that of BaH₂? Why or why not?
- Which of the s-block elements would you select to carry out a chemical reduction on a small scale? Consider cost, reactivity, and stability in making your choice. How would your choice differ if the reduction were carried out on an industrial scale?

Structure and Reactivity

- Beryllium iodide reacts vigorously with water to produce HI. Write a balanced chemical equation for this reaction and explain why it is violent.
- Predict the products of each reaction and then balance each chemical equation.
 - $\text{Mg}(\text{OH})_2(\text{aq}) + (\text{NH}_4)_3\text{PO}_4(\text{aq}) \rightarrow$
 - calcium carbonate and sulfuric acid \rightarrow
 - $\text{CaCl}_2(\text{aq}) + \text{Na}_3\text{PO}_4(\text{aq}) \rightarrow$
 - the thermal decomposition of SrCO₃
- Predict the products of each reaction and then balance each chemical equation.
 - $\text{Sr}(\text{s}) + \text{O}_2(\text{g}) \rightarrow$
 - the thermal decomposition of CaCO₃(s)
 - $\text{CaC}_2(\text{s}) + \text{H}_2\text{O}(\text{l}) \rightarrow$
 - $\text{RbHCO}_3(\text{s}) + \text{H}_2\text{SO}_4(\text{aq}) \rightarrow$
- Indicate whether each pair of substances will react and, if so, write a balanced chemical equation for the reaction.
 - an alkyl chloride and magnesium metal
 - strontium metal and nitrogen
 - magnesium metal and cold water
 - beryllium and nitrogen
- Using a thermodynamic cycle and information presented in [Chapter 3](#) and [Chapter 4](#), calculate the lattice energy of magnesium nitride (Mg₃N₂). (ΔH_f° for Mg₃N₂ is -463 kJ/mol, and ΔH° for $\text{N}(\text{g}) + 3\text{e}^- \rightarrow \text{N}^{3-}$ is +1736 kJ.) How does the lattice energy of Mg₃N₂ compare with that of MgCl₂ and MgO? (See [Thermodynamics Tables](#) for the enthalpy of formation values.)
- The solubility products of the carbonate salts of magnesium, calcium, and strontium are 6.82×10^{-6} , 3.36×10^{-9} , and 5.60×10^{-10} , respectively. How many milligrams of each compound would be present in 200.0 mL of a saturated solution of each? How would the solubility depend on the pH of the solution? Why?
- The solubility products of BaSO₄ and CaSO₄ are 1.08×10^{-10} and 4.93×10^{-5} , respectively. What accounts for this difference? When 500.0 mL of a solution that contains 1.00 M Ba(NO₃)₂ and 3.00 M Ca(NO₃)₂ is mixed with a 2.00 M solution of Na₂SO₄, a precipitate forms. What is the identity of the precipitate? How much of it will form before the second salt precipitates?
- Electrolytic reduction is used to produce magnesium metal from MgCl₂. The goal is to produce 200.0 kg of Mg by this method.
 - How many kilograms of MgCl₂ are required?
 - How many liters of chlorine gas will be released at standard temperature and pressure?
 - How many hours will it take to process the magnesium metal if a total current of 1.00×10^4 A is used?

9. A sample consisting of 20.35 g of finely divided calcium metal is allowed to react completely with nitrogen. What is the mass of the product?
10. What mass of magnesium hydride will react with water to produce 1.51 L of hydrogen gas at standard temperature and pressure?

Answers

- 1.
- 2.
3.
 - a. $2\text{Sr}(s) + \text{O}_2(g) \rightarrow 2\text{SrO}(s)$
 - b. $\text{CaCO}_3(s) \rightarrow \text{CaO}(s) + \text{CO}_2(g)$
 - c. $\text{CaC}_2(s) + 2\text{H}_2\text{O}(l) \rightarrow \text{C}_2\text{H}_2(g) + \text{Ca}(\text{OH})_2(aq)$
 - d. $2\text{RbHCO}_3(s) + \text{H}_2\text{SO}_4(aq) \rightarrow \text{Rb}_2\text{SO}_4(aq) + 2\text{CO}_2(g) + 2\text{H}_2\text{O}(l)$
- 4.
- 5.
- 6.
7. The Ba^{2+} ion is larger and has a lower hydration energy than the Ca^{2+} ion. The precipitate is BaSO_4 ; 117 g of BaSO_4 .
- 8.
9. 25.09 g of Ca_3N_2
- 10.

Learning Objective

- To be familiar with the roles of the s-block elements in biology.

The s-block elements play important roles in biological systems. Covalent hydrides, for example, are the building blocks of organic compounds, and other compounds and ions containing s-block elements are found in tissues and cellular fluids. In this section, we describe some ways in which biology depends on the properties of the group 1 and group 2 elements.

Covalent Hydrides

There are three major classes of hydrides—covalent, ionic, and metallic—but only covalent hydrides occur in living cells and have any biochemical significance. As you learned in [Chapter 3](#), carbon and hydrogen have similar electronegativities, and the C–H bonds in organic molecules are strong and essentially nonpolar. Little acid–base chemistry is involved in the cleavage or formation of these bonds. In contrast, because hydrogen is less electronegative than oxygen and nitrogen (symbolized by Z), the H–Z bond in the hydrides of these elements is polarized ($\text{H}^{\delta+} - \text{Z}^{\delta-}$). Consequently, the hydrogen atoms in these H–Z bonds are relatively acidic. Moreover, S–H bonds are relatively weak due to poor s orbital overlap, so they are readily cleaved to give a proton. Hydrides in which H is bonded to O, N, or S atoms are therefore polar, hydrophilic molecules that form hydrogen bonds. They also undergo acid–base reactions by transferring a proton.

Note the Pattern

Covalent hydrides in which H is bonded to O, N, or S atoms are polar and hydrophilic, form hydrogen bonds, and transfer a proton in their acid-base reactions.

Hydrogen bonds are crucial in biochemistry, in part because they help hold proteins in their biologically active folded structures. Hydrogen bonds also connect the two intertwining strands of DNA (deoxyribonucleic acid), the substance that contains the genetic code for all organisms. (For more information on DNA, see [Section 23.6](#).) Because hydrogen bonds are easier to break than the covalent bonds that form the individual DNA strands, the two intertwined strands can be separated to give intact single strands, which is essential for the duplication of genetic information.

In addition to the importance of hydrogen bonds in biochemical molecules, the extensive hydrogen-bonding network in water is one of the keys to the existence of life on our planet. Based on its molecular mass, water should be a gas at room temperature (20°C), but the strong intermolecular interactions in liquid water greatly increase its boiling point. Hydrogen bonding also produces the relatively open molecular arrangement found in ice, which causes ice to be less dense than water. Because ice floats on the surface of water, it creates an insulating layer that allows aquatic organisms to survive during cold winter months.

These same strong intermolecular hydrogen-bonding interactions are also responsible for the high heat capacity of water and its high heat of fusion. A great deal of energy must be removed from water for it to freeze. Consequently, as noted in [Chapter 9](#), large bodies of water act as “thermal buffers” that have a stabilizing effect on the climate of adjacent land areas. Perhaps the most striking example of this effect is the fact that humans can live comfortably at very high latitudes. For example, palm trees grow in southern England at the same latitude (51°N) as the southern end of frigid Hudson Bay and northern Newfoundland in North

America, areas known more for their moose populations than for their tropical vegetation. Warm water from the Gulf Stream current in the Atlantic Ocean flows clockwise from the tropical climate at the equator past the eastern coast of the United States and then turns toward England, where heat stored in the water is released. The temperate climate of Europe is largely attributable to the thermal properties of water.

Note the Pattern

Strong intermolecular hydrogen-bonding interactions are responsible for the high heat capacity of water and its high heat of fusion.

Macrominerals

The members of group 1 and group 2 that are present in the largest amounts in organisms are sodium, potassium, magnesium, and calcium, all of which form monatomic cations with a charge of +1 (group 1, M^+) or +2 (group 2, M^{2+}). Biologically, these elements can be classified as *macrominerals*.

For example, calcium is found in the form of relatively insoluble calcium salts that are used as structural materials in many organisms. Hydroxyapatite [$Ca_5(PO_4)_3OH$] is the major component of bones, calcium carbonate ($CaCO_3$) is the major component of the shells of mollusks and the eggs of birds and reptiles, and calcium oxalate (CaO_2CCO_2) is found in many plants. Because calcium and strontium have similar sizes and charge-to-radius ratios, small quantities of strontium are always found in bone and other calcium-containing structural materials. Normally this is not a problem because the Sr^{2+} ions occupy sites that would otherwise be occupied by Ca^{2+} ions. When trace amounts of radioactive $^{90}_{38}Sr$ are released into the atmosphere from nuclear weapons tests or a nuclear accident, however, the radioactive strontium eventually reaches the ground, where it is taken up by plants that are consumed by dairy cattle. The isotope then becomes concentrated in cow's milk, along with calcium. Because radioactive strontium coprecipitates with calcium in the hydroxyapatite that surrounds the bone marrow (where white blood cells are produced), children, who typically ingest more cow's milk than adults, are at substantially increased risk for leukemia, a type of cancer characterized by the overproduction of white blood cells.

Ion Transport

The Na^+ , K^+ , Mg^{2+} , and Ca^{2+} ions are important components of intracellular and extracellular fluids. Both Na^+ and Ca^{2+} are found primarily in *extracellular* fluids, such as blood plasma, whereas K^+ and Mg^{2+} are found primarily in *intracellular* fluids. Substantial inputs of energy are required to establish and maintain these concentration gradients and prevent the system from reaching equilibrium. Thus energy is needed to transport each ion across the cell membrane toward the side with the higher concentration. The biological machines that are responsible for the selective transport of these metal ions are complex assemblies of proteins called ion pumps. Ion pumps recognize and discriminate between metal ions in the same way that crown ethers and cryptands do, with a high affinity for ions of a certain charge and radius.

Defects in the ion pumps or their control mechanisms can result in major health problems. For example, *cystic fibrosis*, the most common inherited disease in the United States, is caused by a defect in the transport system (in this case, chloride ions). Similarly, in many cases, *hypertension*, or high blood pressure, is thought to be due to defective Na^+ uptake and/or excretion. If too much Na^+ is absorbed from the diet (or if too little is excreted), water diffuses from tissues into the blood to dilute the solution, thereby decreasing the osmotic pressure in the circulatory system. The increased volume increases the blood pressure, and ruptured arteries called *aneurysms* can result, often in the brain. Because high blood pressure causes other medical problems as well, it is one of the most important biomedical disorders in modern society.

For patients who suffer from hypertension, low-sodium diets that use $NaCl$ substitutes, such as KCl , are often prescribed. Although KCl and $NaCl$ give similar flavors to foods, the K^+ is not readily taken up by the highly specific Na^+ -uptake system. This approach to controlling hypertension is controversial, however, because direct correlations between dietary Na^+ content and blood pressure are difficult to demonstrate in the general population. More important, recent observations indicate that high blood pressure may correlate more closely with inadequate intake of calcium in the diet than with excessive sodium levels. This finding is important because the typical "low-sodium" diet is also low in good sources of calcium, such as dairy products.

Some of the most important biological functions of the group 1 and group 2 metals are due to small changes in the cellular concentrations of the metal ion. The transmission of nerve impulses, for example, is accompanied by an increased flux of Na^+ ions

into a nerve cell. Similarly, the binding of various hormones to specific receptors on the surface of a cell leads to a rapid influx of Ca^{2+} ions; the resulting sudden rise in the intracellular Ca^{2+} concentration triggers other events, such as muscle contraction, the release of neurotransmitters, enzyme activation, or the secretion of other hormones.

Within cells, K^+ and Mg^{2+} often activate particular enzymes by binding to specific, negatively charged sites in the enzyme structure. *Chlorophyll*, the green pigment used by all plants to absorb light and drive the process of *photosynthesis*, contains magnesium. During photosynthesis, CO_2 is reduced to form sugars such as glucose. The structure of the central portion of a chlorophyll molecule resembles a crown ether (part (a) in [Figure 13.2.4](#)) with four five-member nitrogen-containing rings linked together to form a large ring that provides a “hole” the proper size to tightly bind Mg^{2+} .

Ionophores

Because the health of cells depends on maintaining the proper levels of cations in intracellular fluids, any change that affects the normal flux of metal ions across cell membranes could well cause an organism to die. Molecules that facilitate the transport of metal ions across membranes are generally called ionophores (*ion* plus *phore* from the Greek *phorein*, meaning “to carry”). Many ionophores are potent antibiotics that can kill or inhibit the growth of bacteria. An example is *valinomycin*, a cyclic molecule with a central cavity lined with oxygen atoms (part (a) in [Figure 20.5.1](#)) that is similar to the cavity of a crown ether (part (a) in [Figure 13.2.4](#)). Like a crown ether, valinomycin is highly selective: its affinity for K^+ is about 1000 times greater than that for Na^+ . By increasing the flux of K^+ ions into cells, valinomycin disrupts the normal K^+ gradient across a cell membrane, thereby killing the cell (part (b) in [Figure 20.5.1](#)).

The structure of the central core of chlorophyll, a magnesium complex present in all photosynthetic tissues. Note the resemblance to the crown ether complexes discussed in [Chapter 13](#).

Figure 20.5.1 Valinomycin Is an Antibiotic That Functions Like an Ionophore (a) This model of the structure of the K^+ –valinomycin complex, determined by x-ray diffraction, shows how the valinomycin molecule wraps itself around the K^+ ion, shielding it from the environment, in a manner reminiscent of a crown ether complex. (For more information on the crown ethers, see [Section 13.2](#).) (b) Valinomycin kills bacteria by facilitating the transport of K^+ ions across the cell membrane, thereby disrupting the normal distribution of ions in the bacterium. At the surface of the membrane, valinomycin binds a K^+ ion. Because the hydrophobic exterior of the valinomycin molecule forms a “doughnut” that shields the positive charge of the metal ion, the K^+ –valinomycin complex is highly soluble in the nonpolar interior of the membrane. After the K^+ –valinomycin complex diffuses across the membrane to the interior of the cell, the K^+ ion is released, and the valinomycin is free to diffuse back to the other side of the membrane to bind another K^+ ion. Valinomycin thereby destroys the normal K^+ gradient across the membrane, killing the cell.

Example 20.5.1

A common way to study the function of a metal ion in biology is to replace the naturally occurring metal with one whose reactivity can be traced by spectroscopic methods. The substitute metal ion must bind to the same site as the naturally occurring ion, and it must have a similar (or greater) affinity for that site, as indicated by its charge density. Arrange the following ions in order of increasing effectiveness as a replacement for Ca^{2+} , which has an ionic radius of 100 pm (numbers in parentheses are ionic radii): Na^+ (102 pm), Eu^{2+} (117 pm), Sr^{2+} (118 pm), F^{3+} (133 pm), Pb^{2+} (119 pm), and La^{3+} (103 pm). Explain your reasoning.

Given: ions and ionic radii

Asked for: suitability as replacement for Ca^{2+}

Strategy:

Use periodic trends to arrange the ions from least effective to most effective as a replacement for Ca^{2+} .

Solution:

The most important properties in determining the affinity of a biological molecule for a metal ion are the size and charge-to-radius ratio of the metal ion. Of the possible Ca^{2+} replacements listed, the F^{-} ion has the opposite charge, so it should have no affinity for a Ca^{2+} -binding site. Na^{+} is approximately the right size, but with a +1 charge it will bind much more weakly than Ca^{2+} . Although Eu^{2+} , Sr^{2+} , and Pb^{2+} are all a little larger than Ca^{2+} , they are probably similar enough in size and charge to bind. Based on its ionic radius, Eu^{2+} should bind most tightly of the three. La^{3+} is nearly the same size as Ca^{2+} and more highly charged. With a higher charge-to-radius ratio and a similar size, La^{3+} should bind tightly to a Ca^{2+} site and be the most effective replacement for Ca^{2+} . The order is $\text{F}^{-} \ll \text{Na}^{+} \ll \text{Pb}^{2+} \sim \text{Sr}^{2+} \sim \text{Eu}^{2+} < \text{La}^{3+}$.

Exercise

The ionic radius of K^{+} is 138 pm. Arrange the following ions in order of increasing affinity for a K^{+} -binding site in an enzyme (numbers in parentheses are ionic radii): Na^{+} (102 pm), Rb^{+} (152 pm), Ba^{2+} (135 pm), Cl^{-} (181 pm), and Tl^{+} (150 pm).

Answer: $\text{Cl}^{-} \ll \text{Na}^{+} < \text{Tl}^{+} \sim \text{Rb}^{+} < \text{Ba}^{2+}$

Summary

Covalent hydrides in which hydrogen is bonded to oxygen, nitrogen, or sulfur are polar, hydrophilic molecules that form hydrogen bonds and undergo acid–base reactions. Hydrogen-bonding interactions are crucial in stabilizing the structure of proteins and DNA and allow genetic information to be duplicated. The hydrogen-bonding interactions in water and ice also allow life to exist on our planet. The group 1 and group 2 metals present in organisms are *macrominerals*, which are important components of intracellular and extracellular fluids. Small changes in the cellular concentration of a metal ion can have a significant impact on biological functions. Metal ions are selectively transported across cell membranes by **ion pumps**, which bind ions based on their charge and radius. **Ionophores**, many of which are potent antibiotics, facilitate the transport of metal ions across membranes.

Key Takeaway

- Among their many roles in biology, the s-block elements allow genetic information to be duplicated and are important components of intracellular and extracellular fluids.

Conceptual Problems

1. Explain the thermochemical properties of water in terms of its intermolecular bonding interactions. How does this affect global climate patterns?
2. Of the three classes of hydrides, which is (are) biochemically significant? How do you account for this?
3. Many proteins are degraded and become nonfunctional when heated higher than a certain temperature, even though the individual protein molecules do not undergo a distinct chemical change. Propose an explanation for this observation.
4. Los Angeles has moderate weather throughout the year, with average temperatures between 57°F and 70°F. In contrast, Palm Springs, which is just 100 miles inland, has average temperatures between 55°F and 95°F. Explain the difference in the average temperature ranges between the two cities.
5. Although all group 1 ions have the same charge (+1), Na^{+} and K^{+} ions are selectively transported across cell membranes. What strategy do organisms employ to discriminate between these two cations?

Structure and Reactivity

1. A 0.156 g sample of a chloride salt of an alkaline earth metal is dissolved in enough water to make 20.5 mL of solution. If this solution has an osmotic pressure of 2.68 atm at 25°C, what is the identity of the alkaline earth metal?
2. The thermal buffering capacity of water is one of the reasons the human body is capable of withstanding a wide range of temperatures. How much heat (in kilojoules) is required to raise the temperature of a 70.0 kg human from 37.0°C to 38.0°C? Assume that 70% of the mass of the body is water and that body fluids have the same specific heat as water.
3. During illness, body temperature can increase by more than 2°C. One piece of folklore is that you should “feed a fever.” Using the data in [Table 8.7.2](#), how many fried chicken drumsticks would a 70.0 kg person need to eat to generate a 2.0°C change in body temperature? Assume the following: there is complete conversion of the caloric content of the chicken to thermal energy, 70% of the mass of the body is solely due to water, and body fluids have the same specific heat as water.
4. Hydrogen bonding is partly responsible for the high enthalpy of vaporization of water ($\Delta H_{\text{vap}} = 43.99 \text{ kJ/mol}$ at 25°C), which contributes to cooling the body during exercise. Assume that a 50.0 kg runner produces 20.0 g of perspiration during a race, and all the perspiration is converted to water vapor at 37.0°C. What amount of heat (in joules) is removed from the runner’s skin if the perspiration consists of only water?

Answer

1. Ba
- 2.
- 3.
- 4.

Unit 3: Stoichiometry
Unit 7: Electro & Thermo Chemistry

Unit 4: Thermochem & Gases
Unit 8: Materials

APPLICATION PROBLEMS

- For each application, which of the indicated substances would you select and why? Base your selections on the properties and reactivities of the alkaline earth metals and their compounds.
 - source of CO_2 at low temperature— BeCO_3 or CaCO_3
 - window material for x-ray tubes—beryllium or strontium
 - source of iodide ions in aqueous solution— BaI_2 or BeI_2
 - formation of a stable organometallic compound by reacting a metal with an alkyl halide—calcium or magnesium
 - synthesis of refractory materials—magnesium oxide or barium oxide
- Ultrahigh-purity tritium, which is needed in the nuclear weapons industry, is obtained by allowing a mixture of tritium and its nuclear decay product, helium-3, to diffuse through a thin block of palladium metal. Explain why this is an effective method for separating the two substances.
- In one technique for harnessing solar energy, the blue-green algae *Anabaena cylindrica* is used to produce H_2 and O_2 photosynthetically. The resulting gases are collected, passed through palladium metal, and then recombined in a fuel cell to produce electricity. Draw a diagram showing how this process might work.
- Scientists speculate that sodium atoms react with atmospheric ozone to produce a high-energy species, which is then reduced by atomic oxygen. This process is believed to occur as meteors enter Earth's atmosphere. Write equations for these reactions. Is sodium regenerated in this process?
- Propose an effective compound for purifying and regenerating air for breathing in a submarine and justify your choice.
- Explain why administering cryptands to a person suffering from iron toxicity could be an effective clinical treatment.
- Calcium magnesium carbonate [$\text{CaMg}(\text{CO}_3)_2$], also known as dolomite, is a primary constituent of soils. It is formed when water containing magnesium ions comes in contact with calcium carbonate. Do you expect dolomite to be more or less resistant to acid rain than calcium carbonate? Why?
- Few classes of reagents have proved to be as useful for organic syntheses as the Grignard reagents (RMgX), which are produced by reacting an organohalogen compound (RX) with magnesium in an ether solvent. The ease of formation of a Grignard reagent depends on the structure of the organohalogen compound.
 - For a given R group, arrange the alkyl halides (RX) in order of decreasing reactivity with Mg and justify your reasoning.
 - Is it possible to make a Grignard reagent using an organosodium compound and MgCl_2 ? Why or why not?
 - Is MgCl_2 or MgI_2 preferable for the reaction described in part (b)?
- The percentage of the population that developed leukemia in the vicinity of the Chernobyl nuclear reactor rose substantially after the nuclear accident in 1986. Why? Based on information in this chapter, what might have been done to reduce the incidence of leukemia in children who lived in the affected region?
- Explain how ingesting large amounts of NaCl could induce a heart attack.
- The general mechanism by which valinomycin functions is described in the text. If you were asked to develop a new antibiotic that functions like valinomycin, what type of structural features would you want to incorporate into it?
- You have been asked to determine the concentrations of both Mg^{2+} and Ca^{2+} in a sample of hard water using EDTA (ethylenediaminetetraacetic acid), which forms stable complexes with both metal ions. The procedure requires two titrations. In the first, you adjust the pH of the water to about 10 by adding a solution of KOH . You then add a small amount of an indicator that, by itself, is blue at pH 10 but which forms a red complex with either Mg^{2+} or Ca^{2+} . Titrating the sample with a solution of EDTA will cause the solution to turn from red to blue when all the metal ions have reacted with the EDTA. The second titration is identical to the first, *except* that it is carried out at pH 13, and the volume of EDTA solution needed to

- reach the endpoint is *less* than in the first titration. What is the difference between what is being measured in these two titrations? Which titration measures the concentration of only a single metal ion? Identify that metal ion and explain how the procedure described allows you to determine the concentrations of *both* Mg^{2+} and Ca^{2+} .
- The primary component of ordinary glass is SiO_2 , which is difficult to work with due to its high melting point ($1700^\circ C$). Adding metal oxides lowers the melting temperature to a workable level ($700\text{--}900^\circ C$) and causes the liquid to flow more easily. Both Na_2O and K_2O are commonly used for this purpose. Which of these oxides produces a glass that hardens more rapidly and at a higher temperature? Why is there a difference?
 - Lead poisoning can be treated by administering EDTA, an organic compound that binds to Pb^{2+} (EDTA is described in Problem 12), thereby removing lead from the system. If you are thinking of administering EDTA as a clinical treatment for Ni^{2+} poisoning because of its effectiveness in removing Pb^{2+} , what additional factors do you need to consider?
 - Silicon, aluminum, and oxygen, the most abundant constituents of Earth's crust, are found in many minerals. For example, two feldspars, which are typical components of granites, are albite and anorthite. Albite has the composition $Na[AlSi_3O_8]$; in anorthite, Al replaces one of the Si ions. Suggest a plausible cation in anorthite in place of Na.
 - When a plant root is immersed in an aqueous environment, its uptake of metal ions is dictated by equilibrium considerations. Metal ions can be captured by reaction with various types of carrier molecules. The resulting complexes can pass through the cell membrane and dissociate, thereby transporting the metal ions into the cell. The Na^+ , K^+ , Mg^{2+} , and Ca^{2+} ions are all transported using this mechanism. Which of these ions would be captured by
 - oxygen donors with a neutral or low (-1) charge?
 - carboxylates, phosphates, and some neutral oxygen donors?
 - polyphosphates with a total negative charge greater than -2 ?
 - nitrogen donors?
 - Sodium carbonate has long been used in the glass industry, for making water softeners, and in the wood pulp and paper industries. Recently, sodium carbonate has proved useful for removing SO_2 and H_2SO_4 from the flue gases of coal- and oil-fired power stations. Write balanced chemical equations showing the reactions that occur when flue gases are passed through solid sodium carbonate.
 - Hard water contains high concentrations of Ca^{2+} and Mg^{2+} . These ions react with soaps (sodium and potassium salts of naturally occurring carboxylic acids) to form an insoluble scum. Explain how adding Na_2CO_3 to hard water can soften the water and improve the ability of soaps to remove dirt and grime.
 - Do you expect $MgCO_3$ or $Mg(OH)_2$ to be more soluble in water? Based on your answer, explain how adding $Ca(OH)_2$ softens water by removing Mg^{2+} . Be sure to show a balanced chemical equation for the reaction.
 - How does a low-sodium diet help lower blood pressure? Do you think a diet high in KCl would also be effective at lowering blood pressure? Explain your answer.

ANSWERS

- $BeCO_3$; less stable to decomposition due to small size of Be
 - Be; low Z results in little absorption of x-rays
 - BaI_2 ; has greater ionic character
 - Mg; smaller size results in stronger polar covalent bonds to carbon
 - MgO ; higher lattice energy and melting point
-
-
-
- KO_2 ; the reaction is $4KO_2(s) + 4CO_2(g) + 2H_2O(g) \rightarrow 4KHCO_3(s) + 3O_2(g)$.
-
- Dolomite will be less resistant to acid rain because $MgCO_3$ is more soluble than $CaCO_3$.
-
- Restrict milk consumption and supplement diet with calcium to minimize the uptake of strontium.
-
-
-

13. The glass containing sodium will have a higher softening or melting temperature because the smaller sodium ions will link the silicate chains more strongly.
14. $2+$
15. Ca
- 16.
17. $\text{Na}_2\text{CO}_3(\text{s}) + \text{SO}_2(\text{g}) \rightarrow \text{Na}_2\text{SO}_3(\text{s}) + \text{CO}_2(\text{g}); \text{Na}_2\text{CO}_3(\text{s}) + \text{H}_2\text{SO}_4(\text{g}) \rightarrow \text{Na}_2\text{SO}_4(\text{s}) + \text{CO}_2(\text{g}) + \text{H}_2\text{O}(\text{g})$

Unit 5: States of Matter

Unit 2: Molecular Structure
Unit 6: Kinetics & Equilibria

Unit 3: Stoichiometry
Unit 7: Electro & Thermo Chemistry

Unit 4: Thermochem & Gases
Unit 8: Materials

Learning Objective

- To understand the trends in properties and reactivity of the d -block elements.

The transition metals, groups 3–12 in the periodic table, are generally characterized by partially filled d subshells in the free elements or their cations. (Although the metals of group 12 do not have partially filled d shells, their chemistry is similar in many ways to that of the preceding groups, and we therefore include them in our discussion.) Unlike the s -block and p -block elements, the transition metals exhibit significant horizontal similarities in chemistry in addition to their vertical similarities.

Electronic Structure and Reactivity of the Transition Metals

The valence electron configurations of the first-row transition metals are given in [Table 21.1.1](#). As we go across the row from left to right, electrons are added to the $3d$ subshell to neutralize the increase in the positive charge of the nucleus as the atomic number increases. With two important exceptions, the $3d$ subshell is filled as expected based on the aufbau principle and Hund's rule. Unexpectedly, however, chromium has a $4s^1 3d^5$ electron configuration rather than the $4s^2 3d^4$ configuration predicted by the aufbau principle, and copper is $4s^1 3d^{10}$ rather than $4s^2 3d^9$. In [Chapter 2](#), we attributed these anomalies to the extra stability associated with half-filled subshells. Because the ns and $(n-1)d$ subshells in these elements are similar in energy, even relatively small effects are enough to produce apparently anomalous electron configurations.

Table 21.1.1 Valence Electron Configurations of the First-Row Transition Metals

Sc	Ti	V	Cr	Mn	Fe	Co	Ni	Cu	Zn
$4s^2 3d^1$	$4s^2 3d^2$	$4s^2 3d^3$	$4s^1 3d^5$	$4s^2 3d^5$	$4s^2 3d^6$	$4s^2 3d^7$	$4s^2 3d^8$	$4s^1 3d^{10}$	$4s^2 3d^{10}$

In the second-row transition metals, electron–electron repulsions within the $4d$ subshell cause additional irregularities in electron configurations that are not easily predicted. For example, Nb and Tc, with atomic numbers 41 and 43, both have a half-filled $5s$ subshell, with $5s^1 4d^4$ and $5s^1 4d^6$ valence electron configurations, respectively. Further complications occur among the third-row transition metals, in which the $4f$, $5d$, and $6s$ orbitals are extremely close in energy. Although La has a $6s^2 5d^1$ valence electron configuration, the valence electron configuration of the next element—Ce—is $6s^2 5d^0 4f^2$. From this point through element 71, added electrons enter the $4f$ subshell, giving rise to the 14 elements known as the lanthanides. After the $4f$ subshell is filled, the $5d$ subshell is populated, producing the third row of the transition metals. Next comes the seventh period, where the actinides have three subshells ($7s$, $6d$, and $5f$) that are so similar in energy that their electron configurations are even more unpredictable.

As we saw in the s -block and p -block elements, the size of neutral atoms of the d -block elements gradually decreases from left to right across a row, due to an increase in the effective nuclear charge (Z_{eff}) with increasing atomic number. In addition, the atomic radius increases down a group, just as it does in the s and p blocks. Because of the *lanthanide contraction*, however, the increase in size between the $3d$ and $4d$ metals is much greater than between the $4d$ and $5d$ metals ([Figure 21.1.1](#)). (For more information on the lanthanides, see [Section 3.3](#).) The effects of the lanthanide contraction are also observed in ionic radii, which explains why, for example, there is only a slight increase in radius from Mo^{3+} to W^{3+} .

Figure 21.1.1 The Metallic Radii of the First-, Second-, and Third-Row Transition Metals Because of the lanthanide contraction, the second- and third-row transition metals are very similar in size.

As you learned in [Chapter 3](#), electrons in $(n - 1)d$ and $(n - 2)f$ subshells are only moderately effective at shielding the nuclear charge; as a result, the effective nuclear charge experienced by valence electrons in the d -block and f -block elements does not change greatly as the nuclear charge increases across a row. Consequently, the ionization energies of these elements increase very slowly across a given row ([Figure 3.3.1](#)). In addition, as we go from the top left to the bottom right corner of the d block, electronegativities generally increase, densities and electrical and thermal conductivities increase, and enthalpies of hydration of the metal cations decrease in magnitude, as summarized in [Figure 21.1.2](#). Consistent with this trend, the transition metals become steadily less reactive and more “noble” in character from left to right across a row. The relatively high ionization energies and electronegativities and relatively low enthalpies of hydration are all major factors in the noble character of metals such as Pt and Au.

Figure 21.1.2 Some Trends in Properties of the Transition Metals The electronegativity of the elements increases, and the hydration energies of the metal cations decrease in magnitude from left to right and from top to bottom of the d block. As a result, the metals in the lower right corner of the d block are so unreactive that they are often called the “noble metals.”

Trends in Transition Metal Oxidation States

The similarity in ionization energies and the relatively small increase in successive ionization energies lead to the formation of metal ions with the same charge for many of the transition metals. This in turn results in extensive horizontal similarities in chemistry, which are most noticeable for the first-row transition metals and for the lanthanides and actinides. Thus all the first-row transition metals except Sc form stable compounds that contain the $2+$ ion, and, due to the small difference between the second and third ionization energies for these elements, all except Zn also form stable compounds that contain the $3+$ ion. The relatively small increase in successive ionization energies causes most of the transition metals to exhibit multiple oxidation states separated by a single electron. Manganese, for example, forms compounds in every oxidation state between -3 and $+7$. Because of the slow but steady increase in ionization potentials across a row, high oxidation states become progressively less stable for the elements on the right side of the d block. The occurrence of multiple oxidation states separated by a single electron causes many, if not most, compounds of the transition metals to be paramagnetic, with one to five unpaired electrons. This behavior is in sharp contrast to

that of the p -block elements, where the occurrence of two oxidation states separated by two electrons is common, which makes virtually all compounds of the p -block elements diamagnetic.

Note the Pattern

Due to a small increase in successive ionization energies, most of the transition metals have multiple oxidation states separated by a single electron.

Note the Pattern:

Most compounds of transition metals are paramagnetic, whereas virtually all compounds of the p -block elements are diamagnetic.

The electronegativities of the first-row transition metals increase smoothly from Sc ($\chi = 1.4$) to Cu ($\chi = 1.9$). Thus Sc is a rather active metal, whereas Cu is much less reactive. The steady increase in electronegativity is also reflected in the standard reduction potentials: thus E° for the reaction $M^{2+}(aq) + 2e^- \rightarrow M^0(s)$ becomes progressively less negative from Ti ($E^\circ = -1.63$ V) to Cu ($E^\circ = +0.34$ V). Exceptions to the overall trends are rather common, however, and in many cases, they are attributable to the stability associated with filled and half-filled subshells. For example, the $4s^2 3d^{10}$ electron configuration of zinc results in its strong tendency to form the stable Zn^{2+} ion, with a $3d^{10}$ electron configuration, whereas Cu^+ , which also has a $3d^{10}$ electron configuration, is the only stable monocation formed by a first-row transition metal. Similarly, with a half-filled subshell, Mn^{2+} ($3d^5$) is much more difficult to oxidize than Fe^{2+} ($3d^6$). The chemistry of manganese is therefore primarily that of the Mn^{2+} ion, whereas both the Fe^{2+} and Fe^{3+} ions are important in the chemistry of iron.

The transition metals form cations by the initial loss of the ns electrons of the metal, even though the ns orbital is *lower* in energy than the $(n-1)d$ subshell in the neutral atoms. This apparent contradiction is due to the small difference in energy between the ns and $(n-1)d$ orbitals, together with screening effects. The loss of one or more electrons reverses the relative energies of the ns and $(n-1)d$ subshells, making the latter lower in energy. Consequently, *all transition-metal cations possess d^n valence electron configurations*, as shown in [Table 21.1.2](#) for the $2+$ ions of the first-row transition metals.

Note the Pattern

All transition-metal cations have d^n electron configurations; the ns electrons are *always* lost *before* the $(n-1)d$ electrons.

Table 21.1.2 d -Electron Configurations of the Dications of the First-Row Transition Metals

Ti^{2+}	V^{2+}	Cr^{2+}	Mn^{2+}	Fe^{2+}	Co^{2+}	Ni^{2+}	Cu^{2+}	Zn^{2+}
d^2	d^3	d^4	d^5	d^6	d^7	d^8	d^9	d^{10}

The most common oxidation states of the first-row transition metals are shown in [Table 21.1.3](#). The second- and third-row transition metals behave similarly but with three important differences:

1. The maximum oxidation states observed for the second- and third-row transition metals in groups 3–8 increase from +3 for Y and La to +8 for Ru and Os, corresponding to the formal loss of all ns and $(n-1)d$ valence electrons. As we go farther to the right, the maximum oxidation state decreases steadily, reaching +2 for the elements of group 12 (Zn, Cd, and Hg), which corresponds to a filled $(n-1)d$ subshell.
2. Within a group, higher oxidation states become more stable down the group. For example, the chromate ion ($[CrO_4]^{2-}$) is a powerful oxidant, whereas the tungstate ion ($[WO_4]^{2-}$) is extremely stable and has essentially no tendency to act as an oxidant.

3. Cations of the second- and third-row transition metals in lower oxidation states (+2 and +3) are much more easily oxidized than the corresponding ions of the first-row transition metals. For example, the most stable compounds of chromium are those of Cr(III), but the corresponding Mo(III) and W(III) compounds are highly reactive. In fact, they are often *pyrophoric*, bursting into flames on contact with atmospheric oxygen. As we shall see, the heavier elements in each group form stable compounds in higher oxidation states that have no analogues with the lightest member of the group.

Note the Pattern

The highest possible oxidation state, corresponding to the formal loss of all valence electrons, becomes increasingly less stable as we go from group 3 to group 8, and it is never observed in later groups.

Note the Pattern

In the transition metals, the stability of higher oxidation states increases down a column.

Table 21.1.3 Common Oxidation States of the First-Row Transition Metals*

	Sc	Ti	V	Cr	Mn	Fe	Co	Ni	Cu	Zn

***The convention of using roman numerals to indicate the oxidation states of a metal is used here.**

Binary transition-metal compounds, such as the oxides and sulfides, are usually written with idealized stoichiometries, such as FeO or FeS, but these compounds are usually cation deficient and almost never contain a 1:1 cation:anion ratio. Thus a substance such as ferrous oxide is actually a nonstoichiometric compound with a range of compositions.

The acid–base character of transition-metal oxides depends strongly on the oxidation state of the metal and its ionic radius. Oxides of metals in lower oxidation states (less than or equal to +3) have significant ionic character and tend to be basic. Conversely, oxides of metals in higher oxidation states are more covalent and tend to be acidic, often dissolving in strong base to form oxoanions.

Example 21.1.1

Two of the group 8 metals (Fe, Ru, and Os) form stable oxides in the +8 oxidation state. Identify these metals; predict the stoichiometry of the oxides; describe the general physical and chemical properties, type of bonding, and physical state of the oxides; and decide whether they are acidic or basic oxides.

Given: group 8 metals

Asked for: identity of metals and expected properties of oxides in +8 oxidation state

Strategy:

Refer to the trends outlined in [Figure 21.1.1](#), [Figure 21.1.2](#), [Table 21.1.1](#), [Table 21.1.2](#), and [Table 21.1.3](#) to identify the metals. Decide whether their oxides are covalent or ionic in character, and, based on this, predict the general physical and chemical properties of the oxides.

Solution:

The +8 oxidation state corresponds to a stoichiometry of MO_4 . Because the heavier transition metals tend to be stable in higher oxidation states, we expect Ru and Os to form the most stable tetroxides. Because oxides of metals in high oxidation states are generally covalent compounds, RuO_4 and OsO_4 should be volatile solids or liquids that consist of discrete MO_4 molecules, which the valence-shell electron-pair repulsion (VSEPR) model predicts to be tetrahedral. Finally, because oxides of transition metals in high oxidation states are usually acidic, RuO_4 and OsO_4 should dissolve in strong aqueous base to form oxoanions.

Exercise

Predict the identity and stoichiometry of the stable group 9 bromide in which the metal has the lowest oxidation state and describe its chemical and physical properties.

Answer: Because the lightest element in the group is most likely to form stable compounds in lower oxidation states, the bromide will be CoBr_2 . We predict that CoBr_2 will be an ionic solid with a relatively high melting point and that it will dissolve in water to give the Co^{2+} (aq) ion.

Summary

The transition metals are characterized by partially filled d subshells in the free elements and cations. The ns and $(n - 1)d$ subshells have similar energies, so small influences can produce electron configurations that do not conform to the general order in which the subshells are filled. In the second- and third-row transition metals, such irregularities can be difficult to predict, particularly for the third row, which has $4f$, $5d$, and $6s$ orbitals that are very close in energy. The increase in atomic radius is greater between the $3d$ and $4d$ metals than between the $4d$ and $5d$ metals because of the lanthanide contraction. Ionization energies and electronegativities increase slowly across a row, as do densities and electrical and thermal conductivities, whereas enthalpies of hydration decrease. Anomalies can be explained by the increased stabilization of half-filled and filled subshells. Transition-metal cations are formed by the initial loss of ns electrons, and many metals can form cations in several oxidation states. Higher oxidation states become progressively less stable across a row and more stable down a column. Oxides of small, highly charged metal ions tend to be acidic, whereas oxides of metals with a low charge-to-radius ratio are basic.

Key Takeaways

- Transition metals are characterized by the existence of multiple oxidation states separated by a single electron.
- Most transition-metal compounds are paramagnetic, whereas virtually all compounds of the p -block elements are diamagnetic.

Conceptual Problems

1. The transition metals show significant horizontal similarities in chemistry in addition to their vertical similarities, whereas the same cannot be said of the s -block and p -block elements. Explain why this is so.
2. The energy of the d subshell does not change appreciably in a given period. Why? What effect does this have on the ionization potentials of the transition metals? on their electronegativities?
3. Standard reduction potentials vary across the first-row transition metals. What effect does this have on the chemical reactivity of the first-row transition metals? Which two elements in this period are more active than would be expected? Why?

- Many transition metals are paramagnetic (have unpaired electrons). How does this affect electrical and thermal conductivities across the rows?
- What is the lanthanide contraction? What effect does it have on the radii of the transition metals of a given group? What effect does it have on the chemistry of the elements in a group?
- Why are the atomic volumes of the transition elements low compared with the elements of groups 1 and 2? Ir has the highest density of any element in the periodic table (22.65 g/cm³). Why?
- Of the elements Ti, Ni, Cu, and Cd, which do you predict has the highest electrical conductivity? Why?
- The chemistry of As is most similar to the chemistry of which transition metal? Where in the periodic table do you find elements with chemistry similar to that of Ge? Explain your answers.
- The coinage metals (group 11) have significant noble character. In fact, they are less reactive than the elements of group 12. Explain why this is so, referring specifically to their reactivity with mineral acids, electronegativity, and ionization energies. Why are the group 12 elements more reactive?

Structure and Reactivity

- Give the valence electron configurations of the 2+ ion for each first-row transition element. Which two ions do you expect to have the most negative E° value? Why?
- Arrange Ru⁴⁺, Cu²⁺, Zn²⁺, Ti⁴⁺, Cr³⁺, and Ni²⁺ in order of increasing radius.
- Arrange Pt²⁺, Hg²⁺, Fe²⁺, Zr²⁺, and Fe²⁺ in order of decreasing radius.
- Of Ti²⁺, V²⁺, Mn²⁺, Fe²⁺, Co²⁺, Ni²⁺, and Zn²⁺, which divalent ion has the smallest ionic radius? Explain your reasoning.

Answers

- Ti²⁺, 3d; V²⁺, 3d; Cr³⁺, 3d; Mn²⁺, 3d; Fe²⁺, 3d; Co²⁺, 3d; Ni²⁺, 3d; Cu²⁺, 3d; Zn²⁺, 3d. Because Z_{eff} increases from left to right, Ti²⁺ and V²⁺ will have the most negative reduction potentials (be most difficult to reduce).
-
- Hg²⁺ > Fe²⁺ > Zr⁴⁺ > Fe³⁺ > Pt⁴⁺

Chapter 21.2: A Brief Survey of Transition Metal Chemistry

Howard University General Chemistry: An Atoms First Approach

Unit 1: Atomic Theory
Unit 5: States of Matter

Unit 2: Molecular Structure
Unit 6: Kinetics & Equilibria

Unit 3: Stoichiometry
Unit 7: Electro & Thermo Chemistry

Unit 4: Thermochem & Gases
Unit 8: Materials

Learning Objective

- To use periodic trends to understand the chemistry of the transition metals.

We turn now to a brief survey of the chemistry of the transition metals, beginning with group 3. As we shall see, the two heaviest members of each group usually exhibit substantial similarities in chemical behavior and are quite different from the lightest member.

Groups 3, 4, and 5

Group 3 (Sc, Y, La, and Ac)

As shown in Table 21.2.1, the observed trends in the properties of the group 3 elements are similar to those of groups 1 and 2. Due to their $ns(n-1)d^1$ valence electron configurations, the chemistry of all four elements is dominated by the +3 oxidation state formed by losing all three valence electrons. As expected based on periodic trends, these elements are highly electropositive metals and powerful reductants, with La (and Ac) being the most reactive. In keeping with their highly electropositive character, the group 3 metals react with water to produce the metal hydroxide and hydrogen gas:

Note the Pattern

The chemistry of the group 3 metals is almost exclusively that of the M^{3+} ion; the elements are powerful reductants.

Moreover, all dissolve readily in aqueous acid to produce hydrogen gas and a solution of the hydrated metal ion: $M^{3+}(aq)$.

Table 21.2.1 Some Properties of the Elements of Groups 3, 4, and 5

Group	Element	Z	Valence Electron Configuration	Electronegativity	Metallic Radius (pm)	Melting Point (°C)	Density (g/cm ³)
3	Sc	21	$4s^2 3d^1$	1.36	162	1541	2.99
	Y	39	$5s^2 4d^1$	1.22	180	1522	4.47
	La	57	$6s^2 5d^1$	1.10	183	918	6.15
	Ac	89	$7s^2 6d^1$	1.10	188	1051	10.07
4	Ti	22	$4s^2 3d^2$	1.54	147	1668	4.51
	Zr	40	$5s^2 4d^2$	1.33	160	1855	6.52

Group	Element	Z	Valence Electron Configuration	Electronegativity	Metallic Radius (pm)	Melting Point (°C)	Density (g/cm ³)
	Hf	72	6s ² 5d ² 4f ¹⁴	1.30	159	2233	13.31
5	V	23	4s ² 3d ³	1.63	134	1910	6.00
	Nb	41	5s ² 4d ³	1.60	146	2477	8.57
	Ta	73	6s ² 5d ³ 4f ¹⁴	1.50	146	3017	16.65

The group 3 metals react with nonmetals to form compounds that are primarily ionic in character. For example, reacting group 3 metals with the halogens produces the corresponding trihalides: MX₃. The trifluorides are insoluble in water because of their high lattice energies, but the other trihalides are very soluble in water and behave like typical ionic metal halides. All group 3 elements react with air to form an oxide coating, and all burn in oxygen to form the so-called *sesquioxides* (M₂O₃), which react with H₂O or CO₂ to form the corresponding hydroxides or carbonates, respectively. Commercial uses of the group 3 metals are limited, but “mischmetal,” a mixture of lanthanides containing about 40% La, is used as an additive to improve the properties of steel and make flints for cigarette lighters.

Group 4 (Ti, Zr, and Hf)

Because the elements of group 4 have a high affinity for oxygen, all three metals occur naturally as oxide ores that contain the metal in the +4 oxidation state resulting from losing all four $ns(n-1)d^2$ valence electrons. They are isolated by initial conversion to the tetrachlorides, as shown for Ti:

followed by reduction of the tetrachlorides with an active metal such as Mg.

Note the Pattern

The chemistry of the group 4 metals is dominated by the +4 oxidation state. Only Ti has an extensive chemistry in lower oxidation states.

In contrast to the elements of group 3, the group 4 elements have important applications. Titanium (melting point = 1668°C) is often used as a replacement for aluminum (melting point = 660°C) in applications that require high temperatures or corrosion resistance. For example, friction with the air heats the skin of supersonic aircraft operating above Mach 2.2 to temperatures near the melting point of aluminum; consequently, titanium is used instead of aluminum in many aerospace applications. The corrosion resistance of titanium is increasingly exploited in architectural applications, as shown in the chapter-opening photo. Metallic zirconium is used in UO₂-containing fuel rods in nuclear reactors, while hafnium is used in the control rods that modulate the output of high-power nuclear reactors, such as those in nuclear submarines.

Consistent with the periodic trends shown in Figure 21.1.2, the group 4 metals become denser, higher melting, and more electropositive down the column (Table 21.2.1). Unexpectedly, however, the atomic radius of Hf is slightly *smaller* than that of Zr due to the lanthanide contraction. Because of their $ns(n-1)d^2$ valence electron configurations, the +4 oxidation state is by far the most important for all three metals. Only titanium exhibits a significant chemistry in the +2 and +3 oxidation states, although compounds of Ti²⁺ are usually powerful reductants. In fact, the Ti²⁺(aq) ion is such a strong reductant that it rapidly reduces water to form hydrogen gas.

Reaction of the group 4 metals with excess halogen forms the corresponding tetrahalides (MX₄), although titanium, the lightest element in the group, also forms dihalides and trihalides (X is not F). The covalent character of the titanium halides increases as the oxidation state of the metal increases because of increasing polarization of the anions by the cation as its charge-to-radius ratio increases. Thus TiCl₂ is an ionic salt, whereas TiCl₄ is a volatile liquid that contains tetrahedral molecules. All three metals react

with excess oxygen or the heavier chalcogens (Y) to form the corresponding dioxides (MO_2) and dichalcogenides (MY_2). Industrially, TiO_2 , which is used as a white pigment in paints, is prepared by reacting TiCl_4 with oxygen at high temperatures:

The group 4 dichalcogenides have unusual layered structures with no M–Y bonds holding adjacent sheets together, which makes them similar in some ways to graphite (Figure 21.2.1). The group 4 metals also react with hydrogen, nitrogen, carbon, and boron to form hydrides (such as TiH_2), nitrides (such as TiN), carbides (such as TiC), and borides (such as TiB_2), all of which are hard, high-melting solids. Many of these binary compounds are nonstoichiometric and exhibit metallic conductivity.

Figure 21.2.1 The Layered Structure of TiS_2 Each titanium atom is surrounded by an octahedral arrangement of six sulfur atoms that are shared to form extended layers of atoms. Because the layers are held together by only van der Waals forces between adjacent sulfur atoms, rather than covalent bonds, the layers slide past one another relatively easily when a mechanical stress is applied.

Group 5 (V, Nb, and Ta)

Like the group 4 elements, all group 5 metals are normally found in nature as oxide ores that contain the metals in their highest oxidation state (+5). Because of the lanthanide contraction, the chemistry of Nb and Ta is so similar that these elements are usually found in the same ores.

Three-fourths of the vanadium produced annually is used in the production of steel alloys for springs and high-speed cutting tools. Adding a small amount of vanadium to steel results in the formation of small grains of V_4C_3 , which greatly increase the strength and resilience of the metal, especially at high temperatures. The other major use of vanadium is as V_2O_5 , an important catalyst for the industrial conversion of SO_2 to SO_3 in the contact process for the production of sulfuric acid. In contrast, Nb and Ta have only limited applications, and they are therefore produced in relatively small amounts. Although niobium is used as an additive in certain stainless steels, its primary application is in superconducting wires such as Nb_3Zr and Nb_3Ge , which are used in superconducting magnets for the magnetic resonance imaging of soft tissues. Because tantalum is highly resistant to corrosion, it is used as a liner for chemical reactors, in missile parts, and as a biologically compatible material in screws and pins for repairing fractured bones.

Note the Pattern

The chemistry of the two heaviest group 5 metals (Nb and Ta) is dominated by the +5 oxidation state. The chemistry of the lightest element (V) is dominated by lower oxidation states, especially +4.

As indicated in Table 21.2.1, the trends in properties of the group 5 metals are similar to those of group 4. Only vanadium, the lightest element, has any tendency to form compounds in oxidation states lower than +5. For example, vanadium is the only

element in the group that forms stable halides in the lowest oxidation state (+2). All three metals react with excess oxygen, however, to produce the corresponding oxides in the +5 oxidation state (M_2O_5), in which polarization of the oxide ions by the high-oxidation-state metal is so extensive that the compounds are primarily covalent in character. Vanadium–oxygen species provide a classic example of the effect of increasing metal oxidation state on the protonation state of a coordinated water molecule: vanadium(II) in water exists as the violet hydrated ion $[V(H_2O)_6]^{2+}$; the blue-green $[V(H_2O)_6]^{3+}$ ion is acidic, dissociating to form small amounts of the $[V(H_2O)_5(OH)]^{2+}$ ion and a proton; and in water, vanadium(IV) forms the blue vanadyl ion $[(H_2O)_4VO]^{2+}$, which contains a formal $V=O$ bond (Figure 21.2.1). Consistent with its covalent character, V_2O_5 is acidic, dissolving in base to give the vanadate ion ($[VO_4]^{3-}$), whereas both Nb_2O_5 and Ta_2O_5 are comparatively inert. Oxides of these metals in lower oxidation states tend to be nonstoichiometric.

Although group 5 metals react with the heavier chalcogens to form a complex set of binary chalcogenides, the most important are the dichalcogenides (MY_2), whose layered structures are similar to those of the group 4 dichalcogenides. The elements of group 5 also form binary nitrides, carbides, borides, and hydrides, whose stoichiometries and properties are similar to those of the corresponding group 4 compounds. One such compound, tantalum carbide (TiC), has the highest melting point of any compound known (3738°C); it is used for the cutting edges of high-speed machine tools.

Groups 6 and 7

Group 6 (Cr, Mo, and W)

As an illustration of the trend toward increasing polarizability as we go from left to right across the d block, in group 6 we first encounter a metal (Mo) that occurs naturally as a sulfide ore rather than as an oxide. Molybdenite (MoS_2) is a soft black mineral that can be used for writing, like PbS and graphite. Because of this similarity, people long assumed that these substances were all the same. In fact, the name *molybdenum* is derived from the Greek *molybdos*, meaning “lead.” More than 90% of the molybdenum produced annually is used to make steels for cutting tools, which retain their sharp edge even when red hot. In addition, molybdenum is the only second- or third-row transition element that is essential for humans. The major chromium ore is chromite ($FeCr_2O_4$), which is oxidized to the soluble $[CrO_4]^{2-}$ ion under basic conditions and reduced successively to Cr_2O_3 and Cr with carbon and aluminum, respectively. Pure chromium can be obtained by dissolving Cr_2O_3 in sulfuric acid followed by electrolytic reduction; a similar process is used for electroplating metal objects to give them a bright, shiny, protective surface layer. Pure tungsten is obtained by first converting tungsten ores to WO_3 , which is then reduced with hydrogen to give the metal.

Consistent with periodic trends, the group 6 metals are slightly less electropositive than those of the three preceding groups, and the two heaviest metals are essentially the same size because of the lanthanide contraction (Table 21.2.2). All three elements have a total of six valence electrons, resulting in a maximum oxidation state of +6. Due to extensive polarization of the anions, compounds in the +6 oxidation state are highly covalent. As in groups 4 and 5, the lightest element exhibits variable oxidation states, ranging from Cr^{2+} , which is a powerful reductant, to CrO_3 , a red solid that is a powerful oxidant. For Mo and W, the highest oxidation state (+6) is by far the most important, although compounds in the +4 and +5 oxidation states are known.

Figure 21.2.2 Aqueous Solutions of Vanadium Ions in Oxidation States of +2 to +5 Because vanadium ions with different oxidation states have different numbers of d electrons, aqueous solutions of the ions have different colors: in acid $V(V)$ forms the pale yellow $[VO_2]^+$ ion; $V(IV)$ is the blue vanadyl ion $[VO]^{2+}$; and $V(III)$ and $V(II)$ exist as the hydrated V^{3+} (blue-green) and V^{2+} (violet) ions, respectively.

Note the Pattern

The metals become increasingly polarizable across the d block.

Table 21.2.2 Some Properties of the Elements of Groups 6 and 7

Group	Element	Z	Valence Electron Configuration	Electronegativity	Metallic Radius (pm)	Melting Point (°C)	Density (g/cm ³)
6	Cr	24	$4s^1 3d^5$	1.66	128	1907	7.15
	Mo	42	$5s^1 4d^5$	2.16	139	2623	10.20
	W	74	$6s^2 5d^4 4f^{14}$	1.70	139	3422	19.30
7	Mn	25	$4s^2 3d^5$	1.55	127	1246	7.30
	Tc	43	$5s^2 4d^5$	2.10	136	2157	11.50
	Re	75	$6s^2 5d^5 4f^{14}$	1.90	137	3186	20.80

Note the Pattern

The chemistry of the two heaviest group 6 metals (Mo and W) is dominated by the +6 oxidation state. The chemistry of the lightest element (Cr) is dominated by lower oxidation states.

As observed in previous groups, the group 6 halides become more covalent as the oxidation state of the metal increases: their volatility increases, and their melting points decrease. Recall that as the electronegativity of the halogens decreases from F to I, they are less able to stabilize high oxidation states; consequently, the maximum oxidation state of the corresponding metal halides decreases. Thus all three metals form hexafluorides, but CrF_6 is unstable at temperatures above -100°C , whereas MoF_6 and WF_6 are stable. Consistent with the trend toward increased stability of the highest oxidation state for the second- and third-row elements, the other halogens can oxidize chromium to only the trihalides, CrX_3 (X is Cl, Br, or I), while molybdenum forms MoCl_5 , MoBr_4 , and MoI_3 , and tungsten gives WCl_6 , WBr_5 , and WI_4 .

Both Mo and W react with oxygen to form the covalent trioxides (MoO_3 and WO_3), but Cr reacts to form only the so-called sesquioxide (Cr_2O_3). Chromium will form CrO_3 , which is a highly toxic compound that can react explosively with organic materials. All the trioxides are acidic, dissolving in base to form the corresponding oxoanions ($[\text{MO}_4]^{2-}$). Consistent with periodic trends, the sesquioxide of the lightest element in the group (Cr_2O_3) is amphoteric. The aqueous chemistry of molybdate and tungstate is complex, and at low pH they form a series of polymeric anions called *isopolymetallates*, such as the $[\text{Mo}_8\text{O}_{26}]^{4-}$ ion, whose structure is as follows:

An isopolymolybdate cluster. The $[\text{Mo}_8\text{O}_{26}]^{4-}$ ion, shown here in both side and top views, is typical of the oxygen-bridged clusters formed by Mo(VI) and W(VI) in aqueous solution.

Reacting molybdenum or tungsten with heavier chalcogens gives binary chalcogenide phases, most of which are nonstoichiometric and electrically conducting. One of the most stable is MoS_2 ; it has a layered structure similar to that of TiS_2 (Figure 21.2.1), in which the layers are held together by only weak van der Waals forces, which allows them to slide past one another rather easily. Consequently, both MoS_2 and WS_2 are used as lubricants in a variety of applications, including automobile engines. Because tungsten itself has an extraordinarily high melting point (3380°C), lubricants described as containing “liquid tungsten” actually contain a suspension of very small WS_2 particles.

As in groups 4 and 5, the elements of group 6 form binary nitrides, carbides, and borides whose stoichiometries and properties are similar to those of the preceding groups. Tungsten carbide (WC), one of the hardest compounds known, is used to make the tips of drill bits.

Group 7 (Mn, Tc, and Re)

Continuing across the periodic table, we encounter the group 7 elements (Table 21.1.2). One group 7 metal (Mn) is usually combined with iron in an alloy called *ferromanganese*, which has been used since 1856 to improve the mechanical properties of steel by scavenging sulfur and oxygen impurities to form MnS and MnO. Technetium is named after the Greek *technikos*, meaning “artificial,” because all its isotopes are radioactive. One isotope, ^{99m}Tc (*m* for metastable), has become an important biomedical tool for imaging internal organs. (For more information on biomedical imaging, see Section 24.5) Because of its scarcity, Re is one of the most expensive elements, and its applications are limited. It is, however, used in a bimetallic Pt/Re catalyst for refining high-octane gasoline.

All three group 7 elements have seven valence electrons and can form compounds in the +7 oxidation state. Once again, the lightest element exhibits multiple oxidation states. Compounds of Mn in oxidation states ranging from -3 to $+7$ are known, with the most common being $+2$ and $+4$ (Figure 21.2.3). In contrast, compounds of Tc and Re in the $+2$ oxidation state are quite rare. Because the electronegativity of Mn is anomalously low, elemental manganese is unusually reactive. In contrast, the chemistry of Tc is similar to that of Re because of their similar size and electronegativity, again a result of the lanthanide contraction. Due to the stability of the half-filled $3d^5$ electron configuration, the aqueous Mn^{3+} ion, with a $3d^4$ valence electron configuration, is a potent oxidant that is able to oxidize water. It is difficult to generalize about other oxidation states for Tc and Re because their stability depends dramatically on the nature of the compound.

Consistent with higher oxidation states being more stable for the heavier transition metals, reacting Mn with F_2 gives only MnF_3 , a high-melting, red-purple solid, whereas Re reacts with F_2 to give ReF_7 , a volatile, low-melting, yellow solid. Again, reaction with the less oxidizing, heavier halogens produces halides in lower oxidation states. Thus reaction with Cl_2 , a weaker oxidant than F_2 , gives MnCl_2 and ReCl_6 . Reaction of Mn with oxygen forms only Mn_3O_4 , a mixed-valent compound that contains two Mn(II) and one Mn(III) per formula unit and is similar in both stoichiometry and structure to magnetite (Fe_3O_4). In contrast, Tc and Re form high-valent oxides, the so-called *heptoxides* (M_2O_7), consistent with the increased stability of higher oxidation states for the second and third rows of transition metals. Under forced conditions, manganese will form Mn_2O_7 , an unstable, explosive, green liquid. Also consistent with this trend, the permanganate ion $[\text{MnO}_4]^-$ is a potent oxidant, whereas $[\text{TcO}_4]^-$ and $[\text{ReO}_4]^-$ are much more stable. Both Tc and Re form disulfides and diselenides with layered structures analogous to that of MoS_2 , as well as more complex *heptasulfides* (M_2S_7). As is typical of the transition metals, the group 7 metals form binary nitrides, carbides, and borides that are generally stable at high temperatures and exhibit metallic properties.

Figure 21.2.3 Compounds of Manganese in Oxidation States $+2$ to $+7$ Like vanadium, compounds of manganese in different oxidation states have different numbers of *d* electrons, which leads to compounds with different colors: the $\text{Mn}^{2+}(\text{aq})$ ion is pale pink; $\text{Mn}(\text{OH})_3$, which contains Mn(III), is a dark brown solid; MnO_2 , which contains Mn(IV), is a black solid; and aqueous solutions of Mn(VI) and Mn(VII) contain the green manganate ion $[\text{MnO}_4]^{2-}$ and the purple permanganate ion $[\text{MnO}_4]^-$, respectively.

Note the Pattern

The chemistry of the group 7 metals (Mn, Tc, and Re) is dominated by lower oxidation states. Compounds in the maximum possible oxidation state ($+7$) are readily reduced.

Groups 8, 9, and 10

In many older versions of the periodic table, groups 8, 9, and 10 were combined in a single group (group VIII) because the elements of these three groups exhibit many horizontal similarities in their chemistry, in addition to the similarities within each column. In part, these horizontal similarities are due to the fact that the ionization potentials of the elements, which increase slowly but steadily across the *d* block, have now become so large that the oxidation state corresponding to the formal loss of all valence electrons is encountered only rarely (group 8) or not at all (groups 9 and 10). As a result, the chemistry of all three groups is dominated by intermediate oxidation states, especially +2 and +3 for the first-row metals (Fe, Co, and Ni). The heavier elements of these three groups are called *precious metals* because they are rather rare in nature and mostly chemically inert.

Note the Pattern

The chemistry of groups 8, 9, and 10 is dominated by intermediate oxidation states such as +2 and +3.

Group 8 (Fe, Ru, and Os)

The chemistry of group 8 is dominated by iron, whose high abundance in Earth's crust is due to the extremely high stability of its nucleus. Ruthenium and osmium, on the other hand, are extremely rare elements, with terrestrial abundances of only about 0.1 ppb and 5 ppb, respectively, and they were not discovered until the 19th century. Because of the high melting point of iron (1538°C), early humans could not use it for tools or weapons. The advanced techniques needed to work iron were first developed by the Hittite civilization in Asia Minor sometime before 2000 BC, and they remained a closely guarded secret that gave the Hittites military supremacy for almost a millennium. With the collapse of the Hittite civilization around 1200 BC, the technology became widely distributed, however, leading to the Iron Age.

Group 9 (Co, Rh, and Ir)

Cobalt is one of the least abundant of the first-row transition metals. Its oxide ores, however, have been used in glass and pottery for thousands of years to produce the brilliant color known as "cobalt blue," and its compounds are consumed in large quantities in the paint and ceramics industries. The heavier elements of group 9 are also rare, with terrestrial abundances of less than 1 ppb; they are generally found in combination with the heavier elements of groups 8 and 10 in Ni–Cu–S ores.

Group 10 (Ni, Pd, and Pt)

Nickel silicates are easily processed; consequently, nickel has been known and used since antiquity. In fact, a 75:25 Cu:Ni alloy was used for more than 2000 years to mint "silver" coins, and the modern US nickel uses the same alloy. In contrast to nickel, palladium and platinum are rare (their terrestrial abundance is about 10–15 ppb), but they are at least an order of magnitude more abundant than the heavier elements of groups 8 and 9. Platinum and palladium are used in jewelry, the former as the pure element and the latter as the Pd/Au alloy known as *white gold*.

Trends in Group 8, 9, and 10

Some properties of the elements in groups 8–10 are summarized in [Table 21.2.3](#). As in earlier groups, similarities in size and electronegativity between the two heaviest members of each group result in similarities in chemistry. We are now at the point in the *d* block where there is no longer a clear correlation between the valence electron configuration and the preferred oxidation state. For example, all the elements of group 8 have eight valence electrons, but only Ru and Os have any tendency to form compounds in the +8 oxidation state, and those compounds are powerful oxidants. The predominant oxidation states for all three group 8 metals are +2 and +3. Although the elements of group 9 possess a total of nine valence electrons, the +9 oxidation state is unknown for these elements, and the most common oxidation states in the group are +3 and +1. Finally, the elements of group 10 all have 10 valence electrons, but all three elements are normally found in the +2 oxidation state formed by losing the ns^2 valence electrons. In addition, Pd and Pt form numerous compounds and complexes in the +4 oxidation state.

Over 2000 years ago, the Bactrian civilization in Western Asia used a 75:25 alloy of copper and nickel for its coins. A modern US nickel has the same composition, but a modern Canadian nickel is nickel-plated steel and contains only 2.5% nickel by mass.

Table 21.2.3 Some Properties of the Elements of Groups 8, 9, and 10

Group	Element	Z	Valence Electron Configuration n	Electronegativity	Metallic Radius (pm)	Melting Point (°C)	Density (g/cm ³)
8	Fe	26	4s ² 3d ⁶	1.83	126	1538	7.87
	Ru	44	5s ¹ 4d ⁷	2.20	134	2334	12.10
	Os	76	6s ² 5d ⁶ 4f ¹⁴	2.20	135	3033	22.59
9	Co	27	4s ² 3d ⁷	1.88	125	1495	8.86
	Rh	45	5s ¹ 4d ⁸	2.28	134	1964	12.40
	Ir	77	6s ² 5d ⁷ 4f ¹⁴	2.20	136	2446	22.50
10	Ni	28	4s ² 3d ⁸	1.91	124	1455	8.90
	Pd	46	4d ¹⁰	2.20	137	1555	12.00
	Pt	78	6s ² 5d ⁸ 4f ¹⁴	2.20	139	1768	21.50

We stated that higher oxidation states become less stable as we go across the *d*-block elements and more stable as we go down a group. Thus Fe and Co form trifluorides, but Ni forms only the difluoride NiF₂. In contrast to Fe, Ru and Os form a series of fluorides up to RuF₆ and OsF₇. The hexafluorides of Rh and Ir are extraordinarily powerful oxidants, and Pt is the only element in group 10 that forms a hexafluoride. Similar trends are observed among the oxides. For example, Fe forms only FeO, Fe₂O₃, and the mixed-valent Fe₃O₄ (magnetite), all of which are nonstoichiometric. In contrast, Ru and Os form the dioxides (MO₂) and the highly toxic, volatile, yellow tetroxides, which contain formal M=O bonds. As expected for compounds of metals in such high oxidation states, the latter are potent oxidants. The tendency of the metals to form the higher oxides decreases rapidly as we go farther across the *d* block.

Note the Pattern

Higher oxidation states become less stable across the *d*-block, but more stable down a group.

Reactivity with the heavier chalcogens is rather complex. Thus the oxidation state of Fe, Ru, Os, Co, and Ni in their disulfides is +2 because of the presence of the disulfide ion (S₂²⁻), but the disulfides of Rh, Ir, Pd, and Pt contain the metal in the +4 oxidation state together with sulfide ions (S²⁻). This combination of highly charged cations and easily polarized anions results in substances that are not simple ionic compounds and have significant covalent character.

The groups 8–10 metals form a range of binary nitrides, carbides, and borides. By far the most important of these is cementite (Fe₃C), which is used to strengthen steel. At high temperatures, Fe₃C is soluble in iron, but slow cooling causes the phases to separate and form particles of cementite, which gives a metal that retains much of its strength but is significantly less brittle than pure iron. Palladium is unusual in that it forms a binary hydride with the approximate composition PdH_{0.5}. Because the H atoms in the metal lattice are highly mobile, thin sheets of Pd are highly permeable to H₂ but essentially impermeable to all other gases, including He. Consequently, diffusion of H₂ through Pd is an effective method for separating hydrogen from other gases.

Groups 11 and 12

Group 11 (Cu, Ag, and Au)

The coinage metals—copper, silver, and gold—occur naturally (like the gold nugget shown here); consequently, these were probably the first metals used by ancient humans. For example, decorative gold artifacts dating from the late Stone Age are known, and some gold Egyptian coins are more than 5000 yr old. Copper is almost as ancient, with objects dating to about 5000 BC.

Bronze, an alloy of copper and tin that is harder than either of its constituent metals, was used before 3000 BC, giving rise to the Bronze Age. Deposits of silver are much less common than deposits of gold or copper, yet by 3000 BC, methods had been developed for recovering silver from its ores, which allowed silver coins to be widely used in ancient times.

Deposits of gold and copper are widespread and numerous, and for many centuries it was relatively easy to obtain large amounts of the pure elements. For example, a single gold nugget discovered in Australia in 1869 weighed more than 150 lb. Because the demand for these elements has outstripped their availability, methods have been developed to recover them economically from even very low-grade ores (as low as 1% Cu content for copper) by operating on a vast scale, as shown in the photo of an open-pit copper mine. Copper is used primarily to manufacture electric wires, but large quantities are also used to produce bronze, brass, and alloys for coins. Much of the silver made today is obtained as a by-product of the manufacture of other metals, especially Cu, Pb, and Zn. In addition to its use in jewelry and silverware, silver is used in Ag/Zn and Ag/Cd button batteries. (For more information on button batteries, see [Section 18.5](#).) Gold is typically found either as tiny particles of the pure metal or as gold telluride (AuTe_2). It is used as a currency reserve, in jewelry, in the electronics industry for corrosion-free contacts, and, in very thin layers, as a reflective window coating that minimizes heat transfer.

This 1 kg gold nugget was found in Australia; in 2005, it was for sale in Hong Kong at an asking price of more than US\$64,000.

Some properties of the coinage metals are listed in [Table 21.2.4](#). The electronegativity of gold ($\chi = 2.40$) is close to that of the nonmetals sulfur and iodine, which suggests that the chemistry of gold should be somewhat unusual for a metal. The coinage metals have the highest electrical and thermal conductivities of all the metals, and they are also the most ductile and malleable. With an $ns(n-1)d^{10}$ valence electron configuration, the chemistry of these three elements is dominated by the +1 oxidation state due to losing the single ns electron. Higher oxidation states are also known, however: +2 is common for Cu and, to a lesser extent, Ag, and +3 for Au because of the relatively low values of the second and (for Au) third ionization energies. All three elements have significant electron affinities due to the half-filled ns orbital in the neutral atoms. As a result, gold reacts with powerful reductants like C_2S_{10} and solutions of the alkali metals in liquid ammonia to produce the gold anion Au^- with a $6s^2 5d^{10}$ valence electron configuration.

The Chuquibambilla copper mine in northern Chile, the world's largest open-pit copper mine, is 4.3 km long, 3 km wide, and 825 m deep. Each gigantic truck in the foreground (and barely visible in the lower right center) can hold 330 metric tn (330,000 kg) of copper ore.

Table 21.2.4 Some Properties of the Elements of Groups 11 and 12

Group	Element	Z	Valence Electron Configuration	Electronegativity	Metallic Radius (pm)	Melting Point (°C)	Density (g/cm ³)
11	Cu	29	$4s^1 3d^{10}$	1.90	128	1085	8.96
	Ag	47	$5s^1 4d^{10}$	1.93	144	962	10.50
	Au	79	$6s^1 5d^{10} 4f^{14}$	2.40	144	1064	19.30
12	Zn	30	$4s^2 3d^{10}$	1.65	134	420	7.13
	Cd	48	$5s^2 4d^{10}$	1.69	149	321	8.69
	Hg	80	$6s^2 5d^{10} 4f^{14}$	1.90	151	-38.8	13.53

All group 11 elements are relatively unreactive, and their reactivity decreases from Cu to Au. Hence they are noble metals that are particularly well suited for use in coins and jewelry. Copper reacts with O_2 at high temperatures to produce Cu_2O and with sulfur to

form Cu_2S . Neither silver nor gold reacts directly with oxygen, although oxides of these elements can be prepared by other routes. Silver reacts with sulfur compounds to form the black Ag_2S coating known as tarnish. Gold is the only metal that does not react with sulfur; it also does not react with nitrogen, carbon, or boron. All the coinage metals do, however, react with oxidizing acids. Thus both Cu and Ag dissolve in HNO_3 and in hot concentrated H_2SO_4 , while Au dissolves in the 3:1 $\text{HCl}:\text{HNO}_3$ mixture known as *aqua regia*. Furthermore, all three metals dissolve in basic cyanide solutions in the presence of oxygen to form very stable $[\text{M}(\text{CN})_2]^-$ ions, a reaction that is used to separate gold from its ores.

Note the Pattern

Although the most important oxidation state for group 11 is +1, the elements are relatively unreactive, with reactivity decreasing from Cu to Au.

All the monohalides except CuF and AuF are known (including AgF). Once again, iodine is unable to stabilize the higher oxidation states (Au^{3+} and Cu^{2+}). Thus all the copper(II) halides except the iodide are known, but the only dihalide of silver is AgF_2 . In contrast, all the gold trihalides (AuX_3) are known, again except the triiodide. No binary nitrides, borides, or carbides are known for the group 11 elements.

Group 12 (Zn, Cd, and Hg)

We next encounter the group 12 elements. Because none of the elements in group 12 has a partially filled $(n-1)d$ subshell, they are not, strictly speaking, transition metals. Nonetheless, much of their chemistry is similar to that of the elements that immediately precede them in the d block. The group 12 metals are similar in abundance to those of group 11, and they are almost always found in combination with sulfur. Because zinc and cadmium are chemically similar, virtually all zinc ores contain significant amounts of cadmium. All three metals are commercially important, although the use of Cd is restricted because of its toxicity. Zinc is used for corrosion protection, in batteries, to make brass, and, in the form of ZnO , in the production of rubber and paints. (For more information on corrosion, see [Section 18.6](#).) Cadmium is used as the cathode in rechargeable NiCad batteries. Large amounts of mercury are used in the production of chlorine and NaOH by the chloralkali process, while smaller amounts are consumed in mercury-vapor streetlights and mercury batteries. (For more information on the uses of mercury, see [Section 18.5](#).)

As shown in [Table 21.2.4](#), the group 12 metals are significantly more electropositive than the elements of group 11, and they therefore have less noble character. They also have much lower melting and boiling points than the preceding transition metals. In contrast to trends in the preceding groups, Zn and Cd are similar to each other, but very different from the heaviest element (Hg). In particular, Zn and Cd are rather active metals, whereas mercury is not. Because mercury, the only metal that is a liquid at room temperature, can dissolve many metals by forming amalgams, medieval alchemists especially valued it when trying to transmute base metals to gold and silver. All three elements in group 12 have $ns^2(n-1)d^{10}$ valence electron configurations; consequently, the +2 oxidation state, corresponding to losing the two ns electrons, dominates their $2+$ chemistry. In addition, mercury forms a series of compounds in the +1 oxidation state that contain the diatomic mercurous ion Hg_2^+ .

Note the Pattern

The most important oxidation state for group 12 is +2; the metals are significantly more electropositive than the group 11 elements, so they are less noble.

All the possible group 12 dihalides (MX_2) are known, and they range from ionic (the fluorides) to highly covalent (such as HgCl_2). The highly covalent character of many mercuric and mercurous halides is surprising given the large size of the cations, and this has been attributed to the existence of an easily distorted $5d^{10}$ subshell. Zinc and cadmium react with oxygen to form amphoteric MO , whereas mercury forms HgO only within a narrow temperature range (350–400°C). Whereas zinc and cadmium dissolve in mineral acids such as HCl with the evolution of hydrogen, mercury dissolves only in oxidizing acids such as HNO_3 and H_2SO_4 . All three metals react with sulfur and the other chalcogens to form the binary chalcogenides; mercury also has an extraordinarily high affinity for sulfur.

Example 21.2.1

For each reaction, explain why the indicated products form.

- $\text{TiCl}_4(\text{l}) + 2\text{H}_2\text{O}(\text{l}) \rightarrow \text{TiO}_2(\text{s}) + 4\text{HCl}(\text{aq})$
- $\text{WO}_3(\text{s}) + 3\text{C}(\text{s}) + 3\text{Cl}_2(\text{g}) + \Delta \rightarrow \text{WCl}_6(\text{s}) + 3\text{CO}(\text{g})$
- $\text{Sc}_2\text{O}_3(\text{s}) + 2\text{OH}^-(\text{aq}) + 3\text{H}_2\text{O}(\text{l}) \rightarrow 2[\text{Sc}(\text{OH})_4]^- (\text{aq})$
- $2\text{KMnO}_4(\text{aq}) + 2\text{H}_2\text{SO}_4(\text{l}) \rightarrow \text{Mn}_2\text{O}_7(\text{l}) + 2\text{KHSO}_4(\text{soln}) + \text{H}_2\text{O}(\text{soln})$
- $4\text{CrCl}_2(\text{aq}) + \text{O}_2(\text{g}) + 4\text{H}^+(\text{aq}) \rightarrow 4\text{Cr}^{3+}(\text{aq}) + 8\text{Cl}^-(\text{aq}) + 2\text{H}_2\text{O}(\text{l})$

Given: balanced chemical equation

Asked for: why the indicated products form

Strategy:

Refer to the periodic trends in this section, [Figure 21.1.1](#), [Figure 21.1.2](#), [Figure 3.3.1](#), [Table 21.1.1](#), [Table 21.1.2](#), [Table 21.1.3](#), [Table 21.2.1](#), [Table 21.2.2](#), [Table 21.2.3](#), and [Table 21.2.4](#), to explain why these products form.

Solution:

- The most stable oxidation state for Ti is +4, and neither reactant is a particularly strong oxidant or reductant; hence a redox reaction is unlikely. Similarly, neither reactant is a particularly strong acid or base, so an acid–base reaction is unlikely. Because TiCl_4 contains Ti in a relatively high oxidation state (+4), however, it is likely to be rather covalent in character, with reactivity similar to that of a semimetal halide such as SiCl_4 . Covalent halides tend to hydrolyze in water to produce the hydrohalic acid and either the oxide of the other element or a species analogous to an oxoacid.
- This reaction involves the oxide of a group 6 metal in its highest oxidation state (WO_3) and two elements, one of which is a reductant (C) and the other an oxidant (Cl_2). Consequently, some sort of redox reaction will occur. Carbon can certainly react with chlorine to form CCl_4 , and WO_3 is a potential source of oxygen atoms that can react with carbon to produce CO, which is very stable. If CO is one of the products, then it seems likely that the other product will contain the metal and chlorine. The most likely combination is WCl_6 (leaving the oxidation state of the metal unchanged).
- One of the reactants is a strong base (OH^-), so an acid–base reaction is likely if the other reactant is acidic. Because oxides like Sc_2O_3 , in which the metal is in an intermediate oxidation state, are often amphoteric, we expect Sc_2O_3 to dissolve in base to form a soluble hydroxide complex.
- Concentrated sulfuric acid is both an oxidant and a strong acid that tends to protonate and dehydrate other substances. The permanganate ion already contains manganese in its highest possible oxidation state (+7), so it cannot be oxidized further. A redox reaction is impossible, which leaves an acid–base reaction as the most likely alternative. Sulfuric acid is likely to protonate the terminal oxygen atoms of permanganate, allowing them to be lost as water.
- Molecular oxygen is an oxidant, so a redox reaction is likely if the other reactant can be oxidized. Because chromium chloride contains chromium in its lowest accessible oxidation state, a redox reaction will occur in which Cr^{2+} ions are oxidized and O_2 is reduced. In the presence of protons, the reduction product of O_2 is water, so we need to determine only the identity of the oxidation product of Cr^{2+} . Chromium forms compounds in two common higher oxidation states: the Cr^{3+} ion, which is the most stable, and the $[\text{Cr}_2\text{O}_7]^{2-}$ ion, which is a more powerful oxidant than O_2 . We therefore predict that the reaction will form $\text{Cr}^{3+}(\text{aq})$ and water.

Exercise

Predict the products of each reactions and then balance each chemical equation.

- $\text{Cr}^{2+}(\text{aq}) + \text{Fe}^{3+}(\text{aq}) \rightarrow$ (In acidic media)
- $\text{Na}_2\text{Cr}_2\text{O}_7(\text{aq}) + \text{H}_2\text{SO}_4(\text{l}) \rightarrow$
- $\text{FeBr}_2(\text{aq}) + \text{O}_2(\text{g}) \rightarrow$ (in acidic media)
- $\text{VBr}_4(\text{l}) + \text{H}_2\text{O}(\text{l}) \rightarrow$
- $\text{ZrO}_2(\text{s}) + \text{C}(\text{s}) + \text{Cl}_2(\text{g}) + \Delta \rightarrow$

Answer:

2+ 3+ 3+ 2+

- $\text{Cr}^{3+}(\text{aq}) + \text{Fe}^{2+}(\text{aq}) + \Delta \rightarrow \text{Cr}^{2+}(\text{aq}) + \text{Fe}^{3+}(\text{aq})$
- $\text{Na}_2\text{Cr}_2\text{O}_7(\text{aq}) + 2\text{H}_2\text{SO}_4(\text{l}) \rightarrow 2\text{NaHSO}_4(\text{soln}) + \text{H}_2\text{O}(\text{soln}) + 2\text{CrO}_3(\text{s})$
- $4\text{FeBr}_2(\text{aq}) + \text{O}_2(\text{g}) + 4\text{H}_2^+(\text{aq}) \rightarrow 4\text{Fe}^{2+}(\text{aq}) + 2\text{H}_2\text{O}(\text{l}) + 8\text{Br}^-(\text{aq})$
- $\text{VBr}_4(\text{l}) + \text{H}_2\text{O}(\text{l}) \rightarrow \text{VO}^+(\text{aq}) + 4\text{Br}^-(\text{aq}) + 2\text{H}^+(\text{aq})$
- $\text{ZrO}_2(\text{s}) + 2\text{C}(\text{s}) + 2\text{Cl}_2(\text{g}) + \Delta \rightarrow \text{ZrCl}_4(\text{s}) + 2\text{CO}(\text{g})$

Summary

The group 3 transition metals are highly electropositive metals and powerful reductants. They react with nonmetals to form compounds that are largely ionic and with oxygen to form sesquioxides (M_2O_3). The group 4 metals also have a high affinity for oxygen. In their reactions with halogens, the covalent character of the halides increases as the oxidation state of the metal increases because the high charge-to-radius ratio causes extensive polarization of the anions. The dichalcogenides have layered structures similar to graphite, and the hydrides, nitrides, carbides, and borides are all hard, high-melting-point solids with metallic conductivity. The group 5 metals also have a high affinity for oxygen. Consistent with periodic trends, only the lightest (vanadium) has any tendency to form compounds in oxidation states lower than +5. The oxides are sufficiently polarized to make them covalent in character. These elements also form layered chalcogenides, as well as nitrides, carbides, borides, and hydrides that are similar to those of the group 4 elements. As the metals become more polarizable across the row, their affinity for oxygen decreases. The group 6 metals are less electropositive and have a maximum oxidation state of +6, making their compounds in high oxidation states largely covalent in character. As the oxidizing strength of the halogen decreases, the maximum oxidation state of the metal also decreases. All three trioxides are acidic, but Cr_2O_3 is amphoteric. The chalcogenides of the group 6 metals are generally nonstoichiometric and electrically conducting, and these elements also form nitrides, carbides, and borides that are similar to those in the preceding groups. The metals of group 7 have a maximum oxidation state of +7, but the lightest element, manganese, exhibits an extensive chemistry in lower oxidation states. As with the group 6 metals, reaction with less oxidizing halogens produces metals in lower oxidation states, and disulfides and diselenides of Tc and Re have layered structures. The group 7 metals also form nitrides, carbides, and borides that are stable at high temperatures and have metallic properties. In groups 8, 9, and 10, the ionization potentials of the elements are so high that the oxidation state corresponding to the formal loss of all valence electrons is encountered rarely (group 8) or not at all (groups 9 and 10). Compounds of group 8 metals in their highest oxidation state are powerful oxidants. The reaction of metals in groups 8, 9, and 10 with the chalcogens is complex, and these elements form a range of binary nitrides, carbides, and borides. The coinage metals (group 11) have the highest electrical and thermal conductivities and are the most ductile and malleable of the metals. Although they are relatively unreactive, they form halides but not nitrides, borides, or carbides. The group 12 elements, whose chemistry is dominated by the +2 oxidation state, are almost always found in nature combined with sulfur. Mercury is the only metal that is a liquid at room temperature, and it dissolves many metals to form amalgams. The group 12 halides range from ionic to covalent. These elements form chalcogenides and have a high affinity for soft ligands.

