Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

To our mentors in nephrology—especially Bill Couser,
Karl M. Koch, and Kailash Jindal

To our colleagues and collaborators, as well as others, whose research
continues to light the way

To our wives and families, who have once again endured the preparation of
this seventh edition with unfailing patience and support

To our patients with renal disease, for whom it is a privilege to care

Jürgen Floege

Richard J. Johnson

CONTENTS

PREFACE

The seventh edition of *Comprehensive Clinical Nephrology* remains the textbook aimed for Fellows preparing for their boards, for practicing nephrologists who want to rapidly review the key aspects for diagnosis and management of their patients, and for a short updated review for both the novice and expert alike on the pathogenesis and treatment of kidney diseases. As always, this remains a single-volume textbook that provides comprehensive coverage of clinical nephrology yet also ensures that inquiring nephrologists can find the key scientific issues and pathophysiology that underlie their clinical work.

The seventh edition boasts updated chapters providing state-of-the-art recommendations for the diagnosis and management of kidney diseases. This includes a new chapter on ultrasound use from a nephrologist's perspective. Other highlights include chapters on geriatric nephrology and palliative nephrology, the mysterious epidemics of CKD that have been identified in various regions of the world, and continued emphasis on ICU nephrology.

By popular demand, we continue to offer readers digital access to the images from the book, and each chapter also includes a larger number of references available online as well as the answers to the multiple-choice questions in each chapter. This is also the fourth edition to feature access to a companion eBooks+ website with fully searchable text, a downloadable image library, and links to PubMed.

Enjoy the new updated book, and feel free to give us suggestions for the next editions!

Richard J. Johnson

CONTRIBUTORS

Sharon Adler, MD
Professor of Medicine
Department of Internal Medicine
David Geffen School of Medicine at UCLA
Los Angeles, California;
Chief
Division of Nephrology and Hypertension
Harbor-UCLA Medical Center
Torrance, California

Anupam Agarwal, MD
Professor and Director
Department of Medicine
University of Alabama at Birmingham
Birmingham, Alabama

Rajiv Agarwal, MD
Professor of Medicine
Indiana University
Indianapolis, Indiana

Venkatesh Aiyagari, MBBS, DM, FAHA
Professor of Neurological Surgery and Neurology
UT Southwestern Medical Center
Dallas, Texas

Valeria Alberton, MD
Department of Pathology
Fernandez Hospital
Buenos Aires, Argentina

Shuchi Anand, MD
Assistant Professor of Medicine
Department of Nephrology
Stanford University Medical Center
Stanford, California

Fatiu Arogundade, MBBS, FMCP, FWACP
Associate Professor and Consultant Nephrologist
Department of Medicine
Pbafemi Awolowo University and Teaching Hospitals Complex
Ile-Ife, Osun State, Nigeria

Vicente Arroyo, MD, PhD
Professor of Medicine
Universitat de Barcelona;
Director
European Foundation for the Study of Chronic liver Failure (EF CLIF)
Barcelona, Spain

Stephen R. Ash, MD, FACP
Director of Dialysis
Department of Nephrology
Indiana University Health Arnett;
Chairman of the Board
Ash Access Technology, Inc.;
CEO
HemoCleanse Technologies, LLC
Lafayette, Indiana

Bourne Auguste, MD
Assistant Professor
Department of Medicine
University of Toronto
Toronto, Ontario, Canada

Matthew A. Bailey, PhD, FRSB
Professor of Renal Physiology
Centre for Cardiovascular Science
University of Edinburgh
Edinburgh, United Kingdom

George L. Bakris, MD, MA
Professor and Director, AHA Comprehensive Hypertension Center
Department of Medicine
University of Chicago
Chicago, Illinois

Anip Bansal, MD
Assistant Professor
Division of Renal Diseases and Hypertension
University of Colorado Anschutz Medical Campus
Aurora, Colorado

Joanne M. Bargman, MD, FRCPC
Department of Medicine
University Health Network
Toronto, Ontario, Canada

Adam D. Barlow, MBChB, MD, FRCS
Consultant Surgeon
Hepatobiliary and Transplant Surgery
Leeds Teaching Hospitals
Leeds, United Kingdom

Jonathan Barratt, PhD, FRCP
Professor
Department of Cardiovascular Sciences
University of Leicester;
Honorary Consultant Nephrologist
John Walls Renal Unit
Leicester General Hospital
Leicester, United Kingdom

Rashad S. Barsoum, MD, FRCP, FRCPE
Professor
Department of Internal Medicine
Kasr-El-Aini Medical School;
Chairman
The Cairo Kidney Center
Cairo, Egypt

William Beaubien-Souligny, MD, PhD
Assistant Professor
Department of Medicine
Centre Hospitalier de l'Université de Montréal
Montréal, Quebec, Canada

Laurence H. Beck Jr, MD, PhD
Associate Professor
Department of Medicine
Boston Medical Center
Associate Professor of Medicine
Boston University School of Medicine
Boston, Massachusetts

Aminu K. Bello, MD, PhD
Associate Professor/Nephrologist
Department of Medicine
University of Alberta
Edmonton, Alberta, Canada

Ariela Benigni, PhD
Department of Molecular Medicine
Istituto di Ricerche Farmacologiche Mario Negri IRCCS
Bergamo, Italy

Tomas Berl, MD
Professor of Medicine
Division of Renal Diseases and Hypertension
University of Colorado
Denver, Colorado

Gemma Bircher, PgDip, MSc, RD
Dietetic Manager
Department of Nutrition and Dietetics
University Hospitals of Leicester
Leicester, United Kingdom

Detlef Bockenhauer, MD, PhD
Professor
Division of Medicine
University College London;
Professor
Great Ormond Street Hospital for Children
London, United Kingdom

Peter Boor, MD, PhD
Pathologist and Group Leader
Institute of Pathology and Department of Nephrology
University Clinic of RWTH Aachen University
Aachen, Germany

Josée Bouchard, MD, FRCPC
Associate Professor
Department of Medicine
Université de Montréal
Montréal, Quebec, Canada

Kate Bramham, MA, MBBS, PhD
Clinical Senior Lecturer
Women and Children's Health
King's College London;
Honorary Consultant Nephrologist
King's Kidney Care
King's College Hospital NHS Foundation Trust
London, United Kingdom

Frank Bridoux, MD, PhD
Professor of Nephrology, Dialysis, Renal Transplantation
CHU Poitiers
Poitiers, France

Edwina Brown, DM(Oxon), FRCP
Professor
Imperial College Renal and Transplant Centre
Hammersmith Hospital
London, United Kingdom

Mark Brown, MBBS, FRACP, MD
Professor
Department of Renal Medicine
St. George Hospital & University of New South Wales
Sydney, NSW, Australia

Emmanuel A. Burdmann, MD, PhD
Associate Professor
Division of Nephrology
University of Sao Paulo Medical School
Sao Paulo, Brazil

David A. Bushinsky, MD
Professor of Medicine and of Pharmacology and Physiology
University of Rochester School of Medicine
Rochester, New York

Renal Anatomy

Wilhelm Kriz, Marlies Elger

The complex structure of the mammalian kidney is best understood in the unipapillary form that is common to all small mammalian species. Fig. 1.1 is a schematic coronal section through a unipapillary kidney, with a cortex enclosing a pyramid-shaped medulla, the tip (papilla) of which protrudes into the renal pelvis. The medulla is divided into an outer and an inner medulla; the outer medulla is further subdivided into an outer and an inner stripe.

STRUCTURE OF THE KIDNEY

The specific components of the kidney are the nephrons, the collecting ducts, and a unique microvasculature.[1] The multipapillary kidney of humans contains about 1 million nephrons, although this number varies considerably. The number of nephrons is established during prenatal development; after birth, new nephrons cannot be developed, and lost nephrons cannot be replaced.

Nephrons

A nephron consists of a renal corpuscle *(glomerulus)* connected to a complicated and twisted tubule that finally drains into a collecting duct (Fig. 1.2 and Table 1.1). Three types of nephrons can be distinguished by the location of renal corpuscles within the cortex: superficial, midcortical, and juxtamedullary nephrons. The tubular part of the nephron consists of a proximal tubule and a distal tubule connected by a loop of Henle (for details see later, as well as Kriz and Bankir[2]). Superficial and midcortical nephrons have short loops that turn back in the outer medulla or even in the cortex. Juxtamedullary nephrons have long loops that turn back at successive levels of the inner medulla.

Collecting Ducts

A collecting duct is formed in the renal cortex when several nephrons join. A connecting tubule is interposed between a nephron and a cortical collecting duct. Cortical collecting ducts descend within the medullary rays of the cortex. They then traverse the outer medulla as unbranched tubes. On entering the inner medulla, they fuse successively and open finally as papillary ducts into the renal pelvis (see Fig. 1.2 and Table 1.1).

Microvasculature

The microvascular pattern of the kidney is similarly organized in mammalian species[1,3] (Fig. 1.3; see also Fig. 1.1). The renal artery, after entering the renal sinus, finally divides into the interlobar arteries, which extend toward the cortex in the space between the wall of the pelvis (or calyx) and the adjacent cortical tissue. At the junction between cortex and medulla, the interlobar arteries divide and pass over into the arcuate arteries, which also branch. The arcuate arteries give rise to the cortical radial arteries (interlobular arteries), which ascend radially through the cortex. No arteries penetrate the medulla.

Afferent arterioles supply the glomerular tufts and generally arise from cortical radial arteries. *Aglomerular* tributaries to the capillary plexus are rarely found. As a result, the blood supply of the peritubular capillaries of the cortex and the medulla is exclusively *postglomerular*.

Glomeruli are drained by efferent arterioles. Two basic types of efferent arterioles can be distinguished: *cortical* efferent arterioles, which derive from superficial and midcortical glomeruli, supply the capillary plexus of the cortex. Efferent arterioles of *juxtamedullary* glomeruli supply the renal medulla. Within the outer stripe of the medulla, these vessels divide into the *descending* vasa recta and then penetrate the inner stripe in cone-shaped vascular bundles. At intervals, individual vessels leave the bundles to supply the capillary plexus at the adjacent medullary level. A fraction of the descending vasa recta enters the inner medulla; few of them reach the papillary region.

Ascending vasa recta drain the renal medulla. In the inner medulla, the vasa recta arise at every level, ascending as unbranched vessels, and traverse the inner stripe within the vascular bundles. The ascending vasa recta that drain the inner stripe may join the vascular bundles; the majority ascends directly to the outer stripe between the bundles. All the ascending vasa recta traverse the outer stripe as individual wavy vessels with wide lumens interspersed among the tubules. Because true capillaries derived from direct branches of efferent arterioles are relatively scarce, the ascending vasa recta form the capillary plexus of the outer stripe. The ascending vasa recta empty into arcuate veins.

The vascular bundles represent a countercurrent exchanger between the blood entering and leaving the medulla. The organization of the vascular bundles also separates the blood flow to the inner stripe from the blood flow to the inner medulla. Descending vasa recta supplying the inner medulla traverse the inner stripe within the vascular bundles. Therefore blood flowing to the inner medulla has not been exposed previously to tubules of the inner or outer stripe. All ascending vasa recta originating from the inner medulla traverse the inner stripe within the vascular bundles. Thus blood that has perfused tubules of the inner medulla does not subsequently perfuse tubules of the inner stripe. However, the blood returning from either the inner medulla or the inner stripe afterward does perfuse the tubules of the outer stripe. This arrangement in the outer stripe may function as the ultimate trap to prevent solute loss from the medulla.

TABLE 1.1 Subdivisions of the Nephron and Collecting Duct System

Section	Subsections
Nephron	
Renal corpuscle	*Glomerulus:* term used most frequently to refer to entire renal corpuscle Bowman's capsule
Proximal tubule	Convoluted part Straight part (pars recta) or thick descending limb of Henle loop
Intermediate tubule	Descending part or thin descending limb of Henle loop Ascending part or thin ascending limb of Henle loop
Distal tubule	Straight part or thick ascending limb of Henle loop: subdivided into medullary and cortical parts; the cortical part contains the macula densa in its terminal portion Convoluted part
Collecting Duct System	
Connecting tubule	Includes the arcades in most species
Collecting duct	Cortical collecting duct Outer medullary collecting duct: subdivided into an outer stripe and an inner stripe portion Inner medullary collecting duct: subdivided into basal, middle, and papillary portions

Central to the renal drainage of the kidney are the arcuate veins, which, in contrast to arcuate arteries, do form real anastomosing arches at the corticomedullary border. The arcuate veins accept the veins from the cortex and the renal medulla. The arcuate veins join to form interlobar veins, which run alongside the corresponding arteries.

The intrarenal arteries and the afferent and efferent glomerular arterioles are accompanied by sympathetic nerve fibers and terminal axons representing the efferent nerves of the kidney.[1] Tubules have direct contact to terminal axons only when the tubules are located around the arteries or the arterioles. Tubular innervation consists of occasional fibers adjacent to perivascular tubules.[4] The density of nerve contacts to convoluted proximal tubules is low; contacts to straight proximal tubules, thick ascending limbs of Henle loops, and collecting ducts (located in medullary rays and outer medulla) have never been encountered. The vast majority of tubular portions have no direct relationships to nerve terminals. Afferent nerves of the kidney are sparse.[5]

Glomerulus (Kidney Corpuscle)

The glomerulus includes a tuft of specialized capillaries attached to the mesangium, both of which are enclosed in a pouch-like extension of the tubule, which represents Bowman's capsule (Figs. 1.4 and 1.5). The capillaries, together with the mesangium, are covered by epithelial cells (podocytes), forming the visceral epithelium of Bowman's capsule. At the vascular pole, this is reflected to become the parietal epithelium of Bowman's capsule. At the interface between the glomerular capillaries and the mesangium on one side and the podocyte layer on the other side, the glomerular basement membrane (GBM) is developed. The space between both layers of Bowman's capsule represents the urinary space, which, at the urinary pole, continues as the tubule lumen.

On entering the tuft, the afferent arteriole immediately divides into several primary capillary branches, each of which gives rise to an anastomosing capillary network representing a glomerular lobule. In contrast, the efferent arteriole is already established inside the tuft by

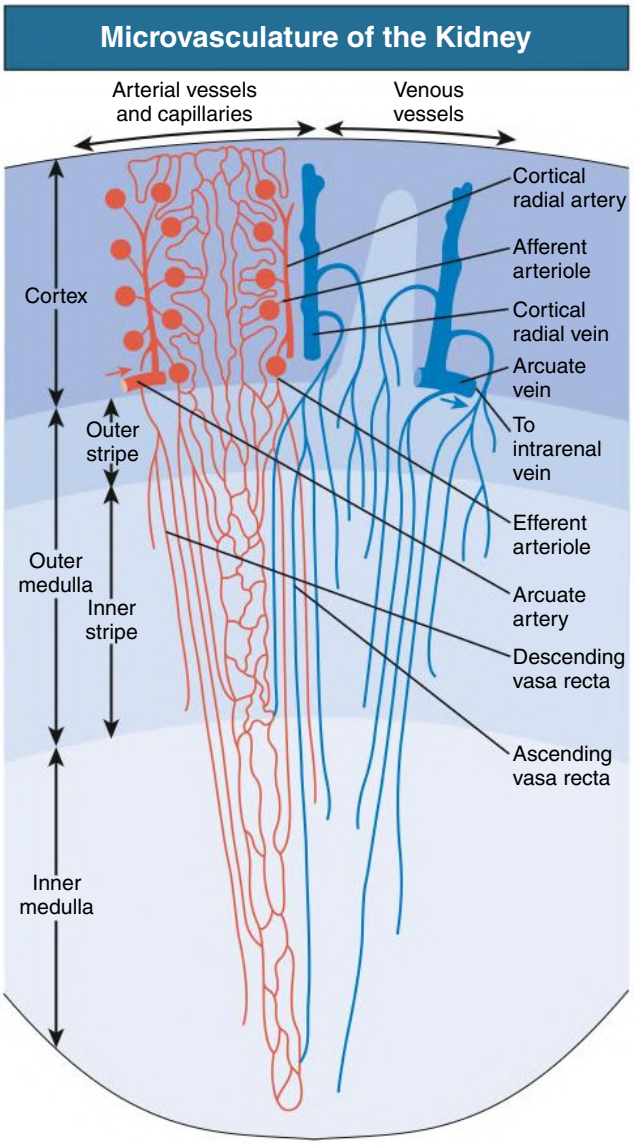

Fig. 1.3 Microvasculature of the Kidney. Afferent arterioles supply the glomeruli and efferent arterioles leave the glomeruli and divide into the descending vasa recta, which, together with the ascending vasa recta, form the vascular bundles of the renal medulla. The vasa recta ascending from the inner medulla all traverse the inner stripe within the vascular bundles, whereas most of the vasa recta from the inner stripe of the outer medulla ascend outside the bundles. Both types traverse the outer stripe as wide, tortuous channels.

confluence of capillaries from each lobule.[6] Thus the efferent arteriole has a significant intraglomerular segment located within the glomerular stalk.

Glomerular capillaries are a unique type of blood vessel made up of nothing but an endothelial tube (Figs. 1.6 and 1.7). A small stripe of the outer aspect of this tube directly abuts the mesangium; the major part bulges toward the urinary space and is covered by the GBM and the podocyte layer. This peripheral portion of the capillary wall represents the filtration area. The glomerular mesangium establishes the axis of a glomerular lobule to which the GBM, together with the glomerular capillaries, are attached.

Glomerular Basement Membrane

The GBM serves as the skeleton of the glomerular tuft. This membrane is a complexly folded sack with an opening at the glomerular hilum

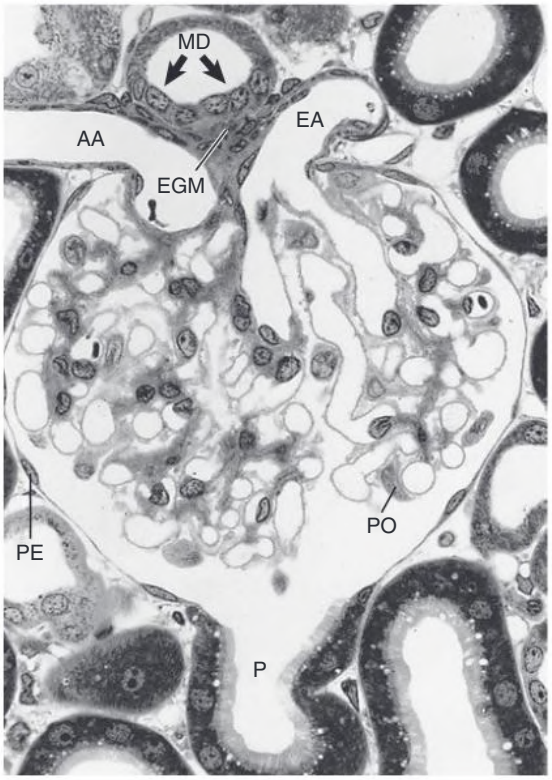

Fig. 1.4 Longitudinal Section Through a Glomerulus (Rat). At the vascular pole, the afferent arteriole *(AA),* the efferent arteriole *(EA),* the extraglomerular mesangium *(EGM),* and the macula densa *(MD)* are seen. At the urinary pole, the parietal epithelium *(PE)* transforms into the proximal tubule *(P). PO,* podocyte. (Light microscopy; magnification ×390.)

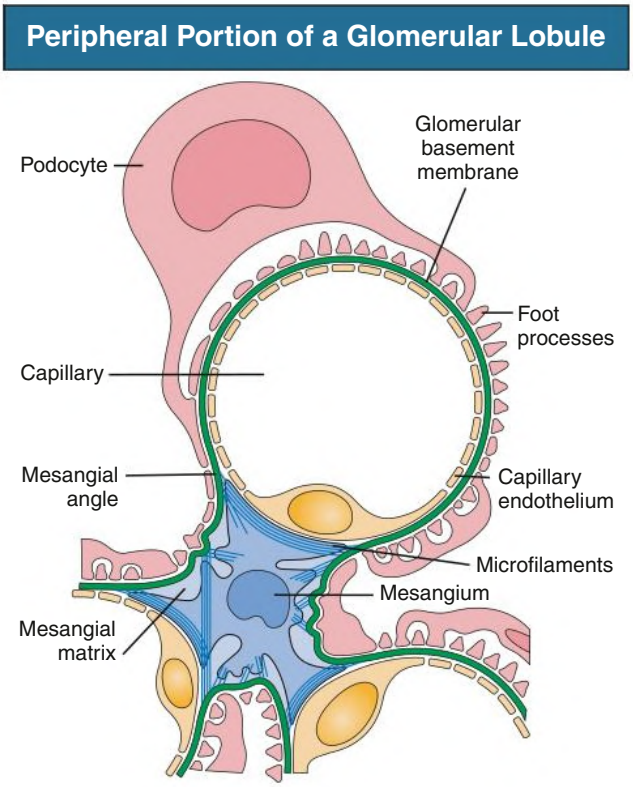

Fig. 1.5 Peripheral Portion of a Glomerular Lobule. This part shows a capillary, the axial position of the mesangium, and the visceral epithelium (podocytes). At the capillary-mesangial interface, the capillary endothelium directly abuts the mesangium.

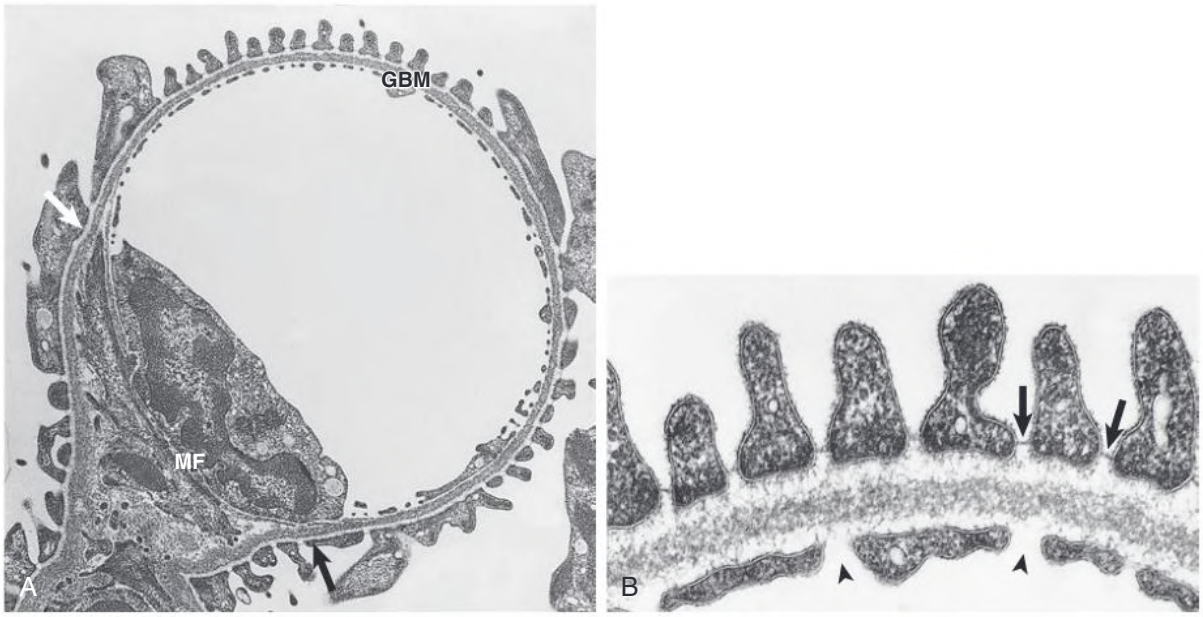

Fig. 1.6 Glomerular Capillary. (A) The layer of interdigitating podocyte processes and the glomerular basement membrane *(GBM)* do not completely encircle the capillary. At the mesangial angles *(arrows),* both deviate from a pericapillary course and cover the mesangium. Mesangial cell processes containing dense bundles of microfilaments *(MF)* interconnect the GBM and bridge the distance between the two mesangial angles. (B) Filtration barrier. The peripheral part of the glomerular capillary wall includes the endothelium with open pores *(arrowheads),* the GBM, and the interdigitating foot processes. The GBM shows a lamina densa bounded by the lamina rara interna and externa. The foot processes are separated by filtration slits bridged by thin diaphragms *(arrows).* (TEM; A, ×8770; B, ×50,440.)

(Fig. 1.8). The outer aspect of this GBM sack is completely covered with podocytes. The interior of the sack is filled with the capillaries and the mesangium. As a result, on its inner aspect, the GBM is in contact with either capillaries or the mesangium. At any transition between these two locations, the GBM changes from a convex pericapillary to a concave perimesangial course; the turning points are called *mesangial angles.* In electron micrographs, the GBM appears as a trilaminar structure, with a lamina densa bounded by two less dense layers, the lamina rara interna and lamina rara externa (see Fig. 1.6). Studies with freeze techniques reveal only one thick, dense layer directly attached to the bases of the epithelium and endothelium.[7]

The major components of the GBM include type IV collagen, laminin, and heparan sulfate proteoglycans similar to other basement membranes. Types V and VI collagen and nidogen (entactin) have also been demonstrated. Unique features of the GBM encompass a distinct spectrum of type IV collagen and laminin isoforms. The mature GBM consists of type IV collagen (with the major part made of α3, α4, and α5 chains, produced by podocytes, and the minor part made of α1, and α2 chains, produced by endothelial cells) and laminin 11, made of α5, β2, and γ1 chains.[8] Type IV collagen is the antigenic target in Goodpasture disease (see Chapter 25), and mutations in the genes of the α3, α4, and α5 chains of type IV collagen are responsible for Alport syndrome (see Chapter 48).

Current models depict the basic structure of the GBM as a three-dimensional network of type IV collagen.[7] The type IV collagen monomer consists of a triple helix that is 400 nm in length, with a large, noncollagenous globular domain at its C-terminal end called NC1. At the N terminus, the helix possesses a triple helical rod 60 nm long: the 7S domain. Interactions between the 7S domains of two triple helices or the NC1 domains of four triple helices allow type IV collagen monomers to form dimers and tetramers. In addition, triple helical strands interconnect by lateral associations through binding of NC1 domains to sites along the collagenous region. This network is complemented by an interconnected network of laminin 11, resulting in a flexible, nonfibrillar polygonal assembly that provides mechanical strength and elasticity to the basement membrane and serves as a scaffold for alignment of other matrix components.[9,10]

The electronegative charge of the GBM mainly results from the presence of polyanionic proteoglycans. The major proteoglycans of the GBM are heparan sulfate proteoglycans, including perlecan and agrin. Proteoglycan molecules aggregate to form a meshwork that is kept well hydrated by water molecules trapped in the interstices of the matrix.

Mesangium

Three major glomerular cell types are all in close contact with the GBM: mesangial cells (MCs), endothelial cells, and podocytes. The mesangial/endothelial/podocyte cell ratio is 2:3:1 in the rat. The mesangial cells and mesangial matrix establish the glomerular mesangium.

Mesangial cells. MCs are irregular in shape, with many processes extending from the cell body toward the GBM (see Figs. 1.5 and 1.6). In these processes, dense assemblies of microfilaments are found, containing α-smooth muscle actin, myosin, and α-actinin.[11] The processes are attached to the GBM directly or through the interposition of microfibrils. The GBM represents the effector structure of mesangial contractility. MC-GBM connections are found throughout the mesangium-GBM interface, but they are especially prominent at the turning points of the GBM infoldings (mesangial angles). A new adhesion complex has been uncovered at these sites,[12] consisting of nephronectin deposited by podocytes into the GBM and α8 β1-integrins enriched in the tips of MC processes inserting to the GBM.

The folding pattern of the GBM is permanently challenged by the expansile forces of the high intraglomerular perfusion pressure. Centripetal MC contraction balances the expansile forces. Thus the

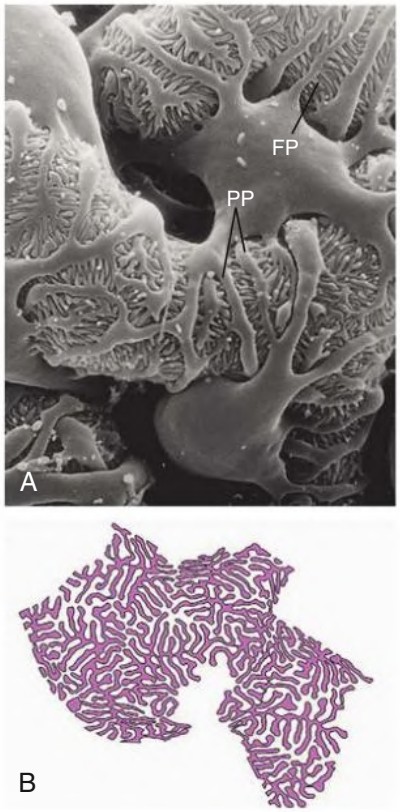

Fig. 1.7 Branching Pattern of Podocyte Foot Processes (Rat). (A) Scanning electron micrograph (SEM) showing the urinary side of the podocyte cover of a glomerular capillary consisting of cell bodies, large primary processes *(PP),* and interdigitating foot processes *(FP)* separated by the filtration slits. (B) Drawing of the basal aspect of the FP-branching pattern as seen by block-face SEM. A fully homogenous branching pattern of foot processes attaches to the glomerular basement membrane (GBM), which may be compared with a pattern of interdigitating filopodia connected by adherens junctions. The high degree of branching (not seen from the luminal aspect) provides a high degree of adaptability to area changes of the underlying GBM. (From Ichimura K, Kakuta S, Kawasaki Y, et al. Morphological process of podocyte development revealed by block-face scanning electron microscopy. *J Cell Sci.* 2017;130:132–142.)

Fig. 1.8 Renal Corpuscle and Juxtaglomerular Apparatus. (Modified from Kriz W, Kaissling B. Structural organization of the mammalian kidney. In Seldin DW, Giebisch G, eds. *The Kidney,* 3rd ed. Lippincott Williams & Wilkins: 2000;587–654.)

folding pattern of the GBM, including the complex convolutions of glomerular capillaries, are maintained by mesangial cells.

MCs possess a great variety of receptors, including those for angiotensin II (Ang II), vasopressin, atrial natriuretic factor, prostaglandins, and other growth factors (tumor growth factor [TGF]-β, platelet-derived growth factor [PDGF], epidermal growth factor [EGF], and connective tissue growth factor [CTGF]).[13]

Mesangial matrix. The mesangial matrix fills the highly irregular spaces between the mesangial cells and the perimesangial GBM, anchoring the mesangial cells to the GBM.[6] Many common extracellular matrix proteins have been demonstrated within the mesangial matrix, including collagen types IV, V, and VI and microfibrillar protein components, such as fibrillin and microfibril-associated glycoprotein. The matrix also contains several glycoproteins, most abundantly fibronectin, and several types of proteoglycans.

Endothelium

Glomerular endothelial cells consist of cell bodies and peripherally located, attenuated, and highly porous cytoplasmic sheets (see Figs. 1.5 and 1.6). Glomerular endothelial pores lack diaphragms, which are encountered only in the endothelium of the final tributaries to the efferent arteriole.[6] The round to oval pores have a diameter of 50 to 100 nm. A layer of membrane-bound and loosely attached molecules (called the glycocalyx) covers the entire luminal surface including, as sieve plugs, the endothelial pores.[14] Because of a great variety of polyanionic glycoproteins (including podocalyxin), the endothelium has a strong negative charge, establishing an exit barrier for negatively charged macromolecules like albumin. Endothelial cells actively participate in processes controlling coagulation and inflammation and have receptors for vascular endothelial growth factor (VEGF), angiopoietins, and TGF-β1. They synthesize and release PDGF-B, endothelin-1, and nitric oxide, among others.[15]

Visceral Epithelium (Podocytes)

The visceral epithelium of Bowman's capsule includes highly differentiated cells called the podocytes (see Fig. 1.7; see also Fig. 1.5). In the developing glomerulus, podocytes have a simple polygonal shape. In humans, podocytes complete mitosis during prenatal life. Differentiated podocytes are unable to replicate; consequently, lost podocytes cannot be replaced in the adult. All efforts of the last decade to find progenitor cells that might migrate into the tuft and replace lost podocytes have failed.

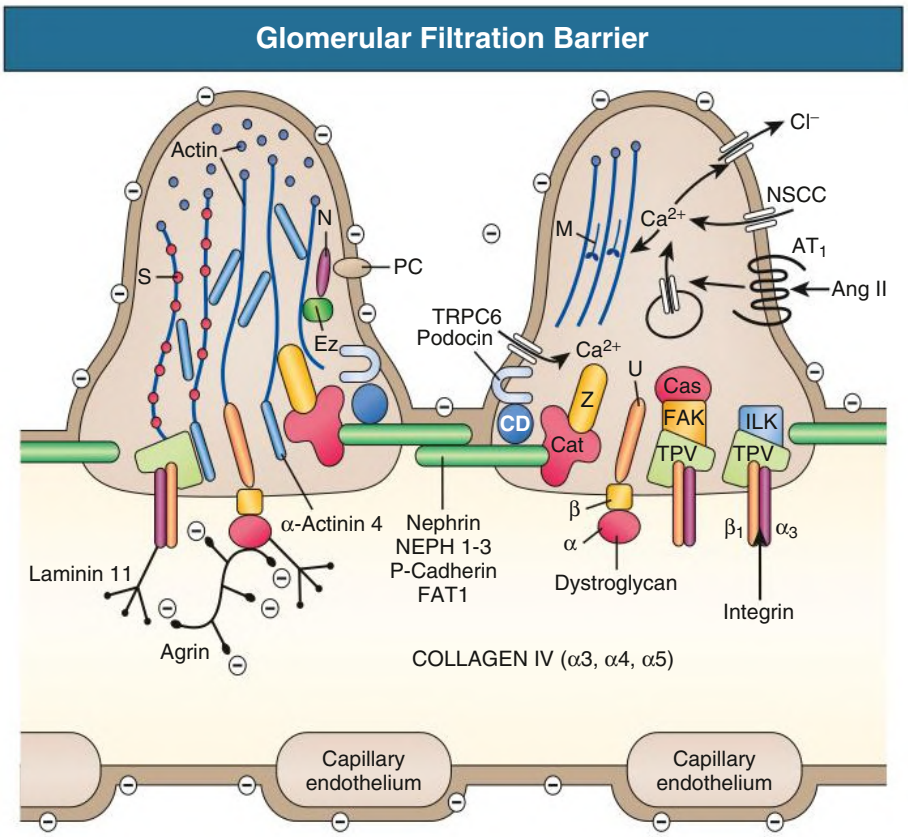

Fig. 1.9 Glomerular Filtration Barrier. Two podocyte foot processes bridged by the slit membrane, the glomerular basement membrane (GBM), and the porous capillary endothelium are shown. The surfaces of podocytes and of the endothelium are covered by a negatively charged glycocalyx containing the sialoprotein podocalyxin (PC). The GBM is mainly composed of type IV collagen (α3, α4, and α5), laminin 11 (α5, β2, and γ1 chains), and the heparan sulfate proteoglycan agrin. The slit membrane represents a porous proteinaceous membrane composed of (as far as is known) nephrin, NEPH 1-3, P-cadherin, and FAT1. The actin-based cytoskeleton of the foot processes connects to both the GBM and the slit membrane. Regarding the connections to the GBM, β1α3 integrin dimers specifically interconnect the TPV complex (talin, paxillin, vinculin) to laminin 11; the β- and α-dystroglycans interconnect utrophin to agrin. The slit membrane proteins are joined to the cytoskeleton by various adapter proteins, including podocin, zonula occludens protein 1 (ZO-1; Z), CD2-associated protein (CD), and catenins (Cat). Among the nonselective cation channels (NSCC), TRPC6 associates with podocin (and nephrin, not shown) at the slit membrane. Only the angiotensin II (Ang II) type 1 receptor (AT_1) is shown as an example of the many surface receptors. *Cas,* p130Cas; *Ez,* ezrin; *FAK,* focal adhesion kinase; *ILK,* integrin-linked kinase; *M,* myosin; *N,* Na^+-H^+ exchanger regulatory factor (NHERF2); *S,* synaptopodin. (Modified from Endlich KH, Kriz W, Witzgall R. Update in podocyte biology. *Curr Opin Nephrol Hypertens.* 2001;10:331–340.)

Podocytes have a voluminous cell body that floats within the urinary space, separated from the GBM by a subpodocyte space.[16] The cell bodies give rise to primary processes that fall apart into foot processes (FPs) that fix the cells to the capillaries (i.e., to the GBM). Sporadic FPs may also arise directly from the cell body. The FPs of neighboring podocytes regularly interdigitate with each other, leaving meandering slits (filtration slits) between them that are bridged by a complex extracellular structure known as the *slit diaphragm* (SD) that may be seen as a modified adherens junction (Fig. 1.9; see also Figs. 1.6 and 1.7). Traditional scanning electron micrograph (SEM) pictures (see Fig. 1.7A) do not convey the correct pattern of how FPs interdigitate and adhere to the GBM. As seen by block-face SEM (see Fig. 1.7B), individual FP may terminate with a final branching, and primary processes fall off into basal ridges that actually are also FPS.[17] Thus the interdigitating FP pattern as it adheres to the GBM is completely homogenous, forming a uniform cover of interdigitating filopodia. This is of utmost importance to understand the adaptive mobility of this cover (see later).

The cell body contains a prominent endoplasmic reticulum and Golgi system and a well-developed endocytotic and autophagic machinery. A complex cytoskeleton accounts for the shape of the cells. In the cell body and the primary processes, microtubules and intermediate filaments (vimentin, desmin) dominate. Within the FPs, microfilaments (β-actin) form prominent U-shaped bundles arranged in the longitudinal axis of two successive FPs in an overlapping pattern. Above, the bends of these bundles are linked to the microtubules of the primary processes; peripherally, these bundles terminate in the dense cytoplasm associated with the sole plates, being part of the anchoring system of the FPs to the GBM (see later). In addition, the cell body and the FPs have a well-developed subplasmalemmal actin network that has intimate contact to the anchor line of the SD and diffusely to the actin bundles of FPs. Multiple actin-associated proteins, including α-actinin-4 and synaptopodin, establish the specific cytoskeleton in podocytes.[18] FPs do not contain myosin II[19]; thus the actin fibers in FPs are not part of a contractile system. Instead, the complex cytoskeleton

of FPs supports the attachment of FPs to the GBM and the maintenance of their interdigitating pattern.[20]

The luminal membrane contains a great variety of receptors (see later) and, together with the luminal surface of the SD, it is covered by a thick surface coat that is rich in sialoglycoproteins, including podocalyxin and podoendin, accounting for the high negative surface charge of the podocytes.

The abluminal cell membrane consists of a narrow band of lateral cell membrane extending from the SD to the GBM and, most importantly, the soles of the FPs abutting to the GBM. A complex anchoring system connects the cytoskeleton of the FPs to the GBM. Two systems are known: (1) α3β1 integrin dimers interconnect the cytoplasmic focal adhesion proteins vinculin, paxillin, and talin with the α3, α4, and α5 chains of type IV collagen and laminin 521; and (2) β-α-dystroglycans interconnect the cytoplasmic adapter protein utrophin with agrin and laminin α5 chains in the GBM.[9]

The junctional connection of podocyte FPs by the SD bridging the filtration slits is complex and unique. Filtration slits have a constant width of about 30 to 40 nm: thus SD has to connect the FPs over a considerable distance. By transmission electron microscopy (TEM), the SD shows up as a single dark line in cross sections and in an en-face view as a homogenous network of fibrillar structures interconnecting both membranes. Combined tannic acid and glutaraldehyde fixed tissue reveals, in en-face view, a zipper-like structure with a row of pores approximately 14 × 2 nm on either side of a central bar. The transmembrane proteins that establish the slit membrane and its connection to the actin cytoskeleton of the FPs include nephrin, P-cadherin, FAT1, NEPH 1-3, podocin, and CD2AP[21] (see Fig. 1.9).

Podocytes contain many surface receptors and ion channels (see Fig. 1.9).[21] Among the transient receptor potential (TRP) cation channels, TRPC5 and TRPC6 have received much attention.[22–24] The major target of this signaling orchestra is the cytoskeleton (see later). Other receptors, such as for TGF-β, FGF-2, and other cytokines/chemokines, are involved in synthesis functions (GBM components) or in the development of podocyte diseases.[21] Megalin is a multiligand endocytotic receptor and the major antigen of Heymann nephritis in the rat[25] but is not present in humans.[13] However, human podocytes express phospholipase A-2 receptor, which is the autoantigen targeted in the majority of patients with idiopathic membranous nephropathy.

Podocytes, by paracrine and autocrine signaling, regulate the interplay with endothelial cells and MCs; during development, they have the exclusive commandership in building a glomerulus. VEGF, angiopoietins, and PDGF, among others, are of crucial importance for the homeostatic maintenance of the tuft.[26]

Function and Maintenance of the Filtration Barrier

Filtration pressure and expansion. Traditionally, the high transmural hydrostatic pressure gradients necessary for filtration have been considered as the main challenge to the filtration barrier. Podocyte FPs were considered as pericyte processes that counteracted variations and derailments in perfusion pressures. This view has been challenged because of the discovery that podocytes are chiefly lost by detachment from the GBM as viable cells. It seems self-contradictory that FPs, which need their cytoskeleton to continually adapt their pattern of attachment to the GBM (see later), would simultaneously function as contractile pericyte-like processes, counteracting the expansion of the GBM by increasing their tone. This agrees with the finding that FPs do not contain any myosin.[19] Consequently, the principal burden for counteracting transmural pressure gradients (i.e., for developing wall tension) falls instead on the GBM.[27]

As previously described, the GBM is an elastic membrane that expands or shrinks in surface area with increasing or decreasing transmural hydrostatic pressure, respectively. Its expansion decreases with increasing pressure and is limited. Thus podocytes situated downstream of the GBM are protected against sudden pressure rises. A situation in which the pressure is high enough to disrupt the GBM has never been reported.

Expansion of the GBM affords the immediate coordinated increase in the cover by interdigitated FPs, thus the FPs and the SD have to increase correspondingly (and vice versa when pressure decreases). The ability to make such acute adaptions has previously been shown in the isolated perfused kidney. It is suggested that the changes in FP length occur by actin polymerization/depolymerization; the mechanism underlying changes in SD length is unknown.[20,27]

Filtrate flow and shear stress. The flow of the filtrate through the filtration barrier represents by far the highest extravascular fluid flow in the body. It consists of the outflow from glomerular capillaries, through the GBM, and into Bowman's space. This latter step creates a problem: in contrast to the exit of filtrate from capillaries, where flow presses the endothelium against the basement membrane, its entry into Bowman's space tends to separate the podocytes from the GBM. This danger explains the high density of integrin-connections of FPs to the GBM.

The shear stress depends on the flow rate and the geometry of the channel; the narrower the channel or the higher the flow velocity, the higher the shear stress. In rats, the filtrate flow amounts to 30 nL/min, creating a shear stress to the FPs within the filtration slit as high as 8 Pa.[28] Much lower values of shear stress to the podocyte cell bodies (0.5 Pas when they come to lie within the urinary orifice) lead to the detachment of podocytes from the GBM and loss with the urine flow as viable cells; this has repeatedly been shown by light microscopy (LM) and TEM in experimental disease models with podocyte loss.[20] Moreover, a high sensitivity of podocytes to shear stress has been shown in cell culture studies.

This led to a new view of the relevance of the slit membrane (in addition to its barrier function; see later). Shear stress tends to lead to deformations of the lateral walls of FPs, thus widening the slit. The interconnection of both opposite FPs by the SD at the narrowest site of the slit is ideally positioned to counteract these destabilizing forces. The SD uses the shear stress against one side of the slit to balance the shear stress against the opposite site. This means that during filtrate flow the SD is permanently under tension, which counteracts the shear stress to both sides of the slit.[20] This hypothesis is supported by the observation that the loss of the SD connection between adjacent FPs represents the earliest failure that starts the detachment of a podocyte (see Pathology).

Barrier function. Filtrate flow through the barrier occurs along an extracellular route, including the endothelial pores, GBM, and slit diaphragm (see Figs. 1.6 and 1.9). All these components are quite permeable for water, resulting in a high permeability for water, small solutes, and ions. On the other hand, the barrier is fairly tight for macromolecules and selective for size, shape, and charge.[21] The charge selectivity of the barrier results from the dense accumulation of negatively charged molecules on the surface coat (glycocalyx) of endothelial cells. Because most plasma proteins, including albumin, are negatively charged, their entrance into the barrier is slowed but not eliminated. Albumin that penetrates the barrier is filtered and reabsorbed in the proximal tubule.

The size/shape selectivity seems to be established by the SD.[14] Uncharged macromolecules up to an effective radius of 1.8 nm pass freely through the filter. Larger components are increasingly restricted and are totally excluded at effective radii of greater than 4 nm. The fate of components that are captured inside the SD is unknown; transcytosis through podocytes has been suggested.[29] Plasma albumin has

an effective radius of 3.6 nm; without the repulsion from the negative charge, plasma albumin would pass through the filter in considerable amounts.

Moeller[30] has proposed an electrophoretic mechanism for the repulsion and exclusion of plasma proteins from the glomerular filter based on the flow of the filtrate through the charged filter, creating a streaming potential.[31] This electrical field is negatively charged on the urinary side of the glomerular filter compared with the capillary side by approximately −0.05 mV/10 mm Hg filtration pressure. Thus albumin molecules (and most plasma proteins, because virtually all are negatively charged) that approach the filter will be exposed to an electrophoretic force driving them back toward the capillary lumen. The charm of this hypothesis consists of its independence from any structural impediment to filtration. The barrier actually consists of a filtration-dependent potential difference; without sufficient convective flow of filtrate, the barrier will become permeable.[31]

Pathology. The hypothesis that the mechanical interconnection of the FPs by the SD is critical for maintenance of an intact barrier and is vulnerable to the physical challenges of filtration is supported by the pathologic changes. The loss of the SD connection between adjacent FPs initiates the detachment of podocytes[20] and the loss of local control of filtrate flow.

Unchanneled filtrate flow through such leaks will exert unbalanced shear stress on the FPs starting local detachment of FPs. Repair of such leaks is difficult in the face of ongoing filtrate flow, accounting for the observation that the damage tends to progress.

Taken together, the layer of interdigitating FPs interconnected by the SD regulates the entry of the filtrate flow into Bowman's space by channeling the flow through the filtration slits. The geometry of the slits is maintained against the shear forces to both opposite FPs through the interconnection of opposing FPS by the SD. Loss of the junctional connection is detrimental because it opens leaks for uncontrolled filtrate flow with the tendency to increase the leaks.[32] This situation also accounts for the fact that podocytes cannot undergo cytokinesis and, when lost, cannot be replaced by progenitors immigrating from outside.

Parietal Epithelium

The parietal epithelium of Bowman's capsule consists of squamous epithelial cells resting on a basement membrane (see Figs. 1.4 and 1.8). The flat cells are filled with bundles of actin filaments running in all directions. In contrast to the GBM, the parietal basement membrane has several proteoglycan-dense layers that, in addition to type IV, contain type XIV collagen. The predominant proteoglycan of the parietal basement membrane is a chondroitin sulfate proteoglycan.[33] A niche of epithelial stem cells may reside within the parietal epithelium at the transition to the proximal tubule and/or to the visceral epithelium,[34,35] but unequivocal evidence is lacking.

Renal Tubule

The renal tubule consists of distinct segments: a proximal tubule (convoluted and straight portions), an intermediate tubule, a distal tubule (straight and convoluted portion), a connecting tubule (CNT), and the collecting duct (see Figs. 1.1 and 1.2; Table 1.1).[1,2,33] Henle's loop includes the straight part of the proximal tubule (representing the thick descending limb), the thin descending and the thin ascending limbs (both thin limbs together represent the intermediate tubule), and the thick ascending limb (representing the straight portion of the distal tubule), which includes the macula densa. The CNT connects the nephron to the collecting duct system.

Tubular epithelium consists of a single layer of cells anchored to a basement membrane. The cells have multiple transport functions

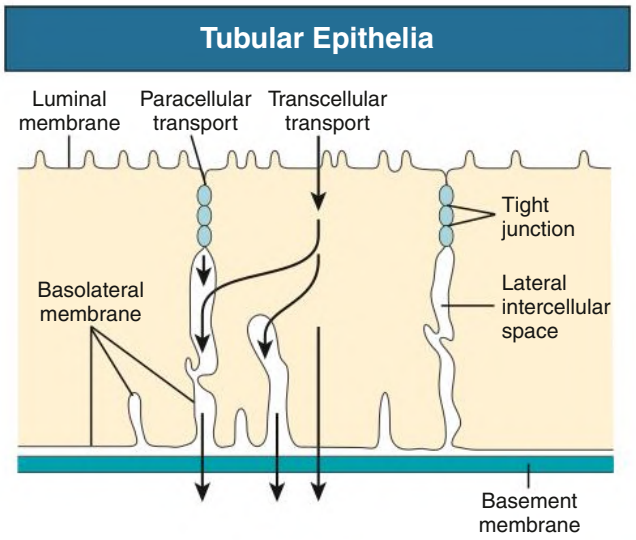

Fig. 1.10 Tubular Epithelia. Transport across the epithelium may follow two routes: transcellular, across luminal and basolateral membranes, and paracellular, through the tight junction and intercellular spaces.

and show numerous structural adaptations to their special roles. They are connected apically by a junctional complex consisting of a belt-like tight junction (zonula occludens), a belt-like adherens junction (zonula adherens), and, at some sites, a desmosome. The tight junction represents a structural border between the luminal and the basolateral cell membrane domain, preventing movements of membrane-associated transport proteins between the two domains. Two different pathways through the epithelium exist (Fig. 1.10): a transcellular pathway, including the transport across the luminal and the basolateral cell membrane and through the cytoplasm, and a paracellular pathway through the junctional complex and the lateral intercellular spaces. The functional characteristics of the paracellular transport are determined by the tight junction, which differs markedly in its elaboration in the various tubular segments. The tight junctional proteins responsible for the specific permeability properties are occludin and especially the claudins.[36] Transcellular transport is determined by apical and basolateral channels, carriers, and transporters. The various nephron segments differ markedly in function, distribution of transport proteins, and responsiveness to hormones and drugs such as diuretics. The cell surface area of the plasmalemmal compartments carrying the transport systems is extensively enlarged in many tubule cells: namely, by microvilli at the luminal membrane domain, by lamellar folds of the basolateral membrane interdigitating with those of the neighboring cells (interdigitations), or by lamellar folds of the basal cell membrane invaginating into the own cell (invaginations).

Proximal Tubule

The proximal tubule reabsorbs the bulk of filtered water and solutes (Fig. 1.11) and is generally subdivided into three segments (known as S_1, S_2, S_3) that differ considerably in cellular organization and, consequently, also in function.[37] The proximal tubule has a prominent brush border and extensive interdigitation by basolateral cell processes. These lateral cell interdigitations extend up to the leaky tight junction, thus considerably increasing the tight junctional belt in length and providing a greatly increased passage for the passive transport of ions. Proximal tubule cells have large prominent mitochondria intimately associated with the basolateral cell membrane where the Na^+,K^+–adenosine triphosphatase (ATPase) is located; this machinery is the molecular mechanism initiating numerous secondary transcellular transport processes. The luminal transporter for Na^+

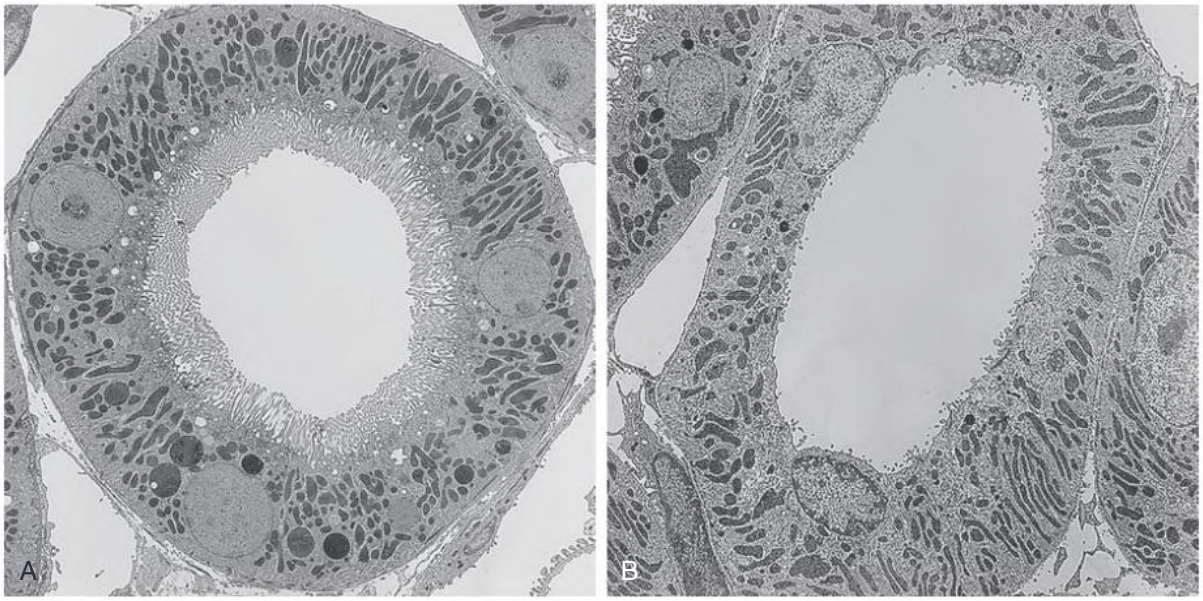

Fig. 1.11 Tubules of the Renal Cortex. (A) Proximal convoluted tubule is equipped with a brush border and a prominent vacuolar apparatus in the apical cytoplasm. The rest of the cytoplasm is occupied by a basal labyrinth consisting of large mitochondria associated with basolateral cell membranes. (B) Distal convoluted tubule also has interdigitated basolateral cell membranes intimately associated with large mitochondria. In contrast to the proximal tubule, however, the apical surface is amplified only by some stubby microvilli. (TEM; A, ×1530; B, ×1830.)

reabsorption specific for the proximal tubule is the Na^+-H^+ exchanger (NHE3) that is located in the plasma membrane of the apical microvilli and accounts for reabsorption of most of the filtered sodium. Other sodium coupled transporters in the microvillous membrane are the sodium-glucose cotransporters SGLT2 and SGLT1 and several sodium-phosphate cotransporters. The abundance of channel protein aquaporin 1 in the apical microvillous membrane and the basolateral cell membrane accounts for the high hydraulic permeability for water of this epithelium. An apical tubulovesicular compartment is part of the prominent endosomal-lysosomal system and is responsible for the reabsorption of macromolecules (active peptides, polypeptides, and proteins such as albumin) that have passed the glomerular filter.

The S_3 and portions of the S_2 segments are engaged in many secretory processes of toxic substances and drugs via organic anion transporters and an organic cation transporter (OCT). Proximal tubule cells are electrically coupled by gap junctions (Nexus).

Intermediate Tubule

The intermediate tubule includes the thin portion of Henle's loop, thin descending and (only in long loops) thin ascending limbs (Fig. 1.12; see also Fig. 1.2). Thin descending limbs of short loops and those of long loops are equipped with different epithelia. The thin descending limbs of short loops have an extremely flat epithelium that, in its beginning part, is permeable to water, and, in its distal part, contains the urea transporter UT-A2 responsible for the uptake of urea coming up from the inner medulla (urea recycling).[38] The thin descending limbs of long loops, in their initial parts within the inner stripe, are quite permeable to Na^+ and Cl^- (uptake from the interstitial space) and have a considerable Na^+,K^+-ATPase activity, the relevance of which is unknown. Along their course down through the inner medulla they lose their salt permeability becoming permeable to water. The transition to the ascending thin limb epithelium occurs already before the bend. The ascending thin limbs have a heavily interdigitated epithelium highly permeable for ions releasing them into the interstitial space but impermeable for water. The relevance of transport functions of the thin limbs for the generation of the osmotic medullary gradient is debated.

Distal Straight Tubule (Thick Ascending Limb of Henle's Loop)

The thick ascending limb of Henle's loop is often called the diluting segment. It is water impermeable but reabsorbs considerable amounts of sodium and chloride, resulting in the separation of salt from water. The salt is trapped in the medulla (see Fig. 1.12), whereas the water is carried away into the cortex, where it may return into the systemic circulation. The specific transporter for Na^+ reabsorption in this segment is the Na^+-K^+-$2Cl^-$ cotransporter 2 (NKCC2),[39] which is specifically inhibited by loop diuretics such as furosemide. This transporter is inserted in the luminal membrane, which is amplified by only solitary microvilli. The tight junctions of the thick ascending limb are elongated by lateral interdigitation of the cells. They have a comparatively low overall permeability; however, they contain the protein Claudin 16 for paracellular reabsorption of divalent ions, notably of magnesium. The cells are heavily interdigitated by basolateral cell processes, which are associated with large mitochondria supplying the energy for the transepithelial transport. The cells synthesize the Tamm-Horsfall protein and release it into the tubular lumen. This protein may help prevent the formation of kidney stones. A short distance before the transition to the distal convoluted tubule, the thick ascending limb contains the macula densa, which adheres to the glomerulus of the same nephron (see Juxtaglomerular Apparatus).

Distal Convoluted Tubule

The epithelium exhibits the most extensive basolateral interdigitation of the cells and the greatest numerical density of mitochondria compared with all other nephron portions (see Fig. 1.11). Apically, the cells are equipped with numerous solitary microvilli. The specific Na^+ transporter of the distal convoluted tubule is the luminal Na^+-Cl^- cotransport system (NCC), which can be inhibited by the thiazide diuretics. Magnesium is reabsorbed via the transient receptor potential channel melastatin subtype 6 (TRPM6) in the luminal membrane[40]

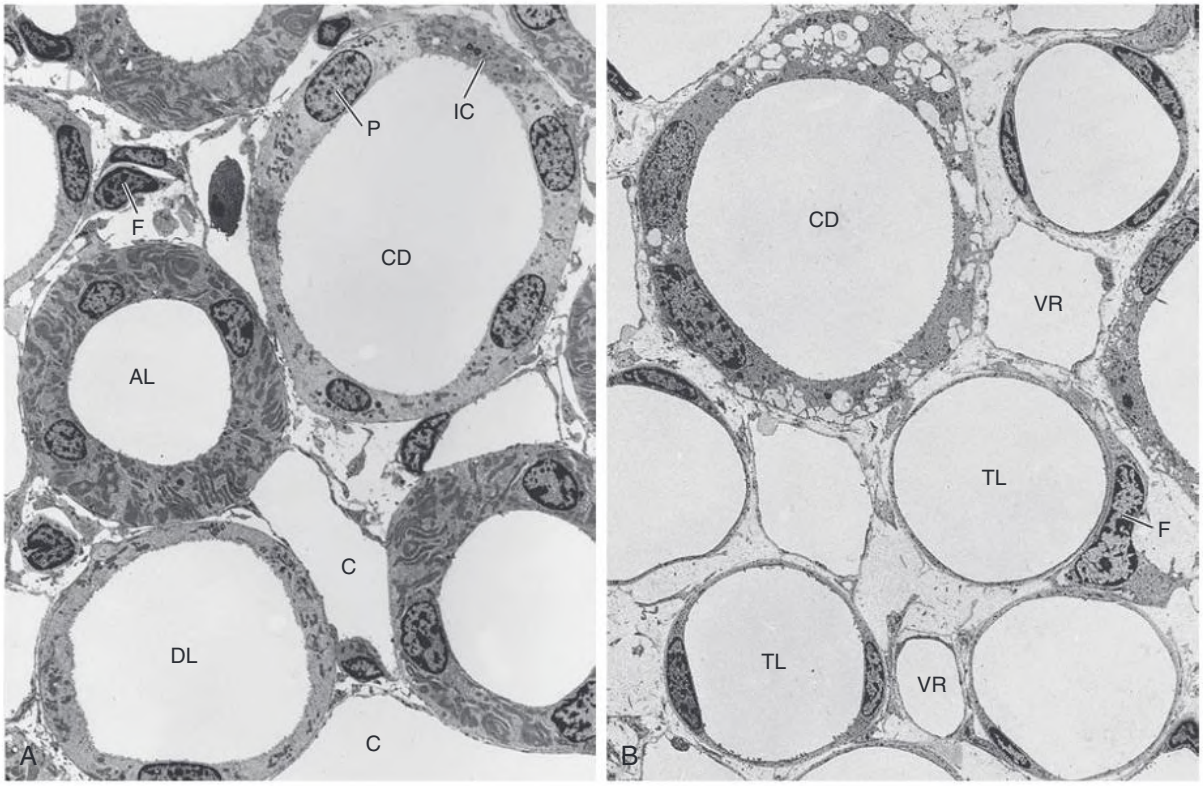

Fig. 1.12 Tubules in the Medulla. (A) Cross-section through the inner stripe of the outer medulla shows a descending thin limb of a long Henle loop *(DL),* the medullary thick ascending limbs of Henle *(AL),* and a collecting duct *(CD)* with principal cells *(P)* and intercalated cells *(IC).* (B) In the inner medulla cross-section, thin descending and ascending limbs *(TL),* a collecting duct *(CD),* and vasa recta *(VR)* are seen. *C,* Peritubular capillaries; *F,* fibroblast. (TEM; A, ×990; B, ×1120.)

and, along the paracellular route, through the tight junctional proteins Claudin 16 and 19.

COLLECTING DUCT SYSTEM

The collecting duct system (see Fig. 1.2) includes the CNT, cortical ducts, and medullary collecting ducts (CDs). The embryologic origin of the CNT, which is interposed between the distal convoluted tubule and the CD, is unclear whether it derives from the nephron anlage or the ureteral bud. Two nephrons may join at the level of the CNT, forming an arcade. Two types of cell establish the CNT: the CNT cell, which is specific to the CNT, and the intercalated (IC) cell, which is also present in varying amounts in the distal convoluted tubule and in the collecting duct. The CNT cells are similar to the CD cells in cellular organization. Both cell types share sensitivity to vasopressin (antidiuretic hormone [ADH]; see later). The amiloride-sensitive epithelial sodium channel, ENaC, and the epithelial calcium channel, TRPV5, are located in the apical membrane, being already present in the distal convoluted tubule and extending into the CNT.

Collecting Ducts

The CDs (see Fig. 1.12) may be subdivided into cortical and medullary ducts, and the medullary ducts into an outer and inner portion; the transitions are gradual. Like the CNT, the CDs are lined by two types of cell: CD cells (principal cells) and IC cells. The IC cells decrease in number as the CD descends into the medulla and are absent from the inner medullary CDs.

The CD cells (Fig. 1.13A) increase in size toward the tip of the papilla. The basal cell membrane amplifies by lamellar invaginations into the cell (basal infoldings). The tight junctions have a large apical-basal depth, and the apical cell surface has a prominent glycocalyx. These cells contain an apical shuttle system for aquaporin 2 under the control of vasopressin, allowing the water permeability of the CDs to switch from very low to permeable.[41] A luminal amiloride-sensitive Na^+ channel is involved in the responsiveness of cortical CDs to aldosterone. The terminal portions of the CD in the inner medulla express the urea transport system UT-A1, which, in an antidiuretic hormone (ADH)-dependent fashion, accounts for the recycling of urea, a process that is crucial in the urine-concentrating mechanism.[42,43]

The second cell type, the IC cell (see Fig. 1.13B), is present in both the CNT and the CD. There are at least two types of IC cells, designated A and B cells, distinguished on the basis of structural, immunocytochemical, and functional characteristics. Type A cells express a H^+-ATPase at their luminal membrane; they secrete protons. Type B cells express the H^+-ATPase at their basolateral membrane; they secrete bicarbonate ions and reabsorb protons.[44]

The CDs are the final regulators of fluid and electrolyte balance, playing important roles in the handling of Na^+, Cl^-, and K^+, as well as in acid-base homeostasis. The responsiveness of the CDs to vasopressin enables an organism to live in arid conditions, allowing it to produce a concentrated urine and, if necessary, a dilute urine.

JUXTAGLOMERULAR APPARATUS

The juxtaglomerular apparatus (JGA) includes the macula densa, the extraglomerular mesangium, the terminal portion of the afferent arteriole with its renin-producing granular cells (also often called

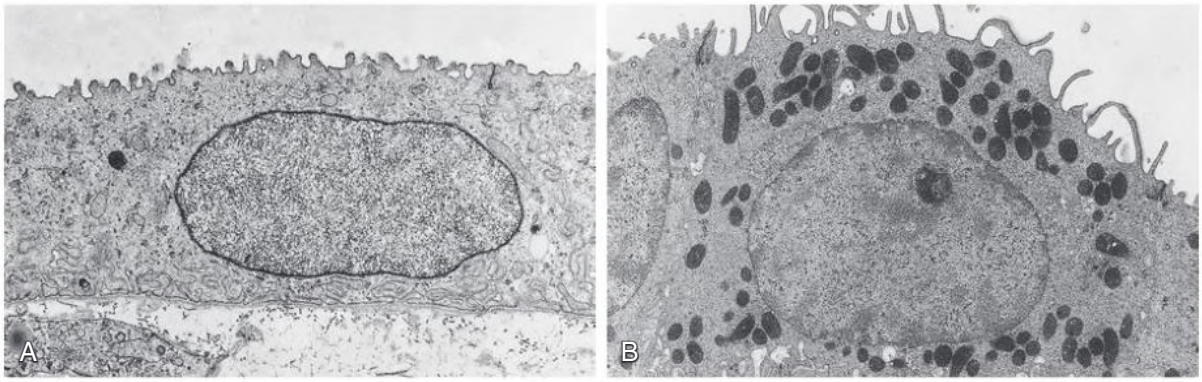

Fig. 1.13 Collecting Duct Cells. (A) Principal cell (collecting duct [CD] cell) of a medullary collecting duct. The apical cell membrane bears some stubby microvilli covered by a prominent glycocalyx; the basal cell membrane forms invaginations. Note the deep tight junction. (B) Intercalated cells, type A. Note the dark cytoplasm (dark cells) with many mitochondria and apical microfolds; the basal membrane forms invaginations. (TEM; A, ×8720; B, ×6970.)

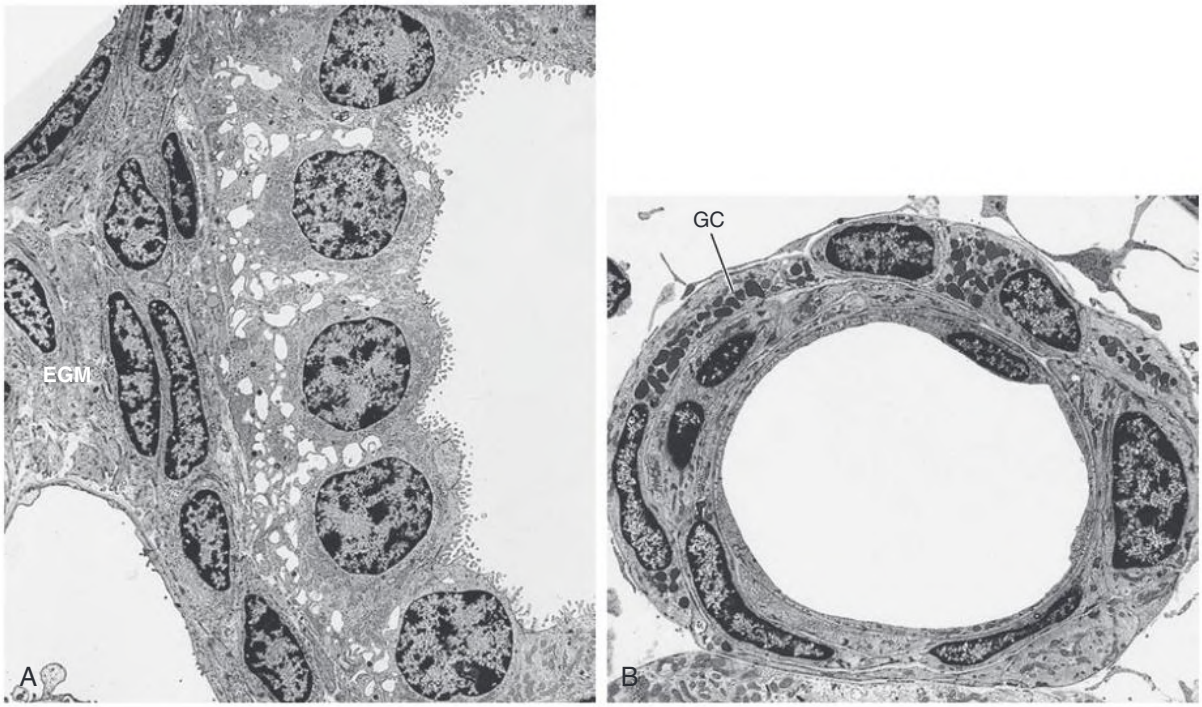

Fig. 1.14 Juxtaglomerular Apparatus. (A) Macula densa of a thick ascending limb of Henle. The cells have prominent nuclei and lateral intercellular spaces. Basally, they attach to the extraglomerular mesangium *(EGM)*. (B) Afferent arteriole near the vascular pole. Several smooth muscle cells are replaced by granular cells *(GC)* containing accumulations of renin granules. (TEM; A, ×1730; B, ×1310.)

juxtaglomerular cells), and the beginning portions of the efferent arteriole (see Fig. 1.8).

The macula densa is a plaque of specialized cells in the wall of the thick ascending limb of Henle at the site where the limb attaches to the extraglomerular mesangium of the parent glomerulus (Fig. 1.14A; see also Fig. 1.4). The most obvious structural feature is the narrowly packed cells with large nuclei, which account for the name macula *densa.* The cells are anchored to a basement membrane, which blends with the matrix of the extraglomerular mesangium. The cells are joined by tight junctions with very low permeability and have prominent lateral intercellular spaces. The width of these spaces varies under different functional conditions.[1] The most conspicuous immunocytochemical difference between macula densa cells and other epithelial cells of the nephron is the high content of neuronal nitric oxide synthase and cyclooxygenase-2 in macula densa cells.[45,46]

The basal aspect of the macula densa is firmly attached to the extraglomerular mesangium, a solid complex of cells and matrix penetrated by neither blood vessels nor lymphatic capillaries. As with the mesangial cells proper, extraglomerular MCs are heavily branched. Their processes are interconnected by gap junctions, contain prominent bundles of microfilaments, and are connected to the basement membrane of Bowman's capsule and to the walls of both glomerular arterioles. As a whole, the extraglomerular mesangium interconnects all structures of the glomerular entrance.[6]

The granular cells are assembled in clusters within the terminal portion of the afferent glomerular arteriole (see Fig. 1.14B), replacing

ordinary smooth muscle cells. "Granular" refers to the specific cytoplasmic granules in which renin, the major secretion product of these cells, is stored. Granular cells are the main site of the body where renin is secreted. Renin release occurs by exocytosis into the surrounding interstitium. Granular cells are connected to extraglomerular MCs, adjacent smooth muscle cells, and endothelial cells by gap junctions and are densely innervated by sympathetic nerve terminals. Granular cells are modified smooth muscle cells; under conditions requiring enhanced renin synthesis (e.g., volume depletion, renal artery stenosis), additional smooth muscle cells located upstream in the wall of the afferent arteriole may transform into granular cells.

The JGA serves two different functions: it regulates the flow resistance of afferent arterioles in the so-called tubule-glomerular feedback mechanism, and it participates in the control of renin synthesis and release from granular cells in the afferent arteriole. Renin release from granular cells is the major source of systemic angiotensin II and thus plays an essential role in controlling extracellular volume and blood pressure, whereas the vasoconstriction of the afferent arteriole locally serves to modulate the filtration of concerned nephron.[47,48]

KIDNEY INTERSTITIUM

The interstitium of the kidney is comparatively sparse, occupying 5% to 7% of the volume of the renal cortex, with a tendency to increase with age. The interstitium increases across the medulla from cortex to papilla. In the outer stripe, it is 3% to 4%, the lowest value of all kidney zones; this is interpreted as forming a barrier to prevent loss of solutes from a hyperosmolar medulla into the cortex. The interstitium is 10% in the inner stripe and up to about 30% in the inner medulla. The cellular constituents of the interstitium include resident fibroblasts (roughly 50%), which establish the scaffold frame for renal corpuscles, tubules, and blood vessels. Furthermore, dendritic cells (also roughly 50%) and varying numbers of macrophages are present. The space between the cells is filled with extracellular matrix, namely, ground substance (proteoglycans, glycoproteins), fibrils, and interstitial fluid.[49]

Fibroblasts are interconnected by specialized contacts and adhere by specific attachments to the basement membranes surrounding the tubules, renal corpuscles, capillaries, and lymphatics. They are the key cells in driving tubulointerstitial fibrosis.[50]

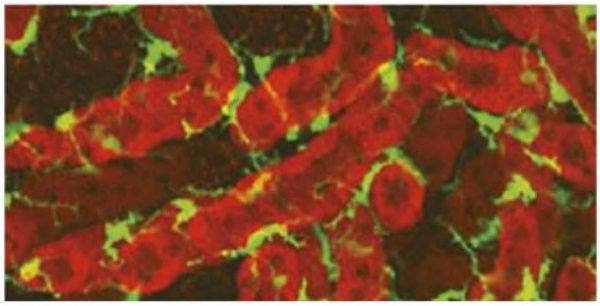

Fig. 1.15 Renal Dendritic Cells. Dendritic cells (CX_3CR1^+ cells, *green*) surrounding tubular segments in the medulla of mice (three-dimensional reconstruction). (Modified from Soos TJ, Sims TN, Barisoni L, et al. CX3CR1+ interstitial dendritic cells form a contiguous network throughout the entire kidney. *Kidney Int.* 2006;70:591–596.)

Kidney fibroblasts are difficult to distinguish from interstitial dendritic cells on a morphologic basis because both may show a stellate cellular shape and both display substantial amounts of mitochondria and endoplasmic reticulum. However, kidney fibroblasts may easily be distinguished by immunocytochemical techniques and by their subplasmalemmal actin cytoskeleton. Dendritic cells constitutively express the major histocompatibility complex class II antigen and may express antigens such as CD11c. Dendritic cells may have an important role in maintaining peripheral tolerance in the kidney (Fig. 1.15).[51] In contrast, fibroblasts in the kidney cortex (not in the medulla) contain the enzyme ecto-5′-nucleotidase (5′-NT). A subset of 5′-NT–positive fibroblasts of the cortex synthesizes erythropoietin.[52] Under normal conditions, these fibroblasts are exclusively found within the juxtamedullary portions of the cortical labyrinth. When there is an increasing demand for erythropoietin, synthesizing cells are recruited from fibroblasts in superficial portions of the cortical labyrinth.[53]

Fibroblasts within the medulla, especially within the inner medulla, have a particular phenotype known as *lipid-laden interstitial cells*. The cells are oriented strictly perpendicularly toward the longitudinal axis of the tubules and vessels (running all in parallel) and contain conspicuous lipid droplets. These fibroblasts of the inner medulla produce large amounts of glycosaminoglycans and, possibly related to the lipid droplets, vasoactive lipids, especially PGE_2.[51]

SELF-ASSESSMENT QUESTIONS

1. Which of the statements concerning the interstitium of the healthy kidney is *incorrect?*
   The renal interstitium contains:
   A. fibroblasts
   B. myofibroblasts
   C. dendritic cells
   D. cells that produce erythropoietin
   E. macrophages
2. Which of the statements concerning the podocyte foot processes is *incorrect?*
   Podocyte foot processes:
   A. contain an actin-based cytoskeleton
   B. have contractile properties
   C. are connected to the glomerular basement membrane (GBM) by integrins
   D. are connected to the GBM by the dystroglycans
   E. are connected to each other by the slit diaphragm
3. Which of the statements concerning the inner stripe of the renal medulla is *incorrect?*
   The inner stripe of the outer medulla contains:
   A. the thin descending limbs of short loops
   B. the thin descending limbs of long loops
   C. the thin ascending limbs of long loops
   D. the thick ascending loops of short loops
   E. venous vasa recta that originate in the inner medulla

Renal Physiology

Matthew A. Bailey, Robert J. Unwin

GLOMERULAR STRUCTURE AND ULTRASTRUCTURE

Urine formation begins with the production of an ultrafiltrate of plasma. Chapter 1 details glomerular ultrastructure, and the essentials are revisited here. The ultrafiltration pathway consists of the fenestrated capillary endothelium, the capillary basement membrane (the noncellular layer), and the visceral epithelial cell layer (podocytes) of Bowman's capsule; the podocytes have large cell bodies and make contact with the basement membrane only by cytoplasmic foot processes. Parietal epithelial cells lining the inside of Bowman's capsule are highly proliferative and may provide a niche for replenishment of the podocyte pool, especially after injury.[1] Mesangial cells fill the intercapillary space and provide structural support for the glomerulus, including secretion of mesangial matrix. They are contractile and can affect glomerular capillary flow and the surface area for filtration.

Filtration is determined principally by the molecular size and shape of the filtered solute and to a lesser extent by its charge. The size cut-off is not absolute. Resistance to filtration begins at an effective molecular radius of approximately 2 nm, and substances with an effective radius greater than 4 nm are not filtered at all. The fenestrations between capillary endothelial cells have a diameter of 50 to 100 nm. The podocyte foot processes have gaps (filtration slits) with a diameter of 30 to 40 nm. These filtration slits are bridged by the slit diaphragms (SDs), which are themselves penetrated by small pores. The SDs likely constitute the main filtration barrier, although the endothelium (by preventing the passage of blood cells) and the basement membrane also contribute.[2] Furthermore, podocytes and endothelial cells are covered by a glycocalyx composed of negatively charged glycoproteins, glycosaminoglycans, and proteoglycans, and the basement membrane is rich in heparan sulfate proteoglycans. This accumulation of fixed negative charges restricts filtration of large negatively charged ions, mainly proteins (Fig. 2.1). Albumin is negatively charged and, with an effective radius of 3.6 nm (35 Å), is normally almost completely excluded from filtration. If the glomerular barrier loses fixed negative charge, as in some forms of early or mild glomerular disease (e.g., minimal change disease), albumin filterability increases and leads to proteinuria. It is possible that some albumin is normally filtered and is then almost completely reabsorbed along the proximal tubule, although this is controversial. Certainly proximal tubular cells can take up albumin via megalin and cubilin, transport proteins in the apical membrane.[3] However, deletion of this tubular transport system in mice causes only a small increase in albuminuria, suggesting that filtration of albumin is both normally low and the major determinant of urinary excretion.[4] Nonetheless, the filtration-to-reabsorption relationship is dynamic and physiologically regulated[5] and may change in diseases such as diabetic nephropathy, contributing to albuminuria.[6]

The glomerular barrier is not a passive unidirectional filter: filtration pressure generates a small potential difference across the filtration barrier, which may help clear the filter by driving negatively charged proteins out of the SD and back into the blood.[7]

GLOMERULAR FILTRATION RATE

The driving force for glomerular filtration *(net ultrafiltration pressure)* is determined by the sum of the hydrostatic and oncotic (colloid osmotic) pressure gradients between plasma and Bowman's space. Single-nephron glomerular filtration rate (SNGFR) is determined by the product of the net ultrafiltration pressure and the *ultrafiltration coefficient*, a composite of the surface area available for filtration (influenced by the contractile mesangium) and the hydraulic conductivity of the glomerular membranes, which is very high compared with other capillary beds. Thus, the SNGFR is calculated as:

$$K_f\,[(P_{gc} - P_{bs}) - (\pi_{gc} - \pi_{bs})]$$

where K_f is the ultrafiltration coefficient, P_{gc} is the glomerular capillary hydrostatic pressure (~45 mm Hg), P_{bs} is the Bowman space hydrostatic pressure (~10 mm Hg), π_{gc} is the glomerular capillary oncotic pressure (~25 mm Hg), and π_{bs} is Bowman's space oncotic pressure (0 mm Hg).

Net ultrafiltration pressure is approximately 10 mm Hg at the afferent end of the capillary tuft. As filtration of plasma from blood proceeds along the glomerular capillaries, proteins are concentrated and the glomerular capillary oncotic pressure (π_{gc}) increases. Loss of fluid would also be expected to cause a reduction in glomerular capillary hydrostatic pressure. Theoretically, toward the efferent end of a glomerular capillary, π_{gc} may equal the net hydrostatic pressure gradient, at which point ultrafiltration pressure would fall to zero. *Filtration equilibrium* is observed in a number of capillary beds (e.g., skeletal muscle). In the healthy glomerulus, however, *net ultrafiltration pressure* progressively declines and filtration equilibrium is never achieved for two reasons: first, the glomerular capillary bed flows into an arteriole, rather than a venous system, and efferent arteriole resistance limits the fall in capillary hydrostatic pressure (Fig. 2.2); second, progressive morphologic changes in the capillary endothelium reduce permeability toward the efferent end.

The total glomerular filtration rate (GFR) is the sum of the SNGFRs of functioning nephrons and the normal range is wide, typically cited at 120 mL/min per 1.73 m^2 surface area. GFR can be measured with renal clearance techniques. The renal clearance of any substance not metabolized by the kidneys is the volume of plasma required to provide that amount of the substance excreted in the urine per unit time. This is a virtual volume that can be expressed mathematically as follows:

$$C_y = U_y/P_y \times V$$

where C_y is the renal clearance of *y;* U_y and P_y are the concentrations of *y* in the urine and plasma, respectively; and V is the urine flow rate. If a substance is freely filtered by the glomerulus and is not reabsorbed

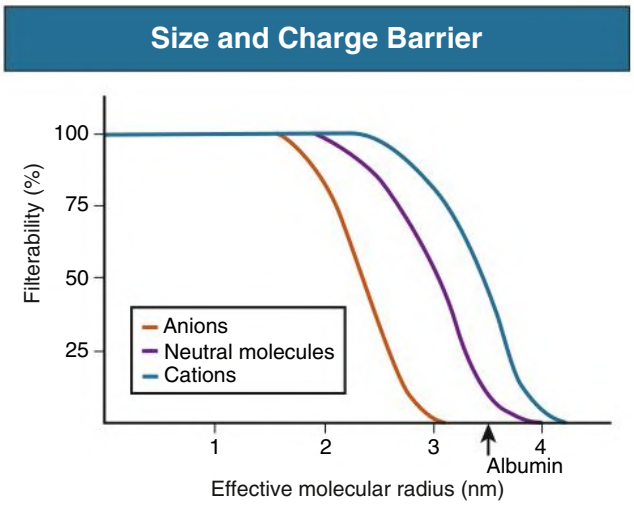

Fig. 2.1 Effects of Size and Electrical Charge on Filterability. Filterability of 100% indicates the substance is freely filtered; that is, its concentration in Bowman's space equals that in glomerular capillary plasma. For molecules and small ions (e.g., Na^+, Cl^-), charge has no effect on filterability; but for ions whose effective molecular radius exceeds 1.6 nm, anions are filtered less easily than neutral molecules or cations. Albumin is an anion with a radius of 3.6 nm, and insignificant amounts of albumin are normally filtered. If the fixed negative charges of the glomerular basement membranes are lost, as in early minimal change nephropathy, charge no longer influences filterability; consequently, significant albumin filtration occurs.

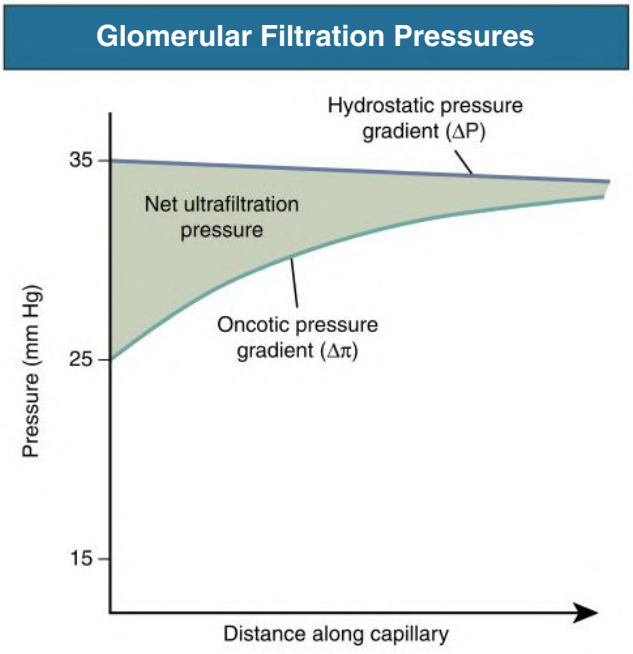

Fig. 2.2 Glomerular Filtration Pressures Along a Glomerular Capillary. Gating of flow by the efferent arteriole maintains a relatively constant hydrostatic pressure gradient ($\Delta P = P_{gc} - P_{bs}$) along the length of a capillary, whereas the opposing oncotic pressure gradient ($\Delta\pi = \pi_{gc}$) increases as protein-free fluid is filtered. The net ultrafiltration pressure falls along the capillary but does not fall to zero, the point of filtration equilibrium.

or secreted by the tubule, its renal clearance equals the GFR; that is, renal clearance measures the volume of plasma filtered through the glomeruli per unit time. The various methods for measuring GFR and their pitfalls are discussed in Chapter 3.

RENAL PLASMA FLOW

The kidneys are approximately 0.5% of total body mass but account for approximately 7% of whole-body oxygen consumption. The renal blood flow (RBF) of approximately 1200 mL/min (~20% of the cardiac output) is delivered into the renal cortex, maintaining a high partial pressure of oxygen sufficient to support aerobic respiration by the proximal tubule. Almost all of the blood arriving by the renal artery is delivered into glomerular capillaries to support ultrafiltration; the *filtration fraction* (i.e., the proportion of plasma that is filtered—GFR/RPF) is 20% to 25%.

The glomerular capillaries drain into the efferent arteriole (rather than into the venous system), after which a second set of capillaries is formed. Capillaries arising from efferent arterioles of cortical (superficial and short-looped) nephrons form the peritubular network entwined around proximal and distal nephron segments in the cortex to provide an exit route for the bulk reabsorption of glomerular filtrate. The efferent arterioles of juxtamedullary (deeper and long-looped) nephrons provide descending vasa recta capillaries and supply blood to the medulla.

RBF can be calculated from measurement of renal plasma flow (RPF; typically ~650 mL/min) and hematocrit. RPF is measured by the clearance technique using substances that undergo both glomerular filtration and almost complete (or *effective*) tubular secretion. Para-aminohippuric acid (PAH, hippurate) is widely used for this purpose. PAH is an organic acid filtered by the glomerulus and then actively secreted into the urine through organic anion transporters (OATs) in the proximal straight tubule. This method is limited because the renal extraction of PAH is always less than 100% and variably underestimates RPF. This effect is compounded in patients with liver or kidney failure, where production of toxins and weak organic acids can interfere with PAH secretion, or during treatment with certain drugs, such as probenecid, which compete with PAH for tubular secretion and reduce PAH clearance. Thus, in a variety of clinical settings, PAH clearance is influenced by the abundance/pharmacokinetics of the OAT pathway and may not accurately reflect true RPF. Given that PAH clearance is also invasive (requiring intravenous [IV] infusion), time consuming, and expensive, alternative imaging approaches are being refined to estimate RBF directly, including Doppler ultrasound[8] and magnetic resonance imaging.[9]

AUTOREGULATION OF RENAL BLOOD FLOW AND GLOMERULAR FILTRATION RATE

Acute physiologic variations in arterial blood pressure cause corresponding changes in RBF and GFR. These are short-lived because compensatory mechanisms return both RBF and GFR toward normal within seconds.[10] In normal physiology, RBF and GFR are *autoregulated* and renal hemodynamics are largely independent of systemic blood pressure (Fig. 2.3). Autoregulation of RBF occurs throughout the preglomerular arterial system but is achieved primarily by the afferent arterioles. Autoregulation results from two main mechanisms:

Myogenic reflex: Increased renal perfusion pressure stretches arteries and afferent arterioles, depolarizing smooth muscle cells to promote constriction of the vessel wall.

Tubuloglomerular feedback (TGF): Increased renal perfusion pressure increases sodium chloride (NaCl) delivery to the macula densa and specialized cells at the junction of the loop of Henle and distal nephron. The macula densa senses increased delivery and responds by causing afferent arteriolar constriction, reducing SNGFR.

These mechanisms are tonically active and dynamic and combine to restore both RBF and P_{gc} toward normal, reversing the initial

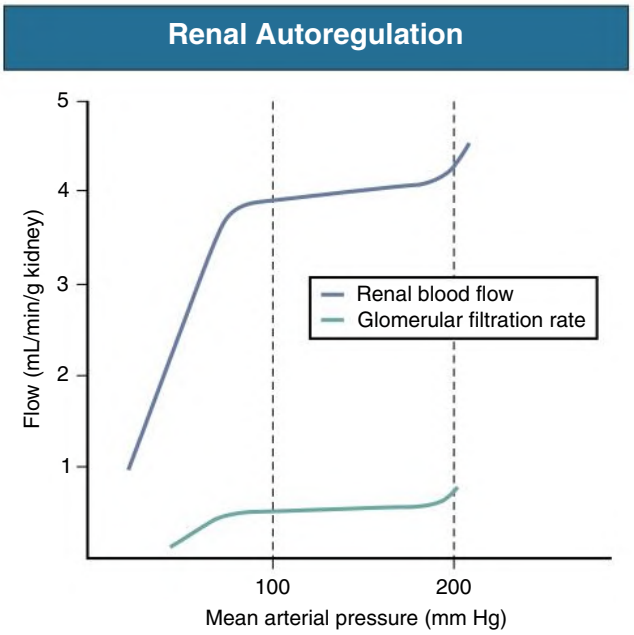

Fig. 2.3 Renal Autoregulation of Renal Blood Flow and Glomerular Filtration Rate. If mean arterial blood pressure is in the range of 80 to 180 mm Hg, fluctuations in blood pressure have only marginal effects on renal blood flow and glomerular filtration rate. This is an intrinsic mechanism and can be modulated or overridden by extrinsic factors. The dashed lines indicate the upper and lower limit of the autoregulatory range.

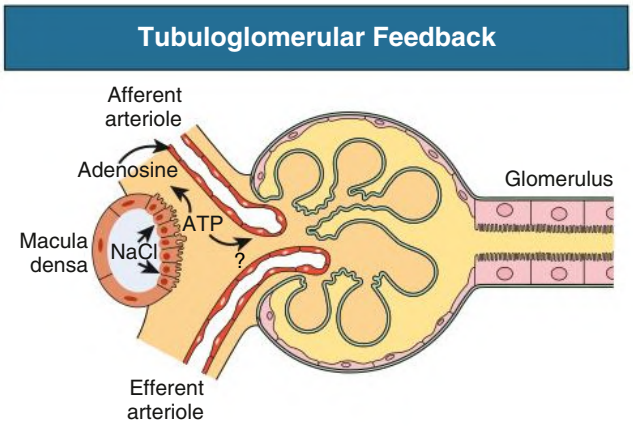

Fig. 2.4 Tubuloglomerular Feedback. Changes in the delivery of NaCl to the macula densa region of the thick ascending limb of the Henle loop cause changes in the afferent arteriolar caliber. The response is mediated by adenosine triphosphate (ATP), either directly or after metabolism to adenosine, and modulated by other locally produced agents such as angiotensin II and nitric oxide. Increased macula densa NaCl delivery results in afferent arteriolar constriction, thereby reducing the glomerular filtration rate (GFR).

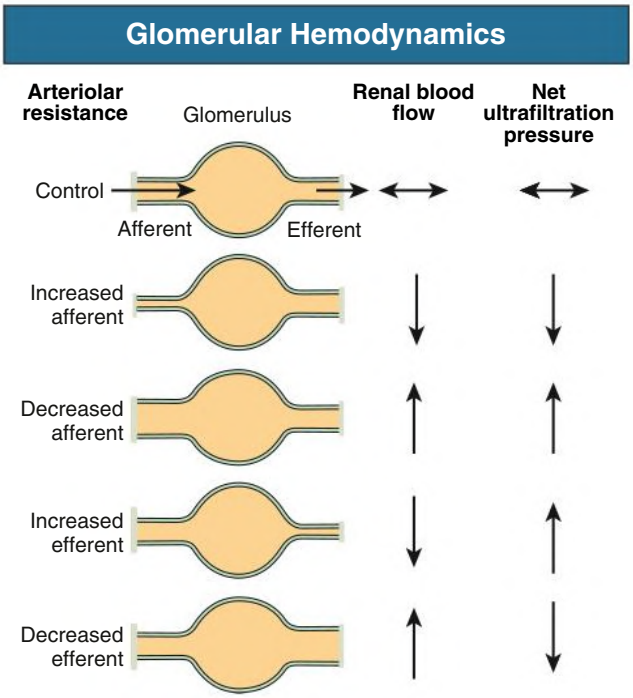

Fig. 2.5 Glomerular Hemodynamics. Changes in afferent or efferent arteriolar resistance will alter renal blood flow and (usually) net ultrafiltration pressure. The effect on ultrafiltration pressure, however, depends on the relative changes in afferent and efferent arteriolar resistance. The overall effect on the glomerular filtration rate will depend not only on renal blood flow and net ultrafiltration pressure but also on the ultrafiltration coefficient (K_f; see Table 2.1).

change in SNGFR. The TGF system is controlled within the juxtaglomerular apparatus (see Chapter 1), which consists of the macula densa region, the adjacent glomerulus, and afferent and efferent arterioles (Fig. 2.4). Both myogenic and TGF mechanisms are dependent on extracellular adenosine triphosphate (ATP) signaling. ATP is released from cells during vascular stretch, inducing vasoconstriction via P2 purinoceptors.[11] ATP is also the primary mediator of TGF. Increased NaCl delivery to the macula densa leads to increased NaCl uptake by these cells through a furosemide-sensitive $Na^+,K^+,2Cl^-$ cotransporter, triggering ATP release into the surrounding extracellular space.[12] ATP can have a direct vasoconstrictor effect on the afferent arteriole, activating $P2X_1$ purinoceptors to depolarize the smooth muscle cells. However, because the macula densa is anatomically separated from the afferent arteriole by the extraglomerular mesangium, the final signal for TGF is likely to be adenosine, rather than ATP, acting on afferent arteriolar A_1 receptors to cause vasoconstriction.[12] The sensitivity of TGF is modulated by locally produced angiotensin II (Ang II), nitric oxide (NO), and certain eicosanoids (see later discussion).

The TGF regulation of GFR may be more complex than usually described, with evidence for regulatory cross-talk between the distal nephron and vasculature sites beyond the macula densa,[13] as well as for synchronization of blood flow across networks of nephrons in response to changes in sodium delivery.[14]

Renal autoregulation is not perfect and renal hemodynamics are modulated by neural and humoral factors. Independent or unequal changes in the resistance of afferent and efferent glomerular arterioles, together with alterations in K_f (thought to result largely from mesangial cell contraction/relaxation), can result in disproportionate, or even contrasting, changes in RBF and GFR. In addition, changes in regional vascular resistance can alter the distribution of blood flow within the kidney. For example, contraction of pericytes in the descending vasa recta causes medullary vasoconstriction.[15] Whole-kidney blood flow may not change because blood can be diverted through the cortex. Sustained vasa recta constriction renders the medulla vulnerable to ischemic injury.[16] Fig. 2.5 indicates how changes in afferent and efferent arteriolar resistance can affect net ultrafiltration. Table 2.1 lists some of the vasoactive factors that can alter renal hemodynamics (see Integrated Control of Renal Function). Damage to the afferent arteriole, as in patients with hypertension and progressive kidney disease, can impair renal autoregulatory mechanisms.

TABLE 2.1 Physiologic and Pharmacologic Influences on Glomerular Hemodynamics

	ARTERIOLAR RESISTANCE					
	Afferent	Efferent	Renal Blood Flow	Net Ultrafiltration Pressure	K_f	GFR
Renal sympathetic nerves	↑↑	↑	↓	↓	↓	↓
Epinephrine	↑	↑	↓	→	?	↓
Adenosine	↑	→	↓	↓	?	↓
Cyclosporine	↑	→	↓	↓	?	↓
NSAIDs	↑↑	↑	↓	↓	?	↓
Angiotensin II	↑	↑↑	↓	↑	↓	↓→
Endothelin-1	↑	↑↑	↓	↑	↓	↓
High-protein diet	↓	→	↑	↑	→	↑
Nitric oxide	↓	↓	↑	?	↑	↑(?)
ANP (high dose)	↓	→	↑	↑	↑	↑
PGE_2/PGI_2	↓	↓(?)	↑	↑	?	↑
Calcium channel blockers	↓	→	↑	↑	?	↑
ACE inhibitors, ARBs	↓	↓↓	↑	↓	↑	?[a]

The overall effect on GFR will depend on renal blood flow, net ultrafiltration pressure, and the ultrafiltration coefficient (K_f), which is controlled by mesangial cell contraction and relaxation. The effects shown are those seen when the agents are applied (or inhibited) in isolation; the actual changes that occur are dose dependent and are modulated by other agents.

[a]In clinical practice, GFR is usually either decreased or unaffected.

ACE, Angiotensin-converting enzyme; *ARBs,* angiotensin receptor blockers; *ANP,* atrial natriuretic peptide; *GFR,* glomerular filtration rate; *NSAIDs,* nonsteroidal anti-inflammatory drugs; *PGE_2/PGI_2,* prostaglandins E_2 and I_2.

TUBULAR TRANSPORT

Vectorial transport is the net movement of substances from tubular fluid to blood (reabsorption) or vice versa (secretion). The cell membrane facing the tubular fluid (*luminal* or *apical*) must have different properties from the membrane facing the blood (*peritubular* or *basolateral*). Such epithelia are "polarized," allowing the net movement of substances across the cell (transcellular route). The *tight junction,* which is a contact point close to the apical side of adjacent cells, limits water and solute movement between cells (paracellular route).

Solute transport across cell membranes uses either passive or active mechanisms.

Passive Transport

Simple diffusion occurs down an electrochemical gradient, which is a composite of the concentration and electrical gradients (electrochemical gradient). With an undissociated molecule, only the concentration gradient is relevant; for a charged ion, the electrical gradient must also be considered. Simple diffusion does not require a direct energy source, although active transport is usually necessary to establish and maintain the electrochemical gradient.

Facilitated diffusion (coupled or carrier-mediated diffusion) depends on an interaction of the molecule or ion with a specific membrane carrier protein that facilitates its passage across the cell membrane's lipid bilayer. In almost all cases of carrier-mediated transport in the kidney, two or more ions or molecules share the carrier: one moiety moves down its electrochemical gradient and the other(s) is transported "uphill," against the gradient.

Diffusion through a membrane channel (or pore) formed by specific integral membrane proteins is a form of facilitated diffusion because it allows charged, polar, and lipophobic molecules to pass through the membrane at a high rate.

Active Transport

Ion movement directly against an electrochemical gradient requires a source of energy and is known as active transport. In cells, this energy is derived from ATP production and its hydrolysis. The most important active cell transport mechanism is the sodium pump, which extrudes sodium ions (Na^+) from inside the cell in exchange for potassium ions (K^+) from outside the cell. In the kidney, this process is confined to the basolateral membrane. The Na pump derives energy from the enzymatic hydrolysis of ATP and is more correctly named Na^+,K^+-ATPase. It exchanges $3Na^+$ for $2K^+$ and is electrogenic because it extrudes a net positive charge from the cell; Na^+,K^+-ATPase is an example of a *primary* active transport mechanism. Other well-defined primary active transport processes in the kidney are the H^+-ATPase, important in proton secretion in the distal nephron, and the Ca^{2+}-ATPase, partly responsible for calcium reabsorption.

Activity of the basolateral Na^+,K^+-ATPase underpins all of the passive transport processes outlined earlier. It keeps intracellular Na^+ concentration low (10–20 mmol/L) and K^+ concentration high (~150 mmol/L), compared with their extracellular concentrations (~140 and 4 mmol/L, respectively). The *pump-leak* model of sodium transport uses the electrochemical gradient established and maintained by the Na pump to allow "leak" of Na^+ into the cell through a variety of membrane transport proteins, ranging from Na^+ channels to carrier proteins that couple Na^+ entry to the influx (*symport* or *cotransport*) or efflux (*antiport* or *countertransport*) of other molecules or ions. In various parts of the nephron, glucose, phosphate, amino acids, K^+, and chloride ions (Cl^-) are all cotransported with Na^+; moreover, H^{2+} and Ca^{2+} can be countertransported against Na^+ entry. In each case, the non-Na molecule or ion is transported against its electrochemical gradient, using energy derived from the "downhill" movement of Na^+. Their ultimate dependence on the Na^+,K^+-ATPase makes them *secondary* active transporters.

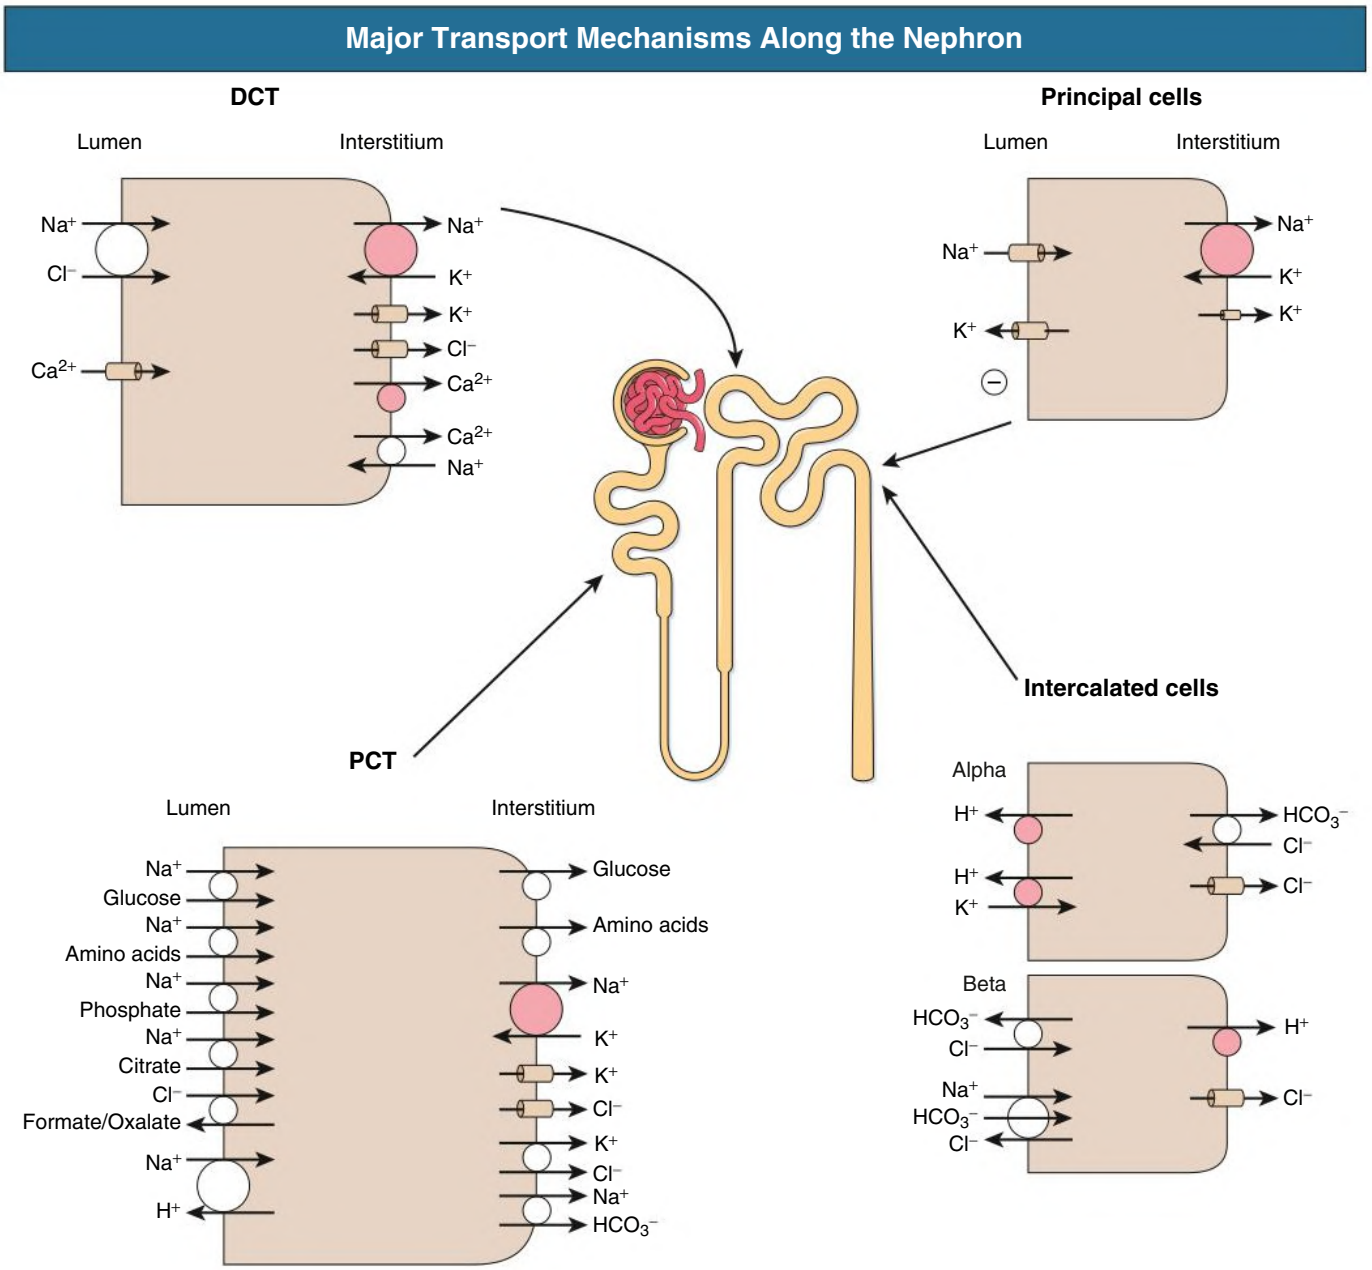

Fig. 2.6 Major Transport Mechanisms Along the Nephron. Major transport proteins for solutes in the apical and basolateral membranes of tubular cells in specific regions of the nephron. Stoichiometry is not indicated; it is not 1:1 in all cases. *Red circles* represent primary active transport; *white circles* represent carrier-mediated transport (secondary active); *cylinders* represent ion channels. In the proximal convoluted tubule (PCT), Na^+ enters the cell through an Na^+-H^+ exchanger and a series of cotransporters. In the distal convoluted tubule (DCT), Na^+ enters the cell through the thiazide-sensitive Na^+-Cl^- cotransporter. In the principal cells of the cortical collecting duct, Na^+ enters through the epithelial sodium channel (ENaC). In all cases, Na^+ is extruded from the cells through the basolateral Na^+,K^+-ATPase. Transporters in the thick ascending limb of Henle are dealt with separately (see Fig. 2.10).

TRANSPORT IN SPECIFIC NEPHRON SEGMENTS

In total, 180 L of plasma (largely protein free) is filtered each day, necessitating massive reabsorption by the nephron. Fig. 2.6 shows major transport mechanisms along the nephron; the loop of Henle is discussed separately.

Proximal Tubule

Proximal tubule cells are adapted for bulk reabsorption of the glomerular filtrate. The apical membrane have microvilli (brush border) to provide a large absorptive area, and the basolateral membrane has folds, also increasing its surface area. Abundant mitochondria are concentrated at the basolateral membrane to supply the Na^+,K^+-ATPase with ATP. Proximal tubule transport is heavily reliant on oxidative phosphorylation (aerobic metabolism) and is susceptible to hypoxia and mitochondrial dysfunction. Drugs that are toxic to mitochondria (e.g., tenofovir) can cause Fanconi syndrome (see Chapter 50), and mitochondrial protection strategies may have potential to improve function in some forms of acute kidney injury.[17]

The proximal convoluted tubule (PCT, *pars convoluta*) makes up the first two-thirds of the proximal tubule, and the final third is the proximal straight tubule *(pars recta)*. The proximal tubular epithelium can also be subdivided into three segments based on subtle structural and functional differences: S_1 is the initial short segment of the PCT; S_2, the remainder of the PCT and the cortical segment of the *pars recta;* and S_3, the medullary segment of the *pars recta.*

The NHE3 isoform of the Na^+-H^+ exchanger (antiporter) is the main route of Na^+ entry into proximal tubular cells. A battery of specialized transporters is also expressed in the apical membrane, coupling Na^+ entry to other solutes. The proximal tubule accounts for the bulk of Na^+, K^+, Cl^-, and bicarbonate (HCO_3^-) reabsorption and the almost complete reabsorption of amino acids and low-molecular-weight proteins (e.g., retinol binding protein, α- and β-microglobulin) that have passed the filtration barrier. The proximal tubule reabsorbs almost all the filtered glucose via the sodium-glucose cotransporters (the SGLTs). SGLT1, which is also expressed in the small intestine, localizes to the apical membrane of the S_3 proximal tubule, reabsorbing approximately 10% of the filtered glucose. Exclusive to the kidney, SGLT2 is expressed predominantly in the brush border of S_1 and S_2 and is the dominant pathway for glucose reabsorption. SGLT2 inhibitors (gliflozins) cause glycosuria and polyuria and lower blood glucose levels and, to a small extent, blood pressure in diabetics. In animal models of diabetes, gliflozins reduce glomerular hyperfiltration by inhibiting TGF, reduce autophagy of renal tubule cells, and lower albuminuria. SGLT2 inhibitors may also preserve mitochondrial function, contributing to their renoprotection.[18] SGLT2 inhibitors are an important new class of antidiabetic and nephroprotective drug used mainly to treat type 2 diabetes, and recent clinical trials have demonstrated a wider benefit in nondiabetic kidney disease and in heart failure.

Many other filtered solutes are also reabsorbed in the proximal tubule (e.g., ~60% of calcium, ~80% of phosphate, and 50% of urea). Constitutive expression of aquaporin 1 (AQP1) water channels in both membranes confers a large hydraulic permeability to cells. Furthermore, the protein junctional complexes (such as Claudin 1 and Zonula Occludens 1) connecting tubular cells are "leaky," facilitating the reabsorption of large amounts of sodium, potassium, and water. The substantial hydraulic permeability requires only a very small osmotic driving force (<5 mOsm/kg/H_2O), and the osmolality of the tubular fluid changes little along the proximal tubule, referred to as "isosmotic" reabsorption.

In the final section of the proximal tubule (late S_2 and S_3), there is efficient secretion of weak organic acids and bases, including most diuretics, PAH (see Renal Blood Flow), nonsteroidal anti-inflammatory drugs (NSAIDs), antiretroviral drugs, and some antibiotics. The molecular machinery for secretion is complex, mediated by 13 members of the SLC22 family of transport proteins.[19]

Loop of Henle

Anatomically, the loop of Henle includes the pars recta of the proximal tubule, the thin descending and ascending limbs (thin ascending limbs are present only in long-looped nephrons), the thick ascending limb, and the macula densa. In addition to its role in further reabsorption of solutes (Na^+, Cl^-, K^+, Ca^{2+}, Mg^{2+}), the loop of Henle is responsible for the kidney's ability to generate a concentrated or dilute urine, described in detail later. The thick limb of Henle also produces *uromodulin* (Tamm-Horsfall protein), normally the most abundant protein in urine. Mutations in the encoding gene *(UMOD)* cause rare autosomal dominant kidney diseases with medullary cyst formation, hyperuricemia, and progressive loss of renal function. Several polymorphisms have been associated with an increased risk for hypertension and chronic kidney disease. A recent mendelian randomization study to assess causality reported that increased urinary levels are causally linked to CKD and increased blood pressure.[19a] The role of uromodulin is not fully understood, but studies in mice suggest that it activates Na^+,K^+,2Cl^- cotransport to promote sodium reabsorption in the thick limb of Henle. Uromodulin may also be a constitutive urinary inhibitor of calcium stone formation and can protect the kidney from ascending urinary tract infections.[20]

Distal Nephron

The distal tubule involves three segments. The distal convoluted tubule (DCT) reabsorbs NaCl via a thiazide-sensitive NaCl cotransporter (NCC) in the apical membrane.[21] The connecting tubule (CNT) is a functional intermediate between the DCT and the initial cortical collecting duct (CD; see Fig. 2.6), which is formed of *principal* cells (i.e., the main cell type) and intercalated cells (i.e., inserted between). Principal cells are responsible for Na^+ reabsorption, K^+ secretion,[22] and regulated water reabsorption (see later discussion). Na^+ enters the principal cell through apical epithelial sodium channels (ENaC) and exits by the basolateral Na^+,K^+-ATPase. This process is electrogenic and establishes a lumen-negative transepithelial potential difference. K^+ enters the principal cell by the same basolateral Na^+,K^+-ATPase and leaves by K^+ transport pathways in both membranes; however, the relative depolarization of the apical membrane (caused by Na^+ entry through ENaC) favors K^+ secretion into the lumen, the major route for which is through renal outer medullary potassium (ROMK) channels.

Intercalated (IC) cells contribute to acid-base homeostasis. Type A (or α) IC cells secrete H^+ into the tubular fluid via H^+-ATPase and H^+,K^+-ATPase. Type B (or β) IC cells mediate HCO_3^- secretion into the final urine, in exchange for Cl^-. An exchanger called pendrin, encoded by *SLC26A4,* mediates this process. Type B IC cells also express a Na^+-dependent chloride-bicarbonate exchanger (NDCBE; *SLC4A8*). Functionally coupled with pendrin, NDCBE achieves electroneutral sodium transport across the type B cell (see Fig. 2.6).[23]

In the medullary CD there are increasingly fewer IC cells, whereas the principal-like cells are modified such that they reabsorb Na^+ but, lacking apical K^+ channels, do not secrete K^+.

Figs. 2.7 and 2.8 show the sites of Na^+ and K^+ reabsorption and secretion along the nephron. Table 2.2 outlines the pathophysiologic consequences of known genetic defects in some of the major transporters in the nephron (see Chapter 49 for details).

GLOMERULOTUBULAR BALANCE

The proportion of filtered Na^+ that is excreted in the urine is so small (normally <1%) that even small changes in the filtered load would cause potentially major changes in the amount excreted in the final urine. For example, if GFR were to increase by 10%, and the rate of reabsorption remained unchanged, Na^+ excretion would increase more than 10-fold. An intrinsic feature of tubular function, however, is that the extent of Na^+ reabsorption in a given nephron segment is proportional to the Na^+ delivery to that segment. This process is called *glomerulotubular balance.* In perfect balance, both the reabsorption and the excretion of Na^+ would change in exactly the same proportion as the change in GFR, but glomerulotubular balance is usually less than perfect. Most studies have focused on the proximal tubule where glomerulotubular balance stabilizes delivery of Na^+ and fluid to the distal nephron, permitting efficient secretion of K^+ and H^+. However, Na^+ reabsorption in the thick limb of Henle and distal tubule is also delivery-dependent. This partly explains why diuretics acting on the proximal tubule are less effective compared with those acting more distally: with distal-acting diuretics, there is less scope further downstream for compensatory Na^+ reabsorption. This also explains why combining two diuretics (acting at different nephron sites) can cause a more striking diuresis and natriuresis.

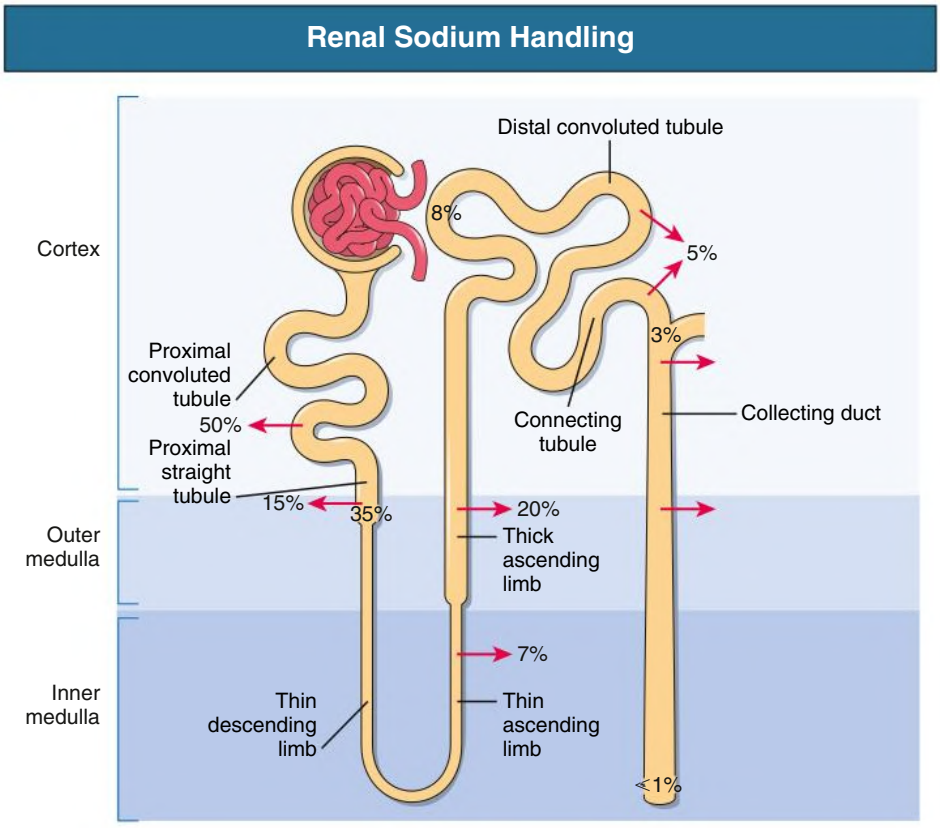

Fig. 2.7 Renal Sodium Handling Along the Nephron. Figures outside the nephron represent the approximate percentage of the filtered load reabsorbed in each region. Figures within the nephron represent the percentages remaining. Most filtered sodium is reabsorbed in the proximal tubule and loop of Henle; normal day-to-day control of sodium excretion is exerted in the distal nephron.

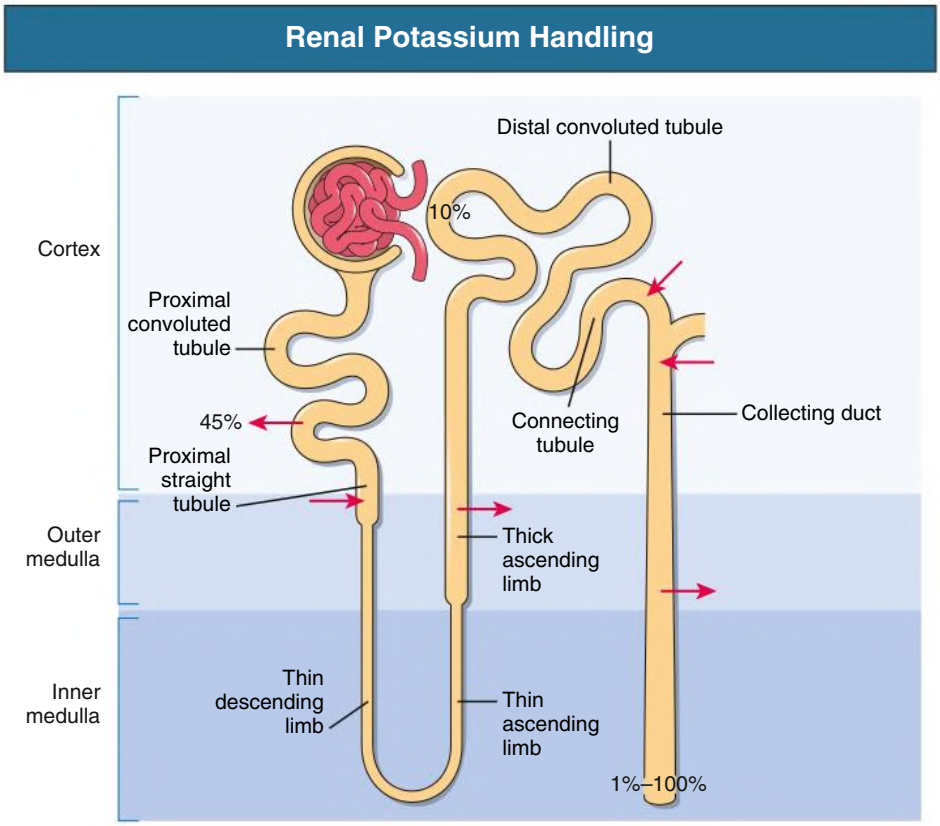

Fig. 2.8 Renal Potassium Handling Along the Nephron. Figures are not given for percentages reabsorbed or remaining in every region because quantitative information is incomplete, but most filtered potassium is reabsorbed in the proximal convoluted tubule and thick ascending limb of Henle; approximately 10% of the filtered load reaches the early distal tubule. Secretion by connecting tubule cells and principal cells in the late distal tubule–cortical collecting duct is variable and is the major determinant of potassium excretion.

TABLE 2.2 Genetic Defects in Transport Proteins Resulting in Renal Disease[a]

Transporter	Consequence of Mutation
Proximal Tubule	
Apical Na^+-cystine cotransporter	Cystinuria
Apical Na^+-glucose cotransporter (SGLT2)	Renal glycosuria
Basolateral Na^+-HCO_3^- cotransporter	Proximal renal tubular acidosis
Intracellular H^+-Cl^- exchanger (ClC5)	Dent disease
Thick Ascending Limb	
Apical Na^+-K^+-$2Cl^-$ cotransporter	Bartter syndrome type 1
Apical K^+ channel	Bartter syndrome type 2
Basolateral Cl^- channel	Bartter syndrome type 3
Basolateral Cl^- channel accessory protein	Bartter syndrome type 4
Distal Convoluted Tubule	
Apical Na^+-Cl^- cotransporter	Gitelman syndrome
Collecting Duct	
Apical Na^+ channel (principal cells)	Overexpression: Liddle syndrome Underexpression: pseudohypoaldosteronism type 1b
Aquaporin 2 channel (principal cells)	Nephrogenic diabetes insipidus
Basolateral Cl^-/HCO_3^- exchanger (intercalated cells)	Distal renal tubular acidosis
Apical H^+-ATPase (intercalated cells)	Distal renal tubular acidosis (with or without deafness)

[a]For more detailed coverage of these clinical conditions, see Chapter 49.
ATP, Adenosine triphosphate.

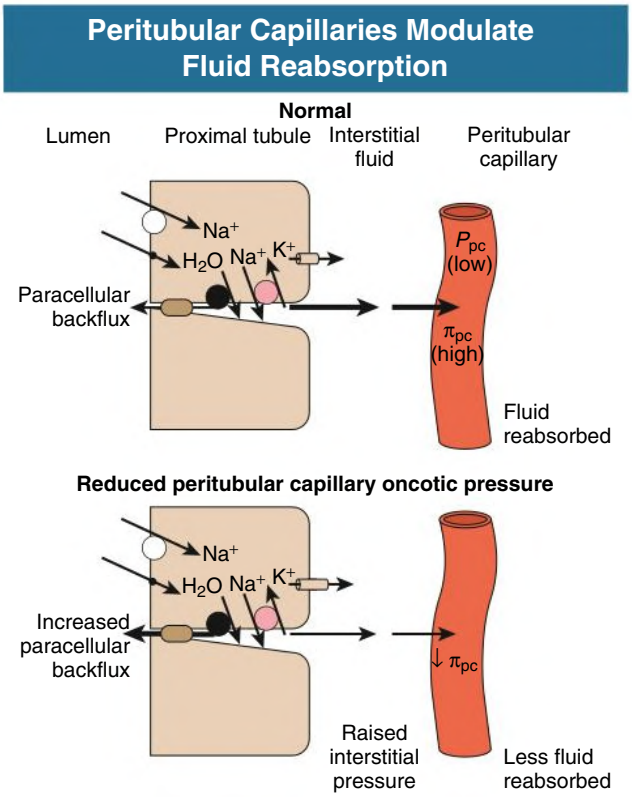

Fig. 2.9 Physical Factors and Proximal Tubular Reabsorption. Influence of peritubular capillary oncotic pressure on net reabsorption in proximal tubules. Uptake of reabsorbate into peritubular capillaries is determined by the balance of hydrostatic and oncotic pressures across the capillary wall. Compared with those in systemic capillaries, the peritubular capillary hydrostatic (P_{pc}) and oncotic (π_{pc}) pressures are low and high, respectively, so that uptake of proximal tubular reabsorbate into the capillaries is favored. If peritubular capillary oncotic pressure decreases (or hydrostatic pressure increases), less fluid is taken up, interstitial pressure increases, and more fluid may leak back into the lumen paracellularly; net reabsorption in proximal tubules would therefore be reduced.

The mechanism of glomerulotubular balance is not fully understood. In the proximal tubule, physical factors (Starling forces) operating across peritubular capillary walls may be involved. Glomerular filtration of an essentially protein-free fluid means that the plasma leaving the glomeruli in the efferent arterioles and supplying the peritubular capillaries has a relatively high oncotic pressure, favoring reabsorption of fluid from the proximal tubules. If GFR were reduced in the absence of a change in RPF, the *filtration fraction* would fall. Peritubular capillary oncotic pressure would also be reduced, and the tendency of the peritubular vasculature to take up fluid reabsorbed from the proximal tubule would be diminished. Backflux of this fluid is thought to occur through the leaky tight junctions, reducing net reabsorption (Fig. 2.9). This mechanism could only work, however, if GFR changed in the absence of a corresponding change in RPF; if the two changed in parallel, filtration fraction would stay constant, with no change in oncotic pressure.

A second contributory factor to glomerulotubular balance in the proximal tubule could be the filtered loads of glucose and amino acids: if more is filtered, the rates of Na^+-coupled glucose and amino acid reabsorption in the proximal tubule will also increase. It has been proposed that the brush border microvilli of the proximal tubule serve a "mechanosensing" function, transmitting changes in torque (caused by altered tubular flow rates) to the tubular cells' actin cytoskeleton and thereby modulating transporter activity.[24] The mechanisms are unknown, but the release of paracrine mediators such as ATP, dopamine, or Ang II into the lumen fluid may contribute.[25]

Although renal sympathetic nerves and certain hormones can influence reabsorption in the proximal tubule and loop of Henle, under normal conditions, the combined effects of autoregulation and glomerulotubular balance ensure a relatively constant load of glomerular filtrate is delivered to the distal tubule, which exert normal day-to-day control of Na^+ excretion. Evidence indicates important roles for the late DCT[21] and the CNT,[26] in addition to the CD.[22] Aldosterone, secreted from the adrenal cortex, activates mineralocorticoid receptors within CNT cells and in principal cells, leading to generation and activation by phosphorylation of the regulatory protein serum- and glucocorticoid-inducible kinase 1 (SGK1). SGK1 increases the density of apical ENaC (see Fig. 2.6) and enhances the basolateral Na^+,K^+-ATPase. Overall, Na^+ transport across the principal cell stimulated and the maximal depolarization of the apical membrane drives K^+ secretion into the tubular fluid. The electrophysiologic coupling of Na^+ reabsorption to K^+ secretion explains why aldosterone promotes antinatriuresis and kaliuresis. Under conditions of volume depletion, however, aldosterone promotes sodium retention *without* promoting urinary potassium excretion. The mechanism underlying this *aldosterone paradox* relates to the major stimulus for aldosterone production.

During hypovolemia, the renin-angiotensin system drives aldosterone synthesis. The combination of high aldosterone and Ang II engages the WNK4 kinase network and activates NCC in the DCT, promoting potassium-sparing sodium reabsorption, while also inhibiting ROMK channels to limit potassium secretion.[21] Ang II also activates NDBCE and pendrin in the type B IC cell to promote potassium-sparing sodium reabsorption. Conversely, when hyperkalemia is the major stimulus for aldosterone release, then NCC is inhibited, pushing sodium reabsorption downstream where it is coupled to potassium secretion in the principal cell. Even modest increases in plasma potassium inhibit NCC activity, accounting for the natriuretic and blood pressure–lowering effects of high dietary potassium intake.[27]

Mineralocorticoid receptors have equal affinity in vitro for aldosterone and cortisol. The circulating concentrations of cortisol vastly exceed those of aldosterone, and in vivo specificity for aldosterone along the distal nephron is conferred by the enzyme 11β-hydroxysteroid dehydrogenase 2, which inactivates cortisol in the vicinity of the receptor.[28] Mutations in the encoding gene, or inhibition of the enzyme by derivatives of glycyrrhetinic acid (found in licorice), cause hypokalemic hypertension because of excessive and unregulated stimulation of Na^+ transport[29] and salt appetite[30] by cortisol (see also Chapter 49).

COUNTERCURRENT SYSTEM

The loop of Henle generates and maintains the interstitial osmotic gradient from the renal cortex (~290 mOsm/kg) to the tip of the medulla (~1200 mOsm/kg). As indicated in Chapter 1, the loops of Henle of superficial nephrons turn at the junction between outer and inner medulla, whereas those of deep nephrons (long-looped nephrons) penetrate the inner medulla to varying degrees. The loops of Henle as a whole reabsorb approximately 40% of filtered Na^+, mostly in the proximal straight tubule and the thick ascending limb, and approximately 25% of filtered water in the proximal straight tubule and the thin descending limbs of deep nephrons. Evidence suggests that the thin descending limb of superficial nephrons is relatively impermeable to water.[31] Both the thin ascending limb (found only in deep nephrons) and the thick ascending limb are essentially impermeable to water. Both segments reabsorb Na^+. In the thin ascending limb, this is passive. The thick ascending limb operates an active pump-leak system: the basolateral Na^+,K^+-ATPase maintains the electrochemical driving force for passive Na^+ entry from the lumen through the Na^+,K^+,$2Cl^-$ cotransporter (NKCC2) and, to a smaller extent, the NHE3 (Fig. 2.10). NKCC2 is directly inhibited by loop diuretics such as furosemide and bumetanide. Na^+ exits the cell through the Na^+,K^+-ATPase, and Cl^- and K^+ exit via basolateral ion channels, and a K^+-Cl^- cotransporter. K^+ can also recycle back across the apical membrane through ion channels and this sustains operation of NKCC2 because the availability of K^+ is a limiting factor for the transporter (K^+ concentration in tubular fluid being lower than Na^+ and Cl^-). Potassium recycling helps to generate a lumen-positive transepithelial potential difference in the thick ascending limb, which drives additional Na^+ reabsorption through the paracellular pathway; for each Na^+ reabsorbed by the transcellular route, another is reabsorbed paracellularly (see Fig. 2.10). Other cations (K^+, Ca^{2+}, Mg^{2+}) are also reabsorbed by this route. The reabsorption of NaCl along the thick ascending limb in the absence of significant water reabsorption means that the tubular fluid leaving this segment is hypotonic; the thick ascending limb is also known as the *diluting segment* for this reason.

The reabsorption in the thick ascending limb of solute without water generates a "horizontal" osmotic gradient of about 200 mOsm/kg between the tubular fluid and interstitium. This separation is the *single osmotic effect*. The U-shaped arrangement of the loop of Henle, in which flow in the descending limb is opposite to that in the ascending limb, multiplies the single effect to generate a much larger vertical (corticomedullary) osmotic gradient. This process is *countercurrent multiplication* (Fig. 2.11). Fluid entering the descending limb from the proximal tubule is isosmotic (~290 mOsm/kg). On encountering the hypertonicity of the medullary interstitial fluid (caused by NaCl reabsorption in the water-impermeable ascending limb), the fluid in the descending limb comes into rapid osmotic equilibrium, either by solute entry into the descending limb (superficial nephrons) or by water exit by osmosis (deep nephrons). These events, combined with continuing NaCl reabsorption in the ascending limb, result in a progressive increase in medullary osmolality from the corticomedullary junction to the papillary tip. A similar osmotic gradient exists in the thin descending limb, and at any level in the ascending limb, the osmolality of the tubule fluid is approximately 200 mOsm/kg less than in the surrounding tissue. The fluid that exits the loop of Henle has an osmolarity of approximately 100mOsm/kg. Further sodium is reabsorbed as the fluid traverses the distal nephron and CD, allowing for the formation of a very dilute urine (~50 mOsm/kg) if required for fluid balance.

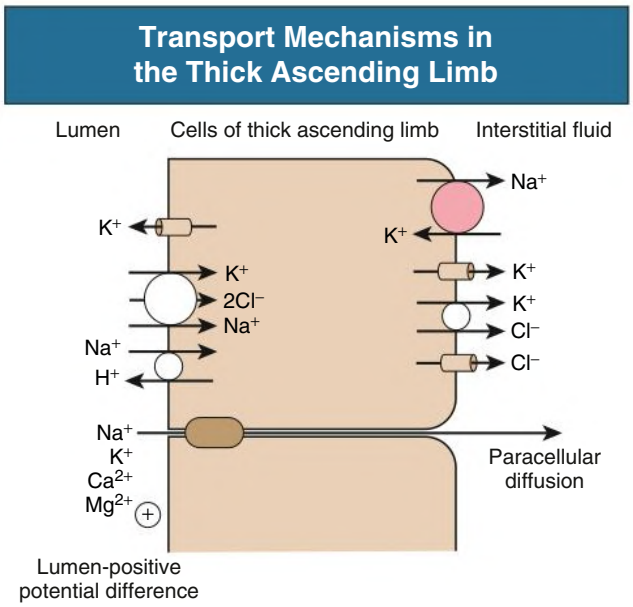

Fig. 2.10 Transport Mechanisms in the Thick Ascending Limb of Henle. The major cellular entry mechanism is the Na^+-K^+-$2Cl^-$ cotransporter. The transepithelial potential difference drives paracellular transport of Na^+, K^+, Ca^{2+}, and Mg^{2+}.

Role of Urea

The thin limbs of the loop of Henle are relatively permeable to urea (ascending more permeable than descending), but the thick ascending limb and beyond are urea-impermeable up to the final section of the inner medullary CD. During antidiuresis, water reabsorption from the CDs concentrates urea, such that in the terminal inner medullary CD there is a large concentration gradient between the luminal fluid and interstitium. This section of the inner medullary CD expresses urea transporters (UT-A1 and UT-A3), allowing passive reabsorption of urea into the inner medullary interstitium. These processes are under the control of vasopressin (AVP, also known as antidiuretic hormone).[32] The interstitial urea exchanges with vasa recta capillaries (see next section) and some urea enters the S_3 segment of the pars recta and the descending and ascending thin limbs; it is then returned to the inner medullary CDs to be reabsorbed. The net result of this urea recycling process is to add urea to the inner medullary interstitium, thereby

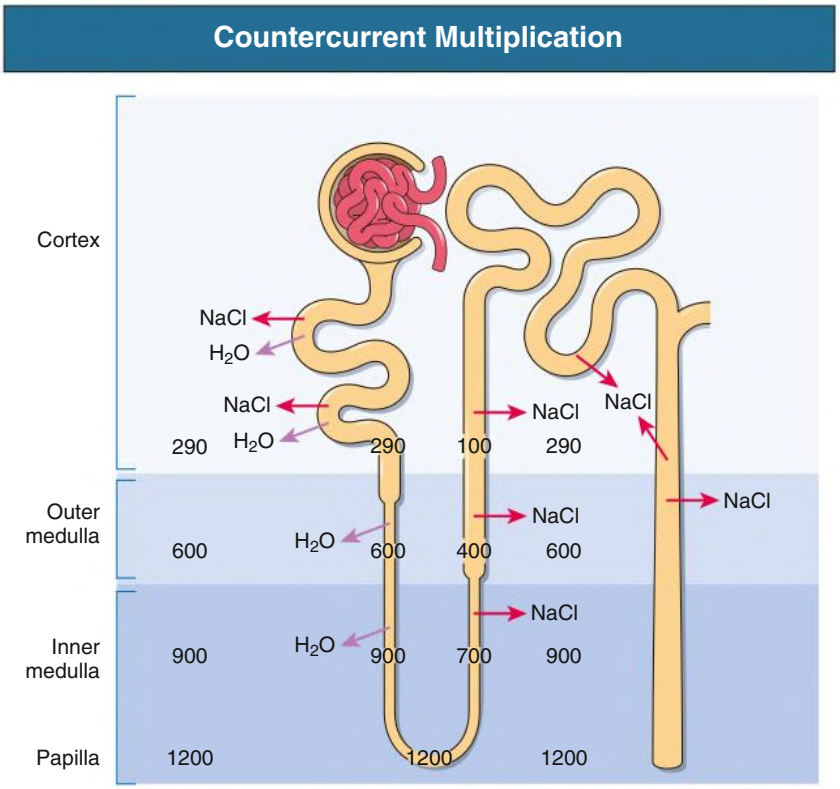

Fig. 2.11 Countercurrent Multiplication by the Loop of Henle. The nephron drawn represents a deep (long-looped) nephron. Figures represent approximate osmolarities (mOsm/kg). Osmotic equilibration occurs in the thin descending limb of Henle, whereas NaCl is reabsorbed in the water-impermeable ascending limb; hypotonic fluid is delivered to the distal tubule. In the absence of vasopressin, this fluid remains hypotonic during its passage through the distal tubule and collecting duct, despite the large osmotic gradient favoring water reabsorption. A large volume of dilute urine is therefore formed. During maximal vasopressin secretion, water is reabsorbed down the osmotic gradient, so that tubular fluid becomes isotonic in the cortical collecting duct and hypertonic in the medullary collecting duct. A small volume of concentrated urine is formed.

increasing interstitial osmolality. The high urea concentration within the medullary CD is balanced by a similarly high urea concentration in the medullary interstitium. This renders urea in the CD osmotically inactive and permits large quantities of urea to be excreted without osmotic diuresis. Moreover, the high urea concentration in the medullary interstitium should also increase osmotic water abstraction from the thin descending limbs of deep nephrons, thus raising the intraluminal Na^+ concentration within the thin descending limbs.

Although until recently this process was thought to drive passive Na^+ reabsorption along the thin ascending limbs, mice with genetic deletion of the urea transporters UT-A1 and UT-A3 have a greatly reduced urea concentration in the inner medullary interstitium but a normal interstitial NaCl gradient.[32] Therefore, the mechanisms responsible for the inner medullary electrolyte gradients are still unclear. It is worth emphasizing, however, that the ultimate driving force for countercurrent multiplication is active Na^+ reabsorption in the thick ascending limb. For this reason, loop diuretics disrupt the osmotic gradient, and genetic mutations in the pathways contributing to efficient Na^+ reabsorption in the thick ascending limb cause salt-wasting Bartter syndrome (see Chapter 49).

Role of the Vasa Recta

The blood supply into the medulla arrives and leaves via the cortex. This U-shaped arrangement of the vasa recta prevents the dissipation of the medullary osmotic gradient by equilibration with the isotonic capillary blood. Solute enters and water leaves the vasa recta as it descends into the medulla, and this is almost entirely offset by the opposite fluxes as the vasa recta ascends back to the cortex and drains into the arcuate vein. This passive process, called *countercurrent exchange* (Fig. 2.12), preserves medullary hypertonicity. Most solutes remain in the interstitium and any water reabsorbed from the collecting duct is swiftly removed, which results in a blood flow rate that is higher in the ascending than in the descending vasa recta.

Renal Medullary Hypoxia

Oxygen also undergoes countercurrent exchange by the medullary capillaries, diffusing from descending to ascending vasa recta and bypassing the deeper regions. This phenomenon, combined with ongoing energy-dependent Na^+ transport in the (outer medullary) thick ascending limb, renders medullary tissue relatively hypoxic. Thus, the partial pressure of oxygen normally decreases from about 50 mm Hg in the cortex to 10 mm Hg in the inner medulla.[33] Medullary cells are adapted to this relatively hypoxic environment, having a higher capacity for glycolysis than cortical cells. Moreover, a number of *heat shock proteins* are expressed in the medulla, which assist cell survival by restoring damaged proteins and by inhibiting apoptosis.[33]

The degree of medullary hypoxia depends on the balance between medullary blood flow, influenced by contractile *pericytes* that surround the descending vasa recta, and oxygen consumption in the thick ascending limb (e.g., inhibition of NKCC2 by furosemide increases medullary oxygenation). In health, this balance is modulated by a variety of autocrine/paracrine agents (e.g., NO, eicosanoids, ATP, adenosine; see later

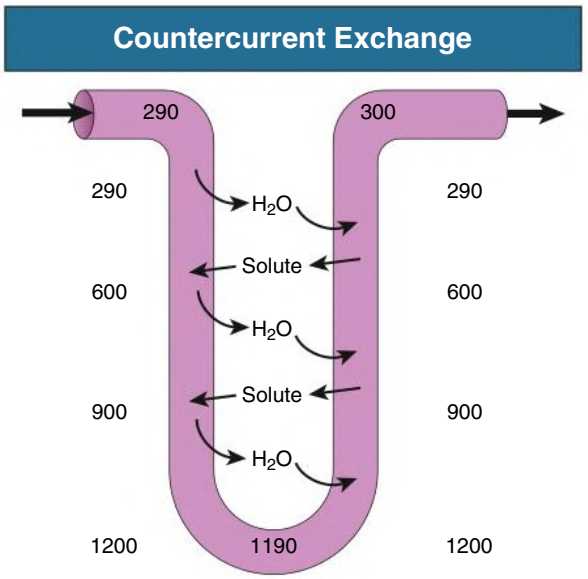

Fig. 2.12 Countercurrent Exchange by the Vasa Recta. Figures represent approximate osmolarities (mOsm/kg). The vasa recta capillary walls are highly permeable, but the U-shaped arrangement of the vessels minimizes the dissipation of the medullary osmotic gradient. Nevertheless, because equilibration across the capillary walls is not instantaneous, a certain amount of solute is removed from the interstitium.

discussion) and by renal nerves, which can alter medullary oxygenation by simultaneously regulating pericyte contraction and thick ascending limb Na^+ transport. Some cases of radiocontrast-induced nephropathy result from a disturbance in the balance between oxygen supply and demand, with consequent hypoxic medullary injury in which the normal cellular adaptations are overwhelmed, with subsequent apoptotic and necrotic cell death.

VASOPRESSIN (ANTIDIURETIC HORMONE) AND WATER REABSORPTION

Vasopressin is a nonapeptide synthesized in specialized neurons of the supraoptic and paraventricular nuclei. Vasopressin is transported from these nuclei to the posterior pituitary and released in response to increases in plasma osmolality and decreases in blood pressure. Osmoreceptors are found in the hypothalamus, and there is also input to this region from arterial baroreceptors and atrial stretch receptors. The actions of vasopressin are mediated by three receptor subtypes: V_{1a}, V_{1b}, and V_2. The V_{1a} receptors are found in vascular smooth muscle and are coupled to the phosphoinositol pathway; they cause an increase in intracellular Ca^{2+} resulting in contraction. V_{1a} receptors also have been identified in the apical membrane of several nephron segments; activation by luminal vasopressin can influence Na^+ transport in these segments. V_{1b} receptors are found in the anterior pituitary, where vasopressin modulates adrenocorticotropic hormone release. V_2 receptors are found in the basolateral membrane of principal cells in the late distal tubule and the whole length of the CD; they are coupled by a G_s protein to cyclic adenosine monophosphate generation, which ultimately leads to the insertion of aquaporin 2 (AQP2) water channels into the apical membrane of this otherwise water-impermeable segment (Fig. 2.13). In the X-linked form of nephrogenic diabetes insipidus, the most common inherited form, the V_2 receptor is defective.[34]

Several aquaporins have been identified in the kidney.[35] AQP1 is found in apical and basolateral membranes of all proximal tubules and of thin descending limbs of long-looped nephrons, conferring high basal water permeability to these segments. AQP3 is constitutively expressed in the basolateral membrane of CNT cells and cortical and outer medullary principal cells. AQP4 is constitutively expressed in the basolateral membrane of outer medullary principal cells and inner medullary CD cells. The variable water permeability of the late distal tubule and CD is determined by AQP2. Acute vasopressin release causes shuttling of AQP2 from intracellular vesicles to the apical membrane, whereas chronically raised vasopressin levels increase transcription and translation of the gene encoding AQP2. Apical insertion of AQP2 allows reabsorption of water, driven by the high interstitial osmolality. Vasopressin also contributes directly to the gradient by stimulating Na^+ reabsorption in the thick ascending limb and urea reabsorption through the UT-A1 and UT-A3 transporters in the inner medullary CD. In the (rare) autosomal recessive and (even rarer) autosomal dominant forms of nephrogenic diabetes insipidus, AQP2 is abnormal and/or fails to translocate to the apical membrane.[34]

More frequently, defects in AQP2 shuttling contribute to the urine-concentrating defects associated with both hypokalemia and hypercalcemia. With chronic hypokalemia, AQP2 expression in the CD is reduced, possibly reflecting the generalized suppression of proteins central to urine concentration[36] and a reduction in the medullary osmotic gradient. With hypercalcemia, an elevated concentration of Ca^{2+} in tubular fluid activates the calcium-sensing receptor in the apical membrane of the principal cell, preventing insertion of AQP2. This is thought to be a protective mechanism to hinder kidney stone formation.[37] In addition, stimulation of the calcium receptor in the basolateral membrane of the thick ascending limb (a receptor similar to that in the parathyroid glands) reduces transcellular solute flux by inhibiting NKCC2 and ROMK channels and also by direct inhibition of paracellular permeability.[37] Overall, this reduces the medullary osmotic gradient for water reabsorption.

INTEGRATED CONTROL OF KIDNEY FUNCTION

The kidneys regulate blood volume by controlling the sodium content of the body and thus the *effective circulating volume,* a conceptual volume reflecting the degree of fullness of the vasculature. Chapter 8 details the regulation of effective circulating volume, and this chapter now introduces some of the key mediator systems. The list is not exhaustive, and it is important to recognize that these systems are not static and do not operate in isolation. Rather, kidney salt and water transport (and indeed blood pressure) has circadian rhythmicity[38] and is influenced by a dynamic web of interlocking control systems operating at whole-body and local, intrarenal levels.

Pressure Natriuresis

Acute increases in arterial blood pressure induce natriuresis. This is the *pressure natriuresis* phenomenon and is considered important for long-term stability of effective circulating volume.[25] Pressure natriuresis occurs because autoregulation of RBF is not perfect, and a rise in renal perfusion pressure increases flow in the medullary vasa recta. Kidney volume is constrained by the renal capsule: elevated flow in the medulla causes a proportionate rise in *renal interstitial hydrostatic pressure* (RIHP), which reduces net reabsorption in the proximal tubule by increasing paracellular backflux through the tight junctions of the tubular wall (see Fig. 2.9) and by inactivating apical membrane sodium transport proteins. Increased RIHP also stimulates the production of nitric oxide (NO) and ATP to inhibit sodium reabsorption in the thick limb of Henle and distal nephron.[39]

Another renal action of NO results from the presence of inducible (type II) nitric oxide synthase (iNOS) in glomerular mesangial cells. Local NO production counteracts the mesangial contractile response

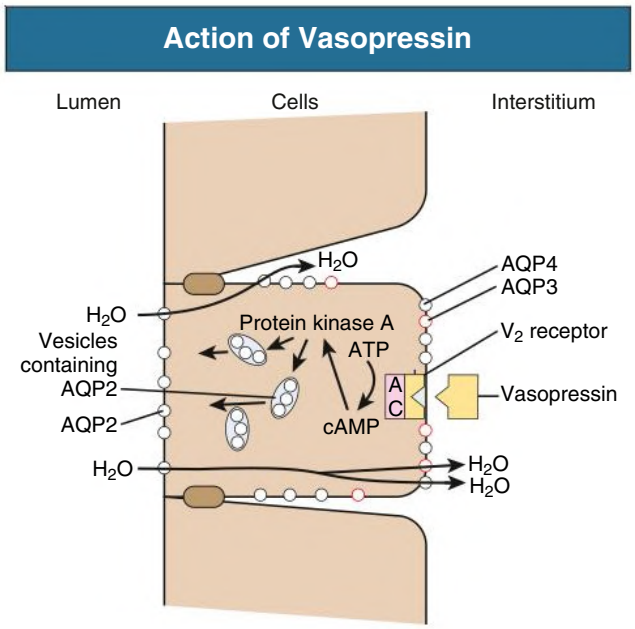

Fig. 2.13 Mechanism of Action of Vasopressin (Antidiuretic Hormone). Vasopressin binds to V_2 receptors on the basolateral membrane of collecting duct principal cells and increases intracellular cyclic adenosine monophosphate (cAMP) production, causing insertion of preformed aquaporin 2 (AQP2) water channels into the apical membrane through intermediate reactions involving protein kinase A. The water permeability of the basolateral membrane, which contains aquaporins 3 and 4, is permanently high. Therefore, vasopressin secretion allows transcellular movement of water from lumen to interstitium. *AC,* Adenylate cyclase; *ATP,* adenosine triphosphate.

to agonists such as Ang II and endothelin (see later discussion). Furthermore, NO may contribute to the regulation of medullary blood flow. Locally synthesized NO offsets the vasoconstrictor effects of other agents on the pericytes of the descending vasa recta, and it reduces Na^+ reabsorption in the thick ascending limb; both actions help protect the renal medulla from hypoxia.

Renal Sympathetic Nerves

Reductions in arterial pressure and/or central venous pressure suppress afferent signaling from arterial baroreceptors and atrial volume receptors, eliciting a reflex increase in renal sympathetic nervous discharge. This reduces urinary Na^+ excretion in at least three ways: (1) constriction of afferent and efferent glomerular arterioles (predominantly afferent), directly reducing RBF and GFR, and indirectly reducing RIHP; (2) direct stimulation of Na^+ reabsorption in the proximal tubule and the thick ascending limb of the Henle loop; and (3) stimulation of renin secretion by afferent arteriolar cells (see later discussion). Renal sympathetic overactivity has long been associated with Na^+ retention and experimental hypertension. The Symplicity-HTN trials initially indicated that bilateral sympathetic efferent denervation caused long-lasting reductions in blood pressure in patients with resistant hypertension. However, this early promise from small studies was not supported in a larger single-blind, sham-controlled trial, and enthusiasm for renal denervation to treat resistant hypertension waned. With advances in technology and refined study design, however, clinical trials such as SPYRAL-pivotal have shown reproducible and sustained reductions in ambulatory blood pressure, establishing confidence in the underlying concept. The next step is to identify those patients for whom renal denervation is clinically indicated and effective.

Renin-Angiotensin-Aldosterone System

The renin-angiotensin-aldosterone system (RAAS) is central to the control of extracellular fluid volume (ECFV) and blood pressure. Renin is synthesized and stored in specialized afferent arteriolar cells that form part of the juxtaglomerular apparatus and is released into the circulation in response to (1) increased renal sympathetic nervous discharge, (2) reduced stretch of the afferent arteriole after a reduction in renal perfusion pressure, and (3) reduced delivery of NaCl to the macula densa region of the nephron (see Fig. 2.4).

Renin catalyzes the production of the decapeptide Ang I from circulating angiotensinogen (synthesized in the liver). Ang I is converted by angiotensin-converting enzyme (ACE) to the octapeptide Ang II, which acts via AT1 receptors to regulate ECFV and blood pressure by:

- Inducing arteriolar vasoconstriction, including renal afferent and (particularly) efferent arterioles, thereby increasing arterial pressure but reducing RBF. The tendency of P_{gc} to increase is offset by Ang II–induced mesangial cell contraction, and reduced K_f and the overall effect on the GFR is unpredictable.
- Directly stimulating sodium reabsorption in the proximal tubule and distal tubule thiazide-sensitive NaCl cotransport.[27]
- Stimulating aldosterone secretion from the zona glomerulosa of adrenal cortex. Aldosterone stimulates distal nephron sodium reabsorption.

Many tissues, including kidney, express a homologue of ACE called ACE2. This membrane-bound protein converts Ang II to Ang(1-7), thereby regulating local Ang II bioactivity. Ang(1-7) also activates the Mas receptor, causing vasodilation, natriuresis, and diuresis. ACE2 operates locally as a RAAS counterregulatory system and the balance between these two pathways determines the net effect on fluid-volume and blood pressure. ACE2 was also identified as a route for SARS-COV2 entry into cells.

Eicosanoids

Eicosanoids are a family of metabolites of arachidonic acid (AA) produced enzymatically by three systems: *cyclooxygenase,* with two isoforms, COX-1 and COX-2, both expressed in the kidney; *cytochrome P-450* (CYP-450); and *lipoxygenase.* The lipoxygenase system is activated (in leukocytes, mast cells, and macrophages) during inflammation and injury and is not considered further here.

The major renal eicosanoids produced by the COX system are the prostaglandins E_2 (PGE_2) and I_2 (PGI_2), both of which are renal vasodilators and buffer the effects of renal vasoconstrictor agents (e.g., Ang II, norepinephrine) and the vasoconstrictor thromboxane A_2. PGE_2 and PGI_2 normally have minimal effects on renal hemodynamics, but during stressful situations such as hypovolemia, they help protect the kidney from excessive functional changes. Consequently, NSAIDs, which are COX inhibitors, can cause significant falls in GFR. PGE_2 also has tubular effects, inhibiting Na^+ reabsorption in the thick ascending limb of the Henle loop and both Na^+ and water reabsorption in the CD.[40] The action of PGE_2 in the thick ascending limb, together with a dilator effect on vasa recta pericytes, is another paracrine regulatory mechanism that helps protect the renal medulla from hypoxia. This may explain why inhibition of COX-2 can reduce medullary blood flow and cause apoptosis of medullary interstitial cells.

The metabolism of AA by renal CYP-450 enzymes yields epoxyeicosatrienoic acids (EETs), 20-hydroxyeicosatetraenoic acid (20-HETE), and dihydroxyeicosatrienoic acids (DHETs). These compounds appear to have multiple autocrine/paracrine/second messenger effects on the renal vasculature and tubules still to be fully unraveled. As with prostaglandins, EETs are vasodilator agents, whereas 20-HETE is a potent renal arteriolar constrictor and may be involved in the vasoconstrictor effect of Ang II and of the TGF mechanism. 20-HETE also constricts

vasa recta pericytes and may be involved in the control of medullary blood flow. Some evidence suggests that locally produced 20-HETE and EETs can inhibit sodium reabsorption in the proximal tubule and thick ascending limb. Indeed, CYP-450 metabolites of AA may contribute to the reduced proximal tubular reabsorption seen in pressure natriuresis.[41]

COX-2 is present in macula densa cells and has a critical role in the release of renin from juxtaglomerular cells (granular cells) in response to reduced NaCl delivery to the macula densa.[41] A low-sodium diet increases COX-2 expression in the macula densa and simultaneously increases renin secretion; the renin response is virtually abolished in COX-2 knockout mice or during pharmacologic inhibition of COX-2. Therefore, it is likely that the low renin observed during administration of NSAIDs is largely a consequence of COX-2 inhibition. In addition to COX-2, the enzyme PGE synthase is expressed in macula densa cells, and the principal COX-2 product responsible for enhancing renin secretion is PGE_2, acting on specific receptors identified in juxtaglomerular cells. It is not clear whether PGI_2 is also synthesized in macula densa cells. nNOS (type I isomer) is also present in macula densa cells and produces NO that blunts TGF. NO also has a permissive role in renin secretion, although the mechanism is not understood. The increase in macula densa COX-2 expression induced by a low-sodium diet is attenuated during administration of selective nNOS inhibitors, which has led to speculation that NO is responsible for the increase in COX-2 activity and the resulting increase in juxtaglomerular renin secretion. Fig. 2.14 shows the established and proposed roles of COX-2 and nNOS in the macula densa.

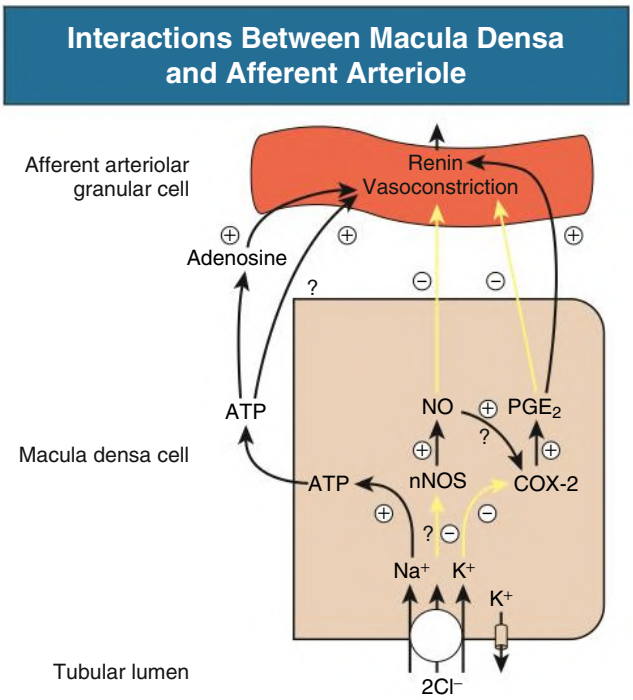

Fig. 2.14 Interactions Between Macula Densa and Afferent Arteriole: Proposed Mediators of Renin Secretion and Tubuloglomerular Feedback. Both cyclooxygenase-2 (COX-2) and neuronal nitric oxide synthase (nNOS) enzyme systems are present in macula densa cells. Increased NaCl delivery to the macula densa stimulates NaCl entry into the cells through the Na^+-K^+-$2Cl^-$ cotransporter. This causes afferent arteriolar constriction through adenosine or adenosine triphosphate (ATP) and also inhibits COX-2 activity; the latter effect might be mediated partly through inhibition of (nNOS-mediated) nitric oxide (NO) production. Generation of prostaglandin E_2 (PGE_2) by COX-2 stimulates renin release. PGE_2 also modulates vasoconstriction, as does NO.

Atrial Natriuretic Peptide

If blood volume increases significantly, the resulting atrial stretch stimulates the release of atrial natriuretic peptide (ANP) from atrial myocytes. This hormone increases sodium excretion by suppressing renin and aldosterone release and through a direct inhibitory effect on sodium reabsorption in the medullary CD. ANP may also increase GFR because high doses cause afferent arteriolar vasodilation and mesangial cell relaxation (thus increasing K_f; see Table 2.1).

Endothelins

The kidney is a rich source of endothelins, predominantly paracrine peptides acting via ET_A and ET_B receptors: endothelin-1 (ET-1) is the major isoform.[42] ETA activation causes sustained vasoconstriction and mesangial contraction, meaning that ET-1 can significantly reduce RBF and GFR (see Table 2.1). ET_A also reduces medullary blood flow and polarizes resident immune cells to a proinflammatory phenotype. In combination, these effects of ET_A activation explain why chronically elevated ET-1 may contribute to kidney diseases. Activation of ET_B inhibits ENaC-mediated sodium reabsorption, causing natriuresis, and mice with CD-specific knockout of ET_B receptors exhibit salt-sensitive hypertension. There is mounting evidence that NO mediates the natriuretic and diuretic effects of medullary ET_B stimulation,[42] highlighting the potential importance of ET-1/NO interactions in the control of Na^+ and water excretion. ET_A antagonists reduce albumin excretion in diabetic kidney disease[43] and are being investigated in other forms of kidney disease with proteinuria. Selective ET_A antagonists were thought to avoid the sodium/water retention and edema seen in trials with nonselective endothelin antagonists; however, they still seem to show this effect, especially at higher doses, suggesting that both ET_B and ET_A play a role in collecting duct sodium excretion.[44]

ATP and Other Metabolic Intermediates

Paracrine signaling is firmly established as a key aspect of renal regulation. Multiple systems form an interlocking network of control that can rapidly adjust hemodynamic and tubular function; such systems support and interact with classical endocrine and neural control mechanisms. One of the most powerful paracrine regulators are the extracellular purines, ATP, adenosine diphosphate (ADP) and adenosine that alter cell function via specific cell surface receptors.[12] *Purinoceptors* are subdivided into P1 and P2 receptors. P1 receptors are responsive to adenosine and are more usually known as *adenosine receptors* (A_1, A_{2a}, A_{2b}, and A_3). P2 receptors are responsive to nucleotides (e.g., ATP, ADP) and are further subdivided into P2X (ligand-gated ion channel) and P2Y (G-protein coupled) receptors, each category having a number of subtypes.[45] As indicated earlier, A_1 and $P2X_1$ receptors are found in afferent arterioles and mediate vasoconstriction. Purinoceptors are also found in the apical and basolateral membranes of renal tubular cells. Stimulation of A_1 receptors enhances proximal tubular reabsorption and inhibits CD Na^+ reabsorption, whereas stimulation of P2 receptors generally has an inhibitory effect on tubular transport.[45] Thus, luminally applied nucleotides, acting on a variety of P2 receptor subtypes, can inhibit Na^+ reabsorption in the proximal tubule, distal tubule, and CD, and stimulation of $P2Y_2$ receptors in the CD inhibits vasopressin-sensitive water reabsorption.

Other metabolic intermediates regulate kidney function, and our understanding of their roles often relies on assigning a cognate ligand to an "orphan" G-protein coupled receptor. The Kreb's cycle intermediate succinate stimulates renin release via GPR91, which may contribute to RAAS activation in type 2 diabetes.[46] Lactate, which accumulates in the kidney after ischemic injury, is the ligand for GPR81, which is

expressed in the renal vasculature. Activation of GPR81 stimulates ET-1 release, causing renal vasoconstriction.[47]

Extracellular Vesicles and other Luminal Factors

All kidney cells release vesicles (including exosomes) and contain proteins, mRNA, and microRNA specific to their cell of origin and have generated much interest as a reservoir for kidney disease biomarker discovery. Vesicles released from one renal cell can be carried in the urine and taken up under hormonal control by downstream cells, influencing their function.[48] Vesicles from distant organs, such as the liver and heart, are also able to transfer microRNA to kidney cells in vivo, but the full implications of this novel organ-to-organ communication system for health and disease are still unknown.[49] Finally, recent studies have also shown the importance and potential clinical relevance of enzymes (serine proteases) in urine that can activate ENaC and thereby affect Na^+ reabsorption, particularly in proteinuric diseases such as the nephrotic syndrome when plasma proteases can be filtered and enter the glomerular filtrate.[50]

SELF-ASSESSMENT QUESTIONS

1. Filtration at the glomerulus is a passive process. Which of the following statements are *true?*
   - **A.** Albumin is too large to be freely filtered.
   - **B.** Albumin is not filtered because the glomerular barrier has a net positive charge.
   - **C.** Hydrostatic pressure in the glomerular capillaries is the only force influencing filtration rate.
   - **D.** Dilation of the afferent arteriole, but not the efferent arteriole, can increase filtration rate.
   - **E.** Mesangial cells do not influence filtration rate.
2. Fanconi syndrome is a disorder of the proximal tubule. Patients can present with glycosuria, polyuria, hypercalciuria, hyperphosphaturia, and low-molecular-weight proteinuria. These features can be explained by which of the following actions of the proximal tubule?
   - **A.** It reabsorbs about 100% of the filtered glucose.
   - **B.** It reabsorbs approximately 65% of the filtered water because of a large transepithelial osmotic gradient.
   - **C.** It actively reabsorbs calcium through Ca^{2+}-ATPase in the apical membrane.
   - **D.** It secretes phosphate through the organic anion transporter system.
   - **E.** It is a tight epithelium, impermeable to paracellular movement of proteins.
3. The corticomedullary osmotic gradient is required for urine concentration. Which of the following would diminish this gradient?
   - **A.** Increased circulating vasopressin.
   - **B.** Increased blood flow through the renal medulla.
   - **C.** Activation of the sympathetic nervous system.
   - **D.** Activation of the renin-angiotensin-aldosterone system.
   - **E.** Increased urea recycling through the collecting duct system.

Assessment of Glomerular Filtration Rate

Lesley A. Inker, Andrew S. Levey

The level of glomerular filtration rate (GFR) is widely accepted as the best overall index of kidney function in health and disease. GFR decline is correlated with decline in other excretory functions of the kidney, such as tubular reabsorption and secretion, and with decline in endocrine and metabolic functions of the kidney. Decreased GFR is strongly associated with complications of acute kidney diseases and disorders (AKD) and chronic kidney disease (CKD), and decreased GFR is one criterion in the definition and staging of AKD and CKD. GFR estimating equations are now recommended for routine use in clinical practice, and estimated GFR (eGFR) is routinely reported when serum creatinine is measured.

GLOMERULAR FILTRATION RATE

GFR is the product of the average filtration rate of each nephron, the filtering unit of the kidneys, multiplied by the number of nephrons in both kidneys. The normal level for GFR is approximately 130 mL/min/1.73 m^2 for men and 120 mL/min/1.73 m^2 for women, with considerable variation among individuals according to age, sex, body size, physical activity, diet, blood pressure, glycemia, pharmacotherapy, and physiologic states such as pregnancy. To standardize GFR for differences in kidney size, which is proportional to body size, GFR is indexed for body surface area (BSA), computed from height and weight, and expressed per 1.73 m^2 BSA. Even after adjustment for BSA, GFR is approximately 8% higher in young men than in women and declines with age; the mean rate of decline is approximately 0.75 mL/min/yr after 40 years of age, but the variation is wide and the sources of variation are poorly understood. During pregnancy, GFR increases by about 50% in the first trimester and returns to normal immediately after delivery. GFR has a diurnal variation and is 10% lower at midnight compared with the afternoon. In an individual, GFR is relatively constant over short intervals of time but varies considerably among people, even after adjustment for the known variables.

Reductions in GFR may result from reduced nephron number from prematurity, nephrectomy or kidney disease, or reduced single-nephron (SN) GFR from physiologic or hemodynamic alterations. An increase in SNGFR caused by increased glomerular capillary pressure or glomerular hypertrophy can compensate for a decrease in nephron number; therefore the level of GFR may not reflect the loss of nephrons. As a result, there may be substantial kidney damage before GFR decreases.

MEASUREMENT AND ESTIMATION OF THE GLOMERULAR FILTRATION RATE

The GFR cannot be measured directly in humans. Instead, it is assessed from clearance measurements or serum levels of filtration markers, which are exogenous or endogenous solutes that are mainly eliminated by glomerular filtration. Both measured GFR (mGFR) and eGFR are associated with systematic and random error (bias and imprecision, respectively) in their determination and thus may differ from the "true GFR."[1]

The classic method for GFR measurement described by Homer Smith is the urinary clearance of inulin and remains the reference (gold standard) against which other clearance methods and filtration markers are evaluated.[2] However, this technique is cumbersome in practice. Therefore many alternative clearance methods and filtration markers are used in clinical centers and as research tools (Table 3.1).[3] As discussed later, newer methods to measure GFR using plasma clearance of fluorescent tracer agents have been developed to shorten the measurement protocol, which might enable point-of-care GFR determination.

The GFR is generally estimated from serum levels of endogenous filtration markers to simplify GFR assessment without requiring administration of exogenous filtration markers and without performing clearance measurements.[4] The principles of GFR estimation are similar in adults and children.

CLEARANCE MEASUREMENTS

Concept of Clearance

Clearance of a substance is defined as the volume of plasma cleared of a marker per unit of time. The clearance of substance x (C_x) can be calculated as $C_x = A_x/P_x$, where A_x is the rate of elimination of x from the plasma, P_x is the average plasma concentration, and C_x is expressed in units of volume per time. Clearance does not represent an actual volume; rather, it is a virtual volume of plasma that is completely cleared of the substance per unit of time. The value for clearance is related to the efficiency of elimination: the greater the efficiency of elimination, the higher the clearance. Clearance of substance x is the sum of the urinary (renal) and nonurinary (extrarenal) clearance; for substances that are eliminated by both renal and extrarenal routes, plasma clearance exceeds urinary clearance. By convention we refer to concentration of the substance in plasma when discussing physiologic principles and serum when discussing

TABLE 3.1 Exogenous Filtration Markers for Estimation of Glomerular Filtration Rate

Marker	Clearance Method	Comments
Inulin	Urinary or plasma clearance during continuous IV infusion	Gold standard.
Iothalamate	Urinary or plasma clearance after bolus IV injection. Urinary clearance after subcutaneous bolus injection	Can be administered as radioactive compound with iodine 125 (^{125}I) as the tracer or in nonradioactive form, with assay using HPLC or MS methods in plasma and whole blood. In radioactive form, potential problem of thyroid uptake of ^{125}I. Iothalamate is secreted, leading to overestimation of GFR.
^{99m}Tc-DTPA	Urinary or plasma clearance after bolus IV injection	Dissociation of ^{99m}Tc leads to plasma protein binding and underestimation of GFR.
^{51}Cr-EDTA	Urinary or plasma clearance after bolus IV injection	10% lower clearance than inulin.
Iohexol	Plasma clearance after bolus IV injection	Low incidence of adverse effects; assay using HPLC or MS methods in plasma and whole blood. Research studies have used capillary blood spots. Iohexol may have extrarenal clearance, leading to overestimation of GFR.
Novel engineered markers conjugated to fluorescein[a]	Plasma clearance or transdermal fluorescence after bolus IV injection	Requires less time than plasma clearance of filtration marker alone. Neither are FDA approved for clinical use as of yet. Initial studies in small samples show strong correlation with iohexol plasma clearance.

[a]The two novel markers include relmapirazin (Lumitrace), a novel agent that has been engineered to not interact with the body and be excreted by the kidney, and visible fluorescent injectate (VFI), which consists of a 150-kDa rhodamine derivative, used to assess plasma volume, and a 5-kDa fluorescein carboxymethylated dextran, used to assess GFR.

^{51}*Cr-EDTA,* Chromium 51–labeled ethylenediaminetetraacetic acid; *GFR,* glomerular filtration rate; *HPLC,* high-performance liquid chromatography; *IV,* intravenous; *MS,* mass spectrophotometric; ^{99m}*Tc-DTPA,* technetium 99m–labeled diethylenetriaminepentaacetic acid.

clinical measures. In practice, laboratory measurements of markers of glomerular filtration are similar in plasma and serum and are generally referred to as serum concentrations.

Urinary Clearance

The rate of urinary excretion of substance *x* can be calculated as the product of the urinary flow rate (V) and the urinary concentration (U_x). Therefore urinary clearance is defined as follows:

$$C_x = (U_x \times V)/P_x$$

The rate of urinary excretion of a substance depends on the rates of filtration, tubular secretion, and tubular reabsorption. Substances that are filtered but not secreted or reabsorbed by the tubules are ideal filtration markers because their urinary clearance can be used as a measure of GFR. For substances that are filtered and secreted, urinary clearance exceeds GFR, and for substances that are filtered and reabsorbed, urinary clearance is less than GFR.

Measurement of urinary clearance requires a timed urine collection for measurement of urine flow rate, as well as urine and plasma concentrations of the filtration marker. The classic protocol of Smith[2] used a continuous intravenous infusion to achieve a steady state and bladder catheterization with multiple timed urine collections. Alternative protocols to assess urinary clearance have been validated, including bolus intravenous or subcutaneous administration rather than continuous intravenous infusion and spontaneous bladder emptying rather than bladder catheterization.[3] Bolus administration of the marker results in declining plasma levels of the filtration markers during the clearance measurement, which may cause errors in determining the average plasma concentration during the clearance measurement.

Plasma Clearance

Measurement of plasma clearance avoids the need for a timed urine collection. GFR is calculated from plasma clearance (C_x) after bolus intravenous administration of an exogenous filtration marker, with the clearance (C_x) computed from the amount of the marker administered (A_x) divided by the average plasma concentration (P_x), which can be computed from the area under the curve of plasma concentration versus time.

$$C_x = A_x/P_x$$

The decline in the plasma level is secondary to the immediate disappearance of the marker from the plasma into its volume of distribution (fast component) and to renal excretion (slow component). Plasma clearance is best estimated by use of a two-compartment model that requires blood sampling early (usually two or three time points until 60 minutes) and late (one to three time points from 120 minutes onward).[5] Novel methods are under investigation to shorten the time required for clearance measurements.[6,7] As with urinary clearance, plasma clearance of a substance depends on filtration, tubular secretion, and tubular reabsorption, but, in addition, extrarenal elimination and the time course for equilibration of the filtration marker between plasma and its volume of distribution. Edematous conditions prolong the distribution from plasma to extracellular fluid and may cause error in GFR. Extrarenal elimination has been demonstrated for several filtration markers.

Accuracy of Clearance Measurements

Sources of errors in measuring GFR include biologic variation in GFR, "nonideal" handling of the filtration marker by the kidney (incomplete filtration, nonzero tubular reabsorption or secretion), measurement error in the serum or urine assays for filtration markers, and measurement error in serum or urine collections. By definition, the classic method of Smith is unbiased, but it may be imprecise. The coefficient of variation (CV) for repeated measurements in individuals using this method is approximately 7%. For other procedures, the smallest reported within-person CVs for repeated measures on different days range from approximately 5% to 15%, with larger values for urinary clearance than for plasma clearances. For a measurement method without bias compared with true GFR, a CV of 10% is equivalent to approximately 90% of measures being within 15% of true GFR (P_{15} of 90%).

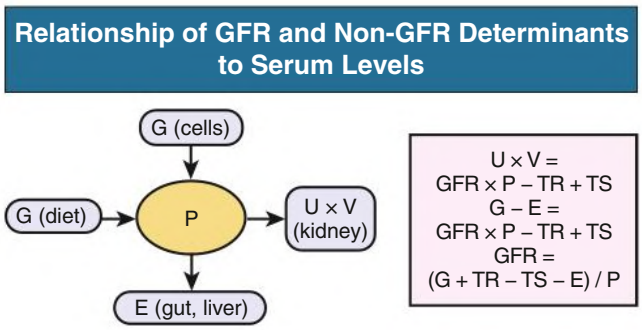

Fig. 3.1 Relationship of GFR and non-GFR Determinants to Serum Levels. *G,* Generation; *GFR,* glomerular filtration rate; *E,* extrarenal elimination; *P,* plasma; *TR,* tubular reabsorption; *TS,* tubular secretion. (Modified from Levey AS, Inker LA, Coresh J. GFR estimation: from physiology to public health. *Am J Kidney Dis.* 2014;63[5]:820-834.)

ESTIMATION OF THE GLOMERULAR FILTRATION RATE

Fig. 3.1 shows the relationship of plasma concentration of substance *x* to its generation (G_x) by cells and dietary intake, urinary excretion ($U_x \times V$), and extrarenal elimination (E_x) by gut and liver. The plasma level is related to the reciprocal of the level of GFR, but it is also influenced by generation, tubular secretion and reabsorption, and extrarenal elimination, collectively termed *non-GFR determinants* of the plasma level.[4]

In the steady state, a constant plasma level of substance *x* is maintained because the rate of generation is equal to the sum of the rates of urinary excretion and extrarenal elimination. Estimating equations incorporate demographic and clinical variables as surrogates for the non-GFR determinants and provide a more accurate estimate of GFR than the reciprocal of the plasma level alone. Most GFR estimating equations have been developed using linear regression to relate observed values of mGFR and serum concentration of the filtration marker, modified by demographic or clinical variables. Another method, as exemplified by the Full Age Spectrum (FAS) equations (see below), is based on hypothetical relationships based on assumptions about age- and sex-adjusted normal values for endogenous filtration markers, age-adjusted normal values for mGFR, and reciprocal changes in mGFR for deviations in observed filtration marker concentrations.[8] Recently, equations have been developed using some features of both methods.

Irrespective of the method for equation development, eGFR in an individual may differ from mGFR if a discrepancy exists between the true and average values of the surrogates for the non-GFR determinants of the filtration marker. Other sources of errors include measurement error in the filtration marker (e.g., failure to calibrate assay for filtration marker to assay used in development of equation), measurement error in mGFR method used in development of the equation, and regression to the mean. In principle, the absolute magnitude of these errors is likely to be greater at higher values for GFR, although such errors may be more clinically significant at lower mGFR. Accuracy of eGFR, as assessed as the percent of eGFR within 30% of mGFR (P_{30}) of 80% to 90%, is generally considered adequate for many clinical circumstances; P_{30} greater than 90% would be optimal.

For application to general populations, GFR estimating equations should be developed and validated in diverse populations including a wide range in age, race-ethnicity, and clinical conditions. To facilitate best practices and communication among patients, providers, and public, a single equation should be used for each filtration marker or combination of filtration markers, and clinical laboratories should automatically report eGFR whenever the filtration marker is measured.

Filtration Markers

Solutes with molecular weight less than approximately 20,000 Da and not bound to plasma proteins are freely filtered by the glomeruli and are candidate filtration markers.

Exogenous Filtration Markers

Iothalamate, iohexol, ethylenediaminetetraacetic acid, and diethylenetriaminepentaacetic acid, often chelated to radioisotopes for ease of detection, are commonly used alternatives to inulin (see Table 3.1).[3] Deviations from ideal behavior of the filtration marker can be inferred from differences from inulin clearance during simultaneous clearance measurements. The most common methods used in the United States are urinary clearance of iothalamate after subcutaneous bolus administration and plasma clearance of iohexol after intravenous bolus administration.[9] Of note, the doses of iothalamate and iohexol that are used to measure GFR are far below the doses used for contrast imaging that have been associated with kidney toxicity and acute kidney injury. The challenge with both methods is assay of the exogenous marker using high performance liquid chromatography for iohexol in plasma samples or capillary blood spots, ^{125}I-labeling for iothalamate, or mass spectroscopy (for both).[10]

Endogenous Filtration Markers

Endogenous filtration markers are substances generated in the body at a relatively constant rate and eliminated largely by glomerular filtration. The plasma level correlates highly with mGFR after accounting for the non-GFR determinants. Currently identified endogenous filtration markers include metabolites (such as creatinine and urea) and low-molecular-weight plasma proteins (such as cystatin C) (Table 3.2). Filtered metabolites may undergo reabsorption or secretion, which may be assessed by comparing their urinary clearance to urinary clearance of exogenous filtration markers. By contrast, filtered plasma proteins are reabsorbed and degraded within the tubule with minimal appearance in the urine. For metabolites excreted in the urine, urinary clearance can be computed from a timed urine collection and a single measurement of serum concentration. If the serum concentration is not constant during the urine collection, as in acute kidney disease or when residual kidney function is assessed in patients undergoing intermittent dialysis, it is necessary to obtain additional blood samples during the urine collection to estimate the average serum concentration.

CREATININE

Metabolism and Excretion

Creatinine is a 113 Da end product of muscle catabolism. Advantages of creatinine include its ease of measurement and the low cost and widespread availability of assays (see Table 3.2). Disadvantages include the large number of conditions affecting its non-GFR determinants, leading to a wide range of GFR for a given serum creatinine level (Table 3.3). For example, a serum creatinine level of 1.5 mg/dL (132 μmol/L) may correspond to a GFR from approximately 20 to 90 mL/min/1.73 m^2.

Creatinine is derived by the metabolism of phosphocreatine in muscle, as well as from dietary meat intake or creatine supplements. Creatinine generation is proportional to muscle mass, which can be estimated from age, sex, and body size, but many other factors can affect creatinine generation. Creatinine is distributed in total body water, not protein bound, and freely filtered across the glomerulus and secreted by

TABLE 3.2 Creatinine, Cystatin C, and Urea as Endogenous Filtration Markers

Variable	Creatinine	Cystatin C	Urea
Molecular Properties			
Weight (Da)	113	13,000	60
Structure	Amino acid derivative	Nonglycosylated basic protein	Organic molecular product of protein metabolism
Physiologic Determinants of Serum Level			
Generation	Varies, according to muscle mass and dietary protein; lower in elderly persons, women, and Whites	Thought to be mostly constant by all nucleated cells; increases in hyperthyroid state and with steroid use; lower in elderly persons and women	Varies, according to dietary protein intake and catabolism
Handling by kidney	Filtered, secreted, and excreted in urine	Filtered, reabsorbed, and catabolized	Filtered, reabsorbed, and excreted in urine
Extrarenal elimination	Yes; increases at reduced GFR	Preliminary evidence of increases at reduced GFR	Yes; increases at reduced GFR
Use in Estimating Equations for GFR			
Demographic and clinical variables as surrogates for physiologic determinants	Age, sex, and race; related to muscle mass	Age, sex	Not applicable
Accuracy	Accurate for GFR <60 mL/min/1.73 m^2	Unknown	Not applicable
Assay			
Method	Colorimetric or enzymatic	PENIA, PETIA, or ELISA	Direct measurement, enzymatic colorimetric, and electrochemical
Assay precision	Very good except at low range	Precise throughout range, but difficult to standardize	Precise throughout range
Clinical laboratory practice	Multiple assays; widely used nonstandard calibration	Not on most autoanalyzers; not standardized	Multiple assays; enzymatic and colorimetric more common
Standardized recommendation materials (SRMs)	SRM 967	ERM-DA471/IFCC	SRM 912a
Reference assay	IDMS	PENIA, PETIA, or ELISA	IDMS

ELISA, Enzyme-linked immunosorbent assay; *GFR,* glomerular filtration rate; *IDMS,* isotope-dilution–mass spectroscopy; *PENIA,* particle-enhanced nephelometric immunoassay; *PETIA,* particle-enhanced turbidimetric immunoassay.

the tubules. Several medications, such as cimetidine, trimethoprim, and fenofibrate, competitively inhibit creatinine secretion, leading to a rise in the serum creatinine concentration without an effect on GFR.

In addition, creatinine is contained in intestinal secretions and can be degraded by bacteria; gastrointestinal elimination of creatinine is increased at higher levels of serum creatinine but can be reduced by changes in gut flora due to antibiotic use. Clinically, it can be difficult to distinguish a rise in serum creatinine concentration caused by inhibition of tubular secretion or extrarenal elimination of creatinine from a decline in GFR.

Creatinine clearance (Clcr) is usually computed from the creatinine excretion in a 24-hour urine collection and single measurement of serum creatinine in the steady state. Creatinine excretion rates vary with age and sex with mean levels of approximately 20 to 25 mg/kg/d and 15 to 20 mg/kg/d in a complete collection in healthy young men and women, respectively. Deviations from estimated creatinine excretion (based on age, sex, weight, and other variables)[11] can indicate errors in timing or completeness of urine collection but cannot be relied on because of wide variability in creatinine generation.

Creatinine Assay

Historically, the most common assay for measurement of serum creatinine was the alkaline picrate (Jaffe) assay that generates a color reaction. Chromogens other than creatinine can interfere with the assay, causing errors of up to 20% in normal individuals. Enzymatic methods are less susceptible to interference, and their use is increasing. Reference materials traceable to an isotope-dilution–mass spectrometry (IDMS) are now available to standardize creatinine measurements, and most manufacturers have now calibrated their instruments using these reference materials.[12,13] Standardization has reduced but not eliminated the error in estimating GFR at higher levels.

Estimated Glomerular Filtration Rate From Serum Creatinine

GFR can be estimated from serum creatinine ($eGFR_{cr}$) by equations that use demographic factors or body size as surrogates for the non-GFR determinants, principally creatinine generation. Despite ongoing refinements in recent years, GFR estimates remain imprecise; none of the equations is expected to work as well in patients with extreme levels for creatinine generation, such as large or small individuals, amputees, bodybuilders, patients with muscle-wasting conditions, or people with an atypical pattern of meat consumption (see Table 3.3). As discussed later, further improvements will probably require additional filtration markers.

Equations Currently Recommended for Use

The Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) 2009 and 2021 creatinine equations were developed from a large

TABLE 3.3 Factors Affecting Serum Creatinine and Cystatin C Concentrations Independent From Glomerular Filtration Rate

Factors	Effect on Creatinine (Direction/*Mechanism*)	Effect on Cystatin C (Direction/*Mechanism*)
Age	Decrease *Lower creatinine generation presumed due to decline in muscle mass. Effect on tubular secretion and extraelimination unknown.*	Decrease *Presumed lower cystatin C generation caused by decreased cellular mass, smaller influence than creatinine. Effect on extraelimination unknown.*
Female sex	Decrease *Lower creatinine generation presumed due to lower muscle mass. Effect on tubular secretion and extraelimination unknown.*	Decrease *Presumed lower cystatin C generation caused by lower cellular mass, smaller influence than creatinine. Effect on extraelimination unknown.*
Race		
Self-identified African American or Black in US or European studies, or African ancestry	Increase *Cause unknown; higher creatinine generation and lower tubular secretion of creatinine observed in some studies, but not consistent. Effect on extraelimination unknown. Factors less well known for race and ethnic groups other than African Americans or Whites.*	No effect
Diet		
Vegetarian	Decrease *Lower creatinine generation.*	No effect
Ingestion of cooked meats and creatinine supplements	Increase *Transient increase in creatinine generation, although this may be blunted by transient increase in GFR.*	No effect
Body Habitus		
Larger muscle mass	Increase *Higher muscle generation caused by increased muscle mass and/or increased protein intake.*	No effect
Smaller muscle mass (e.g., amputation, anorexia)	Decrease *Lower creatinine generation caused by reduced muscle mass and/or reduced protein intake.*	No effect
Malnutrition, muscle wasting, in context of chronic illness	Decrease *Lower creatinine generation caused by reduced muscle mass and/or reduced protein intake.*	Possible increase *Presumed higher cystatin C generation in conditions associated with inflammation.*
Obesity	No change *Excess fat mass, not muscle mass, which does not contribute to creatinine generation.*	Increase *Presumed higher cystatin C generation by excess fat mass.*
Medications		
Trimethoprim, cimetidine, fibric acid derivatives other than gemfibrozil, dolutegravir, and cobicistat PARP inhibitors,[a] tyrosine kinase inhibitors[b]	Increase *Reduced tubular secretion of creatinine.*	No known effects, not studied
Ketoacids, some cephalosporins	Interference with alkaline picrate assay for creatinine.	No known effects, not studied

[a]Such as olaparib and rucaparib.

GFR, Glomerular filtration rate; *PARP,* poly-ADP ribose polymerase.

database of adults, including those with and without kidney disease, with and without diabetes, and with and without a history of organ transplantation.[14] The 2009 equation includes age, sex, and race (categorized as African American vs. non–African American), and standardized serum creatinine. It estimates mGFR assessed from urinary clearance of iothalamate. It uses a two-slope "spline" for serum creatinine and is accurate across the full range of eGFR. It has been extensively validated and is accurate across a wide range of patient characteristics, including age, sex, race, body mass index (BMI), and presence or absence of diabetes or history of organ transplantation. The 2012 Kidney Disease: Improving Global Outcomes (KDIGO) guidelines recommend that clinical laboratories use CKD-EPI creatinine equations to report eGFR in adults in North America, Europe, and Australia whenever serum creatinine is measured or to use other

equations if they are shown to be superior to CKD-EPI equations in other populations (Box 3.1).[15]

The 2021 equation was developed from the same dataset used for development of the 2009 equation without inclusion of a term for Black race, in response to the call to remove race from clinical algorithms in medicine.[16–19] It is less accurate than the 2009 equation but sufficiently accurate for use in clinical practice and more accurate than prior equations. Importantly, it avoids potential for misclassification by race in a multiracial population.[20–22] The 2021 equation is now recommended for use by the American Society of Nephrology and National Kidney Foundation.[23]

There is insufficient information on racial and ethnic groups other than African-American and White individuals to be certain about the accuracy of GFR estimates in these populations.

The Chronic Kidney Disease in Children (CKiD) 2009 creatinine equation was developed from a moderate-sized study of children with CKD and decreased GFR.[24] The equation uses height and standardized serum creatinine to estimate mGFR assessed from plasma clearance of iohexol. It underestimates mGFR at higher eGFR. The 2012 KDIGO guidelines recommend its use for children with kidney disease but do not recommend reporting eGFR whenever serum creatinine is measured in children. An updated and more accurate equation (CKiD 2021) is based on a larger sample size with age up to 25 years, and uses age and sex in addition to height and recalibrated iohexol measurements.[25] Of note, the CKD-EPI and CKiD creatinine equations often give different results in the transition years from adolescence to young adulthood, reflecting their development in separate study populations.

Equations Previously Recommended for Use

The Cockcroft-Gault equation for adults, developed in 1976, estimates measured Clcr from serum creatinine, age, sex, and body weight, in addition to serum creatinine.[26] Comparison to normal values for Clcr requires computation of BSA and adjustment to 1.73 m^2. The Cockcroft-Gault formula has several limitations. First, it is not precise, in particular in the GFR range above 60 mL/min. Second, it estimates Clcr rather than GFR and thus is expected to overestimate mGFR. Third, the formula was derived by older assay methods for serum creatinine, which cannot be calibrated to newer assay methods and would be expected to lead to variable systematic bias in estimating Clcr (generally an overestimate). Fourth, it systematically overestimates measured Clcr in edematous or obese patients. Fifth, the large age term means that all older adults will have lower levels of estimated GFR. The Schwartz equation for children, developed in 1976, estimates measured Clcr using serum creatinine and height.[27] When using standardized creatinine, it overestimates mGFR.

The Modification of Diet in Renal Disease (MDRD) study equation for adults was developed in 1999[28] and updated for use with standardized serum creatinine in 2006.[29] It is more accurate than the Cockcroft-Gault equation.[30] However, it was derived from a study population with CKD, so it underestimates the mGFR in populations with higher levels of GFR, and numeric values should not be reported for GFR levels greater than 60 mL/min/1.73 m^2.[31]

Other Equations That Could Be Considered for Use in Selected Populations

The Lund-Malmo Revised (LMR) equation for adults and the Berlin Initiative Study (BIS) equation for the elderly (age ≥70 years) use standardized creatinine and were developed in European and US populations that predominantly included White participants.[32,33] The FAS 2016 creatinine equation is based on hypothetical relationships rather than linear regression, which overcomes the limitation of discontinuity at the transition from adolescence to young adulthood.[34] Variations of the FAS equations combined with features of equations derived from linear regression have also been proposed.[35–37] These equations were derived from data on White persons from North America and Europe and appear as accurate as the CKD-EPI equation in White persons but less accurate in African-American persons.[38–41] Other equations have been developed in Asian and African populations that improve the accuracy of GFR estimates in the study population; however, the equations do not generalize well to other populations.[42–47]

CYSTATIN C

Metabolism and Excretion

Cystatin C is a 122–amino acid protein with molecular weight of 13 kDa (see Table 3.2).[48] Cystatin C is produced in all nucleated cells and is distributed in extracellular fluid. In health, approximately 99% of the filtered cystatin C is reabsorbed by the proximal tubular cells, where it is almost completely catabolized, with the remainder eliminated in the urine largely intact; in kidney disease, tubular uptake may be impaired, leading to an increase in urinary excretion.[49]

Some evidence suggests the existence of tubular secretion and extrarenal elimination. Smoking, inflammation, adiposity, thyroid diseases, certain malignant neoplasms, and use of glucocorticoids appear to be associated with higher cystatin C levels independent of mGFR.[50,51] Therefore factors other than GFR must be considered in interpreting cystatin C levels.

Cystatin C Assay

Several assays are available (all more expensive than those for creatinine). Reference materials for standardization of cystatin C from the International Federation of Clinical Chemists (IFCC) are now available, and standardization across clinical laboratories is improving.[52–54]

Estimated Glomerular Filtration Rate From Serum Cystatin C

Cystatin C is less affected by muscle than creatinine and is less affected by age, sex, and race than creatinine. However, eGFR based on serum cystatin C ($eGFR_{cys}$) is not more accurate than $eGFR_{cr}$, because of variation in other conditions affecting non-GFR determinants of serum cystatin C. Equations combining both these filtration markers ($eGFR_{cr-cys}$) appear to be more precise than equations using either marker alone. The 2012 CKD-EPI cystatin C and creatinine–cystatin C equations for adults were developed from a large database of adults, including those

with and without kidney disease or diabetes, are expressed for use with standardized serum creatinine and cystatin C and are recommended by the 2012 KDIGO guidelines (see Box 3.1).[15,55] The creatinine–cystatin C equation uses age, sex, and race, whereas the cystatin C uses age and sex without race. The 2021 creatinine–cystatin C equation was derived from the same dataset as the 2012 equation and is almost as accurate but does not use race. In patients with reduced muscle mass (e.g., neuromuscular or liver disease, low BMI) or in patients with diabetes, $eGFR_{cys}$ may be more accurate than $eGFR_{cr}$. Other recent equations using cystatin C have been developed; most but not all studies show that regional modifications appear to be less important for $eGFR_{cys}$ than for $eGFR_{cr}$.[33,56–58]

Some studies show that a lower $eGFR_{cys}$ is a better predictor of the risk for cardiovascular disease and total mortality than is a lower $eGFR_{cr}$.[59] In our view, this is likely due to confounding by non-GFR determinants of cystatin C and creatinine. Because of better accuracy and risk prediction, $eGFR_{cr\text{-}cys}$ is recommended as a confirmatory test for CKD, but full implementation will require standardization, greater availability, and cost reductions of cystatin C assays, as well as better understanding of non-GFR determinants of serum cystatin C (see Box 3.1).

The CKiD creatinine–cystatin C equation (also including urea nitrogen) for children was developed in 2009 and updated in 2012 but is not expressed for use with standardized cystatin C assays.[24,60] A CKiD 2021 cystatin C equation estimates mGFR and uses standardized cystatin C, age, sex, and height and recalibrated iohexol measurements.[25] Several equations are available for use in children and adults. The Caucasian Asian Pediatric and Adult (CAPA) equation, developed in 2014, estimates mGFR using variety of methods and includes only age and standardized serum cystatin C; the FAS 2017 cystatin C equation includes age, sex, and standardized serum cystatin C and performs similarly to the CKD-EPI 2012 cystatin C equation; and the FAS 2017 creatinine–cystatin C equation performs similarly to the CKD-EPI 2012 creatinine–cystatin C equation.[53,61]

UREA AND OTHER METABOLITES

The serum urea level has limited value as an index of GFR, in view of widely variable non-GFR determinants, primarily urea generation and tubular reabsorption (see Table 3.2).

Urea is a 60 Da end product of protein catabolism by the liver. Factors associated with the increased generation of urea include protein loading from hyperalimentation and absorption of blood after a gastrointestinal hemorrhage. Catabolic states caused by infection, corticosteroid administration, or chemotherapy also increase urea generation. Decreased urea generation is seen in patients with severe malnutrition and liver disease.

Urea is freely filtered by the glomerulus and then passively reabsorbed in both proximal and distal nephrons. As a result of tubular reabsorption, urinary clearance of urea underestimates GFR. Reduced kidney perfusion in the patient with volume depletion and states of antidiuresis are associated with increased urea reabsorption. This leads to a greater decrease in urea clearance than the concomitant decrease in GFR. At mGFR of less than about 20 mL/min/1.73 m^2, the overestimation of mGFR by measured Clcr resulting from creatinine secretion approximates the underestimation of measured GFR by measured urea clearance from urea reabsorption; thus the average of measured creatinine and urea clearance approximates the mGFR.

Recent advances in assays for metabolites have revealed a number of compounds that are highly correlated with mGFR and could be used for GFR estimation.[62] An eGFR from a panel of four novel metabolites (pseudouridine, acetylthreonine, phenylacetylglutamine, and tryptophan) without demographic factors was as accurate as eGFRcr and eGFRcys but not more accurate than eGFRcr-cys; the most accurate equation included the four novel metabolites, creatinine, cystatin C, and demographic characteristics.[63] Assays for the four novel metabolites are not available.

OTHER LOW-MOLECULAR-WEIGHT SERUM PROTEINS

β2-Microglobulin (β2M) and β-trace protein (βTP) are low-molecular-weight serum proteins being evaluated as filtration markers for estimating GFR and for their role in prognosis. As with cystatin C, β2M and βTP are freely filtered by the glomerulus and extensively reabsorbed and degraded by the proximal tubule, with only small amounts excreted in the urine under normal conditions.

Serum β2M and βTP levels are more strongly correlated with mGFR than serum creatinine and, like cystatin C, they are less influenced by age and sex than creatinine. The CKD-EPI 2020 eGFR from a panel of all four markers, age, and sex without race is as accurate as the CKD-EPI 2012 creatinine–cystatin C equation that requires race.[64] In addition, studies have shown that β2M and βTP are better predictors of adverse health outcomes than creatinine and are potentially as accurate as cystatin C in the general population and in patients with CKD.[65] A recent study shows that serum β2M and βTP can be used to estimate residual kidney function in patients on dialysis.[66,67] The likely explanation is that they are too large to be filtered by conventional hemodialysis membranes or the peritoneum, so their serum concentrations reflect residual kidney function rather than the dialysis dose. β2M and βTP assays are not standardized across clinical laboratories, and further study of the usefulness of these equations in clinical practice is required.

CLINICAL APPLICATION OF ESTIMATED GLOMERULAR FILTRATION RATE

Chronic Kidney Disease

CKD is a heterogeneous group of disorders characterized by abnormalities in kidney structure or function for more than 3 months with implications for health. Estimation of GFR is necessary for the detection, evaluation, and management of patients with CKD. GFR less than 60 mL/min/1.73 m^2 for 3 months or longer is one of the criteria for the definition of CKD (see Box 3.1).[15] Guidelines recommend testing of patients at increased risk for CKD for decreased GFR and albuminuria, as a marker of kidney damage, and recommend staging of kidney disease severity and estimating prognosis using levels of albuminuria and GFR (see Box 3.1).[15] The Kidney Failure Risk Equation uses age, sex, GFR, and urine albumin-to-creatinine ratio to predict the risk for onset of kidney replacement therapy (KRT) within 2 or 5 years.[68]

Use of serum creatinine alone as an index of GFR is not recommended and can lead to delays in detection of CKD and misclassification of the severity of CKD. Use of estimating equations allows reporting of eGFR by clinical laboratories whenever serum creatinine is measured. Current estimating equations are less accurate in people with variation in non-GFR determinants of serum creatinine concentration (see Table 3.3). In these patients, more accurate GFR estimates require additional testing, such as measurement of cystatin C, measured Clcr, or mGFR. The KDIGO CKD guidelines recommend use of $eGFR_{cr}$ as an initial test followed by $eGFR_{cr\text{-}cys}$ or a clearance measurement for confirmation in conditions in which eGFR may be inaccurate (Fig. 3.2).[1] Examination of the consistency of GFR estimates and clearance measurements is recommended. If the results are inconsistent, clinicians should consider possible explanations, such as differences between observed and expected creatinine excretion for measured Clcr and non-GFR determinants of creatinine and cystatin C for eGFR, then eliminate the inconsistent value from consideration, repeat the measurement, or determine mGFR using an exogenous marker.

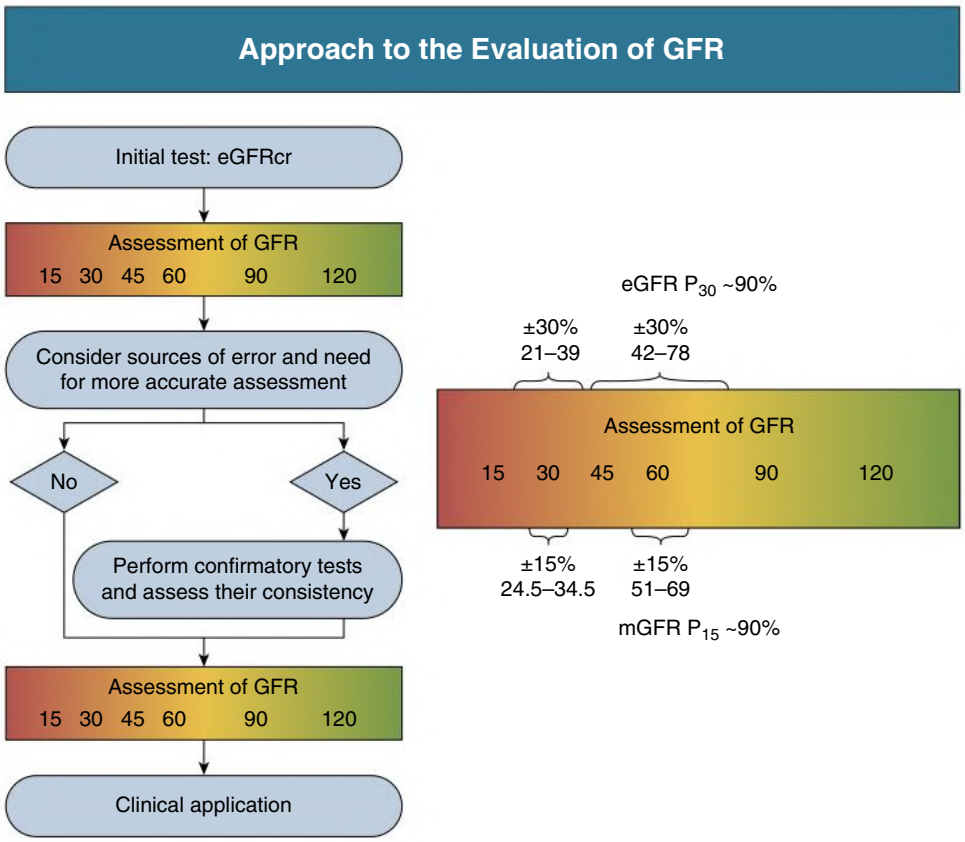

Fig. 3.2 An Approach to the Evaluation of GFR. Our approach is to use initial and confirmatory testing to develop a final assessment of true glomerular filtration rate (GFR) and to apply it in individual decision-making. *Left,* We would initially estimate GFR using serum creatinine ($eGFR_{cr}$)—the findings from this assessment must be interpreted in light of its limitations. Estimation of GFR based on serum cystatin C ($eGFR_{cys}$), both creatinine and cystatin C ($eGFR_{cr\text{-}cys}$), and measured creatinine clearance (Clcr) are useful confirmatory tests in some circumstances, and measured GFR (mGFR) is an appropriate confirmatory test if available and performed using an accurate procedure. We recommend using the most convenient confirmatory test that will enable clinical decision-making, recognizing that more than one confirmatory test might be required. Clinical application of the findings requires additional clinical information, for example, a clinical action plan based on chronic kidney disease GFR categories, drug-dosing recommendations, or use in predictive instruments. *Right,* It is important to determine how accurate an assessment of GFR needs to be for clinical decision-making. If accuracy within 30% is acceptable, eGFR may be sufficient, provided that there are not large deviations in non-GFR determinants of creatinine or cystatin C. If greater accuracy is needed, mGFR is recommended, and some methods can provide accuracy of within 15%. At a GFR of 60 mL/min/1.73 m^2, 30% accuracy for eGFR corresponds to an eGFR of 42 to 78 mL/min/1.73 m^2, and 15% for mGFR corresponds to 51 to 69 mL/min/1.73 m^2. At a GFR of 30 mL/min/1.73 m^2, 30% accuracy for eGFR corresponds to eGFR of 21 to 39 mL/min/1.73 m^2, and 15% for mGFR corresponds to 25.5 to 34.5 mL/min/1.73 m^2. (Modified from Levey AS, Coresh J, Tighiouart H, Greene T, Inker LA. Measured and estimated glomerular filtration rate: current status and future directions. *Nat Rev Nephrol.* 2020;16[1]:51–64.)

Change in serum creatinine is routinely used to assess the progression of kidney disease in populations, and quantitative associations with risk for KRT are now available. Changes in eGFR over 1 to 3 years were associated with higher risk for developing KRT in the subsequent time period compared with a stable eGFR for people at high and lower levels of eGFR.[69,70] The current level of eGFR was more strongly associated with risk of KRT than the rate of decline.[71] Similar results were observed for associations with mortality. A meta-analysis and statistical simulation from clinical trials demonstrates conditions in which an eGFR decline could be a valid surrogate endpoint for kidney disease progression.[72,73]

Acute Kidney Disease

AKD is a heterogeneous group of disorders characterized by abnormalities in kidney structure or function for 3 months or less with implications for health. Acute kidney injury (AKI) is a subset of AKD in which the decline in GFR is sufficient to cause an increase in serum creatinine by 0.3 mg/dL over 48 hours or by 50% over 7 days (see Box 3.1).[74] Change in GFR induces a nonsteady state in the serum levels of endogenous filtration markers (Fig. 3.3). After a decline in GFR, there is a lag before the rise in serum level because of the time required for retention of an endogenous filtration marker. Conversely, after recovery of GFR, there is a lag before the excretion of the retained marker. During the nonsteady state, neither the serum level nor the GFR estimated from the serum level accurately reflects the mGFR. Nonetheless, a change in the eGFR in the nonsteady state can be a useful indication of the magnitude and direction of the change in mGFR. If the eGFR is decreasing, the decline in eGFR is less than the decline in mGFR. Conversely, if the eGFR is increasing, the rise in eGFR is greater than the rise in mGFR. The more rapid the change in eGFR, the greater is the change in measured GFR. When eGFR reaches a new steady state, it more accurately reflects mGFR. A GFR estimating equation for use

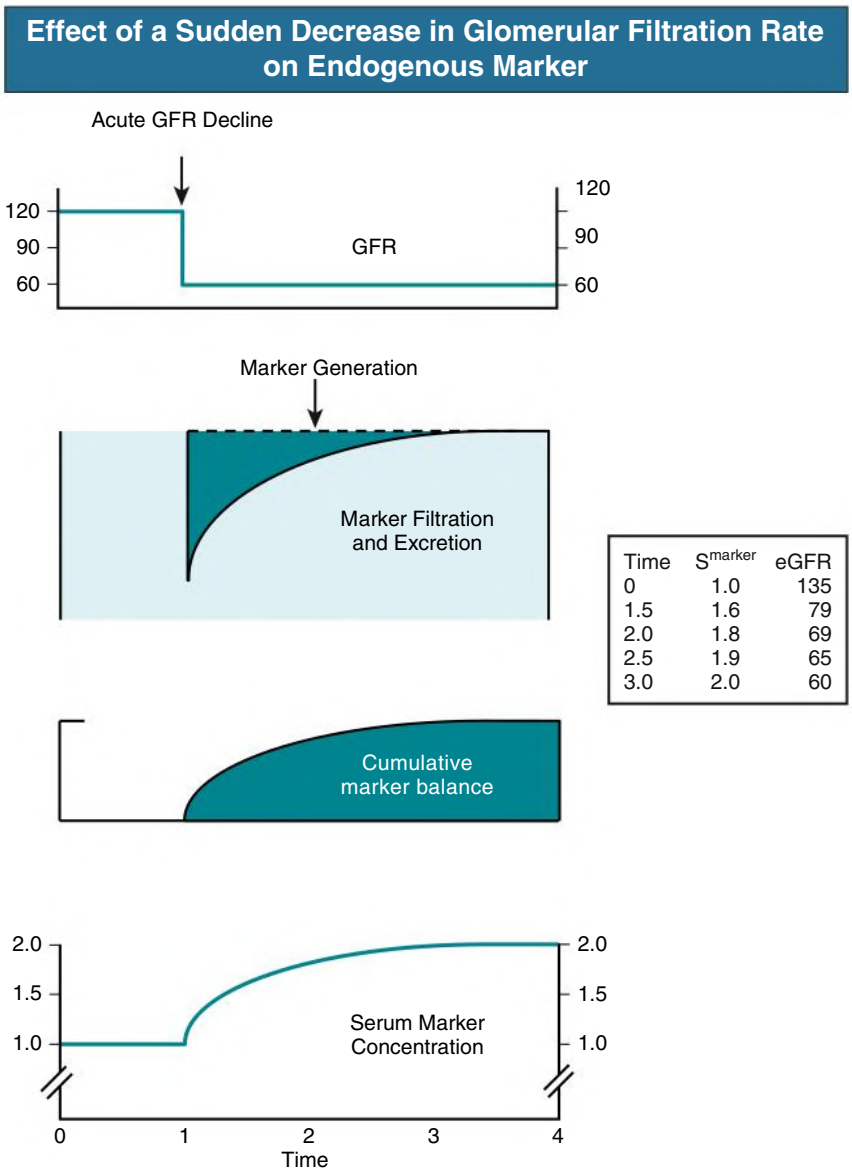

Fig. 3.3 Change in Serum Creatinine and eGFR after a Sudden Decrease in GFR. Graphs show the effect of acute GFR decline *(top)* on generation, filtration and excretion, balance of endogenous marker *(middle),* and concentration of serum marker (S^{marker}) *(bottom).*

in the nonsteady state has been proposed ("kinetic eGFR"), but has not yet been validated compared with change in mGFR.[75]

Simulations of creatinine kinetics after an abrupt GFR decline shows that the absolute and proportionate increase in serum creatinine are influenced by the baseline GFR and the magnitude of decline in GFR.[76] In patients with AKI, serum cystatin C appears to increase more rapidly than serum creatinine.[77] More data are required to establish whether changes in serum cystatin C are a more sensitive indicator of rapidly changing kidney function than changes in serum creatinine. In addition, similar to CKD, $eGFR_{cr}$ might be inappropriate in patients with differences in muscle mass or dietary protein intake, and in such patients it would be possible to confirm the change in $eGFR_{cr}$ with changes in $eGFR_{cys}$ or clearance measures (see Fig. 3.2).

LIVING KIDNEY DONOR CANDIDATES

KDIGO guidelines for the evaluation of the living kidney donor state that eGFR could be used in the evaluation of living kidney donor candidates (see Box 3.1).[78] In the United States, where evaluation of living kidney donor candidates requires a measured clearance, eGFR could be used as a first test with measured clearance as a confirmatory test.[79,80] Performance of multiple tests and assessment of the consistency of their results is helpful to identify possible sources of error. Elsewhere, if a clearance measurement is not required, eGFR could be used to accept or decline donor candidates if the probability is very high that mGFR is above or below, respectively, the thresholds for decision-making.[81]

DRUG DOSING

Pharmacokinetic properties of many drugs are affected by acute and chronic kidney disease. Drug dosing must be adjusted in patients with alterations in GFR to ensure therapeutic levels. The Cockcroft-Gault formula has been widely used to assess pharmacokinetic properties of drugs in patients with impaired kidney function, but, because of the limitations described previously, the KDIGO Controversies Conference Report recommended that GFR, as it is best evaluated in an individual patient, be used to assess kidney function for drug dosing, rather than a specific equation (see Box 3.1).[82] Using the MDRD Study or CKD-EPI

equation led to more accurate classification of mGFR categories for drug dosing adjustment than estimated Clcr using the Cockcroft-Gault equation.[83] In AKI, use of the kinetic eGFR may provide additional benefit.[84] Studies of predicted and observed vancomycin kinetics suggest that eGFRcr or eGFRcys using the CKD-EPI equations is more accurate than estimated Clcr using the Cockcroft-Gault equation.[85–87] The most recent update from the FDA acknowledges the importance of accurate GFR estimates for drug dosing and recommends eGFR using the MDRD Study or CKD-EPI equations rather than estimated Clcr using the Cockcroft and Gault equation for pharmacokinetic studies for drug development.[88] For drug dosing, GFR should be expressed without indexing for BSA for patients in whom BSA differs substantially from the index value of 1.73 m^2; to convert from mL/min/1.73 m^2 to mL/min, multiply by BSA/1.73 m^2. The accuracy of nonindexed eGFR compared with nonindexed mGFR is similar to the accuracy of indexed eGFR compared with indexed mGFR.[89]

SELF-ASSESSMENT QUESTIONS

1. A 59-year-old, 100-kg, 193-cm-tall man has a serum creatinine concentration of 1.5 mg/dL. Estimated glomerular filtration rate (eGFR) using the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) creatinine equation and standardized serum creatinine is 53 mL/min/1.73 m^2, but measured GFR (mGFR) is 90 mL/min/1.73 m^2. What factor *most* likely explains the underestimation of mGFR?
   - **A.** Nonsteady state of serum creatinine.
   - **B.** Drug-induced inhibition of tubular secretion of creatinine.
   - **C.** Decreased extrarenal elimination of creatinine.
   - **D.** Increased creatinine generation from large muscle mass or diet.
2. An 80-year-old woman has a serum creatinine concentration of 1.0 mg/dL for 3 months. Her eGFR using the CKD-EPI creatinine equation and standardized serum creatinine is 57 mL/min/1.73 m^2. She has no chronic kidney disease risk factors. What laboratory tests could be performed to confirm the diagnosis of chronic kidney disease?
   - **A.** Measure urine albumin-to-creatinine ratio.
   - **B.** Measure GFR using an exogenous filtration marker.
   - **C.** Measure serum cystatin C and calculate estimation of GFR based on serum cystatin C ($eGFR_{cys}$).
   - **D.** Image the kidneys and urinary tract.
   - **E.** Examine the urine sediment.
   - **F.** Any or all of the above.
3. A 40-year-old man with type 1 diabetes mellitus and urine albumin-to-creatinine ratio of 450 mg/g begins angiotensin-converting enzyme (ACE) inhibitor therapy to slow the progression of kidney disease. Within 2 weeks, estimate GFR using serum creatinine ($eGFR_{cr}$) declines from 75 to 65 mL/min/1.73 m^2. What is the *most* likely cause for decline in eGFR?
   - **A.** Effect of ACE inhibitor on serum creatinine assay.
   - **B.** Effect of ACE inhibitor on GFR.
   - **C.** Effect of ACE inhibitor on tubular secretion of creatinine.
   - **D.** Effect of ACE inhibitor on muscle mass.

Urinalysis

David Navarro, Nuno Moreira Fonseca, Giuseppe Garigali, Giovanni B. Fogazzi

DEFINITION

Urinalysis is critical for evaluation of kidney and urinary tract disease. When a patient is first seen by a nephrologist, urinalysis must always be performed. Reagent strips are still the most widely used method for urinalysis to supply physicochemical information, but the nephrologist should be aware of their limitations and order more sensitive and specific measurements by other methods in the case of reagent strip abnormalities (e.g., the accurate measurement of proteinuria in case of reagent strip positivity for albumin).[1] Urine sediment examination is an integral part of urinalysis.[2,3] For kidney patients, urine sediment examination should ideally be performed by nephrologists, who may be able to attribute clinical relevance to findings that may escape laboratory personnel.[4]

URINE SAMPLE

The use of an early morning urine sample is suggested by the Kidney Disease: Improving Global Outcomes (KDIGO) guideline,[1] especially for the measurement of albumin (see later).

However, the 24-hour urine collection is still widely used for the measurement of multiple parameters, even though errors caused by improper timing and missed samples can lead to overcollection or undercollection of urine. Errors can be minimized by giving the patient clear written instructions (e.g., at 7:00 AM discard the first urine of the morning, then collect in a capacious—of at least 2.5 L—and graduated container *all* the urine produced, including that passed at 7:00 AM of the day after; measure the volume of urine carefully and record it). Written instructions should also be provided for other types of urine samples (e.g., when testing for orthostatic proteinuria, one sample produced while the patient has been recumbent for some hours and another sample produced while the patient has been standing).

Strenuous physical exercise (e.g., running, soccer) should be avoided for at least 24 hours before the urine sample delivery to avoid exercise-induced proteinuria and hematuria or urinary casts. In women, urinalysis must be avoided during menstruation because of the high probability of blood contamination.

For urine microscopy, a midstream sample of the first morning urine is recommended by some international guidelines because this urine is the most concentrated and acidic and theoretically the best for the preservation of particles.[5] On the other hand, the prolonged persistence in the bladder may favor the lysis of cells and casts, which may lead to false-negative results. For this reason, we use a combined dipstick and urine microscopy on the second morning urine.[6]

After handwashing, the external genitalia are washed and wiped dry with a paper towel. Then, women should spread the labia of the vagina and men withdraw the foreskin of the glans and collect the midstream urine after the first portion is discarded. The same procedures can be used for children. For small infants, bags for urine are often used, even though these carry a high probability of contamination. A suprapubic bladder puncture may occasionally be necessary. In special situations, urine can also be collected through a bladder catheter, although this procedure may cause hematuria. Permanent indwelling catheters are almost invariably associated with bacteriuria, leukocyturia, hematuria, and candiduria.

The container for urine should be clean and have a capacity of at least 50 mL. It should have a wide base to avoid accidental spillage and should be capped. The label should identify the patient and the hour of urine collection.[5]

Several elements (but especially leukocytes) can lyse rapidly after collection; thus ideally the sample should be handled and examined as soon as possible. We recommend analysis within 3 hours from collection. If this is not possible, refrigeration of specimens at 4°C to 8°C assists preservation but may cause precipitation of phosphates or urates, which can hamper examination. Alternatively, chemical preservatives such as formaldehyde or glutaraldehyde can be used but can modify the urine pH, with consequent changes in urinary findings, and so cannot be universally recommended.

PHYSICAL CHARACTERISTICS

Color

The color of normal urine ranges from pale to dark yellow and amber, depending on the concentration of the urochrome. Abnormal changes in color can be caused by pathologic conditions, drugs, or foods (Table 4.1).

The most frequent pathologic conditions that can cause color changes of the urine are gross hematuria, hemoglobinuria, or myoglobinuria (pink, red, brown, or black urine); bilirubinuria (dark yellow to brown urine); and massive uric acid crystalluria (pink urine). Less frequent causes are urinary infection, mainly from *Klebsiella* spp., *Proteus mirabilis, Escherichia coli, Providencia stuartii,* or *Enterococcus* spp. in patients with permanent bladder catheter (purple urine, nowadays known as "purple urine bag syndrome"), chyluria (white milky urine), porphyrinuria (associated with the excretion in the urine of porphobilinogen), and alkaptonuria (red urine turning black over time).

The main drugs responsible for abnormal urine color are rifampin (yellow-orange to red urine); desferrioxamine (pinkish urine); phenytoin (red urine); chloroquine and nitrofurantoin (brown urine); triamterene, propofol, and blue dyes of enteral feeds (green urine); methylene blue (blue urine); and metronidazole, methyldopa, and imipenem-cilastatin (urine darkening on standing).

Among the foods responsible are beetroot (red urine), senna and rhubarb (yellow to brown or red urine), and carotene (brown urine).

TABLE 4.1 Abnormal Changes in Urine Color and its Causes

Urine Color	Causes
Pink	Conditions: massive uric acid crystalluria, hematuria, hemoglobinuria, myoglobinuria Drugs: desferrioxamine
Purple	Conditions: urinary tract infection
Blue	Drugs: methylene blue
Green	Drugs: triamterene, propofol, blue dyes of enteral feeds
Orange	Conditions: bilirubinuria Drugs: rifampin
Red	Conditions: hematuria, hemoglobinuria, myoglobinuria, porphyrinuria Drugs: rifampin, phenytoin, phenazopyridine Foods: beetroot, senna, rhubarb
Brown	Conditions: hematuria, hemoglobinuria, myoglobinuria, bilirubinuria Drugs: chloroquine, nitrofurantoin Foods: carotene, senna, rhubarb
Black	Conditions: hematuria, hemoglobinuria, myoglobinuria, porphyrinuria, and alkaptonuria (red urine turning black over time) Drugs: metronidazole, methyldopa, imipenem-cilastatin (urine darkens over time)
White	Conditions: chyluria

Turbidity

Normal urine is transparent. Urine can be turbid because of a high concentration of any urine particle, especially cells, crystals, and bacteria. The most frequent causes of turbidity are urinary tract infection (UTI), heavy hematuria, and genital secretions. Importantly, pathologic urine can be transparent.

Odor

A change in urine odor may be caused by the ingestion of some foods, such as asparagus. A pungent odor, caused by the production of ammonia, is typical of most bacterial UTIs, whereas there is often a sweet or fruity odor with ketones in the urine. Some rare conditions confer a characteristic odor to the urine. These include maple syrup urine disease (maple syrup odor), phenylketonuria (musty odor), isovaleric acidemia (sweaty feet odor), and hypermethioninemia (rancid butter or fishy odor).

Relative Density

Relative density can be measured by specific gravity or osmolality. *Specific gravity* (SG) refers to the weight of a volume of urine compared with the weight of the same volume of distilled water and depends on the mass and number of the dissolved particles. SG is most frequently evaluated by reagent strip (see discussion of chemical characteristics), which measures the ionic concentration of urine; alternatively, SG can be measured by refractometry. With reagent strip underestimation occurs with urine of pH above 6.5, whereas overestimation is found with urine protein concentration above 7.0 g/L.

For SG, we suggest refractometry for everyday practice because refractometers are inexpensive, simple to use, require only one drop of urine, and are more accurate than reagent strips. SG of 1.000 to 1.003 is seen with marked urinary dilution, as observed in patients with diabetes insipidus or water intoxication. SG of 1.010 is often called *isosthenuric* urine because it is of similar SG (and osmolality) to plasma, so it is often observed in conditions in which urinary concentration is impaired, such as acute tubular necrosis (ATN) and chronic kidney disease (CKD) with reduced glomerular filtration rate (GFR). SG above 1.040 almost always indicates the presence of some extrinsic osmotic agent, such as radiocontrast.

Osmolality is measured by an osmometer and depends only on the number of particles present and is not influenced by urine temperature or protein concentrations. Measurement of osmolality is hence more reliable than SG by either reagent strip or refractometry, although it can be influenced by high glucose concentrations.

CHEMICAL CHARACTERISTICS

Chemical characteristics of urine are most frequently evaluated by reagent strips. These plastic strips bear several pads (the most used are SG, pH, glucose, hemoglobin, albumin, leukocyte esterase, nitrites, bile pigments, and ketones), each pad being impregnated with chemical reagents meant to detect a specific urine feature. In clinical laboratories of wealthier countries, the reagent strip reading is performed by automated reader devices, using reflectance spectrometry, which supply highly reproducible results. Alternatively, the reading is performed manually, which is simple and quick but is exposed to subjectivity and incorrect procedures. Correct procedures imply rapid plunging of the strip in the urine; removal of the urine in excess on the pads to avoid color carryover from one pad to the close ones; adherence to the time interval between removal of the strip from urine and the reading of results as indicated by the manufacturer; and matching of the color developed in the pad with the color scale reported on the strip box under adequate light conditions.

Reagent strips have the advantages of simplicity and low cost and supply a full urinary profile within 2 to 3 minutes. Disadvantages include semiquantitative results only, susceptibility to interference by substances and urine discoloration. Sensitivity and specificity of reagent strips greatly differ across studies, which partly depend on the brand used (there is no standardization across manufacturers). Table 4.2 summarizes the main causes of false-negative and false-positive results that can occur with strip reagent testing.

pH

The pH is determined by a strip that covers the pH range of 5.0 to 8.5 or to 9.0, with intervals of only 0.5, which limits precision. Moreover, significant deviations from true pH are observed for values below 5.5 and above 7.5. In the presence of formaldehyde, the strip supplies reduced pH values. When an accurate measurement of pH is necessary, a pH meter with a glass electrode is mandatory.

Urine pH reflects the presence of hydrogen ions (H^+), but this does not necessarily reflect the overall acid load in the urine because most of the acid is excreted as ammonia. Low pH is often observed with metabolic acidosis (in which acid is secreted), high-protein meals (which generate more acid and ammonia), and volume depletion (in which aldosterone is stimulated, resulting in an acid urine). High pH is often observed with renal tubular acidosis, vegetarian diets (caused by minimal nitrogen and acid generation), and infection because of urease-positive organisms that generate ammonia from urea.

Measurement of urine pH is also needed for a correct interpretation of other urine parameters (e.g., specific gravity, albumin) and several urine sediment findings, particularly for the evaluation of crystalluria.

TABLE 4.2 Urine Reagent Strip Testing

Constituent	False-Negative Results	False-Positive Results
Specific gravity (SG)	Urine pH > 6.5	Urine protein > 7.0 g/L
pH	Reduced values in presence of formaldehyde	—
Hemoglobin	High urine specific gravity Ascorbic acid Formaldehyde (0.5 g/L) used to preserve samples	Myoglobin Microbial peroxidases
Glucose	Ascorbic acid Bacteria	Very acidic urine pH Oxidizing detergents
Albumin	Low urine specific gravity Albumin < 0.25–0.30 g/L Low urine Tubular proteins Monoclonal heavy/light chains	Urine SG ≥ 1.030 Urine pH > 8.0 Quaternary ammonium detergents Chlorhexidine Polyvinylpyrrolidone
Leukocyte esterase	High urine specific gravity Ascorbic acid Glucose ≥ 20 g/L Protein >5.0 g/L Cephalothin (strong inhibition) Tetracycline (strong inhibition) Cephalexin (moderate inhibition) Tobramycin (mild inhibition)	Formaldehyde (0.4 g/L) Imipenem Meropenem Clavulanate Abnormally colored urine
Nitrites	Bacteria that do not reduce nitrates to nitrites Lack of vegetables in diet Short bladder incubation time	Abnormally colored urine
Ketones	Improper storage	Free sulfhydryl groups (e.g., captopril) Levodopa Abnormally colored urine

Main causes of false-negative and false-positive results of urine reagent strips. False results also may occur when time-expired strips are used.

Hemoglobin

Hemoglobin is detected by a dipstick based on the pseudoperoxidase activity of the heme moiety of hemoglobin, which catalyzes the reaction of a peroxide and a chromogen to form a colored product.

False-negative results are most frequently caused by high SG or by ascorbic acid, a strong reducing agent, which can result in low-grade microhematuria being completely missed. Some reagent strips also include a vitamin C pad to reduce these false-negative results.[7]

The most important causes of false-positive results are myoglobinuria, resulting from rhabdomyolysis, and a high concentration of bacteria with pseudoperoxidase activity (*Enterobacteriaceae*, *Staphylococcus* spp., and *Streptococcus* spp.).[8]

Glucose

By reagent strip, with glucose oxidase as catalyst, glucose is first oxidized to gluconic acid and hydrogen peroxide. Through the catalyzing activity of a peroxidase, hydrogen peroxide then reacts with a reduced colorless chromogen to form a colored product. The reagent strip detects glucose concentrations of 0.5 to 20 g/L. When more precise quantification of urine glucose is needed, enzymatic methods such as hexokinase must be used. False-negative results for glucose occur in the presence of ascorbic acid and bacteria. False-positive findings may be observed in the presence of oxidizing detergents and very acidic urine pH.

Protein

Although historically the definition of proteinuria has varied, the definitions in the KDIGO guideline are increasingly used.[1] It is accepted that physiologic proteinuria does not exceed 150 mg/24 hours for adults[1] and 140 mg/m^2 for children,[9] in whom, however, the normal values do vary by age.[1] Three different approaches can be used for the evaluation of proteinuria, as described next.