Key Takeaway

- The elements tend to become more polarizable going across the d block and higher oxidation states become less stable; higher oxidation states become more stable going down a group.

Conceptual Problems

- The valence electron configuration of Sc is $4s^2 3d^1$, yet it does not lose the d^1 electron to form 1+ ion. Why?
- Give the ground-state electron configuration for Mn, Mn^{2+} , Au, Au^{3+} , Mo, and Mo^{3+} .
- A great deal of research is being conducted on the use of titanium alloys as materials for transportation applications (airplanes, ships, automobiles, etc.). Why is Ti particularly suited to this purpose? What is the primary disadvantage that needs to be overcome?
- Both Ti and Ta are used for bioimplants because they are highly resistant to corrosion. Their uses also extend to other applications where corrosion must be avoided. Why are these metals so corrosion resistant?
- Give two reasons why Zr is used to make the casing for UO_2 fuel in water-cooled nuclear reactors.

- Why is chromium added to steel to form stainless steel? What other elements might also be effective additives for this purpose? Why did you select these elements?
- Tungsten is commonly used as the filament in electric light bulbs. Why is tungsten particularly suited to this purpose?
- Palladium metal is used to purify H_2 by removing other gases. Why is Pd so permeable to H_2 ?
- Give the valence electron configuration for Sc, Fe, Re, Ag, Zr, Co, V, Pr, Hg, Cr, Ni, Ce, Cu, and Tb.
- The Hg–Hg bond is much stronger than the Cd–Cd bond, reversing the trend found among the other transition-metal groups. Explain this anomaly.
- Which of the transition metals are most likely to form compounds in the +6 oxidation state? Why?

Structure and Reactivity

- Do you expect $TiCl_4$, $TiCl_3$, $TiCl_2$, and Ti to be oxidized, reduced, or hydrolyzed by water? Explain your reasoning.
- The atomic radii of vanadium, niobium, and tantalum are 134 pm, 146 pm, and 146 pm, respectively. Why does the radius increase from vanadium to niobium but not from niobium to tantalum?
- The most stable oxidation state for the metals of groups 3, 4, and 5 is the highest oxidation state possible. In contrast, for nearly all the metals of groups 8, 9, and 10, intermediate oxidation states are most stable. Why?
- Most of the transition metals can form compounds in multiple oxidation states. Ru, for example, can form compounds in the +8, +6, +4, +3, +2, and –2 oxidation states. Give the valence electron configuration of Ru in each oxidation state. Why does Ru exhibit so many oxidation states? Which ones are the most stable? Why?
- Predict the maximum oxidation states of Cu, Cr, Mo, Rh, Zr, Y, Ir, Hg, and Fe.
- In the +4 oxidation state all three group 7 metals form the dioxides (MO_2). Which of the three metals do you expect to form the most stable dioxide? Why?
- Of $[Fe(H_2O)_6]^{2+}$, $OsBr_7$, CoF_4 , PtF_6 , FeI_3 , $[Ni(H_2O)_6]^{2+}$, OsO_4 , IrO_4 , NiO , RhS_2 , and PtH , which do not exist? Why?
- The chemistry of gold is somewhat anomalous for a metal. With which elements does it form the Au ion? Does it form a stable sulfide?
- Of Os^{4+} , Pt^{10+} , Cr^{6+} , Ir^{9+} , Ru^{8+} , Re^{7+} , and Ni^{10+} , which are not likely to exist? Why?
- Of Ag_2S , Cu_2S , AuI_3 , CuF , AuF , AgN , and AuO , which are not likely to exist?
- There is evidence that the Au ion exists. What would be its electron configuration? The compound $CsAu$ has been isolated; it does not exhibit a metallic luster and does not conduct electricity. Is this compound an alloy? What type of bonding is involved? Explain your answers.
- Of Hg_2Cl_2 , ZnO , HgF_2 , $Cs_2[ZnCl_5]$, and $HgNa$, which are not likely to exist?
- Mercurous oxide (Hg_2O) and mercurous hydroxide [$Hg_2(OH)_2$] have never been prepared. Why not? What products are formed if a solution of aqueous sodium hydroxide is added to an aqueous solution of mercurous nitrate [$Hg_2(NO_3)_2$]?
- Arrange Fe_2O_3 , TiO_2 , V_2O_5 , MoO_3 , Mn_2O_7 , and OsO_4 in order of increasing basicity.
- Mercurous sulfide has never been prepared. What products are formed when H_2S gas is bubbled through an aqueous solution of mercurous nitrate?
- Arrange Sc_2O_3 , VO , V_2O_5 , Cr_2O_3 , Fe_2O_3 , Fe_3O_4 , and ZnO in order of increasing acidity.
- Arrange Sc_2O_3 , V_2O_5 , CrO_3 , Mn_2O_7 , MnO_2 , and VO_2 in order of increasing basicity.
- Predict the products of each reaction and then balance each chemical equation.
 - $Ti + \text{excess } Cl_2$, heated
 - V_2O_5 in aqueous base
 - $K_2Cr_2O_7 + H_2SO_4$
 - $RuBr_2 \cdot 2H_2O$, in water
 - $[CrO_4]^{2-}$ in aqueous acid
 - $Hg^{2+} + Hg$, in aqueous acid
- Predict the products of each reaction and then balance each chemical equation.
 - $AgBr + h\nu$
 - $W + \text{excess } Cl_2$, heated
 - $CuO + H_2$, heated
 - Fe_2O_3 in aqueous acid
 - $RhCl_3 + NH_3$, in water
 - $Fe^{2+} + [MnO_4]^-$, in water

2+ + 3+ 2+

20. What do you predict to be the coordination number of Pt^{2+} , Au^{3+} , Fe^{3+} , and Os^{4+} ?
21. Of La, Sc, Cr, and Hf, which is most likely to form stable compounds in the +4 oxidation state? Why?
22. Give the most common oxidation state for Y, W, Ru, Ag, Hg, Zn, Cr, Nb, and Ti.
23. Give the most common oxidation state for Os, Cd, Hf, V, Ac, Ni, Mn, Pt, and Fe.
24. Give the highest oxidation state observed for Zr, Fe, Re, Hg, Ni, La, and Mo.
25. Give the highest oxidation state observed for Ag, Co, Os, Au, W, and Mn.
26. Arrange La, Cs, Y, Pt, Cd, Mo, Fe, Co, and Ir in order of increasing first ionization energy.
27. Briefly explain the following trends within the transition metals.
 - a. Transition-metal fluorides usually have higher oxidation states than their iodides.
 - b. For a given metal, the lowest-oxidation-state oxide is basic and the highest-oxidation-state oxide is acidic.
 - c. Halides of the transition metals become more covalent with increasing oxidation state and are more prone to hydrolysis.
28. Propose a method to prepare each of the following compounds: $\text{TiCl}_4[(\text{CH}_3)_2\text{O}]_2$, Na_2TiO_3 , V_2O_5 , and $\text{Na}_2\text{Cr}_2\text{O}_7$.
29. Of the group 5 elements, which
 - a. has the greatest tendency to form ions in the lower oxidation states?
 - b. has the greatest tendency to form a polymeric fluoride?
 - c. does not form an MX_2 species?
 - d. forms the most basic oxide?
 - e. has the greatest tendency to form complexes with coordination numbers higher than 6?

Learning Objective

- To understand how metals are extracted from their ores.

Very few of the transition metals are found in nature as free metals. Consequently, almost all metallic elements must be isolated from metal oxide or metal sulfide ores. Metallurgy is the set of processes by which metals are extracted from their ores and converted to more useful forms.

Metallurgy consists of three general steps: (1) mining the ore, (2) separating and concentrating the metal or the metal-containing compound, and (3) reducing the ore to the metal. Additional processes are sometimes required to improve the mechanical properties of the metal or increase its purity. Many ores contain relatively low concentrations of the desired metal; for example, copper ores that contain even 1% Cu by mass are considered commercially useful.

After an ore has been mined, the first step in processing is usually to crush it because the rate of chemical reactions increases dramatically with increased surface area. Next, one of three general strategies is used to separate and concentrate the compound(s) of interest: *settling* and *flotation*, which are based on differences in density between the desired compound and impurities; *pyrometallurgy*, which uses chemical reduction at high temperatures; and *hydrometallurgy*, which employs chemical or electrochemical reduction of an aqueous solution of the metal. Other methods that take advantage of unusual physical or chemical properties of a particular compound may also be used. For example, crystals of magnetite (Fe_3O_4) are tiny but rather powerful magnets; in fact, magnetite (also known as *lodestone*) was used to make the first compasses in China during the first century BC. If a crushed ore that contains magnetite is passed through a powerful magnet, the Fe_3O_4 particles are attracted to the poles of the magnet, allowing them to be easily separated from other minerals.

Note the Pattern

Metallurgy depends on the separation of a metal compound from its ore and reduction to the metal at high temperature (pyrometallurgy) or in aqueous solution (hydrometallurgy).

Settling and flotation have been used for thousands of years to separate particles of dense metals such as gold, using the technique known as *panning*, in which a sample of gravel or sand is swirled in water in a shallow metal pan. Because the density of gold (19.3 g/cm^3) is so much greater than that of most silicate minerals (about 2.5 g/cm^3), silicate particles settle more slowly and can be poured off with the water, leaving dense gold particles on the bottom of the pan. Conversely, in flotation, the compound of interest is made to float on top of a solution. Blowing air through a suspension of the crude ore in a mixture of water and an organic liquid, such as pine tar, produces a “froth” that contains tiny particles of hydrophobic solids, such as metal sulfides, while more hydrophilic oxide minerals remain suspended in the aqueous phase (Figure 21.3.1). To make the separation more efficient, small amounts of an anionic sulfur-containing compound, such as $\text{Na}_2\text{C}_2\text{H}_5\text{OCS}_2$, are added; the additive binds to the sulfur-rich surface of the metal sulfide particles and makes the metal sulfide particles even more hydrophobic. The resulting froth is highly enriched in the desired metal sulfide(s), which can be removed simply by skimming. This method works even for compounds as dense as PbS (7.5 g/cm^3).

Figure 21.3.1 Froth Flotation(a) When air is blown through a mixture of a finely ground metal sulfide ore and water, the more hydrophobic metal sulfides form a froth that can be easily removed, allowing them to be separated from more hydrophilic metal oxides and silicates. (b) A froth containing precious metal sulfides is formed as a by-product during the production of metallic nickel. (c) An anionic sulfur additive with hydrophobic “tails” can be used to enhance the hydrophobic character of metal sulfide particles, which causes them to be attracted to the air/water interface in the foam.

Pyrometallurgy

In pyrometallurgy, an ore is heated with a reductant to obtain the metal. Theoretically, it should be possible to obtain virtually any metal from its ore by using coke, an inexpensive form of crude carbon, as the reductant. An example of such a reaction is as follows:

Unfortunately, many of the early transition metals, such as Ti, react with carbon to form stable binary carbides. Consequently, more expensive reductants, such as hydrogen, aluminum, magnesium, or calcium, must be used to obtain these metals. Many metals that occur naturally as sulfides can be obtained by heating the sulfide in air, as shown for lead in the following equation:

The reaction is driven to completion by the formation of SO_2 , a stable gas.

Pyrometallurgy is also used in the iron and steel industries. The overall reaction for the production of iron in a blast furnace is as follows:

The actual reductant is CO , which reduces Fe_2O_3 to give $Fe(l)$ and $CO_2(g)$; the CO_2 is then reduced back to CO by reaction with excess carbon. As the ore, lime, and coke drop into the furnace (Figure 21.3.2), any silicate minerals in the ore react with the lime to produce a low-melting mixture of calcium silicates called *slag*, which floats on top of the molten iron. Molten iron is then allowed to run out the bottom of the furnace, leaving the slag behind. Originally, the iron was collected in pools called *pigs*, which is the origin of the name *pig iron*.

Figure 21.3.2 A Blast Furnace for Converting Iron Oxides to Iron Metal(a) The furnace is charged with alternating layers of iron ore (largely Fe_2O_3) and a mixture of coke (C) and limestone ($CaCO_3$). Blasting hot air into the mixture from the bottom causes it to ignite, producing CO and raising the temperature of the lower part of the blast furnace to about $2000^\circ C$. As the CO that is formed initially rises, it reduces Fe_2O_3 to form CO_2 and elemental iron, which absorbs heat and melts as it falls into the hottest part of the furnace. Decomposition of $CaCO_3$ at high temperatures produces CaO (lime) and additional CO_2 , which reacts with excess coke to form more CO. (b) This blast furnace in Magnitogorsk, Russia, was the largest in the world when it was built in 1931.

Iron that is obtained directly from a blast furnace has an undesirably low melting point (about $1100^\circ C$ instead of $1539^\circ C$) because it contains a large amount of dissolved carbon. It contains other impurities (such as Si, S, P, and Mn from contaminants in the iron ore that were also reduced during processing) that must be removed because they make iron brittle and unsuitable for most structural applications. In the Bessemer process, oxygen is blown through the molten pig iron to remove the impurities by selective oxidation because these impurities are more readily oxidized than iron (Figure 21.3.3). In the final stage of this process, small amounts of other metals are added at specific temperatures to produce steel with the desired combination of properties.

Figure 21.3.3 A Basic Oxygen Furnace for Converting Crude Iron to Steel(a) A blast of oxygen is used to agitate the molten iron and oxidize impurities to products that dissolve in the less dense slag layer. The slag and the molten steel are removed by tilting the entire furnace and pouring the liquids out through the taphole. (b) A basic oxygen furnace is being filled with molten iron from a blast furnace.

Hydrometallurgy

The most selective methods for separating metals from their ores are based on the formation of metal complexes. For example, gold is often found as tiny flakes of the metal, usually in association with quartz or pyrite deposits. In those circumstances, gold is

typically extracted by using *cyanide leaching*, which forms a stable gold–cyanide complex— $[\text{Au}(\text{CN})_2]$:

Virtually pure gold can be obtained by adding powdered zinc to the solution:

A related method, which is used to separate Co^{3+} , Ni^{2+} , and Cu^{+} from Fe, Mn, and Ti, is based on the formation of stable, soluble ammonia complexes of ions of the late transition metals.

Example 3

Suppose you are working in the chemistry laboratory of a mining company that has discovered a new source of tungsten ore containing about 5% WS_2 in a granite matrix (granite is a complex aluminosilicate mineral). You have been asked to outline an economical procedure for isolating WS_2 from the ore and then converting it to elemental tungsten in as few steps as possible. What would you recommend?

Given: composition of ore

Asked for: procedure to isolate metal sulfide

Strategy:

Determine which method would be most effective for separating the metal sulfide from the ore. Then determine the best method for reducing the metal to the pure element.

Solution:

You need to separate and concentrate the WS_2 , convert it to a suitable form so it can be reduced to the metal (if necessary), and then carry out the reduction. Because the new ore is a binary metal sulfide, you could take advantage of the hydrophilic nature of most metal sulfides to separate WS_2 by froth flotation. Then, because most metal sulfides cannot be reduced directly to the metal using carbon, you will probably need to convert WS_2 to an oxide for subsequent reduction. One point to consider is whether the oxide can be reduced using carbon because many transition metals react with carbon to form stable carbides. Here is one possible procedure for producing tungsten from this new ore:

1. Grind the ore and separate WS_2 from the silicate matrix by flotation.
2. Convert the crude WS_2 to an oxide by roasting in air (because W is in group 6, you anticipate that roasting will yield WO_3 , the oxide in the highest possible oxidation state). The reaction will also produce SO_2 , which will have to be removed by scrubbing the exhaust gases to minimize environmental pollution.
3. Reduce the oxide with hydrogen gas at high temperature to avoid carbide formation:

Exercise

Propose an economical procedure for converting a silicate mineral deposit containing BaCO_3 to the pure Ba metal.

Answer:

1. Dissolve the sample containing barium carbonate in $\text{HCl}(aq)$ to give $\text{Ba}^{2+}(aq)$, which will allow the insoluble silicate minerals to be removed by filtration.
2. Precipitate the barium from solution as BaCO_3 by adding solid Na_2CO_3 .
3. Dissolve the solid BaCO_3 in concentrated HCl and remove the water by evaporation to obtain anhydrous BaCl_2 .
4. Reduce molten BaCl_2 to the metal by electrolysis.

Summary

The conversion of metals from their ores to more useful forms is called **metallurgy**, which consists of three general steps: mining, separation and concentration, and reduction. Settling and flotation are separation methods based on differences in density, whereas pyrometallurgy is based on a chemical reduction at elevated temperatures, and hydrometallurgy uses chemical or electrochemical reduction of an aqueous solution. In pyrometallurgy, a reductant must be used that does not form stable compounds with the metal of interest. In hydrometallurgy, metals are separated via the formation of metal complexes.

Key Takeaway

- A metal is separated from its ore and then isolated by using pyrometallurgy or hydrometallurgy or by taking advantage of unusual chemical or physical properties of a particular compound.

Conceptual Problems

1. Coke is a plentiful and inexpensive reductant that is used to isolate metals from their ores. Of Cr, Co, W, Cu, Ni, Os, Fe, Mn, La, and Hf, which cannot be isolated using this reductant? Why?
2. Hydrometallurgy is the preferred method for separating late transition metals from their ores. What types of ligands are most effective in this process?

Answer

1. Coke cannot be used as a reductant for metals that form stable carbides, such as the early transition metals (La, Hf, and W).
- 2.

Structure and Reactivity

1. Tantalum and niobium are frequently found together in ores. These elements can be separated from other metals present by treatment with a solution of HF. Explain why this is an effective separation technique.
2. A commercially important ore of chromium is chromite (FeCr_2O_4), which is an analogue of magnetite (Fe_3O_4). Based on what you know about the oxidation states of iron in magnetite, predict the oxidation states of the metal ions in chromite.
3. Pure vanadium is obtained by reducing VCl_4 with H_2 or Mg or by reducing V_2O_5 with Ca. Write a balanced chemical equation for each reaction. Why is carbon not used for the reduction?
4. Manganese is an important additive in steel because of its reactivity with oxygen and sulfur, both of which contribute to brittleness. Predict the products of reacting Mn with these species.
5. The diagram of a blast furnace in [Figure 21.3.2](#) illustrates several important features of the reduction of Fe_2O_3 to iron. Write a balanced chemical equation for each step of the process described in the figure and give the overall equation for the conversion. Oxygen is blown through the final product to remove impurities. Why does this step not simply reverse the process and produce iron oxides?
6. Metallic Zr is produced by the Kroll method, which uses Na as the reductant. Write a balanced chemical equation for each reaction involved in this process. The product is frequently contaminated with Hf. Propose a feasible method for separating the two elements.
7. The compound Cr_2O_3 is important commercially; among other things, it is used as a pigment in paint and as a catalyst for the manufacture of butadiene. Write a balanced chemical equation to show how you would produce this compound from
 - a. chromium metal.
 - b. ammonium dichromate.
 - c. CrCl_3 in a basic solution.

Answer

- 1.
- 2.
- 3.

Carbon cannot be used as a reductant because vanadium forms stable carbides, such as VC and VC₂.

- 4.
- 5.
- 6.
- 7.

Learning Objectives

- To know the most common structures observed for metal complexes.
- To predict the relative stabilities of metal complexes with different ligands.

One of the most important properties of metallic elements is their ability to act as Lewis acids that form complexes with a variety of Lewis bases. A metal complex consists of a central metal atom or ion that is bonded to one or more ligands (from the Latin *ligare*, meaning “to bind”), which are ions or molecules that contain one or more pairs of electrons that can be shared with the metal. Metal complexes can be neutral, such as $\text{Co}(\text{NH}_3)_3\text{Cl}_3$; positively charged, such as $[\text{Nd}(\text{H}_2\text{O})_9]^{3+}$; or negatively charged, such as $[\text{UF}_8]^{4-}$. Electrically charged metal complexes are sometimes called complex ions. A coordination compound contains one or more metal complexes.

Coordination compounds are important for at least three reasons. First, most of the elements in the periodic table are metals, and almost all metals form complexes, so metal complexes are a feature of the chemistry of more than half the elements. Second, many industrial catalysts are metal complexes, and such catalysts are steadily becoming more important as a way to control reactivity. For example, a mixture of a titanium complex and an organometallic compound of aluminum is the catalyst used to produce most of the polyethylene and polypropylene “plastic” items we use every day. Finally, transition-metal complexes are essential in biochemistry. Examples include hemoglobin, an iron complex that transports oxygen in our blood; cytochromes, iron complexes that transfer electrons in our cells; and complexes of Fe, Zn, Cu, and Mo that are crucial components of certain enzymes, the catalysts for all biological reactions. Metal complexes are so important in biology that we consider the topic separately in [Section 21.6](#).

History of the Coordination Compounds

Coordination compounds have been known and used since antiquity; probably the oldest is the deep blue pigment called Prussian blue: $\text{KFe}_2(\text{CN})_6$. The chemical nature of these substances, however, was unclear for a number of reasons. For example, many compounds called “double salts” were known, such as $\text{AlF}_3 \cdot 3\text{KF}$, $\text{Fe}(\text{CN})_2 \cdot 4\text{KCN}$, and $\text{ZnCl}_2 \cdot 2\text{CsCl}$, which were combinations of simple salts in fixed and apparently arbitrary ratios. Why should $\text{AlF}_3 \cdot 3\text{KF}$ exist but not $\text{AlF}_3 \cdot 4\text{KF}$ or $\text{AlF}_3 \cdot 2\text{KF}$? And why should a 3:1 $\text{KF}:\text{AlF}_3$ mixture have different chemical and physical properties than either of its components? Similarly, *adducts* of metal salts with neutral molecules such as ammonia were also known—for example, $\text{CoCl}_3 \cdot 6\text{NH}_3$, which was first prepared sometime before 1798. Like the double salts, the compositions of these adducts exhibited fixed and apparently arbitrary ratios of the components. For example, $\text{CoCl}_3 \cdot 6\text{NH}_3$, $\text{CoCl}_3 \cdot 5\text{NH}_3$, $\text{CoCl}_3 \cdot 4\text{NH}_3$, and $\text{CoCl}_3 \cdot 3\text{NH}_3$ were all known and had very different properties, but despite all attempts, chemists could not prepare $\text{CoCl}_3 \cdot 2\text{NH}_3$ or $\text{CoCl}_3 \cdot \text{NH}_3$.

Although the chemical *composition* of such compounds was readily established by existing analytical methods, their chemical *nature* was puzzling and highly controversial. The major problem was that what we now call *valence* (i.e., the oxidation state) and *coordination number* were thought to be identical. As a result, highly implausible (to modern eyes at least) structures were proposed for such compounds, including the “Chattanooga choo-choo” model for $\text{CoCl}_3 \cdot 4\text{NH}_3$ shown here.

The Great Wave Off Kanagawa. The Japanese artist Katsushika Hokusai

used Prussian blue to create this famous woodcut.

The modern theory of coordination chemistry is based largely on the work of Alfred Werner (1866–1919; Nobel Prize in Chemistry in 1913). In a series of careful experiments carried out in the late 1880s and early 1890s, he examined the properties of several series of metal halide complexes with ammonia. For example, five different “adducts” of ammonia with PtCl_4 were known at the time: $\text{PtCl}_4 \cdot n\text{NH}_3$ ($n = 2\text{--}6$). Some of Werner’s original data on these compounds are shown in Table 21.4.1. The electrical conductivity of aqueous solutions of these compounds was roughly proportional to the number of ions formed per mole, while the number of chloride ions that could be precipitated as AgCl after adding Ag^+ (aq) was a measure of the number of “free” chloride ions present. For example, Werner’s data on $\text{PtCl}_4 \cdot 6\text{NH}_3$ in Table 21.4.1 showed that all the chloride ions were present as free chloride. In contrast, $\text{PtCl}_4 \cdot 2\text{NH}_3$ was a neutral molecule that contained no free chloride ions.

Alfred Werner (1866–1919)

Werner, the son of a factory worker, was born in Alsace. He developed an interest in chemistry at an early age, and he did his first independent research experiments at age 18. While doing his military service in southern Germany, he attended a series of chemistry lectures, and he subsequently received his PhD at the University of Zurich in Switzerland, where he was appointed professor of chemistry at age 29. He won the Nobel Prize in Chemistry in 1913 for his work on coordination compounds, which he performed as a graduate student and first presented at age 26. Apparently, Werner was so obsessed with solving the riddle of the structure of coordination compounds that his brain continued to work on the problem even while he was asleep. In 1891, when he was only 25, he woke up in the middle of the night and, in only a few hours, had laid the foundation for modern coordination chemistry.

Table 21.4.1 Werner’s Data on Complexes of Ammonia with PtCl_4

Complex	Conductivity (ohm^{-1})	Number of Ions per Formula Unit	Number of Cl^- Ions Precipitated by Ag^+
$\text{PtCl}_4 \cdot 6\text{NH}_3$	523	5	4
$\text{PtCl}_4 \cdot 5\text{NH}_3$	404	4	3
$\text{PtCl}_4 \cdot 4\text{NH}_3$	299	3	2
$\text{PtCl}_4 \cdot 3\text{NH}_3$	97	2	1
$\text{PtCl}_4 \cdot 2\text{NH}_3$	0	0	0

These data led Werner to postulate that metal ions have two different kinds of valence: (1) a *primary valence* (oxidation state) that corresponds to the positive charge on the metal ion and (2) a *secondary valence* (coordination number) that is the total number of ligands bound to the metal ion. If Pt had a primary valence of 4 and a secondary valence of 6, Werner could explain the properties of the $\text{PtCl}_4 \cdot n\text{NH}_3$ adducts by the following reactions, where the metal complex is enclosed in square brackets:

Further work showed that the two missing members of the series— $[\text{Pt}(\text{NH}_3)\text{Cl}_5]^-$ and $[\text{PtCl}_6]^{2-}$ —could be prepared as their mono- and dipotassium salts, respectively. Similar studies established coordination numbers of 6 for Co^{3+} and Cr^{3+} and 4 for Pt^{2+} and

Pd^{2+} .

Werner's studies on the analogous Co^{3+} complexes also allowed him to propose a structural model for metal complexes with a coordination number of 6. Thus he found that $[\text{Co}(\text{NH}_3)_6]\text{Cl}_3$ (yellow) and $[\text{Co}(\text{NH}_3)_5\text{Cl}]\text{Cl}_2$ (purple) were 1:3 and 1:2 electrolytes. Unexpectedly, however, two different $[\text{Co}(\text{NH}_3)_4\text{Cl}_2]\text{Cl}$ compounds were known: one was red, and the other was green (part (a) in Figure 21.4.1). Because both compounds had the same chemical composition and the same number of groups of the same kind attached to the same metal, there had to be something different about the *arrangement* of the ligands around the metal ion. Werner's key insight was that the six ligands in $[\text{Co}(\text{NH}_3)_4\text{Cl}_2]\text{Cl}$ had to be arranged at the vertices of an octahedron because that was the only structure consistent with the existence of two, and only two, arrangements of ligands (part (b) in Figure 21.4.1). His conclusion was corroborated by the existence of only two different forms of the next compound in the series: $\text{Co}(\text{NH}_3)_3\text{Cl}_3$.

Figure 21.4.1 Complexes with Different Arrangements of the Same Ligands Have Different Properties The $[\text{Co}(\text{NH}_3)_4\text{Cl}_2]^+$ ion can have two different arrangements of the ligands, which results in different colors: if the two Cl ligands are next to each other, the complex is red (a), but if they are opposite each other, the complex is green (b).

Example 21.4.1

In Werner's time, many complexes of the general formula MA_4B_2 were known, but no more than two different compounds with the same composition had been prepared for any metal. To confirm Werner's reasoning, calculate the maximum number of different structures that are possible for six-coordinate MA_4B_2 complexes with each of the three most symmetrical possible structures: a hexagon, a trigonal prism, and an octahedron. What does the fact that no more than two forms of any MA_4B_2 complex were known tell you about the three-dimensional structures of these complexes?

Given: three possible structures and the number of different forms known for MA_4B_2 complexes

Asked for: number of different arrangements of ligands for MA_4B_2 complex for each structure

Strategy:

Sketch each structure, place a B ligand at one vertex, and see how many different positions are available for the second B ligand.

Solution:

The three regular six-coordinate structures are shown here, with each coordination position numbered so that we can keep track of the different arrangements of ligands. For each structure, all vertices are equivalent. We begin with a symmetrical MA_6 complex and simply replace two of the A ligands in each structure to give an MA_4B_2 complex:

For the hexagon, we place the first B ligand at position 1. There are now three possible places for the second B ligand: at position 2 (or 6), position 3 (or 5), or position 4. These are the only possible arrangements. The (1, 2) and (1, 6) arrangements are chemically identical because the two B ligands are adjacent to each other. The (1, 3) and (1, 5) arrangements are also identical because in both cases the two B ligands are separated by an A ligand.

Turning to the trigonal prism, we place the first B ligand at position 1. Again, there are three possible choices for the second B ligand: at position 2 or 3 on the same triangular face, position 4 (on the other triangular face but adjacent to 1), or position 5 or 6 (on the other triangular face but not adjacent to 1). The (1, 2) and (1, 3) arrangements are chemically identical, as are the (1, 5) and (1, 6) arrangements.

In the octahedron, however, if we place the first B ligand at position 1, then we have only two choices for the second B ligand: at position 2 (or 3 or 4 or 5) or position 6. In the latter, the two B ligands are at opposite vertices of the octahedron, with the metal lying directly between them. Although there are four possible arrangements for the former, they are chemically identical because in all cases the two B ligands are adjacent to each other.

The number of possible MA_4B_2 arrangements for the three geometries is thus: hexagon, 3; trigonal prism, 3; and octahedron, 2. The fact that only two different forms were known for all MA_4B_2 complexes that had been prepared suggested that the correct structure was the octahedron but did not prove it. For some reason one of the three arrangements possible for the other two structures could have been less stable or harder to prepare and had simply not yet been synthesized. When combined with analogous results for other types of complexes (e.g., MA_3B_3), however, the data were best explained by an octahedral structure for six-coordinate metal complexes.

Exercise

Determine the maximum number of structures that are possible for a four-coordinate MA_2B_2 complex with either a square planar or a tetrahedral symmetrical structure.

Answer: square planar, 2; tetrahedral, 1

Structures of Metal Complexes

The coordination numbers of metal ions in metal complexes can range from 2 to at least 9. In general, the differences in energy between different arrangements of ligands are greatest for complexes with low coordination numbers and decrease as the coordination number increases. Usually only one or two structures are possible for complexes with low coordination numbers, whereas several different energetically equivalent structures are possible for complexes with high coordination numbers ($n > 6$). The following presents the most commonly encountered structures for coordination numbers 2–9. Many of these structures should be familiar to you from our discussion of the valence-shell electron-pair repulsion (VSEPR) model in [Chapter 6](#) because they correspond to the lowest-energy arrangements of n electron pairs around a central atom.

Note the Pattern

Compounds with low coordination numbers exhibit the greatest differences in energy between different arrangements of ligands.

Coordination Number 2

Although it is rare for most metals, this coordination number is surprisingly common for d^{10} metal ions, especially Cu^+ , Ag^+ , Au^+ , and Hg^{2+} . An example is the $[Au(CN)_2]^-$ ion, which is used to extract gold from its ores, as described in [Section 21.3](#). As expected based on VSEPR considerations, these complexes have the linear L–M–L structure shown here.

Coordination Number 3

Although it is also rare, this coordination number is encountered with d^{10} metal ions such as Cu^+ and Hg^{2+} . Among the few known examples is the HgI_3^- ion. Three-coordinate complexes almost always have the trigonal planar structure expected from the VSEPR model.

Coordination Number 4

Two common structures are observed for four-coordinate metal complexes: tetrahedral and square planar. The tetrahedral structure is observed for all four-coordinate complexes of nontransition metals, such as $[\text{BeF}_4]^{2-}$, and d^{10} ions, such as $[\text{ZnCl}_4]^{2-}$. It is also found for four-coordinate complexes of the first-row transition metals, especially those with halide ligands (e.g., $[\text{FeCl}_4]^-$ and $[\text{FeCl}_4]^{2-}$). In contrast, square planar structures are routinely observed for four-coordinate complexes of second- and third-row transition metals with d^8 electron configurations, such as Rh^+ and Pd^{2+} , and they are also encountered in some complexes of Ni^{2+} and Cu^{2+} .

Tetrahedral and square planar ML_4

Coordination Number 5

This coordination number is less common than 4 and 6, but it is still found frequently in two different structures: trigonal bipyramidal and square pyramidal. Because the energies of these structures are usually rather similar for most ligands, many five-coordinate complexes have distorted structures that lie somewhere between the two extremes.

Trigonal bipyramidal and square pyramidal ML_5

Coordination Number 6

This coordination number is by far the most common. The six ligands are almost always at the vertices of an octahedron or a distorted octahedron. The only other six-coordinate structure is the trigonal prism, which is very uncommon in simple metal complexes.

Octahedral and trigonal prismatic ML_6

Coordination Number 7

This relatively uncommon coordination number is generally encountered for only large metals (such as the second- and third-row transition metals, lanthanides, and actinides). At least three different structures are known, two of which are derived from an octahedron or a trigonal prism by adding a ligand to one face of the polyhedron to give a “capped” octahedron or trigonal prism. By far the most common, however, is the pentagonal bipyramid.

Pentagonal bipyramidal ML_7

Coordination Number 8

This coordination number is relatively common for larger metal ions. The simplest structure is the cube, which is rare because it does not minimize interligand repulsive interactions. Common structures are the square antiprism and the dodecahedron, both of which can be generated from the cube.

Square antiprismatic and trigonal dodecahedral ML_8

Coordination Number 9

This coordination number is found in larger metal ions, and the most common structure is the tricapped trigonal prism, as in $[\text{Nd}(\text{H}_2\text{O})_9]^{3+}$.

Tricapped trigonal prismatic ML_9

Stability of Metal Complexes

The thermodynamic stability of a metal complex depends greatly on the properties of the ligand and the metal ion and on the type of bonding. Recall that the metal–ligand interaction is an example of a Lewis acid–base interaction. Lewis bases can be divided into two categories: hard bases, which contain small, relatively nonpolarizable donor atoms (such as N, O, and F), and soft bases, which contain larger, relatively polarizable donor atoms (such as P, S, and Cl). Metal ions with the highest affinities for hard bases are hard acids, whereas metal ions with the highest affinity for soft bases are soft acids. Some examples of hard and soft acids and bases are given in Table 21.4.2. Notice that hard acids are usually cations of electropositive metals; consequently, they are relatively nonpolarizable and have higher charge-to-radius ratios. Conversely, soft acids tend to be cations of less electropositive metals; consequently, they have lower charge-to-radius ratios and are more polarizable. Chemists can predict the relative stabilities of complexes formed by the d -block metals with a remarkable degree of accuracy by using a simple rule: *hard acids prefer to bind to hard bases, and soft acids prefer to bind to soft bases.*

Table 21.4.2 Examples of Hard and Soft Acids and Bases

	Acids	Bases
hard	H ⁺	NH ₃ , RNH ₂ , N ₂ H ₄
	Li ⁺ , Na ⁺ , K ⁺	H ₂ O, ROH, R ₂ O
	Be ²⁺ , Mg ²⁺ , Ca ²⁺ , VO ²⁺	OH ⁻ , F ⁻ , Cl ⁻ , CH ₃ CO ₂ ⁻
	Al ³⁺ , Sc ³⁺ , Cr ³⁺	CO ₃ ²⁻
	Ti ⁴⁺	PO ₄ ³⁻
soft	BF ₃ , Al ₂ Cl ₆ , CO ₂ , SO ₃	
	Cu ⁺ , Ag ⁺ , Au ⁺ , Tl ⁺ , Hg ₂ ²⁺	H ⁻
	Pd ²⁺ , Pt ²⁺ , Hg ²⁺	CN ⁻ , SCN ⁻ , I ⁻ , RS ⁻
	GaCl ₃ , GaBr ₃ , GaI ₃	CO, R ₂ S

Because the interaction between hard acids and hard bases is primarily electrostatic in nature, the stability of complexes involving hard acids and hard bases increases as the positive charge on the metal ion increases and as its radius decreases. For example, the complex of Al³⁺ ($r = 53.5$ pm) with four fluoride ligands (AlF₄⁻) is about 10⁸ times more stable than InF₄⁻, the corresponding fluoride complex of In³⁺ ($r = 80$ pm). In general, the stability of complexes of divalent first-row transition metals with a given ligand varies inversely with the radius of the metal ion, as shown in the following series: The inversion in the order at copper is due to the anomalous structure of copper(II) complexes, which will be discussed shortly.

c o m p l e x s Mn ²⁺ t a b i l i t y	< Fe ²⁺	< Co ²⁺	< Ni ²⁺	< Cu ²⁺	> Zn ²⁺
--	--------------------	--------------------	--------------------	--------------------	--------------------

i o n i c r a 83	78	74.5	69	73	74
i u s (p m)					

Because a hard metal interacts with a base in much the same way as a proton, by binding to a lone pair of electrons on the base, the stability of complexes of hard acids with hard bases increases as the ligand becomes more basic. For example, because ammonia is a stronger base than water, metal ions bind preferentially to ammonia. Consequently, adding ammonia to aqueous solutions of many of the first-row transition-metal cations results in the formation of the corresponding ammonia complexes.

In contrast, the interaction between soft metals (such as the second- and third-row transition metals and Cu^+) and soft bases is largely covalent in nature. Most soft-metal ions have a filled or nearly filled d subshell, which suggests that metal-to-ligand π bonding is important. Complexes of soft metals with soft bases are therefore much more stable than would be predicted based on electrostatic arguments.

Note the Pattern

Hard acids prefer to bind to hard bases, and soft acids prefer to bind to soft bases.

The hard acid–hard base/soft acid–soft base concept also allows us to understand why metals are found in nature in different kinds of ores. Recall from [Section 21.2](#) that most of the first-row transition metals are isolated from oxide ores but that copper and zinc tend to occur naturally in sulfide ores. This is consistent with the increase in the soft character of the metals across the first row of the transition metals from left to right. Recall also that most of the second- and third-row transition metals occur in nature as sulfide ores, consistent with their greater soft character.

Ligands like chloride, water, and ammonia are said to be *monodentate* (one-toothed, from the Greek *mono*, meaning “one,” and the Latin *dent-*, meaning “tooth”): they are attached to the metal via only a single atom. Ligands can, however, be *bidentate* (two-toothed, from the Greek *di*, meaning “two”), *tridentate* (three-toothed, from the Greek *tri*, meaning “three”), or, in general, *polydentate* (many-toothed, from the Greek *poly*, meaning “many”), indicating that they are attached to the metal at two, three, or several sites, respectively. Ethylenediamine ($\text{H}_2\text{NCH}_2\text{CH}_2\text{NH}_2$, often abbreviated as en) and diethylenetriamine ($\text{H}_2\text{NCH}_2\text{CH}_2\text{NHCH}_2\text{CH}_2\text{NH}_2$, often abbreviated as dien) are examples of a bidentate and a tridentate ligand, respectively, because each nitrogen atom has a lone pair that can be shared with a metal ion. When a bidentate ligand such as ethylenediamine binds to a metal such as Ni^{2+} , a five-membered ring is formed. A metal-containing ring like that shown is called a *chelate* ring (from the Greek *chele*, meaning “claw”). Correspondingly, a polydentate ligand is a *chelating agent*, and complexes that contain polydentate ligands are called *chelate complexes*.

Experimentally, it is observed that metal complexes of polydentate ligands are significantly more stable than the corresponding complexes of chemically similar monodentate ligands; this increase in stability is called the **chelate effect**. For example, the complex of Ni^{2+} with three ethylenediamine ligands, $[\text{Ni}(\text{en})_3]^{2+}$, should be chemically similar to the Ni^{2+} complex with six ammonia ligands, $[\text{Ni}(\text{NH}_3)_6]^{2+}$. In fact, the equilibrium constant for the formation of $[\text{Ni}(\text{en})_3]^{2+}$ is almost 10 orders of magnitude larger than the equilibrium constant for the formation of $[\text{Ni}(\text{NH}_3)_6]^{2+}$:

Note the Pattern

Chelate complexes are more stable than the analogous complexes with monodentate ligands.

The stability of a chelate complex depends on the size of the chelate rings. For ligands with a flexible organic backbone like ethylenediamine, complexes that contain five-membered chelate rings, which have almost no strain, are significantly more stable than complexes with six-membered chelate rings, which are in turn much more stable than complexes with four- or seven-membered rings. For example, the complex of copper(II) with two ethylenediamine ligands is about 1000 times more stable than the corresponding complex with triethylenediamine ($\text{H}_2\text{NCH}_2\text{CH}_2\text{CH}_2\text{NH}_2$, abbreviated as *trien*):

Example 21.4.2

Arrange $[\text{Cr}(\text{en})_3]^{3+}$, $[\text{CrCl}_6]^{3-}$, $[\text{CrF}_6]^{3-}$, and $[\text{Cr}(\text{NH}_3)_6]^{3+}$ in order of increasing stability.

Given: four Cr(III) complexes

Asked for: relative stabilities

Strategy:

A Determine the relative basicity of the ligands to identify the most stable complexes.

B Decide whether any complexes are further stabilized by a chelate effect and arrange the complexes in order of increasing stability.

Solution:

A The metal ion is the same in each case: Cr^{3+} . Consequently, we must focus on the properties of the ligands to determine the stabilities of the complexes. Because the stability of a metal complex increases as the basicity of the ligands increases, we need to determine the relative basicity of the four ligands. Our earlier discussion of acid–base properties suggests that ammonia and ethylenediamine, with nitrogen donor atoms, are the most basic ligands. The fluoride ion is a stronger base (it has a higher charge-to-radius ratio) than chloride, so the order of stability expected due to ligand basicity is $[\text{CrCl}_6]^{3-} < [\text{CrF}_6]^{3-} < [\text{Cr}(\text{NH}_3)_6]^{3+} \approx [\text{Cr}(\text{en})_3]^{3+}$.

B Because of the chelate effect, we expect ethylenediamine to form a stronger complex with Cr^{3+} than ammonia. Consequently, the likely order of increasing stability is $[\text{CrCl}_6]^{3-} < [\text{CrF}_6]^{3-} < [\text{Cr}(\text{NH}_3)_6]^{3+} < [\text{Cr}(\text{en})_3]^{3+}$.

Exercise

Arrange $[\text{Co}(\text{NH}_3)_6]^{3+}$, $[\text{CoF}_6]^{3-}$, and $[\text{Co}(\text{en})_3]^{3+}$ in order of decreasing stability.

Answer: $[\text{Co}(\text{en})_3]^{3+} > [\text{Co}(\text{NH}_3)_6]^{3+} > [\text{CoF}_6]^{3-}$

Isomers of Metal Complexes

As we discussed earlier in this section, the existence of coordination compounds with the same formula but different arrangements of the ligands was crucial in the development of coordination chemistry. Two or more compounds with the same formula but different arrangements of the atoms are called isomers. Because isomers usually have different physical and chemical properties, it is important to know which isomer we are dealing with if more than one isomer is possible. Recall from [Chapter 6.4](#) that in many cases more than one structure is possible for organic compounds with the same molecular formula; examples discussed previously include *n*-butane versus isobutane and *cis*-2-butene versus *trans*-2-butene. As we will see, coordination compounds exhibit the same types of isomers as organic compounds, as well as several kinds of isomers that are unique. (For more information on isomers in organic compounds, see [Section 23.2](#).)

Structural Isomers

Isomers that contain the same number of atoms of each kind but differ in which atoms are bonded to one another are called structural isomers. Isobutane and *n*-butane are examples of structural isomers. One kind of isomerism consists of two compounds that have the same empirical formula but differ in the number of formula units present in the molecular formula. An example in coordination compounds is two compounds with the empirical formula $\text{Pt}(\text{NH}_3)_2\text{Cl}_2$. One is a simple square planar platinum(II) complex, $\text{Pt}(\text{NH}_3)_2\text{Cl}_2$, and the other is an ionic compound that contains the $[\text{Pt}(\text{NH}_3)_4]^{2+}$ cation and the $[\text{PtCl}_4]^{2-}$ anion, $[\text{Pt}(\text{NH}_3)_4][\text{PtCl}_4]$. As you might expect, these compounds have very different physical and chemical properties. One arrangement of the Cl^- and NH_3 ligands around the platinum ion in the former gives the anticancer drug cisplatin, whereas the other arrangement has no known biomedical applications.

Geometrical Isomers

Metal complexes that differ only in which ligands are adjacent to one another (*cis*) or directly across from one another (*trans*) in the coordination sphere of the metal are called geometrical isomers. They are most important for square planar and octahedral complexes.

Because all vertices of a square are equivalent, it does not matter which vertex is occupied by the ligand B in a square planar MA_3B complex; hence only a single geometrical isomer is possible in this case (and in the analogous MAB_3 case). All four structures shown here are chemically identical because they can be superimposed simply by rotating the complex in space:

For an MA_2B_2 complex, there are two possible isomers: either the A ligands can be adjacent to one another (*cis*), in which case the B ligands must also be *cis*, or the A ligands can be across from one another (*trans*), in which case the B ligands must also be *trans*. Even though it is possible to draw the *cis* isomer in four different ways and the *trans* isomer in two different ways, all members of each set are chemically equivalent:

Because there is no way to convert the *cis* structure to the *trans* by rotating or flipping the molecule in space, they are fundamentally different arrangements of atoms in space. Probably the best-known examples of *cis* and *trans* isomers of an MA_2B_2 square planar complex are *cis*- $\text{Pt}(\text{NH}_3)_2\text{Cl}_2$, also known as cisplatin, and *trans*- $\text{Pt}(\text{NH}_3)_2\text{Cl}_2$, which is actually toxic rather than therapeutic.

The anticancer drug cisplatin and its inactive trans isomer. Cisplatin is especially effective against tumors of the reproductive organs (the testes in males and the ovaries in females), which primarily affect individuals in their 20s and were notoriously difficult to cure. For example, after being diagnosed with metastasized testicular cancer in 1991 and given only a 50% chance of survival, Lance Armstrong was cured by treatment with cisplatin and went on to win an unprecedented seven Tour de France bicycle races.

Square planar complexes that contain symmetrical bidentate ligands, such as $[\text{Pt}(\text{en})_2]^{2+}$, have only one possible structure, in which curved lines linking the two N atoms indicate the ethylenediamine ligands:

Octahedral complexes also exhibit *cis* and *trans* isomers. Like square planar complexes, only one structure is possible for octahedral complexes in which only one ligand is different from the other five (MA_5B). Even though we usually draw an octahedron in a way that suggests that the four “in-plane” ligands are different from the two “axial” ligands, in fact all six vertices of an octahedron are equivalent. Consequently, no matter how we draw an MA_5B structure, it can be superimposed on any other representation simply by rotating the molecule in space. Two of the many possible orientations of an MA_5B structure are as follows:

If two ligands in an octahedral complex are different from the other four, giving an MA_4B_2 complex, two isomers are possible. The two B ligands can be *cis* or *trans*. *Cis*- and *trans*- $[\text{Co}(\text{NH}_3)_4\text{Cl}_2]\text{Cl}$ are examples of this type of system:

Replacing another A ligand by B gives an MA_3B_3 complex for which there are also two possible isomers. In one, the three ligands of each kind occupy opposite triangular faces of the octahedron; this is called the *fac* isomer (for facial). In the other, the three ligands of each kind lie on what would be the meridian if the complex were viewed as a sphere; this is called the *mer* isomer (for meridional):

Example 21.4.3

Draw all the possible geometrical isomers for the complex $[Co(H_2O)_2(ox)BrCl]^-$, where ox is $^-O_2CCO_2^-$, which stands for oxalate.

Given: formula of complex

Asked for: structures of geometrical isomers

Solution:

This complex contains one bidentate ligand (oxalate), which can occupy only adjacent (*cis*) positions, and four monodentate ligands, two of which are identical (H_2O). The easiest way to attack the problem is to go through the various combinations of ligands systematically to determine which ligands can be *trans*. Thus either the water ligands can be *trans* to one another or the two halide ligands can be *trans* to one another, giving the two geometrical isomers shown here:

In addition, two structures are possible in which one of the halides is *trans* to a water ligand. In the first, the chloride ligand is in the same plane as the oxalate ligand and *trans* to one of the oxalate oxygens. Exchanging the chloride and bromide ligands gives the other, in which the bromide ligand is in the same plane as the oxalate ligand and *trans* to one of the oxalate oxygens:

This complex can therefore exist as four different geometrical isomers.

Exercise

Draw all the possible geometrical isomers for the complex $[Cr(en)_2(CN)_2]^+$.

Answer:

Two geometrical isomers are possible: *trans* and *cis*.

Summary

Transition metals form **metal complexes**, polyatomic species in which a metal ion is bound to one or more **ligands**, which are groups bound to a metal ion. **Complex ions** are electrically charged metal complexes, and a **coordination compound** contains one or more metal complexes. Metal complexes with low coordination numbers generally have only one or two possible structures, whereas those with coordination numbers greater than six can have several different structures. Coordination numbers of two and three are common for d^{10} metal ions. Tetrahedral and square planar complexes have a coordination number of four; trigonal bipyramidal and square pyramidal complexes have a coordination number of five; and octahedral complexes have a coordination number of six. At least three structures are known for a coordination number of seven, which is generally found for only large metal ions. Coordination numbers of eight and nine are also found for larger metal ions. The stability of metal complexes with first-row transition metals in a +2 oxidation state varies inversely with their ionic radius. Lewis bases can be **hard bases**, which have small, relatively nonpolarizable donor atoms, or **soft bases**, with larger, relatively polarizable donor atoms. **Hard acids** have the highest affinity for hard bases, and **soft acids** have the highest affinity for soft bases. Soft metals and soft bases form complexes that are more stable than would be predicted based on electrostatic arguments, which suggests that metal-to-ligand π bonding is important. Ligands that are strong bases form the most stable complexes with metal ions that are hard acids. Exceptionally stable complexes are formed by chelates, which are polyatomic ligands with two or more donor atoms; this enhanced stability is known as the chelate effect. Many metal complexes form **isomers**, which are two or more compounds with the same formula but different arrangements of atoms. **Structural isomers** differ in which atoms are bonded to one another, while **geometrical isomers** differ only in the arrangement of ligands around the metal ion. Ligands adjacent to one another are **cis**, while ligands across from one another are **trans**.

Key Takeaways

- Coordination compounds are a major feature of the chemistry of over half the elements.
- Coordination compounds have important roles as industrial catalysts in controlling reactivity, and they are essential in biochemical processes.

Conceptual Problems

1. Give two reasons a metal can bind to only a finite number of ligands. Based on this reasoning, what do you predict is the maximum coordination number of Ti? of Ac?
2. Can a tetrahedral MA_2B_2 complex form *cis* and *trans* isomers? Explain your answer.
3. The group 12 elements are never found in their native (free) form but always in combination with one other element. What element is this? Why? Which of the group 12 elements has the highest affinity for the element you selected?

Answer

- 1.
- 2.
3. The group 12 metals are rather soft and prefer to bind to a soft anion such as sulfide rather than to a hard anion like oxide; hence they are usually found in nature as sulfide ores. Because it is the softest of these metals, mercury has the highest affinity for sulfide.

Structure and Reactivity

1. Complexes of metals in the +6 oxidation state usually contain bonds to which two Lewis bases? Why are these bonds best described as covalent rather than ionic? Do Ca, Sr, and Ba also form covalent bonds with these two Lewis bases, or is their bonding best described as ionic?
2. Cr, Mn, Fe, Co, and Ni form stable CO complexes. In contrast, the earlier transition metals do not form similar stable complexes. Why?
3. The transition metals Cr through Ni form very stable cyanide complexes. Why are these complexes so much more stable than similar compounds formed from the early transition metals?
4. Of $Co(en)_3^{2+}$, CoF_6^{2-} , $Co(NH_3)_6^{2+}$, and $Co(dien)_2^{2+}$, which species do you expect to be the most stable? Why?

- Of Ca^{2+} , Ti^{4+} , V^{5+} , Mn^{2+} , Fe^{3+} , Co^{2+} , Ni^{2+} , and Zn^{2+} , which divalent metal ions forms the most stable complexes with ligands such as NH_3 ? Why?
- Match each Lewis base with the metal ion with which it is most likely to form a stable complex:
 Lewis bases: NH_3 , F^- , RS^- , OH^- , and Cl_3^-
 Metals: Sc^{3+} , Cu^{2+} , W^{6+} , Mg^{2+} , V^{5+} , Fe^{4+} , Zr^{4+} , Co^{2+} , Ti^{4+} , Au^{3+} , Al^{3+} , and Mn^{7+}
- Of ReF_2 , ReCl_5 , MnF_6 , Mn_2O_7 , and ReO , which are not likely to exist?
- Of WF_2 , CrF_6 , MoBr_6 , Wl_6 , CrO_3 , MoS_2 , W_2S_3 , and MoH , which are not likely to exist?

Answers

- Metals in the +6 oxidation state are stabilized by oxide (O^{2-}) and fluoride (F^-). The M-F and M-O bonds are polar covalent due to extreme polarization of the anions by the highly charged metal. Ca, Sr, and Ba can be oxidized only to the dications (M^{2+}), which form ionic oxides and fluorides.
-
- Cyanide is a relatively soft base, and the early transition-metal cations are harder acids than the later transition metals.
-
- The formation of complexes between NH_3 and a divalent cation is largely due to electrostatic interactions between the negative end of the ammonia dipole moment and the positively charged cation. Thus the smallest divalent cations (Ni^{2+} , Zn^{2+} , and Cu^{2+}) will form the most stable complexes with ammonia.
-
- Re^{2+} is a very soft cation, and F^- and O^{2-} are very hard bases, so ReO and ReF_2 are unlikely to exist. MnF_6 is also unlikely to exist: although fluoride should stabilize high oxidation states, in this case Mn^{7+} is probably too small to accommodate six F^- ions.

Learning Objective

- To understand how crystal field theory explains the electronic structures and colors of metal complexes.

One of the most striking characteristics of transition-metal complexes is the wide range of colors they exhibit ([Figure 21.2.2](#) and [Figure 21.2.3](#)). In this section, we describe crystal field theory (CFT), a bonding model that explains many important properties of transition-metal complexes, including their colors, magnetism, structures, stability, and reactivity. The central assumption of CFT is that metal–ligand interactions are purely electrostatic in nature. Even though this assumption is clearly not valid for many complexes, such as those that contain neutral ligands like CO, CFT enables chemists to explain many of the properties of transition-metal complexes with a reasonable degree of accuracy.

d-Orbital Splittings

CFT focuses on the interaction of the five $(n - 1)d$ orbitals with ligands arranged in a regular array around a transition-metal ion. We will focus on the application of CFT to octahedral complexes, which are by far the most common and the easiest to visualize. Other common structures, such as square planar complexes, can be treated as a distortion of the octahedral model. According to CFT, an octahedral metal complex forms because of the electrostatic interaction of a positively charged metal ion with six negatively charged ligands or with the negative ends of dipoles associated with the six ligands. In addition, the ligands interact with one other electrostatically. As you learned in our discussion of the valence-shell electron-pair repulsion (VSEPR) model in [Chapter 6](#), the lowest-energy arrangement of six identical negative charges is an octahedron, which minimizes repulsive interactions between the ligands.

We begin by considering how the energies of the d orbitals of a transition-metal ion are affected by an octahedral arrangement of six negative charges. Recall from [Chapter 2](#) that the five d orbitals are initially degenerate (have the same energy). If we distribute six negative charges *uniformly* over the surface of a sphere, the d orbitals remain degenerate, but their energy will be higher due to repulsive electrostatic interactions between the spherical shell of negative charge and electrons in the d orbitals (part (a) in [Figure 21.5.1](#)). Placing the six negative charges at the vertices of an octahedron does not change the average energy of the d orbitals, but it does remove their degeneracy: the five d orbitals split into two groups whose energies depend on their orientations. As shown in part (b) in [Figure 21.5.1](#), the d_{z^2} and $d_{x^2-y^2}$ orbitals point *directly* at the six negative charges located on the x , y , and z axes. Consequently, the energy of an electron in these two orbitals (collectively labeled the e_g orbitals) will be greater than it will be for a spherical distribution of negative charge because of increased electrostatic repulsions. In contrast, the other three d orbitals (d_{xy} , d_{xz} , and d_{yz} , collectively called the t_{2g} orbitals) are all oriented at a 45° angle to the coordinate axes, so they point *between* the six negative charges. The energy of an electron in any of these three orbitals is lower than the energy for a spherical distribution of negative charge.

Figure 21.5.1 An Octahedral Arrangement of Six Negative Charges around a Metal Ion Causes the Five d Orbitals to Split into Two Sets with Different Energies(a) Distributing a charge of -6 uniformly over a spherical surface surrounding a metal ion causes the energy of all five d orbitals to increase due to electrostatic repulsions, but the five d orbitals remain degenerate. Placing a charge of -1 at each vertex of an octahedron causes the d orbitals to split into two groups with different energies: the $d_{x^2-y^2}$ orbitals increase in energy, while the, d_{xy} , d_{xz} , and d_{yz} orbitals decrease in energy. The average energy of the five d orbitals is the same as for a spherical distribution of a -6 charge, however. Attractive electrostatic interactions between the negatively charged ligands and the positively charged metal ion (far right) cause all five d orbitals to decrease in energy but does not affect the splittings of the orbitals. (b) The two e_g orbitals (left) point directly at the six negatively charged ligands, which increases their energy compared with a spherical distribution of negative charge. In contrast, the three t_{2g} orbitals (right) point between the negatively charged ligands, which decreases their energy compared with a spherical distribution of charge.

The difference in energy between the two sets of d orbitals is called the crystal field splitting energy (Δ_o), where the subscript o stands for octahedral. As we shall see, the magnitude of the splitting depends on the charge on the metal ion, the position of the metal in the periodic table, and the nature of the ligands. (Crystal field splitting energy also applies to tetrahedral complexes: Δ_t .) It is important to note that the splitting of the d orbitals in a crystal field does *not* change the total energy of the five d orbitals: the two e_g orbitals *increase* in energy by $0.6\Delta_o$, whereas the three t_{2g} orbitals decrease in energy by $0.4\Delta_o$. Thus the total change in energy is $2(0.6\Delta_o) + 3(-0.4\Delta_o) = 0$.

Note the Pattern

Crystal field splitting does not change the total energy of the d orbitals.

Thus far, we have considered only the effect of repulsive electrostatic interactions between electrons in the d orbitals and the six negatively charged ligands, which increases the total energy of the system and splits the d orbitals. Interactions between the positively charged metal ion and the ligands results in a net stabilization of the system, which decreases the energy of all five d orbitals without affecting their splitting (as shown at the far right in part (a) in [Figure 21.5.1](#)).

Electronic Structures of Metal Complexes

We can use the d -orbital energy-level diagram in [Figure 21.5.1](#) to predict electronic structures and some of the properties of transition-metal complexes. We start with the Ti^{3+} ion, which contains a single d electron, and proceed across the first row of the transition metals by adding a single electron at a time. We place additional electrons in the lowest-energy orbital available, while keeping their spins parallel as required by Hund's rule. As shown in [Figure 21.5.2](#), for d^1-d^3 systems—such as $[Ti(H_2O)_6]^{3+}$, $[V(H_2O)_6]^{3+}$, and $[Cr(H_2O)_6]^{3+}$, respectively—the electrons successively occupy the three degenerate t_{2g} orbitals with their spins parallel, giving one, two, and three unpaired electrons, respectively. We can summarize this for the complex $[Cr(H_2O)_6]^{3+}$, for example, by saying that the chromium ion has a d^3 electron configuration or, more succinctly, Cr^{3+} is a d^3 ion.

Figure 21.5.2 The Possible Electron Configurations for Octahedral d^n Transition-Metal Complexes ($n = 1-10$) Two different configurations are possible for octahedral complexes of metals with d^4 , d^5 , d^6 , and d^7 configurations; the magnitude of Δ_o determines which configuration is observed.

When we reach the d^4 configuration, there are two possible choices for the fourth electron: it can occupy either one of the empty e_g orbitals or one of the singly occupied t_{2g} orbitals. Recall from [Chapter 2](#) that placing an electron in an already occupied orbital results in electrostatic repulsions that increase the energy of the system; this increase in energy is called the spin-pairing energy (P). If Δ_o is less than P , then the lowest-energy arrangement has the fourth electron in one of the empty e_g orbitals. Because this arrangement results in four unpaired electrons, it is called a *high-spin configuration*, and a complex with this electron configuration, such as the $[\text{Cr}(\text{H}_2\text{O})_6]^{2+}$ ion, is called a *high-spin complex*. Conversely, if Δ_o is greater than P , then the lowest-energy arrangement has the fourth electron in one of the occupied t_{2g} orbitals. Because this arrangement results in only two unpaired electrons, it is called a *low-spin configuration*, and a complex with this electron configuration, such as the $[\text{Mn}(\text{CN})_6]^{3-}$ ion, is called a *low-spin complex*. Similarly, metal ions with the d^5 , d^6 , or d^7 electron configurations can be either high spin or low spin, depending on the magnitude of Δ_o .

In contrast, only one arrangement of d electrons is possible for metal ions with d^8 – d^{10} electron configurations. For example, the $[\text{Ni}(\text{H}_2\text{O})_6]^{2+}$ ion is d^8 with two unpaired electrons, the $[\text{Cu}(\text{H}_2\text{O})_6]^{2+}$ ion is d^9 with one unpaired electron, and the $[\text{Zn}(\text{H}_2\text{O})_6]^{2+}$ ion is d^{10} with no unpaired electrons.

Note the Pattern

If Δ_o is less than the spin-pairing energy, a high-spin configuration results. Conversely, if Δ_o is greater, a low-spin configuration forms.

Factors That Affect the Magnitude of Δ_o

The magnitude of Δ_o dictates whether a complex with four, five, six, or seven d electrons is high spin or low spin, which affects its magnetic properties, structure, and reactivity. Large values of Δ_o (i.e., $\Delta_o > P$) yield a low-spin complex, whereas small values of Δ_o (i.e., $\Delta_o < P$) produce a high-spin complex. As we noted, the magnitude of Δ_o depends on three factors: the charge on the metal ion, the principal quantum number of the metal (and thus its location in the periodic table), and the nature of the ligand. Values of Δ_o for some representative transition-metal complexes are given in [Table 21.5.1](#)

Table 21.5.1 Crystal Field Splitting Energies for Some Octahedral (Δ_o)* and Tetrahedral (Δ_t) Transition-Metal Complexes

Octahedral Complexes	Δ_o (cm^{-1})	Octahedral Complexes	Δ_o (cm^{-1})	Tetrahedral Complexes	Δ_t (cm^{-1})
$[\text{Ti}(\text{H}_2\text{O})_6]^{3+}$	20,300	$[\text{Fe}(\text{CN})_6]^{4-}$	32,800	VCl_4	9010
$[\text{V}(\text{H}_2\text{O})_6]^{2+}$	12,600	$[\text{Fe}(\text{CN})_6]^{3-}$	35,000	$[\text{CoCl}_4]^{2-}$	3300

*Energies obtained by spectroscopic measurements are often given in units of wave numbers (cm^{-1}); the wave number is the reciprocal of the wavelength of the corresponding electromagnetic radiation expressed in centimeters: $1 \text{ cm}^{-1} = 11.96 \text{ J/mol}$.

Octahedral Complexes	Δ_o (cm^{-1})	Octahedral Complexes	Δ_o (cm^{-1})	Tetrahedral Complexes	Δ_t (cm^{-1})
$[\text{V}(\text{H}_2\text{O})_6]^{3+}$	18,900	$[\text{CoF}_6]^{3-}$	13,000	$[\text{CoBr}_4]^{2-}$	2900
$[\text{CrCl}_6]^{3-}$	13,000	$[\text{Co}(\text{H}_2\text{O})_6]^{2+}$	9300	$[\text{CoI}_4]^{2-}$	2700
$[\text{Cr}(\text{H}_2\text{O})_6]^{2+}$	13,900	$[\text{Co}(\text{H}_2\text{O})_6]^{3+}$	27,000		
$[\text{Cr}(\text{H}_2\text{O})_6]^{3+}$	17,400	$[\text{Co}(\text{NH}_3)_6]^{3+}$	22,900		
$[\text{Cr}(\text{NH}_3)_6]^{3+}$	21,500	$[\text{Co}(\text{CN})_6]^{3-}$	34,800		
$[\text{Cr}(\text{CN})_6]^{3-}$	26,600	$[\text{Ni}(\text{H}_2\text{O})_6]^{2+}$	8500		
$\text{Cr}(\text{CO})_6$	34,150	$[\text{Ni}(\text{NH}_3)_6]^{2+}$	10,800		
$[\text{MnCl}_6]^{4-}$	7500	$[\text{RhCl}_6]^{3-}$	20,400		
$[\text{Mn}(\text{H}_2\text{O})_6]^{2+}$	8500	$[\text{Rh}(\text{H}_2\text{O})_6]^{3+}$	27,000		
$[\text{MnCl}_6]^{3-}$	20,000	$[\text{Rh}(\text{NH}_3)_6]^{3+}$	34,000		
$[\text{Mn}(\text{H}_2\text{O})_6]^{3+}$	21,000	$[\text{Rh}(\text{CN})_6]^{3-}$	45,500		
$[\text{Fe}(\text{H}_2\text{O})_6]^{2+}$	10,400	$[\text{IrCl}_6]^{3-}$	25,000		
$[\text{Fe}(\text{H}_2\text{O})_6]^{3+}$	14,300	$[\text{Ir}(\text{NH}_3)_6]^{3+}$	41,000		

***Energies obtained by spectroscopic measurements are often given in units of wave numbers (cm^{-1}); the wave number is the reciprocal of the wavelength of the corresponding electromagnetic radiation expressed in centimeters: $1 \text{ cm}^{-1} = 11.96 \text{ J/mol}$.**

Charge on the Metal Ion

Increasing the charge on a metal ion has two effects: the radius of the metal ion decreases, and negatively charged ligands are more strongly attracted to it. Both factors decrease the metal–ligand distance, which in turn causes the negatively charged ligands to interact more strongly with the d orbitals. Consequently, the magnitude of Δ_o increases as the charge on the metal ion increases. Typically, Δ_o for a tripositive ion is about 50% greater than for the dipositive ion of the same metal; for example, for $[\text{V}(\text{H}_2\text{O})_6]^{2+}$, $\Delta_o = 11,800 \text{ cm}^{-1}$; for $[\text{V}(\text{H}_2\text{O})_6]^{3+}$, $\Delta_o = 17,850 \text{ cm}^{-1}$.

Principal Quantum Number of the Metal

For a series of complexes of metals from the same group in the periodic table with the same charge and the same ligands, the magnitude of Δ_o increases with increasing principal quantum number: $\Delta_o(3d) < \Delta_o(4d) < \Delta_o(5d)$. The data for hexaammine complexes of the trivalent group 9 metals illustrate this point:

$$[\text{Co}(\text{NH}_3)_6]^{3+} + \Delta_o = 22,900 \text{ cm}^{-1}$$

$$[\text{Rh}(\text{NH}_3)_6]^{3+} + \Delta_o = 34,100 \text{ cm}^{-1}$$

$$[\text{Ir}(\text{NH}_3)_6]^{3+} + \Delta_o = 40,000 \text{ cm}^{-1}$$

The increase in Δ_o with increasing principal quantum number is due to the larger radius of valence orbitals down a column. In addition, repulsive ligand–ligand interactions are most important for smaller metal ions. Relatively speaking, this results in shorter M–L distances and stronger d orbital–ligand interactions.

The Nature of the Ligands

Experimentally, it is found that the Δ_o observed for a series of complexes of the same metal ion depends strongly on the nature of the ligands. For a series of chemically similar ligands, the magnitude of Δ_o decreases as the size of the donor atom increases. For example, Δ_o values for halide complexes generally decrease in the order $\text{F}^- > \text{Cl}^- > \text{Br}^- > \text{I}^-$ because smaller, more localized charges, such as we see for F^- , interact more strongly with the d orbitals of the metal ion. In addition, a small neutral ligand with a

highly localized lone pair, such as NH_3 , results in significantly larger Δ_o values than might be expected. Because the lone pair points directly at the metal ion, the electron density along the M–L axis is greater than for a spherical anion such as F^- . The experimentally observed order of the crystal field splitting energies produced by different ligands is called the spectrochemical series, shown here in order of decreasing Δ_o :

The values of Δ_o listed in [Table 21.5.1](#) illustrate the effects of the charge on the metal ion, the principal quantum number of the metal, and the nature of the ligand.

Note the Pattern

The largest Δ_o s are found in complexes of metal ions from the third row of the transition metals with charges of at least +3 and ligands with localized lone pairs of electrons.

Colors of Transition-Metal Complexes

The striking colors exhibited by transition-metal complexes are caused by excitation of an electron from a lower-energy d orbital to a higher-energy d orbital, which is called a $d-d$ transition ([Figure 21.5.3](#)). For a photon to effect such a transition, its energy must be equal to the difference in energy between the two d orbitals, which depends on the magnitude of Δ_o .

Recall from [Chapter 2](#) that the color we observe when we look at an object or a compound is due to light that is transmitted or reflected, not light that is absorbed, and that reflected or transmitted light is complementary in color to the light that is absorbed. Thus a green compound absorbs light in the red portion of the visible spectrum and vice versa, as indicated by the color wheel in End-of-Chapter Application Problem 6 in [Chapter 2](#). Because the energy of a photon of light is inversely proportional to its wavelength, the color of a complex depends on the magnitude of Δ_o , which depends on the structure of the complex. For example, the complex $[\text{Cr}(\text{NH}_3)_6]^{3+}$ has strong-field ligands and a relatively large Δ_o . Consequently, it absorbs relatively high-energy photons, corresponding to blue-violet light, which gives it a yellow color. A related complex with weak-field ligands, the $[\text{Cr}(\text{H}_2\text{O})_6]^{3+}$ ion, absorbs lower-energy photons corresponding to the yellow-green portion of the visible spectrum, giving it a deep violet color.

Figure 21.5.3 A $d-d$ Transition In a $d-d$ transition, an electron in one of the t_{2g} orbitals of an octahedral complex such as the $[\text{Cr}(\text{H}_2\text{O})_6]^{3+}$ ion absorbs a photon of light with energy equal to Δ_o , which causes the electron to move to an empty or singly occupied e_g orbital.

We can now understand why emeralds and rubies have such different colors, even though both contain Cr^{3+} in an octahedral environment provided by six oxide ions. Although the chemical identity of the six ligands is the same in both cases, the Cr–O distances are different because the compositions of the host lattices are different (Al_2O_3 in rubies and $\text{Be}_3\text{Al}_2\text{Si}_6\text{O}_{18}$ in emeralds). In ruby, the Cr–O distances are relatively short because of the constraints of the host lattice, which increases the d orbital–ligand interactions and makes Δ_o relatively large. Consequently, rubies absorb green light and the transmitted or reflected light is red, which gives the gem its characteristic color. In emerald, the Cr–O distances are longer due to relatively large $[\text{Si}_6\text{O}_{18}]^{12-}$ silicate rings; this results in decreased d orbital–ligand interactions and a smaller Δ_o . Consequently, emeralds absorb light of a longer wavelength (red), which gives the gem its characteristic green color. It is clear that the environment of the transition-metal ion, which is determined by the host lattice, dramatically affects the spectroscopic properties of a metal ion.

Crystal Field Stabilization Energies

Recall from [Chapter 6](#) that stable molecules contain more electrons in the lower-energy (bonding) molecular orbitals in a molecular orbital diagram than in the higher-energy (antibonding) molecular orbitals. If the lower-energy set of d orbitals (the t_{2g} orbitals) is selectively populated by electrons, then the stability of the complex increases. For example, the single d electron in a d complex such as $[\text{Ti}(\text{H}_2\text{O})_6]^{3+}$ is located in one of the t_{2g} orbitals. Consequently, this complex will

Gem-quality crystals of ruby and emerald. The colors of both minerals are due to the

be more stable than expected on purely electrostatic grounds by $0.4\Delta_o$. The additional stabilization of a metal complex by selective population of the lower-energy d orbitals is called its crystal field stabilization energy (CFSE). The CFSE of a complex can be calculated by multiplying the number of electrons in t_{2g} orbitals by the energy of those orbitals ($-0.4\Delta_o$), multiplying the number of electrons in e_g orbitals by the energy of those orbitals ($+0.6\Delta_o$), and summing the two. Table 21.5.2 gives CFSE values for octahedral complexes with different d electron configurations. The CFSE is highest for low-spin d^6 complexes, which accounts in part for the extraordinarily large number of $Co(III)$ complexes known. The other low-spin configurations also have high CFSEs, as does the d^8 configuration.

presence of small amounts of Cr^{3+} impurities in octahedral sites in an otherwise colorless metal oxide lattice.

Table 21.5.2 CFSEs for Octahedral Complexes with Different Electron Configurations (in Units of Δ_o)

	High Spin		CFSE (Δ_o)	Low Spin		CFSE (Δ_o)
d^0			0			
d^1	1		0.4			
d^2	1 1		0.8			
d^3	1 1 1		1.2			
d^4	1 1 1	1	0.6	1 ↓ 1 1		1.6
d^5	1 1 1	1 1	0.0	1 ↓ 1 ↓ 1		2.0
d^6	1 ↓ 1 1	1 1	0.4	1 ↓ 1 ↓ 1 ↓		2.4
d^7	1 ↓ 1 ↓ 1	1 1	0.8	1 ↓ 1 ↓ 1 ↓	1	1.8
d^8	1 ↓ 1 ↓ 1 ↓	1 1	1.2			
d^9	1 ↓ 1 ↓ 1 ↓	1 ↓ 1	0.6			
d^{10}	1 ↓ 1 ↓ 1 ↓	1 ↓ 1 ↓	0.0			

CFSEs are important for two reasons. First, the existence of CFSE nicely accounts for the difference between experimentally measured values for bond energies in metal complexes and values calculated based solely on electrostatic interactions. Second, CFSEs represent relatively large amounts of energy (up to several hundred kilojoules per mole), which has important chemical consequences.

Note the Pattern

Octahedral d^3 and d^8 complexes and low-spin d^6 , d^5 , d^7 , and d^4 complexes exhibit large CFSEs.

Tetragonal and Square Planar Complexes

If two *trans* ligands in an octahedral complex are either chemically different from the other four, as in the $trans-[Co(NH_3)_4Cl_2]^+$ ion, or at a different distance from the metal than the other four, the result is a tetragonally distorted octahedral complex. The electronic structures of such complexes are best viewed as the result of distorting an octahedral complex. Consider, for example, an octahedral complex such as $[Co(NH_3)_6]^{3+}$ and then slowly remove two *trans* NH_3 molecules by moving them away from the metal along the $\pm z$ axes, as shown in the top half of Figure 21.5.4. As the two axial Co–N distances increase simultaneously, the d orbitals that interact most strongly with the two axial ligands will decrease in energy due to a decrease in electrostatic repulsions between electrons in these orbitals and the negative ends of the ligand dipoles. The affected d orbitals are those with a component along the $\pm z$ axes—namely, d_{z^2} , d_{xz} , and d_{yz} . They will not be affected equally, however. Because the d_{z^2} orbital points directly at the two ligands being removed, its energy will decrease much more rapidly than the energy of the other two, as shown in the bottom half of Figure 21.5.4. In addition, the positive charge on the metal will increase somewhat as the axial ligands are removed, causing the four remaining in-plane ligands to be more strongly attracted to the metal. This will increase their interactions with the other two d

orbitals and increase their energy. Again, the two d orbitals will not be affected equally. Because the $d_{x^2-y^2}$ orbital points directly at the four in-plane ligands, its energy will increase more rapidly than the energy of the d_{xy} orbital, which points between the in-plane ligands. If we remove the two axial ligands to an infinite distance, we obtain a square planar complex. The energies of the d_{z^2} and d_{xy} orbitals actually cross as the axial ligands are removed, and the largest orbital splitting in a square planar complex is identical in magnitude to Δ_o .

Figure 21.5.4 d-Orbital Splittings for Tetragonal and Square Planar Complexes Moving the two axial ligands away from the metal ion along the z axis initially gives an elongated octahedral complex (center) and eventually produces a square planar complex (right). As shown below the structures, an axial elongation causes the d_{z^2} , d_{xz} , d_{xz} and d_{yz} orbitals to decrease in energy and the $d_{x^2-y^2}$ and d_{xy} orbitals to increase in energy. As explained in the text, the change in energy is not the same for all five d orbitals. Removing the two axial ligands completely causes the energy of the d_{z^2} and d_{xy} orbitals is reversed.

Tetrahedral Complexes

In a tetrahedral arrangement of four ligands around a metal ion, none of the ligands lies on any of the three coordinate axes (part (a) in Figure 23.14); consequently, none of the five d orbitals points directly at the ligands. Nonetheless, the d_{xy} , d_{xz} , and d_{yz} orbitals interact more strongly with the ligands than do $d_{x^2-y^2}$ and d_{z^2} again resulting in a splitting of the five d orbitals into two sets. The splitting of the energies of the orbitals in a tetrahedral complex (Δ_t) is much smaller than that for Δ_o , however, for two reasons. First, the d orbitals interact less strongly with the ligands in a tetrahedral arrangement. Second, there are only four negative charges rather than six, which decreases the electrostatic interactions by one-third if all other factors are equal. It can be shown that, for complexes of the same metal ion with the same charge, the same ligands, and the same M–L distance, $\Delta_t = 4/9 \Delta_o$. The relationship between the splitting of the five d orbitals in octahedral and tetrahedral crystal fields imposed by the same ligands is shown schematically in part (b) in Figure 21.5.5.

Figure 21.5.5 d-Orbital Splittings for a Tetrahedral Complex (a) In a tetrahedral complex, none of the five d orbitals points directly at or between the ligands. (b) Because the d_{xy} , d_{xz} , and d_{yz} orbitals (the t_{2g} orbitals) interact more strongly with the ligands than do the $d_{x^2-y^2}$ and d_{z^2} orbitals (the e_g orbitals), the order of orbital energies in a tetrahedral complex is the opposite of the order in an octahedral complex.

Note the Pattern

$\Delta_t < \Delta_o$ because of weaker d -orbital–ligand interactions and decreased electrostatic interactions.

Because Δ_o is so large for the second- and third-row transition metals, *all* four-coordinate complexes of these metals are square planar due to the much higher CFSE for square planar versus tetrahedral structures. The only exception is for d^{10} metal ions such as Cd^{2+} , which have zero CFSE and are therefore tetrahedral as predicted by the VSEPR model. Four-coordinate complexes of the first-row transition metals can be either square planar or tetrahedral. The former is favored by strong-field ligands, whereas the latter is favored by weak-field ligands. For example, the $[\text{Ni}(\text{CN})_4]^{2-}$ ion is square planar, while the $[\text{NiCl}_4]^{2-}$ ion is tetrahedral.

Example 21.5.1

For each complex, predict its structure, whether it is high spin or low spin, and the number of unpaired electrons present.

1. $[\text{CoF}_6]^{3-}$
2. $[\text{Rh}(\text{CO})_2\text{Cl}_2]^-$

Given: complexes

Asked for: structure, high spin versus low spin, and the number of unpaired electrons

Strategy:

A From the number of ligands, determine the coordination number of the compound.

B Classify the ligands as either strong field or weak field and determine the electron configuration of the metal ion.

C Predict the relative magnitude of Δ_o and decide whether the compound is high spin or low spin.

D Place the appropriate number of electrons in the d orbitals and determine the number of unpaired electrons.

Solution:

1. **A** With six ligands, we expect this complex to be octahedral.
B The fluoride ion is a small anion with a concentrated negative charge, but compared with ligands with localized lone pairs of electrons, it is weak field. The charge on the metal ion is +3, giving a d^6 electron configuration.
C Because of the weak-field ligands, we expect a relatively small Δ_o , making the compound high spin.
D In a high-spin octahedral d^6 complex, the first five electrons are placed individually in each of the d orbitals with their spins parallel, and the sixth electron is paired in one of the t_{2g} orbitals, giving four unpaired electrons.
2. **A** This complex has four ligands, so it is either square planar or tetrahedral.
B C Because rhodium is a second-row transition metal ion with a d^8 electron configuration and CO is a strong-field ligand, the complex is likely to be square planar with a large Δ_o , making it low spin. Because the strongest d -orbital interactions are along the x and y axes, the orbital energies increase in the order d_{z^2} , d_{yz} , and d_{xz} (these are degenerate); d_{xy} ; and $d_{x^2-y^2}$
D The eight electrons occupy the first four of these orbitals, leaving the $d_{x^2-y^2}$ orbital empty. Thus there are no unpaired electrons.

Exercise

For each complex, predict its structure, whether it is high spin or low spin, and the number of unpaired electrons present.

2+

1. $[\text{Mn}(\text{H}_2\text{O})_6]^{2+}$
2. $[\text{PtCl}_4]^{2-}$

Answer:

1. octahedral; high spin; five
2. square planar; low spin; no unpaired electrons

Consequences of d -Orbital Splitting

The splitting of the d orbitals because of their interaction with the ligands in a complex has important consequences for the chemistry of transition-metal complexes; they can be divided into structural effects and thermodynamic effects. Although the two kinds of effects are interrelated, we will consider them separately.

Structural Effects

There are two major kinds of structural effects: effects on the ionic radius of metal ions with regular octahedral or tetrahedral geometries, and structural distortions that are observed for specific electron configurations.

Ionic Radii

Figure 21.5.6 is a plot of the ionic radii of the divalent fourth-period metal ions versus atomic number. Only Ca^{2+} (d^0), Mn^{2+} (high-spin d^5), and Zn^{2+} (d^{10}) fall on the smooth curve calculated based on the effective nuclear charge (Z_{eff}), which assumes that the distribution of d electrons is spherically symmetrical. All the other divalent ions fall below this curve because they have asymmetrical distributions of d electrons. (The points shown for Cr^{2+} and Cu^{2+} are only estimated values; as you will learn shortly, these two ions do not form any truly octahedral complexes.) To see why an asymmetrical distribution of d electrons makes a metal ion smaller than expected, consider the Ti^{2+} ion, which has a d^2 configuration with both electrons in the t_{2g} orbitals. Because the t_{2g} orbitals are directed between the ligands, the two d electrons are unable to shield the ligands from the nuclear charge. Consequently, the ligands experience a higher effective nuclear charge than expected, the metal–ligand distance is unusually short, and the ionic radius is smaller than expected. If instead the two electrons were distributed uniformly over all five d orbitals, they would be much more effective at screening the ligands from the nuclear charge, making the metal–ligand distances longer and giving a larger ionic radius.

Figure 21.5.6 The Effect of d -Orbital Splittings on the Radii of the Divalent Ions of the Fourth-Period Metals Because these radii are based on the structures of octahedral complexes and Cr^{2+} and Cu^{2+} do not form truly octahedral complexes, the points for these ions are shown as open circles. The dashed line represents the behavior predicted based on the effects of screening and variation in effective nuclear charge (Z_{eff}), assuming a spherical distribution of the 3d electrons.

A similar effect is observed for the V^{2+} ion, which has a d^3 configuration. Because the three electrons in the t_{2g} orbitals provide essentially no shielding of the ligands from the metal, the ligands experience the full increase of +1 in nuclear charge that occurs in going from Ti^{2+} to V^{2+} . Consequently, the observed ionic radius of the V^{2+} ion is significantly smaller than that of the Ti^{2+} ion.

Skipping the Cr^{2+} ion for the moment, we next consider the $d^5 \text{Mn}^{2+}$ ion. Because the nuclear charge increases by $+2$ from V^{2+} to Mn^{2+} , we might expect Mn^{2+} to be smaller than V^{2+} . The two electrons that are also added from V^{2+} to Mn^{2+} occupy the e_g orbitals, however, which point directly at the six ligands. Because these electrons are localized directly between the metal ion and the ligands, they are effective at screening the ligands from the increased nuclear charge. As a result, the ionic radius actually *increases* significantly as we go from V^{2+} to Mn^{2+} , despite the higher nuclear charge of the latter.

Exactly the same effects are seen in the second half of the first-row transition metals. In the Fe^{2+} , Co^{2+} , and Ni^{2+} ions, the extra electrons are added successively to the t_{2g} orbitals, resulting in poor shielding of the ligands from the nuclear charge and abnormally small ionic radii. Skipping over Cu^{2+} , we again see that adding the last two electrons causes a significant increase in the ionic radius of Zn^{2+} , despite its higher nuclear charge.