Albumin Reagent Strip

The albumin reagent strip test is based on the effect of albumin on a buffer (tetrabromophenol blue), which causes a change in pH proportional to the concentration of the albumin itself. The strip is sensitive to albumin but has a very low sensitivity to other proteins, such as tubular proteins and light-chain immunoglobulins; thus it will not detect tubular proteinuria or overflow proteinuria, which can occur in monoclonal gammopathies. Moreover, the detection limit is 0.25 to 0.3 g/L, so it does not identify microalbuminuria and is influenced by hydration status (false-negative results may occur at low urine SG, and vice versa) and urine pH (false-positive results at strongly alkaline pH). The reagent strip supplies only a semiquantitative measurement of urine albumin, which is expressed on a scale from 0 to +++ or ++++. Some manufacturers also supply numerical results, although these represent only approximate quantitative measurements. Some reagent strips also include a creatinine pad, which supplies an albumin/creatinine ratio (ACR) and reduces the variability caused by changing diuresis and urine dilution.[10] Nevertheless, for accurate quantification, other methods are needed.

24-Hour Protein Excretion

The 24-hour protein excretion averages the variation of proteinuria caused by the circadian rhythm and is still considered the reference

method.[1] The measurement of proteinuria can be done by chemical assays, turbidimetric techniques, or dye-binding techniques, which quantify total proteins rather than only albumin. However, the 24-hour urine collection can be impractical in some settings (e.g., children, outpatients, elderly patients) and is subject to error from overcollection or undercollection.[11]

Protein/Creatinine Ratio and Albumin/Creatinine Ratio on Random Urine Sample

The protein/creatinine ratio (PCR) measured on an early morning urine sample represents a practical alternative to the 24-hour urine collection because the sample is easy to supply and is not influenced by variation in water intake or rate of diuresis.[1] The PCR is obtained by the ratio between urine protein excretion and creatinine excretion, expressed as milligrams per milligrams or milligrams per millimole. A close correlation between the PCR in a random urine sample and the 24-hour protein excretion has been demonstrated in a wide range of patients, including those with different types of glomerulonephritis (GN) evaluated longitudinally during treatment.[9] However, the results may be influenced by reduced creatinine excretion because of low muscle mass. Thus, in elderly and female patients, PCR values can be higher than in young men. Some investigators consider a normal PCR sufficient to rule out pathologic proteinuria, but an elevated PCR should be confirmed and quantified with a 24-hour collection.[12] Others have found poor correlation between PCR and 24-hour proteinuria at high levels of protein excretion[13] or that PCR is an unreliable method to monitor some patients with lupus nephritis.[14]

The KDIGO guideline suggests ACR rather than PCR as the first measurement of proteinuria in adults because albuminuria is a reliable marker of the outcome of CKD, and it provides a specific and sensitive measure of changes in glomerular permeability in several kidney diseases.[1]

However, false-negative results may occur with ACR, especially in tubulointerstitial diseases and monoclonal gammopathies, in which urine proteins are mostly composed of tubular proteins and monoclonal light chains, respectively. In children, the KDIGO guideline recommends the measurement of PCR rather than ACR because the latter can miss the identification of congenital disorders associated with nonalbumin proteinuria.[1] KDIGO also recommends PCR in preference to ACR for patients with glomerulonephritis.

Specific Proteins

Albumin. Albuminuria may be classified as mildly, moderately, or severely increased.[1] In persons with diabetes, abnormal albuminuria is correlated with a risk for progressive kidney function loss and is correlated among those with or without diabetes with increased risk for CKD, cardiovascular morbidity, and all-cause mortality.[15] Semiquantitative reagent strips are available to screen for urine albumin in this range. Once the reagent strip is positive, a quantitative method must be used for confirmation.[1]

Tubular proteins. When an isolated tubular lesion is suspected, specific tubular proteins such as α_1-microglobulin, retinol-binding protein, or β_2-microglobulin should be measured.[1] This can be done by qualitative analysis of urine proteins, using electrophoresis.

Bence Jones protein. Bence Jones proteinuria indicates the presence of free monoclonal immunoglobulin (heavy or light chains) as occurs with monoclonal gammopathies. Bence Jones proteinuria is revealed by urine electrophoresis, whereas light-chain identification requires urine immunofixation.[16]

Leukocyte Esterase

The leukocyte esterase dipstick test evaluates the presence of leukocytes based on the activity of an indoxyl esterase released from lysed neutrophil granulocytes. Leukocyte esterase may be positive but microscopy negative when leukocytes are lysed because of low SG, alkaline pH, or a delay in sample handling and examination. False-negative results derive from vitamin C,[7] high glucose (≥20 g/L), or high protein (≥5 g/L) concentration or from the presence of antibiotics, such as cephalothin and tetracycline (strong inhibition), cephalexin (moderate inhibition), or tobramycin (mild inhibition). The sensitivity is also reduced by high SG because this prevents leukocyte lysis. False-positive results may occur when formaldehyde is used as a urine preservative, from the presence in the urine of imipenem, meropenem, or clavulanate,[17] and with all discolored urine.

Nitrites

The dipstick nitrites test detects bacteria that reduce nitrates to nitrites by nitrate reductase activity. This includes most gram-negative uropathogenic bacteria, but not *Pseudomonas, Staphylococcus albus,* or *Enterococcus.* False-negative results also may occur on a diet with low content of nitrate (vegetables), which form the substrate for nitrite production and short bladder incubation time. Thus, the sensitivity of the dipstick nitrites test is low, whereas specificity is high.[18] False-positive results may occur in the presence of abnormally colored urine.

Bile Pigments

Measurement of urinary urobilinogen and bilirubin concentrations has lost its clinical value in the detection of liver disease after the introduction of serum tests of liver enzyme function.

Ketones

The ketone dipstick tests for acetoacetate and acetone (but not β-hydroxybutyrate), which are excreted into urine during diabetic acidosis or during fasting, vomiting, or strenuous exercise. It is based on the reaction of the ketones with nitroprusside.

URINE MICROSCOPY

In current days, urine microscopy is carried out almost exclusively in clinical laboratories. The lack of clinico-laboratory correlation[4] may have an impact on the diagnosis and management of kidney patients. We believe urine microscopy remains a fundamental skill for nephrologists, as we will explore later.

Methods

A shared standardization for urine microscopy sample preparation and examination is lacking. We instruct the patient to deliver the second urine specimen of the morning because it avoids the lysis of particles that can occur in the bladder overnight (Box 4.1). In our laboratory we use the following standardized procedures for urine sample preparation and examination.[6] We centrifuge an aliquot of urine within 3 hours from collection and concentrate it by removal of a fixed aliquot of supernatant urine. After this, the sediment is resuspended with a Pasteur pipette, and a fixed aliquot is transferred to the slide and prepared using a coverslip with a fixed surface. Some suggest the use of noncentrifuged urine because centrifugation may cause the damage and/or lysis of particles during the procedure. On the other hand, with this approach, clinically important particles (e.g., erythrocyte casts), when in small numbers, can easily be missed.

We recommend the use of phase-contrast microscopy because it improves the identification of almost all particles, especially cells and casts, whereas polarized light is mandatory for the correct identification of lipids and crystals, especially when they have uncommon morphologies.[6]

BOX 4.1 Standardized Procedures for Preparation and Examination of Urine Sediment Used in the Authors' Laboratory

- Written instructions for the patient to deliver a correct urine sample (i.e., the second urine of the morning after discarding the first portion of urine [midstream urine] collected in a proper container).
- Sample handling and examination within 3 hours of collection.
- Macroscopic examination of the sample and sediment.
- Testing the urine sample with a reagent strip for specific gravity, pH, albumin, hemoglobin, leukocyte esterase, and nitrites.
- Centrifugation of a 10-mL aliquot of urine at 400 g for 10 minutes.
- Removal of 9.5 mL of supernatant urine.
- Gentle but thorough resuspension with a Pasteur pipette of the sediment in the remaining 0.5 mL of urine.
- Transfer by a precision pipette of 50 µL of resuspended urine to a glass slide.
- Covering of sample with a 24 × 32 mm glass coverslip.
- Examination of the urine sediment with a phase contrast microscope at low (×160) and high magnification (×400).
- Use of polarized light to identify doubtful lipids and crystals.
- Matching of the microscopic findings with reagent strip results.
- Cells expressed as lowest/highest number seen per high-power field, casts as number per low-power field, and all other elements (e.g., bacteria, crystals) on scale from 0 to ++++.

At least 20 microscopic fields, in different areas of the sample, should be examined at both low magnification (e.g., ×100 or ×200) and high magnification (e.g., ×400). More extensive examination may be required in certain clinical settings, such as isolated microhematuria of unknown origin, for which we suggest examination of 50 low-power fields (lpf) to look for erythrocyte casts.[19]

For correct examination, both pH and SG of the sample must be known. Both alkaline pH (≥7.0) and low SG (especially ≤1.010) favor the lysis of erythrocytes and leukocytes, which can cause discrepancies between dipstick readings and the microscopic examination (see earlier discussion). Alkaline pH also impairs the formation of casts and favors the precipitation of amorphous phosphates. On the contrary, high SG (≥1.030) may reduce the sensitivity of reagent strips for hemoglobin and leukocyte esterase.

We quantify the particles seen as number per microscopic field, whereas if counting chambers are used, the elements are quantified as number per volume.

Cells

Erythrocytes

Urinary erythrocytes have a mean diameter of approximately 6 µm. In the urine, there are two main types of erythrocytes: *isomorphic,* with regular shapes and contours, derived from the urinary excretory system or from nonglomerular kidney diseases; and *dysmorphic,* with irregular shapes and contours, which are of glomerular origin (see Fig. 4.1A–B).[20] Erythrocyte dysmorphism is thought to result from deformation of the erythrocytes as they pass through gaps in the glomerular basement membrane, followed by physicochemical insults when the erythrocytes pass through the tubular system.[21]

The distinction between glomerular and nonglomerular hematuria is of special value in the evaluation of patients with isolated microhematuria, in whom it is important to decide whether nephrologic or urologic investigation is needed.

Unfortunately, there is no agreement on the criteria to classify hematuria as glomerular or nonglomerular. Some define glomerular hematuria as more than 80% of erythrocytes being dysmorphic; others define the discriminating cut-off as low as 10% or 15%.[6] Still, others define hematuria as glomerular when at least 5% of erythrocytes examined are *acanthocytes,*[22] a subtype of dysmorphic erythrocytes with a distinguishing appearance easily identifiable by the presence of one or more blebs of different size and shape protruding from a ring-shaped body (see Fig. 4.1B, *inset*).

In our laboratory, glomerular hematuria is diagnosed when there are 40% or more dysmorphic erythrocytes and/or 5% or more acanthocytes and/or one or more red blood cell casts/50 lpf (×160). With this approach, a good correlation was found between urinary sediment and kidney biopsy findings in 16 patients with long-standing isolated microhematuria.[19] Rare types of erythrocytes found in the urine include sickle cells, elliptocytes, spherocytes, and dacryocytes.[23]

Leukocytes

Urinary *neutrophils* have an average diameter of approximately 10 µm and are the most frequently found leukocytes in the urine. Neutrophils are identified by their granular cytoplasm and lobulated nucleus (see Fig. 4.1C). In most patients, neutrophils indicate UTI, but they may also result from urine contamination caused by genital secretions. Variable numbers of neutrophils are often found in acute interstitial nephritis (AIN).[24] Neutrophils can be found in low numbers in chronic interstitial nephritis and in proliferative GN.[25]

Eosinophils, which can be identified only by the use of stains (e.g., Hansel), were once considered a marker of acute allergic interstitial nephritis. This is not specific, however, because eosinophils may be present in various types of GN, prostatitis, chronic pyelonephritis, urinary schistosomiasis, and cholesterol embolism.[26]

Lymphocytes, whose identification also requires staining, may indicate acute cellular rejection in kidney allograft recipients, although this is not sufficiently reliable to preclude the need for kidney biopsy. Lymphocytes are also a typical finding in patients with chyluria.

Macrophages are mononucleated or multinucleated cells of variable size (13–95 µm in diameter) and variable appearance, with some being granular (see Fig. 4.1D). In patients with nephrotic syndrome, macrophages may be engorged with lipid drops, appearing as oval fat bodies (see lipids). Macrophages have been found in the urine of patients with active GN. In our experience, macrophages are frequently seen in the urine of kidney transplant recipients with BK virus infection (see later discussion). However, urinary macrophages are not diagnostic of any specific condition.

Renal Tubular Epithelial Cells

The renal tubular epithelial cells (RTECs) derive from the exfoliation of the tubular epithelium. In the urine, RTECs can differ in size (diameter approximately 9–25 µm, average 14 µm) and shape, from roundish to rectangular or columnar, with a central or peripheral large nucleus (see Fig. 4.1E). RTECs are not found in the normal individual but can be found when there is acute tubular damage, including ATN,[27] AIN,[24] and acute cellular rejection. In smaller numbers, RTECs also can be found in glomerular diseases.[25] In ATN, these cells are frequently damaged and necrotic and may be present in casts (so-called epithelial casts).

Transitional Epithelial Cells

The transitional epithelial cells derive from the exfoliation of the uroepithelium, which lines the urinary tract from the calyces to the bladder in women and to the proximal urethra in men. This multilayered epithelium has small cells in the deep layers and larger cells in the superficial layers. When cells of the deep epithelial layers (average diameter 18 µm; see Fig. 4.1F) are present in large numbers (e.g., ≥1/high-power field [hpf]), this suggests severe uroepithelial damage, such as caused

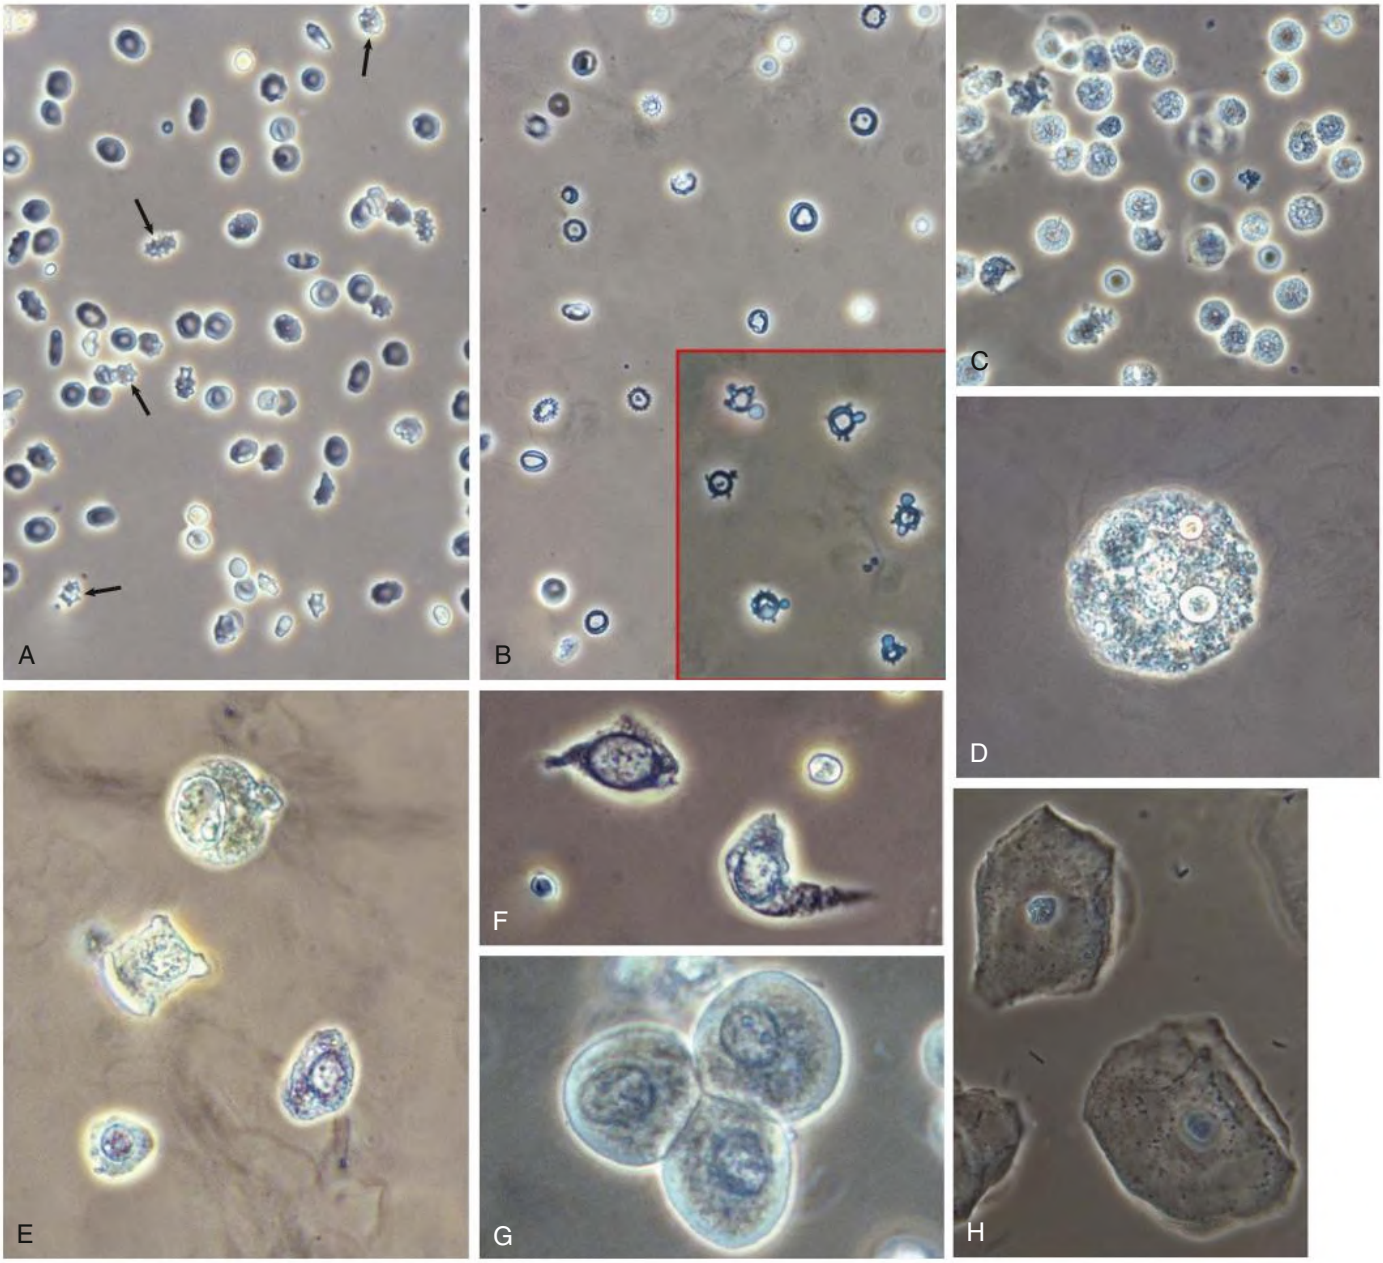

Fig. 4.1 Urinary Sediment Cells. (A) Isomorphic nonglomerular erythrocytes (diameter ~6 µm). The *arrows* indicate the so-called crenated erythrocytes, which are a finding in nonglomerular hematuria. (B) Dysmorphic glomerular erythrocytes (diameter ~6 µm). The dysmorphism consists mainly of irregularities of the cell membrane. *Inset,* Acanthocytes, with their typical ring-formed cell bodies with one or more blebs of different sizes and shapes. (C) Neutrophils (diameter ~10 µm). Note their typical lobulated nucleus and granular cytoplasm. (D) Granular phagocytic macrophage (diameter ~60 µm). (E) Different types of renal tubular epithelial cells (diameter ~14 µm). (F) Two cells from deep layers of uroepithelium (diameter ~18 µm). (G) Three cells from superficial layers of uroepithelium (diameter ~25 µm). (Note the difference in shape, size, and ratio of nucleus to cytoplasm between the two types of uroepithelial cells. (H) Squamous epithelial cells (diameter ~50 µm). (All images by phase-contrast microscopy; original magnification ×400.)

by neoplasia, stones, obstruction, or long-standing bladder catheters or ureteral stents.[6] Transitional cells of the superficial layers (average diameter ~25 µm; see Fig. 4.1G) are a common finding associated with mild uroepithelial damage, as may occur in cystitis.

Squamous Epithelial Cells

Squamous epithelial cells (SECs; average diameter 50 µm; see Fig. 4.1H) derive from the urethra or from the external genitalia. In small numbers, SECs are a normal finding, but in large numbers, they indicate urine contamination from genital secretions and reflect improper urine collection technique.

Lipids

Lipids are found in the urine as *drops,* which are spherical, translucent, yellowish particles of different sizes that can be isolated or in clusters, free or within cells or casts; as *oval fat bodies,* which are RTECs or

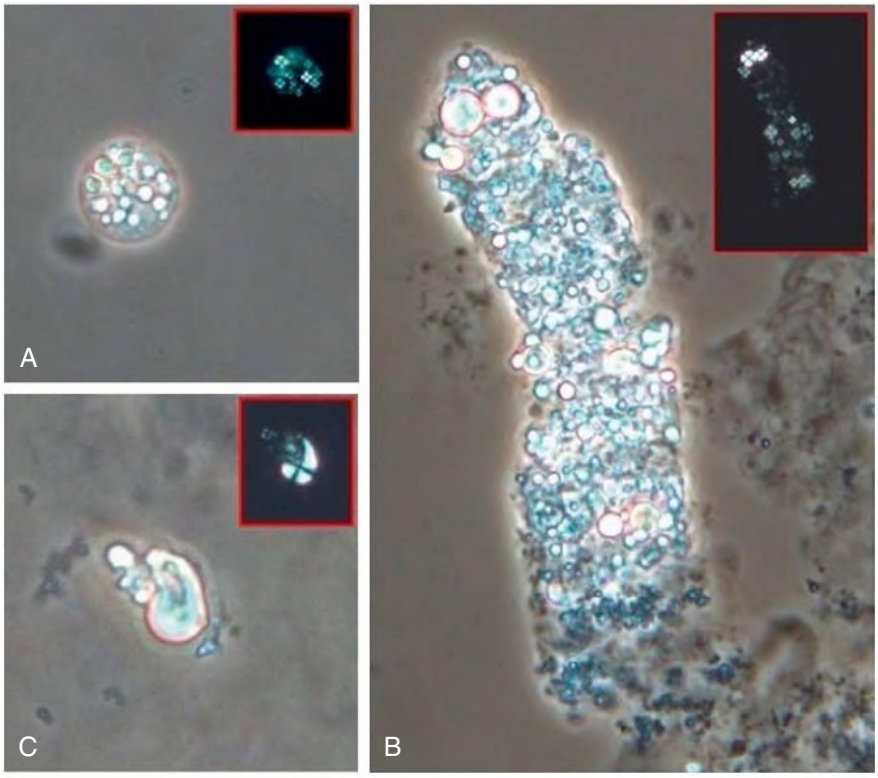

Fig. 4.2 Fat Particles. (A) Oval fat body and (B) fat cast–containing lipid drops with very variable diameter which, under polarized light, show a symmetric "Maltese cross" birefringence *(insets).* (C) Fat particle with an ovoidal shape and multiple blebs as found in the urine of patients with Fabry disease which, under polarized light, shows a truncated and asymmetric Maltese cross appearance *(inset)* (Phase-contrast microscopy, original magnification ×400.)

macrophages gorged with lipid drops (Fig. 4.2A); as *fat casts,* cylindrical structures containing variable amounts of fat drops, or even oval fat bodies (see Fig. 4.2B); and *cholesterol crystals* (see Crystals and Fig. 4.4F). All these particles contain mainly cholesterol esters and free cholesterol. Under polarized light, lipids are birefringent and show "Maltese crosses" with symmetric arms (see Fig. 4.2A and 4.2B *inset*), whereas cholesterol crystals are nonbirefringent. These lipids are typical of glomerular diseases associated with marked proteinuria.

In Fabry disease, urine sediment may contain fat particles even in the absence of proteinuria. These particles contain glycosphingolipids (especially globotriaosylceramide-3) and differ from the fat particles previously described because they show quite variable shapes, often with external protrusions and/or an internal lamellar structure, and irregular or truncated Maltese crosses under polarized light (see Fig. 4.2C).[28]

Casts

Casts are cylindrical structures that form in the lumen of distal renal tubules and collecting ducts. Their matrix is made of Tamm-Horsfall glycoprotein, today known as uromodulin, which is secreted by the cells of the thick ascending limb of Henle loop. Trapping of particles within the cast matrix results in casts with different appearances, each of which may have specific clinical significance (Table 4.3). It is important to remember that because casts form in the renal tubules, whatever particle is contained in a cast derives from the kidneys. Specific casts include the following:

- *Hyaline casts* are colorless with a low refractive index (Fig. 4.3A). They are easily seen with phase-contrast microscopy but can be overlooked when bright-field microscopy is used. Hyaline casts can be found both in normal and pathologic urine and especially in the setting of dehydration.
- *Hyaline-granular casts* contain variable amounts of granules within the hyaline matrix (see Fig. 4.3B) and are the most common mixed casts (see later discussion). Hyaline-granular casts can occasionally be found in normal subjects. They are common in patients with kidney diseases such as GN and AIN, in which case they are associated with other types of casts.[24,25]
- *Granular casts* can be finely (see Fig. 4.3C) or coarsely granular. Both types indicate kidney disease. In patients with acute kidney injury (AKI), granular casts, together with RTECs[27] or epithelial casts,[29] are a sensitive marker of ATN.
- *Waxy casts* derive their name from their appearance, which is similar to that of melted wax (see Fig. 4.3D). They are typically found in patients with kidney disease associated with reduced GFR, whether acute, rapidly progressive, or chronic.[30]
- *Fat casts* contain variable amounts of lipid drops, isolated, in clumps, or packed or even oval fat bodies or cholesterol crystals (see Fig. 4.2B). Fat casts are typical of glomerular diseases associated with marked proteinuria.
- *Erythrocyte casts* may contain a few erythrocytes (see Fig. 4.3E) or so many that the matrix of the cast cannot be identified. Erythrocyte casts are a marker of *renal bleeding,* most frequently of glomerular origin, even though they have also been found in patients with AIN.[24]
- *Hemoglobin casts* generally have a brownish hue and a coarsely granular appearance, which derives from the degradation of erythrocytes entrapped within the cast matrix (see Fig. 4.3F). In such cases, hemoglobin casts have the same clinical significance as

TABLE 4.3 Types of Casts and Their Main Clinical Associations

Cast	Main Clinical Associations
Hyaline	Normal individual; kidney disease
Hyaline-granular	Normal subject; kidney disease
Granular	Kidney disease; AKI associated with ATN
Waxy	Kidney disease with possible functional impairment
Fat	Marked proteinuria, usually but not invariably in the nephrotic range
Erythrocyte	Glomerular hematuria, most frequently because of active proliferative GN; AIN
Leukocyte	AIN; acute pyelonephritis; active proliferative GN
Containing renal tubular epithelial cell (so-called epithelial casts)	AKI associated with ATN; active proliferative GN; nonproliferative GN associated with heavy proteinuria; AIN
Hemoglobin	Glomerular hematuria, most frequently because of active proliferative GN; hemoglobinuria caused by intravascular hemolysis
Myoglobin	AKI because of rhabdomyolysis
Bilirubin	Jaundice caused by increased direct bilirubin
Bacterial, fungal	Bacterial or fungal kidney infections
Crystalline	Crystalline nephropathies
Mixed	According to components present in the cast

AIN, Acute interstitial nephritis; *AKI,* acute kidney injury; *ATN,* acute tubular necrosis; *GN,* glomerulonephritis.

erythrocyte casts. However, hemoglobin casts also may derive from hemoglobinuria, as may occur in intravascular hemolysis. In these patients, hemoglobin casts usually have a smooth surface.

- *Leukocyte casts* contain variable amounts of polymorphonuclear leukocytes (see Fig. 4.3G). They can be found in patients with acute pyelonephritis and AIN[24] and in active proliferative GN.[25]
- *Renal tubular epithelial cell containing casts* (so-called epithelial casts) contain variable numbers of RTECs, which can be identified by their prominent nucleus (see Fig. 4.3H). Epithelial casts indicate damage of the renal tubular epithelium and can therefore be found in the urine of patients with ATN,[27] AIN,[24] and glomerular disease.[25]
- *Myoglobin casts* are cylinders pigmented by myoglobin, akin to hemoglobin casts (see Fig. 4.3F). They can be distinguished from myoglobin casts according only to the clinical setting. Myoglobin casts are observed in the urine of patients with AKI associated with rhabdomyolysis.
- *Bilirubin casts* are cylinders pigmented with bilirubin, which can stain any particle contained in the cast (see Fig. 4.3I). They are observed in the urine of patients with jaundice associated with increased direct (conjugated) bilirubin.
- *Crystalline casts* may contain crystals of different nature. These casts are an important diagnostic element in crystalline-induced nephropathies, which are usually associated with AKI.[31]
- *Casts containing microorganisms* (bacteria and yeasts) indicate a kidney infection.
- *Mixed casts* contain components of different nature, such as granules, cells, and lipids. Their clinical significance is the same as that of pure casts.

Crystals

Correct identification of urine crystals requires the combined knowledge of their most frequent morphologies, their birefringence features under polarized light, and urine pH range at which each type of crystals precipitates. For unusual crystals, however, additional investigation may be needed, such as infrared or Raman spectroscopy and other techniques that are available in specialized laboratories.[32]

Examination of the urine for crystals is a key test in the assessment of patients with stone disease, with some rare inherited metabolic disorders (e.g., cystinuria, hyperoxaluria, phosphoribosyltransferase deficiency), and with suspected drug nephrotoxicity.[6] The search for crystalluria is best performed on the first voided morning urine samples, which are the most concentrated. We classify crystals into four categories: common crystals, pathologic crystals, rare crystals caused by drugs, and other crystals.

Common Crystals

Uric acid crystals and amorphous urates. These crystals most commonly appear as rhomboidal or barrel-like structures with a typical yellow amber color (Fig. 4.4A). However, uric acid crystals may have a wide spectrum of appearances, such as needle-like or grenade-like morphology.[33,34] Under polarized light, uric acid crystals are strongly birefringent and polychromatic. They are found in acidic urine (pH 5.0–5.8).

Amorphous urates are tiny granules of irregular shape that polarize light and precipitate in acidic urine.

Calcium oxalate crystals. There are two types of calcium oxalate crystals: bihydrated (or weddellite) crystals, which most often have a bipyramidal appearance (see Fig. 4.4B), and monohydrated (or whewellite) crystals, which are ovoid, dumbbell-shaped, or biconcave disks (see Fig. 4.4C). Monohydrated crystals are birefringent under polarized light, whereas bihydrated crystals in most instances are not. Both types precipitate at pH 5.4 to 6.7.

Calcium phosphate crystals (brushite) and amorphous phosphates. Calcium phosphate crystals are pleomorphic, appearing as prisms, star-like particles, or needles of various sizes and shapes (see Fig. 4.4D) that are strongly birefringent under polarized light. Rarely, calcium phosphate can appear as plates with a granular surface that do not polarize light. Both types of crystals precipitate in alkaline urine (pH ≥ 7.0).

Amorphous phosphates are tiny particles identical to amorphous urates, but they do not polarize light and precipitate at a pH of 7.0 or higher.

Triple phosphate (struvite) crystals. These crystals contain magnesium ammonium phosphate and most frequently have the appearance of "coffin lids" (see Fig. 4.4E), although variants such as flower-like and scissors-like structures can be found. These crystals usually polarize light strongly and are found in alkaline urine (pH ≥ 7.0).

Pathologic Crystals

Cholesterol crystals. These are thin, transparent plates, often clumped together, with sharp edges (see Fig. 4.4F), which do not polarize light. They can be found at any urinary pH.

Cystine crystals. These are hexagonal plates with irregular sides that are often heaped on one another (see Fig. 4.4G). They either do not polarize light or show a whitish birefringence. They are insoluble in a urine pH up to 7.4. Their presence is pathognomonic of the autosomal recessive inherited condition cystinuria (see Chapter 50), and their persistence in urine samples indicates a high risk for urinary stone formation.[35]

Fig. 4.3 Casts. (A) Hyaline cast. (B) Hyaline-granular cast. (C) Finely granular cast. (D) Waxy cast. (E) Erythrocyte cast. (F) Hemoglobin cast with a coarsely granular appearance and typical brownish hue. (G) Leukocyte cast. Note the lobulated nucleus of polymorphonuclear leukocytes *(arrows)*. (H) Epithelial cell cast. (All images by phase-contrast microscopy; original magnification ×400.)

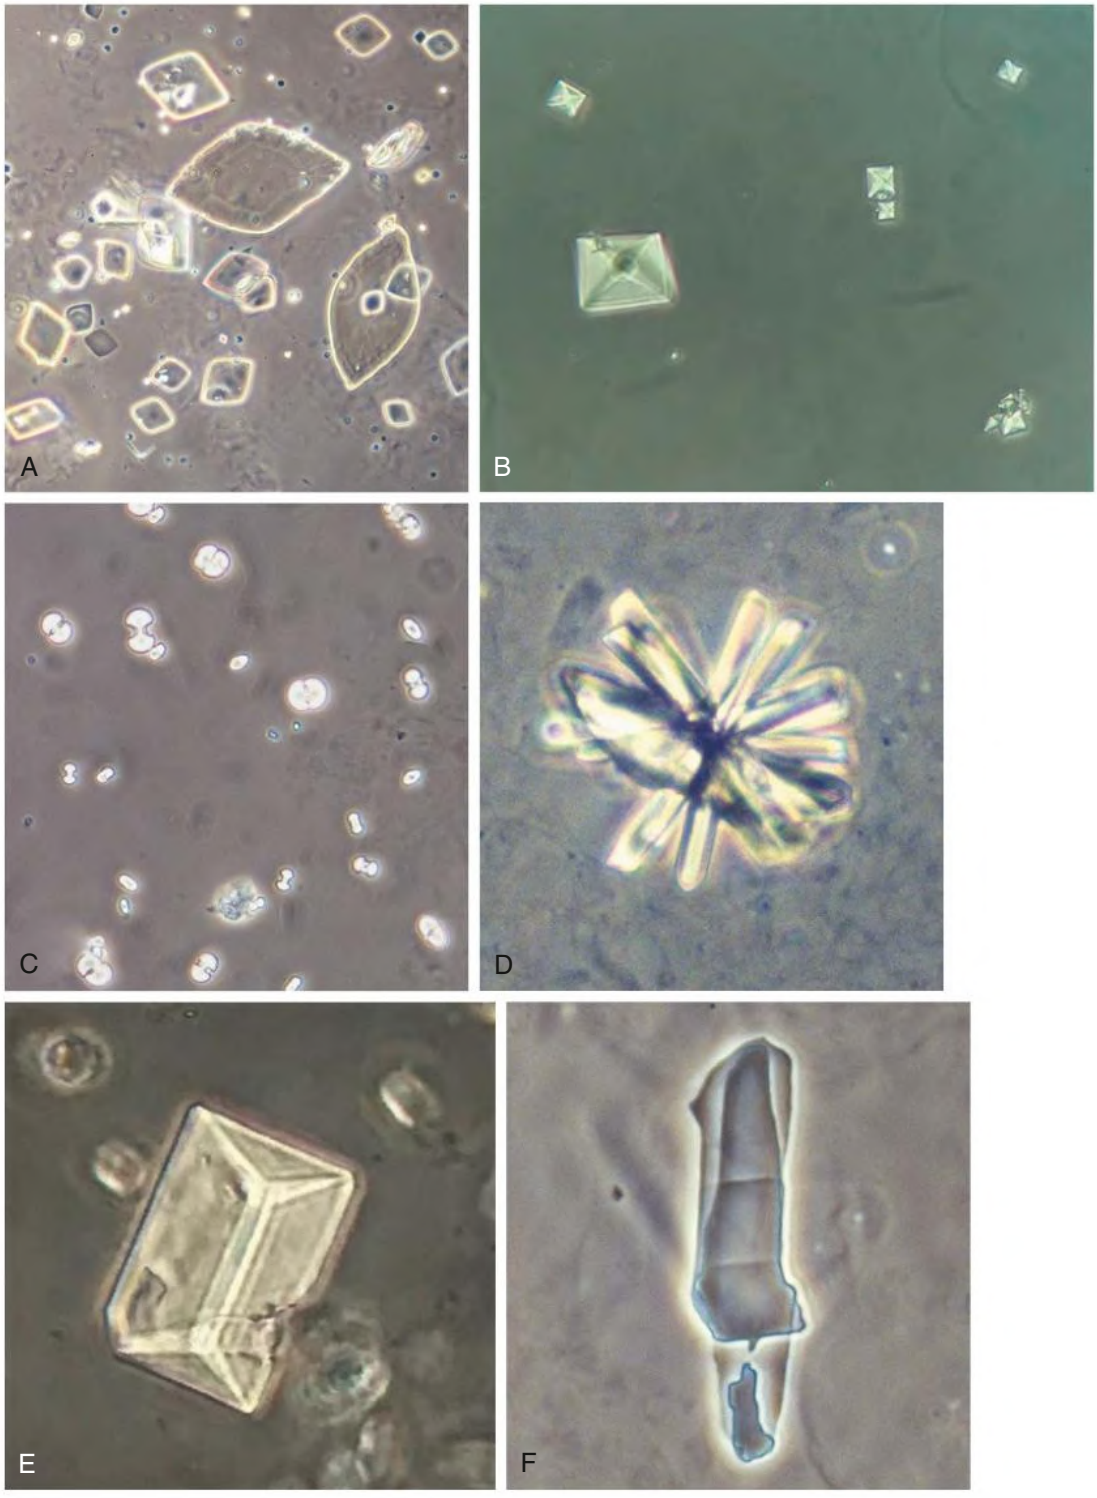

Fig. 4.4 Crystals. (A) Uric acid crystals. This rhomboid shape is the most common. (B) Bihydrated calcium oxalate crystals. They appear as bipyramidal colorless structures of variable size. (C) Different types of monohydrated calcium oxalate crystals. (D) Star-like brushite (calcium phosphate) crystal. (E) Struvite (triple phosphate) crystal, with typical "coffin-lid" appearance. (F) Cholesterol crystal.

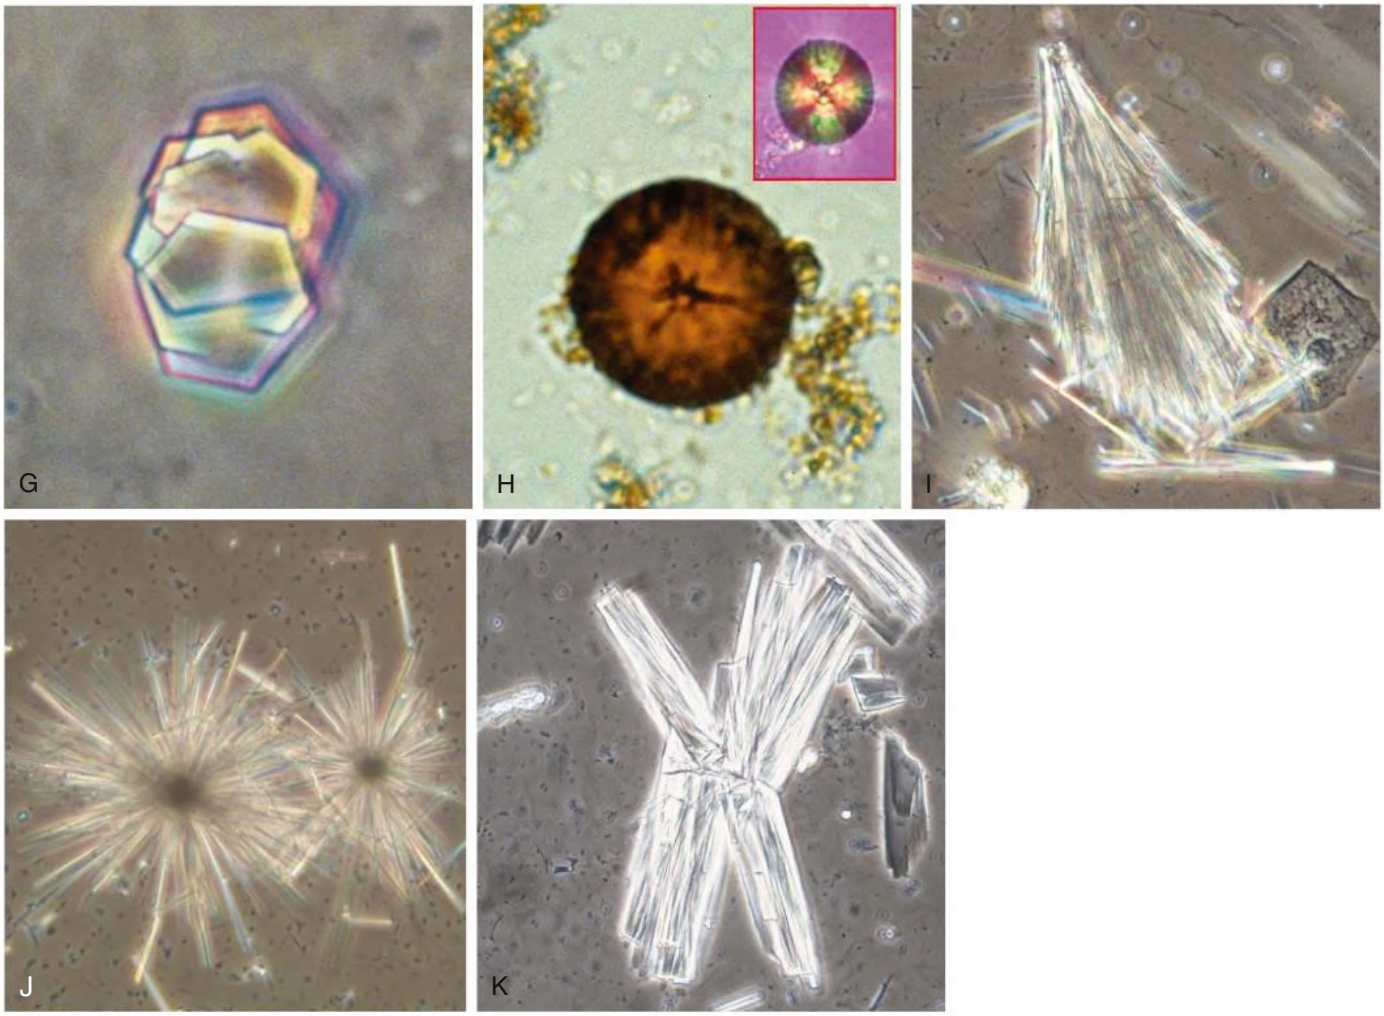

Fig. 4.4, cont'd (G) Cystine crystals heaped one on the other. (H) 2,8-Dihydroxyadenine crystal by bright-field microscopy; *inset,* by polarized light. (I) Amoxicillin crystal resembling a broom or brush. (J) Star-like ciprofloxacin crystals. (K) Large crystal of indinavir. (All images by phase-contrast microscopy; original magnification ×400.) (H, Courtesy Doctor Michel Daudon, Paris.)

2,8-dihydroxyadenine (2,8-DHA) crystals. These are spherical brownish structures with a central umbilicus and a birefringent cross-like appearance under polarized light (see Fig. 4.4H). They are a marker of homozygous deficiency of the enzyme adenine phosphoribosyltransferase.[36]

Tyrosine and leucine crystals. Both crystals are rare and can be found in the urine of patients with severe liver disease. In addition, tyrosine crystals may be found in patients with tyrosinemia. Leucine crystals appear as yellow-brown spheres with concentric striations, which are birefringent under polarized light. Tyrosine crystals are needle-shaped and often aggregate.

Crystals Caused by Drugs

Several drugs can cause crystalluria. This happens in the presence of several factors that increase drug supersaturation, such as drug overdose, dehydration, hypoalbuminemia, or reduced kidney function, in the setting of a crystallization favoring pH range (which varies from drug to drug).

Drugs that can cause crystalluria include antimicrobials (sulfadiazine, amoxicillin [see Fig. 4.4I], ciprofloxacin[6] [see Fig. 4.4J], ceftriaxone, and sulfamethoxazole[37]); antivirals (acyclovir, indinavir[6] [see Fig. 4.4K], atazanavir, and darunavir[38]); and other drugs (such as naftidrofuryl oxalate, orlistat, intravenous vitamin C, primidone, felbamate, piridoxylate, sulfasalazine, and methotrexate).[3,39]

In the presence of crystals with morphologies that differ from those previously described, a drug-related etiology must be sought. Calcium oxalate crystals of drug-related origin (naftidrofuryl oxalate, orlistat, and vitamin C), however, are indistinguishable from other causes.[6]

Other Crystals

Hippuric acid crystals, calcium carbonate crystals, and ammonium biurate crystals are rare, and it is unclear whether they are clinically significant.

Clinical Significance of Crystals

Uric acid, calcium oxalate, and calcium phosphate crystals may have no clinical significance because they can reflect transient supersaturation of the urine caused by ingestion of some foods (e.g., meat for uric acid, spinach or chocolate for calcium oxalate, milk or cheese for calcium phosphate) or mild dehydration. However, the persistence of calcium oxalate or uric acid crystalluria may reflect hypercalciuria, hyperoxaluria, or hyperuricosuria. In calcium stone formers, the evaluation of crystalluria is an important tool to assess calcium stone disease activity.[40]

Fig. 4.5 Egg of *Schistosoma haematobium* (Diameter, ~100 µm). Note the thick shell, which contains the *miracidium,* and the typical terminal spike *(arrow).* (Phase-contrast microscopy; original magnification ×400.)

Large numbers of uric acid crystals may be associated with AKI caused by acute urate nephropathy, whereas large numbers of monohydrated calcium oxalate crystals, especially with a spindle shape, may be associated with AKI from ethylene glycol intoxication. Triple phosphate crystals are usually associated with UTI caused by urea-splitting microorganisms such as *Proteus* spp., *Ureaplasma urealyticum,* and *Corynebacterium urealyticum.*

Cholesterol crystals are found in association with other fat particles in patients with marked proteinuria. Cystine crystals are pathognomonic of cystinuria, and 2,8-dihydroxyadenine crystals are pathognomonic of adenine phosphoribosyltransferase enzyme deficiency. Crystalluria may be isolated and asymptomatic or associated with hematuria, obstructive uropathy, or AKI caused by the precipitation of crystals within the renal tubules.[6,31]

Organisms

Bacteria: Two types of bacteria are most frequently found in urine—*cocci,* which have a round to oval shape, and rods, which appear as short sticks. High numbers of bacteria in association with leukocytes are a marker of urinary tract infection. However, the copresence of high numbers of squamous epithelial cells and/or *Candida albicans* and/or *Trichomonas vaginalis* suggests urine contamination from genital secretions.

Candida albicans: It is the most frequent yeast found in urine. Its shape is ovoidal, with one or two round to elongated protruding buds of variable size.

Trichomonas vaginalis: It is a protozoon characterized by a pyriform body, the presence of flagella at the two extremities of the body, and quick and whirling movements through the slide.

Schistosoma haematobium: It is an endemic parasite in several geographic regions (see Chapter 56). The search in the urinary sediment of its eggs is the simplest and fastest diagnostic tool. Their distinguishing feature is a terminal spike (Fig. 4.5). The eggs are most frequently found in the urine collected between 10 AM and 2 PM, when the parasite female lays the eggs, and after physical exercise such as running, which favors the detachment of the eggs from the bladder mucosa.

Contaminants

A large number of particles can contaminate urine. These particles may come from the patient (e.g., spermatozoa; erythrocytes from menstruation; leukocytes from vaginitis, cloth or synthetic fibers from underclothes), the laboratory (e.g., glass fragments from coverslips, starch from gloves), or the environment (e.g., pollens, plant cells, fungal spores).[6]

INTERPRETATION OF URINE SEDIMENT FINDINGS

Examination of the urine sediment, coupled with the knowledge of proteinuria and other urine and blood findings, results in urine sediment profiles that aid in diagnosis of urinary tract diseases (Table 4.4).

Acute Kidney Injury

In patients with AKI, the finding in the urine sediment of RTECs, in association with granular casts and/or epithelial casts, is the hallmark of ATN,[27,29] whereas these elements are rarely found in prerenal AKI.[27] In the latter, hyaline and/or hyaline-granular casts may be seen, along with high SG and low pH. A score based on the number of RTECs and granular casts significantly correlates with the progression and severity of AKI, with new AKI urine biomarkers (NGAL, KIM-1, IL 18), with the need for dialysis, and with death.[27] Depending on the cause of the tubular damage, other elements can be seen (e.g., high numbers of dysmorphic erythrocytes and erythrocyte casts in active proliferative glomerular diseases; myoglobin-pigmented casts in AKI because of rhabdomyolysis; and massive amounts of uric acid crystals in acute uric acid nephropathy caused by tumor lysis syndrome).

Acute Interstitial Nephritis

In AIN, the most frequent findings are variable numbers of leukocytes and isomorphic erythrocytes. RTECs may also be present, together with epithelial, leukocyte, and/or erythrocyte casts.[24]

Active Proliferative Glomerulonephritis

Dysmorphic erythrocytes and erythrocyte and hemoglobin casts are the hallmark of active proliferative glomerulonephritis. Usually, the number of erythrocytes ranges from 30 to 40 cells/hpf to more than 100 cells/hpf, with the higher figure found especially in patients with extracapillary or necrotizing glomerular lesions. Leukocytes are also common in mild numbers (e.g., 3–5/hpf) in most patients, but in those with acute postinfectious GN or active proliferative lupus nephritis, we have seen samples with up to 30 to 40 leukocytes/hpf. Leukocyte casts and waxy casts[30] may also be observed. In patients with marked proteinuria, fat particles can be also seen.

Nephrotic Syndrome

The typical nephrotic sediment contains lipids, casts, and RTECs. Fat, epithelial, granular, hyaline, and hyaline-granular casts are frequent, whereas erythrocyte or hemoglobin casts, leukocyte casts, and waxy casts are few or absent. Erythrocytes may be totally absent, especially in minimal change disease or may be in low to moderate numbers (e.g., 3–5/hpf to 20–30/hpf), which is seen especially in membranous nephropathy and focal segmental glomerulosclerosis. Leukocytes are usually not found.

Urinary Tract Infection

Bacteria and leukocytes are the hallmarks of UTI, with or without superficial transitional epithelial cells and/or isomorphic erythrocytes. In patients with pyelonephritis, RTECs and leukocyte casts can also be found. When the infection is caused by urease-producing bacteria such as *Proteus* spp., *Ureaplasma urealyticum,* and *Corynebacterium urealyticum,* triple phosphate (struvite) crystals are often present. The finding of bacteria and leukocytes, together with a high number of squamous epithelial cells, suggests the presence of urine contamination from genital secretion rather than UTI.

TABLE 4.4 Main Urinary Profiles

Kidney Disease	Hallmark	Associated Findings
AKI with ATN (proteinuria: absent to +)	RTECs Epithelial casts Granular casts	Variable according to cause of ATN (e.g., high number of dysmorphic erythrocytes in active proliferative GN; myoglobin casts in rhabdomyolysis; uric acid crystals in acute urate nephropathy)
Acute interstitial nephritis (proteinuria: absent to +)	Leukocytes Isomorphic erythrocytes	RTECs Leukocyte casts Erythrocyte casts
Active proliferative glomerulonephritis (proteinuria: + to ++++)	Dysmorphic erythrocytes (moderate to high number) Erythrocyte/hemoglobin casts	Leukocytes (low to moderate number) RTECs Epithelial, hyaline, hyaline-granular, granular, waxy, leukocytic casts
Nephrotic syndrome (proteinuria: ++++)	Fat particles High number of casts (fat, hyaline, hyaline-granular, granular epithelial)	Renal tubular epithelial cells Dysmorphic erythrocytes (absent or low-to-moderate number)
Urinary tract infection (proteinuria: absent)	Bacteria Leukocytes	Isomorphic erythrocytes Transitional epithelial cells Triple phosphate crystals (for infections caused by urease-producing bacteria) Epithelial ± leukocyte casts (in pyelonephritis)
Polyomavirus BK infection (proteinuria: absent)	Decoy cells	Decoy cell casts (in BK virus nephropathy) Macrophages
Urologic diseases (proteinuria: absent)	Isomorphic erythrocytes (low to high number) Leukocytes Transitional cells (deep, superficial, atypical)	Crystals (urolithiasis) Atypical/malignant transitional cell (neoplasia of excretory urinary system)

AKI, Acute kidney injury; *ATN,* acute tubular necrosis; *GN,* glomerulonephritis; *RTEC,* renal tubular epithelial cell.

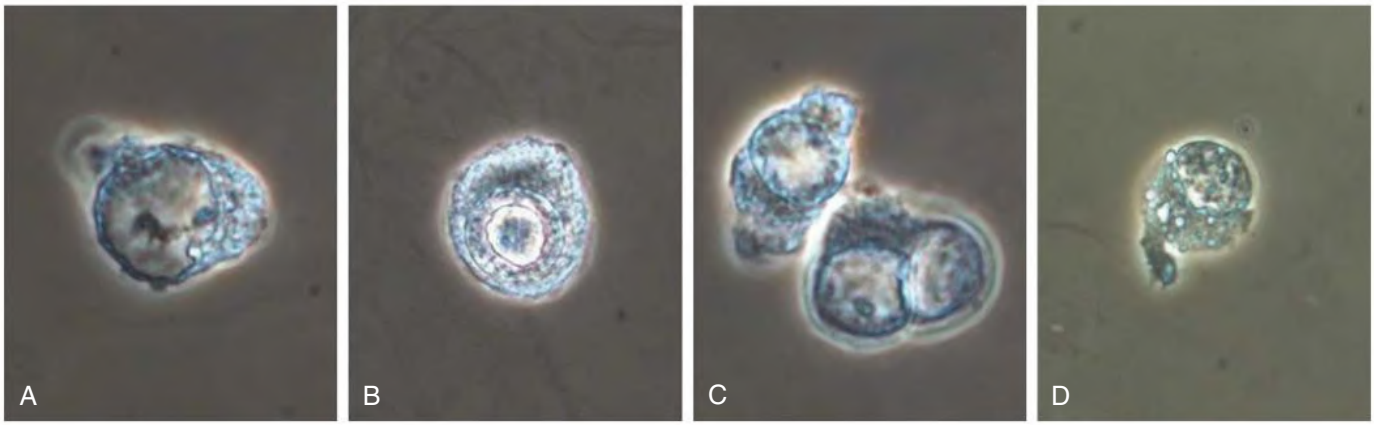

Fig. 4.6 Decoy Cells. (A) Cell with nuclear ground-glass or gelatinous appearance (phenotype 1). (B) Cytomegalovirus-like cell with a large intranuclear inclusion surrounded by a clear halo (phenotype 2). (C) A binucleated cell (bottom, phenotype 3) and a cell with an enlarged ground glass nucleus (phenotype 1). (D) Cell with clumped chromatin (phenotype 4). (Phase-contrast microscopy; original magnification ×400.)

BK Virus Infection

The KDIGO clinical practice guideline for kidney transplant recipients recommends monitoring for BK polyomavirus (BKV) reactivation (which may lead to BKV nephropathy [BKVN] and graft loss) by measuring viral nucleic acid in the blood (i.e., viremia).[41] This approach is expensive and not always available.[42] As an alternative, searching for "decoy cells" on either smeared or cytocentrifuged alcohol-fixed and Papanicolaou-stained urine specimens provides satisfactory diagnostic accuracy.[42,43]

However, decoy cells can also be easily identified by phase-contrast microscopy in routine unstained samples[44] (Fig. 4.6). Four decoy cell phenotypes are recognized[45]: (1) nuclear ground-glass or gelatinous appearance (see Fig. 4.6A); (2) intranuclear inclusion surrounded by a clear halo (cytomegalovirus-like; see Fig. 4.6B); (3) multinucleated cells (see Fig. 4.6C); and (4) vesicular nuclei with clumped chromatin and nucleoli (see Fig. 4.6D). In addition, hybrid forms are frequently seen, as are cells with eccentric nucleus and comet-like appearance. The presence of decoy cells may indicate solely the reactivation of BKV

infection; however, when they persist over time, are in high numbers, or are found in urinary casts, they are a reliable marker of likely BKVN, which should be confirmed by measurement of BK viremia.[42,43,45]

Urologic Diseases

Urinary tract disorders such as cancer, urolithiasis, and hydronephrosis are associated with variable numbers of isomorphic urinary erythrocytes, which are often associated with leukocytes or transitional epithelial cells (from deep or superficial layers of uroepithelium). In addition, in uroepithelial cancer, malignant transitional cells can be found, which show abnormal size and shape, increased number and size of nuclei, and enlarged nucleoli.[46]

Nonspecific Urinary Abnormalities

Some urine sediment findings are nonspecific. This occurs when variable numbers of hyaline or hyaline-granular casts are found with or without low numbers of isomorphic erythrocytes, leukocytes, common crystals, or superficial transitional epithelial cells. In such cases, the correct interpretation of the urinary findings requires adequate clinical information and the knowledge of other laboratory tests.

AUTOMATED ANALYSIS OF URINE SEDIMENT

In high-income countries, automated urinary sediment analyzers are increasingly used in clinical laboratories where several hundreds of urine samples are analyzed every day. Three main types of automated instruments using different technology are available: flow cytometry, automated intelligent microscopy, and cuvette-based microscopy.

Flow cytometry supplies quantitative results and graphics ("scattergrams") of the identified particles.[47]

Intelligent microscopy supplies quantitative results and images of the particles present in the sample, which are pooled and shown on the screen by particle categories (e.g., all erythrocytes, leukocytes).[48]

Cuvette-based microscopy supplies high-quality grayscale images of elements within whole microscopic fields, obtained with both bright-field and phase-contrast microscopy.[49]

Compared with manual microscopy, automated urine sediment analyzers offer several advantages: small volumes of urine are required (1–3 mL); high numbers of samples can be examined in a short time (up to 130/h); elimination of the drawbacks caused by sample centrifugation (e.g., time consumption, loss/lysis of particles); and quantitative results with small variation coefficients. However, they also have limitations: their findings correlate well with manual microscopy for elements such as erythrocytes, leukocytes, and SECs, but not for others such as casts and nonsquamous epithelial cells (i.e., RTECs and deep and superficial transitional cells). Finally, they cannot identify the subtypes of pathologic casts, lipids, decoy cells, and malignant atypical epithelial cells.

For these reasons, in spite of their continuous diagnostic improvement, automated instruments cannot yet replace manual microscopy for samples from renal patients.[50]

SELF-ASSESSMENT QUESTIONS

1. The reagent strip for protein:
   - **A.** detects exclusively urinary albumin.
   - **B.** detects Bence Jones proteinuria.
   - **C.** is not influenced by the pH of the urine.
   - **D.** is not influenced by the specific gravity of the urine.
2. Regarding the preparation of the urine sample and its microscopic examination, which of the following is *false*?
   - **A.** The sample should be examined within 3 hours of collection.
   - **B.** All crystals are birefringent under polarized light.
   - **C.** When collecting the urine sample, only the midstream urine should be collected.
   - **D.** Phase-contrast microscopy is helpful for particle identification.
3. The automated urine sediment analyzers available today:
   - **A.** are adequate for the evaluation of the kidney patient.
   - **B.** require high volumes of urine.
   - **C.** adequately identify renal tubular epithelial cells.
   - **D.** allow the examination of a high number of samples in a short period of time.

Point of Care Ultrasound in Nephrology

William Beaubien-Souligny, Abhilash Koratala

DEFINITION AND SCOPE

Point-of-care ultrasonography (POCUS) is a limited ultrasound examination performed by the clinician at the patient's bedside to answer focused questions. Most of these questions are binary in nature; for example, "Does the patient have hydronephrosis?" "Is there a pericardial effusion?" In conjunction with history and physical examination findings, POCUS helps to arrive at a diagnosis or narrow the differential diagnosis. Although it may expedite care and eliminate the need for further imaging, POCUS is not a replacement for comprehensive ultrasound studies. The latter usually involves detailed assessment of an anatomic region and a report that includes a set of standard parameters, whereas POCUS answers focused clinical questions to guide the diagnostic process and management.

The scope of nephrologist-performed POCUS has recently expanded. Kidney ultrasound; volume status assessment using focused cardiac, lung, and abdominal vein Doppler ultrasound; and vascular access ultrasound are all within the scope of contemporary nephrology practice.[1,2] Fig. 5.1 illustrates the common nephrology-relevant POCUS applications. POCUS has evolved as one of the pillars of bedside clinical examination.[3,4]

BASIC PHYSICS AND INSTRUMENTATION

The *piezoelectric crystals* in the ultrasound transducer produce high-frequency sound waves and convert the returning echoes (from the organs) into electrical signals, which are then displayed as a two-dimensional grayscale image on the monitor. Although some newer handheld ultrasound devices use chip technology instead of piezoelectric crystals, the wave characteristics, modes, and principles of image acquisition essentially remain the same.

Ultrasound Imaging Modes

Various modes of ultrasound display allow evaluation of different aspects of a tissue. The key modes pertinent to POCUS are described below.

B-Mode

B, or the brightness mode, denotes the regular two-dimensional (2D) grayscale display composed of several dots of varying brightness. It is the universal imaging mode, where structures appear in different shades of gray from black to white (Fig. 5.2A).

M-Mode

M, or the motion mode, is a unidimensional imaging mode that displays the movement of a structure over time. It is used to detect and/or quantify the movement of structures (e.g., respiratory variations in the diameter of the inferior vena cava [Fig. 5.2B], excursion of cardiac valves, pleural sliding).

Color Doppler

In color flow mode, the velocity of mobile acoustic interfaces (red blood cells [RBCs]) is measured as a shift in frequency and represented as a range of colors. This mode is used to detect the presence of flow and identify its direction. When the RBCs move away from the transducer, the reflected frequency is lower than the transmitted frequency, and the difference or shift is represented as *blue*. On the other hand, if the RBCs move toward the transducer, reflected frequency is higher than the transmitted frequency and the shift is represented as *red*. The detection of frequency shift is optimal when the angle of insonation (direction of the ultrasound beam) is parallel to the flow, whereas a perpendicular angle (90 degrees) results in minimal color display with ambiguous directionality. Fig. 5.2C illustrates the arterial and venous flow in a renal allograft using color Doppler.

Spectral Doppler

This mode enables quantitative assessment of the blood flow by graphically representing velocity over time. The spectral waveform is displayed above the baseline if the flow is toward the transducer (analogous to red in color mode) and below the baseline if the flow is away from the transducer (blue in color mode). Spectral Doppler is of two main types: pulsed wave (PW) and continuous wave (CW) Doppler. PW Doppler involves emission of ultrasound waves in pulses and is used to quantify blood flow at a particular location (e.g., to measure the velocity in the renal artery, to assess the flow pattern in portal vein). Figure 5.2D illustrates PW Doppler tracing of a renal artery.

CW Doppler involves continuous emission of ultrasound waves and can measure higher velocities than PW Doppler. However, it does not sample a specific area and displays the signals received from all the vessels along the path of the Doppler line. This mode is useful in echocardiography when accurate measurement of peak velocity across a region is needed, such as the assessment of valvular stenosis.

Transducer Selection

The transducer or probe is a component of the ultrasound machine that contains piezoelectric crystals and is used to acquire images. There are various types of transducers that differ by frequency, crystal arrangement, and shape. High-frequency waves produce high-resolution images but penetrate shallower depths. Conversely, low-frequency waves penetrate deeper at the expense of resolution. Therefore high-frequency transducers are typically used to image superficial structures such as an arteriovenous fistula, and low-frequency transducers are used for deeper structures such as the kidney and the heart. For

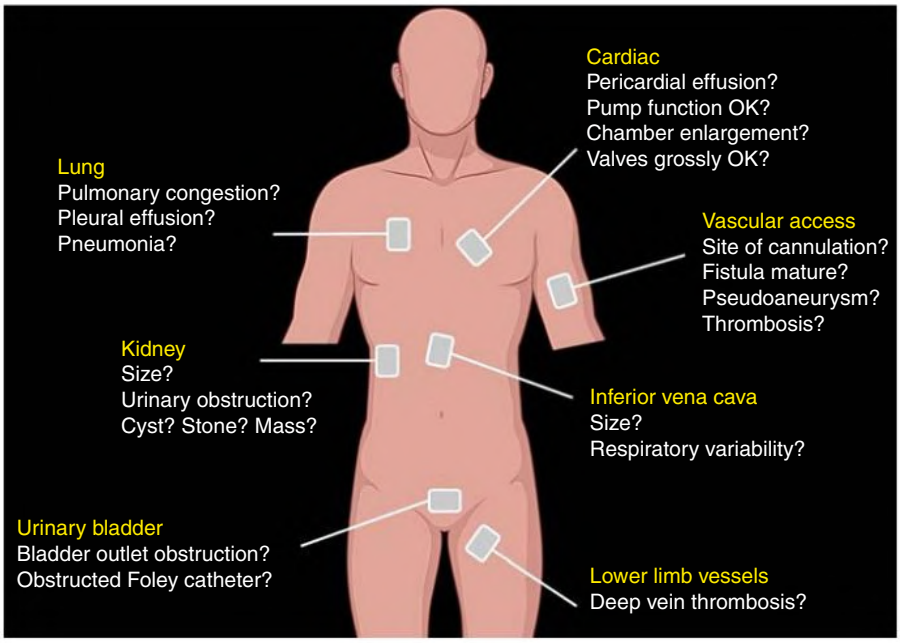

Fig. 5.1 Common sonographic applications and focused questions encountered in nephrology practice. (Created with Biorender.com.)

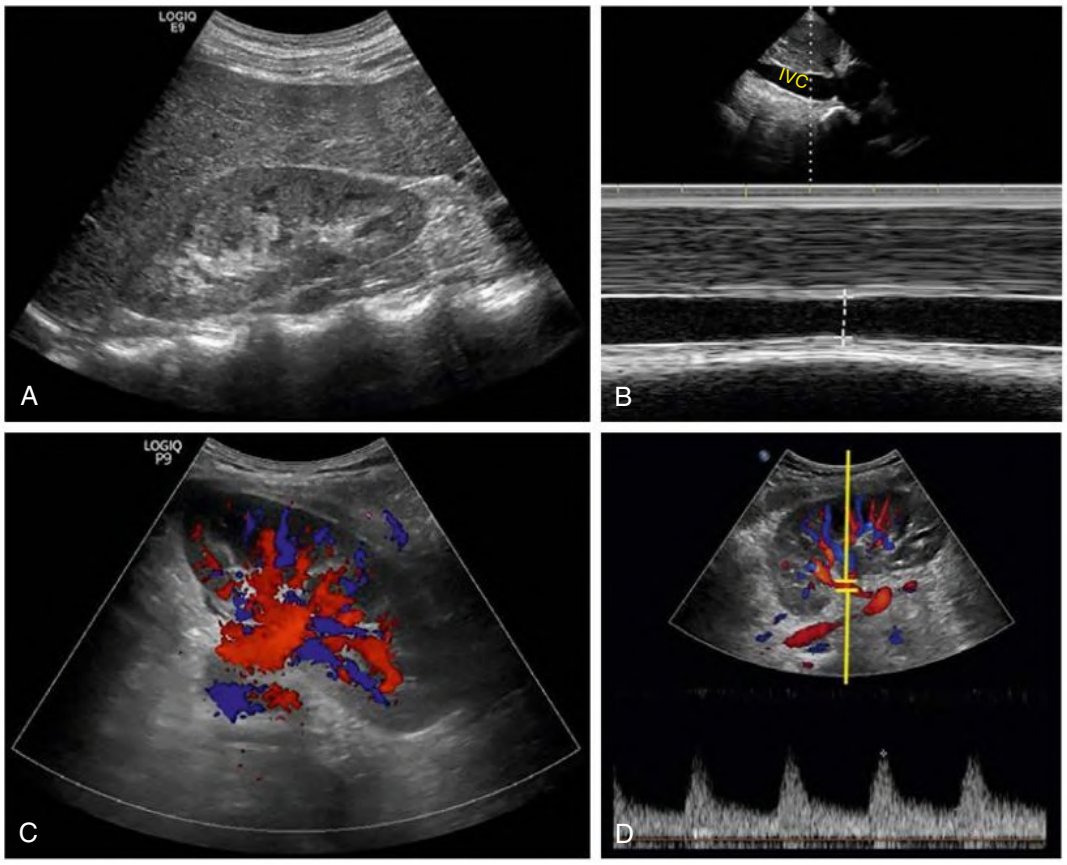

Fig. 5.2 (A) Grayscale image of a normal kidney. (B) M-mode image of the inferior vena cava. Tracing represents movement of the structure over time along the cursor *(dotted line).* (C) Color Doppler image of a normal transplanted kidney. (D) Pulsed wave Doppler image of renal artery. Note the Doppler line, which is like the M-mode cursor but with a small opening called sample volume, which should be placed in the region of interest to measure the flow. (Created with Biorender.com.)

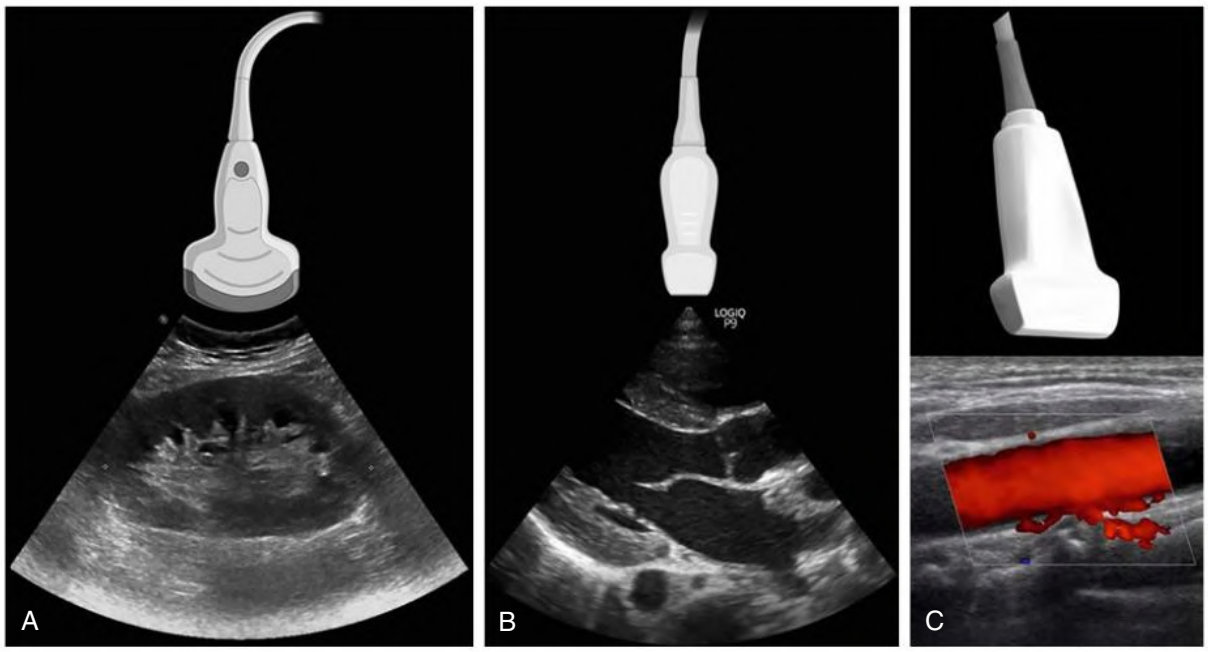

Fig. 5.3 Curvilinear (A), phased array (B), and linear (C) transducers illustrating their respective fields of view. (Created with Biorender.com.)

nephrology-related applications, the three most common types of transducers are curvilinear, phased array, and linear. A *curvilinear transducer* is a low-frequency probe that consists of curvilinear or convex arrangement of crystals and produces a broad field of view (Fig. 5.3A). This allows scanning wider areas and deeper structures; hence it is best suited for abdominal applications. A *phased array transducer* is also a low-frequency transducer but with a small footprint and central arrangement of crystals producing a pie-shaped image (Fig. 5.3B). Because this enables scanning through narrow spaces such as rib interspaces, it is well suited for cardiac applications. Moreover, *phased,* or differential, excitation of piezoelectric elements produces sequential pulses of ultrasound waves, which allows optimal imaging of mobile structures (e.g., heart). A *linear transducer* is a high-frequency probe with crystals arranged in a straight line and produces a rectangular image (Fig. 5.3C). It is best suited for vascular applications, which require higher resolution. Some newer handheld ultrasound devices combine these different properties into one transducer, allowing multisystem scanning by changing the presets (e.g., abdomen, vascular, cardiac) without actually switching the probe.

Image Orientation and Interpretation

Understanding the image orientation is key to accurate interpretation. A structure that is closer to the transducer is displayed at the top of the image, whereas a structure that is farther from the transducer is displayed at the bottom. What is displayed on the right and left of the image depends on the direction of transducer orientation marker (probe marker) while obtaining the image. This marker can be a dot, a light, or a ridge on the transducer and corresponds to the orientation marker on the screen (screen indicator), which is toward the left in the abdomen preset. During a standard abdominal exam, the probe marker is pointed toward the patient's head when obtaining longitudinal images. Therefore the superior pole of the kidney is on the left and the lower pole is on the right of the image in the long axis view. Fig. 5.4 illustrates image orientation.

The displayed echogenicity or brightness of a tissue or structure depends on the strength of the reflected signals. Structures that efficiently transmit sound waves without reflection appear black and are described as *anechoic* (i.e., not making echoes). Examples include urine, blood, bile, and serous fluid in cysts. On the other hand, *hyperechoic* structures reflect more sound waves (make more echoes) and appear bright/white. Examples include calcified and fibrous structures such as stones, diaphragm, and pericardium. Some hyperechoic structures (e.g., stones, bones) create shadows due to near-total reflection of ultrasound waves precluding visualization of the underlying structures. Air is also a poor ultrasound transmitter, and its presence will preclude imaging of deeper structures. Most soft tissues appear in different shades of gray and are described in terms of *relative echogenicity,* that is, in comparison with the brightness of surrounding structures. Structures that reflect fewer sound waves compared to surrounding structures are described as being *hypoechoic* (e.g., renal cortex vs. liver). The term *isoechoic* is used to describe structures that make echoes of similar intensity to that of the surrounding structures. For example, cortex of the kidney can be isoechoic to that of the medulla in some cases of chronic kidney disease, where corticomedullary differentiation is lost.

KIDNEY AND BLADDER ULTRASOUND

Technique

Kidney ultrasound is performed using a curvilinear transducer. If the latter is not available, a phased array transducer can be used to rule out gross abnormalities such as hydronephrosis; however, parenchymal characteristics and small lesions may not be well visualized. Liver and spleen act as *acoustic windows* to image the right and left kidneys, respectively—meaning that the right kidney is visualized through the liver and the left kidney is visualized through the spleen; otherwise, bowel gas will impede the view. Examination is performed with the patient in the supine position, though lateral decubitus, oblique, or even prone positions may sometimes be required for visualization of the left kidney due to overlying bowel gas. To acquire longitudinal views of the kidney, the transducer is positioned in the mid or anterior axillary line at the tenth rib interspace, with the orientation marker pointing toward the patient's head and aiming slightly posterior. The transducer may have to be moved superiorly or inferiorly depending

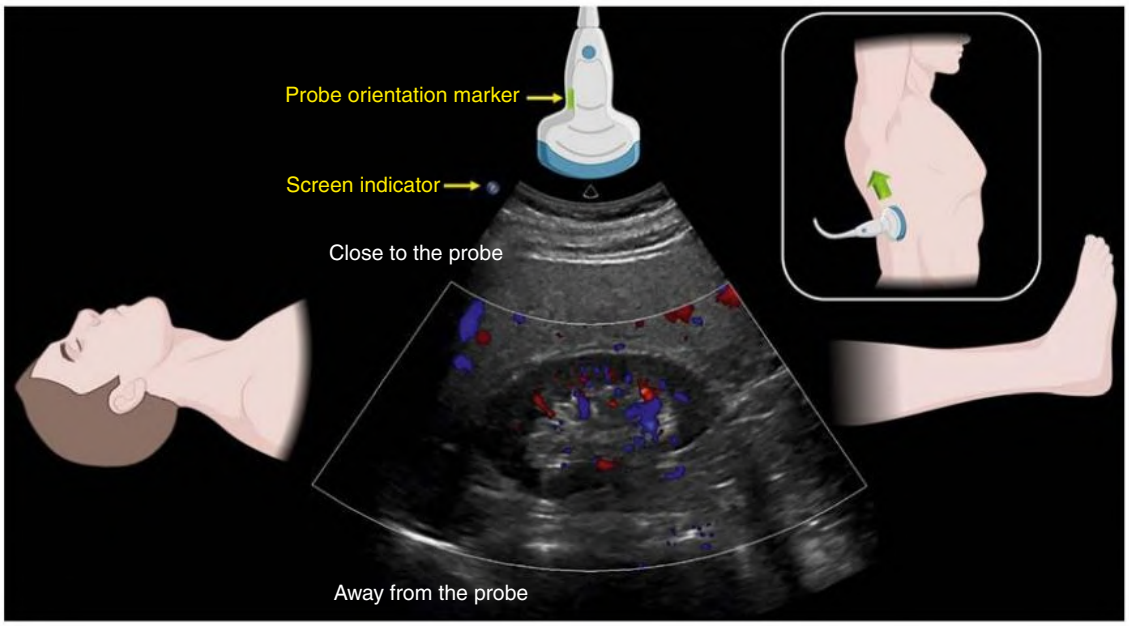

Fig. 5.4 Orientation to an Ultrasound Image. The *green arrow* denotes direction of the probe orientation marker. The right kidney is shown here, but the principles remain the same for any organ being imaged. (Created with Biorender.com.)

on the patient's body habitus. Once the entire long axis of the kidney is in view, the transducer must be fanned (tilted) anteriorly and posteriorly to image it completely. The transducer is then rotated 90 degrees counterclockwise to obtain a short axis or transverse view of the kidney. With the transverse view obtained, the transducer is fanned superiorly and inferiorly to visualize the kidney from pole to pole. Although comprehensive Doppler evaluation to detect renal artery stenosis is beyond the scope of POCUS, color Doppler images of the kidney should be obtained. They provide a global assessment of kidney perfusion and allow detection of gross vascular abnormalities such as an arteriovenous malformation that can sometimes mimic a dilated collecting system.[5]

Image acquisition of the transplanted kidney is relatively easy because of its superficial location in the pelvis. Longitudinal and transverse views should be obtained, paying attention to the surgical anatomy and perinephric space to evaluate for collections such as hematoma or lymphocele. In children and thin individuals, a linear transducer may be used to obtain images with higher resolution.

The urinary bladder is also imaged using a curvilinear transducer with the patient supine. Usually, the transverse view is obtained first by placing the transducer just above the pubic symphysis with the orientation marker to the patient's right and aiming the beam inferiorly. A fanning movement should be performed to visualize the bladder superoinferiorly. The transducer is then rotated 90 degrees clockwise with the orientation marker facing the patient's head to obtain the longitudinal view and fanned to visualize the right and left walls of the bladder.

Interpretation

On sonographic images, the kidney appears as a well-defined, bean-shaped structure surrounded by an echogenic capsule. The kidney is about 9 to 12 cm long in the longitudinal plane and varies with patient height. Kidney parenchyma is composed of the outer cortex and inner medulla, which in turn is organized into multiple pyramids. Cortex is usually *hypoechoic* (or *isoechoic*) compared to the adjacent normal liver and spleen. Cortical tissue normally extends into the medulla, separating pyramids in the form of columns called columns of Bertin. These columns can sometimes hypertrophy and mimic a neoplasm. The medullary pyramids appear *anechoic* or *hypoechoic* compared to the cortex. These are prominent in young children but not always well visualized in adults. The echogenic sinus fat, which encases the renal collecting system, occupies the majority of the inner kidney. The undilated collecting system is not typically visible as a distinct structure; therefore the appearance of an *anechoic* area amid sinus fat should raise the suspicion for hydronephrosis. On the other hand, the collecting system of a well-functioning transplanted kidney is often slightly dilated, likely because of a combination of an increased volume of urine produced (solitary functioning kidney) and loss of the ureter's tonicity from denervation.[6] In the transverse or short axis view, the midportion of the kidney is C-shaped, with the vessels entering and leaving through the hilum, and the poles appear circular (Fig. 5.5).

The urinary bladder appears as an *anechoic,* fluid-filled structure (urine is black on ultrasound). It is ovoid to rectangular when full, but the shape varies with the amount of urine present. Note should be made of the uterus in females and the prostate in males where applicable.

When evaluating a patient with acute kidney injury (AKI), excluding urinary obstruction is the main indication for POCUS. In addition, evaluating kidney size and echogenicity gives information about chronicity of the kidney dysfunction (see Chapter 97).

Hydronephrosis

Hydronephrosis is essentially *anechoic* backlogged urine that appears as branching, interconnected areas in the renal collecting system. The severity of hydronephrosis is qualitatively graded as mild, moderate, or severe (Fig. 5.6). In mild hydronephrosis, there is dilation of the renal pelvis and calyces, but the overall parenchymal architecture is retained. In moderate hydronephrosis, the medullary pyramids start to flatten due to back pressure in addition to increasing dilation of the pelvicalyceal system. In severe cases, the renal pelvis and calyces appear ballooned (occupying most of the kidney), and corticomedullary differentiation is lost (making the parenchyma thin). If the hydronephrotic area demonstrates internal echoes, pyonephrosis (pus in

Fig. 5.6 Mild (A), moderate (B), and severe (C) hydronephrosis.

the collecting system) should be considered in the appropriate clinical context, such as when the patient presents with fever and flank pain. False negatives for hydronephrosis can occur in the setting of acute or partial obstruction, volume depletion, and retroperitoneal fibrosis.[7,8] It is prudent to perform repeat POCUS examination and/or excretory urography when the suspicion for obstruction is high.

Prominent renal vasculature and vascular malformations can mimic hydronephrosis, as both blood and urine appear *anechoic.* However, demonstrating the presence of flow using color Doppler confirms vasculature (Fig. 5.7A–B). Similarly, cysts are also *anechoic* and may be confused with hydronephrosis, particularly when close to the renal pelvis (parapelvic cysts) (Fig. 5.7C–D). However, cysts tend to be round and well circumscribed as opposed to hydronephrosis, which is an irregular branching structure. In addition, continuity can be demonstrated between dilated renal pelvis and hydroureter while the cyst is not connected to the ureter. Comparison with prior imaging helps when available.

Stones

Kidney stones may be encountered in patients with urinary obstruction. On grayscale images, they appear as *hyperechoic* structures with a posterior acoustic shadow. Acoustic shadowing is the black area or signal void seen beyond structures that do not transmit ultrasound waves. In the color Doppler mode, stones exhibit the "twinkling sign," which refers to a rapidly alternating focus of color Doppler signals mimicking turbulent flow, which is more pronounced with rougher stones.

Urinary Bladder

Sonographic evaluation of urinary obstruction should always include images of the urinary bladder. It helps in assessing urinary retention,

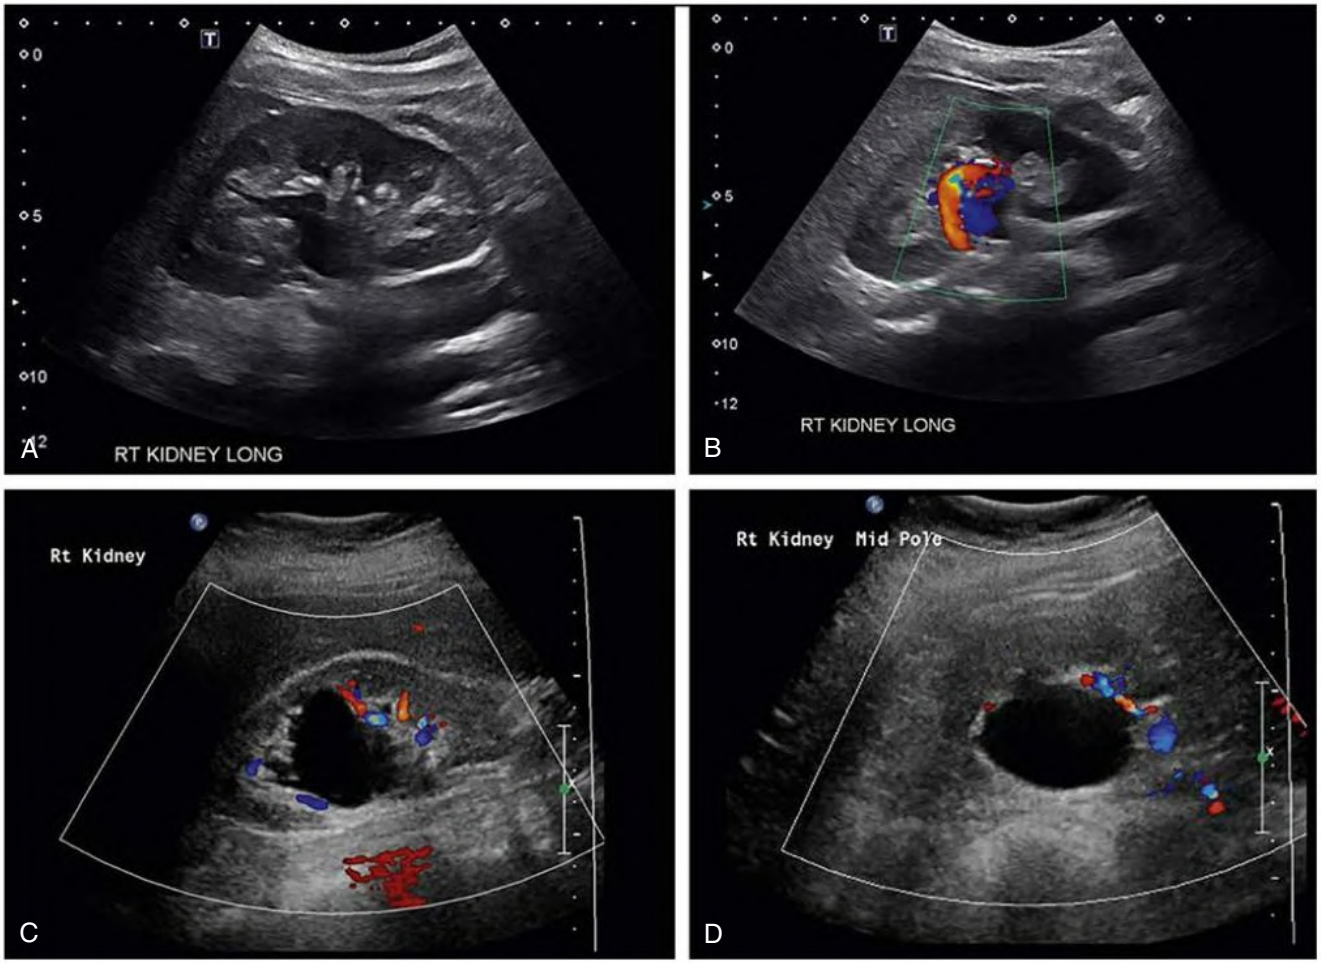

Fig. 5.7 (A) Grayscale image of the kidney demonstrating an anechoic area mimicking mild hydronephrosis. (B) Color Doppler image of the same kidney demonstrating blood flow suggestive of vasculature (arteriovenous malformation in this case). (C–D) Longitudinal and transverse images of kidney demonstrating a large parapelvic cyst mimicking hydronephrosis.

and pathologies such as enlarged prostate, bladder stones, and masses may be found that guide management. Furthermore, a misplaced or obstructed Foley catheter can be easily identified (Fig. 5.8).

FOCUSED CARDIAC ULTRASOUND

Accurate assessment of volume status allows effective management of patients with complex fluid and electrolyte disorders commonly encountered in nephrology practice. Goal-directed ultrasonography of the pump, pipes, and leaks provides helpful insights into a patient's hemodynamics. Pump represents focused cardiac ultrasound (FoCUS), pipes represent inferior vena cava (IVC) ultrasound and venous Doppler, and the leaks indicate assessment of the extravascular lung water and ascites. Though separately mentioned here, IVC ultrasound is often considered a component of FoCUS.

Technique

There are five standard views of FoCUS, namely, parasternal long axis, parasternal short axis, apical four-chamber, subcostal four-chamber, and subcostal IVC. It is important to be familiar with all these views, as some of them may not be well visualized depending on the patient's body habitus, surgical dressings, and so forth, necessitating an alternative approach. The following is a brief description of the image acquisition technique as well as key cardiac structures visualized in each of these views. Also, note that by convention the screen indicator is displayed to the right in the cardiac preset (as opposed to left in the abdominal and vascular presets) but still corresponds to the probe marker. Therefore failure to select the appropriate preset results in flipped images.

Parasternal Long Axis (PLAX) View

This view images the heart in *its* long axis, which is oblique with respect to the *body's* long axis. The transducer is placed just to the left of the sternum *(parasternal)* in the third or fourth intercostal space with the probe marker toward patient's right shoulder.

In the PLAX image (Fig. 5.9A), the right ventricular outflow tract (RVOT) is seen on the top of the screen as it is closer to the transducer. The long axis view of the left ventricle (LV) is seen posterior to it with its inflow (i.e., the left atrium [LA] and mitral valve) and the outflow (i.e., the aortic valve and ascending aorta [Ao]). Slight rotation and tilting of the transducer may be needed to fully open the LV cavity. The depth of the image should be appropriately adjusted to visualize the descending aorta, which appears as an anechoic circular structure posterior to the LA/LV. This is an important landmark to differentiate pericardial from pleural effusion in this view (see below).

Parasternal Short Axis (PSAX) View

This view images the heart in its transverse plane. It is obtained by rotating the transducer 90 degrees clockwise from the PLAX position

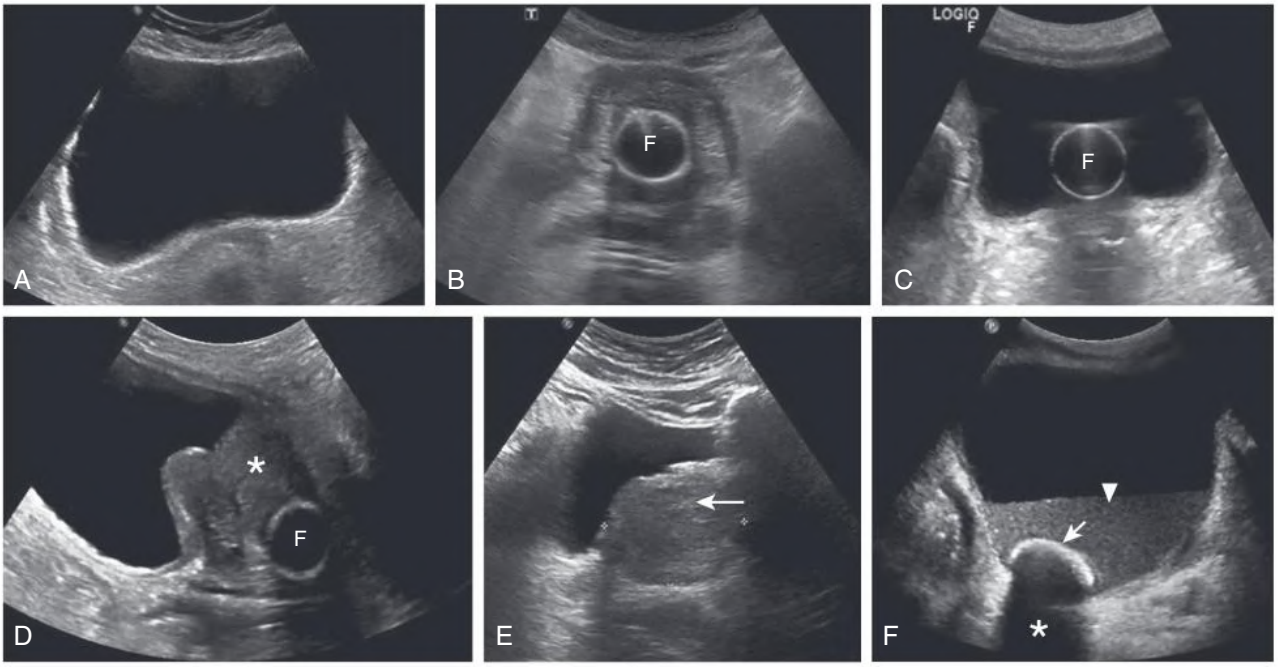

Fig. 5.8 (A) Normal urinary bladder ultrasound, transverse plane. (B) Decompressed bladder with Foley catheter. (Created with Biorender.com.)

such that the orientation marker is facing the patient's left shoulder. There are three main levels of visualization in PSAX that can be obtained by tilting the probe superiorly and inferiorly. The aortic valve can be seen by tilting up the transducer toward the patient's right shoulder. The mitral valve level is obtained when the probe is almost perpendicular to the chest wall. The papillary muscle level comes into view when the face of the probe is slightly tilted down toward the patient's left flank.

Of these, the papillary muscle or the midventricular view is considered a standard FoCUS view and consists of the semilunar right

ventricle (RV) on the top followed by the round LV with papillary muscles appearing as inward projections (Fig. 5.9B). This view allows evaluation of the radial function of the LV and detection of the RV enlargement.

Apical Four-Chamber View

This view images the heart in its coronal plane from the apex. It is obtained by placing the transducer in the fourth or fifth intercostal space (where the apical impulse is felt) with the orientation marker facing the patient's left shoulder (somewhere between 2 o'clock and 3 o'clock positions). Another approach is to slide the transducer inferolaterally from the PSAX position toward the apex. Whenever possible, positioning the patient in the left lateral position improves the image quality; this also applies to parasternal views.

The apical four-chamber view demonstrates all four chambers of the heart and the tricuspid and mitral valves. The right atrium (RA) and RV are on the left of the screen and the LA/LV on the right (Fig. 5.9C). This is a good view to assess atrioventricular valve regurgitation using color Doppler and vegetations, if they are large enough to be seen on transthoracic echo. The apical five-chamber view is obtained by tilting the transducer slightly anterior from the four-chamber view, which brings the LV outflow tract and the aortic valve into view (fifth chamber).

Subcostal Four-Chamber View

This view images the heart through the liver from the subxiphoid area. The transducer is placed just below the xiphoid process in the midline with the orientation marker toward the patient's left side. The transducer should be pressed firmly and tilted such that it is almost parallel to the skin surface. Having the patient bend their knees when possible helps to relax the abdominal wall musculature. This view is particularly useful in patients with difficult or inaccessible chest windows, such as those with hyperinflated lungs (obstructive airway disease, mechanical ventilation), surgical dressings, and so forth.

The subcostal four-chamber view shows the same structures as an apical four-chamber view but appears tilted because a different scan plane is used (Fig. 5.9D). RV size can be underestimated in this view; hence caution should be exercised when commenting on the relative chamber size. In general, it is a good practice to corroborate abnormal findings in at least two different cardiac views.

Subcostal Inferior Vena Cava View

This view is obtained by rotating the transducer approximately 90 degrees counterclockwise from the subcostal four-chamber view. The IVC is seen as a longitudinal anechoic structure joining the heart (RA) (Fig. 5.2B). The hepatic vein is often seen entering the IVC close to the IVC-RA junction. Care must be taken to visualize the widest diameter of the IVC by tiling the transducer from left to right (the ultrasound beam should pass through the center of the vessel). When assessing the RA pressure, maximal diameter and respiratory variation of the IVC are measured just distal to the hepatic vein–IVC confluence, or approximately 2 cm from the IVC-RA junction. IVC size should not be measured at the IVC-RA junction because the diaphragmatic pull can mimic collapse and lead to misinterpretation. A transverse view of the IVC can be obtained by rotating the transducer 90 degrees counterclockwise from this position; this helps to clarify the measurements when in doubt. Care must be taken to avoid mistaking the aorta for the IVC. Contrary to the IVC, the aorta is not in direct contact with the liver, and no IVC-RA junction will be seen.

Interpretation

FoCUS quickly provides the answers to the five Es, that is, the qualitative estimation of left ventricular *ejection;* the presence or absence of pericardial *effusion; equality* (relative ventricular size); *entrance* (IVC size and collapsibility); and the *exit* (stroke volume measurement at the left ventricular outflow tract [LVOT]).[9,10] In addition, attention should be paid to any gross abnormalities such as intracardiac thrombi and valvular vegetations. Also, a quick color Doppler assessment of atrioventricular valves in the apical four-chamber view is helpful to exclude significant regurgitant lesions leading to pulmonary or systemic vascular congestion.

Ejection

Assessment of LV systolic function, or the *ejection,* is a key component of volume status assessment. Qualitative estimation of or "eyeballing" the ejection fraction is done by observing wall motion and comparison of the chamber size between systole and diastole. Wall motion constitutes both thickening and inward motion of the endocardium during systole. In general, the walls should approximate by one-third or more. In patients with depressed LV function, both wall thickening and inward motion are decreased. On the other hand, a hyperdynamic ventricle, that is, where ventricular walls/papillary muscles in the parasternal short axis view almost touch at end systole, may indicate volume depletion if the overall clinical picture is suggestive. In addition, the movement of the mitral valve should be observed. Normally, the anterior leaflet almost touches the interventricular septum with each heartbeat. If the ejection fraction is low, reduced stroke volume results in decreased blood flow across the mitral valve, and it does not open maximally, increasing the distance between the septum and anterior leaflet (Video 5.1). When visual estimation is ambiguous or the physician does not have enough experience in eyeballing, M-mode measurement of this motion can be helpful. The distance between the peak of mitral valve tracing during early passive diastolic filling (E-point) and interventricular septum of greater than 7 mm is generally considered as a marker of significant LV systolic dysfunction (LVEF <30%).[11] This is called E-point septal separation (EPSS).

Effusion

Pericardial *effusion* is an important cause of hypotension and hemodynamic compromise. On ultrasound, it appears as an *anechoic* space between the two pericardial layers. PLAX and subcostal views allow better visualization of the effusion, though it is generally identifiable on all the standard FoCUS views (Fig. 5.10A–B). In the PLAX view, a left pleural effusion may be mistaken for pericardial effusion because the pleural space is immediately posterior to the pericardium. The descending thoracic aorta is an anatomic landmark that helps to differentiate pericardial and pleural effusions in this view. Pericardial effusion is seen anterior to the descending aorta, whereas the pleural effusion is seen posteriorly or starts at the same level (Fig. 5.10C–D). Moreover, a collapsed lung is often seen as a mobile echogenic structure within the pleural effusion.

With respect to severity, a separation between the pericardial layers in diastole of less than 1 cm is considered mild effusion, whereas 1 to 2 cm is considered moderate and greater than 2 cm severe.[12] Whenever a pericardial effusion is detected, note should be made of right atrial collapse at the onset of systole, or diastolic right ventricular collapse. These suggest cardiac tamponade, as does a dilated IVC with minimal or absent respiratory variation.

Equality

Equality refers to relative chamber size, particularly of the RV compared to LV. A normal RV is less than two-thirds the size of the LV and can quickly dilate with pressure or volume overload. When the RV is mildly enlarged, it is slightly more than two-thirds the size of the LV and is of the same size as the LV when moderately enlarged.

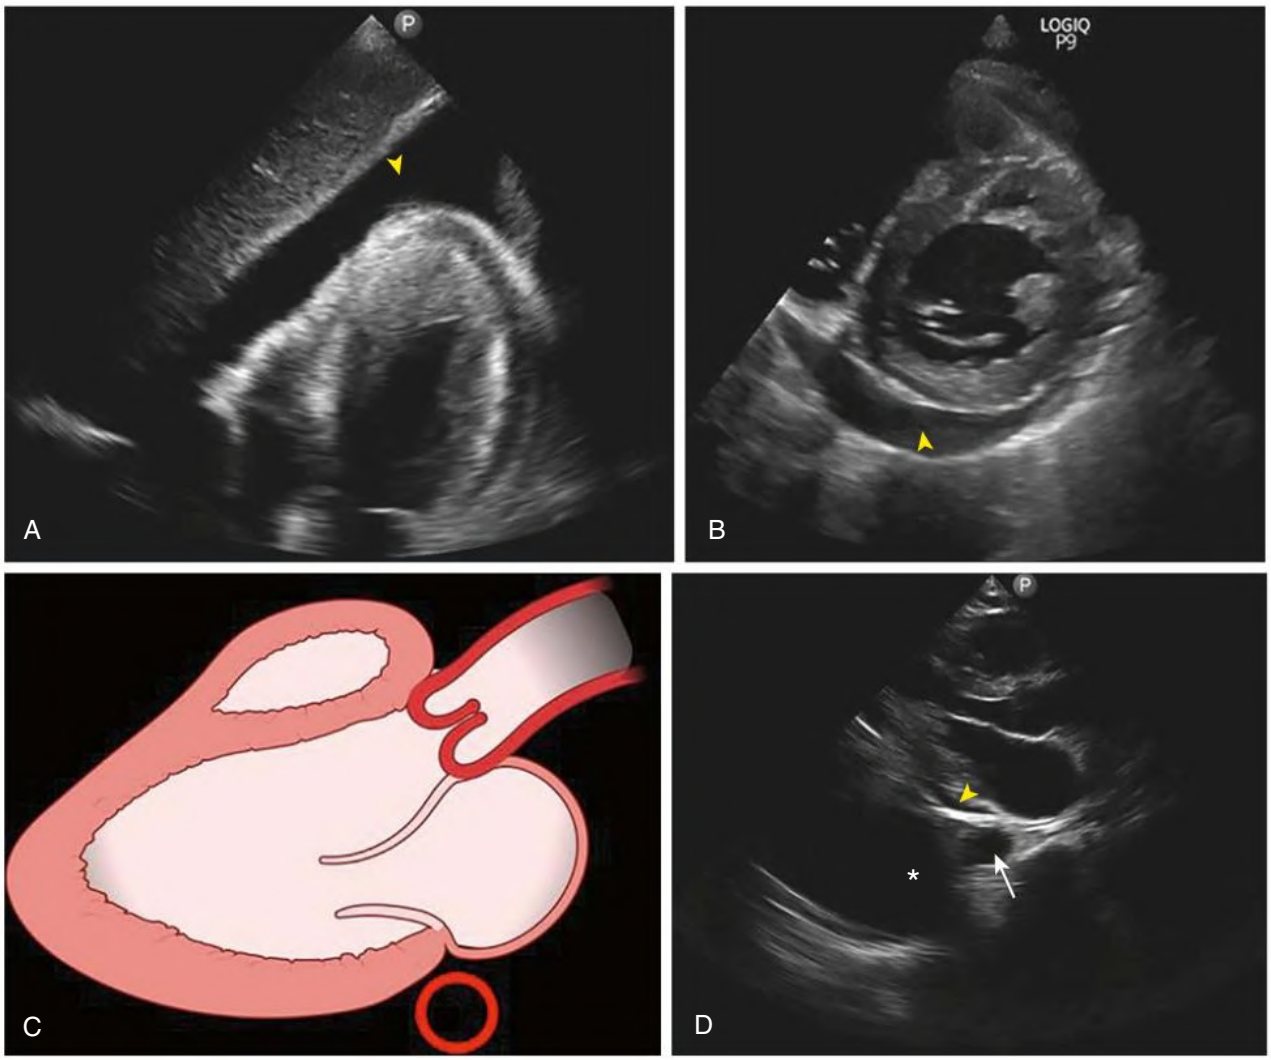

Fig. 5.10 Subcostal (A) and parasternal short axis (B) views demonstrating pericardial effusion *(arrowhead)*. (C) Schematic of normal parasternal long axis view. (D) Parasternal long axis view demonstrating a small pericardial effusion *(arrowhead)* anterior to the descending aorta *(arrow)* and a left pleural effusion *(asterisk)* posterior to it. (C, Created with Biorender.com.)

Severe RV dilation is characterized by it being bigger than the LV (Fig. 5.11A). The apical four-chamber and PSAX are good views to assess this. With volume overload, the RV becomes dilated and the interventricular septum is flattened predominantly in diastole, giving a D-shaped appearance to the LV in the PSAX view. This is called the *D-sign* (Fig. 5.11B). This occurs in both systole and diastole if there is pressure overload (e.g., pulmonary embolism or severe pulmonary hypertension). Although these patients are often hypotensive, indiscriminate administration of intravenous fluids results in further compromise of the LV cavity from excess preload-induced RV dilation leading to drop in cardiac output.

Entrance

Entrance (to the heart) refers to evaluation of IVC size and collapsibility to estimate RA pressure, which is a driver of systemic venous congestion and congestive nephropathy.[13] In spontaneously breathing patients, the IVC collapses during inspiration due to negative intrathoracic pressure. An IVC diameter of 2.1 cm or less and collapsibility greater than 50% with a sudden inspiration (a sniff) indicates normal RA pressure of 3 mm Hg (0–5 mm Hg); an IVC diameter greater than 2.1 cm with less than 50% inspiratory collapse indicates high RA pressure of 15 mm Hg (10–20 mm Hg); scenarios in between are ascribed to an intermediate value of 8 mm Hg (5–10 mm Hg). These cutoffs cannot be used in mechanically ventilated patients because the IVC is dilated at baseline due to positive pressure ventilation and may not collapse at all during the respiratory cycle. Moreover, not all patients are able to sniff on request and IVC collapsibility can significantly vary with magnitude of the inspiratory effort. In general, IVC ultrasound can be used as an indicator of *fluid tolerance,* that is, as a stop point for administering fluids when the IVC is plethoric. However, assessment of *fluid responsiveness* (increase in cardiac output in response to fluids) should not be based on IVC alone. Bedside stroke volume should be measured when possible as described below. Video 5.2 illustrates a small collapsible IVC and a plethoric IVC.

Exit

Exit (from the heart) refers to measurement of the stroke volume at the LVOT. In the emergency medicine literature, *exit* was originally used to denote assessment of the aortic root for thoracic aortic aneurysm and thoracic aortic dissection.[10] In patients with tenuous fluid status but no gross volume overload, assessing fluid responsiveness using FoCUS is helpful when intravenous fluid therapy is contemplated. The passive

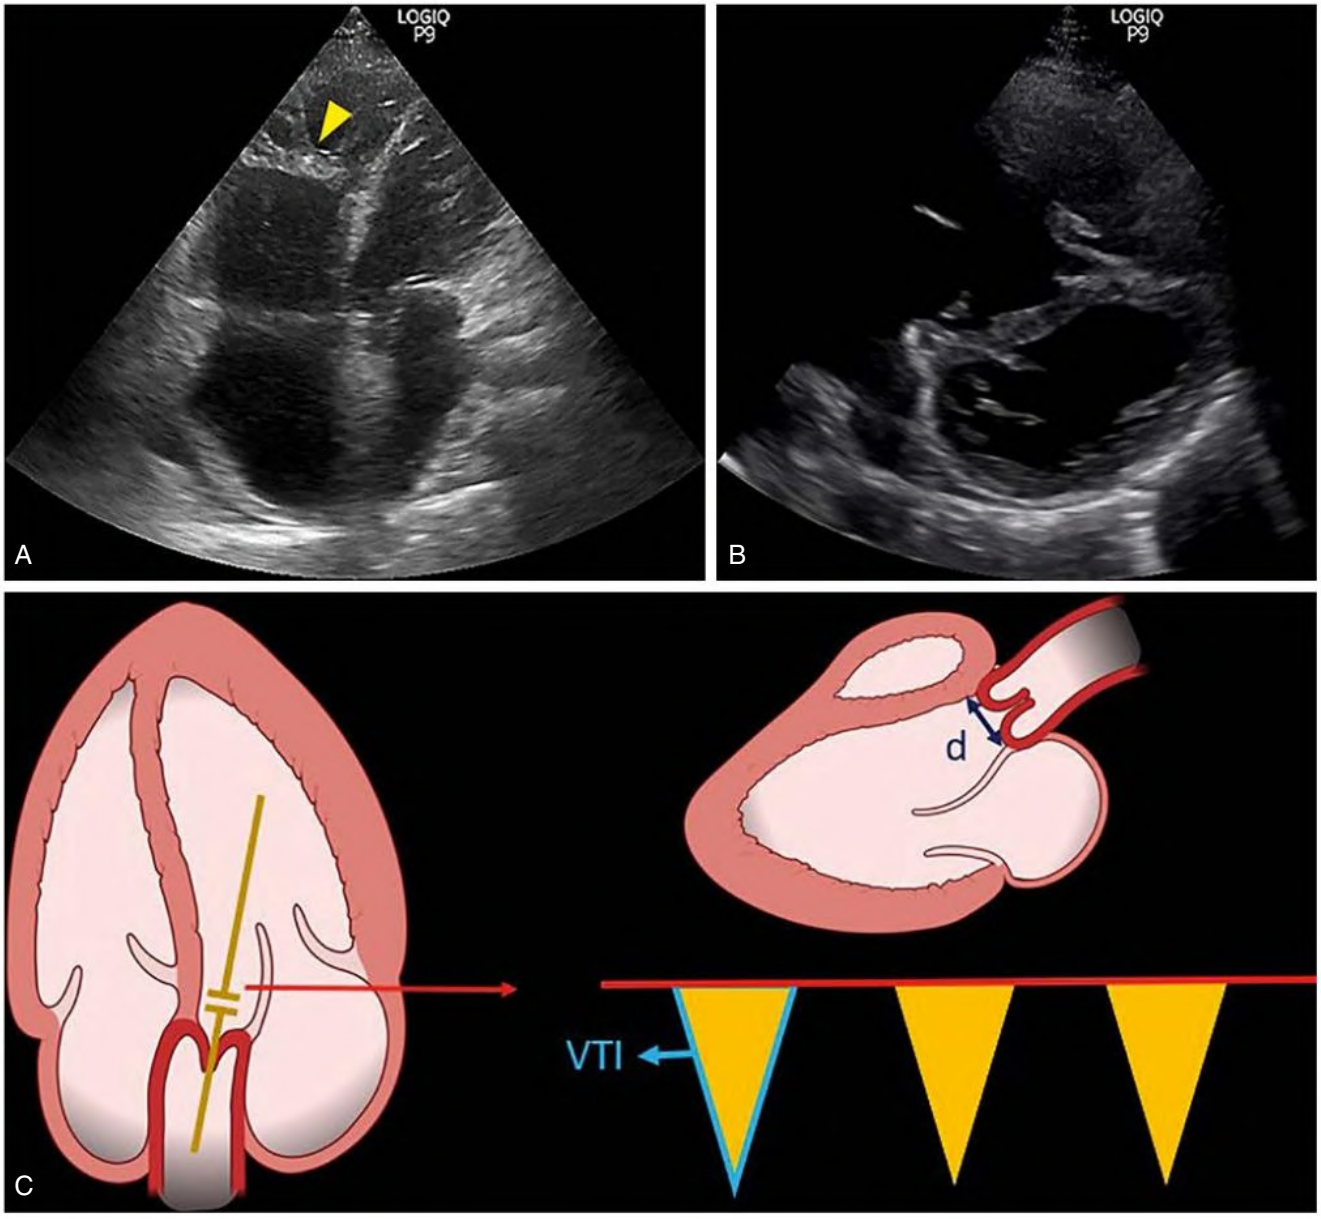

Fig. 5.11 Apical four-chamber (A) and parasternal short axis (B) views obtained from a patient with severe pulmonary hypertension. Note severe enlargement of the right ventricle (larger than left ventricle in apical view) and interventricular septal flattening with D-sign on short axis. *Arrowhead* points to hypertrophied moderator band in the right ventricle. (C) Components of stroke volume assessment. Velocity time integral (VTI) is obtained by tracing the pulsed wave Doppler envelope of the left ventriuclar outflow tract (LVOT) in apical five-chamber view. Cross sectional area of the LVOT is obtained by measuring its diameter *(d)* at the base of the aortic valve in midsystole and using the formula for area of a circle, πr^2 (where r = radius, or diameter divided by 2). (Created with Biorender.com.)

leg raise is a simple bedside method of predicting fluid responsiveness. It is performed by tilting the patient from a 45-degree semirecumbent head-up position to a 45-degree leg-up position, which transfers up to 300 to 400 mL of blood into the central circulation and acting as an autogenous fluid bolus. Stroke volume is measured at the LVOT before and 1 minute after the leg raise; an increase by 10% suggests fluid responsiveness.[14] Stroke volume is the product of the cross-sectional area (CSA) of the LVOT and the velocity time integral (VTI). LVOT CSA is derived from the LVOT diameter in PLAX view using the formula πr^2, and LVOT VTI is obtained by tracing the envelope of the Doppler spectrum of systolic flow in the apical five-chamber view (Fig. 5.11C). As the LVOT diameter is constant for a given person, VTI (normal: approximately 18–22 cm) is generally used as a surrogate for cardiac output changes, assuming the heart rate is relatively constant. This parameter is also used to differentiate between true hypovolemia (VTI will be low) and high cardiac output states (VTI will be high); both conditions are often associated with a hyperdynamic left ventricle and small IVC.

ULTRASOUND OF THE LUNG AND PLEURA

Because air transmits ultrasound poorly, the normally aerated lung parenchyma prevents the visualization of anatomic structures beyond the interface between the parietal and the visceral pleura. Nonetheless,

ultrasound can provide important information related to the pleural and subpleural space. A key feature of lung ultrasound is that it relies on the interpretation of artifacts, which are nonanatomic images generated by the interaction between ultrasound and tissues.

Technique

Lung and pleural ultrasound can be performed using most entry-level POCUS devices. Linear (vascular probe), phased array (cardiac), and curvilinear (abdominal) transducers may be used. However, the preferred transducer will depend on the type of pathology, and multiple types of transducers may be required. The linear transducer has improved resolution of superficial structures, which makes it better for assessing the chest wall, pleura, and superficial subpleural space. Phased array and curvilinear transducers can image structures at a higher depth, which make them superior for imaging lung consolidation and pleural effusion. All transducers are able to visualize artifacts arising from below the pleural line. However, phased array and curvilinear transducers may be superior to linear transducers for this indication.[15] Ultrasound manufacturers usually include a preconfigured setting for lung ultrasound.

To adequately visualize the structures and to reduce artifacts, it is important to position the probe at a perpendicular (90-degree) angle to the chest. This usually produces normal A-line artifacts, as shown in Fig. 5.12A–B. Using a cephalocaudal orientation, the rib shadows help with the identification of intercostal spaces. Because lung ultrasound only provides information at the site where the transducer is located, multiple sites of assessment on the thorax are always required: protocols include assessment of 28 zones (16 right zones and 12 left zones),[16] eight zones (four on each side),[17] or six zones (three on each side).[18] Multiple factors related to the clinical context must be considered when deciding the number of zones to assess. For example, a six-zone protocol might be sufficient for the rapid assessment of an acutely dyspneic patient (Fig. 5.13).[18] On the other hand, evaluation of lung congestion in asymptomatic or minimally symptomatic patients may require more than six zones.[16] Although the evidence is limited, the use of simpler protocols (eight zones) may be comparable to the more time-consuming 28-zone approach.[17]

Interpretation

After adequate visualization of an intercostal space (the area between two rib shadows), the first step is to examine the hyperechoic pleural line just deep to intercostal muscles. This line oscillates or shimmers with respiration, which represents pleural sliding. The presence of sliding confirms that air is not present between the parietal and visceral pleurae (Video 5.3). Movement transmitted from the heart, commonly referred to as a *lung pulse,* also serves the same purpose. This can rule out the presence of a pneumothorax or subcutaneous emphysema at the site of assessment. It is important to first exclude these diagnoses because air will preclude the assessment of deeper structures and produce a pseudonormal A-line pattern that could mislead. Lung sliding and lung pulse can be better visualized by decreasing the depth of the image and by using a linear transducer.

After confirmation of the pleural sliding, depth should be increased up to 10 to 12 cm below the pleural line to examine the subpleural space and optimize the visualization of artifacts, which are illustrated in Fig. 5.12A–D. The normal A-line pattern represents linear artifacts that are parallel and equidistant from the pleural line. These are created by ultrasound reverberation from the pleural interface. B-lines represent linear artifacts that arise from the pleural line, extend to the end of the image without fading, and move synchronously with lung sliding. They tend to completely or partially erase A-line in their path (Video 5.4). B-lines can become *confluent* or *coalescent,* completely erasing the A-lines and giving a *white lung* appearance in cases where there is severe loss of lung aeration. B-lines are the hallmark of increased density of lung parenchyma in the first millimeters below the pleural interface with partial aeration and generally represent increased extravascular lung water. However, they can be seen in multiple pathologies as summarized in Table 5.1. One or two isolated B-line artifacts per rib interspace may not indicate pathology, particularly in the dependent lung zones. The visualization of three or more B-lines in a rib interspace (a *B-line region*) is often significant, and more than two positive B-line regions bilaterally constitute *interstitial syndrome*. The distribution of B-lines, associated ultrasound findings, and clinical context may help differentiate between possible etiologies.

Consolidated or atelectatic lung parenchyma will transmit ultrasound because it is devoid of air and will produce variable appearance on ultrasound, from a *hypoechoic* region to a tissue or liver-like appearance *(hepatization)* (Fig. 5.12E–F). It is important to note that central consolidations that do not reach the pleura are not detected by ultrasound because air is present between the pathology and the transducer. Because of this, lung ultrasound has variable sensitivity for the diagnosis of pneumonia.

Pleural effusion appears as an *anechoic* space above the diaphragm, usually surrounding the atelectatic lung. Effusions can be identified, characterized, and quantified using POCUS (Fig. 5.12G–H). Detection of small pleural effusions require the phased array or curvilinear transducer to be positioned in the midaxillary line to obtain a coronal view of the interface between the lung, the diaphragm, and the liver/spleen. Seeing the dorsal vertebral column in this position usually implies the presence of fluid permitting the transmission of sound. This is called the *spine sign* and is the most sensitive sign to detect a small pleural effusion. Unlike uniformly anechoic simple effusions, complex effusions often contain swirling internal echoes *(plankton sign)* and may demonstrate fibrin stranding or distinct septations. Although most complex effusions tend to be of infectious etiology, a hemothorax with partially clotted blood can have a similar appearance and should be interpreted in the appropriate clinical context.

Clinical Applications

Lung and pleural ultrasound is a valuable adjunct to physical examination in the management of patients with undifferentiated dyspnea and those with difficult-to-determine fluid status. Both of these clinical scenarios are frequently encountered in the care of patients with kidney disease, including those on kidney replacement therapy.

In patients with dyspnea, POCUS is highly sensitive to detect pneumothorax,[19] pleural effusions,[20] and diffuse interstitial syndromes such as acute pulmonary edema,[21] acute respiratory distress syndrome (ARDS), and diffuse viral pneumonia[22] (see Table 5.1). Subpleural consolidations, an irregular pleural line, or a patchy involvement with spared areas all suggest diffuse pneumonia or ARDS, whereas a homogenous distribution of B-lines without pleural anomalies is more compatible with pulmonary edema. B-lines observed in a single location on the thorax may indicate localized pneumonia, partial atelectasis, or pulmonary embolism. However, the sensitivity of lung ultrasound is moderate for bacterial pneumonia[23] and low for pulmonary embolism.[24] These pathologies may present with dyspnea in the presence of primarily an A-line pattern with lung sliding. An A-line pattern will also be seen in acute exacerbations of asthma or chronic obstructive pulmonary disease. A diagnostic algorithm based on the bedside lung ultrasound in emergency (BLUE) protocol[18] used in the intensive care and emergency medicine settings is presented in Fig. 5.13.

Even in the absence of dyspnea, pulmonary congestion may be present, and its detection provides important information to guide fluid management decisions. For example, B-lines are detected in a significant

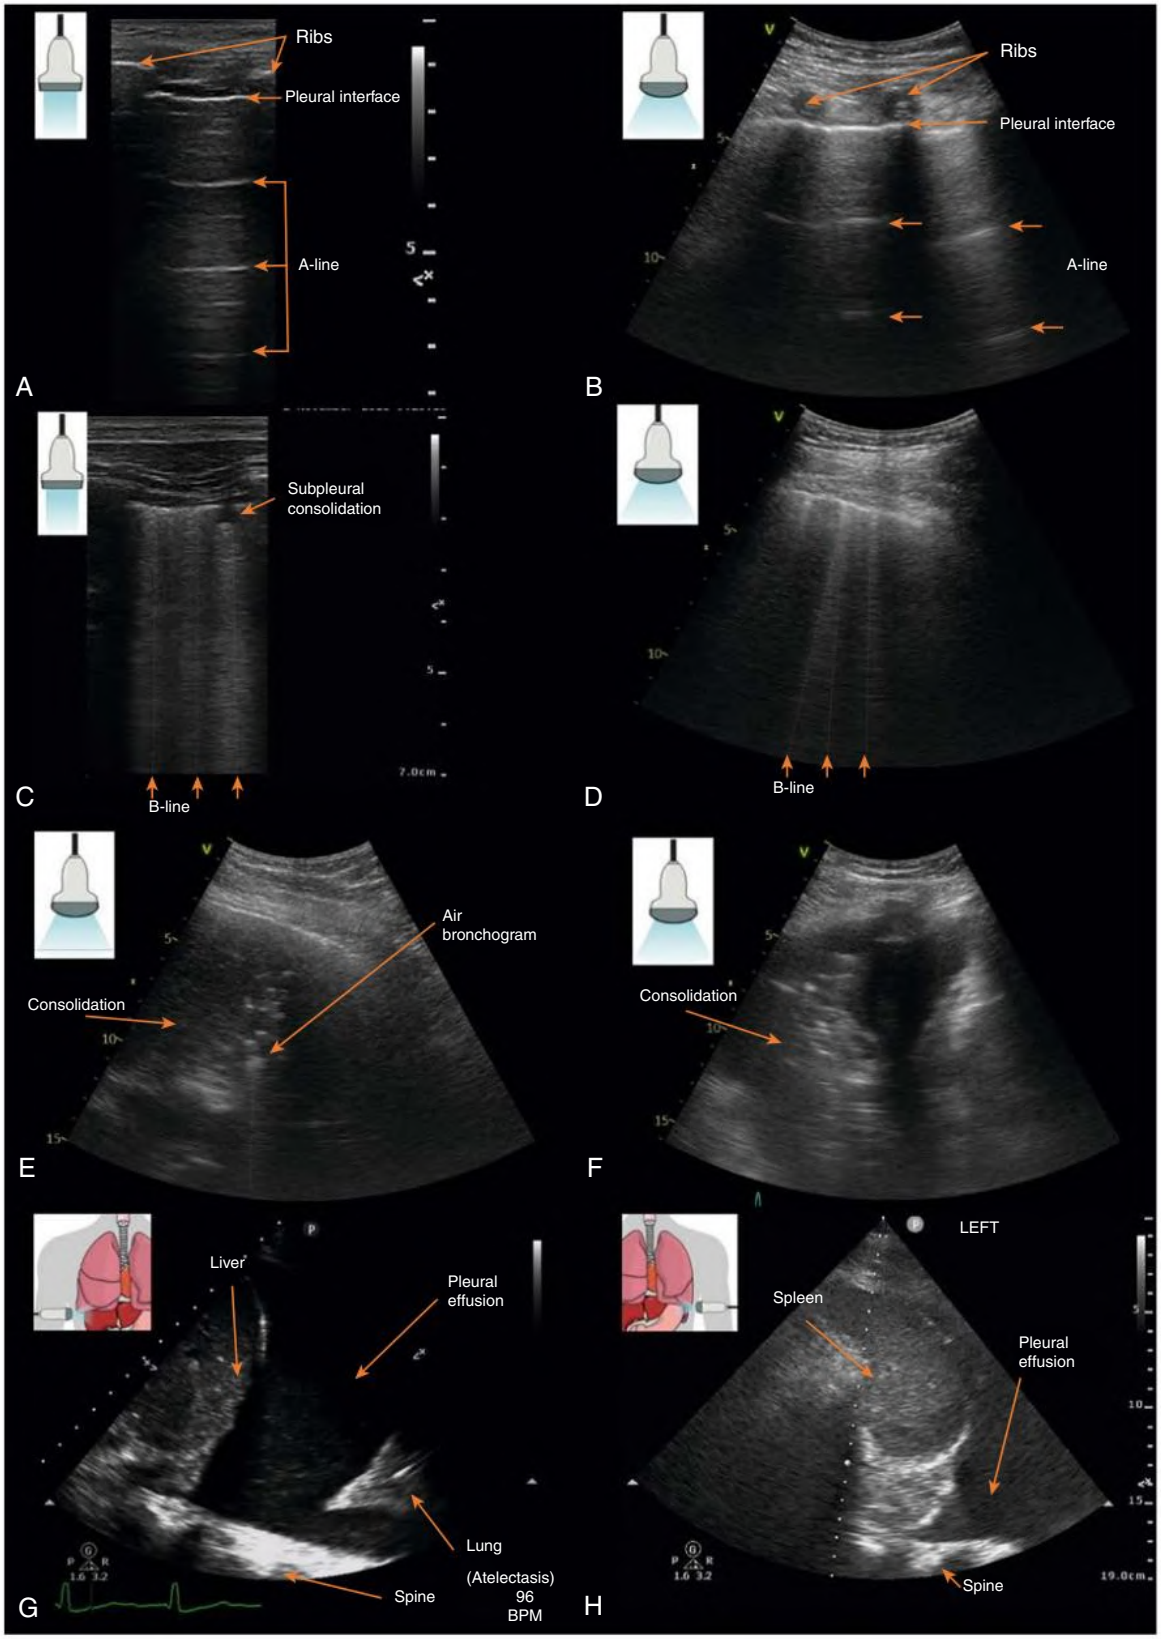

Fig. 5.12 Examples of Lung and Pleural Ultrasound. Normal ultrasound (A-line pattern) using a linear transducer (A) and a curvilinear transducer (B). B-lines shown using a linear transducer (C) and a curvilinear transducer (D). Note that B-lines move with respiration (see Video 5.4). Examples of lung consolidation (also referred often as the C-pattern) showing a heterogeneous tissue-like appearance (E–F). Pleural effusion of the right lower thorax region (G) and to the left lower thorax region (H).

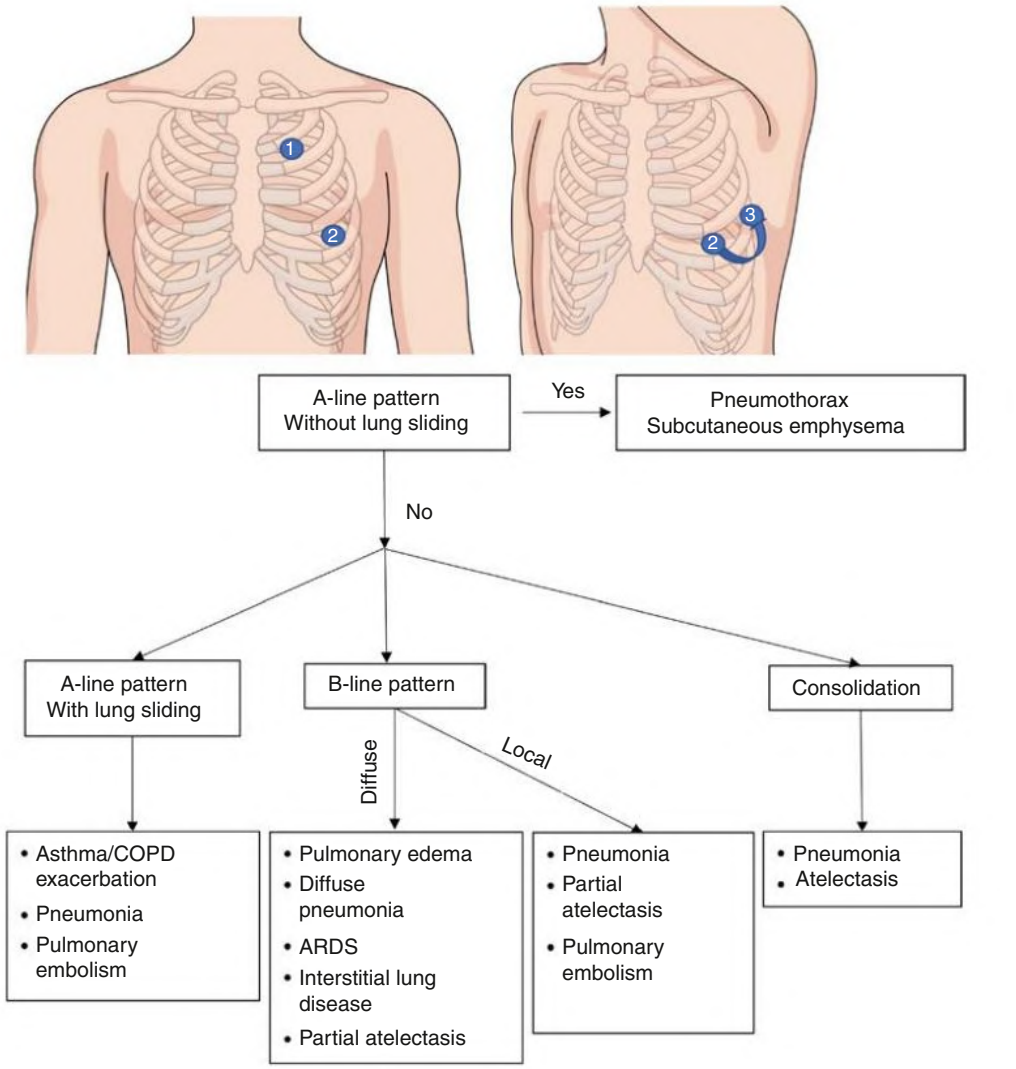

Fig. 5.13 Proposed Approach to Acute Dyspnea Using Lung Ultrasound Based on the Bedside Lung Ultrasound in Emergency (BLUE) Protocol.[4] Three zones on each side are assessed: the upper point *(1)*, the lower point *(2)*, and the posterolateral point *(3)*. The original BLUE protocol also includes assessment of lower extremity veins to detect deep venous thrombosis suggestive of pulmonary embolism. *ARDS,* Acute respiratory distress syndrome; *COPD,* chronic obstructive pulmonary disease.

proportion of asymptomatic patients with end-stage kidney disease[25] and chronic heart failure, and B-lines appear to be more sensitive than chest auscultation to identify pulmonary congestion.[26] In hemodialysis patients, the B-line count is reduced in proportion to the amount of intradialytic ultrafiltration[27] and seems to correlate with mortality,[16,17,28] although it is unclear whether modifying fluid removal prescription to target resolution of B-lines improves outcomes.[29] A recent small trial showed that target weight prescription guided by lung ultrasound improved blood pressure without increasing the risk of intradialytic hypotension[30] and improved LV filling pressures by echocardiography.[31] Interestingly, two single-center trials performed in ambulatory chronic heart failure patients showed that the addition of lung ultrasound to the physical examination may reduce the risk of hospitalization.[32,33]

ARTERIAL AND VENOUS DOPPLER OF THE KIDNEY AND OTHER ORGANS

Doppler ultrasonography enables assessment of blood flow velocity and patterns during the cardiac cycle at various locations in the circulatory system. Arterial Doppler waveforms are influenced by upstream and downstream factors including pulse pressure, the presence of stenosis, blood flow, and vascular resistance of the downstream vascular bed. Venous Doppler waveforms are primarily influenced by the pattern of venous return during the cardiac cycle and systemic venous compliance. The next sections provide a brief overview of this topic; a more detailed account can be found elsewhere.[34,35]

Arterial Doppler

A comprehensive ultrasound examination to evaluate suspected renal artery stenosis involves visualizing the renal arteries throughout their course from the aorta to the level of the segmental and interlobar arteries. In addition, accurate flow velocities need to be measured at multiple sites, which depends on an appropriate angle of insonation and requires a higher operator skill level. Therefore it is better performed by a trained sonographer, rather than a physician, using POCUS to answer focused questions at the bedside.

On the other hand, renal resistive index (RI), which is an indirect indicator of renal artery stenosis, is a ratio and therefore is less

TABLE 5.1 Differential Diagnosis of B-Line Artifacts on Lung Ultrasound

Etiology of B-Lines	Associated Findings/Comments
Diffuse Pattern	
Pulmonary edema	Higher severity in dependent lung regions
Viral pneumonia	Nonhomogeneous distribution (some areas are "spared") with irregular pleural line and subpleural consolidations[a]
ARDS	Nonhomogeneous distribution with irregular pleural line and subpleural consolidations
Interstitial lung disease	Nonhomogeneous distribution irregular pleural line and subpleural consolidations
Local Pattern	
Localized pneumonia	Sensitivity is imperfect because the pneumonia must extend to the pleural interface before ultrasound can detect it Pleural sliding often decreased/absent
Partial atelectasis	Pleural sliding often decreased/absent
Pulmonary embolism	Low sensitivity

Lung ultrasound findings must be interpreted in the appropriate clinical context and in conjunction with physical examination/other sonographic findings. For example, history might indicate preexisting interstitial lung disease or suggest an infectious etiology in a patient presenting with fever, etc.

[a]Pleural line irregularities and subpleural consolidations are better appreciated using a linear transducer.

dependent on the angle of insonation. RI is calculated from intrarenal arterial (typically interlobar) Doppler tracing using the following formula:

$$(\text{Peak systolic velocity} - \text{End diastolic velocity})/\text{Peak systolic velocity}$$

The normal range is approximately 0.50 to 0.70. Despite its name, the renal vascular resistance is only one factor affecting the RI, and the interpretation must take into consideration the influence of systemic hemodynamics. Hemodynamically significant renal artery stenosis is often associated with a lower RI in the affected kidney. A side-to-side difference of greater than 0.05 is highly suggestive of unilateral renal artery stenosis and should prompt further investigations to confirm the diagnosis. RI may also provide prognostic information in this context; the presence of a high RI (>0.80) is associated with a lower chance of response to revascularization.[36] Similarly, in kidney transplant recipients, an RI of 0.80 or greater has been shown to be associated with increased incidence of mortality.[37] Elevated renal RI is also found in advanced chronic kidney disease and acute kidney injury and does not inform on the cause of kidney injury. Moreover, it is uncertain whether an elevated RI can help to predict the likelihood of recovery from acute kidney injury.[38-40]

Venous Doppler

The normal Doppler tracing of portal and intrarenal veins (usually interlobar) is relatively continuous, whereas hepatic vein Doppler is triphasic with a dominant systolic component. Portal waveform is above the baseline, as the flow is toward the transducer, whereas in renal veins it is below the baseline, as the flow is away from the transducer while acquiring the images. Similarly, the systolic and diastolic waves of the hepatic vein are below the baseline. Intrarenal Doppler can be technically challenging because the vessels are small, and the pulsed wave Doppler sample volume gets displaced with respiratory movement of the kidney.

When the RA pressure increases, venous return during systole is reduced (because the RA is already distended), and the venous circulation become distended and thus less compliant. This results in the alteration of the associated venous waveforms. First, the usually dominant systolic wave on hepatic vein Doppler is progressively reduced and even reversed in severe cases. Next, portal and intrarenal vein waveforms become increasingly pulsatile, ultimately resulting in flow reversal during systole when RA pressure is severely elevated. In other words, in cases of severe congestion, venous return occurs only during diastole (Fig. 5.14). Interestingly, these changes can be reversed with measures aimed at reducing RA pressure, such as diuretic or ultrafiltration therapy, and can be monitored in real time.

These venous Doppler flow alterations have been associated with adverse outcomes in congestive heart failure,[41,42] after cardiac surgery,[43,44] and in general critically ill patients.[45] A venous excess ultrasound (VExUS) grading system combining the presence of these abnormal venous Doppler signals may have some advantages in certain clinical settings (e.g., significant tricuspid regurgitation, ventricular pacing, portal hypertension) and correlates with the risk of acute kidney injury in a cohort of cardiac surgery patients.[46] However, it is unknown whether using these sonographic markers to guide management will improve outcomes.

Not all dyspnea is due to extravascular lung water, nor is all hypotension due to hypovolemia. Therefore the use of multiorgan POCUS in conjunction with conventional clinical assessment aids in diagnosis. Table 5.2 summarizes typical POCUS findings in major types of shock (hypovolemic, cardiogenic, obstructive, and distributive). The same applies to undifferentiated hypotension without overt shock. However, it is not uncommon to encounter overlapping etiologies in clinical practice; therefore these findings should not be considered absolute.

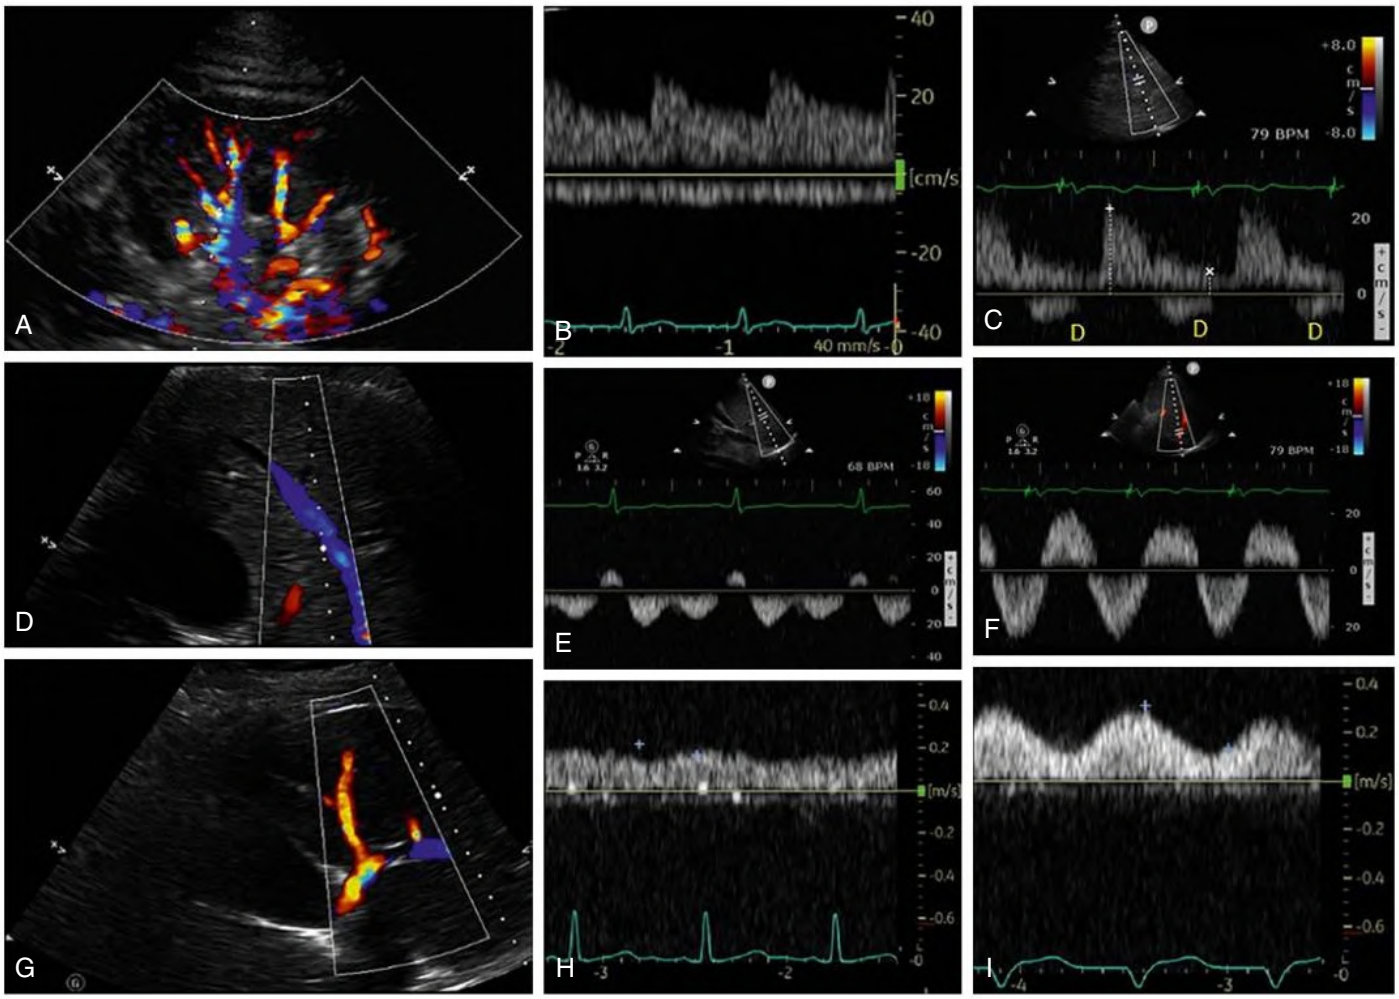

Fig. 5.14 Examples of Normal and Abnormal Venous Doppler Waveforms. (A) Color Doppler image showing the site of intrarenal Doppler assessment. (B) Normal intrarenal Doppler showing a normal arterial resistive index (above the baseline) and a continuous venous signal during the cardiac cycle (below the baseline). (C) Abnormal intrarenal Doppler showing both a high resistive index and discontinued venous signal only present in diastole (indicated by letter *D*). (D) Color Doppler image showing the right hepatic vein. (E) Normal hepatic vein Doppler with dominant systolic component. (F) Abnormal hepatic vein flow with reverse systolic component and only D-wave below the baseline. (G) Color Doppler image showing the main portal vein. (H) Normal portal vein Doppler showing minimal (<30%) variation in velocities during the cardiac cycle. (I) Abnormal portal vein Doppler with pulsatility (≥50% variation) during the cardiac cycle.

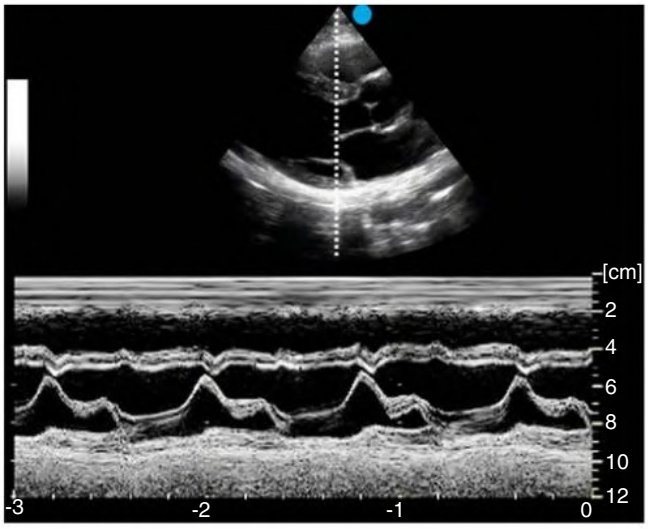
TABLE 5.2 Characteristic Point-of-Care Ultrasound Findings in Major Types of Shock

Type of Shock	Hypovolemic	Cardiogenic	Obstructive	Distributive
Hemodynamic mechanism	Volume depletion	Pump failure	Obstruction of pump function (e.g., pulmonary embolism, pericardial effusion)	Vasodilation leading to improper distribution of cardiac output resulting in impaired organ perfusion
Lung ultrasound	A-lines	Diffuse B-lines Pleural effusions	A-lines Focal B-lines may be seen in lung infarction	A-lines Pleural line irregularities with diffuse B-lines in ARDS Consolidation in pneumonia
FoCUS including IVC	Hyperdynamic LV (increased *ejection*) Decreased stroke volume *(exit)* Small, collapsible IVC *(entry)*	Decreased LV *ejection* Decreased cardiac output *(exit)* Plethoric IVC *(entry)* Chamber enlargement in some cases (altered *equality*)	Pericardial *effusion* Dilated RV in pulmonary embolism (altered *equality*) Decreased cardiac output *(exit)* Plethoric IVC *(entry)*	Hyperdynamic LV (increased *ejection*) with increased cardiac output *(exit)* Decreased LV function in septic cardiomyopathy IVC variable *(entry)*
Venous Doppler	Hepatic: S > D Portal: continuous Intrarenal: continuous	Hepatic: S < D, possible S reversal Portal: pulsatile, possible systolic flow reversal Intrarenal: Pulsatile, possible systolic flow reversal	Variable depending on the etiology	Similar to hypovolemic if volume depleted Similar to cardiogenic if excessively volume resuscitated or cardiomyopathy
Others	Intraperitoneal free fluid in case of hemorrhage	Ascites Bowel wall edema	Deep vein thrombosis in case of pulmonary embolism	Source of sepsis (e.g., cholecystitis, pyonephrosis)

ARDS, Acute respiratory stress syndrome; *FoCUS,* focused cardiac ultrasound; *IVC,* inferior vena cava; *LV,* left ventricle; *RV,* right ventricle; *S,* systolic wave; *D,* diastolic wave.

SELF-ASSESSMENT QUESTIONS

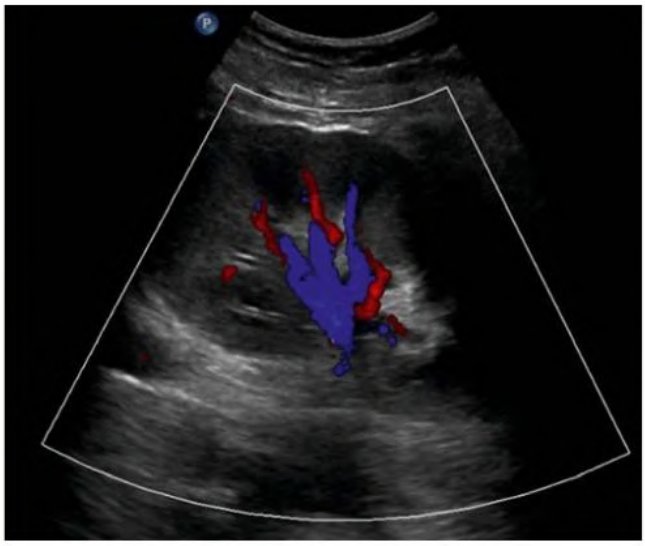
1. Which ultrasound mode is used to obtain the following image?



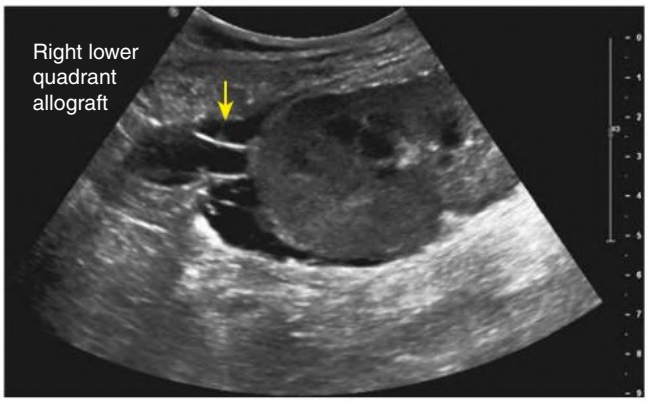
A. Color Doppler
B. M-mode
C. Pulsed wave Doppler
D. Continuous wave Doppler

2. Below are the grayscale and color Doppler images of the left kidney obtained from a patient with AKI. What is the sonographic finding?

A. Hydronephrosis
B. Parapelvic cyst
C. Prominent blood vessels
D. Hematoma



3. You are evaluating a renal transplant recipient in early postoperative period. The allograft demonstrates an abnormal appearing area at the upper pole *(arrow)*. What is the likely diagnosis?



A. Hematoma
B. Urinoma
C. Hydronephrosis
D. Pelvic ascites

4. B-lines on lung ultrasound can be seen in which of the following conditions?

A. Pulmonary edema
B. Pulmonary fibrosis
C. Pneumonia
D. All the above

5. Which of the following images represents normal portal vein Doppler waveform?

A. A
B. B
C. C
D. D

Radiologic and Nuclear Imaging in Nephrology

David T.G. Wymer, David C. Wymer

Options for imaging of patients with kidney disease have changed significantly in recent years. Intravenous urography (IVU) is infrequently used and has mostly been replaced by ultrasound, computed tomography (CT), magnetic resonance imaging (MRI), and nuclear medicine scanning. Rapidly changing computer-based data manipulation has resulted in major technologic advances in each of these modalities. Three-dimensional (3D) or even 4D (time-sensitive) image analysis is now available. *Molecular imaging,* which visualizes cellular function using biomarkers, is providing both functional and anatomic information.

The American College of Radiology (ACR) has published Appropriateness Criteria[1] that suggest the best choice of imaging modality to answer the clinical questions while minimizing cost and potential adverse effects, such as contrast-induced adverse events and radiation exposure. Tables 6.1 through 6.3 list relative radiation exposures, first-choice imaging modalities in kidney disease, and risk estimates, respectively. Risks of imaging and cost need to be balanced against benefits.

ULTRASOUND

Ultrasound is relatively inexpensive and provides a rapid way to assess renal location, contour, and size without radiation exposure. Nephrologists are increasingly undertaking bedside ultrasound examination; the practical techniques as well as the appropriate interpretative skills are discussed in Chapters 5 and 97. Portable ultrasound is available and is essential in the pediatric or emergency setting. Obstructing renal calculi can be readily detected, and renal masses can be identified as cystic or solid. In cases of suspected obstruction, the progression or regression of hydronephrosis is readily evaluated. Color Doppler imaging permits assessment of renal vascularity and perfusion. Unlike the other imaging modalities, ultrasound is highly dependent on operator skills. Limitations of ultrasound include lack of an acoustic window, body habitus, and poor patient cooperation.

Kidney Size

The kidney is imaged in the transverse and sagittal planes and is normally 9 to 12 cm in length in adults. Differences in kidney size can be detected with all imaging modalities. Figure. 6.1 shows the common causes of enlarged and shrunken kidneys.

Renal Echo Pattern

The normal kidney cortex is hypoechoic compared with the fat-containing echogenic renal sinus (Fig. 6.2A). The cortical echotexture is defined as isoechoic or hypoechoic compared with the liver or spleen. In children, the renal pyramids are hypoechoic (Fig. 6.2B) and the cortex is characteristically hyperechoic compared with the liver and the spleen. In adults, an increase in cortical echogenicity is a sensitive marker for parenchymal renal disease but is nonspecific (Fig. 6.3). Decreased cortical echogenicity can be found in acute pyelonephritis and acute renal vein thrombosis.

The normal renal contour is smooth, and the cortical mantle should be uniform and slightly thicker toward the poles. Two common benign pseudomasses that can be seen with ultrasound are the dromedary hump and the column of Bertin. The column of Bertin results from bulging of cortical tissue into the medulla; it is seen as a mass with an echotexture similar to that of the cortex, but it is found within the central renal sinus (Fig. 6.4). The renal pelvis and proximal ureter are anechoic. An *extrarenal pelvis* refers to the renal pelvis location outside the renal hilum. The ureter is not identified beyond the pelvis in nonobstructed patients.

Obstruction can be identified by the presence of hydronephrosis (Fig. 6.5). Parenchymal and pelvicalyceal nonobstructing renal calculi as well as ureteral obstructing calculi can be readily detected (Fig. 6.6). The upper ureter also will be dilated if obstruction is distal to the pelviureteral junction (see Fig. 6.5C). False-negative ultrasound examination findings with no hydronephrosis occasionally occur in early obstruction. Obstruction without ureteral dilation also may occur in retroperitoneal fibrosis and in transplanted kidneys as a result of periureteral fibrosis.

Renal Cysts

Cysts can be identified as anechoic lesions and are a frequent coincidental finding during renal imaging. Ultrasound usually readily identifies renal masses as cystic or solid (Figs. 6.7 and 6.8). However, hemorrhagic cysts may be mistakenly called solid because of increased echogenicity. Differentiation of cysts as simple or complex is required to plan intervention.

Simple Cysts

A simple cyst on ultrasound is anechoic, has a thin or imperceptible wall, and demonstrates through-transmission because of the relatively rapid progression of the sound wave through fluid compared with adjacent soft tissue.

Complex Cysts

Complex cysts contain calcifications, septations, and mural nodules. Instead of being anechoic, these masses may contain internal echoes representing hemorrhage, pus, or protein. Complex cysts may be benign or malignant; cyst wall nodularity, septations, and vascularity strongly suggest malignancy. Complex cysts identified by ultrasound require further evaluation by contrast-enhanced CT (or MRI) to identify abnormal contrast enhancement of the cyst wall, mural nodule, or septum, which may indicate malignancy.

TABLE 6.1 Relative Radiation Doses of Imaging Examinations

Examination	Effective Dose (mSv)
Chest: PA radiograph	0.02
Lumbar spine	1.8
KUB abdomen	0.53
CT abdomen	10
CT chest	20–40
PET-CT	25
Ultrasound or MRI	0

CT, Computed tomography; *KUB,* kidney, ureter, bladder (plain film); *MRI,* magnetic resonance imaging; *mSv,* millisieverts; *PA,* posteroanterior; *PET,* positron emission tomography.

TABLE 6.2 Suggested Imaging in Renal Disease

Pathology	First-Choice Imaging
Acute kidney injury, chronic kidney disease	Ultrasound
Hematuria	Ultrasound or CT
Proteinuria, nephrotic syndrome	Ultrasound Multiphase CT urography
Hypertension with normal kidney function	Ultrasound Consider CTA or MRA
Hypertension with impaired kidney function	Ultrasound with Doppler
Kidney infection	Contrast-enhanced CT
Hydronephrosis identified on ultrasound	Nuclear renogram
Retroperitoneal fibrosis	Contrast-enhanced CT
Papillary or cortical necrosis	Contrast-enhanced CT
Renal vein thrombosis	Contrast-enhanced CT
Kidney infarction	Contrast-enhanced CT
Nephrocalcinosis and nephrolithiasis	CT

These recommendations assume availability of all common imaging modalities.
CT, Computed tomography; *CTA,* computed tomographic angiography; *MRA,* magnetic resonance angiography.
Modified from American College of Radiology. Appropriateness criteria: http://www.acr.org/ac.

Bladder

Real-time imaging can be used to evaluate for bladder wall tumors and bladder stones. Color flow Doppler evaluation of the bladder in well-hydrated patients can be used to identify a ureteral jet, produced when peristalsis propels urine into the bladder. The incoming urine has a higher specific gravity relative to the urine already in the bladder (Fig. 6.9). Absence of the ureteral jet can indicate total ureteral obstruction.

Renal Vasculature

Color Doppler investigation of the kidneys provides a detailed evaluation of the renal vascular anatomy. The main renal arteries can be identified in most patients (Fig. 6.10). Power Doppler imaging is a more sensitive indicator of flow, but unlike color Doppler imaging, power Doppler provides no information about flow direction and cannot be used to assess vascular waveforms. However, power Doppler imaging is exquisitely sensitive for detection of renal parenchymal flow and has been used to identify cortical infarction.

TABLE 6.3 Risk Estimates in Diagnostic Imaging

Imaging Risk	Estimated Risk
Cancer from 10 mSv of radiation (1 body CT)[2]	1 in 1000
Contrast-induced nephropathy in patient with reduced GFR[4]	Uncertain but higher with diabetes or hyperuricemia
Nephrogenic systemic fibrosis[4,6]	1 in 25,000 to 1 in 30,000 (depends on gadolinium agent) Higher risk if GFR >30 mL/min
Death from iodine contrast anaphylaxis[5]	1 in 130,000
Death from gadolinium contrast anaphylaxis[6]	1 in 280,000

CT, Computed tomography; *GFR,* glomerular filtration rate; *mSv,* millisieverts.

RENAL ARTERY DUPLEX SCANNING

The role of gray-scale and color Doppler sonography in evaluating for renal artery stenosis is controversial. The principle is that a narrowing in the artery will cause a velocity change commensurate with the degree of stenosis, as well as a change in the normal renal artery waveform downstream from the lesion. The normal renal artery waveform demonstrates a rapid systolic upstroke and an early systolic peak (Fig. 6.11A). The waveform becomes damped downstream from a stenosis. This consists of a slow systolic acceleration (tardus) and a decreased and rounded systolic peak (parvus) (see Fig. 6.11B). It also results in a decrease in the *resistive index,* defined as the end-diastolic velocity (EDV) subtracted from the peak systolic velocity (PSV) divided by PSV: (PSV − EDV)/PSV. The normal resistive index is 0.70 to 0.72.

The entire length of the renal artery should be examined for the highest velocity signal. The origins of the renal arteries are important to identify because this area is often affected by atherosclerosis, but the arteries are often difficult to visualize because of overlying bowel gas. Within the kidney, medullary branches and cortical branches in the upper, middle, and lower thirds should be included to attempt detection of stenosis in accessory or branch renal arteries.

Proximal and distal criteria exist for diagnosis of significant renal artery stenosis, usually defined as stenosis greater than 60%. The *proximal* criteria detect changes in the Doppler signal at the site of stenosis and provide sensitivities and specificities ranging from, respectively, 0% to 98% and 37% to 98%.[2,3] Technical failure rates are typically 10% to 20%.[4] Renal artery stenosis also may be missed if PSV is low because of poor cardiac output or aortic stenosis. False-positive results can occur when renal artery velocity is increased because of high-flow states, such as hyperthyroidism or vessel tortuosity. The *distal* criteria are related to detection of a tardus-parvus waveform distal to a stenosis; sensitivities and specificities of 66% to 100% and 67% to 94%, respectively, have been reported.[5,6] Technical failure with distal criteria is much lower than with proximal evaluation (<5%). False-negative results can occur from stiff poststenotic vessels, which will decrease the tardus-parvus effect. The tardus-parvus effect also may be a result of aortic stenosis, low cardiac output, or collateral vessels in complete occlusion, giving a false-positive result.

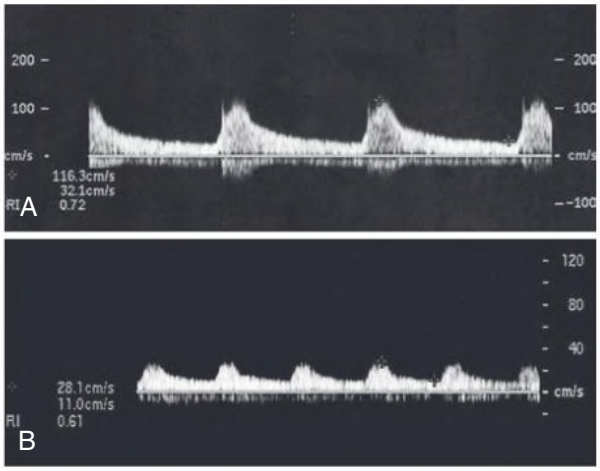

Fig. 6.11 Renal Artery Color Doppler Image and Spectral Imaging. (A) Normal renal artery tracing shows rapid systolic upstroke and early systolic peak velocity (~100 cm/s). (B) Tardus-parvus waveform demonstrates slow systolic upstroke (acceleration) and decreased peak systolic velocity (~20 cm/s) associated with renal artery stenosis. Note different scales on vertical axis.

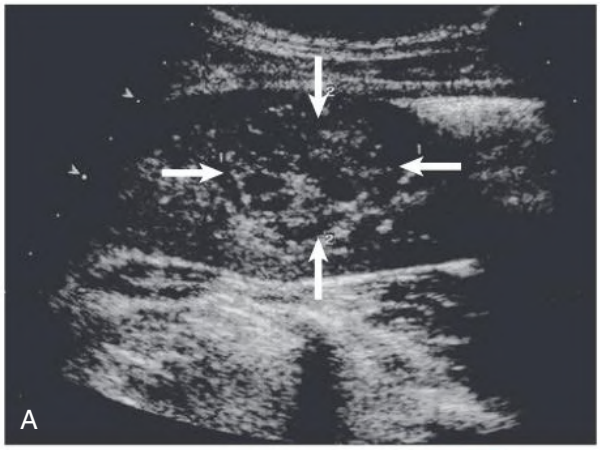

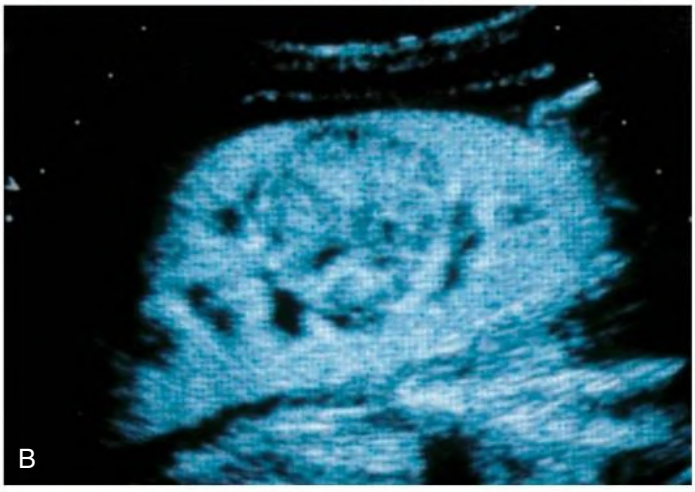

Fig. 6.12 Contrast Ultrasonography. (A) Sagittal kidney ultrasound image with a large, central kidney cell carcinoma *(arrows)*. (B) Central carcinoma better seen after injection of contrast material. (Courtesy Dr. Christoph F. Dietrich.)

Combining the proximal and distal criteria improves detection of stenoses. Sensitivity of 97% and specificity of 98% can be achieved when both the extrarenal and the intrarenal arteries are examined.[7] When it is technically successful, Doppler ultrasound has a negative predictive value of more than 90%.[7] However, reliable results require a skilled and experienced sonographer and a long examination time. Despite these limitations, Doppler studies also have several advantages. Noninvasive, inexpensive, and widely available, Doppler studies also allow structural and functional assessment of the renal arteries and imaging without exposure to radiation or contrast material.

Some physicians prefer computed tomography angiography (CTA) or magnetic resonance angiography (MRA) as a faster and more reliable test than ultrasound, but at present the choice should depend on local expertise and preference. For further discussion of the diagnosis and management of renovascular disease, see Chapter 41.

CONTRAST-ENHANCED AND THREE-DIMENSIONAL ULTRASOUND

Ultrasound contrast agents, initially introduced to assess cardiac perfusion, are now being used to evaluate perfusion to other organs, such as the kidney. These intravenous agents are microbubbles 1 to 4 μm in diameter (smaller than erythrocytes) that consist of a shell surrounding the echo-producing gas core. The microbubbles oscillate in response to the ultrasound beam frequency and give a characteristic increased echo signal on the image. Preliminary studies evaluating renal perfusion in dysfunctional kidneys show reduced flow compared with normal kidneys, as well as improved lesion detection (Fig. 6.12). However, the clinical adoption of microbubble imaging in the kidney remains uncertain, particularly with the general availability and robustness of CT and MRI.

Two-dimensional ultrasound images can be reconstructed into 3D volume images by a process similar to 3D reconstructions for MRI and CT. Potential applications include vascular imaging and fusion with MRI or positron emission tomography (PET).

PLAIN RADIOGRAPHY AND FLUOROSCOPY

Although infrequently used today in high-income countries, contrast urography may still be a key investigation in parts of the world where cross-sectional imaging is not readily available. Plain radiography, often called KUB (kidneys, ureter, bladder), still has an important role in the identification of soft tissue masses, bowel gas patterns, calcifications, and renal location.

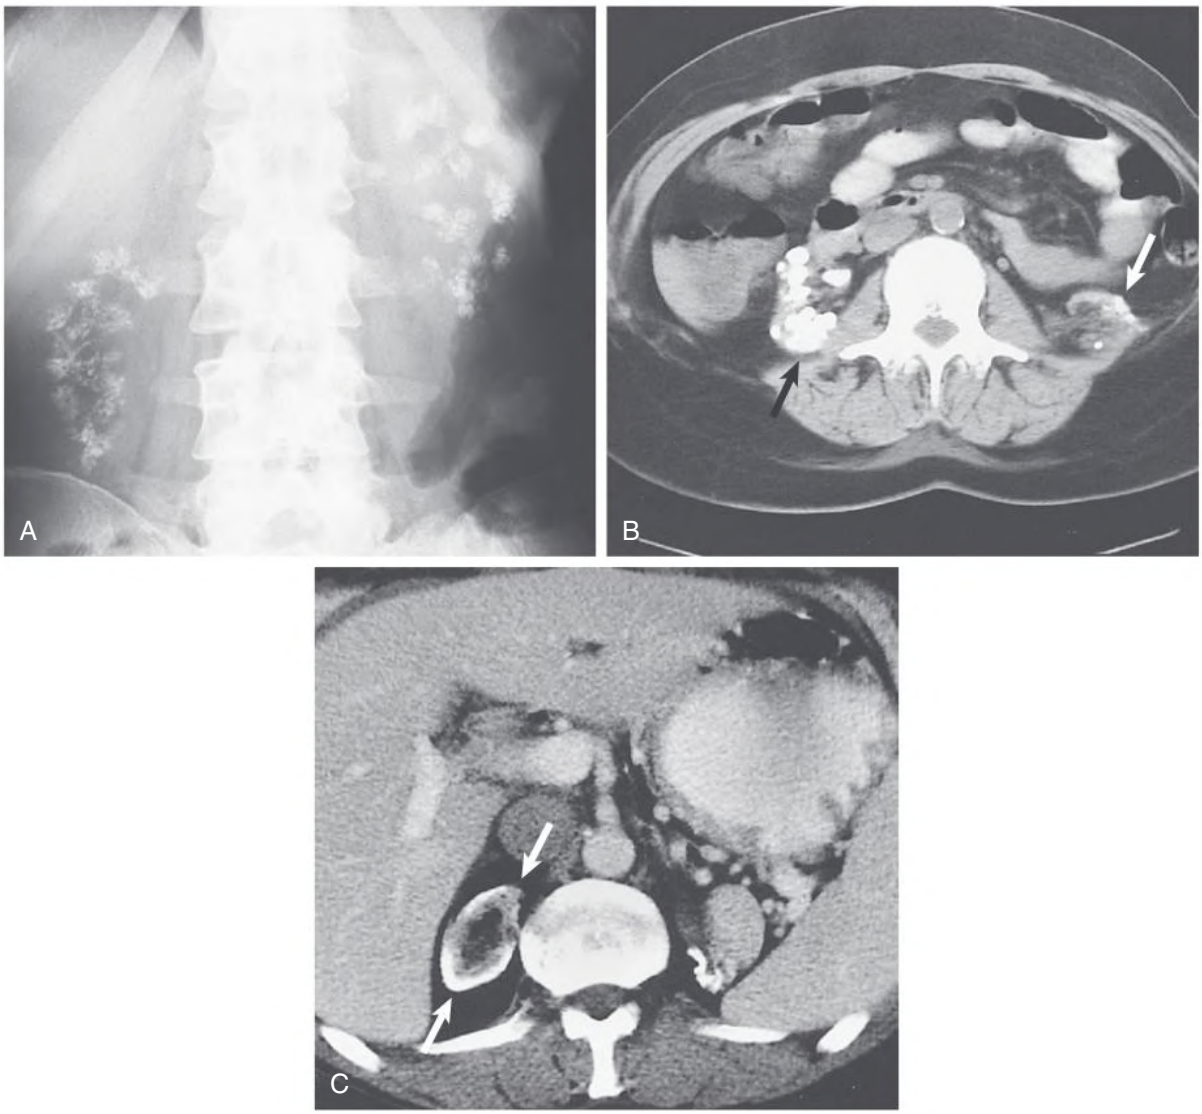

Fig. 6.13 Nephrocalcinosis. (A) Plain radiograph shows bilateral medullary nephrocalcinosis in a patient with distal renal tubular acidosis. (B) Noncontrast computed tomography (CT) scan in a patient with hereditary oxalosis and dense bilateral renal calcification *(arrows)*. The left kidney is atrophic. (C) Noncontrast CT scan shows cortical nephrocalcinosis in the right kidney *(arrows)* after cortical necrosis.

Renal Calcification

Most renal calculi are radiodense, although only about 60% of urinary stones detected on CT are visible on plain films.[8] CT demonstrates nonopaque stones, which include uric acid, xanthine, and struvite stones. However, neither CT nor plain radiography may detect calculi associated with protease inhibitor therapy.[9] Oblique films are sometimes obtained to confirm whether a suspicious upper quadrant calcification is renal in origin. CT is the imaging modality of choice for detection of urinary calculi.[10]

Nephrocalcinosis may be medullary (Fig. 6.13A–B) or cortical (Fig. 6.13C) and is localized or diffuse. The causes of nephrocalcinosis are discussed in Chapter 57 (see Box 57.7).

RETROGRADE PYELOGRAPHY

Retrograde pyelography is performed when the ureters are poorly visualized on other imaging studies or when samples of urine must be obtained from the kidney for cytology or culture. Patients who have severe allergies to contrast agents or impaired kidney function can be evaluated with retrograde pyelography. The examination is performed by placing a catheter through the ureteral orifice under cystoscopic guidance and advancing it into the renal pelvis. The catheter is slowly withdrawn under fluoroscopy while radiocontrast is injected (see Figs. 58.2 and 58.11). This provides excellent visualization of the renal pelvis and ureter and can be used for cytologic sampling from suspect areas.

ANTEGRADE PYELOGRAPHY

Antegrade pyelography is performed through a percutaneous renal puncture and is used when retrograde pyelography is not possible. Ureteral pressures can be measured, hydronephrosis evaluated, and ureteral lesions identified (Fig. 58.14). The examination is often performed as a prelude to nephrostomy placement. Both antegrade and retrograde pyelography are invasive and should be performed only when other studies are inadequate.

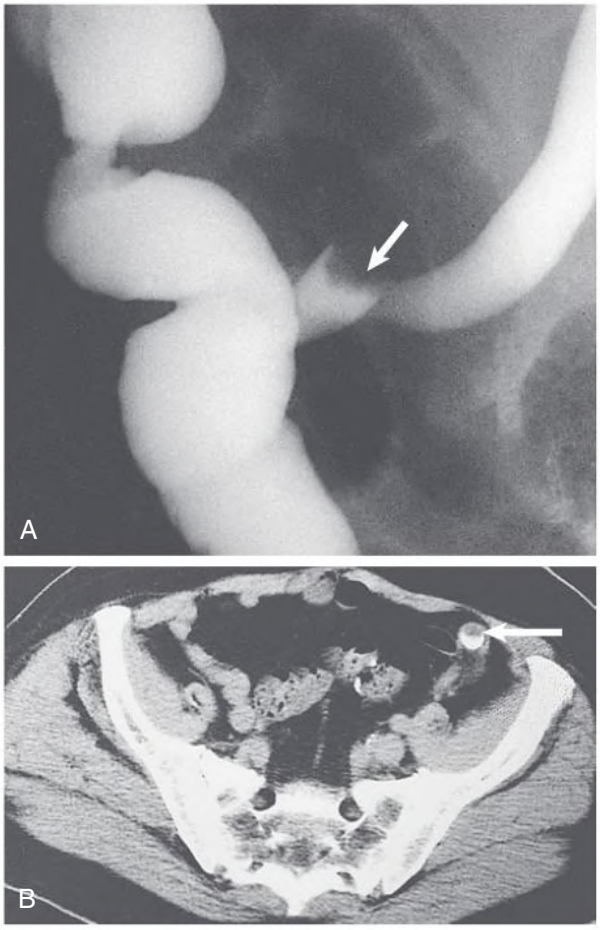

Fig. 6.14 Imaging of an Ileal Conduit. (A) Loop-o-gram. A recurrent transitional carcinoma is present in the reimplanted left ureter *(arrow)*. (B) Computed tomography scan clearly shows the tumor as a filling defect in anterior aspect of the opacified ureter *(arrow)*.

IMAGING ILEAL CONDUITS

After cystectomy or bladder failure, numerous types of continent or incontinent urinary diversions can be surgically created. One of the most common diversions is the ileal conduit: an ileal loop is isolated from the small bowel, and the ureters are implanted into the loop. This end of the loop is closed, and the other end exits through the anterior abdominal wall. This type of conduit can be evaluated by an excretory or a retrograde study. The excretory or *antegrade* study is performed and monitored in the same way as an IVU. A *retrograde* examination, also referred to as a "loop-o-gram," is obtained when the ureters and conduit are suboptimally evaluated on the excretory study. A Foley catheter is placed into the stoma and contrast slowly instilled. The ureters should fill by reflux because the ureteral anastomoses are not of the antireflux variety (see Fig. 6.14).

CYSTOGRAPHY

A cystogram is obtained when more detailed radiographic evaluation of the bladder is required. *Voiding* cystography is performed to identify ureteral reflux and assess bladder function and urethral anatomy. A urethral catheter is placed into the bladder, the urine drained, contrast infused, and the bladder filled under fluoroscopic guidance. Early frontal and oblique films with the patient supine are obtained while the bladder is filling. Ureteroceles are best identified on early films. When the bladder is full, multiple films are obtained with varying degrees of obliquity. Reflux may be seen on these films. To obtain a voiding cystogram, the catheter is removed, the patient voids, and the contrast is followed into the urethra. Occasionally, bladder diverticula are seen only on the voiding films. When the patient has completely voided, a final film is used to assess the amount of residual urine and the mucosal pattern.

Radionuclide cystography is an alternative often used in children. It is useful in the diagnosis of reflux, but it does not provide the detailed anatomy seen with contrast cystography.

Fig. 6.15 Bilateral pelvic kidneys *(arrows)* on computed tomography.

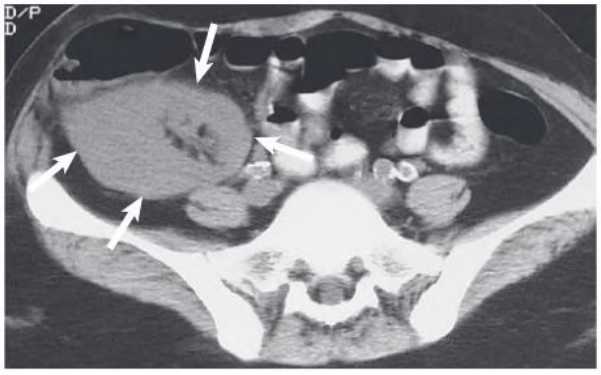

Fig. 6.16 Normal kidney transplant *(arrows)* on computed tomography.

COMPUTED TOMOGRAPHY

Computed tomography of the kidneys is performed to evaluate renal masses, locate ectopic kidneys (Figs. 6.15 and 6.16), investigate calculi, assess retroperitoneal masses, and evaluate the extent of parenchymal involvement in patients with acute pyelonephritis (Figs. 6.17 and 6.18). Helical CT scanners allow the abdomen and pelvis to be scanned at submillimeter intervals with single breath–held acquisitions, which eliminates motion artifact. Newer multidetector row CT results in multiple slices of information (64-slice and even 320-slice machines) being acquired simultaneously, allowing the entire abdomen and pelvis to be covered in very fast acquisition times of less than 30 seconds. Although the improved CT imaging usually comes at a price of increased radiation exposure to the patient, new reconstruction software with *iterative reconstruction* significantly reduces radiation exposure by as much as 30%. The CT data can be reconstructed in multiple planes and even 3D for improved anatomic visualization and localization.

Tissue Density

The Hounsfield unit (HU) scale is a measurement of relative densities determined by CT. Distilled water at standard pressure and temperature is defined as 0 HU; the radiodensity of air is defined as −1000 HU. All other tissue densities are derived from this measurement (Table 6.4). Tissues can vary in their exact HU measurements and will

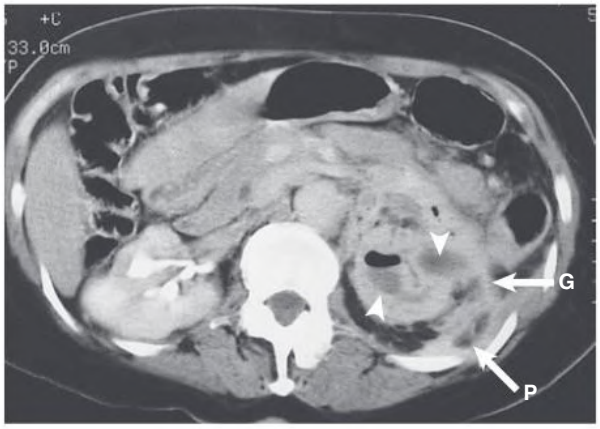

Fig. 6.17 Emphysematous Pyelonephritis. Contrast-enhanced computed tomography scan shows gas *(arrowheads)* within an enlarged left kidney and marked enhancement of the Gerota fascia *(G)* and posterior perirenal space *(P),* indicative of inflammatory involvement.

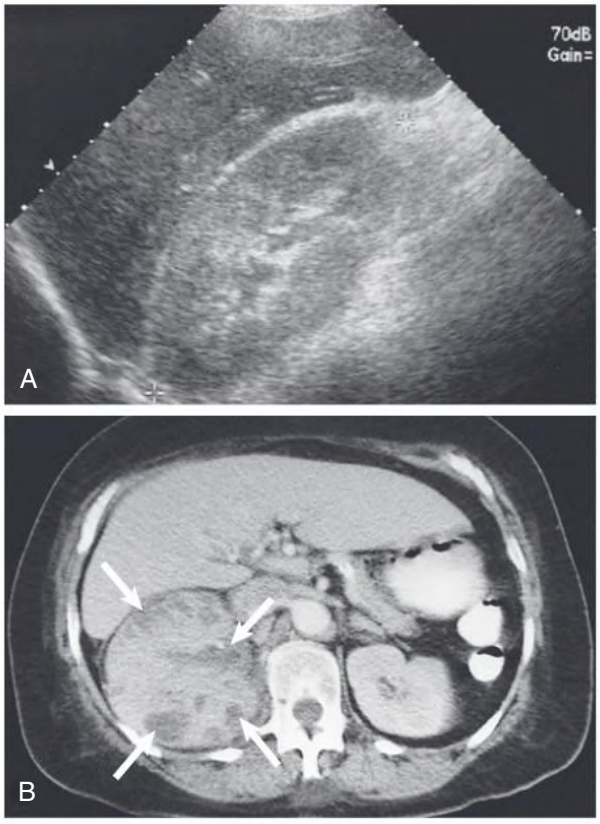

Fig. 6.18 Acute Pyelonephritis. (A) Ultrasound image demonstrates an enlarged echogenic kidney. Bipolar length of kidney is 12.9 cm. (B) Computed tomography scan with contrast enhancement obtained 24 hours later demonstrates multiple nonenhancing abscesses *(arrows).*

also change with contrast enhancement. Water, fat, and soft tissue often can look identical on the scan, depending on the window and level settings of the image, so actual HU measurement is essential to characterize the tissues accurately.

Contrast-Enhanced and Noncontrast Computed Tomography

CT examination of the kidneys can be performed with or without intravenous administration of contrast material. Noncontrast imaging allows the kidneys to be evaluated for the presence of calcium deposition and hemorrhage, which are obscured after contrast administration.

TABLE 6.4 Computed Tomography Determination of Density of Common Substances

Substance	Hounsfield Units[a]
Air	–1000
Fat	–120
Water	0
Muscle	+40
Bone	+400 or more

[a]The Hounsfield unit (HU) scale is a measurement of relative densities compared with distilled water.

Noncontrast CT is the examination of choice in patients with suspected nephrolithiasis and has replaced the KUB and IVU in most situations. The study consists of unenhanced images from the kidneys through the bladder for detection of calculi. CT is highly sensitive (97%–100%) and specific (94%–96%) for diagnosis of urinary calculi.[10] Noncontrast CT can identify a possible obstructing calculus and the extent of parenchymal and perinephric involvement.

In cases other than stone evaluation, the kidneys are imaged after contrast administration. The kidneys are imaged in the corticomedullary phase for evaluation of the renal vasculature and in the nephrographic phase for evaluation of the kidney parenchyma. The degree of enhancement can be assessed in both solid masses and complex cysts.

Computed Tomography Urography

Delayed images through the kidneys and bladder are performed for evaluation of the opacified and distended collecting system, ureters, and bladder.[11,12] After acquisition, the axial images can be reformatted into coronal or sagittal planes to optimize visualization of the entire collecting system (Fig. 6.19). The CT study can be tailored to the individual clinical scenario. For example, the corticomedullary phase can be eliminated to decrease the radiation dose if there is no concern about a vascular abnormality or no need for presurgical planning. A diuretic or saline bolus can be administered after contrast to better distend the collecting system and ureters during the excretory phase.

The kidneys should be similar in size and show equivalent enhancement and excretion. During the corticomedullary phase, there is brisk enhancement of the cortex. The cortical mantle should be intact. Any disruption of the cortical enhancement requires further evaluation; it may be caused by acute pyelonephritis (see Fig. 6.18), scarring, mass lesions, or infarction (Fig. 6.20). During the excretory phase, the entire kidney and renal pelvis enhance. Delayed excretion and delay in pelvicalyceal appearance of contrast material may be found in obstruction (Fig. 6.21) but also in parenchymal disease such as acute tubular necrosis (ATN).

The ureters are often seen segmentally because of active peristalsis. The ureters should be free of filling defects and smooth. In the abdomen, the ureters lie in the retroperitoneum, passing anterior to the transverse processes of the vertebral bodies. In the pelvis, the ureters course laterally and posteriorly, eventually draining into the posteriorly located vesicoureteral junction. At the vesicoureteral junction, the ureters gently taper. Medial bowing or displacement of the ureter is often abnormal and can be seen secondary to ureter displacement from retroperitoneal masses, lymphadenopathy, and retroperitoneal fibrosis.

The bladder should be rounded and smooth walled. Benign indentations on the bladder include the uterus, prostate gland, and bowel. In chronic bladder outlet obstruction and neurogenic bladder, numerous trabeculations and diverticula may be seen around the bladder outline. Other incidental bladder diverticula, such as the Hutch diverticulum,

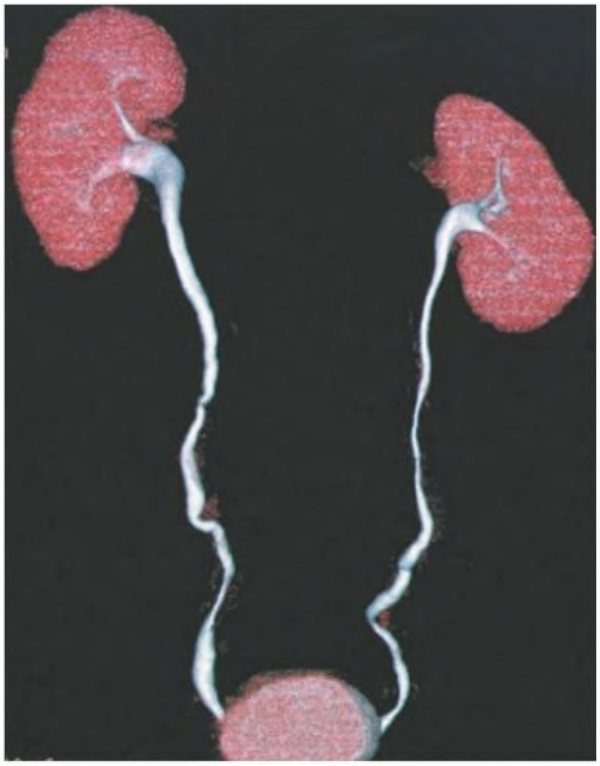

Fig. 6.19 Noncontrast Computed Tomography (CT) of Bladder and Kidney. Computer-reformatted, volume-rendered CT urogram obtained from axial CT acquisition.

can be seen and are usually of no significance unless they are large and do not empty completely on voiding.

Computed Tomographic Angiography

Helical scanning facilitates CT angiography (CTA), which can produce images similar to conventional angiograms but is less invasive. A bolus of contrast material is administered, and the images are reconstructed at 0.5- to 3-mm consecutive intervals. The contrast bolus is timed for optimal enhancement of the aorta. The tightly focused and narrow CT beam allows higher resolution and better subsequent multiplanar reconstructions. The aorta and branch vessels are well demonstrated (Fig. 6.22). This technique is widely used in living transplant donor evaluation (see Fig. 104.2), providing information not only on arterial and venous anatomy but also on size, number, and location of the kidneys and any ureteral anomalies of number or position.

In addition, CTA can be used to evaluate for atheromatous renal artery stenosis, with sensitivity of 96% and specificity of 99% for the detection of hemodynamically significant stenosis compared with digital subtraction angiography (DSA).[2] Furthermore, CTA allows visualization of both the arterial wall and lumen, which helps in planning renal artery revascularization procedures. Another advantage of CTA is the depiction of accessory renal arteries and nonrenal causes of hypertension, such as adrenal masses. CTA can be used to diagnose fibromuscular dysplasia but has a lower sensitivity (87%) than DSA.[3]

Dual-Energy Computed Tomography

In dual-energy CT (DECT), two or more CT data sets are acquired using different tube potentials, usually 140 and 80 kilovolts (kV), resulting in different x-ray spectra. The density values at the acquired spectra differentiate materials on the basis of the photoelectric effect. The most common application of DECT is to allow the acquisition of "virtual noncontrast" images. A single acquisition after the administration of contrast can, using the photoelectric characteristics of iodine,

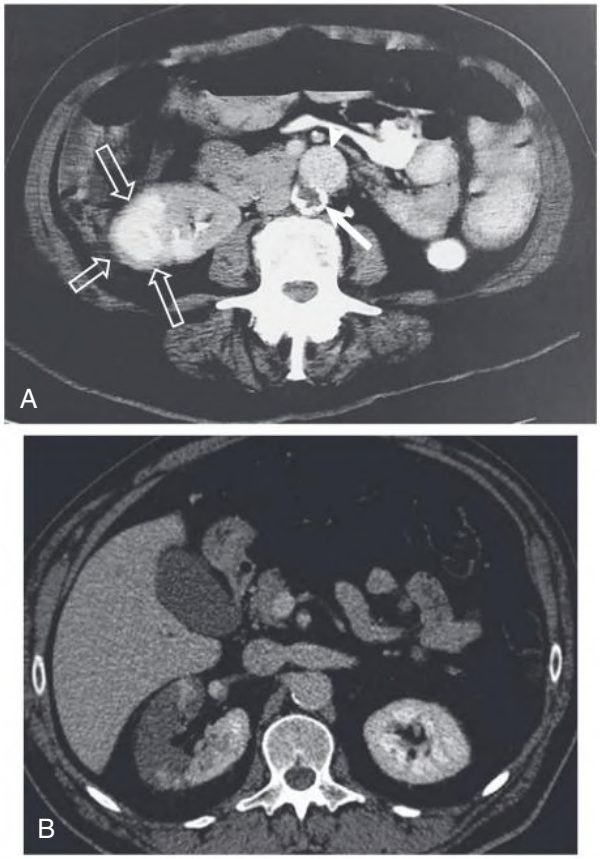

Fig. 6.20 Renal Infarction. (A) Computed tomography (CT) scan showing a chronic calcified infarct *(open arrows)* involving half of the right kidney after aortic bypass surgery. The native aorta has a densely calcified wall *(arrow)*. The aortic graft is anterior to the native aorta *(arrowhead)*. (B) CT scan showing acute infarct in the right kidney with decreased parenchymal enhancement *(arrows)*.

be used to create a full set of images that appear as though no contrast was administered (Fig. 6.23A). These can be used to better identify kidney stones, differentiate stones and calcification from early excreted contrast in the urinary system, and can be compared against the postcontrast images to verify whether or not something is demonstrating enhancement. Among the more specialized uses of DECT include allowing kidney stone differentiation (i.e., differentiation of uric acid from magnesium or calcium), which may permit tailored treatment strategies.[4,5] Radiation dose in DECT has been shown to be the same as traditional CT, and optimized protocols can even reduce overall dose.[6]

Limitations of Computed Tomography

CT does have some limitations. The cradle that the patient lies on usually has an upper weight limit of 100 to 200 kg (300–400 lb), but newer scanners can now accommodate up to 270 kg (600 lb). Obese patients often have suboptimal scans because of weight artifact and need higher radiation exposures to adjust for x-ray attenuation. Contrast-enhanced CT studies may be contraindicated in patients with an allergy to radiographic contrast. For further discussion on contrast use in patients with impaired kidney function, see Radiologic Contrast Agents.

CT is very sensitive to metal artifact and patient motion. Retroperitoneal clips and intramedullary rods will cause extensive streak artifact, which severely degrades the images. However, recent advances in image reconstruction can be used to significantly decrease the streak artifact from metal implants, although this is still not perfect (see Fig. 6.23B). Patients who are unable to remain motionless will also have suboptimal or even nondiagnostic studies, and sedation or general anesthesia may be needed to obtain diagnostic scans, particularly in children. Critically ill patients may not be stable enough for transport to the CT suite, and ultrasound can be considered as an alternative to CT in that setting.

Fig. 6.22 Normal Renal Arteries. Three-dimensional reformatted computed tomography angiogram.

MAGNETIC RESONANCE IMAGING

Although it rarely should be the first examination used to evaluate the kidneys, MRI is typically an adjunct to other imaging. The major advantage of MRI over other modalities is direct multiplanar imaging. CT is limited to slice acquisition in the axial plane of the abdomen, and coronal and sagittal planes are acquired only by reconstruction, which can lead to loss of information.

Images on MR are typically described as T1 or T2 based on their acquisition. Fat is bright on T1 and not as bright on rapid acquisition T2 sequences (Fig. 6.24). The sequences and imaging planes selected must be tailored to the individual MR study. Diffusion-weighted imaging (DWI) evaluates the freedom of water molecules to diffuse in tissues; restriction of diffusion is imaged as bright areas on the DWI image set. Using the DWI data, regional apparent diffusion coefficients of the tissue can be calculated and an image of the distribution of the coefficients of the tissue can be produced. Dark areas on what is known as an apparent diffusion coefficient map are seen in infection, neoplasia, inflammation, and ischemia (Fig. 6.25). Because diffusion occurs in three dimensions, more advanced acquisitions can be obtained that show the direction of diffusion. This process is called diffusion tensor imaging (DTI). This is mostly seen in brain and neurologic imaging for imaging axonal tracts, but visualization of the orientation of renal tubules can be done with this method as well (Fig. 6.26).

On T1-weighted sequences, the normal kidney cortex is higher in signal than the medulla, producing a distinct corticomedullary differentiation, which becomes indistinct in parenchymal kidney disease. It is analogous to the echogenic kidney seen on ultrasound. On rapid acquisition T2 sequences, the corticomedullary distinction is not as

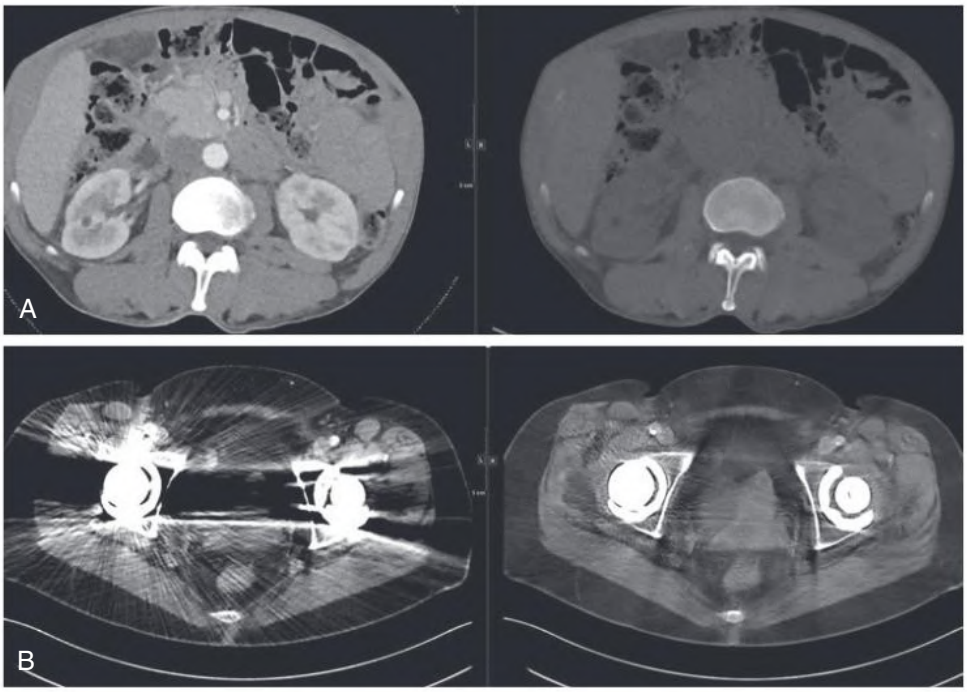

Fig. 6.23 (A) Following only one postcontrast computed tomography (CT) acquisition with dual energy, mathematical algorithms are used to obtain two sets of images. On the left is the standard postcontrast image, and on the right is the virtual noncontrast calculated image. (B) New CT software postprocessing permits much more diagnostic image quality with metal artifact reduction. The usual image obtained is at *right,* and the image using metal artifact reduction is at *left.*

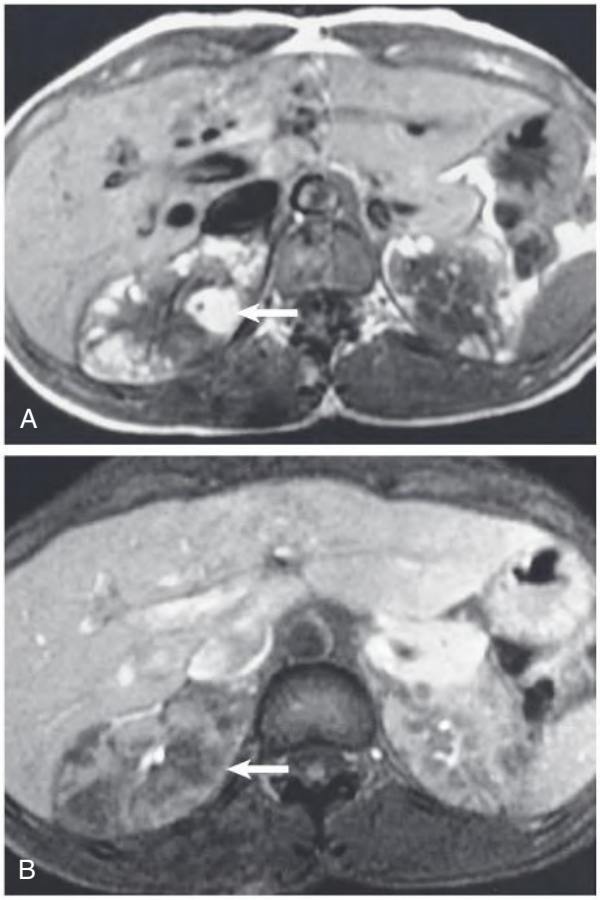

Fig. 6.24 Tuberous Sclerosis on Magnetic Resonance (MR) Imaging. Multiple renal angiomyolipomas are seen. (A) T1-weighted MR image. The tumors are high in signal on T1 because of their fat; *arrow* shows the largest tumor. (B) T1-weighted MR image with fat suppression. The fat within the tumors is now low in signal *(arrow)*.

sharp but should still be present. Usually, at least one sequence is performed in the axial plane. Sagittal and coronal images cover the entire length of the kidney and can make some subtle renal parenchymal abnormalities more conspicuous (Fig. 6.27).

Contrast-Enhanced Magnetic Resonance Imaging

As with CT, intravenous contrast material can be administered to allow further characterization of kidney lesions. Gadolinium is a *paramagnetic* contrast agent frequently used in MRI. Nephrotoxicity to gadolinium agents is rare and insignificant.[7] A scleroderma-like condition could be seen with early contrast agents in subjects with chronic kidney disease (CKD), but this is not observed with agents used today (see Magnetic Resonance Contrast Agents). Paramagnetic contrast agents are being evaluated for measurement of glomerular function.

After injection of gadolinium, the vessels appear high in signal, or white, on T1-weighted sequences. Multiple images can be obtained in a single breath–held acquisition. This technique is useful for lesion characterization in patients who cannot receive iodinated contrast material. As with contrast-enhanced CT, the kidneys initially show symmetric cortical enhancement, which progresses to excretion. A delay in enhancement can be seen with renal artery stenosis.

Magnetic Resonance Urography

Two techniques are used to perform magnetic resonance urography (MRU).[13] The first technique is sometimes called *static* MRU. Because

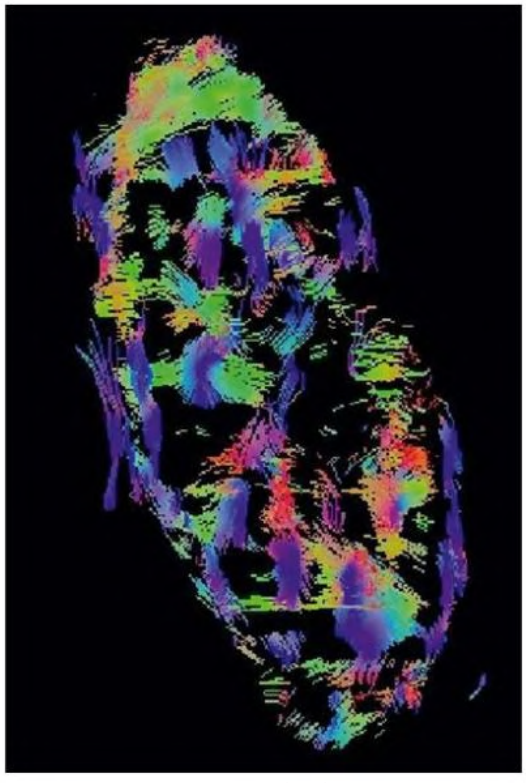

Fig. 6.26 Diffusion Tensor Imaging (DTI) Permits Imaging of Eigenvectors of Relative Diffusion Through Tissues. This image shows a kidney DTI with visualization of the diffusion through the medullary tubules.

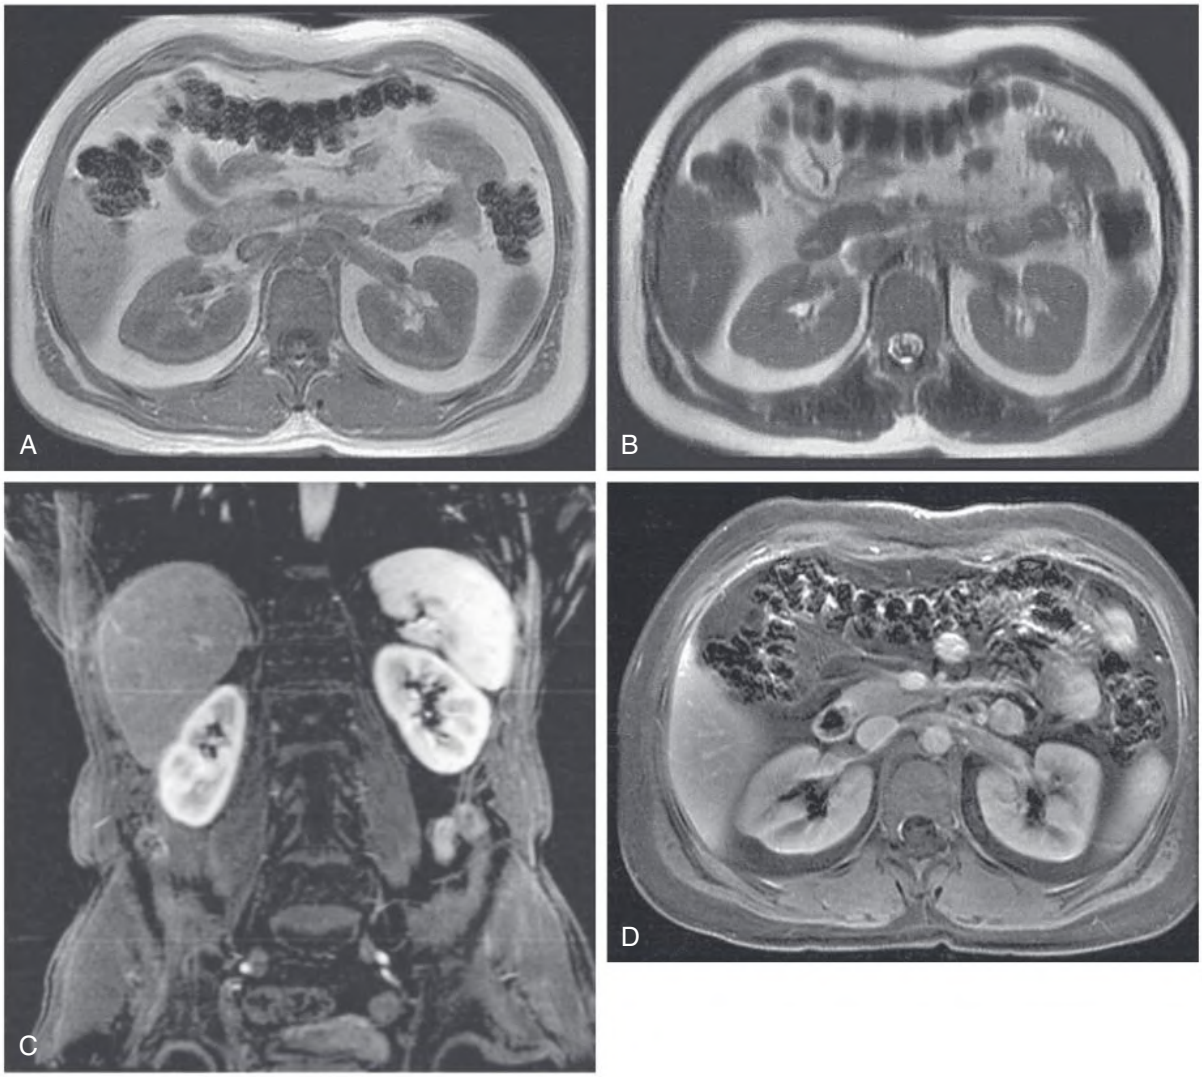

Fig. 6.27 Normal Magnetic Resonance (MR) Images Through Kidneys. (A) T1-weighted MR image. Note the distinct corticomedullary differentiation. (B) Fast spin echo MR image. Urine in the collecting tubules causes the high signal within the renal pelvis on this sequence. (C) Coronal T1-weighted, fat-suppressed MR image after contrast administration. (D) Axial T1-weighted, fat-suppressed image after contrast administration.

urine contains abundant water, it will demonstrate high signal on a T2-weighted image. Therefore, a heavily T2-weighted sequence accentuates the static fluid in the collecting system and ureters, which stands out against the darker background soft tissues. Static MRU can be performed rapidly, which is a benefit in imaging of children. A disadvantage is that any fluid in the abdomen or pelvis, such as fluid collections or fluid in the small bowel, will demonstrate a similar bright signal that can obscure superimposed structures. Also, the collecting system and ureters need to be distended for acquisition of good MR images.

The second technique, often referred to as *excretory* MRU, is similar to CT urography (CTU). Intravenous administration of gadolinium is followed by T1-weighted imaging. This technique allows some assessment of kidney function because the contrast is filtered by the kidney and excreted into the urine (see Fig. 58.10). The opacified collecting system and ureters are well seen, and a diuretic can be administered to further dilate the renal pelvis and ureters if necessary. MRU has limited capacity to detect calculi because calcification is poorly visualized by MRI.

Because CTU and MRU are comparable for identifying the cause and anatomic location of urinary obstruction, the choice of modality is a matter of local preference. CTU is the better choice in the evaluation of urinary tract calculi. In patients with reduced glomerular filtration rate (GFR) caused by obstruction, MRU is superior to CTU in identifying noncalculous causes of obstruction, whereas CTU is superior in identifying calculi as a cause of obstruction.[14] CTU is also more widely available, faster, and less expensive than MRU. MRU is better suited in patients with allergy to iodinated contrast agents and sometimes in children when radiation is an issue. MRU is also useful in depicting the anatomy in patients with urinary diversion to bowel conduits.

Magnetic Resonance Angiography

Although magnetic resonance angiography (MRA) can be performed with or without intravenous contrast, contrast provides better images. The aorta and branch vessels are beautifully demonstrated (Fig. 6.28). By adjustment of timing and type of sequences, the abdominal venous structures can be visualized (Fig. 6.29). MRA is performed to evaluate the renal arteries for stenosis and is less invasive than catheter angiography

Fig. 6.28 Magnetic Resonance Angiography. Coronal three-dimensional magnetic resonance angiogram after contrast administration shows normal renal arteries.

Fig. 6.29 Magnetic resonance venography.

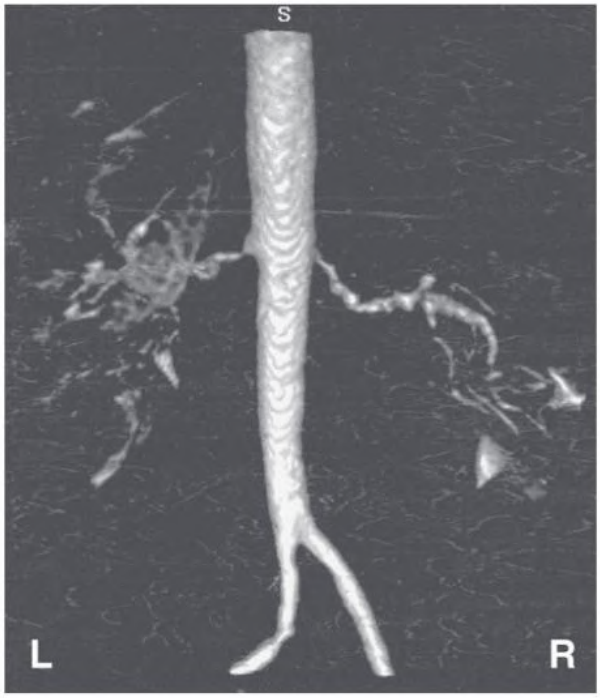

Fig. 6.30 Dysplasia on Magnetic Resonance (MR) Angiography. Posterior view of coronal three-dimensional MR angiogram shows typical beaded appearance of fibromuscular dysplasia of the right renal artery and focal high grade stenosis of the origin of the left renal artery.

(Fig. 6.30). Technical advances, including faster sequences, now give sensitivity of 97% and specificity of 93% compared with DSA for contrast-enhanced MRA in the detection of renal artery stenosis.[15] MRA without gadolinium has a lower sensitivity (53%–100%) and specificity (65%–97%) for detection of renal artery stenosis.[16] MRA has limited ability to assess accessory renal arteries and therefore is not an ideal study to evaluate fibromuscular dysplasia. It has become the most commonly used modality in patients with hypertension, declining kidney function, or allergy to iodinated contrast agents.[17] Where MRA is unavailable, Doppler ultrasound can be used.

Disadvantages of Magnetic Resonance Imaging

Like CT, MRI has some disadvantages. The table and gantry are confining, so claustrophobic patients may be unable to cooperate. Patients with some types of internal metallic hardware cannot undergo MRI. MRI safety guidelines have been developed with an extensive list of devices that are or are not MRI approved, and any devices in the patient need to be checked against this list. Examples of contraindications include neural stimulator devices and cerebral aneurysm clips. Many cardiac pacemakers are now compatible with MRI, but if the patient is pacemaker dependent, they cannot be scanned.

Determination of in-stent stenosis is impossible, as metallic artifacts from renal artery stents completely obscure the lumen. Even with the new, fast imaging techniques, patients need to be able to cooperate with breath-holding instructions to minimize motion-related artifacts. The safety of the use of MRI contrast agents in patients with impaired kidney function is discussed later (see Magnetic Resonance Contrast Agents).

MRI can be used in the intensive care unit and in critically ill patients only if they are stable enough to be transported to the MRI suite and have no implanted metallic devices. Ventilated patients can undergo MRI; however, specific MRI-compatible, nonferromagnetic

ventilators and other life support devices must be used. Because of the confined nature of the MRI gantry, visualization and monitoring of the patient during the scan are compromised.

Incidental Findings

Incidental kidney lesions are being found with increasing frequency. Almost 70% of renal cell carcinomas are discovered incidentally on imaging studies performed for other reasons. There is an age-dependent incidence of renal cysts, from about 5% in patients younger than 30 years to almost one-third of those older than 60 years.[18] The differentiation of solid and cystic lesions is the first mandate because as many as two-thirds of solid lesions are found to be malignant.[19] MRI is ideally suited for lesion evaluation and is often better than ultrasound, particularly for complex cystic lesions. Parameters being characterized include solid versus cystic appearance, overall lesion complexity, lesion enhancement, involvement of renal vasculature and collecting system, and extension into perirenal tissues and organs. Diffusion-weighted MRI sequences are often useful as a means of further differentiating benign and malignant solid lesions.

MEASUREMENT OF GLOMERULAR FILTRATION RATE

Renal blood flow and split kidney function can be evaluated by CT and MRI.[20-22] The attenuation of the accumulated contrast material within the kidney is directly proportional to the GFR. Taking into account the renal volume, the function of each kidney can be determined. Although both modalities yield similar information, MRI is used more in children and in patients with allergy to contrast agents. However, scintigraphy is still widely used for assessing kidney function, as discussed later.

ANGIOGRAPHY

Angiography is now most often performed for therapeutic intervention, such as embolotherapy or angioplasty and stenting, preceded by diagnostic angiography to evaluate the renal arteries for possible stenosis (Fig. 6.31). With improved resolution and scanning techniques, CTA and MRA have replaced conventional angiography, even for detection of accessory renal arteries, which are often small and bilateral but a possible cause of hypertension. However, angiography remains the gold standard reference test for the diagnosis of renal artery stenosis and fibromuscular dysplasia. There also remains a role for diagnostic angiography in the evaluation of medium- and large-vessel vasculitis and detection of renal infarction.

The conventional angiogram is performed through arterial puncture, followed by catheter placement in the aorta and subsequent selective renal artery catheterization as necessary. Contrast is administered intraarterially, and the images are obtained with DSA. DSA uses computer reconstruction and manipulation to generate the images, with the advantage that previously administered and excreted contrast material and bones can be digitally removed to better visualize the renal vasculature. Angiography can cause contrast-induced nephropathy and cholesterol embolization (see Chapter 41). Pathologic evidence of cholesterol embolization is common, but clinically significant symptoms occur infrequently (1%–2%).[23]

RENAL VENOGRAPHY

Catheter venography was once used for evaluation of renal vein and gonadal vein thrombosis and for renal vein sampling to measure renin, but it has largely been replaced with Doppler ultrasound, followed by contrast-enhanced CT or MRI (see Fig. 6.17).

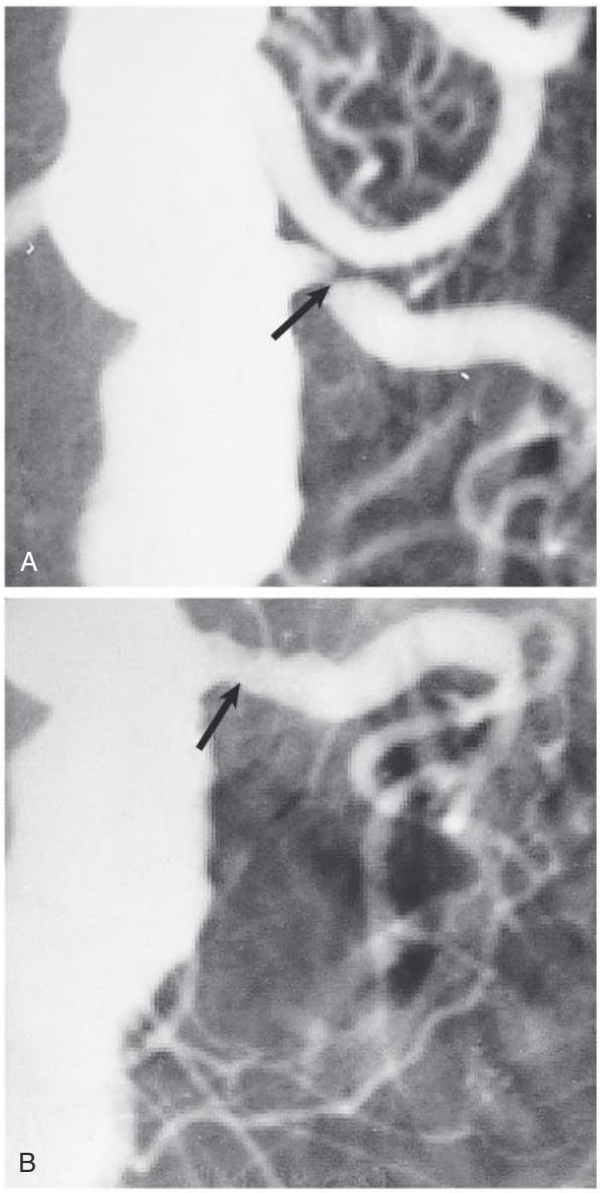

Fig. 6.31 Left Renal Artery Stenosis and Angioplasty. (A) Aortogram demonstrating a tight left renal artery stenosis *(arrow).* (B) Postangioplasty image with marked improvement of the stenosis *(arrow).* (Courtesy Dr. Harold Mitty.)

NUCLEAR SCINTIGRAPHY

Nuclear scintigraphy evaluates function and anatomy seen with other diagnostic imaging modalities. Radiotracers are designed to accumulate in tissues or organs on the basis of underlying functions unique to that organ. The gamma camera captures the photons from a radiotracer within the patient and generates an image. Single-photon emission computed tomography (SPECT) is a specialized type of imaging in which the emitted photons are measured at multiple angles, similar to CT, and multiplanar or even 3D images can be created. Three categories of radiotracers that differ in mode of renal clearance are used in kidney imaging: glomerular filtration, tubular secretion, and tubular retention agents (Table 6.5).

TABLE 6.5 Choice of Radionuclide in Kidney Imaging

Imaging Target	Radiotracer
Glomerular filtration rate	^{99m}Tc-DTPA
Glomerular filtration rate with renal impairment	^{99m}Tc-MAG3, ^{131}I-OIH
Effective renal plasma flow	^{99m}Tc-MAG3, ^{131}I-OIH
Kidney scarring	^{99m}Tc-DMSA, ^{99}Tc-GH
Renal pseudotumor	^{99m}Tc-DMSA
Upper renal tract obstruction	^{99m}Tc-DTPA
Upper renal tract obstruction with reduced GFR	^{99m}Tc-MAG3

^{99m}Tc-DMSA, Technetium 99m–labeled dimercaptosuccinate; *^{99m}Tc-DTPA,* technetium 99m–labeled diethylenetriaminepentaacetic acid; *^{99m}Tc-MAG3,* mercaptoacetyltriglycine; *^{99m}Tc-GH,* technetium 99m glucoheptonate; *^{131}I-OIH,* 131I orthoiodohippurate.

Scintigraphy remains superior to the other imaging modalities in the evaluation of renal flow. It is the study of choice in the evaluation of renal transplants and functional obstruction, especially when ultrasound evidence is equivocal. Scintigraphy is also widely used to measure GFR, although CT or MRI is preferred in some centers.

Although CT, MRI, and contrast-enhanced ultrasound can be used to evaluate kidney function (e.g., after nephron-sparing surgery), scintigraphy remains the preferred modality. Both CTA and MRA have replaced nuclear scintigraphy in the evaluation of renal artery stenosis and benign renal masses, such as a column of Bertin. Nuclear medicine is still used to assess the functional significance of renal artery stenosis independent of anatomy.

Glomerular Filtration Agents

Glomerular filtration agents can be used to measure GFR. Technetium 99m–labeled diethylenetriaminepentaacetic acid (^{99m}Tc-DTPA) is the most common glomerular agent used for imaging and also can be used for GFR calculation. In patients with poor kidney function, renal imaging with tubular secretion agents such as mercaptoacetyltriglycine (^{99m}Tc-MAG3) is superior to DTPA.[24,25]

Tubular Secretion Agents

^{99m}Tc-labeled MAG3 is handled primarily by tubular secretion and can be used to estimate effective renal plasma flow. The clearance rate for ^{99m}Tc-MAG3 is 340 mL/min.[26]

Tubular Retention Agents

Tubular retention agents include ^{99m}Tc-labeled dimercaptosuccinate (DMSA) and less often ^{99m}Tc-labeled glucoheptonate (GH). These agents provide excellent cortical imaging and can be used in suspected renal scarring or infarction, in pyelonephritis, and for clarification of renal pseudotumors. These agents bind with high affinity to sulfhydryl groups on the surface of proximal tubular cells.

Renogram

A renogram (or renal scintigram) is generated by scintigraphy and provides information about blood flow, renal uptake, and excretion. Time-activity graphs are produced that plot blood flow of the radiotracer into each kidney relative to the aorta. Peak cortical enhancement and pelvicalyceal clearance of the tracer are also plotted. DTPA or MAG3 can be used to generate the renogram. The relative radiotracer uptake can be measured and can provide split or differential information about kidney function (Fig. 6.32).

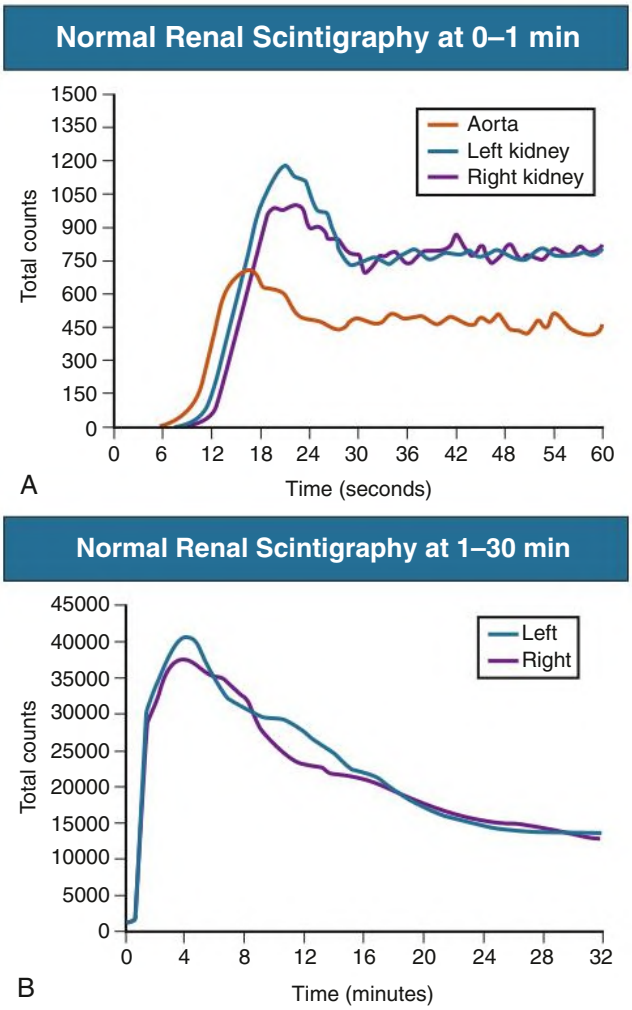

Fig. 6.32 Normal ^{99m}Tc-Labeled DTPA Study: Time-Activity Curves. (A) Early (0–1 minute), showing renal blood flow. (B) Later (1–30 minutes), showing renal uptake and excretion of tracer. (Courtesy Dr. Chun Kim.)

The blood pool or flow images are obtained after bolus injection of the radiotracers. Images are obtained with the gamma camera every few seconds for the first minute. The second component of the renogram evaluates kidney function by measuring radiotracer uptake and excretion by the kidney. In health, the peak renal cortical concentration occurs between 3 and 5 minutes after injection of tracer. Delayed transit of the isotope secondary to kidney dysfunction (e.g., ATN or rejection) or obstructive uropathy will alter the curve of the renogram.

In cases of suspected obstructive uropathy, a diuresis renogram can be obtained. A loop diuretic is injected intravenously when radiotracer activity is present in the renal pelvis; a computer-generated washout curve is obtained. In patients with true obstruction, activity will remain in the renal pelvis, whereas it will quickly wash out in patients without an obstruction (Fig. 6.33; see also Fig. 58.12).

Cortical Imaging

Imaging of the kidney cortex is performed with tubular retention agents, usually ^{99m}Tc-DMSA. Information about renal size, location, and contour can be obtained (Fig. 6.34). The cortical study is used most frequently for evaluation of renal scarring, particularly in children with reflux or chronic infections (see Chapter 61). Cortical imaging

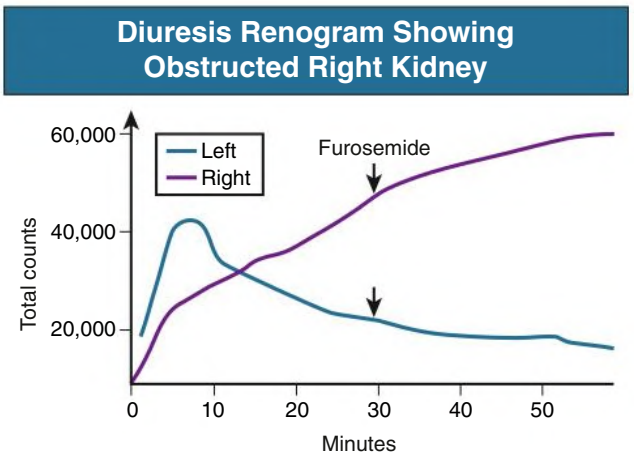

Fig. 6.33 Diuresis Renogram Showing Obstructed Right Kidney. Isotope continues to accumulate in the right kidney despite intravenous furosemide (given at 30 minutes). Isotope excretion in the left kidney is normal.

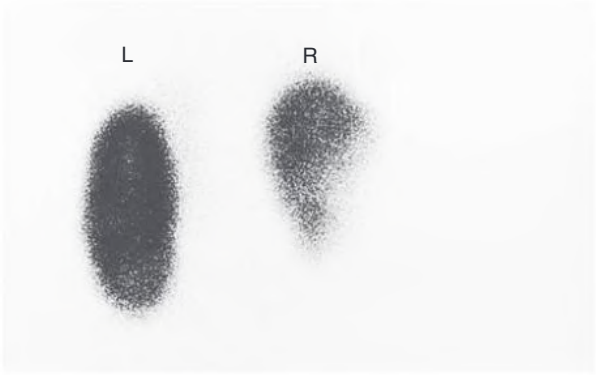

Fig. 6.34 Renal Infarct. ^{99m}Tc-DMSA scan in a newborn with an infarct of the right lower pole *(R)* secondary to embolus from umbilical catheter. (Courtesy Dr. Chun Kim.)

may be better than ultrasound in the evaluation of the young patient with urinary tract infection.[27] An infection, scar, or space-occupying lesion (tumor or cyst) will create a cortical defect, and correlation of the cortical defect site with other cross-sectional imaging should be performed to differentiate these entities.

Vesicoureteral Reflux

In children with suspected vesicoureteral reflux, a standard cystogram is obtained. If reflux is shown, follow-up is subsequently performed with radioisotope cystography, which exposes the child to a lower radiation dose and can be used to quantitate the bladder capacity when reflux occurs. The study is performed after instillation of technetium pertechnetate through a catheter into the bladder. Images are obtained during voiding.

Kidney Transplant

Kidney transplants are easily evaluated with scintigraphy. ^{99m}Tc-MAG3 is cleared through tubular secretion, which is maintained in most kidneys to a better degree than glomerular filtration in kidney failure. Because many transplant recipients have declining kidney function, ^{99m}Tc-MAG3 is the first-choice nuclide.

As with the normal kidneys, information about blood flow and function can be determined. Postoperative complications involving the artery, vein, or ureter are also well delineated. Nuclear imaging can help define ATN versus rejection in transplant patients with declining kidney function. Ultrasound with Doppler evaluation of resistive index is often a complementary investigation, and choice of imaging modality in part depends on local expertise and preference.

Fig. 6.35 Normal Positron Emission Tomography Scan. Note normal radiotracer uptake in brain, heart, intestines, and liver, with normal excretion in kidneys.

POSITRON EMISSION TOMOGRAPHY

Positron emission tomography (PET) scanning uses radioactive positron emitters, most often fluorine-18–labeled fluorodeoxyglucose (FDG). The FDG is intravenously injected and distributes in the body according to metabolic activity. Any process, such as a tumor or infection, that causes increased metabolic activity will result in an area of increased uptake on the scan. These areas of abnormality need to be differentiated from normally hypermetabolic tissues, such as brain, liver, bone marrow, and to some extent heart and bowel (Fig. 6.35). Because FDG is cleared through the kidneys and excreted in the urine, which can obscure renal masses or infection, PET scanning has a limited role in renal imaging but is useful in the staging and follow-up of metastatic renal cancer.[28,29] Other ligands exist with lower levels of urinary excretion, but the application of this in renal imaging is still being investigated.

MOLECULAR IMAGING

With molecular imaging, radiology is moving from the identification of generic anatomy and nonspecific enhancement patterns to assessment of specific molecular differences in tissues and disease processes. Nuclear imaging presently is molecular based but still nonspecific (e.g., FDG-PET, renal DTPA). The newer focus of molecular imaging studies is dynamic processes such as metabolic activity, cell proliferation, apoptosis, receptor status, fibrosis, and antigen modulation.

Typically, this involves imaging of biochemical and physiologic processes. Techniques are being developed with optical scanning, MRI, and ultrasound as well as with radionuclides.

Applications are established in clinical practice, particularly in oncology (e.g., CD20 imaging in lymphoma), and work is under way for renal-specific molecular imaging. For example, MR renal cell imaging may be available soon to help differentiate ATN from renal rejection and renal cell cancer from benign tumors.

RADIOLOGIC CONTRAST AGENTS

X-Ray Contrast Agents

Contrast agents continue to have a role in many imaging techniques. A triiodinated benzene ring forms the chemical basis for CT intravascular contrast agents. Conventional contrast agents have high osmolality, about five times greater than plasma osmolality. Modifications to the benzene ring have led to newer contrast agents, including low-osmolar (which is still hyperosmolar compared with normal plasma) and more recently iso-osmolar nonionic agents, which are less nephrotoxic.

In patients with normal GFR, the kidneys eliminate almost all the contrast agent. Extrarenal routes of excretion include the liver and bowel wall and account for less than 1% of elimination, but this can increase when kidney function is compromised. The half-time in patients with normal GFR is 1 to 2 hours, compared with 2 to 4 hours in dialysis patients.[30]

Contrast reactions for iodinated agents occur in 3.1% to 4.7% of patients.[31-33] Of those patients who have a contrast reaction, 20% will experience a reaction on reexposure that may be similar or worse. Contrast reactions can be anaphylactoid or chemotoxic reactions. The anaphylactoid reactions mimic an allergic response, whereas the chemotoxic reactions are believed to be mediated by direct toxic effects of the contrast material. The exact mechanism of contrast reaction is not known but is likely to be multifactorial. Formation of antigen-antibody complexes, complement activation, protein binding, and histamine release have been cited as possible mechanisms.