The Jahn–Teller Effect

Because simple octahedral complexes are not known for the Cr^{2+} and Cu^{2+} ions, only estimated values for their radii are shown in [Figure 21.5.6](#). We see in [Figure 21.5.2](#) that both the Cr^{2+} and Cu^{2+} ions have electron configurations with an odd number of electrons in the e_g orbitals. Because the single electron (in the case of Cr^{2+}) or the third electron (in the case of Cu^{2+}) can occupy either one of two degenerate e_g orbitals, they have what is called a *degenerate ground state*. The Jahn–Teller theorem states that such non-linear systems are not stable; they will undergo a distortion that makes the complex less symmetrical and splits the degenerate states, which decreases the energy of the system. The distortion and resulting decrease in energy are collectively referred to as the *Jahn–Teller effect*. Neither the nature of the distortion nor its magnitude is specified, and in fact, they are difficult to predict. In principle, Jahn–Teller distortions are possible for many transition-metal ions; in practice, however, they are observed only for systems with an odd number of electrons in the e_g orbitals, such as the Cr^{2+} and Cu^{2+} ions.

To see how a geometrical distortion can decrease the energy of such a system, consider an octahedral Cu^{2+} complex, the $[\text{Cu}(\text{H}_2\text{O})_6]^{2+}$ ion, which has been elongated along the z axis. As indicated in [Figure 21.5.7](#), this kind of distortion splits both the e_g and t_{2g} sets of orbitals. Because the axial ligands interact most strongly with the d_{z^2} orbital, the splitting of the e_g set (δ_1) is significantly larger than the splitting of the t_{2g} set (δ_2), but both δ_1 and δ_2 are much, much smaller than the Δ_o . This splitting does not change the center of gravity of the energy within each set, so a Jahn–Teller distortion results in no net change in energy for a filled or half-filled set of orbitals. If, however, the e_g set contains one (as in the d^4 ions, Cr^{2+} and Mn^{3+}) or three (as in the d^9 ion, Cu^{2+}) electrons, the distortion decreases the energy of the system. For Cu^{2+} , for example, the change in energy after distortion is $2(-\delta_1/2) + 1(\delta_1/2) = -\delta_1/2$. For Cu^{2+} complexes, the observed distortion is *always* an elongation along the z axis by as much as 50 pm; in fact, many Cu^{2+} complexes are so distorted that they are effectively square planar. In contrast, the distortion observed for most Cr^{2+} complexes is a *compression* along the z axis. In both cases, however, the net effect is the same: the distorted system is more stable than the undistorted system.

Note the Pattern

Jahn–Teller distortions are most important for d^9 and high-spin d^4 complexes; the distorted system is more stable than the undistorted one.

Figure 21.5.7 The Jahn–Teller Effect Increasing the axial metal–ligand distances in an octahedral d^9 complex is an example of a Jahn–Teller distortion, which causes the degenerate pair of e_g orbitals to split in energy by an amount δ_1 ; δ_1 and δ_2 are much smaller than Δ_0 . As a result, the distorted system is more stable (lower in energy) than the undistorted complex by $\delta_1/2$.

Thermodynamic Effects

As we previously noted, CFSEs can be as large as several hundred kilojoules per mole, which is the same magnitude as the strength of many chemical bonds or the energy change in most chemical reactions. Consequently, CFSEs are important factors in determining the magnitude of hydration energies, lattice energies, and other thermodynamic properties of the transition metals.

Hydration Energies

The hydration energy of a metal ion is defined as the change in enthalpy for the following reaction:

Although hydration energies cannot be measured directly, they can be calculated from experimentally measured quantities using thermochemical cycles. As shown in part (a) in Figure 21.5.8, a plot of the hydration energies of the fourth-period metal dications versus atomic number gives a curve with two valleys. Note the relationship between the plot in part (a) in Figure 21.5.8 and the plot of ionic radii in Figure 21.5.6 the overall shapes are essentially identical, and only the three cations with spherically symmetrical distributions of d electrons (Ca^{2+} , Mn^{2+} , and Zn^{2+}) lie on the dashed lines. In part (a) in Figure 21.5.8, the dashed line corresponds to hydration energies calculated based solely on electrostatic interactions. Subtracting the CFSE values for the $[M(H_2O)_6]^{2+}$ ions from the experimentally determined hydration energies gives the points shown as open circles, which lie very near the calculated curve. Thus CFSEs are primarily responsible for the differences between the measured and calculated values of hydration energies.

Figure 21.5.8 Thermochemical Effects of d -Orbital Splittings (a) A plot of the hydration energies of the divalent fourth-period metal ions versus atomic number (solid circles) shows large deviations from the smooth curve calculated, assuming a spherical distribution of d electrons (dashed line). Correcting for CFSE gives the points shown as open circles, which, except for Ti^{2+} and Cr^{2+} , are close to the calculated values. The apparent deviations for these ions are caused by the fact that solutions of the Ti^{2+} ion in water are not stable, and Cr^{2+} does not form truly octahedral complexes. (b) A plot of the lattice energies for the fourth-period metal dichlorides versus atomic number shows similar deviations from the smooth curve calculated, assuming a spherical distribution of d electrons (dashed lines), again illustrating the importance of CFSEs.

Lattice Energies

Values of the lattice energies for the fourth-period metal dichlorides are plotted versus atomic number in part (b) in [Figure 21.6.2](#). Recall that the lattice energy is defined as the negative of the enthalpy change for the following reaction. Like hydration energies, lattice energies are determined indirectly by using a thermochemical cycle:

The shape of the lattice-energy curve is essentially the mirror image of the hydration-energy curve in part (a) in [Figure 21.5.8](#), with only Ca^{2+} , Mn^{2+} , and Zn^{2+} lying on the smooth curve. It is not surprising that the explanation for the deviations from the curve is exactly the same as for the hydration energy data: all the transition-metal dichlorides, except $MnCl_2$ and $ZnCl_2$, are more stable than expected due to CFSE.

Summary

Crystal field theory (CFT) is a bonding model that explains many properties of transition metals that cannot be explained using valence bond theory. In CFT, complex formation is assumed to be due to electrostatic interactions between a central metal ion and a set of negatively charged ligands or ligand dipoles arranged around the metal ion. Depending on the arrangement of the ligands, the d orbitals split into sets of orbitals with different energies. The difference between the energy levels in an octahedral complex is called the **crystal field splitting energy (Δ_o)**, whose magnitude depends on the charge on the metal ion, the position of the metal in the periodic table, and the nature of the ligands. The **spin-pairing energy (P)** is the increase in energy that occurs when an electron is added to an already occupied orbital. A high-spin configuration occurs when the Δ_o is less than P, which produces complexes with the maximum number of unpaired electrons possible. Conversely, a low-spin configuration occurs when the Δ_o is greater than P, which produces complexes with the minimum number of unpaired electrons possible. Strong-field ligands interact strongly with the d orbitals of the metal ions and give a large Δ_o , whereas weak-field ligands interact more weakly and give a smaller Δ_o . The colors of transition-metal complexes depend on the environment of the metal ion and can be explained by CFT. Distorting an octahedral complex by moving opposite ligands away from the metal produces a tetragonal or square planar arrangement, in which interactions with equatorial ligands become stronger. Because none of the d orbitals points directly at the ligands in a tetrahedral complex, these complexes have smaller values of the crystal field splitting energy Δ_t . The **crystal field stabilization energy (CFSE)** is the additional stabilization of a complex due to placing electrons in the lower-energy set of d orbitals. CFSE explains the unusual curves seen in plots of ionic radii, hydration energies, and lattice energies versus atomic number. The **Jahn–Teller theorem** states that a non-linear molecule with a spatially degenerate electronic ground state will undergo a geometrical distortion to remove the degeneracy and lower the overall energy of the system.

Key Takeaway

- Crystal field theory, which assumes that metal–ligand interactions are only electrostatic in nature, explains many important properties of transition-metal complexes, including their colors, magnetism, structures, stability, and reactivity.

Conceptual Problems

- Describe crystal field theory in terms of its
 - assumptions regarding metal–ligand interactions.
 - weaknesses and strengths compared with valence bond theory.
- In CFT, what causes degenerate sets of d orbitals to split into different energy levels? What is this splitting called? On what does the magnitude of the splitting depend? _____
- Will the value of Δ_o increase or decrease if I^{-} ligands are replaced by NO_2^{-} ligands? Why?
- For an octahedral complex of a metal ion with a d^6 configuration, what factors favor a high-spin configuration versus a low-spin configuration?
- How can CFT explain the color of a transition-metal complex?

Structure and Reactivity

1. Do strong-field ligands favor a tetrahedral or a square planar structure? Why?
2. For each complex, predict its structure, whether it is high spin or low spin, and the number of unpaired electrons present.

3. For each complex, predict its structure, whether it is high spin or low spin, and the number of unpaired electrons present.
 - a. $[\text{Cu}(\text{NH}_3)_4]^{2+}$
 - b. $[\text{Ni}(\text{CN})_4]^{2-}$
4. The ionic radii of V^{2+} , Fe^{2+} , and Zn^{2+} are all roughly the same (approximately 76 pm). Given their positions in the periodic table, explain why their ionic radii are so similar.

Answer

- 1.
2.
 - a. d_0 , square planar, neither high nor low spin, single unpaired electron
 - b. d_7 , square planar, low spin, no unpaired electrons
- 3.
- 4.

Learning Objective

- To become familiar with some of the roles of transition-metal complexes in biological systems.

In [Chapter 1](#), you learned that 19 of the elements in the periodic table are *essential elements* that are necessary for most organisms, including humans, and in [Chapter 3](#) we discussed some of the biological functions of these elements. In this section, we describe several systems that illustrate the roles transition metals play in biological systems. Our goal is for you to understand why the chemical properties of these elements make them essential for life. We begin with a discussion of the strategies organisms use to extract transition metals from their environment. The section continues with a brief discussion of the use of transition metals in reactions that involve the transfer of electrons, reactions of small molecules such as O_2 , Lewis-acid catalysis, and the generation of reactive organic radicals.

Uptake and Storage of Transition Metals

In [Chapter 1](#), we described the three possible dietary levels for any essential element: deficient, optimal, and toxic, in order of increasing concentration in the diet. If the concentration of an essential element in the diet is too low, an organism must be able to extract the element from the environment and concentrate it. If the concentration of an essential element in the diet is too high, an organism must be able to limit its intake to avoid toxic effects. Moreover, organisms must be able to switch off the uptake process rapidly if dietary levels rise suddenly, and they must be able to store essential elements for future use.

Three distinct steps are involved in transition metal uptake. First, the metal must be “mobilized” from the environment and brought into contact with a cell in a form that can be absorbed. Second, the metal must be transported across the cell membrane into the cell. Third, the element must be transported to its point of utilization within a cell or to other cells within the organism. In our discussion, we focus on the uptake, transport, and storage of iron, which illustrates the most important points. Because iron deficiency (anemia) is the most widespread nutritional deficiency known in humans, the uptake of iron is especially well understood.

Iron complexes in biological systems. Iron(III) forms very stable octahedral complexes with hydroxamate and catecholate ligands.

In Chapter 16, you learned that the solubility of metal ions such as Fe^{3+} , which form highly insoluble hydroxides, depends on the pH and the presence of complexing agents. In an oxygen-containing atmosphere, iron exists as Fe(III) because of the positive reduction potential of Fe^{3+} ($\text{Fe}^{3+} + \text{e}^- \rightarrow \text{Fe}^{2+}$; $E^\circ = +0.77 \text{ V}$). Because ferric hydroxide $[\text{Fe}(\text{OH})_3]$ is highly insoluble ($K_{\text{sp}} \approx 1 \times 10^{-39}$), the equilibrium concentration of $\text{Fe}^{3+}(\text{aq})$ at pH 7.0 is very low, about 10^{-18} M . You would have to drink $2 \times 10^{13} \text{ L}$ of iron-saturated water per day (roughly 5 mi³) to consume the recommended daily intake of Fe for humans, which is about 1 mg/day. Animals such as humans can overcome this problem by consuming concentrated sources of iron, such as red meat, but microorganisms cannot.

Consequently, most microorganisms synthesize and secrete organic molecules called siderophores to increase the total concentration of available iron in the surrounding medium. Siderophores are generally cyclic compounds that use bidentate ligands, such as the *hydroxamate* and *catecholate* groups shown here, to bind Fe^{3+} in an octahedral arrangement. Typical siderophores are *ferrichrome*, a cyclic peptide produced by fungi, and *enterobactin*, a cyclic ester produced by bacteria (Figure 21.6.1). Attaching the three iron ligands to a cyclic framework greatly increases the stability of the resulting Fe^{3+} complex due to the chelate effect described in Section 21.4. The formation constants for the Fe^{3+} complexes of ferrichrome and enterobactin are about 10^{32} and 10^{40} , respectively, which are high enough to allow them to dissolve almost any Fe(III) compound.

Figure 21.6.1 Siderophores Ferrichrome (a) and enterobactin (b) are siderophores that use hydroxamate and catecholate ligands, respectively, to bind Fe^{3+} . The “wrapped” drawing of enterobactin (c) shows how the cyclic ester framework places the three catecholate ligands in the correct orientation to bind to a single Fe^{3+} ion, which is an application of the chelate effect. The actual structure of ferrichrome is similar to that of enterobactin, with the three hydroxamate ligands adjacent to one another for optimal binding of Fe^{3+} . Note: For clarity, most or all hydrogen atoms have been omitted in this and the following structures.

Siderophores increase the $[\text{Fe}^{3+}]$ in solution, providing the bacterium that synthesized them (as well as any competitors) with a supply of iron. In addition, siderophores neutralize the positive charge on the metal ion and provide a hydrophobic “wrapping” that enables the Fe^{3+} -siderophore complex to be recognized by a specific protein that transports it into the interior of a cell. Once it is inside a cell, the iron is reduced to Fe^{2+} , which has a much lower affinity for the siderophore and spontaneously dissociates.

In contrast, multicellular organisms can increase the concentration of iron in their diet by lowering the pH in the gastrointestinal tract. At pH 1.0 (the approximate pH of the stomach), most Fe(III) salts dissolve to form $\text{Fe}^{3+}(\text{aq})$, which is absorbed by specific proteins in the intestinal wall. A protein called *transferrin* forms a complex with iron(III), allowing it to be transported to other cells. Proteins that bind tightly to Fe(III) can also be used as antibacterial agents because iron is absolutely essential for bacterial growth. For example, milk, tears, and egg white all contain proteins similar to transferrin, and their high affinity for Fe^{3+} allows them to sequester iron, thereby preventing bacteria from growing in these nutrient-rich media.

Iron is released from transferrin by reduction to Fe^{2+} , and then it is either used immediately (e.g., for the synthesis of hemoglobin) or stored in a very large protein called *ferritin* for future use (Figure 21.6.2). Ferritin uses oxygen to oxidize Fe^{2+} to Fe^{3+} , which at neutral pH precipitates in the central cavity of the protein as a polymeric mixture of $\text{Fe}(\text{OH})_3$ and FePO_4 . Because a fully loaded ferritin molecule can contain as many as 4500 Fe atoms, which corresponds to about 25% Fe by mass, ferritin is an effective way to store iron in a highly concentrated form. When iron is needed by a cell, the Fe^{3+} is reduced to the much more soluble Fe^{2+} by a reductant such as ascorbic acid (vitamin C). The structure of ferritin contains channels at the junctions of the subunits, which provide pathways for iron to enter and leave the interior of a molecule.

Figure 21.6.2 Ferritin, an Iron Storage Protein A schematic drawing of the structure of iron-loaded ferritin, showing the almost spherical protein shell inside which the iron hydroxide/phosphate core is formed.

Metalloproteins and Metalloenzymes

A protein that contains one or more metal ions tightly bound to amino acid side chains is called a metalloprotein; some of the most common ligands provided by amino acids are shown here. A metalloprotein that catalyzes a chemical reaction is a metalloenzyme. Thus all metalloenzymes are metalloproteins, but the converse is not true. Recent estimates suggest that more than 40% of all known enzymes require at least one metal ion for activity, including almost all the enzymes responsible for the synthesis, duplication, and repair of DNA (deoxyribonucleic acid) and RNA (ribonucleic acid).

Electron-Transfer Proteins

Proteins whose function is to transfer electrons from one place to another are called *electron-transfer proteins*. Because they do *not* catalyze a chemical reaction, electron-transfer proteins are *not* enzymes; they are biochemical reductants or oxidants consumed in an enzymatic reaction. The general reaction for an electron-transfer protein is as follows:

Because many transition metals can exist in more than one oxidation state, electron-transfer proteins usually contain one or more metal ions that can undergo a redox reaction. Incorporating a metal ion into a protein has three important biological consequences:

1. The protein environment can adjust the redox potential (E^0), of the metal ion over a rather large potential range, whereas the redox potential of the simple hydrated metal ion $[M_n(aq)]$, is essentially fixed.
2. The protein can adjust the structure of the metal complex to ensure that electron transfer is rapid.
3. The protein environment provides specificity, ensuring that the electron is transferred to only the desired site.

Three important classes of metalloproteins transfer electrons: blue copper proteins, cytochromes, and iron-sulfur proteins, which generally transfer electrons at high (> 0.20 V), intermediate (± 0 V), and low (-0.20 to -0.50 V) potentials, respectively (Table 21.6.1). Although these electron-transfer proteins contain different metals with different structures, they are all designed to ensure rapid electron transfer to and from the metal. Thus when the protein collides with its physiological oxidant or reductant, electron transfer can occur before the two proteins diffuse apart. For electron transfer to be rapid, the metal sites in the oxidized and reduced forms of the protein must have similar structures.

Ligands used in biological systems. These metal ligands are commonly found in metalloproteins.

Table 21.6.1 Some Properties of the Most Common Electron-Transfer Proteins

Protein	Metal Center	M/e Transferred	Reduction Potential (V)
* A sulfur bound to an organic group is represented as SR.			
† See Figure 21.6.3 for the structure of imidazole (Im).			

Protein	Metal Center	M/e ⁻ Transferred	Reduction Potential (V)
iron-sulfur proteins*	$[\text{Fe}(\text{SR})_4]^{2-}$	1 Fe	-0.1 to +0.1
	$[(\text{RS})_2\text{FeS}_2\text{Fe}(\text{SR})_2]^{2-}$	2 Fe	-0.2 to -0.4
	$[\text{Fe}_3\text{S}_4(\text{SR})_3]^{3-}$	3 Fe	-0.1 to -0.2
	$[\text{Fe}_4\text{S}_4(\text{SR})_4]^{2-}$	4 Fe	-0.3 to -0.5
cytochromes	Fe-heme (low spin)	1 Fe	~0
blue copper proteins [†]	$[\text{Cu}(\text{Im})_2(\text{SR})(\text{SR}_2)]^-$	1 Cu	≥ +0.20

[†] See Figure 21.6.3 for the structure of imidazole (Im).

Blue Copper Proteins

Blue copper proteins were first isolated from bacteria in the 1950s and from plant tissues in the early 1960s. The intense blue color of these proteins is due to a strong absorption band at a wavelength of about 600 nm. Although simple Cu^{2+} complexes, such as $[\text{Cu}(\text{H}_2\text{O})_6]^{2+}$ and $[\text{Cu}(\text{NH}_3)_4]^{2+}$, are also blue due to an absorption band at 600 nm, the intensity of the absorption band is about 100 times less than that of a blue copper protein. Moreover, the reduction potential for the $\text{Cu}^{2+}/\text{Cu}^+$ couple in a blue copper protein is usually +0.3 to +0.5 V, considerably more positive than that of the aqueous $\text{Cu}^{2+}/\text{Cu}^+$ couple (+0.15 V).

The copper center in blue copper proteins has a distorted tetrahedral structure, in which the copper is bound to four amino acid side chains (Figure 21.6.3). Although the most common structures for four-coordinate Cu^{2+} and Cu^+ complexes are square planar and tetrahedral, respectively, the structures of the oxidized (Cu^{2+}) and reduced (Cu^+) forms of the protein are essentially identical. Thus the protein forces the Cu^{2+} ion to adopt a higher-energy structure that is more suitable for Cu^+ , which makes the Cu^{2+} form easier to reduce and raises its reduction potential.

Moreover, by forcing the oxidized and reduced forms of the metal complex to have essentially the same structure, the protein ensures that electron transfer to and from the copper site is rapid because only minimal structural reorganization of the metal center is required. Kinetics studies on simple metal complexes have shown that electron-transfer reactions tend to be slow when the structures of the oxidized and reduced forms of a metal complex are very different, and fast when they are similar. You will see that other metal centers used for biological electron-transfer reactions are also set up for minimal structural reorganization after electron transfer, which ensures the rapid transfer of electrons.

Cytochromes

The cytochromes (from the Greek *cytos*, meaning “cell”, and *chroma*, meaning “color”) were first identified in the 1920s by spectroscopic studies of cell extracts. Based on the wavelength of the maximum absorption in the visible spectrum, they were classified as cytochromes *a* (with the longest wavelength), cytochromes *b* (intermediate wavelength), and cytochromes *c* (shortest wavelength). It quickly became apparent that there was a correlation between their spectroscopic properties and other physical properties. For examples, cytochromes *c* are generally small, soluble proteins with a reduction potential of about +0.25 V, whereas cytochromes *b* are larger, less-soluble proteins with reduction potentials of about 0 V.

All cytochromes contain iron, and the iron atom in all cytochromes is coordinated by a planar array of four nitrogen atoms provided by a cyclic tetradentate ligand called a *porphyrin*. The iron-porphyrin unit is called a *heme* group. The structures of a typical porphyrin (protoporphyrin IX) and its iron complex (protoheme) are shown here. In addition to the four nitrogen atoms of the porphyrin, the iron in a cytochrome is usually bonded to two additional ligands provided by the protein, as shown in Figure 21.6.4.

Figure 21.6.3 A Blue Copper Protein In both the oxidized and reduced forms of a blue copper protein, the copper is coordinated by four ligands (two histidine imidazole nitrogen atoms, a cysteine thiolate sulfur, and a thioether sulfur of a methionine) in a roughly tetrahedral arrangement.

Figure 21.6.4 A Cytochrome c In a cytochrome c, the heme iron is coordinated to the nitrogen atom of a histidine imidazole and the sulfur atom of a methionine thioether, in addition to the four nitrogen atoms provided by the porphyrin.

A cytochrome. Shown here is protoporphyrin IX and its iron complex, protoheme.

In contrast to the blue copper proteins, two electron configurations are possible for both the oxidized and reduced forms of a cytochrome, and this has significant structural consequences. Thus Fe^{2+} is d^6 and can be either high spin (with four unpaired electrons) or low spin (with no unpaired electrons; Figure 21.5.2). Similarly, Fe^{3+} is d^5 and can also be high spin (with five unpaired electrons) or low spin (with one unpaired electron). In low-spin heme complexes, both the Fe^{2+} and the Fe^{3+} ions are small enough to fit into the “hole” in the center of the porphyrin; hence the iron atom lies almost exactly in the plane of the four porphyrin nitrogen atoms in both cases. Because cytochromes *b* and *c* are low spin in both their oxidized and reduced forms, the structures of the oxidized and reduced cytochromes are essentially identical. Hence minimal structural changes occur after oxidation or reduction, which makes electron transfer to or from the heme very rapid.

Note the Pattern

Electron transfer reactions occur most rapidly when minimal structural changes occur during oxidation or reduction.

Iron–Sulfur Proteins

Although all known bacteria, plants, and animals use iron–sulfur proteins to transfer electrons, the existence of these proteins was not recognized until the late 1950s. Iron–sulfur proteins transfer electrons over a wide range of reduction potentials, and their iron content can range from 1 to more than 12 Fe atoms per protein molecule. In addition, most iron–sulfur proteins contain stoichiometric amounts of sulfide (S^{2-}).

These properties are due to the presence of four different kinds of iron–sulfur units, which contain one, two, three, or four iron atoms per Fe–S complex (Figure 21.6.5). In all cases, the Fe^{2+} and Fe^{3+} ions are coordinated to four sulfur ligands in a tetrahedral environment. Due to tetrahedral coordination by weak-field sulfur ligands, the iron is high spin in both the Fe^{3+} and Fe^{2+} oxidation states, which results in similar structures for the oxidized and reduced forms of the Fe–S complexes. Consequently, only small structural changes occur after oxidation or reduction of the Fe–S center, which results in rapid electron transfer.

Figure 21.6.5 Fe–S Centers in Proteins Four kinds of iron–sulfur centers, containing one, two, three, and four iron atoms, respectively, are known in electron-transfer proteins. Although they differ in the number of sulfur atoms provided by cysteine thiolates versus sulfide, in all cases the iron is coordinated to four sulfur ligands in a roughly tetrahedral environment.

Reactions of Small Molecules

Although small molecules, such as O_2 , N_2 , and H_2 , do not react with organic compounds under ambient conditions, they do react with many transition-metal complexes. Consequently, virtually all organisms use metalloproteins to bind, transport, and catalyze the reactions of these molecules. Probably the best-known example is hemoglobin, which is used to transport O_2 in many multicellular organisms.

Note the Pattern

Under ambient conditions, small molecules, such as O_2 , N_2 , and H_2 , react with transition-metal complexes but not with organic compounds.

Oxygen Transport

Many microorganisms and most animals obtain energy by *respiration*, the oxidation of organic or inorganic molecules by O_2 . At $25^\circ C$, however, the concentration of dissolved oxygen in water in contact with air is only about 0.25 mM. Because of their high surface area-to-volume ratio, aerobic microorganisms can obtain enough oxygen for respiration by passive diffusion of O_2 through the cell membrane. As the size of an organism increases, however, its volume increases much more rapidly than its surface area, and the need for oxygen depends on its volume. Consequently, as a multicellular organism grows larger, its need for O_2 rapidly outstrips the supply available through diffusion. Unless a transport system is available to provide an adequate supply of oxygen for the interior cells, organisms that contain more than a few cells cannot exist. In addition, O_2 is such a powerful oxidant that the oxidation reactions used to obtain metabolic energy must be carefully controlled to avoid releasing so much heat that the water in the cell boils. Consequently, in higher-level organisms, the respiratory apparatus is located in internal compartments called *mitochondria*, which are the power plants of a cell. Oxygen must therefore be transported not only to a cell but also to the proper compartment within a cell.

Three different chemical solutions to the problem of oxygen transport have developed independently in the course of evolution, as indicated in [Table 21.6.2](#). Mammals, birds, reptiles, fish, and some insects use a heme protein called *hemoglobin* to transport oxygen from the lungs to the cells, and they use a related protein called *myoglobin* to temporarily store oxygen in the tissues. Several classes of invertebrates, including marine worms, use an iron-containing protein called *hemerythrin* to transport oxygen, whereas other classes of invertebrates (arthropods and mollusks) use a copper-containing protein called *hemocyanin*. Despite the presence of the *hem-* prefix, hemerythrin and hemocyanin do not contain a metal–porphyrin complex.

Table 21.6.2 Some Properties of the Three Classes of Oxygen-Transport Proteins

Protein	Source	M per Subunit	M per O_2 Bound	Color (deoxy form)	Color (oxy form)
hemoglobin	mammals, birds, fish, reptiles, some insects	1 Fe	1 Fe	red-purple	red
hemerythrin	marine worms	2 Fe	2 Fe	colorless	red
hemocyanin	mollusks, crustaceans, spiders	2 Cu	2 Cu	colorless	blue

Myoglobin and Hemoglobin

Myoglobin is a relatively small protein that contains 150 amino acids. The functional unit of myoglobin is an iron–porphyrin complex that is embedded in the protein ([Figure 21.6.6](#)). In myoglobin, the heme iron is five-coordinate, with only a single histidine imidazole ligand from the protein (called the *proximal histidine* because it is near the iron) in addition to the four nitrogen atoms of the porphyrin. A second histidine imidazole (the *distal histidine* because it is more distant from the iron) is located on the other side of the heme group, too far from the iron to be bonded to it. Consequently, the iron atom has a vacant coordination site, which is where O_2 binds. In the ferrous form (*deoxymyoglobin*), the iron is five-coordinate and high spin. Because high-spin Fe^{2+} is

too large to fit into the “hole” in the center of the porphyrin, it is about 60 pm above the plane of the porphyrin. When O_2 binds to deoxymyoglobin to form $oxy\text{myoglobin}$, the iron is converted from five-coordinate (high spin) to six-coordinate (low spin; [Figure 21.6.7](#)). Because low-spin Fe^{2+} and Fe^{3+} are smaller than high-spin Fe^{2+} , the iron atom moves into the plane of the porphyrin ring to form an octahedral complex. The O_2 pressure at which half of the molecules in a solution of myoglobin are bound to O_2 ($P_{1/2}$) is about 1 mm Hg (1.3×10^{-3} atm).

Note the Pattern

A vacant coordination site at a metal center in a protein usually indicates that a small molecule will bind to the metal ion, whereas a coordinatively saturated metal center is usually involved in electron transfer.

Figure 21.6.6 The Structure of Deoxymyoglobin, Showing the Heme Group The iron in deoxymyoglobin is five-coordinate, with one histidine imidazole ligand from the protein. Oxygen binds at the vacant site on iron.

Figure 21.6.7 Oxygen Binding to Myoglobin and Hemoglobin (a) The Fe^{2+} ion in deoxymyoglobin is high spin, which makes it too large to fit into the “hole” in the center of the porphyrin. (b) When O_2 binds to deoxymyoglobin, the iron is converted to low-spin Fe^{2+} , which is smaller, allowing the iron to move into the plane of the four nitrogen atoms of the porphyrin to form an octahedral complex.

Hemoglobin consists of two subunits of 141 amino acids and two subunits of 146 amino acids, both similar to myoglobin; it is called a *tetramer* because of its four subunits. Because hemoglobin has very different O_2 -binding properties, however, it is not simply a “super myoglobin” that can carry four O_2 molecules simultaneously (one per heme group). The shape of the O_2 -binding curve of myoglobin (Mb; [Figure 21.6.7](#)) can be described mathematically by the following equilibrium:

In contrast, the O_2 -binding curve of hemoglobin is S shaped ([Figure 21.6.8](#)). As shown in the curves, at low oxygen pressures, the affinity of deoxyhemoglobin for O_2 is substantially lower than that of myoglobin, whereas at high O_2 pressures the two proteins have comparable O_2 affinities. The physiological consequences of the unusual S-shaped O_2 -binding curve of hemoglobin are enormous. In the lungs, where O_2 pressure is highest, the high oxygen affinity of deoxyhemoglobin allows it to be completely

loaded with O₂, giving four O₂ molecules per hemoglobin. In the tissues, however, where the oxygen pressure is much lower, the decreased oxygen affinity of hemoglobin allows it to release O₂, resulting in a net transfer of oxygen to myoglobin.

Figure 21.6.8 The O₂-Binding Curves of Myoglobin and Hemoglobin The curve for myoglobin can be described by a simple equilibrium between deoxy- and oxymyoglobin, but the S-shaped curve for hemoglobin can be described only in terms of a cooperative interaction between the four hemes.

The S-shaped O₂-binding curve of hemoglobin is due to a phenomenon called *cooperativity*, in which the affinity of one heme for O₂ depends on whether the other hemes are already bound to O₂. Cooperativity in hemoglobin requires an interaction between the four heme groups in the hemoglobin tetramer, even though they are more than 3000 pm apart, and depends on the change in structure of the heme group that occurs with oxygen binding. The structures of deoxyhemoglobin and oxyhemoglobin are slightly different, and as a result, deoxyhemoglobin has a much lower O₂ affinity than myoglobin, whereas the O₂ affinity of oxyhemoglobin is essentially identical to that of oxymyoglobin. Binding of the first two O₂ molecules to deoxyhemoglobin causes the overall structure of the protein to change to that of oxyhemoglobin; consequently, the last two heme groups have a much higher affinity for O₂ than the first two.

Oxygen is not unique in its ability to bind to a ferrous heme complex; small molecules such as CO and NO bind to deoxymyoglobin even more tightly than does O₂. The interaction of the heme iron with oxygen and other diatomic molecules involves the transfer of electron density from the filled *t_{2g}* orbitals of the low-spin *d⁶* Fe²⁺ ion to the empty π* orbitals of the ligand. In the case of the Fe²⁺-O₂ interaction, the transfer of electron density is so great that the Fe-O₂ unit can be described as containing low-spin Fe³⁺ (*d⁵*) and O₂⁻. We can therefore represent the binding of O₂ to deoxymyoglobin and its release as a reversible redox reaction:

As shown in Figure 21.6.9, the Fe-O₂ unit is bent, with an Fe-O-O angle of about 130°. Because the π* orbitals in CO are empty and those in NO are singly occupied, these ligands interact more strongly with Fe²⁺ than does O₂, in which the π* orbitals of the neutral ligand are doubly occupied.

Figure 21.6.9 Binding of O₂ and CO to the Iron of Myoglobin Because the Fe–O–O unit is bent, while the Fe–C–O unit is linear, the imidazole group of the distal histidine in hemoglobin interferes with CO binding and decreases the affinity of hemoglobin for CO.

Although CO has a much greater affinity for a ferrous heme than does O₂ (by a factor of about 25,000), the affinity of CO for deoxyhemoglobin is only about 200 times greater than that of O₂, which suggests that something in the protein is decreasing its affinity for CO by a factor of about 100. Both CO and NO bind to ferrous hemes in a linear fashion, with an Fe–C(N)–O angle of about 180°, and the difference in the preferred geometry of O₂ and CO provides a plausible explanation for the difference in affinities. As shown in [Figure 21.6.9](#), the imidazole group of the distal histidine is located precisely where the oxygen atom of bound CO would be if the Fe–C–O unit were linear. Consequently, CO cannot bind to the heme in a linear fashion; instead, it is forced to bind in a bent mode that is similar to the preferred structure for the Fe–O₂ unit. This results in a significant decrease in the affinity of the heme for CO, while leaving the O₂ affinity unchanged, which is important because carbon monoxide is produced continuously in the body by degradation of the porphyrin ligand (even in nonsmokers). Under normal conditions, CO occupies approximately 1% of the heme sites in hemoglobin and myoglobin. If the affinity of hemoglobin and myoglobin for CO were 100 times greater (due to the absence of the distal histidine), essentially 100% of the heme sites would be occupied by CO, and no oxygen could be transported to the tissues. Severe carbon-monoxide poisoning, which is frequently fatal, has exactly the same effect. Thus the primary function of the distal histidine appears to be to decrease the CO affinity of hemoglobin and myoglobin to avoid self-poisoning by CO.

Hemerythrin

Hemerythrin is used to transport O₂ in a variety of marine invertebrates. It is an *octamer* (eight subunits), with each subunit containing *two* iron atoms and binding *one* molecule of O₂. Deoxyhemerythrin contains two Fe²⁺ ions per subunit and is colorless, whereas oxyhemerythrin contains two Fe³⁺ ions and is bright reddish violet. These invertebrates also contain a monomeric form of hemerythrin that is located in the tissues, analogous to myoglobin. The binding of oxygen to hemerythrin and its release can be described by the following reaction, where the HO₂⁻ ligand is the hydroperoxide anion derived by the deprotonation of hydrogen peroxide (H₂O₂):

Thus O₂ binding is accompanied by the transfer of *two* electrons (one from each Fe²⁺) and a proton to O₂.

Hemocyanin

Hemocyanin is used for oxygen transport in many arthropods (spiders, crabs, lobsters, and centipedes) and in mollusks (shellfish, octopi, and squid); it is responsible for the bluish-green color of their blood. The protein is a polymer of subunits that each contain two copper atoms (rather than iron), with an aggregate molecular mass of greater than 1,000,000 amu. Deoxyhemocyanin contains two Cu⁺ ions per subunit and is colorless, whereas oxyhemocyanin contains two Cu²⁺ ions and is bright blue. As with hemerythrin, the binding and release of O₂ correspond to a two-electron reaction:

Although hemocyanin and hemerythrin perform the same basic function as hemoglobin, these proteins are not interchangeable. In fact, hemocyanin is so foreign to humans that it is one of the major factors responsible for the common allergies to shellfish.

Note the Pattern

Myoglobin, hemoglobin, hemerythrin, and hemocyanin all use a transition-metal complex to transport oxygen.

Enzymes Involved in Oxygen Activation

Many of the enzymes involved in the biological reactions of oxygen contain metal centers with structures that are similar to those used for O₂ transport. Many of these enzymes also contain metal centers that are used for electron transfer, which have structures similar to those of the electron-transfer proteins discussed previously. In this section, we briefly describe two of the most important examples: dioxygenases and methane monooxygenase.

Dioxygenases are enzymes that insert both atoms of O_2 into an organic molecule. In humans, dioxygenases are responsible for cross-linking collagen in connective tissue and for synthesizing complex organic molecules called *prostaglandins*, which trigger inflammation and immune reactions. Iron is by far the most common metal in dioxygenases; and the target of the most commonly used drug in the world, aspirin, is an iron enzyme that synthesizes a specific prostaglandin. Aspirin inhibits this enzyme by binding to the iron atom at the active site, which prevents oxygen from binding.

Methane monooxygenase catalyzes the conversion of methane to methanol. The enzyme is a monooxygenase because only one atom of O_2 is inserted into an organic molecule, while the other is reduced to water:

Because methane is the major component of natural gas, there is enormous interest in using this reaction to convert methane to a liquid fuel (methanol) that is much more convenient to ship and store. Because the C–H bond in methane is one of the strongest C–H bonds known, however, an extraordinarily powerful oxidant is needed for this reaction. The active site of methane monooxygenase contains two Fe atoms that bind O_2 , but the details of how the bound O_2 is converted to such a potent oxidant remain unclear.

Metal Ions as Lewis Acids

Reactions catalyzed by metal ions that do not change their oxidation states during the reaction are usually group transfer reactions, in which a group such as the phosphoryl group ($-PO_3^{2-}$) is transferred. These enzymes usually use metal ions such as Zn^{2+} , Mg^{2+} , and Mn^{2+} , and they range from true metalloenzymes, in which the metal ion is tightly bound, to metal-activated enzymes, which require the addition of metal ions for activity. Because tight binding is usually the result of specific metal–ligand interactions, metalloenzymes tend to be rather specific for a particular metal ion. In contrast, the binding of metal ions to metal-activated enzymes is largely electrostatic in nature; consequently, several different metal ions with similar charges and sizes can often be used to give an active enzyme.

Note the Pattern

Metalloenzymes generally contain a specific metal ion, whereas metal-activated enzymes can use any of several metal ions of similar size and charge.

A metal ion that acts as a Lewis acid can catalyze a group transfer reaction in many different ways, but we will focus on only one of these, using a zinc enzyme as an example. *Carbonic anhydrase* is found in red blood cells and catalyzes the reaction of CO_2 with water to give carbonic acid.

Although this reaction occurs spontaneously in the absence of a catalyst, it is too slow to absorb all the CO_2 generated during respiration. Without a catalyst, tissues would explode due to the buildup of excess CO_2 pressure. Carbonic anhydrase contains a single Zn^{2+} ion per molecule, which is coordinated by three histidine imidazole ligands and a molecule of water. Because Zn^{2+} is a Lewis acid, the pK_a of the $Zn^{2+}-OH_2$ unit is about 8 versus 14 for pure water. Thus at pH 7–8, a significant fraction of the enzyme molecules contain the $Zn^{2+}-OH^-$ group, which is much more reactive than bulk water. When carbon dioxide binds in a nonpolar site next to the $Zn^{2+}-OH^-$ unit, it reacts rapidly to give a coordinated bicarbonate ion that dissociates from the enzyme:

Thus the function of zinc in carbonic anhydrase is to generate the hydroxide ion at pH 7.0, far less than the pH required in the absence of the metal ion.

Enzymes That Use Metals to Generate Organic Radicals

An *organic radical* is an organic species that contains one or more unpaired electrons. Chemists often consider organic radicals to be highly reactive species that produce undesirable reactions. For example, they have been implicated in some of the irreversible chemical changes that accompany aging. It is surprising, however, that organic radicals are also essential components of many important enzymes, almost all of which use a metal ion to generate the organic radical

The active site of carbonic anhydrase.

within the enzyme. These enzymes are involved in the synthesis of hemoglobin and DNA, among other important biological molecules, and they are the targets of pharmaceuticals for the treatment of diseases such as anemia, sickle-cell anemia, and cancer. In this section, we discuss one class of radical enzymes that use vitamin B₁₂.

Vitamin B₁₂ was discovered in the 1940s as the active agent in the cure of pernicious anemia, which does not respond to increased iron in the diet. Humans need only tiny amounts of vitamin B₁₂, and the average blood concentration in a healthy adult is only about 3.5×10^{-8} M. The structure of vitamin B₁₂, shown in Figure 21.6.10, is similar to that of a heme, but it contains cobalt instead of iron, and its structure is much more complex. In fact, vitamin B₁₂ has been called the most complex nonpolymeric biological molecule known and was the first naturally occurring organometallic compound to be isolated. When vitamin B₁₂ (the form present in vitamin tablets) is ingested, the axial cyanide ligand is replaced by a complex organic group.

Figure 21.6.10 Vitamin B₁₂ In the body, the axial cyanide ligand found in the vitamin is replaced by a complex organic unit. Heterolytic cleavage of the Co–C bond in the resulting organometallic complex generates an organic radical for the catalysis of rearrangement reactions.

The cobalt–carbon bond in the enzyme-bound form of vitamin B₁₂ and related compounds is unusually weak, and it is particularly susceptible to *homolytic cleavage*:

Homolytic cleavage of the Co³⁺–CH₂R bond produces two species, each of which has an unpaired electron: a d^7 Co²⁺ derivative and an organic radical, $\cdot\text{CH}_2\text{R}$, which is used by vitamin B₁₂-dependent enzymes to catalyze a wide variety of reactions. Virtually all vitamin B₁₂-catalyzed reactions are rearrangements in which an H atom and an adjacent substituent exchange positions:

In the conversion of ethylene glycol to acetaldehyde, the initial product is the hydrated form of acetaldehyde, which rapidly loses water:

The enzyme uses the $\cdot\text{CH}_2\text{R}$ radical to temporarily remove a hydrogen atom from the organic substrate, which then rearranges to give a new radical. Transferring the hydrogen atom back to the rearranged radical gives the product and regenerates the $\cdot\text{CH}_2\text{R}$ radical.

The metal is not involved in the actual catalytic reaction; it provides the enzyme with a convenient mechanism for generating an organic radical, which does the actual work. Many examples of similar reactions are now known that use metals other than cobalt

to generate an enzyme-bound organic radical.

Note the Pattern

Nearly all vitamin B₁₂-catalyzed reactions are rearrangements that occur via a radical reaction.

Summary

Three separate steps are required for organisms to obtain essential transition metals from their environment: mobilization of the metal, transport of the metal into the cell, and transfer of the metal to where it is needed within a cell or an organism. The process of iron uptake is best understood. To overcome the insolubility of Fe(OH)₃, many bacteria use organic ligands called **siderophores**, which have high affinity for Fe(III) and are secreted into the surrounding medium to increase the total concentration of dissolved iron. The iron–siderophore complex is absorbed by a cell, and the iron is released by reduction to Fe(II). Mammals use the low pH of the stomach to increase the concentration of dissolved iron. Iron is absorbed in the intestine, where it forms an Fe(III) complex with a protein called transferrin that is transferred to other cells for immediate use or storage in the form of ferritin.

Proteins that contain one or more tightly bound metal ions are called **metalloproteins**, and metalloproteins that catalyze biochemical reactions are called **metalloenzymes**. Proteins that transfer electrons from one place to another are called electron-transfer proteins. Most electron-transfer proteins are metalloproteins, such as iron–sulfur proteins, cytochromes, and blue copper proteins that accept and donate electrons. The oxidized and reduced centers in all electron-transfer proteins have similar structures to ensure that electron transfer to and from the metal occurs rapidly. Metalloproteins also use the ability of transition metals to bind small molecules, such as O₂, N₂, and H₂, to transport or catalyze the reactions of these small molecules. For example, hemoglobin, hemerythrin, and hemocyanin, which contain heme iron, nonheme iron, and copper, respectively, are used by different kinds of organisms to bind and transfer O₂. Other metalloenzymes use transition-metal ions as Lewis acids to catalyze group transfer reactions. Finally, some metalloenzymes use homolytic cleavage of the cobalt–carbon bond in derivatives of vitamin B₁₂ to generate an organic radical that can abstract a hydrogen atom and thus cause molecular rearrangements to occur.

Key Takeaway

- Organisms have developed strategies to extract transition metals from the environment and use the metals in electron-transfer reactions, reactions of small molecules, Lewis-acid catalysis, and the generation of reactive organic radicals.

Conceptual Problems

1. What are the advantages of having a metal ion at the active site of an enzyme?
2. Why does the structure of the metal center in a metalloprotein that transfers electrons show so little change after oxidation or reduction?

Structure and Reactivity

1. In enzymes, explain how metal ions are particularly suitable for generating organic radicals.
2. A common method for treating carbon-monoxide poisoning is to have the patient inhale pure oxygen. Explain why this treatment is effective.

APPLICATION PROBLEMS

- Tungsten bronzes are semimetallic solids that are inert to strong acids and bases, lustrous, and good conductors of electricity; they are used in the production of bronze or metallic paints. These nonstoichiometric compounds have the general formula M_xWO_3 , where $M = Na, K$, a group 2 metal, or a lanthanide and $x < 1$. The properties of tungsten bronzes suggest that at least some of the tungsten atoms are in the +6 oxidation state. Given the high oxidation state, why do these solids conduct electricity?
- Gout is a painful disorder caused by the overproduction of uric acid, which is deposited as sodium urate crystals in joints. The enzyme that catalyzes the production of uric acid contains Fe and Mo. Molecular oxygen is a substrate in this reaction. Based on the oxidation states of the metals, what do you expect one of the products of the reaction to be?
- A laboratory technician added aqueous ammonia to an aqueous solution of Mn^{2+} , which produced a pale pink precipitate. She left the solution exposed to air and went home. The next day she returned to the lab and found that her pink precipitate had turned brown-black. Write balanced chemical equations to show what had happened.
- Plants use Mn(IV) during photosynthesis to produce dioxygen from water. Write a balanced chemical equation showing this reaction and suggest why Mn is well suited for this purpose.
- Rust stains (Fe_2O_3) can be removed from fabrics by oxalic acid (HO_2CCO_2H). Write a balanced chemical equation showing the reaction that occurs and predict the solubility of the product in water.
- It has been suggested that complexes that can coordinate N_2 are used by bacteria to fix atmospheric nitrogen. One such complex is $[Ru(NH_3)_5 \cdot N_2]Cl_2$, which was first discovered in 1965. Sigma bonding with N_2 in this complex would be weak because the N_2 molecule is symmetrical and has zero dipole moment.
 - What is the oxidation state of Ru in this complex?
 - How does N_2 bond to the metal? Describe the type of bonding involved.
 - Speculate why this complex might be a suitable vehicle for nitrogen fixation.
- Monel metal, which contains 68% Ni, 32% Cu, and traces of Fe and Mn, is highly corrosion resistant. It is used, for example, to make items that will be used in marine environments and to hold corrosive fluorine compounds. Based on its composition, why is Monel particularly suitable for these purposes?
- From 1845 to 1850, a fungus known as “potato blight” caused a potato famine in Ireland. Approximately 25% of the Irish population either died or emigrated as a direct result. A spray called *Bordeaux mixture* is now used to kill the fungus; it is made by the reaction of $CuSO_4$ with $Ca(OH)_2$. What is the formula of the Bordeaux mixture? Write a balanced chemical equation for the reaction.
- Many transition metals and their compounds are used as catalysts. Given MnO_2 , $FeCl_3$, Pt, and Ni, which would you select for each purpose and why?
 - removing NO_x from exhaust fumes
 - producing CCl_4 from CS_2 and Cl_2
 - producing H_2 from NH_3
 - decomposing $KClO_3$ to give O_2
- The Fe^{2+} site in hemoglobin binds oxygen reversibly; consequently, it is suitable for transporting oxygen in blood. Various other small molecules can bind to the iron instead, thus preventing oxygen transport. Based on the type of bonding, why are CO and NO particularly toxic? Would they be as toxic if hemoglobin contained a V center instead of Fe^{2+} ? Why?
- In 1951, G. Wilkinson reported a surprising iron–hydrocarbon compound that is now called *ferrocene*. Ferrocene is orange and has a structure in which the metal is sandwiched between two planar cyclopentadienyl ($C_5H_5^-$) rings. It can be viewed

as a compound of Fe^- with two C_5H_5 rings. Ferrocene does not contain $\text{Fe}-\text{C}$ σ bonds but another type of bond formed by the lateral overlap of orbitals. Which metal orbitals are involved? A similar structure is obtained with Ru^- . One of these metals forms a sandwich complex that has a staggered conformation, and the other forms a complex that is eclipsed. Which metal produces which conformation? Why?

- The Ziegler–Natta catalyst is used for the polymerization of ethylene to form high-density polyethylene, a widely used lightweight plastic. The active form of the catalyst is believed to be $\text{TiCl}_3\text{CH}_2\text{CH}_3$, and the first step in the polymerization reaction is believed to be binding of the double bond in ethylene to Ti. If you were interested in developing a similar catalyst for this same purpose, would you choose chlorides of Zr, Hf, V, Nb, Ta, Cr, Mo, or W? Why?
- Cobalt(II) chloride is used as a visual indicator of humidity because it exists as a blue complex when dry and a pink complex when exposed to moisture in the air. The bonding environment around the cobalt in one of these complexes is octahedral; in the other, it is tetrahedral. What reaction occurs to produce the color change? Write a balanced chemical equation for this reaction, indicating the species present.
- A platinum complex that is widely available commercially is chloroplatinic acid $\{\text{H}_2[\text{PtCl}_6]\}$, which is used to make platinized asbestos, a catalyst. What is the structure of chloroplatinic acid? Is it distorted from an idealized geometry? Do you expect it to be colored? Justify your answers.

ANSWERS

- The tungsten bronzes can be viewed as the products of partial reduction of WO_3 by an active metal to give a mixture of W(VI) and W(V). In the solid, the d orbitals of the metal overlap to form a partially filled band, which is responsible for the luster and metallic conductivity.
-
-
-
-
-
-
-
- Pt; it can oxidize ammonia to NO, so it should be able to reduce NO_x as well.
 - Ni; it has a low affinity for S and is hard to oxidize about the +2 state.
 - FeCl_3 ; it catalyzes the formation of NH_3 from the elements, so it must also catalyze its decomposition.
 - MnO_2 ; this is a well-known catalyst for decomposition of KClO_3 and has been mentioned several times in the text.

Learning Objective

- To understand the trends in properties and the reactivity of the group 13 elements.

Group 13 is the first group to span the dividing line between metals and nonmetals, so its chemistry is more diverse than that of groups 1 and 2, which include only metallic elements. Except for the lightest element (boron), the group 13 elements are all relatively electropositive; that is, they tend to lose electrons in chemical reactions rather than gain them. Although group 13 includes aluminum, the most abundant metal on Earth, none of these elements was known until the early 19th century because they are never found in nature in their free state. Elemental boron and aluminum, which were first prepared by reducing B_2O_3 and $AlCl_3$, respectively, with potassium, could not be prepared until potassium had been isolated and shown to be a potent reductant. Indium (In) and thallium (Tl) were discovered in the 1860s by using spectroscopic techniques, long before methods were available for isolating them. Indium, named for its indigo (deep blue-violet) emission line, was first observed in the spectrum of zinc ores, while thallium (from the Greek *thallos*, meaning “a young, green shoot of a plant”) was named for its brilliant green emission line. Gallium (Ga; Mendeleev’s *eka*-aluminum) was discovered in 1875 by the French chemist Paul Émile Lecoq de Boisbaudran during a systematic search for Mendeleev’s “missing” element in group 13.

Note the Pattern

Group 13 elements are never found in nature in their free state.

Preparation and General Properties of the Group 13 Elements

As reductants, the group 13 elements are less powerful than the alkali metals and alkaline earth metals. Nevertheless, their compounds with oxygen are thermodynamically stable, and large amounts of energy are needed to isolate even the two most accessible elements—boron and aluminum—from their oxide ores.

Although boron is relatively rare (it is about 10,000 times less abundant than aluminum), concentrated deposits of borax [$Na_2B_4O_5(OH)_4 \cdot 8H_2O$] are found in ancient lake beds (Figure 22.1.1) and were used in ancient times for making glass and glazing pottery. Boron is produced on a large scale by reacting borax with acid to produce boric acid [$B(OH)_3$], which is then dehydrated to the oxide (B_2O_3). Reduction of the oxide with magnesium or sodium gives amorphous boron that is only about 95% pure:

Figure 22.1.1 Borax Deposits(a) Concentrated deposits of crystalline borax $[Na_2B_4O_5(OH)_4 \cdot 8H_2O]$ are found in ancient lake beds, such as the Mojave Desert and Death Valley in the western United States. (b) Borax is used in various cleaning products, including 20 Mule Team Borax, a laundry detergent named for the teams of 20 mules that hauled wagons full of borax from desert deposits to railroad terminals in the 1880s.

Pure, crystalline boron, however, is extremely difficult to obtain because of its high melting point (2300°C) and the highly corrosive nature of liquid boron. It is usually prepared by reducing pure BCl_3 with hydrogen gas at high temperatures or by the thermal decomposition of boron hydrides such as diborane (B_2H_6):

The reaction shown in Equation 22.1.3 is used to prepare boron fibers, which are stiff and light. Hence they are used as structural reinforcing materials in objects as diverse as the US space shuttle and the frames of lightweight bicycles that are used in races such as the Tour de France. Boron is also an important component of many ceramics and heat-resistant borosilicate glasses, such as Pyrex, which is used for ovenware and laboratory glassware.

In contrast to boron, deposits of aluminum ores such as *bauxite*, a hydrated form of Al_2O_3 , are abundant. With an electrical conductivity about twice that of copper on a weight for weight basis, aluminum is used in more than 90% of the overhead electric power lines in the United States. However, because aluminum–oxygen compounds are stable, obtaining aluminum metal from bauxite is an expensive process. Aluminum is extracted from oxide ores by treatment with a strong base, which produces the soluble hydroxide complex $[Al(OH)_4]^-$. Neutralization of the resulting solution with gaseous CO_2 results in the precipitation of $Al(OH)_3$:

Thermal dehydration of $Al(OH)_3$ produces Al_2O_3 , and metallic aluminum is obtained by the electrolytic reduction of Al_2O_3 using the *Hall–Heroult process* described in Chapter 19. Of the group 13 elements, only aluminum is used on a large scale: for example, each Boeing 777 airplane is about 50% aluminum by mass.

The other members of group 13 are rather rare: gallium is approximately 5000 times less abundant than aluminum, and indium and thallium are even scarcer. Consequently, these metals are usually obtained as by-products in the processing of other metals. The extremely low melting point of gallium (29.6°C), however, makes it easy to separate from aluminum. Due to its low melting point and high boiling point, gallium is used as a liquid in thermometers that have a temperature range of almost 2200°C. Indium and thallium, the heavier group 13 elements, are found as trace impurities in sulfide ores of zinc and lead. Indium is used as a crushable seal for high-vacuum cryogenic devices, and its alloys are used as low-melting solders in electronic circuit boards. Thallium, on the other hand, is so toxic that the metal and its compounds have few uses. Both indium and thallium oxides are released in flue dust when sulfide ores are converted to metal oxides and SO_2 . Until relatively recently, these and other toxic elements were allowed to disperse in the air, creating large “dead zones” downwind of a smelter. The flue dusts are now trapped and serve as a relatively rich source of elements such as In and Tl (as well as Ge, Cd, Te, and As).

Table 22.1.1 summarizes some important properties of the group 13 elements. Notice the large differences between boron and aluminum in size, ionization energy, electronegativity, and standard reduction potential, which is consistent with the observation that boron behaves

Source: Thomas D. Kelly and Grecia R. Matos, “Historical Statistics for Mineral and Material Commodities in the United States,” US Geological Survey Data Series 140, 2010, accessed July 20, 2011,

chemically like a nonmetal and aluminum like a metal. All group 13 elements have $ns^2 np^1$ valence electron configurations, and all tend to lose their three valence electrons to form compounds in the +3 oxidation state. The heavier elements in the group can also form compounds in the +1 oxidation state formed by the formal loss of the single np valence electron. Because the group 13 elements generally contain only six valence electrons in their neutral compounds, these compounds are all moderately strong Lewis acids.

type of oxide	acidic	amphoteric	amphoteric	amphoteric	basic
product of reaction with N_2	BN	AlN	GaN	InN	none
product of reaction with X_2 [§]	BX_3	Al_2X_6	Ga_2X_6	In_2X_6	TlX

*This is the name used in the United States; the rest of the world inserts an extra *i* and calls it *aluminium* which is consistent with the naming convention for metals other than those with customary names such as iron.

[†]The configuration shown does not include filled *d* and *f* subshells.

[‡]The values cited are for six-coordinate ions in the most common oxidation state, except for Al^{3+} , for which the value for the four-coordinate ion is given. The B^{3+} ion is not a known species; the radius cited is an estimated four-coordinate value.

[§]X is Cl, Br, or I. Reaction with F_2 gives the trifluorides (MF_3) for all group 13 elements.

Note the Pattern

Neutral compounds of the group 13 elements are electron deficient, so they are generally moderately strong Lewis acids.

In contrast to groups 1 and 2, the group 13 elements show no consistent trends in ionization energies, electron affinities, and reduction potentials, whereas electronegativities actually *increase* from aluminum to thallium. Some of these anomalies, especially for the series Ga, In, Tl, can be explained by the increase in the effective nuclear charge (Z_{eff}) that results from poor shielding of the nuclear charge by the filled $(n-1)d^{10}$ and $(n-2)f^{14}$ subshells. Consequently, although the actual nuclear charge increases by 32 as we go from indium to thallium, screening by the filled $5d$ and $4f$ subshells is so poor that Z_{eff} increases significantly from indium to thallium. Thus the first ionization energy of thallium is actually greater than that of indium.

Note the Pattern

Anomalies in periodic trends among Ga, In, and Tl can be explained by the increase in the effective nuclear charge due to poor shielding.

Reactions and Compounds of Boron

Elemental boron is a semimetal that is remarkably unreactive; in contrast, the other group 13 elements all exhibit metallic properties and reactivity. We therefore consider the reactions and compounds of boron separately from those of other elements in the group.

All group 13 elements have fewer valence electrons than valence orbitals, which generally results in delocalized, metallic bonding. With its high ionization energy, low electron affinity, low electronegativity, and small size, however, boron does not form a metallic lattice with delocalized valence electrons. Instead, boron forms unique and intricate structures that contain *multicenter bonds*, in which a pair of electrons holds together three or more atoms.

Note the Pattern

Elemental boron forms multicenter bonds, whereas the other group 13 elements exhibit metallic bonding.

The basic building block of elemental boron is not the individual boron atom, as would be the case in a metal, but rather the B_{12} *icosahedron*. (For more information on B_{12} , see [Section 3.4](#).) Because these icosahedra do not pack together very well, the structure of solid boron contains voids, resulting in its low density ([Figure 22.1.2](#)). Elemental boron can be induced to react with many nonmetallic elements to give binary compounds that have a variety of applications. For example, plates of boron carbide (B_4C) can stop a 30-caliber, armor-piercing bullet, yet they weigh 10%–30% less than conventional armor. Other important compounds of boron with nonmetals include boron nitride (BN), which is produced by heating boron with excess nitrogen ([Equation 22.1.6](#)); boron oxide (B_2O_3), which is formed when boron is heated with excess oxygen ([Equation 22.1.7](#)); and the boron trihalides (BX_3), which are formed by heating boron with excess halogen ([Equation 22.1.8](#)).

Figure 22.1.2 Solid Boron Contains B_{12} Icosahedra Unlike metallic solids, elemental boron consists of a regular array of B_{12} icosahedra rather than individual boron atoms. Note that each boron atom in the B_{12} icosahedron is connected to five other boron atoms within the B_{12} unit. (a) The allotrope of boron with the simplest structure is α -rhombohedral boron, which consists of B_{12} octahedra in an almost cubic close-packed lattice. (b) A side view of the structure shows that icosahedra do not pack as efficiently as spheres, making the density of solid boron less than expected.

As is typical of elements lying near the dividing line between metals and nonmetals, many compounds of boron are amphoteric, dissolving in either acid or base.

Boron nitride is similar in many ways to elemental carbon. With eight electrons, the B–N unit is *isoelectronic* with the C–C unit, and B and N have the same average size and electronegativity as C. The most stable form of BN is similar to graphite, containing six-membered B_3N_3 rings arranged in layers. At high temperature and pressure, hexagonal BN converts to a cubic structure similar to diamond, which is one of the hardest substances known. Boron oxide (B_2O_3) contains layers of trigonal planar BO_3 groups (analogous to BX_3) in which the oxygen atoms bridge two boron atoms. It dissolves many metal and nonmetal oxides, including SiO_2 , to give a wide range of commercially important borosilicate glasses. A small amount of CoO gives the deep blue color characteristic of “cobalt blue” glass.

At high temperatures, boron also reacts with virtually all metals to give *metal borides* that contain regular three-dimensional networks, or *clusters*, of boron atoms. The structures of two metal borides— ScB_{12} and CaB_6 —are shown in Figure 22.1.3. Because metal-rich borides such as ZrB_2 and TiB_2 are hard and corrosion resistant even at high temperatures, they are used in applications such as turbine blades and rocket nozzles.

Figure 22.1.3 The Structures of ScB_{12} and CaB_6 , Two Boron-Rich Metal Borides (a) The structure of ScB_{12} consists of B_{12} clusters and Sc atoms arranged in a face-centered cubic lattice similar to that of NaCl, with B_{12} units occupying the anion positions and scandium atoms the cation positions. The B_{12} units here are not icosahedra but cubooctahedra, with alternating square and triangular faces. (b) The structure of CaB_6 consists of octahedral B_6 clusters and calcium atoms arranged in a body-centered cubic lattice similar to that of CsCl, with B_6 units occupying the anion positions and calcium atoms the cation positions.

Boron hydrides were not discovered until the early 20th century, when the German chemist Alfred Stock undertook a systematic investigation of the binary compounds of boron and hydrogen, although binary hydrides of carbon, nitrogen, oxygen, and fluorine have been known since the 18th century. Between 1912 and 1936, Stock oversaw the preparation of a series of boron–hydrogen compounds with unprecedented structures that could not be explained with simple bonding theories. All these compounds contain multicenter bonds, as discussed in Chapter 19 (Figure 19.2.3). The simplest example is diborane (B_2H_6), which contains two bridging hydrogen atoms (part (a) in Figure 22.1.4). An extraordinary variety of polyhedral boron–hydrogen clusters is now

known; one example is the $B_{12}H_{12}^{2-}$ ion, which has a polyhedral structure similar to the icosahedral B_{12} unit of elemental boron, with a single hydrogen atom bonded to each boron atom.

A related class of polyhedral clusters, the carboranes, contain both CH and BH units; an example is shown here. Replacing the hydrogen atoms bonded to carbon with organic groups produces substances with novel properties, some of which are currently being investigated for their use as liquid crystals and in cancer chemotherapy.

The enthalpy of combustion of diborane (B_2H_6) is -2165 kJ/mol, one of the highest values known:

Figure 22.1.4 The Structures of Diborane (B_2H_6) and Aluminum Chloride (Al_2Cl_6)(a) The hydrogen-bridged dimer B_2H_6 contains two three-center, two-electron bonds as described for the $B_2H_7^-$ ion in Figure 20.2.3. (b) In contrast, the bonding in the halogen-bridged dimer Al_2Cl_6 can be described in terms of electron-pair bonds, in which a chlorine atom bonded to one aluminum atom acts as a Lewis base by donating a lone pair of electrons to another aluminum atom, which acts as a Lewis acid.

Consequently, the US military explored using boron hydrides as rocket fuels in the 1950s and 1960s. This effort was eventually abandoned because boron hydrides are unstable, costly, and toxic, and, most important, B_2O_3 proved to be highly abrasive to rocket nozzles. Reactions carried out during this investigation, however, showed that boron hydrides exhibit unusual reactivity.

Because boron and hydrogen have almost identical electronegativities, the reactions of boron hydrides are dictated by minor differences in the distribution of electron density in a given compound. In general, two distinct types of reaction are observed: electron-rich species such as the BH_4^- ion are reductants, whereas electron-deficient species such as B_2H_6 act as oxidants.

Example 22.1.1

For each reaction, explain why the given products form.

- $\text{B}_2\text{H}_6(\text{g}) + 3\text{O}_2(\text{g}) \rightarrow \text{B}_2\text{O}_3(\text{s}) + 3\text{H}_2\text{O}(\text{l})$
- $\text{BCl}_3(\text{l}) + 3\text{H}_2\text{O}(\text{l}) \rightarrow \text{B}(\text{OH})_3(\text{aq}) + 3\text{HCl}(\text{aq})$
- $2\text{BI}_3(\text{s}) + 3\text{H}_2(\text{g}) + \Delta \rightarrow 6\text{B}(\text{s}) + 6\text{HI}(\text{g})$

Given: balanced chemical equations

Asked for: why the given products form

Strategy:

Classify the type of reaction. Using periodic trends in atomic properties, thermodynamics, and kinetics, explain why the reaction products form.

Solution:

- Molecular oxygen is an oxidant. If the other reactant is a potential reductant, we expect that a redox reaction will occur. Although B_2H_6 contains boron in its highest oxidation state (+3), it also contains hydrogen in the -1 oxidation state (the hydride ion). Because hydride is a strong reductant, a redox reaction will probably occur. We expect that H will be oxidized to H^+ and O_2 will be reduced to O^{2-} , but what are the actual products? A reasonable guess is B_2O_3 and H_2O , both stable compounds.
- Neither BCl_3 nor water is a powerful oxidant or reductant, so a redox reaction is unlikely; a hydrolysis reaction is more probable. Nonmetal halides are acidic and react with water to form a solution of the hydrohalic acid and a nonmetal oxide or hydroxide. In this case, the most probable boron-containing product is boric acid $[\text{B}(\text{OH})_3]$.
- We normally expect a boron trihalide to behave like a Lewis acid. In this case, however, the other reactant is elemental hydrogen, which usually acts as a reductant. The iodine atoms in BI_3 are in the lowest accessible oxidation state (-1), and boron is in the $+3$ oxidation state. Consequently, we can write a redox reaction in which hydrogen is oxidized and boron is reduced. Because compounds of boron in lower oxidation states are rare, we expect that boron will be reduced to elemental boron. The other product of the reaction must therefore be HI.

Exercise

Predict the products of the reactions and write a balanced chemical equation for each reaction.

- $\text{B}_2\text{H}_6(\text{g}) + \text{H}_2\text{O}(\text{l}) + \Delta \rightarrow$
- $\text{BBr}_3(\text{l}) + \text{O}_2(\text{g}) \rightarrow$
- $\text{B}_2\text{O}_3(\text{s}) + \text{Ca}(\text{s}) + \Delta \rightarrow$

Answer:

- $\text{B}_2\text{H}_6(\text{g}) + \text{H}_2\text{O}(\text{l}) + \Delta \rightarrow 2\text{B}(\text{OH})_3(\text{s}) + 6\text{H}_2(\text{g})$
- $\text{BBr}_3(\text{l}) + \text{O}_2(\text{g}) \rightarrow$ no reaction
- $6\text{B}_2\text{O}_3(\text{s}) + 18\text{Ca}(\text{s}) + \Delta \rightarrow \text{B}_{12}(\text{s}) + 18\text{CaO}(\text{s})$

Reactions and Compounds of the Heavier Group 13 Elements

All four of the heavier group 13 elements (Al, Ga, In, and Tl) react readily with the halogens to form compounds with a 1:3 stoichiometry:

The reaction of Tl with iodine is an exception: although the product has the stoichiometry TlI_3 , it is *not* thallium(III) iodide, but rather a thallium(I) compound, the Tl⁺ salt of the triiodide ion (I_3^-). This compound forms because iodine is not a powerful enough oxidant to oxidize thallium to the $+3$ oxidation state.

Of the halides, only the fluorides exhibit behavior typical of an ionic compound: they have high melting points (>950°C) and low solubility in nonpolar solvents. In contrast, the trichlorides, tribromides, and triiodides of aluminum, gallium, and indium, as well as TlCl_3 and TlBr_3 , are more covalent in character and form halogen-bridged dimers (part (b) in [Figure 22.1.4](#)). Although the structure of these dimers is similar to that of diborane (B_2H_6), the bonding can be described in terms of electron-pair bonds rather than the delocalized electron-deficient bonding found in diborane. Bridging halides are poor electron-pair donors, so the group 13 trihalides are potent Lewis acids that react readily with Lewis bases, such as amines, to form a Lewis acid–base adduct:

In water, the halides of the group 13 metals hydrolyze to produce the metal hydroxide $[\text{M}(\text{OH})_3]$:

In a related reaction, $\text{Al}_2(\text{SO}_4)_3$ is used to clarify drinking water by the precipitation of hydrated $\text{Al}(\text{OH})_3$, which traps particulates. The halides of the heavier metals (In and Tl) are less reactive with water because of their lower charge-to-radius ratio. Instead of forming hydroxides, they dissolve to form the hydrated metal complex ions: $[\text{M}(\text{H}_2\text{O})_6]^{3+}$.

Note the Pattern

Of the group 13 halides, only the fluorides behave as typical ionic compounds.

Note the Pattern

Group 13 trihalides are potent Lewis acids that react with Lewis bases to form a Lewis acid–base adduct.

Like boron ([Equation 22.1.7](#)), all the heavier group 13 elements react with excess oxygen at elevated temperatures to give the trivalent oxide (M_2O_3), although Tl_2O_3 is unstable:

Aluminum oxide (Al_2O_3), also known as alumina, is a hard, high-melting-point, chemically inert insulator used as a ceramic and as an abrasive in sandpaper and toothpaste. Replacing a small number of Al^{3+} ions in crystalline alumina with Cr^{3+} ions forms the gemstone ruby, whereas replacing Al^{3+} with a mixture of Fe^{2+} , Fe^{3+} , and Ti^{4+} produces blue sapphires. The gallium oxide compound MgGa_2O_4 gives the brilliant green light familiar to anyone who has ever operated a xerographic copy machine. All the oxides dissolve in dilute acid, but Al_2O_3 and Ga_2O_3 are amphoteric, which is consistent with their location along the diagonal line of the periodic table, also dissolving in concentrated aqueous base to form solutions that contain $\text{M}(\text{OH})_4^-$ ions.

Aluminum, gallium, and indium also react with the other group 16 elements (chalcogens) to form chalcogenides with the stoichiometry M_2Y_3 . However, because Tl(III) is too strong an oxidant to form a stable compound with electron-rich anions such as S^{2-} , Se^{2-} , and Te^{2-} , thallium forms only the thallium(I) chalcogenides with the stoichiometry Tl_2Y . Only aluminum, like boron, reacts directly with N_2 (at very high temperatures) to give AlN , which is used in transistors and microwave devices as a nontoxic heat sink because of its thermal stability; GaN and InN can be prepared using other methods. All the metals, again except Tl, also react with the heavier group 15 elements (pnictogens) to form the so-called III–V compounds, such as GaAs . These are semiconductors, whose electronic properties, such as their band gaps, differ from those that can be achieved using either pure or doped group 14 elements. (For more information on band gaps, see [Section 12.6](#).) For example, nitrogen- and phosphorus-doped gallium arsenide ($\text{GaAs}_{1-x-y}\text{P}_x\text{N}_y$) is used in the displays of calculators and digital watches.

Note the Pattern

All group 13 oxides dissolve in dilute acid, but Al_2O_3 and Ga_2O_3 are amphoteric.

Unlike boron, the heavier group 13 elements do not react directly with hydrogen. Only the aluminum and gallium hydrides are known, but they must be prepared indirectly; AlH_3 is an insoluble, polymeric solid that is rapidly decomposed by water, whereas GaH_3 is unstable at room temperature.

Complexes of Group 13 Elements

Boron has a relatively limited tendency to form complexes, but aluminum, gallium, indium, and, to some extent, thallium form many complexes. Some of the simplest are the hydrated metal ions $[\text{M}(\text{H}_2\text{O})_6]^{3+}$, which are relatively strong Brønsted–Lowry acids that can lose a proton to form the $\text{M}(\text{H}_2\text{O})_5(\text{OH})^{2+}$ ion:

Group 13 metal ions also form stable complexes with species that contain two or more negatively charged groups, such as the oxalate ion. The stability of such complexes increases as the number of coordinating groups provided by the ligand increases.

Example 22.1.2

For each reaction, explain why the given products form.

- $2\text{Al}(\text{s}) + \text{Fe}_2\text{O}_3(\text{s}) + \Delta \rightarrow 2\text{Fe}(\text{l}) + \text{Al}_2\text{O}_3(\text{s})$
- $2\text{Ga}(\text{s}) + 6\text{H}_2\text{O}(\text{l}) + 2\text{OH}^-(\text{aq}) + \Delta \rightarrow 3\text{H}_2(\text{g}) + 2\text{Ga}(\text{OH})_4^-(\text{aq})$
- $\text{In}_2\text{Cl}_6(\text{s}) \rightarrow 2\text{In}^{3+}(\text{aq}) + 6\text{Cl}^-(\text{aq})$ (in water)

Given: balanced chemical equations

Asked for: why the given products form

Strategy:

Classify the type of reaction. Using periodic trends in atomic properties, thermodynamics, and kinetics, explain why the reaction products form.

Solution:

- Aluminum is an active metal and a powerful reductant, and Fe_2O_3 contains Fe(III), a potential oxidant. Hence a redox reaction is probable, producing metallic Fe and Al_2O_3 . Because Al is a main group element that lies above Fe, which is a transition element, it should be a more active metal than Fe. Thus the reaction should proceed to the right. In fact, this is the thermite reaction, which is so vigorous that it produces molten Fe and can be used for welding. (For more information on the thermite reaction, see [Section 9.2](#).)
- Gallium lies immediately below aluminum in the periodic table and is amphoteric, so it will dissolve in either acid or base to produce hydrogen gas. Because gallium is similar to aluminum in many of its properties, we predict that gallium will dissolve in the strong base.
- The metallic character of the group 13 elements increases with increasing atomic number. Indium trichloride should therefore behave like a typical metal halide, dissolving in water to form the hydrated cation.

Exercise

Predict the products of the reactions and write a balanced chemical equation for each reaction.

- $\text{LiH}(\text{s}) + \text{Al}_2\text{Cl}_6(\text{soln}) \rightarrow$
- $\text{Al}_2\text{O}_3(\text{s}) + \text{OH}^-(\text{aq}) \rightarrow$
- $\text{Al}(\text{s}) + \text{N}_2(\text{g}) + \Delta \rightarrow$
- $\text{Ga}_2\text{Cl}_6(\text{soln}) + \text{Cl}^-(\text{soln}) \rightarrow$

Answer:

- $8\text{LiH(s)} + \text{Al}_2\text{Cl}_6(\text{soln}) \rightarrow 2\text{LiAlH}_4(\text{soln}) + 6\text{LiCl(s)}$
- $\text{Al}_2\text{O}_3(\text{s}) + 2\text{OH}^-(\text{aq}) + 3\text{H}_2\text{O(l)} \rightarrow 2\text{Al(OH)}_4^-(\text{aq})$
- $2\text{Al(s)} + \text{N}_2(\text{g}) + \Delta \rightarrow 2\text{AlN(s)}$
- $\text{Ga}_2\text{Cl}_6(\text{soln}) + 2\text{Cl}^-(\text{soln}) \rightarrow 2\text{GaCl}_4^-(\text{soln})$

Summary

Isolation of the group 13 elements requires a large amount of energy because compounds of the group 13 elements with oxygen are thermodynamically stable. Boron behaves chemically like a nonmetal, whereas its heavier congeners exhibit metallic behavior. Many of the inconsistencies observed in the properties of the group 13 elements can be explained by the increase in Z_{eff} that arises from poor shielding of the nuclear charge by the filled $(n-1)d^{10}$ and $(n-2)f^{14}$ subshells. Instead of forming a metallic lattice with delocalized valence electrons, boron forms unique aggregates that contain multicenter bonds, including *metal borides*, in which boron is bonded to other boron atoms to form three-dimensional networks or *clusters* with regular geometric structures. All neutral compounds of the group 13 elements are electron deficient and behave like Lewis acids. The trivalent halides of the heavier elements form halogen-bridged dimers that contain electron-pair bonds, rather than the delocalized electron-deficient bonds characteristic of diborane. Their oxides dissolve in dilute acid, although the oxides of aluminum and gallium are amphoteric. None of the group 13 elements reacts directly with hydrogen, and the stability of the hydrides prepared by other routes decreases as we go down the group. In contrast to boron, the heavier group 13 elements form a large number of complexes in the +3 oxidation state.

Key Takeaways

- Compounds of the group 13 elements with oxygen are thermodynamically stable.
- Many of the anomalous properties of the group 13 elements can be explained by the increase in Z_{eff} moving down the group.

Conceptual Problems

1. None of the group 13 elements was isolated until the early 19th century, even though one of these elements is the most abundant metal on Earth. Explain why the discovery of these elements came so late and describe how they were finally isolated.
2. Boron and aluminum exhibit very different chemistry. Which element forms complexes with the most ionic character? Which element is a metal? a semimetal? What single property best explains the difference in their reactivity?
3. The usual oxidation state of boron and aluminum is +3, whereas the heavier elements in group 13 have an increasing tendency to form compounds in the +1 oxidation state. Given that all group 13 elements have an $ns\ np$ electron configuration, how do you explain this difference between the lighter and heavier group 13 elements?
4. Do you expect the group 13 elements to be highly reactive in air? Why or why not?
5. Which of the group 13 elements has the least metallic character? Explain why.
6. Boron forms multicenter bonds rather than metallic lattices with delocalized valence electrons. Why does it prefer this type of bonding? Does this explain why boron behaves like a semiconductor rather than a metal? Explain your answer.
7. Because the B–N unit is isoelectronic with the C–C unit, compounds that contain these units tend to have similar chemistry, although they exhibit some important differences. Describe the differences in physical properties, conductivity, and reactivity of these two types of compounds.
8. Boron has a strong tendency to form clusters. Does aluminum have this same tendency? Why or why not?
9. Explain why a B–O bond is much stronger than a B–C bond.
10. The electron affinities of boron and aluminum are -27 and -42 kJ/mol, respectively. Contrary to the usual periodic trends, the electron affinities of the remaining elements in group 13 are between those of B and Al. How do you explain this apparent anomaly?

- The reduction potentials of B and Al in the +3 oxidation state are -0.87 V and -1.66 V , respectively. Do you expect the reduction potentials of the remaining elements of group 13 to be greater than or less than these values? How do you explain the differences between the expected values and those given in [Table 20.1.1](#) ?
- The compound Al_2Br_6 is a halide-bridged dimer in the vapor phase, similar to diborane (B_2H_6). Draw the structure of Al_2Br_6 and then compare the bonding in this compound with that found in diborane. Explain the differences.
- The compound AlH_3 is an insoluble, polymeric solid that reacts with strong Lewis bases, such as Me_3N , to form adducts with 10 valence electrons around aluminum. What hybrid orbital set is formed to allow this to occur?

Answers

- The high stability of compounds of the group 13 elements with oxygen required powerful reductants such as metallic potassium to be isolated. Al and B were initially prepared by reducing molten AlCl_3 and B_2O_3 , respectively, with potassium.
-
-
-
- Due to its low electronegativity and small size, boron is an unreactive semimetal rather than a metal.
-
- The B–N bond is significantly more polar than the C–C bond, which makes B–N compounds more reactive and generally less stable than the corresponding carbon compounds. Increased polarity results in less delocalization and makes the planar form of BN less conductive than graphite.
-
- Partial pi bonding between O and B increases the B–O bond strength.
-
- Periodic trends predict that the cations of the heavier elements should be easier to reduce, so the elements should have less negative reduction potentials. In fact, the reverse is observed because the heavier elements have anomalously high Z_{eff} values due to poor shielding by filled $(n - 1)d$ and $(n - 2)f$ subshells.

Structure and Reactivity

- Is $\text{B}(\text{OH})_3$ a strong or a weak acid? Using bonding arguments, explain why.
- Using bonding arguments, explain why organoaluminum compounds are expected to be potent Lewis acids that react rapidly with weak Lewis bases.
- Imagine that you are studying chemistry prior to the discovery of gallium, element 31. Considering its position in the periodic table, predict the following properties of gallium:
 - chemical formulas of its most common oxide, most common chloride, and most common hydride
 - solubility of its oxide in water and the acidity or basicity of the resulting solution
 - the principal ion formed in aqueous solution
- The halides of Al, Ga, In, and Tl dissolve in water to form acidic solutions containing the hydrated metal ions, but only the halides of aluminum and gallium dissolve in aqueous base to form soluble metal-hydroxide complexes. Show the formulas of the soluble metal–hydroxide complexes and of the hydrated metal ions. Explain the difference in their reactivities.
- Complete and balance each chemical equation.
 - $\text{BCl}_3(\text{g}) + \text{H}_2(\text{g}) + \Delta \rightarrow$
 - $6\text{C}_2\text{H}_4(\text{g}) + \text{B}_2\text{H}_6(\text{g}) \rightarrow$
 - $\text{B}_2\text{H}_6(\text{g}) + 3\text{Cl}_2(\text{g}) \rightarrow$
 - $\text{B}_2\text{H}_6(\text{g}) + 2(\text{C}_2\text{H}_5)_2\text{S}(\text{g}) \rightarrow$
- Complete and balance each chemical equation.
 - $\text{BBr}_3(\text{g}) + \text{H}_2(\text{g}) + \Delta \rightarrow$
 - $\text{BF}_3(\text{g}) + \text{F}(\text{g}) \rightarrow$
 - $\text{LiH}(\text{s}) + \text{B}_2\text{H}_6(\text{g}) \rightarrow$
 - $\text{B}(\text{OH})_3(\text{s}) + \text{NaOH}(\text{aq}) \rightarrow$
- Write a balanced chemical equation for each reaction.

- a. the dissolution of Al_2O_3 in dilute acid
 - b. the dissolution of Ga_2O_3 in concentrated aqueous base
 - c. the dissolution of Tl_2O in concentrated aqueous acid
 - d. $\text{Ga}(\text{l}) + \text{Sg}(\text{s})$
 - e. $\text{Tl}(\text{s}) + \text{H}_2\text{S}(\text{g})$
8. Write a balanced chemical equation for the reaction that occurs between Al and each species.
 - a. Cl_2
 - b. O_2
 - c. S
 - d. N_2
 - e. H_2O
 - f. H (aq)
 9. Write a balanced chemical equation that shows how you would prepare each compound from its respective elements or other common compounds.
 - a. In_2I_6
 - b. $\text{B}(\text{OH})_3$
 - c. Ga_2O_3
 - d. $[\text{Tl}(\text{H}_2\text{O})_6]^{3+}$
 - e. $\text{Al}(\text{OH})_4$
 - f. In_4C_3
 10. Write a balanced chemical equation that shows how you would prepare each compound from its respective elements or other common compounds.
 - a. BCl_3
 - b. InCl_3
 - c. Tl_2S
 - d. $\text{Al}(\text{OH})_3$
 - e. In_2O_3
 - f. AlN
 11. Diborane is a spontaneously flammable, toxic gas that is prepared by reacting NaBH_4 with BF_3 . Write a balanced chemical equation for this reaction.
 12. Draw the Lewis electron structure of each reactant and product in each chemical equation. Then describe the type of bonding found in each reactant and product.
 - a. $2\text{B}(\text{s}) + 3\text{X}_2(\text{g}) + \Delta \rightarrow 2\text{BX}_3(\text{g})$
 - b. $4\text{B}(\text{s}) + 3\text{O}_2(\text{g}) + \Delta \rightarrow 2\text{B}_2\text{O}_3(\text{s})$
 - c. $2\text{B}(\text{s}) + \text{N}_2(\text{g}) + \Delta \rightarrow 2\text{BN}(\text{s})$
 13. Draw the Lewis electron structure of each reactant and product in each chemical equation. Then describe the type of bonding found in each reactant and product.
 - a. $\text{B}_2\text{H}_6(\text{g}) + 3\text{O}_2(\text{g}) \rightarrow \text{B}_2\text{O}_3(\text{s}) + 3\text{H}_2\text{O}(\text{l})$
 - b. $\text{B}_2\text{H}_6(\text{g}) + 6\text{CH}_3\text{CH}=\text{CH}_2(\text{g}) \rightarrow 2[\text{B}(\text{CH}_2\text{CH}_2\text{CH}_3)_3](\text{l})$

Learning Objective

- To understand the trends in properties and reactivity of the group 14 elements.

The elements of group 14 show a greater range of chemical behavior than any other family in the periodic table. Three of the five elements—carbon, tin, and lead—have been known since ancient times. For example, some of the oldest known writings are Egyptian hieroglyphics written on papyrus with ink made from *lampblack*, a finely divided carbon soot produced by the incomplete combustion of hydrocarbons (Figure 22.2.1). *Activated carbon* is an even more finely divided form of carbon that is produced from the thermal decomposition of organic materials, such as sawdust. Because it adsorbs many organic and sulfur-containing compounds, activated carbon is used to decolorize foods, such as sugar, and to purify gases and wastewater.