Reactions may be minor, intermediate, or severe. Minor reactions include heat sensation, nausea, and mild urticaria. Intermediate reactions include vasovagal reaction, bronchospasm, and generalized urticaria. Severe reactions include profound hypotension, pulmonary edema, and cardiac arrest. The use of low-osmolar or iso-osmolar contrast agents reduces the incidence of minor and intermediate contrast reactions. The reported incidence of death related to high-osmolar contrast agents is 1 in 40,000. Immediate treatment of reactions should be directed toward the symptoms. In patients with a history of contrast allergy, pretreatment is recommended with antihistamines and corticosteroids on reexposure.

Contrast-Induced Nephropathy

Although acute kidney injury (AKI) associated with the administration of contrast material has been reported as the third most common cause of in-hospital AKI, recent data indicate this risk has been markedly overestimated.[33] The original studies and reports often occurred using high-osmolarity contrast agents in subjects who were not well hydrated. Biopsies from those patients often showed osmotic nephrosis or acute tubular necrosis.[34] Today, contrast-induced AKI is rare, even in patients with GFR less than 45 mL/min/1.73m^2, and thus the risk of AKI does not preclude the use of intravenous contrast if clinically necessary. Despite the concern for long-term complications, there is evidence suggesting that intravenous contrast carries little risk for dialysis dependence or mortality.[35]

Studies of the pathogenesis of contrast-induced nephropathy have suggested that the injury is due to the high osmolality of the agent, which can induce renal vasoconstriction, activation of the polyol-fructokinase pathway in the proximal tubule associated with oxidative stress,[36] and possibly the effects of the acute osmotic-induced uricosuria. Most underlying cellular events were thought to occur within the first 60 minutes after administration of the contrast agent, with the greatest risk in the first 10 minutes. Tubular injury produces oxygen free radicals, possibly from the vasoconstriction. In animal studies, reduction in antioxidant enzymes associated with hypovolemia contributes to the injury.[37]

An important differential diagnosis for contrast-induced nephropathy in patients with vascular disease undergoing catheter angiography is cholesterol embolization (see Chapter 41).

Possible risk factors include preexisting chronic kidney disease, diabetes, cardiovascular disease, use of diuretics, advanced age (>75 years), multiple myeloma in dehydrated patients, hypertension, uricosuria, and high-dose contrast. In patients with kidney failure, contrast administration may result in fluid overload because of thirst induced by the osmotic load. Hydration with normal saline is the mainstay of prevention; there is no substantial evidence that sodium bicarbonate offers any advantage over saline.[38] Oral *N*-acetylcysteine, a thiol-containing antioxidant, is often given in conjunction with hydration but has not proved consistently to be protective.[39] Note that even the use of hydration is controversial, with excessive hydration putting these patients at risk of fluid overload.[40]

In patients with estimated GFR less than 60 mL/min/1.73m^2, low-osmolar or iso-osmolar contrast agents can be used and the doses reduced. Repetitive, closely performed contrast studies should be avoided. In high-risk patients, alternative imaging studies (ultrasound, MRI, or noncontrast CT) always should be considered. Issues related to contrast-induced nephropathy are further discussed in Chapter 72.

Magnetic Resonance Contrast Agents

The two classes of MRI contrast agents are diffusion and nondiffusion agents. Diffusion agents, with appropriate timing of imaging sequences, can delineate vessels and parenchymal tissues. Nondiffusion agents remain in the bloodstream and are primarily useful for MRA. All the contrast agents are based on the paramagnetic properties of gadolinium. Gadolinium itself is highly toxic and is given only when it is tightly chelated (e.g., Gd-tetraazacyclododecane-1,4,7,10-tetraacetic acid [Gd-DOTA], Gd-diethylenetriamine penta-acetic acid [Gd-DTPA]).

Minor reactions such as headache and nausea occur in 3% to 5% of patients, but life-threatening reactions and nephrotoxic reactions are rare. In patients with reduced GFR, a rare severe reaction (nephrogenic systemic fibrosis [NSF]), has been described (see Chapter 91). Guidelines confirm that MRI using high-risk gadolinium-containing contrast agents is contraindicated in patients with AKI and in those with chronic kidney disease stages 4 and 5 (i.e., GFR <30 mL/min/1.73 m^2),[16] because some agents have been linked to NSF. Cases of NSF are particularly associated with the linear structure chelates (such as gadodiamide, gadopentetate, and gadoversetamide). However, some linear chelates have a higher dissociation constant and to date have not been associated with NSF (such as gadobenate).[41] The newer macrocyclic gadolinium-containing contrast agents (e.g., gadoterate and gadoteridol) also have not been associated with NSF, even in patients with GFR less than 30 mL/min/1.73 m^2. Recently, studies have shown gadolinium deposition and retention in tissues, especially the brain, and especially after multiple injections of the contrast material. To date, there are no documented adverse events associated with this retention. The choice of gadolinium agent in each case should be determined by discussion between the nephrologist and radiologist.

Radiomics and Artificial Intelligence

Radiomics and artificial intelligence are areas of ongoing research. Radiomics deals with the conversion of images into data formats that allow assessment and quantification of pixel or voxel gray levels (spatial heterogenicity). This allows texture analysis that can be used as is or with further machine learning and adaption of artificial intelligence algorithms.

These tools are being studied for differentiating benign and malignant lesions as well as characterizing renal cell cancer types. Additionally, these tools may be useful in following response of renal cell cancer to chemotherapeutic agents.[42-44]

Although these techniques show promise, there are still many limitations and challenges before these tools can be adapted to routine clinical use.

SELF-ASSESSMENT QUESTIONS

1. On ultrasound, compared with the liver, the normal adult kidney cortex is:
   A. isoechoic.
   B. hyperechoic.
   C. hypoechoic.
   D. anechoic.
2. Which of the following imaging modalities has the *least* chance of inducing contrast nephropathy?
   A. CO_2 angiography.
   B. Contrast-enhanced CT.
   C. Contrast-enhanced MRI.
   D. Intravenous urography.
3. The imaging modality that exposes the patient to the *least* radiation risk is:
   A. CT urography.
   B. dual-energy CT with virtual noncontrast imaging.
   C. intravenous urography.
   D. diffusion-weighted MRI.
4. Which of the following is a mandatory reason that an MRI of the kidneys *cannot* be performed?
   A. Cardiac pacemaker in a patient who is not pacemaker dependent.
   B. Titanium total hip replacement less than 6 weeks old.
   C. When eGFR is 35 mL/min.
   D. History of cerebral aneurysm clip.
5. Which of the following is usually the recommended *best* modality to evaluate for kidney stones?
   A. Noncontrast CT scan.
   B. MRI.
   C. Ultrasound.
   D. Nuclear medicine renogram.

Kidney Biopsy

Peter S. Topham, Rob MacGinley

Percutaneous kidney biopsy was first described in the early 1950s by Iversen and Brun[1] and Alwall.[2] These early biopsies were performed with the patient in the sitting position by use of a suction needle and intravenous urography for guidance. An adequate tissue diagnosis was achieved in less than 40% of these early cases. In 1954 Kark and Muehrcke[3] described a modified technique using the Franklin-modified Vim-Silverman needle, with the patient in a prone position and an exploring needle used to localize the kidney before insertion of the biopsy needle. These modifications yielded a tissue diagnosis in 96% of cases, and no major complications were reported. Since then, the kidney biopsy procedure has remained largely unchanged, although the use of real-time ultrasound and refinement of biopsy needle design have offered significant improvements. Kidney biopsy now provides a tissue diagnosis in more than 95% of patients, with a life-threatening complication rate of less than 0.1%.

INDICATIONS FOR KIDNEY BIOPSY

Ideally, analysis of a kidney biopsy sample should identify a specific diagnosis, reflect the level of disease activity, and provide information to allow informed decisions about treatment. Although not always able to fulfill these criteria, the kidney biopsy remains a valuable clinical tool and is particularly beneficial in the clinical situations discussed in Box 7.1.

Nephrotic Syndrome

Routine clinical and serologic examination of patients with nephrotic syndrome usually allows the clinician to determine whether a systemic disorder is present. In adults and in adolescents beyond puberty without systemic disease, the glomerular pathologic process cannot be predicted with confidence by noninvasive criteria alone; therefore a renal biopsy should be performed. In children age 1 year up to puberty, a presumptive diagnosis of minimal change disease (MCD) usually can be made. Kidney biopsy is reserved for nephrotic children with atypical features, including microhematuria, hypocomplementemia, reduced glomerular filtration rate (GFR), and failure to respond to corticosteroids. Antibodies against phospholipase A2 receptor 1 (PLA_2R1) are found in 80% of patients with membranous nephropathy and are a noninvasive aid to diagnosis,[4] response to treatment,[5] and prediction of remission.[6] Unfortunately, the test only identifies 70% of cases of primary membranous nephropathy. In addition, biopsy still provides information on disease chronicity and the extent of irreversible fibrosis.

Acute Kidney Injury

In most patients with acute kidney injury (AKI) on a background of chronic kidney disease (CKD), the cause can be determined without a renal biopsy. In a minority of patients, however, a confident diagnosis cannot be made, and a renal biopsy should be performed urgently so appropriate treatment can be started before irreversible renal injury develops. This is particularly true in patients with AKI accompanied by an active urine sediment or with suspected drug- or infection-induced acute interstitial nephritis.

Systemic Disease Associated With Kidney Dysfunction

Patients with diabetes mellitus and kidney dysfunction do not usually require biopsy if they have clinical features that suggest diabetic nephropathy (e.g., isolated proteinuria, diabetes of long duration, other microvascular complications). However, kidney biopsy should be performed if the presentation is atypical, such as proteinuria associated with glomerular hematuria, absence of retinopathy or neuropathy (in patients with type 1 diabetes), onset of proteinuria less than 5 years from the documented onset of diabetes, uncharacteristically rapid change in kidney function or kidney disease of acute onset, or immunologic abnormalities.

Serologic testing for antineutrophil cytoplasmic antibody (ANCA) and for anti–glomerular basement membrane (anti-GBM) antibodies usually allows a confident diagnosis of kidney small-vessel vasculitis or Goodpasture disease without invasive measures. Nonetheless, a kidney biopsy still should be performed to confirm the diagnosis and clarify the extent of chronic fibrosis and thus the potential for recovery. This information may be important in helping decide whether to initiate or continue immunosuppressive therapy, particularly when complications of immunosuppression are observed or expected.

Lupus nephritis usually can be diagnosed by noninvasive criteria such as autoantibodies, urine protein excretion, kidney function, and urine sediment abnormalities, which can also be used to inform decisions about initial immunosuppressive treatment. However, a kidney biopsy will clarify the underlying pathologic lesion, level of active inflammation, and extent of chronic fibrosis, thereby providing robust guidance for therapy.

The diagnosis of viral infection–related nephropathy (e.g., hepatitis B virus–associated membranous nephropathy) is suggested by characteristic histologic lesions together with evidence of active viral infection. However, the identification of virus-specific protein or DNA or RNA in the kidney biopsy tissue by immunopathologic and molecular pathologic techniques (e.g., in situ hybridization) can confirm the diagnosis.

Other systemic diseases, such as amyloidosis, sarcoidosis, and myeloma can be diagnosed with kidney biopsy. However, a kidney biopsy is indicated only if the diagnosis remains uncertain or if knowledge of kidney involvement would change management.

Kidney Transplant Dysfunction

Kidney levels of calcineurin inhibitors require a kidney biopsy to determine the cause. In the early posttransplantation period, this is most

BOX 7.1 Indications for Kidney Biopsy

Nephrotic Syndrome
- Routinely indicated in adults
- In prepubertal children, indicated only if clinical features atypical of minimal change disease are present

Acute Kidney Injury
- Indicated if obstruction, reduced kidney perfusion, and acute tubular necrosis have been ruled out

Systemic Disease With Kidney Dysfunction
- Indicated in patients with small-vessel vasculitis, anti–glomerular basement membrane disease, and systemic lupus
- Indicated in patients with diabetes only if atypical features present

Nonnephrotic Proteinuria
- May be indicated if proteinuria is >1 g/24 h

Isolated Microscopic Hematuria
- Indicated only in unusual circumstances

Unexplained Chronic Kidney Disease
- May be diagnostic (e.g., identify immunoglobulin A nephropathy even in "end-stage kidney")

Familial Kidney Disease
- Biopsy of one affected member may give diagnosis and minimize further investigation of family members

Kidney Transplant Dysfunction
- Indicated if ureteral obstruction, urinary sepsis, renal artery stenosis, and toxic calcineurin inhibitor levels are not present

useful in differentiating acute rejection from acute tubular necrosis (ATN) and the BK virus nephropathy. Later, kidney biopsy can differentiate acute rejection from chronic allograft nephropathy, recurrent or de novo glomerulonephritis (GN), and calcineurin inhibitor toxicity. The location of the kidney transplant in the iliac fossa facilitates biopsy of the allograft and allows repeated biopsies when indicated. This has encouraged many units to adopt a policy of protocol (surveillance) biopsies to detect subclinical acute rejection and kidney scarring and to guide the choice of immunosuppressive therapy (see Chapter 109).

Nonnephrotic Proteinuria

The value of kidney biopsy in patients with nonnephrotic proteinuria is debatable. All conditions that result in nephrotic syndrome can cause nonnephrotic proteinuria, except for MCD. However, the benefit of specific treatment with corticosteroids and other immunosuppressive agents in these patients probably does not justify the risk for significant drug-related side effects. In patients with proteinuria of more than 1 g/day, generic treatment with strict blood pressure control and angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) reduces proteinuria and reduces the risk for development of progressive kidney dysfunction (see Chapter 82). Nonetheless, although the kidney biopsy may not lead to an immediate change in management, it can be justified in these circumstances if it will provide prognostic information, identify a disease for which a different therapeutic approach is indicated, or provide clinically important information about the future risk for disease recurrence after kidney transplantation.

Isolated Microhematuria

Patients with microhematuria should be evaluated to identify structural lesions such as kidney stones or kidney and urothelial malignant neoplasms. The absence of a structural lesion suggests that the hematuria may have a glomerular source. Biopsy studies have identified glomerular lesions in up to 75% of biopsies.[7] In all series, immunoglobulin A (IgA) nephropathy is the most common lesion, followed by thin basement membrane nephropathy and normal kidney morphology. In the absence of nephrotic proteinuria, kidney impairment, or hypertension, the prognosis for patients with these conditions is excellent, and because specific therapies are not available, kidney biopsy is not necessary and patients require only follow-up. Biopsy should be performed only if the result would reassure the patient, avoid repeated urologic investigations, or provide specific information, as in the evaluation of potential living kidney donors, in familial hematuria, or for life insurance and employment purposes.

Unexplained Chronic Kidney Disease

Kidney biopsy can be informative in the patient with unexplained chronic kidney impairment and normal-sized kidneys, because in contrast to AKI, it is often difficult to determine the underlying cause with clinical criteria alone. In almost half of such patients, the biopsy will demonstrate an unexpected cause of CKD.[8] However, if both kidneys are small (<9 cm on ultrasound), the risks of biopsy are increased, and the diagnostic information may be limited by extensive glomerulosclerosis and tubulointerstitial fibrosis. In this setting, however, immunofluorescence studies still may be informative. For example, glomerular IgA deposition may be identified despite advanced structural damage.

Familial Kidney Disease

A kidney biopsy can be helpful in the investigation of patients with a family history of kidney disease. A biopsy performed in one affected family member may secure the diagnosis for the whole family and avoid the need for repeat investigation. Conversely, a kidney biopsy may unexpectedly identify inherited disease, thereby prompting evaluation of other family members.

Role of Repeat Kidney Biopsy

In some patients, a repeat biopsy may be indicated. For example, the pathologic changes in lupus nephritis may evolve, necessitating treatment adjustment. In addition, corticosteroid-resistant, corticosteroid-dependent, or frequently relapsing MCD may represent a missed diagnosis of focal segmental glomerulosclerosis (FSGS), which may be detected on repeat biopsy. Some nephrologists think repeat biopsy in patients who have had aggressive immunosuppressive therapy of crescentic GN can help determine the most appropriate next line of therapy.

VALUE OF KIDNEY BIOPSY

Biopsy Adequacy

In the assessment of a kidney biopsy, the number of glomeruli in the sample is the major determinant of whether the biopsy will be diagnostically informative.

For a focal entity such as FSGS, the diagnosis could be made on a biopsy specimen containing a single glomerulus that contains a typical sclerosing lesion. However, the probability that FSGS is not present in a patient with nephrotic syndrome and minimal changes on the biopsy specimen depends on the actual proportion of abnormal glomeruli in the kidney and the number of glomeruli obtained in the biopsy specimen. For example, if 20% of glomeruli in the kidney have sclerosing

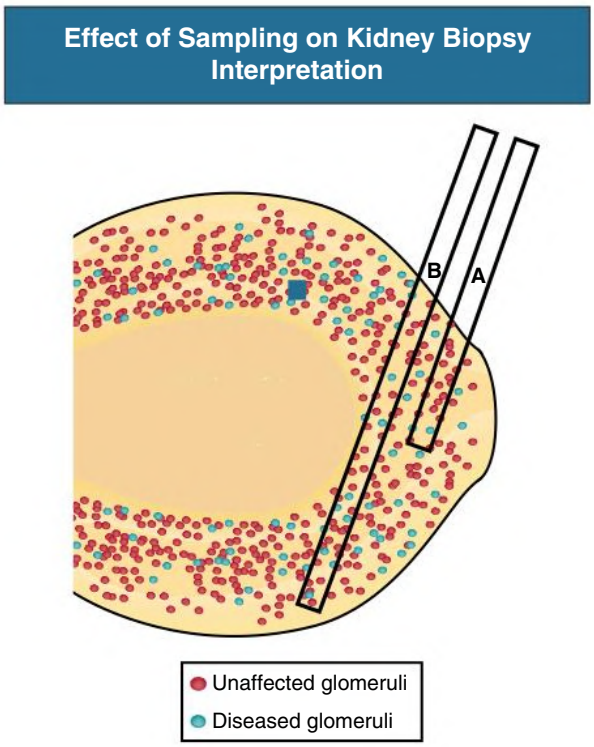

Fig. 7.1 Effect of Sampling on Kidney Biopsy Interpretation. *Red dots* represent unaffected glomeruli. *Blue dots* represent diseased glomeruli. The size of the biopsy core affects the probability that the observed glomerular involvement is a true reflection of involvement in the whole kidney. In a biopsy specimen containing 10 glomeruli (core A), of which three are abnormal (30%), there is a 95% probability that the actual glomerular involvement is between 7% and 65%. In the same kidney, if the biopsy specimen contained 30 glomeruli with 30% being abnormal (core B), the 95% confidence intervals are narrowed to 15% and 50%.

lesions and five glomeruli are sampled, there is a 35% chance that all the glomeruli in the biopsy specimen will be normal and the biopsy will miss the diagnosis. By contrast, in the same kidney, if 10 or 20 glomeruli are sampled, the chance of obtaining all normal glomeruli is reduced to 10% and less than 1%, respectively, and the biopsy is therefore more discriminating. This argument assumes that any segmental lesions present in the biopsy specimen are actually identified; this requires the biopsy specimen to be sectioned at multiple levels.

Unless all glomeruli are affected equally, the probability that the observed involvement in the biopsy specimen accurately reflects true involvement in the kidney depends not only on the number of glomeruli sampled but also on the proportion of affected glomeruli (Fig. 7.1).

Therefore the interpretation of the biopsy should account for the number of glomeruli obtained. A typical biopsy sample will contain 10 to 15 glomeruli and will be diagnostically useful. Nonetheless, it must be appreciated that because of the sampling issue, a biopsy sample of this size will occasionally be unable to diagnose focal diseases and at best will provide imprecise guidance on the extent of glomerular involvement.

An adequate biopsy also should provide samples for immunohistologic examination and electron microscopy (EM). Immunohistologic examination is performed by either immunofluorescence on frozen material or immunoperoxidase on fixed tissue, according to local protocols and expertise. It is helpful for the biopsy cores to be viewed under an operating microscope immediately after being taken to ensure that they contain cortex and that when the cores are divided, the immunohistologic and EM samples both contain glomeruli.

If the material obtained for a complete pathologic evaluation is insufficient, a discussion with the pathologist should address how best to proceed before the tissue is placed in fixative, so the material can be processed in a way that will provide maximum information for the specific clinical scenario. For example, if the patient has heavy proteinuria, most information will be gained from EM because it can demonstrate podocyte foot process effacement, focal sclerosis, electron-dense deposits of immune complexes, and the organized deposits of amyloid.

If a sample is supplied for immunofluorescence microscopy but contains no glomeruli, it may be possible to reprocess the paraffin-embedded part of the sample to identify immune deposits by immunoperoxidase or immunofluorescence techniques.

Is Kidney Biopsy Always Necessary?

Early studies suggested that kidney biopsy provided diagnostic clarity in most patients, but that this information did not alter management, except for those with heavy proteinuria or systemic disease. More recent prospective studies have suggested that the kidney biopsy identifies a diagnosis different from that predicted on clinical grounds in 50% to 60% of patients and leads to a treatment change in 20% to 50%.[9] This is particularly apparent in patients with heavy proteinuria or AKI, more than 80% of whom have biopsy findings that alter their management.[10]

PREBIOPSY EVALUATION

The prebiopsy evaluation identifies issues that may compromise the safety and success of the procedure (Fig. 7.2). It will determine whether the patient has two normal-sized unobstructed kidneys, sterile urine, controlled blood pressure, and no bleeding diathesis. A thorough history should be taken to identify evidence of a bleeding diathesis, such as previous prolonged surgical bleeding, spontaneous bleeding, family history of bleeding, and ingestion of medication that increases bleeding risk, including antiplatelet agents and anticoagulants.

Important clinical history also relates to patients' previous experiences of biopsies as well as psychological conditions and level of comprehension.[11]

An ultrasound scan should be performed to assess kidney size and identify significant anatomic abnormalities, such as solitary kidney, polycystic or simple cystic kidneys, malpositioned kidneys, horseshoe kidneys, small kidneys, and hydronephrosis.

We recommend hematology studies prebiopsy including platelet count and coagulation profile with prothrombin time and activated partial thromboplastin time. The value of the bleeding time (BT) and thromboelastography (TEG) for predicting bleeding risk after kidney biopsy is unclear. Retrospective studies, however, demonstrated a three- to fivefold increase in bleeding complications after kidney biopsy in patients with prolonged BT. Prospective studies of percutaneous liver biopsy patients showed a fivefold increase in bleeding complications in those with uncorrected BT.[12] A consensus document concluded that the BT is a poor predictor of postsurgical bleeding, but it does correlate with clinical bleeding episodes in uremic patients.[13]

TEG provides an overall measure of the coagulation, platelet, and fibrinolytic systems in one assay and thus may be more predictive of clinical bleeding.[14] A more recent study of 417 patients indicated that TEG abnormalities in patients with renal dysfunction are variable and fail to predict bleeding after kidney biopsy.[15] The role of TEG in the patient undergoing native kidney biopsy requires further evaluation.

Management of Bleeding Risk

Several approaches to the management of bleeding risk have been adopted.

Aspirin

Patients should ideally discontinue aspirin 7 days prior to kidney biopsy. However, because cardiovascular disease is very common in

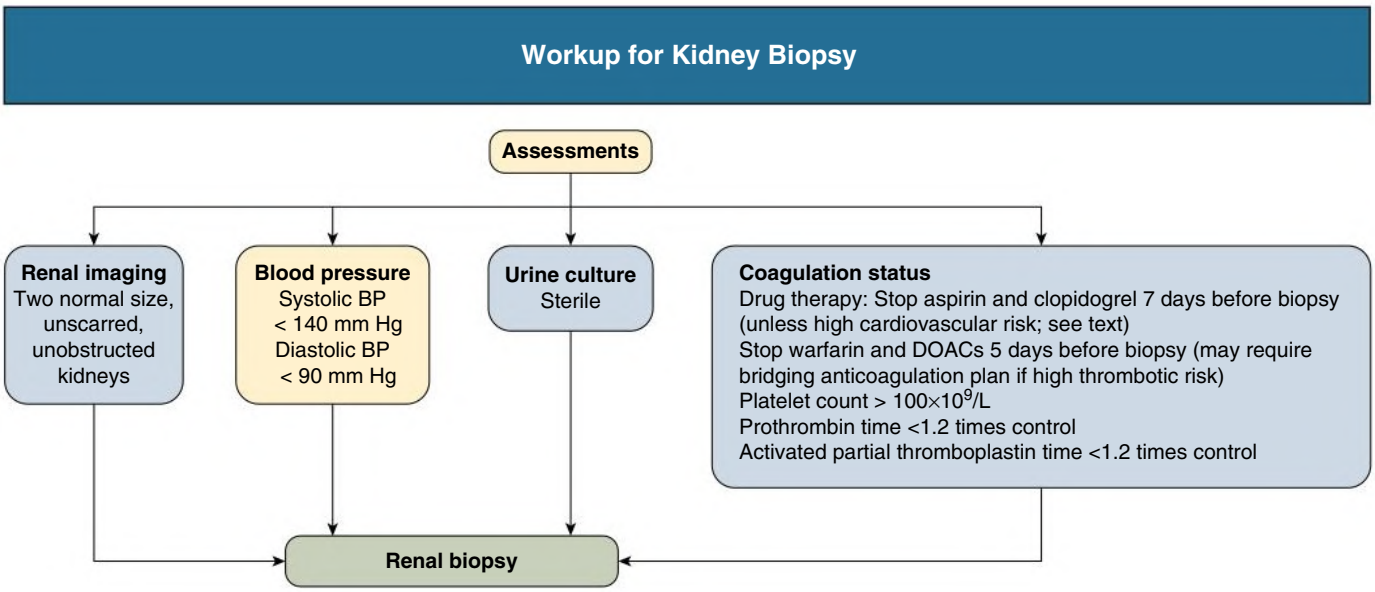

Fig. 7.2 Workup for Kidney Biopsy. *BP,* Blood pressure; *DOACs,* direct oral anticoagulants.

subjects with kidney disease, aspirin discontinuation policies have led to increased cardiac events of recurrent myocardial infarction of 40% and stroke increase three- to fourfold.[16] Although there is an associated increased risk of minor bleeding but not major bleeding, aspirin should be continued in the setting of active cardiovascular risk (e.g., ongoing angina, recent coronary angioplasty, transient ischemic attack).[17]

Clopidogrel

There is very limited data examining safety of continuing clopidogrel at the time of biopsy, so most guidelines suggest cessation 7 days prior to biopsy. Platelet transfusion also can be used to reverse clopidogrel-induced platelet dysfunction when the kidney biopsy is urgent.

Warfarin and Direct Oral Anticoagulants

Warfarin and direct oral anticoagulants (DOACs) should be stopped 5 days prior to biopsy. In low-risk patients, there is no need to have bridging anticoagulation,[18] but in individuals with a mechanical valve, antiphospholipid syndrome, high-risk thrombophilia, or venous thromboembolism within 3 months, bridging low-molecular-weight or unfractionated heparin should be used.[17]

Procoagulants

The use of desmopressin (DDAVP) has been suggested in a small study with minimal clinically significant effect[19] as a strategy to lessen minor and major bleeding because it is a synthetic analog of vasopressin and increases platelet adhesion to the blood vessel wall by releasing factor VII and von Willebrand factor. Because of its increased side effect profile (hyponatremia, hypotension, tachycardia, facial flushing, nausea, and abdominal pain) and minimal clinical evidence supporting its use, it is no longer recommended.[17]

Contraindications to Kidney Biopsy

The contraindications to percutaneous kidney biopsy are listed in Box 7.2. The major contraindication is a bleeding diathesis. If the disorder cannot be corrected and the biopsy is deemed indispensable, alternative approaches can be used, such as open biopsy, laparoscopic biopsy, or transvenous (usually transjugular) biopsy. Inability of the patient to comply with instructions during kidney biopsy is another major contraindication. Sedation or, in extreme cases, general anesthesia may be necessary.

BOX 7.2 Contraindications to Kidney Biopsy

Kidney Status
- Multiple cysts
- Solitary kidney
- Acute pyelonephritis
- Perinephric abscess
- Kidney neoplasm

Patient Status
- Uncontrolled bleeding diathesis
- Uncontrolled blood pressure
- Uremia
- Obesity
- Uncooperative patient

Most contraindications are relative rather than absolute. Clinical circumstances that necessitate urgent kidney biopsy may be overridden, except for uncontrolled bleeding diathesis.

Hypertension (>140/90 mm Hg), hypotension, perinephric abscess, pyelonephritis, hydronephrosis, severe anemia, large kidney tumors, and cysts are relative contraindications to kidney biopsy. When possible, these should be corrected before the biopsy is undertaken.

The presence of a solitary functioning kidney has been considered a contraindication to percutaneous biopsy, and some argue that the risk of biopsy is reduced by direct visualization at open biopsy. However, the postbiopsy nephrectomy rate of 1 in 2000 to 1 in 5000 is comparable to the mortality rate associated with the general anesthetic required for an open procedure. Therefore in the absence of risk factors for bleeding, percutaneous biopsy of a solitary functioning kidney can be justified if there is a clinically important indication for kidney biopsy.

KIDNEY BIOPSY TECHNIQUE

Percutaneous Kidney Biopsy

Native Kidney Biopsy

At our centers, the kidney biopsy is performed by nephrologists with continuous (real-time) ultrasound guidance and disposable automated biopsy needles. We use 16-gauge needles as a compromise between the greater tissue yield of larger needles and the trend toward fewer bleeding

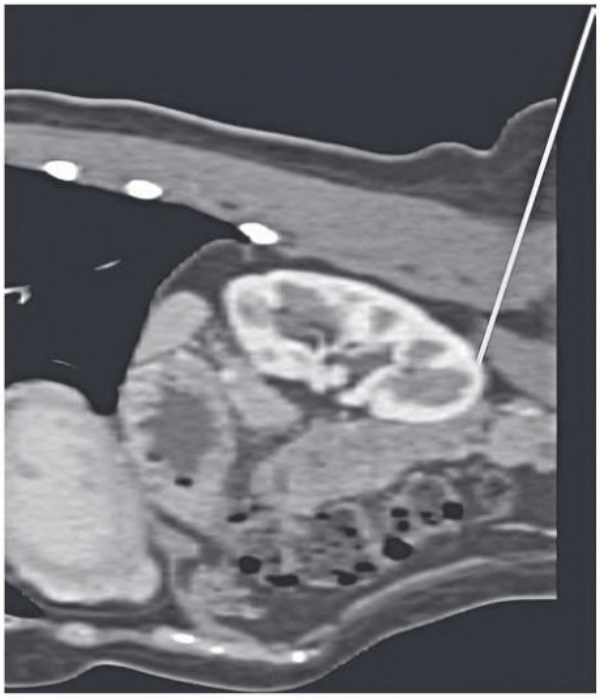

Fig. 7.3 Computed Tomography Through the Left Kidney. The angle of approach of the needle is demonstrated. Note the relative adjacency of the lower pole of the kidney to other structures, particularly the large bowel.

complications of smaller needles as recommended by recent guidelines.[17] For most patients, premedication or sedation is not required as long as there is adequate education and informed consent provided. A history of anxiety may require prebiopsy counseling and intraprocedural relation therapy.[11] The patient is prone, and a pillow is placed under the abdomen at the level of the umbilicus to straighten the lumbar spine and splint the kidneys. Fig. 7.3 shows the anatomic relationships of the left kidney. Ultrasound is used to localize the lower pole of the kidney where the biopsy will be performed (usually the left kidney). An indelible pen mark is used to indicate the point of entry of the biopsy needle. The skin is sterilized with povidone-iodine (Betadine) or chlorhexidine solution. A sterile fenestrated sheet is placed over the area to maintain a sterile field. Local anesthetic (2% lidocaine [lignocaine]) is infiltrated into the skin at the point previously marked.

While the anesthetic takes effect, the ultrasound probe is covered in a sterile sheath. Sterile ultrasound jelly is applied to the skin and, under ultrasound guidance, a 10-cm, 21-gauge needle is guided to the renal capsule and further local anesthetic infiltrated into the perirenal tissues, then along the track of the needle on withdrawal. A stab incision is made through the dermis to ease passage of the biopsy needle. This is passed under ultrasound guidance to the kidney capsule (Fig. 7.4). As the needle approaches the capsule, the patient is instructed to take a breath until the kidney is moved to a position such that the lower pole rests just under the biopsy needle, and then to stop breathing. The biopsy needle tip is advanced to the kidney capsule, and the trigger mechanism is released, firing the needle into the kidney (Fig. 7.5). The needle is immediately withdrawn, the patient is asked to resume breathing, and the contents of the needle are examined (Fig. 7.6). We examined the tissue core under an operating microscope to ensure that kidney cortex has been obtained (Fig. 7.7). A second pass of the needle is usually necessary to obtain additional tissue for immunohistologic examination and EM. If insufficient tissue is obtained, further passes of the needle are made. In our experience, however, passing the needle more than four times is associated with a modest increase in the postbiopsy complication rate.

Fig. 7.4 Kidney Biopsy Procedure. The biopsy needle is introduced at an angle of approximately 70 degrees to the skin and is guided by continuous ultrasound. The operator is shown wearing a surgical gown. This is not strictly necessary; sterile gloves and maintenance of a sterile field are sufficient.

Fig. 7.5 Kidney Biopsy Imaging. Ultrasound scan shows the needle entering the lower pole of the left kidney. *Arrows* indicate the needle track, which appears as a fuzzy white line.

No single fixative has been developed that allows good-quality light microscopy, immunofluorescence, and EM to be performed on the same sample. Therefore the kidney tissue is often divided into three samples and placed in formalin for light microscopy, normal saline for subsequent snap-freezing in liquid nitrogen for immunofluorescence, and glutaraldehyde for EM. Some centers can produce satisfactory light microscopy, immunohistochemistry, and EM on formalin-fixed biopsy material, although this depends on the expertise of individual laboratories.

The percutaneous kidney biopsy technique has several variations. Whereas most biopsies are guided by ultrasound, some operators use ultrasound only to localize the kidney and determine the depth and angle of approach of the needle and perform the biopsy without further ultrasound guidance. The success and complication rates appear

to be no different from those seen with continuous ultrasound guidance. For technically challenging biopsies, computed tomography (CT) can be used to guide the biopsy needle.

For obese patients and patients with respiratory conditions who find the prone position difficult, the supine anterolateral approach recently has been described.[20] This technique provides good access to the lower pole of the kidney, is better tolerated than the prone position by these patients, and has a diagnostic yield and safety profile comparable to that of the standard technique for native kidney biopsy.

Kidney Transplant Biopsy

Biopsy of the transplant kidney is facilitated by the proximity of the kidney to the anterior abdominal wall and the lack of movement on respiration. It is performed under real-time ultrasound guidance with use of an automated biopsy needle. It is important to confirm that the transplanted kidney is in the normal extraperitoneal position—occasionally it will be intraperitoneal (simultaneous pancreas and kidney transplants in particular), and bowel injury becomes a potential hazard. In most patients, the kidney transplant biopsy is performed to identify the cause of acute allograft dysfunction. In these circumstances, the goal is to identify acute rejection, and therefore the diagnosis can be made on a formalin-fixed sample alone for light microscopy. If vascular rejection is suspected, a snap-frozen sample for C4d immunostaining also should be obtained (although some laboratories can detect C4d on formalin-fixed material). If recurrent or de novo GN is suspected in patients with chronic allograft dysfunction, additional samples for EM and immunohistologic examination should be collected.

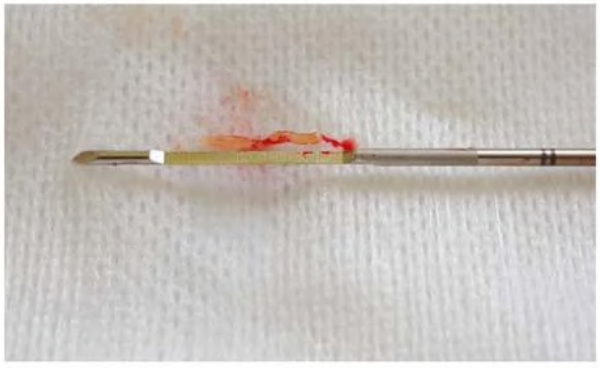

Fig. 7.6 Kidney Biopsy Sample. A core of kidney tissue is demonstrated in the sampling notch of the biopsy needle.

Special Situations

Pregnancy. In the setting of pregnancy, the risk of biopsy must be weighed against any potential benefit of diagnosis and treatment, especially considering that treatment options may be limited due to teratogenicity. Biopsy has been shown safe in all stages of pregnancy, but often after 32 weeks the baby is delivered first. A lateral position is undertaken to be able to perform the biopsy safely. A recent review study in which biopsy was performed for suspected glomerulonephritis or preeclampsia reported that therapy was altered in 66% of cases, suggesting it is useful in selected cases.[21]

Pediatrics. Renal biopsy in the pediatric setting has the added difficulty of much smaller kidneys and the need for a general anesthetic due to patient cooperation. Multiple cohort studies report that ultrasound-guided, percutaneous biopsies with a spring-loaded device and 18-gauge needle are safe with a complication rate of 4.1% and are successful in 99% of cases,[22] thus with a reduced number of passes resulting in similar complication rates. Kidney biopsy in pediatric kidney transplantation for surveillance has also been shown to have the same safety profile as in adults.[23]

Postbiopsy Monitoring

After the biopsy, the patient is placed supine and subjected to strict bed rest for 6 to 8 hours. The blood pressure is monitored frequently, the urine examined for visible hematuria, and the skin puncture site examined for excessive bleeding. If there is no evidence of bleeding after 6 hours, the patient is sat up in bed and subsequently allowed to ambulate. If visible hematuria develops, bed rest is continued until the bleeding settles. We advise minimal activity for 48 hours after biopsy and avoidance of contact sports and activities requiring straining for 2 weeks.

Conventionally, patients have been observed for complications in the hospital for 24 hours after biopsy. However, outpatient kidney biopsy with same-day discharge after 6 to 12 hours of observation has become increasingly popular for both native and kidney transplant biopsies. We recommend 6 hours for low-risk and 12 hours for high-risk biopsies (patients with significant renal impairment, patients undergoing biopsy for AKI, patients with elevated blood pressure prebiopsy, patients aged more than 70 years, and patients with abnormal bleeding profile or requiring early recommencement of

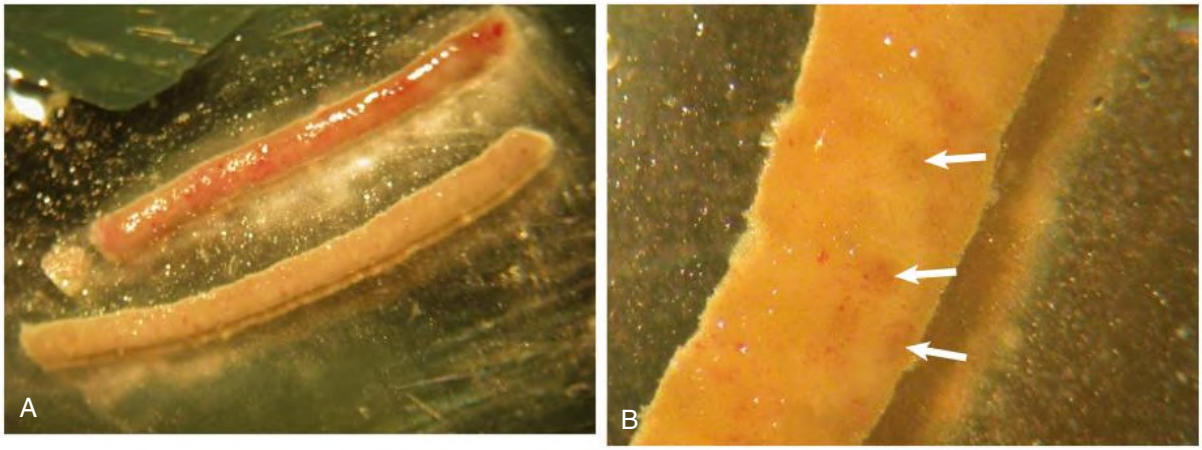

Fig. 7.7 Kidney Biopsy Micrographs. Appearance of kidney biopsy material under the operating microscope. (A) Low-power view shows two good-sized cores. (B) Higher magnification view shows the typical appearance of glomeruli *(arrows)*.

anticoagulation).[17] Some studies suggest that as much as one-third of serious bleeding complications requiring transfusion may occur after 8 hours postbiopsy, whereas up to 91% occur within 12 hours.[24]

Early identification of postbiopsy bleeding is potentially useful in patients with stable observations and no clinical symptoms of bleeding. Ultrasound scanning 1 hour after biopsy has been investigated as a method to predict bleeding complications.[25,26] In the older study the absence of hematoma predicted an uncomplicated course, but identifying a hematoma did not reliably predict adverse outcomes; identification of hematoma at 1 hour had a 95% negative predictive value and 43% positive predictive value for a significant complication. The role of postbiopsy imaging in the wider clinical setting remains to be determined given the additional expense of routine scanning and the uncertainty about how best to manage findings that are detected only by ultrasound—an issue that was not addressed in the more recent study.[26]

Alternatives to the Percutaneous Approach

When the percutaneous approach is contraindicated, other approaches to kidney biopsy have been described. The choice of technique depends on the safety, morbidity, recovery period, and adequacy of the technique, but mainly on the local expertise available.

Transvenous (Transjugular or Transfemoral) Kidney Biopsy

Transvenous sampling of the kidney is theoretically safer than the percutaneous approach because the needle passes from the venous system into the renal parenchyma and is directed away from large blood vessels. Any bleeding that occurs should be directed back into the venous system, and if capsular perforation develops, significant bleeding points can be immediately identified and controlled by coil embolization. Others argue that coil embolization of the punctured vein is unhelpful because significant bleeding into a perirenal hematoma or the urine indicates an arterial breach that requires selective angiography and arterial embolization.

Transvenous kidney biopsy cannot be regarded as routine because it involves specialist skills and additional time and expense compared with the percutaneous approach. The main indication for this approach is an uncontrollable bleeding diathesis. It also has been advocated for patients receiving artificial ventilation in the intensive care unit; the need to obtain tissue from more than one organ, including the kidney, liver, or heart; large-volume ascites that preclude the prone position; uncontrolled hypertension; morbid obesity; severe respiratory insufficiency; solitary kidney; failed percutaneous approach; and coma.

The patient lies supine, and the right internal jugular vein is cannulated. A guidewire is passed into the inferior vena cava (IVC), and a catheter is passed over the guidewire and selectively into the right renal vein, which is shorter and enters the IVC at a more favorable angle than the left renal vein. A sheath is passed over the catheter to a suitable peripheral location in the kidney with the aid of contrast enhancement. Finally, the biopsy device (usually a side-cut biopsy needle system) is passed through the sheath, and samples are taken. Contrast is then injected into the biopsy track to identify capsular perforation, and embolization coils are inserted if brisk bleeding is identified.

The quality of kidney tissue obtained by transjugular biopsy is variable, although studies report diagnostic yields of more than 90%.[27] The complication rate appears comparable to that seen with percutaneous kidney biopsy, which is reassuring given that these are high-risk patients.

Open Kidney Biopsy

Open kidney biopsy is useful when percutaneous biopsy is contraindicated. In a series of 934 patients, tissue adequacy was 100% with no major complications.[28] This is an effective approach with minimal postprocedure complications, but the risk of general anesthesia and the delayed recovery time have prevented its widespread adoption. Open biopsy still may be performed, however, when a kidney biopsy is required in patients who are otherwise undergoing abdominal surgery.

Laparoscopic Kidney Biopsy

Laparoscopic renal biopsy requires general anesthesia and two laparoscopic ports in the posterior and anterior axillary lines to gain access to the retroperitoneal space. Laparoscopic biopsy forceps are used to obtain cortical biopsy samples, and the biopsy sites are coagulated with laser and packed to prevent hemorrhage. In the largest study of laparoscopic kidney biopsy, adequate tissue was obtained in 96% of 74 patients.[29] Significant bleeding occurred in three patients, the colon was injured in one, and a biopsy was performed inadvertently on the spleen and liver, respectively, in two others. Inadvertent biopsy was subsequently averted using intraoperative ultrasound in difficult cases.

COMPLICATIONS OF KIDNEY BIOPSY

The complication rates compiled from large series of kidney biopsies are shown in Table 7.1.[30]

Pain

Patients should be informed about the inevitable dull ache around the needle entry site when the local anesthetic wears off after renal biopsy. Simple analgesia with acetaminophen (paracetamol) or acetaminophen-codeine combinations usually suffices. More severe pain in the loin or abdomen on the side of the biopsy suggests significant perirenal hemorrhage. Opiates may be necessary for pain relief, with appropriate investigation to clarify the severity of the bleed. Patients with visible hematuria may develop clot colic and describe the typical severe pain associated with ureteral obstruction.

Hemorrhage

A degree of perirenal bleeding accompanies every kidney biopsy. The mean decrease in hemoglobin after a biopsy is approximately 1 g/dL.[31] Significant perirenal hematomas are almost invariably associated with severe loin pain, although some hematomas are asymptomatic. Both visible hematuria and painful hematoma are seen in 3% to 4% of patients after biopsy.

The initial management is strict bed rest and maintenance of normal coagulation indices. If bleeding is brisk and associated with hypotension or prolonged and fails to settle with bed rest, renal angiography should be performed to identify the source of bleeding. Coil

TABLE 7.1 Complications in 118,064 Native Kidney Biopsies

Complication	Percentage
Hematoma	11
Pain	4.3
Visible hematuria	3.5
Need for blood transfusion	1.6
Need for intervention to control bleeding	0.3
Death	0.06 (0.03 for outpatient biopsies)

Data from Douketis JD, Spyropoulos AC, Kaatz S, et al. Perioperative bridging anticoagulation in patients with atrial fibrillation. *N Engl J Med.* 2015;373(9):823–833.

embolization can be performed during the same procedure, and this has largely eliminated the need for open surgical intervention and nephrectomy.

Arteriovenous Fistula

Most postbiopsy arteriovenous fistulas are detected by Doppler ultrasound or contrast-enhanced CT and, when looked for specifically, can be found in as many as 18% of patients. Because most are clinically silent and more than 95% resolve spontaneously within 2 years, fistulas should not be routinely sought. In a small minority of patients, arteriovenous fistulas can lead to visible hematuria (typically recurrent, dark red, and often with blood clots), hypertension, and renal impairment, which requires embolization.

Other Complications

A variety of rare complications have been reported, including biopsy performed on other organs (liver, spleen, pancreas, bowel, gallbladder), pneumothorax, hemothorax, calyceal-peritoneal fistula, dispersion of carcinoma, and Page kidney (compression of kidney by perirenal hematoma leading to renin-mediated hypertension).

Death

Death resulting directly from kidney biopsy is much less common in recent biopsy series compared with earlier reports. Most deaths are the result of uncontrolled hemorrhage in high-risk patients, particularly those with severe kidney impairment.

SELF-ASSESSMENT QUESTIONS

1. A 68-year-old woman with nonnephrotic proteinuria of unknown cause attended the outpatient unit for a kidney biopsy. She had a history of hypertension, chronic alcohol abuse, and osteoarthritis. Which of the following would be a contraindication to renal biopsy for this patient?
   A. Ingestion of naproxen 24 hours earlier
   B. Blood pressure of 162/94 mm Hg
   C. Dipstick urinalysis positive for nitrites and leukocytes
   D. Presence of simple cysts in both kidneys (four in left, three in right)
   E. Body mass index of 36 kg/m^2
2. A 32-year-old woman was referred to the Kidney-obstetric clinic for evaluation of kidney disease. Which is a recognized indication for kidney biopsy during pregnancy?
   A. Isolated proteinuria, ratio of protein to creatinine of 320 mg/mmol
   B. Asymptomatic proteinuria with nonvisible hematuria
   C. Episodic visible hematuria
   D. Symptomatic nephrotic syndrome after 32 weeks of gestation
   E. Unexplained deterioration in kidney function before 32 weeks of gestation
3. A 75-year-old man was admitted as an emergency with AKI. He had been unwell for 4 months with myalgia, arthralgia, and generalized fatigue. More recently, he had developed epistaxis and a nonblanching leg rash. Six months earlier, he had a myocardial infarction followed by right coronary artery angioplasty and stenting. He was taking aspirin (75 mg), clopidogrel (75 mg), bisoprolol (5 mg), ramipril (5 mg), and atorvastatin (40 mg). On examination, his blood pressure was 148/86 mm Hg, and he was euvolemic. A purpuric rash was present on both lower legs. Test results were as follows:
   - Serum creatinine: 523 µmol/L (60–110)
   - Serum C-reactive protein: 25 mg/L (<10)
   - Urine dipstick: 3+ blood, 2+ protein, 0 nitrites, 0 leukocytes
   - Antinuclear antibodies: negative
   - Anti–neutrophil cytoplasmic antibodies: negative
   - Anti–glomerular basement membrane antibodies: negative

   An urgent kidney biopsy is requested to determine the cause of AKI. What should be done to minimize the risk for postbiopsy bleeding?
   A. Undertake a transjugular kidney biopsy
   B. Transfuse platelets before the biopsy
   C. Administer DDAVP
   D. Stop aspirin and clopidogrel and wait 24 hours before performing the biopsy
   E. Administer vitamin K and proceed if international normalized ratio and activated partial thromboplastin time ratio are normal
4. A 32-year-old man was seen in the nephrology clinic with proteinuria. He has a history of type 1 diabetes mellitus and hypertension. He was treated with lisinopril (10 mg), amlodipine (5 mg), aspirin (75 mg), simvastatin (40 mg), and insulin. On examination, he was overweight (body mass index: 30 kg/m^2), blood pressure was 146/84 mm Hg, and edema was present to midcalf level bilaterally. Test results were as follows:
   - Serum creatinine: 123 µmol/L (60–110)
   - Serum albumin: 28 g/L (37–49)
   - Urinary protein/creatinine ratio: 460 mg/mmol (<15)

   Which additional feature would provide justification for undertaking a kidney biopsy?
   A. Presence of diabetic retinopathy
   B. Duration of diabetes of 12 years
   C. Presence of nonselective proteinuria
   D. Negative dipstick urinalysis 4 months earlier
   E. Hemoglobin A1c of 7.2%

Disorders of Extracellular Volume

David H. Ellison

EXTRACELLULAR FLUID COMPARTMENT

Water makes up 60% of a typical man's body weight and 50% of a woman's body weight. Total body water (TBW) is distributed in two compartments: the intracellular fluid (ICF) compartment (55%–65% of TBW) and extracellular fluid (ECF) compartment (35%–45% of TBW). The ECF is further subdivided into two spaces: the *interstitial* space, which accounts for about 75% of the ECF, and the *intravascular* space, which represents the remaining 25% (Fig. 8.1).

Water diffuses freely between the intracellular space and the extracellular spaces in response to gradients in effective osmolality, where effective osmolality (tonicity) is the product of the solute concentration and its reflection coefficient (similar to the inverse of permeability). Therefore, the amount of water in different compartments depends primarily on the quantity of effective osmoles in that compartment. The major cation in the ECF is sodium ion (Na^+), and the major intracellular cation is potassium ion (K^+); the number of cations always equals the number of anions in fluid. This uneven ion distribution is maintained by active transport through the Na^+/K^+-adenosine triphosphate (ATP)-dependent pumps on the cell membrane, which determines the relative volume of different compartments. Because sodium is the predominant extracellular cation, the ECF volume is determined primarily by the sodium content of the body. Total body sodium largely depends on salt intake and kidney excretion; the latter is tightly regulated.

Fluid movement between the intravascular and interstitial spaces of the ECF occurs across the capillary wall and is governed by Starling forces: the capillary hydrostatic pressure and colloid osmotic pressure. Unlike cell membranes, capillary membranes are highly permeable to small solutes, such as Na^+, rendering small molecules incapable of generating transcapillary water movement. Plasma proteins, especially albumin, play special roles in retaining fluid within capillaries because proteins are poorly permeable across capillary membranes. The outward transcapillary hydrostatic pressure gradient exceeds the corresponding inward oncotic pressure gradient, thereby favoring movement of plasma ultrafiltrate into the interstitial space.

Titze and colleagues[1] suggest that this model is oversimplified. They emphasize that not all fluid compartments are in osmotic equilibrium and not all extracellular sodium is osmotically active. Accordingly, sodium can be stored in compartments such as the skin (whether osmotically silent[2] or osmotically active[3] is not clear) and then released in a rhythmic manner that is independent of ECF volume.[4] The existence of such compartments has been recognized for many years; for example, in cartilage, glycosaminoglycans attract sodium to generate a hypertonic environment into which water movement is resisted by rigid collagen,[5] and a "gel phase" containing glycosaminoglycans was incorporated into the well-known model generated by Guyton and colleagues.[6] Immune cells contribute to the skin sodium storage, which may help determine the ability of skin to resist microbial pathogens. Sodium homeostasis relies on the crucial role of the lymphatics in returning sodium to the circulation. Despite these important caveats to the concept of a uniform interstitial environment, treating edema removes fluid primarily from an "interstitial" (nonplasma) compartment, indicating that most extravascular fluid is in osmotic equilibrium with plasma.[7]

The ECF volume determines the adequacy of the circulation and, in turn, the adequacy of delivery of oxygen, nutrients, and other substances needed for organ functions; it is also necessary for removal of waste products. This is achieved despite day-to-day variation in the intake of sodium and water, with the ECF volume varying by only 1% to 2%.

REGULATION OF EXTRACELLULAR FLUID HOMEOSTASIS

Circulatory stability depends on homeostatic mechanisms that include an *afferent* sensing limb, involving volume and stretch detectors distributed throughout the vascular bed, and an *efferent* effector limb (Table 8.1). Adjustments in the effector mechanisms occur in response to afferent stimuli by sensing-limb detectors to modify circulatory parameters. Disorders of either sensing mechanisms or effector mechanisms can lead to failure of adjustment of sodium handling by the kidney, with resultant hypertension or edema formation in the patient with positive sodium balance or hypotension and hypovolemia in the patient with negative sodium balance.

Afferent (Sensor) Limb

Afferent limb (sensing) sites include low-pressure cardiopulmonary receptors (atrial, ventricular, and pulmonary stretch receptors), high-pressure arterial baroreceptors (carotid, aortic arch, and kidney sensors), central nervous system (CNS) receptors, and hepatic receptors. The cardiac atria possess the distensibility and compliance needed to monitor changes in intrathoracic venous volume. Atrial distention and a sodium load cause release of atrial natriuretic peptide (ANP), a polypeptide normally stored in secretory granules within atrial myocytes. The closely related brain natriuretic peptide (BNP) is stored primarily

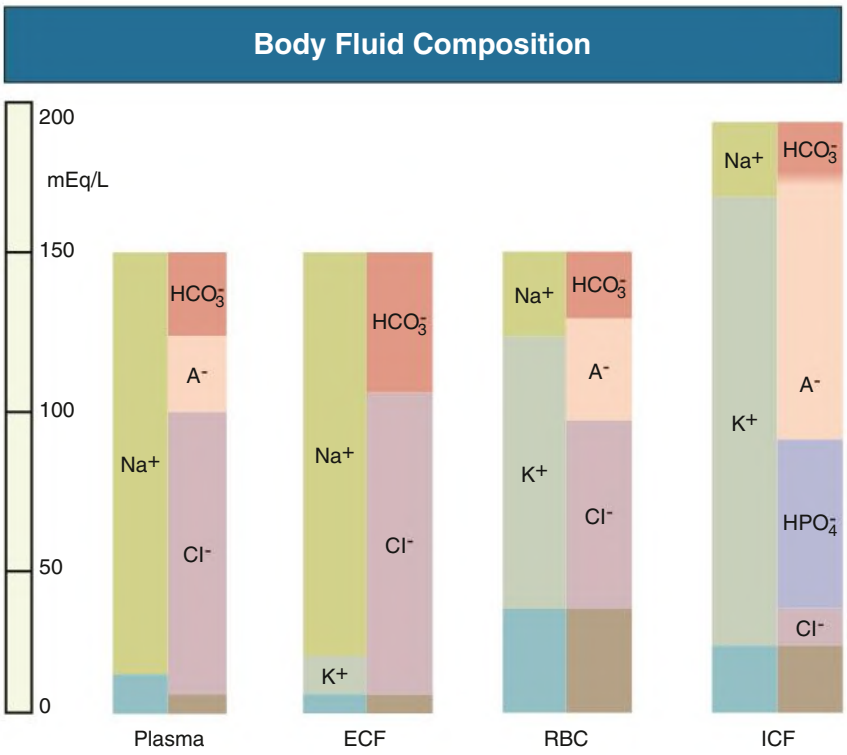

Fig. 8.1 Gamblegram of Body Composition. A 70-kg man contains 42 L (60%) of water, whereas a 60-kg woman contains 36 L (50%) of water. Of water, two-thirds is intracellular (ICF) and one-third is extracellular *(ECF)*. The osmolality in compartments is similar, even though solute concentrations differ, owing to valence of ions. *RBC,* Red blood cell; *A,* Other anions.

Central nervous system receptors	
Hepatic receptors	

[a]Pressure sensors are unspecified receptors contributing to pressure natriuresis.

in ventricular myocardium and is released when ventricular diastolic pressure rises. An increase in left atrial pressure also sends signals to the hypothalamus that can suppress the release of antidiuretic hormone (ADH), also called arginine vasopressin (AVP). These atrial-renal and atrial-hypothalamic reflexes enhance kidney sodium and water excretion on sensing of a distended left atrium.

The sensitive arterial stretch receptors in the carotid artery and in the aortic arch respond to a decrease in arterial pressure. Information from these nerve endings is carried by the vagal and glossopharyngeal nerves to vasomotor centers in the medulla and brainstem. In a normal situation, these receptors exert a tonic restraining effect on the heart and circulation by inhibiting the sympathetic outflow and augmenting parasympathetic activity. In addition, changes in transmural pressure across the arterial vessels and the atria also influence the secretion of AVP and renin and the release of ANP. Activation of the arterial receptors signals the kidney to retain sodium and water through increases in sympathetic activity and vasopressin release. Stimulation of the sympathetic nervous system (SNS) also enhances the renin-angiotensin-aldosterone system (RAAS). A rise in arterial pressure elicits the opposite response, resulting in decreased catecholamine release and natriuresis.

Kidney-sensing mechanisms include the juxtaglomerular apparatus (JGA), which is involved in the generation and release of renin from the kidney and in tubuloglomerular feedback (TGF) (see later discussion). Renin secretion is inversely related to perfusion pressure and directly related to intrarenal tissue pressure. Solute delivery to the macula densa is also an important determinant of renin release; an increase in sodium chloride entry into macula densa cells inhibits renin release, whereas a decrease in entry stimulates it. Kidney nerve stimulation through activation of β-adrenergic receptors of the JGA directly enhances renin release. Other receptors reside in the CNS and hepatic circulation but have been less well defined.

Kidney Hemodynamics and Sodium Excretion

Increases or decreases in glomerular filtration rate (GFR) lead to parallel changes in NaCl reabsorption (Fig. 8.2), the phenomenon of glomerulotubular balance (GTB), so that GFR is not a major determinant of net solute excretion. A second process, TGF, senses NaCl at the macula densa to adjust GFR. High luminal NaCl concentration at the macula densa occurs during high loop segment flow rates and volume expansion. This leads to constriction of the nearby afferent arteriole.

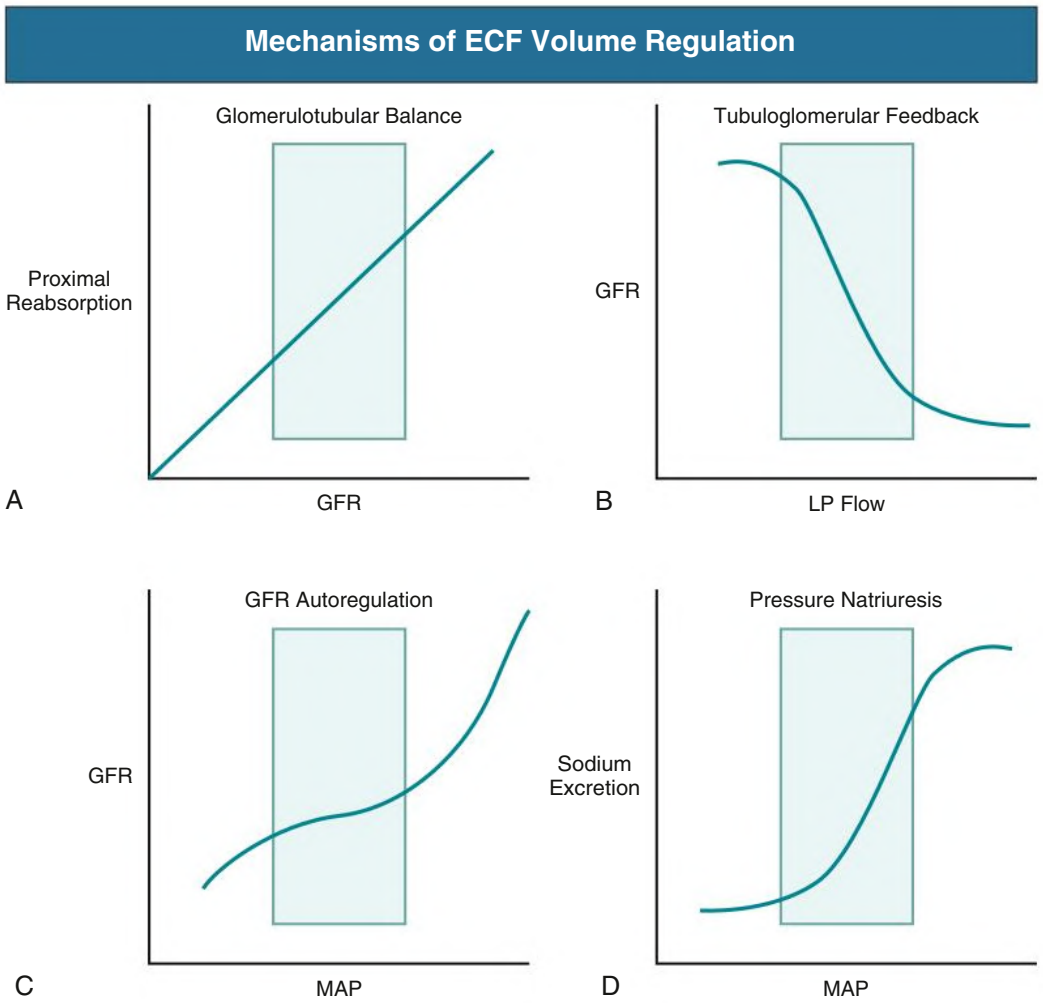

Fig. 8.2 Overall Mechanisms of Extracellular Fluid (ECF) Volume Regulation. (A) Proximal reabsorption rises with increased glomerular filtration rate (GFR) (glomerulotubular balance). (B) Relationship between late proximal (LP) flow and GFR (tubuloglomerular feedback). (C) GFR is autoregulated across mean arterial pressure (MAP). (D) Sodium excretion increases, as MAP increases, the pressure natriuresis. *Boxes* indicate typical operating ranges.

This process reduces GFR (see Fig. 8.2) and therefore proximal flow, tending to keep solute excretion rates constant. Although functionally independent of GTB, the sequential arrangement of GTB and TGF means they work in concert and are remarkably effective at maintaining NaCl excretion rates in the face of changing GFR.[8]

The importance of TGF for kidney health has been emphasized recently by the introduction of sodium glucose cotransporter 2 inhibitors. These drugs inhibit glucose and sodium reabsorption along the proximal tubule and were developed as treatments for diabetes mellitus. Nevertheless, they have shown a remarkable ability to slow the progression of chronic kidney disease (CKD), not only when caused by diabetes, but also from other causes.[9] Although the mechanisms are likely pleiotropic, they strongly activate TGF by delivering more sodium to the macula densa, thereby reducing intraglomerular pressure, an effect similar to that observed with angiotensin-converting enzyme (ACE) inhibitors.[10]

Pressure Natriuresis

Both kidney blood flow and GFR are autoregulated (see Fig. 8.2), meaning they are relatively insensitive to variations in arterial pressure, within a range of typical pressure values. In contrast, urinary Na^+ excretion is strongly affected by even modest variations in pressure, with a rise in pressure increasing kidney Na^+ excretion (see Fig. 8.2). This process appears to be intrinsic to the kidney, but the shape of the relationship is strikingly altered by the RAAS. This phenomenon, termed *pressure natriuresis*, likely results from the adjustment of Na^+ reabsorption by several segments of the nephron, via pathways that remain incompletely defined. The dominant importance of pressure natriuresis, at least under sodium retentive conditions, is clear from experimental models. Natriuretic sensitivity to natriuretic peptides in heart failure can be restored[11] by a rise in kidney perfusion pressure (RPP). Conversely, escape from the sodium retentive effects of aldosterone[12] or angiotensin II (Ang II)[13] also requires a rise in RPP.

Efferent (Effector) Limb

The stimulation of the effector limb of the ECF volume homeostasis leads to activation of effector mechanisms (see Table 8.1). These effector mechanisms aim predominantly at modulation of kidney sodium and water excretion to preserve circulatory stability.

Renin-Angiotensin-Aldosterone System

Renin secretion from the JGA increases in response to depletion of the ECF volume as a result of the processes described previously. Renin converts angiotensinogen to Ang I, which is then converted to Ang II

by the action of the ACE; Ang II can subsequently affect circulatory stability and ECF volume homeostasis. Ang II is a vasoconstrictor that stimulates sodium retention and aldosterone release, which all maintain arterial pressure when ECF volume is low. Ang II has complex effects on GFR and kidney plasma flow (RPF), but when the ECF volume is low, it preferentially increases kidney efferent arteriolar tone, thus tending to preserve GFR. Ang II also increases the filtration fraction by altering Starling forces across the glomerulus, which leads to enhanced proximal sodium and water retention.[14]

Ang II also augments sympathetic neurotransmission and enhances the TGF mechanism. In addition to these indirect mechanisms, Ang II directly enhances proximal tubular volume reabsorption by activating apical membrane sodium-hydrogen (Na^+-H^+) exchangers. Ang II also enhances sodium absorption by stimulating aldosterone secretion, which, in turn, increases sodium reabsorption in the aldosterone-sensitive distal nephron.

Sympathetic Nervous System

Sympathetic nerves that originate in the prevertebral celiac and paravertebral ganglia innervate cells of the afferent and efferent arterioles, JGA, and kidney tubule. Sympathetic nerves alter kidney sodium and water handling by direct and indirect mechanisms.[15] Increased nerve stimulation indirectly stimulates proximal tubular sodium reabsorption by altering preglomerular and postglomerular arteriolar tone, thereby influencing filtration fraction. Kidney nerves directly stimulate proximal tubular fluid reabsorption through receptors on the basolateral membrane of the proximal convoluted tubule cells. These effects on sodium handling are further amplified by the ability of the sympathetic nerves to stimulate renin release, which leads to the formation of Ang II and aldosterone.

Natriuretic Peptides

ANP and BNP augment sodium and water excretion by increasing GFR, possibly by dilating the afferent arteriole and constricting the efferent arteriole. Furthermore, they inhibit sodium reabsorption in the cortical collecting tubule and inner medullary collecting duct, reduce renin and aldosterone secretion, and oppose the vasoconstrictive effects of Ang II.[16] Circulating levels of ANP and BNP are elevated in congestive heart failure (CHF) and in cirrhosis with ascites but do not overcome the sodium-retaining effects of low RPP.

Prostaglandins

Prostaglandins are derived from arachidonic acid and modulate kidney blood flow and sodium handling. Important kidney prostaglandins include prostaglandin I_2, which mediates baroreceptor (but not β-adrenergic) stimulation of renin release. Prostaglandin E_2 is stimulated by Ang II and has vasodilatory properties. Increased levels of Ang II, AVP, and catecholamines stimulate synthesis of prostaglandins, which, in turn, act to dilate the kidney vasculature, inhibit sodium and water reabsorption, and stimulate renin release. In situations of ECF or effective arterial blood volume (EABV) depletion, the combination of prostaglandin-mediated afferent arteriolar dilation and Ang II–mediated efferent arteriolar constriction plays a central role in autoregulatory maintenance of GFR. Often, in these situations, interference with efferent vasoconstriction (e.g., ACE inhibition), and with afferent vasodilation (e.g., nonsteroidal antiinflammatory drugs [NSAIDs]) leads to a precipitous decline in GFR, manifested as acute kidney injury (AKI).

Arginine Vasopressin

The polypeptide AVP is synthesized in supraoptic and paraventricular nuclei of the hypothalamus and is secreted by the posterior pituitary gland. Hypertonicity is the predominant stimulus for AVP release under typical conditions. Substantial reductions in EABV, however, act as a second, nonosmotic regulatory pathway.[17] AVP release is suppressed in response to ECF volume overload sensed by increased afferent impulses from arterial baroreceptors and atrial receptors, whereas decreased ECF volume has the opposite effect. AVP release leads to antidiuresis via V_2 receptors and, at higher concentrations, to systemic vasoconstriction through the V_1 receptors.[18] The antidiuretic action of AVP results from the effect on the principal cell of the collecting duct through activation of the V_2 receptor. AVP increases the synthesis and provokes the insertion of aquaporin 2 (AQP2) water channels into the luminal membrane, thereby allowing water to be reabsorbed down the favorable osmotic gradient generated by the countercurrent multiplier system. AVP also enhances Na^+ reabsorption via the epithelial sodium channel, ENaC, and thereby K^+ secretion. AVP appears to have synergistic effects with aldosterone on sodium transport in the cortical collecting duct.[19] AVP stimulates potassium secretion by the distal nephron, and this preserves potassium balance during ECF depletion, when circulating levels of vasopressin are high and tubular delivery of sodium and fluid is reduced. It should be noted, however, that states of excess AVP secretion are manifested primarily by excess water, and not salt, accumulation, because of offset physiologic control mechanisms.

Other Hormones

Other hormones that contribute to kidney sodium handling and ECF volume homeostasis include nitric oxide (NO), endothelin, and the kallikrein-kinin system. NO is an endothelium-derived mediator that participates in the natriuretic responses to increases in blood pressure or ECF volume expansion. Endothelins, in addition to their potent actions to constrict vascular smooth muscle, are natriuretic factors. Endothelin 1, via the endothelin B (ET_B) receptor, increases NO production, which tends to increase urinary salt excretion. Kinins are potent vasodilator peptides, but their physiologic roles are not yet fully defined.

Terms Useful for Disorders of Extracellular Fluid Volume

In clinical practice, it is helpful to view disorders of ECF volume as distinct from disorders of water balance. The latter reflect gain or loss of electrolyte-free water, typically resulting in changes in plasma osmolality (hyponatremia or hypernatremia); when losses or gains are substantial, detectable changes in ECF volume can occur. Changes in ECF volume, however, often termed *volume contraction* or *volume expansion,* reflect gain or loss of NaCl. Water is often retained or lost secondarily.

Loss of salt and water produces true depletion of ECF volume, but there are many pathologic conditions (e.g., heart failure [HF]; cirrhosis) in which ECF volume is expanded but the kidneys behave as if it is contracted. To account for this discrepancy, the term EABV is used to describe the blood volume detected by the sensitive arterial baroreceptors. The EABV can change independently of the total ECF volume. The state of the EABV is often inferred from the behavior of the kidneys.

EXTRACELLULAR FLUID VOLUME CONTRACTION

Contraction of ECF volume typically results from sodium losses that exceed intake. Losses may be in the kidney or extrarenal through the gastrointestinal (GI) tract, skin, and lungs or by sequestration in potential spaces in the body (e.g., abdomen, muscle) that are not in hemodynamic equilibrium with the ECF (Table 8.2). The reduction in ECF volume occurs from both the interstitial and intravascular compartments. The loss of solute-free water (e.g., diabetes insipidus [DI]) has a lesser effect on intravascular volume because water is lost from

TABLE 8.2 Major Causes of Extracellular Fluid Volume Depletion

Kidney	Extrarenal
Diuretic use	Gastrointestinal losses
Tubular disorders	• Vomiting
• Genetic	• Gastrointestinal suctioning
• Bartter and Gitelman syndromes	Diarrhea
• Pseudohypoaldosteronism type 1	• Ileostomy and colostomy secretions
• Acquired tubular disorders	Dermal losses
• Acute kidney injury	• Sweat
• Recovery phase of oliguric kidney injury	• Exudative skin disease
• Release of urinary tract obstruction	Third-space sequestration
Hormonal and metabolic disturbances	• Ascites

• Solute diuresis	• External
Kidney water loss	
• Diabetes insipidus	

all aqueous spaces in the body, and the body's solute content remains unchanged. Thus, in this case of disordered water balance, hypertonicity—rather than ECF volume contraction—predominates.

Extrarenal Causes

Gastrointestinal Losses

Approximately 3 to 6 L of fluids and digestive juices are secreted daily throughout the GI tract, and most of this fluid is reabsorbed along more distal portions. Vomiting or nasogastric suction may cause volume loss that is usually accompanied by metabolic alkalosis, whereas diarrhea may result in volume depletion that is accompanied by metabolic acidosis. This results from abnormal loss of bicarbonate or salts of organic anions in the stool. An exception to this general principle is the rare syndrome known as congenital chloride-wasting diarrhea, in which, because of mutations in a protein that exchanges chloride for bicarbonate in the colon,[20] infants typically present with diarrhea and metabolic alkalosis.

Dermal Losses

Sweat is typically hypotonic, leading to more water loss than salt loss. Sweat production can be excessive in high ambient temperature or with prolonged exercise in hot, humid climates and may lead to volume depletion. Loss of the skin barrier with superficial burns and exudative skin lesions may lead to significant ECF volume depletion.

Third-Space Sequestration

Body fluid accumulation in potential spaces that are not in hemodynamic equilibrium with the ECF compartment can cause volume depletion. This pathologic accumulation, often called third-space sequestration, includes ascites, hydrothorax, and intestinal obstruction, with fluid collecting in the peritoneal cavity, pleural space, and intestines, respectively, and leading to significant ECF volume loss. Severe pancreatitis may result in retroperitoneal fluid collections.

Hemorrhage

Hemorrhage occurring internally (e.g., from bleeding esophageal varices) or externally (e.g., trauma) may lead to significant volume loss.

Kidney Losses

In health, approximately 25,000 mmol of sodium is filtered every day. The small quantities of sodium excreted in urine relative to the filtered load depend on intact tubular reabsorptive mechanisms to adjust urinary sodium excretion to maintain ECF homeostasis. Impairment in the integrity of these mechanisms can result in significant volume depletion.

Diuretic Use

Most of the widely used diuretic medications inhibit sodium transport pathways along the nephron (see later discussion). Diuretics may cause sodium wasting by the kidney with volume contraction and metabolic acid-base disturbances.

Genetic and Acquired Tubular Disorders

Tubular sodium reabsorption may be disrupted in several genetic disorders that include Bartter syndrome and Gitelman syndrome; these are often called "tubulopathies." They are caused by mutations of sodium, potassium, or chloride transporters or in regulatory factors. Although they result in sodium wasting and volume contraction, they typically present with hypokalemic metabolic alkalosis. They are discussed in more detail in Chapter 49. Pseudohypoaldosteronism type 1 (PHA1) is another rare inherited disorder characterized by sodium wasting and hyperkalemic metabolic acidosis and is caused by mutations in either the epithelial sodium channel (ENaC) or the mineralocorticoid receptor.

Acquired tubular disorders that may be accompanied by salt wasting include AKI, during the recovery phase of oliguric AKI, or urinary obstruction (see Chapters 61 and 74). Sjögren syndrome may cause a phenotype resembling Gitelman syndrome, as may treatment with cisplatin.

Hormonal and Metabolic Disturbances

Mineralocorticoid deficiency and resistance states often lead to sodium wasting. This may occur in the setting of primary adrenal insufficiency (Addison disease) and PHA1. Salt wasting also can be seen in chronic tubular and interstitial kidney diseases. Severe hyperglycemia or high levels of blood urea during release of urinary tract obstruction can lead to obligatory kidney sodium and water loss secondary to glycosuria or urea diuresis, respectively.

Water Loss via the Kidney

DI represents a spectrum of diseases resulting from AVP deficiency (central DI) or tubular resistance to AVP (nephrogenic DI). The most common causes of polyuria from nephrogenic DI in adults are chronic lithium ingestion, hypercalcemia, and, less frequently, hypokalemia (see Chapter 9). In these disorders the tubular reabsorption of solute-free water is impaired. This generally results in a lesser effect on ECF volume because, in contrast to sodium, there is a relatively smaller amount of the TBW in the ECF compartment compared with the ICF compartment.

BOX 8.1 Clinical Evaluation of Extracellular Fluid Volume Depletion

Mild to Moderate Volume Loss

- Thirst
- Delay in capillary refill
- Postural dizziness, weakness
- Dry mucous membranes and axillae
- Cool, clammy extremities and collapsed peripheral veins
- Tachypnea
- Tachycardia with pulse rate >100 beats/min or postural pulse increment of 30 beats/min or more
- Postural hypotension (systolic blood pressure decrease >20 mm Hg on standing)
- Low jugular venous pulse
- Oliguria

Severe Volume Loss and Hypovolemic Shock

- Depressed mental status (or loss of consciousness)
- Peripheral cyanosis
- Reduced skin turgor (in young patients)
- Marked tachycardia, low pulse volume
- Supine hypotension (systolic blood pressure <100 mm Hg)

Clinical Manifestations of Extracellular Fluid Volume Contraction

The spectrum of the clinical manifestations of volume contraction (Box 8.1) depends on the amount and rate of ECF volume loss and on the vascular and kidney responses to that loss. The history and physical examination are usually the key factors in evaluating the presence and causes of hypovolemia because laboratory testing may appear normal. Symptoms are usually nonspecific and can range from mild postural symptoms, thirst, muscle cramps, and weakness to drowsiness and disturbed mentation with profound volume loss. Physical examination may reveal tachycardia, cold clammy skin, postural or recumbent hypotension, and reduced urine output, depending on the degree of volume loss. Low jugular venous pressure (JVP; ≤5) is consistent with volume depletion. However, the JVP may be elevated in patients with pulmonary hypertension or when the EABV is low. The lack of symptoms or discernible physical findings does not preclude volume depletion, and hemodynamic monitoring and administration of a fluid challenge may be necessary.

Laboratory Tests

Hemoconcentration and increased serum albumin concentration may be seen early with hypovolemia, but anemia or hypoalbuminemia caused by a concomitant disease may confound interpretation of these laboratory values. In healthy individuals, the ratio of blood urea nitrogen (BUN) to serum creatinine is approximately 10:1 to 20:1 (measured in milligrams per deciliter). In volume-contracted states, this ratio may increase because of an associated differential increase in urea reabsorption in the collecting duct. Several clinical conditions affect this ratio. Upper GI tract hemorrhage and administration of corticosteroids increase urea production, and hence the ratio of BUN to creatinine increases. Malnutrition and liver disease diminish urea production, making the ratio less helpful.

Urine osmolality and specific gravity may be elevated in hypovolemic states but may be altered by an underlying kidney disease that leads to kidney sodium wasting, concomitant intake of diuretics, or a solute diuresis. Hypovolemia normally promotes avid kidney sodium reabsorption, resulting in low urine sodium concentration and low fractional excretion of sodium. Urine chloride follows a similar pattern because sodium and chloride are generally reabsorbed together. Volume depletion with metabolic alkalosis (e.g., with vomiting) is an exception because of the need to excrete the excess bicarbonate in conjunction with sodium to maintain electroneutrality; in this case, urine chloride concentration is a better index of ECF volume contraction. The fractional excretion of sodium (FE_{Na}) is calculated by the following formula:

$$FE_{Na} = [U_{Na} \times P_{creat}/U_{creat} \times P_{Na}] \times 100$$

where U_{Na} and U_{creat} are urinary sodium and creatinine concentrations, respectively, and P_{Na} and P_{creat} are plasma sodium and creatinine concentrations, respectively. In an oliguric patient with AKI, FE_{Na} less than 1% is consistent with volume depletion; FE_{Na} greater than 1% is more consistent with acute tubular necrosis, although the sensitivity and specificity of this test are limited.[21]

Therapy of Extracellular Fluid Volume Contraction

The goal of treatment is to replace the fluid deficit and ongoing losses with a fluid that resembles the lost fluid. The first step is to determine the urgency of the hypovolemic condition. In severe hypovolemia or hypovolemic shock, immediate treatment should be initiated, typically with 1 to 2 L of isotonic crystalloid. The adequacy of repletion can then be monitored clinically with central venous pressure monitoring or, in the intensive care unit (ICU), with respiratory variation in the arterial pressure tracing. Estimating the magnitude of volume deficit is imprecise; thus a key component of successful treatment is frequent monitoring and adjustment of therapy.

Mild volume contraction usually can be corrected orally. It is important to note, however, that unlike oral rehydration solutions used for childhood diarrhea (50–90 mmol/L sodium), sports drinks typically contain very little NaCl (7–20 mmol/L) and do not replace substantial sodium losses, although normal kidneys can typically adjust for the discrepancy when losses are mild.

Crystalloid solutions (isotonic or slightly hypotonic) with sodium as the principal cation are effective because they distribute primarily in the ECF. One-third of an infusate of isotonic saline (0.9% NaCl) remains in the intravascular compartment, whereas two-thirds distributes into the interstitial compartment. Colloid-containing solutions include human albumin (5% and 25%) and hetastarch (6% hydroxyethyl starch [HES]), which remain within the vascular compartment (provided the transcapillary barrier is intact and not disrupted by capillary leak states such as often occurs with multiorgan failure). The solutions augment the plasma oncotic pressure and thus expand the plasma volume by counteracting the capillary hydraulic pressure.

Colloid-containing solutions have not shown an advantage in the treatment of hypovolemic states. A large multicenter trial that randomized medical and surgical critical patients to receive fluid resuscitation with 4% albumin or normal saline showed similar mortality, morbidity, and hospitalization rates in the two groups.[22] Another study randomly assigned ICU patients with severe sepsis to fluid resuscitation with either 6% HES or Ringer acetate solution.[23] Patients who received HES had increased mortality and were more likely to receive kidney replacement therapy. Consequently, artificial colloids should be avoided in patients with severe sepsis or at risk for developing AKI.[24]

Isotonic saline or a balanced salt solution (e.g., lactated Ringer's solution) is usually the preferred initial choice in volume-depleted

patients with normal serum [Na^+] and most of those with low serum [Na^+]. Furthermore, isotonic saline is the preferred fluid to restore ECF volume in hypovolemic patients with hypernatremia. Once euvolemia is established, hypotonic (0.45% NaCl) saline should be delivered to gradually correct tonicity. Administration of large volumes of isotonic saline may result in the development of hyperchloremic metabolic acidosis or AKI. Although a smaller randomized trial of patients admitted to the ICU did not detect a difference in AKI,[25] a recent large pragmatic trial of critically ill patients found that the use of balanced salt solutions was associated with an improved composite outcome of death, new kidney replacement therapy, or persistent kidney dysfunction compared with subjects receiving isotonic saline.[26]

Hypovolemic shock may be accompanied by lactic acidosis resulting from tissue hypoperfusion. Fluid resuscitation restores tissue oxygenation and will decrease the production of lactate, but lactated Ringer solution is inappropriate because the infused lactate will not be converted to bicarbonate. Correction of acidosis with sodium bicarbonate ($NaHCO_3$) has the potential for increasing tonicity, expanding volume, worsening intracellular acidosis from increased carbon dioxide production, and not improving hemodynamics compared with isotonic saline. Whether $NaHCO_3$ effectively corrects the impaired cardiac contractility associated with lactic acidosis has not been well documented by clinical studies. Therefore, $NaHCO_3$ to manage lactic acidosis in the setting of volume depletion is often avoided unless the arterial pH is less than 7.1.

EXTRACELLULAR FLUID VOLUME EXPANSION

Expansion of ECF volume usually results from kidney sodium and water retention. Generalized edema results from an apparent increase in the interstitial fluid volume, most often in response to HF, cirrhosis with ascites, and nephrotic syndrome. Weight gain of several kilograms usually precedes clinically apparent edema. Localized excess fluid may accumulate in the peritoneal and pleural cavities, leading to ascites and pleural effusion, respectively.

Pathogenesis

Kidney sodium and water retention secondary to arterial underfilling leads to an alteration in capillary hemodynamics that favors fluid movement from the intravascular compartment into the interstitium. In general, these two processes account for edema formation.

Capillary Hemodynamic Disturbances

According to the Starling equation, the exchange of fluid between the plasma and the interstitium is determined by the hydrostatic and oncotic pressures in each compartment. Interstitial fluid excess results from a decrease in plasma oncotic pressure or an increase in capillary hydrostatic pressure. In other words, edema is a result of an increase in fluid movement from the intravascular compartment to the interstitial space or a decrease in fluid movement from the interstitial space to the intravascular compartment, or both. Thus, the degree of interstitial fluid accumulation as determined by rate of fluid removal by the lymphatic vessels is a determinant of edema.

The capillary hydrostatic pressure is relatively insensitive to alterations in arterial pressure. The stability of the capillary pressure is a result of variations in the precapillary sphincter, which governs how much arterial pressure is transmitted to the capillary, a locally controlled response called *autoregulation.* In contrast, the venous end is not similarly well regulated. Therefore, when the blood volume expands, as in HF and kidney disease, capillary hydrostatic pressure increases and edema ensues. Venous obstruction works by the same mechanism to cause edema, as exemplified by ascites formation in liver cirrhosis and by acute pulmonary edema after sudden impairment in cardiac function (e.g., myocardial infarction). In hepatic cirrhosis and nephrotic syndrome, another factor in edema formation is reduction in plasma oncotic pressure, with fluid transudation into the interstitial space. Even normal conditions favor net filtration into the interstitium because capillary hydrostatic pressure exceeds the plasma colloid pressure in several tissues throughout the capillary. In these tissues, a substantial amount of filtered fluid is returned to the circulation through lymphatic channels, which minimizes edema formation.

TABLE 8.3 Major Causes of Extracellular Fluid Volume Expansion

Primary Kidney Sodium Retention	Secondary Kidney Sodium Retention[a]
Acute kidney injury	Cardiac failure
Advanced chronic kidney disease	Cirrhosis
Glomerular diseases	Nephrotic syndrome
	Idiopathic edema
	Drug-induced edema
	Pregnancy

[a]Secondary to reduced effective arterial blood volume depletion (arterial underfilling).

Kidney Sodium Retention

The mechanism for maintenance of ECF volume expansion and edema formation is kidney sodium retention, which can be primary or secondary in response to reduction in EABV (Table 8.3).

Primary sodium retention by the kidney. A primary defect in kidney sodium excretion can occur with AKI, CKD, or glomerular disease. Patients with AKI have limited ability to excrete sodium and water. Advanced CKD may lead to sodium and water retention by GFR reduction, although in the absence of proteinuria, frank edema is uncommon. Primary sodium retention by the kidney characterizes some forms of glomerulonephritis and occurs through incompletely understood mechanisms in the presence of a relatively suppressed RAAS but frequently with decreased GFR. Filtered proteases may cleave and activate the sodium channel, ENaC, in these situations.[27]

Mineralocorticoid excess or enhanced mineralocorticoid activity are associated with sodium retention. However, because of mineralocorticoid escape (discussed previously), the clinical manifestation is generally hypertension rather than hypervolemia. In normal individuals, administration of a high-dose mineralocorticoid initially increases kidney sodium retention so that ECF volume is increased. However, kidney sodium retention then ceases, spontaneous natriuresis ensues, sodium balance is reestablished, and there is no detectable edema. This escape from mineralocorticoid-mediated sodium retention explains why edema is not a characteristic feature of primary hyperaldosteronism. The pathophysiologic mechanism of mineralocorticoid escape involves an increase in GFR and reduction of proximal tubular sodium and water reabsorption. This leads to an increase in sodium and water delivery to the distal nephron site of aldosterone action, which overrides the sodium reabsorption of aldosterone. Other contributing mechanisms include decreased expression of distal tubular thiazide-sensitive NaCl cotransporters,[28] increased secretion of ANP,[29] and pressure natriuresis. Regardless of the mechanisms involved, RPP must rise to enable the escape process[12]; because this can occur during primary kidney salt retention, these states are typically characterized by hypertension and not edema.

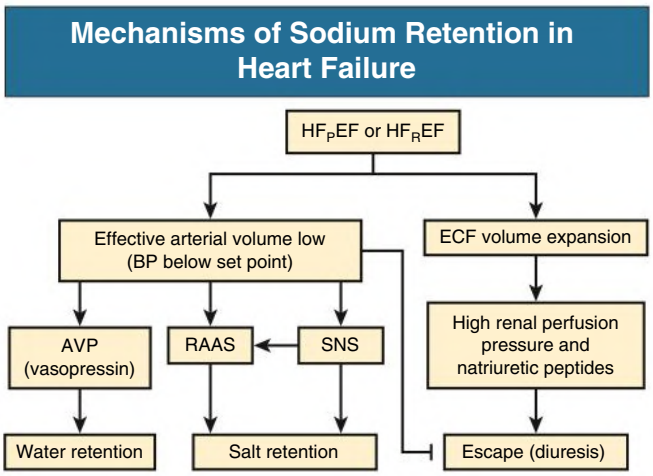

Fig. 8.3 Mechanisms of Sodium Retention in Heart Failure. Heart failure, from reduced ejection fraction (HF_REF) or preserved ejection fraction (HF_PEF), activates neurohormonal systems, which lead to sodium and water retention, including the renin-angiotensin-aldosterone system (RAAS), the sympathetic nervous system (SNS), and arginine vasopressin (AVP). Ensuing ECF volume expansion increases natriuretic peptide secretion. Low kidney perfusion pressure (blood pressure below set point) causes resistance to natriuretic peptides and prevents escape from sodium and water retention from aldosterone, angiotensin II, and AVP.

Secondary sodium retention by the kidneys. An estimated 85% of blood circulates on the low-pressure venous side of the circulation, and 15% in the high-pressure arterial circulation. Thus, an increase in total blood volume could occur, even when there is underfilling of the arterial circulation, if the increase in total blood volume is primarily caused by expansion of the venous compartment. Underfilling of the arterial circulation could result from a decrease in cardiac output, as occurs in low-output cardiac failure, or from systemic arterial vasodilation, which occurs early in cirrhosis as a result of decreased systemic vascular resistance (SVR) in the splanchnic circulation.[30] Because arterial pressure is determined by the product of cardiac output and SVR, both states would be characterized by a decline in arterial pressure below the kidney's set point. This model proposes that kidney sodium retention triggered by arterial underfilling (arterial pressure less than pressure set point) is a compensatory response necessary to restore arterial circulatory integrity.

If there is arterial underfilling from decreased cardiac output or systemic arterial vasodilation, the hypotension is sensed by the arterial stretch receptors. This leads to activation of the efferent limb of body fluid volume homeostasis. Specifically, a decrease in glossopharyngeal and vagal tone from the carotid and aortic receptors to the CNS leads to a rapid increase in sympathetic activity with associated activation of the RAAS axis. If it is severe enough, the underfilling also leads to nonosmotic release of vasopressin. Additionally, a decrease in pressure at the kidney baroreceptors and decreased NaCl delivery to the macula densa increase renin secretion and thereby Ang II and aldosterone. The resultant increase in SVR and kidney sodium and water retention attenuates the arterial underfilling, through the Frank-Starling mechanism, and tends to restore arterial perfusion. Together, these actions maintain the arterial circulatory integrity and restore perfusion to vital organs at the expense of expanded ECF volume and edema.

Sodium and Water Retention in Heart Failure

HF can occur with reduced or preserved ejection fraction (HF_REF and HF_PEF, respectively), but the mechanisms involved in kidney sodium and water retention appear to involve similar mediators.[31] Decreased cardiac output with arterial underfilling leads to reduced stretch of arterial baroreceptors and reduced perfusion pressure in the kidney. In the case of HF_PEF, this often involves a decrease below a hypertensive baseline or below a baseline raised by CKD. This results in increased sympathetic discharge from the CNS and activation of the RAAS. Adrenergic stimulation and increased Ang II activate receptors on the proximal tubular epithelium that enhance sodium reabsorption. The kidney vasoconstriction of the glomerular efferent arteriole by Ang II in HF also alters net Starling forces in the peritubular capillary in a direction to enhance sodium reabsorption.[32] Thus, Ang II and α-adrenergic stimulation increase sodium reabsorption in the proximal tubule by a direct effect on the proximal tubule epithelium and secondarily by kidney vasoconstriction. This subsequently leads to decreased sodium delivery to the collecting duct, which impairs escape from both aldosterone and natriuretic peptides.[11,33] This failure of escape explains why sodium retention and ECF volume expansion occur in HF (Fig. 8.3). Accordingly, patients with HF may have substantial natriuresis when spironolactone, a competitive mineralocorticoid receptor antagonist (MRA), is given in adequate doses to compete with increased endogenous aldosterone levels.[34]

The atrial-renal reflexes, which normally enhance kidney sodium excretion, are also impaired because plasma levels of ANP do not increase further when patients with dilated cardiomyopathy and mild HF receive a saline load, and the natriuretic response is also blunted. Autonomic dysfunction and blunted arterial baroreceptor sensitivity in HF are associated with increased circulating catecholamines and increased kidney sympathetic activity. There is also evidence for parasympathetic withdrawal in HF, in addition to the increase in sympathetic drive.

Another outcome of the neurohumoral activation that occurs in HF is the baroreceptor-mediated nonosmotic release of AVP.[35] This nonosmotic AVP stimulation overrides the osmotic regulation of AVP and is the major factor leading to the hyponatremia associated with end-stage HF.[36] AVP causes antidiuresis by activating V_2 receptors on the basolateral surface of the principal cells in the collecting duct.[37] Activation of these receptors initiates a cascade of intracellular signaling events by means of the adenylyl cyclase–cyclic adenosine monophosphate (cAMP) pathway, leading to an increase in AQP2 water channel protein expression and its trafficking to the apical membrane of the collecting duct. This sequence of events leads to increased water reabsorption and can cause hyponatremia, which is an ominous prognostic indicator in patients with HF.[38] Concurrently, increased nonosmotic AVP release stimulates V_1 receptors on vascular smooth muscle

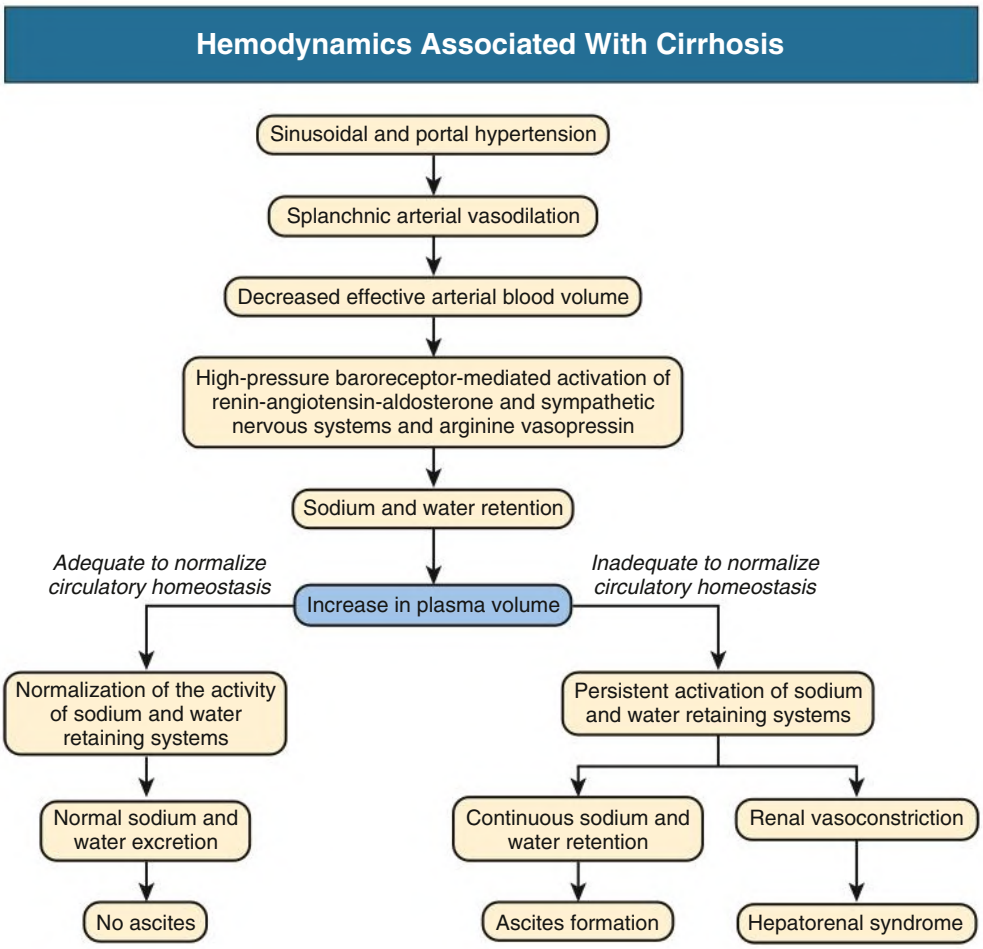

Fig. 8.4 Pathogenesis of Functional Kidney Abnormalities and Ascites Formation in Cirrhosis. (Modified from Ginés P, Cardenas A, Sola E, Schrier RW. Liver disease and the kidney. In: Coffman TM, Falk RJ, Molitoris BA, et al, eds. *Schrier's Diseases of the Kidney*. Wolters Kluwer; 2012:1965–1996.)

cells and thereby may increase SVR. This adaptive vasoconstrictive response may become maladaptive and contribute to cardiac dysfunction in patients with severe HF.

Sodium and Water Retention in Cirrhosis

Many pathogenetic aspects of sodium and water retention are similar in cirrhosis and HF (Fig. 8.4). However, arterial underfilling in cirrhosis occurs secondary to splanchnic arterial vasodilation, with resultant water and sodium retention. Ascites formation in cirrhosis is likely initiated by sinusoidal and portal hypertension[39] from distortion of hepatic architecture, increased hepatic vascular tone, or increased splenohepatic flow. Decreased intrahepatic bioavailability of NO and increased production of vasoconstrictors (Ang II, endothelin) also are responsible for increased resistance in the hepatic vasculature.[40] Portal hypertension caused by increased sinusoidal pressure activates vasodilatory mechanisms in the splanchnic circulation.[41] These mechanisms, mediated at least partly by NO and carbon monoxide (CO) overproduction, lead to splanchnic and peripheral arteriolar vasodilation. In advanced stages of cirrhosis, arteriolar vasodilation causes underfilling of the systemic arterial vascular space. This event, through a decrease in EABV, leads to a fall in arterial pressure. Consequently, baroreceptor-mediated activation of the RAAS, SNS stimulation, and nonosmotic release of ADH occur to restore the blood volume homeostasis.[42] This involves compensatory vasoconstriction as well as kidney sodium and water retention. However, splanchnic vasodilation also increases splanchnic lymph production, which exceeds the lymph-transporting capacity, and thus lymph leakage into the peritoneal cavity occurs with ascites development.[43] Persistent kidney sodium and water retention (along with lymph leakage into the peritoneal cavity from increased splanchnic vascular permeability) play the major role in sustained ascites formation.

Sodium and Water Retention in Nephrotic Syndrome

Unlike HF and liver cirrhosis, in which the kidneys are structurally normal, the nephrotic syndrome is characterized by diseased kidneys. Many nephrotic patients have a higher arterial blood pressure, higher GFR, and less impairment of sodium and water excretion than patients with HF and cirrhosis. Two mechanisms, underfill and overfill, may account for nephrotic edema; components of each mechanism may exist in different edematous conditions (Fig. 8.5). The underfill theory suggests that reduced plasma oncotic pressure from proteinuria increases fluid movement from the vascular to interstitial compartment. The resultant arterial underfilling culminates in activation of homeostatic mechanisms involving the SNS and the RAAS. The overfill theory implicates primary kidney sodium and water retention that translates into elevated total plasma volume, hypertension, and suppressed RAAS. Distinguishing between the two mechanisms is important because it influences the approach to diuretic use in nephrotic patients.

The following observations support the underfill theory for edema formation. Plasma volume, systemic arterial blood pressure, and cardiac output are diminished in some nephrotic patients, especially in

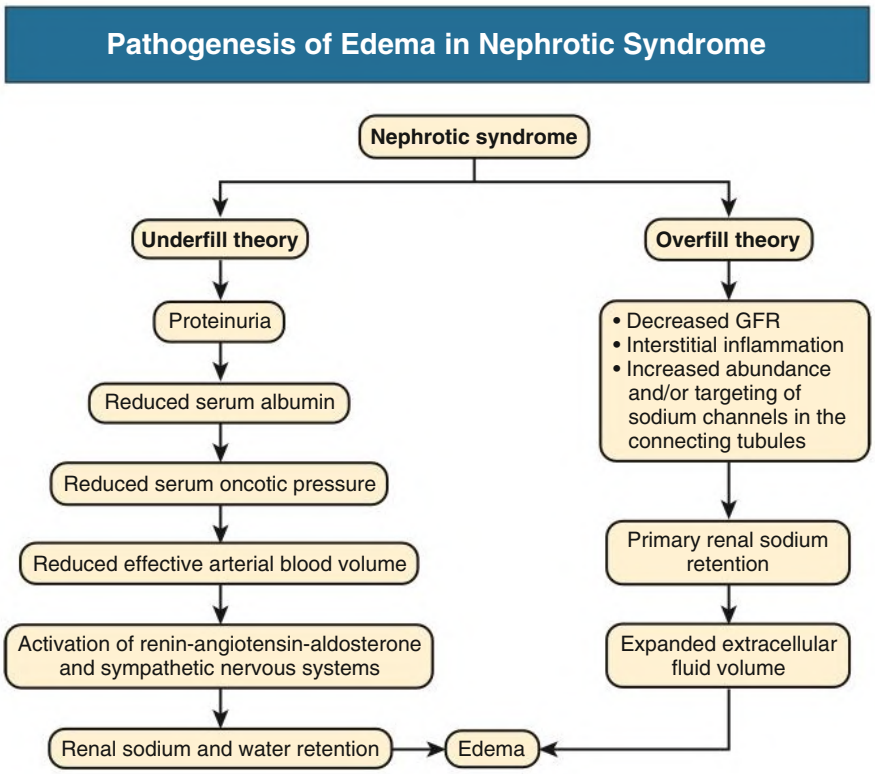

Fig. 8.5 Underfill and Overfill Mechanisms in Pathogenesis of Edema in Nephrotic Syndrome. The ratio of underfill and overflow likely varies depending on the cause of the nephrotic syndrome. *GFR,* Glomerular filtration rate.

children with minimal change disease (MCD; see Chapter 18). The Starling forces governing the fluid movement across the capillary wall equal the difference of the hydrostatic pressure and the oncotic pressure gradients. The gradual decrease in the plasma albumin concentration and the plasma oncotic pressure is mitigated by the reduced entry of albumin into the interstitial space and a concurrent decline in interstitial oncotic pressure. Consequently, less ECF volume expansion and edema formation is noted unless hypoalbuminemia is severe.[44] Thus, nephrotic patients who are underfilled and are predisposed to AKI despite generalized edema generally have serum albumin concentration of less than 2 g/dL (20 g/L). However, serum albumin concentration may not be the primary driver of ECF volume expansion because either spontaneous or steroid-induced remission of minimal change leads to natriuresis before albumin rises[45]; this suggests that other mechanisms, in addition to low oncotic pressure, must be involved.

Observations supporting the overfill theory include studies of adults with MCD who have increased blood volume and blood pressure. After remission induced by corticosteroids, plasma volume and blood pressure decline, with an increase in plasma renin activity. However, evaluation of intravascular volume is somewhat unreliable because the afferent stimulus for edema formation appears to be a dynamic process, with different results at different phases of edema formation.[44] Also supporting primary kidney sodium retention, experimental studies in animals with unilateral nephrotic syndrome demonstrate that sodium retention occurs secondary to increased reabsorption in the collecting tubules.[46] Increased abundance and apical targeting of ENaC subunits may be mediated, in part, by proteolytic cleavage of the channel by filtered proteases.[47–49]

In summary, nephrotic patients with arterial underfilling are more likely to have MCD with severe hypoalbuminemia, preserved GFR, and low blood pressure or postural hypotension. Other glomerular diseases, especially those involving kidney inflammation, are more often associated with an overfill picture with volume expansion, raised blood pressure, and a decline in GFR. It has been postulated that interstitial inflammatory cells, a feature of some glomerular diseases other than MCD, may facilitate an increase in sodium retention and hypertension by releasing mediators that cause vasoconstriction.[50]

Drug-Induced Edema

Although they are no longer commonly used, systemic vasodilators such as minoxidil and diazoxide induce arterial underfilling and subsequent retention of sodium with water (causing edema) through mechanisms similar to those in HF or cirrhosis. Dihydropyridine calcium channel blockers may cause peripheral edema, which is related to redistribution of fluid from the vascular space into the interstitium, possibly induced by preferential dilation of resistance arterioles in the absence of an appropriate microcirculatory myogenic reflex. This facilitates transmission of the systemic pressure to the capillary circulation.[51] Fluid retention and HF exacerbation may be seen with thiazolidinedione therapy in patients with type 2 diabetes mellitus, involving activation of peroxisome proliferator–activated receptor γ (PPARγ). Although this can simulate sodium reabsorption by the sodium channels in collecting tubule cells,[52] additional effects are likely involved, including effects on vascular smooth muscle to reduce arterial pressure.[53] NSAIDs can exacerbate volume expansion in HF and cirrhotic patients by decreasing vasodilatory prostaglandins in the afferent arteriole of the glomerulus.[54]

Idiopathic Edema

This poorly defined syndrome occurs most often in premenopausal women and is characterized by intermittent edema secondary to sodium and water retention. Patients often complain of face and hand edema, leg swelling, and variable weight gain[55] and often misuse diuretics or laxatives, which may chronically stimulate the RAAS. The diagnosis of idiopathic edema is usually made by exclusion of other causes after history, physical examination, and sometimes diuretic screening.

Sodium and Water Retention in Pregnancy

In the first trimester of normal pregnancy, systemic arterial vasodilation and a decrease in blood pressure occur in association with a compensatory increase in cardiac output.[56] The lower arterial pressure activates the RAAS, contributing to the kidney sodium and water retention and expanding the plasma volume (10%–30%).[57] Decreased plasma osmolality, stimulated thirst, and persistent nonosmotic vasopressin release are other features of normal pregnancy. In contrast to diseases such as HF and cirrhosis, pregnancy is associated with an increase in GFR and kidney blood flow. The increased GFR leads to higher filtered load and increased distal sodium delivery in pregnancy, which contributes to the better escape from the sodium-retaining effect of aldosterone and attenuates edema formation. See Chapter 44 for more details.

Clinical Manifestations of Extracellular Fluid Volume Expansion

A history of an underlying disease, such as coronary artery disease, hypertension, or liver cirrhosis, can pinpoint the underlying mechanism of edema formation. Patients with left HF may present with exertional dyspnea, orthopnea, and paroxysmal nocturnal dyspnea. Patients with right-sided HF or biventricular failure may exhibit weight gain and lower limb swelling. Physical examination reveals increased JVP, pulmonary crackles, a third heart sound, or dependent peripheral edema that may be elicited in the ankles or sacrum.

Nephrotic patients may present with periorbital edema, especially when caused by minimal change disease. However, those with severe disease may exhibit marked generalized edema with anasarca. Patients with cirrhosis present with ascites and lower limb edema caused by portal hypertension and hypoalbuminemia. Physical examination may reveal stigmata of chronic liver disease and splenomegaly.

Diagnostic and Therapeutic Approach to Extracellular Volume Expansion

Management of ECF volume expansion consists of recognizing and treating the underlying cause and attempting to achieve negative sodium balance by dietary sodium restriction and administration of diuretics. Before embarking on diuretic therapy, it is imperative to appreciate that ECF volume expansion may have occurred to compensate for arterial underfilling, as in HF and cirrhosis. A judicious approach is therefore necessary to avoid a precipitous fall in cardiac output and tissue perfusion. Nevertheless, it has become clear that diuresis of 3 to 5 L/day is typically tolerated safely in patients with acute decompensated HF, and that a modest rise in serum creatinine concentration should be accepted, as long as decongestion is taking place.[58]

Moderate dietary sodium restriction (2–3 g Na^+/day; 86–130 mmol/day) should be encouraged. Salt substitutes contain potassium chloride and should not be used in patients with advanced kidney impairment or those taking potassium-sparing diuretics. Restriction of total fluid intake is usually necessary only for patients with hyponatremia. Medications that promote sodium retention (e.g., NSAIDs) should be discontinued. Diuretics are the cornerstone of therapy to remove excess volume. Other measures can be used in patients with inadequate response or lack of response to diuretics. In those with liver cirrhosis, large-volume paracentesis with albumin infusion provides symptomatic relief and is commonly included as part of the treatment regimen. Although extracorporeal fluid removal by ultrafiltration can be used in patients with acute decompensated HF accompanied by kidney impairment or diuretic resistance, a randomized controlled trial did not indicate benefit.[59]

Although salt and fluid removal is a central feature of the treatment of HF, there are a number of other approaches that have been shown to ameliorate symptoms and prolong life. ACE inhibitors, angiotensin receptor blockers (ARBs), β-blockers, and mineralocorticoid receptor antagonists have been shown to be useful in those with HF_REF. Recently, SGLT2 inhibitors, which have a modest diuretic effect, have also been shown to improve mortality in patients with HF.

Diuretics

Principles of Action

Diuretics are the mainstays of therapy for edematous states, with five classes based on the predominant sites of diuretic action along the nephron (Fig. 8.6). Most diuretics work from the tubule lumen and reach this site by secretion across the proximal tubule epithelium. All diuretics except osmotic agents have a high degree of protein binding, which limits glomerular filtration and traps them in vascular spaces, allowing them to be delivered to the proximal convoluted tubule for secretion.[60] Most diuretics either act by inhibiting sodium reabsorption with an accompanying anion, usually chloride (loop diuretics or thiazides), or inhibit sodium reabsorption through channels in the luminal membrane (amiloride directly or aldosterone antagonists, indirectly). The resultant natriuresis decreases the ECF volume.

Loop diuretics, which are used commonly to treat edematous conditions, have relatively short half-lives, and each dose is followed by a phase of natriuresis and a phase of antinatriuresis (often referred to as postdiuretic Na^+ retention). A low-salt diet can ensure that postdiuretic Na^+ retention does not overcome effective diuresis. A second type of adaptation occurs during chronic treatment. During continued administration of a diuretic, the magnitude of each natriuretic response declines, so daily salt excretion once again equals daily salt intake. This is known as the *braking phenomenon;* mechanisms include activation of the SNS and RAAS, decreased systemic and kidney arterial blood pressure, hypertrophy of the distal nephron cells with increased expression of epithelial transporters, and perhaps alterations in natriuretic hormones (e.g., ANP).[60]

Classes of Diuretics

Loop diuretics. Loop diuretics such as furosemide, bumetanide, and torsemide act by blocking the Na^+-K^+-Cl^- cotransporters at the luminal surface of thick ascending limb (TAL) cells, thereby diminishing net reabsorption.[61] These agents are the most potent of all diuretics, inhibiting the reabsorption of 25% of filtered sodium, which normally occurs along the TAL. Moreover, the nephron segments past the TAL typically do not possess the capacity to reabsorb completely the volume of fluid exiting the TAL. Thus, a substantial percentage of the solute rejected from the TAL is excreted.

The oral bioavailability of furosemide averages 50%, but varies between 10% and 100%; the oral bioavailabilities of bumetanide and torsemide are higher (~80%). Loop diuretics have short elimination half-lives, so the dosing interval needs to be short to maintain adequate levels in the lumen. Excessive prolongation of dosing interval provides more time for postdiuretic sodium retention to overcome natriuresis. This is the reason that loop diuretics are typically given twice daily. When escalating diuretics in congested hospitalized patients, several algorithms recommend repeating furosemide doses as frequently as every 6 hours, given the short intravenous (IV) half-life of furosemide and bumetanide.[62] For oral use, torsemide has a longer half-life than bumetanide or furosemide, permitting it to be used once daily in some cases.