Figure 22.2.1 Very Small Particles of Noncrystalline Carbon Are Used to Make Black Ink(a) Since ancient times, ink sticks have been the major source of black ink in Asia. Plant oils or resinous woods such as pine are burned, and the resulting soot (*lampblack*) is collected, mixed with binders such as animal glues and minerals, compressed into a solid stick, and allowed to dry. Liquid ink is made by rubbing the ink stick against the surface of a special stone ink dish with small amounts of water. (b) A 19th-century Japanese painting illustrates how ink is made from an ink stick.

Tin and lead oxides and sulfides are easily reduced to the metal by heating with charcoal, a discovery that must have occurred by accident when prehistoric humans used rocks containing their ores for a cooking fire. However, because tin and copper ores are often found together in nature, their alloy—*bronze*—was probably discovered before either element, a discovery that led to the Bronze Age. The heaviest element in group 14, lead, is such a soft and malleable metal that the ancient Romans used thin lead foils as writing tablets, as well as lead cookware and lead pipes for plumbing. (Recall that the atomic symbols for tin and lead come from their Latin names: Sn for *stannum* and Pb for *plumbum*.)

Although the first glasses were prepared from silica (silicon oxide, SiO_2) around 1500 BC, elemental silicon was not prepared until 1824 because of its high affinity for oxygen. Jöns Jakob Berzelius was finally able to obtain amorphous silicon by reducing Na_2SiF_6 with molten potassium. The crystalline element, which has a shiny blue-gray luster, was not isolated until 30 yr later. The last member of the group 14 elements to be discovered was germanium, which was found in 1886 in a newly discovered silver-colored ore by the German chemist Clemens Winkler, who named the element in honor of his native country.

Preparation and General Properties of the Group 14 Elements

The natural abundance of the group 14 elements varies tremendously. Elemental carbon, for example, ranks only 17th on the list of constituents of Earth's crust. Pure graphite is obtained by reacting coke, an amorphous form of carbon used as a reductant in the production of steel, with silica to give silicon carbide (SiC). This is then thermally decomposed at very high temperatures (2700°C) to give graphite:

One allotrope of carbon, diamond, is metastable under normal conditions, with a ΔG_f° of 2.9 kJ/mol versus graphite. At pressures greater than 50,000 atm, however, the diamond structure is favored and is the most stable form of carbon. Because the structure of diamond is more compact than that of graphite, its density is significantly higher (3.51 g/cm³ versus 2.2 g/cm³). Because of its high thermal conductivity, diamond powder is used to transfer heat in electronic devices.

The most common sources of diamonds on Earth are ancient volcanic pipes that contain a rock called *kimberlite*, a lava that solidified rapidly from deep inside the Earth. Most kimberlite formations, however, are much newer than the diamonds they contain. In fact, the relative amounts of different carbon isotopes in diamond show that diamond is a chemical and geological "fossil" older than our solar system, which means that diamonds on Earth predate the existence of our sun. Thus diamonds were most likely created deep inside Earth from primordial grains of graphite present when Earth was formed (part (a) in [Figure 22.2.2](#)). Gem-quality diamonds can now be produced synthetically and have chemical, optical, and physical characteristics identical to those of the highest-grade natural diamonds.

Figure 22.2.2 Crystalline Samples of Carbon and Silicon, the Lightest Group 14 Elements(a) The 78.86-carat Ahmadabad diamond, a historic Indian gem purchased in Gujarat in the 17th century by the French explorer Jean-Baptiste Tavernier and sold in 1995 for \$4.3 million, is a rare example of a large single crystal of diamond, the less-stable allotrope of carbon. (b) Large single crystals of highly purified silicon are the basis of the modern electronics industry. They are sliced into very thin wafers that are highly polished and then cut into smaller pieces for use as chips.

Although oxygen is the most abundant element on Earth, the next most abundant is silicon, the next member of group 14. Pure silicon is obtained by reacting impure silicon with Cl₂ to give SiCl₄, followed by the fractional distillation of the impure SiCl₄ and reduction with H₂:

Several million tons of silicon are annually produced with this method. Amorphous silicon containing residual amounts of hydrogen is used in photovoltaic devices that convert light to electricity, and silicon-based solar cells are used to power pocket calculators, boats, and highway signs, where access to electricity by conventional methods is difficult or expensive. Ultrapure silicon and germanium form the basis of the modern electronics industry (part (b) in [Figure 22.2.2](#)).

In contrast to silicon, the concentrations of germanium and tin in Earth's crust are only 1–2 ppm. The concentration of lead, which is the end product of the nuclear decay of many radionuclides, is 13 ppm, making lead by far the most abundant of the heavy group 14 elements. (For more information on radionuclides, see [Chapter 24](#)) No concentrated ores of germanium are known; like indium,

germanium is generally recovered from flue dusts obtained by processing the ores of metals such as zinc. Because germanium is essentially transparent to infrared radiation, it is used in optical devices.

Tin and lead are soft metals that are too weak for structural applications, but because tin is flexible, corrosion resistant, and nontoxic, it is used as a coating in food packaging. A “tin can,” for example, is actually a steel can whose interior is coated with a thin layer (1–2 μm) of metallic tin. Tin is also used in superconducting magnets and low-melting-point alloys such as solder and pewter. Pure lead is obtained by heating galena (PbS) in air and reducing the oxide (PbO) to the metal with carbon, followed by electrolytic deposition to increase the purity:

or

By far the single largest use of lead is in lead storage batteries. (For more information on batteries, see [Chapter 19](#))

As you learned in [Chapter 3](#), the group 14 elements all have $ns^2 np^2$ valence electron configurations. All form compounds in which they formally lose either the two np and the two ns valence electrons or just the two np valence electrons, giving a +4 or +2 oxidation state, respectively. Because covalent bonds decrease in strength with increasing atomic size and the ionization energies for the heavier elements of the group are higher than expected due to a higher Z_{eff} , the relative stability of the +2 oxidation state increases smoothly from carbon to lead.

Note the Pattern

The relative stability of the +2 oxidation state increases, and the tendency to form catenated compounds decreases, from carbon to lead in group 14.

Recall that many carbon compounds contain multiple bonds formed by π overlap of singly occupied $2p$ orbitals on adjacent atoms. (For more information on atomic orbitals, see [Chapter 2](#).) Compounds of silicon, germanium, tin, and lead with the same stoichiometry as those of carbon, however, tend to have different structures and properties. For example, CO_2 is a gas that contains discrete $\text{O}=\text{C}=\text{O}$ molecules, whereas the most common form of SiO_2 is the high-melting solid known as quartz, the major component of sand. Instead of discrete SiO_2 molecules, quartz contains a three-dimensional network of silicon atoms that is similar to the structure of diamond but with an oxygen atom inserted between each pair of silicon atoms. Thus each silicon atom is linked to four other silicon atoms by bridging oxygen atoms. (For more information on the properties of solids, see [Section 12.1](#).) The tendency to catenate—to form chains of like atoms—decreases rapidly as we go down group 14 because bond energies for both the E–E and E–H bonds decrease with increasing atomic number (where E is any group 14 element). Consequently, inserting a CH_2 group into a linear hydrocarbon such as n -hexane is exergonic ($\Delta G^\circ = -45 \text{ kJ/mol}$), whereas inserting an SiH_2 group into the silicon analogue of n -hexane (Si_6H_{14}) actually costs energy ($\Delta G^\circ \approx +25 \text{ kJ/mol}$). As a result of this trend, the thermal stability of catenated compounds decreases rapidly from carbon to lead.

In [Table 22.2.1](#) we see, once again, that there is a large difference between the lightest element (C) and the others in size, ionization energy, and electronegativity. As in group 13, the second and third elements (Si and Ge) are similar, and there is a reversal in the trends for some properties, such as ionization energy, between the fourth and fifth elements (Sn and Pb). As for group 13, these effects can be explained by the presence of filled $(n - 1)d$ and $(n - 2)f$ subshells, whose electrons are relatively poor at screening the outermost electrons from the higher nuclear charge.

Table 22.2.1 Selected Properties of the Group 14 Elements

Property	Carbon	Silicon	Germanium	Tin	Lead
----------	--------	---------	-----------	-----	------

Property	Carbon	Silicon	Germanium	Tin	Lead
atomic symbol	C	Si	Ge	Sn	Pb
atomic number	6	14	32	50	82
atomic mass (amu)	12.01	28.09	72.64	118.71	207.2
valence electron configuration*	$2s^2 2p^2$	$3s^2 3p^2$	$4s^2 4p^2$	$5s^2 5p^2$	$6s^2 6p^2$
melting point/boiling point (°C)	4489 (at 10.3 MPa)/3825	1414/3265	939/2833	232/2602	327/1749
density (g/cm ³) at 25°C	2.2 (graphite), 3.51 (diamond)	2.33	5.32	7.27(white)	11.30
atomic radius (pm)	77 (diamond)	111	125	145	154
first ionization energy (kJ/mol)	1087	787	762	709	716
most common oxidation state	+4	+4	+4	+4	+4
ionic radius (pm) [†]	≈29	≈40	53	69	77.5
electron affinity (kJ/mol)	-122	-134	-119	-107	-35
electronegativity	2.6	1.9	2.0	2.0	1.8
standard reduction potential (E° , V) (for $EO_2 \rightarrow E$ in acidic solution)	0.21	-0.86	-0.18	-0.12	0.79
product of reaction with O_2	CO_2 , CO	SiO_2	GeO_2	SnO_2	PbO
type of oxide	acidic (CO_2)	acidic neutral (CO)	amphoteric	amphoteric	amphoteric
product of reaction with N_2	none	Si_3N_4	none	Sn_3N_4	none
product of reaction with X_2 [‡]	CX_4	SiX_4	GeX_4	SnX_4	PbX_2
product of reaction with H_2	CH_4	none	none	none	none

*The configuration shown does not include filled *d* and *f* subshells.

[†] The values cited are for six-coordinate +4 ions in the most common oxidation state, except for C^{4+} and Si^{4+} , for which values for the four-coordinate ion are estimated.

[‡] X is Cl, Br, or I. Reaction with F_2 gives the tetrafluorides (EF_4) for all group 14 elements, where E represents any group 14 element.

Note the Pattern

The group 14 elements follow the same pattern as the group 13 elements in their periodic properties.

Reactions and Compounds of Carbon

Carbon is the building block of all organic compounds, including biomolecules, fuels, pharmaceuticals, and plastics, whereas inorganic compounds of carbon include metal carbonates, which are found in substances as diverse as fertilizers and antacid tablets, halides, oxides, carbides, and carboranes. Like boron in group 13, the chemistry of carbon differs sufficiently from that of its heavier congeners to merit a separate discussion.

The structures of the allotropes of carbon—diamond, graphite, fullerenes, and nanotubes—are distinct, but they all contain simple electron-pair bonds (Figure 3.4.1). Although it was originally believed that fullerenes were a new form of carbon that could be prepared only in the laboratory, fullerenes have been found in certain types of meteorites. Another possible allotrope of carbon has also been detected in impact fragments of a carbon-rich meteorite; it appears to consist of long chains of carbon atoms linked by alternating single and triple bonds, $(-C\equiv C-C\equiv C-)_n$. Carbon nanotubes (“buckytubes”) are being studied as potential building blocks for ultramicroscale detectors and molecular computers and as tethers for space stations. They are currently used in electronic devices, such as the electrically conducting tips of miniature electron guns for flat-panel displays in portable computers.

Although all the carbon tetrahalides (CX_4) are known, they are generally not obtained by the direct reaction of carbon with the elemental halogens (X_2) but by indirect methods such as the following reaction, where X is Cl or Br:

The carbon tetrahalides all have the tetrahedral geometry predicted by the valence-shell electron-pair repulsion (VSEPR) model, as shown for CCl_4 and CF_4 . Their stability decreases rapidly as the halogen increases in size because of poor orbital overlap and increased crowding. Because the C–F bond is about 25% stronger than a C–H bond, fluorocarbons are thermally and chemically more stable than the corresponding hydrocarbons, while having a similar hydrophobic character. A polymer of tetrafluoroethylene ($F_2C=CF_2$), analogous to polyethylene, is the nonstick Teflon lining found on many cooking pans, and similar compounds are used to make fabrics stain resistant (such as Scotch-Gard) or waterproof but breathable (such as Gore-Tex).

Note the Pattern

The stability of the carbon tetrahalides decreases with increasing size of the halogen due to increasingly poor orbital overlap and crowding.

Carbon reacts with oxygen to form either CO or CO_2 , depending on the stoichiometry. Carbon monoxide is a colorless, odorless, and poisonous gas that reacts with the iron in hemoglobin to form an Fe–CO unit, which prevents hemoglobin from binding, transporting, and releasing oxygen in the blood (see Figure 3 in this discussion of myoglobin). In the laboratory, carbon monoxide can be prepared on a small scale by dehydrating formic acid with concentrated sulfuric acid:

Carbon monoxide also reacts with the halogens to form the oxohalides (COX_2). Probably the best known of these is phosgene ($Cl_2C=O$), which is highly poisonous and was used as a chemical weapon during World War I:

Despite its toxicity, phosgene is an important industrial chemical that is prepared on a large scale, primarily in the manufacture of polyurethanes.

Carbon dioxide can be prepared on a small scale by reacting almost any metal carbonate or bicarbonate salt with a strong acid. As is typical of a nonmetal oxide, CO_2 reacts with water to form acidic solutions containing carbonic acid (H_2CO_3). In contrast to its reactions with oxygen, reacting carbon with sulfur at high temperatures produces only carbon disulfide (CS_2):

The selenium analogue CSe_2 is also known. Both have the linear structure predicted by the VSEPR model, and both are vile smelling (and in the case of CSe_2 , highly toxic), volatile liquids. The sulfur and selenium analogues of carbon monoxide, CS and CSe , are unstable because the $C=Y$ bonds (Y is S or Se) are much weaker than the $C=O$ bond due to poorer π orbital overlap.

Note the Pattern

Pi bonds between carbon and the heavier chalcogenides are weak due to poor orbital overlap.

Binary compounds of carbon with less electronegative elements are called *carbides*. The chemical and physical properties of carbides depend strongly on the identity of the second element, resulting in three general classes: ionic carbides, interstitial carbides, and covalent carbides. The reaction of carbon at high temperatures with electropositive metals such as those of groups 1 and 2 and aluminum produces *ionic carbides*, which contain discrete metal cations and carbon anions. The identity of the anions depends on the size of the second element. For example, smaller elements such as beryllium and aluminum give *methides* such as Be_2C and Al_4C_3 , which formally contain the C^{4-} ion derived from methane (CH_4) by losing all four H atoms as protons. In contrast, larger C^{4-} metals such as sodium and calcium give carbides with stoichiometries of Na_2C_2 and CaC_2 . Because these carbides contain the C^{2-} ion, which is derived from acetylene ($HC\equiv CH$) by losing both H atoms as protons, they are more properly called *acetylides*. As discussed in Section 19.4, reacting ionic carbides with dilute aqueous acid results in protonation of the anions to give the parent hydrocarbons: CH_4 or C_2H_2 . For many years, miners' lamps used the reaction of calcium carbide with water to produce a steady supply of acetylene, which was ignited to provide a portable lantern.

The reaction of carbon with most transition metals at high temperatures produces *interstitial carbides*. Due to the less electropositive nature of the transition metals, these carbides contain covalent metal-carbon interactions, which result in different properties: most interstitial carbides are good conductors of electricity, have high melting points, and are among the hardest substances known. Interstitial carbides exhibit a variety of nominal compositions, and they are often nonstoichiometric compounds whose carbon content can vary over a wide range. Among the most important are tungsten carbide (WC), which is used industrially in high-speed cutting tools, and cementite (Fe_3C), which is a major component of steel.

Elements with an electronegativity similar to that of carbon form *covalent carbides*, such as silicon carbide (SiC ; Equation 22.2.1) and boron carbide (B_4C). These substances are extremely hard, have high melting points, and are chemically inert. For example, silicon carbide is highly resistant to chemical attack at temperatures as high as $1600^\circ C$. Because it also maintains its strength at high temperatures, silicon carbide is used in heating elements for electric furnaces and in variable-temperature resistors.

19th-century miner's lamp.
The lamp uses burning acetylene, produced by the slow reaction of calcium carbide with water, to provide light.

Note the Pattern

Carbides formed from group 1 and 2 elements are ionic. Transition metals form interstitial carbides with covalent metal-carbon interactions, and covalent carbides are chemically inert.

Example 22.2.1

For each reaction, explain why the given product forms.

- $CO(g) + Cl_2(g) \rightarrow Cl_2C=O(g)$
- $CO(g) + BF_3(g) \rightarrow F_3B:C\equiv O(g)$
- $Sr(s) + 2C(s) + \Delta \rightarrow SrC_2(s)$

Given: balanced chemical equations

Asked for: why the given products form

Strategy:

Classify the type of reaction. Using periodic trends in atomic properties, thermodynamics, and kinetics, explain why the observed reaction products form.

Solution:

1. Because the carbon in CO is in an intermediate oxidation state (+2), CO can be either a reductant or an oxidant; it is also a Lewis base. The other reactant (Cl_2) is an oxidant, so we expect a redox reaction to occur in which the carbon of CO is further oxidized. Because Cl_2 is a two-electron oxidant and the carbon atom of CO can be oxidized by two electrons to the +4 oxidation state, the product is phosgene ($\text{Cl}_2\text{C}=\text{O}$).
2. Unlike Cl_2 , BF_3 is not a good oxidant, even though it contains boron in its highest oxidation state (+3). Nor can BF_3 behave like a reductant. Like any other species with only six valence electrons, however, it is certainly a Lewis acid. Hence an acid–base reaction is the most likely alternative, especially because we know that CO can use the lone pair of electrons on carbon to act as a Lewis base. The most probable reaction is therefore the formation of a Lewis acid–base adduct.
3. Typically, both reactants behave like reductants. Unless one of them can also behave like an oxidant, no reaction will occur. We know that Sr is an active metal because it lies far to the left in the periodic table and that it is more electropositive than carbon. Carbon is a nonmetal with a significantly higher electronegativity; it is therefore more likely to accept electrons in a redox reaction. We conclude, therefore, that Sr will be oxidized, and C will be reduced. Carbon forms ionic carbides with active metals, so the reaction will produce a species formally containing either C^{4-} or C_2^{2-} . Those that contain C^{4-} usually involve small, highly charged metal ions, so Sr^{2+} will produce the acetylide (SrC_2) instead.

Exercise

Predict the products of the reactions and write a balanced chemical equation for each reaction.

1. $\text{C}(\text{s}) + \text{excess O}_2(\text{g}) + \Delta \rightarrow$
2. $\text{C}(\text{s}) + \text{H}_2\text{O}(\text{l}) \rightarrow$
3. $\text{NaHCO}_3(\text{s}) + \text{H}_2\text{SO}_4(\text{aq}) \rightarrow$

Answer:

1. $\text{C}(\text{s}) + \text{excess O}_2(\text{g}) + \Delta \rightarrow \text{CO}_2(\text{g})$
2. $\text{C}(\text{s}) + \text{H}_2\text{O}(\text{l}) \rightarrow$ no reaction
3. $\text{NaHCO}_3(\text{s}) + \text{H}_2\text{SO}_4(\text{aq}) \rightarrow \text{CO}_2(\text{g}) + \text{NaHSO}_4(\text{aq}) + \text{H}_2\text{O}(\text{l})$

Reactions and Compounds of the Heavier Group 14 Elements

Although silicon, germanium, tin, and lead in their +4 oxidation states often form binary compounds with the same stoichiometry as carbon, the structures and properties of these compounds are usually significantly different from those of the carbon analogues. Silicon and germanium are both semiconductors with structures analogous to diamond. Tin has two common allotropes: white (β) tin has a metallic lattice and metallic properties, whereas gray (α) tin has a diamond-like structure and is a semiconductor. The metallic β form is stable above 13.2°C , and the nonmetallic α form is stable below 13.2°C . Lead is the only group 14 element that is metallic in both structure and properties under all conditions.

Based on its position in the periodic table, we expect silicon to be amphoteric. In fact, it dissolves in strong aqueous base to produce hydrogen gas and solutions of silicates, but the only aqueous acid that it reacts with is hydrofluoric acid, presumably due to the formation of the stable SiF_6^{2-} ion. Germanium is more metallic in its behavior than silicon. For example, it dissolves in hot oxidizing acids, such as HNO_3 and H_2SO_4 , but in the absence of an oxidant, it does not dissolve in aqueous base. Although tin has an even more metallic character than germanium, lead is the only element in the group that behaves purely as a metal. Acids do not readily attack it because the solid acquires a thin protective outer layer of a Pb^{2+} salt, such as PbSO_4 .

All group 14 dichlorides are known, and their stability increases dramatically as the atomic number of the central atom increases. Thus CCl_2 is dichlorocarbene, a highly reactive, short-lived intermediate that can be made in solution but cannot be isolated in pure form using standard techniques; SiCl_2 can be isolated at very low temperatures, but it decomposes rapidly above -150°C , and GeCl_2 is relatively stable at temperatures below 20°C . In contrast, SnCl_2 is a polymeric solid that is indefinitely stable at room temperature, whereas PbCl_2 is an insoluble crystalline solid with a structure similar to that of SnCl_2 .

Note the Pattern

The stability of the group 14 dichlorides increases dramatically from carbon to lead.

Although the first four elements of group 14 form tetrahalides (MX_4) with all the halogens, only fluorine is able to oxidize lead to the +4 oxidation state, giving PbF_4 . The tetrahalides of silicon and germanium react rapidly with water to give amphoteric oxides (where M is Si or Ge):

In contrast, the tetrahalides of tin and lead react with water to give hydrated metal ions.

Because of the stability of its +2 oxidation state, lead reacts with oxygen or sulfur to form PbO or PbS , respectively, whereas heating the other group 14 elements with excess O_2 or S_8 gives the corresponding dioxides or disulfides, respectively. The dioxides of the group 14 elements become increasingly basic as we go down the group.

Note the Pattern

The dioxides of the group 14 elements become increasingly basic down the group.

Because the Si–O bond is even stronger than the C–O bond (~ 452 kJ/mol versus ~ 358 kJ/mol), silicon has a strong affinity for oxygen. The relative strengths of the C–O and Si–O bonds contradict the generalization that bond strengths decrease as the bonded atoms become larger. This is because we have thus far assumed that a formal single bond between two atoms can always be described in terms of a single pair of shared electrons. In the case of Si–O bonds, however, the presence of relatively low-energy, empty d orbitals on Si and nonbonding electron pairs in the p or sp^n hybrid orbitals of O results in a partial π bond (Figure 22.2.3). Due to its partial π double bond character, the Si–O bond is significantly stronger and shorter than would otherwise be expected. A similar interaction with oxygen is also an important feature of the chemistry of the elements that follow silicon in the third period (P, S, and Cl). Because the Si–O bond is unusually strong, silicon–oxygen compounds dominate the chemistry of silicon.

Figure 22.2.3 Pi Bonding between Silicon and Oxygen Silicon has relatively low-energy, empty 3d orbitals that can interact with filled 2p hybrid orbitals on oxygen. This interaction results in a partial π bond in which both electrons are supplied by oxygen, giving the Si–O bond partial double bond character and making it significantly stronger (and shorter) than expected for a single bond.

Note the Pattern

Because silicon–oxygen bonds are unusually strong, silicon–oxygen compounds dominate the chemistry of silicon.

Compounds with anions that contain only silicon and oxygen are called *silicates*, whose basic building block is the SiO_4^{4-} unit:

The number of oxygen atoms shared between silicon atoms and the way in which the units are linked vary considerably in different silicates. Converting one of the oxygen atoms from terminal to bridging generates chains of silicates, while converting two oxygen atoms from terminal to bridging generates double chains. In contrast, converting three or four oxygens to bridging generates a variety of complex layered and three-dimensional structures, respectively.

The silicates include many glasses as well as the gemstone known as *opal*, which typically contains 10%–15% water. In a large and important class of materials called *aluminosilicates*, some of the Si atoms are replaced by Al atoms to give aluminosilicates such as *zeolites*, whose three-dimensional framework structures have large cavities connected by smaller tunnels (Figure 22.2.4). Because the cations in zeolites are readily exchanged, zeolites are used in laundry detergents as water-softening agents: the more loosely bound Na^+ ions inside the zeolite cavities are displaced by the more highly charged Mg^{2+} and Ca^{2+} ions present in hard water, which bind more tightly. Zeolites are also used as catalysts and for water purification.

Opal gemstones.

Figure 22.2.4 Zeolites Are Aluminosilicates with Large Cavities Connected by Channels The cavities normally contain hydrated cations that are loosely bound to the oxygen atoms of the negatively charged framework by electrostatic interactions. The sizes and arrangements of the channels and cavities differ in different types of zeolites. For example, in zeolite A the aluminosilicate cages are arranged in a cubic fashion, and the channels connecting the cavities intersect at right angles. In contrast, the cavities in faujasite are much larger, and the channels intersect at 120° angles. In these idealized models, the oxygen atoms that connect each pair of silicon atoms have been omitted.

Silicon and germanium react with nitrogen at high temperature to form *nitrides* (M_3N_4):

Silicon nitride has properties that make it suitable for high-temperature engineering applications: it is strong, very hard, and chemically inert, and it retains these properties to temperatures of about 1000°C.

Because of the diagonal relationship between boron and silicon, metal silicides and metal borides exhibit many similarities. Although metal silicides have structures that are as complex as those of the metal borides and carbides, few silicides are structurally similar to the corresponding borides due to the significantly larger size of Si (atomic radius 111 pm versus 87 pm for B). Silicides of active metals, such as Mg_2Si , are ionic compounds that contain the Si^{4-} ion. They react with aqueous acid to form silicon hydrides such as SiH_4 :

Unlike carbon, catenated silicon hydrides become thermodynamically less stable as the chain lengthens. Thus straight-chain and branched *silanes* (analogous to alkanes) are known up to only $n = 10$; the germanium analogues (*germanes*) are known up to $n = 9$. In contrast, the only known hydride of tin is SnH_4 , and it slowly decomposes to elemental Sn and H_2 at room temperature. The simplest lead hydride (PbH_4) is so unstable that chemists are not even certain it exists. Because $E=E$ and $E\equiv E$ bonds become weaker with increasing atomic number (where E is any group 14 element), simple silicon, germanium, and tin analogues of alkenes, alkynes, and aromatic hydrocarbons are either unstable ($Si=Si$ and $Ge=Ge$) or unknown. Silicon-based life-forms are therefore likely to be found only in science fiction.

Note the Pattern

The stability of group 14 hydrides decreases down the group, and $E=E$ and $E\equiv E$ bonds become weaker.

The only important organic derivatives of lead are compounds such as tetraethyllead $[(CH_3CH_2)_4Pb]$. Because the Pb–C bond is weak, these compounds decompose at relatively low temperatures to produce alkyl radicals ($R\cdot$), which can be used to control the rate of combustion reactions. For 60 yr, hundreds of thousands of tons of lead were burned annually in automobile engines in the form of an anti-knock additive, tetra methyl lead, producing a mist of lead oxide particles along the highways that constituted a potentially serious public health problem. The use of catalytic converters reduced the amount of carbon monoxide, nitrogen oxides, and hydrocarbons released into the atmosphere through automobile exhausts, but it did nothing to decrease lead emissions. Because lead poisons catalytic converters, however, its use as a gasoline additive has been banned in most of the world.

Compounds that contain Si–C and Si–O bonds are stable and important. High-molecular-mass polymers called *silicones* contain an $(Si-O)_n$ backbone with organic groups attached to Si (Figure 22.2.5). The properties of silicones are determined by the chain length, the type of organic group, and the extent of cross-linking between the chains. Without cross-linking, silicones are waxes or oils, but cross-linking can produce flexible materials used in sealants, gaskets, car polishes, lubricants, and even elastic materials, such as the plastic substance known as Silly Putty.

Figure 22.2.5 Silicones Are Polymers with Long Chains of Alternating Silicon and Oxygen Atoms The structure of a linear silicone polymer is similar to that of quartz, but two of the oxygen atoms attached to each silicon atom are replaced by the carbon atoms of organic groups, such as the methyl groups ($-CH_3$) shown here. The terminal silicon atoms are bonded to three methyl groups. Silicones can be oily, waxy, flexible, or elastic, depending on the chain length, the extent of cross-linking between the chains, and the type of organic group.

A child playing with Silly Putty, a silicone polymer with unusual mechanical properties. Gentle pressure causes Silly Putty to flow or stretch, but it cannot be flattened when hit with a hammer.

Example 22.2.2

For each reaction, explain why the given products form.

- $\text{Pb(s)} + \text{Cl}_2(\text{g}) \rightarrow \text{PbCl}_2(\text{s})$
- $\text{Mg}_2\text{Si(s)} + 4\text{H}_2\text{O(l)} \rightarrow \text{SiH}_4(\text{g}) + 2\text{Mg(OH)}_2(\text{s})$
- $\text{GeO}_2(\text{s}) + 4\text{OH}^-(\text{aq}) \rightarrow \text{GeO}_4^{4-}(\text{aq}) + 2\text{H}_2\text{O(l)}$

Given: balanced chemical equations

Asked for: why the given products form

Strategy:

Classify the type of reaction. Using periodic trends in atomic properties, thermodynamics, and kinetics, explain why the observed reaction products form.

Solution:

- Lead is a metal, and chlorine is a nonmetal that is a strong oxidant. Thus we can expect a redox reaction to occur in which the metal acts as a reductant. Although lead can form compounds in the +2 and +4 oxidation states, Pb^{4+} is a potent oxidant (the inert-pair effect). Because lead prefers the +2 oxidation state and chlorine is a weaker oxidant than fluorine, we expect PbCl_2 to be the product.
- This is the reaction of water with a metal silicide, which formally contains the Si^{4-} ion. Water can act as either an acid or a base. Because the other compound is a base, we expect an acid–base reaction to occur in which water acts as an acid. Because Mg_2Si contains Si in its lowest possible oxidation state, however, an oxidation–reduction reaction is also a possibility. But water is a relatively weak oxidant, so an acid–base reaction is more likely. The acid (H_2O) transfers a proton to the base (Si^{4-}), which can accept four protons to form SiH_4 . Proton transfer from water produces the OH^- ion, which will combine with Mg^{2+} to give magnesium hydroxide.
- We expect germanium dioxide (GeO_2) to be amphoteric because of the position of germanium in the periodic table. It should dissolve in strong aqueous base to give an anionic species analogous to silicate.

Exercise

Predict the products of the reactions and write a balanced chemical equation for each reaction.

- $\text{PbO}_2(\text{s}) + \Delta \rightarrow$
- $\text{GeCl}_4(\text{s}) + \text{H}_2\text{O(l)} \rightarrow$
- $\text{Sn(s)} + \text{HCl(aq)} \rightarrow$

Answer:

- $\text{PbO}_2 + \Delta \rightarrow \text{PbO}(\text{s}) + 1/2 \text{O}_2(\text{g})$
- $\text{GeCl}_4(\text{s}) + 2\text{H}_2\text{O}(\text{l}) \rightarrow \text{GeO}_2(\text{s}) + 4\text{HCl}(\text{aq})$
- $\text{Sn}(\text{s}) + 2\text{HCl}(\text{aq}) \rightarrow \text{Sn}^{2+}(\text{aq}) + \text{H}_2(\text{g}) + 2\text{Cl}^{-}(\text{aq})$

Summary

The group 14 elements show the greatest range of chemical behavior of any group in the periodic table. Because the covalent bond strength decreases with increasing atomic size and greater-than-expected ionization energies due to an increase in Z_{eff} , the stability of the +2 oxidation state increases from carbon to lead. The tendency to form multiple bonds and to catenate decreases as the atomic number increases. The stability of the carbon tetrahalides decreases as the halogen increases in size because of poor orbital overlap and steric crowding. Carbon forms three kinds of carbides with less electronegative elements: ionic carbides, which contain metal cations and C^{4-} (methide) or C_2^{2-} (acetylide) anions; interstitial carbides, which are characterized by covalent metal-carbon interactions and are among the hardest substances known; and covalent carbides, which have three-dimensional covalent network structures that make them extremely hard, high melting, and chemically inert. Consistent with periodic trends, metallic behavior increases down the group. Silicon has a tremendous affinity for oxygen because of partial Si-O π bonding. Dioxides of the group 14 elements become increasingly basic down the group and their metallic character increases. Silicates contain anions that consist of only silicon and oxygen. Aluminosilicates are formed by replacing some of the Si atoms in silicates by Al atoms; aluminosilicates with three-dimensional framework structures are called zeolites. Nitrides formed by reacting silicon or germanium with nitrogen are strong, hard, and chemically inert. The hydrides become thermodynamically less stable down the group. Moreover, as atomic size increases, multiple bonds between or to the group 14 elements become weaker. Silicones, which contain an Si-O backbone and Si-C bonds, are high-molecular-mass polymers whose properties depend on their compositions.

Key Takeaway

- The group 14 elements show the greatest diversity in chemical behavior of any group; covalent bond strengths decrease with increasing atomic size, and ionization energies are greater than expected, increasing from C to Pb.

Conceptual Problems

- Why is the preferred oxidation state of lead +2 rather than +4? What do you expect the preferred oxidation state of silicon to be based on its position in the periodic table?
- Carbon uses $p\pi-p\pi$ overlap to form compounds with multiple bonds, but silicon does not. Why? How does this same phenomenon explain why the heavier elements in group 14 do not form catenated compounds?
- Diamond is both an electrical insulator and an excellent thermal conductor. Explain this property in terms of its bonding.
- The lighter chalcogens (group 16) form π bonds with carbon. Does the strength of these π bonds increase or decrease with increasing atomic number of the chalcogen? Why?
- The heavier group 14 elements can form complexes that contain expanded coordination spheres. How does this affect their reactivity compared with the reactivity of carbon? Is this a thermodynamic effect or a kinetic effect? Explain your answer.
- Refer to [Table 20.2.1](#) for the values of the electron affinities of the group 14 elements. Explain any discrepancies between these actual values and the expected values based on usual periodic trends.
- Except for carbon, the elements of group 14 can form five or six electron-pair bonds. What hybrid orbitals are used to allow this expanded coordination? Why does carbon not form more than four electron-pair bonds?
- Which of the group 14 elements is least stable in the +4 oxidation state? Why?

Structure and Reactivity

- Predict the products of each reaction and balance each chemical equation.
 - $\text{CaC}_2(\text{s}) + \text{HCl}(\text{g}) \rightarrow$
 - $\text{Pb}(\text{s}) + \text{Br}_2(\text{l}) + \Delta \rightarrow$

- c. $(\text{CH}_3)_3\text{N}(\text{l}) + \text{H}_2\text{O}_2(\text{aq}) \rightarrow$
d. $\text{Pb}(\text{N}_3)_2(\text{s}) + \Delta \rightarrow$
2. Write a balanced chemical equation to indicate how you would prepare each compound.
- SiF_6 from its elements and other common compounds
 - SiO_2 from SiCl_4
 - GeS_2 from its elements
 - $\text{Si}(\text{CH}_3)_4$ from Si
3. Write a balanced chemical equation to indicate how you would prepare each compound.
- CO_2 from CuO
 - methane from Be_2C
 - $\text{Si}(\text{OH})_4$ from Si
 - Si_3N_4 from Si

Answers

- $\text{CaC}_2(\text{s}) + 2\text{HCl}(\text{g}) \rightarrow \text{CaCl}_2(\text{s}) + \text{C}_2\text{H}_2(\text{g})$
 - $\text{Pb}(\text{s}) + \text{Br}_2(\text{l}) + \Delta \rightarrow \text{PbBr}_2(\text{s})$
 - $(\text{CH}_3)_3\text{N}(\text{l}) + \text{H}_2\text{O}_2(\text{aq}) \rightarrow (\text{CH}_3)_3\text{N}-\text{O}(\text{l}) + \text{H}_2\text{O}(\text{l})$
 - $\text{Pb}(\text{N}_3)_2(\text{s}) + \Delta \rightarrow \text{Pb}(\text{s}) + 3\text{N}_2(\text{g})$
-
- $\text{CuO}(\text{s}) + \text{CO}(\text{s}) + \Delta \rightarrow \text{Cu}(\text{s}) + \text{CO}_2(\text{g})$
 - $\text{Be}_2\text{C}(\text{s}) + 4\text{HCl}(\text{aq}) \rightarrow 2\text{BeCl}_2(\text{aq}) + \text{CH}_4(\text{g})$
 - $\text{Si}(\text{s}) + 2\text{Cl}_2(\text{g}) \rightarrow \text{SiCl}_4(\text{l}); \text{SiCl}_4(\text{l}) + 4\text{H}_2\text{O}(\text{l}) \rightarrow \text{Si}(\text{OH})_4(\text{s}) + 4\text{HCl}(\text{aq})$
 - $3\text{Si}(\text{s}) + 2\text{N}_2(\text{g}) + \Delta \rightarrow \text{Si}_3\text{N}_4(\text{s})$

Chapter 22.3: The Elements of Group 15 (The Pnicogens)

Howard University General Chemistry: An Atoms First Approach

Unit 1: Atomic Theory
Unit 5: States of Matter

Unit 2: Molecular Structure
Unit 6: Kinetics & Equilibria

Unit 3: Stoichiometry
Unit 7: Electro & Thermo Chemistry

Unit 4: Thermochem & Gases
Unit 8: Materials

Learning Objective

- To understand the trends in properties and reactivity of the group 14 elements: the pnicogens.

Like the group 14 elements, the lightest member of group 15, nitrogen, is found in nature as the free element, and the heaviest elements have been known for centuries because they are easily isolated from their ores.

Antimony (Sb) was probably the first of the pnicogens to be obtained in elemental form and recognized as an element. Its atomic symbol comes from its Roman name: *stibium*. It is found in stibnite (Sb_2S_3), a black mineral that has been used as a cosmetic (an early form of mascara) since biblical times, and it is easily reduced to the metal in a charcoal fire (Figure 22.3.1). The Egyptians used antimony to coat copper objects as early as the third millennium BC, and antimony is still used in alloys to improve the tonal quality of bells.

Figure 22.3.1 The Ancient Egyptians Used Finely Ground Antimony Sulfide for Eye Makeup(a) Crystals of the soft black mineral stibnite (Sb_2S_3) on a white mineral matrix. (b) A fragment of an Egyptian painting on limestone from the 16th–13th centuries BC shows the use of ground stibnite (“kohl”) as black eye shadow. Small vases of ground stibnite have been found among the funeral goods buried with Egyptian pharaohs.

In the form of its yellow sulfide ore, *orpiment* (As_2S_3), arsenic (As) has been known to physicians and professional assassins since ancient Greece, although elemental arsenic was not isolated until centuries later. The history of bismuth (Bi), in contrast, is more difficult to follow because early alchemists often confused it with other metals, such as lead, tin, antimony, and even silver (due to its slightly pinkish-white luster). Its name comes from the old German *wismut*, meaning “white metal.” Bismuth was finally isolated in the 15th century, and it was used to make movable type for printing shortly after the invention of the Gutenberg printing process in 1440. Bismuth is used in printing because it is one of the few substances known whose solid state is less dense than the liquid. Consequently, its alloys expand as they cool, filling a mold completely and producing crisp, clear letters for typesetting.

Phosphorus was discovered in 1669 by the German alchemist Hennig Brandt, who was looking for the “philosophers’ stone,” a mythical substance capable of converting base metals to silver or gold. Believing that human urine was the source of the key ingredient, Brandt obtained several dozen buckets of urine, which he allowed to putrefy. The urine was distilled to dryness at high temperature and then condensed; the last fumes were collected under water, giving a waxy white solid that had unusual properties. For example, it glowed in the dark and burst into flames when removed from the water. (Unfortunately for Brandt, however, it did not turn lead into gold.) The element was given its current name (from the Greek *phos*, meaning “light,” and *phoros*, meaning

“bringing”) in the 17th century. For more than a century, the only way to obtain phosphorus was the distillation of urine, but in 1769 it was discovered that phosphorus could be obtained more easily from bones. During the 19th century, the demand for phosphorus for matches was so great that battlefields and paupers’ graveyards were systematically scavenged for bones. Early matches were pieces of wood coated with elemental phosphorus that were stored in an evacuated glass tube and ignited when the tube was broken (which could cause unfortunate accidents if the matches were kept in a pocket!).

Unfortunately, elemental phosphorus is volatile and highly toxic. It is absorbed by the teeth and destroys bone in the jaw, leading to a painful and fatal condition called “phossy jaw,” which for many years was accepted as an occupational hazard of working in the match industry.

Although nitrogen is the most abundant element in the atmosphere, it was the last of the pnictogens to be obtained in pure form. In 1772, Daniel Rutherford, working with Joseph Black (who discovered CO₂), noticed that a gas remained when CO₂ was removed from a combustion reaction. Antoine Lavoisier called the gas *azote*, meaning “no life,” because it did not support life. When it was discovered that the same element was also present in nitric acid and nitrate salts such as KNO₃ (nitre), it was named nitrogen. About 90% of the nitrogen produced today is used to provide an inert atmosphere for processes or reactions that are oxygen sensitive, such as the production of steel, petroleum refining, and the packaging of foods and pharmaceuticals.

Preparation and General Properties of the Group 15 Elements

Because the atmosphere contains several trillion tons of elemental nitrogen with a purity of about 80%, it is a huge source of nitrogen gas. Distillation of liquefied air yields nitrogen gas that is more than 99.99% pure, but small amounts of very pure nitrogen gas can be obtained from the thermal decomposition of sodium azide:

In contrast, Earth’s crust is relatively poor in nitrogen. The only important nitrogen ores are large deposits of KNO₃ and NaNO₃ in the deserts of Chile and Russia, which were apparently formed when ancient alkaline lakes evaporated. Consequently, virtually all nitrogen compounds produced on an industrial scale use atmospheric nitrogen as the starting material. Phosphorus, which constitutes only about 0.1% of Earth’s crust, is much more abundant in ores than nitrogen. Like aluminum and silicon, phosphorus is always found in combination with oxygen, and large inputs of energy are required to isolate it.

The other three pnictogens are much less abundant: arsenic is found in Earth’s crust at a concentration of about 2 ppm, antimony is an order of magnitude less abundant, and bismuth is almost as rare as gold. All three elements have a high affinity for the chalcogens and are usually found as the sulfide ores (M₂S₃), often in combination with sulfides of other heavy elements, such as copper, silver, and lead. Hence a major source of antimony and bismuth is flue dust obtained by smelting the sulfide ores of the more abundant metals.

In group 15, as elsewhere in the *p* block, we see large differences between the lightest element (N) and its congeners in size, ionization energy, electron affinity, and electronegativity (Table 22.3.1). The chemical behavior of the elements can be summarized rather simply: nitrogen and phosphorus behave chemically like nonmetals, arsenic and antimony behave like semimetals, and bismuth behaves like a metal. With their *ns* *np*³ valence electron configurations, all form compounds by losing either the three *np* valence electrons to form the +3 oxidation state or the three *np* and the two *ns* valence electrons to give the +5 oxidation state, whose stability decreases smoothly from phosphorus to bismuth. In addition, the relatively large magnitude of the electron affinity of the lighter pnictogens enables them to form compounds in the –3 oxidation state (such as NH₃ and PH₃), in which three electrons are formally added to the neutral atom to give a filled *np* subshell. Nitrogen has the unusual ability to form compounds in nine different oxidation states, including –3, +3, and +5. Because neutral covalent compounds of the trivalent pnictogens contain a lone pair of electrons on the central atom, they tend to behave as Lewis bases.

Table 22.3.1 Selected Properties of the Group 15 Elements

Property	Nitrogen	Phosphorus	Arsenic	Antimony	Bismuth
----------	----------	------------	---------	----------	---------

Property	Nitrogen	Phosphorus	Arsenic	Antimony	Bismuth
atomic symbol	N	P	As	Sb	Bi
atomic number	7	15	33	51	83
atomic mass (amu)	14.01	30.97	74.92	121.76	209.98
valence electron configuration*	$2s^2 2p^3$	$3s^2 3p^3$	$4s^2 4p^3$	$5s^2 5p^3$	$6s^2 6p^3$

product of reaction with X ₂	none	PX ₃ , PX ₅	AsF ₅ , AsX ₃	SbF ₅ , SbCl ₅ , SbBr ₃ , SbI ₃	BiF ₅ , BiX ₃
product of reaction with H ₂	none	none	none	none	none

*The configuration shown does not include filled *d* and *f* subshells.

[†] For white phosphorus.

[‡] For gray arsenic.

[§] The values cited are for six-coordinate ions in the indicated oxidation states. The N⁵⁺, P⁵⁺, and As⁵⁺ ions are not known species.

^{||} The chemical form of the elements in these oxidation states varies considerably. For N, the reaction is $\text{NO}_3^- + 3\text{H}^+ + 2\text{e}^- \rightarrow \text{HNO}_2 + \text{H}_2\text{O}$; for P and As, it is $\text{H}_3\text{EO}_4 + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{H}_3\text{EO}_3 + \text{H}_2\text{O}$; and for Sb it is $\text{Sb}_2\text{O}_5 + 4\text{e}^- + 10\text{H}^+ \rightarrow 2\text{Sb}^{3+} + 5\text{H}_2\text{O}$.

Note the Pattern

In group 15, the stability of the +5 oxidation state decreases from P to Bi.

Note the Pattern

Because neutral covalent compounds of the trivalent group 15 elements have a lone pair of electrons on the central atom, they tend to be Lewis bases.

Reactions and Compounds of Nitrogen

Like carbon, nitrogen has four valence orbitals (one 2s and three 2p), so it can participate in at most four electron-pair bonds by using sp^3 hybrid orbitals. Unlike carbon, however, nitrogen does not form long chains because of repulsive interactions between lone pairs of electrons on *adjacent* atoms. These interactions become important at the shorter internuclear distances encountered with the smaller, second-period elements of groups 15, 16, and 17. (For more information on internuclear distance, see [Section 3.2](#) and [Section 4.1](#).) Stable compounds with N–N bonds are limited to chains of no more than three N atoms, such as the azide ion (N_3^-).

Nitrogen is the only pnictogen that normally forms multiple bonds with itself and other second-period elements, using π overlap of adjacent np orbitals. Thus the stable form of elemental nitrogen is N_2 , whose $N\equiv N$ bond is so strong ($D_{N\equiv N} = 942$ kJ/mol) compared with the N–N and N=N bonds ($D_{N-N} = 167$ kJ/mol; $D_{N=N} = 418$ kJ/mol) that all compounds containing N–N and N=N bonds are thermodynamically unstable with respect to the formation of N_2 . In fact, the formation of the $N\equiv N$ bond is so thermodynamically favored that virtually all compounds containing N–N bonds are potentially explosive.

Again in contrast to carbon, nitrogen undergoes only two important chemical reactions at room temperature: it reacts with metallic lithium to form lithium nitride, and it is reduced to ammonia by certain microorganisms. (For more information lithium, see [Chapter 19](#).) At higher temperatures, however, N_2 reacts with more electropositive elements, such as those in group 13, to give binary nitrides, which range from covalent to ionic in character. Like the corresponding compounds of carbon, binary compounds of nitrogen with oxygen, hydrogen, or other nonmetals are usually covalent molecular substances.

Few binary molecular compounds of nitrogen are formed by direct reaction of the elements. At elevated temperatures, N_2 reacts with H_2 to form ammonia, with O_2 to form a mixture of NO and NO_2 , and with carbon to form *cyanogen* ($N\equiv C-C\equiv N$); elemental nitrogen does not react with the halogens or the other chalcogens. Nonetheless, all the binary nitrogen halides (NX_3) are known. Except for NF_3 , all are toxic, thermodynamically unstable, and potentially explosive, and all are prepared by reacting the halogen with NH_3 rather than N_2 . Both nitrogen monoxide (NO) and nitrogen dioxide (NO_2) are thermodynamically unstable, with positive free energies of formation. Unlike NO, NO_2 reacts readily with excess water, forming a 1:1 mixture of nitrous acid (HNO_2) and nitric acid (HNO_3):

Nitrogen also forms N_2O (dinitrogen monoxide, or nitrous oxide), a linear molecule that is isoelectronic with CO_2 and can be represented as $N\equiv N^+ = O^-$. Like the other two oxides of nitrogen, nitrous oxide is thermodynamically unstable. The structures of the three common oxides of nitrogen are as follows:

Note the Pattern

Few binary molecular compounds of nitrogen are formed by the direct reaction of the elements.

At elevated temperatures, nitrogen reacts with highly electropositive metals to form *ionic nitrides*, such as Li_3N and Ca_3N_2 . These compounds consist of ionic lattices formed by M^{n+} and N^{3-} ions. Just as boron forms interstitial borides and carbon forms interstitial carbides, with less electropositive metals nitrogen forms a range of *interstitial nitrides*, in which nitrogen occupies holes in a close-packed metallic structure. Like the interstitial carbides and borides, these substances are typically very hard, high-melting materials that have metallic luster and conductivity.

Nitrogen also reacts with semimetals at very high temperatures to produce *covalent nitrides*, such as Si_3N_4 and BN , which are solids with extended covalent network structures similar to those of graphite or diamond. Consequently, they are usually high melting and chemically inert materials.

Ammonia (NH_3) is one of the few thermodynamically stable binary compounds of nitrogen with a nonmetal. It is not flammable in air, but it burns in an O_2 atmosphere:

About 10% of the ammonia produced annually is used to make fibers and plastics that contain amide bonds, such as nylons and polyurethanes, while 5% is used in explosives, such as ammonium nitrate, TNT (trinitrotoluene), and nitroglycerine. Large amounts of anhydrous liquid ammonia are used as fertilizer.

Nitrogen forms two other important binary compounds with hydrogen. Hydrazoic acid (HN_3), also called hydrogen azide, is a colorless, highly toxic, and explosive substance. Hydrazine (N_2H_4) is also potentially explosive; it is used as a rocket propellant and to inhibit corrosion in boilers.

Note the Pattern

B, C, and N all react with transition metals to form interstitial compounds that are hard, high-melting materials.

Example 22.3.1

For each reaction, explain why the given products form when the reactants are heated.

- $\text{Sr}(s) + \text{N}_2\text{O}(g) + \Delta \rightarrow \text{SrO}(s) + \text{N}_2(g)$
- $\text{NH}_4\text{NO}_2(s) + \Delta \rightarrow \text{N}_2(g) + 2\text{H}_2\text{O}(g)$
- $\text{Pb}(\text{NO}_3)_2(s) + \Delta \rightarrow \text{PbO}_2(s) + 2\text{NO}_2(g)$

Given: balanced chemical equations

Asked for: why the given products form

Strategy:

Classify the type of reaction. Using periodic trends in atomic properties, thermodynamics, and kinetics, explain why the observed reaction products form.

Solution:

- As an alkali metal, strontium is a strong reductant. If the other reactant can act as an oxidant, then a redox reaction will occur. Nitrous oxide contains nitrogen in a low oxidation state (+1), so we would not normally consider it an oxidant. Nitrous oxide is, however, thermodynamically unstable ($\Delta H_f^\circ > 0$ and $\Delta G_f^\circ > 0$), and it can be reduced to N_2 , which is a stable species. Consequently, we predict that a redox reaction will occur.
- When a substance is heated, a decomposition reaction probably will occur, which often involves the release of stable gases. In this case, ammonium nitrite contains nitrogen in two different oxidation states (-3 and +3), so an internal redox reaction is a possibility. Due to its thermodynamic stability, N_2 is the probable nitrogen-containing product, whereas we predict that H and O will combine to form H_2O .
- Again, this is probably a thermal decomposition reaction. If one element is in an usually high oxidation state and another in a low oxidation state, a redox reaction will probably occur. Lead nitrate contains the Pb^{2+} cation and the nitrate anion, which contains nitrogen in its highest possible oxidation state (+5). Hence nitrogen can be reduced, and we know that lead can be oxidized to the +4 oxidation state. Consequently, it is likely that lead(II) nitrate will

decompose to lead(IV) oxide and nitrogen dioxide when heated. Even though PbO_2 is a powerful oxidant, the release of a gas such as NO_2 can often drive an otherwise unfavorable reaction to completion (Le Châtelier's principle). Note, however, that PbO_2 will probably decompose to PbO at high temperatures.

Exercise

Predict the product(s) of each reaction and write a balanced chemical equation for each reaction.

- $\text{NO}(\text{g}) + \text{H}_2\text{O}(\text{l}) + \Delta \rightarrow$
- $\text{NH}_4\text{NO}_3(\text{s}) + \Delta \rightarrow$
- $\text{Sr}(\text{s}) + \text{N}_2(\text{g}) \rightarrow$

Answer:

- $\text{NO}(\text{g}) + \text{H}_2\text{O}(\text{l}) + \Delta \rightarrow$ no reaction
- $\text{NH}_4\text{NO}_3(\text{s}) + \Delta \rightarrow \text{N}_2\text{O}(\text{g}) + 2\text{H}_2\text{O}(\text{g})$
- $3\text{Sr}(\text{s}) + \text{N}_2(\text{g}) \rightarrow \text{Sr}_3\text{N}_2(\text{s})$

Reactions and Compounds of the Heavier Pnicogens

Like the heavier elements of group 14, the heavier pnicogens form catenated compounds that contain only single bonds, whose stability decreases rapidly as we go down the group. For example, phosphorus exists as multiple allotropes, the most common of which is *white phosphorus*, which consists of P_4 tetrahedra and behaves like a typical nonmetal. As is typical of a molecular solid, white phosphorus is volatile, has a low melting point (44.1°C), and is soluble in nonpolar solvents. It is highly strained, with bond angles of only 60° , which partially explains why it is so reactive and so easily converted to more stable allotropes. Heating white phosphorus for several days converts it to *red phosphorus*, a polymer that is air stable, virtually insoluble, denser than white phosphorus, and higher melting, properties that make it much safer to handle. A third allotrope of phosphorus, *black phosphorus*, is prepared by heating the other allotropes under high pressure; it is even less reactive, denser, and higher melting than red phosphorus. As expected from their structures, white phosphorus is an electrical insulator, and red and black phosphorus are semiconductors. The three heaviest pnicogens—arsenic, antimony, and bismuth—all have a metallic luster, but they are brittle (not ductile) and relatively poor electrical conductors.

Note the Pattern

As in group 14, the heavier group 15 elements form catenated compounds that contain only single bonds, whose stability decreases as we go down the group.

The reactivity of the heavier pnicogens decreases as we go down the column. Phosphorus is by far the most reactive of the pnicogens, forming binary compounds with every element in the periodic table except antimony, bismuth, and the noble gases. Phosphorus reacts rapidly with O_2 , whereas arsenic burns in pure O_2 if ignited, and antimony and bismuth react with O_2 only when heated. None of the pnicogens reacts with nonoxidizing acids such as aqueous HCl_{3+} , but all dissolve in oxidizing acids such as HNO_3 . Only bismuth behaves like a metal, dissolving in HNO_3 to give the hydrated Bi^{3+} cation.

Note the Pattern

The reactivity of the heavier group 15 elements decreases as we go down the column.

The heavier pnicogens can use energetically accessible $3d$, $4d$, or $5d$ orbitals to form dsp^3 or d^2sp^3 hybrid orbitals for bonding. Consequently, these elements often have coordination numbers of 5 or higher. Phosphorus and arsenic form halides (e.g., AsCl_5) that are generally covalent molecular species and behave like typical nonmetal halides, reacting with water to form the

corresponding oxoacids (in this case, H_3AsO_4). All the pentahalides are potent Lewis acids that can expand their coordination to accommodate the lone pair of a Lewis base:

In contrast, bismuth halides have extended lattice structures and dissolve in water to produce hydrated ions, consistent with the stronger metallic character of bismuth.

Except for BiF_3 , which is essentially an ionic compound, the trihalides are volatile covalent molecules with a lone pair of electrons on the central atom. Like the pentahalides, the trihalides react rapidly with water. In the cases of phosphorus and arsenic, the products are the corresponding acids, H_3PO_3 and H_3AsO_3 , where E is P or As:

Phosphorus halides are also used to produce insecticides, flame retardants, and plasticizers.

With energetically accessible d orbitals, phosphorus and, to a lesser extent, arsenic are able to form π bonds with second-period atoms such as N and O. This effect is even more important for phosphorus than for silicon, resulting in very strong P–O bonds and even stronger P=O bonds. The first four elements in group 15 also react with oxygen to produce the corresponding oxide in the +3 oxidation state. Of these oxides, P_4O_6 and As_4O_6 have cage structures formed by inserting an oxygen atom into each edge of the P_4 or As_4 tetrahedron (part (a) in [Figure 20.3.2](#)), and they behave like typical nonmetal oxides. For example, P_4O_6 reacts with water to form phosphorous acid (H_3PO_3). Consistent with its position between the nonmetal and metallic oxides, Sb_4O_6 is amphoteric, dissolving in either acid or base. In contrast, Bi_2O_3 behaves like a basic metallic oxide, dissolving in acid to give solutions that contain the hydrated Bi^{3+} ion. The two least metallic elements of the heavier pnictogens, phosphorus and arsenic, form very stable oxides with the formula E_4O_{10} in the +5 oxidation state (part (b) in [Figure 20.3.2](#)). In contrast, Bi_2O_5 is so unstable that there is no absolute proof it exists.

Figure 22.3.2 The Structures of Some Cage Compounds of Phosphorus(a, b) The structures of P_4O_6 and P_4O_{10} are both derived from the structure of white phosphorus (P_4) by inserting an oxygen atom into each of the six edges of the P_4 tetrahedron; P_4O_{10} contains an additional terminal oxygen atom bonded to each phosphorus atom. (c) The structure of P_4S_3 is also derived from the structure of P_4 by inserting three sulfur atoms into three adjacent edges of the tetrahedron.

The heavier pnictogens form sulfides that range from molecular species with three-dimensional cage structures, such as P_4S_3 (part (c) in [Figure 20.3.2](#)), to layered or ribbon structures, such as Sb_2S_3 and Bi_2S_3 , which are semiconductors. Reacting the heavier pnictogens with metals produces substances whose properties vary with the metal content. Metal-rich *phosphides* (such as M_4P) are hard, high-melting, electrically conductive solids with a metallic luster, whereas phosphorus-rich phosphides (such as MP_{15}) are lower melting and less thermally stable because they contain catenated P_n units. Many organic or organometallic compounds of the heavier pnictogens containing one to five alkyl or aryl groups are also known. Because of the decreasing strength of the pnictogen–carbon bond, their thermal stability decreases from phosphorus to bismuth.

Note the Pattern

Phosphorus has the greatest ability to form π bonds with elements such as O, N, and C.

Note the Pattern

The thermal stability of organic or organometallic compounds of group 15 decreases down the group due to the decreasing strength of the pnictogen-carbon bond.

Example 22.3.2

For each reaction, explain why the given products form.

- $\text{Bi(s)} + 3/2 \text{Br}_2(\text{l}) \rightarrow \text{BiBr}_3(\text{s})$
- $2(\text{CH}_3)_3\text{As(l)} + \text{O}_2(\text{g}) \rightarrow 2(\text{CH}_3)_3\text{As=O(s)}$
- $\text{PBr}_3(\text{l}) + 3\text{H}_2\text{O(l)} \rightarrow \text{H}_3\text{PO}_3(\text{aq}) + 3\text{HBr(aq)}$
- $\text{As(s)} + \text{Ga(s)} + \Delta \rightarrow \text{GaAs(s)}$

Given: balanced chemical equations

Asked for: why the given products form

Strategy:

Classify the type of reaction. Using periodic trends in atomic properties, thermodynamics, and kinetics, explain why the reaction products form.

Solution:

- Bromine is an oxidant, and bismuth is a metal that can be oxidized. Hence a redox reaction is likely to occur. To identify the product, recall that bismuth can form compounds in either the +3 or +5 oxidation state. The heaviest pnictogen, bismuth is rather difficult to oxidize to the +5 oxidation state because of the inert-pair effect. Hence the product will probably be bismuth(III) bromide.
- Trimethylarsine, with a lone pair of electrons on the arsenic atom, can act as either a Lewis base or a reductant. If arsenic is oxidized by two electrons, then oxygen must be reduced, most probably by two electrons to the -2 oxidation state. Because As(V) forms strong bonds to oxygen due to π bonding, the expected product is $(\text{CH}_3)_3\text{As=O}$.
- Phosphorus tribromide is a typical nonmetal halide. We expect it to react with water to produce an oxoacid of P(III) and the corresponding hydrohalic acid. Because of the strength of the P=O bond, phosphorous acid (H_3PO_3) is actually HP(O)(OH)_2 , which contains a P=O bond and a P-H bond.
- Gallium is a metal with a strong tendency to act as a reductant and form compounds in the +3 oxidation state. In contrast, arsenic is a semimetal. It can act as a reductant to form compounds in the +3 or +5 oxidation state, or it can act as an oxidant, accepting electrons to form compounds in the -3 oxidation state. If a reaction occurs, then a binary compound will probably form with a 1:1 ratio of the elements. GaAs is an example of a III-V compound, many of which are used in the electronics industry. (For more information on electrical properties of semiconductors, see [Section 12.6](#).)

Exercise

Predict the products of each reaction and write a balanced chemical equation for each reaction.

- $\text{PCl}_5(\text{s}) + \text{H}_2\text{O(l)} \rightarrow$
- $\text{Bi}_2\text{O}_5(\text{s}) + \Delta \rightarrow$
- $\text{Ca}_3\text{P}_2(\text{s}) + \text{H}^+(\text{aq}) \rightarrow$
- $\text{NaNH}_2(\text{s}) + \text{PH}_3(\text{soln}) \rightarrow$

Answer:

- $\text{PCl}_5(\text{s}) + 4\text{H}_2\text{O(l)} \rightarrow \text{H}_3\text{PO}_4(\text{aq}) + 5\text{HCl(aq)}$
- $\text{Bi}_2\text{O}_5(\text{s}) + \Delta \rightarrow \text{Bi}_2\text{O}_3(\text{s}) + \text{O}_2(\text{g})$
- $\text{Ca}_3\text{P}_2(\text{s}) + 6\text{H}^+(\text{aq}) \rightarrow 2\text{PH}_3(\text{g}) + 3\text{Ca}^{2+}(\text{aq})$
- $\text{NaNH}_2(\text{s}) + \text{PH}_3(\text{soln}) \rightarrow \text{NaPH}_2(\text{s}) + \text{NH}_3(\text{soln})$

Summary

In group 15, nitrogen and phosphorus behave chemically like nonmetals, arsenic and antimony behave like semimetals, and bismuth behaves like a metal. Nitrogen forms compounds in nine different oxidation states. The stability of the +5 oxidation state decreases from phosphorus to bismuth because of the inert-pair effect. Due to their higher electronegativity, the lighter pnictogens form compounds in the -3 oxidation state. Because of the presence of a lone pair of electrons on the pnictogen, neutral covalent compounds of the trivalent pnictogens are Lewis bases. Nitrogen does not form stable catenated compounds because of repulsions between lone pairs of electrons on adjacent atoms, but it does form multiple bonds with other second-period atoms. Nitrogen reacts with electropositive elements to produce solids that range from covalent to ionic in character. Reaction with electropositive metals produces ionic nitrides, reaction with less electropositive metals produces interstitial nitrides, and reaction with semimetals produces covalent nitrides. The reactivity of the pnictogens decreases with increasing atomic number. Compounds of the heavier pnictogens often have coordination numbers of 5 or higher and use dsp^3 or d^2sp^3 hybrid orbitals for bonding. Because phosphorus and arsenic have energetically accessible d orbitals, these elements form π bonds with second-period atoms such as O and N. Phosphorus reacts with metals to produce phosphides. Metal-rich phosphides are hard, high-melting, electrically conductive solids with metallic luster, whereas phosphorus-rich phosphides, which contain catenated phosphorus units, are lower melting and less thermally stable.

Key Takeaway

- The reactivity of the heavier group 15 elements decreases down the group, as does the stability of their catenated compounds.

Conceptual Problems

- Nitrogen is the first diatomic molecule in the second period of elements. Why is N_2 the most stable form of nitrogen? Draw its Lewis electron structure. What hybrid orbitals are used to describe the bonding in this molecule? Is the molecule polar?
- The polymer $(SN)_n$ has metallic luster and conductivity. Are the constituent elements in this polymer metals or nonmetals? Why does the polymer have metallic properties?
- Except for NF_3 , all the halides of nitrogen are unstable. Explain why NF_3 is stable.
- Which of the group 15 elements forms the most stable compounds in the +3 oxidation state? Explain why.
- Phosphorus and arsenic react with the alkali metals to produce salts with the composition M_3Z_{11} . Compare these products with those produced by reaction of P and As with the alkaline earth metals. What conclusions can you draw about the types of structures favored by the heavier elements in this part of the periodic table?

Structure and Reactivity

- PF_3 reacts with F_2 to produce PF_5 , which in turn reacts with F^- to give salts that contain the PF_6^- ion. In contrast, NF_3 does not react with F_2 , even under extreme conditions; NF_5 and the NF_6^- ion do not exist. Why?
- Red phosphorus is safer to handle than white phosphorus, reflecting their dissimilar properties. Given their structures, how do you expect them to compare with regard to reactivity, solubility, density, and melting point?
- Bismuth oxalate $[Bi_2(C_2O_4)_3]$ is a poison. Draw its structure and then predict its solubility in H_2O , dilute HCl, and dilute HNO_3 . Predict its combustion products. Suggest a method to prepare bismuth oxalate from bismuth.
- Small quantities of NO can be obtained in the laboratory by reaction of the iodide ion with acidic solutions of nitrite. Write a balanced chemical equation that represents this reaction.
- Although pure nitrous acid is unstable, dilute solutions in water are prepared by adding nitrite salts to aqueous acid. Write a balanced chemical equation that represents this type of reaction.
- Metallic versus nonmetallic behavior becomes apparent in reactions of the elements with an oxidizing acid, such as HNO_3 . Write balanced chemical equations for the reaction of each element of group 15 with nitric acid. Based on the products, predict which of these elements, if any, are metals and which, if any, are nonmetals.
- Predict the product(s) of each reaction and then balance each chemical equation.
 - $P_4O_{10}(s) + H_2O(l) \rightarrow$

- b. $\text{AsCl}_3(\text{l}) + \text{H}_2\text{O}(\text{l}) \rightarrow$
 c. $\text{Bi}_2\text{O}_3(\text{s}) + \text{H}_2\text{O}(\text{l}) \rightarrow$
 d. $\text{Sb}_4\text{O}_6(\text{s}) + \text{OH}^- (\text{aq}) \rightarrow$
 e. $(\text{C}_2\text{H}_5)_3\text{Sb}(\text{l}) + \text{O}_2(\text{g}) + \Delta \rightarrow$
 f. $\text{SbCl}_3(\text{s}) + \text{LiAlH}_4(\text{soln}) \rightarrow$
 g. $\text{Ca}(\text{s}) + \text{N}_2\text{O}(\text{g}) \xrightarrow{\Delta} \text{CaO}(\text{s}) + \text{N}_2(\text{g})$

8. Write a balanced chemical equation to show how you would prepare each compound.

- a. H_3PO_4 from P
 b. Sb_2O_5 from Sb
 c. SbH_3 from Sb

Chapter 22.4: The Elements of Group 16 (The Chalcogens)

Howard University General Chemistry: An Atoms First Approach

Unit 1: Atomic Theory
Unit 5: States of Matter

Unit 2: Molecular Structure
Unit 6: Kinetics & Equilibria

Unit 3: Stoichiometry
Unit 7: Electro & Thermo Chemistry

Unit 4: Thermochem & Gases
Unit 8: Materials

Learning Objective

- To understand the trends in properties and reactivity of the group 16 elements: the chalcogens.

The chalcogens are the first group in the p block to have no stable metallic elements. All isotopes of polonium (Po), the only metal in group 16, are radioactive, and only one element in the group, tellurium (Te), can even be described as a semimetal. As in groups 14 and 15, the lightest element of group 16, oxygen, is found in nature as the free element.

Of the group 16 elements, only sulfur was known in ancient times; the others were not discovered until the late 18th and 19th centuries. Sulfur is frequently found as yellow crystalline deposits of essentially pure S_8 in areas of intense volcanic activity or around hot springs. As early as the 15th century BC, sulfur was used as a fumigant in Homeric Greece because, when burned, it produces SO_2 fumes that are toxic to most organisms, including vermin hiding in the walls and under the floors of houses. Hence references to sulfur are common in ancient literature, frequently in the context of religious purification. In fact, the association of sulfur with the divine was so pervasive that the prefixes *thio-* (meaning “sulfur”) and *theo-* (meaning “god”) have the same root in ancient Greek. Though used primarily in the production of sulfuric acid, sulfur is also used to manufacture gunpowder and as a cross-linking agent for rubber, which enables rubber to hold its shape but retain its flexibility.

Note the Pattern

Group 16 is the first group in the p block with no stable metallic elements.

Oxygen was not discovered until 1771, when the Swedish pharmacist Carl Wilhelm Scheele found that heating compounds such as KNO_3 , Ag_2CO_3 , and HgO produced a colorless, odorless gas that supported combustion better than air. The results were not published immediately, however, so Scheele’s work remained unknown until 1777. Unfortunately, this was nearly two years *after* a paper by the English chemist Joseph Priestley had been published, describing the isolation of the same gas by using a magnifying glass to focus the sun’s rays on a sample of HgO . Oxygen is used primarily in the steel industry during the conversion of crude iron to steel using the Bessemer process. Another important industrial use of oxygen is in the production of TiO_2 , which is commonly used as a white pigment in paints, paper, and plastics.

Tellurium was discovered accidentally in 1782 by the Austrian chemist Franz Joseph Müller von Reichenstein, the chief surveyor of mines in Transylvania who was also responsible for the analysis of ore samples. The silvery-white metal had the same density as antimony but very different properties. Because it was difficult to analyze, Müller called it *metallum problematicum* (meaning “difficult metal”). The name *tellurium* (from the Latin *tellus*, meaning “earth”) was coined by another Austrian chemist, Martin Klaproth, who demonstrated in 1798 that Müller’s “difficult metal” was actually a new element. Tellurium is used to color glass and ceramics, in the manufacture of blasting caps, and in thermoelectric devices.

Selenium (Se) was first isolated in 1817 by the Swedish chemist Jöns Jakob Berzelius, who also discovered silicon. He had invested money in a sulfuric acid plant and decided to investigate a foul-smelling contaminant that formed a red precipitate. Although he initially thought the

A crystalline sulfur deposit.
This sulfur deposit is located around a volcanic vent in Kilauea Crater, Hawaii.

contaminant was tellurium, further study showed that it was actually a new element similar to tellurium. To emphasize the similarities, Berzelius named the new element selenium (after the Greek *selene*, meaning “moon”). Selenium is used primarily as a minor ingredient to decolorize glass. Because it is photosensitive, selenium is also used to capture images in the photocopying process (Figure 22.4.1).

Jöns Jakob Berzelius (1779–1848)

Berzelius was born into a well-educated Swedish family, but both parents died when he was young. He studied medicine at the University of Uppsala, where his experiments with electroshock therapy caused his interests to turn to electrochemistry. Berzelius devised the system of chemical notation that we use today. In addition, he discovered six elements (cerium, thorium, selenium, silicon, titanium, and zirconium).

Figure 22.4.1 The Chemistry of Photocopying Because amorphous selenium is a photosensitive semiconductor, exposing an electrostatically charged Se film to light causes the positive charge on the film to be discharged in all areas that are white in the original. Dark areas in the original block the light and generate an invisible, positively charged image. To produce an image on paper, negatively charged toner particles are attracted to the positive image, transferred to a negatively charged sheet of blank paper, and fused with the paper at high temperature to give a permanent image.

The heaviest chalcogen, polonium, was isolated after an extraordinary effort by Marie Curie. (For more information on radioactivity and polonium, see Section 1.5.) Although she was never able to obtain macroscopic quantities of the element, which she named for her native country of Poland, she demonstrated that its chemistry required it to be assigned to group 16. Marie Curie was awarded a second Nobel Prize in Chemistry in 1911 for the discovery of radium and polonium.

Preparation and General Properties of the Group 16 Elements

Oxygen is by far the most abundant element in Earth’s crust and in the hydrosphere (about 44% and 86% by mass, respectively). The same process that is used to obtain nitrogen from the atmosphere produces pure oxygen. Oxygen can also be obtained by the electrolysis of water, the decomposition of alkali metal or alkaline earth peroxides or superoxides, or the thermal decomposition of simple inorganic salts, such as potassium chlorate in the presence of a catalytic amount of MnO_2 :

(For more information on electrolysis, see Chapter 19. For more information on the alkali metals and the alkaline earth metals, see Chapter 20.)

Unlike oxygen, sulfur is not very abundant, but it is found as elemental sulfur in rock formations overlying salt domes, which often accompany petroleum deposits. Sulfur is also recovered from H_2S and organosulfur compounds in crude oil and coal and from metal sulfide ores such as *pyrite* (FeS_2).

Because selenium and tellurium are chemically similar to sulfur, they are usually found as minor contaminants in metal sulfide ores and are typically recovered as by-products. Even so, they are as abundant in Earth’s crust as silver, palladium, and gold. One of the best sources of selenium and tellurium is the “slime” deposited during the electrolytic purification of copper. Both of these elements are notorious for the vile odors of many of their compounds. For example, when the body absorbs even trace amounts of

tellurium, dimethyltellurium $[(\text{CH}_3)_2\text{Te}]$ is produced and slowly released in the breath and perspiration, resulting in an intense garlic-like smell that is commonly called “tellurium breath.”

With their $ns^2 np^4$ electron configurations, the chalcogens are two electrons short of a filled valence shell. Thus in reactions with metals, they tend to acquire two additional electrons to form compounds in the -2 oxidation state. This tendency is greatest for oxygen, the chalcogen with the highest electronegativity. The heavier, less electronegative chalcogens can lose either four np electrons or four np and two ns electrons to form compounds in the $+4$ and $+6$ oxidation state, respectively, as shown in Table 22.4.1 As with the other groups, the lightest member in the group, in this case oxygen, differs greatly from the others in size, ionization energy, electronegativity, and electron affinity, so its chemistry is unique. Also as in the other groups, the second and third members (sulfur and selenium) have similar properties because of shielding effects. Only polonium is metallic, forming either the hydrated Po^{2+} or Po^{4+} ion in aqueous solution, depending on conditions.

Pyrite (FeS_2). Because of its lustrous golden yellow cubic crystals, FeS_2 is sometimes mistaken for gold, giving rise to its common name “fool’s gold.” Real gold, however, is much denser than FeS_2 , and gold is soft and malleable rather than hard and brittle.

Table 22.4.1 Selected Properties of the Group 16 Elements

Property	Oxygen	Sulfur	Selenium	Tellurium	Polonium
atomic symbol	O	S	Se	Te	Po
atomic number	8	16	34	52	84
atomic mass (amu)	16.00	32.07	78.96	127.60	209

Reactions and Compounds of Oxygen

As in groups 14 and 15, the lightest group 16 member has the greatest tendency to form multiple bonds. Thus elemental oxygen is found in nature as a diatomic gas that contains a net double bond: O=O. As with nitrogen, electrostatic repulsion between lone pairs of electrons on adjacent atoms prevents oxygen from forming stable catenated compounds. In fact, except for O₂, all compounds that contain O–O bonds are potentially explosive. Ozone, peroxides, and superoxides are all potentially dangerous in pure form. Ozone (O₃), one of the most powerful oxidants known, is used to purify drinking water because it does not produce the characteristic taste associated with chlorinated water. Hydrogen peroxide (H₂O₂) is so thermodynamically unstable that it has a tendency to undergo explosive decomposition when impure:

Note the Pattern

As in groups 14 and 15, the lightest element in group 16 has the greatest tendency to form multiple bonds.

Despite the strength of the O=O bond ($D(\text{O}_2) = 494 \text{ kJ/mol}$), O₂ is extremely reactive, reacting directly with nearly all other elements except the noble gases. Some properties of O₂ and related species, such as the peroxide and superoxide ions, are in [Table 22.4.2](#)[†]. With few exceptions, the chemistry of oxygen is restricted to negative oxidation states because of its high electronegativity ($\chi = 3.4$). Unlike the other chalcogens, oxygen does not form compounds in the +4 or +6 oxidation state. Oxygen is second only to fluorine in its ability to stabilize high oxidation states of metals in both ionic and covalent compounds. For example, AgO is a stable solid that contains silver in the unusual Ag(II) state, whereas OsO₄ is a volatile solid that contains Os(VIII). Because oxygen is so electronegative, the O–H bond is highly polar, creating a large bond dipole moment that makes hydrogen bonding much more important for compounds of oxygen than for similar compounds of the other chalcogens.

Table 22.4.2 Some Properties of O₂ and Related Diatomic Species

Species	Bond Order	Number of Unpaired e ⁻	O–O Distance (pm)*
O ₂ ⁺	2.5	1	112
O ₂	2	2	121
O ₂ ⁻	1.5	1	133
O ₂ ²⁻	1	0	149

***Source of data: Lauri Vaska, "Dioxygen-Metal Complexes: Toward a Unified View," *Accounts of Chemical Research* 9 (1976): 175.**

Metal oxides are usually basic, and nonmetal oxides are acidic, whereas oxides of elements that lie on or near the diagonal band of semimetals are generally amphoteric. A few oxides, such as CO and PbO₂, are neutral and do not react with water, aqueous acid, or aqueous base. Nonmetal oxides are typically covalent compounds in which the bonds between oxygen and the nonmetal are polarized (E^{δ+}-O^{δ-}). Consequently, a lone pair of electrons on a water molecule can attack the partially positively charged E atom to eventually form an oxoacid. An example is reacting sulfur trioxide with water to form sulfuric acid:

The oxides of the semimetals and of elements such as Al that lie near the metal/nonmetal dividing line are amphoteric, as we expect:

Note the Pattern

Oxides of metals tend to be basic, oxides of nonmetals tend to be acidic, and oxides of elements in or near the diagonal band of semimetals are generally amphoteric.

Example 22.4.1

For each reaction, explain why the given products form.

1. $Ga_2O_3(s) + 2OH^-(aq) + 3H_2O(l) \rightarrow 2Ga(OH)_4^-(aq)$
2. $3H_2O_2(aq) + 2MnO_4^-(aq) + 2H^+(aq) \rightarrow 3O_2(g) + 2MnO_2(s) + 4H_2O(l)$
3. $KNO_3(s) + \Delta \rightarrow KNO(s) + O_2(g)$

Given: balanced chemical equations

Asked for: why the given products form

Strategy:

Classify the type of reaction. Using periodic trends in atomic properties, thermodynamics, and kinetics, explain why the observed reaction products form.

Solution:

1. Gallium is a metal. We expect the oxides of metallic elements to be basic and therefore not to react with aqueous base. A close look at the periodic table, however, shows that gallium is close to the diagonal line of semimetals. Moreover, aluminum, the element immediately above gallium in group 13, is amphoteric. Consequently, we predict that gallium will behave like aluminum ([Equation 22.37](#)).
2. Hydrogen peroxide is an oxidant that can accept two electrons per molecule to give two molecules of water. With a strong oxidant, however, H₂O₂ can also act as a reductant, losing two electrons (and two protons) to produce O₂. Because the other reactant is permanganate, which is a potent oxidant, the only possible reaction is a redox reaction in which permanganate is the oxidant and hydrogen peroxide is the reductant. Recall that reducing permanganate often gives MnO₂, an insoluble brown solid. Reducing MnO₄⁻ to MnO₂ is a three-electron reduction, whereas the oxidation of H₂O₂ to O₂ is a two-electron oxidation.
3. This is a thermal decomposition reaction. Because KNO₃ contains nitrogen in its highest oxidation state (+5) and oxygen in its lowest oxidation state (-2), a redox reaction is likely. Oxidation of the oxygen in nitrate to atomic oxygen is a two-electron process per oxygen atom. Nitrogen is likely to accept two electrons because oxoanions of nitrogen are known only in the +5 (NO₃⁻) and +3 (NO₂⁻) oxidation states.

Exercise

Predict the product(s) of each reaction and write a balanced chemical equation for each reaction.

1. $\text{SiO}_2(\text{s}) + \text{H}^+(\text{aq}) \rightarrow$
2. $\text{NO}(\text{g}) + \text{O}_2(\text{g}) \rightarrow$
3. $\text{SO}_3(\text{g}) + \text{H}_2\text{O}(\text{l}) \rightarrow$
4. $\text{H}_2\text{O}_2(\text{aq}) + \text{I}^-(\text{aq}) \rightarrow$

Answer:

1. $\text{SiO}_2(\text{s}) + \text{H}^+(\text{aq}) \rightarrow$ no reaction
2. $2\text{NO}(\text{g}) + \text{O}_2(\text{g}) \rightarrow 2\text{NO}_2(\text{g})$
3. $\text{SO}_3(\text{g}) + \text{H}_2\text{O}(\text{l}) \rightarrow \text{H}_2\text{SO}_4(\text{aq})$
4. $\text{H}_2\text{O}_2(\text{aq}) + 2\text{I}^-(\text{aq}) \rightarrow \text{I}_2(\text{aq}) + 2\text{OH}^-(\text{aq})$

Reactions and Compounds of the Heavier Chalcogens

Because most of the heavier chalcogens (group 16) and pnictogens (group 15) are nonmetals, they often form similar compounds. For example, both third-period elements of these groups (phosphorus and sulfur) form catenated compounds and form multiple allotropes. Consistent with periodic trends, the tendency to catenate decreases as we go down the column.

Sulfur and selenium both form a fairly extensive series of catenated species. For example, elemental sulfur forms S_8 rings packed together in a complex “crankshaft” arrangement (Figure 18.4.3), and molten sulfur contains long chains of sulfur atoms connected by S–S bonds. Moreover, both sulfur and selenium form polysulfides (S_n^{2-}) and polyselenides (Se_n^{2-}), with $n \leq 6$. The only stable allotrope of tellurium is a silvery white substance whose properties and structure are similar to those of one of the selenium allotropes. Polonium, in contrast, shows no tendency to form catenated compounds. The striking decrease in structural complexity from sulfur to polonium is consistent with the decrease in the strength of single bonds and the increase in metallic character as we go down the group.

As in group 15, the reactivity of elements in group 16 decreases from lightest to heaviest. For example, selenium and tellurium react with most elements but not as readily as sulfur does. As expected for nonmetals, sulfur, selenium, and tellurium do not react with water, aqueous acid, or aqueous base, but all dissolve in strongly oxidizing acids such as HNO_3 to form oxoacids such as H_2SO_4 . In contrast to the other chalcogens, polonium behaves like a metal, dissolving in dilute HCl to form solutions that contain the Po^{2+} ion.

Note the Pattern

Just as with the other groups, the tendency to catenate, the strength of single bonds, and reactivity decrease down the group.

Fluorine reacts directly with all chalcogens except oxygen to produce the hexafluorides (YF_6), which are extraordinarily stable and unreactive compounds. Four additional stable fluorides of sulfur are known; thus sulfur oxidation states range from +1 to +6 (Figure 22.4.2). In contrast, only four fluorides of selenium (SeF_6 , SeF_4 , FSeSeF , and SeSeF_2) and only three of tellurium (TeF_4 , TeF_6 , and Te_2F_{10}) are known.

Figure 22.4.2 The Structures of the Known Fluorides of Sulfur Five stable sulfur fluorides are known, containing sulfur in oxidation states ranging from +1 to +6. All are volatile molecular compounds that vary tremendously in stability and toxicity. Although both SF_6 and S_2F_{10} are very stable, S_2F_{10} is toxic and SF_6 is not. The other three are highly reactive substances.

Direct reaction of the heavier chalcogens with oxygen at elevated temperatures gives the dioxides (YO_2), which exhibit a dramatic range of structures and properties. The dioxides become increasingly metallic in character down the group, as expected, and the coordination number of the chalcogen steadily increases. Thus SO_2 is a gas that contains V-shaped molecules (as predicted by the valence-shell electron-pair repulsion model), SeO_2 is a white solid with an infinite chain structure (each Se is three coordinate), TeO_2 is a light yellow solid with a network structure in which each Te atom is four coordinate, and PoO_2 is a yellow ionic solid in which each Po^{4+} ion is eight coordinate.

The dioxides of sulfur, selenium, and tellurium react with water to produce the weak, diprotic oxoacids (H_2YO_3 —sulfurous, selenous, and tellurous acid, respectively). Both sulfuric acid and selenic acid (H_2SeO_4) are strong acids, but telluric acid [$\text{Te}(\text{OH})_6$] is quite different. Because tellurium is larger than either sulfur or selenium, it forms weaker π bonds to oxygen. As a result, the most stable structure for telluric acid is $\text{Te}(\text{OH})_6$, with six Te–OH bonds rather than Te=O bonds. Telluric acid therefore behaves like a weak *triprotic* acid in aqueous solution, successively losing the hydrogen atoms bound to three of the oxygen atoms. As expected for compounds that contain elements in their highest accessible oxidation state (+6 in this case), sulfuric, selenic, and telluric acids are oxidants. Because the stability of the highest oxidation state decreases with increasing atomic number, telluric acid is a stronger oxidant than sulfuric acid.

Note the Pattern

The stability of the highest oxidation state of the chalcogens decreases down the column.

Sulfur and, to a lesser extent, selenium react with carbon to form an extensive series of compounds that are structurally similar to their oxygen analogues. For example, CS_2 and CSe_2 are both volatile liquids that contain C=S or C=Se bonds and have the same linear structure as CO_2 . Because these double bonds are significantly weaker than the C=O bond, however, CS_2 , CSe_2 , and related compounds are less stable and more reactive than their oxygen analogues. The chalcogens also react directly with nearly all metals to form compounds with a wide range of stoichiometries and a variety of structures. Metal chalcogenides can contain either the simple chalcogenide ion (Y^{2-}), as in Na_2S and FeS , or polychalcogenide ions (Y_n^{2-}), as in FeS_2 and Na_2S_5 .

Note the Pattern

The dioxides of the group 16 elements become increasingly basic, and the coordination number of the chalcogen steadily increases down the group.

Ionic chalcogenides like Na_2S react with aqueous acid to produce *binary hydrides* such as hydrogen sulfide (H_2S). Because the strength of the Y–H bond decreases with increasing atomic radius, the stability of the binary hydrides decreases rapidly down the group. It is perhaps surprising that hydrogen sulfide, with its familiar rotten-egg smell, is much more toxic than hydrogen cyanide (HCN), the gas used to execute prisoners in the “gas chamber.” Hydrogen sulfide at relatively low concentrations deadens the olfactory receptors in the nose, which allows it to reach toxic levels without detection and makes it especially dangerous.

Example 22.4.2

For each reaction, explain why the given product forms or no reaction occurs.

- $\text{SO}_2(\text{g}) + \text{Cl}_2(\text{g}) \rightarrow \text{SO}_2\text{Cl}_2(\text{l})$
- $\text{SF}_6(\text{g}) + \text{H}_2\text{O}(\text{l}) \rightarrow$ no reaction
- $2\text{Se}(\text{s}) + \text{Cl}_2(\text{g}) \rightarrow \text{Se}_2\text{Cl}_2(\text{l})$

Given: balanced chemical equations

Asked for: why the given products (or no products) form

Strategy:

Classify the type of reaction. Using periodic trends in atomic properties, thermodynamics, and kinetics, explain why the reaction products form or why no reaction occurs.

Solution:

- One of the reactants (Cl_2) is an oxidant. If the other reactant can be oxidized, then a redox reaction is likely. Sulfur dioxide contains sulfur in the +4 oxidation state, which is 2 less than its maximum oxidation state. Sulfur dioxide is also known to be a mild reducing agent in aqueous solution, producing sulfuric acid as the oxidation product. Hence a redox reaction is probable. The simplest reaction is the formation of SO_2Cl_2 (sulfuryl chloride), which is a tetrahedral species with two S–Cl and two S=O bonds.

- Sulfur hexafluoride is a nonmetallic halide. Such compounds normally react vigorously with water to produce an oxoacid of the nonmetal and the corresponding hydrohalic acid. In this case, however, we have a highly stable species, presumably because all of sulfur's available orbitals are bonding orbitals. Thus SF_6 is not likely to react with water.
- Here we have the reaction of a chalcogen with a halogen. The halogen is a good oxidant, so we can anticipate that a redox reaction will occur. Only fluorine is capable of oxidizing the chalcogens to a +6 oxidation state, so we must decide between SeCl_4 and Se_2Cl_2 as the product. The stoichiometry of the reaction determines which of the two is obtained: SeCl_4 or Se_2Cl_2 .

Exercise

Predict the products of each reaction and write a balanced chemical equation for each reaction.

- $\text{Te(s)} + \text{Na(s)} \rightarrow$
- $\text{SF}_4(\text{g}) + \text{H}_2\text{O(l)} \rightarrow$
- $\text{CH}_3\text{SeSeCH}_3(\text{soln}) + \text{K(s)} \rightarrow$
- $\text{Li}_2\text{Se(s)} + \text{H}^+(\text{aq}) \rightarrow$

Answer:

- $\text{Te(s)} + 2\text{Na(s)} \rightarrow \text{Na}_2\text{Te(s)}$
- $\text{SF}_4(\text{g}) + 3\text{H}_2\text{O(l)} \rightarrow \text{H}_2\text{SO}_3(\text{aq}) + 4\text{HF(aq)}$
- $\text{CH}_3\text{SeSeCH}_3(\text{soln}) + 2\text{K(s)} \rightarrow 2\text{KCH}_3\text{Se(soln)}$
- $\text{Li}_2\text{Se(s)} + 2\text{H}^+(\text{aq}) \rightarrow \text{H}_2\text{Se(g)} + 2\text{Li}^+(\text{aq})$

Summary

Because the electronegativity of the chalcogens decreases down the group, so does their tendency to acquire two electrons to form compounds in the -2 oxidation state. The lightest member, oxygen, has the greatest tendency to form multiple bonds with other elements. It does not form stable catenated compounds, however, due to repulsions between lone pairs of electrons on adjacent atoms. Because of its high electronegativity, the chemistry of oxygen is generally restricted to compounds in which it has a negative oxidation state, and its bonds to other elements tend to be highly polar. Metal oxides are usually basic, and nonmetal oxides are acidic, whereas oxides of elements along the dividing line between metals and nonmetals are amphoteric. The reactivity, the strength of multiple bonds to oxygen, and the tendency to form catenated compounds all

decrease down the group, whereas the maximum coordination numbers increase. Because Te=O bonds are comparatively weak, the most stable oxoacid of tellurium contains six Te–OH bonds. The stability of the highest oxidation state (+6) decreases down the group. Double bonds between S or Se and second-row atoms are weaker than the analogous C=O bonds because of reduced orbital overlap. The stability of the binary hydrides decreases down the group.

Key Takeaways

- The chalcogens have no stable metallic elements.
- The tendency to catenate, the strength of single bonds, and the reactivity all decrease moving down the group.

Conceptual Problems

1. Unlike the other chalcogens, oxygen does not form compounds in the +4 or +6 oxidation state. Why?
2. Classify each oxide as basic, acidic, amphoteric, or neutral.
 - a. CaO
 - b. SO₂
 - c. NO
 - d. Rb₂O
 - e. PbO₂
3. Classify each oxide as basic, acidic, amphoteric, or neutral.
 - a. BaO
 - b. Br₂O
 - c. SnO
 - d. B₂O₃
 - e. Sb₂O₃
4. Polarization of an oxide affects its solubility in acids or bases. Based on this, do you expect RuO₂ to be an acidic, a basic, or a neutral oxide? Is the compound covalent? Justify your answers.
5. Arrange CrO₃, Al₂O₃, Sc₂O₃, and BaO in order of increasing basicity.
6. As the atomic number of the group 16 elements increases, the complexity of their allotropes decreases. What factors account for this trend? Which chalcogen do you expect to polymerize the most readily? Why?
7. Arrange H₃BO₃, HIO₄, and HNO₂ in order of increasing acid strength.
8. Of OF₂, SO₂, P₄O₆, SiO₂, and Al₂O₃, which is most ionic?
9. Of CO₂, NO₂, O₂, SO₂, Cl₂O, H₂O, NH₃, and CH₄, which do you expect to have the
 - a. most polar covalent bond(s)?
 - b. least polar covalent bond(s)?
10. Of Na₂O₂, MgO, Al₂O₃, and SiO₂, which is most acidic?
11. Give an example of
 - a. a covalent hydride that engages in strong hydrogen bonding.
 - b. an amphoteric oxide.
12. The Si–O bond is shorter and stronger than expected. What orbitals are used in this bond? Do you expect Si to interact with Br in the same way? Why or why not?

Answers

1. Oxygen has the second highest electronegativity of any element; consequently, it prefers to share or accept electrons from other elements. Only with fluorine does oxygen form compounds in positive oxidation states.
- 2.
3.
 - a. basic
 - b. acidic
 - c. amphoteric
 - d. acidic
 - e. amphoteric

- 4.
5. $\text{CrO}_3 < \text{Al}_2\text{O}_3 < \text{Sc}_2\text{O}_3 < \text{BaO}$
- 6.
7. $\text{H}_3\text{BO}_3 < \text{HNO}_2 < \text{HIO}_4$
- 8.
9. Most polar: H_2O ; least polar: O_2
- 10.
11.
 - a. H_2O , HF , or NH_3
 - b. SnO or Al_2O_3
- 12.

Structure and Reactivity

1. Considering its position in the periodic table, predict the following properties of selenium:
 - a. chemical formulas of its most common oxide, most common chloride, and most common hydride
 - b. solubility of its hydride in water, and the acidity or basicity of the resulting solution
 - c. the principal ion formed in aqueous solution
2. Using arguments based on electronegativity, explain why ZnO is amphoteric. What product would you expect when ZnO reacts with an aqueous
 - a. acid?
 - b. base?
3. Write a balanced chemical equation for the reaction of sulfur with
 - a. $\text{O}_2(\text{g})$.
 - b. $\text{S}^{2-}(\text{aq})$.
 - c. $\text{F}_2(\text{g})$.
 - d. $\text{HNO}_3(\text{aq})$.

Answer

- 1.
- 2.
3.
 - a. $\text{S}_8 + 8\text{O}_2 \rightarrow 8\text{SO}_2(\text{g})$
 - b. $\text{S}_8(\text{s}) + 8\text{S}^{2-}(\text{aq}) \rightarrow 8\text{S}_2^{2-}(\text{aq})$
 - c. $\text{S}_8(\text{s}) + 24\text{F}_2(\text{g}) \rightarrow 8\text{SF}_6(\text{g})$
 - d. $\text{S}_8(\text{s}) + 48\text{HNO}_3(\text{aq}) \rightarrow 8\text{H}_2\text{SO}_4(\text{aq}) + 48\text{NO}_2(\text{g}) + 16\text{H}_2\text{O}(\text{l})$

Unit 7: Electro & Thermo Chemistry

Unit 4: Thermochem & Gases
Unit 8: Materials

Learning Objective

- To understand the periodic trends and reactivity of the group 17 elements: the halogens.

Because the halogens are highly reactive, none is found in nature as the free element. Hydrochloric acid, which is a component of *aqua regia* (a mixture of HCl and HNO₃ that dissolves gold), and the mineral fluorspar (CaF₂) were well known to alchemists, who used them in their quest for gold. Despite their presence in familiar substances, none of the halogens was even recognized as an element until the 19th century.

Note the Pattern

Because the halogens are highly reactive, none is found in nature as the free element.

Chlorine was the first halogen to be obtained in pure form. In 1774, Carl Wilhelm Scheele (the codiscoverer of oxygen) produced chlorine by reacting hydrochloric acid with manganese dioxide. Scheele was convinced, however, that the pale green gas he collected over water was a compound of oxygen and hydrochloric acid. In 1811, Scheele's "compound" was identified as a new element, named from the Greek *chloros*, meaning "yellowish green" (the same stem as in *chlorophyll*, the green pigment in plants). That same year, a French industrial chemist, Bernard Courtois, accidentally added too much sulfuric acid to the residue obtained from burned seaweed. A deep purple vapor was released, which had a biting aroma similar to that of Scheele's "compound." The purple substance was identified as a new element, named iodine from the Greek *iodes*, meaning "violet." Bromine was discovered soon after by a young French chemist, Antoine Jérôme Balard, who isolated a deep red liquid with a strong chlorine-like odor from brine from the salt marshes near Montpellier in southern France. Because many of its properties were intermediate between those of chlorine and iodine, Balard initially thought he had isolated a compound of the two (perhaps ICl). He soon realized, however, that he had discovered a new element, which he named bromine from the Greek *bromos*, meaning "stench." Currently, organic chlorine compounds, such as PVC (polyvinylchloride), consume about 70% of the Cl₂ produced annually; organobromine compounds are used in much smaller quantities, primarily as fire retardants.

Because of the unique properties of its compounds, fluorine was believed to exist long before it was actually isolated. The mineral fluorspar (now called *fluorite* [CaF₂]) had been used since the 16th century as a "flux," a low-melting-point substance that could dissolve other minerals and ores. In 1670, a German glass cutter discovered that heating fluorspar with strong acid produced a solution that could etch glass. The solution was later recognized to contain the acid of a new element, which was named fluorine in 1812. Elemental fluorine proved to be very difficult to isolate, however, because both HF and F₂ are extraordinarily reactive and toxic. After being poisoned three times while trying to isolate the element, the French chemist Henri Moissan succeeded in 1886 in electrolyzing a sample of KF in anhydrous HF to produce a pale green gas (Figure 22.5.1). For this achievement, among others, Moissan narrowly defeated Mendeleev for the Nobel Prize in Chemistry in 1906. Large amounts of fluorine are now consumed in the production of *cryolite* (Na₃AlF₆), a key intermediate in the production of aluminum metal. Fluorine is also found in teeth as *fluoroapatite* [Ca₅(PO₄)₃F], which is formed by reacting hydroxyapatite [Ca₅(PO₄)₃OH] in tooth enamel with fluoride ions in toothpastes, rinses, and drinking water.

A crystal of the mineral fluorite (CaF_2). The purple color of some fluorite crystals is due to small inclusions of highly oxidizing impurities, which generate detectable amounts of ozone when the crystals are crushed.

Figure 22.5.1 Isolation of Elemental Fluorine The French chemist Henri Moissan was the first person to isolate elemental fluorine. A reproduction of the U-shaped electrolysis cell with which Moissan first isolated elemental fluorine in 1866 is shown with samples of cryolite (left) and fluorspar (right). Fluorspar is the raw material from which anhydrous hydrofluoric acid (HF) is prepared. Cryolite is a rare mineral that contains the fluoride ion.

The heaviest halogen is astatine (At), which is continuously produced by natural radioactive decay. All its isotopes are highly radioactive, and the most stable has a half-life of only about 8 h. Consequently, astatine is the least abundant naturally occurring element on Earth, with less than 30 g estimated to be present in Earth's crust at any one time.

Preparation and General Properties of the Group 17 Elements

All the halogens except iodine are found in nature as salts of the halide ions (X^-), so the methods used for preparing F_2 , Cl_2 , and Br_2 all involve oxidizing the halide. Reacting CaF_2 with concentrated sulfuric acid produces gaseous hydrogen fluoride:

Fluorine is produced by the electrolysis of a 1:1 mixture of HF and K^+HF_2^- at 60–300°C in an apparatus made of Monel, a highly corrosion-resistant nickel–copper alloy:

Fluorine is one of the most powerful oxidants known, and both F_2 and HF are highly corrosive. Consequently, the production, storage, shipping, and handling of these gases pose major technical challenges.

Although chlorine is significantly less abundant than fluorine, elemental chlorine is produced on an enormous scale. Fortunately, large subterranean deposits of rock salt (NaCl) are found around the world (Figure 22.15 "A Subterranean Salt Mine"), and seawater consists of about 2% NaCl by mass, providing an almost inexhaustible reserve. Inland salt lakes such as the Dead Sea and the Great Salt Lake are even richer sources, containing about 23% and 8% NaCl by mass, respectively. Chlorine is prepared industrially by the chloralkali process, which uses the following reaction:

Figure 22.5.2 A Subterranean Salt Mine Subterranean deposits of rock salt are located worldwide, such as this one at Petralia in Sicily.

Bromine is much less abundant than fluorine or chlorine, but it is easily recovered from seawater, which contains about 65 mg of Br per liter. Salt lakes and underground brines are even richer sources; for example, the Dead Sea contains 4 g of Br per liter. Iodine is the least abundant of the nonradioactive halogens, and it is a relatively rare element. Because of its low electronegativity, iodine tends to occur in nature in an oxidized form. Hence most commercially important deposits of iodine, such as those in the Chilean desert, are iodate salts such as $\text{Ca}(\text{IO}_3)_2$. The production of iodine from such deposits therefore requires *reduction* rather than oxidation. The process is typically carried out in two steps: reduction of iodate to iodide with sodium hydrogen sulfite, followed by reaction of iodide with additional iodate:

Because the halogens all have $ns^2 np^5$ electron configurations, their chemistry is dominated by a tendency to accept an additional electron to form the closed-shell ion (X^{-}). Only the electron affinity and the bond dissociation energy of fluorine differ significantly from the expected periodic trends shown in Table 22.5.1. Electron–electron repulsion is important in fluorine because of its small atomic volume, making the electron affinity of fluorine less than that of chlorine. Similarly, repulsions between electron pairs on adjacent atoms are responsible for the unexpectedly low F–F bond dissociation energy. (As discussed earlier, this effect is also responsible for the weakness of O–O, N–N, and N–O bonds.)

Note the Pattern

Oxidative strength decreases down group 17.

Note the Pattern

Electrostatic repulsions between lone pairs of electrons on *adjacent* atoms cause single bonds between N, O, and F to be weaker than expected.

Table 22.5.1 Selected Properties of the Group 17 Elements

Property	Fluorine	Chlorine	Bromine	Iodine	Astatine
atomic symbol	F	Cl	Br	I	At
atomic number	9	17	35	53	85
atomic mass (amu)	19.00	35.45	79.90	126.90	210
valence electron configuration*	$2s^2 2p^5$	$3s^2 3p^5$	$4s^2 4p^5$	$5s^2 5p^5$	$6s^2 6p^5$
melting point/boiling point (°C)	−220/−188	−102/−34.0	−7.2/58.8	114/184	302/—
density (g/cm ³) at 25°C	1.55 (g/L)	2.90 (g/L)	3.10	4.93	—
atomic radius (pm)	42	79	94	115	127
first ionization energy (kJ/mol)	1681	1251	1140	1008	926
normal oxidation state(s)	−1	−1 (+1, +3, +5, +7)	−1 (+1, +3, +5, +7)	−1 (+1, +3, +5, +7)	−1, +1
ionic radius (pm) [†]	133	181	196	220	—
electron affinity (kJ/mol)	−328	−349	−325	−295	−270
electronegativity	4.0	3.2	3.0	2.7	2.2

*The configuration shown does not include filled *d* and *f* subshells.

Property	Fluorine	Chlorine	Bromine	Iodine	Astatine
standard reduction potential (E° , V) ($X_2 \rightarrow X^-$ in basic solution)	+2.87	+1.36	+1.07	+0.54	+0.30
dissociation energy of $X_2(g)$ (kJ/mol)	158.8	243.6	192.8	151.1	~80
product of reaction with O_2	O_2F_2	none	none	none	none
type of oxide	acidic	acidic	acidic	acidic	acidic
product of reaction with N_2	none	none	none	none	none
product of reaction with H_2	HF	HCl	HBr	HI	HAt
*The configuration shown does not include filled <i>d</i> and <i>f</i> subshells.					
† The values cited are for the six-coordinate anion (X^-).					

Because it is the most electronegative element in the periodic table, fluorine forms compounds in only the -1 oxidation state. Notice, however, that all the halogens except astatine have electronegativities greater than 2.5, making their chemistry exclusively that of nonmetals. The halogens all have relatively high ionization energies, but the energy required to remove electrons decreases substantially as we go down the column. Hence the heavier halogens also form compounds in positive oxidation states ($+1$, $+3$, $+5$, and $+7$), derived by the formal loss of *ns* and *np* electrons.

Note the Pattern

Because ionization energies decrease down the group, the heavier halogens form compounds in positive oxidation states ($+1$, $+3$, $+5$, and $+7$).

Reactions and Compounds of the Halogens

Fluorine is the most reactive element in the periodic table, forming compounds with every other element except helium, neon, and argon. The reactions of fluorine with most other elements range from vigorous to explosive; only O_2 , N_2 , and Kr react slowly. There are three reasons for the high reactivity of fluorine:

1. Because fluorine is so electronegative, it is able to remove or at least share the valence electrons of virtually any other element.
2. Because of its small size, fluorine tends to form very strong bonds with other elements, making its compounds thermodynamically stable.
3. The F-F bond is weak due to repulsion between lone pairs of electrons on adjacent atoms, reducing both the thermodynamic and kinetic barriers to reaction.

With highly electropositive elements, fluorine forms ionic compounds that contain the closed-shell F^- ion. In contrast, with less electropositive elements (or with metals in very high oxidation states), fluorine forms covalent compounds that contain terminal F atoms, such as SF_6 . Because of its high electronegativity and $2s^2 2p^5$ valence electron configuration, fluorine normally participates in only one electron-pair bond. Only a very strong Lewis acid, such as AlF_3 , can share a lone pair of electrons with a fluoride ion, forming AlF_6^{3-} .

The halogens (X_2) react with metals (M) according to the general equation

For elements that exhibit multiple oxidation states fluorine tends to produce the highest possible oxidation state and iodine the lowest. For example, vanadium reacts with the halogens to give VF_5 , VCl_4 , VBr_4 , and VI_3 .

Metal halides in the +1 or +2 oxidation state, such as CaF_2 , are typically ionic halides, which have high melting points and are often soluble in water. As the oxidation state of the metal increases, so does the covalent character of the halide due to polarization of the M-X bond. With its high electronegativity, fluoride is the least polarizable, and iodide, with the lowest electronegativity, is the most polarizable of the halogens. Halides of small trivalent metal ions such as Al^{3+} tend to be relatively covalent. For example, AlBr_3 is a volatile solid that contains bromide-bridged Al_2Br_6 molecules. In contrast, the halides of larger trivalent metals, such as the lanthanides, are essentially ionic. For example, indium tribromide (InBr_3) and lanthanide tribromide (LnBr_3) are all high-melting-point solids that are quite soluble in water.

Note the Pattern

As the oxidation state of the metal increases, the covalent character of the corresponding metal halides also increases due to polarization of the M-X bond.

All halogens react vigorously with hydrogen to give the hydrogen halides (HX). Because the H-F bond in HF is highly polarized ($\text{H}^{\delta+}-\text{F}^{\delta-}$), liquid HF has extensive hydrogen bonds, giving it an unusually high boiling point and a high dielectric constant. As a result, liquid HF is a polar solvent that is similar in some ways to water and liquid ammonia; after a reaction, the products can be recovered simply by evaporating the HF solvent. (Hydrogen fluoride must be handled with extreme caution, however, because contact of HF with skin causes extraordinarily painful burns that are slow to heal.) Because fluoride has a high affinity for silicon, aqueous hydrofluoric acid is used to etch glass, dissolving SiO_2 to give solutions of the stable SiF_6^{2-} ion.

Except for fluorine, all the halogens react with water in a disproportionation reaction, where X is Cl, Br, or I:

The most stable oxoacids are the *perhalic acids*, which contain the halogens in their highest oxidation state (+7). The acid strengths of the oxoacids of the halogens increase with increasing oxidation state, whereas their stability and acid strength decrease down the group. Thus perchloric acid (HOClO_3 , usually written as HClO_4) is a more potent acid and stronger oxidant than perbromic acid. Although all the oxoacids are strong oxidants, some, such as HClO_4 , react rather slowly at low temperatures. Consequently, mixtures of the halogen oxoacids or oxoanions with organic compounds are potentially explosive if they are heated or even agitated mechanically to initiate the reaction. Because of the danger of explosions, *oxoacids and oxoanions of the halogens should never be allowed to come into contact with organic compounds.*

Glass etched with hydrogen fluoride.

© Thinkstock

Note the Pattern

Both the acid strength and the oxidizing power of the halogen oxoacids decrease down the group.

The halogens react with one another to produce *interhalogen compounds*, such as ICl_3 , BrF_5 , and IF_7 . In all cases, the heavier halogen, which has the lower electronegativity, is the central atom. The maximum oxidation state and the number of terminal halogens increase smoothly as the ionization energy of the central halogen decreases and the electronegativity of the terminal halogen increases. Thus depending on conditions, iodine reacts with the other halogens to form IF_n ($n = 1-7$), ICl or ICl_3 , or IBr , whereas bromine reacts with fluorine to form only BrF , BrF_3 , and BrF_5 but not BrF_7 . The interhalogen compounds are among the most powerful Lewis acids known, with a strong tendency to react with halide ions to give complexes with higher coordination numbers, such as the IF_8^- ion:

All group 17 elements form compounds in odd oxidation states (-1, +1, +3, +5, +7). The interhalogen compounds are also potent oxidants and strong fluorinating agents; contact with organic materials or water can result in an explosion.

Note the Pattern

All group 17 elements form compounds in odd oxidation states (-1, +1, +3, +5, +7), but the importance of the higher oxidation states generally decreases down the group.

Example 22.5.1

For each reaction, explain why the given products form.

- $\text{ClF}_3(\text{g}) + \text{Cl}_2(\text{g}) \rightarrow 3\text{ClF}(\text{g})$
- $2\text{KI}(\text{s}) + 3\text{H}_2\text{SO}_4(\text{aq}) \rightarrow \text{I}_2(\text{aq}) + \text{SO}_2(\text{g}) + 2\text{KHSO}_4(\text{aq}) + 2\text{H}_2\text{O}(\text{l})$
- $\text{Pb}(\text{s}) + 2\text{BrF}_3(\text{l}) \rightarrow \text{PbF}_4(\text{s}) + 2\text{BrF}(\text{g})$

Given: balanced chemical equations

Asked for: why the given products form

Strategy:

Classify the type of reaction. Using periodic trends in atomic properties, thermodynamics, and kinetics, explain why the observed reaction products form.

Solution:

- When the reactants have the same element in two different oxidation states, we expect the product to have that element in an intermediate oxidation state. We have Cl^{3+} and Cl^0 as reactants, so a possible product would have Cl in either the +1 or +2 oxidation state. From our discussion, we know that +1 is much more likely. In this case, Cl_2 is behaving like a reductant rather than an oxidant.
- At first glance, this appears to be a simple acid-base reaction, in which sulfuric acid transfers a proton to I^- to form HI. Recall, however, that I⁻ can be oxidized to I_2 . Sulfuric acid contains sulfur in its highest oxidation state (+6), so it is a good oxidant. In this case, the redox reaction predominates.
- This is the reaction of a metallic element with a very strong oxidant. Consequently, a redox reaction will occur. The only question is whether lead will be oxidized to Pb(II) or Pb(IV). Because BrF_3 is a powerful oxidant and fluorine is able to stabilize high oxidation states of other elements, it is likely that PbF_4 will be the product. The two possible reduction products for BrF_3 are BrF and Br_2 . The actual product will likely depend on the ratio of the reactants used. With excess BrF_3 , we expect the more oxidized product (BrF). With lower ratios of oxidant to lead, we would probably obtain Br_2 as the product.

Exercise

Predict the products of each reaction and write a balanced chemical equation for each reaction.

- $\text{CaCl}_2(\text{s}) + \text{H}_3\text{PO}_4(\text{l}) \rightarrow$
- $\text{GeO}_2(\text{s}) + \text{HF}(\text{aq}) \rightarrow$
- $\text{Fe}_2\text{O}_3(\text{s}) + \text{HCl}(\text{g}) \rightarrow$
- $\text{NaClO}_2(\text{aq}) + \text{Cl}_2(\text{g}) \rightarrow$

Answer:

- $\text{CaCl}_2(\text{s}) + \text{H}_3\text{PO}_4(\text{l}) \rightarrow 2\text{HCl}(\text{g}) + \text{Ca}(\text{HPO}_4)(\text{soln})$
- $\text{GeO}_2(\text{s}) + 6\text{HF}(\text{aq}) \rightarrow \text{GeF}_6(\text{aq}) + 2\text{H}_2\text{O}(\text{l}) + 2\text{H}(\text{aq})$
- $\text{Fe}_2\text{O}_3(\text{s}) + 6\text{HCl}(\text{g}) + \Delta \rightarrow 2\text{FeCl}_3(\text{s}) + 3\text{H}_2\text{O}(\text{g})$

Summary

The halogens are so reactive that none is found in nature as the free element; instead, all but iodine are found as halide salts with the X^- ion. Their chemistry is exclusively that of nonmetals. Consistent with periodic trends, ionization energies decrease down the group. Fluorine, the most reactive element in the periodic table, has a low F–F bond dissociation energy due to repulsions between lone pairs of electrons on adjacent atoms. Fluorine forms ionic compounds with electropositive elements and covalent compounds with less electropositive elements and metals in high oxidation states. All the halogens react with hydrogen to produce hydrogen halides. Except for F_2 , all react with water to form oxoacids, including the *perhalic acids*, which contain the halogens in their highest oxidation state. Halogens also form *interhalogen compounds*; the heavier halogen, with the lower electronegativity, is the central atom.

Key Takeaway

- The halogens are highly reactive.
- All halogens have relatively high ionization energies, and the acid strength and oxidizing power of their oxoacids decreases down the group.

Conceptual Problems

1. The lightest elements of groups 15, 16, and 17 form unusually weak single bonds. Why are their bonds so weak?
2. Fluorine has an anomalously low F–F bond energy. Why? Why does fluorine form compounds only in the -1 oxidation state, whereas the other halogens exist in multiple oxidation states?
3. Compare AlI_3 , InCl_3 , GaF_3 , and LaBr_3 with respect to the type of M–X bond formed, melting point, and solubility in nonpolar solvents.
4. What are the formulas of the interhalogen compounds that will most likely contain the following species in the indicated oxidation states: I (+3), Cl (+3), I (-1), Br (+5)?
5. Consider this series of bromides: AlBr_3 , SiBr_4 , and PBr_5 . Does the ionic character of the bond between the Br atoms and the central atom decrease or increase in this series?
6. Chromium forms compounds in the +6, +3, and +2 oxidation states. Which halogen would you use to produce each oxidation state? Justify your selections.
7. Of ClF_7 , BrF_5 , IF_7 , BrF_3 , ICl_3 , IF_3 , and IF_5 , which one is least likely to exist? Justify your selection.

Answers

1. Electrostatic repulsions between lone pairs on adjacent atoms decrease bond strength.
- 2.
- 3.
- 4.
5. Ionic character decreases as $\Delta\chi$ decreases from Al to P.
- 6.
7. ClF_7

Structure and Reactivity

1. SiF_4 reacts easily with NaF to form SiF_6^{2-} . In contrast, CF_4 is totally inert and shows no tendency to form CF_6^{2-} under even extreme conditions. Explain this difference.
2. Predict the products of each reaction and then balance each chemical equation.
 - a. $\text{Xe}(\text{g}) + \text{excess } \text{F}_2(\text{g}) \rightarrow$
 - b. $\text{Se}(\text{s}) + \text{Cl}_2(\text{g}) \rightarrow$

- c. $\text{SO}_2(\text{g}) + \text{Br}_2(\text{g}) \rightarrow$
 d. $\text{NaBH}_4(\text{s}) + \text{BF}_3(\text{soln}) \rightarrow$
3. Write a balanced chemical equation for the reaction of aqueous HF with
- SiO_2 .
 - Na_2CO_3 .
 - CaO .
4. Oxyhalides of sulfur, such as the *thionyl halides* (SOX_2 , where X is F, Cl, or Br), are well known. Because the thionyl halides react vigorously with trace amounts of water, they are used for dehydrating hydrated metal salts. Write a balanced chemical equation to show the products of reaction of SOCl_2 with water.
5. Write a balanced chemical equation describing each reaction.
- the burning of sulfur in a chlorine atmosphere
 - the dissolution of iodine in a potassium iodide solution
 - the hydrolysis of PCl_3
 - the preparation of HF from calcium fluoride and sulfuric acid
 - the thermal decomposition of KClO_3
 - the oxidation of sulfide ion by elemental iodine
6. Write the complete Lewis electron structure, the type of hybrid used by the central atom, and the number of lone pair electrons present on the central atom for each compound.
- CF_4
 - PCl_3
 - XeF_4

Answers

- Carbon has no low energy d orbitals that can be used to form a set of $d^2 sp^3$ hybrid orbitals. It is also so small that it is impossible for six fluorine atoms to fit around it at a distance that would allow for formation of strong C-F bonds.
-
- $\text{SiO}_2(\text{s}) + 6\text{HF}(\text{aq}) \rightarrow \text{SiF}_6^{2-}(\text{aq}) + 2\text{H}^+(\text{aq}) + 2\text{H}_2\text{O}(\text{l})$
 - $\text{Na}_2\text{CO}_3(\text{s}) + 2\text{HF}(\text{aq}) \rightarrow \text{CO}_2(\text{g}) + 2\text{NaF}(\text{aq}) + \text{H}_2\text{O}(\text{l})$
 - $\text{CaO}(\text{s}) + 2\text{HF}(\text{aq}) \rightarrow \text{CaF}_2(\text{s}) + \text{H}_2\text{O}(\text{l})$
-
- $\text{S}_8(\text{s}) + 4\text{Cl}_2(\text{g}) \rightarrow 4\text{S}_2\text{Cl}_2(\text{l})$
 - $\text{I}_2(\text{s}) + \text{KI}(\text{aq}) \rightarrow \text{I}_3^-(\text{aq}) + \text{K}^+(\text{aq})$
 - $\text{PCl}_3(\text{l}) + 3\text{H}_2\text{O}(\text{l}) \rightarrow \text{H}_3\text{PO}_3(\text{aq}) + 3\text{HCl}(\text{aq})$
 - $\text{CaF}_2(\text{s}) + \text{H}_2\text{SO}_4(\text{aq}) \rightarrow 2\text{HF}(\text{aq}) + \text{CaSO}_4(\text{s})$
 - $2\text{KClO}_3(\text{s}) + \Delta \rightarrow 2\text{KCl}(\text{s}) + 3\text{O}_2(\text{g})$
 - $8\text{S}^{2-}(\text{aq}) + 8\text{I}_2(\text{aq}) \rightarrow \text{S}_8(\text{s}) + 16\text{I}^-(\text{aq})$

Chapter 22.6: The Elements of Group 18 (The Noble Gases)

Howard University General Chemistry: An Atoms First Approach

Unit 1: Atomic Theory
Unit 5: States of Matter

Unit 2: Molecular Structure
Unit 6: Kinetics & Equilibria

Unit 3: Stoichiometry
Unit 7: Electro & Thermo Chemistry

Unit 4: Thermochem & Gases
Unit 8: Materials

Learning Objective

- To understand the trends in properties and reactivity of the group 18 elements: the noble gases.

The noble gases were all isolated for the first time within a period of only five years at the end of the 19th century. Their very existence was not suspected until the 18th century, when early work on the composition of air suggested that it contained small amounts of gases in addition to oxygen, nitrogen, carbon dioxide, and water vapor. Helium was the first of the noble gases to be identified, when the existence of this previously unknown element on the sun was demonstrated by new spectral lines seen during a solar eclipse in 1868. (For more information on spectroscopy, see [Chapter 2.](#)) Actual samples of helium were not obtained until almost 30 years later, however. In the 1890s, the English physicist J. W. Strutt (Lord Rayleigh) carefully measured the density of the gas that remained after he had removed all O₂, CO₂, and water vapor from air and showed that this residual gas was slightly denser than pure N₂ obtained by the thermal decomposition of ammonium nitrite. In 1894, he and the Scottish chemist William Ramsay announced the isolation of a new “substance” (not necessarily a new element) from the residual nitrogen gas. Because they could not force this substance to decompose or react with anything, they named it *argon* (Ar), from the Greek *argos*, meaning “lazy.” Because the measured molar mass of argon was 39.9 g/mol, Ramsay speculated that it was a member of a new group of elements located on the right side of the periodic table between the halogens and the alkali metals. He also suggested that these elements should have a preferred valence of 0, intermediate between the +1 of the alkali metals and the -1 of the halogens.

J. W. Strutt (Lord Rayleigh) (1842–1919)

Lord Rayleigh was one of the few members of British higher nobility to be recognized as an outstanding scientist. Throughout his youth, his education was repeatedly interrupted by his frail health, and he was not expected to reach maturity. In 1861 he entered Trinity College, Cambridge, where he excelled at mathematics. A severe attack of rheumatic fever took him abroad, but in 1873 he succeeded to the barony and was compelled to devote his time to the management of his estates. After leaving the entire management to his younger brother, Lord Rayleigh was able to devote his time to science. He was a recipient of honorary science and law degrees from Cambridge University.

Sir William Ramsay (1852–1916)

Born and educated in Glasgow, Scotland, Ramsay was expected to study for the Calvinist ministry. Instead, he became interested in chemistry while reading about the manufacture of gunpowder. Ramsay earned his PhD in organic chemistry at the University of Tübingen in Germany in 1872. When he returned to England, his interests turned first to physical chemistry and then to inorganic chemistry. He is best known for his work on the oxides of nitrogen and for the discovery of the noble gases with Lord Rayleigh.

In 1895, Ramsay was able to obtain a terrestrial sample of helium for the first time. Then, in a single year (1898), he discovered the next three noble gases: krypton (Kr), from the Greek *kryptos*, meaning “hidden,” was identified by its orange and green emission

lines; neon (Ne), from the Greek *neos*, meaning “new,” had bright red emission lines; and xenon (Xe), from the Greek *xenos*, meaning “strange,” had deep blue emission lines. The last noble gas was discovered in 1900 by the German chemist Friedrich Dorn, who was investigating radioactivity in the air around the newly discovered radioactive elements radium and polonium. The element was named radon (Rn), and Ramsay succeeded in obtaining enough radon in 1908 to measure its density (and thus its atomic mass). For their discovery of the noble gases, Rayleigh was awarded the Nobel Prize in Physics and Ramsay the Nobel Prize in Chemistry in 1904. Because helium has the lowest boiling point of any substance known (4.2 K), it is used primarily as a cryogenic liquid. Helium and argon are both much less soluble in water (and therefore in blood) than N_2 , so scuba divers often use gas mixtures that contain these gases, rather than N_2 , to minimize the likelihood of the “bends,” the painful and potentially fatal formation of bubbles of $N_2(g)$ that can occur when a diver returns to the surface too rapidly.

Preparation and General Properties of the Group 18 Elements

Fractional distillation of liquid air is the only source of all the noble gases except helium. Although helium is the second most abundant element in the universe (after hydrogen), the helium originally present in Earth’s atmosphere was lost into space long ago because of its low molecular mass and resulting high mean velocity. Natural gas often contains relatively high concentrations of helium (up to 7%), however, and it is the only practical terrestrial source.

The elements of group 18 all have closed-shell valence electron configurations, either $ns^2 np^6$ or $1s^2$ for He. Consistent with periodic trends in atomic properties, these elements have high ionization energies that decrease smoothly down the group. From their electron affinities, the data in Table 22.6.1 indicate that the noble gases are unlikely to form compounds in negative oxidation states. A potent oxidant is needed to oxidize noble gases and form compounds in positive oxidation states. Like the heavier halogens, xenon and perhaps krypton should form covalent compounds with F, O, and possibly Cl, in which they have *even* formal oxidation states (+2, +4, +6, and possibly +8). These predictions actually summarize the chemistry observed for these elements.

Table 22.6.1 Selected Properties of the Group 18 Elements

Property	Helium	Neon	Argon	Krypton	Xenon	Radon
atomic symbol	He	Ne	Ar	Kr	Xe	Rn
atomic number	2	10	18	36	54	86
atomic mass (amu)	4.00	20.18	39.95	83.80	131.29	222
valence electron configuration*	$1s^2$	$2s^2 2p^6$	$3s^2 3p^6$	$4s^2 4p^6$	$5s^2 5p^6$	$6s^2 6p^6$
triple point/boiling point (°C)	—/−269 [†]	−249 (at 43 kPa)/−246	−189 (at 69 kPa)/−189	−157/−153	−112 (at 81.6 kPa)/−108	−71/−62
density (g/L) at 25°C	0.16	0.83	1.63	3.43	5.37	9.07
atomic radius (pm)	31	38	71	88	108	120
first ionization energy (kJ/mol)	2372	2081	1521	1351	1170	1037
normal oxidation state(s)	0	0	0	0 (+2)	0 (+2, +4, +6, +8)	0 (+2)
electron affinity (kJ/mol)	> 0	> 0	> 0	> 0	> 0	> 0

*The configuration shown does not include filled *d* and *f* subshells.

[†] This is the normal boiling point of He. Solid He does not exist at 1 atm pressure, so no melting point can be given.

Property	Helium	Neon	Argon	Krypton	Xenon	Radon

*The configuration shown does not include filled *d* and *f* subshells.

† This is the normal boiling point of He. Solid He does not exist at 1 atm pressure, so no melting point can be given.

Reactions and Compounds of the Noble Gases

For many years, it was thought that the only compounds the noble gases could form were *clathrates*. Clathrates are solid compounds in which a gas, the guest, occupies holes in a lattice formed by a less volatile, chemically dissimilar substance, the host (Figure 22.6.1). Because clathrate formation does not involve the formation of chemical bonds between the guest (Xe) and the host molecules (H₂O, in the case of xenon hydrate), the guest molecules are immediately released when the clathrate is melted or dissolved. In addition to the noble gases, many other species form stable clathrates. One of the most interesting is methane hydrate, large deposits of which occur naturally at the bottom of the oceans. It is estimated that the amount of methane in such deposits could have a major impact on the world's energy needs later in this century.

Figure 22.6.1 The Structure of Xenon Hydrate, a Clathrate Small gaseous atoms or molecules such as Xe or CH₄ can occupy cavities in a lattice of hydrogen-bonded water molecules to produce a stable structure with a fixed stoichiometry (in this case, Xe·5.75H₂O). (The hydrogen atoms of the water molecules have been omitted for clarity.) Warming the solid hydrate or decreasing the pressure of the gas causes it to collapse, with the evolution of gas and the formation of liquid water.

The widely held belief in the intrinsic lack of reactivity of the noble gases was challenged when Neil Bartlett, a British professor of chemistry at the University of British Columbia, showed that PtF₆, a compound used in the Manhattan Project, could oxidize O₂. Because the ionization energy of xenon (1170 kJ/mol) is actually lower than that of O₂, Bartlett recognized that PtF₆ should also be able to oxidize xenon. When he mixed colorless xenon gas with deep red PtF₆ vapor, yellow-orange crystals immediately formed (Figure 22.6.2). Although Bartlett initially postulated that

they were Xe PtF_6 , it is now generally agreed that the reaction also involves the transfer of a fluorine atom to xenon to give the XeF^+ ion:

Figure 20.6.2 The Synthesis of the First Chemical Compound of Xenon(a) An apparatus containing platinum hexafluoride, the red vapor at the bottom left, and xenon, the colorless gas in the small tube at the upper right. (b) When the glass seal separating the two gases is broken and the gases are allowed to mix, a bright yellow solid is formed, which is best described as $\text{XeF}^+ \text{PtF}_5^-$.

“Burning snowballs.” Like xenon, methane (CH_4) forms a crystalline clathrate with water: methane hydrate. When the solid is warmed, methane is released and can be ignited to give what appears to be burning snow.

Subsequent work showed that xenon reacts directly with fluorine under relatively mild conditions to give XeF_2 , XeF_4 , or XeF_6 , depending on conditions; one such reaction is as follows:

The ionization energies of helium, neon, and argon are so high (Table 22.6.1) that no stable compounds of these elements are known. The ionization energies of krypton and xenon are lower but still very high; consequently only highly electronegative elements (F, O, and Cl) can form stable compounds with xenon and krypton without being oxidized themselves. Xenon reacts directly with only two elements: F_2 and Cl_2 . Although XeCl_2 and KrF_2 can be prepared directly from the elements, they are substantially less stable than the xenon fluorides.

Note the Pattern

The ionization energies of helium, neon, and argon are so high that no stable compounds of these elements are known.

Because halides of the noble gases are powerful oxidants and fluorinating agents, they decompose rapidly after contact with trace amounts of water, and they react violently with organic compounds or other reductants. The xenon fluorides are also Lewis acids; they react with the fluoride ion, the only Lewis base that is not oxidized immediately on contact, to form anionic complexes. For example, reacting cesium fluoride with XeF_6 produces CsXeF_7 , which gives Cs_2XeF_8 when heated:

The XeF_8^{2-} ion contains eight-coordinate xenon and has the square antiprismatic structure shown here, which is essentially identical to that of the IF_8^- ion. Cs_2XeF_8 is surprisingly stable for a polyatomic ion that contains xenon in the +6 oxidation state, decomposing only at temperatures greater than 300°C . Major factors in the stability of Cs_2XeF_8 are almost certainly the formation of a stable ionic lattice and the high coordination number of xenon, which protects the central atom from attack by other species. (Recall from Section 20.4 that this latter effect is responsible for the extreme stability of SF_6 .)

For a previously “inert” gas, xenon has a surprisingly high affinity for oxygen, presumably because of π bonding between O and Xe. Consequently, xenon forms an extensive series of oxides and oxoanion salts. For example, hydrolysis of either XeF_4 or XeF_6 produces XeO_3 , an explosive white solid:

Treating a solution of XeO_3 with ozone, a strong oxidant, results in further oxidation of xenon to give either XeO_4 , a colorless, explosive gas, or the surprisingly stable perxenate ion (XeO_6^{4-}), both of which contain xenon in its highest possible oxidation state (+8). The chemistry of the xenon halides and oxides is best understood by analogy to the corresponding compounds of iodine. For example, XeO_3 is isoelectronic with the iodate ion (IO_3^-), and XeF_8^{2-} is isoelectronic with the IF_8^- ion.

Note the Pattern

Xenon has a high affinity for both fluorine and oxygen.

Because the ionization energy of radon is less than that of xenon, in principle radon should be able to form an even greater variety of chemical compounds than xenon. Unfortunately, however, radon is so radioactive that its chemistry has not been extensively explored.

Example 22.6.1

On a virtual planet similar to Earth, at least one isotope of radon is not radioactive. A scientist explored its chemistry and presented her major conclusions in a trailblazing paper on radon compounds, focusing on the kinds of compounds formed and their stoichiometries. Based on periodic trends, how did she summarize the chemistry of radon?

Given: nonradioactive isotope of radon

Asked for: summary of its chemistry

Strategy:

Based on the position of radon in the periodic table and periodic trends in atomic properties, thermodynamics, and kinetics, predict the most likely reactions and compounds of radon.

Solution:

We expect radon to be significantly easier to oxidize than xenon. Based on its position in the periodic table, however, we also expect its bonds to other atoms to be weaker than those formed by xenon. Radon should be more difficult to oxidize to its highest possible oxidation state (+8) than xenon because of the inert-pair effect. Consequently, radon should form an extensive series of fluorides, including RnF_2 , RnF_4 , RnF_6 , and possibly RnF_8 (due to its large radius). The ion RnF_8^{2-} should also exist. We expect radon to form a series of oxides similar to those of xenon, including RnO_3 and possibly RnO_4 . The biggest surprise in radon chemistry is likely to be the existence of stable chlorides, such as RnCl_2 and possibly even RnCl_4 .

Exercise

Predict the stoichiometry of the product formed by reacting XeF_6 with a 1:1 stoichiometric amount of KF and propose a reasonable structure for the anion.

Answer: KXeF_7 ; the xenon atom in XeF_7^- has 16 valence electrons, which according to the valence-shell electron-pair repulsion model could give either a square antiprismatic structure with one fluorine atom missing or a pentagonal bipyramid if the $5s^2$ electrons behave like an inert pair that does not participate in bonding.

Summary

The noble gases have a closed-shell valence electron configuration. The ionization energies of the noble gases decrease with increasing atomic number. Only highly electronegative elements can form stable compounds with the noble gases in positive oxidation states without being oxidized themselves. Xenon has a high affinity for both fluorine and oxygen, which form stable compounds that contain xenon in even oxidation states up to +8.

Key Takeaways

- The noble gases are characterized by their high ionization energies and low electron affinities.
- Potent oxidants are needed to oxidize the noble gases to form compounds in positive oxidation states.

Conceptual Problems

1. The chemistry of the noble gases is largely dictated by a balance between two competing properties. What are these properties? How do they affect the reactivity of these elements?
2. Of the group 18 elements, only krypton, xenon, and radon form stable compounds with other atoms and then only with very electronegative elements. Why?
3. Give the type of hybrid orbitals used by xenon in each species.
 - a. XeF_2
 - b. XeF_4
 - c. XeO_3
 - d. XeOF_4
 - e. XeO_4^{4-}
 - f. XeO_6
4. Which element is the least metallic—B, Ga, Tl, Pb, Ne, or Ge?
5. Of Br, N, Ar, Bi, Se, He, and S, which would you expect to form positive ions most easily? negative ions most easily?
6. Of BCl_3 , BCl_4^- , CH_4 , $\text{H}_3\text{N}\cdot\text{BF}_3$, PCl_3 , PCl_5 , XeO_3 , H_2O , and F^- , which species do you expect to be
 - a. electron donors?
 - b. electron acceptors?
 - c. neither electron donors nor acceptors?
 - d. both electron donors and acceptors?
7. Of HCl , HClO_4 , HBr , H_2S , HF , KrF_2 , and PH_3 , which is the strongest acid?
8. Of CF_4 , NH_3 , NF_3 , H_2O , OF_2 , SiF_4 , H_2S , XeF_4 , and SiH_4 , which is the strongest base?

Structure and Reactivity

1. Write a balanced chemical equation showing how you would prepare each compound from its elements and other common compounds.
 - a. XeF_2
 - b. XeF_4
 - c. XeF_6
 - d. XeOF_4
 - e. XeO_3
2. Write a balanced chemical equation showing how you would make each compound.
 - a. XeF_2 from Xe gas
 - b. NaXeF_7 from its elements
 - c. RnO_3 from Rn
3. In an effort to synthesize XeF_6 , a chemist passed fluorine gas through a glass tube containing xenon gas. However, the product was not the one expected. What was the actual product?
4. Write a balanced chemical equation to describe the reaction of each species with water.
 - a. B_2H_6
 - b. F_2

- c. C
5. Using heavy water (D_2O) as the source of deuterium, how could you prepare each compound?
- $LiAlD_4$
 - D_2SO_4
 - SiD_4
 - DF
6. Predict the product(s) of each reaction and write a balanced chemical equation for each reaction.
- $Al_2O_3(s)$ in $OH^- (aq)$
 - $Ar(g) + F_2(g)$
 - $PI_3(s) + H_2O(l)$
 - $H_3PO_3(l) + OH^- (aq)$
 - $Bi(s) + \text{excess } Br_2(l)$

Answers

- $Xe(g) + F_2(g) \rightarrow XeF_2(s)$
 - $Xe(g) + 2F_2(g) \rightarrow XeF_4(s)$
 - $Xe(g) + 3F_2(g) \rightarrow XeF_6(s)$
 - $2XeF_6(s) + SiO_2(s) \rightarrow 2XeOF_4(l) + SiF_4(l)$
 - $XeF_6(s) + 3H_2O(l) \rightarrow XeO_3(s) + 6HF(aq)$
-
- SiF_4 ; $SiO_2(s) + 2F_2(g) \rightarrow SiF_4(l) + 2O_2(g)$
-
- $2Na(s) + 2D_2O(l) \rightarrow D_2(g) + 2NaOD(aq)$
 $2Li(s) + D_2(g) \rightarrow 2LiD(s)$
 $4LiD(s) + AlCl_3(soln) \rightarrow LiAlD_4(s) + 3LiCl(soln)$
 - $D_2O(l) + SO_3(g) \rightarrow D_2SO_4(l)$
 - $SiCl_4(l) + LiAlD_4(s)$ [from part (a)] $\rightarrow SiD_4(g) + LiCl(s) + AlCl_3(s)$
 - $CaF_2(s) + D_2SO_4(l)$ [from part (b)] $\rightarrow 2DF(g) + CaSO_4(s)$
-

APPLICATION PROBLEMS

- Borax ($\text{Na}_2\text{B}_4\text{O}_5(\text{OH})_4 \cdot 8\text{H}_2\text{O}$) is used as a flux during welding operations. As brass is heated during welding, for example, borax cleans the surface of Cu_2O and prevents further oxidation of the fused metal. Explain why borax is effective at cleaning the surface and preventing surface oxidation.
- Extensive research is being conducted into using GaAs as a material for computer memory chips. It has been found, for example, that chips made from GaAs are up to 10 times faster than those made from silicon. Propose an explanation for this increase in speed.
- Cement that has a high content of alumina (Al_2O_3) is particularly resistant to corrosion, so it is used for structures that must be resistant to seawater and acidic conditions. Why is this material so effective under these service conditions? Failure occurs under prolonged exposure to a hot, wet environment. Why?
- Aluminum is light and ductile. If you were considering using aluminum rather than steel as a structural material for building a high-speed ferry, what disadvantages would you need to consider in using aluminum for these service conditions?
- Life on Earth is based on carbon. A possible explanation is that no other element in the periodic table forms compounds that are so diverse in their chemistry and physical properties. Discuss the chemistry of carbon with regard to
 - types of bonding.
 - the states of matter of carbon compounds.
 - the properties of elemental C.
 - the reactivity of elemental C and its compounds.
 Then compare B, Al, Si, N, and P with C in terms of these properties.
- After a traffic accident in which a tanker truck carrying liquid nitrogen overturned, a reporter at the scene warned of a danger to residents in the vicinity of the accident because nitrogen would react with hydrocarbons in the asphalt to produce ammonia gas. Comment on the credibility of this statement.
- Nitrogen forms a hydride called hydrazoic acid (HN_3), which is a colorless, highly toxic, explosive substance that boils at 37°C . The thermal decomposition of one of its salts— NaN_3 —is used to inflate automotive air bags. The N_3^- ion is isoelectronic with CO_2 .
 - Draw the Lewis electron structure of the N_3^- anion.
 - Write a balanced chemical equation for the thermal decomposition of NaN_3 .
 - Based on your answer to part (b), propose an explanation for why many people have suffered skin burns when their air bags exploded.
- Hydrazine (N_2H_4), a rocket fuel, is a colorless, oily liquid with a melting point of 1.4°C , and it is a powerful reducing agent. The physical properties of hydrazine presumably reflect the presence of multiple hydrogen-bond acceptors and donors within a single molecule. Explain the basis for this statement.
- Because the N–C bond is almost as strong as the N–H bond, organic analogues of ammonia, hydrazine, and hydroxylamine are stable and numerous. Conceptually at least, they are formed by the successive replacement of H atoms by alkyl or aryl groups. Methylhydrazine and dimethylhydrazine, for example, were used as fuels in the US *Apollo* space program. They react spontaneously and vigorously with liquid N_2O_4 , thus eliminating the need for an ignition source. Write balanced chemical equations for these reactions and calculate ΔG° for each reaction.

10. In an effort to remove a troublesome stain from a sink, a member of the cleaning staff of a commercial building first used bleach on the stain and then decided to neutralize the bleach with ammonia. What happened? Why?
11. A slow reaction that occurs on the ocean floor is the conversion of carbonate to bicarbonate, which absorbs CO_2 . Write a balanced chemical equation for this reaction. Silicate sediments play an important role in controlling the pH of seawater. Given the reaction, propose a chemical explanation for this.
12. Marketing surveys have shown that customers prefer to buy a bright red steak rather than a dull gray one. It is known that NO combines with myoglobin to form a bright red NO complex. What would you add to beef during processing to ensure that this reaction occurs and yields the desired appearance?
13. Covalent azides are used as detonators and explosives. Ionic azides, in contrast, are usually much more stable and are used in dyestuffs. Why is there such a difference between these two types of compounds? The N_3^- ion is considered a pseudohalide. Why?
14. The heads of modern “strike anywhere” matches contain a mixture of a nonvolatile phosphorus sulfide (P_4S_3) and an oxidizing agent (KClO_3), which is ignited by friction when the match is struck against a rough object. Safety matches separate the oxidant and the reductant by putting KClO_3 in the head and a paste containing nonvolatile red phosphorus on the match box or cover. Write a balanced chemical equation for the reaction that occurs when a match is rubbed against the abrasive end of a matchbox.
15. Paris green was a common pigment in paints and wallpaper of the Napoleonic era. It is a mixed acetate/arsenite salt of copper with the formula $\text{Cu}_2(\text{OAc})_2(\text{AsO}_3)$. In damp conditions, certain fungi are able to convert arsenite salts to volatile, toxic organoarsenic compounds. Shortly after his exile in 1815 to the remote island of St. Helena in the southern Atlantic Ocean, Napoleon died. As a forensic scientist investigating the cause of Napoleon’s mysterious death, you notice that the walls of his enclosed bedchamber are covered in green wallpaper. What chemical clues would you look for to determine the cause of his death?
16. Selenium, an element essential to humans, appears to function biologically in an enzyme that destroys peroxides. Why is selenium especially suited for this purpose? Would sulfur or tellurium be as effective? Why or why not?
17. One way to distinguish between fool’s gold (FeS_2 , or iron pyrite) and real gold is to heat the sample over a fire. If your sample of “gold” were actually fool’s gold, what would happen?
18. Calcium hypochlorite is sold as swimming pool bleach. It is formed by the hydrolysis of Cl_2O , which gives only one product, followed by neutralization with lime [$\text{Ca}(\text{OH})_2$]. Write balanced chemical equations for these reactions.
19. There is much interest in the superheavy elements beyond $Z = 111$ because of their potentially unique properties. Predict the valence electron configurations, preferred oxidation states, and products of the reaction with aqueous acid for elements 113 and 115.
20. Zeolites have become increasingly important in chemical engineering. They can be used as desiccants because the dehydrated zeolite absorbs small molecules, such as water. To be retained by the zeolite frame, a molecule must satisfy two conditions. What are they? Why can linear CO_2 and tetrahedral CH_4 not be held by a typical zeolite, even though they can penetrate it easily?

Learning Objective

- To know the major classes of organic compounds and identify important functional groups.

In [Section 6.4](#), you were introduced to several structural units that chemists use to classify organic compounds and predict their reactivities. These functional groups, which determine the chemical reactivity of a molecule under a given set of conditions, can consist of a single atom (such as Cl) or a group of atoms (such as CO₂H). The major families of organic compounds are characterized by their functional groups. [Figure 23.1.1](#) (click on it to enlarge) summarizes five families introduced in earlier chapters, gives examples of compounds that contain each functional group, and lists the suffix or prefix used in the systematic nomenclature of compounds that contain each functional group.

Class	General Formula	Example	Common Name (Systematic Name)	Common Suffix/Prefix (Systematic)
Hydrocarbons				
Alkanes	C _n H _{2n+2}	CH ₄ , C ₂ H ₆	alkane	-ane
Alkenes	C _n H _{2n}	C ₂ H ₄ , C ₃ H ₆	alkene	-ene
Alkynes	C _n H _{2n-2}	C ₂ H ₂ , C ₃ H ₄	alkyne	-yne
Arenes	C _n H _n		benzene	-ene
Halogen-Containing Compounds				
Alkyl halides	RX	CH ₃ Cl	alkyl halide	-halide
Aryl halides	ArX		aryl halide	-halide
Oxygen-Containing Compounds				
Alcohols	C _n H _{2n+2} O	CH ₃ OH	alcohol	-ol
Phenols	ArOH		phenol	-ol
Ethers	C _n H _{2n+2} O	CH ₃ OC ₂ H ₅	ether	-ether
Aldehydes	C _n H _{2n} O	CH ₃ CHO	aldehyde	-al
Ketones	C _n H _{2n} O	CH ₃ COCH ₃	ketone	-one
Carboxylic acids	C _n H _{2n} O ₂	CH ₃ COOH	carboxylic acid	-oic acid
Carboxylic Acid Derivatives				
Esters	C _n H _{2n} O ₂	CH ₃ COOCH ₃	ester	-oate
Amides	C _n H _{2n-1} N	CH ₃ CONH ₂	amide	-amide
Nitrogen-Containing Compounds				
Amines	C _n H _{2n+3} N	CH ₃ NH ₂	amine	-amine
Nitriles	C _n H _n N	HC≡N	nitrile	-nitrile
Nitro compounds	ArNO ₂		nitro compound	-nitro

Figure 23.1.1 Major Classes of Organic Compounds The first family listed in [Figure 23.1.1 "Major Classes of Organic Compounds"](#) is the hydrocarbons. These include alkanes, with the general molecular formula C_nH_{2n+2} where *n* is an integer; alkenes, represented by C_nH_{2n}; alkynes, represented by C_nH_{2n-2}; and arenes. Halogen-substituted alkanes, alkenes, and arenes form a second major family of organic compounds, which include the alkyl halides and the aryl halides. Oxygen-containing organic compounds, a third family, may be divided into two main types: those that contain at least one C–O bond, which include alcohols, phenols (derivatives of benzene), and ethers, and those that contain a carbonyl group (C=O), which include aldehydes, ketones, and carboxylic acids. Carboxylic acid derivatives, the fourth family listed, are compounds in which the OH of the –CO₂H functional group is replaced by either an alkoxy (–OR) group, producing an ester, or by an amido (–NRR', where R and R' can be H and/or alkyl groups), forming an amide. Nitrogen-containing organic compounds, the fifth family, include amines; nitriles, which have a C≡N bond; and nitro compounds, which contain the –NO₂ group.

As you learned in [Section 6.4](#), the systematic nomenclature of organic compounds indicates the positions of substituents using the lowest numbers possible to identify their locations in the carbon chain of the parent compound. If two compounds have the same systematic name, then they are the same compound. Although systematic names are preferred because they are unambiguous, many

organic compounds are known by their common names rather than their systematic names. Common nomenclature uses the prefix *form*—for a compound that contains no carbons other than those in the functional group, and *acet*—for those that have one carbon atom in addition [two in the case of acetone, $(\text{CH}_3)_2\text{C}=\text{O}$]. Thus methanal and ethanal, respectively, are the systematic names for formaldehyde and acetaldehyde.

Recall that in the systematic nomenclature of aromatic compounds, the positions of groups attached to the aromatic ring are indicated by numbers, starting with 1 and proceeding around the ring in the direction that produces the lowest possible numbers. For example, the position of the first CH_3 group in dimethyl benzene is indicated with a 1, but the second CH_3 group, which can be placed in any one of three positions, produces 1,2-dimethylbenzene, 1,3-dimethylbenzene, or 1,4-dimethylbenzene (Figure 23.1.2). In common nomenclature, in contrast, the prefixes *ortho*-, *meta*-, and *para*- are used to describe the relative positions of groups attached to an aromatic ring. If the CH_3 groups in dimethylbenzene, whose common name is xylene, are adjacent to each other, the compound is commonly called *ortho*-xylene, abbreviated *o*-xylene. If they are across from each other on the ring, the compound is commonly called *para*-xylene or *p*-xylene. When the arrangement is intermediate between those of *ortho*- and *para*- compounds, the name is *meta*-xylene or *m*-xylene.

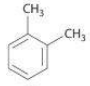

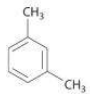

Prefix	Positions of Methyl Groups	Example	Common Name (Systematic Name)
<i>ortho</i> -	1,2		<i>o</i> -xylene (1,2-dimethylbenzene)
<i>meta</i> -	1,3		<i>m</i> -xylene (1,3-dimethylbenzene)
<i>para</i> -	1,4		<i>p</i> -xylene (1,4-dimethylbenzene)

Figure 23.1.2 Common Nomenclature for Aromatic Ring Substitutions We begin our discussion of the structure and reactivity of organic compounds by exploring structural variations in the simple saturated hydrocarbons known as alkanes. These compounds serve as the scaffolding to which the various functional groups are most often attached.

Summary

Functional groups are structural units that determine the chemical reactivity of a molecule under a given set of conditions. Organic compounds are classified into several major categories based on the functional groups they contain. In the systematic names of organic compounds, numbers indicate the positions of functional groups in the basic hydrocarbon framework. Many organic compounds also have common names, which use the prefix *form*—for a compound that contains no carbons other than those in the functional group and *acet*—for those that have one additional carbon atom.

Key Takeaway

- Functional groups determine the chemical reactivity of an organic molecule.

Conceptual Problems

1. Can two substances have the same systematic name and be different compounds?
2. Is a carbon–carbon multiple bond considered a functional group?

Learning Objective

- To learn how organic compounds with the same molecular formula can have different three-dimensional structures.

In earlier discussions of organic compounds, we focused on differences in how the functional groups were connected to the carbon framework. Differences in connectivity resulted in different chemical compounds with different names. You learned, for example, that although 1-propanol (*n*-propanol) and 2-propanol (isopropanol) have the same molecular formula (C_3H_8O), they have different physical and chemical properties. Just as with metal complexes, compounds that have the same molecular formula but different arrangements of atoms are called isomers. (For more information on metal complexes, see [Section 21.4](#).) In this section, we describe various types of isomers, beginning with those whose three-dimensional structures differ only as the result of rotation about a C–C bond.

Conformational Isomers

The C–C single bonds in ethane, propane, and other alkanes are formed by the overlap of an sp^3 hybrid orbital on one carbon atom with an sp^3 hybrid orbital on another carbon atom, forming a σ bond ([Figure 23.2.1](#)). Each sp^3 hybrid orbital is cylindrically symmetrical (all cross-sections are circles), resulting in a carbon–carbon single bond that is also cylindrically symmetrical about the C–C axis. Because rotation about the carbon–carbon single bond can occur without changing the overlap of the sp^3 hybrid orbitals, there is no significant electronic energy barrier to rotation. Consequently, many different arrangements of the atoms are possible, each corresponding to different degrees of rotation. Differences in three-dimensional structure resulting from rotation about a σ bond are called differences in *conformation*, and each different arrangement is called a conformational isomer (or conformer).

Note the Pattern

Conformational isomers differ in their three-dimensional structure due to rotation about a σ bond.

Figure 23.2.1 Carbon–Carbon Bonding in Alkanes Overlapping sp^3 hybrid orbitals on adjacent carbon atoms form a cylindrically symmetrical σ bond. Because rotation about the bond does not affect the overlap of the bonding orbitals, there is no electronic energy barrier to rotation.

The simplest alkane to have a conformational isomer is ethane. Differences between the conformations of ethane are depicted especially clearly in drawings called *Newman projections*, such as those shown in part (a) in [Figure 23.2.2](#) In a Newman projection, the ethane molecule is viewed along the C–C axis, with the carbon that is in front shown as a vertex and the carbon that is in back shown as a circle. The three hydrogen atoms nearest the viewer are shown bonded to the front carbon, and the three hydrogen atoms farthest from the viewer are shown bonded to the circle. In one extreme, called the *eclipsed conformation*, the C–H bonds on adjacent carbon atoms lie in the same plane. In the other extreme, called the *staggered conformation*, the hydrogen atoms are positioned as far from one another as possible. Rotation about the C–C bond produces an infinite number of conformations between these two extremes, but the staggered conformation is the most stable because it minimizes electrostatic repulsion between the hydrogen atoms on adjacent carbons.

Figure 23.2.2 Eclipsed and Staggered Conformations of Ethane(a) In a Newman projection, the molecule is viewed along a C–C axis. The carbon in front is represented as a vertex, whereas the carbon that is bonded to it is represented as a circle. In ethane, the C–H bonds to each carbon are positioned at 120° from each other. In the fully eclipsed conformation, the C–H bonds on adjacent carbon atoms are parallel and lie in the same plane. In the staggered conformation, the hydrogen atoms are positioned as far apart as possible. (b) The eclipsed conformation is 12.6 kJ/mol higher in energy than the staggered conformation because of electrostatic repulsion between the hydrogen atoms. An infinite number of conformations of intermediate energy exist between the two extremes.

In a Newman projection, the angles between adjacent C–H bonds on the same carbon are drawn at 120° , although H–C–H angles in alkanes are actually tetrahedral angles of 109.5° , which for chains of more than three carbon atoms results in a *kinked* structure. (For more information on bond angles and molecular modeling, see [Section 6.3](#)) Despite this three-dimensional inaccuracy, Newman projections are useful for predicting the relative stability of conformational isomers. As shown in part (b) in [Figure 23.2.2](#), the higher energy of the eclipsed conformation represents an energy barrier of 12.6 kJ/mol that must be overcome for rotation about the C–C bond to occur. This barrier is so low, however, that rotation about the C–C bond in ethane is very fast at room temperature and occurs several million times per second for each molecule.

Longer-chain alkanes can also be represented by Newman projections. In more complex alkanes and alkane derivatives, rotation can occur about *each* C–C bond in a molecule. Newman projections are therefore useful for revealing *steric barriers* to rotation at a particular C–C bond due to the presence of bulky substituents. [Figure 23.2.3](#) shows a plot of potential energy versus the angle of rotation about the central C–C bond (between carbon atoms 2 and 3) of *n*-butane (C_4H_{10}). The structure that minimizes electrostatic repulsion is the one in which the methyl groups, corresponding to carbon atoms 1 and 4, are as far apart as possible; that is, the staggered conformation. Notice that because the substituents on C2 and C3 in *n*-butane are not all the same, energetically nonequivalent eclipsed and staggered conformations are possible; most molecules interconvert rapidly between these conformations by a series of simple rotations.

Figure 23.2.3 *Potential Energy Plot and Newman Projections of Eclipsed and Staggered Conformations of n-Butane* In these projections, the molecule is viewed along the C2–C3 axis. The least stable structure is the eclipsed conformation in which the two methyl groups (C1 and C4) are adjacent to each other. The most stable structure is the staggered conformation in which the methyl groups are as far apart as possible. Because the substituents on each central carbon atom are not all the same, a 120° rotation about the C2–C3 bond generates energetically nonequivalent eclipsed and staggered conformations.

Example 23.2.1

Draw Newman projections showing the staggered and eclipsed conformations of 1,1,1-trichloroethane (CCl_3CH_3).

Given: organic molecule

Asked for: staggered and eclipsed conformations

Strategy:

A Identify the C–C bond of interest. Then draw the Newman projection by representing one carbon as a vertex and the other as a circle.

B Draw bonds to each carbon at 120° angles from one another, with one arrangement representing the staggered conformation and the other the eclipsed conformation.

C Complete the Newman projections by attaching the appropriate atoms or substituent groups to the central C atoms in each conformation.

Solution:

A There is only one C–C bond: C1 is connected to three Cl atoms and C2 to three H atoms. We draw C1 as a point and C2 as a circle.

B Now we draw bonds on each carbon at 120° angles from one another to represent the staggered conformation and the eclipsed conformation.

C We then attach the H and Cl atoms to the carbon atoms in each conformation as shown.

Exercise

Draw Newman projections to illustrate the staggered and eclipsed conformations of propane (C_3H_8) as viewed along the C1–C2 axis.

Answer:

Structural Isomers

Unlike conformational isomers, which do not differ in connectivity, structural isomers differ in connectivity, as illustrated here for 1-propanol and 2-propanol. (For more information on structural isomers, see [Section 21.4](#).) Although these two alcohols have the same molecular formula (C_3H_8O), the position of the $-OH$ group differs, which leads to differences in their physical and chemical properties.

In the conversion of one structural isomer to another, *at least one bond must be broken and reformed at a different position in the molecule*. Consider, for example, the following five structures represented by the formula C_5H_{12} :

Of these structures, (a) and (d) represent the same compound, as do (b) and (c). No bonds have been broken and reformed; the molecules are simply rotated about a 180° vertical axis. Only three—*n*-pentane (a) and (d), 2-methylbutane (b) and (c), and 2,2-dimethylpropane (e)—are structural isomers. Because no bonds are broken in going from (a) to (d) or from (b) to (c), these alternative representations are not structural isomers. The three structural isomers—either (a) or (d), either (b) or (c), and (e)—have distinct physical and chemical properties.

Note the Pattern

Structural isomers differ in their connectivity.

Example 23.2.2

Draw all the structural isomers of C_6H_{14} .

Given: organic molecule

Asked for: all structural isomers

Strategy:

A Draw the simplest structural isomer, which is often the straight-chain alkane.

B Obtain branched isomers by substituting one hydrogen along the chain with an appropriate group from the chain.

C If possible, substitute more than one hydrogen with appropriate groups to obtain isomers that are more highly branched.

Solution:

A The simplest structural isomer is the straight-chain alkane *n*-hexane ($CH_3CH_2CH_2CH_2CH_2CH_3$).

B Removing a methyl group from one end and reattaching it to adjacent carbons while substituting hydrogen in its place give two other structures:

C To obtain yet another structural isomer, move two methyl groups to create a molecule with two branches:

We create one more structural isomer by attaching two methyl groups to the same carbon atom:

Thus there are four structural isomers of C_6H_{14} .

Exercise

Draw all the structural isomers of C_4H_9Cl .

Answer:

Stereoisomers

Molecules with the same connectivity but different arrangements of the atoms in space are called stereoisomers. There are two types of stereoisomers: geometric and optical. *Geometric isomers* differ in the relative position(s) of substituents in a rigid molecule. (For more information on stereoisomers, see [Section 21.4](#)) Simple rotation about a C–C σ bond in an alkene, for example, cannot occur because of the presence of the π bond. The substituents are therefore rigidly locked into a particular spatial arrangement (part (a) in [Figure 6.4.4](#)). Thus a carbon–carbon multiple bond, or in some cases a ring, prevents one geometric isomer from being readily converted to the other. The members of an isomeric pair are identified as either *cis* or *trans*, and interconversion between the two forms requires breaking and reforming one or more bonds. Because their structural difference causes them to have different physical and chemical properties, *cis* and *trans* isomers are actually two distinct chemical compounds.

Note the Pattern

Stereoisomers have the same connectivity but different arrangements of atoms in space.

Optical isomers are molecules whose structures are mirror images but cannot be superimposed on one another in any orientation. Optical isomers have *identical physical properties*, although their chemical properties may differ in asymmetric environments. Molecules that are nonsuperimposable mirror images of each other are said to be *chiral* (pronounced “ky-ral,” from the Greek *cheir*, meaning “hand”). Examples of some familiar chiral objects are your hands, feet, and ears. As shown in part (a) in [Figure 23.2.4](#), your left and right hands are nonsuperimposable mirror images. (Try putting your right shoe on your left foot—it just doesn’t work.) An *achiral* object is one that *can* be superimposed on its mirror image, as shown by the superimposed flasks in part (b) in [Figure 23.2.4](#)

Figure 23.2.4 Chiral and Achiral Objects (a) Objects that are nonsuperimposable mirror images of each other are chiral, such as the left and the right hand. (b) The unmarked flask is achiral because it can be superimposed on its mirror image.

Most chiral organic molecules have at least one carbon atom that is bonded to four different groups, as occurs in the bromochlorofluoromethane molecule shown in part (a) in [Figure 23.2.5](#). This carbon, often designated by an asterisk in structural drawings, is called a *chiral center* or *asymmetric carbon atom*. If the bromine atom is replaced by another chlorine (part (b) in [Figure 23.2.5](#)), the molecule and its mirror image can now be superimposed by simple rotation. Thus the carbon is no longer a chiral center. Asymmetric carbon atoms are found in many naturally occurring molecules, such as lactic acid, which is present in milk and muscles, and nicotine, a component of tobacco. A molecule and its nonsuperimposable mirror image are called *enantiomers* (from the Greek *enantiou*, meaning “opposite”).

Figure 23.2.5 Comparison of Chiral and Achiral Molecules (a) Bromochlorofluoromethane is a chiral molecule whose stereocenter is designated with an asterisk. Rotation of its mirror image does not generate the original structure. To superimpose the mirror images, bonds must be broken and reformed. (b) In contrast, dichlorofluoromethane and its mirror image can be rotated so they are superimposable.

Example 23.2.3

Draw the *cis* and *trans* isomers of each compound.

- 1,3-dimethylcyclopentane
- 3,4-dichloro-3-hexene

Given: organic compounds

Asked for: *cis* and *trans* isomers

Strategy:

Draw the unsubstituted compound corresponding to the systematic name given. Then place substituents on the same side to obtain the *cis* isomer and on opposite sides to obtain the *trans* isomer.

Solution:

1. The name tells us that this compound contains a five-carbon ring with two methyl groups attached. The 1,3 notation means that the methyl groups are not adjacent in the five-membered ring:

Placing the methyl substituents on the same side of the ring gives the *cis* isomer, whereas placing them on opposite sides of the ring gives the *trans* isomer:

2. The compound 3-hexene can exist as a *cis* or *trans* isomer:

Replacing the hydrogen atoms on the third and fourth carbons by chlorine does not change the overall structures of the isomers:

Exercise

Draw the *cis* and *trans* isomers of each compound.

1. 2-butene
2. 1-methyl-3-chlorocyclopentane

Answer:

- 1.

2.

Example 22.3.4

Which of these compounds exist as at least one pair of enantiomers?

1.

2.

3.

4.

Given: organic compounds

Asked for: existence of enantiomers

Strategy:

Determine whether the compound is chiral. In most cases, this means that at least one carbon is bonded to four different groups. If the compound is chiral, it exists as enantiomers.

Solution:

1. The carbons in $-\text{CH}_3$ and $-\text{CH}_2-$ are each bound to more than one hydrogen, so they are achiral. The central carbon is bound to two identical ethyl groups, so it is also achiral. Because there are no chiral centers in this compound, it has no enantiomers.
2. All carbons are bonded to at least two H atoms except for the one bonded to Br, which is bonded to four different groups: $-\text{Br}$, $-\text{CH}_3$, $-\text{H}$, and $-\text{CH}_2\text{CH}_3$. The compound therefore has one chiral center and, as a result, exists as enantiomers: the structure shown and its nonsuperimposable mirror image.
3. The carbons in each $-\text{CH}_3$ are bonded to more than one hydrogen, so they are achiral. One carbon is bonded to two $-\text{CH}_3$ groups, making it achiral also. This compound has no enantiomers.
4. One carbon is bonded to three hydrogens and one to two oxygens, so they are achiral. The central carbon is bonded to four different groups: $-\text{CH}_3$, $-\text{H}$, $-\text{NH}_2$, and $-\text{CO}_2\text{H}$, so it is chiral, and the compound has two enantiomers.

Exercise

Which of these compounds have at least one pair of enantiomers?

1.

2.

3.

4.

Answer:

(c)

Optical Activity of Enantiomers

Although enantiomers have identical densities, melting and boiling points, colors, and solubility in most solvents, they differ in their interaction with *plane-polarized light*, which consists of electromagnetic waves oscillating in a single plane. In contrast, normal (unpolarized) light consists of electromagnetic waves oscillating in all directions perpendicular to the axis of propagation. When normal light is passed through a substance called a polarizer, only light oscillating in one direction is transmitted. A polarizer selectively filters out light that oscillates in any but the desired plane (Figure 23.2.6).

Figure 23.2.6 Detecting the Optical Activity of Chiral Substances When polarized light is passed through a solution that contains an achiral compound, there is no net rotation of the plane of polarization of the light. In contrast, when polarized light is passed through a solution that contains one enantiomer of a chiral compound, as shown here, the light is rotated either clockwise [dextrorotatory, (+) enantiomer] or counterclockwise [levorotatory, (-) enantiomer] by an angle that depends on the molecular structure and concentration of the compound, the path length, and the wavelength of the light.

When plane-polarized light is passed through a solution, electromagnetic radiation interacts with the solute and solvent molecules. If the solution contains an achiral compound, the plane-polarized light enters and leaves the solution unchanged because achiral molecules cause it to rotate in random directions. The solute is therefore said to be *optically inactive*. If the solution contains a single enantiomer of a chiral compound, however, the plane-polarized light is rotated in only one direction, and the solute is said to be *optically active*. A clockwise rotation is called *dextrorotatory* (from the Latin *dextro*, meaning “to the right”) and is indicated in the name of the compound by (+), whereas a counterclockwise rotation is called *levorotatory* (from the Latin *levo*, meaning “to the left”) and is designated (-). As you will soon discover, this designation is important in understanding how chiral molecules interact with one another.

Note the Pattern

Chiral molecules are optically active; achiral molecules are not.

The magnitude of the rotation of plane-polarized light is directly proportional to the number of chiral molecules in a solution; it also depends on their molecular structure, the temperature, and the wavelength of the light. Because of these variables, every chiral compound has a specific rotation, which is defined as the amount (in degrees) by which the plane of polarized light is rotated when

the light is passed through a solution containing 1.0 g of solute per 1.0 mL of solvent in a tube 10.0 cm long. A chiral solution that contains equal concentrations of a pair of enantiomers is called a *racemic mixture*. In such a solution, the optical rotations exactly cancel one another, so there is no net rotation, and the solution is optically inactive. The categories of stereoisomers are summarized in [Figure 23.2.7](#).

Figure 23.2.7 Classification of Stereoisomers In both types of stereoisomer—geometric and optical—isomeric molecules have identical connectivity, but the arrangement of atoms in space differs. Cis and trans isomers exhibit different physical and chemical properties, whereas enantiomers differ only in their interaction with plane-polarized light and reactions in asymmetric environments. Depending on the direction in which they rotate polarized light, enantiomers are identified as (+) or (–). The designations L- and D- represent an alternative labeling system.

Interactions of Enantiomers with Other Chiral Molecules

In living organisms, virtually every molecule that contains a chiral center is found as a single enantiomer, not a racemic mixture. At the molecular level, our bodies are chiral and interact differently with the individual enantiomers of a particular compound. For example, the two enantiomers of carvone produce very different responses in humans: (–)-carvone is the substance responsible for the smell of spearmint oil, and (+)-carvone—the major flavor component of caraway seeds—is responsible for the characteristic aroma of rye bread.

A pharmaceutical example of a chiral compound is ibuprofen, a common analgesic and anti-inflammatory agent that is the active ingredient in pain relievers such as Motrin and Advil ([Figure 23.5.2](#)). The drug is sold as a racemic mixture that takes approximately 38 minutes to achieve its full effect in relieving pain and swelling in an adult human. Because only the (+) enantiomer is active in humans, however, the same mass of medication would relieve symptoms in only about 12 minutes if it consisted of only the (+) enantiomer. Unfortunately, isolating only the (+) enantiomer would substantially increase the cost of the drug. Conversion of the (–) to (+) enantiomer in the human body accounts for the delay in feeling the full effects of the drug. A racemic mixture of another drug, the sedative thalidomide, was sold in Europe from 1956 to the early 1960s. It was prescribed to treat nausea during pregnancy, but unfortunately only the (+) enantiomer was safe for that purpose. The (–) enantiomer was discovered to be a relatively potent *teratogen*, a substance that causes birth defects, which caused the children of many women who had taken thalidomide to be born with missing or undeveloped limbs. As a result, thalidomide was quickly banned for this use. It is currently used to treat leprosy, however, and it has also shown promise as a treatment for AIDS (acquired immunodeficiency syndrome).

These examples dramatically illustrate the point that the biological activities of enantiomers may be very different. But how can two molecules that differ only by being nonsuperimposable mirror images cause such different responses? The biological effects of many substances—including molecules such as carvone that have a scent and drugs such as ibuprofen and thalidomide—depend on their interaction with chiral sites on specific receptor proteins. As schematically illustrated in [Figure 23.2.8](#), only one enantiomer of a chiral substance interacts with a particular receptor, thereby initiating a response. The other enantiomer may not bind at all, or it may bind to *another* receptor, producing a different response.

Figure 23.2.8 The Interaction of Chiral Molecules with Biological Receptors Only one enantiomer of a chiral molecule fits into a chiral receptor site, which typically is a small portion of a large protein. The binding of a molecule to its receptor elicits a characteristic response. The other enantiomer cannot fit into the same site and thus elicits no response. It may, however, produce a different response by binding to another site.

Summary

Isomers are different compounds that have the same molecular formula. For an organic compound, rotation about a σ bond can produce different three-dimensional structures called **conformational isomers (or conformers)**. In a Newman projection, which represents the view along a C–C axis, the eclipsed conformation has the C–H bonds on adjacent carbon atoms parallel to each other and in the same plane, representing one conformational extreme. In the staggered conformation, the opposite extreme, the hydrogen atoms are as far from one another as possible. Electrostatic repulsions are minimized in the staggered conformation. **Structural isomers** differ in the connectivity of the atoms. Structures that have the same connectivity but whose components differ in their orientations in space are called **stereoisomers**. Stereoisomers can be geometric isomers, which differ in the placement of substituents in a rigid molecule, or optical isomers, nonsuperimposable mirror images. Molecules that are nonsuperimposable mirror images are chiral molecules. A molecule and its nonsuperimposable mirror image are called enantiomers. These differ in their interaction with plane-polarized light, light that oscillates in only one direction. A compound is optically active if its solution rotates plane-polarized light in only one direction and optically inactive if its rotations cancel to produce no net rotation. A clockwise rotation is called dextrorotatory and is indicated in the compound's name by (+), whereas a counterclockwise rotation is called levorotatory, designated by (–). The **specific rotation** is the amount (in degrees) by which the plane of polarized light is rotated when light is passed through a solution containing 1.0 g of solute per 1.0 mL of solvent in a tube 10.0 cm long. A solution that contains equal concentrations of each enantiomer in a pair is a racemic mixture; such solutions are optically inactive.

Key Takeaways

- Isomers can be conformational or structural.
- Stereoisomers have the same connectivity but can be optical or geometric isomers.

Conceptual Problems

1. What hybrid orbitals are used to form C–C bonds in saturated hydrocarbons? Describe the bond.
2. How are conformational isomers related? Sketch two conformational isomers of propane, looking along the C1–C2 axis.
3. Why do alkanes with more than two carbons have a kinked structure? Explain why a kinked structure is so stable.
4. Are *n*-pentane and 2-methylbutane conformational isomers or structural isomers? How would you separate these compounds from a mixture of the two?
5. How are structural isomers different from stereoisomers? Do stereoisomers have free rotation about all carbon–carbon bonds? Explain your answers.
6. Which of these objects is chiral?
 - a. a shoe

- b. a laced football
 - c. an automobile
 - d. a fork
7. Which of these objects is chiral?
- a. a rollerblade
 - b. an unmarked baseball bat
 - c. a bicycle
 - d. your arms
 - e. a spoon
8. Are all stereoisomers also enantiomers? Are all enantiomers stereoisomers? Explain your answers.