The intrinsic potency of a diuretic is defined by its dose-response curve, which is generally sigmoidal. The steep dose-response is the reason that loop diuretics are often referred to as *threshold drugs*. This is exemplified by furosemide, which can initiate diuresis in a person with normal kidney function with an IV dose of 10 mg, and a maximal effect

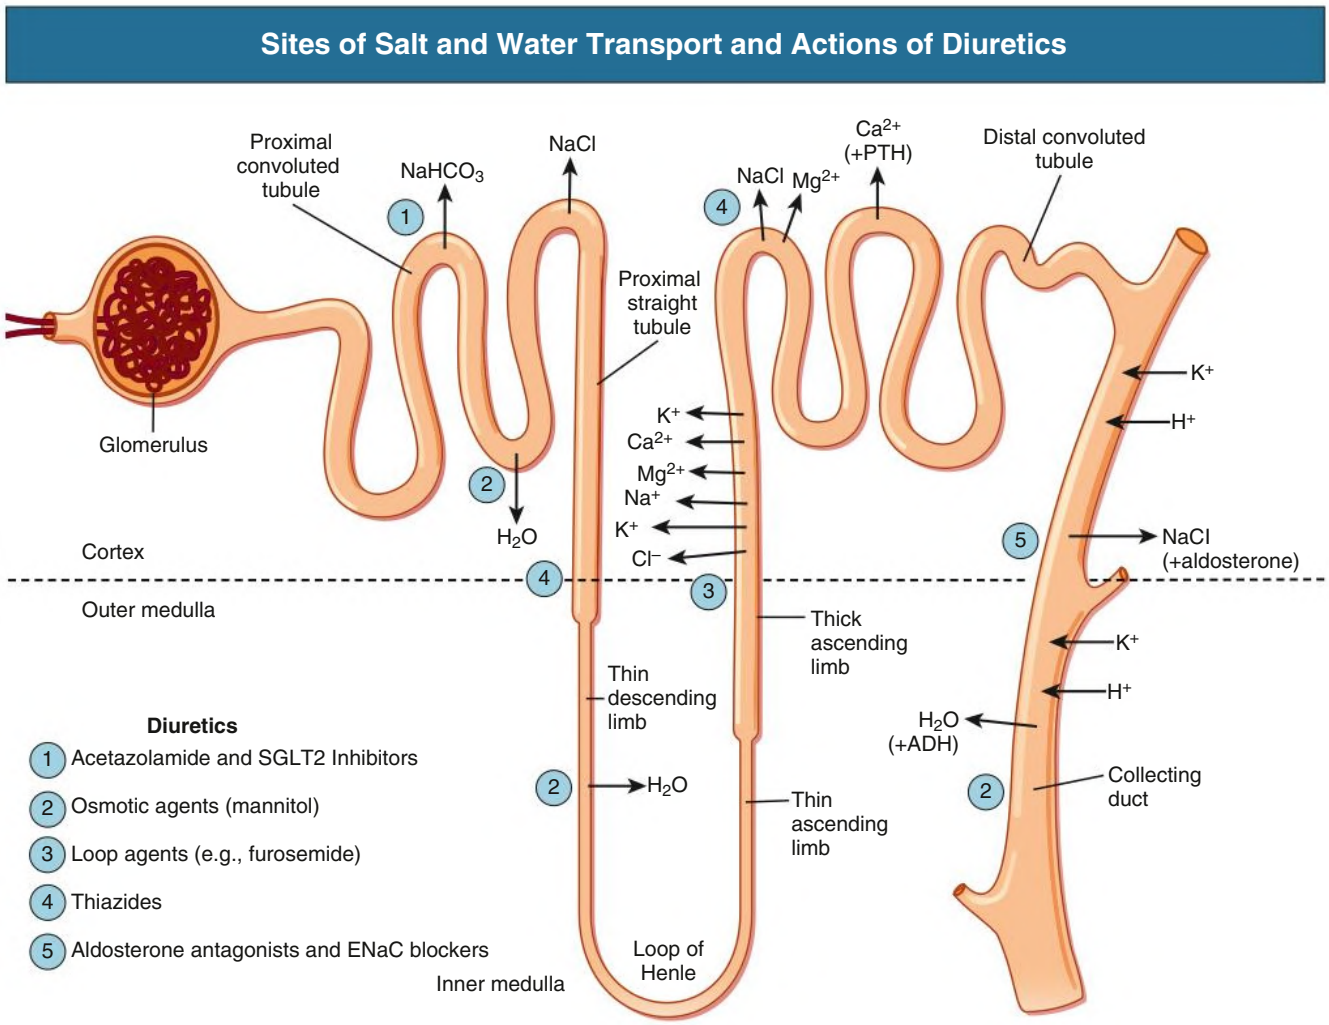

Fig. 8.6 Sites of Salt and Water Transport and Actions of Diuretics. Specific sites are indicated by numbers. (Modified from Ives HE. Diuretic agents. In: Katzung BG, ed. *Basic and Clinical Pharmacology*. McGraw-Hill Medical; 2006:237.)

is seen with 40 mg. A larger dose provides minimal or no extra increase in natriuresis, and side effects may increase. In contrast, the effective diuretic dose is often substantially higher in patients with HF, advanced cirrhosis, and kidney failure; guidelines are available for diuretic dosing in these situations.[62] Patients who respond poorly to intermittent doses of a loop diuretic may receive continuous IV infusion, which might enhance the response by virtue of maintaining an effective amount of drug at the site of action.[63] A Cochrane review suggested that continuous infusions led to greater diuresis and a better safety profile, but the quality of the evidence is poor.[64] A randomized trial in acute decompensated HF found no difference in the primary end points—the global assessment of symptoms over the course of 72 hours and the change in serum creatinine from baseline to 72 hours—for continuous versus bolus infusion of furosemide. A higher dose of diuretic was more effective without clinically important negative effects on kidney function.[65] Despite this negative result, this study did not include diuretic-resistant patients or those with significant kidney dysfunction, and so continuous infusion is still employed in some cases.

Although pharmacologically similar to other loop diuretics, ethacrynic acid has greater ototoxic potential and therefore is reserved for patients allergic to other agents.

Distal convoluted tubule diuretics. Thiazide and thiazide-like diuretics (chlorothiazide, hydrochlorothiazide, chlorthalidone, metolazone, and indapamide) inhibit NaCl absorption in the distal convoluted tubule, where up to 5% of filtered sodium and chloride is reabsorbed, and are therefore less potent than loop diuretics. Thiazides have a relatively longer half-life and can be administered once or twice daily. Metolazone has pharmacologic characteristics similar to classical thiazide diuretics and is more often used in conjunction with other classes of diuretics.

Thiazides are used commonly to treat hypertension (see Chapter 37). For edema, they are occasionally used alone in patients with mild HF, but more often they are used in combination to synergize the effect of loop diuretics by blocking multiple nephron segment sites. Because thiazide diuretics must reach the lumen to be effective, higher doses are required in patients with impaired kidney function. Thiazides as sole agents (possibly excluding the thiazide-like diuretics metolazone and indapamide) lose some effectiveness at GFR less than 30 mL/min but may still be useful in some patients.[66] Regardless, thiazide diuretics still enhance the diuretic effect of loop diuretics when coadministered with loop diuretics to overcome diuretic resistance. If used, such combination therapy should be closely monitored because of a risk for hypokalemia and excessive ECF depletion.

Collecting duct diuretics. Amiloride, triamterene, and the mineralocorticoid receptor antagonists spironolactone and eplerenone act on the collecting duct. Amiloride and triamterene act primarily in

the connecting tubule and cortical collecting duct (the aldosterone-sensitive distal nephron) by interfering with sodium reabsorption through the apical sodium channel ENaC; this inhibits potassium secretion by dissipating the electronegative gradient (normally created by sodium reabsorption) that favors potassium secretion. Spironolactone and eplerenone are competitive antagonists of aldosterone and cause natriuresis and potassium retention. Finerenone is a new nonsteroidal mineralocorticoid receptor antagonist, which has properties that appear to differ from those of spironolactone and eplerenone; it appears to block the mineralocorticoid receptor as a bulky, passive agonist. It was recently approved by the US Food and Drug Administration (FDA) to slow progression of CKD in the setting of diabetes mellitus.[67] Potassium-sparing diuretics are considered weak diuretics because they block only about 3% of the filtered sodium load reaching their site of action and thus are most often used with other diuretics to augment diuresis or preserve potassium. If combination therapy is used, careful monitoring is essential to prevent dangerous hyperkalemia. Vulnerable patients include those with underlying kidney dysfunction, those with HF, patients with diabetes, and those concurrently taking ACE inhibitors, ARBs, NSAIDs, or β-blockers.

Collecting duct diuretics are considered first-line agents in certain conditions. For example, spironolactone is used in patients with liver cirrhosis with ascites and amiloride in the treatment of Liddle syndrome, a rare autosomal dominant condition characterized by a primary increase in ENaC function (see Chapter 47).

Proximal tubule diuretics. A substantial component of sodium reabsorption along the proximal tubule is mediated by a luminal Na^+-H^+ exchanger. The activity of this transporter depends on both the generation of protons inside the cell and their elimination in the luminal brush border. Both actions are catalyzed by carbonic anhydrase. Acetazolamide inhibits carbonic anhydrase, thereby reducing proton secretion in the proximal tubule lumen, thus increasing sodium bicarbonate excretion. Acetazolamide is a weak diuretic because distal segments reabsorb much of the inhibited Na^+ and because proximal inhibition activates the TGF to reduce Na^+ filtration.[8] Acetazolamide generates hyperchloremic metabolic acidosis, particularly with prolonged use. It also may cause hypokalemia because of increased distal sodium delivery; it may cause hypophosphatemia, but the mechanism of this is not well understood. Rarely used as a single agent, acetazolamide is most frequently used with other diuretics, in treatment of metabolic alkalosis accompanied by edematous states, and in chronic obstructive pulmonary disease. It is also used in acute and chronic high-altitude sickness because of its ability to stimulate ventilation as a compensatory response to the metabolic acidosis, although unpleasant paresthesias may occur.

Osmotic diuretics. Osmotic diuretics such as mannitol are inert substances that are freely filtered at the glomerulus but are poorly reabsorbed. Mannitol is used intravenously and produces diuresis by increasing the osmotic pressure within the lumen of the proximal tubule and loop of Henle. This causes enhanced water diuresis and to a lesser extent sodium and potassium excretion. Mannitol is not used for edematous states but rather to treat cerebral edema induced by trauma or neoplasms and to reduce intraocular pressure. Mannitol is also used in the treatment of dialysis disequilibrium syndrome, preventing the brisk decline in serum osmolality that would otherwise occur with dialysis. This helps prevent a shift of fluid into the brain that may occur with rapid rate of solute removal by dialysis, which is thought to be responsible for the symptoms.

Aquaretics. The "vaptans" are drugs that block either V_2 receptors alone or V_1 and V_2 receptors together and increase electrolyte-free water excretion. They are used in electrolyte disorders, such as the syndrome of inappropriate antidiuretic hormone secretion, but have also been approved to slow CKD progression in autosomal dominant polycystic kidney disease. Because they have little effect on urinary sodium excretion, they are not typically effective in addressing edema.

SGLT2 inhibitors. SGLT2 inhibitors, initially introduced as drugs to control hyperglycemia, have pleiotropic effects that improve kidney and cardiovascular outcomes, even in the absence of diabetes mellitus. Although not marketed as diuretics, these agents cause a mild diuresis, both by inhibiting sodium glucose cotransport along the proximal tubule and by inhibiting the Na^+-H^+ exchanger. Sodium glucose cotransport and sodium proton antiport appear to be coupled functionally along the proximal tubule. These drugs induce a mild but sustained reduction in ECF volume that may contribute to their beneficial effects.[68]

Adverse Effects

Many common diuretics are derived from sulfanilamide and may therefore induce allergy in susceptible patients, manifested as hypersensitivity reactions, usually as a rash or, rarely, acute interstitial nephritis. The most serious and common adverse effects of diuretics, however, are electrolyte disturbances.

Loop diuretics impair tubular reabsorption by inhibiting the Na/K/2Cl cotransporter along the luminal membrane of thick ascending limb cell. This transporter lies in parallel with a potassium channel that permits potassium to diffuse back into the lumen. Coupled with basolateral chloride exit, this drives an electrical potential difference oriented with the lumen positive with respect to blood. This drives magnesium and calcium reabsorption. Loop diuretics eliminate this potential difference and can, therefore, increase calcium and magnesium excretion. Thiazide diuretics exert the same effect on magnesium, although the mechanism is different. In a recent study of community-dwelling subjects, the use of a thiazide was associated with prevalent hypomagnesemia, whereas loop diuretic use was not.[69] Unlike loop diuretics, thiazide diuretics decrease urinary calcium losses and are therefore preferred in the treatment of hypercalciuric states and in patients with osteoporosis. Thiazide diuretics interfere with urine-diluting mechanisms by blocking sodium reabsorption at the distal convoluted tubule, an effect that may contribute to hyponatremia.[70] Acutely, loop and thiazide diuretics increase the excretion of uric acid, whereas chronic administration results in reduced uric acid excretion. The chronic effect is likely caused by enhanced absorption in the proximal convoluted tubule secondary to volume depletion. Other adverse effects with large doses may include ototoxicity with loop diuretics, particularly with aminoglycoside coadministration, and gynecomastia, which may develop with spironolactone.

Approach to Diuretic Treatment of Extracellular Fluid Volume Expansion

Although the mechanisms underlying expansion of the ECF volume are similar in the different clinical syndromes, some evidence-based differences in diuretic approach are recommended. For HF, either HF_REF or HF_PEF, initial treatment involves loop diuretics. A starting dose of 20 to 40 mg furosemide, or an equivalent, is typical, and may be effective, but it may be necessary to increase, or double, subsequent doses if the initial dose does not elicit a diuresis. Such a diuresis should occur promptly after drug administration and be notable to the patient. This approach is based on the threshold nature of the loop diuretic dose response curve. It is often necessary to use loop diuretics twice daily, but it is always important to ensure that each dose is above the threshold. The pharmacokinetic profile of torsemide is more favorable than that of furosemide; some clinicians prefer this drug, but solid evidence to support this choice is lacking currently.

For cirrhotic ascites, patients are typically started on a combination of spironolactone and furosemide, at a fixed ratio (100 mg spironolactone to 40 mg furosemide).[71] Single-agent spironolactone can be used but causes more potassium imbalance. Doses can be titrated retaining the same ratio of spironolactone and furosemide.

For nephrotic syndrome and CKD, loop diuretics are indicated, but higher doses than used for HF are typically required because both CKD and nephrotic syndrome are diuretic-resistant conditions.

Diuretic Resistance

Diuretic *resistance* typically refers to edema that has become refractory to maximal doses of loop diuretics. Apparent resistance may be the result of drug interactions. NSAIDs block prostaglandin-mediated increases in kidney blood flow and natriuresis and can precipitate HF exacerbations.[54] Arterial underfilling in cirrhosis and HF increases proximal tubular sodium reabsorption, which reduces delivery of sodium to the distal nephron segment sites of diuretic action. Yet in HF, resistance most commonly results from activation of distal nephron transport.[72] This problem can be addressed by combining loop and thiazide diuretics because the latter block the distal nephron sites responsible. To prevent loop diuretic-induced renin-angiotensin-aldosterone effects, many patients are treated with aldosterone antagonists, especially because these agents are essential parts of the treatment regimen for HF_REF. If other approaches fail, a thiazide diuretic can be added. In nephrotic syndrome, the filtered protein in tubular fluid may contain serine proteases, which cleave and activate ENaC, thereby promoting excess sodium reabsorption.[49] ENaC can be inhibited with amiloride.

SELF-ASSESSMENT QUESTIONS

1. A 58-year-old woman with a history of alcohol dependence and known chronic liver disease presents to the emergency department with increasing breathlessness and distended abdomen. Vital signs reveal temperature of 36.9°C (98.5°F), respiratory rate of 17 breaths/min, oxygen saturation of 93% on room air, pulse rate of 76 beats/min, and blood pressure of 93/58 mm Hg without significant orthostatic change. Physical examination reveals scleral icterus, and JVP is flat. Cardiac auscultation is normal; breath sounds are decreased at the bases. Her abdomen is distended with a fluid wave and a positive shifting dullness. The patient has bilateral pitting edema to the mid-calves and intact peripheral pulses. Which of the following is the primary mechanism responsible for *maintaining* volume excess in this patient?
   - **A.** Reduction in plasma oncotic pressure resulting from synthetic hypoalbuminemia causing an increase in fluid movement from the vascular to the interstitial compartment.
   - **B.** Underfilling of the arterial circulation resulting from splanchnic venous dilation causing neurally and hormonally mediated kidney sodium retention.
   - **C.** Primary kidney sodium and water retention that results in elevated total plasma volume.
   - **D.** Decrease in plasma osmolality with stimulation of thirst and persistent release of antidiuretic hormone.
2. Laboratory investigations of the patient described in question 1 reveal serum sodium of 128 mmol/L, potassium of 3.7 mmol/L, chloride of 101 mmol/L, bicarbonate of 23 mg/dL, BUN of 56 mg/dL, and creatinine of 1.0 mg/dL. Albumin is 3.0 g/dL. Reasonable initial approaches to remove excess volume in this patient include all of the following *except:*
   - **A.** Prescribe a diet restricted to 2.3 g (100 mmol) of sodium daily to mitigate kidney retention of sodium and prevent diuretic resistance.
   - **B.** Perform a large-volume paracentesis with albumin infusion to rapidly decompress the abdomen.
   - **C.** Administer spironolactone up to 400 mg/day, with a loop diuretic to increase sodium excretion.
   - **D.** Administer intravenous mannitol to increase osmotic pressure within the tubule and thus sodium and water reabsorption.
3. Over the next 3 days, the patient previously described becomes febrile, with a temperature of 37.8°C (100°F), and confused. Her pulse rate is 120 beats/min with blood pressure of 88/52 mm Hg. The JVP is now near the angle of the jaw when the patient is sitting at 45 degrees. Hemoglobin is 7.6 g/dL, total white blood cell (WBC) count 15,000 (85% polymorphonuclear leukocytes), and platelet count 81,000 × 10^9 cells/L. Analysis of the ascitic fluid reveals 100 RBCs/μL and 450 WBCs/μL, but no organisms on Gram stain. BUN is 48 mg/dL, serum creatinine is 1.7 mg/dL, and urine sodium is 65 mEq/L, with a fractional sodium excretion of 1.4%. Appropriate immediate measures for the patient at this time would include which of the following?
   - **A.** Administer 50 g of albumin, with the goal of improving her hemodynamic profile.
   - **B.** Administer fluid resuscitation with 6% hydroxyethyl starch to expand extracellular fluid compartment rapidly and restore blood pressure.
   - **C.** Treat for presumptive bacterial peritonitis.
   - **D.** Insert jugular venous dialysis access for urgent initiation of dialysis.

Disorders of Water Metabolism

Ali Kashkouli, Tomas Berl, Jeff M. Sands

PHYSIOLOGY OF WATER BALANCE

The maintenance of the tonicity of body fluids within a narrow physiologic range is made possible by homeostatic mechanisms that control the intake and excretion of water. Vasopressin, known as arginine vasopressin (AVP) or antidiuretic hormone (ADH), governs the excretion of water by its effect on the renal collecting system. Osmoreceptors located in the hypothalamus control the secretion of vasopressin in response to changes in tonicity.

In the steady state, water intake matches water losses. Water intake is regulated by the need to maintain a physiologic serum osmolality of 285 to 290 mOsm/kg H_2O. Despite major fluctuations of solute and water intake, the total solute concentration (i.e., the tonicity) of body fluids is maintained virtually constant. The ability to dilute and to concentrate the urine allows wide flexibility in urine flow (see Chapter 2). During water loading, the diluting mechanisms permit excretion of 20 to 25 L of urine daily, and during water deprivation, the urine volume may be as low as 0.5 L/day.[1–3]

VASOPRESSIN

AVP plays a critical role in determining the concentration of urine: It is a 9-amino acid cyclic peptide, synthesized and secreted by the supraoptic and paraventricular magnocellular nuclei in the hypothalamus. AVP has a half-life of 15 to 20 minutes and is rapidly metabolized in the liver and the kidney.

Osmotic Stimuli for Vasopressin Release

Substances restricted to the extracellular fluid (ECF), such as hypertonic saline and mannitol, decrease cell volume by acting as effective osmoles and enhancing osmotic water movement from the cell. This stimulates vasopressin release; in contrast, urea and glucose readily cross cell membranes and thus do not cause changes in cell volume. The "osmoreceptor" cells, located close to the supraoptic nuclei in the anterior hypothalamus, are sensitive to changes in serum osmolality as small as 1% and bring about the release of AVP by a pathway that involves the activation of transient receptor potential (TRPV4) channels.[4] In humans, the osmotic threshold for AVP release is 280 to 290 mOsm/kg H_2O[5] (Fig. 9.1). This system is so efficient that serum osmolality usually does not vary by more than 1% to 2% despite wide fluctuations in water intake.

Nonosmotic Stimuli for Vasopressin Release

Decreased effective circulating volume (e.g., heart failure, cirrhosis, vomiting) causes discharge from parasympathetic afferent nerves in the carotid sinus baroreceptors and increases AVP secretion. Much higher vasopressin levels can be achieved with hypovolemia than with hyperosmolality, although a large (7%) decrease in blood volume is required before this response is elicited. Other nonosmotic stimuli include nausea, pain, pregnancy, and fructose (such as from sugary beverages).[6] AVP levels (as reflected by elevation of serum copeptin, a surrogate marker) are also elevated in patients with metabolic syndrome and in patients with chronic kidney disease (CKD) compared with healthy individuals. The function of the V1a and V1b receptors in human disease are still being evaluated, although a recent study suggests that V1b may have a role in driving fat in response to fructose, possibly as a means for increasing metabolic water reserves.[6]

Mechanism of Vasopressin Action

AVP binds three types of receptors coupled to G proteins: the V_{1a} (vascular and hepatic), V_{1b} (anterior pituitary and pancreatic islet), and V_2 (renal) receptors. The V_2 receptor is primarily localized in the collecting duct and leads to an increase in water permeability through aquaporin 2 (AQP2), a member of a family of cellular water transporters (Fig. 9.2). AQP1 is localized in the apical and basolateral region of the proximal tubule epithelial cells and the descending limb of the loop of Henle and accounts for the high water permeability of these nephron segments. AQP1 is constitutively expressed, and not subject to regulation by AVP.[7] AQP2 is localized exclusively in apical plasma membranes and intracellular vesicles in the collecting duct principal cells. AVP affects both the short-term and the long-term regulation of AQP2. The short-term regulation, also described as the *shuttle hypothesis,* explains the rapid and reversible increase (within minutes) in collecting duct water permeability after AVP administration. This involves the insertion of water channels from subapical vesicles into the luminal membrane. Long-term regulation relates to AVP-mediated increases in the transcription of genes involved in AQP2 production and occurs if AVP levels are elevated for 24 hours or more. An increased number of AQP2 channels per cell elevates the maximal water permeability of the collecting duct epithelium.[7]

Aquaporins 3 and 4 are located on the basolateral membranes of the collecting duct (Fig. 9.2) and are probably involved in water exit from the cell. AQP3 is expressed along the entire collecting duct, whereas AQP4 is found in the inner medullary collecting duct. AQP4 is also found in the hypothalamus and is a candidate osmoreceptor for the control of AVP release.[7]

AVP also stimulates urea transporters in the inner medullary collecting duct. Urea transporter A1 (UT-A1) is found exclusively in apical plasma membranes and intracellularly in inner medullary collecting ducts. UT-A3 is found predominantly in the basolateral plasma membrane in inner medullary collecting ducts. Urea reabsorption into the inner medullary interstitium is important for increasing inner medullary tonicity and the driving force for water reabsorption.[8]

Thirst and Water Balance

Hypertonicity is the most potent stimulus for thirst, with a change of only 2% to 3% in serum osmolality producing a strong desire to drink.

The osmotic threshold for thirst usually occurs at 290 to 295 mOsm/kg H_2O and is greater than the threshold for vasopressin release (see Fig. 9.1). This osmolality closely approximates the level at which maximal concentration of urine is achieved. Hypovolemia, hypotension, and angiotensin II (Ang II) are also stimuli for thirst. Between the limits imposed by the osmotic thresholds for thirst and AVP release, serum osmolality may be regulated more precisely by small, osmoregulated adjustments in urine flow and water intake. The exact level at which balance occurs depends on insensible losses, water intake, and water generated from metabolism.

QUANTITATION OF RENAL WATER EXCRETION

Urine volume can be considered as having two components. The osmolar clearance (C_{osm}) is the volume needed to excrete solutes at the concentration of solutes in serum. The free water clearance (C_{water}) is the volume of water that has been added to (positive C_{water}) or subtracted from (negative C_{water}) isotonic urine (C_{osm}) to create either hypotonic or hypertonic urine.

Urine volume flow (V) includes the isotonic portion of urine (C_{osm}) plus the free water clearance (C_{water}).

$$V = C_{osm} + C_{water}$$

Therefore:

$$C_{water} = V - C_{osm}$$

The C_{osm} solute clearance is determined by urine flow, urine osmolality, and serum osmolality P_{osm} as follows:

$$C_{osm} = \left(\frac{U_{osm} \times V}{P_{osm}}\right)$$

Therefore:

$$C_{water} = V - \left(\frac{U_{osm} \times V}{P_{osm}}\right) = V\left(1 - \frac{U_{osm}}{P_{osm}}\right)$$

This relationship reflects the following:

1. In hypotonic urine ($U_{osm} < P_{osm}$), C_{water} is positive.
2. In isotonic urine ($U_{osm} = P_{osm}$), C_{water} is zero.
3. In hypertonic urine ($U_{osm} > P_{osm}$), C_{water} is negative (i.e., water is retained).

If excretion of free water in a polyuric patient is unaccompanied by water intake, the patient becomes hypernatremic. Conversely, failure to excrete free water with increased water intake can cause hyponatremia.

A limitation of the previous equation is that it fails to predict clinically important alterations in serum tonicity and serum sodium concentration (serum $[Na^+]$) because urea is included in the calculation of urine osmolality. Urea is an important component of urinary osmolality; however, urea equilibrates across most cell membranes in the body and does

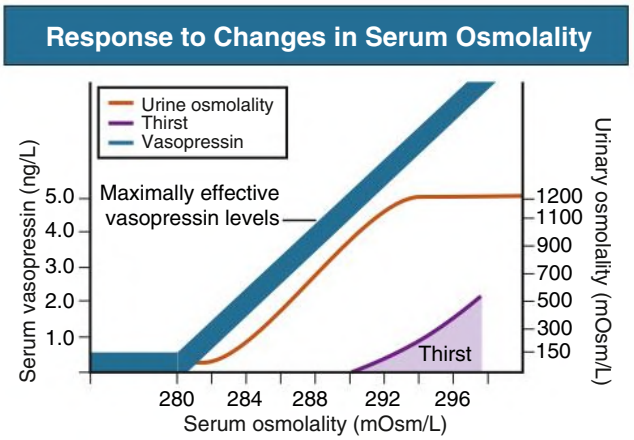

Fig. 9.1 Mechanisms Maintaining Serum Osmolality. Thirst, vasopressin levels, and urinary osmolality in response to changes in serum osmolality. (Modified from Narins RG, Krishna GC. Disorders of water balance. In: Stein JH, ed. *Internal Medicine.* Little, Brown; 1987:794.)

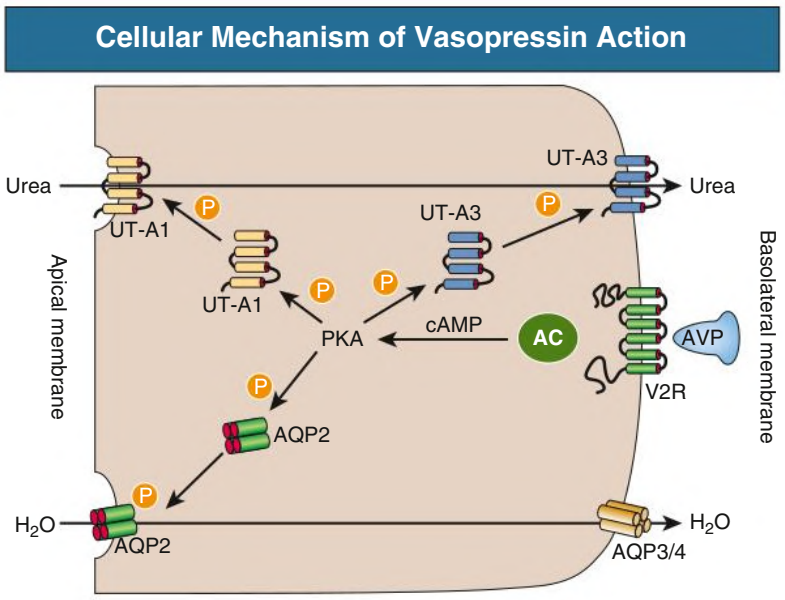

Fig. 9.2 Cellular Mechanism of Vasopressin Action. Arginine vasopressin (AVP) binds to V_2 receptors (V2R) on the basolateral membrane and activates G proteins, stimulates adenylyl cyclase (AC), and initiates a signaling cascade (cAMP, PKA) resulting in aquaporin 2 (AQP2) and urea transporter A1 (UT-A1) phosphorylation (P) and accumulation in the apical membrane. Water exits the cell through AQP3 and AQP4 in the basolateral membrane. Urea exits the cell through urea transporter A3 (UT-A3) in the basolateral membrane. *cAMP,* Cyclic adenosine monophosphate; *PKA,* protein kinase A.

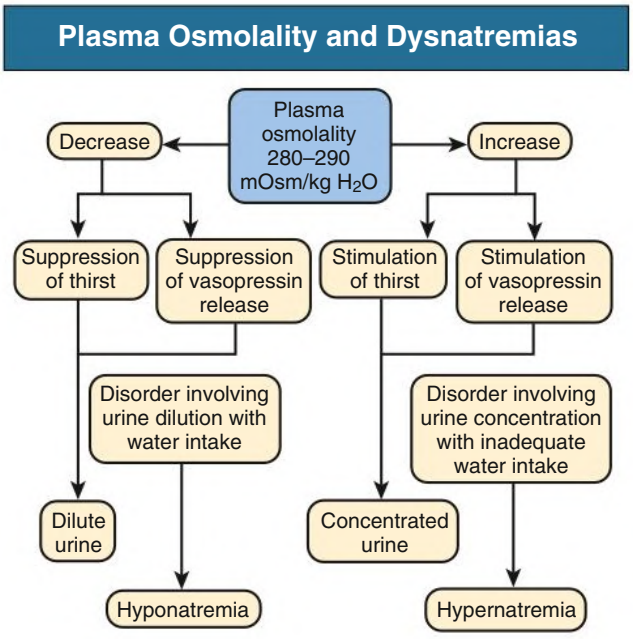

Fig. 9.3 Maintenance of serum osmolality and pathogenesis of dysnatremias. (Modified from Halterman R, Berl T. Therapy of dysnatremic disorders. In: Brady HR, Wilcox CS, eds. *Therapy in Nephrology and Hypertension.* Saunders; 1999:257–269.)

not cause water movement between fluid compartments. Therefore, urea does not influence serum Na^+ concentration or the release of vasopressin, and changes in serum $[Na^+]$ are better predicted by electrolyte free water clearance [Cwater(e)]. The equation can be modified, replacing P_{osm} by serum $[Na^+]$ (P_{Na}), and the urine osmolality by urine $[Na^+]$ and urine $[K^+]$, potassium concentration, ($U_{Na} + U_K$):

$$C_{water}(e) = V\left(1 - \frac{U_{Na} + U_K}{P_{Na}}\right)$$

If $U_{Na} + U_K$ is less than P_{Na}, then $C_{water}(e)$ is positive and serum $[Na^+]$ increases. If $U_{Na} + U_K$ is greater than P_{Na}, then $C_{water}(e)$ is negative and serum $[Na^+]$ decreases. In the clinical setting, it is more appropriate to use the equation for electrolyte free clearance to predict if a patient's serum $[Na^+]$ will increase or decrease in the face of the prevailing water excretion. For example, in a patient with high urea excretion, the original equation would predict negative water excretion and a decrease in serum $[Na^+]$, but, in fact, $[Na^+]$ increases, which is accurately predicted by the latter equation.

SERUM SODIUM CONCENTRATION, OSMOLALITY, AND TONICITY

The kidney's countercurrent mechanism, which allows urinary concentration and dilution, acts in concert with the hypothalamic osmoreceptors through AVP secretion to maintain serum $[Na^+]$ and tonicity within a very narrow range[9] (Fig. 9.3). A defect in the urine-diluting capacity coupled with excess water intake leads to hyponatremia. A defect in urine-concentrating ability with inadequate water intake leads to hypernatremia.

Serum $[Na^+]$ along with its accompanying anions accounts for nearly all the osmotic activity of the serum. Calculated serum osmolality is given by 2$[Na^+]$ mmol/L + BUN (mg/dL)/2.8 + glucose (mg/dL)/18, where BUN is blood urea nitrogen and 2.8 and 18 represent correction factors based on molecular weights of the respective molecules so as to unify the equation units to mmol/L. The addition of other solutes to ECF results in an increase in measured osmolality (Table 9.1). Solutes that are permeable across cell membranes do not cause water movement and therefore yield hypertonicity without cellular dehydration, as in uremia or ethanol intoxication. By contrast, in diabetic ketoacidosis, when glucose cannot freely cross cell membranes in the absence of insulin, water moves from the cells to the ECF, leading to cellular dehydration and lowering serum $[Na^+]$. This can be viewed as translocational because the decrease in serum $[Na^+]$ does not reflect a change in total body water but rather the movement of water from intracellular to extracellular space. Therefore, serum $[Na^+]$ can be corrected by 1.6 mmol/L for every 100 mg/dL (5.6 mmol/L) increase in serum glucose, although this may somewhat underestimate the impact of glucose to decrease serum $[Na^+]$.

TABLE 9.1 Effects of Osmotically Active Substances on Serum Sodium (Na^+) Levels

Substances That Increase Osmolality Without Changing Serum Na^+	Substances That Increase Osmolality and Decrease Serum Na^+ (Translocational Hyponatremia)
Urea	Hyperglycemia
Ethanol	Mannitol
Ethylene glycol	Glycine
Isopropyl alcohol	Maltose
Methanol	

Pseudohyponatremia occurs when the solid phase of serum (usually 6%–8%) is increased by large increments in either lipids or proteins (e.g., in hypertriglyceridemia and paraproteinemias). Serum osmolality is normal in pseudohyponatremia. This false result occurs because the usual method, indirect ion-selective potentiometry, measures the concentration of sodium in whole serum and not just the liquid phase, in which the concentration of sodium is 150 mmol/L. Many laboratories use direct ion-selective potentiometry, giving the true aqueous sodium-related osmolality, so if there is a divergence in the plasma sodium between the indirect and direct methods of measurement, a diagnosis of pseudohyponatremia becomes probable. In the absence of a direct-reading potentiometer, an estimate of serum water may be obtained from the following formula[10]:

$$\text{Serum water content (\%)} = 99.1 - (0.1 \times L) - (0.07 \times P)$$

where *L* and *P* refer to the total lipid and protein concentration (in g/L), respectively. For example, if the formula reveals that serum water is 90% of the serum sample rather than the normal 93% (which yields a serum sodium concentration of 140 mmol/L as 150 × 0.93 = 140), the concentration of measured sodium would be expected to decrease to 135 mmol/L (150 × 0.90).

ESTIMATION OF TOTAL BODY WATER

In normal individuals, total body water is approximately 60% of body weight (50% in females and obese individuals). With hyponatremia or hypernatremia, the change in total body water can be calculated from the serum $[Na^+]$ by the following formula:

$$\text{Water excess} = 0.6W \times \left(1 - \frac{[Na^+]_{obs}}{140}\right)$$

$$\text{Water deficit} = 0.6W \times \left(\frac{[Na^+]_{obs}}{140} - 1\right)$$

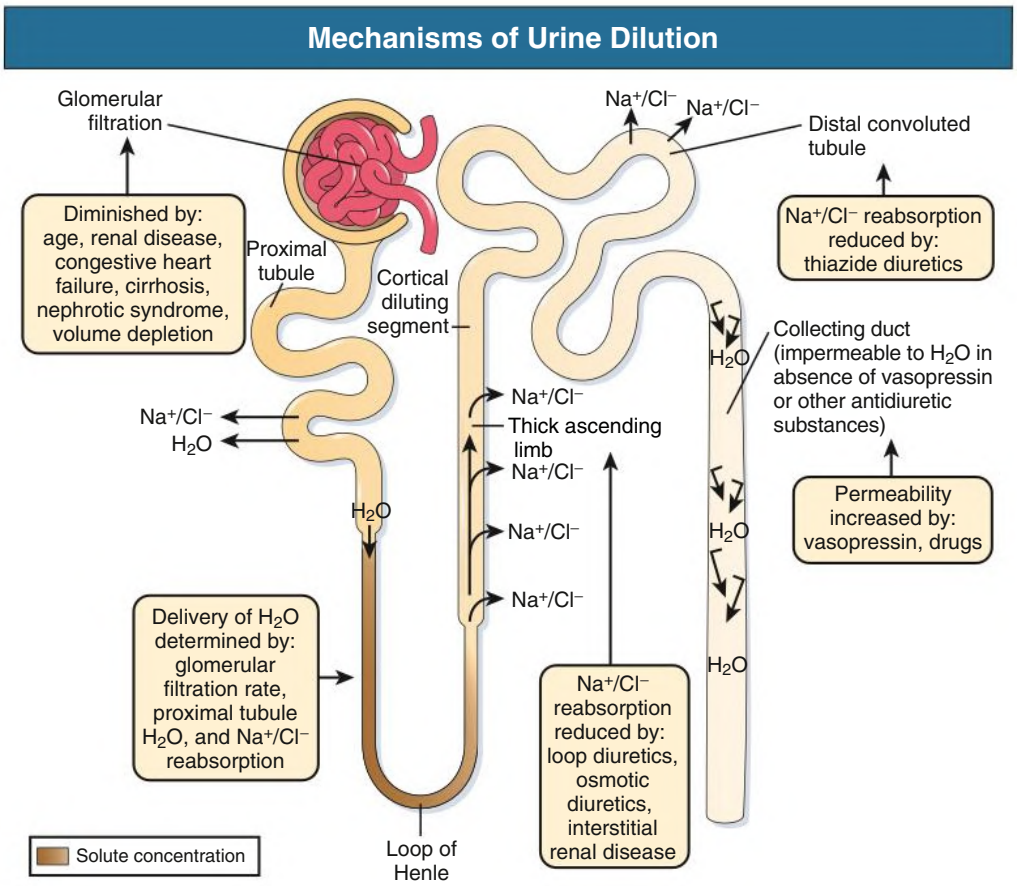

Fig. 9.4 Mechanisms of Urine Dilution. Normal determinants of urinary dilution and disorders causing hyponatremia. (Modified from Cogan MC. Normal water homeostasis. In: Cogan MC, ed. *Fluid and Electrolytes*. Lange; 1991:98–106.)

where $[Na^+]_{obs}$ is observed sodium concentration (in mmol/L) and W is body weight (in kilograms). By use of this formula, a change of 10 mmol/L in the serum $[Na^+]$ in a 70-kg individual is equivalent to a change of 3 L in free water.

HYPONATREMIC DISORDERS

Hyponatremia is defined as serum $[Na^+]$ of less than 135 mmol/L. If translocational and pseudohyponatremia are not responsible for the hyponatremia, the decrease in serum sodium concentration reflects a low serum osmolarity, also designated as hypotonicity. The underlying cause of hypotonic hyponatremia is a disturbance in the urinary diluting mechanism.[11] Fig. 9.4 depicts the normal diluting process and the sites at which it can be disrupted so as to impair water excretion, causing its retention and culminating in hyponatremia. A diminished glomerular filtration rate (GFR) and/or an increase in proximal tubular fluid reabsorption decrease distal delivery of filtrate to the diluting segments of the nephron, quantitatively limiting maximal water excretion. Also, hyponatremia may result from a decrement in Na^+-Cl^- transport from the thick ascending limb of the loop of Henle [TAL] or distal convoluted tubule, critical processes in the generation of a dilute tubular fluid. Most frequently, hyponatremia results from nonosmotic vasopressin secretion despite the presence of serum hypo-osmolality. This renders the collecting duct water permeable, thereby not allowing for the excretion of a maximally dilute urine.

Etiology and Classification of Hyponatremia

Once the patient is ascertained as being hypo-osmolar, the next step is to determine whether the individual is hypovolemic, euvolemic, or hypervolemic (Fig. 9.5).

Hypovolemia: Hyponatremia Associated With Decreased Total Body Sodium

A patient with hypovolemic hyponatremia has both a total body Na^+ and a water deficit, with the Na^+ deficit exceeding the water deficit. This occurs in patients with high gastrointestinal (GI) and renal losses of water and solute accompanied by free water or hypotonic fluid intake. The underlying mechanism is the nonosmotic release of vasopressin stimulated by volume contraction, which maintains vasopressin secretion despite the hypotonic state. Measurement of urine $[Na^+]$ is a useful tool in helping to diagnose these conditions (see Fig. 9.5).

Gastrointestinal and third-space sequestered losses. The kidney responds to volume contraction by conserving Na^+ and Cl^-. A similar response is observed in burn patients and patients with sequestration of fluids in third spaces, as in the peritoneal cavity with peritonitis or pancreatitis or in the bowel lumen with ileus. In all these, urine $[Na^+]$ is usually less than 10 mmol/L, and the urine is hyperosmolar. An exception occurs in patients with vomiting and metabolic alkalosis. Here, increased bicarbonate ion ($HCO3^-$) excretion obligates simultaneous cation excretion, resulting in a urine $[Na^+]$ that may exceed 20 mmol/L despite severe volume depletion; however, the urine $[Cl^-]$ remains less than 10 mmol/L. Sodium

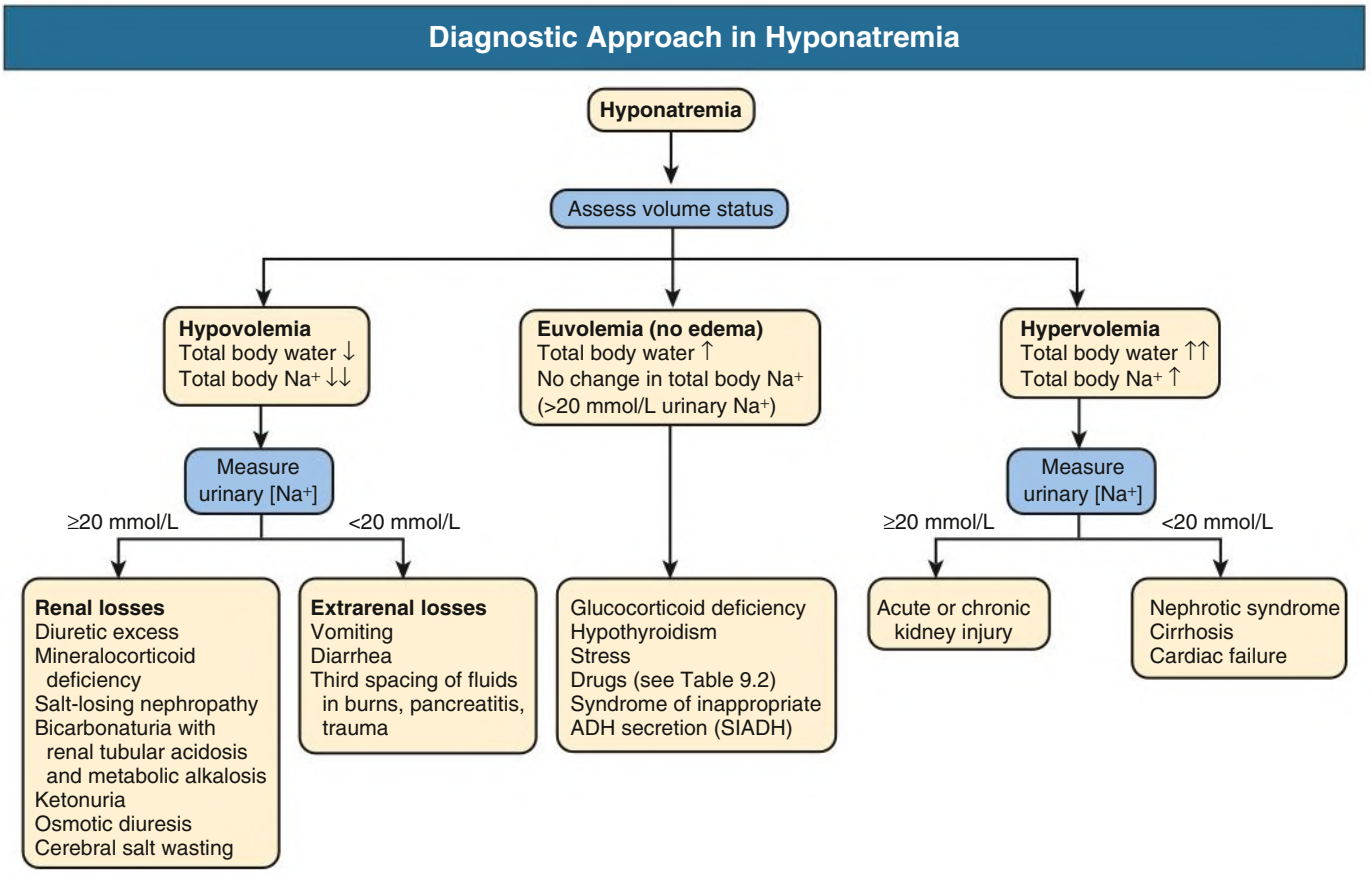

Fig. 9.5 Algorithm for diagnostic assessment of the patient with hyponatremia. (Modified from Halterman R, Berl T. Therapy of dysnatremic disorders. In: Brady HR, Wilcox CS, eds. *Therapy in Nephrology and Hypertension.* Saunders; 1999:257–269.)

conservation is also impaired in CKD that may also result in high urine [Na^+] despite volume depletion.

Diuretics. Diuretic use is one of the most common causes of hypovolemic hyponatremia associated with a high urine [Na^+]. Loop diuretics inhibit Na^+-Cl^- reabsorption in the thick ascending limb (TAL), impairing the generation of a hypertonic medullary interstitium. Therefore, despite increased AVP secretion, responsiveness to AVP is diminished and free water is excreted. In contrast, thiazide diuretics act in the distal tubule where they interfere with urine dilution, limiting free water excretion. Hyponatremia usually occurs within 14 days of initiation of therapy, with manifestation in approximately one-third of patients within 5 days. Underweight women and elderly patients are most susceptible. Postulated mechanisms for diuretic-induced hyponatremia include the following:

- Hypovolemia-stimulated AVP release and decreased fluid delivery to the diluting segment
- Impaired water excretion through interference with maximal urinary dilution in the cortical diluting segment
- K^+ depletion, directly stimulating water intake by alterations in osmoreceptor sensitivity and increasing thirst

Water retention can mask the physical findings of hypovolemia, making the patients with diuretic-induced hyponatremia appear euvolemic.

Salt-losing nephropathy. A salt-losing state may occur in patients with advanced CKD (GFR < 15 mL/min), particularly from interstitial disease. It is characterized by hyponatremia and hypovolemia. In proximal (type 2) renal tubular acidosis, there is renal Na^+ and K^+ wasting despite only moderately reduced GFR and bicarbonaturia further obligating urine Na^+ excretion.

Mineralocorticoid deficiency. Mineralocorticoid deficiency is characterized by hyponatremia with ECF volume contraction, urine [Na^+] greater than 20 mmol/L, and high serum K^+, urea, and creatinine. Decreased ECF volume provides the nonosmotic stimulus for AVP release.

Osmotic diuresis. An osmotically active, nonreabsorbable solute obligates the renal excretion of Na^+ and results in volume depletion. In the face of continuing water intake, the diabetic patient with severe glycosuria, the patient with a urea diuresis after relief of urinary tract obstruction, and the patient with mannitol diuresis all undergo urinary losses of Na^+ and water, leading to hypovolemia and hyponatremia. Urine [Na^+] is typically greater than 20 mmol/L. The ketone bodies β-hydroxybutyrate and acetoacetate also obligate urinary electrolyte losses and aggravate the renal Na^+ wasting seen in diabetic ketoacidosis, starvation, and alcoholic ketoacidosis.

Cerebral salt wasting. Cerebral salt wasting is a syndrome described primarily in patients with subarachnoid hemorrhage. The primary defect is salt wasting from the kidneys with subsequent volume contraction, which stimulates vasopressin release. The exact mechanism is not understood, but it is postulated that brain natriuretic peptide increases urine volume and Na^+ excretion. Serum uric acid is often low, similar to that observed in syndrome of inappropriate antidiuretic hormone (SIADH; see later). The diagnosis requires evidence of inappropriate sodium losses and reduced effective blood volume, usually with signs of orthostatic hypotension. These criteria are rarely fulfilled, suggesting that cerebral salt wasting is overdiagnosed.

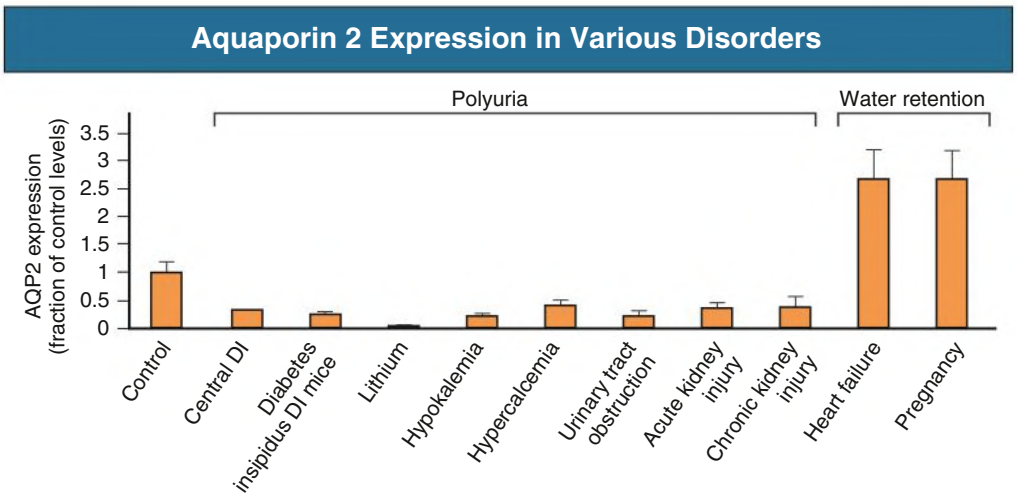

Fig. 9.6 Changes In Aquaporin 2 (Aqp2) Expression Seen in Association With Different Water Balance Disorders. Levels are expressed as a fraction (percentage) of control levels. AQP2 expression is reduced, sometimes dramatically, in a wide range of hereditary and acquired forms of diabetes insipidus (DI) characterized by different degrees of polyuria. Conversely, congestive heart failure and pregnancy are conditions associated with increased expression of AQP2 levels and excessive water retention. (Modified from Nielsen S, Knepper MA, Kwon TH. Regulation of water balance. Urine concentration and dilution. In: Schrier RW, ed. *Diseases of the Kidney and Urinary Tract.* 8th ed. Lippincott Williams & Wilkins; 2007:96–123.)

Hypervolemia: Hyponatremia Associated With Increased Total Body Sodium

Hyponatremia can also develop in hypervolemic states, such as congestive heart failure (CHF), nephrotic syndrome, and cirrhosis, in which the total body water is increased more than total body Na^+ (see Fig. 9.5 and Chapter 8).

Congestive heart failure. Edematous patients with CHF have reduced effective intravascular volume as a result of decreased systemic mean arterial pressure (MAP) and cardiac output. This reduction is sensed by aortic and carotid baroreceptors activating nonosmotic pathways, resulting in vasopressin release. In addition, the relative "hypovolemic" state stimulates the renin-angiotensin axis and increases norepinephrine production, which, in turn, decreases GFR. This causes an increase in proximal tubular reabsorption and a decrease in water delivery to the distal tubule.

The neurohumorally mediated decrease in delivery of tubular fluid to the distal nephron and an increase in vasopressin secretion mediate hyponatremia by limiting Na^+-Cl^- and water excretion. In addition, low cardiac output and high Ang II levels are potent stimuli of thirst. There is also excessive intracellular targeting of AQP2 to the apical cell membrane of the collecting duct, most likely from high AVP levels (Fig. 9.6).[12]

As cardiac function improves with afterload reduction, plasma vasopressin decreases, with concomitant improvement in water excretion. The degree of hyponatremia has also been correlated with the severity of cardiac disease and with patient survival; serum [Na^+] less than 125 mmol/L reflects severe CHF.

Hepatic failure. Patients with cirrhosis and hepatic insufficiency also have increased ECF volume (ascites, edema). Because of splanchnic venous dilation, they have increased plasma volume. Cirrhotic patients have an increased cardiac output because of multiple arteriovenous fistulas in their alimentary tract, lungs, and skin. Vasodilation and arteriovenous fistulas cause a decrease in MAP. As the severity of cirrhosis increases, there are progressive increases in plasma renin, norepinephrine, AVP, and endothelin, and an associated decline in MAP and serum [Na^+]. In experimental models, expression of AQP2 is upregulated in collecting ducts.[7]

Nephrotic syndrome. In some patients with nephrotic syndrome, especially those with minimal change disease, low plasma oncotic pressure from hypoalbuminemia alters Starling forces, leading to intravascular volume contraction and stimulation of AVP with hyponatremia. In contrast, most nephrotic patients have a renal defect in sodium excretion resulting in increased effective circulating volume. Hyponatremia may still occur in these latter conditions. In experimental models of nephrotic syndrome, expression of AQP2, AQP3, and UT-A1 are downregulated in the collecting duct (which would have countering effects), but so are the sodium transporters, NKCC2, NHE3, and Na-K-ATPase, in the TAL, resulting in hyponatremia.[7]

Advanced chronic kidney disease. Patients with severely reduced GFR, either acute or chronic, have a profound increase in fractional excretion of Na^+ to maintain normal salt balance given the overall decreased number of functioning nephrons. Edema usually develops when the Na^+ ingested exceeds the capacity of the kidneys to excrete this load. Likewise, if water intake exceeds threshold, there is positive water balance and hyponatremia. At a GFR of 5 mL/min, only 7.2 L of filtrate is formed daily. Approximately 30%, or 2.2 L, of this filtered fluid will reach the diluting segment of the nephron, which is therefore the maximum solute-free water that can be excreted daily. As GFR progressively declines, a defect in renal concentration precedes a disorder in urinary dilution. The excretion of free water as a function of remaining glomeruli is well maintained until kidney failure is very advanced.[13]

Older age. Aging results in 20% reduction in maximum urine osmolality in people older than 60 years. The concentrating defect is not related to a decrease in GFR or an abnormality in AVP secretion.

Euvolemia: Hyponatremia Associated With Normal Total Body Sodium

Euvolemic hyponatremia is the most common dysnatremia in hospitalized patients. These patients have no physical signs of increased or decreased total body Na^+.

Glucocorticoid deficiency. Cortisol exhibits a negative feedback on ACTH and vasopressin production so primary or secondary

glucocorticoid deficiency leads to impaired water excretion from excess circulating vasopressin. This can be corrected by physiologic doses of corticosteroids but not by volume expansion. Hyponatremia may be enhanced by reduced renal blood flow and decreased distal fluid delivery to the diluting segments of the nephron.

Hypothyroidism. Hyponatremia occurs in patients with severe hypothyroidism, who usually meet the clinical criteria for myxedema coma. A decrease in cardiac output leads to nonosmotic release of AVP. A reduction in GFR leads to diminished free water excretion through decreased distal delivery to the distal nephron. The exact mechanisms are unclear. In patients with untreated hypothyroidism who have moderately severe disease, a vasopressin-independent mechanism is suggested by normal suppression of vasopressin after water loading. However, in patients with more advanced hypothyroidism, elevated vasopressin levels are reported in the basal state and after a water load. Hyponatremia is readily reversed by hormonal replacement treatment.

Psychosis. Patients with acute psychosis may develop hyponatremia. Psychogenic drugs, particularly selective serotonin reuptake inhibitors (SSRIs), are associated with hyponatremia, but psychosis can cause hyponatremia independently.[14] The pathophysiologic process involves an increased thirst perception, a mild defect in osmoregulation that causes vasopressin to be secreted at lower osmolality, and an enhanced renal response to vasopressin. Individuals with self-induced water intoxication may also be more prone to rhabdomyolysis.

Postoperative hyponatremia. Postoperative hyponatremia mainly is a result of excessive infusion of electrolyte-free water (hypotonic saline or 5% dextrose in water) and the presence of AVP, which prevents water excretion. Hyponatremia can also occur despite infusion with near-isotonic (normal) saline within 24 hours of induction of anesthesia.[15] Young premenstrual girls are at higher risk of acute postoperative hyponatremia accompanied by cerebral edema. The mechanism has not been fully elucidated, and the patients at highest risk cannot be prospectively identified. Nevertheless, hypotonic fluids should be avoided after surgery, isotonic fluids minimized, and serum [Na^+] checked if hyponatremia is suspected (e.g., symptoms of headache or nausea).

Exercise-induced hyponatremia. Hyponatremia is seen in long-distance runners. A study at a marathon race associated increased risk of hyponatremia with body mass index less than 20 kg/m^2, running time exceeding 4 hours, and greatest weight gain.[16] A study in ultramarathon runners showed elevated AVP despite normal or low serum [Na^+]. The mechanism may be because of an exuberant AVP response in relation to exercise-induced dehydration.

Drugs causing hyponatremia. Drug-induced hyponatremia is becoming the most common cause of hyponatremia.[14] Thiazide diuretics and SSRIs are the most commonly implicated medications. Hyponatremia can be mediated by AVP analogs, such as desmopressin (DDAVP, 1-desamino-D-arginine AVP), that enhance AVP release and agents potentiating the action of AVP. In other cases, the mechanism is unknown (Table 9.2). Desmopressin for nocturia in elderly patients and enuresis in young persons has caused hyponatremia in some of these subjects, so it is not routinely used to treat these conditions. Desmopressin for nocturia should be used only when the number of voidings are not tolerable and are debilitating (>2/night). Upon awakening, the drug is likely to be still active for several more hours, requiring great attention to water restriction. Hyponatremia may also result from use of intravenous immunoglobulin (IVIG).[17] The mechanism of IVIG-associated hyponatremia is multifactorial, involving pseudohyponatremia (because of increases in serum protein concentration), translocation (because of sucrose in the solution), and true dilutional hyponatremia (because of the retention of water, particularly when associated with acute kidney injury [AKI]).[17]

TABLE 9.2 Drugs Associated With Hyponatremia[a]

Vasopressin Analogs	Drugs That Potentiate Renal Action of Vasopressin
Desmopressin (DDAVP)	Chlorpropamide
Oxytocin	Cyclophosphamide
	Nonsteroidal anti-inflammatory drugs (NSAIDs)
	Acetaminophen
Drugs That Enhance Vasopressin Release	**Drugs That Cause Hyponatremia by Unknown Mechanisms**
Chlorpropamide	Haloperidol
Clofibrate	Fluphenazine
Carbamazepine-oxcarbazepine	Amitriptyline
Vincristine	Thioridazine
Nicotine	Fluoxetine
Narcotics	Methamphetamine (MDMA, "ecstasy")
Antipsychotics/antidepressants (SSRIs)	Intravenous immunoglobulin (IVIG)
Ifosfamide

Syndrome of inappropriate antidiuretic hormone secretion. Despite being the most common cause of hyponatremia in hospitalized patients, SIADH is a diagnosis of exclusion. A defect in osmoregulation causes AVP to be inappropriately stimulated, leading to urine concentration (Table 9.3). A few causes deserve special mention. Central nervous system (CNS) disturbances such as hemorrhage, tumors, infections, and trauma cause SIADH by excess AVP secretion. Small cell lung cancers, cancer of the duodenum and pancreas, and olfactory neuroblastoma cause ectopic production of AVP. Idiopathic cases of SIADH are unusual except in elderly patients, in whom hyponatremia is frequently multifactorial,[18] but in whom as many as 10% have abnormal AVP secretion without known cause.

Several patterns of abnormal AVP release have emerged from studies of patients with clinical SIADH[19] and have now been reproduced employing the simpler, more reliable, and more stable copeptin assay.[20] In one-third of patients with SIADH, AVP release varies appropriately with serum [Na^+] but begins at a lower threshold of serum osmolality, implying a "resetting of the osmostat." Ingestion of free water then leads to water retention to maintain the serum [Na^+] at a new lower level, usually 125 to 130 mmol/L. In two-thirds of patients, AVP release does not correlate with serum [Na^+], but a solute-free urine cannot be excreted. Therefore, ingested water is retained, giving rise to moderate nonedematous volume expansion and dilutional hyponatremia. In about 10% of patients, AVP levels are not measurable, suggesting that the *syndrome of inappropriate antidiuresis* (SIAD) is a more accurate term.[19] It was suggested that such patients may have a nephrogenic syndrome of antidiuresis, and a gain-of-function mutation in the AVP receptor. However, none of the six patients who had unmeasurable copeptin (a surrogate marker for AVP) levels had an identifiable gain of function mutation.[20]

The diagnostic criteria for SIADH are summarized in Box 9.1.[1] Plasma AVP may be in the "normal" range (up to 10 ng/L), but this

BOX 9.1 Diagnostic Criteria for Syndrome of Inappropriate Antidiuretic Hormone Secretion

Essential Diagnostic Criteria

- Decreased extracellular fluid effective osmolality (270 mOsm/kg H_2O)
- Inappropriate urine concentration (>100 mOsm/kg H_2O)
- Clinical euvolemia
- Elevated urine Na^+ concentration under conditions of normal salt and water intake
- Absence of adrenal, thyroid, pituitary, or renal insufficiency or diuretic use

Supplemental Criteria

- Abnormal water-load test result (inability to excrete at least 90% of a 20-mL/kg water load in 4 hours and/or failure to dilute urine osmolality to <100 mOsm/kg)
- Serum vasopressin level inappropriately elevated relative to the serum osmolality
- No significant correction of serum Na^+ level with volume expansion, but improvement after fluid restriction
- Hypouricemia and elevated fractional excretion of uric acid

Modified from Verbalis J. The syndrome of inappropriate antidiuretic hormone secretion and other hypo-osmolar disorders. In: Schrier RW, ed. *Diseases of the Kidney and Urinary Tract*. 9 ed. Philadelphia: Lippincott Williams & Wilkins; 2013:2012-54.

is inappropriate given the hypo-osmolar state. The measurement of plasma AVP is rarely needed because the urinary osmolality provides an excellent surrogate bioassay. Thus, a hypertonic urine (>300 mOsm/kg H_2O) provides strong evidence for the presence of AVP in the circulation because such urinary tonicities are unattainable in its absence. Likewise, a urinary osmolality lower than 100 mOsm/kg H_2O reflects the virtual absence of the hormone. Urinary osmolarities in the range of 100 to 300 mOsm/kg H_2O can occur in the presence or absence of AVP. A decrease in serum uric acid concentration associated with a high fractional excretion (>10%) is frequently encountered in the patient with SIADH.

Clinical Manifestations of Hyponatremia

Most patients with serum [Na^+] greater than 125 mmol/L are asymptomatic. In patients with less than 125 mmol/L, but more specifically less than 120 mmol/L, which is typically the definition of "severe hyponatremia," headache, yawning, lethargy, nausea, reversible ataxia, psychosis, seizures, and coma may occur as a result of cerebral edema. Neurologic symptoms in a hyponatremic patient call for immediate attention and treatment.

"Moderate hyponatremia" and "mild hyponatremia" are normally defined with ranges from 120 to 129 mmol/L and 130 to 134 mmol/L, respectively. In the setting of nonsevere disease, complications are less frequently manifested.

The catastrophic consequence of significant hyponatremia is cerebral edema so severe that there is increased intracerebral pressure, tentorial herniation, respiratory depression, and death. These events occur with rapid development of hyponatremia, usually in hospitalized postoperative patients receiving diuretics or hypotonic fluids. Untreated severe hyponatremia has a mortality rate as high as 50%, and it is in this group where the complications from not only the hyponatremia itself but also its overcorrection are most commonly seen.

Cerebral Edema

The development of cerebral edema largely depends on the cerebral adaptation to hypotonicity. Decreases in extracellular osmolality cause movement of water into cells, increasing intracellular volume and causing tissue edema. The water channel AQP4 appears to play a key role in the movement of water across the blood-brain barrier. AQP4 knockout mice are protected from hyponatremic brain

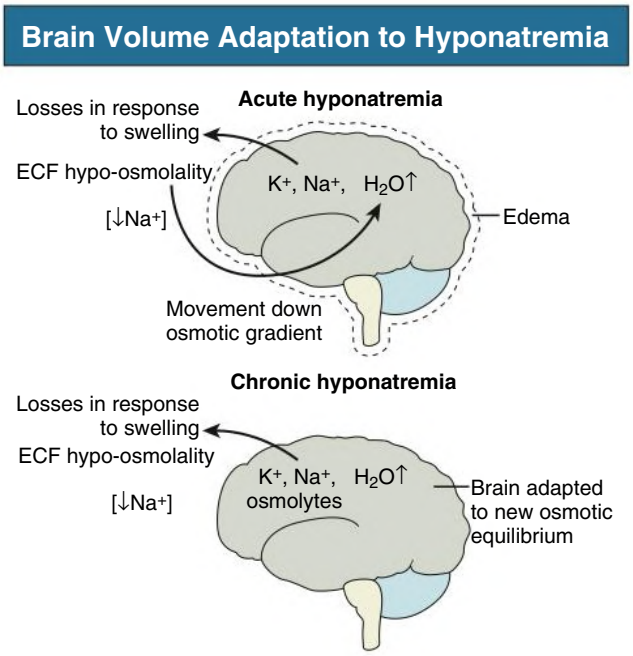

Fig. 9.7 Brain Volume Adaptation to Hyponatremia. During acute hyponatremia, water enters the brain to establish osmotic equilibrium with the ECF. As an acute adaptive change, NaCl exits from the brain interstitial space, followed by loss of potassium from cells several hours later. In chronic hyponatremia, the brain loses osmolytes, which lead to further water losses from the brain and an almost full restoration of brain water to levels marginally greater than baseline. (Modified from Verbalis J. The syndrome of inappropriate antidiuretic hormone secretion and other hypo-osmolar disorders. In: Schrier RW, ed. *Diseases of the Kidney and Urinary Tract.* 9th ed. Lippincott Williams & Wilkins; 2013:2012–2054.)

swelling, whereas animals overexpressing AQP4 have exaggerated brain swelling.[21] Cellular edema within the fixed confines of the cranium increases intracranial pressure, leading to the neurologic syndrome. In most hyponatremic patients, mechanisms of volume regulation prevent cerebral edema.

Within 1 to 3 hours after hyponatremia develops, a decrease in cerebral extracellular volume occurs by movement of fluid into the cerebrospinal fluid, which is then shunted back into the systemic circulation. Loss of extracellular solutes Na^+ and Cl^- can occur as early as 30 minutes after the onset of hyponatremia (Fig. 9.7). If hyponatremia persists for longer than 3 hours, the brain adapts by losing cellular osmolytes, including K^+ and organic solutes, which tends to lower the osmolality of the brain, resulting in water losses. Thereafter, if hyponatremia persists, other organic osmolytes, such as phosphocreatine, myoinositol, and amino acids (e.g., glutamine, taurine), are lost, greatly decreasing cerebral swelling. As a result of these adaptations, most patients have minimal symptoms despite severe hyponatremia ($[Na^+] < 120$ mmol/L).

Certain patients are at increased risk for development of acute cerebral edema in the course of hyponatremia[12] (Table 9.4). Hospitalized premenstrual girls with hyponatremia are more symptomatic and more likely to have complications of therapy than postmenopausal women or men. This increased risk of cerebral edema is independent of the rate of development or the magnitude of hyponatremia. The best management of these patients is to avoid the administration of hypotonic fluids in the postoperative setting. Children are particularly vulnerable to the development of acute cerebral edema, perhaps because of a relatively high ratio of brain to skull volume.

TABLE 9.4 Persons at Risk for Neurologic Complications With Hyponatremia

Acute Cerebral Edema	Osmotic Demyelination Syndrome (Central Pontine Myelinolysis)
Postoperative menstruating women	Liver transplant recipients
Elderly women taking thiazides	Alcoholic patients
Children	Malnourished patients
Patients with polydipsia secondary to psychiatric disorders	Hypokalemic patients
	Burn patients
Hypoxemic patients	Elderly women taking thiazides
Marathon runners	Hypoxemic patients
	Severe hyponatremia ($[Na^+] < 105$ mmol/L)

Patient groups at risk for acute cerebral edema and central pontine myelinolysis (osmotic demyelination).
From Thurman JM, Berl T. Therapy of dysnatremic disorders. In: Wilcox CS, ed. *Therapy in Nephrology and Hypertension*. 3rd ed. Elsevier; 2008:337–352.

Osmotic Demyelination

Another neurologic syndrome can occur in hyponatremic patients as a complication of correction of hyponatremia. Osmotic demyelination most often affects the central pons and is therefore also termed *central pontine myelinolysis* (CPM). It occurs at all ages; Table 9.4 lists patients at highest risk. Osmotic demyelination syndrome is especially common after liver transplantation, with a reported incidence of 13% to 29% at autopsy. The risk of CPM is related to the severity and chronicity of the hyponatremia. It rarely occurs with serum $[Na^+]$ greater than 120 mmol/L or a short duration of hyponatremia (<48 hours). The symptoms are biphasic. Initially, there is a generalized encephalopathy associated with rapid correction of serum $[Na^+]$. At 2 to 3 days after correction, the patient displays behavioral changes, cranial nerve palsies, and progressive weakness, culminating in quadriplegia and a "locked-in" syndrome. T2-weighted magnetic resonance imaging shows nonenhancing and hyper-intense pontine and extrapontine lesions. These lesions may not appear until 2 weeks after development, so a diagnosis of myelinolysis should not be excluded if the imaging is initially normal.

The pathogenesis of osmotic demyelination syndrome is uncertain; one suggestion is that sodium-coupled amino acid transporters (e.g., SNAT2) are downregulated by hypotonicity, thereby delaying the return of osmolytes to the brain, rendering it more sensitive to the correction of hyponatremia.[22] Although $[Na^+]$ and $[K^+]$ return to normal in a few hours, osmotically active solutes require several days to return to normal levels. This temporary imbalance causes cerebral dehydration and can lead to a potential breakdown of the blood-brain barrier. Astrocytes appear to be an early target of the disease, activating microglial cells resulting in the expression of proinflammatory cytokines.[23]

Although CPM was originally considered to be uniformly fatal, a substantial number of patients can have some neurologic recovery, even with severe symptoms at onset, suggesting there are reversible forms of osmotic demyelination.

Treatment of Hyponatremia

Symptoms and duration of hyponatremia determine treatment. Acutely hyponatremic patients (developing within 48 hours) are at great risk for permanent neurologic sequelae from cerebral edema if the hyponatremia remains uncorrected. Patients with chronic

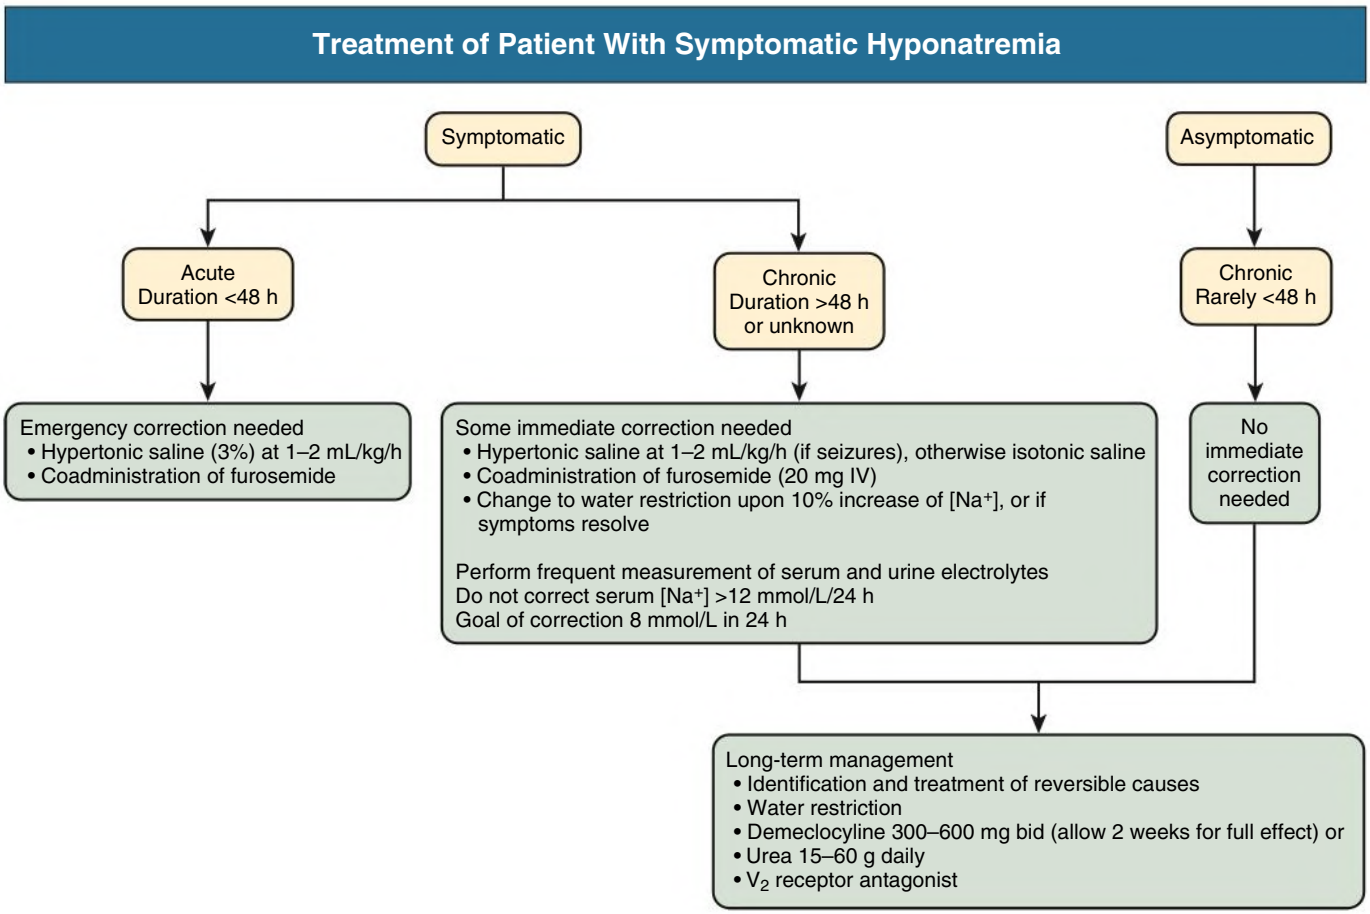

Fig. 9.8 Algorithm for management of the patient with symptomatic (and "asymptomatic") hyponatremia. *IV,* Intravenous. (Modified from Thurman JM, Berl T. Therapy of dysnatremic disorders. In: Wilcox CS, ed. *Therapy in Nephrology and Hypertension.* 3rd ed. Elsevier; 2008:337–352.)

hyponatremia are at risk for osmotic demyelination if the hyponatremia is corrected too rapidly.

Acute Symptomatic Hyponatremia

Acute symptomatic hyponatremia with seizures or other neurologic manifestations almost always develops in hospitalized patients receiving hypotonic fluids (Fig. 9.8). Treatment should be prompt because the risk of acute cerebral edema far exceeds the risk of osmotic demyelination. The cell volume adaptive response, whereby the brain decreases its water content in acute hyponatremia, may be inhibited by female hormones, possibly explaining the large female predominance. A contribution of hypoxia also may be important, because when hypoxia is combined with hyponatremia in experimental animals, the volume adaptive response is abrogated, resulting in brain edema and increased mortality.[24] Because the neurologic complications associated with acute symptomatic hyponatremia are devastating, patients require prompt treatment with 3% NaCl.[12] A rapid increment of 4 to 6 mmol/L within the first 6 hours appears to be sufficient to reverse cerebral edema; correction to normal levels is unnecessary.[25] Initial treatment should entail an infusion of 3% NaCl 1 to 2 mL/kg over 60 minutes or a 100 mL bolus over 10 minutes followed by two further doses to raise the plasma sodium to the specified level. Administration of a loop diuretic enhances free water excretion and hastens the normalization of serum [Na^+]. If the patient presents with severe neurologic symptoms, such as seizures, obtundation, or coma, 3% NaCl may be infused at higher rates (4–6 mL/kg/hr). Patients should be monitored carefully for changes in neurologic and pulmonary status, and serum electrolytes should be checked every 2 hours.

Chronic Symptomatic Hyponatremia

If the hyponatremia has taken more than 48 hours to evolve or if the duration is not known, correction should be cautious (see Fig. 9.8). Controversy exists as to whether it is the rate of correction or the magnitude of correction of hyponatremia that predisposes to neurologic complications. It is difficult to dissociate these two variables because a rapid correction rate is usually accompanied by a greater absolute magnitude of correction during a given time. Three important principles guide treatment:

1. Because cerebral water is increased by approximately 10% in severe chronic hyponatremia, the goal is to increase the serum Na^+ level by 10%, or about 10 mmol/L, in the first 24 hours.
2. A correction rate of 1.0 to 1.5 mmol/L in any given hour should not be exceeded.
3. The goal of treatment is an increase of 6 to 10 mmol/L every 24 hours but do not increase by more than 12 mmol/L every 24 hours and 18 mmol/L per 48 hours.

Numerous formulas have been used to assess the expected changes in serum sodium with various infusions, but the one proposed by Adrogue and Madias is the most widely employed.[26] Although helpful in the initial treatment phase, it does not take into account ongoing renal and extrarenal losses, thus commonly resulting in correction larger than those predicted by the formula. The risk for overcorrection

TABLE 9.5 Treatment of Patients With Chronic Asymptomatic Hyponatremia

Treatment	Mechanism of Action	Dose	Advantages	Limitations
Fluid restriction	Decreases availability of free water	Variable	Effective and inexpensive; not complicated	Noncompliance
Pharmacologic Inhibition of Vasopressin Action				
Lithium	Inhibits kidney's response to vasopressin	900–1200 mg/day	Unrestricted water intake	Polyuria, narrow therapeutic range, neurotoxicity
Demeclocycline	Inhibits kidney's response to vasopressin	300–600 mg twice daily	Effective; unrestricted water intake	Neurotoxicity, polyuria, photosensitivity, nephrotoxicity
V_2 receptor antagonist	Antagonizes vasopressin action	—	Addresses underlying mechanisms	Limited clinical experience
Increased Solute (Salt) Intake				
With furosemide	Increases free water clearance	Titrate to optimal dose; coadminister 2–3 g NaCl	Effective	Ototoxicity, K^+ depletion
With urea	Osmotic diuresis	30–60 g/day	Effective; unrestricted water intake	Polyuria, unpalatable, gastrointestinal symptoms

can be mitigated by the coadministration of DDAVP, thus preventing the excretion of a hypotonic urine.[27] If the aforementioned noted limits are exceeded, relowering of serum sodium can be achieved by the infusion of dextrose and water and the administration of DDAVP.[27]

Chronic "Asymptomatic" Hyponatremia

Patients with chronic hyponatremia are often asymptomatic. However, epidemiologic data consistently show higher mortality rates than matched controls with normal serum sodium levels.[28] Formal neurologic testing frequently reveals subtle impairments, including gait disturbances that reverse with correction of the hyponatremia. This results in an increased risk for falls and fractures.[29] Therefore, even "asymptomatic" patients should be treated in an attempt to restore serum sodium to near-normal levels, particularly if they display gait instability or have sustained a fall. These patients should also be evaluated for hypothyroidism, adrenal insufficiency, and SIADH and should have their medications reviewed.

Fluid restriction. Stopping any medication associated with hyponatremia and fluid restriction is the cornerstone of therapy in patients with chronic asymptomatic hyponatremia (Table 9.5). Intake of all fluids should be restricted, and fructose-containing fluids should be avoided because fructose stimulates vasopressin release independently of osmolarity. This approach is usually successful if patients are compliant. It involves a calculation of the fluid restriction that will maintain a specific serum $[Na^+]$. The daily osmolar load (OL) and the minimal urinary osmolality $(U_{osm})_{min}$ determine a patient's maximal urine volume (V_{max}), as follows:

$$V_{max} = \frac{OL}{(U_{osm})_{min}}$$

The value of $(U_{osm})_{min}$ is a function of the severity of the diluting disorder. In the absence of circulating vasopressin, it can be as low as 50 mOsm/kg H_2O. In a normal North American diet, the daily osmolar load is approximately 10 mOsm/Kg (700 mOsm for a 70-kg person). Assuming that a patient with SIADH has U_{osm} that cannot be lowered to less than 500 mOsm/kg H_2O, the same osmolar load of 700 mOsm allows only 1.4 L of urine to be excreted daily. Therefore, if the intake exceeds 1.4 L/day, the serum Na^+ concentration will decrease. Measurement of urine $[Na^+]$ and $[K^+]$ can guide the required degree of water restriction.[30] Unless the ratio of urine $[Na^+]$ plus $[K^+]$ over serum $[Na^+]$ is 0.5 or less, the needed water restriction is not likely to be complied with. Likewise, a urinary osmolality greater than 500 mOsm/kg also predicts poor response to water restriction.[1] In a report from a hyponatremia registry, the increment in serum sodium observed in patients placed on water restriction did not achieve statistical significance compared with their baseline admission serum sodium.[31] If the diluting defect is so severe that fluid restriction to less than 1 L is necessary or if the serum Na^+ concentration remains low (<130 mmol/L), an alternative approach to treatment should be considered, such as increasing solute excretion or pharmacologic inhibition of AVP.

Increase solute excretion. If the patient remains unresponsive to fluid restriction, solute intake can be increased to facilitate an obligatory increase in excretion of solute and free water. This can be achieved by increasing oral salt and protein intake in the diet to increase the C_{osm} of the urine. Loop diuretics combined with high sodium intake (2–3 g of additional salt) are effective in the management of hyponatremia. A single dose of a loop diuretic (e.g., 40 mg furosemide) is usually sufficient but should be doubled if the diuresis induced in the first 8 hours is less than 60% of the total daily urine output.

In patients with SIADH, urine osmolality is fixed. In the collecting duct, urea is an effective osmole that increases water loss, thereby decreasing water retention and sodium loss. This permits improvement in hyponatremia and without altering urine concentration. The dose of urea is usually 30 to 60 g/day. The limitations are GI distress and unpalatability.

Pharmacologic inhibition of vasopressin. *Vaptans* are novel oral V_2 receptor antagonists that block vasopressin binding to the collecting duct tubular epithelial cells and increase free water excretion without significantly altering electrolyte excretion.[32–34] Vaptans are effective in the treatment of hyponatremia in euvolemic and hypervolemic patients.[35] Conivaptan, a V_2 and V_{1a} antagonist, is the only vaptan available for IV use,[34] but treatment should be limited to 4 days because it is a potent cytochrome P-450 3A4 (CYP3A4) inhibitor and should generally be avoided in patients at risk for variceal bleeding, given that the antagonism of V_1 receptors would tend to vasodilate existing varices. Tolvaptan, an oral V_2 antagonist, is available at doses of 15 to 60 mg/day. In the tolvaptan trials (TEMPO) in patients with polycystic kidney disease, higher doses were used and some cases of hepatic toxicity, as well as rhabdomyolysis, were encountered. This has led to a Food and Drug Administration (FDA) warning requiring careful monitoring of liver function tests and creatine kinase (CK,

CPK) levels. Although the recommendation is to use tolvaptan for less than 30 days, some clinicians are treating chronically for patients with severe SIADH using the lowest dose that can maintain normal serum osmolality so long as liver function tests remain normal. Several newer V_2 selective vaptans (mozavaptan, satavaptan, and lixivaptan) have been made available, but tolvaptan remains the most extensively studied.

An alternative pharmacologic treatment is demeclocycline, 600 to 1200 mg/day given 1 to 2 hours after meals; calcium-, aluminum-, and magnesium-containing antacids should be avoided. Onset of action is usually 3 to 6 days after initiation of treatment. Dose should be titrated to the minimum that keeps serum [Na^+] within the desired range with unrestricted water intake. Demeclocycline can cause photosensitivity or (in children) tooth or bone abnormalities. Polyuria leads to noncompliance, and nephrotoxicity may occur, especially in patients with underlying liver disease. Lithium was previously used to antagonize AVP action but has been superseded by the vaptans and demeclocycline.

Hypovolemic Hyponatremia

When thiazides are prescribed, especially in elderly women, serum [Na^+] should be monitored and water intake restricted. If hyponatremia develops, the thiazide should be discontinued.

Neurologic syndromes directly related to hyponatremia are unusual in hypovolemic hyponatremia because loss of Na^+ and water limits any osmotic shifts in the brain. Restoration of ECF volume with crystalloids or colloids interrupts the nonosmotic release of AVP. AVP antagonists should not be used in these patients.[35]

Hypervolemic Hyponatremia

Congestive heart failure. In patients with CHF, sodium and water restriction is critical. Treatment with a combination of angiotensin-converting enzyme (ACE) inhibitors and loop diuretics increase cardiac output, thereby decreasing the neurohumoral mediators that impair water excretion. Loop diuretics also diminish the action of AVP on the collecting tubules. Thiazides should be avoided because they impair urinary dilution and may worsen hyponatremia. V_2 antagonists increase serum [Na^+] in patients with heart failure, and correction of serum [Na^+] is associated with better long-term outcomes.[35] However, in the much larger randomized controlled EVEREST trial in patients with decompensated heart failure, tolvaptan did not affect long-term clinical outcomes, but some improvement in secondary outcomes, such as urine output, dyspnea, and edema, were noted. In principle, a vaptan with V_1 antagonist activity could have additional benefit in the CHF patient, but this remains unproven.

Cirrhosis. In patients with cirrhosis, water and sodium restriction is the mainstay of therapy. Loop diuretics increase C_{water}. V_2 antagonists increase water excretion and increase serum [Na^+].[35] The response to vaptans in cirrhosis is more attenuated than in patients with SIADH or CHF, which suggests that vasopressin-independent mechanisms may also contribute to the hyponatremia. The administration of V_2 antagonists to patients with liver failure is not associated with decrements in blood pressure. Combined V_1 and V_2 antagonists (e.g., conivaptan) should not be used in these patients, and in view of the potential liver toxicity, the use of tolvaptan should probably be limited to management of serum hyponatremia before liver transplant.[35]

HYPERNATREMIC DISORDERS

Hypernatremia is defined as serum [Na^+] greater than 145 mmol/L and reflects serum hyperosmolarity. The renal concentrating mechanism provides the first defense mechanism against water depletion and hyperosmolarity. The components of the normal concentrating mechanism are shown in Fig. 9.9. Disorders of urine concentration may result from decreased delivery of solute (with decreasing GFR) or the inability to generate interstitial hypertonicity because of decreased Na^+ and Cl^- reabsorption in the ascending limb of Henle's loop (loop diuretics), decreased medullary urea accumulation (poor dietary intake), or alterations in medullary blood flow. Hypernatremia may also result from failure to release or respond to vasopressin. Thirst is the first and most important defense mechanism in preventing hypernatremia.

Etiology and Classification of Hypernatremia

Patients with hypernatremia fall into three broad categories based on volume status.[13] A diagnostic algorithm is helpful in the evaluation of these patients (Fig. 9.10).

Hypovolemia: Hypernatremia Associated With Low Total Body Sodium

Patients with hypovolemic hypernatremia sustain losses of both Na^+ and water but with a relatively greater loss of water. On physical examination, there are signs of hypovolemia, including orthostatic hypotension, tachycardia, flat neck veins, poor skin turgor, and altered mental status. Patients generally have hypotonic water loss from the kidneys or the GI tract; in the GI tract, the urine [Na^+] will be low.

Hypervolemia: Hypernatremia Associated With Increased Total Body Sodium

Hypernatremia with increased total body Na^+ is the least common form of hypernatremia. It results from the administration of hypertonic solutions such as 3% NaCl and $NaHCO_3$ for the treatment of metabolic acidosis, hyperkalemia, and cardiorespiratory arrest. It may also result from inadvertent dialysis against a dialysate with a high Na^+ concentration or from consumption of salt tablets. Therapeutic hypernatremia is also becoming common as hypertonic saline solutions have emerged as an alternative to mannitol for treatment of increased intracranial pressure.[25] Hypernatremia is also increasingly recognized in hypoalbuminemic hospitalized patients with kidney failure who are edematous and unable to concentrate their urine.

Euvolemia: Hypernatremia Associated With Normal Body Sodium

Most patients with hypernatremia secondary to water loss appear euvolemic with normal total body Na^+ because loss of water without Na^+ does not lead to overt volume contraction unless severe. Water loss need not result in hypernatremia unless unaccompanied by water intake. Because hypodipsia is uncommon, hypernatremia usually develops only in those who have no access to water and in very young children and old persons, who may have an altered perception of thirst. Extrarenal water loss occurs from the skin and respiratory tract in febrile or other hypermetabolic states and is associated with a high urine osmolality because the osmoreceptor-AVP renal response is intact. The urine Na^+ concentration varies with intake. Renal water loss leading to euvolemic hypernatremia results either from a defect in AVP production or release (central diabetes insipidus) or from a failure of the collecting duct to respond to the hormone (nephrogenic diabetes insipidus). Defense against the development of hyperosmolality requires the appropriate stimulation of thirst and the patient's ability to respond by drinking water.

Polyuric disorders can result from either an increase in C_{osm} or an increase in C_{water}. An increase in C_{osm} occurs with loop diuretic use, renal salt wasting, excess salt ingestion, vomiting (bicarbonaturia), alkali administration, and administration of mannitol (as a diuretic,

Mechanisms of Urine Concentration

Diagnostic Approach in Hypernatremia

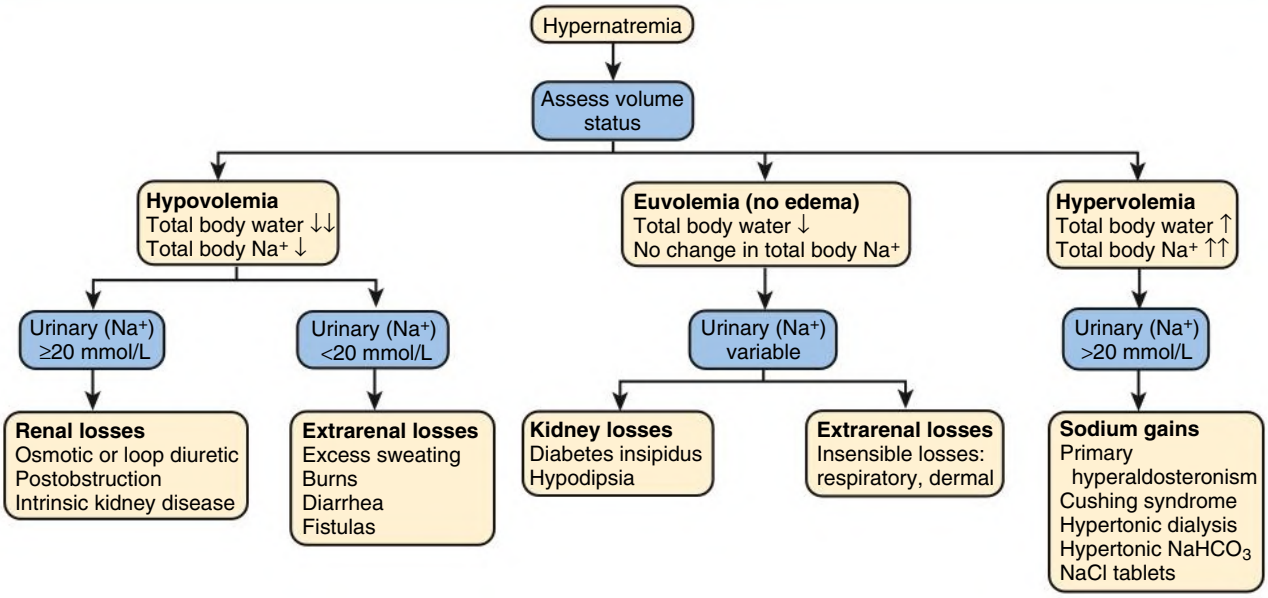

Fig. 9.10 Algorithm for diagnostic assessment of the patient with hypernatremia. (Modified from Halterman R, Berl T. Therapy of dysnatremic disorders. In: Brady HR, Wilcox CS, eds. *Therapy in Nephrology and Hypertension.* Saunders; 1999:257–269.)

TABLE 9.6 Interpretation of Water Deprivation Test

Condition	Urinary Osmolality With Water Deprivation (mOsm/kg H_2O)	Serum Vasopressin After Dehydration (pg/mL)	Increase in Urinary Osmolality With Exogenous Vasopressin or Desmopressin
Normal	>800	>2	Little or no increase
Complete central diabetes insipidus	<300	Undetectable	Substantially increased
Partial central diabetes insipidus	300–800	<1.5	Increase of >10% of urinary osmolality after water deprivation
Nephrogenic diabetes insipidus	<300–500	>5	Little or no increase
Primary polydipsia	>500	<5	Little or no increase

From Lanese D, Teitelbaum I. Hypernatremia. In: Jacobson HR, Striker GE, Klahr S, eds. *The Principals and Practice of Nephrology*. 2nd ed. Mosby; 1995:893–898.

for bladder lavage, or for the treatment of cerebral edema). An increase in C_{water} occurs with excess ingestion of water (psychogenic polydipsia) or in abnormalities of the renal concentrating mechanism (DI).

Diabetes Insipidus

DI is characterized by polyuria and polydipsia and is caused by defects in AVP action. Patients with central and nephrogenic DI and primary polydipsia present with polyuria and polydipsia. These entities can be differentiated by clinical evaluation, with measurements of AVP levels and response to a water deprivation test, followed by AVP administration (Table 9.6).[36]

WATER DEPRIVATION TEST

Test procedure: Water intake is restricted until the patient loses 3% to 5% of body weight or until three consecutive hourly determinations of urinary osmolality are within 10% of each other. (Caution must be exercised to ensure patient does not become excessively dehydrated.) Aqueous vasopressin is given as 5 units subcutaneously, and urinary osmolality is measured after 60 minutes. Expected responses are outlined in Table 9.6.

BOX 9.2 Causes of Central Diabetes Insipidus

Congenital Causes
- Autosomal dominant
- Autosomal recessive

Acquired Causes
- *Posttraumatic*
- *Iatrogenic (postsurgical)*
- *Tumors (metastatic from breast, craniopharyngioma, pinealoma)*
- *Histiocytosis*
- Granuloma (tuberculosis, sarcoid)
- Aneurysm
- Meningitis
- Encephalitis
- Guillain-Barré syndrome
- *Drugs*
- Idiopathic

Entries in italics are the most common causes.

Central diabetes insipidus

Clinical features. Central DI usually has an abrupt onset. Patients have a constant need to drink, have a predilection for cold water, and typically have nocturia. By contrast, the compulsive water drinker may give a vague history of the onset and has large variations in water intake and urine output. Nocturia is unusual in compulsive water drinkers. A serum osmolality of more than 295 mOsm/kg H_2O suggests central DI, and less than 270 mOsm/kg H_2O suggests compulsive water drinking.

Causes. Central DI is caused by infection, tumors, granuloma, and trauma affecting the CNS in 50% of patients; in the other 50% it is idiopathic (Box 9.2). In a survey of 79 children and young adults, central DI was idiopathic in half the patients. The other half had tumors or Langerhans cell histiocytosis; these patients had an 80% risk for development of anterior pituitary hormone deficiency compared with the patients with idiopathic disease.[5]

Autosomal dominant DI is caused by point mutations in a precursor gene for vasopressin that cause "misfolding" of the provasopressin peptide, preventing its release from the hypothalamic and posterior pituitary neurons.[5] Patients present with a mild polyuria and polydipsia in the first year of life. These children have normal physical and mental development. There is a rare autosomal recessive central DI associated with diabetes mellitus, optic atrophy, and deafness (Wolfram syndrome).[37] DI is usually partial with gradual onset in Wolfram syndrome. The defect resulting in Wolfram syndrome is linked to the *WFS1* gene, which encodes an endoplasmic reticulum membrane-embedded protein called wolframin that is expressed in pancreatic beta cells and neurons.

A rare clinical entity involving the combination of central DI and deficient thirst has been reported in approximately 100 patients. When vasopressin secretion and thirst are both impaired, affected patients are vulnerable to recurrent episodes of hypernatremia. Formerly called essential hypernatremia, the disorder is now called central DI with deficient thirst, or *adipsic* DI.[38]

Differential diagnosis. Under basal conditions, AVP levels are unhelpful because there is a significant overlap among the polyuric disorders. Measurement of circulating AVP or copeptin levels after a water deprivation test is more useful (see Table 9.6).

Treatment. Central DI is treated with hormone replacement or pharmacologic agents (Table 9.7). In acute settings, when renal water losses are extensive, DDAVP is the treatment of choice. For chronic central DI, desmopressin acetate is the agent of choice. It has a long half-life and none of the significant vasoconstrictive effects of aqueous AVP. DDAVP is administered at the dose of 10 to 20 μg intranasally every 12 to 24 hours. It is tolerated well, safe to use in pregnancy, and resistant to degradation by circulating vasopressinase. Oral DDAVP (0.1–0.8 mg every 12 hours) is available as second-line therapy. In patients with partial DI, in addition to DDAVP itself, agents that potentiate the release of AVP may be used, including chlorpropamide, clofibrate, and carbamazepine.

Congenital nephrogenic diabetes insipidus. Inherited forms of DI are caused by mutations in genes for V_2-receptors or AQP2.[5] These entities are discussed further in Chapter 49. Urine volumes are typically very high, and there is a risk for severe hypernatremia if patients do not have free access to water. Thus, patients must drink enough water to match urine output and prevent dehydration. Therapy for congenital nephrogenic DI is only partially effective and includes a thiazide diuretic, a very low salt diet, and indomethacin. Sildenafil improved urine concentration in a patient with congenital nephrogenic DI.[39] Simvastatin induces an increase in urine AQP2 and osmolality in hypercholesterolemic patients, suggesting that it may be useful in congenital nephrogenic DI.[39] Metformin results in a sustained increase in urine osmolality in rodent models of nephrogenic diabetes insipidus, but it has not been tested in patients.[39]

Acquired nephrogenic diabetes insipidus. Acquired nephrogenic DI is more common than congenital nephrogenic DI but rarely as severe. In patients with acquired nephrogenic DI, the ability to elaborate a maximal concentration of urine is impaired, but urine-concentrating mechanisms are partially preserved. For this reason, urine volumes are less than 3 to 4 L/day, which contrasts with the much higher volumes seen in patients with congenital or central DI or compulsive water drinking. Table 9.8 outlines the causes and mechanisms of acquired nephrogenic DI.

Chronic kidney disease. A defect in urine-concentrating ability may develop in patients with CKD of any etiology, but this defect is most prominent in tubulointerstitial diseases, particularly medullary cystic disease. (A complete discussion on the mechanisms of abnormalities in urine concentration and dilution in CKD can be found in Berl and Combs[13]). Disruption of inner medullary structures and diminished medullary concentration are thought to play a role; alterations in V_2 receptor and AQP2 expression also contribute (see Fig. 9.6). To achieve daily osmolar clearance, patients should be advised to maintain a fluid intake that matches their urine volume.

Electrolyte disorders. Hypokalemia causes a reversible abnormality in urine-concentrating ability. Hypokalemia stimulates water intake and reduces interstitial tonicity, which relates to the decreased Na^+-Cl^- reabsorption in the TAL. Hypokalemia resulting from diarrhea, chronic diuretic use, and primary aldosteronism also decreases intracellular cyclic adenosine monophosphate accumulation and causes a reduction in AVP-sensitive AQP2 expression (see Fig. 9.6).

Hypercalcemia also impairs urine-concentrating ability, resulting in mild polydipsia. The pathophysiologic mechanism is multifactorial and includes a reduction in medullary interstitial tonicity caused by decreased vasopressin-stimulated adenylyl cyclase in the TAL and a defect in adenylyl cyclase activity with decreased AQP2 expression in the collecting duct, mediated by the calcium-sensing receptor.[7]

Pharmacologic agents. Lithium is the most common cause of nephrogenic DI, occurring in up to 50% of patients receiving long-term lithium therapy. Lithium causes downregulation of AQP2 in the collecting duct; experimentally, it also increases cyclooxygenase-2 (COX-2) expression and urinary prostaglandins, which may contribute to the polyuria.[7] The concentrating defect of lithium may persist even when the drug is discontinued. The epithelial sodium channel (ENaC) is the entrance pathway for lithium into collecting duct principal cells. Amiloride inhibits lithium uptake through ENaC and has been used clinically to treat nephrogenic DI caused by lithium. Aldosterone administration dramatically increased urine production in experimental nephrogenic DI caused by lithium (an effect associated with decreased expression of AQP2 on luminal membranes of collecting duct), whereas administration of the mineralocorticoid receptor blocker spironolactone decreased urine output and increased AQP2 expression.[7] Clopidogrel, P2Y12-R purinergic receptor antagonist, ameliorates lithium-induced NDI in mice by increasing water and sodium reabsorption in the collecting duct.[39] It is not yet known if spironolactone or clopidogrel will be a useful treatment for lithium-induced nephrogenic DI in patients.

Other drugs impairing urine-concentrating ability include amphotericin, foscarnet, and demeclocycline, which reduce renal medullary adenylyl cyclase activity, thereby decreasing the effect of AVP on the collecting ducts.

Sickle cell anemia. Patients with sickle cell disease and trait often have a urine-concentrating defect. In the hypertonic medullary interstitium, the "sickled" red cells cause occlusion of the vasa recta and papillary damage. Although initially reversible, medullary infarcts

TABLE 9.7 Treatment of Central Diabetes Insipidus

Disease	Drug	Dose	Interval (hr)
Complete central diabetes insipidus	Desmopressin (DDAVP)	10–20 µg intranasally	12–24
	Desmopressin (DDAVP)	0.1–0.8 mg orally	Every 12
Partial central diabetes insipidus	Desmopressin (DDAVP)	10–20 µg intranasally	12–24
	Aqueous vasopressin	5–10 U subcutaneously	4–6
	Chlorpropamide	250–500 mg	24
	Clofibrate	500 mg	6 or 8
	Carbamazepine	400–600 mg	24

TABLE 9.8 Acquired Nephrogenic Diabetes Insipidus: Causes and Mechanisms

Disease State	Defect in Medullary Interstitial Tonicity	Defect in cAMP Generation	Downregulation of Aquaporin 2	Other

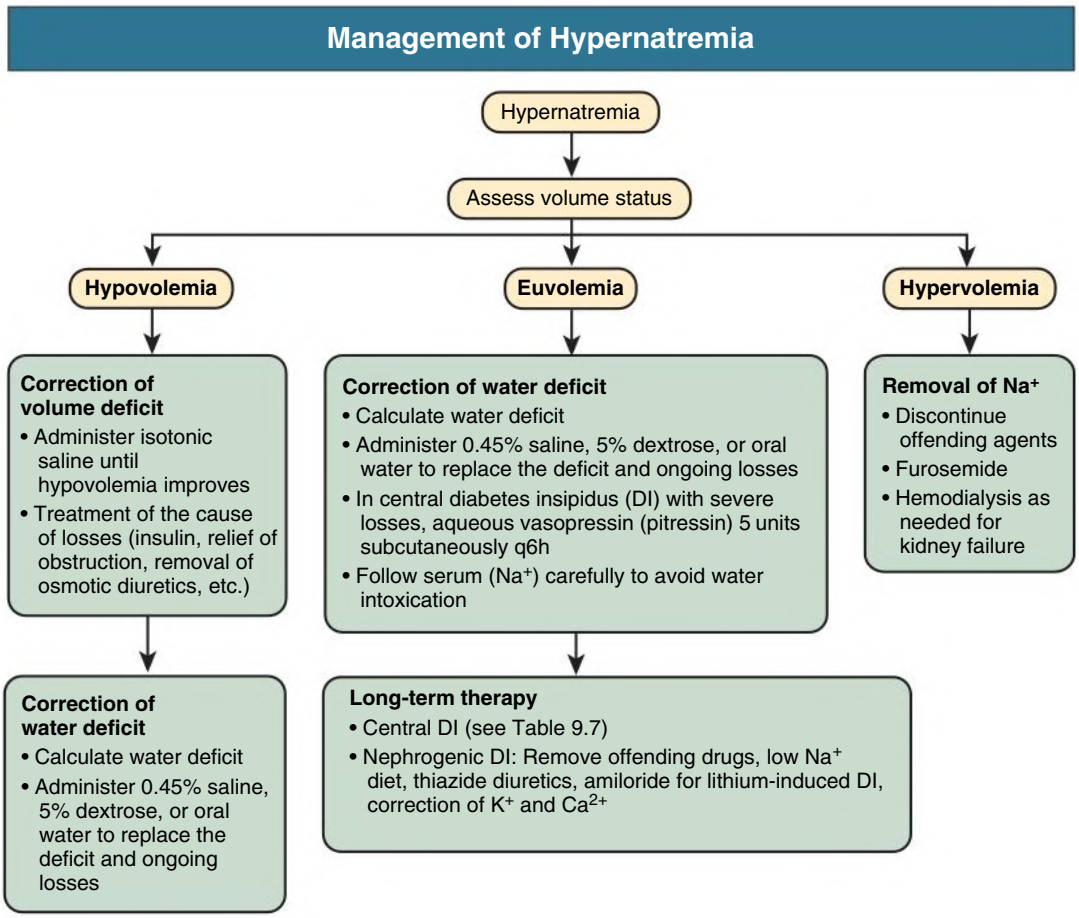

Fig. 9.11 Algorithm for management of the patient with hypernatremia. (Modified from Thurman JM, Berl T. Therapy of dysnatremic disorders. In: Wilcox CS, ed. *Therapy in Nephrology and Hypertension.* 3rd ed. Saunders; 2008:337–352.)

occur with sickle cell disease in the second to third decade of life, and even with sickle cell trait by the fourth to fifth decade, and the concentrating defects become irreversible.

Dietary abnormalities. Extensive water intake or a marked decrease in salt and protein intake leads to impairment of maximal urine-concentrating ability through a reduction in medullary interstitial tonicity. On a low-protein diet with excessive water intake, there is a decrease in vasopressin-stimulated osmotic water permeability that is reversed with feeding.

Gestational diabetes insipidus. In gestational DI, there is an increase in circulating vasopressinase, which is produced by the placenta. Patients are typically unresponsive to AVP but respond to desmopressin, which is resistant to vasopressinase.

Clinical Manifestations of Hypernatremia

Certain patients are at increased risk for development of severe hypernatremia (Box 9.3). Signs and symptoms mostly relate to the CNS and include altered mental status, lethargy, irritability, restlessness, seizures (usually in children), muscle twitching, hyperreflexia, and spasticity. Fever, nausea or vomiting, labored breathing, and intense thirst can also occur. In children, mortality of acute hypernatremia ranges from 10% to 70%; as many as two-thirds of survivors have neurologic sequelae. In contrast, mortality in patients with chronic hypernatremia is 10%.

In adults, serum [Na^+] greater than 160 mmol/L is associated with 75% mortality, although this may reflect associated comorbidities rather than hypernatremia. Chronic hypernatremia is independently associated with higher mortality in patients with CKD.[40] Patients presenting to the intensive care unit with a serum [Na^+] greater than 155 mmol/L have a significantly increased risk of mortality, with an odds ratio of 3.64.[41] Thus, both acute and chronic hypernatremia are associated with an increased risk of mortality.

BOX 9.3 Patient Groups at Risk for Development of Severe Hypernatremia

- Elderly patients
- Infants
- Hospitalized patients
  - Hypertonic infusions
  - Tube feedings
  - Osmotic diuretics
  - Lactulose
  - Mechanical ventilation
- High-risk patient groups
  - Altered mental status
  - Uncontrolled diabetes mellitus
- Underlying polyuric disorders

From Thurman JM, Berl T. Therapy of dysnatremic disorders. In: Wilcox CS, ed. *Therapy in Nephrology and Hypertension.* 3rd ed. Philadelphia: Elsevier; 2008:337–352.

Treatment of Hypernatremia

Hypernatremia occurs in predictable clinical settings, allowing opportunities for prevention. Elderly and hospitalized patients are at high

risk because of impaired thirst and inability to access free water independently.[42] Certain clinical situations, such as recovery from AKI, catabolic states, therapy with hypertonic solutions, uncontrolled diabetes, and burns, should prompt close attention to serum sodium concentration and increased administration of free water.

Hypernatremia always reflects a hyperosmolar state. The primary goal in the treatment of these patients is the restoration of serum tonicity. Fig. 9.11 outlines specific management options.[12] Because restoration of volume takes precedence over restoration of tonicity, in hypovolemic hypernatremic patients, sodium-containing solutions should be used until euvolemia is achieved. Thereafter, dextrose in water or oral water intake should be given to decrease serum sodium concentration.

The rapidity with which hypernatremia should be corrected is controversial. Some animal studies and case series in pediatric patients suggest that a correction rate of more than 0.5 mmol/L/hr in $[Na^+]$ can cause seizures. Cerebral edema also can be caused by rapid correction of hypernatremia by the net movement of water into the brain. Most clinicians believe that even in adults, correction should be achieved during 48 hours at a rate no greater than 2 mmol/L/hr, but the current maximum rate for correction in adults has not been definitively established because there are no reports of cerebral edema with rapid correction in this population. One study in a population of chronically hypernatremic patients showed that there was no difference in 30-day mortality between rapid correction (>12 mmol/L/day) versus less than 12 mmol/L/day, so a more rapid correction could potentially be a safe option.[43]

SELF-ASSESSMENT QUESTIONS

1. A 78-year-old woman sustained a stroke and is receiving enteral nutrition by nasoduodenal tube at a nursing home. She is transferred to the hospital with altered mental status. Nursing home staff reported that she had plentiful urine output 2 days before transfer. Laboratory data on hospital arrival reveal serum sodium of 165 mmol/L, blood urea nitrogen (BUN) 60 mg/dL, and creatinine 1.6 mg/dL; all were normal 6 weeks earlier. Additional laboratory data include serum osmolality of 341 mOsm/kg and urine osmolality 690 mOsm/kg, urine sodium 7 mmol/L, and urine potassium 32 mmol/L. The most likely explanation for this patient's polyuria and hypernatremia and the most appropriate confirmatory test are:

A. Nephrogenic diabetes insipidus and measurement of ADH.
B. Central diabetes insipidus and measurement of ADH.
C. Lithium toxicity and measurement of serum lithium level.
D. Increased solute load and measurement of electrolyte-free water clearance.

2. A 71-year-old woman with a history of coronary artery disease and mild hypertension is seen in the clinic. She is free of symptoms. Her medications include lisinopril (20 mg/day), occasional zolpidem tartrate (Ambien), and multivitamins. Her blood pressure is 140/95 mm Hg, weight 62 kg, and skin turgor normal. Examination reveals no evidence of edema or ascites. Laboratory results are as follows:

- Serum creatinine: 0.9 mg/dL.
- Sodium: 120 mmol/L.
- Potassium: 3.9 mmol/L.
- Chloride: 95 mmol/L.
- HCO_3^-: 22 mmol/L.
- U_{osm}: 686 mOsm/kg.
- U_{Na}: 127 mmol/L.
- Normal thyroid and adrenal function.
- Chest radiograph unremarkable.

Which of the following statements explains this patient's status?

A. Patient is unlikely to have improved water excretion because she is not taking a thiazide diuretic.
B. Patient probably has idiopathic SIADH.
C. The hyponatremia is probably a consequence of poor solute intake.
D. Patient's hyponatremia is caused by age-related decrements in vasopressin metabolism.

3. A 74-year-old man with a history of heart failure is admitted with increasing shortness of breath. He is treated with lisinopril 20 mg/day, hydrochlorothiazide (HCTZ) 50 mg/day, and digoxin 0.25 mg/day. Examination reveals blood pressure of 145/90 mm Hg, pulse rate 88/min, respiratory rate 24/min, and O_2 saturation 90% on 2 L. His electrolytes are normal. The patient is prescribed a low-sodium restricted diet, furosemide 40 mg twice daily, and fluid restriction. In the next 24 hours, he excretes 2.5 L of urine. Laboratory results are as follows:

- Serum creatinine: 1.8 mg/dL.
- BUN: 25 mg/dL.
- Sodium: 147 mmol/L.
- Potassium: 3.7 mmol/L.
- HCO_3^-: 26 mmol/L.
- Chloride: 120 mmol/L.
- U_{osm}: 392 mOsm/kg.
- U_{Na}: 59 mmol/L.
- U_K: 32 mmol/L.

Which of the following treatment regimens is most likely to prevent worsening of this patient's hypernatremia?

A. 1 mL of half-normal per milliliter of urine.
B. 0.5 mL of 5% dextrose in water per milliliter of urine.
C. 0.5 mL of normal saline per milliliter of urine.
D. 0.5 mL of normal saline per milliliter of urine.

Disorders of Potassium Metabolism

I. David Weiner, Stuart L. Linas, Charles S. Wingo

INTRODUCTION

Potassium disorders are some of the most frequently encountered fluid and electrolyte abnormalities in clinical medicine. Patients with disorders of potassium metabolism may be asymptomatic, or they may have symptoms ranging from mild weakness to sudden death. An abnormal serum potassium level, once verified, should be promptly addressed, but inappropriate treatment can worsen symptoms and even lead to death.