Answers

1. sp^3 ; it is a σ bond that is cylindrically symmetrical (all cross sections perpendicular to the internuclear axis are circles).
2. 3
3. The sp^3 hybridized orbitals form bonds at tetrahedral angles (109.5°), which forces the carbon atoms to form a zigzag chain.
- 4.
- 5.
- 6.
7. (a), (c), and (d)
- 8.

Structure and Reactivity

1. Single bonds between carbon atoms are free to rotate 360° .
 - a. Explain what happens to the potential energy of an *n*-hexane molecule as rotation occurs around the C2–C3 bond.
 - b. Draw Newman projections of the *n*-hexane conformations corresponding to the energy minima and maxima in the diagram, which shows potential energy versus degrees of rotation about the C3–C4 axis.

2. Sketch all the structural isomers of each compound.
 - a. $C_6H_{13}Br$
 - b. $C_3H_6Cl_2$
3. Draw all the possible structural isomers of each compound.
 - a. $C_5H_{11}Br$
 - b. $C_4H_8Cl_2$
4. Sketch all the isomers of each compound. Identify the *cis*- and *trans*-isomers.
 - a. monochlorobutene
 - b. bromochloropropene
5. Which molecules are chiral? On the structural formulas of the chiral molecules, identify any chiral centers with an asterisk.
 - a. 2,2-dimethylpentane
 - b. 1,2-dimethylpentane
 - c. 2,4-dimethylpentane
 - d. 1-chloro-2-methylpentane
6. Which molecules are chiral? On the structural formulas of the chiral molecules, identify any chiral centers with an asterisk.
 - a. 1,1-dichloropropane
 - b. 1,2-dichloropropane
 - c. 1,3-dichloropropane
 - d. 1,1,2-trichloropropane
7. Draw the structures of the enantiomers of each compound.

- a. $\text{CH}_2\text{CHCHClBr}$
- b. 4-chloro-2-hexene
- c. methylethylpropylamine

8. Draw the structures of the enantiomers of each compound.

- a. 4-methyl-2-hexene
- b. methylethylhexylamine
- c. $\text{CH}_3\text{CH}_2\text{CH}(\text{CH}_3)\text{Cl}$

9. Draw the structures of the enantiomers of each compound.

- a.
- b.

10. Draw the structures of the enantiomers of each compound.

- a.
- b.
- c.

Learning Objective

- To understand the relationship between structure and reactivity for a series of related organic compounds.

Understanding why organic molecules react as they do requires knowing something about the structure and properties of the transient species that are generated during chemical reactions. Identifying transient intermediates enables chemists to elucidate reaction mechanisms, which often allows them to control the products of a reaction. In designing the synthesis of a molecule, such as a new drug, for example, chemists must be able to understand the mechanisms of intermediate reactions to maximize the yield of the desired product and minimize the occurrence of unwanted reactions. Moreover, by recognizing the common reaction mechanisms of simple organic molecules, we can understand how more complex systems react, including the much larger molecules encountered in biochemistry.

Nearly all chemical reactions, whether organic or inorganic, proceed because atoms or groups of atoms having a positive charge or a partial positive charge interact with atoms or groups of atoms having a negative charge or a partial negative charge. Thus when a bond in a hydrocarbon is cleaved during a reaction, identifying the transient species formed, some of which are charged, allows chemists to determine the mechanism and predict the products of a reaction.

Chemists often find that the reactivity of a molecule is affected by the degree of substitution of a carbon that is bonded to a functional group. These carbons are designated as *primary*, *secondary*, or *tertiary*. A primary carbon is bonded to only one other carbon and a functional group, a secondary carbon is bonded to two other carbons and a functional group, and a tertiary carbon is bonded to three other carbons and a functional group.

Reactive Intermediates

Cleaving a C–H bond can generate either C^+ and H^- , C^- and H^+ or C^- and H^+ , all of which are unstable and therefore highly reactive. The most common species formed is C^+ , which is called a carbocation (part (a) in [Figure 23.3.1](#)). A carbocation has only six valence electrons and is therefore electron deficient. It is an electrophile (from “electron” and the Greek suffix *phile*, meaning “loving”), which is a species that needs electrons to complete its octet. (Recall that electron-deficient compounds, such as those of the group 13 elements, act as Lewis acids in inorganic reactions.) In general, when a highly electronegative atom, such as Cl, is bonded to a carbocation, it draws electrons away from the carbon and destabilizes the positive charge. In contrast, alkyl groups and other species stabilize the positive charge by increasing electron density at the carbocation. Thus a tertiary carbocation (R_3C^+) is more stable than a primary carbocation (RCH_2^+).

Note the Pattern

The reactivity of a molecule is often affected by the degree of substitution of the carbon bonded to a functional group.

Adding one electron to a carbocation produces a neutral species called a radical. (For more information on radicals, see [Section 15.6](#)) An example is the methyl radical ($\cdot\text{CH}_3$), shown in part (b) in [Figure 23.3.1](#). Because the carbon still has less than an octet of electrons, it is electron deficient and also behaves as an electrophile. Like carbocations, radicals can be stabilized by carbon substituents that can donate some electron density to the electron-deficient carbon center. Like carbocations, a tertiary radical ($\text{R}_3\text{C}\cdot$) is more stable than a primary radical ($\text{RCH}_2\cdot$).

Figure 23.3.1 Transient Intermediates in Organic Reactions (a) The simplest carbocation is the methyl cation (CH_3^+), which has six valence electrons and is an electrophile. Its structure is trigonal planar, with an sp^2 hybridized carbon and a vacant p orbital. (b) The methyl radical ($\cdot\text{CH}_3$) is a radical that, like the carbocation, is trigonal planar and an electrophile. It is also sp^2 hybridized, but there is a single electron in the unhybridized p orbital. (c) The simplest organic carbanion is CH_3^- , which has a trigonal pyramidal structure with an sp^3 hybridized carbon that has a lone pair of electrons. Because it has a strong tendency to share its lone pair with another atom or molecule, a carbanion is a nucleophile.

Adding an electron to a radical produces a carbanion, which contains a negatively charged carbon with eight valence electrons (part (c) in [Figure 23.3.1](#)). The methyl anion (CH_3^-) has a structure that is similar to NH_3 with its lone pair of electrons, but it has a much stronger tendency to share its lone pair with another atom or molecule. A carbanion is a nucleophile (from “nucleus” and *phile*), an electron-rich species that has a pair of electrons available to share with another atom. Carbanions are destabilized by groups that donate electrons, so the relationship between their structure and reactivity is exactly the opposite of carbocations and radicals. That is, a tertiary carbanion (R_3C^-) is less stable than a primary carbanion (RCH_2^-). Carbanions are most commonly encountered in organometallic compounds such as methyllithium (CH_3Li) or methylmagnesium chloride (CH_3MgCl), where the more electropositive metal ion stabilizes the negative charge on the more electronegative carbon atom.

Electrophiles such as carbocations seek to gain electrons and thus have a strong tendency to react with nucleophiles, which are negatively charged species or substances with lone pairs of electrons. Reacting electrophiles with nucleophiles is a central theme in organic reactions.

Note the Pattern

Electrophiles react with nucleophiles.

Example 23.3.1

Classify each species as an electrophile, a nucleophile, or neither.

1. BF_3
2. CH_4
3. $(\text{CH}_3)_3\text{C}^+$
4. NH_2^-

Given: molecular formulas

Asked for: mode of reactivity

Strategy:

Determine whether the compound is electron deficient, in which case it is an electrophile; electron rich, in which case it is a nucleophile; or neither.

Solution:

1. The BF_3 molecule is a neutral compound that contains a group 13 element with three bonds to B. The boron atom has only six valence electrons, so it tends to accept an electron pair. The compound is therefore an electrophile.
2. The CH_4 molecule has four bonds to C, which is typical of a neutral group 14 compound. The carbon atom has no lone pairs to share and no tendency to gain electrons, and each hydrogen atom forms one bond that contains two valence electrons. Thus CH_4 is neither an electrophile nor a nucleophile.
3. The $(\text{CH}_3)_3\text{C}^+$ cation contains a group 14 atom (carbon) with only three bonds. It therefore has only six valence electrons and seeks electrons to complete an octet. Hence $(\text{CH}_3)_3\text{C}^+$, a carbocation, is an electrophile.
4. The NH_2^- anion contains a group 15 element with a lone pair of electrons, two bonds, and a negative charge, giving N a total of eight electrons. With its negative charge, the N atom has two lone pairs of electrons, making it a potent nucleophile.

Exercise

Classify each compound as an electrophile, a nucleophile, or neither.

1. $\text{C}_6\text{H}_5\text{OH}$
2. AlBr_3
3. $(\text{CH}_3)_4\text{C}$

Answer:

1. nucleophile
2. electrophile
3. neither

Summary

The reactivity of a molecule is often affected by the degree of substitution of the carbon bonded to a functional group; the carbon is designated as primary, secondary, or tertiary. Identifying the transient species formed in a chemical reaction, some of which are charged, enables chemists to predict the mechanism and products of the reaction. One common transient species is a **carbocation**, a carbon with six valence electrons that is an **electrophile**; that is, it needs electrons to complete its octet. A **radical** is a transient species that is neutral but electron deficient and thus acts as an electrophile. In contrast, a **carbanion** has eight valence electrons and is negatively charged. It is an electron-rich species that is a **nucleophile** because it can share a pair of electrons. In chemical reactions, electrophiles react with nucleophiles.

Key Takeaway

- Electrophiles have a strong tendency to react with nucleophiles.

Conceptual Problems

1. Arrange CH_2F^+ , CHCl_2^+ , CH_3^+ , and CHF_2^+ in order of increasing stability. Explain your reasoning.
2. Arrange CH_3CH_2^- , CHBr_2^- , CH_3^- , and CHBrCl^- in order of decreasing stability. Explain your reasoning.

3. Identify the electrophile and the nucleophile in each pair.
 - a. CH_3^- and Li^+
 - b. CH_3O^- and formaldehyde
 - c. H^+ and propene
 - d. benzene and Cl^-
4. Identify the electrophile and the nucleophile in each pair.
 - a. CH_3^- and Br^+
 - b. $\text{HC}\equiv\text{CNa}$ and pentanal
 - c. acetone and CN^-
 - d. $(\text{CH}_3)_2\text{S}$ and CH_3I

Answers

1. $\text{CHF}_2^+ < \text{CHCl}_2^+ < \text{CH}_2\text{F}^+ < \text{CH}_3^+$; electronegative substituents destabilize the positive charge. The greater the number of electronegative substituents and the higher their electronegativity, the more unstable the carbocation.
- 2.
3.
 - a. CH_3^- , nucleophile; Li^+ , electrophile
 - b. CH_3O^- , nucleophile; formaldehyde, electrophile
 - c. H^+ , electrophile; propene, nucleophile
 - d. benzene, electrophile; Cl^- , nucleophile
- 4.

Structure and Reactivity

1. Draw Lewis electron structures of the products of carbon–hydrogen cleavage reactions. What is the charge on each species?
2. Identify the electrophile and the nucleophile in each reaction; then complete each chemical equation.
 - a. $\text{CH}_3^- + \text{Cl}^+ \rightarrow$
 - b. $\text{CH}_3\text{CH}=\text{CH}_2 + \text{HBr} \rightarrow$
 - c. $(\text{CH}_3)_3\text{N} + \text{BCl}_3 \rightarrow$

Learning Objective

- To become familiar with the common classes of organic reactions.

Certain patterns are encountered repeatedly in organic reactions, many reflecting the interactions of nucleophiles and electrophiles. In this section, we discuss five common types of organic reactions: substitution reactions, elimination reactions, addition reactions, radical reactions, and oxidation–reduction reactions. You have encountered many of these types of reactions previously, such as the formation of peptides by the elimination of water, the oxidation–reduction reactions that generate voltage in batteries, and chain reactions that involve organic radicals. (For more information on peptide formation, see [Section 12.8](#). For more information on batteries, see [Chapter 19](#). For more information on radicals, see [Section 14.6](#).) In this section, we expand our discussion to include some of the mechanisms behind these reactions.

Substitution

In a substitution reaction, one atom or a group of atoms in a substance is replaced by another atom or group of atoms from another substance. A typical substitution reaction is reacting the hydroxide ion with methyl chloride:

Methyl chloride has a polar C–Cl bond, with the carbon atom having a partial positive charge. In [Equation 24.1](#), the electronegative Cl atom is replaced by another electronegative species that is a stronger nucleophile, in this case OH^- . Reactions of this sort are called *nucleophilic substitution reactions*. For this type of reaction to occur, the nucleophilic reactant must possess a pair of electrons and have a greater affinity for the electropositive carbon atom than the original substituent.

One type of nucleophilic substitution reaction is shown in [Equation 24.1](#). It proceeds by a mechanism in which the lone pair of electrons on the entering nucleophile (OH^-) attacks the partially positively charged carbon atom of the polar C–Cl bond, causing the C–Cl bond to weaken and break:

Figure 23.4.1

Note the Pattern

In nucleophilic substitution reactions, the nucleophile must possess a pair of electrons and have a greater affinity for the electropositive species than the original substituent.

The convention for writing such a mechanism is to draw arrows showing the direction of electron flow—that is, from the electron-rich center (the nucleophile) to the electron-poor center (the electrophile). The intermediate species, enclosed by square brackets, represents a transient arrangement of atoms that is only postulated to exist. If the atom under attack (in this case, the partially positively charged carbon atom) had $-\text{CH}_3$ groups bonded to it rather than H atoms, the bulky methyl groups would interfere with the attack by OH^- , making the reaction *sterically hindered*. The reaction would then proceed in two discrete steps in a second type of substitution reaction: the $\text{C}-\text{Cl}$ bond would break, forming the $(\text{CH}_3)_3\text{C}^+$ carbocation (the electrophile), which would then react with hydroxide (the nucleophile) in a separate step to give the product, $(\text{CH}_3)_3\text{COH}$.

An example of a nucleophilic substitution reaction involves the chemical warfare agent known as *mustard gas* $[(\text{ClCH}_2\text{CH}_2)_2\text{S}]$, which caused about 400,000 casualties during World War I. Mustard gas is toxic because it contains a chloride that can be displaced by nucleophilic amino groups in proteins, thereby allowing the molecule to irreversibly bond to a protein. Because the other product of the reaction is HCl , mustard gas causes severe burns to mucous membranes in the respiratory tract. If mustard gas reacts with DNA (deoxyribonucleic acid), cross-linking of the DNA strands through sulfur occurs, which results in coding errors, the inhibition of replication, and disruption of other DNA functions. If mustard gas reacts with RNA (ribonucleic acid), protein synthesis is altered (see [Section 22.6](#)).

Mustard gas.

Elimination

Some reactions involve the removal, or “elimination,” of adjacent atoms from a molecule. This results in the formation of a multiple bond and the release of a small molecule, so they are called elimination reactions. They have the general form

Figure 23.4.2

and are similar to cleavage reactions in inorganic compounds. (For more information on cleavage reactions, see [Section 7.5](#).) A typical example is the conversion of ethyl chloride to ethylene:

Note the Pattern

Elimination reactions are similar to cleavage reactions in inorganic compounds.

Much of the approximately 26 million tons of ethylene produced per year in the United States is used to synthesize plastics, such as polyethylene. In [Equation 23.4.2](#), the $\text{A}-\text{B}$ molecule eliminated is HCl , whose components are eliminated as H^+ from the carbon atom on the left and Cl^- from the carbon on the right. When an acid is produced, as occurs here, the reaction is generally carried out in the presence of a base (such as NaOH) to neutralize the acid.

Addition

A reaction in which the components of a species $\text{A}-\text{B}$ are added to adjacent atoms across a carbon-carbon multiple bond is called an addition reaction. An example is the reverse of the reaction shown in [Equation 23.4.2](#), reacting HCl with ethylene to give ethyl chloride:

Note the Pattern

An addition reaction is the reverse of an elimination reaction.

Although a multiple bond is stronger than a single bond, the π bonds of the multiple bond are weaker than the σ bond. The high electron density located between multiply bonded carbon atoms, however, causes alkenes and alkynes to behave like nucleophiles, where nucleophilic attack occurs from the more weakly bound π electrons. Hence alkenes and alkynes are regarded as functional groups. Nucleophilic attack occurs on the $\text{H}^{\delta+}$ atom of the polar HCl bond, initially producing a species with a carbon that has only three bonds, a carbocation. In a second nucleophilic attack, Cl^- , the electrophile in [Equation 23.4.3](#) attacks the carbocation:

Alcohols, an important class of organic compounds, are often produced by addition reactions. Initial attack by the π bond of an alkene on a $\text{H}^{\delta+}$ of H_3O^+ produces a carbocation. The carbocation then undergoes nucleophilic attack by a lone pair of electrons from H_2O followed by elimination of H^+ to form the alcohol.

Radical Reactions

Many important organic reactions involve radicals, such as the combustion of fuels. Probably the best known is reacting a saturated hydrocarbon, such as ethane, with a halogen, such as Br_2 . The overall reaction is as follows:

Radical chain reactions occur in three stages: *initiation*, *propagation*, and *termination*. (For more information on radicals, see [Section 14.6](#).) At high temperature or in the presence of light, the relatively weak $\text{Br}-\text{Br}$ bond is broken in an initiation step that produces an appreciable number of $\text{Br}\cdot$ atoms. During propagation, a bromine atom attacks ethane, producing a radical, which then reacts with another bromine molecule to produce ethyl bromide:

The sum of the two propagation steps corresponds to the balanced chemical equation for the overall reaction. There are three possible termination steps: the combination of (1) two bromine atoms, (2) two ethyl radicals, or (3) an ethyl and a bromine radical:

Because radicals are powerful nucleophiles and hence highly reactive, such reactions are not very selective. For example, the chlorination of *n*-butane gives a roughly 70:30 mixture of 2-chlorobutane, formed from the more stable radical by reacting a secondary carbon and 1-chlorobutane.

Note the Pattern

Because radicals are highly reactive, radical reactions are usually not very selective.

Oxidation–Reduction Reactions

Oxidation–reduction reactions, which are common in organic chemistry, can often be identified by changes in the number of oxygen atoms at a particular position in the hydrocarbon skeleton or in the number of bonds between carbon and oxygen at that position. An increase in either corresponds to an oxidation, whereas a decrease corresponds to a reduction. Conversely, an increase in the number of hydrogen atoms in a hydrocarbon is often an indication of a reduction. We can illustrate these points by considering how the oxidation state of the carbon atom changes in the series of compounds, which is shown in part (a) in [Figure 23.4.3](#). (For a review of oxidation states and formal charges, see [Section 7.5](#), and [Section 8.10](#).) The number of oxygen atoms or the number of bonds to oxygen changes throughout the series. Hence the conversion of methane to formic acid is an oxidation,

whereas the conversion of carbon dioxide to methanol is a reduction. Also, the number of hydrogen atoms increases in going from the most oxidized to least oxidized compound. As expected, as the oxidation state of carbon increases, the carbon becomes a more potent electrophile. Thus the carbon of CO_2 is a stronger electrophile (i.e., more susceptible to nucleophilic attack) than the carbon of an alkane such as methane.

	OXIDATION				
Functional group:	$\text{R}_3\text{C}-\text{H}$	$\text{R}_3\text{C}-\text{OH}$	$\text{R}_2\text{C}=\text{O}$	RCO_2H	$\text{O}=\text{C}=\text{O}$
	Alkane	Alcohol	Carbonyl	Carboxylic acid	Carbon dioxide
Oxidation state of carbon:	-4	-2	0	+2	+4
	← REDUCTION				
(a) Oxygen-containing organic compounds					

	OXIDATION		
Functional group:	$\text{R}_3\text{C}-\text{NH}_2$	$\text{R}_2\text{C}=\text{NH}$	$\text{RC}\equiv\text{N}$
	Amine	Imine	Nitrile
Oxidation state of carbon:	-2	0	+2
	← REDUCTION		
(b) Nitrogen-containing organic compounds			

Figure 23.4.3 The Oxidation State of Carbon in Oxygen- and Nitrogen-Containing Functional Groups (a) In a hydrocarbon, oxidation is indicated by an increase in the number of oxygen atoms or carbon–oxygen bonds or a decrease in the number of hydrogen atoms. (b) In nitrogen-containing compounds, the number of carbon–nitrogen bonds changes with the oxidation state of carbon.

Similarly, in compounds with a carbon–nitrogen bond, the number of bonds between the C and N atoms increases as the oxidation state of the carbon increases (part (b) in Figure 23.4.3). In a nitrile, which contains the $-\text{C}\equiv\text{N}$ group, the carbon has the same oxidation state (+2) as in a carboxylic acid, characterized by the $-\text{CO}_2\text{H}$ group. We therefore expect the carbon of a nitrile to be a rather strong electrophile.

Example 23.4.1

Write an equation to describe each reaction. Identify the electrophile and the nucleophile in each reaction.

- the nucleophilic substitution reaction of potassium cyanide with 1-chloropropane to give $\text{CH}_3\text{CH}_2\text{CH}_2\text{CN}$ (butyronitrile)
- the electrophilic addition reaction of HBr with *cis*-2-butene

Given: reactants, products, and reaction mechanism

Asked for: equation and identification of electrophile and nucleophile

Strategy:

Use the mechanisms described to show how the indicated products are formed from the reactants.

Solution:

- The CN^- ion of KCN is a potent nucleophile that can displace the chlorine atom of 1-chloropropane, releasing a chloride ion. Substitution results in the formation of a new C–C bond:

The carbon bonded to chlorine is an electrophile because of the highly polar C–Cl bond.

- In the electrophilic addition of a hydrogen halide to an alkene, the reaction is as follows:

The first step is nucleophilic attack of the π electrons of the double bond on the electrophilic hydrogen of the polar H–Br bond to generate the transient carbocation, followed by nucleophilic attack by the halide to give the product. Thus the alkene is the nucleophile, and the proton of the acid is the electrophile.

Exercise

Write an equation to describe each reaction. In each reaction, identify the electrophile and nucleophile.

- the nucleophilic substitution reaction of sodium methoxide (NaOCH_3) with benzyl bromide ($\text{C}_6\text{H}_5\text{CH}_2\text{Br}$)
- the acid-catalyzed electrophilic addition reaction of water with cyclopentene

Answer:

1. OCH_3^- (methoxide ion) + $\text{C}_6\text{H}_5\text{CH}_2\text{Br}$ (benzyl bromide) \rightarrow $\text{C}_6\text{H}_5\text{CH}_2\text{OCH}_3$ (benzylmethyl ether) + Br^- ; OCH_3^- is the nucleophile, and $\text{C}_6\text{H}_5\text{CH}_2\text{Br}$ is the electrophile.

2.

Cyclopentene is the nucleophile, and H_3O^+ is the electrophile.

Summary

There are common patterns to how organic reactions occur. In a **substitution reaction**, one atom or a group of atoms in a substance is replaced by another atom or a group of atoms from another substance. Bulky groups that prevent attack cause the reaction to be sterically hindered. In an **elimination reaction**, adjacent atoms are removed with subsequent formation of a multiple bond and a small molecule. An **addition reaction** is the reverse of an elimination reaction. Radical reactions are not very selective and occur in three stages: initiation, propagation, and termination. **Oxidation–reduction reactions** in organic chemistry are identified by the change in the number of oxygens in the hydrocarbon skeleton or the number of bonds between carbon and oxygen or carbon and nitrogen.

Key Takeaway

- The common classes of organic reactions—substitution, elimination, addition, oxidation-reduction, and radical—all involve reacting electrophiles with nucleophiles.

Conceptual Problems

- Identify the nucleophile and the electrophile in the nucleophilic substitution reaction of 2-bromobutane with KCN.
- Identify the nucleophile and the electrophile in the nucleophilic substitution reaction of 1-chloropentane with sodium methoxide.
- Do you expect an elimination reaction to be favored by a strong or a weak base? Why?
- Why do molecules with π bonds behave as nucleophiles when mixed with strong electrophiles?

Answer –

1. CN^- is the nucleophile, and $\text{C}_2\text{H}_5\text{C}^{\delta+}\text{HBrCH}_3$ is the electrophile.
- 2.
- 3.
- 4.

Structure and Reactivity

1. Sketch the mechanism for the nucleophilic substitution reaction of potassium cyanide with iodoethane.
2. Sketch the mechanism for the nucleophilic substitution reaction of NaSH with 1-bromopropane.
3. Sketch the mechanism for the elimination reaction of cyclohexylchloride with potassium ethoxide. Identify the electrophile and the nucleophile in this reaction.
4. What is the product of the elimination reaction of 1-bromo-2-methylpropane with sodium ethoxide?
5. Write the structure of the product expected from the electrophilic addition of HBr to *cis*-3-hexene.
6. Write the structure of the product expected from the electrophilic addition of 1-methylcyclopentene to HBr. Identify the electrophile and the nucleophile, and then write a mechanism for this reaction.
7. Write a synthetic scheme for making propene from propane. After synthesizing propene, how would you make 2-bromopropane?
8. Write a synthetic scheme for making ethylene from ethane. After synthesizing ethylene, how would you make iodoethane?
9. From the high-temperature reaction of Br_2 with 3-methylpentane, how many monobrominated isomers would you expect to be produced? Which isomer is produced from the most stable radical?
10. For the photochemical reaction of Cl_2 with 2,4-dimethylpentane, how many different monochlorinated isomers would you expect to be produced? Which isomer is produced from the most stable precursor radical?
11. How many different radicals can be formed from the photochemical reaction of Cl_2 with 3,3,4-trimethylhexane?
12. How many monobrominated isomers would you expect from the photochemical reaction of Br_2 with
 - a. isobutene?
 - b. 2,2,3-trimethylpentane?
13. Arrange acetone, ethane, carbon dioxide, acetaldehyde, and ethanol in order of increasing oxidation state of carbon.
14. What product(s) do you expect from the reduction of a ketone? the oxidation of an aldehyde?
15. What product(s) do you expect from the reduction of formaldehyde? the oxidation of ethanol?

Answers

- 1.
- 2.
- 3.
- 4.
- 5.
- 6.
- 7.
- 8.
9. four; 3-bromo-3-methylpentane
- 10.
11. seven
- 12.
- 13.
- 14.
15. methanol; acetaldehyde, followed by acetic acid and finally CO_2

Learning Objective

- To understand the general properties of functional groups and the differences in their reactivity.

The general properties and reactivity of each class of organic compounds (Figure 23.1.1) is largely determined by its functional groups. In this section, we describe the relationships between structure, physical properties, and reactivity for the major classes of organic compounds. We also show you how to apply these relationships to understand some common reactions that chemists use to synthesize organic compounds.

Alkanes, Alkenes, and Alkynes

The boiling points of alkanes increase smoothly with increasing molecular mass. They are similar to those of the corresponding alkenes and alkynes because of similarities in molecular mass between analogous structures (Table 23.5.1). In contrast, the melting points of alkanes, alkenes, and alkynes with similar molecular masses show a much wider variation because the melting point strongly depends on how the molecules stack in the solid state. It is therefore sensitive to relatively small differences in structure, such as the location of a double bond and whether the molecule is *cis* or *trans*.

Table 23.5.1 Boiling Points (in °C) of Alkanes, Alkenes, and Alkynes of Comparable Molecular Mass

Class	Length of Carbon Chain		
	Two C Atoms	Three C Atoms	Four C Atoms
alkane	-88.6	-42.1	-0.5
alkene	-103.8	-47.7	-6.3
alkyne	-84.7	-23.2	8.1

Because alkanes contain only C–C and C–H bonds, which are strong and not very polar (the electronegativities of C and H are similar; Figure 3.3.9), they are not easily attacked by nucleophiles or electrophiles. Consequently, their reactivity is limited, and often their reactions occur only under extreme conditions. For example, *catalytic cracking* can be used to convert straight-chain alkanes to highly branched alkanes, which are better fuels for internal combustion engines. Catalytic cracking is one example of a pyrolysis reaction (from the Greek *pyros*, meaning “fire,” and *lysis*, meaning “loosening”), in which alkanes are heated to a sufficiently high temperature to induce cleavage of the weakest bonds: the C–C single bonds. The result is a mixture of radicals derived from essentially random cleavage of the various C–C bonds in the chain. Pyrolysis of *n*-pentane, for example, is nonspecific and can produce these four radicals:

Recombination of these radicals (a termination step) can produce ethane, propane, butane, *n*-pentane, *n*-hexane, *n*-heptane, and *n*-octane. Radicals that are formed in the middle of a chain by cleaving a C–H bond tend to produce branched hydrocarbons. In catalytic cracking, lighter alkanes are removed from the mixture by distillation.

Radicals are also produced during the combustion of alkanes, with CO_2 and H_2O as the final products. As discussed in [Section 23.3](#) radicals are stabilized by the presence of multiple carbon substituents that can donate electron density to the electron-deficient carbon. The chemical explanation of octane ratings rests partly on the stability of radicals produced from the different hydrocarbon fuels. Recall that *n*-heptane, which does not burn smoothly, has an octane rating of 0, and 2,2,4-trimethylpentane (“isooctane”), which burns quite smoothly, has a rating of 100. Isooctane has a branched structure and is capable of forming tertiary radicals that are comparatively stable.

In contrast, the radicals formed during the combustion of *n*-heptane, whether primary or secondary, are less stable and hence more reactive, which partly explains why burning *n*-heptane causes premature ignition and engine knocking.

In [Section 23.2](#), we explained that rotation about the carbon–carbon multiple bonds of alkenes and alkynes cannot occur without breaking a π bond, which therefore constitutes a large energy barrier to rotation ([Figure 23.5.1](#)). Consequently, the *cis* and *trans* isomers of alkenes generally behave as distinct compounds with different chemical and physical properties. A four-carbon alkene has four possible isomeric forms: three structural isomers, which differ in their connectivity, plus a pair of geometric isomers from one structural isomer (2-butene). These two geometric isomers are *cis*-2-butene and *trans*-2-butene. The four isomers have significantly different physical properties.

Figure 23.5.1 Carbon–Carbon Bonding in Alkenes and Interconversion of *Cis* and *Trans* Isomers In butane, there is only a small energy barrier to rotation about the C2–C3 σ bond. In the formation of *cis*- or *trans*-2-butene from butane, the *p* orbitals on C2 and C3 overlap to form a π bond. To convert *cis*-2-butene to *trans*-2-butene or vice versa through rotation about the double bond, the π bond must be broken. Because this interconversion is energetically unfavorable, *cis* and *trans* isomers are distinct compounds that generally have different physical and chemical properties.

Alkynes in which the triple bond is located at one end of a carbon chain are called *terminal alkynes* and contain a hydrogen atom attached directly to a triply bonded carbon: $\text{R}-\text{C}\equiv\text{C}-\text{H}$. Terminal alkynes are unusual in that the hydrogen atom can be removed relatively easily as H^+ , forming an *acetylide ion* ($\text{R}-\text{C}\equiv\text{C}^-$). Acetylide ions are potent nucleophiles that are especially useful reactants for making longer carbon chains by a nucleophilic substitution reaction. As in earlier examples of such reactions, the nucleophile attacks the partially positively charged atom in a polar bond, which in the following reaction is the carbon of the Br–C bond:

Alkenes and alkynes are most often prepared by elimination reactions ([Figure 23.4.2](#)). A typical example is the preparation of 2-methyl-1-propene, whose derivative, 3-chloro-2-methyl-1-propene, is used as a fumigant and insecticide. The parent compound can be prepared from either 2-hydroxy-2-methylpropane or 2-bromo-2-methylpropane:

The reaction on the left proceeds by eliminating the elements of water (H^+ plus OH^-), so it is a dehydration reaction. If an alkane contains two properly located functional groups, such as $-\text{OH}$ or $-\text{X}$, both of them may be removed as H_2O or HX with the formation of a carbon-carbon triple bond:

Note the Pattern

Alkenes and alkynes are most often prepared by elimination reactions.

Arenes

Most arenes that contain a single six-membered ring are volatile liquids, such as benzene and the xylenes, although some arenes with substituents on the ring are solids at room temperature. In the gas phase, the dipole moment of benzene is zero, but the presence of electronegative or electropositive substituents can result in a net dipole moment that increases intermolecular attractive forces and raises the melting and boiling points. For example, 1,4-dichlorobenzene, a compound used as an alternative to naphthalene in the production of mothballs, has a melting point of 52.7°C , which is considerably greater than the melting point of benzene (5.5°C). (For more information on 1,4-dichlorobenzene, see [Section 11.5](#).)

Certain aromatic hydrocarbons, such as benzene and benz[a]pyrene, are potent liver toxins and carcinogens. In 1775, a British physician, Percival Pott, described the high incidence of cancer of the scrotum among small boys used as chimney sweeps and attributed it to their exposure to soot. His conclusions were correct: benz[a]pyrene, a component of chimney soot, charcoal-grilled meats, and cigarette smoke, was the first chemical carcinogen to be identified.

Although arenes are usually drawn with three $\text{C}=\text{C}$ bonds, benzene is about 150 kJ/mol more stable than would be expected if it contained three double bonds. This increased stability is due to the delocalization of the π electron density over all the atoms of the ring. (For more information on delocalization, see [Section 6.5](#)) Compared with alkenes, arenes are poor nucleophiles. Consequently, they do not undergo addition reactions like alkenes; instead, they undergo a variety of electrophilic aromatic substitution reactions that involve the replacement of $-\text{H}$ on the arene by a group $-\text{E}$, such as $-\text{NO}_2$, $-\text{SO}_3\text{H}$, a halogen, or an alkyl group, in a two-step process. The first step involves addition of the electrophile (E) to the π system of benzene, forming a carbocation. In the second step, a proton is lost from the adjacent carbon on the ring:

The carbocation formed in the first step is stabilized by resonance.

Note the Pattern

Arenes undergo substitution reactions rather than elimination because of increased stability arising from delocalization of their π electron density.

Many substituted arenes have potent biological activity. Some examples include common drugs and antibiotics such as aspirin and ibuprofen, illicit drugs such as amphetamines and peyote, the amino acid phenylalanine, and hormones such as adrenaline (Figure 23.5.2).

Figure 23.5.2 Biologically Active Substituted Arenes Aspirin (antifever activity), ibuprofen (antifever and anti-inflammatory activity), and amphetamine (stimulant) have pharmacological effects. Phenylalanine is an amino acid. Adrenaline is a hormone that elicits the “fight or flight” response to stress. Chiral centers are indicated with an asterisk.

Alcohols and Ethers

Both alcohols and ethers can be thought of as derivatives of water in which at least one hydrogen atom has been replaced by an organic group, as shown here. Because of the electronegative oxygen atom, the individual O–H bond dipoles in alcohols cannot cancel one another, resulting in a substantial dipole moment that allows alcohols to form hydrogen bonds. Alcohols therefore have significantly higher boiling points than alkanes or alkenes of comparable molecular mass, whereas ethers, without a polar O–H bond, have intermediate boiling points due to the presence of a small dipole moment (Table 23.5.2). The larger the alkyl group in the molecule, however, the more “alkane-like” the alcohol is in its properties. Because of their polar nature, alcohols and ethers tend to be good solvents for a wide range of organic compounds.

Table 23.5.2 Boiling Points of Alkanes, Ethers, and Alcohols of Comparable Molecular Mass

	Name	Formula	Molecular Mass (amu)	Boiling Point (°C)
alkane	propane	C ₃ H ₈	44	-42.1
	<i>n</i> -pentane	C ₅ H ₁₂	72	36.1
	<i>n</i> -heptane	C ₇ H ₁₆	100	98.4
ether	dimethylether	(CH ₃) ₂ O	46	-24.8
	diethylether	(CH ₃ CH ₂) ₂ O	74	34.5
	di- <i>n</i> -propylether	(CH ₃ CH ₂ CH ₂) ₂ O	102	90.1
alcohol	ethanol	CH ₃ CH ₂ OH	46	78.3
	<i>n</i> -butanol	CH ₃ (CH ₂) ₃ OH	74	117.7
	<i>n</i> -hexanol	CH ₃ (CH ₂) ₅ OH	102	157.6

Alcohols are usually prepared by adding water across a carbon–carbon double bond or by a nucleophilic substitution reaction of an alkyl halide using hydroxide, a potent nucleophile (Figure 23.4.1). As you will see in Section 23.6, alcohols can also be prepared by reducing compounds that contain the carbonyl functional group (C=O; part (a) in Figure 23.4.3). Alcohols are classified as primary, secondary, or tertiary, depending on whether the –OH group is bonded to a primary, secondary, or tertiary carbon. For example, the compound 5-methyl-3-hexanol is a secondary alcohol.

Ethers, especially those with two different alkyl groups (ROR'), can be prepared by a substitution reaction in which a nucleophilic alkoxide ion (RO⁻) attacks the partially positively charged carbon atom of the polar C–X bond of an alkyl halide (R'X):

Although both alcohols and phenols have an –OH functional group, phenols are 10^6 – 10^8 more acidic than alcohols. This is largely because simple alcohols have the –OH unit attached to an sp^3 hybridized carbon, whereas phenols have an sp^2 hybridized carbon atom bonded to the oxygen atom. The negative charge of the phenoxide ion can therefore interact with the π electrons in the ring, thereby delocalizing and stabilizing the negative charge through resonance. (For more information on resonance, see [Section 5.3](#).) In contrast, the negative charge on an alkoxide ion cannot be stabilized by these types of interactions.

Alcohols undergo two major types of reactions: those involving cleavage of the O–H bond and those involving cleavage of the C–O bond. Cleavage of an O–H bond is a reaction characteristic of an acid, but alcohols are even weaker acids than water. The acidic strength of phenols, however, is about a million times greater than that of ethanol, making the pK_a of phenol comparable to that of the NH_4^+ ion (9.89 versus 9.25, respectively):

Note the Pattern

Alcohols undergo two major types of reactions: cleavage of the O–H bond and cleavage of the C–O bond.

Cleavage of the C–O bond in alcohols occurs under acidic conditions. The –OH is first protonated, and nucleophilic substitution follows:

In the absence of a nucleophile, however, elimination can occur, producing an alkene ([Figure 23.4.2](#)).

Ethers lack the –OH unit that is central to the reactivity of alcohols, so they are comparatively unreactive. Their low reactivity makes them highly suitable as solvents for carrying out organic reactions.

Aldehydes and Ketones

Aromatic aldehydes, which have intense and characteristic flavors and aromas, are the major components of such well-known flavorings as vanilla and cinnamon ([Figure 23.5.3](#)). Many ketones, such as camphor and jasmine, also have intense aromas. Ketones are found in many of the hormones responsible for sex differentiation in humans, such as progesterone and testosterone. (For more information on the aqueous solubility of aldehydes and ketones, see [Section 8.1](#).)

Name	Formula	Use
Formaldehyde	CH_2O	Biological preservative
Cinnamaldehyde	$\text{C}_6\text{H}_5\text{CH}=\text{CHCHO}$	Cinnamon
Citral	$(\text{CH}_2)_2\text{C}=\text{CHCH}_2\text{CH}_2\text{C}(\text{CH}_3)=\text{CHCHO}$	Antiseptic, perfumes
Benzaldehyde	$\text{C}_6\text{H}_5\text{CHO}$	Manufacture of dyes, almond flavoring
Vanillin		Vanilla flavoring

Figure 23.5.3 Some Familiar Aldehydes and Their Uses

In compounds containing a carbonyl group, nucleophilic attack can occur at the carbon atom of the carbonyl, whereas electrophilic attack occurs at oxygen.

Aldehydes and ketones contain the carbonyl functional group, which has an appreciable dipole moment because of the polar $\text{C}=\text{O}$ bond. The presence of the carbonyl group results in strong intermolecular interactions that cause aldehydes and ketones to have higher boiling points than alkanes or alkenes of comparable molecular mass (Table 23.5.3). As the mass of the molecule increases, the carbonyl group becomes less important to the overall properties of the compound, and the boiling points approach those of the corresponding alkanes.

Table 23.5.3 Boiling Points of Alkanes, Aldehydes, and Ketones of Comparable Molecular Mass

	Name	Formula	Molecular Mass (amu)	Boiling Point ($^{\circ}\text{C}$)
alkane	<i>n</i> -butane	C_4H_{10}	58	-0.5
	<i>n</i> -pentane	C_5H_{12}	72	36.1
aldehyde	propionaldehyde (propanal)	$\text{C}_3\text{H}_6\text{O}$	58	48.0
	butyraldehyde (butanal)	$\text{C}_4\text{H}_8\text{O}$	72	74.8
ketone	acetone (2-propanone)	$\text{C}_3\text{H}_6\text{O}$	58	56.1
	methyl ethyl ketone (2-butanone)	$\text{C}_4\text{H}_8\text{O}$	72	79.6

Aldehydes and ketones are typically prepared by oxidizing alcohols (part (a) in Figure 23.5.1). In their reactions, the partially positively charged carbon atom of the carbonyl group is an electrophile that is subject to nucleophilic attack. Conversely, the lone pairs of electrons on the oxygen atom of the carbonyl group allow electrophilic attack to occur. Aldehydes and ketones can therefore undergo both nucleophilic attack (at the carbon atom) and electrophilic attack (at the oxygen atom).

Note the Pattern

Nucleophilic attack occurs at the partially positively charged carbon of a carbonyl functional group. Electrophilic attack occurs at the lone pairs of electrons on the oxygen atom.

Aldehydes and ketones react with many organometallic compounds that contain stabilized carbanions. One of the most important classes of such compounds are the Grignard reagents, organomagnesium compounds with the formula RMgX (X is Cl, Br, or I) that are so strongly polarized that they can be viewed as containing R^- and MgX^+ . These reagents are named for the French chemist Victor Grignard (1871–1935), who won a Nobel Prize in Chemistry in 1912 for their development. In a Grignard reaction, the carbonyl functional group is converted to an alcohol, and the carbon chain of the carbonyl compound is lengthened by the addition of the R group from the Grignard reagent. One example is reacting cyclohexylmagnesium chloride, a Grignard reagent, with formaldehyde:

The nucleophilic carbanion of the cyclohexyl ring attacks the electrophilic carbon atom of the carbonyl group. Acidifying the solution results in protonation of the intermediate to give the alcohol. Aldehydes can also be prepared by reducing a carboxylic acid group ($-\text{CO}_2\text{H}$) (part (a) in [Figure 23.4.3](#)), and ketones can be prepared by reacting a carboxylic acid derivative with a Grignard reagent. The former reaction requires a powerful reducing agent, such as a metal hydride.

Example 23.5.1

Explain how each reaction proceeds to form the indicated product.

1.

2.

Given: chemical reaction

Asked for: how products are formed

Strategy:

A Identify the functional group and classify the reaction.

B Use the mechanisms described to propose the initial steps in the reaction.

Solution:

1. **A** One reactant is an alcohol that undergoes a substitution reaction.

B In the product, a bromide group is substituted for a hydroxyl group. The first step in this reaction must therefore be protonation of the $-\text{OH}$ group of the alcohol by H^+ of HBr , followed by the elimination of water to give the carbocation:

The bromide ion is a good nucleophile that can react with the carbocation to give an alkyl bromide:

2. **A** One reactant is a Grignard reagent, and the other contains a carbonyl functional group. Carbonyl compounds act as electrophiles, undergoing nucleophilic attack at the carbonyl carbon.

B The nucleophile is the phenyl carbanion of the Grignard reagent:

The product is benzyl alcohol.

Exercise

Predict the product of each reaction.

Answer:

1.

2.

Carboxylic Acids

The pungent odors of many carboxylic acids are responsible for the smells we associate with sources as diverse as Swiss cheese, rancid butter, manure, goats, and sour milk. The boiling points of carboxylic acids tend to be somewhat higher than would be expected from their molecular masses because of strong hydrogen-bonding interactions between molecules. In fact, most simple carboxylic acids form dimers in the liquid and even in the vapor phase. (For more information on the vapor phase, see [Section 11.2](#).) The four lightest carboxylic acids are completely miscible with water, but as the alkyl chain lengthens, they become more “alkane-like,” so their solubility in water decreases.

Compounds that contain the carboxyl functional group are acidic because carboxylic acids can easily lose a proton: the negative charge in the carboxylate ion (RCO_2^-) is stabilized by delocalization of the π electrons:

As a result, carboxylic acids are about 10^{10} times more acidic than the corresponding simple alcohols whose anions (RO^-) are not stabilized through resonance.

Carboxylic acids are typically prepared by oxidizing the corresponding alcohols and aldehydes (part (a) in [Figure 23.4.2](#)). They can also be prepared by reacting a Grignard reagent with CO_2 , followed by acidification:

The initial step in the reaction is nucleophilic attack by the R^- group of the Grignard reagent on the electrophilic carbon of CO_2 :

Delocalization of π bonding over three atoms (O–C–O) makes carboxylic acids and their derivatives less susceptible to nucleophilic attack than aldehydes and ketones with their single π bond. The reactions of carboxylic acids are dominated by two factors: their polar $-\text{CO}_2\text{H}$ group and their acidity. Reaction with strong bases, for example, produce carboxylate salts, such as sodium stearate:

where R is $\text{CH}_3(\text{CH}_2)_{16}$. As you learned in [Section 13.6](#), long-chain carboxylate salts are used as soaps.

Note the Pattern

Delocalization of π bonding over three atoms makes carboxylic acids and their derivatives less susceptible to nucleophilic attack as compared with aldehydes and ketones.

Carboxylic Acid Derivatives

Replacing the $-\text{OH}$ of a carboxylic acid with groups that have different tendencies to participate in resonance with the $\text{C}=\text{O}$ functional group produces derivatives with rather different properties. Resonance structures have significant effects on the reactivity of carboxylic acid derivatives, but their influence varies substantially, being least important for halides and most important for the nitrogen of amides. In this section, we take a brief look at the chemistry of two of the most familiar and important carboxylic acid derivatives: esters and amides.

Esters

Esters have the general formula $\text{RCO}_2\text{R}'$, where R and R' can be virtually any alkyl or aryl group. Esters are often prepared by reacting an alcohol ($\text{R}'\text{OH}$) with a carboxylic acid (RCO_2H) in the presence of a catalytic amount of strong acid. (For more information on esters and catalysts, see [Section 7.5](#).) The purpose of the acid (an electrophile) is to protonate the doubly bonded oxygen atom of the carboxylic acid (a nucleophile) to give a species that is *more* electrophilic than the parent carboxylic acid.

The nucleophilic oxygen atom of the alcohol attacks the electrophilic carbon atom of the protonated carboxylic acid to form a new C–O bond. The overall reaction can be written as follows:

Figure 23.5.4

Because water is eliminated, this is a dehydration reaction. If an aqueous solution of an ester and strong acid or base is heated, the reverse reaction will occur, producing the parent alcohol $\text{R}'\text{OH}$ and either the carboxylic acid RCO_2H (under strongly acidic conditions) or the carboxylate anion RCO_2^- (under basic conditions).

As stated earlier, esters are familiar to most of us as fragrances, such as banana and pineapple. Other esters with intense aromas function as sex attractants, or *pheromones*, such as the pheromone from the oriental fruit fly. Research on using synthetic insect pheromones as a safer alternative to insecticides for controlling insect populations, such as cockroaches, is a rapidly growing field in organic chemistry.

Amides

In the general structure of an amide,

the two substituents on the amide nitrogen can be hydrogen atoms, alkyl groups, aryl groups, or any combination of those species. Although amides appear to be derived from an acid and an amine, in practice they usually cannot be prepared by this synthetic route. In principle, nucleophilic attack by the lone electron pair of the amine on the carbon of the carboxylic acid could occur, but because carboxylic acids are weak acids and amines are weak bases, an acid–base reaction generally occurs instead:

Amides are therefore usually prepared by the nucleophilic reaction of amines with more electrophilic carboxylic acid derivatives, such as esters.

The lone pair of electrons on the nitrogen atom of an amide can participate in π bonding with the carbonyl group, thus reducing the reactivity of the amide (Figure 23.5.3) and inhibiting free rotation about the C–N bond. Amides are therefore the least reactive of the carboxylic acid derivatives. The stability of the amide bond is crucially important in biology because amide bonds form the backbones of peptides and proteins. (For more information on peptides and proteins, see Section 12.8.) The amide bond is also found in many other biologically active and commercially important molecules, including penicillin; urea, which is used as fertilizer; saccharin, a sugar substitute; and valium, a potent tranquilizer. (For more information on the structure of penicillin, see Section 7.2.)

Note the Pattern

Amides are the least reactive of the carboxylic acid derivatives because amides participate in π bonding with the carbonyl group.

Figure 23.5.5 The Electronic Structure of an Amide (a) An unhybridized $2p_z$ orbital on nitrogen, containing a lone electron pair of electrons, can interact with the π orbital of the carbonyl group to give a three-center, four-electron bond. This interaction reduces the reactivity of the amide, making amides the least reactive of the carboxylic acid derivatives. (b) A comparison of the electrostatic potential maps of acetaldehyde and formamide shows that the negative charge (indicated in blue) is more localized on the oxygen atom of acetaldehyde than it is in formamide. Formamide is therefore less reactive.

Amines

Amines are derivatives of ammonia in which one or more hydrogen atoms have been replaced by alkyl or aryl groups. They are therefore analogous to alcohols and ethers. Like alcohols, amines are classified as primary, secondary, or tertiary, but in this case the designation refers to the number of alkyl groups bonded to the nitrogen atom, not to the number of adjacent carbon atoms. In primary amines, the nitrogen is bonded to two hydrogen atoms and one alkyl group; in secondary amines, the nitrogen is bonded to one hydrogen and two alkyl groups; and in tertiary amines, the nitrogen is bonded to three alkyl groups. With one lone pair of electrons and C–N bonds that are less polar than C–O bonds, ammonia and simple amines have much lower boiling points than water or alcohols with similar molecular masses. Primary amines tend to have boiling points intermediate between those of the corresponding alcohol and alkane. Moreover, secondary and tertiary amines have lower boiling points than primary amines of comparable molecular mass.

Tertiary amines form cations analogous to the ammonium ion (NH_4^+), in which all four H atoms are replaced by alkyl groups. Such substances, called quaternary ammonium salts, can be chiral if all four substituents are different. (Amines with three different substituents are also chiral because the lone pair of electrons represents a fourth substituent.)

Alkylamines can be prepared by nucleophilic substitution reactions of alkyl halides with ammonia or other amines:

The primary amine formed in the first reaction (Equation 23.5.6) can react with more alkyl halide to generate a secondary amine (Equation 23.5.7), which in turn can react to form a tertiary amine (Equation 23.5.8). Consequently, the actual reaction mixture contains primary, secondary, and tertiary amines and even quaternary ammonium salts.

The reactions of amines are dominated by two properties: their ability to act as weak bases and their tendency to act as nucleophiles, both of which are due to the presence of the lone pair of electrons on the nitrogen atom. Amines typically behave as bases by accepting a proton from an acid to form an ammonium salt, as in the reaction of triethylamine (the ethyl group is represented as Et) with aqueous HCl (the lone pair of electrons on nitrogen is shown):

which gives triethylammonium chloride. Amines can react with virtually any electrophile, including the carbonyl carbon of an aldehyde, a ketone, or an ester. Aryl amines such as aniline ($\text{C}_6\text{H}_5\text{NH}_2$) are much weaker bases than alkylamines because the lone pair of electrons on nitrogen interacts with the π bonds of the aromatic ring, delocalizing the lone pair through resonance (Figure 23.5.6).

Note the Pattern

The reactions of amines are dominated by their ability to act as weak bases and their tendency to act as nucleophiles.

Figure 23.5.6 Structures and Basicity of Aniline and Cyclohexylamine Delocalization of the lone electron pair on N over the benzene ring reduces the basicity of aryl amines, such as aniline, compared with that of alkylamines, such as cyclohexylamine. These electrostatic potential maps show that the electron density on the N of cyclohexylamine is more localized than it is in aniline, which makes cyclohexylamine a stronger base.

Example 23.5.2

Predict the products formed in each reaction and show the initial site of attack and, for part (b), the final products.

- $C_6H_5CH_2CO_2H + KOH \rightarrow$
-

Given: reactants

Asked for: products and mechanism of reaction

Strategy:

Use the strategy outlined in Example 7.

Solution:

- The proton on the carboxylic acid functional group is acidic. Thus reacting a carboxylic acid with a strong base is an acid–base reaction, whose products are a salt—in this case, $C_6H_5CH_2CO_2^- K^+$ —and water.
- The nitrogen of cyclohexylamine contains a lone pair of electrons, making it an excellent nucleophile, whereas the carbonyl carbon of ethyl acetate is a good electrophile. We therefore expect a reaction in which nucleophilic attack on the carbonyl carbon of the ester produces an amide and ethanol. The initial site of attack and the reaction products are as follows:

Exercise

Predict the products of each reaction. State the initial site of attack.

1. acetic acid with 1-propanol
2. aniline ($C_6H_5NH_2$) with propyl acetate [$CH_3C(=O)OCH_2CH_2CH_3$]

Answer:

1. Initial attack occurs with protonation of the oxygen of the carbonyl. The products are:

2. Initial attack occurs at the carbon of the carbonyl group. The products are:

Reactions like we have discussed in this section and [Section 24.4](#) are used to synthesize a wide range of organic compounds. When chemists plan the synthesis of an organic molecule, however, they must take into consideration various factors, such as the availability and cost of reactants, the need to minimize the formation of undesired products, and the proper sequencing of reactions to maximize the yield of the target molecule and minimize the formation of undesired products. Because the synthesis of many organic molecules requires multiple steps, in designing a synthetic scheme for such molecules, chemists must often work backward from the desired product in a process called *retrosynthesis*. Using this process, they can identify the reaction steps needed to synthesize the desired product from the available reactants.

Summary

There are strong connections among the structure, the physical properties, and the reactivity for compounds that contain the major functional groups. Hydrocarbons that are alkanes undergo catalytic cracking, which can convert straight-chain alkanes to highly branched alkanes. Catalytic cracking is one example of a **pyrolysis reaction**, in which the weakest bond is cleaved at high temperature, producing a mixture of radicals. The multiple bond of an alkene produces geometric isomers (*cis* and *trans*). Terminal alkynes contain a hydrogen atom directly attached to a triply bonded carbon. Removal of the hydrogen forms an acetylide ion, a potent nucleophile used to make longer carbon chains. Arenes undergo substitution rather than elimination because of enhanced stability from delocalization of their π electron density. An alcohol is often prepared by adding the elements of water across a double bond or by a substitution reaction. Alcohols undergo two major types of reactions: those involving cleavage of the O–H bond and those involving cleavage of the C–O bond. Phenols are acidic because of π interactions between the oxygen atom and the ring. Ethers are comparatively unreactive. Aldehydes and ketones are generally prepared by oxidizing alcohols. Their chemistry is characterized by nucleophilic attack at the carbon atom of the carbonyl functional group and electrophilic attack at the oxygen atom. **Grignard reagents** ($RMgX$, where X is Cl, Br, or I) convert the carbonyl functional group to an alcohol and lengthen the carbon chain. Compounds that contain the carboxyl functional group are weakly acidic because of delocalization of the π electrons, which causes them to easily lose a proton and form the carboxylate anion. Carboxylic acids are generally prepared by oxidizing alcohols and aldehydes or reacting a Grignard reagent with CO_2 . Carboxylic acid derivatives include esters, prepared by reacting a carboxylic acid and an alcohol, and amides, prepared by the nucleophilic reaction of amines with more electrophilic carboxylic acid derivatives, such as esters. Amides are relatively unreactive because of π bonding interactions between the lone pair on nitrogen and the carbonyl group. Amines can also be primary, secondary, or tertiary, depending on the number of alkyl groups bonded to the amine. **Quaternary ammonium salts** have four substituents attached to nitrogen and can be chiral. Amines are often prepared by a nucleophilic substitution reaction between a polar alkyl halide and ammonia or other amines. They are nucleophiles, but their base strength depends on their substituents.

Key Takeaway

- The physical properties and reactivity of compounds containing the common functional groups are intimately connected to their structures.

Conceptual Problems

1. Why do branched-chain alkanes have lower melting points than straight-chain alkanes of comparable molecular mass?
2. Describe alkanes in terms of their orbital hybridization, polarity, and reactivity. What is the geometry about each carbon of a straight-chain alkane?
3. Why do alkenes form *cis* and *trans* isomers, whereas alkanes do not? Do alkynes form *cis* and *trans* isomers? Why or why not?
4. Which compounds can exist as *cis* and *trans* isomers?
 - a. 2,3-dimethyl-1-butene
 - b. 3-methyl-1-butene
 - c. 2-methyl-2-pentene
 - d. 2-pentene
5. Which compounds can exist as *cis* and *trans* isomers?
 - a. 3-ethyl-3-hexene
 - b. 1,1-dichloro-1-propene
 - c. 1-chloro-2-pentene
 - d. 3-octene
6. Which compounds have a net dipole moment?
 - a. *o*-nitrotoluene
 - b. *p*-bromonitrobenzene
 - c. *p*-dibromobenzene
7. Why is the boiling point of an alcohol so much greater than that of an alkane of comparable molecular mass? Why are low-molecular-mass alcohols reasonably good solvents for some ionic compounds, whereas alkanes are not?
8. Is an alcohol a nucleophile or an electrophile? What determines the mode of reactivity of an alcohol? How does the reactivity of an alcohol differ from that of an ionic compound containing OH, such as KOH?
9. How does the reactivity of ethers compare with that of alcohols? Why? Ethers can be cleaved under strongly acidic conditions. Explain how this can occur.
10. What functional group is common to aldehydes, ketones, carboxylic acids, and esters? This functional group can react with both nucleophiles and electrophiles. Where does nucleophilic attack on this functional group occur? Where does electrophilic attack occur?
11. What key feature of a Grignard reagent allows it to engage in a nucleophilic attack on a carbonyl carbon?
12. Do you expect carboxylic acids to be more or less water soluble than ketones of comparable molecular mass? Why?
13. Because amides are formally derived from an acid plus an amine, why can they not be prepared by the reaction of an acid with an amine? How are they generally prepared?
14. Is an amide susceptible to nucleophilic attack, electrophilic attack, or both? Specify where the attack occurs.
15. What factors determine the reactivity of amines?

Structure and Reactivity

1. What is the product of the reaction of 2-butyne with excess HBr?
2. What is the product of the reaction of 3-hexyne with excess HCl?
3. What elements are eliminated during the dehydrohalogenation of an alkyl halide? What products do you expect from the dehydrohalogenation of 2-chloro-1-pentene?
4. What elements are eliminated during the dehydration of an alcohol? What products do you expect from the dehydration of ethanol?
5. Predict the products of each reaction.
 - a. sodium phenoxide with ethyl chloride
 - b. 1-chloropropane with NaOH
6. Show the mechanism and predict the organic product of each reaction.
 - a. 2-propanol + HCl
 - b. cyclohexanol + H₂SO₄
7. A Grignard reagent can be used to generate a carboxylic acid. Show the mechanism for the first step in this reaction using CH₃CH₂MgBr as the Grignard reagent. What is the geometry about the carbon of the -CH₂ of the intermediate species formed in this first step?
8. Draw a molecular orbital picture showing the bonding in an amide. What orbital is used for the lone pair of electrons on nitrogen?
9. What is the product of the reaction of
 - a. acetic acid with ammonia?
 - b. methyl acetate with ethylamine, followed by heat?
10. Develop a synthetic scheme to generate
 - a. 1,1-dichloroethane from 1,1-dibromoethane.
 - b. 2-bromo-1-heptene from 1-bromopentane.

Answers

Learning Objective

- To identify the common structural units of important biological molecules.

All the functional groups described in this chapter are found in the organic molecules that are constantly synthesized and destroyed by every living organism on Earth. A detailed understanding of the reactions that occur in living organisms is the goal of biochemistry, which deals with a wide variety of organic structures and reactions. The most abundant substances found in living systems belong to four major classes: proteins, carbohydrates, lipids, and nucleic acids. Here we briefly describe the structure and some functions of these biological molecules.

Proteins

In [Section 12.8](#), we described proteins as biologically active polymers formed from amino acids linked together by amide bonds. In addition to an amine group and a carboxylic acid group, each amino acid contains a characteristic R group ([Figure 9.7.1](#)). In the simplest amino acid, glycine, the R group is hydrogen (–H), but in other naturally occurring amino acids, the R group may be an alkyl group or a substituted alkyl group, a carboxylic group, or an aryl group. The nature of the R group determines the particular chemical properties of each amino acid. In [Figure 9.7.1](#), all the amino acids found in proteins except glycine are chiral compounds, which suggests that their interactions with other chiral compounds are selective. Some proteins, called enzymes, catalyze biological reactions, whereas many others have structural, contractile, or signaling functions. Because we have described proteins previously, we will not discuss them further.

Carbohydrates

Carbohydrates are the most abundant of the organic compounds found in nature. They constitute a substantial portion of the food we consume and provide us with the energy needed to support life. Table sugar, milk, honey, and fruits all contain low-molecular-mass carbohydrates that are easily assimilated by the human body. In contrast, the walls of plant cells and wood contain high-molecular-mass carbohydrates that we cannot digest.

Once thought to be hydrates of carbon with the general formula $C_n(H_2O)_m$, carbohydrates are actually polyhydroxy aldehydes or polyhydroxy ketones (i.e., aldehydes or ketones with several –OH groups attached to the parent hydrocarbon). The simplest carbohydrates consist of unbranched chains of three to eight carbon atoms: one carbon atom is part of a carbonyl group, and some or all of the others are bonded to hydroxyl groups. The structure of a carbohydrate can be drawn either as a hydrocarbon chain, using a *Fischer projection*, or as a ring, using a *Haworth projection* ([Figure 23.6.1](#)). The Haworth projection is named after the British chemist Sir Walter Norman Haworth, who was awarded a Nobel Prize in Chemistry in 1937 for his discovery that sugars exist mainly in their cyclic forms, as well as for his collaboration on the synthesis of vitamin C. The cyclic form is the product of nucleophilic attack by the oxygen of a hydroxyl group on the electrophilic carbon of the carbonyl group within the same molecule, producing a stable ring structure composed of five or six carbons that minimizes bond strain ([Figure 23.6.1](#)). The substituents on the right side of the carbon chain in a Fischer projection are in the “down” position in the corresponding Haworth projection. Attack by the hydroxyl group on either side of the carbonyl group leads to the formation of two cyclic forms, called *anomers*: an α form, with the –OH in the “down” position, and a β form, with the –OH in the “up” position.

The general structure of an amino acid. An amino acid is chiral except when R is an H atom.

Walter Norman Haworth (1883–1950)

At age 14, Walter Norman Haworth left school to join his father to learn linoleum design and manufacturing, but he became interested in chemistry through his use of dyes. Private tutoring enabled him to pass the entrance exam of the University of Manchester, where he received his doctorate in 1911. During World War I, Haworth organized the laboratories at St. Andrews for the production of chemicals and drugs, returning to the investigation of carbohydrates after the war.

Figure 23.6.1 Fischer Projection and Haworth Projection of Glucose In solution, simple sugars exist predominantly in the ring form, the product of nucleophilic attack by the oxygen of a hydroxyl group on the electrophilic carbon of the carbonyl group. The α and β forms, called anomers, differ in the configuration at C1.

Carbohydrates are classified according to the number of single *saccharide*, or sugar, units they contain (from the Latin *saccharum*, meaning “sugar”). The simplest are *monosaccharides*; a *disaccharide* consists of two linked monosaccharide units; a *trisaccharide* has three linked monosaccharide units; and so forth. Glucose is a monosaccharide, and sucrose (common table sugar) is a disaccharide. The hydrolysis of sucrose produces glucose and another monosaccharide, fructose, in a reaction catalyzed by an enzyme or by acid:

Polysaccharides hydrolyze to produce more than 10 monosaccharide units.

The common monosaccharides contain several chiral carbons and exist in several isomeric forms. One isomer of glucose, for example, is galactose, which differs from glucose in the position of the -OH bond at carbon-4:

Because carbons-2, -3, -4, and -5 of glucose are chiral, changing the position of the -OH on carbon-4 does not produce an enantiomer of glucose but a different compound, galactose, with distinct physical and chemical properties. Galactose is a hydrolysis product of lactose, a disaccharide found in milk. People who suffer from *galactosemia* lack the enzyme needed to

convert galactose to glucose, which is then metabolized to CO_2 and H_2O , releasing energy. Galactose accumulates in their blood and tissues, leading to mental retardation, cataracts, and cirrhosis of the liver.

Because carbohydrates have a carbonyl functional group and several hydroxyl groups, they can undergo a variety of biochemically important reactions. The carbonyl group, for example, can be oxidized to form a carboxylic acid or reduced to form an alcohol. The hydroxyl groups can undergo substitution reactions, resulting in derivatives of the original compound. One such derivative is Sucralose, an artificial sweetener that is six times sweeter than sucrose; it is made by replacing two of the hydroxyl groups on sucrose with chlorine. Carbohydrates can also eliminate hydroxyl groups, producing alkenes.

Note the Pattern

Because carbohydrates have a carbonyl functional group and several hydroxyl groups, they can undergo a variety of reactions.

Two familiar polysaccharides are *starch* and *cellulose*, which both hydrolyze to produce thousands of glucose units. They differ only in the connection between glucose units and the amount of branching in the molecule (Figure 23.6.2). Starches can be coiled or branched and are hydrolyzed by the enzymes in our saliva and pancreatic juices. Animal starch, called *glycogen*, is stored in the liver and muscles. It consists of branched glucose units linked by bonds that produce a coiled structure. The glucose units in cellulose, in contrast, are linked to give long, unbranched chains. The chains in cellulose stack in parallel rows held together by hydrogen bonds between hydroxyl groups. This arrangement produces a rigid structure that is insoluble in water.

Figure 23.6.2 The Polysaccharides Starch and Cellulose Starches (a) and cellulose (b) differ in the connection between glucose units and the amount of branching in the molecule. Starches can be coiled or branched, whereas cellulose, the primary structural material of plants, has long, unbranched chains held together by hydrogen bonds.

Cellulose is the primary structural material of plants and one of the most abundant organic substances on Earth. Because our enzymes are not able to hydrolyze the bonds between the glucose units in cellulose, we are unable to digest it. A recently marketed product containing a high percentage of cellulose was sold as a dietetic substance for rapid weight loss, but those who consumed it experienced severe intestinal discomfort because the cellulose could not be digested. The product was quickly removed from the market.

Example 23.6.1

The Fischer projection of xylose, found in many varieties of apples, is shown. Draw the ring form (Haworth projection) of xylose.

Given: Fischer projection of a sugar

Asked for: cyclic structure

Strategy:

A Identify the nucleophile and the electrophile. Indicate the point of attack, remembering that cyclic structures are most stable when they contain at least five atoms in the ring to prevent bond strain from bond angles that are too small.

B Draw the cyclic form of the structure.

Solution:

A The carbonyl carbon (C1) is a good electrophile, and each oxygen is a good nucleophile. Nucleophilic attack occurs from the -OH group on C4, producing a stable five-membered ring.

B Because of rotation about the bond between C1 and C2, ring formation gives both a and b anomers, with the following structures (H atoms have been omitted for clarity):

Exercise

Draw the cyclic form(s) of galactose, whose Fischer projection is shown in the previous discussion.

Answer:

Lipids

Lipids (from the Greek *lipos*, meaning “fat” or “lard”) are characterized by their insolubility in water. They form a family of compounds that includes fats, waxes, some vitamins, and steroids. *Fatty acids*, the simplest lipids, have a long hydrocarbon chain that ends with a carboxylic acid functional group. In saturated fatty acids, the hydrocarbon chains contain only C–C bonds, so they can stack in a regular array (part (a) in [Figure 23.6.3](#)). In contrast, unsaturated fatty acids have a single double bond in the hydrocarbon chain (monounsaturated) or more than one double bond (polyunsaturated). These double bonds give fatty acid chains a kinked structure, which prevents the molecules from packing tightly (part (b) in [Figure 23.6.3](#)). As a result of reduced van der Waals interactions, the melting point of an unsaturated fatty acid is lower than that of a saturated fatty acid of comparable molecule mass, thus producing an oil rather than a solid. (For more information on van der Waals interactions, see [Section 11.2](#).) Fish oils and vegetable oils, for example, have a higher concentration of unsaturated fatty acids than does butter.

Figure 23.6.3 Fatty Acids, the Simplest Class of Lipids Fatty acids are composed of a long chain that terminates in a carboxylic acid functional group. (a) Molecules of saturated fatty acids, which contain no carbon–carbon double bonds, can stack in a regular

array. (b) Molecules of unsaturated fatty acids, which contain one or more *cis* carbon–carbon double bonds, have kinked structures that cannot pack closely together.

The double bonds of unsaturated fatty acids can be hydrogenated in an addition reaction that produces a saturated fatty acid:

They can also be oxidized to produce an aldehyde or carboxylic acid. (For more information on hydrogenation, see [Section 14.8](#).)

Unsaturated fatty acids are the starting compounds for the biosynthesis of *prostaglandins*. These hormone-like substances are involved in regulating blood pressure, tissue inflammation, and contracting and relaxing smooth muscles. Drugs such as aspirin and ibuprofen inhibit the production of prostaglandins, thereby reducing inflammation.

Waxes are esters produced by the nucleophilic attack of an alcohol on the carbonyl carbon of a long-chain carboxylic acid ([Figure 23.5.4](#)). For example, the wax used in shoe polish and wax paper, which is derived from beeswax, is formed from a straight-chain alcohol with 15 carbon atoms and a fatty acid with 31 carbon atoms. *Triacylglycerols* are a particularly important type of ester in living systems; they are used by the body to store fats and oils. These compounds are formed from one molecule of glycerol (1,2,3-trihydroxypropane) and three fatty acid molecules. During warmer months of the year, animals that hibernate consume large quantities of plants, seeds, and nuts that have a high fat and oil content. They convert the fatty acids to triacylglycerols and store them. Hydrolysis of stored triacylglycerols during hibernation (the reverse of [Figure 23.5.4](#)) releases alcohols and carboxylic acids that the animal uses to generate energy for maintaining cellular activity, respiration, and heart rate. Derivatives of triacylglycerols with a phosphate group are major components of all cell membranes.

Steroids are lipids whose structure is composed of three cyclohexane rings and one cyclopentane ring fused together. The presence of various substituents, including double bonds, on the basic steroid ring structure produces a large family of steroid compounds with different biological activities. For example, *cholesterol*, a steroid found in cellular membranes, contains a double bond in one ring and four substituents: a hydroxyl group, two methyl groups, and a hydrocarbon chain.

Cholesterol is the starting point for the biosynthesis of steroid hormones, including testosterone, the primary male sex hormone, and progesterone, which helps maintain pregnancy. These cholesterol derivatives lack the long hydrocarbon side chain, and most contain one or more ketone groups.

Cholesterol is synthesized in the human body in a multistep pathway that begins with a derivative of acetic acid. We also consume cholesterol in our diets: eggs, meats, fish, and dairy products all contain cholesterol, but vegetables and other plant-derived foods do not contain cholesterol. Excess cholesterol in the human body can cause gallstones, which are composed of nearly 100% cholesterol, or lipid deposits called plaque in arteries. A buildup of plaque can block a coronary artery and result in a heart attack ([Figure 23.6.4](#)).

Nucleic Acids

Nucleic acids are the basic structural components of DNA (deoxyribonucleic acid) and RNA (ribonucleic acid), the biochemical substances found in the nuclei of all cells that transmit the information needed to direct cellular growth and reproduction. Their structures are derived from cyclic nitrogen-containing compounds called *pyrimidines* and *purines*, which can engage in hydrogen bonding through the lone electron pair on nitrogen (in pyrimidine and purine) or through the hydrogen of the amine (in purine):

Figure 23.6.4 *Plaque in an Artery* Plaque, a lipid deposit, forms from excess cholesterol in the body. This artery is nearly blocked by a thick deposit of plaque, which greatly increases the risk of a heart attack due to reduced blood flow to the heart.

The same cyclic structures are found in substances such as caffeine, a purine that is a stimulant, and the antifungal agent flucytosine, a pyrimidine. (For more information on the structure of caffeine, see [Section 7.2](#).)

When a pyrimidine or a purine is linked to a sugar by a bond called a *glycosidic bond*, a *nucleoside* is formed. Adding a phosphoric acid group to the sugar then produces a *nucleotide* (part (a) in [Figure 23.6.5](#)). The linkage of nucleotides forms a polymeric chain that consists of alternating sugar and phosphate groups, which is the backbone of DNA and RNA (part (b) in [Figure 23.6.5](#)).

While the function of DNA is to preserve genetic information, RNA translates the genetic information in DNA and carries that information to cellular sites where proteins are synthesized. Many antibiotics function by interfering with the synthesis of proteins in one or more kinds of bacteria. Chloramphenicol, for example, is used against infections of the eye or outer ear canal; it inhibits the formation of peptide bonds between amino acids in a protein chain. Puromycin, which is used against herpes simplex type I, interrupts extension of a peptide chain, causing the release of an incomplete protein and the subsequent death of the virus.

Figure 23.6.5 *The Formation of Nucleic Acids*(a) When pyrimidine or purine and a sugar react to form a glycosidic bond, a nucleoside is produced. Adding a phosphoric acid group to the sugar of a nucleoside produces a nucleotide. (b) Nucleotides link together to form long polymeric chains. A DNA molecule consists of two such chains held together by hydrogen bonding between the purine and pyrimidine components on different chains.

Mutations in the DNA of an organism may lead to the synthesis of defective proteins. *Phenylketonuria (PKU)*, for example, is a condition caused by a defective enzyme. Left untreated, it produces severe brain damage and mental retardation. *Albinism* is caused by a defective enzyme that is unable to produce melanin, the pigment responsible for the color of skin and hair. *Cystic fibrosis*, the most common inherited disease in the United States, blocks pancreatic function and causes thick mucus secretions that make breathing difficult. An area of intense research in combating cancer involves the synthesis of drugs that stop uncontrolled cell growth by interfering with DNA replication.

Key Takeaway

The four major classes of organic compounds found in biology are proteins, carbohydrates, lipids, and nucleic acids. Their structures and reactivity are determined by the functional groups present.

Summary

Proteins are biologically active polymers formed from amino acids linked together by amide bonds. All the amino acids in proteins are chiral compounds except glycine. The most common organic compounds found in nature are the **carbohydrates**, polyhydroxy aldehydes or polyhydroxy ketones in unbranched chains of three to eight carbons. They are classified according to the number of sugar, or saccharide, units, and they can be drawn as a chain in a Fischer projection or in a cyclic form called a Haworth projection. The two cyclic forms in a Haworth projection are called anomers. Many sugars contain at least one chiral center. With their carbonyl and hydroxyl functional groups, carbohydrates can undergo a variety of biochemically relevant reactions. Starch and cellulose differ only in the connectivity between glucose units. Starches can be branched or unbranched, but cellulose, the structural material of plants, is unbranched, and cannot be digested by humans. **Lipids** are insoluble in water. The simplest lipids, fatty acids, have a long hydrocarbon chain ending in a carboxylic acid functional group. Their physical properties depend on the number of double bonds in the chain. Prostaglandins, hormone-like substances, are formed from unsaturated fatty acids, and waxes are long-chain esters of saturated fatty acids. Triacylglycerols, which the body uses to store fats and oils, consist of glycerol esterified to three fatty acid molecules. Steroids, which include cholesterol and the steroid hormones, are characterized by three cyclohexane rings and one cyclopentane ring fused together. The basic structural units of DNA and RNA are the **nucleic acids**, whose structures are derived from nitrogen-containing cyclic compounds called pyrimidines and purines. These structures are linked to a sugar through a glycosidic bond, forming a nucleoside. Adding a phosphoric acid group produces a nucleotide. Nucleotides link to form a polymeric chain that is the backbone of DNA and RNA.

Key Takeaway

- An understanding of the reactivity of functional groups is necessary to understanding the reactions that occur in living systems.

Conceptual Problems

1. What are the strengths and limitations of using a Haworth projection? of using a Fischer projection?
2. Nutritionists will often state that a leafy salad contains no calories. Do you agree?
3. Would you expect margarine, a polyunsaturated fat, to have a higher or lower melting point than butter, a saturated fat?

Structure and Reactivity

1. Propose a method for synthesizing the dipeptide alanylglycine (Ala-Gly), starting with the individual amino acids (Figure 9.7.1).
2. Are all the naturally occurring amino acids chiral compounds? Do you expect proteins to contain both enantiomers of alanine and other amino acids? Explain your answer.
3. The structures of cholesterol and testosterone were shown in this section. Identify the functional groups in each.
4. The structures of glucose and purine were shown in this section. Identify the functional groups in each.

Answer

1. Use a condensation reaction:

- 2.
- 3.
- 4.

APPLICATION PROBLEMS

- After exercise, the concentration of lactic acid increases in both muscle tissue and blood. In fact, it is responsible for muscle cramps that may develop after vigorous exercise. Using the structure of lactic acid shown here, draw the conformational isomers of lactic acid as viewed along the C2–C3 axis, where C3 is the carbon of the methyl group. Which would you predict to be the most stable conformation? Why?

- Cyclohexanecarboxylic acid is a liquid used in insecticide formulations. A derivative of this compound, 2-methylcyclohexanecarboxylic acid is shown here. Sketch the *cis* and *trans* isomers of this derivative. Arrange the conformations of its geometric isomers in order of increasing energy.

- Coniine is a naturally occurring compound with insect-paralyzing properties. Ingestion of this compound causes weakness, vomiting, labored respiration, and eventual death. Does coniine have a chiral carbon? If so, indicate the carbon with an asterisk.

- A compound that has been found to be an effective hypertensive is captopril, sold commercially as Hypertil and Tensoprel, among other names. Captopril has a chiral center at C2. Draw the enantiomers that result from this chiral center. Indicate any other chiral centers in captopril with an asterisk.

- The structure of phenobarbital, a compound used to treat epilepsy, is shown here. Identify the functional groups.

- The compound 2-amino-2-methyl-1-propanol is used not only in the synthesis of pharmaceuticals but also in cosmetic creams, polishes, and cleaning compounds. Is it a chiral compound?
- Glycerol (1,2,3-propanetriol, or 1,2,3-trihydroxypropane) is produced from sugars by fermentation. It also is obtained from oils and fats as a by-product during the manufacture of soaps. Glycerol can be converted to glyceric acid by the

following sequence:

Both glyceraldehyde and glyceric acid are derivatives of biochemical intermediates in sugar metabolism.

- a. Is the conversion of glycerol to glyceric acid an oxidative process or a reductive process?
 - b. How many of these compounds are chiral? Indicate any chiral centers with an asterisk.
8. When exposed to light or heat, peroxides (ROOR) can undergo radical reactions. The first step is the dissociation of the peroxide into two alkoxy radicals. Each alkoxy radical then reacts with a species such as HBr to form an alcohol.
- a. Write chemical equations for these reactions.
 - b. One of the products of the second step can react with an alkene to generate another radical. Show a chemical equation for this reaction, using ethylene as the alkene.
 - c. The product of part (b) can then react with HBr to form two products. What are those products?
 - d. Identify any propagation reactions in part (b) or part (c). Show all possible termination reactions.
9. The structure of isophytol is shown here. This compound is used to prepare vitamins E and K. Does isophytol form *cis* and *trans* isomers? If so, draw these isomers.

10. Isopentyl acetate, also known as “oil of banana,” has the structure shown here. Show the first step in the mechanism for reaction of isopentyl acetate with C_6H_5MgBr , which gives the first ionic adduct.

11. An enkephalin is a pentapeptide that controls pain in humans. Enkephalins function by binding to the same specific sites in brain cells that are known to bind morphine and heroin. Methionine enkephalin has the structure Tyr-Gly-Gly-Phe-Met.
- a. Use [Figure 5.16 "The Structures of 10 Amino Acids"](#) to draw the structure of methionine enkephalin.
 - b. Rotation about the amide bond that connects residues 3 and 4 is restricted because of electron delocalization. Draw the *cis* and *trans* isomers.

ANSWERS

1. The first staggered conformation minimizes electrostatic repulsions between adjacent atoms:

- 2.
3. yes

- 4.
5. three amides and a phenyl group
- 6.
- 7.

- 8.
- 9.
- 10.
- 11.

Until now, you have studied chemical processes in which atoms share or transfer electrons to form new compounds, leaving the atomic nuclei largely unaffected. In this chapter, we examine some properties of the atomic nucleus and the changes that can occur in atomic nuclei.

Nuclear reactions differ from other chemical processes in one critical way: in a nuclear reaction, the identities of the elements change. In addition, nuclear reactions are often accompanied by the release of enormous amounts of energy, as much as a *billion* times more than the energy released by chemical reactions. Moreover, the yields and rates of a nuclear reaction are generally unaffected by changes in temperature, pressure, or the presence of a catalyst.

We begin by examining the structure of the atomic nucleus and the factors that determine whether a particular nucleus is stable or decays spontaneously to another element. We then discuss the major kinds of nuclear decay reactions, as well as the properties and uses of the radiation emitted when nuclei decay. You will learn how radioactive emissions can be used to study the mechanisms of chemical reactions and biological processes and how to calculate the amount of energy released during a nuclear reaction. You will also discover why houses are tested for radon gas, how radiation is used to probe organs such as the brain, and how the energy from nuclear reactions can be harnessed to produce electricity. Last, we explore the nuclear chemistry that takes place in stars, and we describe the role that stars play in producing most of the elements in the universe.

The glow caused by intense radiation. The high-energy particles ejected into the surrounding water or air by an intense radioactive source such as this nuclear reactor core produce a ghostly bluish glow.

Learning Objective

- To understand the factors that affect nuclear stability.

Although most of the known elements have at least one isotope whose atomic nucleus is stable indefinitely, all elements have isotopes that are unstable and disintegrate, or *decay*, at measurable rates by emitting radiation. Some elements have no stable isotopes and eventually decay to other elements. In contrast to the chemical reactions that were the main focus of earlier chapters and are due to changes in the arrangements of the valence electrons of atoms, the process of nuclear decay results in changes inside an atomic nucleus. We begin our discussion of nuclear reactions by reviewing the conventions used to describe the components of the nucleus.

The Atomic Nucleus

As you learned in [Chapter 1](#), each element can be represented by the notation ${}^A_Z X$ where A , the mass number, is the sum of the number of protons and the number of neutrons, and Z , the atomic number, is the number of protons. The protons and neutrons that make up the nucleus of an atom are called nucleons, and an atom with a particular number of protons and neutrons is called a nuclide. Nuclides with the same number of protons but different numbers of neutrons are called **isotopes**. Isotopes can also be represented by an alternative notation that uses the name of the element followed by the mass number, such as carbon-12. The stable isotopes of oxygen, for example, can be represented in any of the following ways:

Because the number of neutrons is equal to $A - Z$, we see that the first isotope of oxygen has 8 neutrons, the second isotope 9 neutrons, and the third isotope 10 neutrons. Isotopes of all naturally occurring elements on Earth are present in nearly fixed proportions, with each proportion constituting an isotope's *natural abundance*. For example, in a typical terrestrial sample of oxygen, 99.76% of the O atoms is oxygen-16, 0.20% is oxygen-18, and 0.04% is oxygen-17.

Any nucleus that is unstable and decays spontaneously is said to be radioactive, emitting subatomic particles and electromagnetic radiation. The emissions are collectively called *radioactivity* and can be measured. Isotopes that emit radiation are called radioisotopes. As you learned in [Chapter 14](#), the rate at which radioactive decay occurs is characteristic of the isotope and is generally reported as a **half-life** ($t_{1/2}$), the amount of time required for half of the initial number of nuclei present to decay in a first-order reaction. (For more information on half-life, see [Section 14.5](#).) An isotope's half-life can range from fractions of a second to billions of years and, among other applications, can be used to measure the age of ancient objects. Example 1 and its corresponding exercise review the calculations involving radioactive decay rates and half-lives.

Example 24.1.1

Fort Rock Cave in Oregon is the site where archaeologists discovered several Indian sandals, the oldest ever found in Oregon. Analysis of the ${}^{14}_6 C$ content of the sagebrush used to make the sandals gave an average decay rate of 5.1

disintegrations per minute (dpm) per gram of carbon. The current $^{14}\text{C}/^{12}\text{C}$ ratio in living organisms is 1.3×10^{-12} , with a decay rate of 15 dpm/g C. How long ago was the sagebrush in the sandals cut? The half-life of ^{14}C is 5730 yr.

Given: radioisotope, current $^{14}\text{C}/^{12}\text{C}$ ratio, initial decay rate, final decay rate, and half-life

Asked for: age

Strategy:

A Use [Equation 14.5.5](#) to calculate N_0/N , the ratio of the number of atoms of ^{14}C originally present in the sample to the number of atoms now present.

B Substitute the value for the half-life of ^{14}C into [Equation 14.5.3](#) to obtain the rate constant for the reaction.

C Substitute the calculated values for N_0/N and the rate constant into [Equation 14.5.7](#) to obtain the elapsed time t .

Solution:

We can use the integrated rate law for a first-order nuclear reaction ([Equation 14.5.7](#)) to calculate the amount of time that has passed since the sagebrush was cut to make the sandals:

$$\ln \frac{N}{N_0} = -kt \quad (\text{Chapter 24.1.1})$$

A From [Equation 14.5.5](#), we know that $A = kN$. We can therefore use the initial and final activities ($A_0 = 15$ and $A = 5.1$) to calculate N_0/N :

$$\frac{A_0}{A} = \frac{kN_0}{kN} = \frac{N_0}{N} = 2.941 \quad (\text{Chapter 24.1.2})$$

B Now we can calculate the rate constant k from the half-life of the reaction (5730 yr) using [Equation 14.5.3](#):

$$t_{1/2} = \frac{0.693}{k} \quad (\text{Chapter 24.1.3})$$

Rearranging this equation to solve for k ,

$$k = \frac{0.693}{t_{1/2}} = \frac{0.693}{5730 \text{ yr}} = 1.21 \times 10^{-4} \text{ yr}^{-1} \quad (\text{Chapter 24.1.4})$$

C Substituting the calculated values into the equation for t ,

$$t = \frac{\ln(N/N_0)}{k} = \frac{\ln(5.1/15)}{1.21 \times 10^{-4} \text{ yr}^{-1}} = 8900 \text{ yr} \quad (\text{Chapter 24.1.5})$$

Thus the sagebrush in the sandals is about 8900 yr old.

Exercise

While trying to find a suitable way to protect his own burial chamber, the ancient Egyptian pharaoh Sneferu developed the pyramid, a burial structure that protected desert graves from thieves and exposure to wind. Analysis of the ^{14}C content of several items in pyramids built during his reign gave an average decay rate of 8.6 dpm/g C. When were the objects in the chamber created?

Answer: about 4600 yr ago, or about 2600 BC

Nuclear Stability

As discussed in [Chapter 1](#), the nucleus of an atom occupies a tiny fraction of the volume of an atom and contains the number of protons and neutrons that is characteristic of a given isotope. Electrostatic repulsions would normally cause the positively charged protons to repel each other, but the nucleus does not fly apart because of the strong nuclear force, an extremely powerful but very short-range attractive force between nucleons ([Figure 24.1.1](#)). All stable nuclei except the hydrogen-1 nucleus (${}^1_1\text{H}$) contain at least one neutron to overcome the electrostatic repulsion between protons. As the number of protons in the nucleus increases, the number of neutrons needed for a stable nucleus increases even more rapidly. Too many protons (or too few neutrons) in the nucleus result in an imbalance between forces, which leads to nuclear instability.

Figure 24.1.1 Competing Interactions within the Atomic Nucleus Electrostatic repulsions between positively charged protons would normally cause the nuclei of atoms (except H) to fly apart. In stable atomic nuclei, these repulsions are overcome by the strong nuclear force, a short-range but powerful attractive interaction between nucleons. If the attractive interactions due to the strong nuclear force are weaker than the electrostatic repulsions between protons, the nucleus is unstable, and it will eventually decay.

The relationship between the number of protons and the number of neutrons in stable nuclei, arbitrarily defined as having a half-life longer than 10 times the age of Earth, is shown graphically in [Figure 24.1.2](#). The stable isotopes form a “peninsula of stability” in a “sea of instability.” Only two stable isotopes, ${}^1_1\text{H}$ and ${}^3_2\text{He}$, have a neutron-to-proton ratio less than 1. Several stable isotopes of light atoms have a neutron-to-proton ratio equal to 1 (e.g., ${}^4_2\text{He}$, ${}^{10}_5\text{B}$, ${}^{40}_{20}\text{Ca}$). All other stable nuclei have a higher neutron-to-proton ratio, which increases steadily to about 1.5 for the heaviest nuclei. Regardless of the number of neutrons, however, all elements with $Z > 83$ are unstable and radioactive.

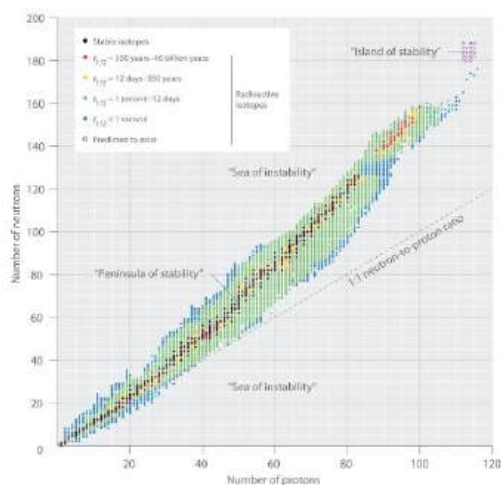

Figure 24.1.2 The Relationship between Nuclear Stability and the Neutron-to-Proton Ratio In this plot of the number of neutrons versus the number of protons, each black point corresponds to a stable nucleus. In this classification, a stable nucleus is arbitrarily defined as one with a half-life longer than 46 billion years (10 times the age of Earth). As the number of protons (the atomic number) increases, the number of neutrons required for a stable nucleus increases even more rapidly. Isotopes shown in red, yellow, green, and blue are progressively less stable and more radioactive; the farther an isotope is from the diagonal band of stable isotopes, the shorter its half-life. The purple dots indicate superheavy nuclei that are predicted to be relatively stable, meaning that they are expected to be radioactive but to have relatively long half-lives. In most cases, these elements have not yet been observed or synthesized.

Data source: National Nuclear Data Center, Brookhaven National Laboratory, Evaluated Nuclear Structure Data File (ENSDF), Chart of Nuclides, <http://www.nndc.bnl.gov/chart>.

As shown in Figure 24.1.3, more than half of the stable nuclei (166 out of 279) have *even* numbers of both neutrons and protons; only 6 of the 279 stable nuclei do not have odd numbers of both. Moreover, certain numbers of neutrons or protons result in especially stable nuclei; these are the so-called *magic numbers* 2, 8, 20, 50, 82, and 126. For example, tin ($Z = 50$) has 10 stable isotopes, but the elements on either side of tin in the periodic table, indium ($Z = 49$) and antimony ($Z = 51$), have only 2 stable isotopes each. Nuclei with magic numbers of *both* protons *and* neutrons are said to be “doubly magic” and are even more stable. Examples of elements with doubly magic nuclei are ${}^4_2\text{He}$ with 2 protons and 2 neutrons, and ${}^{208}_{82}\text{Pb}$ with 82 protons and 126 neutrons, which is the heaviest known stable isotope of any element.

The pattern of stability suggested by the magic numbers of nucleons is reminiscent of the stability associated with the closed-shell electron configurations of the noble gases in group 18 and has led to the hypothesis that the nucleus contains shells of nucleons that are in some ways analogous to the shells occupied by electrons in an atom. As shown in Figure 24.1.2, the “peninsula” of stable isotopes is surrounded by a “reef” of radioactive isotopes, which are stable enough to exist for varying lengths of time before they eventually decay to produce other nuclei.

Figure 24.1.3 The Relationship between the Number of Protons and the Number of Neutrons and Nuclear Stability Most stable nuclei contain even numbers of both neutrons and protons.

Example 24.1.2

Classify each nuclide as stable or radioactive.

1. ${}_{15}^{30}\text{P}$
2. ${}_{43}^{98}\text{Tc}$
3. tin-118
4. ${}_{94}^{239}\text{Pu}$

Given: mass number and atomic number

Asked for: predicted nuclear stability

Strategy:

Use the number of protons, the neutron-to-proton ratio, and the presence of even or odd numbers of neutrons and protons to predict the stability or radioactivity of each nuclide.

Solution:

1. This isotope of phosphorus has 15 neutrons and 15 protons, giving a neutron-to-proton ratio of 1.0. Although the atomic number, 15, is much less than the value of 83 above which all nuclides are unstable, the neutron-to-proton ratio is less than that expected for stability for an element with this mass. As shown in [Figure 24.1.2](#), its neutron-to-proton ratio should be greater than 1. Moreover, this isotope has an odd number of both neutrons and protons, which also tends to make a nuclide unstable. Consequently, ${}_{15}^{30}\text{P}$ is predicted to be radioactive, and it is.
2. This isotope of technetium has 55 neutrons and 43 protons, giving a neutron-to-proton ratio of 1.28, which places ${}_{43}^{98}\text{Tc}$ near the edge of the band of stability. The atomic number, 55, is much less than the value of 83 above which all isotopes are unstable. These facts suggest that ${}_{43}^{98}\text{Tc}$ might be stable. However, ${}_{43}^{98}\text{Tc}$ has an odd number of both neutrons and protons, a combination that seldom gives a stable nucleus. Consequently, ${}_{43}^{98}\text{Tc}$ is predicted to be radioactive, and it is.
3. Tin-118 has 68 neutrons and 50 protons, for a neutron-to-proton ratio of 1.36. As in part b, this value and the atomic number both suggest stability. In addition, the isotope has an *even* number of both neutrons and protons, which tends to increase nuclear stability. Most important, the nucleus has 50 protons, and 50 is one of the magic numbers associated with especially stable nuclei. Thus ${}_{50}^{118}\text{Sn}$ should be particularly stable.
4. This nuclide has an atomic number of 94. Because all nuclei with $Z > 83$ are unstable, ${}_{94}^{239}\text{Pu}$ must be radioactive.

Exercise

Classify each nuclide as stable or radioactive.

1. ${}_{90}^{232}\text{Th}$
2. ${}_{20}^{40}\text{Ca}$
3. ${}_{8}^{15}\text{O}$
4. ${}_{57}^{139}\text{La}$

Answer:

1. radioactive
2. stable
3. radioactive
4. stable

Superheavy Elements

In addition to the “peninsula of stability,” [Figure 24.1.2](#) shows a small “island of stability” that is predicted to exist in the upper right corner. This island corresponds to the superheavy elements, with atomic numbers near the magic number 126. Because the

next magic number for neutrons should be 184, it was suggested that an element with 114 protons and 184 neutrons might be stable enough to exist in nature. Although these claims were met with skepticism for many years, since 1999 a few atoms of isotopes with $Z = 114$ and $Z = 116$ have been prepared and found to be surprisingly stable. One isotope of element 114 lasts 2.7 seconds before decaying, described as an “eternity” by nuclear chemists. Moreover, there is recent evidence for the existence of a nucleus with $A = 292$ that was found in ${}_{114}^{292}\text{Th}$. With an estimated half-life greater than 10^8 years, the isotope is particularly stable. Its measured mass is consistent with predictions for the mass of an isotope with $Z = 122$. Thus a number of relatively long-lived nuclei may well be accessible among the superheavy elements.

Summary

Subatomic particles of the nucleus (protons and neutrons) are called **nucleons**. A **nuclide** is an atom with a particular number of protons and neutrons. An unstable nucleus that decays spontaneously is **radioactive**, and its emissions are collectively called *radioactivity*. Isotopes that emit radiation are called **radioisotopes**. Each nucleon is attracted to other nucleons by the **strong nuclear force**. Stable nuclei generally have even numbers of both protons and neutrons and a neutron-to-proton ratio of at least 1. Nuclei that contain *magic numbers* of protons and neutrons are often especially stable. **Superheavy elements**, with atomic numbers near 126, may even be stable enough to exist in nature.

Key Takeaway

- Nuclei with magic numbers of neutrons or protons are especially stable, as are those nuclei that are doubly magic.

Conceptual Problems

1. What distinguishes a nuclear reaction from a chemical reaction? Use an example of each to illustrate the differences.
2. What do chemists mean when they say a substance is *radioactive*?
3. What characterizes an isotope? How is the mass of an isotope of an element related to the atomic mass of the element shown in the periodic table?
4. In a typical nucleus, why does electrostatic repulsion between protons not destabilize the nucleus? How does the neutron-to-proton ratio affect the stability of an isotope? Why are all isotopes with $Z > 83$ unstable?
5. What is the significance of a *magic number* of protons or neutrons? What is the relationship between the number of stable isotopes of an element and whether the element has a magic number of protons?
6. Do you expect Bi to have a large number of stable isotopes? Ca? Explain your answers.
7. Potassium has three common isotopes, ${}_{19}^{39}\text{K}$, ${}_{19}^{40}\text{K}$, and ${}_{19}^{41}\text{K}$, but only potassium-40 is radioactive (a beta emitter). Suggest a reason for the instability of ${}_{19}^{40}\text{K}$.
8. Samarium has 11 relatively stable isotopes, but only 4 are nonradioactive. One of these 4 isotopes is ${}_{64}^{144}\text{Sm}$, which has a lower neutron-to-proton ratio than lighter, radioactive isotopes of samarium. Why is ${}_{64}^{144}\text{Sm}$ more stable?

Answers

- 1.
- 2.
- 3.
- 4.
5. Isotopes with magic numbers of protons and/or neutrons tend to be especially stable. Elements with magic numbers of protons tend to have more stable isotopes than elements that do not.
- 6.
7. Potassium-40 has 19 protons and 21 neutrons. Nuclei with odd numbers of both protons and neutrons tend to be unstable. In addition, the neutron-to-proton ratio is very low for an element with this mass, which decreases nuclear stability.
- 8.

Numerical Problems

- Write the nuclear symbol for each isotope using notation.
 - chlorine-39
 - lithium-8
 - osmium-183
 - zinc-71
- Write the nuclear symbol for each isotope using A_ZX notation.
 - lead-212
 - helium-5
 - oxygen-19
 - plutonium-242
- Give the number of protons, the number of neutrons, and the neutron-to-proton ratio for each isotope.
 - iron-57
 - ${}^{185}\text{W}$
 - potassium-39
 - ${}^{131}\text{Xe}$
- Give the number of protons, the number of neutrons, and the neutron-to-proton ratio for each isotope.
 - technetium-99m
 - ${}^{140}\text{La}$
 - radium-227
 - ${}^{208}\text{Bi}$
- Which of these nuclides do you expect to be radioactive? Explain your reasoning.

Unit 4: Thermochem & Gases
Unit 8: Materials

Learning Objectives

- To know the different kinds of radioactive decay.
- To balance a nuclear reaction.

The two general kinds of nuclear reactions are nuclear decay reactions and nuclear transmutation reactions. In a nuclear decay reaction, also called *radioactive decay*, an unstable nucleus emits radiation and is transformed into the nucleus of one or more other elements. The resulting *daughter nuclei* have a lower mass and are lower in energy (more stable) than the *parent nucleus* that decayed. In contrast, in a nuclear transmutation reaction, a nucleus reacts with a subatomic particle or another nucleus to form a product nucleus that is *more massive* than the starting material. As we shall see, nuclear decay reactions occur spontaneously under all conditions, but nuclear transmutation reactions occur only under very special conditions, such as the collision of a beam of highly energetic particles with a target nucleus or in the interior of stars. We begin this section by considering the different classes of radioactive nuclei, along with their characteristic nuclear decay reactions and the radiation they emit.

Note the Pattern

Nuclear decay reactions occur spontaneously under all conditions, whereas nuclear transmutation reactions are induced.

Classes of Radioactive Nuclei

The three general classes of radioactive nuclei are characterized by a different decay process or set of processes:

1. **Neutron-rich nuclei.** The nuclei on the upper left side of the band of stable nuclei in [Figure 24.1.2](#) have a neutron-to-proton ratio that is too high to give a stable nucleus. These nuclei decay by a process that *converts a neutron to a proton*, thereby *decreasing* the neutron-to-proton ratio.
2. **Neutron-poor nuclei.** Nuclei on the lower right side of the band of stable nuclei have a neutron-to-proton ratio that is too low to give a stable nucleus. These nuclei decay by processes that have the net effect of *converting a proton to a neutron*, thereby *increasing* the neutron-to-proton ratio.
3. **Heavy nuclei.** With very few exceptions, heavy nuclei (those with $A \geq 200$) are intrinsically unstable regardless of the neutron-to-proton ratio, and all nuclei with $Z > 83$ are unstable. This is presumably due to the cumulative effects of electrostatic repulsions between the large number of positively charged protons, which cannot be totally overcome by the strong nuclear force, regardless of the number of neutrons present. Such nuclei tend to decay by emitting an α particle (a helium nucleus, ${}^4_2\text{He}$), which decreases the number of protons and neutrons in the original nucleus by 2. Because the neutron-to-proton ratio in an α particle is 1, the net result of alpha emission is an increase in the neutron-to-proton ratio.

Note the Pattern

Nuclear decay reactions always produce daughter nuclei that have a more favorable neutron-to-proton ratio and hence are more stable than the parent nucleus.

Nuclear Decay Reactions

Just as we use the number and type of *atoms* present to balance a chemical equation, we can use the number and type of *nucleons* present to write a balanced nuclear equation for a nuclear decay reaction. This procedure also allows us to predict the identity of either the parent or the daughter nucleus if the identity of only one is known. Regardless of the mode of decay, *the total number of nucleons is conserved* in all nuclear reactions.

To describe nuclear decay reactions, chemists have extended the A_ZX notation for nuclides to include radioactive emissions. [Table 24.2.1](#) lists the name and symbol for each type of emitted radiation. We introduced the most common of these, α and β particles and γ rays, in [Chapter 1](#) and [Chapter 14](#). The most notable addition is the positron, a particle that has the same mass as an electron but a *positive* charge rather than a negative charge.

Table 24.2.1 Nuclear Decay Emissions and Their Symbols

Identity	Symbol	Charge	Mass (amu)
helium nucleus	${}^4_2\alpha$	+2	4.001506
electron	${}^0_{-1}\beta$ or β^-	-1	0.000549
photon	${}^0_0\gamma$	—	—
neutron	1_0n	0	1.008665
proton	1_1p	+1	1.007276
positron	${}^0_{+1}\beta$ or β^+	+1	0.000549

Like the notation used to indicate isotopes, the upper left superscript in the symbol for a particle gives the mass number, which is the total number of protons and neutrons. For a proton or a neutron, $A = 1$. Because neither an electron nor a positron contains protons or neutrons, its mass number is 0. The numbers should not be taken literally, however, as meaning that these particles have zero mass; ejection of a beta particle (an electron) simply has a negligible effect on the mass of a nucleus.

Similarly, the lower left subscript gives the charge of the particle. Because protons carry a positive charge, $Z = +1$ for a proton. In contrast, a neutron contains no protons and is electrically neutral, so $Z = 0$. In the case of an electron, $Z = -1$, and for a positron, $Z = +1$. Because γ rays are high-energy photons, both A and Z are 0. In some cases, two different symbols are used for particles that are identical but produced in different ways. For example, the symbol ${}^0_{-1}e$ which is usually simplified to e^- , represents a free electron or an electron associated with an *atom*, whereas the symbol ${}^0_{-1}\beta$ which is often simplified to β^- , denotes an electron that originates from within the *nucleus*, which is a β particle. Similarly, ${}^4_2He^{2+}$ refers to the nucleus of a helium atom, and ${}^4_2\alpha$ denotes an identical particle that has been ejected from a heavier nucleus.

There are six fundamentally different kinds of nuclear decay reactions, and each releases a different kind of particle or energy. The essential features of each reaction are shown in [Figure 24.2.1](#). The most common are *alpha* and *beta decay* and *gamma emission*, but the others are essential to an understanding of nuclear decay reactions.

Decay Type	Radiation Emitted	Generic Equation	Model
Alpha decay	${}^4_2\alpha$	${}^A_ZX \rightarrow {}^{A-4}_{Z-2}X + {}^4_2\alpha$	
Beta decay	${}^0_{-1}\beta$	${}^A_ZX \rightarrow {}^{A}_{Z+1}X + {}^0_{-1}\beta$	
Positron emission	${}^0_{+1}\beta$	${}^A_ZX \rightarrow {}^{A}_{Z-1}X + {}^0_{+1}\beta$	
Electron capture	X rays	${}^A_ZX + {}^0_{-1}e \rightarrow {}^{A}_{Z-1}X + \text{X ray}$	
Gamma emission	${}^0_0\gamma$	${}^A_ZX^* \xrightarrow{\text{Relaxation}} {}^A_ZX + {}^0_0\gamma$	
Spontaneous fission	Neutrons	${}^{A+B+C}_{Z+Y}X \rightarrow {}^A_ZX + {}^B_YX + C^1_0n$	

Figure 24.2.1 Common Modes of Nuclear Decay

Alpha Decay

Many nuclei with mass numbers greater than 200 undergo alpha (α) decay, which results in the emission of a helium-4 nucleus as an alpha (α) particle ${}^4_2\alpha$. The general reaction is as follows:

The daughter nuclide contains two fewer protons and two fewer neutrons than the parent. Thus α -particle emission produces a daughter nucleus with a mass number $A - 4$ and a nuclear charge $Z - 2$ compared to the parent nucleus. Radium-226, for example, undergoes alpha decay to form radon-222:

Because nucleons are conserved in this and all other nuclear reactions, the sum of the mass numbers of the products, $222 + 4 = 226$, equals the mass number of the parent. Similarly, the sum of the atomic numbers of the products, $86 + 2 = 88$, equals the atomic number of the parent. Thus the nuclear equation is balanced.

Note the Pattern

Just as the total number of atoms is conserved in a chemical reaction, the total number of nucleons is conserved in a nuclear reaction.

Beta Decay

Nuclei that contain too many neutrons often undergo beta (β) decay, in which a neutron is converted to a proton and a high-energy electron that is ejected from the nucleus as a β particle:

The general reaction for beta decay is therefore

Although beta decay does *not* change the mass number of the nucleus, it does result in an increase of +1 in the atomic number because of the addition of a proton in the daughter nucleus. Thus beta decay decreases the neutron-to-proton ratio, moving the nucleus toward the band of stable nuclei. For example, carbon-14 undergoes beta decay to form nitrogen-14:

Once again, the number of nucleons is conserved, and the charges are balanced. The parent and the daughter nuclei have the same mass number, 14, and the sum of the atomic numbers of the products is 6, which is the same as the atomic number of the carbon-14 parent.

Positron Emission

Because a positron has the same mass as an electron but opposite charge, positron emission is the opposite of beta decay. Thus positron emission is characteristic of neutron-poor nuclei, which decay by transforming a proton to a neutron and emitting a high-energy positron:

The general reaction for positron emission is therefore

Like beta decay, positron emission does not change the mass number of the nucleus. In this case, however, the atomic number of the daughter nucleus is *lower* by 1 than that of the parent. Thus the neutron-to-proton ratio has increased, again moving the nucleus closer to the band of stable nuclei. For example, carbon-11 undergoes positron emission to form boron-11:

Nucleons are conserved, and the charges balance. The mass number, 11, does not change, and the sum of the atomic numbers of the products is 6, the same as the atomic number of the parent carbon-11 nuclide.

Electron Capture

A neutron-poor nucleus can decay by either positron emission or electron capture (EC), in which an electron in an inner shell reacts with a proton to produce a neutron:

When a second electron moves from an outer shell to take the place of the lower-energy electron that was absorbed by the nucleus, an x-ray is emitted. The overall reaction for electron capture is thus

Electron capture does not change the mass number of the nucleus because both the proton that is lost and the neutron that is formed have a mass number of 1. As with positron emission, however, the atomic number of the daughter nucleus is *lower* by 1 than that of the parent. Once again, the neutron-to-proton ratio has increased, moving the nucleus toward the band of stable nuclei. For example, iron-55 decays by electron capture to form manganese-55, which is often written as follows:

The atomic numbers of the parent and daughter nuclides differ in [Equation 20.11](#), although the mass numbers are the same. To write a balanced nuclear equation for this reaction, we must explicitly include the captured electron in the equation:

Both positron emission and electron capture are usually observed for nuclides with low neutron-to-proton ratios, but the decay rates for the two processes can be very different.

Gamma Emission

Many nuclear decay reactions produce daughter nuclei that are in a nuclear excited state, which is similar to an atom in which an electron has been excited to a higher-energy orbital to give an electronic excited state. Just as an electron in an electronic excited state emits energy in the form of a photon when it returns to the ground state, a nucleus in an excited state releases energy in the form of a photon when it returns to the ground state. (For more information on electron ground states, see [Chapter 2](#)) These high-energy photons are γ rays. Gamma (γ) emission can occur virtually instantaneously, as it does in the alpha decay of uranium-238 to thorium-234, where the asterisk denotes an excited state:

If we disregard the decay event that created the excited nucleus, then

or more generally,

Gamma emission can also occur after a significant delay. For example, technetium-99 m has a half-life of about 6 hours before emitting a γ ray to form technetium-99. (The m is for metastable, which is explained in [Section 14.5](#).)

Because γ rays are energy, their emission does not affect either the mass number or the atomic number of the daughter nuclide. Gamma-ray emission is therefore the only kind of radiation that does not necessarily involve the conversion of one element to another, although it is almost always observed in conjunction with some other nuclear decay reaction.

Spontaneous Fission

Only very massive nuclei with high neutron-to-proton ratios can undergo spontaneous fission, in which the nucleus breaks into two pieces that have different atomic numbers and atomic masses. This process is most important for the transactinide elements, with $Z \geq 104$. Spontaneous fission is invariably accompanied by the release of large amounts of energy, and it is usually accompanied by the emission of several neutrons as well. An example is the spontaneous fission of ${}_{98}^{254}\text{Cf}$ which gives a distribution of fission products; one possible set of products is shown in the following equation:

Once again, the number of nucleons is conserved. Thus the sum of the mass numbers of the products ($118 + 132 + 4 = 254$) equals the mass number of the reactant. Similarly, the sum of the atomic numbers of the products [$46 + 52 + (4 \times 0) = 98$] is the same as the atomic number of the parent nuclide.

Example 24.2.1

Write a balanced nuclear equation to describe each reaction.

1. the beta decay of ${}_{16}^{35}\text{S}$
2. the decay of ${}_{80}^{201}\text{Hg}$ by electron capture
3. the decay of ${}_{15}^{30}\text{P}$ by positron emission

Given: radioactive nuclide and mode of decay

Asked for: balanced nuclear equation

Strategy:

A Identify the reactants and the products from the information given.

B Use the values of A and Z to identify any missing components needed to balance the equation.

Solution:

A We know the identities of the reactant and one of the products (a β particle). We can therefore begin by writing an equation that shows the reactant and one of the products and indicates the unknown product as ${}_Z^AX$

B Because both protons and neutrons must be conserved in a nuclear reaction, the unknown product must have a mass number of $A = 35 - 0 = 35$ and an atomic number of $Z = 16 - (-1) = 17$. The element with $Z = 17$ is chlorine, so the balanced nuclear equation is as follows:

A We know the identities of both reactants: ${}_{80}^{201}\text{Hg}$. The reaction is as follows:

B Both protons and neutrons are conserved, so the mass number of the product must be $A = 201 + 0 = 201$, and the atomic number of the product must be $Z = 80 + (-1) = 79$, which corresponds to the element gold. The balanced nuclear equation is thus

- A** As in part (a), we are given the identities of the reactant and one of the products—in this case, a positron. The unbalanced nuclear equation is therefore

B The mass number of the second product is $A = 30 - 0 = 30$, and its atomic number is $Z = 15 - 1 = 14$, which corresponds to silicon. The balanced nuclear equation for the reaction is as follows:

Exercise

Write a balanced nuclear equation to describe each reaction.

- ${}_{6}^{11}\text{C}$ by positron emission
- the beta decay of molybdenum-99
- the emission of an α particle followed by gamma emission from
- ${}_{74}^{185}\text{C}$

Answer:

- ${}_{6}^{11}\text{C} \rightarrow {}_{5}^{11}\text{B} + {}_{+1}^0\beta$
- ${}_{42}^{99}\text{C} \rightarrow {}_{43}^{90m}\text{Tc} + {}_{-1}^0\beta$
- ${}_{74}^{185}\text{W} \rightarrow {}_{72}^{181}\text{Hf} + {}_0^0\gamma\beta + {}_2^4\alpha$

Example 24.2.2

Predict the kind of nuclear change each unstable nuclide undergoes when it decays.

- ${}_{22}^{45}\text{Ti}$
- ${}_{94}^{292}\text{Pu}$
- ${}_{5}^{12}\text{B}$
- ${}_{100}^{256}\text{Fm}$

Given: nuclide

Asked for: type of nuclear decay

Strategy:

Based on the neutron-to-proton ratio and the value of Z , predict the type of nuclear decay reaction that will produce a more stable nuclide.

Solution:

1. This nuclide has a neutron-to-proton ratio of only 1.05, which is much less than the requirement for stability for an element with an atomic number in this range. Nuclei that have low neutron-to-proton ratios decay by converting a proton to a neutron. The two possibilities are positron emission, which converts a proton to a neutron and a positron, and electron capture, which converts a proton and a core electron to a neutron. In this case, both are observed, with positron emission occurring about 86% of the time and electron capture about 14% of the time.
2. Nuclei with $Z > 83$ are too heavy to be stable and usually undergo alpha decay, which decreases both the mass number and the atomic number. Thus ${}_{94}^{292}\text{Pu}$ is expected to decay by alpha emission.
3. This nuclide has a neutron-to-proton ratio of 1.4, which is very high for a light element. Nuclei with high neutron-to-proton ratios decay by converting a neutron to a proton and an electron. The electron is emitted as a β particle, and the proton remains in the nucleus, causing an increase in the atomic number with no change in the mass number. We therefore predict that ${}_{5}^{12}\text{B}$ will undergo beta decay.
4. This is a massive nuclide, with an atomic number of 100 and a mass number much greater than 200. Nuclides with $A \geq 200$ tend to decay by alpha emission, and even heavier nuclei tend to undergo spontaneous fission. We therefore predict that ${}_{100}^{256}\text{Fm}$ will decay by either or both of these two processes. In fact, it decays by both spontaneous fission and alpha emission, in a 97:3 ratio.

Exercise

Predict the kind of nuclear change each unstable nuclide undergoes when it decays.

1. ${}_{14}^{32}\text{Si}$
2. ${}_{21}^{43}\text{Sc}$
3. ${}_{91}^{231}\text{Pa}$

Answer:

1. beta decay
2. positron emission or electron capture
3. alpha decay

Radioactive Decay Series

The nuclei of all elements with atomic numbers greater than 83 are unstable. Thus all isotopes of all elements beyond bismuth in the periodic table are radioactive. Because alpha decay decreases Z by only 2, and positron emission or electron capture decreases Z by only 1, it is impossible for any nuclide with $Z > 85$ to decay to a stable daughter nuclide in a single step, except via nuclear fission. Consequently, radioactive isotopes with $Z > 85$ usually decay to a daughter nucleus that is radioactive, which in turn decays to a second radioactive daughter nucleus, and so forth, until a stable nucleus finally results. This series of sequential alpha- and beta-decay reactions is called a radioactive decay series. The most common is the uranium-238 decay series, which produces lead-206 in a series of 14 sequential alpha- and beta-decay reactions (Figure 24.2.2). Although a radioactive decay series can be written for almost any isotope with $Z > 85$, only two others occur naturally: the decay of uranium-235 to lead-207 (in 11 steps) and thorium-232 to lead-208 (in 10 steps). A fourth series, the decay of neptunium-237 to bismuth-209 in 11 steps, is known to have occurred on the primitive Earth. With a half-life of “only” 2.14 million years, all the neptunium-237 present when Earth was formed decayed long ago, and today all the neptunium on Earth is synthetic.

Figure 24.2.2 A Radioactive Decay Series Three naturally occurring radioactive decay series are known to occur currently: the uranium-238 decay series, the decay of uranium-235 to lead-207, and the decay of thorium-232 to lead-208.

Due to these radioactive decay series, small amounts of very unstable isotopes are found in ores that contain uranium or thorium. These rare, unstable isotopes should have decayed long ago to stable nuclei with a lower atomic number, and they would no longer be found on Earth. Because they are generated continuously by the decay of uranium or thorium, however, their amounts have reached a steady state, in which their rate of formation is equal to their rate of decay. In some cases, the abundance of the daughter isotopes can be used to date a material or identify its origin, as described in [Chapter 14](#).

Induced Nuclear Reactions

The discovery of radioactivity in the late 19th century showed that some nuclei spontaneously transform into nuclei with a different number of protons, thereby producing a different element. When scientists realized that these naturally occurring radioactive isotopes decayed by emitting subatomic particles, they realized that—in principle—it should be possible to carry out the reverse reaction, converting a stable nucleus to another more massive nucleus by bombarding it with subatomic particles in a nuclear transmutation reaction.

The first successful nuclear transmutation reaction was carried out in 1919 by Ernest Rutherford, who showed that α particles emitted by radium could react with nitrogen nuclei to form oxygen nuclei. As shown in the following equation, a proton is emitted in the process:

Rutherford's nuclear transmutation experiments led to the discovery of the neutron. He found that bombarding the nucleus of a light target element with an α particle usually converted the target nucleus to a product that had an atomic number higher by 1 and a mass number higher by 3 than the target nucleus. Such behavior is consistent with the emission of a proton after reaction with the α particle. Very light targets such as Li, Be, and B reacted differently, however, emitting a new kind of highly penetrating radiation rather than a proton. Because neither a magnetic field nor an electrical field could deflect these high-energy particles, Rutherford concluded that they were electrically neutral. (For more information on high-energy particles, see [Chapter 1](#).) Other observations suggested that the mass of the neutral particle was similar to the mass of the proton. In 1932, James Chadwick (Nobel Prize in Physics, 1935), who was a student of Rutherford's at the time, named these neutral particles *neutrons* and proposed that they were fundamental building blocks of the atom. The reaction that Chadwick initially used to explain the production of neutrons was as follows:

Because α particles and atomic nuclei are both positively charged, electrostatic forces cause them to repel each other. Only α particles with very high kinetic energy can overcome this repulsion and collide with a nucleus ([Figure 24.2.3](#)). Neutrons have no electrical charge, however, so they are not repelled by the nucleus. Hence bombardment with neutrons is a much easier way to prepare new isotopes of the lighter elements. In fact, carbon-14 is formed naturally in the atmosphere by bombarding nitrogen-14 with neutrons generated by cosmic rays:

Figure 24.2.3 A Nuclear Transmutation Reaction Bombarding a target of one element with high-energy nuclei or subatomic particles can create new elements. Electrostatic repulsions normally prevent a positively charged particle from colliding and reacting with a positively charged nucleus. If the positively charged particle is moving at a very high speed, however, its kinetic energy may be great enough to overcome the electrostatic repulsions, and it may collide with the target nucleus. Such collisions can result in a nuclear transmutation reaction.

Example 24.2.3

In 1933, Frédéric Joliot and Irène Joliot-Curie (daughter of Marie and Pierre Curie) prepared the first artificial radioactive isotope by bombarding aluminum-27 with α particles. For each $^{27}_{13}\text{Al}$ that reacted, one neutron was released. Identify the product nuclide and write a balanced nuclear equation for this transmutation reaction.

Given: reactants in a nuclear transmutation reaction

Asked for: product nuclide and balanced nuclear equation

Strategy:

A Based on the reactants and one product, identify the other product of the reaction. Use conservation of mass and charge to determine the values of Z and A of the product nuclide and thus its identity.

B Write the balanced nuclear equation for the reaction.

Solution:

A Bombarding an element with α particles usually produces an element with an atomic number that is 2 greater than the atomic number of the target nucleus. Thus we expect that aluminum ($Z = 13$) will be converted to phosphorus ($Z = 15$). With one neutron released, conservation of mass requires that the mass number of the other product be 3 greater than the mass number of the target. In this case, the mass number of the target is 27, so the mass number of the product will be 30. The second product is therefore phosphorus-30, $^{30}_{15}\text{P}$.

B The balanced nuclear equation for the reaction is as follows:

Exercise

Because all isotopes of technetium are radioactive and have short half-lives, it does not exist in nature. Technetium can, however, be prepared by nuclear transmutation reactions. For example, bombarding a molybdenum-96 target with deuterium nuclei ^2_1H produces technetium-97. Identify the other product of the reaction and write a balanced nuclear equation for this transmutation reaction.

Answer: neutron, $^1_0n, ^{96}_{42}\text{Mo} + ^2_1\text{H} \rightarrow ^{97}_{43}\text{Tc} + ^1_0n$

We noted earlier in this section that very heavy nuclides, corresponding to $Z \geq 104$, tend to decay by spontaneous fission. Nuclides with slightly lower values of Z , such as the isotopes of uranium ($Z = 92$) and plutonium ($Z = 94$), do not undergo spontaneous fission at any significant rate. Some isotopes of these elements, however, such as $^{235}_{92}\text{U}$ and $^{239}_{94}\text{Pu}$ undergo *induced nuclear fission* when they are bombarded with relatively low-energy neutrons, as shown in the following equation for uranium-235 and in [Figure 24.2.4](#):

Figure 24.2.4 Neutron-Induced Nuclear Fission Collision of a relatively slow-moving neutron with a fissile nucleus can split it into two smaller nuclei with the same or different masses. Neutrons are also released in the process, along with a great deal of energy.

Any isotope that can undergo a nuclear fission reaction when bombarded with neutrons is called a *fissile isotope*.

During nuclear fission, the nucleus usually divides asymmetrically rather than into two equal parts, as shown in [Figure 24.2.4](#). Moreover, every fission event of a given nuclide does not give the same products; more than 50 different fission modes have been identified for uranium-235, for example. Consequently, nuclear fission of a fissile nuclide can never be described by a single equation. Instead, as shown in [Figure 24.2.5](#), a distribution of many pairs of fission products with different yields is obtained, but the mass ratio of each pair of fission products produced by a single fission event is always roughly 3:2.

Figure 24.2.5 Mass Distribution of Nuclear Fission Products of ${}_{92}^{235}\text{U}$ Nuclear fission usually produces a range of products with different masses and yields, although the mass ratio of each pair of fission products from a fission event is approximately 3:2. As shown in this plot, more than 50 different fission products are known for ${}_{92}^{235}\text{U}$.

Data source: T. R. England and B. F. Rider, Los Alamos National Laboratory, LA-UR-94-3106, ENDF-349 (1993).

Synthesis of Transuranium Elements

Uranium ($Z = 92$) is the heaviest naturally occurring element. Consequently, all the elements with $Z > 92$, the transuranium elements, are artificial and have been prepared by bombarding suitable target nuclei with smaller particles. The first of the transuranium elements to be prepared was neptunium ($Z = 93$), which was synthesized in 1940 by bombarding a ${}_{92}^{238}\text{U}$ target with neutrons. As shown in [Equation 24.2.21](#), this reaction occurs in two steps. Initially, a neutron combines with a ${}_{92}^{238}\text{U}$ nucleus to form ${}_{92}^{239}\text{U}$, which is unstable and undergoes beta decay to produce ${}_{93}^{239}\text{Np}$:

Subsequent beta decay of ${}_{93}^{239}\text{Np}$ produces the second transuranium element, plutonium ($Z = 94$):

Bombarding the target with more massive nuclei creates elements that have atomic numbers significantly greater than that of the target nucleus ([Table 20.2.2](#)). Such techniques have resulted in the creation of the superheavy elements 114 and 116, both of which

lie in or near the “island of stability” discussed in [Section 24.1](#) .

Table 20.2.2 Some Reactions Used to Synthesize Transuranium Elements

${}_{94}^{239}\text{Pu} + {}_2^4\alpha \rightarrow {}_{96}^{242}\text{Cm} + {}_0^1n$
${}_{94}^{239}\text{Pu} + {}_2^4\alpha \rightarrow {}_{95}^{241}\text{Am} + {}_1^1p + {}_0^1n$
${}_{96}^{242}\text{Cm} + {}_2^4\alpha \rightarrow {}_{97}^{243}\text{Bk} + {}_1^1p + 2{}_0^1n$
${}_{99}^{253}\text{Es} + {}_2^4\alpha \rightarrow {}_{101}^{256}\text{Md} + {}_0^1n$
${}_{92}^{238}\text{U} + {}_6^{12}\text{C} \rightarrow {}_{98}^{246}\text{Cf} + 4{}_0^1n$
${}_{98}^{252}\text{Cf} + {}_5^{10}\text{B} \rightarrow {}_{103}^{256}\text{Lr} + 6{}_0^1n$

A device called a *particle accelerator* is used to accelerate positively charged particles to the speeds needed to overcome the electrostatic repulsions between them and the target nuclei by using electrical and magnetic fields. Operationally, the simplest particle accelerator is the linear accelerator ([Figure 24.2.6](#)), in which a beam of particles is injected at one end of a long evacuated tube. Rapid alternation of the polarity of the electrodes along the tube causes the particles to be alternately accelerated toward a region of opposite charge and repelled by a region with the same charge, resulting in a tremendous acceleration as the particle travels down the tube. A modern linear accelerator such as the Stanford Linear Accelerator (SLAC) at Stanford University is about 2 miles long.

Figure 24.2.6 A Linear Particle Accelerator (a) An aerial view of the SLAC, the longest linear particle accelerator in the world; the overall length of the tunnel is 2 miles. (b) Rapidly reversing the polarity of the electrodes in the tube causes the charged particles to be alternately attracted as they enter one section of the tube and repelled as they leave that section. As a result, the particles are continuously accelerated along the length of the tube.

To achieve the same outcome in less space, a particle accelerator called a *cyclotron* forces the charged particles to travel in a circular path rather than a linear one. The particles are injected into the center of a ring and accelerated by rapidly alternating the polarity of two large D-shaped electrodes above and below the ring, which accelerates the particles outward along a spiral path toward the target.

The length of a linear accelerator and the size of the D-shaped electrodes in a cyclotron severely limit the kinetic energy that particles can attain in these devices. These limitations can be overcome by using a *synchrotron*, a hybrid of the two designs. A synchrotron contains an evacuated tube similar to that of a linear accelerator, but the tube is circular and can be more than a mile in diameter ([Figure 24.2.7](#)). Charged particles are accelerated around the circle by a series of magnets whose polarities rapidly alternate.

Figure 24.2.7 A Synchrotron An aerial photograph of what is currently the world's most powerful particle accelerator, the Tevatron at the Fermi National Accelerator Laboratory (Fermilab) in Illinois. The large tube characteristic of a synchrotron is 4 miles in circumference, contains 1000 superconducting magnets cooled by liquid helium, and can accelerate a beam of protons to almost the speed of light, giving them an energy greater than 1 TeV (teraelectronvolt = 10^3 GeV = 10^{12} eV) for collisions with other particles.

Summary

In **nuclear decay reactions (or radioactive decay)**, the *parent nucleus* is converted to a more stable *daughter nucleus*. Nuclei with too many neutrons decay by converting a neutron to a proton, whereas nuclei with too few neutrons decay by converting a proton to a neutron. Very heavy nuclei (with $A \geq 200$ and $Z > 83$) are unstable and tend to decay by emitting an **α particle**. When an unstable nuclide undergoes radioactive decay, the total number of nucleons is conserved, as is the total positive charge. Six different kinds of nuclear decay reactions are known. **Alpha decay** results in the emission of an α particle, ${}^4_2\text{He}$, and produces a daughter nucleus with a mass number that is lower by 4 and an atomic number that is lower by 2 than the parent nucleus. **Beta decay** converts a neutron to a proton and emits a high-energy electron, producing a daughter nucleus with the same mass number as the parent and an atomic number that is higher by 1. **Positron emission** is the opposite of beta decay and converts a proton to a neutron plus a positron. Positron emission does not change the mass number of the nucleus, but the atomic number of the daughter nucleus is lower by 1 than the parent. In **electron capture (EC)**, an electron in an inner shell reacts with a proton to produce a neutron, with emission of an x-ray. The mass number does not change, but the atomic number of the daughter is lower by 1 than the parent. In **gamma emission**, a daughter nucleus in a *nuclear excited state* undergoes a transition to a lower-energy state by emitting a γ ray. Very heavy nuclei with high neutron-to-proton ratios can undergo **spontaneous fission**, in which the nucleus breaks into two pieces that can have different atomic numbers and atomic masses with the release of neutrons. Many very heavy nuclei decay via a **radioactive decay series**—a succession of some combination of alpha- and beta-decay reactions. In **nuclear transmutation reactions**, a target nucleus is bombarded with energetic subatomic particles to give a product nucleus that is more massive than the original. All **transuranium elements**—elements with $Z > 92$ —are artificial and must be prepared by nuclear transmutation reactions. These reactions are carried out in *particle accelerators* such as *linear accelerators*, *cyclotrons*, and *synchrotrons*.

Key Takeaway

- Nuclear decay reactions occur spontaneously under all conditions and produce more stable daughter nuclei, whereas nuclear transmutation reactions are induced and form a product nucleus that is more massive than the starting material.

Conceptual Problems

- Describe the six classifications of nuclear decay reactions. What is the most common mode of decay for elements that have heavy nuclei? Why?
- Complete the following table for these five nuclear reactions.

	Alpha Decay	Beta Decay	Gamma Emission	Positron Emission	Electron Capture
identity of particle or radiation	helium-4 nucleus				
mass number of parent – mass number of daughter	4				
atomic number of parent – atomic number of daughter		-1			
effect on neutron-to-proton ratio		decreases			

- What is the most common decay process for elements in row 5 of the periodic table that contain too few neutrons for the number of protons present? Why?
- Explain the difference between the symbols e^- and β^+ . What is the difference in meaning between the symbols ${}^4_2 He$ and ${}^4_2 \alpha$?
- What is a mass number? Which particles have a mass number of zero?
- What are the key differences between the equations written for chemical reactions and for nuclear reactions? How are they similar?
- Can all the kinds of nuclear decay reactions discussed be characterized by the general equation: parent \rightarrow daughter + particle? Explain your answer.
- Which types of nuclear decay reactions conserve both mass number and atomic number? In which do the parent and daughter nuclei have the same mass number but different atomic numbers? Which do not convert one element to another?
- Describe a radioactive decay series. How many series occur naturally? Of these, which one no longer occurs in nature? Why?
- Only nine naturally occurring elements have an atomic number greater than 83, and all of them are radioactive. Except for some isotopes of uranium that have a very long half-life, the half-lives of the heavy elements are so short that these elements should have been completely converted to lighter, more stable elements long ago. Why are these elements still present in nature?

11. Why are neutrons preferred to protons when preparing new isotopes of the lighter elements?
12. Why are particle accelerators and cyclotrons needed to create the transuranium elements?

Answers

- 1.
- 2.
3. Both positron decay and electron capture increase the neutron-to-proton ratio; electron capture is more common for heavier elements such those of row 5.
- 4.
5. The mass number is the sum of the numbers of protons and neutrons present. Particles with a mass number of zero include β particles (electrons) and positrons; gamma rays and x-rays also have a mass number of zero.
- 6.
- 7.
- 8.
- 9.
- 10.
11. Unlike protons, neutrons have no charge, which minimizes the electrostatic barrier to colliding and reacting with a positively charged nucleus.
- 12.

Numerical Problems

1. What type of particle is emitted in each nuclear reaction?
 - a. ${}_{94}^{238}\text{Pu} \rightarrow {}_{92}^{234}\text{U}$
 - b. ${}_{18}^{32}\text{Si} \rightarrow {}_{18}^{32}\text{P}$
 - c. ${}_{206}^{81}\text{F} \rightarrow {}_{80}^{206}\text{O}$
 - d. ${}_{81}^{206}\text{Tl} \rightarrow {}_{82}^{206}\text{Pb}$
2. What type of particle is emitted in each nuclear reaction?
 - a. ${}_{90}^{224}\text{Th} \rightarrow {}_{88}^{224}\text{Ra}$
 - b. ${}_{86}^{210}\text{Rn} \rightarrow {}_{84}^{206}\text{Fr}$
 - c. ${}_{83}^{208}\text{Bi} \rightarrow {}_{81}^{208}\text{Tl}$
 - d. ${}_{17}^{35}\text{Cl} \rightarrow {}_{16}^{35}\text{S}$
3. Predict the mode of decay and write a balanced nuclear reaction for each isotope.
 - a. ${}_{92}^{254}\text{U}$
 - b. ${}_{88}^{268}\text{Es}$
 - c. ${}_{16}^{99}\text{S}$
 - d. ${}_{42}^{98}\text{Mo}$
4. Predict the mode of decay and write a balanced nuclear reaction for each isotope.
 - a. ${}_{7}^{231}\text{N}$
 - b. ${}_{91}^{231}\text{Pa}$
 - c. ${}_{8}^{77}\text{Be}$
 - d. ${}_{32}^{77}\text{Ge}$
5. Balance each nuclear reaction.
 - a. ${}_{84}^{208}\text{Po} \rightarrow \alpha + \text{Pb}$
 - b. ${}_{88}^{228}\text{Ra} \rightarrow \alpha + \text{Rn}$
 - c. ${}_{90}^{231}\text{Th} \rightarrow \text{Ra} + \alpha + \gamma$
 - d. ${}_{91}^{231}\text{Pa} \rightarrow {}_{89}^{227}\text{Ac} + \alpha + \gamma$
 - e. ${}_{67}^{166}\text{Ho} \rightarrow {}_{68}^{166}\text{Er} + \beta^- + \gamma$
 - f. ${}_{89}^{214}\text{Ac} \rightarrow {}_{90}^{214}\text{Th} + \beta^- + \gamma$
6. Complete each nuclear reaction.
 - a. ${}_{84}^{210}\text{Po} \rightarrow {}_{82}^{206}\text{Pb}$
 - b. ${}_{85}^{217}\text{At} \rightarrow {}_{83}^{213}\text{Bi} + \alpha$

- c. $Ra \rightarrow {}_{86}^{220}Rn + \alpha$
 d. ${}^{208}_{82}Tl \rightarrow {}_{82}^{208}Pb + \beta^-$
 e. $Np \rightarrow {}^{239}_{94}Pu + \beta^-$
 f. $Fe \rightarrow {}^{52}_{26}Mn + \beta^+ + \gamma$

7. Write a balanced nuclear equation for each reaction.

- a. β^+ decay of ${}_{20}^{87}Rb$
 b. β^- decay of ${}_{26}^{68}Mg$
 c. α decay of ${}_{81}^{208}Mt$

8. Write a balanced nuclear equation for each reaction.

- a. β^+ decay of ${}_{41}^{45}K$
 b. β^- decay of ${}_{146}^{146}Sc$
 c. α decay of ${}_{62}^{146}Sm$

9. The decay products of several isotopes are listed here. Identify the type of radiation emitted and write a balanced nuclear equation for each.

- a. ${}_{82}^{218}Po \rightarrow {}_{82}^{214}Pb$
 b. ${}_{14}^{32}Si \rightarrow {}_{14}^{32}P$
 c. an excited state of an iron-57 nucleus decaying to its ground state
 d. conversion of thallium-204 to lead-204

10. The decay products of several isotopes are listed here. Identify the type of radiation emitted and write a balanced nuclear equation for each.

- a. ${}_{84}^{216}Po \rightarrow {}_{84}^{212}At$
 b. ${}_{84}^{216}Po \rightarrow {}_{82}^{212}Pb$
 c. bismuth-211 converted to thallium-207
 d. americium-242 converted to rhodium-107 with the emission of four neutrons

11. Predict the most likely mode of decay and write a balanced nuclear reaction for each isotope.

- a. ${}_{92}^{238}U$
 b. ${}_{84}^{210}Po$
 c. ${}_{16}^{35}S$
 d. molybdenum-93m

12. Predict the most likely mode of decay and write a balanced nuclear reaction for each isotope.

- a. ${}_{7}^{16}N$
 b. ${}_{90}^{224}Th$
 c. ${}_{49}^{64}In$
 d. ${}_{32}^{68}Ge$

13. For each nuclear reaction, identify the type(s) of decay and write a balanced nuclear equation.

- a. ${}_{84}^{216}Po \rightarrow {}_{84}^{213}At$
 b. ${}_{91}^{228}Pa \rightarrow \alpha + {}_{91}^{228}Pa$
 c. ${}_{90}^{231}Th \rightarrow ? + \alpha + \gamma$
 d. ${}_{91}^{231}Pa \rightarrow ? + \beta + \gamma$

14. For each nuclear reaction, identify the type(s) of decay and write a balanced nuclear equation.

- a. ${}_{82}^{192}Po \rightarrow {}_{82}^{208}Pb + ?$
 b. ${}_{78}^{241}Ir \rightarrow {}_{78}^{184}Pt + ?$
 c. ${}_{77}^{241}Am \rightarrow {}_{26}^{57}Fe + ? + ?$
 d. ${}_{32}^{77}Ge \rightarrow ? + ?$

15. Identify the parent isotope and write a balanced nuclear reaction for each process.

- a. Lead-205 is formed via an alpha emission.
 b. Titanium-46 is formed via beta and gamma emission.
 c. Argon-36 is formed via a beta decay and a gamma emission.

16. Identify the parent isotope and write a balanced nuclear reaction for each process.

- a. Iodine-130 is formed by ejecting an electron and a gamma ray from a nucleus.
 b. Uranium-240 is formed by alpha decay.
 c. Curium-247 is formed by releasing a helium dication and a gamma ray.

17. Write a balanced nuclear equation for each process.
- Bromine undergoes a decay and produces a gas with an atomic mass of 80 amu.
 - An element emits two neutrons while decaying into two metals, each of which can be extracted and converted to chlorides with the formula MCl_2 . The masses of the two salts are 162.9 and 210.9 g/mol, respectively.
18. Write a balanced nuclear equation for each process.
- An unknown element emits γ rays plus particles that are readily blocked by paper. The sample also contains a substantial quantity of tin-104.
 - An unstable element undergoes two different decay reactions: beta decay to produce a material with a mass of 222 amu and alpha decay to astatine.
19. Bombarding ${}_{98}^{249}\text{Cf}$ with ${}_{12}^{12}\text{C}$ produced a transuranium element with a mass of 257 amu, plus several neutral subatomic particles. Identify the element and write a nuclear reaction for this transmutation.
20. One transuranium element, ${}_{95}^{253}\text{Es}$, is prepared by bombarding ${}_{92}^{238}\text{U}$ with 15 neutrons. What is the other product of this reaction? Write a balanced transmutation reaction for this conversion.
21. Complete this radioactive decay series:
- $${}_{88}^{223}\text{Rn} \xrightarrow{\alpha} \text{Rn} \xrightarrow{\alpha} \text{Po} \xrightarrow{\alpha} \text{Pb} \xrightarrow{\beta} \text{Bi} \xrightarrow{\alpha} \text{Tl} \xrightarrow{\beta} \text{Pb}$$
22. Complete each nuclear fission reaction.
- ${}_{92}^{235}\text{U} + {}_0^1n \rightarrow {}_{36}^{90}\text{Kr} + ? + 2{}_0^1n$
 - $? + {}_0^1n \rightarrow {}_{55}^{140}\text{Cs} + {}_{96}^{96}\text{Y} + 4{}_0^1n$
23. Complete each nuclear fission reaction.
- ${}_{92}^{235}\text{U} + {}_0^1n \rightarrow {}_{57}^{145}\text{La} + ? + 3{}_0^1n$
 - $? + {}_0^1n \rightarrow {}_{42}^{95}\text{Mo} + {}_{57}^{145}\text{La} + 2{}_0^1n + 7{}_0^{-1}\beta$
24. A stable nuclide absorbs a neutron, emits an electron, and then splits into two α particles. Identify the nuclide.
25. Using ${}_{16}^{16}\text{O}$, how would you synthesize an element with atomic number 106 from ${}_{98}^{252}\text{Cf}$? Write a balanced nuclear equation for the reaction.
26. Using ${}_{10}^{10}\text{B}$ and ${}_{98}^{252}\text{Cf}$, how would you synthesize an element with atomic number 103? Write a balanced nuclear equation for the reaction.

Learning Objectives

- To know the differences between ionizing and nonionizing radiation and their effects on matter.
- To identify natural and artificial sources of radiation.

Because nuclear reactions do not typically affect the valence electrons of the atom (although electron capture draws an electron from an orbital of the lowest energy level), they do not directly cause chemical changes. Nonetheless, the particles and the photons emitted during nuclear decay are very energetic, and they can indirectly produce chemical changes in the matter surrounding the nucleus that has decayed. For instance, an α particle is an ionized helium nucleus (He^{2+}) that can act as a powerful oxidant. In this section, we describe how radiation interacts with matter and the some of the chemical and biological effects of radiation.

Ionizing versus Nonionizing Radiation

The effects of radiation on matter are determined primarily by the energy of the radiation, which depends on the nuclear decay reaction that produced it. Nonionizing radiation is relatively low in energy; when it collides with an atom in a molecule or an ion, most or all of its energy can be absorbed without causing a structural or a chemical change. Instead, the kinetic energy of the radiation is transferred to the atom or molecule with which it collides, causing it to rotate, vibrate, or move more rapidly. Because this energy can be transferred to adjacent molecules or ions in the form of heat, many radioactive substances are warm to the touch. Highly radioactive elements such as polonium, for example, have been used as heat sources in the US space program. As long as the intensity of the nonionizing radiation is not great enough to cause overheating, it is relatively harmless, and its effects can be neutralized by cooling.

In contrast, ionizing radiation is higher in energy, and some of its energy can be transferred to one or more atoms with which it collides as it passes through matter. If enough energy is transferred, electrons can be excited to very high energy levels, resulting in the formation of positively charged ions:

Molecules that have been ionized in this way are often highly reactive, and they can decompose or undergo other chemical changes that create a cascade of reactive molecules that can damage biological tissues and other materials (Figure 24.3.1). Because the energy of ionizing radiation is very high, we often report its energy in units such as mega-electronvolts (MeV) per particle: 1 MeV/particle = 96 billion J/mol.

The Effects of Ionizing Radiation on Matter

The effects of ionizing radiation depend on four factors:

- The type of radiation, which dictates how far it can penetrate into matter
- The energy of the individual particles or photons
- The number of particles or photons that strike a given area per unit time
- The chemical nature of the substance exposed to the radiation

The relative abilities of the various forms of ionizing radiation to penetrate biological tissues are illustrated in Figure 24.3.2. Because of its high charge and mass, α radiation interacts strongly with matter. Consequently, it does not penetrate deeply into an object, and it can be stopped by a

Figure 24.3.1
Radiation Damage

When high-energy particles emitted by radioactive decay interact with matter, they can break bonds or ionize molecules, resulting in

piece of paper, clothing, or skin. In contrast, γ rays, with no charge and essentially no mass, do not interact strongly with matter and penetrate deeply into most objects, including the human body. Several inches of lead or more than 12 inches of special concrete are needed to completely stop γ rays. Because β particles are intermediate in mass and charge between α particles and γ rays, their interaction with matter is also intermediate. Beta particles readily penetrate paper or skin, but they can be stopped by a piece of wood or a relatively thin sheet of metal.

changes in physical properties such as ductility or color. The glass electrical insulator on the left has not been exposed to radiation, but the insulator on the right has received intense radiation doses over a long period of time. Radiation damage changed the chemical structure of the glass, causing it to become bright blue.

Figure 24.3.2 Depth of Penetration of Ionizing Radiation The depth of penetration of alpha, beta, and gamma radiation varies with the particle. Because α particles interact strongly with matter, they do not penetrate deeply into the human body. In contrast, β particles do not interact as strongly with matter and penetrate more deeply. Gamma rays, which have no charge, are stopped by only very dense materials and can pass right through the human body without being absorbed.

Because of their great penetrating ability, γ rays are by far the most dangerous type of radiation when they come from a source *outside* the body. Alpha particles, however, are the most damaging if their source is *inside* the body because internal tissues absorb all of their energy. Thus danger from radiation depends strongly on the type of radiation emitted and the extent of exposure, which allows scientists to safely handle many radioactive materials if they take precautions to avoid, for example, inhaling fine particulate dust that contains alpha emitters. Some properties of ionizing radiation are summarized in [Table 24.3.1](#)

Table 24.3.1 Some Properties of Ionizing Radiation

Type	Energy Range (MeV)	Penetration Distance in Water*	Penetration Distance in Air*
α particles	3–9	< 0.05 mm	< 10 cm
β particles	≤ 3	< 4 mm	1 m
x-rays	$< 10^{-2}$	< 1 cm	< 3 m
γ rays	10^{-2} – 10^1	< 20 cm	> 3 m

*Distance at which half of the radiation has been absorbed.

Wilhelm Röntgen

Born in the Lower Rhine Province of Germany, Röntgen was the only child of a cloth manufacturer and merchant. His family moved to the Netherlands where he showed no particular aptitude in school, but where he was fond of roaming the countryside. Röntgen was expelled from technical school in Utrecht after being unjustly accused of drawing a caricature of one of the teachers. He began studying mechanical engineering in Zurich, which he could enter without having the credentials of a regular student, and received a PhD at the University of Zurich in 1869. In 1876 he became professor of physics.

There are many different ways to measure radiation exposure, or the *dose*. The roentgen (R), which measures the amount of energy absorbed by dry air, can be used to describe quantitative exposure. Named after the German physicist Wilhelm Röntgen (1845–1923; Nobel Prize in Physics, 1901), who discovered x-rays. The roentgen is actually defined as the amount of radiation needed to produce an electrical charge of 2.58×10^{-4} C in 1 kg of dry air. Damage to biological tissues, however, is proportional to the amount of energy absorbed by *tissues*, not air. The most common unit used to measure the effects of radiation on biological tissue is the rad (radiation absorbed dose); the SI equivalent is the *gray* (Gy). The rad is defined as the amount of radiation that causes 0.01 J of energy to be absorbed by 1 kg of matter, and the gray is defined as the amount of radiation that causes 1 J of energy to be absorbed per kilogram:

$$1 \text{ rad} = 0.010 \text{ J/kg} \quad 1 \text{ Gy} = 1 \text{ J/kg} \quad (24.3.2)$$

Thus a 70 kg human who receives a dose of 1.0 rad over his or her entire body absorbs $0.010 \text{ J}/70 \text{ kg} = 1.4 \times 10^{-4}$ J, or 0.14 mJ. To put this in perspective, 0.14 mJ is the amount of energy transferred to your skin by a 3.8×10^{-5} g droplet of boiling water. Because the energy of the droplet of water is transferred to a relatively large area of tissue, it is harmless. A radioactive particle, however, transfers its energy to a single molecule, which makes it the atomic equivalent of a bullet fired from a high-powered rifle.

Because α particles have a much higher mass and charge than β particles or γ rays, the difference in mass between α and β particles is analogous to being hit by a bowling ball instead of a table tennis ball traveling at the same speed. Thus the amount of tissue damage caused by 1 rad of α particles is much greater than the damage caused by 1 rad of β particles or γ rays. Thus a unit called the rem (roentgen equivalent in man) was devised to describe the *actual* amount of tissue damage caused by a given amount of radiation. The number of rems of radiation is equal to the number of rads multiplied by the *RBE* (relative biological effectiveness) factor, which is 1 for β particles, γ rays, and x-rays and about 20 for α particles. Because actual radiation doses tend to be very small, most measurements are reported in *millirems* (1 mrem = 10^{-3} rem).

Natural Sources of Radiation

We are continuously exposed to measurable background radiation from a variety of natural sources, which, on average, is equal to about 150–600 mrem/yr (Figure 24.3.3). One component of background radiation is *cosmic rays*, high-energy particles and γ rays emitted by the sun and other stars, which bombard Earth continuously. Because cosmic rays are partially absorbed by the atmosphere before they reach Earth's surface, the exposure of people living at sea level (about 30 mrem/yr) is significantly less than the exposure of people living at higher altitudes (about 50 mrem/yr in Denver, Colorado). Every 4 hours spent in an airplane at greater than 30,000 ft adds about 1 mrem to a person's annual radiation exposure.

Figure 24.3.3 The Radiation Exposure of a Typical Adult in the United States The average radiation dose from natural sources for an adult in the United States is about 150–600 mrem/yr. Radon accounts for more than half of an adult's total radiation exposure, whereas background radiation (terrestrial and cosmogenic) and exposure from medical sources account for about 15% each.

Data source: Office of Civilian Radioactive Waste Management

A second component of background radiation is *cosmogenic radiation*, produced by the interaction of cosmic rays with gases in the upper atmosphere. When high-energy cosmic rays collide with oxygen and nitrogen atoms, neutrons and protons are released. These, in turn, react with other atoms to produce radioactive isotopes, such as $^{14}_6\text{C}$:

The carbon atoms react with oxygen atoms to form CO_2 , which is eventually washed to Earth's surface in rain and taken up by plants. About 1 atom in 1×10^{12} of the carbon atoms in our bodies is radioactive $^{14}_6\text{C}$, which decays by beta emission. About 5000 $^{14}_6\text{C}$ nuclei disintegrate in your body during the 15 s or so that it takes you to read this paragraph. Tritium (^3_1H) is also produced in the upper atmosphere and falls to Earth in precipitation. The total radiation dose attributable to $^{14}_6\text{C}$ is estimated to be 1 mrem/yr, while that due to ^3_1H is about 1000 times less.

The third major component of background radiation is *terrestrial radiation*, which is due to the remnants of radioactive elements that were present on primordial Earth and their decay products. For example, many rocks and minerals in the soil contain small amounts of radioactive isotopes, such as $^{232}_{90}\text{Th}$ and $^{238}_{92}\text{U}$, as well as radioactive daughter isotopes, such as $^{226}_{88}\text{Ra}$. The amount of background radiation from these sources is about the same as that from cosmic rays (approximately 30 mrem/yr). These isotopes are also found in small amounts in building materials derived from rocks and minerals, which significantly increases the radiation exposure for people who live in brick or concrete-block houses (60–160 mrem/yr) instead of houses made of wood (10–20 mrem/yr). Our tissues also absorb radiation (about 40 mrem/yr) from naturally occurring radioactive elements that are present in our bodies. For example, the average adult contains about 140 g of potassium as the K^+ ion. Naturally occurring potassium contains 0.0117% $^{40}_{19}\text{K}$, which decays by emitting both a β particle and a γ ray. In the last 20 seconds, about the time it took you to read this paragraph, approximately 40,000 $^{40}_{19}\text{K}$ nuclei disintegrated in your body.

By far the most important source of background radiation is *radon*, the heaviest of the noble gases (group 18). Radon-222 is produced during the decay of $^{238}_{92}\text{U}$, and other isotopes of radon are produced by the decay of other heavy elements. Even though radon is chemically inert, all its isotopes are radioactive. For example, $^{222}_{86}\text{Rn}$ undergoes two successive alpha-decay events to give $^{214}_{82}\text{Pb}$:

Because radon is a dense gas, it tends to accumulate in enclosed spaces such as basements, especially in locations where the soil contains greater-than-average amounts of naturally occurring uranium minerals. Under most conditions, radioactive decay of radon poses no problems because of the very short range of the emitted α particle. If an atom of radon happens to be in your lungs when it decays, however, the chemically reactive daughter isotope polonium-218 can become irreversibly bound to molecules in the lung tissue. Subsequent decay of $^{218}_{84}\text{Po}$ releases an α particle directly into one of the cells lining the lung, and the resulting damage can eventually cause lung cancer. The $^{218}_{84}\text{Po}$ isotope is also readily absorbed by particles in cigarette smoke, which adhere to the surface of the lungs and can hold the radioactive isotope in place. Recent estimates suggest that radon exposure is a contributing factor in about 15% of the deaths due to lung cancer. Because of the potential health problem radon poses, many states require houses to be tested for radon before they can be sold. By current estimates, radon accounts for more than half of the radiation exposure of a typical adult in the United States.

Artificial Sources of Radiation

In addition to naturally occurring background radiation, humans are exposed to small amounts of radiation from a variety of artificial sources. The most important of these are the x-rays used for diagnostic purposes in medicine and dentistry, which are photons with much lower energy than γ rays. A single chest x-ray provides a radiation dose of about 10 mrem, and a dental x-ray about 2–3 mrem. Other minor sources include television screens and computer monitors with cathode-ray tubes, which also produce x-rays. Luminescent paints for watch dials originally used radium, a highly toxic alpha emitter if ingested by those painting the dials. Radium was replaced by tritium (^3_1H) and promethium ($^{147}_{61}\text{Pr}$), which emit low-energy β particles that are absorbed by the watch crystal or the glass covering the instrument. Radiation exposure from television screens, monitors, and luminescent dials totals about 2 mrem/yr. Residual fallout from previous atmospheric nuclear-weapons testing is estimated to account for about twice this amount, and the nuclear power industry accounts for less than 1 mrem/yr (about the same as a single 4 h jet flight).

Example 24.3.1

Calculate the annual radiation dose in rads a typical 70 kg chemistry student receives from the naturally occurring $^{40}_{19}\text{K}$ in his or her body, which contains about 140 g of potassium (as the K^+ ion). The natural abundance of $^{40}_{19}\text{K}$ is 0.0117%. Each

1.00 mol of ^{40}K undergoes 1.05×10^7 decays/s, and each decay event is accompanied by the emission of a 1.32 MeV β particle.

Given: mass of student, mass of isotope, natural abundance, rate of decay, and energy of particle

Asked for: annual radiation dose in rads

Strategy:

A Calculate the number of moles of ^{40}K present using its mass, molar mass, and natural abundance.

B Determine the number of decays per year for this amount of ^{40}K .

C Multiply the number of decays per year by the energy associated with each decay event. To obtain the annual radiation dose, use the mass of the student to convert this value to rads.

Solution:

A The number of moles of ^{40}K present in the body is the total number of potassium atoms times the natural abundance of potassium atoms present as ^{40}K divided by the atomic mass of ^{40}K :

$$\text{moles } ^{40}\text{K} = 140 \text{ gK} \times \frac{0.0117 \text{ mol}^{40}\text{K}}{100 \text{ mol K}} \times \frac{1 \text{ mol K}}{40.0 \text{ gK}} = 4.10 \times 10^{-4} \text{ mol } ^{40}\text{K}$$

B We are given the number of atoms of ^{40}K that decay per second in 1.00 mol of ^{40}K , so the number of decays per year is as follows:

$$\left(\frac{\text{decays}}{\text{year}} = 4.10 \times 10^{-4} \text{ mol } ^{40}\text{K} \times \frac{1.05 \times 10^7 \text{ decays}}{\text{mol } ^{40}\text{K}} \times \frac{60 \text{ min}}{1 \text{ h}} \times \frac{24 \text{ h}}{1 \text{ day}} \times \frac{365 \text{ day}}{1 \text{ yr}} \right)$$

C The total energy the body receives per year from the decay of ^{40}K is equal to the total number of decays per year multiplied by the energy associated with each decay event:

$$\begin{aligned} \text{total energy per year} &= \frac{1.36 \times 10^{11} \text{ decays}}{\text{yr}} \times \frac{1.32 \text{ MeV}}{\text{decay}} \times \frac{10^6 \text{ eV}}{\text{MeV}} \times \frac{1.602 \times 10^{-19} \text{ J}}{\text{eV}} \\ &= 2.87 \times 10^{-2} \text{ J/yr} \end{aligned}$$

We use the definition of the rad ($1 \text{ rad} = 10^{-2} \text{ J/kg}$ of tissue) to convert this figure to a radiation dose in rads. If we assume the dose is equally distributed throughout the body, then the radiation dose per year is as follows:

$$\begin{aligned} \text{radiation dose per year} &= \frac{2.87 \times 10^{-2} \text{ J/yr}}{70 \text{ kg}} \times \frac{1 \text{ rad}}{1 \times 10^{-2} \text{ J/kg}} \\ &= 4.10 \times 10^{-2} \text{ rad/yr} = 41 \text{ mrad/yr} \end{aligned}$$

This corresponds to almost half of the normal background radiation most people experience.

Exercise

Because strontium is chemically similar to calcium, small amounts of the Sr^{2+} ion are taken up by the body and deposited in calcium-rich tissues such as bone, using the same mechanism that is responsible for the absorption of Ca^{2+} . Consequently, the radioactive strontium (^{90}Sr) found in fission waste and released by atmospheric nuclear-weapons testing is a major health concern. A normal 70 kg human body has about 280 mg of strontium, and each mole of ^{90}Sr undergoes 4.55×10^{14} decays/s by the emission of a 0.546 MeV β particle. What would be the annual radiation dose in rads for a 70 kg person if 0.10% of the strontium ingested were ^{90}Sr ?

Answer: 5.7×10^3 rad/yr (which is 10 times the fatal dose)

Assessing the Impact of Radiation Exposure

One of the more controversial public policy issues debated today is whether the radiation exposure from artificial sources, when combined with exposure from natural sources, poses a significant risk to human health. The effects of single radiation doses of different magnitudes on humans are listed in [Table 24.3.2](#). Because of the many factors involved in radiation exposure (length of exposure, intensity of the source, and energy and type of particle), it is difficult to quantify the specific dangers of one radioisotope versus another. Nonetheless, some general conclusions regarding the effects of radiation exposure are generally accepted as valid.

Table 24.3.2 The Effects of a Single Radiation Dose on a 70 kg Human

Dose (rem)	Symptoms/Effects
< 5	no observable effect
5–20	possible chromosomal damage
20–100	temporary reduction in white blood cell count
50–100	temporary sterility in men (up to a year)
100–200	mild radiation sickness, vomiting, diarrhea, fatigue; immune system suppressed; bone growth in children retarded
> 300	permanent sterility in women
> 500	fatal to 50% within 30 days; destruction of bone marrow and intestine
> 3000	fatal within hours

Radiation doses of 600 rem and higher are invariably fatal, while a dose of 500 rem kills half the exposed subjects within 30 days. Smaller doses (≤ 50 rem) appear to cause only limited health effects, even though they correspond to tens of years of natural radiation. This does not, however, mean that such doses have no ill effects; they may cause long-term health problems, such as cancer or genetic changes that affect offspring. The possible detrimental effects of the much smaller doses attributable to artificial sources (< 100 mrem/yr) are more difficult to assess.

The tissues most affected by large, whole-body exposures are bone marrow, intestinal tissue, hair follicles, and reproductive organs, all of which contain rapidly dividing cells. The susceptibility of rapidly dividing cells to radiation exposure explains why cancers are often treated by radiation. Because cancer cells divide faster than normal cells, they are destroyed preferentially by radiation. Long-term radiation-exposure studies on fruit flies show a linear relationship between the number of genetic defects and both the magnitude of the dose and the exposure time. In contrast, similar studies on mice show a much lower number of defects when a given dose of radiation is spread out over a long period of time rather than received all at once. Both patterns are plotted in [Figure 24.3.4](#), but which of the two is applicable to humans? According to one hypothesis, mice have very low risk from low doses because their bodies have ways of dealing with the damage caused by natural radiation. At much higher doses, however, their natural repair mechanisms are overwhelmed, leading to irreversible damage. Because mice are biochemically much more similar to humans than are fruit flies, many scientists believe that this model also applies to humans. In contrast, the linear model assumes that *all* exposure to radiation is intrinsically damaging and suggests that stringent regulation of low-level radiation exposure is necessary. Which view is more accurate? The answer—while yet unknown—has extremely important consequences for regulating radiation exposure.

Figure 24.3.4 Two Possible Relationships between the Number of Genetic Defects and Radiation Exposure Studies on fruit flies show a linear relationship between the number of genetic defects and the magnitude of the radiation dose and exposure time, which is consistent with a cumulative effect of radiation. In contrast, studies on mice show an S-shaped curve, which suggests that the number of defects is lower when radiation exposure occurs over a longer time. Which of these relationships is more applicable to humans is a matter of considerable debate.

Summary

The effects of radiation on matter depend on the energy of the radiation. **Nonionizing radiation** is relatively low in energy, and the energy is transferred to matter in the form of heat. **Ionizing radiation** is relatively high in energy, and when it collides with an atom, it can completely remove an electron to form a positively charged ion that can damage biological tissues. Alpha particles do not penetrate very far into matter, whereas γ rays penetrate more deeply. Common units of radiation exposure, or dose, are the **roentgen (R)**, the amount of energy absorbed by dry air, and the **rad (radiation absorbed dose)**, the amount of radiation that produces 0.01 J of energy in 1 kg of matter. The **rem (roentgen equivalent in man)** measures the actual amount of tissue damage caused by a given amount of radiation. Natural sources of radiation include *cosmic radiation*, consisting of high-energy particles and γ rays emitted by the sun and other stars; *cosmogenic radiation*, which is produced by the interaction of cosmic rays with gases in the upper atmosphere; and *terrestrial radiation*, from radioactive elements present on primordial Earth and their decay products. The risks of ionizing radiation depend on the intensity of the radiation, the mode of exposure, and the duration of the exposure.

Key Takeaway

- Nonionizing radiation is relatively low in energy and can be used as a heat source, whereas ionizing radiation, which is higher in energy, can penetrate biological tissues and is highly reactive.

Key Equation

rad

Equation 24.3.2: 1 rad = 0.01 J/kg

Conceptual Problems

1. Why are many radioactive substances warm to the touch? Why do many radioactive substances glow?
2. Describe the differences between nonionizing and ionizing radiation in terms of the intensity of energy emitted and the effect each has on an atom or molecule after collision. Which nuclear decay reactions are more likely to produce ionizing radiation? nonionizing radiation?
3. Would you expect nonionizing or ionizing radiation to be more effective at treating cancer? Why?

- Historically, concrete shelters have been used to protect people from nuclear blasts. Comment on the effectiveness of such shelters.
- Gamma rays are a very high-energy radiation, yet α particles inflict more damage on biological tissue. Why?
- List the three primary sources of naturally occurring radiation. Explain the factors that influence the dose that one receives throughout the year. Which is the largest contributor to overall exposure? Which is the most hazardous?
- Because radon is a noble gas, it is inert and generally unreactive. Despite this, exposure to even low concentrations of radon in air is quite dangerous. Describe the physical consequences of exposure to radon gas. Why are people who smoke more susceptible to these effects?
- Most medical imaging uses isotopes that have extremely short half-lives. These isotopes usually undergo only one kind of nuclear decay reaction. Which kind of decay reaction is usually used? Why? Why would a short half-life be preferred in these cases?
- Which would you prefer: one exposure of 100 rem, or 10 exposures of 10 rem each? Explain your rationale.

Answers

-
-
- Ionizing radiation is higher in energy and causes greater tissue damage, so it is more likely to destroy cancerous cells.
-
-
-
-
-
-
- Ten exposures of 10 rem are less likely to cause major damage.

Numerical Problems

- A 2.14 kg sample of rock contains 0.0985 g of uranium. How much energy is emitted over 25 yr if 99.27% of the uranium is ^{238}U , which has a half-life of 4.46×10^8 yr, if each decay event is accompanied by the release of 4.039 MeV? If a 180 lb individual absorbs all of the emitted radiation, how much radiation has been absorbed in rads?
- There is a story about a “radioactive boy scout” who attempted to convert thorium-232, which he isolated from about 1000 gas lantern mantles, to uranium-233 by bombarding the thorium with neutrons. The neutrons were generated via bombarding an aluminum target with α particles from the decay of americium-241, which was isolated from 100 smoke detectors. Write balanced nuclear reactions for these processes. The “radioactive boy scout” spent approximately 2 h/day with his experiment for 2 yr. Assuming that the alpha emission of americium has an energy of 5.24 MeV/particle and that the americium-241 was undergoing 3.5×10^6 decays/s, what was the exposure of the 60.0 kg scout in rads? The intrepid scientist apparently showed no ill effects from this exposure. Why?

Learning Objectives

- To calculate a mass-energy balance and a nuclear binding energy.
- To understand the differences between nuclear fission and fusion.

Nuclear reactions, like chemical reactions, are accompanied by changes in energy. The energy changes in nuclear reactions, however, are enormous compared with those of even the most energetic chemical reactions. In fact, the energy changes in a typical nuclear reaction are so large that they result in a measurable change of mass. In this section, we describe the relationship between mass and energy in nuclear reactions and show how the seemingly small changes in mass that accompany nuclear reactions result in the release of enormous amounts of energy.

Mass–Energy Balance

The relationship between mass (m) and energy (E) was introduced in [Chapter 2](#) and is expressed in the following equation:

$$E = mc^2 \quad (24.4.1)$$

where c is the speed of light (2.998×10^8 m/s), and E and m are expressed in units of joules and kilograms, respectively. Albert Einstein first derived this relationship in 1905 as part of his special theory of relativity: the mass of a particle is directly proportional to its energy. Thus according to [Equation 20.4.1](#), every mass has an associated energy, and similarly, any reaction that involves a change in energy must be accompanied by a change in mass. This implies that all exothermic reactions should be accompanied by a decrease in mass, and all endothermic reactions should be accompanied by an increase in mass. Given the law of conservation of mass, how can this be true? (For more information on the conservation of mass, see [Chapter 7](#).) The solution to this apparent contradiction is that *chemical reactions are indeed accompanied by changes in mass*, but these changes are simply too small to be detected. This situation is similar to the wave–particle duality discussed in [Chapter 6](#). As you may recall, all particles exhibit wavelike behavior, but the wavelength is inversely proportional to the mass of the particle (actually, to its momentum, the product of its mass and velocity). Consequently, wavelike behavior is detectable only for particles with very small masses, such as electrons. For example, the chemical equation for the combustion of graphite to produce carbon dioxide is as follows:

Combustion reactions are typically carried out at constant pressure, and under these conditions, the heat released or absorbed is equal to ΔH . As you learned in [Chapter 18](#), when a reaction is carried out at constant volume, the heat released or absorbed is equal to ΔE . For most chemical reactions, however, $\Delta E \approx \Delta H$. If we rewrite Einstein's equation as

$$\Delta E = (\Delta m)c^2 \quad (24.4.3)$$

we can rearrange the equation to obtain the following relationship between the change in mass and the change in energy:

$$\Delta m = \frac{\Delta E}{c^2} \quad (24.4.4)$$

Because $1 \text{ J} = 1 (\text{kg} \cdot \text{m}^2/\text{s}^2)$, the change in mass is as follows:

$$\Delta m = \frac{-393.5 \text{ kJ/mol}}{(2.998 \times 10^8)^2} = \frac{-3.935 \times 10^5 \left(\frac{\text{kg} \cdot \cancel{\text{m}^2}}{\cancel{\text{s}^2}} \right) / \left(\frac{\text{s}^2 \cdot \text{mol}}{\cancel{\text{m}^2}} \right)}{(2.998 \times 10^8 \cancel{\text{m}}/\cancel{\text{s}})^2} = -4.38 \times 10^{-12} \text{ kg} \quad (24.4.5)$$

This is a mass change of about 3.6×10^{-11} g/g carbon that is burned, or about 100-millionths of the mass of an electron per atom of carbon. In practice, this mass change is much too small to be measured experimentally and is negligible.

In contrast, for a typical nuclear reaction, such as the radioactive decay of ^{14}C to ^{14}N and an electron (a β particle), there is a much larger change in mass:

We can use the experimentally measured masses of subatomic particles and common isotopes given in [Table 24.2.1](#) and [Table A4](#) to calculate the change in mass directly. The reaction involves the conversion of a neutral ^{14}C atom to a positively charged ^{14}N ion (with six, not seven, electrons) and a negatively charged β particle (an electron), so the mass of the products is identical to the mass of a neutral ^{14}N atom. The total change in mass during the reaction is therefore the difference between the mass of a neutral ^{14}N atom (14.003074 amu) and the mass of a ^{14}C atom (14.003242 amu):

$$\begin{aligned} \Delta m &= \text{mass}_{\text{products}} - \text{mass}_{\text{reactants}} \\ &= 14.003074 \text{ amu} - 14.003242 \text{ amu} = -0.000168 \text{ amu} \end{aligned} \quad (24.4.7)$$

The difference in mass, which has been released as energy, corresponds to almost one-third of an electron. The change in mass for the decay of 1 mol of ^{14}C is $-0.000168 \text{ g} = -1.68 \times 10^{-4} \text{ g} = -1.68 \times 10^{-7} \text{ kg}$. Although a mass change of this magnitude may seem small, it is about 1000 times larger than the mass change for the combustion of graphite. The energy change is as follows:

$$\begin{aligned} \Delta E &= (\Delta m)c^2 = (-1.68 \times 10^{-7} \text{ kg}) (2.998 \times 10^8 \text{ m/s})^2 \\ &= 1.51 \times 10^{10} \text{ (kg} \cdot \text{m}^2) / \text{s}^2 = 1.51 \times 10^{10} \text{ J} = 1.51 \times 10^7 \text{ kJ} \end{aligned} \quad (24.4.8)$$

The energy released in this nuclear reaction is more than 100,000 times greater than that of a typical chemical reaction, even though the decay of ^{14}C is a relatively low-energy nuclear reaction.

Because the energy changes in nuclear reactions are so large, they are often expressed in kiloelectronvolts ($1 \text{ keV} = 10^3 \text{ eV}$), mega-electronvolts ($1 \text{ MeV} = 10^6 \text{ eV}$), and even giga-electronvolts ($1 \text{ GeV} = 10^9 \text{ eV}$) per atom or particle. The change in energy that accompanies a nuclear reaction can be calculated from the change in mass using the relationship $1 \text{ amu} = 931 \text{ MeV}$. The energy released by the decay of one atom of ^{14}C is thus

$$(-1.68 \times 10^{-4} \text{ amu}) (931 \text{ MeV/amu}) = -0.156 \text{ MeV} = -156 \text{ keV} \quad (24.4.9)$$

Example 24.4.1

Calculate the changes in mass (in atomic mass units) and energy (in joules per mole and electronvolts per atom) that accompany the radioactive decay of ^{238}U to ^{234}Th and an α particle. The α particle absorbs two electrons from the surrounding matter to form a helium atom.

Given: nuclear decay reaction

Asked for: changes in mass and energy

Strategy:

A Use the mass values in [Table 24.2.1](#) and [Table A4](#) to calculate the change in mass for the decay reaction in atomic mass units.

B Use [Equation 24.4.4](#) to calculate the change in energy in joules per mole.

C Use the relationship between atomic mass units and mega-electronvolts to calculate the change in energy in electronvolts per atom.