NORMAL PHYSIOLOGY OF POTASSIUM METABOLISM

Potassium Intake

Potassium is necessary for essentially all cellular functions, is present in most foods, and is excreted primarily by the kidney. The typical Western diet provides about 70 mmol of potassium daily, even though the recommended intake for people with normal renal function is closer to 120 mmol per day.[1] The gastrointestinal (GI) tract efficiently absorbs potassium, and total dietary potassium intake depends on the composition of the diet. Table 10.1 shows the potassium content of several foods high in potassium.

Potassium Distribution

After absorption from the GI tract, potassium distributes rapidly into the extracellular fluid (ECF) and intracellular fluid (ICF) compartments. Cellular potassium uptake is rapid and limits the magnitude of changes in serum potassium concentration. During potassium deficiency, shift of potassium from intracellular to extracellular compartments limits the change in extracellular potassium concentration.

Most body potassium is intracellular, with only 1% to 2% in the ECF. Potassium is the major intracellular cation, with cytosolic K^+ concentrations about 100 to 120 mmol/L. Total intracellular K^+ content is 3000 to 3500 mmol in healthy adults and is found primarily in muscle (70%), with a lesser amount in bone, red blood cells, liver, and skin (Table 10.2). The electrogenic sodium pump, Na^+,K^+-ATPase, is the primary effector of this asymmetric potassium distribution: It transports two potassium ions into cells and extrudes three sodium ions, which results in high intracellular potassium concentration (high $[K^+_i]$) and low intracellular sodium concentration (low $[Na^+_i]$). Potassium-selective ion channels are the predominant determinant of the resting membrane potential. Therefore, the intracellular/extracellular $[K^+]$ ratio largely determines the resting cell membrane potential and the intracellular electronegativity. Maintenance of this ratio and membrane potential is critical for normal nerve conduction and muscular contraction.

Under some conditions, the normal distribution of potassium between the extracellular and intracellular pools is altered (Fig. 10.1). Plasma osmolality, several hormones, and exercise are frequent causes of potassium shifts. Because the amount of extracellular K^+ relative to intracellular K^+ is low, modest net movement of K^+ into or out of the extracellular pool can result in substantial changes in extracellular K^+ concentration.

Several hormones, most prominently catecholamines, insulin, and aldosterone, have important roles in regulating serum K^+. The effect of catecholamines differs depending on which adrenergic receptor subtype they activate. Activation of β_2-adrenergic receptors stimulates Na^+,K^+-ATPase, inducing cellular potassium uptake and decreasing serum K^+, whereas α_1-adrenergic receptor activation has the opposite effect. Thus, drugs that block the β_2-adrenoreceptor tend to increase serum K^+, and those that block the α_1-adrenoreceptor tend to lower serum K^+.

Insulin has important effects on serum K^+. It activates Na^+,K^+-ATPase, directly increasing cellular K^+ uptake and decreasing serum K^+. This effect is rapid and enables insulin administration to be a component of the acute therapy of hyperkalemia. Importantly, insulin stimulates Na^+,K^+-ATPase through a mechanism that is distinct from its stimulation of glucose entry and does not involve effects on either α- or β-adrenoreceptors. Thus, the effects of insulin and β_2-adrenoceptor activation are additive. In people with diabetes, hyperglycemia resulting from either the lack of adequate insulin release or responsiveness leads to hyperosmolality, which can also induce cellular potassium shifts (see later).

Aldosterone regulates serum potassium in part by altering the distribution of potassium between ECF and ICF by enhancing cellular potassium uptake through stimulation of Na^+,K^+-ATPase.[2] Indeed, aldosterone administration can cause hypokalemia in the absence of altered potassium balance through mechanisms involving altered cellular K^+ distribution.[2,3] Pharmacologic inhibition of aldosterone action with mineralocorticoid receptor blockers (MRBs) can cause hyperkalemia.

Serum osmolality is another important factor that alters cellular potassium distribution. Hyperosmolality can cause hyperkalemia when it is the result of "effective osmoles," such as mannitol or persistent hyperglycemia in the absence of adequate insulin and/or insulin responsiveness. The likely mechanism is that the increased serum osmolality induces water movement out of the cells, decreasing cell volume and increasing intracellular $[K^+]$, which stimulates K^+-permeable channels and increases K^+ movement out of cells. Urea in patients with high blood urea nitrogen (BUN) levels is an "ineffective osmole" because it rapidly crosses plasma membranes and thus does not alter cell volume. Administering glucose to a nondiabetic patient, because it stimulates insulin secretion, can actually stimulate insulin-induced cellular potassium uptake and decrease serum K^+.

Exercise has multiple effects on K^+. Cellular K^+ release is required for repolarization of contracting skeletal muscle cells and can result in mild

TABLE 10.1 Select Foods With High Potassium Content

Food	Portion Size	K^+ (mmol)
Artichoke, boiled	1, medium	27
Avocado	1, medium	38
Banana	Medium	12
Cantaloupe, cut up	1 cup	13
Grapefruit juice	8 oz	10
Hamburger, lean	8 oz	18
Milk	8 oz	10
Orange juice	8 oz	12
Potato, baked	7 oz	22
Prunes	10	16
Raisins	⅔ cup	19
Sirloin steak	8 oz	23
Squash	1 cup	15–20
Tomato juice	6 oz	10
Tomato paste	½ cup	31

TABLE 10.2 Distribution of Total Body Potassium in Organs and Body Compartments

Organ/Fluid	Total K^+ Amount	Body Compartment	K^+ Concentration
Muscle	2650 mmol	Intracellular fluid	100–120 mmol/L
Liver	250 mmol	Extracellular fluid	~4 mmol/L
Interstitial fluid	35 mmol		
Red blood cells	350 mmol		
Plasma	15 mmol		

hyperkalemia during strenuous physical exercise. Catecholamines released during exercise can contribute to this hyperkalemia because α_1-adrenergic receptor activation shifts potassium out of cells. The local increase in extracellular potassium induces arterial dilation in normal blood vessels, which increases skeletal muscle blood flow and acts as an adaptive mechanism during exercise. The skeletal muscle interstitial acidosis associated with intense exercise may also contribute to K^+ release.[4] Catecholamines released during exercise, however, also activate β_2-adrenoceptors, which stimulates skeletal muscle cellular potassium uptake and minimizes the severity of exercise-induced hyperkalemia and can also lead to hypokalemia after cessation of exercise. With preexisting potassium depletion, postexercise hypokalemia may be severe and can cause rhabdomyolysis.[5]

Metabolic acidosis is often associated with abnormal serum potassium. Although hyperkalemia may be seen with lactic acidosis, this may be because of tissue ischemia leading to cellular death and cytoplasmic K^+ release. In diabetic ketoacidosis, the hyperglycemia and insulin deficiency are likely the primary mechanisms of the associated hyperkalemia. In type 4 renal tubular acidosis (RTA), hyperkalemia contributes to the metabolic acidosis by inhibiting net acid excretion in the form of ammonium.[6]

Renal Potassium Handling With Normal Kidney Function

Long-term potassium homeostasis occurs primarily through changes in renal potassium excretion. Serum potassium is almost completely

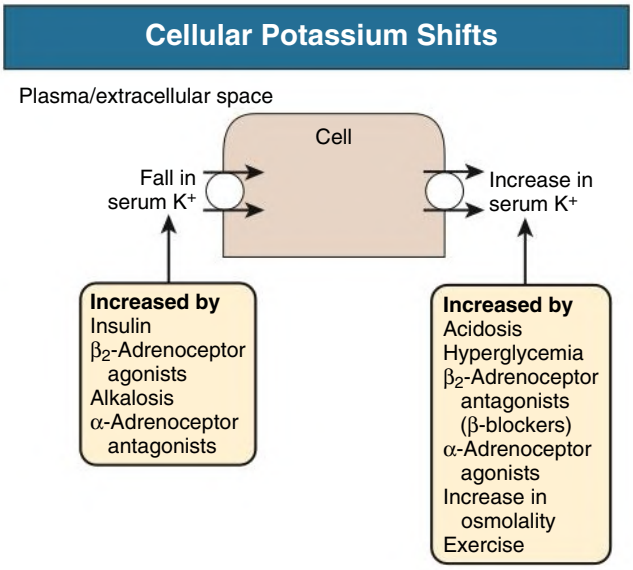

Fig. 10.1 Regulation of extracellular/intracellular potassium shifts.

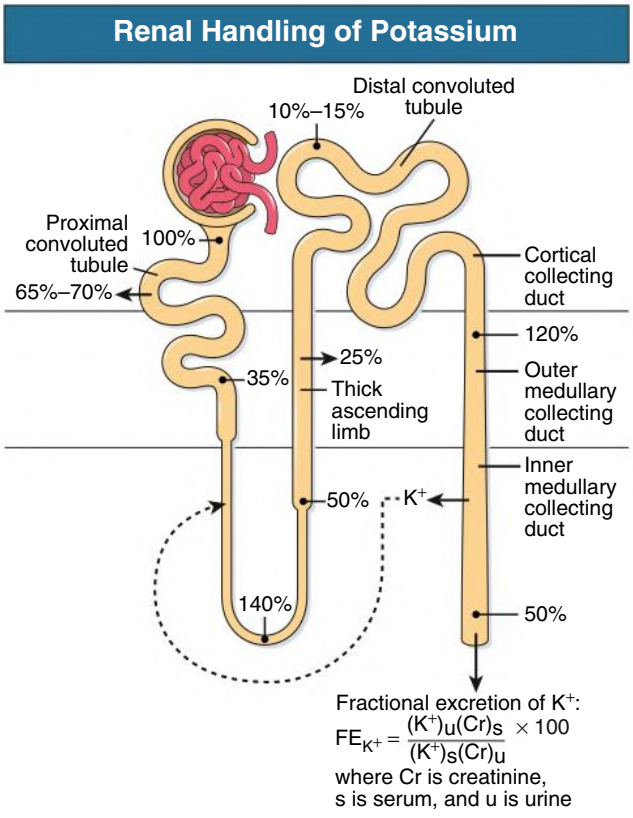

Fig. 10.2 Renal handling of potassium.

ionized, is not bound to plasma proteins, and is filtered efficiently by the glomerulus (Fig. 10.2). The proximal tubule reabsorbs the majority (~65%–70%) of filtered potassium, but there is relatively little variation in proximal tubule potassium reabsorption in response to hypokalemia or hyperkalemia. In the loop of Henle, potassium is secreted in the descending loop, at least in deep nephrons, particularly with adaptation to a large K^+ intake, and is reabsorbed in the ascending loop through the action of the Na^+-K^+-$2Cl^-$ cotransporter (Fig. 10.3A). However, most K^+ transported by this protein is recycled back into the tubular lumen through an apical K^+ channel, and thus there is little net

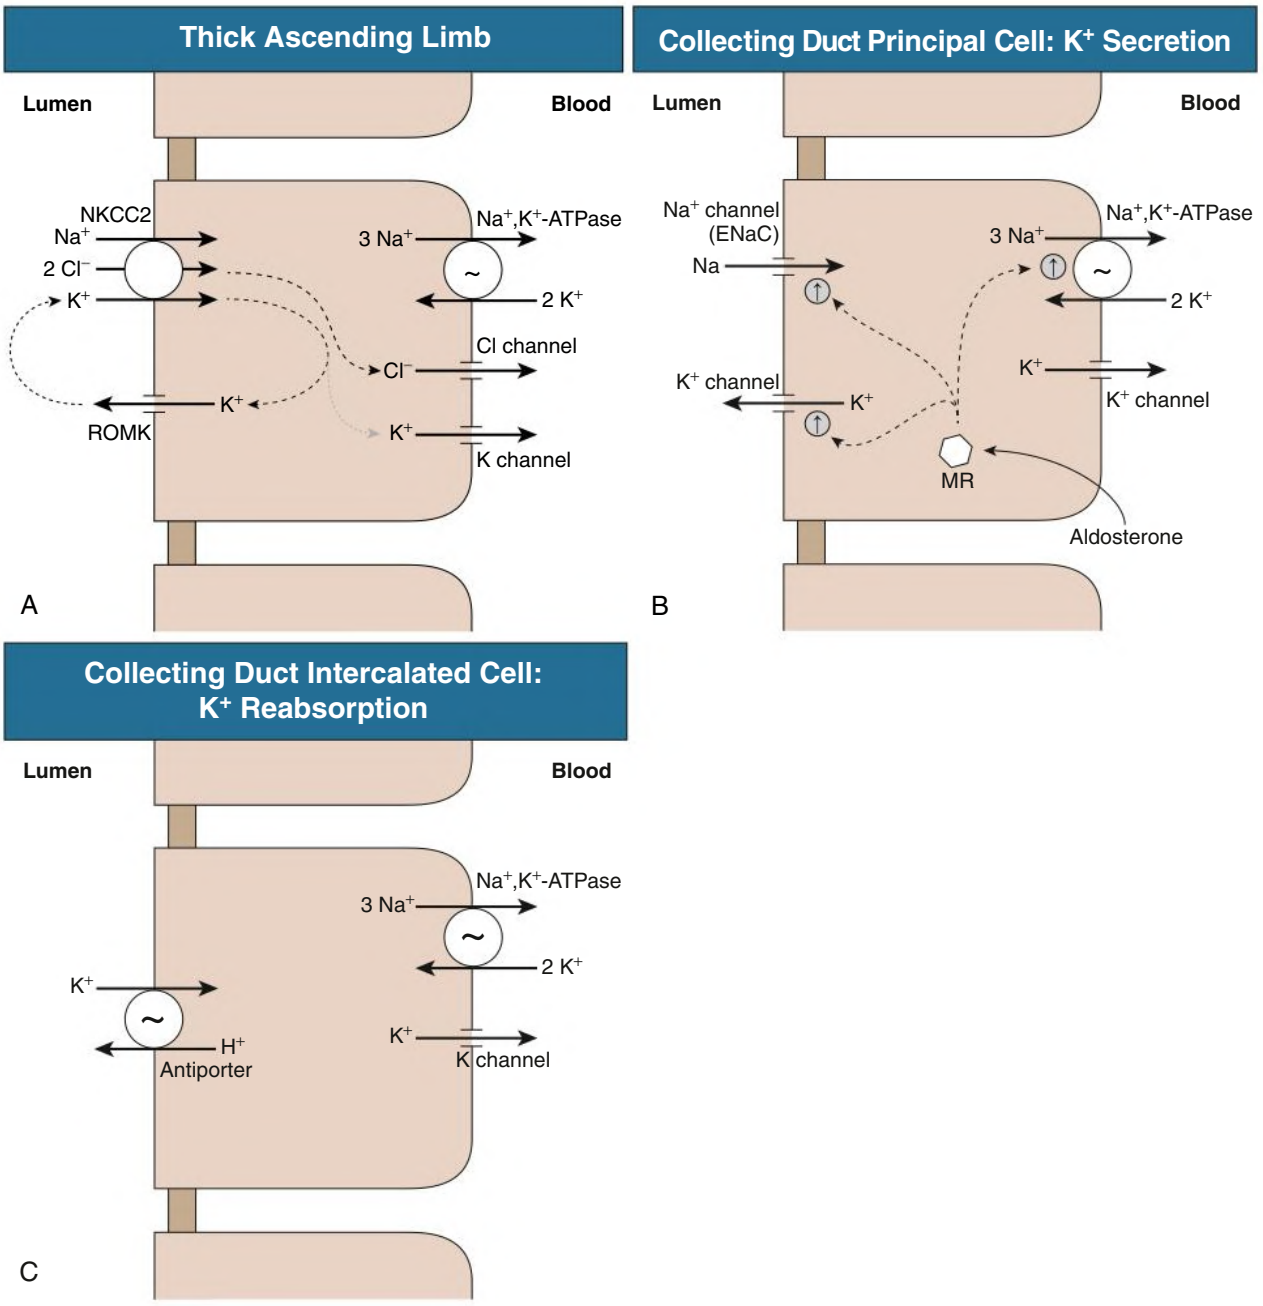

Fig. 10.3 Mechanisms of Potassium Reabsorption and Secretion. Potassium transport in the thick ascending limb of Henle loop (TAL) and in the collecting tubule principal and intercalated cells. (A) In the TAL, the majority of K^+ reabsorbed by the apical Na+,K^+-$2Cl^-$ cotransporter (NKCC2) recycles across the apical membrane through apical renal outer medulla K^+ (ROMK) channel. (B) In the cortical collecting duct principal cell, K^+ secretion involves integrated functions of the basolateral Na^+, K^+-ATPase, apical Na^+ channel (ENaC), and apical K^+ channel. Aldosterone stimulates this process through interaction with the mineralocorticoid receptor (MR), resulting in increased expression and activity of each of these processes. Although cortisol can also activate MR, the enzyme 11β-hydroxysteroid dehydrogenase type 2, which is present in the principal cell, converts cortisol to cortisone, a steroid hormone that does not activate MR. (C) Collecting duct intercalated cells can reabsorb K^+ through the actions of an apical H^+-K^+-ATPase.

potassium reabsorption. This absorption can be reversed to secretion by administration of a loop diuretic or by substantial potassium loading. Nonetheless, the magnitude of the change in loop of Henle potassium transport in various physiologic conditions is relatively small.

The collecting duct and its proximal extension, the initial collecting tubule, are the primary sites where the kidney regulates K^+ excretion. These segments have the ability both to secrete K^+, enabling adaptation to K^+ excess states, and to reabsorb K^+, enabling adaptation to K^+ depletion states. The principal cell of the cortical collecting duct secretes potassium, whereas intercalated cells throughout the entire collecting duct reabsorb potassium. In the principal cell, sodium is reabsorbed through the apical epithelial sodium channel (ENaC), which stimulates basolateral Na^+,K^+-ATPase (see Fig. 10.3B); active potassium uptake by this protein maintains a high intracellular K^+.

After basolateral potassium uptake, K^+ is secreted into the luminal fluid by two types of potassium channels and by KCl cotransporters. Intercalated cells actively reabsorb potassium through an apical H^+-K^+-ATPase[7] (Fig. 10.3C); this protein actively secretes H^+ into the luminal fluid in exchange for reabsorption of luminal potassium. The presence of two separate potassium transport processes, secretion by principal cells and reabsorption by intercalated cells, contributes to rapid and effective regulation of renal potassium excretion.

Several factors influence principal cell potassium secretion. These include luminal flow rate, distal sodium delivery, aldosterone, extracellular potassium intake, and extracellular pH. Luminal flow rate and distal sodium delivery frequently vary together, but changes in luminal flow rate appear more important by activating flow-induced K^+ secretion through large conductance (BK) potassium channels.[8,9] Reduced luminal flow, such as occurs in prerenal azotemia and in obstructive uropathy, may contribute to the hyperkalemia that is often seen in these conditions. Decreased sodium reabsorption, whether from reduced luminal sodium delivery or treatment with ENaC inhibitors (i.e., potassium-sparing diuretics), decreases K^+ secretion by altering electrochemical forces for K^+ secretion. Conversely, increased sodium delivery to the collecting duct, as may occur with a high salt diet or with administration of either loop or thiazide diuretics, increases principal cell sodium reabsorption and causes a secondary increase in potassium secretion. Aldosterone has many effects that increase principal cell potassium secretion, including increased Na^+,K^+-ATPase, increased apical expression of ENaC, and increased apical K^+ channels. The net effect is increased principal cell-mediated K^+ secretion. Changes in extracellular potassium directly alter Na^+,K^+-ATPase activity, thereby altering K^+ secretion. Metabolic acidosis decreases K^+ secretion, both through direct effects on potassium channels and through changes in interstitial ammonia concentration, which decreases K^+ secretion.[10]

Intercalated cell-mediated potassium reabsorption occurs in parallel with principal cell-mediated potassium secretion. Active potassium reabsorption occurs through the action of the potassium-reabsorbing protein, H^+-K^+-ATPase. The major factors regulating H^+-K^+-ATPase expression and activity include potassium balance, aldosterone, and acid-base status. Potassium depletion increases H^+-K^+-ATPase expression, resulting in increased active potassium reabsorption and decreased net potassium excretion. Aldosterone increases H^+-K^+-ATPase expression and activity and, by decreasing net potassium excretion, may minimize changes in urinary potassium excretion during aldosterone excess that otherwise would lead to more severe hypokalemia. Metabolic acidosis has both direct and indirect effects, mediated through alterations in ammonia metabolism, that increase H^+-K^+-ATPase potassium reabsorption.[6]

Regulators of renal K^+ transport in the distal nephron include the "with no lysine" (WNK) kinases.[11,12] Under basal conditions, WNK kinases activate Na^+ reabsorption in the distal convoluted tubule and inhibit the renal outer medulla potassium (ROMK) channel. This combination of effects—increased DCT Na^+ reabsorption, which decreases collecting duct Na^+ delivery, in conjunction with decreased ROMK expression—promotes decreased K^+ secretion. The specific mechanisms through which WNK regulates K^+ secretion are under active investigation, and medications targeting WNK inhibition are in development and may in the future enable entirely new treatments of hypertension and K^+ disorders.[13]

The intestinal tract also contributes to renal potassium homeostasis. Potassium sensors, present in either the intestinal tract or the portal venous system, elicit a rapid increase in renal potassium excretion through mechanisms independent of serum potassium and aldosterone.[2,14] This reflex system, which is still not understood fully, supplies a mechanism to "sense" dietary potassium intake and alter renal potassium excretion without involving aldosterone concentration and prior to changes in serum potassium. This mechanism contributes to the greater safety of oral compared with intravenous (IV) potassium administration.

The contribution of the intestinal tract to K^+ excretion in fecal contents is unclear. An early study suggested stool potassium averaged 12% of dietary intake in normal subjects and 34% in patients with severe renal insufficiency.[15] In contrast, a study examining anephric patients showed fecal K^+ excretion averaged approximately 3 mEq/day, which did not differ from that observed in control patients with intact renal function.[16] In this latter study, fecal K^+ excretion was not altered by either MRB therapy or mineralocorticoid agonists.[16]

Renal Potassium Handling in Chronic Kidney Disease

Because the kidneys are the major route for elimination of potassium, as kidney function declines, the balance between dietary potassium intake, renal potassium excretion, and baseline serum potassium changes. In general, most patients with chronic kidney disease (CKD) maintain their serum potassium in the normal range, although there is a graded increase in mean serum K^+ as the glomerular filtration rate (GFR) declines. The risk of developing hyperkalemia is increased in patients with stage 4 and 5 CKD; patients with stage 3 CKD who have diabetes mellitus, tubulointerstitial disease, or receive certain drugs also are at increased risk.

Many of the medications used in the treatment of patients with CKD alter potassium homeostasis. Common medications that predispose to hyperkalemia (Table 10.3) include agents that inhibit the epithelial Na channel (ENaC) or the renin-angiotensin-aldosterone system (RAAS), nonsteroidal antiinflammatory drugs (NSAIDs), and calcineurin inhibitors. Medications that can directly inhibit ENaC, such as amiloride, triamterene, trimethoprim, and pentamidine, acutely reduce the rate of renal K^+ excretion and can cause hyperkalemia. Drugs that inhibit the RAAS, such as mineralocorticoid receptor blockers (MRBs), angiotensin receptor blockers (ARBs), and angiotensin-converting enzyme (ACE) inhibitors, direct renin inhibitors, and heparin can inhibit aldosterone's action or generation, which reduces renal K^+ excretion. Mineralocorticoid blockers are increasingly used in patients with CHF and with refractory hypertension and may slow the progression of CKD. NSAIDs that inhibit prostaglandin synthesis and β-blockers that inhibit renin release and catecholamine action can also increase the risk of hyperkalemia. In contrast, both loop and thiazide diuretics increase renal K^+ excretion and predispose to hypokalemia.

Patients with CKD generally tolerate hyperkalemia with fewer cardiac and electrocardiographic (ECG) abnormalities than do patients with normal kidney function, although the mechanism is incompletely understood. In particular, patients with CKD appear to tolerate serum $[K^+]$ of 5.0 to 5.5 mmol/L with no significant adverse effect, and levels of 5.5 to 6.0 mmol/L are associated with lower mortality than $[K^+]$ of 3.5 to 3.9 mmol/L.[17] Nevertheless, severe hyperkalemia (>6.0 mmol/L or presence of ECG changes) can be lethal and should be treated aggressively.

HYPOKALEMIA

Epidemiology

The incidence of potassium disorders depends greatly on the patient population. Less than 1% of adults with normal kidney function who are not receiving medications develop frank hypokalemia or hyperkalemia. However, diets with high sodium and low potassium content may lead to potassium depletion. Thus, hypokalemia or hyperkalemia suggests that either an underlying disease is present or that the

TABLE 10.3 Drugs Classes Associated With Hyperkalemia

Class	Mechanism	Examples
Potassium-containing drugs	Increased potassium intake	KCl, penicillin G, Na citrate, K citrate
β-Adrenergic receptor blockers (β-blockers)	Inhibit renin release	Propranolol, metoprolol, atenolol
ACE inhibitors	Inhibit conversion of angiotensin I to angiotensin II	Captopril, lisinopril
ARBs	Inhibit activation of AT_1 receptor by angiotensin II	Losartan, valsartan, irbesartan
Direct renin inhibitors	Inhibit renin activity, leading to decreased angiotensin II production	Aliskiren
Heparin	Inhibit aldosterone synthase, rate-limiting enzyme for aldosterone synthesis	Heparin sodium
Aldosterone receptor antagonists	Block aldosterone receptor activation	Spironolactone, eplerenone, finerenone
Potassium-sparing diuretics	Block collecting duct apical ENaC Na channel, decreasing gradient for K^+ secretion	Amiloride, triamterene; certain antibiotics, specifically trimethoprim and pentamidine
NSAIDs and COX-2 inhibitors	Inhibit prostaglandin stimulation of collecting duct K^+ secretion; inhibit renin release	Ibuprofen, diclofenac
Digitalis glycosides	Inhibit Na^+, K^+-ATPase necessary for collecting duct K^+ secretion and regulation of K^+ distribution into cells	Digoxin
Calcineurin inhibitors	Inhibit Na^+, K^+-ATPase necessary for collecting duct K^+ secretion	Cyclosporine, tacrolimus

ACE, Angiotensin-converting enzyme; *ARBs,* angiotensin receptor blockers; *COX,* cyclooxygenase; *ENaC,* epithelial sodium channel; *NSAIDs,* nonsteroidal antiinflammatory drugs.

individual is taking drugs that alter potassium handling. For example, hypokalemia may be present in as many as half of patients taking diuretics[18] and is present in many patients with primary or secondary hyperaldosteronism.

Clinical Manifestations

Potassium deficiency, because it alters the ratio of extracellular to intracellular potassium, alters the resting membrane potential, which can impair normal functioning of almost every cell in the body. Several studies have shown that hypokalemia, even when mild, is associated with increased long-term mortality. Overall, children and young adults tolerate hypokalemia better than elderly persons. Prompt correction is warranted in patients with coronary heart disease or in patients receiving digitalis glycosides because hypokalemia increases the risk of lethal cardiac arrhythmias.

Mortality

Several clinical studies have shown chronic hypokalemia is associated with increased mortality.[19–23] This association persists after extensive statistical analysis of confounding and associated factors. At present, whether correction of the abnormal K^+ alters the associated mortality is unknown. However, because treatment is generally well tolerated, targeting a serum/plasma K^+ of 4.0 mEq/L or greater is a reasonable goal.

Cardiovascular

Potassium deficiency increases blood pressure, salt-sensitive changes in BP, and the cardiac sensitivity to arrhythmias. Epidemiologic studies link hypokalemia and a low-potassium diet with an increased prevalence of hypertension, and experimental studies show hypokalemia increases blood pressure by 5 to 10 mm Hg and that potassium supplementation can lower blood pressure by a similar amount.[24] Potassium deficiency also increases the effect of dietary NaCl on blood pressure. This effect involves multiple mechanisms, including stimulating sodium retention and increasing intravascular volume and sensitizing the vasculature to endogenous vasoconstrictors.[24] In part, sodium retention is related to increased NCC- and ENaC-mediated sodium reabsorption in the distal convoluted tubule and cortical collecting duct, respectively.[25]

Hypokalemia also predisposes to arrhythmia, including ventricular tachycardia and ventricular fibrillation[26] and the risk of sudden cardiac death. Diuretic-induced hypokalemia is of particular concern because sudden cardiac death may occur more frequently in those treated with thiazide diuretics.[26] Ventricular arrhythmias are also more common in patients receiving digoxin who develop hypokalemia.

Hormonal

Hypokalemia impairs insulin release and induces insulin resistance, resulting in worsened glucose control in diabetic patients.[27] The insulin resistance that usually occurs with thiazide diuretic therapy is caused by endothelial dysfunction mediated by thiazide-induced hypokalemia and hyperuricemia.[28]

Muscular

Hypokalemia can lead to skeletal muscle weakness and to an increased risk of exertion-related rhabdomyolysis. Hypokalemia hyperpolarizes skeletal muscle cells, thereby impairing the ability to generate the action potential needed for muscle contraction. Hypokalemia also reduces skeletal muscle blood flow, possibly by impairing local nitric oxide release; this effect can predispose patients to rhabdomyolysis during vigorous exercise.[29] Severe hypokalemia can also lead to respiratory muscle weakness and, if severe, respiratory failure.

Kidney Related

Hypokalemia leads to several important disturbances of kidney function. Reduced medullary blood flow and increased renal vascular resistance may predispose to hypertension, tubulointerstitial and cystic changes, alterations in acid-base balance, and impairment of urinary concentrating mechanisms.

Potassium depletion causes tubulointerstitial fibrosis that is generally greatest in the outer medulla. The degree of reversibility is related to the duration of hypokalemia, and if prolonged, hypokalemia may result in kidney failure. Experimental studies suggest an increased risk for irreversible kidney injury when hypokalemia is present during the neonatal period.[30] Longstanding potassium depletion also causes kidney hypertrophy and predisposes to kidney cyst formation, particularly when there is increased mineralocorticoid activity.

Metabolic alkalosis is a common acid-base consequence of severe potassium depletion. It results primarily from increased net acid excretion caused by increased potassium reabsorption and proton excretion in the collecting tubule as well as enhanced ammonia excretion, in combination in stimulation of proximal tubule bicarbonate reabsorption.[31]

Severe hypokalemia can cause mild polyuria, typically 2 to 3 L/day. Both increased thirst and mild nephrogenic diabetes insipidus contribute to the polyuria.[32] The nephrogenic diabetes insipidus is caused by decreased expression of several proteins, such as the water transporter aquaporin 2 (AQP2), and the urea transporters (UT)-A1, UT-A3, and UT-B, which are involved in urine concentration and water reabsorption.

Hypokalemia increases both ammonia production and expression of collecting duct proteins involved in ammonia secretion. This leads to increased ammonia excretion in the urine, increasing net acid excretion and leading to development of metabolic alkalosis. In addition, there is increased ammonia to the renal veins, from where it is added to the systemic circulation. In patients with acute or chronic liver disease, this increased ammonia delivery may exceed hepatic ammonia clearance, increase plasma ammonia levels and either precipitate or worsen hepatic encephalopathy.[6]

Etiology

Hypokalemia results typically from one of four etiologies: pseudohypokalemia, redistribution, extrarenal potassium loss, or urinary potassium loss; multiple etiologies may coexist in a specific patient.

Pseudohypokalemia

Pseudohypokalemia refers to the condition in which serum potassium decreases, artifactually, after phlebotomy. The most common cause is acute leukemia; the large numbers of abnormal leukocytes take up potassium when the blood is stored in a collection vial for prolonged periods at room temperature. Rapid separation of plasma and storage at 4°C is used to confirm this diagnosis. If confirmed, only plasma potassium measurements, and not serum levels, should be used for subsequent clinical decision making to avoid this artifact leading to inappropriate treatment.

Redistribution

Because less than 2% of total body potassium is in the ECF compartment, quantitatively small potassium shifts from the ECF to the ICF compartment can cause substantial hypokalemia. A chronic increase in aldosterone secretion increases the pump-leak kinetics and reduces plasma K^+ in the absence of perceptible increases in urinary K^+ excretion if intake is constant.

A clinically rare, but dramatic, cause of redistribution-induced hypokalemia is *hypokalemic periodic paralysis.* In this condition, acute and severe hypokalemia resulting from redistribution leads to flaccid paralysis or severe muscular weakness. It occurs typically during the night or the early morning, or after a carbohydrate-rich meal, and can persist for 6 to 24 hours. A genetic defect in a dihydropyridine-sensitive calcium channel has been identified in some patients, whereas other cases are associated with hyperthyroidism. Aggressive potassium administration during the attack is necessary to speed recovery and avoid the risk of respiratory failure.

Nonrenal Potassium Loss

The skin and the GI tract excrete small amounts of potassium under normal circumstances. Occasionally, excessive sweating or chronic diarrhea results in substantial potassium loss and leads to hypokalemia.[33] Vomiting or nasogastric suction may also result in loss of potassium, although gastric fluids typically contain only 5 to 8 mmol/L of potassium. The concomitant metabolic alkalosis, however, can increase urinary potassium loss and contribute to development of hypokalemia.[34]

Renal Potassium Loss

The most common cause of hypokalemia is urinary potassium loss, which typically results from drugs, endogenous hormone production, or, more rarely, intrinsic kidney defects.

Drugs. Both thiazide and loop diuretics increase urinary potassium excretion, and the incidence of diuretic-induced hypokalemia is related to both dose and treatment duration. When loop and thiazide diuretics are dosed to produce similar effects on sodium excretion, thiazide diuretics have greater effects on urinary potassium and are more likely to lead to hypokalemia. Some penicillin analogs, such as piperacillin/tazobactam, increase distal tubular delivery of a nonreabsorbable anion, which obligates the presence of a cation such as potassium and thereby increases urinary potassium excretion.[35] The antifungal agent amphotericin B directly increases collecting duct potassium secretion. Aminoglycosides may cause hypokalemia either with or without simultaneous nephrotoxicity. The mechanism is incompletely understood but may relate to magnesium depletion (see later discussion). Cisplatin is an antineoplastic agent that can induce hypokalemia from renal potassium wasting; the increased potassium excretion may persist after discontinuation of the medication. Toluene exposure, from sniffing certain glues, can cause potassium wasting, leading to hypokalemia.[36] In addition, certain herbal products, including herbal cough mixtures, licorice tea, licorice root, and gan cao, contain glycyrrhizic and glycyrrhetinic acids, which have mineralocorticoid-like effects.[37]

Endogenous hormones. Aldosterone is an important hormone regulating total body potassium homeostasis. Aldosterone predominantly causes hypokalemia by stimulating cellular potassium uptake,[2] but it can also lead to inappropriately high urinary potassium excretion during, and likely contributing to, hypokalemia.

Genetic causes. Genetic defects leading to excessive aldosterone production and resulting in hypokalemia is occasionally seen (see Chapter 49). These conditions include glucocorticoid-remediable aldosteronism, congenital adrenal hyperplasia, and apparent mineralocorticoid excess. These conditions are discussed in detail in Chapter 49.

Magnesium depletion. Magnesium deficiency can cause inappropriately high potassium excretion despite hypokalemia.[38] This appears to occur because intracellular magnesium inhibits the apical ROMK channels that are critical for distal nephron K^+ secretion. In magnesium deficiency, decreased intracellular magnesium reduces the magnesium-mediated inhibition of ROMK channels, leading to increased ROMK-mediated K^+ secretion and thereby to increased net K^+ secretion.[39] Magnesium deficiency occurs most often as a complication of prolonged diuretic use or from proton pump inhibitor (PPI) therapy. It may also result from ethanol abuse, uncontrolled diabetes mellitus, and after solid organ transplant. Magnesium deficiency should be suspected when potassium replacement does not correct hypokalemia; treatment of the underlying cause of hypomagnesemia, such as discontinuation of PPI agents, generally reverses the potassium wasting.

Primary renal defect. Intrinsic renal potassium transport defects leading to hypokalemia are rare. They include *Bartter syndrome* and *Gitelman syndrome,* which have clinical phenotypes similar to those that follow use of loop and thiazide diuretics, respectively, and *Liddle syndrome.* These are discussed in Chapter 49.

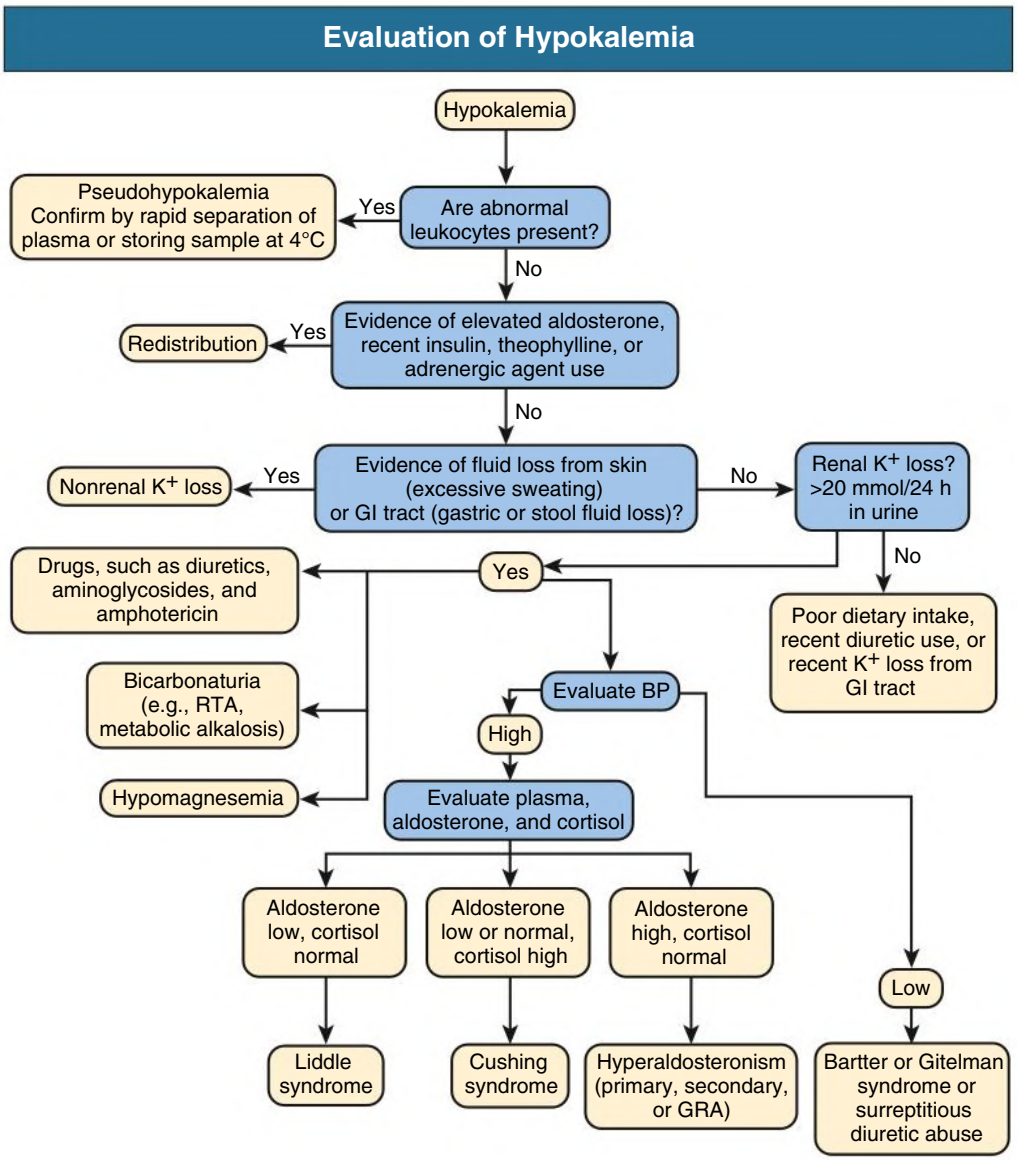

Fig. 10.4 Diagnostic evaluation of hypokalemia. *BP*, Blood pressure; *GI*, gastrointestinal; *GRA*, glucocorticoid-remediable aldosteronism; *RTA*, renal tubular acidosis.

Bicarbonaturia. Bicarbonaturia can result from metabolic alkalosis, distal renal tubular acidosis, or treatment of proximal renal tubular acidosis. In each case, the increased distal tubular bicarbonate delivery increases potassium secretion.

Diagnostic Evaluation

The evaluation of hypokalemia is summarized in Fig. 10.4. The clinician should first exclude pseudohypokalemia or potassium redistribution from the extracellular to the intracellular space. Insulin, aldosterone, fludrocortisone, and sympathomimetic agents, such as theophylline and β_2-adrenoceptor agonists, are common causes of potassium redistribution. In the hypertensive patient, hypokalemia in the absence of diuretic use suggests primary aldosteronism diuretic use suggests primary aldosteronis, for which specific testing is appropriate (see Chapter 49).

If neither pseudohypokalemia nor potassium redistribution is present, hypokalemia indicates that total body potassium depletion caused by either renal, GI, or skin losses is present. Urinary potassium loss is caused most often by diuretics. Hypomagnesemia can also cause potassium wasting and frequently results from loop or thiazide diuretic use. Less common causes of renal potassium loss include proximal and distal RTA, diabetic ketoacidosis, and ureterosigmoidostomy. Primary aldosteronism should be considered in the patient who also has hypertension. Less commonly, surreptitious diuretic use or vomiting, laxative abuse, and genetic causes such as Bartter or Gitelman syndrome should be considered when the cause of the hypokalemia is not obvious. Excessive potassium loss may also result from skin losses from excessive sweating or from the GI tract from diarrhea, vomiting, nasogastric suction, or GI fistula. Occasionally, patients are reluctant to admit to self-induced diarrhea, and the diagnosis may need to be confirmed by direct testing of the stool for cathartic agents.

Treatment

Primary short-term risks of hypokalemia are cardiovascular arrhythmias and neuromuscular weakness. Overly rapid therapy can cause acute hyperkalemia, which can cause ventricular fibrillation and sudden death. The rate of K replacement should balance these risks.

In the great majority of hypokalemic patients, emergency therapy is not necessary. The body responds to potassium losses by shifting potassium from ICF to ECF, thereby minimizing the change in extracellular

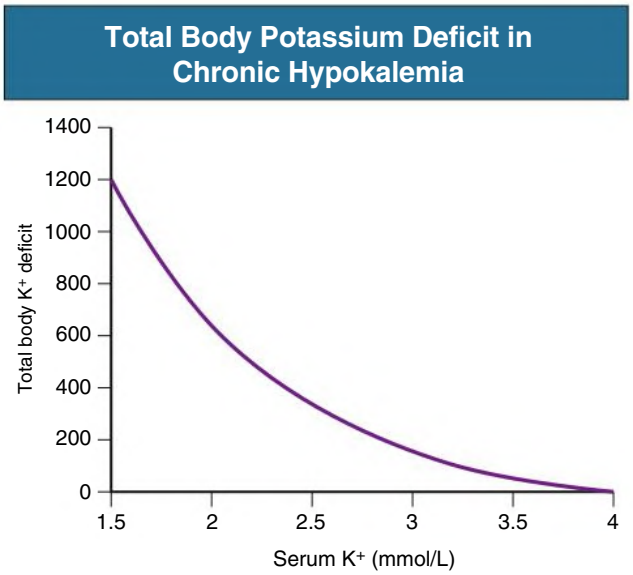

Fig. 10.5 Total Body Potassium Deficit in Hypokalemia. Because of shift of potassium from the intracellular fluid to the extracellular fluid compartment during chronic potassium depletion, the magnitude of deficiency can be masked and is generally much larger than would be calculated solely from the extracellular fluid volume volume and the change in serum potassium.

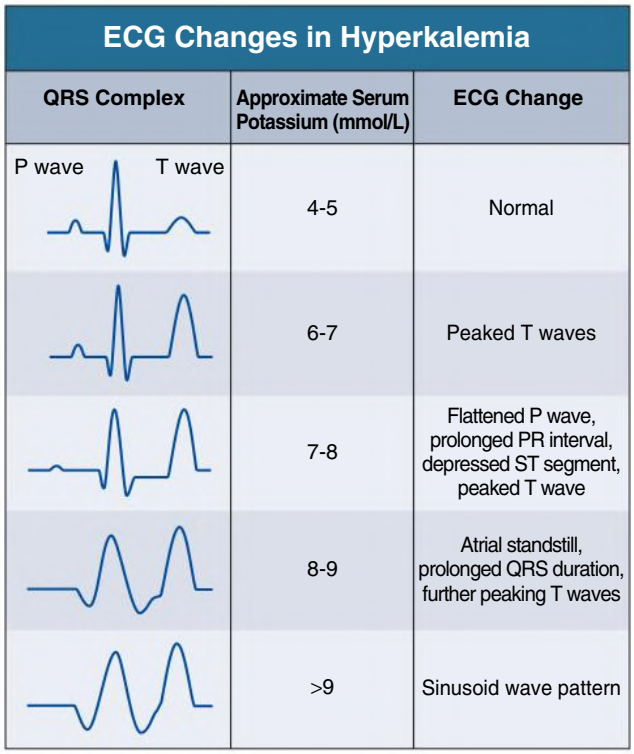

Fig. 10.6 Electrocardiographic (ECG) Changes in Hyperkalemia. Progressive hyperkalemia results in identifiable changes in the electrocardiogram. These include peaking of the T wave, flattening of the P wave, prolongation of the PR interval, depression of the ST segment, prolongation of the QRS complex, and, eventually, progression to a sine wave pattern. Ventricular fibrillation may occur at any time during this ECG progression.

[K^+]. During potassium replacement, there is shift of potassium back into ICF. Consequently, the amount of potassium replacement needed is much greater than predicted by the change in extracellular [K^+] and the ECF volume (Fig. 10.5).

Oral or enteral potassium administration is preferred if the patient can take oral medication and has normal GI tract function. Acute hyperkalemia is highly unusual when potassium is given orally. This reflects several factors, most prominently gut sensors that minimize changes in serum potassium levels. When potassium is given intravenously, acute hyperkalemia can occur if the administration rate is too rapid and, if it occurs, can cause sudden cardiac death. Thus, unless immediate life-threatening conditions are present, the maximum rate of IV KCl administration should not exceed 10 mmol/h. In life-threatening conditions, such as hypokalemia leading to respiratory compromise, severe hypokalemia in a patient requiring urgent surgery, and the patient with an acute myocardial infarction and life-threatening ventricular ectopy, more rapid administration may be needed. In these patients, potassium chloride (KCl) can be administered intravenously at a dose of 5 to 10 mmol over 15 to 20 minutes. Continuous ECG monitoring should be used under these circumstances. This dose can be repeated as needed.

The choice of the parenteral fluid used to administer the potassium can affect the response. In patients without diabetes mellitus, dextrose-containing fluids lead to a reflex increase in serum insulin levels, which can cause redistribution of potassium from ECF to ICF. As a result, administering KCl in dextrose-containing solutions, such as dextrose 5% in water (D5W), can stimulate cellular potassium uptake to an extent that results in paradoxical worsening of the hypokalemia.[40] Consequently, parenteral KCl should be administered in dextrose-free solutions.

The underlying condition should be treated whenever possible. If patients with diuretic-induced hypokalemia require ongoing diuretic administration, the addition of potassium-sparing diuretics may be considered. When oral replacement therapy is required, KCl is the preferred drug in most patients, except those with metabolic acidosis, in whom potassium citrate may be considered as a concomitant alkali source. Hypomagnesemia, if present, should be treated; otherwise, there may be ongoing urinary potassium losses that delay or preclude correction of the hypokalemia. If clinically indicated for other reasons, the use of β-blockers, ACE inhibitors, or ARBs can assist in maintaining serum potassium levels.

HYPERKALEMIA

Epidemiology

Hyperkalemia is distinctly unusual in healthy individuals with normal kidney function not being treated with drugs that alter K^+ handling, with less than 1% of normal healthy adults developing hyperkalemia. This low frequency is a testament to potent renal mechanisms for potassium excretion. Because of this, chronic hyperkalemia, if not caused by pseudohyperkalemia or redistribution, should strongly suggest impaired renal potassium excretion, whether from decreased nephron/collecting duct number, from medications that decrease renal potassium excretion, or from adrenal insufficiency.

Clinical Manifestations

Hyperkalemia can be asymptomatic, can cause mild symptoms, or can be life threatening. Importantly, the mortality risk of hyperkalemia is independent of the patient's clinical symptoms and reflects acute effects of hyperkalemia on cardiac conduction and repolarization. This is demonstrable on the ECG (Fig. 10.6). The initial effect of hyperkalemia is a generalized increase in the height of the T waves, most evident in the precordial leads, but typically present in all leads, which is known as "tenting." More severe hyperkalemia is associated with delayed electrical conduction, resulting in an increased PR interval and a widened QRS complex. This is followed by progressive flattening and eventual absence of the P waves. Under extreme conditions, the QRS

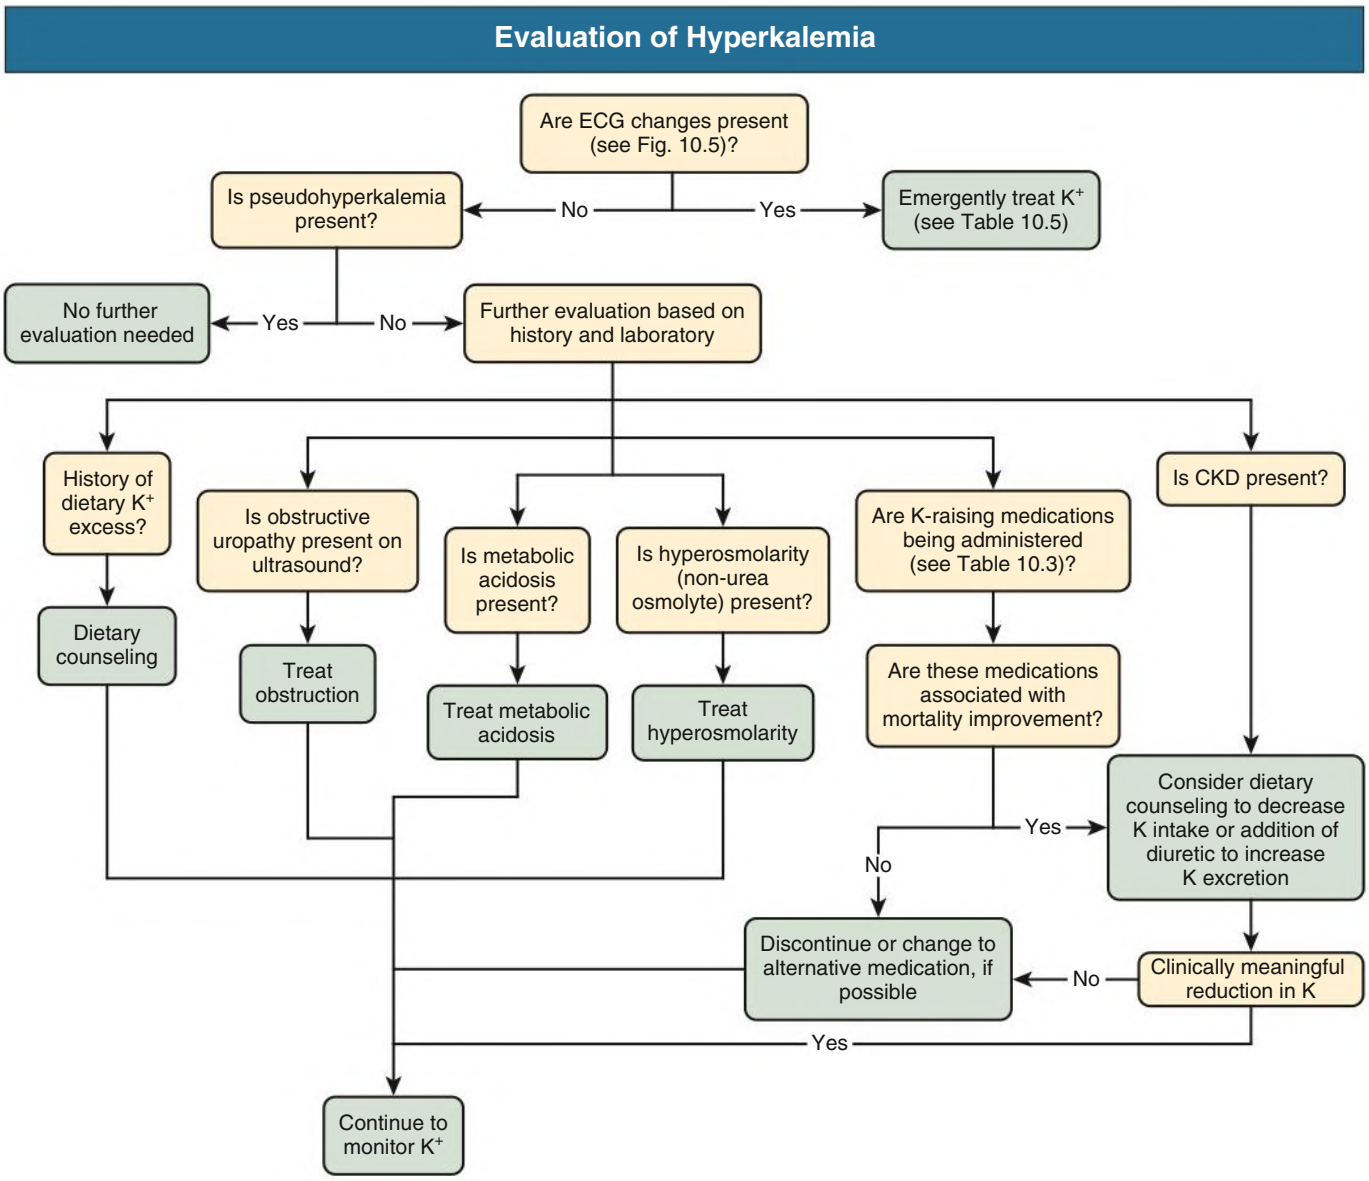

Fig. 10.7 Workup of hyperkalemia. *CKD,* Chronic kidney disease; *ECG,* electrocardiography.

complex widens sufficiently that it merges with the T wave, resulting in a junctional rhythm that degenerates to a sine wave pattern. Finally, ventricular fibrillation develops. Although the ECG findings correlate generally with the degree of hyperkalemia, the rate of progression from mild to severe cardiac effects can be unpredictable and may not correlate well with changes in the serum potassium concentration.

Hyperkalemia also has effects on noncardiac tissues. Skeletal muscle cells are particularly sensitive to hyperkalemia, causing generalized weakness. In patients with severe hyperkalemia, diaphragmatic muscle weakness may lead to respiratory failure.

Mortality

Several clinical studies have shown that chronic hyperkalemia is independently associated with increased mortality.[19–22,41–44] Whether correction of the abnormal K^+ alters the associated mortality is unknown. However, the relatively recent availability of generally well-tolerated enteric K^+-binding resins enables pharmacologic therapy of hyperkalemia without having to discontinue medications that have beneficial effects on mortality, such as ACE inhibitors/ARB, β-blockers, and MRBs, in specific clinical conditions but that can also increase potassium levels. Future studies are needed to determine whether correction of hyperkalemia with enteric K^+-binding medications will improve mortality.

Etiology

Hyperkalemia can result from pseudohyperkalemia, potassium redistribution from intracellular to extracellular space, or imbalances between potassium intake and renal potassium excretion. A diagnostic approach is shown in Fig. 10.7.

Pseudohyperkalemia

Pseudohyperkalemia refers to the condition where potassium release from blood cells occurs after the phlebotomy procedure. This most commonly results from damaged erythrocytes and is identified clinically by the presence of free hemoglobin in the plasma, reported as "hemolysis" by most clinical laboratories. If hemolysis is present, the reported serum $[K^+]$ measurement does not accurately reflect the actual serum $[K^+]$. Treatment should not be prescribed based on this value, and repeat measurement is necessary. Ischemia from prolonged tourniquet time or from exercise of the limb in the presence of a tourniquet can also lead to abnormally increased potassium values. Potassium

can also be released from the other cellular elements present in blood during clotting. This can occur in patients with severe leukocytosis (>70,000/cm^3) or thrombocytosis. About one-third of patients with platelet counts of 500 to 1000 × 10^9/L exhibit pseudohyperkalemia.

Pseudohyperkalemia is diagnosed by showing that the serum [K^+] is more than 0.3 mmol/L higher than in a simultaneous plasma sample. If not caused by hemolysis, future potassium levels may need to be measured in plasma samples to allow for accurate measurement of extracellular [K^+].

Redistribution

Redistribution of potassium from ICF to ECF may occur with severe hyperglycemia (from development of hyperosmolarity), during insulin deficiency, and with administration of drugs that alter cellular K^+ uptake, such as β_2-adrenoceptor blockers, ACE inhibitors, ARB, and MR blockers. During diabetic ketoacidosis, both the hyperosmolarity that results from the hyperglycemia and the insulin deficiency contribute to transcellular K^+ shifts that are the primary cause of the often-observed hyperkalemia. During treatment with insulin, resolution both of the hyperglycemia, and its resultant hyperosmolarity, and of the insulin deficiency leads to increased cellular potassium uptake and a decrease in the serum potassium. In the patient with diabetic ketoacidosis who presents with a normal serum potassium, potassium redistribution from the insulin deficiency and hyperglycemia-induced hyperosmolarity may be masking substantial total body potassium deficiency resulting from hyperglycemia-induced polyuria. In this case, severe hypokalemia may develop during insulin treatment. Close and careful management of serum potassium may be needed. Patients who have received mannitol may also develop hyperosmolarity-induced hyperkalemia. Digoxin overdose can block cellular potassium uptake and lead to hyperkalemia that requires rapid treatment.

Excess Intake

Excessive potassium ingestion generally does not lead to chronic hyperkalemia unless other contributing factors are present. Under normal conditions, the kidney has the capacity to excrete several multiples of the mean daily potassium intake. However, if renal potassium excretion is impaired, as from drugs, acute kidney injury (AKI), or CKD, excessive potassium intake can contribute to the development of hyperkalemia.

Common sources of excess potassium intake are potassium supplements, salt substitutes, enteral nutrition products, and several common foods. As many as 4% of patients receiving potassium supplements develop hyperkalemia. "Salt substitutes" have an average of 10 to 13 mmol K/g. Many enteral nutrition products contain at least 40 mmol/L KCl; administration of 100 mL/h of such products can result in a potassium intake of about 100 mmol/day. Also, many food products are particularly high in potassium (see Table 10.1).

Impaired Renal Potassium Excretion

Chronic hyperkalemia typically involves a component of impaired renal potassium excretion. As previously discussed, renal potassium excretion is determined primarily by collecting duct potassium secretion. The number of collecting duct segments parallels GFR, and therefore impaired GFR, whether from CKD or AKI, results in impaired capacity to excrete potassium. In CKD, adaptive increases in the ability of each collecting duct segment to secrete potassium may allow renal potassium excretion to remain moderately well preserved until GFR is reduced to 10 to 20 mL/min. Multiple drugs affect renal potassium secretion (see Table 10.3); these drugs are sometimes used in combination, which further exacerbates the risk of hyperkalemia.

Obstructive uropathy leads frequently to hyperkalemia, at least in part from decreased collecting duct ENaC and Na^+,K^+-ATPase expression and activity. Hyperkalemia may persist after relief of the obstruction.[45] This impairment appears to be related to a persistent defect in collecting duct K^+ secretion and not to aldosterone deficiency.[45]

Mineralocorticoid hormones are necessary for the normal response to hyperkalemia. Lack of these hormones both causes potassium redistribution from ICF to ECF and reduces the maximal ability of the kidneys to secrete potassium. Primary adrenal insufficiency should be strongly considered in the patient with chronic hyperkalemia and other findings suggestive of adrenal insufficiency, such as spontaneous hypotension and hyponatremia.

The colon can excrete potassium, but adaptive changes in enteric potassium excretion are quantitatively small and generally are not sufficient to maintain normal potassium homeostasis.

A rare genetic disorder, pseudohypoaldosteronism type 2 (PHA2; also known as Gordon syndrome) is characterized by hypertension, hyperkalemia, non–anion gap metabolic acidosis, and normal GFR[46] and is discussed in Chapter 49.

Determining the Role of Excessive Potassium Intake in Chronic Hyperkalemia

In most patients, a careful history and measurement of K^+ in a 24-hour urine collection will identify the role of excessive dietary potassium intake in the development of chronic hyperkalemia. In selected patients, specifically those not using diuretics and either unable to be compliant with or preferring not to perform a 24-hour urine collection, assessment of the urine potassium/creatinine ratio in a random urine specimen may be used, with urinary potassium greater than 60 mmol K^+/g creatinine suggesting excessive dietary K^+ intake is present. If there is a clinical concern about possible hypoaldosteronism as a primary cause of the hyperkalemia, such as in a patient with concomitant normal or low blood pressure and hyponatremia, the transtubular K^+ gradient (TTKG), when considered in context with assessment of K^+ intake, can be helpful (Table 10.4).

Treatment

Acute Therapy

Acute therapies for hyperkalemia are divided into those that minimize the cardiac effects of hyperkalemia, those that induce potassium uptake by cells resulting in a decrease in serum potassium, and those that remove potassium from the body (Table 10.5). Sodium bicarbonate ($NaHCO_3$) therapy should not be used unless the patient is frankly acidotic (pH < 7.2) or there is substantial endogenous renal function. Hypertonic $NaHCO_3$ therapy (e.g., 50 mmol in 50 mL of sterile water) can worsen intravascular volume overload, as frequently seen in the patient with oliguric AKI; can cause acute hypernatremia; and can acutely *increase* serum potassium in the anephric patient, likely as a result of the acute increase in plasma osmolality.[47]

Blocking cardiac effects. IV calcium administration rapidly antagonizes the effects of hyperkalemia on the myocardial conduction system and on myocardial repolarization and does so without changing plasma K^+. Calcium should be given intravenously as the initial therapy if unambiguous ECG changes of hyperkalemia are present. If the ECG is ambiguous, comparison with a previous ECG may be helpful. Patients with a prolonged PR interval, a widened QRS complex, or the absence of P waves should receive IV calcium in the form of either calcium chloride or calcium gluconate without delay. Responses typically occur within 1 to 3 minutes but generally last for only 20 to 60 minutes. Doses may be repeated as needed if ECG changes persist or they recur. If a delay in more definitive therapy, such as institution of dialysis, is anticipated, a continuous calcium infusion can be used.

IV calcium is relatively safe if certain precautions are taken. IV calcium should not be administered in $NaHCO_3$-containing

solutions because calcium carbonate ($CaCO_3$) precipitation can occur. Hypercalcemia, which occurs during rapid calcium infusion, can potentiate the myocardial toxicity of digoxin. Thus, patients taking digoxin, particularly if they have evidence of digoxin toxicity as a contributing cause of hyperkalemia, should be given calcium as a slow infusion over 20 to 30 minutes.

Cellular potassium uptake. The second most rapid way to treat hyperkalemia is to stimulate cellular potassium uptake using either insulin or β_2-adrenergic agonist administration. Insulin rapidly stimulates cellular potassium uptake and should be administered intravenously to ensure rapid and predictable bioavailability. The effect of insulin on serum $[K^+]$ is seen generally within 10 to 20 minutes and can last for 4 to 6 hours. Glucose is generally coadministered to avoid hypoglycemia but may not be needed if hyperglycemia coexists. This is particularly important because extracellular glucose in patients with diabetes mellitus can function as an "ineffective osmole" and can increase the serum potassium concentration. It is important to recognize that decreased kidney function can lead to delayed insulin clearance, and hypoglycemia can result from IV insulin administration, even if glucose is coadministered, because glucose uptake may occur more rapidly than insulin clearance. Accordingly, patients given IV insulin for treatment of hyperkalemia should be closely monitored for the development of hypoglycemia. If dialysis is indicated and a delay in its initiation is anticipated, administering a continuous infusion of insulin, 4 to 10 U/h (with 10% dextrose in water, $D_{10}W$), may be beneficial; periodic monitoring of serum glucose and potassium is required.

β_2-Adrenoceptor agonists directly stimulate cellular potassium uptake and can be administered via IV, subcutaneously (SC), or by inhalation. However, β_2-agonist therapy frequently causes tachycardia, and as many as 25% of patients do not respond to β_2-agonist therapy given by nebulizer.[48] A common mistake when administering nebulized β_2-adrenoceptor agonists is underdosage; the dose required is two to eight times that usually given for bronchodilation and is 50 to 100 times greater than the dose administered by metered dose inhalers.

Potassium removal. Most patients with persistent, severe hyperkalemia benefit from K^+ removal from the ECF. Definitive treatment of these patients requires potassium elimination through the kidneys, GI tract, or dialysis. Patients with chronic hyperkalemia may also benefit from drugs that stimulate renal or stool K^+ excretion. With chronic or mild hyperkalemia, loop or thiazide diuretics increase renal potassium excretion; this is particularly important for patients with hyperkalemic renal tubular acidosis (Type 4 RTA), in whom the hyperkalemia is an important causative factor in the development of the metabolic acidosis.[49,50] With life-threatening hyperkalemia, diuretics should generally not be used because the rate of renal potassium excretion is not adequate. If a rapidly reversible cause of kidney failure is identified (e.g., obstructive uropathy or prerenal azotemia and kidney failure from volume depletion), treating the underlying condition may be sufficient, as long as there is close observation of serum potassium and continuous ECG monitoring.

A second mode of potassium elimination is with enteric K^+-binding medications. Cation exchange resins, such as sodium polystyrene sulfonate or calcium polystyrene sulfonate (calcium resonium), have been used for decades. These resins exchange sodium or calcium, respectively, for potassium in the GI tract, enabling potassium elimination. They can be administered orally or as a retention enema. The rate of potassium removal is relatively slow, requiring about 4 hours for onset, although

TABLE 10.4 Transtubular Potassium Gradient

The transtubular potassium gradient (TTKG) is a measurement of net K^+ secretion by the collecting duct after correcting for changes in urinary osmolality and is often used to determine whether hyperkalemia is caused by aldosterone deficiency/resistance or whether the hyperkalemia is secondary to nonrenal causes. As with all diagnostic aids, clinical correlation is indicated, and potassium intake should be assessed.

$$TTKG = \frac{[K^+]_U / [K^+]_S}{Osmo_U / Osmo_S}$$

where $[K^+]_U$ and $[K^+]_S$ are the concentration of K^+ in urine and serum, respectively, and $Osmo_U$ and $Osmo_S$ are the osmolality of urine and serum, respectively.

TTKG Value	Indication
6–12	Normal
>10	Suggests normal aldosterone action and extrarenal cause of hyperkalemia
<5–7	Suggests aldosterone deficiency or resistance
After 0.05 mg 9α-Fludrocortisone:	
>10	Hypoaldosteronism is likely.
No change	Suggests a renal tubule defect from either K^+-sparing diuretics (amiloride, triamterene, spironolactone), aldosterone resistance (interstitial renal disease, sickle cell disease, urinary tract obstruction, PHA1), or increased distal K^+ reabsorption (PHA2, urinary tract obstruction)

TABLE 10.5 Acute Treatment of Hyperkalemia

Mechanism	Therapy	Dose	Onset	Duration
Antagonize membrane effects	Calcium	Calcium gluconate, 10% solution, 10 mL IV over 10 min	1–3 min	30–60 min
Cellular potassium uptake	Insulin	Regular insulin, 10 U IV, with dextrose 50%, 50 mL, if plasma glucose <250 mg/dL	30 min	4–h
	β_2-Adrenergic agonist	Nebulized albuterol, 10 mg	30 min	2–h
Potassium removal	Sodium polystyrene sulfonate or calcium polystyrene sulfonate (calcium resonium)	30–60 g PO in 20% sorbitol *or* 30–60 g in water, per retention enema	4–6 h	6–12 h
	Patiromer	16.8–25.2 g	4–6 h	6–12 h
	Sodium zirconium cyclosilicate	10 g	4–6 h	6–12 h
	Hemodialysis	—	Immediate	Until dialysis completed

administering the resin as a retention enema results in more rapid onset of action. When given orally, cation exchange resins are generally administered with 20% sorbitol to avoid constipation. If given as an enema, sorbitol should be avoided because rectal administration of cation exchange resins with sorbitol may increase the risk of colonic perforation.[51] Questions have been raised recently as to the efficacy of these compounds and whether the risk of colonic perforation exceeds their benefits.[52] Two new enteric potassium-binding medications, patiromer and sodium zirconium cyclosilicate,[53,54] have been developed. They have a better subjective side effect profile than the K^+-binding resins, which leads to better long-term tolerability. Although all enteric K^+-binding medications appear to lower K^+ levels within 6 to 24 hours, none should be relied on for the treatment of life-threatening hyperkalemia.

Acute hemodialysis is the primary method of potassium removal in AKI or advanced CKD when hyperkalemia is life-threatening. Serum potassium can decrease as much as 1.2 to 1.5 mmol/h with a low potassium (2 mmol/L) dialysate. In general, the more severe the hyperkalemia, the more rapid should be the reduction in serum potassium until K^+ is less than 6.0 mEq/L. However, care should be taken to avoid reducing the serum potassium too rapidly in patients with coronary heart disease or severe cardiac arrhythmias. In these patients, longer dialysis with dialysate potassium of 3 mmol/L allows serum potassium to equilibrate to that level. However, rigorous data supporting which patients should be treated with higher K^+dialysate are not available. Our policy is to use 3 mmol/L K^+ dialysate in patients with a history of sudden cardiac death. We also recommend rechecking serum potassium after completion of the dialysis procedure to verify effective correction of the hyperkalemia, waiting 1 to 2 hours to allow transcellular reequilibration. Continuous dialysis modalities, such as peritoneal dialysis and continuous venovenous hemodialysis, generally do not remove potassium sufficiently quickly for use in patients with life-threatening hyperkalemia but may be justified under unusual circumstances where hemodialysis is not available.

If dialysis is delayed, as when access to equipment or nursing support is not immediate, or while vascular access is being established, other therapies should be instituted and continued until hemodialysis is begun.

Specific therapies are available for certain causes of hyperkalemia. For example, digoxin-specific Fab fragments are beneficial in patients with severe digitalis glycoside toxicity.[55] Hyperkalemia in patients with acute urinary tract obstruction may be treated by relieving the obstruction, but the rate of potassium excretion afterward is variable, and frequent measurement of serum potassium is necessary.

Chronic Treatment

Management of chronic hyperkalemia is a common and often challenging problem, particularly in the CKD patient. Patients with CKD have impaired capacity to excrete a potassium load rapidly and are often treated with medications, such as ACE inhibitors, ARB, β-blockers, and MRBs, that can cause hyperkalemia.

Although most patients with chronic hyperkalemia are receiving medicines associated with the development of hyperkalemia, discontinuing all drugs that can cause hyperkalemia may not be the correct approach. Many medicines, such as ACE inhibitors, ARBs, β-blockers, and MRBs, have significant cardiovascular, renoprotective, and mortality benefits. Discontinuing these drugs simply because of mild hyperkalemia is therefore not recommended in the first-line management. However, if the patient is receiving combined therapy with ACE inhibitor and ARB, discontinuing one of these drugs may decrease the risk of further hyperkalemia, and this does not appear to be associated with adverse renal effects. Similarly, if a patient is receiving combination therapy of either an ACE inhibitor or an ARB with a direct renin inhibitor, such as aliskiren, the direct renin inhibitor may be discontinued.

Instead of immediately discontinuing such beneficial drugs without review, a careful assessment should be made for medicines that cause hyperkalemia but are not necessary for renoprotective or cardioprotective benefits and therefore can be discontinued, such as NSAIDs, cyclooxygenase (COX)-2 inhibitors, potassium-sparing diuretics (e.g., amiloride, triamterene), and oral KCl or potassium citrate supplementation. If hyperkalemia persists, addition of diuretics to increase potassium excretion can be considered. Thiazide diuretics may be preferred because, when adjusted for their effect on sodium excretion, thiazide diuretics are associated with a greater increase in renal potassium excretion than loop diuretics. In the patient with CKD, the thiazide diuretic metolazone may be effective.[56] Combination of thiazide and loop diuretics is more effective than either alone. Finally, screening for and treating metabolic acidosis may facilitate correction of the hyperkalemia. Alkali therapy may also increase K^+ clearance.

A dietary history should be obtained, and if the patient is ingesting a diet with potassium-rich foods, instruction on avoidance of these foods should be provided. However, routine instruction in a low-potassium diet for CKD patients is not recommended. Recent studies have suggested that a diet higher in potassium-rich foods may be associated with slower progression of CKD.[57]

Finally, chronic therapy with drugs that increase enteric K^+ excretion can be considered, such as patiromer or sodium zirconium cyclosilicate.[53,54] These drugs may allow for greater use of drugs that improve mortality in selected patient populations but whose use is otherwise limited because of development of hyperkalemia (e.g., ACE inhibitors and ARBs).

Synthetic mineralocorticoid therapy, such as fludrocortisone, has also been used for the treatment of chronic hyperkalemia. This approach may be helpful in patients with chronic hypotension caused by adrenal insufficiency who have normal kidney function. In CKD patients, the accompanying renal sodium retention, intravascular volume expansion, and increased blood pressure are relative contraindications to synthetic mineralocorticoids. Furthermore, selective blockade of the mineralocorticoid receptor appears to decrease kidney injury in several experimental models of renal injury, suggesting that administration of synthetic mineralocorticoids may be injurious. As a result, their adverse effects may exceed their benefits in patients with CKD.

SELF-ASSESSMENT QUESTIONS

1. Deficiency of which of the following ions can result in renal potassium wasting?
   - **A.** Phosphate
   - **B.** Calcium
   - **C.** Sulfate
   - **D.** Magnesium
2. Which of the following drugs is not associated with development of hyperkalemia?
   - **A.** Terazosin
   - **B.** Propranolol
   - **C.** Spironolactone
   - **D.** Cyclosporine
3. Hypokalemia is associated with which of the following conditions?
   - **A.** Decreased insulin sensitivity
   - **B.** Increased renal interstitial fibrosis
   - **C.** Increased risk of hepatic encephalopathy
   - **D.** Polyuria
   - **E.** All of the above

Disorders of Calcium, Phosphate, and Magnesium Metabolism

Bryan Kestenbaum, Pascal Houillier

CALCIUM HOMEOSTASIS AND DISORDERS OF CALCIUM METABOLISM

Distribution of Calcium in the Organism

Most (>99%) calcium in the body is bound and associated with bony structures. Free calcium, in diffusible nonionized or ionized forms, is found in the intracellular fluid (ICF) and extracellular fluid (ECF) compartments. Similar to potassium, there is a steep concentration gradient between calcium (Ca^{2+}) inside cells and the extracellular compartment (Fig. 11.1).

The serum calcium concentration is tightly regulated within a narrow range by parathyroid hormone (PTH) and calcitriol (1,25-dihydroxycholecalciferol). Fig. 11.2 demonstrates physiologic defense mechanisms used to counter changes in the serum Ca^{2+} concentration.[1] Acute alkalosis causes a decrease in serum Ca^{2+}, and acute acidosis causes an increase in Ca^{2+}. The long-term maintenance of calcium homeostasis depends on intestinal Ca^{2+} absorption, bone accretion and resorption, and urinary excretion (Fig. 11.3).

The extracellular ionized Ca^{2+} concentration is sensed by principal cells in the parathyroid glands via the calcium-sensing receptor (CaSR), which is the primary determinant of PTH synthesis and release. PTH secretion increases or decreases within seconds in response to changes in extracellular ionized Ca^{2+}. The CaSR is present in numerous tissues, including the kidneys.[2] Mutations of the *CASR* gene cause clinical syndromes characterized by hypercalcemia or hypocalcemia (see later).

Intestinal, Skeletal, and Kidney Handling of Calcium

Only about 25% of dietary calcium is absorbed in the gastrointestinal (GI) tract under normal conditions. Intestinal calcium absorption falls precipitously in chronic kidney disease (CKD) because of decreased kidney synthesis of calcitriol. Calcium absorption can be subdivided into transcellular and paracellular flow (Fig. 11.4). Transcellular flux takes place through the apical transient receptor potential channel vanilloid subtype 6 (TRPV6) calcium channel.[3] Calcitriol stimulates active calcium transport by binding to and activating the vitamin D receptor (VDR), which induces expression of TRPV6, calbindin-D_{9k}, and Ca^{2+}-ATPase (PMCA1b).[4] Other hormones, including estrogens, prolactin, growth hormone, and parathyroid hormone (PTH), as well as the amount of dietary calcium intake, also stimulate intestinal calcium absorption, either directly or indirectly (Fig. 11.5).[5]

The primary source of vitamin D derives from exposure to ultraviolet light, which converts 7-dehydrocholesterol to cholecalciferol (vitamin D3) in the skin. Cholecalciferol can also be obtained through supplementation and dietary sources; however, the cholecalciferol content of most foods is low. Ergocalciferol (vitamin D_2) is an alternative vitamin D supplement that does not occur naturally in humans. Cholecalciferol and ergocalciferol (which contains an additional methyl group) have minimal inherent biologic function and require two hydroxylation steps for full hormonal activity. The first step, 25-hydroxylation, occurs in the liver by vitamin D 25-hydroxylase encoded by the *CYP2R1* gene. This step is believed to be nonrate limiting; however, polymorphisms in *CYP2R1* are associated with differences in circulating 25-hydroxyvitamin D concentrations in the general population. The serum 25-hydroxyvitamin D concentration is widely accepted as the measure of vitamin D stores. Further hydroxylation to 1,25-dihydroxyvitamin D (calcitriol) is performed by 25-hydroxyvitamin D-1 alpha hydroxylase encoded by the *CYP27B1* gene. This step occurs predominantly in the kidneys but can also occur in macrophages, parathyroid glands, and other tissues. The activated, 1-hydoxy forms of vitamin D are subsequently catabolized by the CYP24A1 enzyme (cytochrome P450 family 24 subfamily A member 1) to prevent toxicity. Serum 1,25-dihydroxyvitamin D concentrations are approximately 1000-times lower than 25-hydroxyvitamin D, highlighting the tight hormonal control of the final hydroxylation step.

An increase in intestinal calcium absorption is required in puberty and pregnancy, whereas in lactation, calcium is mostly obtained from maternal bone.[6] In puberty and pregnancy, calcitriol synthesis is increased to enhance calcium absorption. Intestinal calcium absorption is also increased in states of vitamin D excess and acromegaly. Rarely, the ingestion of calcium and alkali in large quantities can overwhelm checks on calcium absorption, resulting in hypercalcemia (milk-alkali syndrome). A decrease in intestinal calcium transport occurs in advanced age, kidney disease (because of reduced calcitriol synthesis), gastrectomy, intestinal malabsorption syndromes, diabetes mellitus, corticosteroid treatment, and estrogen deficiency and with dietary factors such as high vegetable fiber and fat content, low calcium-to-phosphate ratio in food, and fructose ingestion. The decrease in calcium absorption in older adults probably results from multiple factors in addition to lower serum calcitriol and intestinal VDR.[7]

The net balance between calcium entry and exit is positive during skeletal growth in children, zero in young adults, and negative in older persons. Exchangeable skeletal calcium contributes to the maintenance of extracellular calcium homeostasis. Several growth factors, hormones, and genetic factors participate in the differentiation from mesenchymal precursor cell to osteoblast and maturation of the osteoclast from its granulocyte-macrophage precursor cell (Fig. 11.6). Bone formation and resorption is also regulated by many hormones, growth factors, and mechanical factors[8,9] (Fig. 11.7).

The kidneys regulate minute-by-minute calcium balance, and the intestine, kidney, and skeleton ensure homeostasis in the mid and long term (Fig. 11.8).[10] The synthesis of calcitriol from substrate 25-hydroxyvitamin D is increased by PTH and reduced by fibroblast growth factor 23 (FGF-23) and perhaps hyperphosphatemia. The adjustment of blood calcium is mainly achieved by modulation of tubular calcium reabsorption, perfectly compensating minor increases or decreases in the filtered calcium load (normally about 220 mmol

[8800 mg] per day; see Fig. 11.3). The bulk of calcium reabsorption in the kidneys occurs in the proximal tubules following the convective flow of salt and water, with relatively smaller contributions from the thick ascending limb and distal tubular segments.

Excess volume delivery to the kidneys, such as with a high-sodium diet, may diminish the concentration gradient between the proximal tubule and peritubular capillary, reducing the driving force for calcium absorption and increasing urinary calcium excretion. This mechanism is suspected to contribute to the pathogenesis of calcium-based kidney stones and provides a rationale for recommending a low-sodium diet in this setting. On the other hand, volume depletion increases the reabsorption of salt, water, and, by convection, calcium in the proximal tubules, exacerbating states of calcium excess. For this reason, intravascular volume repletion is an essential first step in the treatment of hypercalcemia.

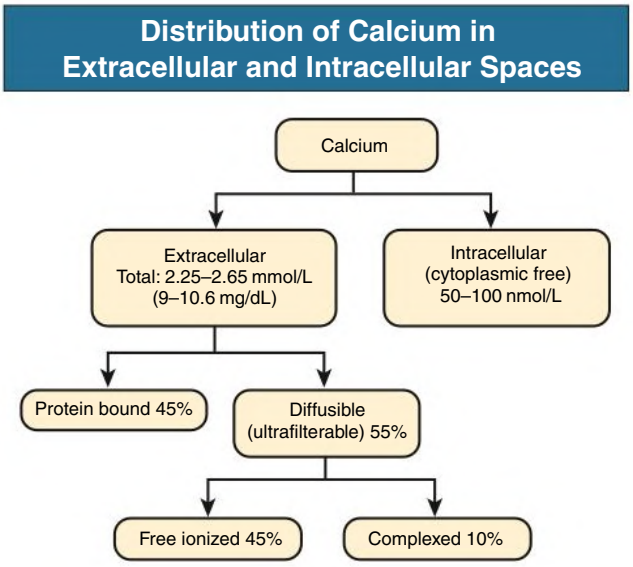

Fig. 11.1 Calcium distribution in extracellular and intracellular spaces.

In the thick ascending limb (TAL), calcium transport is paracellular, functionally linked with activity of the Na^+-K^+-$2Cl^-$ transporter and the attendant lumen-positive transepithelial voltage. Stimulation of the basolateral CaSR decreases the paracellular pathway permeability to calcium.[11] The result is decreased calcium reabsorption through the Claudin-16 and 19 complex in tight junctions (Fig. 11.9). In contrast, understimulation of the CaSR by low serum calcium levels increases tubular calcium reabsorption. In the distal tubules, active calcium transport occurs via the transcellular route through the transient receptor potential channel vanilloid subtype 5 (TRPV5). This channel is located in the apical membrane and coupled with a specific basolateral calcium-ATPase (PMCa1b) and Na^+-Ca^{2+} exchanger (NCX1). Both PTH and calcitriol increase distal tubular Ca^{2+} transport. Several classes of diuretics alter kidney calcium handling. Loop diuretics increase urinary calcium excretion by inhibiting the Na^+-K^+-$2Cl^-$ cotransporter, whereas thiazide diuretics and amiloride increase distal tubular calcium absorption.

HYPERCALCEMIA

Routine measurement of the serum calcium concentration [Ca^{2+}] reports the total concentration in the tube, including bound and unbound fractions. Increased serum [Ca^{2+}] can therefore result from an increase in serum proteins (false hypercalcemia) or reflect a real increase in ionized [Ca^{2+}] (true hypercalcemia). If laboratory assays for ionized calcium are not available, serum [Ca^{2+}] can be corrected using serum albumin: each

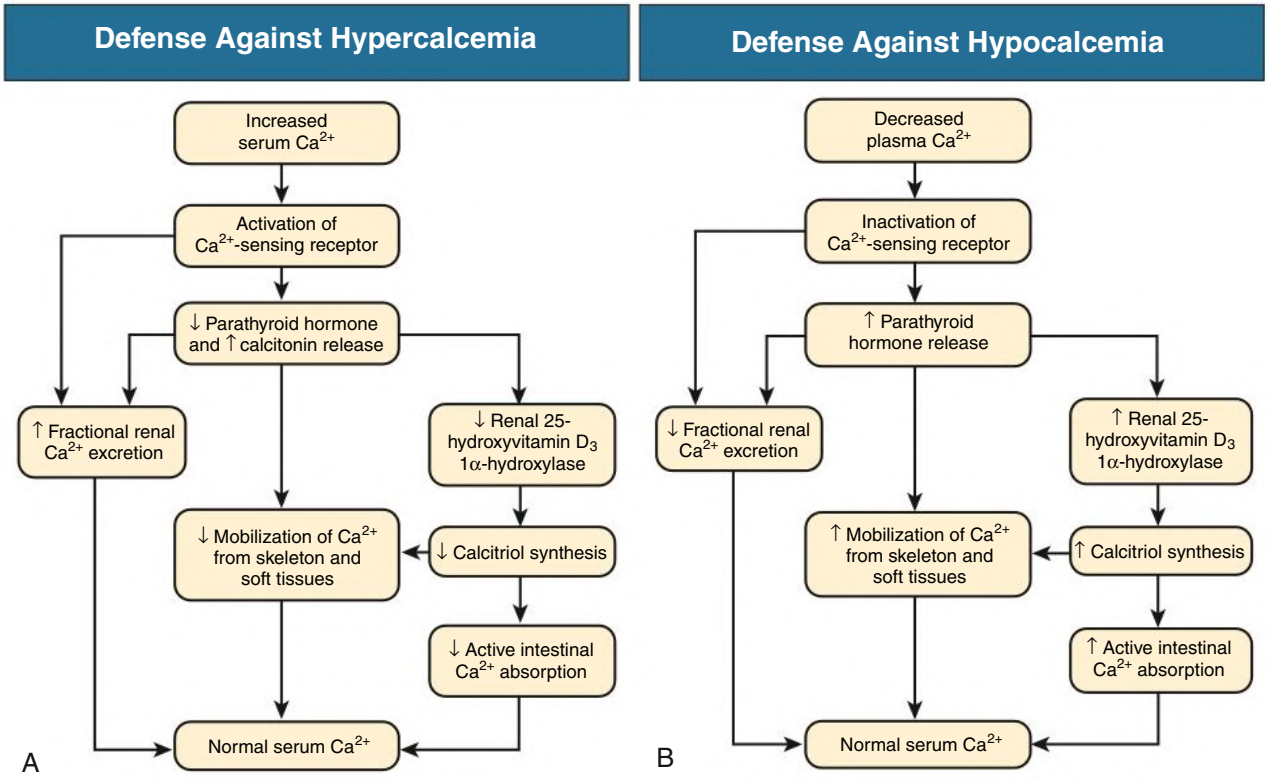

Fig. 11.2 Calcium Regulation. Physiologic defense mechanisms against increases or decreases in serum calcium levels. (A) Hypercalcemia. (B) Hypocalcemia. (Modified from Kumar R. Vitamin D and calcium transport. *Kidney Int.* 1991;40:1177–1189.)

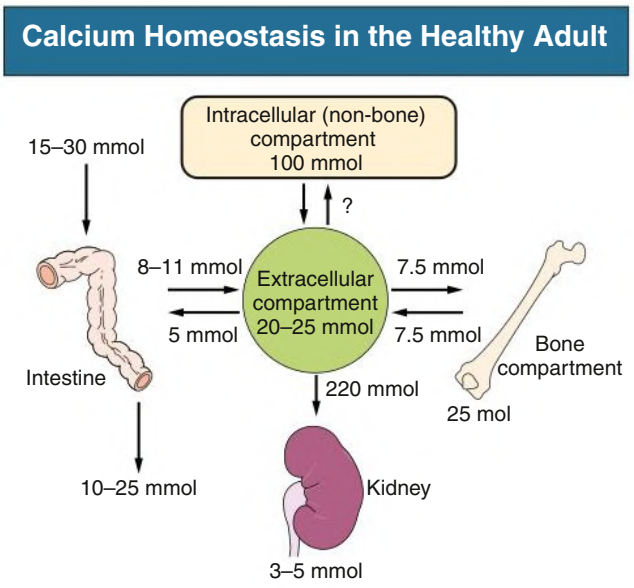

Fig. 11.3 Calcium Homeostasis in Healthy Adults. Net zero Ca^{2+} balance is the result of net intestinal absorption (absorption minus secretion) and urinary excretion, which by definition are the same. After its passage into the extracellular fluid, Ca^{2+} enters the extracellular space, is deposited in bone, or is eliminated via the kidneys. Entry and exit fluxes between the extracellular and intracellular spaces (skeletal and nonskeletal compartments) are also of identical magnitude under steady-state conditions.

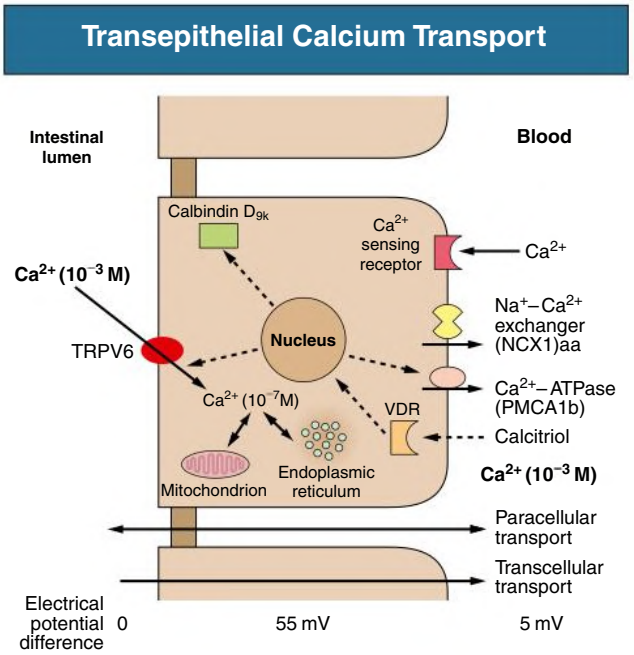

Fig. 11.4 Transepithelial Calcium Transport in the Small Intestine. Calcium penetrates into the enterocyte channels via a transient receptor potential calcium channel (TRPV6) through the brush border membrane along a favorable electrochemical gradient. Under physiologic conditions, the cation is pumped out of the cell at the basolateral side against a steep electrochemical gradient by the adenosine triphosphate–consuming pump Ca^{2+}-ATPase. When there is a major elevation of intracytoplasmic Ca^{2+}, the cation leaves the cell using the Na^{+}-Ca^{2+} exchanger. Passive Ca^{2+} influx and efflux are sensitive to calcitriol, which binds the vitamin D receptor (VDR).

(From Kinyamu HK. Association between intestinal vitamin D receptor, calcium absorption, and serum 1,25 dihydroxyvitamin D in normal young and elderly women. *J Bone Miner Res.* 1997;12:922–928.)

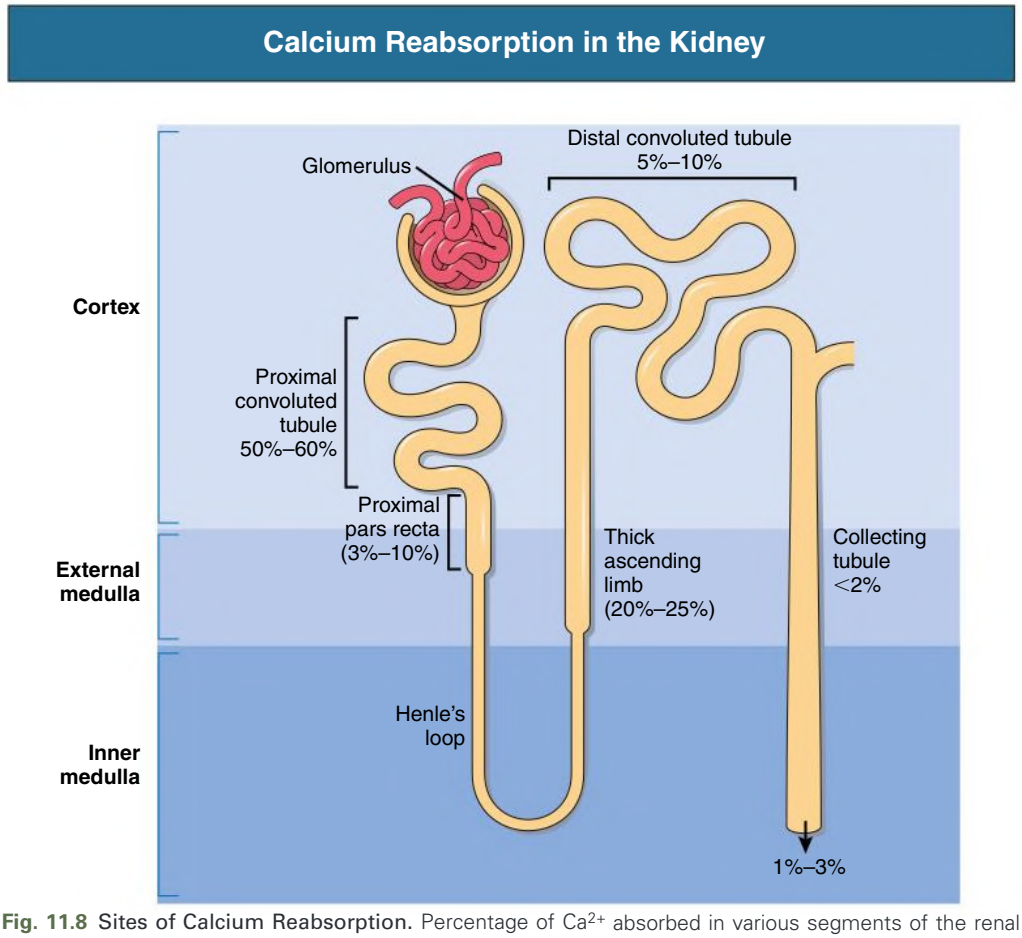

Fig. 11.8 Sites of Calcium Reabsorption. Percentage of Ca^{2+} absorbed in various segments of the renal tubule after glomerular ultrafiltration. (Modified from Martin T, Gooi JH, Sims NA. Molecular mechanisms in coupling of bone formation to resorption. *Crit Rev Eukaryot Gene Expr.* 2009[19]:73–88.)

1.0 g/dL higher serum albumin concentration is associated with a concomitant 0.20 to 0.25 mmol/L (0.8–1.0 1.0 mg/dL) greater serum [Ca^{2+}]. However, simple correction for serum albumin may not be valid in patients with CKD stages 3 to 5.[12]

Causes of Hypercalcemia

Hypercalcemia may be caused by an increase in intestinal calcium absorption, excess bone resorption, enhanced kidney tubular reabsorption, or a combination of these processes. The most common clinical causes of hypercalcemia are malignancy and primary hyperparathyroidism, which can be distinguished by measurement of PTH. Regardless of the primary cause, secondary volume depletion prolongs hypercalcemia by interfering with urinary calcium excretion (Fig. 11.10).

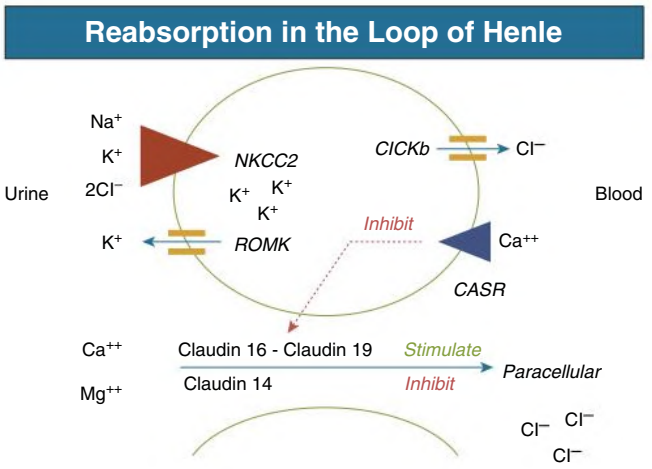

Fig. 11.9 Reabsorption in the Loop of Henle. Transport of Na^+, K^+, $2Cl^-$ into the cell via *NKCC2* drives paracellular reabsorption of calcium and magnesium through a claudin 16-claudin 19 complex. Stimulation of the calcium-sensing receptor on the basolateral cell surface, such as by hypercalcemia, inhibits calcium and magnesium reabsorption.

Malignant Neoplasia

An important cause of hypercalcemia is excessive bone resorption induced by neoplastic processes, usually solid tumors.[13] Tumors of the neck, breast, lung, and kidney are the most common, followed by hematopoietic neoplasias, particularly myeloma. Tumors causing hypercalcemia act on the skeleton by direct invasion (metastases) or by producing factors that stimulate osteoclastic activity (paraneoplastic processes). The most common tumor-derived factor is PTH-related protein (PTHrP). Only 8 of the 13 first amino acids of PTHrP are homologous to the N-terminal fragment of PTH, but the effects of both hormones on target cells are similar because they share a common receptor (the PTH/PTHrP receptor, PTH1R). In multiple myeloma and lymphomas, osteoclast-activating factors secreted by clonal cells include interleukins (IL-1α, IL-1β, IL-6) and tumor necrosis factor (TNF)-α. Certain tumors, especially kidney masses, may secrete other osteoclast-activating factors, such as PGE_1 and PGE_2. Some lymphoid tumors, including Hodgkin disease, T-cell lymphoma, and leiomyoblastoma, can synthesize excess quantities of calcitriol, which promote hypercalcemia.

Primary Hyperparathyroidism

In more than 80% of patients, hyperparathyroidism is caused by an adenoma of a single parathyroid gland; 10% to 15% have diffuse hyperplasia of all glands, and less than 1% have parathyroid carcinoma.

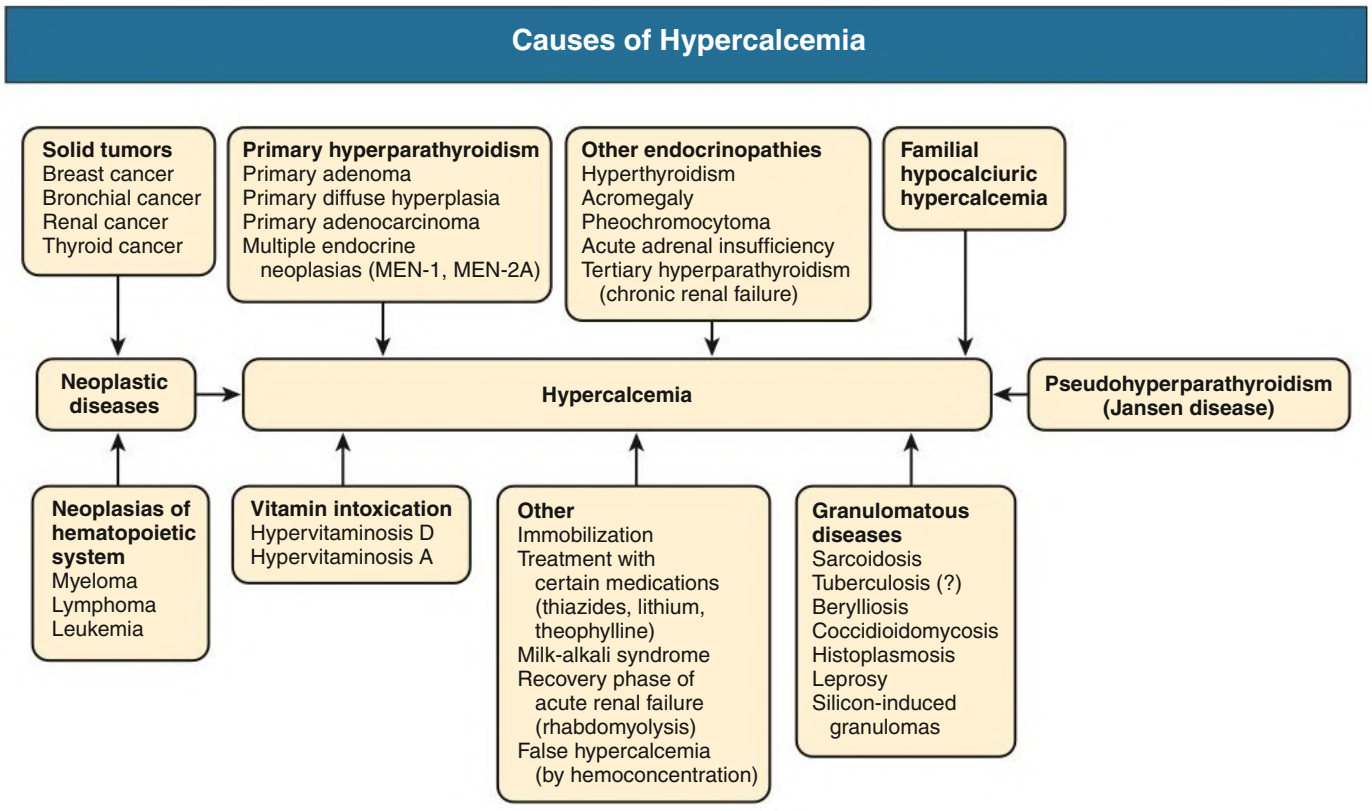

Fig. 11.10 Causes of Hypercalcemia. Neoplastic diseases and primary hyperparathyroidism are the most common causes of hypercalcemia. (From Harada S, et al. Control of osteoblast function and regulation of bone mass. *Nature.* 2003;12:922–928.)

Primary hyperparathyroidism typically presents in middle age with asymptomatic mild hypercalcemia and a high or high normal serum PTH concentration. Under normal conditions, even a mild increase in serum [Ca^{2+}] should potently suppress PTH secretion. Consequently, primary hyperparathyroidism should be suspected when both serum [Ca^{2+}] and PTH are at the higher end of the normal range. Urinary calcium excretion is increased in primary hyperparathyroidism, which may assist in the diagnosis.

Primary hyperparathyroidism is usually idiopathic but can be inherited either as diffuse hyperplasia of the parathyroid glands alone or as a component in multiple glandular hereditary endocrine disorders. Patients with multiple endocrine neoplasia type 1 (MEN-1) have various combinations of parathyroid, anterior pituitary, enteropancreatic, and other endocrine tumors, resulting in hypersecretion of prolactin, gastrin, and PTH. MEN-1 is caused by inactivating germ-line mutations of a tumor suppressor gene *(MEN-1)* that is inherited as an autosomal dominant trait. In MEN-2A, the thyroid medulla and the adrenal medulla are involved, resulting in hypersecretion of calcitonin and catecholamines. MEN-2A is caused by activating mutations of the *RET* proto-oncogene. It is also inherited as an autosomal dominant trait. MEN-4 is characterized by the occurrence of parathyroid and anterior pituitary tumors possibly associated with tumors of the adrenals, kidneys, and reproductive organs; it is because of cyclin-dependent kinase inhibitor (CDNK1B) mutations.[14]

Granulomatous Diseases

The formation of macrophage-laden granulomas in specific infectious and inflammatory diseases can promote unchecked activity of macrophage-associated 1 alpha hydroxylase activity, leading to excess calcitriol synthesis and hypercalcemia. Common granulomatous diseases associated with hypercalcemia are sarcoidosis and tuberculosis; other conditions include histoplasmosis, coccidioidomycosis, berylliosis, and leprosy. Laboratory measurement of the serum 1,25-dihydroxyvitamin D concentration can help identify these conditions.

Other Endocrine Causes

Other endocrine disorders associated with moderate hypercalcemia include hyperthyroidism, acromegaly, pheochromocytoma, and acute adrenal insufficiency.

Inherited Causes

Familial Hypocalciuric Hypercalcemia

Familial hypocalciuric hypercalcemia (FHH) is a rare hereditary disease, most often caused by inactivating mutations in the *CASR* gene with autosomal dominant transmission,[15] more rarely in the gene for G-protein subunit α_{11} (GNA11), or adaptor-related protein complex 2, sigma 1 subunit (AP2S1).[16] The key clinical finding in FHH is an inappropriately low urinary calcium excretion in the setting of high-normal serum [Ca^{2+}]. Serum PTH levels are often normal or moderately increased, potentially mimicking the diagnosis of primary hyperparathyroidism. The key distinction is low urine calcium excretion in FHH, assessed by calculating the fractional excretion of calcium (FE_{Ca}) from a 24-hour urine collection:

$$\text{Fraction excretion of calcium}\,(FE_{Ca}) = \frac{(\text{Urine calcium}) \times (\text{Serum creatinine})}{(\text{Serum calcium}) \times (\text{Urine creatinine})}$$

In FHH, the FE_{Ca} is usually less than 0.01; however, some overlap may still be seen with primary hyperparathyroidism.[17] FHH rarely leads to severe hypercalcemia except in the neonatal period.

Jansen Disease

Jansen disease is a rare hereditary form of short-limbed dwarfism characterized by severe hypercalcemia, hypophosphatemia, and metaphyseal chondrodysplasia. The condition is caused by activating mutations of the gene coding for the PTH1R receptor, a particular form of pseudohyperparathyroidism.

Other Causes

Hypercalcemia is seen with protracted bedrest, especially in the setting of prolonged hospitalization. Hypercalcemia is rarely observed with intoxication from vitamin A or D supplements and thiazide diuretics. Large doses of oral calcium (5–10 g/day), when ingested with alkali (antacids), can lead to hypercalcemia and nephrocalcinosis (milk-alkali syndrome).

Hypercalcemia in Chronic Kidney Disease

The natural history of CKD includes a gradual reduction in serum [Ca^{2+}] because of reduced calcitriol synthesis. The presence of hypercalcemia in patients with advanced CKD or end-stage kidney disease (ESKD) should alert the clinician to a potential iatrogenic cause, specifically the overadministration of calcium-containing phosphate binders and vitamin D receptor agonists (calcitriol, paricalcitol). A second potential cause of hypercalcemia in ESKD is tertiary hyperparathyroidism, in which the parathyroid glands lose responsiveness to therapy with severe elevation of serum PTH.

Clinical Manifestations

The severity of symptoms and signs caused by hypercalcemia depends not only on the degree but also the rapidity of development. Common symptoms are fatigue, muscle weakness, inability to concentrate, nervousness, increased sleepiness, and depression. GI symptoms include constipation, nausea and vomiting, and, rarely, peptic ulcer disease or pancreatitis. Kidney-related signs include hypertension, polyuria (secondary to nephrogenic diabetes insipidus), salt wasting, kidney stones and their complications, and, occasionally, tubulointerstitial disease with medullary and, to a lesser extent, cortical nephrocalcinosis. Patients with chronic hypercalcemia often present with a modest elevation in the serum creatinine concentration, indicating reduced GFR. Neuropsychiatric manifestations are common and include headache, loss of memory, somnolence, stupor, and, rarely, coma. Ocular symptoms include conjunctivitis from crystal deposition and, rarely, band keratopathy. The electrocardiogram (ECG) may show shortening of the QT interval and coving of the ST wave. Hypercalcemia may increase cardiac contractility and can amplify digitalis toxicity.

Diagnosis

In addition to the clinical history, examination, and review of medications, measurement of ionized [Ca^{2+}] and serum PTH are the first steps in investigating the cause of hypercalcemia. Primary hyperparathyroidism should be suspected if the PTH concentration is high or high-normal in the presence of a high or high-normal serum [Ca^{2+}], although FHH is not excluded by this laboratory pattern. If PTH is appropriately suppressed with hypercalcemia, then the possibility of a neoplastic disorder should be considered. Subsequent laboratory steps to determine the cause of hypercalcemia include serum protein electrophoresis and measurement of PTHrP, 25-hydroxyvitamin D, and 1,25-dihydroxyvitamin D.

Treatment

The treatment of hypercalcemia is aimed at the underlying cause, although severe (>3.25 mmol/L) and symptomatic hypercalcemia always requires rapid correction. Initially, the patient should be volume

expanded with isotonic saline or balanced crystalloids to inhibit tubular calcium reabsorption and enhance urinary calcium excretion. Only when euvolemia is established can loop diuretics be considered to further augment urinary calcium excretion; however, intravenous (IV) fluids should be continued to prevent hypovolemia. Volume expansion must be carefully managed in patients with heart failure or advanced kidney disease. Oral intake, IV administration of fluids and electrolytes, and acid-base balance should be carefully monitored.

Bisphosphonates are the treatment of choice, especially in patients with hypercalcemia associated with cancer.[13] These agents inhibit bone resorption and calcitriol synthesis. Bisphosphonates can be administered orally in less severe disease or by IV in severe hypercalcemia. Common bisphosphonates include pamidronate 15 to 90 mg IV over 1 to 3 days and zoledronate 4 mg IV once; IV doses should be infused in 500 mL of isotonic saline or dextrose over at least 2 hours (pamidronate) or 15 minutes (zoledronate). Although package warnings state that bisphosphonates should be used with caution in patients with CKD, this warning pertains to the theoretical possibility of inducing hypocalcemia. Bisphosphonates have been safely used in patients with CKD for the correction of hypercalcemia. Calcitonin acts within hours, especially after IV administration. Human, porcine, or salmon calcitonin can be given. However, calcitonin often has no effect, or only a short-term effect, because of the rapid development of tachyphylaxis.

Denosumab, a monoclonal antibody to the receptor activator of nuclear factor κ-B ligand (RANKL), is a potent inhibitor of bone resorption that can be useful in bisphosphonate-refractory hypercalcemia. Denosumab is not removed by the kidneys. The typical dose is 120 mg subcutaneously and can be repeated no earlier than 1 week after the first administration.[18]

Corticosteroids such as prednisone (or prednisolone), 0.5 to 1.0 mg/kg daily, are mainly indicated in patients with sarcoidosis or tuberculosis, to decrease macrophage synthesis of calcitriol. Corticosteroids also can be used in patients with hypercalcemia associated with some hematopoietic tumors (e.g., myeloma, lymphoma) and even for some solid tumors such as breast cancer. Ketoconazole, an antifungal agent that can inhibit renal and extrarenal calcitriol synthesis, can also be used to treat hypervitaminosis D.

In rare cases of malignant hypercalcemia, treatment with prostaglandin antagonists such as indomethacin or aspirin can be successful. Hyperkalemia and impaired kidney function may occur with indomethacin. Hypercalcemia caused by thyrotoxicosis can rapidly resolve with IV administration of propranolol or less rapidly with oral administration.

In patients with primary hyperparathyroidism, consideration for parathyroidectomy is based on the severity of hypercalcemia and the accompanying complications of the disease, including loss of bone mineral density, nephrolithiasis, and kidney dysfunction. For nonsurgical, asymptomatic candidates, potential medical therapies include bisphosphonates and the CaSR agonist cinacalcet (a calcimimetic).[19] Cinacalcet is also effective in patients with parathyroid carcinoma. Surgical parathyroidectomy remains an important therapeutic option in patients with ESKD who are unresponsive to vitamin D analogs and calcimimetics.[20]

HYPOCALCEMIA

A decrease in total serum [Ca^{2+}] may occur as a result of reduced serum albumin (false hypocalcemia) or can reflect a real change in ionized [Ca^{2+}] (true hypocalcemia). False hypocalcemia is best excluded by direct measurement of ionized [Ca^{2+}]. Alternatively, total serum [Ca^{2+}] can be corrected for serum albumin as described previously. Causes of true hypocalcemia can be divided into conditions that are associated with high or low serum phosphate concentrations (Fig. 11.11).

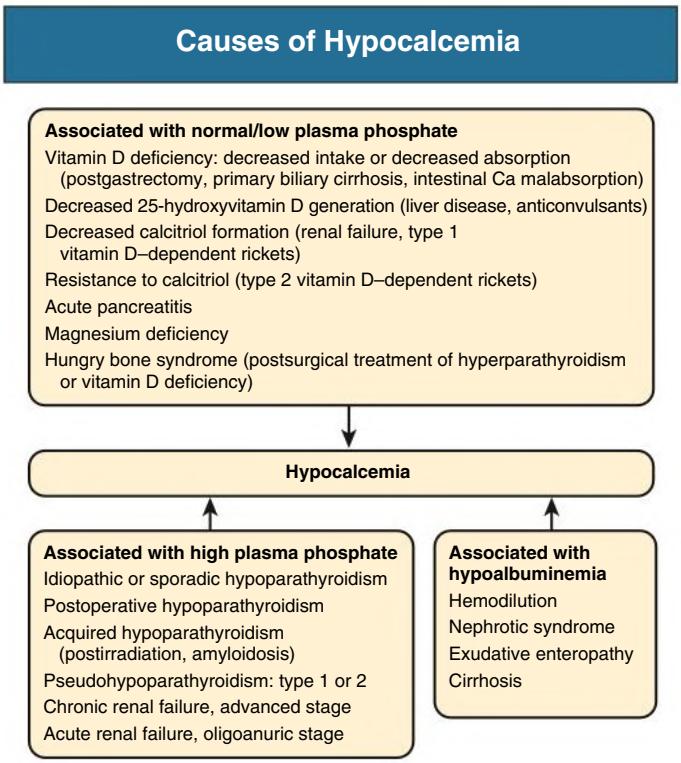

Fig. 11.11 Causes of hypocalcemia.