Solution:

A Using particle and isotope masses from [Table 24.2.1](#) and [Table A4](#), we can calculate the change in mass as follows:

$$\begin{aligned} \Delta m &= \text{mass}_{\text{products}} - \text{mass}_{\text{reactants}} \left(\text{mass } ^{234}\text{Th} + \text{mass } \frac{4}{2}\alpha \right) - \text{mass } ^{238}\text{U} \\ &= (234.043601 \text{ amu} + 4.002603 \text{ amu} - 238.050788 \text{ amu}) = -0.004584 \text{ amu} \end{aligned}$$

B Thus the change in mass for 1 mol of ^{235}U is -0.004584 g or -4.584×10^{-6} kg. The change in energy in joules per mole is as follows:

$$\Delta E = (\Delta m)c^2 = (-4.584 \times 10^{-6} \text{ kg})(2.998 \times 10^8 \text{ m/s})^2 = -4.120 \times 10^{11} \text{ J/mol}$$

C The change in energy in electronvolts per atom is as follows:

$$\Delta E = -4.384 \times 10^{-3} \text{ amu} \times \frac{931 \text{ MeV}}{\text{amu}} \times \frac{1 \times 10^6 \text{ eV}}{1 \text{ MeV}} = -4.27 \times 10^6 \text{ eV/atom}$$

Exercise

Calculate the changes in mass (in atomic mass units) and energy (in kilojoules per mole and kiloelectronvolts per atom) that accompany the radioactive decay of tritium (^3H) to ^3He and a β particle.

Answer: $\Delta m = -2.0 \times 10^{-5}$ amu; $\Delta E = -1.9 \times 10^6$ kJ/mol = -19 keV/atom

Nuclear Binding Energies

We have seen that energy changes in both chemical and nuclear reactions are accompanied by changes in mass. Einstein's equation, which allows us to interconvert mass and energy, has another interesting consequence: The mass of an atom is always less than the sum of the masses of its component particles. The only exception to this rule is hydrogen-1 (^1H), whose measured mass of 1.007825 amu is identical to the sum of the masses of a proton and an electron. In contrast, the experimentally measured mass of an atom of deuterium (^2H) is 2.014102 amu, although its calculated mass is 2.016490 amu:

$$\begin{aligned} m_{^2\text{H}} &= m_{\text{neutron}} + m_{\text{proton}} + m_{\text{electron}} \\ &= 1.008665 \text{ amu} + 1.007276 \text{ amu} + 0.000549 \text{ amu} = 2.016490 \text{ amu} \end{aligned} \quad (24.4.10)$$

The difference between the sum of the masses of the components and the measured atomic mass is called the mass defect of the nucleus. Just as a molecule is more stable than its isolated atoms, a nucleus is more stable (lower in energy) than its isolated components. Consequently, when isolated nucleons assemble into a stable nucleus, energy is released. According to [Equation 24.4.2](#), this release of energy must be accompanied by a decrease in the mass of the nucleus.

The amount of energy released when a nucleus forms from its component nucleons is the nuclear binding energy ([Figure 24.4.1](#)). In the case of deuterium, the mass defect is 0.002388 amu, which corresponds to a nuclear binding energy of 2.22 MeV for the deuterium nucleus. Because the magnitude of the mass defect is proportional to the nuclear binding energy, both values indicate the stability of the nucleus.

Note the Pattern

Just as a molecule is more stable (lower in energy) than its isolated atoms, a nucleus is more stable than its isolated components.

Figure 24.4.1 Nuclear Binding Energy in Deuterium The mass of a ${}^2\text{H}$ atom is less than the sum of the masses of a proton, a neutron, and an electron by 0.002388 amu; the difference in mass corresponds to the nuclear binding energy. The larger the value of the mass defect, the greater the nuclear binding energy and the more stable the nucleus.

Not all nuclei are equally stable. Chemists describe the *relative* stability of different nuclei by comparing the binding energy *per nucleon*, which is obtained by dividing the nuclear binding energy by the mass number (A) of the nucleus. As shown in [Figure 24.4.2](#) the binding energy per nucleon increases rapidly with increasing atomic number until about $Z = 26$, where it levels off to about 8–9 MeV per nucleon and then decreases slowly. The initial increase in binding energy is not a smooth curve but exhibits sharp peaks corresponding to the light nuclei that have equal numbers of protons and neutrons (e.g., ${}^4\text{He}$, ${}^{12}\text{C}$, and ${}^{16}\text{O}$). As mentioned earlier, these are particularly stable combinations.

Because the maximum binding energy per nucleon is reached at ${}^{56}\text{Fe}$, all other nuclei are thermodynamically unstable with regard to the formation of ${}^{56}\text{Fe}$. Consequently, heavier nuclei (toward the right in [Figure 24.4.2](#)) should spontaneously undergo reactions such as alpha decay, which result in a decrease in atomic number. Conversely, lighter elements (on the left in [Figure 24.4.2](#)) should spontaneously undergo reactions that result in an increase in atomic number. This is indeed the observed pattern.

Figure 24.4.2 The Curve of Nuclear Binding Energy This plot of the average binding energy per nucleon as a function of atomic number shows that the binding energy per nucleon increases with increasing atomic number until about $Z = 26$, levels off, and then decreases. The sharp peaks correspond to light nuclei that have equal numbers of protons and neutrons.

Note the Pattern

Heavier nuclei spontaneously undergo nuclear reactions that decrease their atomic number. Lighter nuclei spontaneously undergo nuclear reactions that increase their atomic number.

Example 24.4.2

Calculate the total nuclear binding energy (in mega-electronvolts) and the binding energy per nucleon for ${}^{56}\text{Fe}$. The experimental mass of the nuclide is given in [Table A4](#).

Given: nuclide and mass

Asked for: nuclear binding energy and binding energy per nucleon

Strategy:

A Sum the masses of the protons, electrons, and neutrons or, alternatively, use the mass of the appropriate number of ${}^1_1\text{H}$ atoms (because its mass is the same as the mass of one electron and one proton).

B Calculate the mass defect by subtracting the experimental mass from the calculated mass.

C Determine the nuclear binding energy by multiplying the mass defect by the change in energy in electronvolts per atom. Divide this value by the number of nucleons to obtain the binding energy per nucleon.

Solution:

A An iron-56 atom has 26 protons, 26 electrons, and 30 neutrons. We could add the masses of these three sets of particles; however, noting that 26 protons and 26 electrons are equivalent to 26 ${}^1_1\text{H}$ atoms, we can calculate the sum of the masses more quickly as follows:

$$\begin{aligned} \text{calculated mass} &= 26 (\text{mass } {}^1_1\text{H}) + 30 (\text{mass } {}^1_0\text{n}) \\ &= 26 (1.007825) \text{ amu} + 30 (1.008665) \text{ amu} = 56.463400 \text{ amu} \\ \text{experimental mass} &= 55.934938 \text{ amu} \end{aligned}$$

B We subtract to find the mass defect:

$$\begin{aligned} \text{mass defect} &= \text{calculated mass} - \text{experimental mass} \\ &= 56.463400 \text{ amu} - 55.934938 \text{ amu} = 0.528462 \text{ amu} \end{aligned}$$

C The nuclear binding energy is thus $0.528462 \text{ amu} \times 931 \text{ MeV/amu} = 492 \text{ MeV}$. The binding energy per nucleon is $492 \text{ MeV}/56 \text{ nucleons} = 8.79 \text{ MeV/nucleon}$.

Exercise

Calculate the total nuclear binding energy (in megaelectronvolts) and the binding energy per nucleon for ${}^{238}\text{U}$.

Answer: $1800 \text{ MeV}/{}^{238}\text{U}$; 7.57 MeV/nucleon

Nuclear Fission and Fusion

First discussed in [Section 24.2](#), nuclear fission is the splitting of a heavy nucleus into two lighter ones. Fission was discovered in 1938 by the German scientists Otto Hahn, Lise Meitner, and Fritz Strassmann, who bombarded a sample of uranium with neutrons in an attempt to produce new elements with $Z > 92$. They observed that lighter elements such as barium ($Z = 56$) were formed during the reaction, and they realized that such products had to originate from the neutron-induced fission of uranium-235:

This hypothesis was confirmed by detecting the krypton-92 fission product. As discussed in [Section 24.2](#), the nucleus usually divides asymmetrically rather than into two equal parts, and the fission of a given nuclide does not give the same products every time.

In a typical nuclear fission reaction, more than one neutron is released by each dividing nucleus. When these neutrons collide with and induce fission in other neighboring nuclei, a self-sustaining series of nuclear fission reactions known as a nuclear chain reaction can result ([Figure 24.4.2](#)). For example, the fission of ${}^{235}\text{U}$ releases two to three neutrons per fission event. If absorbed by other ${}^{235}\text{U}$ nuclei, those neutrons induce additional fission events, and the rate of the fission reaction increases geometrically. Each series of events is called a *generation*. Experimentally, it is found that some minimum mass of a fissile isotope is required to sustain a nuclear chain reaction; if the mass is too low, too many neutrons are able to escape without being captured and inducing a fission reaction. The minimum mass capable of supporting sustained fission is called the critical mass. This amount depends on the purity

of the material and the shape of the mass, which corresponds to the amount of surface area available from which neutrons can escape, and on the identity of the isotope. If the mass of the fissile isotope is greater than the critical mass, then under the right conditions, the resulting *supercritical mass* can release energy explosively. The enormous energy released from nuclear chain reactions is responsible for the massive destruction caused by the detonation of nuclear weapons such as fission bombs, but it also forms the basis of the nuclear power industry.

Nuclear fusion, in which two light nuclei combine to produce a heavier, more stable nucleus, is the opposite of nuclear fission. As in the nuclear transmutation reactions discussed in [Section 24.2](#), the positive charge on both nuclei results in a large electrostatic energy barrier to fusion. This barrier can be overcome if one or both particles have sufficient kinetic energy to overcome the electrostatic repulsions, allowing the two nuclei to approach close enough for a fusion reaction to occur. The principle is similar to adding heat to increase the rate of a chemical reaction. (For more information on chemical kinetics, see [Chapter 14](#)) As shown in the plot of nuclear binding energy per nucleon versus atomic number in [Figure 24.4.3](#), fusion reactions are most exothermic for the lightest element. For example, in a typical fusion reaction, two deuterium atoms combine to produce helium-3, a process known as deuterium–deuterium fusion (D–D fusion):

Figure 24.4.3 A Nuclear Chain Reaction The process is initiated by the collision of a single neutron with a ^{235}U nucleus, which undergoes fission, as shown in [Figure 24.2.3](#). Because each neutron released can cause the fission of another ^{235}U nucleus, the rate of a fission reaction accelerates geometrically. Each series of events is a generation.

In another reaction, a deuterium atom and a tritium atom fuse to produce helium-4 ([Figure 24.4.4](#)), a process known as deuterium–tritium fusion (D–T fusion):

Figure 24.4.4 Nuclear Fusion In a nuclear fusion reaction, lighter nuclei combine to produce a heavier nucleus. As shown, fusion of ^3H and ^2H to give ^4He and a neutron releases an enormous amount of energy. In principle, nuclear fusion can produce much more energy than fission, but very high kinetic energy is required to overcome electrostatic repulsions between the positively charged nuclei and initiate the fusion reaction.

Initiating these reactions, however, requires a temperature comparable to that in the interior of the sun (approximately 1.5×10^7 K). Currently, the only method available on Earth to achieve such a temperature is the detonation of a fission bomb. For example, the so-called hydrogen bomb (or H bomb) is actually a deuterium–tritium bomb (a D–T bomb), which uses a nuclear fission reaction to create the very high temperatures needed to initiate fusion of solid lithium deuteride (LiD), which releases neutrons that then react with Li , producing tritium. The deuterium–tritium reaction releases energy explosively. Example 9 and its corresponding exercise demonstrate the enormous amounts of energy produced by nuclear fission and fusion reactions. In fact, fusion reactions are the power sources for all stars, including our sun.

Example 24.4.3

Calculate the amount of energy (in electronvolts per atom and kilojoules per mole) released when the neutron-induced fission of ${}^{235}_{92}\text{U}$ produces ${}^{144}_{55}\text{Cs}$, ${}^{90}_{37}\text{Rb}$, and two neutrons:

Given: balanced nuclear reaction

Asked for: energy released in electronvolts per atom and kilojoules per mole

Strategy:

A Following the method used in Example 7, calculate the change in mass that accompanies the reaction. Convert this value to the change in energy in electronvolts per atom.

B Calculate the change in mass per mole of ${}^{235}_{92}\text{U}$. Then use Equation 24.4.1 to calculate the change in energy in kilojoules per mole.

Solution:

A The change in mass that accompanies the reaction is as follows:

$$\begin{aligned}\Delta m &= \text{mass}_{\text{products}} - \text{mass}_{\text{reactants}} = \text{mass} \left({}^{144}_{55}\text{Cs} + {}^{90}_{37}\text{Rb} + {}^1_0\text{n} \right) - \text{mass} \left({}^{238}_{92}\text{U} \right) \\ \Delta m &= (143.932077 \text{ amu} + 89.914802 \text{ amu} + 1.008665 \text{ amu}) - 235.043930 \text{ amu} \\ &= -0.188386 \text{ amu}\end{aligned}$$

The change in energy in electronvolts per atom is as follows:

$$\left(\Delta E = \left(-0.188386 \text{ amu} \right) \left(931 \text{ MeV/amu} \right) = -175 \text{ MeV} \right)$$

B The change in mass per mole of ${}^{235}_{92}\text{U}$ is $-0.188386 \text{ g} = -1.88386 \times 10^{-4} \text{ kg}$, so the change in energy in kilojoules per mole is as follows:

$$\Delta E = (\Delta m) c^2 = \left(-1.88386 \times 10^{-4} \text{ kg} \right) \left(2.998 \times 10^8 \text{ m/s} \right)^2$$

$$= -1.693 \times 10^{13} \text{ J/mol} = -1.693 \times 10^{10} \text{ kJ/mol}$$

Exercise

Calculate the amount of energy (in electronvolts per atom and kilojoules per mole) released when deuterium and tritium fuse to give helium-4 and a neutron:

Answer: $\Delta E = -17.6 \text{ MeV/atom} = -1.697 \times 10^9 \text{ kJ/mol}$

Summary

Nuclear reactions are accompanied by large changes in energy, which result in detectable changes in mass. The change in mass is related to the change in energy according to Einstein's equation: $\Delta E = (\Delta m)c^2$. Large changes in energy are usually reported in kiloelectronvolts or megaelectronvolts (thousands or millions of electronvolts). With the exception of ${}^1_1\text{H}$, the experimentally determined mass of an atom is always *less* than the sum of the masses of the component particles (protons, neutrons, and electrons) by an amount called the **mass defect** of the nucleus. The energy corresponding to the mass defect is the **nuclear binding energy**, the amount of energy released when a nucleus forms from its component particles. In **nuclear fission**, nuclei split into lighter nuclei with an accompanying release of multiple neutrons and large amounts of energy. The **critical mass** is the minimum mass required to support a self-sustaining **nuclear chain reaction**. **Nuclear fusion** is a process in which two light nuclei combine to produce a heavier nucleus plus a great deal of energy.

Key Takeaway

- Unlike a chemical reaction, a nuclear reaction results in a significant change in mass and an associated change of energy, as described by Einstein's equation.

Conceptual Problems

1. How do chemical reactions compare with nuclear reactions with respect to mass changes? Does either type of reaction violate the law of conservation of mass? Explain your answers.
2. Why is the amount of energy released by a nuclear reaction so much greater than the amount of energy released by a chemical reaction?
3. Explain why the mass of an atom is less than the sum of the masses of its component particles.
4. The stability of a nucleus can be described using two values. What are they, and how do they differ from each other?
5. In the days before true chemistry, ancient scholars (*alchemists*) attempted to find the *philosopher's stone*, a material that would enable them to turn lead into gold. Is the conversion of $\text{Pb} \rightarrow \text{Au}$ energetically favorable? Explain why or why not.
6. Describe the energy barrier to nuclear fusion reactions and explain how it can be overcome.
7. Imagine that the universe is dying, the stars have burned out, and all the elements have undergone fusion or radioactive decay. What would be the most abundant element in this future universe? Why?
8. Numerous elements can undergo fission, but only a few can be used as fuels in a reactor. What aspect of nuclear fission allows a nuclear chain reaction to occur?
9. How are transmutation reactions and fusion reactions related? Describe the main impediment to fusion reactions and suggest one or two ways to surmount this difficulty.

Numerical Problems

1. Using the information provided in [Table A4](#), complete each reaction and calculate the amount of energy released from each in kilojoules.

- a. ${}^{238}_{92}\text{Pa} \rightarrow ? + \beta^-$
- b. ${}^{216}_{87}\text{Fr} \rightarrow ? + \alpha$

199 +

- c. ${}^{210}_{83}\text{Bi} \rightarrow ? + \beta$
- Using the information provided in [Table A4](#), complete each reaction and calculate the amount of energy released from each in kilojoules.
 - ${}^{194}_{81}\text{Tl} \rightarrow ? + \beta$
 - ${}^{214}_{82}\text{Pb} \rightarrow ? + \alpha$
 - ${}^{214}_{82}\text{Pb} \rightarrow ? + \beta$
 - Using the information provided in [Table A4](#), complete each reaction and calculate the amount of energy released from each in kilojoules per mole.
 - ${}^{234}_{91}\text{Pa} \rightarrow ? + {}^0_{-1}\beta$
 - ${}^{226}_{88}\text{Ra} \rightarrow ? + {}^4_2\alpha$
 - Using the information provided in [Table A4](#), complete each reaction and then calculate the amount of energy released from each in kilojoules per mole.
 - ${}^{60}_{27}\text{Co} \rightarrow ? + {}^0_{-1}\beta$ (The mass of cobalt-60 is 59.933817 amu.)
 - technetium-94 (mass = 93.909657 amu) undergoing fission to produce chromium-52 and potassium-40
 - Using the information provided in [Table A4](#), predict whether each reaction is favorable and the amount of energy released or required in megaelectronvolts and kilojoules per mole.
 - the beta decay of bismuth-208 (mass = 207.979742 amu)
 - the formation of lead-206 by alpha decay
 - Using the information provided, predict whether each reaction is favorable and the amount of energy released or required in megaelectronvolts and kilojoules per mole.
 - alpha decay of oxygen-16
 - alpha decay to produce chromium-52
 - Calculate the total nuclear binding energy (in megaelectronvolts) and the binding energy per nucleon for ${}^{87}_{38}\text{Sr}$ if the measured mass of ${}^{87}_{38}\text{Sr}$ is 86.908877 amu.
 - Calculate the total nuclear binding energy (in megaelectronvolts) and the binding energy per nucleon for ${}^{60}_{28}\text{Ni}$.
 - The experimentally determined mass of ${}^{55}_{25}\text{Mn}$ is 52.941290 amu. Find each of the following.
 - the calculated mass
 - the mass defect
 - the nuclear binding energy
 - the nuclear binding energy per nucleon
 - The experimentally determined mass of ${}^{32}_{16}\text{S}$ is 28.996610 amu. Find each of the following.
 - the calculated mass
 - the mass defect
 - the nuclear binding energy
 - the nuclear binding energy per nucleon
 - Calculate the amount of energy that is released by the neutron-induced fission of ${}^{235}_{92}\text{U}$ to give ${}^{141}_{54}\text{Ba}$, ${}^{92}_{38}\text{Kr}$ (mass = 91.926156 amu), and three neutrons. Report your answer in electronvolts per atom and kilojoules per mole.
 - Calculate the amount of energy that is released by the neutron-induced fission of ${}^{235}_{92}\text{U}$ to give ${}^{90}_{38}\text{Sr}$, ${}^{143}_{54}\text{Xe}$, and three neutrons. Report your answer in electronvolts per atom and kilojoules per mole.
 - Calculate the amount of energy released or required by the fusion of helium-4 to produce the unstable beryllium-8 (mass = 8.00530510 amu). Report your answer in kilojoules per mole. Do you expect this to be a spontaneous reaction?
 - Calculate the amount of energy released by the fusion of ${}^6_3\text{Li}$ and deuterium to give two helium-4 nuclei. Express your answer in electronvolts per atom and kilojoules per mole.
 - How much energy is released by the fusion of two deuterium nuclei to give one tritium nucleus and one proton? How does this amount compare with the energy released by the fusion of a deuterium nucleus and a tritium nucleus, which is accompanied by ejection of a neutron? Express your answer in megaelectronvolts and kilojoules per mole. Pound for pound, which is a better choice for a fusion reactor fuel mixture?

Answers

- ${}^{238}_{91}\text{Pa} \rightarrow {}^{238}_{92}\text{U} + {}^0_{-1}\beta \quad -5.540 \times 10^{-16} \text{ kJ}$
 - ${}^{216}_{87}\text{Fr} \rightarrow {}^{212}_{85}\text{At} + {}^4_2\alpha \quad -1.470 \times 10^{-15} \text{ kJ}$

- c. ${}_{83}^{199}\text{Bi} \rightarrow {}_{82}^{199}\text{Pb} + {}_{-1}^0\beta - 5.458 \times 10^{-16} \text{ kJ}$
- 2.
3. a. ${}_{91}^{234}\text{Pa} \rightarrow {}_{92}^{234}\text{U} + {}_{-1}^0\beta \quad 2.118 \times 10^8 \text{ kJ/mol}$
 b. ${}_{88}^{226}\text{Ra} \rightarrow {}_{86}^{222}\text{Rn} + {}_{+2}^4\alpha \quad 4.700 \times 10^8 \text{ kJ/mol}$
- 4.
5. a. The beta decay of bismuth-208 to polonium is endothermic ($\Delta E = 1.400 \text{ MeV/atom}$, $1.352 \times 10^8 \text{ kJ/mol}$).
 b. The formation of lead-206 by alpha decay of polonium-210 is exothermic ($\Delta E = -5.405 \text{ MeV/atom}$, $-5.218 \times 10^8 \text{ kJ/mol}$).
- 6.
7. 757 MeV/atom, 8.70 MeV/nucleon
- 8.
9. a. 53.438245 amu
 b. 0.496955 amu
 c. 463 MeV/atom
 d. 8.74 MeV/nucleon
- 10.
11. -173 MeV/atom ; $1.67 \times 10^{10} \text{ kJ/mol}$
- 12.
13. $\Delta E = +9.0 \times 10^6 \text{ kJ/mol}$ beryllium-8; no
- 14.
15. D-D fusion: $\Delta E = -4.03 \text{ MeV/tritium nucleus formed} = -3.89 \times 10^8 \text{ kJ/mol tritium}$; D-T fusion: $\Delta E = -17.6 \text{ MeV/tritium nucleus} = -1.70 \times 10^8 \text{ kJ/mol}$; D-T fusion

Learning Objective

- To understand how nuclear reactors function.

The ever-increasing energy needs of modern societies have led scientists and engineers to develop ways of harnessing the energy released by nuclear reactions. To date, all practical applications of nuclear power have been based on nuclear fission reactions. Although nuclear fusion offers many advantages in principle, technical difficulties in achieving the high energies required to initiate nuclear fusion reactions have thus far precluded using fusion for the controlled release of energy. In this section, we describe the various types of nuclear power plants that currently generate electricity from nuclear reactions, along with some possible ways to harness fusion energy in the future. In addition, we discuss some of the applications of nuclear radiation and radioisotopes, which have innumerable uses in medicine, biology, chemistry, and industry.

Pitchblende. Pitchblende, the major uranium ore, consisting mainly of uranium oxide.

Nuclear Reactors

When a critical mass of a fissile isotope is achieved, the resulting flux of neutrons can lead to a self-sustaining reaction. A variety of techniques can be used to control the flow of neutrons from such a reaction, which allows nuclear fission reactions to be maintained at safe levels. Many levels of control are required, along with a fail-safe design, because otherwise the chain reaction can accelerate so rapidly that it releases enough heat to melt or vaporize the fuel and the container, a situation that can release enough radiation to contaminate the surrounding area. Uncontrolled nuclear fission reactions are relatively rare, but they have occurred at least 18 times in the past. The most recent event resulted from the damaged Fukushima Dai-ichi plant after the March 11, 2011, earthquake and tsunami that devastated Japan. The plant used fresh water for cooling nuclear fuel rods to maintain controlled, sustainable nuclear fission. When the water supply was disrupted, so much heat was generated that a partial meltdown occurred. Radioactive iodine levels in contaminated seawater from the plant were over 4300 times the regulated safety limit. To put this in perspective, drinking one liter of fresh water with this level of contamination is the equivalent to receiving double the annual dose of radiation that is typical for a person. Dismantling the plant and decontaminating the site is estimated to require 30 years at a cost of approximately \$12 billion.

There is compelling evidence that uncontrolled nuclear chain reactions occurred naturally in the early history of our planet, about 1.7 billion years ago in uranium deposits near Oklo in Gabon, West Africa (Figure 24.5.1). The natural abundance of ^{235}U 2 billion years ago was about 3%, compared with 0.72% today; in contrast, the “fossil nuclear reactor” deposits in Gabon now contain only 0.44% ^{235}U . An unusual combination of geologic phenomena in this region apparently resulted in the formation of deposits of

essentially pure uranium oxide containing 3% ^{235}U , which coincidentally is identical to the fuel used in many modern nuclear plants. When rainwater or groundwater saturated one of these deposits, the water acted as a natural *moderator* that decreased the kinetic energy of the neutrons emitted by radioactive decay of ^{235}U , allowing the neutrons to initiate a chain reaction. As a result, the entire deposit “went critical” and became an uncontrolled nuclear chain reaction, which is estimated to have produced about 100 kW of power. It is thought that these natural nuclear reactors operated only intermittently, however, because the heat released would have vaporized the water. Removing the water would have shut down the reactor until the rocks cooled enough to allow water to reenter the deposit, at which point the chain reaction would begin again. This on–off cycle is believed to have been repeated for more than 100,000 years, until so much ^{235}U was consumed that the deposits could no longer support a chain reaction.

Figure 20.19 A “Fossil Nuclear Reactor” in a Uranium Mine Near Oklo in Gabon, West Africa More than a billion years ago, a number of uranium-rich deposits in West Africa apparently “went critical,” initiating uncontrolled nuclear fission reactions that may have continued intermittently for more than 100,000 years, until the concentration of uranium-235 became too low to support a chain reaction. This photo shows a geologist standing in a mine dug to extract the concentrated uranium ore. Commercial interest waned rapidly after it was recognized that the uranium ore was severely depleted in uranium-235, the isotope of interest.

In addition to the incident in Japan, another recent instance of an uncontrolled nuclear chain reaction occurred on April 25–26, 1986, at the Chernobyl nuclear power plant in the former Union of Soviet Socialist Republics (USSR; now in the Ukraine; [Figure 24.5.2](#)). During testing of the reactor’s turbine generator, a series of mechanical and operational failures caused a chain reaction that quickly went out of control, destroying the reactor core and igniting a fire that destroyed much of the facility and released a large amount of radioactivity. Thirty people were killed immediately, and the high levels of radiation in a 20 mi radius forced nearly 350,000 people to be resettled or evacuated. In addition, the accident caused a disruption to the Soviet economy that is estimated to have cost almost \$13 billion. It is somewhat surprising, however, that the long-term health effects on the 600,000 people affected by the accident appear to be much less severe than originally anticipated. Initially, it was predicted that the accident would result in tens of thousands of premature deaths, but an exhaustive study almost 20 yr after the event suggests that 4000 people will die prematurely from radiation exposure due to the accident. Although significant, in fact it represents only about a 3% increase in the cancer rate among the 600,000 people most affected, of whom about a quarter would be expected to eventually die of cancer even if the accident had not occurred.

Figure 24.5.2 The Chernobyl Nuclear Power Plant In 1986, mechanical and operational failures during testing at the Chernobyl power plant in the USSR (now in the Ukraine) caused an uncontrolled nuclear chain reaction. The resulting fire destroyed much of the facility and severely damaged the core of the reactor, resulting in the release of large amounts of radiation that was spread over the surrounding area by the prevailing winds. The effects were devastating to the health of the population in the region and to the Soviet economy.

If, on the other hand, the neutron flow in a reactor is carefully regulated so that only enough heat is released to boil water, then the resulting steam can be used to produce electricity. Thus a nuclear reactor is similar in many respects to the conventional power plants discussed in [Section 9.8](#), which burn coal or natural gas to generate electricity; the only difference is the source of the heat that converts water to steam.

Light-Water Reactors

We begin our description of nuclear power plants with light-water reactors, which are used extensively to produce electricity in countries such as Japan, Israel, South Korea, Taiwan, and France—countries that lack large reserves of fossil fuels. The essential components of a light-water reactor are depicted in [Figure 24.5.3](#). All existing nuclear power plants have similar components, although different designs use different fuels and operating conditions. *Fuel rods* containing a fissile isotope in a structurally stabilized form (such as uranium oxide pellets encased in a corrosion-resistant zirconium alloy) are suspended in a cooling bath that transfers the heat generated by the fission reaction to a secondary cooling system. The heat is used to generate steam for the production of electricity. In addition, *control rods* are used to absorb neutrons and thereby control the rate of the nuclear chain reaction. Control rods are made of a substance that efficiently absorbs neutrons, such as boron, cadmium, or, in nuclear submarines, hafnium. Pulling the control rods out increases the neutron flux, allowing the reactor to generate more heat, whereas inserting the rods completely stops the reaction, a process called “scramming the reactor.”

Figure 24.5.3 A Light-Water Nuclear Fission Reactor for the Production of Electric Power The fuel rods are made of a corrosion-resistant alloy that encases the partially enriched uranium fuel; controlled fission of ^{235}U in the fuel produces heat. Water surrounds the fuel rods and moderates the kinetic energy of the neutrons, slowing them to increase the probability that they will induce fission. Control rods that contain elements such as boron, cadmium, or hafnium, which are very effective at absorbing neutrons, are used to control the rate of the fission reaction. A heat exchanger is used to boil water in a secondary cooling system, creating steam to drive the turbine and produce electricity. The large hyperbolic cooling tower, which is the most visible portion of the facility, condenses the steam in the secondary cooling circuit; it is often located at some distance from the actual reactor.

Despite this apparent simplicity, many technical hurdles must be overcome for nuclear power to be an efficient and safe source of energy. Uranium contains only 0.72% uranium-235, which is the only naturally occurring fissile isotope of uranium. Because this abundance is not enough to support a chain reaction, the uranium fuel must be at least partially enriched in ^{235}U , to a concentration of about 3%, for it to be able to sustain a chain reaction. At this level of enrichment, a nuclear explosion is impossible; far higher levels of enrichment (greater than or equal to 90%) are required for military applications such as nuclear weapons or the nuclear reactors in submarines. Enrichment is accomplished by converting uranium oxide to UF_6 , which is volatile and contains discrete UF_6 molecules. Because $^{235}\text{UF}_6$ and $^{238}\text{UF}_6$ have different masses, they have different rates of effusion and diffusion, and they can be separated using a gas diffusion process, as described in [Chapter 10](#). Another difficulty is that neutrons produced by nuclear fission are too energetic to be absorbed by neighboring nuclei, and they escape from the material without inducing fission in nearby ^{235}U nuclei. Consequently, a moderator must be used to slow the neutrons enough to allow them to be captured by other ^{235}U nuclei. High-speed neutrons are scattered by substances such as water or graphite, which decreases their kinetic energy and increases the probability that they will react with another ^{235}U nucleus. The moderator in a light-water reactor is the water that is used as the primary coolant. The system is highly pressurized to about 100 atm to keep the water from boiling at 100°C.

All nuclear reactors require a powerful cooling system to absorb the heat generated in the reactor core and create steam that is used to drive a turbine that generates electricity. In 1979, an accident occurred when the main water pumps used for cooling at the nuclear power plant at Three Mile Island in Pennsylvania stopped running, which prevented the steam generators from removing heat. Eventually, the zirconium casing of the fuel rods ruptured, resulting in a meltdown of about half of the reactor core. Although there was no loss of life and only a small release of radioactivity, the accident produced sweeping changes in nuclear power plant operations. The US Nuclear Regulatory Commission tightened its oversight to improve safety.

The main disadvantage of nuclear fission reactors is that the spent fuel, which contains too little of the fissile isotope for power generation, is much more radioactive than the unused fuel due to the presence of many daughter nuclei with shorter half-lives than ^{235}U . The decay of these daughter isotopes generates so much heat that the spent fuel rods must be stored in water for as long as 5 yr before they can be handled. Even then, the radiation levels are so high that the rods must be stored for many, many more years to allow the daughter isotopes to decay to nonhazardous levels. How to store these spent fuel rods for hundreds of years is a pressing issue that has not yet been successfully resolved. As a result, some people are convinced that nuclear power is not a viable option for providing our future energy needs, although a number of other countries continue to rely on nuclear reactors for a large fraction of their energy.

Heavy-Water Reactors

Deuterium (^2H) absorbs neutrons much less effectively than does hydrogen (^1H), but it is about twice as effective at slowing neutrons. Consequently, a nuclear reactor that uses D_2O instead of H_2O as the moderator is so efficient that it can use *unenriched* uranium as fuel. Using a lower grade of uranium reduces operating costs and eliminates the need for plants that produce enriched uranium. Because of the expense of D_2O , however, only countries like Canada, which has abundant supplies of hydroelectric power for generating D_2O by electrolysis, have made a major investment in heavy-water reactors. (For more information on electrolysis, see [Chapter 19](#).)

Breeder Reactors

A *breeder reactor* is a nuclear fission reactor that produces more fissionable fuel than it consumes. This does not violate the first law of thermodynamics because the fuel produced is not the same as the fuel consumed. Under heavy neutron bombardment, the nonfissile ^{238}U isotope is converted to ^{239}Pu , which can undergo fission:

The overall reaction is thus the conversion of nonfissile ^{238}U to fissile ^{239}Pu , which can be chemically isolated and used to fuel a new reactor. An analogous series of reactions converts nonfissile ^{232}Th to ^{233}U , which can also be used as a fuel for a nuclear reactor. Typically, about 8–10 yr are required for a breeder reactor to produce twice as much fissile material as it consumes, which is enough to fuel a replacement for the original reactor plus a new reactor. The products of the fission of ^{239}Pu , however, have substantially longer half-lives than the fission products formed in light-water reactors.

Nuclear Fusion Reactors

Although nuclear fusion reactions, such as those in [Equation 24.4.12](#) and [Equation 24.4.13](#), are thermodynamically spontaneous, the positive charge on both nuclei results in a large electrostatic energy barrier to the reaction. (As you learned in [Chapter 18](#), thermodynamic spontaneity is unrelated to the reaction rate.) Extraordinarily high temperatures (about 1.0×10^8 °C) are required to overcome electrostatic repulsions and initiate a fusion reaction. Even the most feasible such reaction, deuterium–tritium fusion (D–T fusion; [Equation 24.4.13](#)), requires a temperature of about 4.0×10^7 °C. Achieving these temperatures and controlling the materials to be fused are extraordinarily difficult problems, as is extracting the energy released by the fusion reaction, because a commercial fusion reactor would require such high temperatures to be maintained for long periods of time. Several different technologies are currently being explored, including the use of intense magnetic fields to contain ions in the form of a dense, high-energy plasma at a temperature high enough to sustain fusion (part (a) in [Figure 24.5.4](#)). Another concept employs focused laser beams to heat and compress fuel pellets in controlled miniature fusion explosions (part (b) in [Figure 24.5.4](#)).

Figure 24.5.4 Two Possible Designs for a Nuclear Fusion Reactor The extraordinarily high temperatures needed to initiate a nuclear fusion reaction would immediately destroy a container made of any known material. (a) One way to avoid contact with the container walls is to use a high-energy plasma as the fuel. Because plasma is essentially a gas composed of ionized particles, it can be confined using a strong magnetic field shaped like a torus (a hollow donut). (b) Another approach to nuclear fusion is inertial confinement, which uses an icosahedral array of powerful lasers to heat and compress a tiny fuel pellet (a mixture of solid LiD and LiT) to induce fusion.

Nuclear reactions such as these are called thermonuclear reactions because a great deal of thermal energy must be invested to initiate the reaction. The amount of energy released by the reaction, however, is several orders of magnitude greater than the energy needed to initiate it. In principle, a nuclear fusion reaction should thus result in a significant net production of energy. In addition, Earth's oceans contain an essentially inexhaustible supply of both deuterium and tritium, which suggests that nuclear fusion could provide a limitless supply of energy. Unfortunately, however, the technical requirements for a successful nuclear fusion reaction are so great that net power generation by controlled fusion has yet to be achieved.

The Uses of Radioisotopes

Nuclear radiation can damage biological molecules, thereby disrupting normal functions such as cell division ([Table 24.3.2](#)). Because radiation is particularly destructive to rapidly dividing cells such as tumor cells and bacteria, it has been used medically to treat cancer since 1904, when radium-226 was first used to treat a cancerous tumor. Many radioisotopes are now available for medical use, and each has specific advantages for certain applications.

In modern *radiation therapy*, radiation is often delivered by a source planted inside the body. For example, tiny capsules containing an isotope such as ^{192}Ir , coated with a thin layer of chemically inert platinum, are inserted into the middle of a tumor that cannot be removed surgically. The capsules are removed when the treatment is over. In some cases, physicians take advantage of the body's own chemistry to deliver a radioisotope to the desired location. For example, the thyroid glands in the lower front of the neck are the only organs in the body that use iodine. Consequently, radioactive iodine is taken up almost exclusively by the thyroid (part (a) in [Figure 24.5.5](#)). Thus when radioactive isotopes of iodine (^{125}I or ^{131}I) are injected into the blood of a patient suffering from thyroid cancer, the thyroid glands filter the radioisotope from the blood and concentrate it in the tissue to be destroyed. In cases where a tumor is surgically inaccessible (e.g., when it is located deep in the brain), an external radiation source such as a ^{60}Co "gun" is used to aim a tightly focused beam of γ rays at it. Unfortunately, radiation therapy damages healthy tissue in addition to the target tumor and results in severe side effects, such as nausea, hair loss, and a weakened immune system. Although radiation therapy is generally not a pleasant experience, in many cases it is the only choice.

Figure 24.5.5 Medical Imaging and Treatment with Radioisotopes (a) Radioactive iodine is used both to obtain images of the thyroid and to treat thyroid cancer. Injected iodine-123 or iodine-131 is selectively taken up by the thyroid gland, where it is incorporated into the thyroid hormone: thyroxine. Because iodine-131 emits low-energy β particles that are absorbed by the surrounding tissue, it can be used to destroy malignant tissue in the thyroid. In contrast, iodine-123 emits higher-energy γ rays that penetrate tissues readily, enabling it to image the thyroid gland, as shown here. (b) Some technetium compounds are selectively absorbed by cancerous cells within bones. The yellow spots show that a primary cancer has metastasized (spread) to the patient's spine (lower center) and ribs (right center).

A second major medical use of radioisotopes is *medical imaging*, in which a radioisotope is temporarily localized in a particular tissue or organ, where its emissions provide a “map” of the tissue or the organ. Medical imaging uses radioisotopes that cause little or no tissue damage but are easily detected. One of the most important radioisotopes for medical imaging is ^{99m}Tc . Depending on the particular chemical form in which it is administered, technetium tends to localize in bones and soft tissues, such as the heart or the kidneys, which are almost invisible in conventional x-rays (part (b) in Figure 24.5.5). Some properties of other radioisotopes used for medical imaging are listed in Table 24.5.1.

Table 24.5.1 Radioisotopes Used in Medical Imaging and Treatment

Isotope	Half-Life	Tissue
^{18}F	110 min	brain
^{24}Na	15 h	circulatory system
^{32}P	14 days	eyes, liver, and tumors
^{59}Fe	45 days	blood and spleen
^{60}Co	5.3 yr	external radiotherapy
^{99m}Tc	6 h	heart, thyroid, liver, kidney, lungs, and skeleton
^{125}I	59.4 days	thyroid, prostate, and brain
^{131}I	8 days	thyroid
^{133}Xe	5 days	lungs
^{201}Tl	3 days	heart

Because γ rays produced by isotopes such as ^{131}I and ^{99m}Tc are emitted randomly in all directions, it is impossible to achieve high levels of resolution in images that use such isotopes. However, remarkably detailed three-dimensional images can be obtained using an imaging technique called *positron emission tomography (PET)*. The technique uses radioisotopes that decay by positron emission, and the resulting positron is annihilated when it collides with an electron in the surrounding matter. (For more information on positron emission, see Section 24.2) In the annihilation process, both particles are converted to energy in the form of two γ rays that are emitted simultaneously and at 180° to each other:

With PET, biological molecules that have been “tagged” with a positron-emitting isotope such as ^{18}F or ^{11}C can be used to probe the functions of organs such as the brain.

Another major health-related use of ionizing radiation is the irradiation of food, an effective way to kill bacteria such as *Salmonella* in chicken and eggs and potentially lethal strains of *Escherichia coli* in beef. Collectively, such organisms cause almost 3 million cases of food poisoning annually in the United States, resulting in hundreds of deaths. Figure 24.5.6 shows how irradiation dramatically extends the storage life of foods such as strawberries. Although US health authorities have given only limited approval of this technique, the growing number of illnesses caused by antibiotic-resistant bacteria is increasing the pressure to expand the scope of food irradiation.

One of the more unusual effects of radioisotopes is in dentistry. Because dental enamels contain a mineral called feldspar (KAlSi_3O_8 , which is also found in granite rocks), teeth contain a small amount of naturally occurring radioactive ^{40}K . The radiation caused by the decay of ^{40}K results in the emission of light (*fluorescence*), which gives the highly desired “pearly white” appearance associated with healthy teeth.

In a sign of how important nuclear medicine has become in diagnosing and treating illnesses, the medical community has become alarmed at the global shortage of ^{99}Tc , a radioisotope used in more than 30 million procedures a year worldwide. Two reactors that produce 60% of the world’s radioactive ^{99}Mo , which decays to ^{99}Tc , are operating beyond their intended life expectancies. Moreover, because most of the reactors producing ^{99}Mo use weapons-grade uranium (^{235}U), which decays to ^{99}Mo during fission, governments are working to phase out civilian uses of technology to produce ^{99}Mo because of concerns that the technology can be used to produce nuclear weapons. Engineers are currently focused on how to make key medical isotopes with other alternatives that don’t require fission. One promising option is by removing a neutron from ^{100}Mo , a stable isotope that makes up about 10% of natural molybdenum, transmuted it to ^{99}Mo .

In addition to the medical uses of radioisotopes, radioisotopes have literally hundreds of other uses. For example, smoke detectors contain a tiny amount of ^{241}Am , which ionizes the air in the detector so an electric current can flow through it. Smoke particles reduce the number of ionized particles and decrease the electric current, which triggers an alarm. Another application is the “go-devil” used to detect leaks in long pipelines. It is a packaged radiation detector that is inserted into a pipeline and propelled through the pipe by the flowing liquid. Sources of ^{60}Co are attached to the pipe at regular intervals; as the detector travels along the pipeline, it sends a radio signal each time it passes a source. When a massive leak causes the go-devil to stop, the repair crews know immediately which section of the pipeline is damaged. Finally, radioactive substances are used in gauges that measure and control the thickness of sheets and films. As shown in Figure 24.5.7, thickness gauges rely on the absorption of either β particles (by paper, plastic, and very thin metal foils) or γ rays (for thicker metal sheets); the amount of radiation absorbed can be measured accurately and is directly proportional to the thickness of the material.

Figure 24.5.6 The Preservation of Strawberries with Ionizing Radiation Fruits such as strawberries can be irradiated by high-energy γ rays to kill bacteria and prolong their storage life. The nonirradiated strawberries on the left are completely spoiled after 15 days in storage, but the irradiated strawberries on the right show no visible signs of spoilage under the same conditions.

Figure 24.5.7 Using Radiation to Control the Thickness of a Material Because the amount of radiation absorbed by a material is proportional to its thickness, radiation can be used to control the thickness of plastic film, tin foil, or paper. As shown, a beta emitter is placed on one side of the material being produced and a detector on the other. An increase in the amount of radiation that reaches the detector indicates a decrease in the thickness of the material and vice versa. The output of the detector can thus be used to control the thickness of the material.

Summary

In nuclear power plants, nuclear reactions generate electricity. *Light-water reactors* use enriched uranium as a fuel. They include fuel rods, a moderator, control rods, and a powerful cooling system to absorb the heat generated in the reactor core. *Heavy-water reactors* use unenriched uranium as a fuel because they use D_2O as the moderator, which scatters and slows neutrons much more effectively than H_2O . A *breeder reactor* produces more fissionable fuel than it consumes. A *nuclear fusion reactor* requires very high temperatures. Fusion reactions are **thermonuclear reactions** because they require high temperatures for initiation. Radioisotopes are used in both radiation therapy and *medical imaging*.

Key Takeaway

- All practical applications of nuclear power have been based on nuclear fission reactions, which nuclear power plants use to generate electricity.

Conceptual Problems

1. In nuclear reactors, two different but interrelated factors must be controlled to prevent a mishap that could cause the release of unwanted radiation. How are these factors controlled?
2. What are the three principal components of a nuclear reactor? What is the function of each component?
3. What is meant by the term *enrichment* with regard to uranium for fission reactors? Why does the fuel in a conventional nuclear reactor have to be “enriched”?
4. The plot in a recent spy/action movie involved the threat of introducing stolen “weapons-grade” uranium, which consists of 93.3% ^{235}U , into a fission reactor that normally uses a fuel containing about 3% ^{235}U . Explain why this could be catastrophic.
5. Compare a heavy-water reactor with a light-water reactor. Why are heavy-water reactors less widely used? How do these two reactor designs compare with a breeder reactor?
6. Conventional light-water fission reactors require enriched fuel. An alternative reactor is the so-called heavy-water reactor. The components of the two different reactors are the same except that instead of using water (H_2O), the moderator in a heavy-water reactor is D_2O , known as “heavy water.” Because D_2O is more efficient than H_2O at slowing neutrons, heavy-water reactors do not require fuel enrichment to support fission. Why is D_2O more effective at slowing neutrons, and why does this allow unenriched fuels to be used?
7. Isotopes emit γ rays in random directions. What difficulties do these emissions present for medical imaging? How are these difficulties overcome?
8. If you needed to measure the thickness of 1.0 mm plastic sheets, what type of radiation would you use? Would the radiation source be the same if you were measuring steel of a similar thickness? What is your rationale? Would you want an isotope with a long or short half-life for this device?

Answers

1. Neutron flow is regulated by using control rods that absorb neutrons, whereas the speed of the neutrons produced by fission is controlled by using a moderator that slows the neutrons enough to allow them to react with nearby fissile nuclei.
- 2.
- 3.
- 4.
- 5.
- 6.
7. It is difficult to pinpoint the exact location of the nucleus that decayed. In contrast, the collision of a positron with an electron causes both particles to be annihilated, and in the process, two gamma rays are emitted in opposite directions, which makes it possible to identify precisely where a positron emitter is located and to create detailed images of tissues.
- 8.

Numerical Problems

1. Palladium-103, which decays via electron capture and emits x-rays with an energy of 3.97×10^{-2} MeV, is often used to treat prostate cancer. Small pellets of the radioactive metal are embedded in the prostate gland. This provides a localized source of radiation to a very small area, even though the tissue absorbs only about 1% of the x-rays. Due to its short half-life, all of the palladium will decay to a stable isotope in less than a year. If a doctor embeds 50 pellets containing 2.50 mg of $^{103}_{46}\text{Pd}$ in the prostate gland of a 73.9 kg patient, what is the patient's radiation exposure over the course of a year?
2. Several medical treatments use cobalt-60, which is formed by bombarding cobalt with neutrons to produce a highly radioactive *gamma* emitter that undergoes 4.23×10^6 emissions/(s·kg) of pure cobalt-60. The energy of the gamma emission is 5.86×10^{-2} MeV. Write the balanced nuclear equation for the formation of this isotope. Is this a transmutation reaction? If a 55.3 kg patient received a 0.50 s exposure to a 0.30 kg cobalt-60 source, what would the exposure be in rads? Predict the potential side effects of this dose.

Learning Objective

- To understand how nuclear transmutation reactions lead to the formation of the elements in stars and how they can be used to synthesize transuranium elements.

The relative abundances of the elements in the known universe vary by more than 12 orders of magnitude. For the most part, these differences in abundance cannot be explained by differences in nuclear stability. Although the $^{56}_{26}\text{Fe}$ nucleus is the most stable nucleus known, the most abundant element in the known universe is not iron, but hydrogen (^1_1H), which accounts for about 90% of all atoms. In fact, ^1_1H is the raw material from which all other elements are formed.

In this section, we explain why ^1_1H and ^4_2He together account for at least 99% of all the atoms in the known universe. We also describe the nuclear reactions that take place in stars, which transform one nucleus into another and create all the naturally occurring elements.

Relative Abundances of the Elements on Earth and in the Known Universe

The relative abundances of the elements in the known universe and on Earth relative to silicon are shown in [Figure 24.6.1](#). The data are estimates based on the characteristic emission spectra of the elements in stars, the absorption spectra of matter in clouds of interstellar dust, and the approximate composition of Earth as measured by geologists. The data in [Figure 24.6.1](#) illustrate two important points. First, except for hydrogen, the most abundant elements have *even* atomic numbers. Not only is this consistent with the trends in nuclear stability discussed in [Section 24.1](#), but it also suggests that heavier elements are formed by combining helium nuclei ($Z = 2$). Second, the relative abundances of the elements in the known universe and on Earth are often very different, as indicated by the data in [Table 24.6.1](#) for some common elements. Some of these differences are easily explained. For example, nonmetals such as H, He, C, N, O, Ne, and Kr are much less abundant relative to silicon on Earth than they are in the rest of the universe. These elements are either noble gases (He, Ne, and Kr) or elements that form volatile hydrides, such as NH_3 , CH_4 , and H_2O . Because Earth's gravity is not strong enough to hold such light substances in the atmosphere, these elements have been slowly diffusing into outer space ever since our planet was formed. Argon is an exception; it is relatively abundant on Earth compared with the other noble gases because it is continuously produced in rocks by the radioactive decay of isotopes such as $^{40}_{19}\text{K}$. In contrast, many metals, such as Al, Na, Fe, Ca, Mg, K, and Ti, are relatively abundant on Earth because they form nonvolatile compounds, such as oxides, that cannot escape into space. Other metals, however, are much *less* abundant on Earth than in the universe; some examples are Ru and Ir. You may recall from [Chapter 1](#) that the anomalously high iridium content of a 66-million-year-old rock layer was a key finding in the development of the asteroid-impact theory for the extinction of the dinosaurs. This section explains some of the reasons for the great differences in abundances of the metallic elements.

Figure 24.6.1 The Relative Abundances of the Elements in the Universe and on Earth In this logarithmic plot, the relative abundances of the elements relative to that of silicon (arbitrarily set equal to 1) in the universe (green bars) and on Earth (purple bars) are shown as a function of atomic number. Elements with even atomic numbers are generally more abundant in the universe than elements with odd atomic numbers. Also, the relative abundances of many elements in the universe are very different from their relative abundances on Earth.

Table 24.6.1 Relative Abundances of Elements on Earth and in the Known Universe

Terrestrial/Universal Element	Abundance Ratio
H	0.0020
He	2.4×10^{-8}
C	0.36
N	0.02
O	46
Ne	1.9×10^{-6}
Na	1200
Mg	48
Al	1600
Si	390
S	0.84
K	5000
Ca	710
Ti	2200
Fe	57

All the elements originally present on Earth (and on other planets) were synthesized from hydrogen and helium nuclei in the interiors of stars that have long since exploded and disappeared. Six of the most abundant elements in the universe (C, O, Ne, Mg, Si, and Fe) have nuclei that are integral multiples of the helium-4 nucleus, which suggests that helium-4 is the primary building block for heavier nuclei.

Synthesis of the Elements in Stars

Elements are synthesized in discrete stages during the lifetime of a star, and some steps occur only in the most massive stars known (Figure 24.6.2). Initially, all stars are formed by the aggregation of interstellar “dust,” which is mostly hydrogen. As the cloud of dust slowly contracts due to gravitational attraction, its density eventually reaches about 100 g/cm^3 , and the temperature increases to about $1.5 \times 10^7 \text{ K}$, forming a dense plasma of ionized hydrogen nuclei. At this point, self-sustaining nuclear reactions begin, and the star “ignites,” creating a *yellow star* like our sun.

Figure 24.6.2 Nuclear Reactions during the Life Cycle of a Massive Star At each stage in the lifetime of a star, a different fuel is used for nuclear fusion, resulting in the formation of different elements. Fusion of hydrogen to give helium is the primary fusion reaction in young stars. As the star ages, helium accumulates and begins to “burn,” undergoing fusion to form heavier elements such as carbon and oxygen. As the adolescent star matures, significant amounts of iron and nickel are formed by fusion of the heavier elements formed previously. The heaviest elements are formed only during the final death throes of the star—the formation of a nova or supernova.

In the first stage of its life, the star is powered by a series of nuclear fusion reactions that convert hydrogen to helium:

The overall reaction is the conversion of four hydrogen nuclei to a helium-4 nucleus, which is accompanied by the release of two positrons, two γ rays, and a great deal of energy:

These reactions are responsible for most of the enormous amount of energy that is released as sunlight and solar heat. It takes several billion years, depending on the size of the star, to convert about 10% of the hydrogen to helium.

Once large amounts of helium-4 have been formed, they become concentrated in the core of the star, which slowly becomes denser and hotter. At a temperature of about 2×10^8 K, the helium-4 nuclei begin to fuse, producing beryllium-8:

Although beryllium-8 has both an even mass number and an even atomic number, its also has a low neutron-to-proton ratio (and other factors beyond the scope of this text) that makes it unstable; it decomposes in only about 10^{-16} s. Nonetheless, this is long enough for it to react with a third helium-4 nucleus to form carbon-12, which is very stable. Sequential reactions of carbon-12 with helium-4 produce the elements with even numbers of protons and neutrons up to magnesium-24:

So much energy is released by these reactions that it causes the surrounding mass of hydrogen to expand, producing a *red giant* that is about 100 times larger than the original yellow star.

As the star expands, heavier nuclei accumulate in its core, which contracts further to a density of about $50,000 \text{ g/cm}^3$, so the core becomes even hotter. At a temperature of about 7×10^8 K, carbon and oxygen nuclei undergo nuclear fusion reactions to produce sodium and silicon nuclei:

At these temperatures, carbon-12 reacts with helium-4 to initiate a series of reactions that produce more oxygen-16, neon-20, magnesium-24, and silicon-28, as well as heavier nuclides such as sulfur-32, argon-36, and calcium-40:

The energy released by these reactions causes a further expansion of the star to form a *red supergiant*, and the core temperature increases steadily. At a temperature of about 3×10^9 K, the nuclei that have been formed exchange protons and neutrons freely. This equilibration process forms heavier elements up to iron-56 and nickel-58, which have the most stable nuclei known.

The Formation of Heavier Elements in Supernovas

None of the processes described so far produces nuclei with $Z > 28$. All naturally occurring elements heavier than nickel are formed in the rare but spectacular cataclysmic explosions called *supernovas* (Figure 24.6.2). When the fuel in the core of a very massive star has been consumed, its gravity causes it to collapse in about 1 s. As the core is compressed, the iron and nickel nuclei within it disintegrate to protons and neutrons, and many of the protons capture electrons to form neutrons. The resulting *neutron star* is a dark object that is so dense that atoms no longer exist. Simultaneously, the energy released by the collapse of the core causes the supernova to explode in what is arguably the single most violent event in the universe. The force of the explosion blows most of the star's matter into space, creating a gigantic and rapidly expanding dust cloud, or *nebula* (Figure 24.6.3). During the extraordinarily short duration of this event, the concentration of neutrons is so great that multiple neutron-capture events occur, leading to the production of the heaviest elements and many of the less stable nuclides. Under these conditions, for example, an iron-56 nucleus can absorb as many as 64 neutrons, briefly forming an extraordinarily unstable iron isotope that can then undergo multiple rapid β -decay processes to produce tin-120:

Although a supernova occurs only every few hundred years in a galaxy such as the Milky Way, these rare explosions provide the only conditions under which elements heavier than nickel can be formed. The force of the explosions distributes these elements throughout the galaxy surrounding the supernova, and eventually they are captured in the dust that condenses to form new stars. Based on its elemental composition, our sun is thought to be a second- or third-generation star. It contains a considerable amount of cosmic debris from the explosion of supernovas in the remote past.

Figure 24.6.3 A Supernova
A view of the remains of Supernova 1987A, located in the Large Magellanic Cloud, showing the circular halo of expanding debris produced by the explosion. Multiple neutron-capture events occur during a supernova explosion, forming both the heaviest elements and many of the less stable nuclides.

Example 24.6.1

The reaction of two carbon-12 nuclei in a carbon-burning star can produce elements other than sodium. Write a balanced nuclear equation for the formation of

1. magnesium-24.
2. neon-20 from two carbon-12 nuclei.

Given: reactant and product nuclides

Asked for: balanced nuclear equation

Strategy:

Use conservation of mass and charge to determine the type of nuclear reaction that will convert the reactant to the indicated product. Write the balanced nuclear equation for the reaction.

Solution:

1. A magnesium-24 nucleus ($Z = 12, A = 24$) has the same nucleons as two carbon-12 nuclei ($Z = 6, A = 12$). The reaction is therefore a fusion of two carbon-12 nuclei, and no other particles are produced: ${}^6_{12}\text{C} + {}^6_{12}\text{C} \rightarrow {}^{12}_{24}\text{Mg}$
2. The neon-20 product has $Z = 10$ and $A = 20$. The conservation of mass requires that the other product have $A = (2 \times 12) - 20 = 4$; because of conservation of charge, it must have $Z = (2 \times 6) - 10 = 2$. These are the characteristics of an α particle. The reaction is therefore ${}^6_{12}\text{C} + {}^6_{12}\text{C} \rightarrow {}^{10}_{20}\text{Ne} + {}^2_4\alpha$

Exercise

How many neutrons must an iron-56 nucleus absorb during a supernova explosion to produce an arsenic-75 nucleus? Write a balanced nuclear equation for the reaction.

Answer: 19 neutrons; ${}^{56}_{26}\text{Fe} + 19{}_0^1n \rightarrow {}^{75}_{26}\text{Fe} \rightarrow {}^{75}_{33}\text{As} + 7{}^0_{-1}\beta$

Summary

By far the most abundant element in the universe is hydrogen. The fusion of hydrogen nuclei to form helium nuclei is the major process that fuels young stars such as the sun. Elements heavier than helium are formed from hydrogen and helium in the interiors of stars. Successive fusion reactions of helium nuclei at higher temperatures create elements with even numbers of protons and neutrons up to magnesium and then up to calcium. Eventually, the elements up to iron-56 and nickel-58 are formed by exchange processes at even higher temperatures. Heavier elements can only be made by a process that involves multiple neutron-capture events, which can occur only during the explosion of a supernova.

Key Takeaways

- Hydrogen and helium are the most abundant elements in the universe.
- Heavier elements are formed in the interior of stars via multiple neutron-capture events.

Conceptual Problems

1. Why do scientists believe that hydrogen is the building block of all other elements? Why do scientists believe that helium-4 is the building block of the heavier elements?
2. How does a star produce such enormous amounts of heat and light? How are elements heavier than Ni formed?
3. Propose an explanation for the observation that elements with even atomic numbers are more abundant than elements with odd atomic numbers.
4. During the lifetime of a star, different reactions that form different elements are used to power the fusion furnace that keeps a star “lit.” Explain the different reactions that dominate in the different stages of a star’s life cycle and their effect on the temperature of the star.
5. A line in a popular song from the 1960s by Joni Mitchell stated, “We are stardust....” Does this statement have any merit or is it just poetic? Justify your answer.
6. If the laws of physics were different and the primary element in the universe were boron-11 ($Z = 5$), what would be the next four most abundant elements? Propose nuclear reactions for their formation.

Answer

- 1.
- 2.
3. The raw material for all elements with $Z > 2$ is helium ($Z = 2$), and fusion of helium nuclei will always produce nuclei with an even number of protons.

- 4.
- 5.
- 6.

Numerical Problems

1. Write a balanced nuclear reaction for the formation of each isotope.
 - a. ${}_{13}^{27}\text{Al}$ from two ${}_{6}^{12}\text{C}$ nuclei
 - b. ${}_{4}^{9}\text{Be}$ from two ${}_{2}^{4}\text{He}$ nuclei
2. At the end of a star's life cycle, it can collapse, resulting in a supernova explosion that leads to the formation of heavy elements by multiple neutron-capture events. Write a balanced nuclear reaction for the formation of each isotope during such an explosion.
 - a. ${}_{46}^{106}\text{Pd}$ from nickel-58
 - b. selenium-79 from iron-56
3. When a star reaches middle age, helium-4 is converted to short-lived beryllium-8 (mass = 8.00530510 amu), which reacts with another helium-4 to produce carbon-12. How much energy is released in each reaction (in megaelectronvolts)? How many atoms of helium must be "burned" in this process to produce the same amount of energy obtained from the fusion of 1 mol of hydrogen atoms to give deuterium?

APPLICATION PROBLEMS

- Until the 1940s, uranium glazes were popular on ceramic dishware. One brand, Fiestaware, had bright orange glazes that could contain up to 20% uranium by mass. Although this practice is less common today due to the negative association of radiation, it is still possible to buy Depression-era glassware that is quite radioactive. Aqueous solutions in contact with this “hot” glassware can reach uranium concentrations up to 10 ppm by mass. If 1.0 g of uranium undergoes 1.11×10^{10} decays/s, each to an α particle with an energy of 4.03 MeV, what would be your exposure in rem and rad if you drank 1.0 L of water that had been sitting for an extended time in a Fiestaware pitcher? Assume that the water and contaminants are excreted only after 18 h and that you weigh 70.0 kg.
- Neutrography is a technique used to take the picture of an object using a beam of neutrons. How does the penetrating power of a neutron compare with alpha, beta, and gamma radiation? Do you expect similar penetration for protons? How would the biological damage of each particle compare with the other types of radiation? (Recall that a neutron’s mass is approximately 2000 times the mass of an electron.)
- Spent fuel elements in a nuclear reactor contain radioactive fission products in addition to heavy metals. The conversion of nuclear fuel in a reactor is shown here:

Neglecting the fission products, write balanced nuclear reactions for the conversion of the original fuel to each product.

- The first atomic bomb used $^{235}_{92}\text{U}$ as a fissile material, but there were immense difficulties in obtaining sufficient quantities of pure $^{235}_{92}\text{U}$. A second fissile element, plutonium, was discovered in 1940, and it rapidly became important as a nuclear fuel. This element was produced by irradiating $^{238}_{92}\text{U}$ with neutrons in a nuclear reactor. Complete the series that produced plutonium, all isotopes of which are fissile:

- Boron neutron capture therapy is a potential treatment for many diseases. As the name implies, when boron-10, one of the naturally occurring isotopes of boron, is bombarded with neutrons, it absorbs a neutron and emits an α particle. Write a balanced nuclear reaction for this reaction. One advantage of this process is that neutrons cause little damage on their own, but when they are absorbed by boron-10, they can cause localized emission of alpha radiation. Comment on the utility of this treatment and its potential difficulties.
- An airline pilot typically flies approximately 80 h per month. If 75% of that time is spent at an altitude of about 30,000 ft, how much radiation is that pilot receiving in one month? over a 30 yr career? Is the pilot receiving toxic doses of radiation?
- At a breeder reactor plant, a 72 kg employee accidentally inhaled 2.8 mg of ^{239}Pu dust. The isotope decays by alpha decay and has a half-life of 24,100 yr. The energy of the emitted α particles is 5.2 MeV, and the dust stays in the employee’s body for 18 h.

- How many plutonium atoms are inhaled?
 - What is the energy absorbed by the body?
 - What is the physical dose in rads?
 - What is the dose in rems? Will the dosage be fatal?
8. For many years, the standard source for radiation therapy in the treatment of cancer was radioactive ^{60}Co , which undergoes beta decay to ^{60}Ni and emits two γ rays, each with an energy of 1.2 MeV. Show the sequence of nuclear reactions. If the half-life for beta decay is 5.27 yr, how many ^{60}Co nuclei are present in a typical source undergoing 6000 dps that is used by hospitals? The mass of ^{60}Co is 59.93 amu.
9. It is possible to use radioactive materials as heat sources to produce electricity. These radioisotope thermoelectric generators (RTGs) have been used in spacecraft and many other applications. Certain Cold War–era Russian-made RTGs used a 5.0 kg strontium-90 source. One mole of strontium-90 releases β particles with an energy of 0.545 MeV and undergoes 2.7×10^{15} decays/s. How many watts of power are available from this RTG (1 watt = 1 J/s)?
10. Potassium consists of three isotopes (potassium-39, potassium-40, and potassium-41). Potassium-40 is the least abundant, and it is radioactive, decaying to argon-40, a stable, nonradioactive isotope, by the emission of a β particle with a half-life of precisely 1.25×10^9 yr. Thus the ratio of potassium-40 to argon-40 in any potassium-40–containing material can be used to date the sample. In 1952, fragments of an early hominid, *Meganthropus*, were discovered near Modjokerto in Java. The bone fragments were lying on volcanic rock that was believed to be the same age as the bones. Potassium–argon dating on samples of the volcanic material showed that the argon-40-to-potassium-40 molar ratio was 0.00281:1. How old were the rock fragments? Could the bones also be the same age? Could radiocarbon dating have been used to date the fragments?

ANSWERS

1. 6.6×10^{-3} rad; 0.13 rem

2.

3.

4.

5.

6.

7. a. 7.1×10^{18} atoms of Pu

b. 0.35 J

c. 0.49 rad

d. 9.8 rem; this dose is unlikely to be fatal.

8.

9. 130 W

10.

- Chapter 3.1: The History of the Periodic Table - *CC BY-NC-SA 4.0*
- Chapter 3.2: Sizes of Atoms and Ions - *CC BY-NC-SA 4.0*
- Chapter 3.3: Energetics of Ion Formation - *CC BY-NC-SA 4.0*
- Chapter 3.4: The Chemical Families - *CC BY-NC-SA 4.0*
- Chapter 3.5: End of Chapter Material - *CC BY-NC-SA 4.0*
- Unit 2: Molecular Structure - *CC BY-NC-SA 4.0*
 - Chapter 4: Ionic Bonding - *CC BY-NC-SA 4.0*
 - Chapter 4.0: What is a Chemical Bond? - *CC BY-NC-SA 4.0*
 - Chapter 4.1: Ionic Bonding - *CC BY-NC-SA 4.0*
 - Chapter 4.2: Lattice Energies in Ionic Solids - *CC BY-NC-SA 4.0*
 - Chapter 4.3: Chemical Formulas - *CC BY-NC-SA 4.0*
 - Chapter 4.4: Naming Ionic Compounds - *CC BY-NC-SA 4.0*
 - Chapter 4.5: End of Chapter Material - *CC BY-NC-SA 4.0*
 - Chapter 5: Covalent Bonding - *CC BY-NC-SA 3.0*
 - Chapter 5.1: Representing Covalent Bonds - *CC BY-NC-SA 3.0*
 - Chapter 5.2: Lewis Electron Dot Symbols - *CC BY-NC-SA 4.0*
 - Chapter 5.3: Lewis Structures - *CC BY-NC-SA 4.0*
 - Chapter 5.4: Exceptions to the Octet Rule - *CC BY-NC-SA 3.0*
 - Chapter 5.5: Properties of Covalent Bonds - *CC BY-NC-SA 4.0*
 - Chapter 5.6: Properties of Polar Covalent Bonds - *CC BY-NC-SA 3.0*
 - Chapter 5.7: Metallic Bonding - *CC BY-NC-SA 4.0*
 - Chapter 5.8: Molecular Representations - *CC BY-NC-SA 3.0*
 - Chapter 6: Molecular Geometry - *CC BY-NC-SA 4.0*
 - Chapter 6.0: Molecular Geometry - *CC BY-NC-SA 4.0*
 - Chapter 6.1: Naming Binary Covalent Compounds - *CC BY-NC-SA 4.0*
 - Chapter 6.2: Hybrid Orbitals - *CC BY-NC-SA 4.0*
 - Chapter 6.3: VSEPR - Molecular Geometry - *CC BY-NC-SA 4.0*
 - Chapter 6.4: Naming Organic Compounds - *CC BY-NC-SA 3.0*
 - Chapter 6.5: Delocalized Bonding and Molecular Orbitals - *CC BY-NC-SA 4.0*
 - Chapter 6.6: Polyatomic Systems, Multiple Bonds, Resonance - *CC BY-NC-SA 4.0*
 - Chapter 6.7: End of Chapter Material - *CC BY-NC-SA 4.0*
- Unit 3: Stoichiometry - *CC BY-NC-SA 4.0*
 - Chapter 7: Stoichiometry - *CC BY-NC-SA 3.0*
 - Chapter 7.1: Again the Mole - *CC BY-NC-SA 4.0*
 - Chapter 7.2: Empirical and Molecular Formulas - *CC BY-NC-SA 4.0*
 - Chapter 7.3: Chemical Equations - *CC BY-NC-SA 4.0*
 - Chapter 7.4: Stoichiometry - *CC BY-NC-SA 4.0*
 - Chapter 7.5: Types of Chemical Reactions - *CC BY-NC-SA 4.0*
 - Chapter 7.6: Chemical Reactions in the Atmosphere - *CC BY-NC-SA 4.0*
 - Chapter 7.7: Industrially Important Chemicals - *CC BY-NC-SA 4.0*
 - Chapter 7.8: End of Chapter Material - *CC BY-NC-SA 4.0*
 - Chapter 7.9: Essential Skills 2 - *CC BY-NC-SA 4.0*
 - Chapter 8: Aqueous Solutions - *CC BY-NC-SA 3.0*
 - Chapter 8.12: End of Chapter Material - *CC BY-NC-SA 3.0*
 - Chapter 8.01: Aqueous Solutions - *CC BY-NC-SA 3.0*
 - Chapter 8.02: Solution Concentrations - *CC BY-NC-SA 3.0*
 - Chapter 8.03: Stoichiometry of Reactions in Solution - *CC BY-NC-SA 3.0*
 - Chapter 8.04: Ionic Equations - *CC BY-NC-SA 3.0*
 - Chapter 8.05: Precipitation Reactions - *CC BY-NC-SA 3.0*
 - Chapter 8.06: Acids and Bases - *CC BY-NC-SA 3.0*
 - Chapter 8.07: Acid Base Reactions - *CC BY-NC-SA 3.0*
 - Chapter 8.08: The Chemistry of Acid Rain - *CC BY-NC-SA 3.0*
 - Chapter 8.09: Quantitative Analysis Using Titration - *CC BY-NC-SA 3.0*
 - Chapter 8.10: Oxidation-Reduction Reactions - *CC BY-NC-SA 3.0*
 - Chapter 8.11: Essential Skills 3 - *CC BY-NC-SA 3.0*
- Unit 4: Thermochemistry - *CC BY-NC-SA 4.0*
 - Chapter 9: Thermochem - *CC BY-NC-SA 4.0*
 - Chapter 9.0: Introduction - *CC BY-NC-SA 3.0*
 - Chapter 9.1 Energy Changes in Chemical Reactions - *CC BY-NC-SA 3.0*

- Chapter 9.2: Enthalpy and Reactions - *CC BY-NC-SA 3.0*
- Chapter 9.3: Hess's Law - *CC BY-NC-SA 3.0*
- Chapter 9.4: Heats of Formation - *CC BY-NC-SA 3.0*
- Chapter 9.5: Enthalpies of Solution - *CC BY-NC-SA 3.0*
- Chapter 9.6: Calorimetry - *CC BY-NC-SA 3.0*
- Chapter 9.7: Thermochem and Nutrition - *CC BY-NC-SA 3.0*
- Chapter 9.8: Energy Sources and the Environment - *CC BY-NC-SA 3.0*
- Chapter 9.9: Essential Skills 4 - *CC BY-NC-SA 3.0*
- Chapter 9.10: End of Chapter Material - *CC BY-NC-SA 3.0*
- Chapter 10: Gases - *CC BY-NC-SA 4.0*
 - Chapter 10.1: Gaseous Elements and Compounds - *CC BY-NC-SA 3.0*
 - Chapter 10.2: Gas Pressure - *CC BY-NC-SA 3.0*
 - Chapter 10.3: The Ideal Gas Law - *CC BY-NC-SA 3.0*
 - Chapter 10.4: The Combined Gas Law - *CC BY-NC-SA 3.0*
 - Chapter 10.5: Gas Mixtures - *CC BY-NC-SA 3.0*
 - Chapter 10.6: Stoichiometry Involving Gases - *CC BY-NC-SA 3.0*
 - Chapter 10.7: The Kinetic Theory of Gases - *CC BY-NC-SA 3.0*
- Unit 5: States of Matter - *CC BY-NC-SA 3.0*
 - Chapter 11: Fluids - *CC BY-NC-SA 3.0*
 - Chapter 11.0: Introduction - *CC BY-NC-SA 3.0*
 - Chapter 11.1: Real Gases - *CC BY-NC-SA 3.0*
 - Chapter 11.2: Intermolecular forces - *CC BY-NC-SA 3.0*
 - Chapter 11.3: Unique Properties of Liquids - *CC BY-NC-SA 3.0*
 - Chapter 11.4: Vapor Pressure - *CC BY-NC-SA 3.0*
 - Chapter 11.5: Changes of State - *CC BY-NC-SA 3.0*
 - Chapter 11.6: Critical Temperature and Pressure - *CC BY-NC-SA 3.0*
 - Chapter 11.7: Phase Diagrams - *CC BY-NC-SA 3.0*
 - Chapter 11.8: Liquid Crystals - *CC BY-NC-SA 3.0*
 - Chapter 11.9: Essential Skills - *CC BY-NC-SA 3.0*
 - Chapter 11.10: End of Chapter Material - *CC BY-NC-SA 3.0*
 - Chapter 12: Solids - *CC BY-NC-SA 3.0*
 - Chapter 12.1: Crystalline and Amorphous Solids - *CC BY-NC-SA 3.0*
 - Chapter 12.2: Arrangement of Atoms in Crystals - *CC BY-NC-SA 3.0*
 - Chapter 12.3 : Structure of Simple Binary Compounds - *CC BY-NC-SA 3.0*
 - Chapter 12.4: Crystal Defects - *CC BY-NC-SA 3.0*
 - Chapter 12.5: Bonding and Properties of Solids - *CC BY-NC-SA 3.0*
 - Chapter 12.6: Metals and Semiconductors - *CC BY-NC-SA 3.0*
 - Chapter 12.7: Superconductors - *CC BY-NC-SA 3.0*
 - Chapter 12.8: Polymers - *CC BY-NC-SA 3.0*
 - Chapter 12.9: Modern Materials - *CC BY-NC-SA 3.0*
 - Chapter 12.10: End of Chapter Material - *CC BY-NC-SA 3.0*
- Chapter 13: Solutions - *CC BY-NC-SA 3.0*
 - Chapter 13.1: Factors Affecting Solubility - *CC BY-NC-SA 3.0*
 - Chapter 13.2: Solubility and Structure - *CC BY-NC-SA 3.0*
 - Chapter 13.3: Units for Concentration - *CC BY-NC-SA 3.0*
 - Chapter 13.4: Temperature and Pressure Effects - *CC BY-NC-SA 3.0*
 - Chapter 13.5: Colligative Properties - *CC BY-NC-SA 3.0*
 - Chapter 13.6: Aggregate Particles - *CC BY-NC-SA 3.0*
 - Chapter 13.7: End of Chapter Materials - *CC BY-NC-SA 3.0*
- Unit 6: Kinetics and Equilibria - *CC BY-NC-SA 3.0*
 - Chapter 14: Chemical Kinetics - *CC BY-NC-SA 3.0*
 - Chapter 14.1: Factors that Affect Reaction Rates - *CC BY-NC-SA 3.0*
 - Chapter 14.2: Reaction Rates and Rate Laws - *CC BY-NC-SA 3.0*
 - Chapter 14.3: Methods of Determining Reaction Order - *CC BY-NC-SA 3.0*
 - Chapter 14.4: Using Graphs to Determine Rate Laws, Rate Constants and Reaction Orders - *CC BY-NC-SA 3.0*
 - Chapter 14.5: Half Lives and Radioactive Decay Kinetics - *CC BY-NC-SA 3.0*
 - Chapter 14.6: Reaction Rates - A Microscopic View - *CC BY-NC-SA 3.0*
 - Chapter 14.7: The Collision Model of Chemical Kinetics - *CC BY-NC-SA 3.0*
 - Chapter 14.8: Catalysis - *CC BY-NC-SA 3.0*
 - Chapter 14.9: End of Chapter Materials - *CC BY-NC-SA 3.0*
 - Chapter 15: Chemical Equilibrium - *CC BY-NC-SA 3.0*

- Chapter 15.1: The Concept of Chemical Equilibrium - *CC BY-NC-SA 3.0*
- Chapter 15.2: The Equilibrium Constant - *CC BY-NC-SA 3.0*
- Chapter 15.3: Solving Equilibrium Problems - *CC BY-NC-SA 3.0*
- Chapter 15.4: Non-equilibrium Conditions - *CC BY-NC-SA 3.0*
- Chapter 15.5: Factors That Affect Equilibrium - *CC BY-NC-SA 3.0*
- Chapter 15.6: Controlling the Products of Reactions - *CC BY-NC-SA 3.0*
- Chapter 15.7: Essential Skills - *CC BY-NC-SA 3.0*
- Chapter 15.8: End of Chapter Materials - *CC BY-NC-SA 3.0*
- Chapter 16: Aqueous Acid-Base Equilibria - *CC BY-NC-SA 3.0*
 - Chapter 16.1: The Autoionization of Water - *CC BY-NC-SA 3.0*
 - Chapter 16.2: A Qualitative Description of Acid-Base Equilibria - *CC BY-NC-SA 3.0*
 - Chapter 16.3: Molecular Structure and Acid-Base Strength - *CC BY-NC-SA 3.0*
 - Chapter 16.4: Quantitative Aspects of Acid-Base Equilibria - *CC BY-NC-SA 3.0*
 - Chapter 16.5: Acid-Base Titrations - *CC BY-NC-SA 3.0*
 - Chapter 16.6: Buffers - *CC BY-NC-SA 3.0*
 - Chapter 16.7: End of Chapter Material - *CC BY-NC-SA 3.0*
- Chapter 17: Solubility and Complexation Equilibria - *CC BY-NC-SA 3.0*
 - Chapter 17.0: Introduction - *CC BY-NC-SA 3.0*
 - Chapter 17.1: Determining the Solubility of Ionic Compounds - *CC BY-NC-SA 3.0*
 - Chapter 17.2: Factors That Affect Solubility - *CC BY-NC-SA 3.0*
 - Chapter 17.3: The Formation of Complex Ions - *CC BY-NC-SA 3.0*
 - Chapter 17.4: Solubility and pH - *CC BY-NC-SA 3.0*
 - Chapter 17.5: Qualitative Analysis Using Selective Precipitation - *CC BY-NC-SA 3.0*
 - Chapter 17.7: End of Chapter Material - *CC BY-NC-SA 3.0*
- Unit 7: Thermodynamics & Electrochemistry - *CC BY-NC-SA 3.0*
 - Chapter 18: Chemical Thermodynamics - *CC BY-NC-SA 3.0*
 - Chapter 18.1: Thermodynamics and Work - *CC BY-NC-SA 3.0*
 - Chapter 18.2: The First Law of Thermodynamics - *CC BY-NC-SA 3.0*
 - Chapter 18.3: The Second Law of Thermodynamics - *CC BY-NC-SA 3.0*
 - Chapter 18.4: Entropy Changes and the Third Law of Thermodynamics - *CC BY-NC-SA 3.0*
 - Chapter 18.5: Free Energy - *CC BY-NC-SA 3.0*
 - Chapter 18.6: Spontaneity and Equilibrium - *CC BY-NC-SA 3.0*
 - Chapter 18.7: Comparing Thermodynamics and Kinetics - *CC BY-NC-SA 3.0*
 - Chapter 18.8: Thermodynamics and Life - *CC BY-NC-SA 3.0*
 - Chapter 18.9: End of Chapter Material - *CC BY-NC-SA 3.0*
 - Chapter 19: Electrochemistry - *CC BY-NC-SA 3.0*
 - Chapter 19.0: Introduction - *CC BY-NC-SA 3.0*
 - Chapter 19.1: Describing Electrochemical Cells - *CC BY-NC-SA 3.0*
 - Chapter 19.2: Standard Potentials - *CC BY-NC-SA 3.0*
 - Chapter 19.3: Comparing Strengths of Oxidants and Reductants - *CC BY-NC-SA 3.0*
 - Chapter 19.4: Electrochemical Cells and Thermodynamics - *CC BY-NC-SA 3.0*
 - Chapter 19.5: Commercial Galvanic Cells - *CC BY-NC-SA 3.0*
 - Chapter 19.6: Corrosion - *CC BY-NC-SA 3.0*
 - Chapter 19.7: Electrolysis - *CC BY-NC-SA 3.0*
 - Chapter 19.8: End of Chapter Materials - *CC BY-NC-SA 3.0*
- Unit 8: Materials - *CC BY-NC-SA 3.0*
 - Chapter 20: Periodic Trends and the s-Block Elements - *CC BY-NC-SA 3.0*
 - Chapter 20.0: Introduction - *CC BY-NC-SA 3.0*
 - Chapter 20.1: Overview of Periodic Trends - *CC BY-NC-SA 3.0*
 - Chapter 20.2: The Chemistry of Hydrogen - *CC BY-NC-SA 3.0*
 - Chapter 20.3: The Alkali Metals (Group 1) - *CC BY-NC-SA 3.0*
 - Chapter 20.4: The Alkaline Earth Metals (Group 2) - *CC BY-NC-SA 3.0*
 - Chapter 20.5: The s-Block Elements in Biology - *CC BY-NC-SA 3.0*
 - Chapter 20.6: End of Chapter Material - *CC BY-NC-SA 3.0*
 - Chapter 21: The d-Block Elements - *CC BY-NC-SA 3.0*
 - Chapter 21.1: General Trends Among the Transition Metals - *CC BY-NC-SA 3.0*

- Chapter 21.2: A Brief Survey of Transition Metal Chemistry - *CC BY-NC-SA 3.0*
- Chapter 21.3: Metallurgy - *CC BY-NC-SA 3.0*
- Chapter 21.4: Coordination Compounds - *CC BY-NC-SA 3.0*
- Chapter 21.5: Crystal Field Theory - *CC BY-NC-SA 3.0*
- Chapter 21.6: Transition Metals in Biology - *CC BY-NC-SA 3.0*
- Chapter 21.7: End of Chapter Materials - *CC BY-NC-SA 3.0*
- Chapter 22: The p-Block Elements - *CC BY-NC-SA 3.0*
 - Chapter 22.1: The Elements of Group 13 - *CC BY-NC-SA 3.0*
 - Chapter 22.2: The Elements of Group 14 - *CC BY-NC-SA 3.0*
 - Chapter 22.3: The Elements of Group 15 (The Pnictogens) - *CC BY-NC-SA 3.0*
 - Chapter 22.4: The Elements of Group 16 (The Chalcogens) - *CC BY-NC-SA 3.0*
 - Chapter 22.5: The Elements of Group 17 (The Halogens) - *CC BY-NC-SA 3.0*
 - Chapter 22.6: The Elements of Group 18 (The Noble Gases) - *CC BY-NC-SA 3.0*
 - Chapter 22.7: End of Chapter Material - *CC BY-NC-SA 3.0*
- Chapter 23: Organic Compounds - *CC BY-NC-SA 3.0*
 - Chapter 23.1: Functional Groups and Classes of Organic Compounds - *CC BY-NC-SA 3.0*
 - Chapter 23.2: Isomers of Organic Compounds - *CC BY-NC-SA 3.0*
 - Chapter 23.3: Reactivity of Organic Molecules - *CC BY-NC-SA 3.0*
 - Chapter 23.4: Common Classes of Organic Reactions - *CC BY-NC-SA 3.0*
 - Chapter 23.5: Common Classes of Organic Compounds - *CC BY-NC-SA 3.0*
 - Chapter 23.6: The Molecules of Life - *CC BY-NC-SA 3.0*
 - Chapter 23.7: End of Chapter Materials - *CC BY-NC-SA 3.0*
- Chapter 24: Nuclear Chemistry - *CC BY-NC-SA 3.0*
 - Chapter 24.0: Introduction - *CC BY-NC-SA 3.0*
 - Chapter 24.1: The Components of the Nucleus - *CC BY-NC-SA 3.0*
 - Chapter 24.2: Nuclear Reactions - *CC BY-NC-SA 3.0*
 - Chapter 24.3: The Interaction of Nuclear Radiation with Matter - *CC BY-NC-SA 3.0*
 - Chapter 24.4: Thermodynamic Stability of the Atomic Nucleus - *CC BY-NC-SA 3.0*
 - Chapter 24.5: Applied Nuclear Chemistry - *CC BY-NC-SA 3.0*
 - Chapter 24.6: The Origin of the Elements - *CC BY-NC-SA 3.0*
 - Chapter 24.7: End of Chapter Material - *CC BY-NC-SA 3.0*