Hypocalcemia Associated With Hyperphosphatemia

Chronic and Acute Kidney Disease

A gradual loss of functioning nephrons leads to reduced calcitriol production and a subsequent decrease in intestinal calcium absorption. In parallel, serum phosphate concentrations progressively rise once the glomerular filtration rate (GFR) falls below approximately 35 mL/min/1.73 m^2. Kidney disease and hyperphosphatemia stimulate the release of fibroblast growth factor 23 (FGF-23), a bone-derived hormone that further suppresses calcitriol synthesis by inhibiting 1-alpha hydroxylase activity. However, hypocalcemia and hyperphosphatemia arising from CKD may be masked by treatments, including calcium-containing phosphate binders and vitamin D receptor agonists.

Hypocalcemia may also be observed in the setting of acute kidney injury (AKI). Several mechanisms may contribute to hypocalcemia in AKI, including an abrupt decline in calcitriol synthesis, an increase in FGF-23, and incomplete PTH response to the fall in serum [Ca^{2+}]. Hypocalcemia may also be observed in the polyureic recovery phase of AKI, especially after rhabdomyolysis.

Hypoparathyroidism

Under normal conditions, PTH increases serum [Ca^{2+}] and enhances urinary excretion of phosphate. Loss of PTH (hypoparathyroidism) therefore leads to hypocalcemia and hyperphosphatemia. Hypoparathyroidism may occur after intentional (parathyroidectomy) or nonintentional (thyroidectomy) removal of the parathyroid glands. Hypoparathyroidism can also be caused by autoimmune destruction of parathyroid tissue, radiation, infiltrative diseases, or genetic conditions affecting development and/or function of the parathyroid glands. Sporadic cases are occasionally seen in patients with pernicious anemia or adrenal insufficiency. Pseudohypoparathyroidism (iPPSD;

Inactivating PTH/PTHrP Signaling Disorders, including former pseudohypoparathyroidism type 1a and 1b) is a group of rare genetic diseases characterized by isolated or syndromic end organ resistance to PTH.[21] Magnesium deficiency impairs the PTH response to hypocalcemia, producing a state of relative hypoparathyroidism. In addition, massive oral phosphate administration, such as used in bowel preparations, can also cause hypocalcemia with hyperphosphatemia, often in association with AKI.[22]

Hypocalcemia Associated With Hypophosphatemia

Hypocalcemia with hypophosphatemia may occur in vitamin D–deficient states because of insufficient daylight exposure, dietary deficiency of vitamin D, decreased absorption after GI surgery, intestinal malabsorption syndromes (steatorrhea), or hepatobiliary disease (primary biliary cirrhosis). However, overt hypocalcemia caused by substrate 25-hydroxyvitamin D deficiency is uncommon because 1,25-dihydroxyvitamin D is tightly maintained at much lower concentrations. Vitamin D–dependent rickets are a rare group of inherited disorders caused by defects in vitamin D metabolic enzymes (discussed in the section on hypophosphatemia).

Hypocalcemia is observed in the majority of critically ill adults and children. No singular mechanism has been identified; defects in calcitriol synthesis, PTH release, and target organ sensitivity to these hormones have been described. Hypocalcemia is also seen with hypomagnesemia in patients with acute pancreatitis caused by saponification in necrotic fat.

An acute decrease in ionized [Ca^{2+}] occurs during acute hyperventilation and the respiratory alkalosis that follows, regardless of the cause of hyperventilation.

Clinical Manifestations

As with hypercalcemia, the symptoms of hypocalcemia depend on the rate of development and severity. The most common manifestations, in addition to fatigue and muscular weakness, are increased irritability, loss of memory, a state of confusion, hallucination, paranoia, and depression. The best-known clinical signs are the Chvostek sign (tapping of facial nerve branches leading to twitching of facial muscle) and the Trousseau sign (carpal spasm in response to forearm ischemia caused by inflation of a sphygmomanometer cuff). Patients with acute hypocalcemia may have paresthesias of the lips and the extremities, muscle cramps, and occasionally frank tetany, laryngeal stridor, or seizures. Chronic hypocalcemia may be associated with cataracts, brittle nails with transverse grooves, dry skin, and decreased or even absent axillary and pubic hair, especially in idiopathic hypoparathyroidism.

On the electrocardiogram (ECG), the corrected QT interval is frequently prolonged, and arrhythmias may occur. The electroencephalogram shows nonspecific signs such as an increase in slow, high-voltage waves. Intracranial calcifications, notably of the basal ganglia, are observed radiographically in 20% of patients with early-onset hypoparathyroidism but much less frequently in patients with postsurgical hypoparathyroidism or pseudohypoparathyroidism.

Treatment

Therapy of hypocalcemia is directed toward the underlying cause. Severe and symptomatic (tetany) hypocalcemia requires rapid treatment with calcium gluconate as an IV bolus (e.g., 10 mL 10% weight/volume [2.2 mmol of calcium], diluted in 50 mL of 5% dextrose in water or isotonic saline), followed by 12 to 24 g over 24 hours. Calcium gluconate is preferred to calcium chloride, which can lead to extensive skin necrosis in accidental extravasation. Acute respiratory alkalosis, if present, should be corrected if possible.

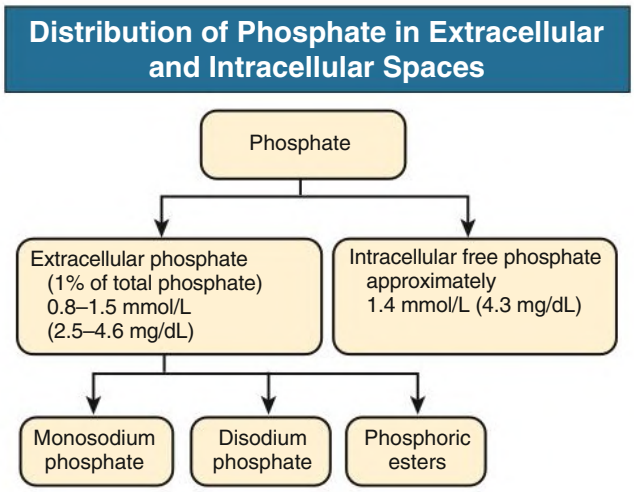

Fig. 11.12 Phosphate distribution in extracellular and intracellular spaces.

Treatment of chronic hypocalcemia includes oral administration of calcium salts, thiazide diuretics, and vitamin D. The amount of elemental calcium of the various salts differs greatly: the calcium content is 40% in carbonate, 36% in chloride, 12% in lactate, and only 8% in gluconate salts. The daily amount prescribed can be 1 to 4 g elemental calcium in adults. Concurrent magnesium deficiency (serum [Mg^{2+}] <0.70 mmol/L) should be treated with oral magnesium oxide or carbonate 100 to 300 mg elemental magnesium/day or with magnesium sulfate 4 to 8 mmol/day intramuscularly or 20 to 40 mmol/day in D5W IV.

Treatment of hypocalcemia secondary to hypoparathyroidism is difficult because urinary calcium excretion increases markedly with calcium and active vitamin D supplementation, potentially leading to nephrocalcinosis/nephrolithiasis and loss of kidney function. To reduce urinary calcium, thiazide diuretics can be used in association with restricted salt intake.

Therapy with vitamin D receptor agonists is the conventional treatment for idiopathic or acquired hypoparathyroidism because these compounds are better tolerated than massive doses of calcium salts. Large amounts of active vitamin D and calcium are often required for extended periods after surgical parathyroidectomy because of massive redistribution of calcium into the bone (hungry bone syndrome). Such patients require regular monitoring to avoid hypercalcemia, hyperphosphatemia, and hypercalciuria.

PHOSPHATE HOMEOSTASIS

Distribution of Phosphate in the Organism

Phosphorus is distributed in the body as 85% within bone and teeth; 15% inside cells; and less than 1% in the extracellular fluid, which includes the circulation. Fig. 11.12 shows the distribution of phosphate in extracellular and intracellular compartments. Within cells, phosphate regulates key enzymatic processes and serves as an essential structural component of nucleic acids and phospholipid membranes. In the bloodstream, phosphate circulates as HPO_4^{2-} and $H_2PO_4^-$ in an approximate 4 to 1 ratio at physiologic pH. Normal serum phosphate concentrations range from 2.8 to 4.5 mg/dL (0.9–1.5 mmol/L) with known circadian fluctuation.[23] The lowest concentrations are observed in the morning between 8 AM and 10 AM, and relatively higher concentrations are seen in late afternoon.[24] Dietary phosphate intake has only a minimal impact on the serum phosphate concentration in normal individuals and nondialyzed persons with mild to moderate CKD.

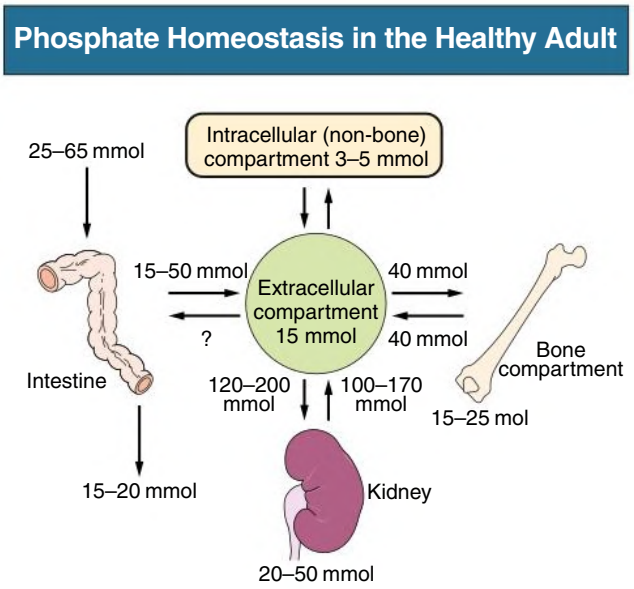

Fig. 11.13 Phosphate Homeostasis in Healthy Adults. At net zero balance, identical net intestinal uptake (absorption minus secretion) and urinary loss occur. After its passage into the extracellular fluid, phosphate enters the intracellular space, is deposited in bone or soft tissue, or is eliminated via the kidneys. Entry and exit fluxes between the extracellular and intracellular spaces (skeletal and nonskeletal compartments) are also the same under steady-state conditions.

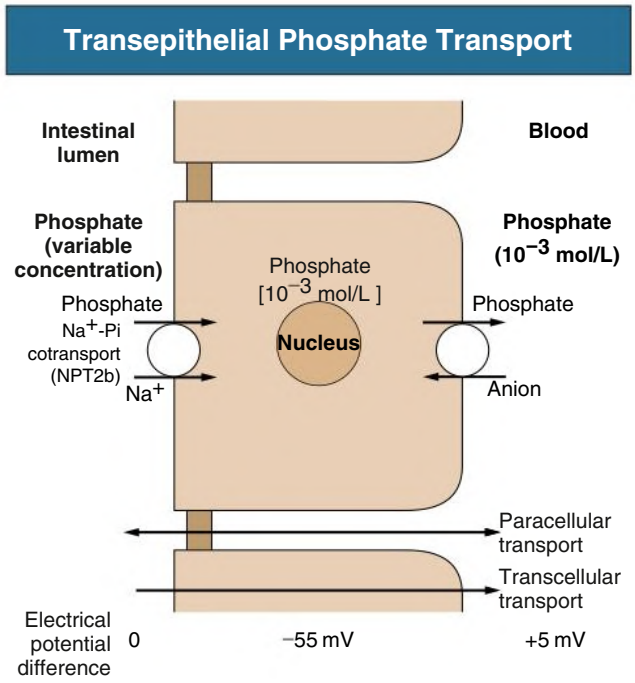

Fig. 11.14 Transepithelial Phosphate Transport in the Small Intestine. Phosphate enters the enterocyte (influx) through the brush border membrane using the Na^+/Pi cotransport system, with a stoichiometry of 2:1, operating against an electrochemical gradient. Phosphate exit at the basolateral side possibly occurs by passive diffusion or more probably by anion exchange.

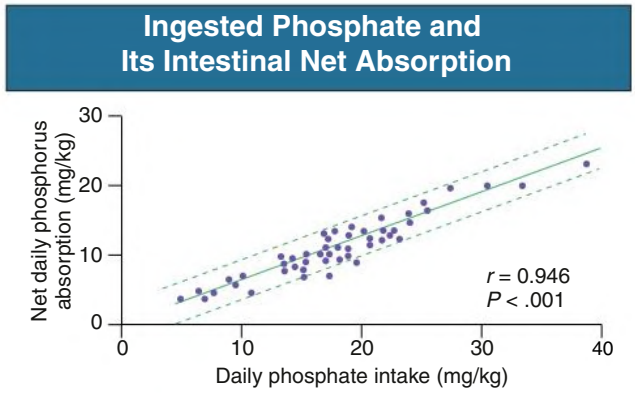

Fig. 11.15 Phosphate Ingestion and Absorption. Relationship between ingested phosphate and phosphorus absorbed in the digestive tract (net absorption) in healthy young adults. (From Wilkinson R. Absorption of calcium, phosphate, and magnesium. In: Nordin BEC, ed. *Calcium and Magnesium Metabolism*. Churchill Livingstone; 1976:36–112.)

Fig. 11.13 shows the balance of ingestion, body distribution, and excretion of phosphate in a healthy person. Phosphate needs are highest in children during growth. Phosphates are widely found in milk products, meat, eggs, and cereals, and are used extensively as food additives.

Phosphate enters epithelial cells via cotransport with sodium. Three different Na^+-Pi cotransporter families have been identified and characterized. Members of the type 1 Na^+-Pi family participate in kidney uric acid transport but do not directly impact phosphate homeostasis.[25] The members of the type 2 family of Na-Pi cotransporters are the key players in phosphate regulation and are NPT2a, NPT2b, and NPT2c (encoded by *SLC34A1*, *SLC34A2*, and *SLC34A3*). NPT2a and NPT2c are expressed in the apical brush border of the proximal tubules, whereas NPT2b is expressed in the small intestine.[26–29] The type 3 family of Na^+-Pi cotransporters (encoded by *SLC20A1* and *SLC20A2*) is ubiquitously expressed. Type 3 transporters do not participate directly in phosphate homeostasis; however, they mediate phosphate entry into vascular smooth muscle cells, which is hypothesized to be an important step in the pathogenesis of kidney-related vascular calcification.[30] Mutations in *SLC20A2* are the cause of primary familial brain calcification syndrome, a rare condition characterized by progressive bilateral calcification of the basal ganglia, thalami, and cerebellum.[31]

Intestinal, Renal, and Skeletal Handling of Phosphate

Intestinal phosphate absorption occurs via transepithelial and paracellular routes (Fig. 11.14). In contrast to the relatively restricted absorption of calcium, intestinal phosphate absorption is permissive, with 60% to 75% of dietary phosphate absorbed (15–50 mmol/day) in a linear, nonsaturable fashion (Fig. 11.15). The amount of intestinal phosphate absorption depends on the source of dietary phosphate: Absorption is highest for phosphate-containing food additives and lowest for plant-based phosphate sources.[32] Cations, such as calcium, magnesium, and aluminum, bind to phosphate in the intestinal tract, limiting its absorption.

Calcitriol is the primary hormonal determinant of intestinal phosphate absorption. Calcitriol upregulates NPT2b cotransporters in the small intestine, increasing phosphate entry via transcellular transport.[33,34] Vitamin D receptor agonists, including calcitriol and its analogs, enhance phosphate and calcium absorption, whereas nonactivated vitamin D supplements, such as cholecalciferol and ergocalciferol, have only a minimal impact on intestinal uptake. In experimental models, nicotinamide, a form of vitamin B_3, inhibits NPT2b expression, suggesting a role in the treatment of hyperphosphatemia. However, nicotinamide had no effect on serum phosphate concentrations in patients with moderate to advanced CKD in a randomized trial.[35]

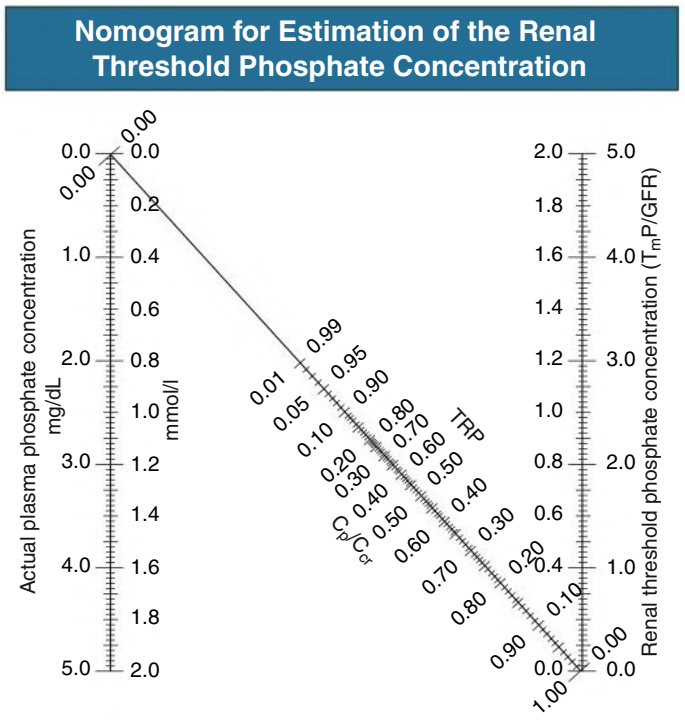

Fig. 11.16 Nomogram for Estimation of Kidney Threshold Phosphate Concentration. A straight line through the appropriate values of phosphate concentration and TRP (amount of phosphate reabsorbed, or C_P/C_{cr}, where *C* is clearance for phosphate or creatinine) passes through the corresponding value of T_mP/GFR. *GFR,* Glomerular filtration rate. (From Murer H, Hernando N, Forster I, Biber J. Proximal tubular phosphate reabsorption: Molecular mechanisms. *Physiol Rev.* 2000;80[4]:1373–1409.)

The kidneys play a major role in phosphate homeostasis by controlling its excretion. In both animals and humans, ingestion of a phosphate-containing meal leads to rapid excretion of phosphate in the urine without detectable changes in serum concentrations.[36] Phosphate is minimally protein bound, freely filtered in the glomerulus, and reabsorbed to a variable extent by the proximal tubules to match the body's needs. Under steady-state conditions, urinary phosphate excretion equals phosphate absorption through the gut. This balance is typically achieved by excretion of 5% to 20% of the filtered phosphate load; however, higher fractional excretions are usually needed to maintain balance in advanced CKD because of the progressive loss of filtering nephrons. The proportion of phosphate reabsorption can be estimated by the urinary fractional excretion of phosphate ($FEPO_4$).

$$\text{Fraction excretion of phosphate } (FEPO_4) = \frac{(\text{Urine phosphate}) \times (\text{Serum creatinine}) \times 100\%}{(\text{Serum phosphate}) \times (\text{Urine creatinine})}$$

$FEPO_4$ values are typically less than 20% in people without kidney disease and can reach values of 50% or higher in advanced CKD to compensate for the loss of functional nephrons.[37] An alternative method for assessing kidney phosphate reabsorption is the maximal tubular reabsorption of phosphate (TmP) factored for GFR (TmP/GFR, Bijvoet index). This value represents the concentration above which most phosphate is excreted in the urine and below which most is reabsorbed. TmP/GFR is calculated from the serum phosphate concentration and the tubular reabsorption of phosphate (Fig. 11.16).

After passage through the glomerulus, phosphate is reabsorbed via NPT2a and NPT2c cotransporters in the proximal tubule. The expression of these transporters, and thus total kidney phosphate reabsorption, is primarily regulated by PTH, FGF-23, and the serum phosphate concentration itself. PTH and FGF-23 downregulate NPT2a and NPTc on the apical brush border, thereby increasing urinary phosphate excretion.[38,39] PTH is believed to act by modulating the sodium-hydrogen exchanger regulator factor-1 (NHERF-1), a scaffolding protein that links membrane bound NPTa to the cytoskeleton.[40] FGF-23 is a hormone that is produced in bone and binds to target receptors in the kidneys. The transmembrane coreceptor α-klotho stabilizes the FGF-23-receptor interaction to promote downregulation of NPT2a and NPT2c on the apical cell surface.[41] Genetic disruption of FGF-23 or klotho in animal models results in an identical phenotype of hyperphosphatemia, calcitriol toxicity, vascular calcification, and premature death.[42]

Although PTH and FGF-23 act synergistically to enhance kidney phosphate excretion, these hormones have opposing actions on vitamin D metabolism. PTH promotes the synthesis of calcitriol by stimulating 1-alpha hydroxylase, which converts substrate 25-hydroxyvitamin D into its active form.[43] In contrast, FGF-23 inhibits calcitriol synthesis by suppressing 1-alpha hydroxylase and by catalyzing its conversion to an inactive 24-hydroxylated compound.[44]

Bone permanently exchanges phosphate with the surrounding milieu. Entry and exit of phosphate from bone amount to approximately 10 mmol/day (slowly exchangeable phosphate) for a total skeleton content of approximately 20,000 mmol. The net balance is positive during growth, zero in the young adult, and negative in older persons.

HYPERPHOSPHATEMIA

Causes of Hyperphosphatemia

Hyperphosphatemia is commonly caused by impaired phosphate excretion in acute or chronic kidney disease.[45] Hyperphosphatemia may also be caused by increased exogenous or endogenous phosphate supply (Fig. 11.17).

Acute Kidney Injury

An acute reduction in GFR leads to phosphate retention and a subsequent increase in serum phosphate. Serum concentrations may reach extremely high values if there is concomitant release from tissues, such as in rhabdomyolysis. Serum FGF-23 concentrations increase rapidly in the setting of AKI, demonstrating a unique sensitivity of this hormonal system to changes in kidney function, phosphate metabolism, or both signals in combination.[46]

Chronic Kidney Disease

Serum phosphate concentrations generally remain within the normal range in CKD until the GFR falls below about 35 mL/min per $1.73m^2$.[47] The preservation of serum phosphate concentrations in CKD highlights the complex regulatory mechanisms involved in phosphate homeostasis. The gradual loss of filtering nephrons leads to phosphate retention, which stimulates the phosphaturic hormones PTH and FGF-23. These hormones defend the serum phosphate concentration by enhancing kidney phosphate excretion. However, the price paid for maintaining phosphate balance in CKD is chronic elevation of both PTH and FGF-23, which are associated with adverse clinical consequences, including bone and cardiovascular disease (see Chapters 85 and 88).[48,49] Moreover, FGF-23 potently suppresses calcitriol synthesis, possibly to limit further intestinal phosphate absorption, leading to reduced calcium absorption and ongoing stimulation of PTH. Eventually, the remaining filtering nephrons can no longer support further phosphate excretion, and serum concentrations begin to rise.

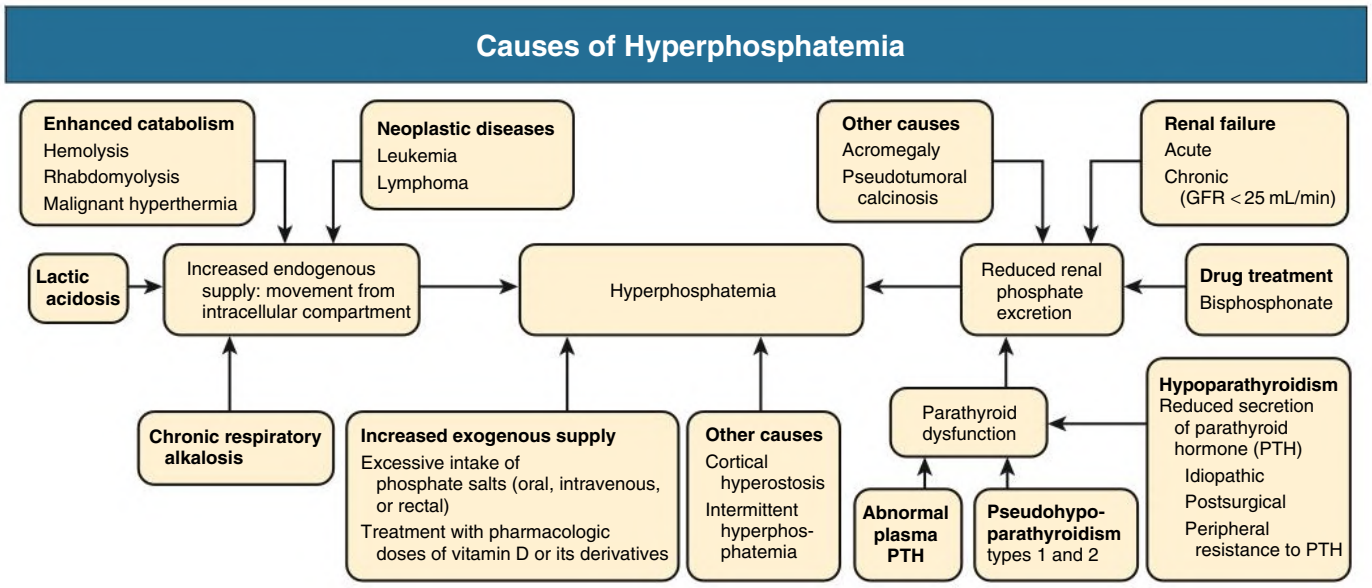

Fig. 11.17 Causes of hyperphosphatemia. *GFR*, Glomerular filtration rate; *PTH*, parathyroid hormone.

By this time, secondary hyperparathyroidism is typically evident, along with elevated FGF-23, calcitriol deficiency, and hypocalcemia.

Lytic States

Excess phosphate loss from tissues can be observed in states of extreme cell lysis, particularly rhabdomyolysis (crush injury) or malignant neoplasms and their treatment (especially lymphomas and leukemias). Hyperphosphatemia in rhabdomyolysis is typically accompanied by hypocalcemia, myoglobinuria, and AKI. Severe hypercatabolic states, such as sepsis or diabetic ketoacidosis, can also cause hyperphosphatemia by increasing phosphate release from cells (which is usually accompanied by an acute reduction in GFR).

Treatment-Induced Hyperphosphatemia

A massive supply of exogenous phosphate, as may occur with phosphate-based laxatives or enemas, can cause hyperphosphatemia. Oral sodium phosphate solutions for colonoscopy contain large quantities of phosphate that can cause precipitation of calcium phosphate crystals within the kidney tubules and AKI.[50] Recovery from this condition is slow and often incomplete, with some cases resulting in permanent dialysis. For these reasons, bowel preparations other than those based on sodium phosphate salts should be used in patients with CKD. Bisphosphonates, in particular etidronate in Paget disease, can sometimes increase serum phosphate concentrations, possibly through increased liberation of tissue phosphate or an increase in tubular reabsorption.

Hypoparathyroidism

States of reduced PTH secretion (idiopathic or postsurgical hypoparathyroidism) or resistance to its peripheral action (pseudohypoparathyroidism) lead to diminished tubular excretion of phosphate. The resulting hyperphosphatemia increases the ultrafiltered load, leading to regulation of serum phosphate concentrations at a new steady state.

Acromegaly

Insulin-like growth factor 1 (IGF-1) and growth hormone (GH) enhance phosphate reabsorption in the proximal tubules by increasing tubular Npt2a expression. Acromegaly, a hormonal disorder characterized by excess GH and stimulation of IGF-1, is frequently associated with hyperphosphatemia.[51]

Familial Tumoral Calcinosis

This rare autosomal recessive disorder is caused by mutations in either *GALNT3* or *FGF23* genes and seen primarily in people of Middle Eastern or African ancestry. *GALNT3* encodes a glycosyl transferase that catalyzes the O-glycosylation of FGF-23 to protect the molecule from enzymatic cleavage. Disruption *GALNT3* yields a less stable form of FGF-23 that is proteolytically degraded within the cell.[52] Direct mutations in *FGF-23* in tumoral calcinosis also yield a less stable form of the molecule, resulting in a shared phenotype.[53] The lack of functional FGF-23 leads to unopposed phosphate reabsorption by the proximal tubules and calcitriol excess, resulting in hyperphosphatemia, hypercalcemia, and soft tissue calcifications. Serum PTH concentrations may be normal or mildly suppressed.

Respiratory Alkalosis by Prolonged Hyperventilation

Respiratory alkalosis caused by prolonged hyperventilation is characterized by kidney resistance to the actions of PTH, hyperphosphatemia, and hypocalcemia. There may also be functional pseudohypoparathyroidism because kidney phosphate clearance is diminished, whereas serum PTH is normal, despite hypocalcemia. There is no decrease in urinary calcium excretion.

Clinical Manifestations

Acute and severe hyperphosphatemia can cause hypocalcemia by blocking calcitriol synthesis via inhibition of 1-alpha hydroxylase. Chronic hyperphosphatemia is suspected to play a causal role in the pathogenesis of kidney-related soft tissue calcification and CKD-mineral bone disorder (see Chapter 88). In extreme cases, hyperphosphatemia can induce tumor-like deposits of calcium phosphate in soft tissue (Teutschlander disease; Fig. 11.18), crystals within the kidney tubules, and vascular calcification within the arteries of the skin (calciphylaxis or calcific uremic arteriolopathy; see Chapter 91).

Treatment

The treatment of acute hyperphosphatemia is aimed at increasing phosphate excretion by the kidneys, either by IV fluids or by kidney replacement therapies in severe AKI. IV dextrose and insulin promote a shift of phosphate into cells, similar to effects on potassium. The treatment of chronic hyperphosphatemia in patients with advanced

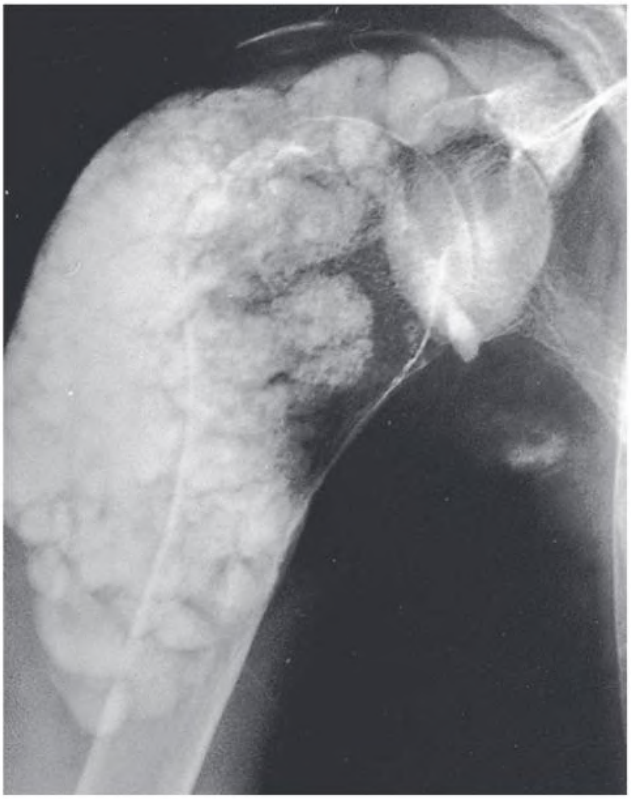

Fig. 11.18 Tumor-like extraskeletal calcification in the shoulder.

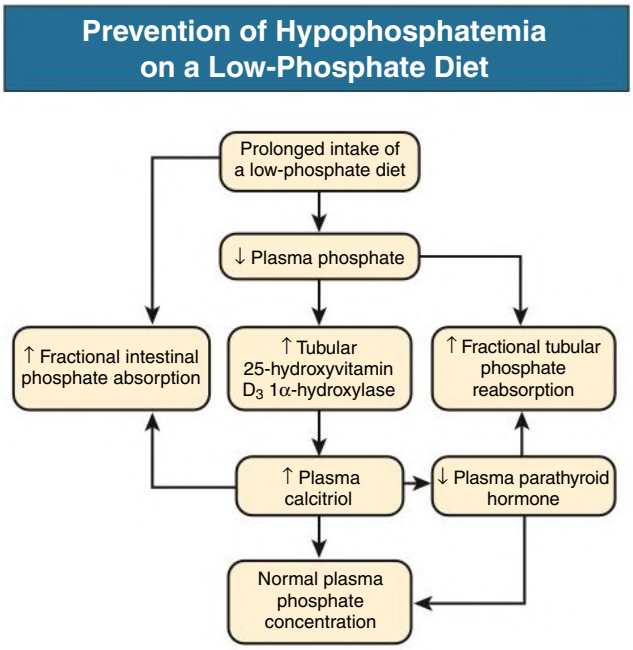

Fig. 11.19 Prevention of Hypophosphatemia. Compensatory mechanisms during prolonged intake of a phosphate-poor diet help prevent hypophosphatemia.

CKD and ESKD may require an oral phosphate binder, which complexes with phosphate in the GI tract to limit absorption (see Chapter 88). Phosphate is removed by dialysis; however, the rate of phosphate elimination during intermittent hemodialysis sessions declines over the course of a single treatment. More frequent sessions may be needed for efficient phosphate clearance.

HYPOPHOSPHATEMIA

Decreased serum phosphate concentrations may occur because of prolonged periods of reduced phosphate intake or malabsorption. However, as shown in Fig. 11.19, several defense mechanisms counter a reduction in serum phosphate that may result from reduced intake.

Causes of Hypophosphatemia

Hypophosphatemia may be caused by genetic diseases or acquired conditions (Fig. 11.20). These conditions may be mechanistically classified into those caused by kidney phosphate wasting, a shift of phosphate into cells, or protracted states of reduced phosphate intake. The urinary phosphate excretion can be used to distinguish among these mechanistic processes. Severe hypophosphatemia (<0.3 mmol/L) is almost always caused by acquired rather than inherited disorders.

Inherited Forms of Hypophosphatemia

Inherited diseases causing hypophosphatemia are usually diagnosed in childhood, when they present with rickets, osteomalacia, dental abscesses, and enthesopathy. These conditions include genetic mutations that culminate in an excess of circulating FGF-23 (hypophosphatemic rickets), disorders of proximal tubular reabsorption (Fanconi syndrome), or defects secondary to another genetically transmitted disease, mainly metabolic disorders or disturbances in the actions of vitamin D.

X-Linked hypophosphatemic rickets. Hypophosphatemic rickets are a group of genetic disorders characterized by a shared phenotype of excess circulating FGF-23, which leads to kidney phosphate wasting, suppressed calcitriol synthesis, and impaired bone mineralization. X-linked hypophosphatemic rickets typically presents in childhood with chronic hypophosphatemia, skeletal deformities, osteomalacia, and short stature; however, the short stature may not be recognized until later in the disease process.[54] The condition is caused by mutations in *PHEX* (phosphate-regulating endopeptidase on the X chromosome), which is believed to play a role in the proteolysis of FGF-23.[55] *PHEX* mutations cause release of excess intact FGF-23 into the circulation with consequent kidney phosphate wasting. PTH levels are typically normal or slightly elevated in response to secondary calcitriol deficiency and hypocalcemia. The alkaline phosphatase level is elevated.

Autosomal-dominant hypophosphatemic rickets. Children with this phosphate-wasting disorder present with skeletal defects, including bowing of the long bones, widening of costochondral joints, and dental abscesses. The condition is caused by activating mutations in *FGF-23.* In contrast to familial tumoral calcinosis, in which *FGF-23* mutations yield an unstable form of the molecule that is prone to proteolysis, mutations in autosomal-dominant hypophosphatemic rickets yield an aberrant form of FGF-23 that is resistant to proteolytic cleavage.[56]

Autosomal-recessive hypophosphatemic rickets. This disorder is caused by mutations in either *DMP1, ENPP1,* or *FAM20C,* which result in increased production of intact FGF-23.[57] *ENPP1* and *FAM20C* mutations are also associated with pathologic calcification of the medium and large arteries.

Fanconi syndrome and proximal renal tubular acidosis. Fanconi syndrome (see Chapter 50) is characterized by complex transport defects in the proximal tubules that lead to impaired reabsorption of glucose, amino acids, bicarbonate, and phosphate. Because more than 70% of the filtered phosphate load is typically reabsorbed in the proximal tubules, Fanconi syndrome is associated with kidney phosphate wasting and hypophosphatemia. Inherited causes of

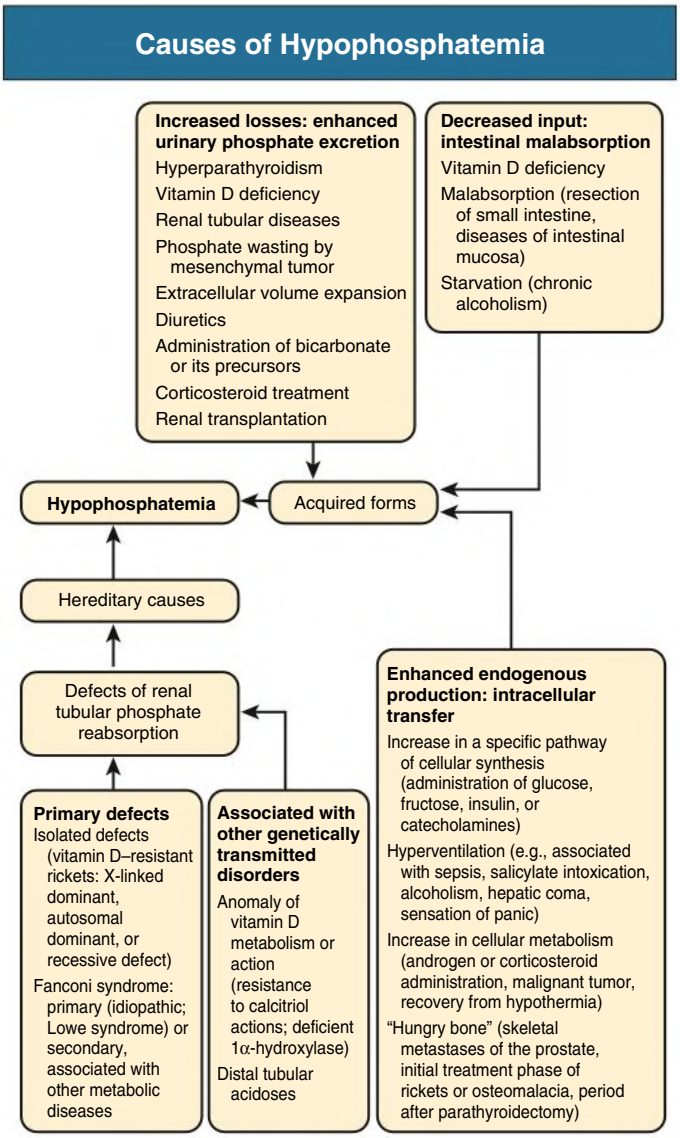

Fig. 11.20 Causes of hypophosphatemia.

Fanconi syndrome include primary disorders (Lowe syndrome, Dent disease) and other metabolic conditions (cystinosis, Wilson disease). In Dent disease and Lowe syndrome, defective recycling of megalin to the apical cell surface of the proximal tubule has been found, implicating a role in abnormal endocytic function.[58]

Fanconi syndrome with kidney phosphate wasting may also occur in adults as an acquired disorder. Common causes are multiple myeloma[59] and specific drugs, such as tenofovir, ifosfamide, and carbonic anhydrase inhibitors. In acquired Fanconi syndromes, kidney 1α-hydroxylase activity may be impaired, leading to reduced calcitriol synthesis and impaired bone mineralization.

Hypophosphatemia linked to other inherited diseases. Several rare inherited disorders of vitamin D metabolism may be associated with hypophosphatemia.[60] These include mutations in *CYP27B1*, which encodes 1α-hydroxylase, and *CYP2R1*. Inactivating mutations in *CYP27B1* (vitamin D–dependent rickets type I) typically present with severe hypocalcemia in the first year of life. The treatment is calcitriol replacement. Mutations in *VDR* (vitamin D–dependent rickets type II) also present early in life. In addition to hypocalcemia, hypophosphatemia, and bone disease, alopecia is a defining feature. *VDR* mutations may respond to extremely high doses of calcitriol depending on the severity of the mutation.

Distal renal tubular acidosis (type 1). Distal renal tubular acidosis type 1 (see Chapter 13) is associated with hypercalciuria and nephrocalcinosis because chronic metabolic acidosis enhances citrate reabsorption in the proximal tubules, preventing formation of soluble calcium-citrate complexes in the urine. Chronic acidosis also increases release of calcium and phosphate from bone. Hypophosphatemia is inconsistently found in this disorder.

Acquired Forms of Hypophosphatemia

The number of acquired diseases that are associated with hypophosphatemia is even greater than the inherited diseases (see Fig. 11.19). True phosphate deficiency associated with total body depletion must be distinguished from shifts of phosphate into cells or increased skeletal mineralization.

Alcoholism. Alcoholism is the most common cause of severe hypophosphatemia in Western countries. The mechanisms are multiple, including prolonged insufficient food intake, GI malabsorption, and, among hospitalized patents, glucose infusion, which stimulates insulin release driving phosphate from the extracellular to intracellular compartment.

Hyperparathyroidism. Primary hyperparathyroidism typically presents in middle age with asymptomatic hypercalcemia.[61] PTH downregulates NPT2a cotransporters in the proximal tubule causing kidney phosphate wasting and hypophosphatemia.

Posttransplantation hypophosphatemia. Kidney phosphate wasting is common in kidney transplant recipients, whether the organ is from a living or deceased donor. The primary cause is residual elevations of PTH, FGF-23, or both phosphaturic hormones in combination as a consequence of previous longstanding kidney disease.[62]

Acute respiratory alkalosis. In acute respiratory alkalosis, serum phosphate concentrations can sometimes decrease considerably to values as low as 0.1 mmol/L (0.3 mg/dL). Such a decrease is never observed in acute metabolic alkalosis. Hypophosphatemia that follows acute and intense hyperventilation is probably the result of muscle sequestration of extracellular phosphate. In contrast, prolonged chronic hyperventilation is associated with hyperphosphatemia (see previous discussion).

Diabetic ketoacidosis. During decompensated diabetes with acidosis provoked by the accumulation of ketone bodies, serum phosphate concentrations may initially be normal or high, even in the presence of hyperphosphaturia. Correction of ketoacidosis by insulin and refilling of the extracellular compartment leads to massive transfer of phosphate into the intracellular compartment, hypophosphatemia, and, subsequently, a reduction in urinary phosphate excretion. Serum phosphate concentrations typically do not decrease to less than 0.3 mmol/L (0.9 mg/dL) unless there is preexisting phosphate deficiency.

Total parenteral nutrition. Hyperalimentation can also be associated with severe hypophosphatemia because of insulin-mediated shift of phosphate into cells, particularly if phosphate is omitted from the parenteral nutrition solution. Severe hypophosphatemia is also a recognized complication of acute refeeding after starvation.

Tumor-induced osteomalacia. Certain mesenchymal tumors (hemangiopericytomas, fibromas, angiosarcomas) may express FGF-23 and other phosphatonins (sFRP-4, matrix extracellular phosphoglycoprotein [MEPE], or FGF-7). These tumors may present with a paraneoplastic syndrome of marked FGF-23 excess (tumor-induced osteomalacia) with clinical features of acute to subacute onset weakness, unexplained skeletal fractures, profound hypophosphatemia, and

kidney phosphate wasting.[63] The condition resolves promptly after tumor resection.

Drug-induced hypophosphatemia. Hypophosphatemia may be caused by specific drugs. Tenofovir disoproxil fumarate (TDF) is associated with an acquired Fanconi syndrome that includes kidney phosphate wasting.[64] IV iron repletion with ferric carboxymaltose is associated with an abrupt rise in serum FGF-23, kidney phosphate wasting, and severe hypophosphatemia.[65] This drug is suspected to stabilize FGF-23 in the circulation. Imatinib mesylate, a tyrosine kinase inhibitor, and sorafenib, a vascular endothelial growth factor (VEGF) inhibitor, are both associated with hypophosphatemia[66]; the mechanism remains unclear.

Continuous kidney replacement therapies. Hypophosphatemia is commonly seen in patients receiving continuous venovenous hemofiltration or hemodialysis for AKI because of the constant removal of phosphate by these modalities. Phosphate repletion or the addition of phosphate to the replacement fluid is often required to maintain serum phosphate concentrations within the normal range.

Clinical Manifestations

Clinical manifestations of hypophosphatemia depend on the rate of onset more than the severity or total body phosphate deficit. In practice, hypophosphatemia is not clinically evident until serum phosphate concentrations are less than 0.65 mmol/L (2.0 mg/dL). Manifestations include metabolic encephalopathy, red and white blood cell dysfunction, sometimes hemolysis, and thrombocytopenia. Reduced muscle strength and decreased myocardial contractility (with occasional rhabdomyolysis and cardiomyopathy, respectively) may also occur.

Treatment

Hypophosphatemia is generally not an emergency. First, the mechanism involved should be defined to determine the most appropriate treatment. Inherited conditions characterized by FGF-23 excess (hypophosphatemic rickets) are treated by phosphate repletion and calcitriol replacement. A recombinant human immunoglobulin G1 (IgG1) monoclonal antibody to FGF-23 (Burosumab) has been developed and approved for the treatment of X-linked hypophosphatemic rickets.[67] This treatment has also been used in cases of tumor-induced osteomalacia in which the tumor cannot be surgically resected. For kidney transplant recipients with hypophosphatemia, treatment is directed toward refractory hyperparathyroidism, which is the usual underlying cause along with elevated FGF-23. Initial treatments include supplementation with cholecalciferol and, if serum phosphate concentrations are extremely low (<0.5 mmol/L), oral phosphate replacement. Management of refractory hyperparathyroidism in kidney transplantation shares similarities with primary hyperparathyroidism: Consideration for parathyroidectomy is based on the severity of hypercalcemia and accompanying bone and other complications of the disease. Cinacalcet may be considered for nonsurgical candidates.

When phosphate deficiency is diagnosed, oral treatment by milk products or phosphate salts should be tried first whenever possible, except in the presence of nephrocalcinosis or nephrolithiasis with urinary phosphate wasting. In severe symptomatic deficiency, phosphate can also be infused by IV in divided doses over 24 hours. In patients undergoing parenteral nutrition, 10 to 25 mmol potassium phosphate should be given for each 1000 kcal, with care taken to avoid hyperphosphatemia because of the risk of inducing soft tissue calcification. Dipyridamole (300 mg divided into four doses per day) reduces the urinary excretion of phosphate in patients with a low renal phosphate threshold.

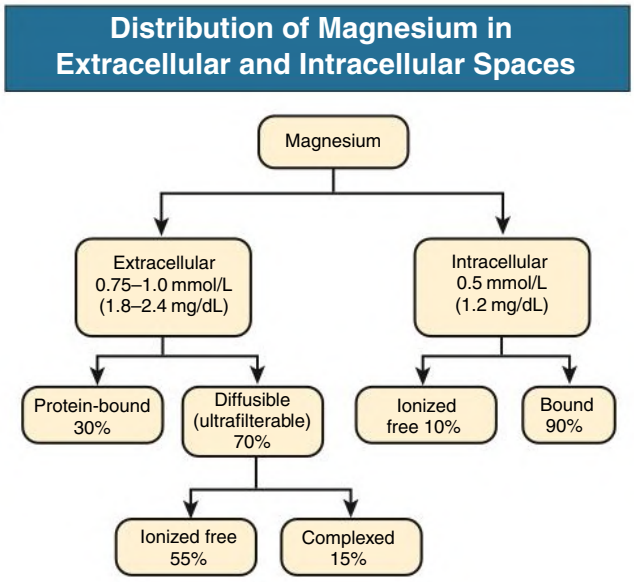

Fig. 11.21 Magnesium Distribution in Extracellular and Intracellular Spaces. Intracellular magnesium concentration is that of free, not total, magnesium.

MAGNESIUM HOMEOSTASIS AND DISORDERS OF MAGNESIUM METABOLISM

Distribution of Magnesium in the Organism and Magnesium Homeostasis

Magnesium is the second most abundant cation in the intracellular fluid after potassium. Magnesium contributes to the regulation of mitochondrial function, inflammatory processes, growth, neuronal activity, cardiac excitability, neuromuscular transmission, vasomotor tone, and blood pressure. The distribution of magnesium within the intracellular and extracellular spaces is shown in Fig. 11.21. Similar to calcium and phosphate, circulating magnesium concentrations [Mg^{2+}] represent only a minute fraction of total body magnesium.

Fig. 11.22 shows the balance of ingestion, body distribution, and excretion of magnesium in healthy individuals. Unlike calcium and phosphate, there is no hormonal system known to specifically regulate whole-body magnesium homeostasis. Magnesium moves into and out of cells through active transport systems. Insulin promotes magnesium influx into cells, whereas stimulation of β-adrenoceptors favors magnesium efflux.[68,69]

Intestinal and Kidney Handling of Magnesium

Magnesium is present in a wide variety of foods, especially nuts, seeds, and beans. Sufficient dietary intake is about 300 mg/day (12 mmol/day). Intestinal magnesium absorption varies from 25% to 60% with a mean of approximately 30%. Compared with calcium and phosphate, magnesium absorption occurs more distally in the GI tract, including the colon. Transcellular magnesium transport in the intestine is mediated by the melastatin-related transient receptor potential cation channels 6 and 7 (TRPM6 and TRPM7).[70,71]

The kidneys are the primary route of magnesium elimination because losses through intestinal secretion and sweat are small under normal conditions. Approximately 70% of circulating [Mg^{2+}] is filtered in the glomerulus (104 mmol or 2500 mg/day). Tubular reabsorption occurs primarily in the thick ascending loop of Henle (65%) with additional reabsorption in the proximal tubules (25%) and distal convoluted tubules (5%; Fig. 11.23).[72] Under normal conditions, the

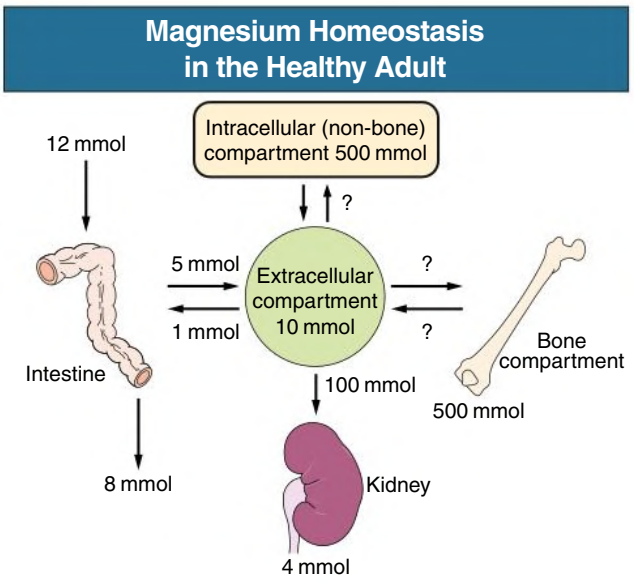

Fig. 11.22 Magnesium Homeostasis in Healthy Adults. Net zero balance results from net intestinal uptake (absorption minus secretion) equaling urinary loss. After its passage into the extracellular fluid, Mg^{2+} enters the intracellular space, is deposited in bone or soft tissue, or is eliminated via the kidneys. Entry and exit fluxes between the extracellular and intracellular spaces (skeletal and nonskeletal compartments) are also of identical magnitude; however, precise values of exchange are still debated.

urinary excretion of magnesium represents approximately 5% of the filtered load (4–5 mmol or 100 mg/day). This value constitutes a general cut point for assessing conditions of kidney magnesium wasting; a fractional magnesium excretion greater than 5% in the presence of hypomagnesemia suggests inappropriate urinary losses.

The bulk reabsorption of salt and water in the proximal tubules drives parallel reabsorption of chloride, potassium, and calcium. Yet the proximal tubules are relatively impermeable to magnesium accounting for its proportionately small reabsorption in this segment.[73] Members of the claudin family of proteins are suspected to facilitate magnesium transport in the proximal tubules; however, the specific components remain unknown.

In the TAL, magnesium is transported via paracellular claudin channels in tight junctions. Specifically, claudins 16 and 19 are hypothesized to include a cation-selective pore that facilitates calcium and magnesium reabsorption.[74] This transport is driven by reabsorption of Na^+, K^+, and $2Cl^-$ through the apical NKCC2 cotransporter, which generates an electrical lumen-positive gradient (see Fig. 11.9). The renal outer medullary potassium (ROMK) channel promotes NKCC2 activity by recycling potassium into the lumen, thereby enhancing magnesium reabsorption. Stimulation of the basolateral CaSR by calcium or magnesium directly decreases paracellular permeability, reducing magnesium reabsorption. Defects in NKCC2 caused by genetic disorders, specific drugs, or electrolyte imbalances lead to kidney magnesium wasting (see later discussion).[28] Approximately 5% of the filtered Mg^{2+} load is reabsorbed in the distal convoluted tubule

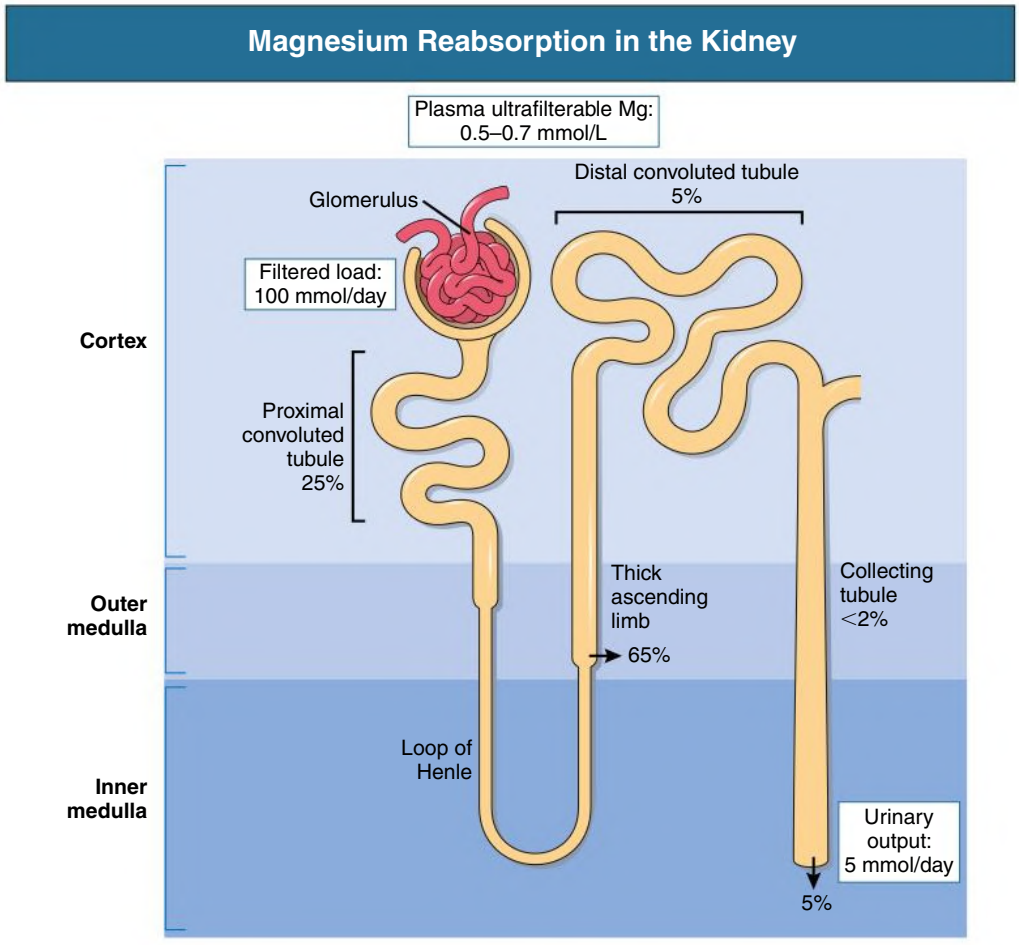

Fig. 11.23 Sites of Magnesium Reabsorption in Various Segments. Percentage absorbed in various segments of the renal tubule from the glomerular ultrafiltrate. (Redrawn from Shimada T, Kakitani M, Yamazaki Y, et al. Targeted ablation of Fgf23 demonstrates an essential physiologic role of FGF23 in phosphate and vitamin D metabolism. *J Clin Invest.* 2004;113[4]:561–568.)

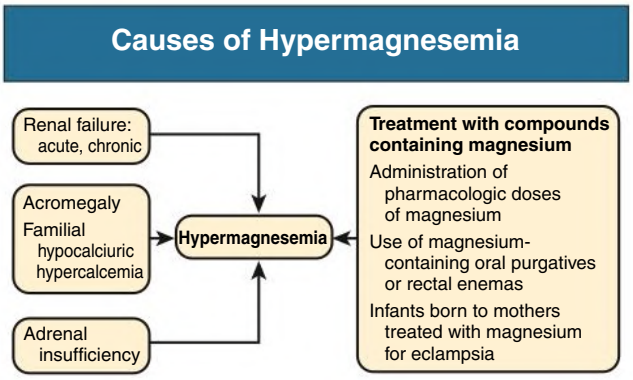

Fig. 11.24 Causes of hypermagnesemia.

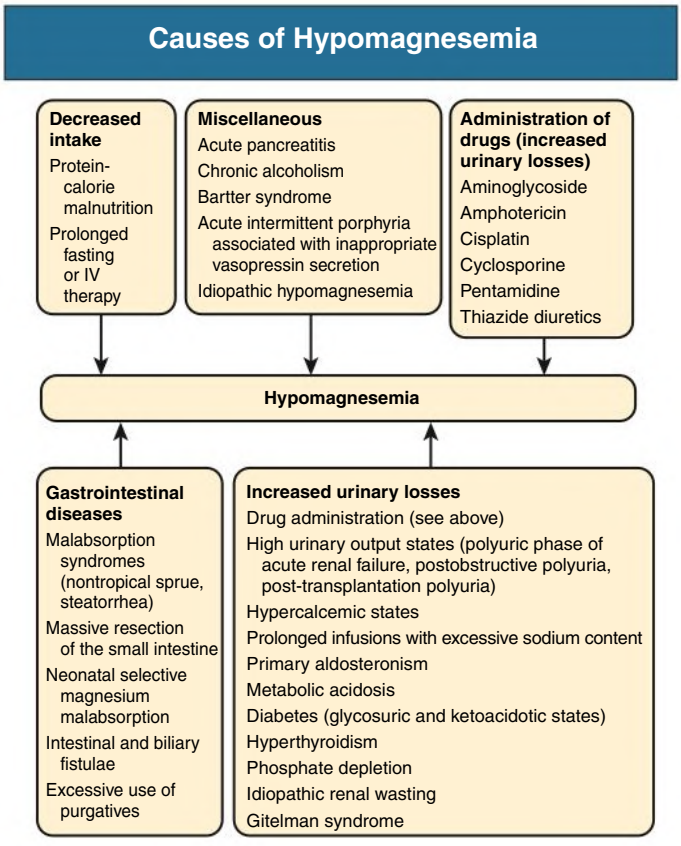

Fig. 11.25 Causes of hypomagnesemia.

via the identical TRPM6 channel found in the intestine. This channel colocalizes with the thiazide-sensitive Na^+ Cl^- cotransporter (NCC).[75] Conditions that impair NCC activity lead to reductions in magnesium reabsorption in the distal tubule.

Tubular magnesium transport is modulated by circulating [Mg^{2+}] and [Ca^{2+}] and by extracellular fluid volume. An increase in serum [Mg^{2+}] or [Ca^{2+}] reduces kidney magnesium reabsorption.[76] Extracellular volume expansion suppresses the reabsorption of sodium, chloride, potassium, and, to a lesser extent, magnesium in the proximal tubules.[77] Other hormones that can increase magnesium reabsorption include PTH, vasopressin, calcitonin, and glucagon.[78]

Hypermagnesemia

Elevated serum [Mg^2] can be seen in patients with acute kidney disease and CKD because of decreased elimination; however, enhanced single-nephron magnesium excretion in CKD tends to prevent overt hypermagnesemia. Elevated serum [Mg^{2+}] may also be observed with an increase in magnesium intake or administration, such as pharmacologic doses of magnesium for treating preeclampsia, oral magnesium-containing laxatives or rectal enemas, and Epsom salts (Fig. 11.24).[79] Mild hypermagnesemia may also occur in patients with adrenal insufficiency, acromegaly, and familial hypocalciuric hypercalcemia.

Clinical Manifestations

Symptoms and signs of hypermagnesemia are the result of the pharmacologic effects of magnesium on the nervous and cardiovascular systems. At concentrations of up to 1.5 mmol/L (3.6 mg/dL), hypermagnesemia is usually asymptomatic. Deep tendon reflexes are typically reduced or lost when serum [Mg^{2+}] exceeds 3.0 mmol/L (7.2 mg/dL). Respiratory paralysis, hypotension, abnormal cardiac conduction, and loss of consciousness may occur as serum [Mg^{2+}] approaches 5.0 mmol/L (12 mg/dL).

Treatment

Treatment of hypermagnesemia consists of cessation of magnesium administration and IV infusion of isotonic fluids and calcium salts, which promote kidney excretion. For management of symptomatic hypermagnesemia, calcium gluconate may be administered by IV as 1 g in 10 mL over 5 to 10 minutes (each gram of calcium gluconate is equal to approximately 90 mg of elemental calcium). Loop diuretics may also be used, where appropriate, to enhance kidney magnesium elimination.

HYPOMAGNESEMIA AND MAGNESIUM DEFICIENCY

Magnesium deficiency refers to a deficit in total body magnesium stores, whereas hypomagnesemia refers to low circulating magnesium concentrations. Although serum concentrations do not directly reflect total body magnesium stores, there is no practical test for whole-body deficiency. Therefore, clinical focus relates to hypomagnesemia. Causes can be broadly classified into conditions of reduced GI intake and disorders of kidney wasting (Fig. 11.25). The fractional excretion of magnesium can be used to distinguish between these mechanistic processes.

Dietary and Gastrointestinal Causes

A temporary reduction in dietary magnesium intake does not usually cause magnesium deficiency because of the remarkable ability of the kidneys to conserve magnesium. However, prolonged and severe dietary deficiency of less than 0.5 mmol/day can produce symptomatic deficiency. Chronic alcoholism is among the most common causes of hypomagnesemia in hospitalized patients predominantly because of marked nutritional deficiency and some degree of inappropriate kidney wasting.[69] Decreased intestinal absorption may also be seen in malabsorption syndromes, such as nontropical sprue, diarrheal illnesses, and after bowel resection. Proton pump inhibitors can inhibit intestinal magnesium absorption; chronic use of these medications is associated with hypomagnesemia.[80] Hypomagnesemia and hypocalcemia are also observed in patients with acute pancreatitis because of saponification in necrotic fat.

Kidney Causes

Diuretics are the most common acquired cause of kidney magnesium wasting in adults. Loop diuretics block the NKCC2 cotransporter, reducing the driving force for adjacent paracellular reabsorption. Thiazide diuretics block the NCC cotransporter in the distal tubule, which colocalizes with TRPM6, leading to reduced kidney magnesium reabsorption. Several other medications interfere with kidney

magnesium reabsorption and are associated with hypomagnesemia: gentamicin, cisplatin, amphotericin, calcineurin inhibitors (cyclosporine and tacrolimus), and monoclonal antibodies to the epidermal growth factor receptor (cetuximab and panitumumab).[81] Hypercalcemia can also induce kidney magnesium wasting by activating the CaSR in the thick ascending limb.

Primary inherited conditions causing kidney magnesium wasting are Bartter and Gitelman syndromes. Bartter syndrome is an autosomal recessive disorder caused by mutations in genes encoding major ion transporters in the TAL.[82] These include the basolateral Cl^- channel (encoded by *CLCNKB*), the NKCC2 cotransporter (encoded by *SLC12A1*), and the ROMK channel (encoded by *KCNJ1*). Genetically mediated dysfunction of this kidney segment leads to a "loop diuretic-like effect" with loss of potassium, calcium, and magnesium in the urine. Bartter syndrome typically presents in childhood with features of growth retardation, polyuria, metabolic alkalosis, hypokalemia, and hypomagnesemia.

Gitelman syndrome is an autosomal recessive disorder caused by inactivating mutations in the gene encoding the NaCl transporter NCC (*SLC12A3*).[83] Genetic disruption of NCC produces a thiazide diuretic–like effect with loss of sodium, potassium, and magnesium in the urine but with increased reabsorption of calcium. In contrast to Bartter syndrome, Gitelman syndrome typically presents in adulthood with muscle cramps, fatigue, hypokalemia, and hypomagnesemia. Bartter and Gitelman syndromes can be distinguished by the kidney handling of calcium. By mimicking the action of loop diuretics, Bartter syndrome is associated with kidney calcium wasting. In contrast, by mimicking the action of thiazide diuretics, Gitelman syndrome is associated with enhanced tubular calcium reabsorption.

The presence of Bartter or Gitelman syndrome is suggested by a constellation of chronic metabolic alkalosis, hypokalemia, and hypomagnesemia in the context of normal to low blood pressures and absence of known diuretic treatment. Two conditions that share these metabolic features are volume depletion caused by vomiting and the surreptitious use of diuretics. The urinary chloride concentration can be helpful for excluding vomiting in this situation (urinary chloride concentration typically <20 mEq/L in states of volume depletion). Differentiating covert diuretic use from Bartter or Gitelman syndromes is difficult because these genetic conditions mimic the effects of loop and thiazide diuretics, respectively.

Clinical Manifestations

Specific clinical manifestations of hypomagnesemia may be difficult to appreciate because of concomitant hypocalcemia and hypokalemia. Moreover, moderate degrees of magnesium deficiency can be difficult to detect because clinical manifestations may be absent, and blood levels may not reflect total body magnesium. Clinical manifestations of moderate to severe magnesium depletion include generalized weakness and neuromuscular hyperexcitability with hyperreflexia, carpopedal spasm, seizure, tremor, and, rarely, tetany. Cardiac findings may include a prolonged QT interval, ST depression, torsades de pointes, and potentiation of digoxin toxicity. The role of magnesium deficiency in seizure activity is demonstrated by its effectiveness as a treatment; among women with eclampsia, IV magnesium administration is more effective than phenytoin for the treatment of seizures.[84]

An important physiologic consequence of hypomagnesemia is blunting of the PTH response to calcium, leading to a state of relative hypoparathyroidism. Reduced PTH secretion consequently results in hypocalcemia and reduced calcitriol synthesis.

Treatment

Magnesium deficiency is managed by administration of magnesium salts. Magnesium sulfate is generally used for parenteral therapy (1500–3000 mg [150–300 mg elemental magnesium] per day). A variety of magnesium salts are available for oral administration, including oxide, hydroxide, sulfate, lactate, chloride, carbonate, and pidolate. The use of oral magnesium is often limited by GI side effects, particularly diarrhea, at higher dosages.

In Bartter and Gitelman syndromes, magnesium and potassium supplementation along with increased sodium intake are initially used to address the attendant electrolyte disturbances. Amiloride, which blocks distal sodium and potassium exchange, can help restore serum potassium and magnesium concentrations if concomitant volume contraction can be avoided. The defective loop sodium transport in Bartter syndrome stimulates prostaglandin synthesis and activates the renin-angiotensin-aldosterone system. These metabolic disturbances are countered by nonsteroidal anti-inflammatory agents and angiotensin-converting enzyme inhibitors, respectively, promoting their use in Bartter syndrome with careful monitoring of kidney function.

SELF-ASSESSMENT QUESTIONS

1. Which is the most common cause of hypercalcemia in patients with a low serum PTH level?
   - **A.** Secondary hyperparathyroidism
   - **B.** Cholecalciferol or ergocalciferol therapy
   - **C.** Malignant neoplasias
   - **D.** Familial hypocalciuric hypercalcemia
   - **E.** Hypomagnesemia
2. Which is a primary cause of hypocalcemia in patients with chronic kidney disease?
   - **A.** Primary hypoparathyroidism
   - **B.** Secondary hyperparathyroidism
   - **C.** Impaired calcitriol synthesis
   - **D.** Blunted response to FGF-23
   - **E.** Treatment with phosphate binders
3. Which kidney tubular segment is responsible for regulating phosphate balance?
   - **A.** Proximal tubule
   - **B.** Thick ascending limb
   - **C.** Distal tubule
   - **D.** Outer collecting duct
   - **E.** Inner collecting duct
4. Hypophosphatemic rickets describe a group of genetic conditions characterized by an increase in circulating concentrations of which molecule?
   - **A.** Calcitriol
   - **B.** Parathyroid hormone
   - **C.** Calcium
   - **D.** FGF-23
   - **E.** Phosphate-regulating endopeptidase on the X chromosome
5. Which of the following is most helpful in distinguishing a genetic cause of hypomagnesemia from surreptitious vomiting?
   - **A.** Serum calcium
   - **B.** Serum phosphate
   - **C.** Urinary chloride
   - **D.** Urinary potassium
   - **E.** Prolonged QT interval

Normal Acid-Base Balance

Biff F. Palmer

DEFINITION

The acid-base status of the body is carefully regulated to maintain arterial pH between 7.35 and 7.45 and intracellular pH between 7.0 and 7.3. This regulation occurs in the setting of continuous production of acidic metabolites and is accomplished by intracellular and extracellular buffering processes with respiratory and renal regulatory mechanisms. This chapter reviews the normal physiology of acid-base homeostasis.

NET ACID PRODUCTION

Both acid and alkali are generated from diet. Lipid and carbohydrate metabolism results in production of carbon dioxide (CO_2), a volatile acid, at the rate of approximately 15,000 mmol/day. Protein metabolism yields amino acids, which can be metabolized to form nonvolatile acid and alkali. Amino acids such as lysine and arginine yield acid on metabolism, whereas the amino acids glutamate and aspartate and organic anions such as acetate and citrate generate alkali. Sulfur-containing amino acids (methionine, cysteine) are metabolized to sulfuric acid (H_2SO_4), and organophosphates are metabolized to phosphoric acid (H_3PO_4). In general, animal foods are high in proteins and organophosphates and provide a net acid diet; plant foods are higher in organic anions and provide a net alkaline load. In addition to acid and alkali generated from diet, there is a small daily production of organic acids, including acetic acid, lactic acid, and pyruvic acid. Also, a small amount of acid is generated by the excretion of alkali into the stool. Under normal circumstances, daily net nonvolatile acid production is approximately 1 mmol of hydrogen ions (H^+) per kilogram of body weight (Fig. 12.1).

BUFFER SYSTEMS IN REGULATION OF PH

Intracellular and extracellular buffer systems minimize the change in pH during the addition of acid or base equivalents but do not remove acid or alkali from the body. The most important buffer system is bicarbonate ion and carbon dioxide (HCO_3^--CO_2). In this system, carbon dioxide concentration [CO_2] is maintained at a constant level set by respiratory control. Addition of acid (HA) leads to conversion of HCO_3^- to CO_2 according to the reaction $HA + NaHCO_3 \rightarrow NaA + H_2O + CO_2$. HCO_3^- is consumed, but [CO_2] does not change because this is maintained by respiration. The net result is that the acid load has been buffered and pH changes are minimal.

Although the HCO_3^--CO_2 buffer system is the most important of the buffers in extracellular fluid (ECF), other buffers such as plasma proteins and phosphate ions also participate in the maintenance of a stable pH. During metabolic acidosis, the skeleton becomes a major buffer source as acid-induced dissolution of bone apatite releases alkaline Ca^{2+} salts and HCO_3^- into the ECF. With chronic metabolic acidosis, this can result in osteomalacia and osteoporosis. The calcium released can result in hypercalciuria and an increased likelihood of renal stones. Within the intracellular fluid (ICF) compartment, pH is maintained by intracellular buffers such as hemoglobin, cellular proteins, organophosphate complexes, and HCO_3^- as well as by the $H^+ - HCO_3^-$ mechanisms that transport acid and alkali in and out of the cell.

RESPIRATORY SYSTEM IN REGULATION OF PH

Removal of acid or alkali from the body is accomplished by the lungs and kidneys. The lungs regulate CO_2 tension (P_{CO_2}), and the kidneys regulate serum bicarbonate concentration [HCO_3^-]. Although the [HCO_3^-]-CO_2 buffer system is not the only buffer system, all extracellular buffer systems are in equilibrium. Because serum [HCO_3^-] is much greater than that of other buffers, changes in the HCO_3^--CO_2 buffer pair easily titrate other buffer systems and thus set pH. The Henderson-Hasselbalch equation explains how the lungs and kidneys function in concert: pH is determined by the ratio of HCO_3^- to CO_2. Conditions associated with similar fractional changes in [[HCO_3^-]] and [CO_2], such as when both are halved, will not change blood pH.

The lungs defend pH by altering alveolar ventilation, which alters the CO_2 excretion rate and thereby controls the arterial CO_2 tension (P_{aCO_2}) of body fluids. Systemic acidosis stimulates the respiratory center, resulting in increased respiratory drive that lowers the P_{aCO_2}. As a result, the fall in blood pH is less than would have occurred in the absence of respiratory compensation. If the fractional change in P_{CO_2} were similar to that in serum [[HCO_3^-]], blood pH would not change. However, respiratory compensation rarely normalizes blood pH, and thus the fractional change in P_{CO_2} is less than the change in serum [[HCO_3^-]]. Quantitatively, the normal respiratory response in metabolic acidosis is a 1.2 mm Hg decrease in P_{aCO_2} for every 1 mmol/L decrease in HCO_3^-; the increase in P_{aCO_2} in response to metabolic alkalosis averages 0.7 mm Hg for every 1 mmol/L increase in HCO_3^- above baseline.[1]

KIDNEY REGULATION OF pH

Buffer systems and respiratory excretion of CO_2 help maintain normal acid-base balance, but the kidneys provide a critical role in acid-base homeostasis. The kidneys normally generate sufficient net acid excretion (NAE) to balance nonvolatile acid produced from normal metabolism. NAE has three components, titratable acids, ammonium (NH_4^+), and bicarbonate, and is calculated by the following formula:

$$NAE = V\left(U_{Am} + U_{TA} - U_{HCO_3^-}\right)$$

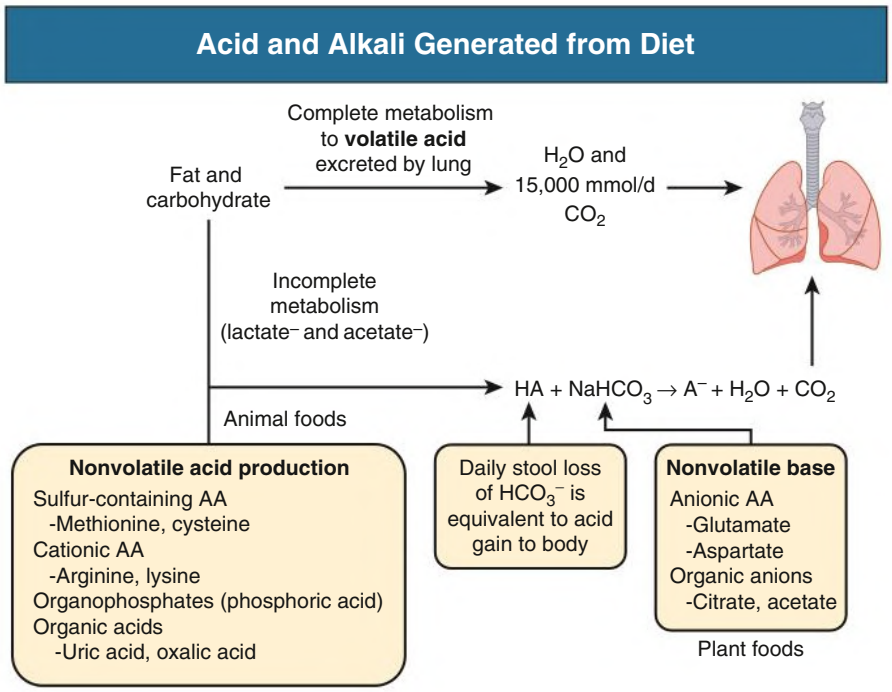

Fig. 12.1 Acid and Alkali Generated From the Diet. A nonvolatile acid is an acid produced from sources other than CO_2 and is not excreted by the lungs. Nonvolatile acids are produced from incomplete metabolism of carbohydrates, fats, and proteins and from metabolism of animal foods. Plant foods tend to produce an alkali load. *AA,* Amino acids.

where $U_{Am}V$ is the rate of NH_4^+ excretion, $U_{TA}V$ is the rate of titratable acid excretion, and $U_{HCO_3^-}V$ is the rate of HCO_3^- excretion. Under basal conditions, approximately 40% of NAE is in the form of titratable acids and 60% is in the form of ammonia (NH_3); urinary bicarbonate concentrations and excretion are essentially zero under normal conditions.

Titratable acidity refers to weak acids filtered at the glomerulus that can act as buffers in the urine. These buffers are referred to as titratable because they are measured by determining the amount of alkali required to titrate the urine back to a pH of 7.4. To serve as a titratable buffer, a buffer must have a pK_a near the range of tubular fluid pH. The most important titratable buffer is phosphate ($HPO_4^{2-} \leftrightarrow H_2PO_4^-$) because it has a favorable pK_a of 6.80 and there is a relatively high rate of urinary excretion. However, when acid production increases, the increase in acid excretion is almost entirely caused by an increase in excretion of NH_4^+ because the ability to increase urinary phosphate is limited.

KIDNEY TRANSPORT MECHANISMS OF HYDROGEN AND BICARBONATE IONS

Glomerulus

The glomerulus is not normally considered a participant in acid-base regulation. However, the glomerulus filters an amount of HCO_3^- equivalent to serum [[HCO_3^-]] multiplied by the glomerular filtration rate (GFR). Under normal circumstances, the filtered load of HCO_3^- averages approximately 4000 mmol/day. Normal acid-base homeostasis requires both the reabsorption of this filtered bicarbonate and the generation of "new" bicarbonate; the latter replenishes bicarbonate and other alkaline buffers consumed in the process of titrating endogenous acid production. From the standpoint of prevention or correction of acidosis, GFR is not regulated by alterations in acid or base and therefore does not contribute to acid-base homeostasis.

Proximal Tubule

The proximal tubule reabsorbs approximately 80% of the filtered load of HCO_3^-. In addition, by titration of luminal pH from 7.4 down to approximately 6.7, the majority of phosphate, the major form of titratable acid, is titrated to its acid form. Finally, ammonia synthesis occurs in the proximal tubule.

Fig. 12.2 shows the acid-base transport mechanisms of the proximal tubule cell. HCO_3^- absorption from the tubular lumen is mediated by H^+ secretion across the membrane.[2] This H^+ secretion is active in that the electrochemical gradient favors H^+ movement from lumen to cell. Two mechanisms mediate active apical H^+ secretion. Approximately two-thirds occurs through the apical membrane Na^+-H^+ antiporter NHE3.[3] This protein uses the inward Na^+ gradient to drive H^+ secretion. The Na^+-H^+ exchanger has a 1:1 stoichiometry and is electroneutral. In parallel with the Na^+-H^+ antiporter, there is an apical membrane H^+-ATPase that mediates approximately one-third of basal proximal tubular HCO_3^- absorption.

Both these H^+ transporters generate base in the cell, which must exit across the basolateral membrane to effect transepithelial transport. This primarily occurs through a basolateral Na^+- HCO_3^--CO_3^{2-} cotransporter.[4] Because this protein transports the equivalent of two net negative charges, the negative cell voltage generated by the basolateral Na^+,K^+-ATPase provides a strong favorable driving force for base efflux. The Na^+ carried on this transporter is moved out of the cell without requiring ATP. The Na^+-$3HCO_3^-$ cotransporter NBCe1, encoded by the gene *SLC4A4,* mediates most of the exit of base from the proximal tubule.[5]

Carbonic anhydrase II is present in the proximal tubular cell cytoplasm, and carbonic anhydrase IV is on the apical and basolateral membranes. Carbonic anhydrase (carbonate dehydratase) has a number of functions in the proximal tubule. Apical membrane carbonic anhydrase allows secreted H^+ ions to react with luminal HCO_3^-, forming H_2CO_3, which rapidly dissociates to CO_2 + H_2O. This CO_2 diffuses across the apical plasma membrane into the cell. There the

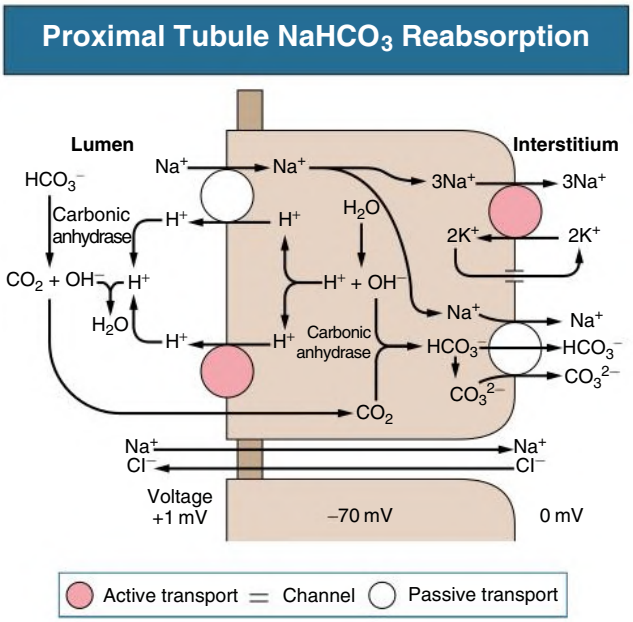

Fig. 12.2 Proximal tubule Sodium Bicarbonate ($NaHCO_3$) Reabsorption. The secretion of H^+ into the proximal tubule lumen involves a Na^+-H^+ antiporter and an H^+-ATPase. Apical membrane H^+ secretion generates OH^-, which reacts with CO_2 to form HCO_3^- and CO_3^{2-}, and these exit with a Na^+ on the basolateral membrane Na^+-HCO_3^--CO_3^{2-} cotransporter. The Na^+ absorbed by the Na^+-H^+ antiporter exits the cell on the basolateral membrane Na^+,K^+-ATPase and the Na^+-HCO_3^--CO_3^{2-} cotransporter. The K^+ that enters the cell on the Na^+,K^+-ATPase exits on a basolateral membrane K^+ channel. Carbonic anhydrase catalyzes the conversion of HCO_3^- to CO_2 and OH^- in the lumen and the reverse reaction in the cell. Electrogenic H^+ secretion generates a small, lumen-positive voltage that generates a current flow across the paracellular pathway.

process is reversed, with use of cytoplasmic carbonic anhydrase, generating intracellular H^+ and HCO_3^-. This H^+ "replenishes" the H^+ secreted across the apical membrane, resulting in net movement of the HCO_3^- from the luminal solution to the cell cytoplasm. The intracellular HCO_3^- is then secreted across the basolateral plasma membrane, as described previously.

Thick Ascending Limb of the Loop of Henle

Tubular fluid arriving at the early distal tubule has a pH and serum [$[HCO_3^-]$] similar to that in the late proximal tubule. Because there is significant water extraction in the loop of Henle, maintenance of a constant serum HCO_3^- concentration requires reabsorption of HCO_3^-. The majority of this HCO_3^- absorption occurs in the thick ascending limb (TAL) through mechanisms similar to those present in the proximal tubule (Fig. 12.3). The majority of apical membrane H^+ secretion is mediated by the Na^+-H^+ antiporter NHE3. As in the proximal tubule, the low intracellular Na^+ concentration maintained by the basolateral Na^+,K^+-ATPase provides the primary driving force for the antiporter. Base efflux across the basolateral membrane is mediated by a Cl^--HCO_3^- exchanger (AE2) and K^+-HCO_3^- cotransport likely mediated by the K^+-Cl^- cotransporter KCC4.[6] These cells also possess an H^+-ATPase. The contribution of this pump to overall acidification in this segment is not clear.

Distal Nephron

Approximately 80% of the filtered HCO_3^- is reabsorbed in the proximal tubule; most but not all of the remainder is absorbed in the TAL. One function of the distal nephron is to reabsorb the remaining 5% of filtered HCO_3^-. In addition, the distal nephron must secrete a quantity of H^+ equal to that generated systemically by metabolism to maintain acid-base balance.

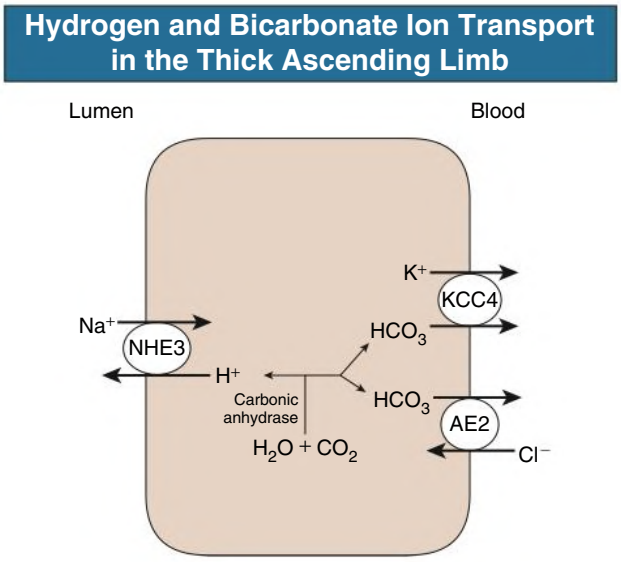

Fig. 12.3 Hydrogen (H^+) and Bicarbonate HCO_3^- Ion Transport in the Thick Ascending Limb. Apical H^+ secretion is mediated by a Na^+-H^+ antiporter. The low intracellular Na^+ concentration, maintained by the basolateral Na^+,K^+-ATPase, provides the primary driving force for the antiporter. Both Cl^--HCO_3^- exchange and K^+-HCO_3^- cotransport mediate base exit across the basolateral membrane.

The distal nephron is subdivided into several distinct portions that differ in their anatomy and acid secretory properties. Most of these segments transport H^+ and HCO_3^- into the luminal fluid, but the main segments appear to be in the collecting duct.[7] The segments of the collecting duct include the cortical collecting duct (CCD), the outer medullary collecting duct, and the inner medullary collecting duct. There are two distinct cell types in the CCD that can be distinguished histologically: the principal cell and the intercalated (IC) cell. The principal cell reabsorbs Na^+ and secretes K^+ and is discussed later. Depending on chronic acid-base status, the CCD is capable of either H^+ or HCO_3^- secretion. These functions are mediated by two types of IC cells: the acid-secreting α-IC cell and the base-secreting β-IC cell. Both IC cell types are rich in carbonic anhydrase II.

Reabsorption of HCO_3^- in the distal nephron is mediated by apical H^+ secretion by the α-IC cell. Two transporters secrete H^+: a vacuolar H^+-ATPase and an H^+-K^+-ATPase (Fig. 12.4). The vacuolar H^+-ATPase is an electrogenic pump related to the H^+ pump present within lysosomes, the Golgi apparatus, and endosomes. The H^+-K^+-ATPase uses the energy derived from adenosine triphosphate hydrolysis to secrete H^+ into the lumen and to reabsorb K^+ in an electroneutral fashion. The activity of the H^+-K^+-ATPase increases in K^+ depletion and thus provides a mechanism by which K^+ depletion enhances both collecting duct H^+ secretion and K^+ absorption.[8]

Active H^+ secretion by the apical membrane generates an intracellular base that must exit the basolateral membrane. A basolateral Cl^--HCO_3^- exchanger (AE1) is the mechanism by which this base exit occurs. The Cl^- that enters the cell in exchange for HCO_3^- exits the cell through a basolateral membrane Cl^- conductance channel (see Fig. 12.4).

The HCO_3^--secreting β-IC cell is a mirror image of the α-IC cell (Fig. 12.5). It possesses an H^+-ATPase on the basolateral membrane, which mediates active H^+ extrusion. Alkali that is generated within the cell then exits on an apical membrane Cl^--HCO_3^- exchanger. This Cl^--HCO_3^- exchanger is distinct from the basolateral Cl^--HCO_3^- exchanger present in the α-IC cell and functions as an anion exchanger or Cl^- channel in the luminal membrane of epithelial cells.[9] The SLC26A4 protein (pendrin) is a family member that mediates apical Cl^--HCO_3^- exchange in the β-IC cell of the kidney. The Na^+-driven Cl^--HCO_3^-

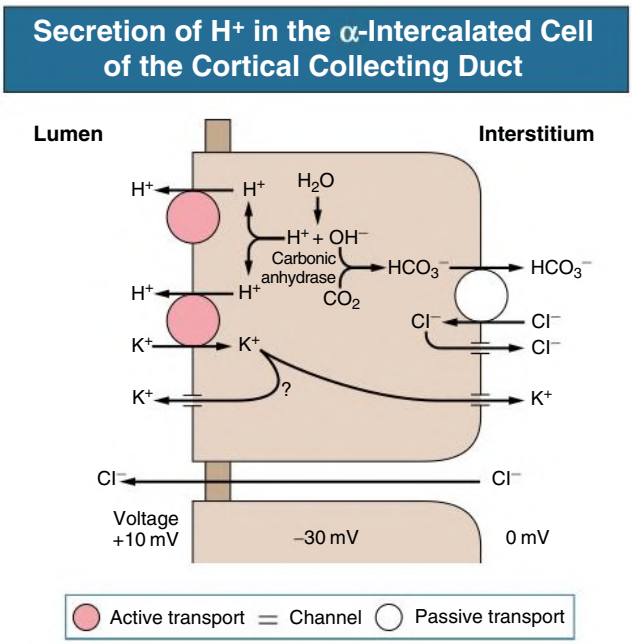

Fig. 12.4 Hydrogen (H^+) Secretion in the Cortical Collecting Duct α-Intercalated Cell. Secretion of hydrogen ions into the lumen by an H^+-ATPase and an H^+-K^+-ATPase. Apical membrane H^+ secretion generates OH^-, which reacts with CO_2 to form HCO_3^-. This bicarbonate exits across the basolateral membrane on a Cl^--HCO_3^- exchanger, a member of the anion exchanger-1 (AE1) family and a truncated form of the red blood cell AE1 Cl^--HCO_3^- exchanger. The Cl^- that enters the cell on the exchanger recycles across a basolateral membrane Cl^- channel. The K^+ that enters the cell on the H^+-K^+-ATPase appears to be able either to recycle across the apical membrane or exit across the basolateral membrane, depending on the potassium balance of the individual. Carbonic anhydrase catalyzes the conversion of CO_2 and OH^- to HCO_3^- in the cell. Electrogenic H^+ secretion generates a lumen-positive voltage that generates a current flow across the paracellular pathway.

exchanger (NDCBE) colocalizes with pendrin on the apical membrane and together may explain a component of electroneutral NaCl reabsorption in the collecting duct that is thiazide sensitive.[10]

The other cortical collecting tubule cell type is the principal cell, which also regulates acid-base transport, although indirectly. Principal cells mediate electrogenic Na^+ reabsorption that results in a net negative luminal charge (Fig. 12.6). The greater this negative charge, the lesser is the electrochemical gradient for electrogenic proton secretion and therefore the greater the rate of net proton secretion. Thus, factors that stimulate Na^+ reabsorption indirectly regulate the H^+ secretory rate.

The medullary collecting duct possesses mechanisms only for H^+ secretion. This H^+ secretion is mediated by α-IC cells but also by cells that appear morphologically distinct from IC cells but are functionally similar.

Net Acid Excretion

For the kidney to generate NAE, it must both reabsorb filtered HCO_3^- and excrete titratable acids and ammonia. Several weak acids, such as phosphate, creatinine, and uric acid, are filtered at the glomerulus and can buffer secreted protons. Of these, phosphate is the most important because of its favorable pK_a of 6.80 and its relatively high rate of urinary excretion (~25–30 mmol/day). However, the capacity of phosphate to buffer protons is maximized at a urine pH of 5.8, and acid-base disturbances generally do not induce substantial changes in urinary phosphate excretion. Other titratable acids, such as creatinine and uric acid, are limited by their lower excretion rate, which is not

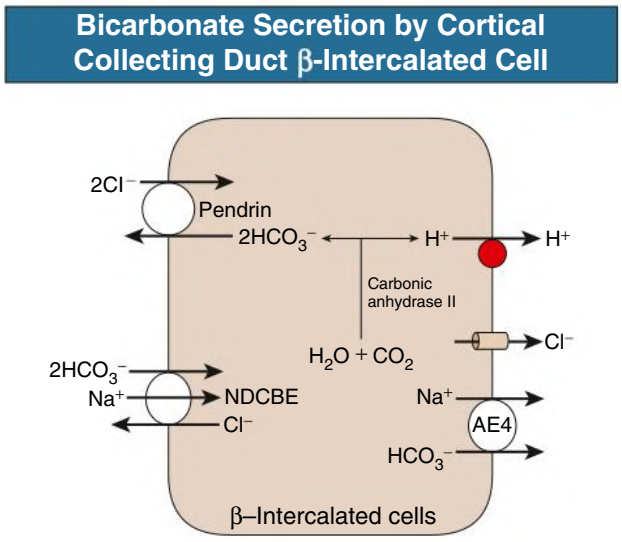

Fig. 12.5 Bicarbonate Secretion by the Cortical Collecting Duct β-Intercalated Cell. H^+ is secreted into the interstitium by an H^+-ATPase. The OH^- generated by basolateral membrane H^+ secretion reacts with CO_2 to form HCO_3^-, which exits across the apical membrane on a Cl^--HCO_3^- exchanger (pendrin). The Cl^- that enters the cell on the exchanger exits across a basolateral membrane Cl^- channel. Carbonic anhydrase catalyzes the conversion of CO_2 and OH^- to HCO_3^- in the cell. The Na^+-driven Cl^--HCO_3^- exchanger *(NDCBE)* colocalizes with pendrin on the apical membrane and mediates thiazide-sensitive electroneutral NaCl reabsorption in this segment.

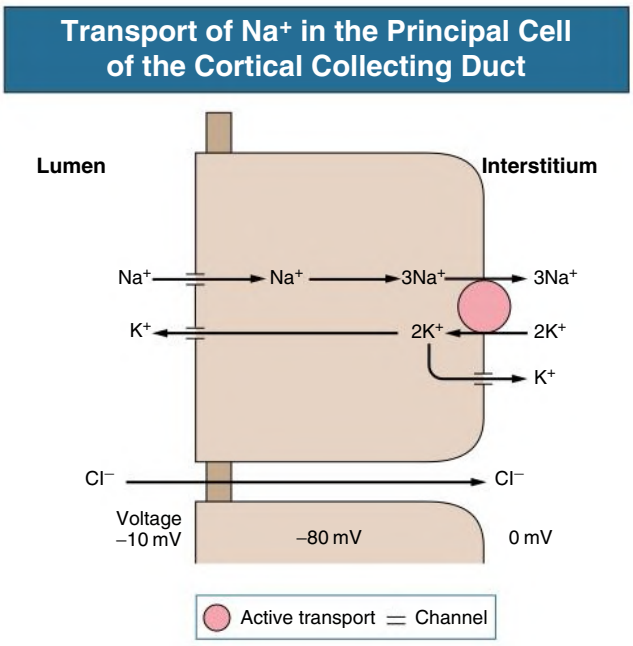

Fig. 12.6 Sodium Transport in the Cortical Collecting Duct Principal Cell. Electrogenic Na^+ absorption is mediated by the Na^+ channel. The Na^+ enters the cell across the apical membrane channel and exits the cell on the basolateral membrane Na^+,K^+-ATPase. The K^+ that enters the cell on the basolateral Na^+,K^+-ATPase can be secreted into the luminal fluid by an apical membrane K^+ channel. Electrogenic Na^+ absorption establishes a lumen-negative voltage that drives a paracellular current.

dramatically changed in response to acid-base disturbances. Titratable acid excretion is a minor component of the increase in NAE in response to metabolic acidosis (Fig. 12.7).

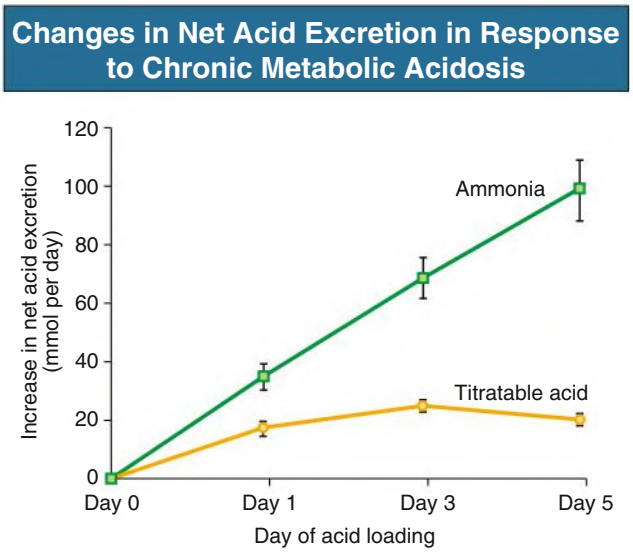

Fig. 12.7 Changes in Net Acid Excretion. Chronic metabolic acidosis increases net acid excretion dramatically over several days; shown quantitatively are the increases in the two major components of net acid excretion: titratable acids and ammonia. Titratable acid excretion increases slightly and predominantly in the first 24 to 48 hours. In contrast, urinary ammonia excretion progressively increases over 7 days and is responsible for most of the increase in net acid excretion in chronic metabolic acidosis. (Data from Elkinton JR, Huth EJ, Webster GD Jr, McCance RA. The renal excretion of hydrogen ion in renal tubular acidosis. I. Quantitative assessment of the response to ammonium chloride as an acid load. *Am J Med.* 1960;36:554–575.)

Ammonia Metabolism

Quantitatively, the most important component of NAE is the NH_3/NH_4^+ system.[12] Unlike for titratable acids, the rate of ammonia (NH_3) production and excretion varies according to physiologic needs. Under normal circumstances, ammonia excretion accounts for approximately 60% of total NAE, and in chronic metabolic acidosis, almost the entire increase in NAE is caused by increased NH_3 metabolism. Ammonia metabolism involves interplay among the proximal tubule, TAL, and collecting duct.

The proximal tubule is responsible for both ammonia production and luminal secretion. Ammonia is synthesized in the proximal tubule predominantly from glutamine metabolism through enzymatic processes in which phosphoenolpyruvate carboxykinase and phosphate-dependent glutaminase are the rate-limiting steps. This results in production of two ammonium (NH_4^+) and two HCO_3^- ions from each glutamine ion. Ammonia is then preferentially secreted into the lumen. The primary mechanism for this luminal secretion appears to be NH_4^+ transport by the apical Na^+-H^+ antiporter NHE3[13] (Fig. 12.8).

Metabolic acidosis increases the mobilization of glutamine from skeletal muscle and intestinal cells. Glutamine is preferentially taken up by the proximal tubular cell through the Na^+- and H^+-dependent glutamine transporter SNAT3. This transporter is a member of the *SCL38* gene family of Na^+-coupled neutral amino acid transporters. SNAT3 expression increases several-fold in metabolic acidosis, and it is preferentially expressed on the cell's basolateral surface, where it is poised for glutamine uptake.[14] The increase in plasma cortisol that typically accompanies metabolic acidosis plays a role in this transporter's upregulation.[15] Metabolic acidosis also causes increased expression and activity of phosphate-activated glutaminase and glutamate dehydrogenase.

Most of the ammonia that leaves the proximal tubule does not reach the distal tubule. Thus, there is transport of ammonia out of the loop of Henle. This ammonia transport appears to occur predominantly in the TAL and is mediated by at least three mechanisms[16] (Fig. 12.9). First, the lumen-positive voltage provides a driving force for passive paracellular NH_4^+ transport out of the TAL. Second, NH_4^+ can be transported out of the lumen by the furosemide-sensitive Na^+-K^+-$2Cl^-$ transporter. Third, NH_4^+ can leave the lumen across the apical membrane K^+ channel of the TAL cell. NH_4^+ exits the cell via the Na^+-H^+ exchanger NHE4, functioning in Na^+-NH_4^+ mode.

In addition, ammonia is secreted by the collecting duct. Although the traditional thought was that NH_3/NH_4^+ then enters the collecting duct by nonionic diffusion driven by the acid luminal pH, increasing evidence suggests that the nonerythroid glycoproteins Rhbg and Rhcg may be involved in collecting duct ammonia secretion.[17,18]

Ammonia excretion can be regulated by three mechanisms. First, ammonia synthesis in the proximal tubule can be regulated. Chronic acidosis and hypokalemia increase ammonia synthesis, whereas hyperkalemia suppresses ammonia synthesis. Second, ammonia delivery from the proximal tubule to the medullary interstitium can be regulated. In particular, chronic metabolic acidosis increases expression of both NHE3 and the loop of Henle Na^+-K^+-$2Cl^-$ cotransporter. Hyperkalemia can inhibit NH_4^+ reabsorption from the TAL. The combined effects of decreased NH_3 synthesis in the proximal tubule and interference in NH_4^+ reabsorption in the thick limb may explain the low urinary $[NH_4^+]$ found in hyperkalemic distal renal tubular acidosis. The reduced availability of ammonia to serve as a urinary buffer leads to a reduction in distal H^+ secretion and development of metabolic acidosis. Also, any interstitial renal disease that destroys renal medullary anatomy may decrease medullary interstitial $[NH_3/NH_4^+]$ transfer. Third, mechanisms that regulate collecting duct H^+ secretion or ammonia transporter expression can regulate ammonia entry into the collecting duct and ammonia excretion. Importantly, the primary mechanisms require synthesis of new proteins to increase both ammonia production and transport. Accordingly, changes in ammonia excretion may be delayed, and the maximal renal response to chronic metabolic acidosis requires 4 to 7 days.

REGULATION OF KIDNEY ACIDIFICATION

The regulation of acid-base balance requires an integrated system that precisely regulates proximal tubular H^+-HCO_3^- transport, distal nephron H^+-HCO_3^- transport, and ammonia synthesis and transport.

Blood pH

The regulation of acid-base balance requires that net H^+ excretion increase in states of acidosis and decrease in states of alkalosis. This form of regulation involves both acute and chronic mechanisms. In the proximal tubule, acute decreases in blood pH increase the rate of HCO_3^- absorption, and acute increases in blood pH inhibit HCO_3^- absorption. These alterations in the rate of HCO_3^- absorption occur whether the change in pH is the result of changes in $Paco_2$ or serum $[HCO_3^-]$. Similarly, in the collecting duct, acute changes in peritubular serum $[HCO_3^-]$ and pH regulate the rate of H^+ secretion.

In addition to acute regulation, mechanisms exist for chronic regulation. Chronic acidosis or alkalosis leads to parallel changes in the activities of the proximal tubule apical membrane Na^+-H^+ antiporter and basolateral membrane Na^+-HCO_3^--CO_3^{2-} cotransporter. Metabolic acidosis acutely increases the kinetic activity of NHE3 through direct pH effects and by phosphorylation; chronic acidosis increases the number of NHE3 transporters.[19,20] In addition, chronic acidosis increases proximal tubular ammonia synthesis by increasing the activities of the enzymes involved in ammonia metabolism.

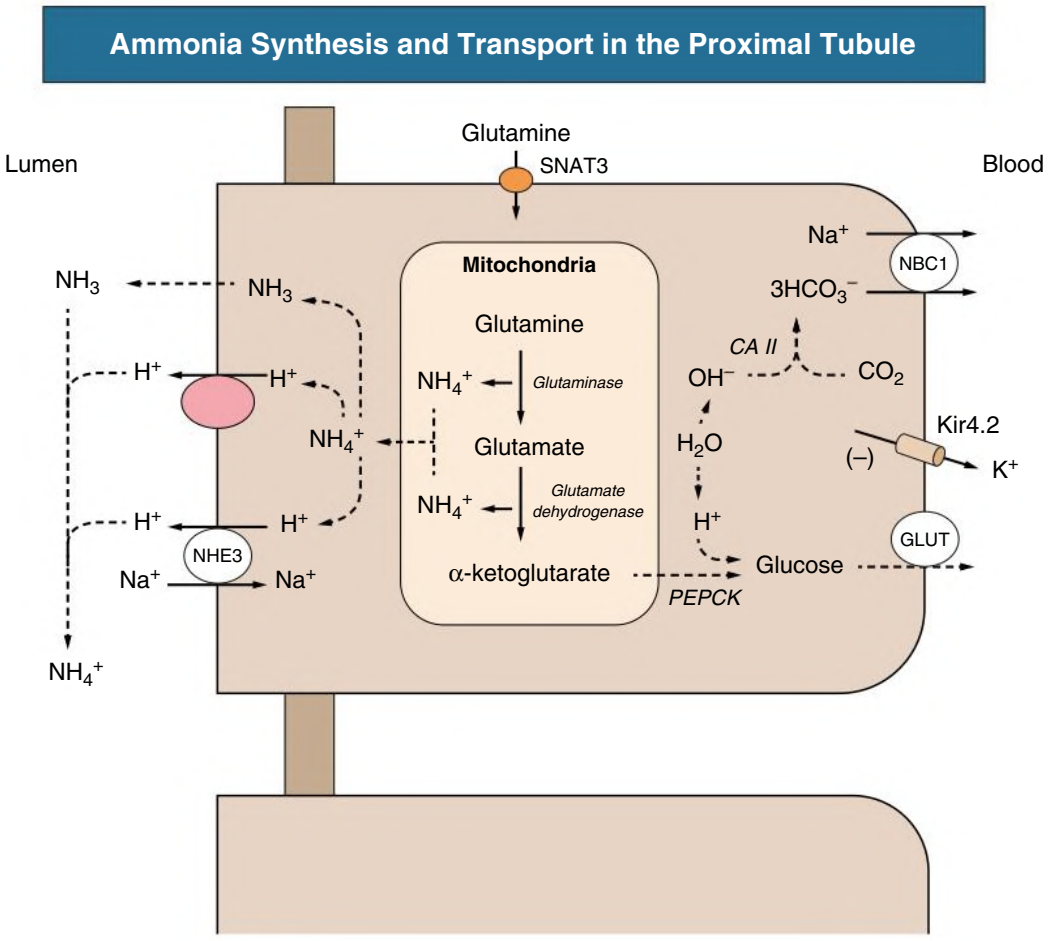

Fig. 12.8 **Ammonia Synthesis and Transport in the Proximal Tubule.** Metabolic acidosis and hypokalemia stimulate proximal ammonia synthesis by stimulating the uptake of glutamine through SNAT3 and increasing the activities of the enzymes involved in ammonia metabolism. The generation of ammonia is the result of glutamine metabolism by enzymes closely linked to gluconeogenesis. Hyperkalemia suppresses ammoniagenesis by increasing cell pH. Increased extracellular K^+ concentration leads to depolarization of the proximal tubular cell (decrease in electronegativity of the cell) as sensed through the inwardly rectifying K^+ subchannel Kir4.2 encoded by *Kcnj15* located on the basolateral membrane. This change results in less HCO_3^- exit coupled to Na^+ via NBCe1 because the cotransporter carries a net negative charge and is driven by intracellular electronegativity. The net effect is increased cell pH and downregulation of proteins involved in ammoniagenesis.

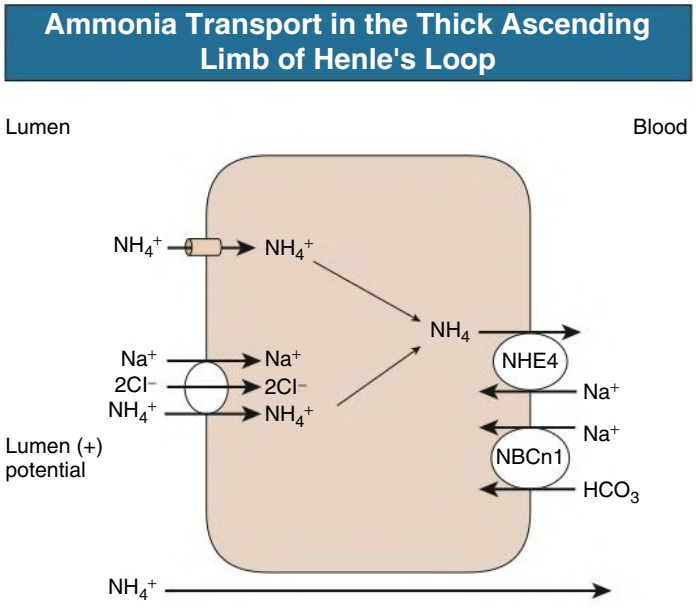

Fig. 12.9 **Ammonia Transport in the Thick Ascending Limb of Henle's Loop.** In addition to reabsorption through the paracellular pathway driven by the lumen-positive potential, ammonium can substitute for K^+ on the Na^+-K^+-$2Cl^-$ transporter and the apical membrane K^+ channel. NH_4^+ exits the cell via the Na^+-H^+ exchanger NHE4. The basolateral Na^+-HCO_3^- cotransporter (NBCn1) functions to maintain an optimal cell pH to facilitate the large transcellular ammonium flux.

The CCD is also modified by chronic acid-base changes. Long-term increases in dietary acid lead to an increase in H^+ secretion, whereas long-term increases in dietary alkali lead to an increased capacity for HCO_3^- secretion.[21] This effect is mediated by changes in the relative number of α- and β-IC cells. For example, during metabolic acidosis, the number of α-IC cells increases and the number of β-IC cells decreases, without a change in the total number of IC cells. Recent evidence suggests that the extracellular protein hensin may be involved in the switch between the predominant IC cell types.[22]

Mineralocorticoids, Distal Sodium Delivery, and Extracellular Fluid Volume

Mineralocorticoid hormones are key regulators of distal nephron and collecting duct H^+ secretion. Two mechanisms appear to be involved. First, mineralocorticoid hormone stimulates Na^+ absorption in principal cells of the CCD (see Fig. 12.6). This leads to a more lumen-negative voltage that then stimulates H^+ secretion. This mechanism is indirect in that it requires the presence of Na^+ and of Na^+ transport. The second mechanism is the direct activation of H^+ secretion by mineralocorticoids. This effect is chronic, requiring long exposure, and involves parallel increases in apical membrane H^+-ATPase and basolateral membrane Cl^--HCO_3^- exchanger activity.

Plasma Volume

Changes in plasma volume have important effects on acid-base homeostasis. This effect appears to be related to a number of factors. First, volume contraction is associated with a decreased GFR, which lowers the filtered load of HCO_3^- and decreases the load placed on the tubules to maintain NAE. Volume contraction also acutely decreases the paracellular permeability of the proximal tubule. This will decrease HCO_3^- backleak around cells, thereby increasing net bicarbonate reabsorption by the proximal tubule. Third, chronic volume contraction is associated with an adaptive increase in the activity of the proximal tubule apical membrane Na^+-H^+ antiporter NHE3. Because this transporter contributes to both $NaHCO_3$ and NaCl absorption, both these capacities will be increased with chronic volume contraction. Further, volume contraction limits distal delivery of chloride. In the presence of chronic metabolic alkalosis, the CCD is poised for HCO_3^- secretion. However, collecting duct HCO_3^- secretion requires luminal Cl^- and is inhibited by Cl^- deficiency.

Potassium

Potassium deficiency is associated with an increase in renal NAE. This effect is multifactorial. First, chronic K^+ deficiency increases the proximal tubule apical membrane Na^+-H^+ antiporter and basolateral membrane Na^+-HCO_3^--CO_3^{2-} cotransporter activities. This effect is similar to that seen with chronic acidosis and may be caused by intracellular acidosis. Chronic K^+ deficiency also increases proximal tubular ammonia production. Finally, chronic K^+ deficiency leads to an increase in collecting duct H^+ secretion. This appears to be related to increased activity of the apical membrane H^+-K^+-ATPase. Such an effect increases the rate of H^+ secretion and the rate of K^+ reabsorption in the collecting duct. In addition, ammonia, whose production is stimulated by hypokalemia, has direct effects that stimulate collecting duct H^+ secretion. Counterbalancing these effects is that K^+ deficiency decreases aldosterone secretion, which can inhibit distal acidification. Thus, in normal individuals, the net effect of K^+ deficiency is typically a minor change in acid-base balance. However, in patients with nonsuppressible mineralocorticoid secretion (e.g., hyperaldosteronism, Cushing syndrome), K^+ deficiency can greatly stimulate renal acidification and cause profound metabolic alkalosis.

Hyperkalemia appears to have opposite effects on renal acidification. The most notable effect of hyperkalemia is inhibition of ammonia synthesis in the proximal tubule and ammonia absorption in the loop of Henle, resulting in inappropriately low levels of urinary ammonia excretion. This contributes to the metabolic acidosis seen in patients with hyperkalemic distal (type 4) renal tubular acidosis.

SELF-ASSESSMENT QUESTIONS

1. Which of the following is *true* regarding the effect of chronic K^+ deficiency on renal acidification?
   - **A.** Decreases basolateral membrane Na^+- HCO_3^--CO_3^{2-} cotransporter activity
   - **B.** Increases proximal tubular ammonia production
   - **C.** Decreases collecting duct H^+ secretion
   - **D.** Increases aldosterone secretion
2. Which one of the following is *true* regarding ammonia handling in the kidney?
   - **A.** Ammonia synthesized in the proximal tubule is primarily reabsorbed in the cortical collecting duct.
   - **B.** Ammonia is reabsorbed passively in the thick ascending limb driven by the lumen-negative voltage.
   - **C.** NH_4^+ is transported into the lumen of the thick ascending limb by the Na^+-K^+-Cl^- transporter.
   - **D.** Nonthyroid glycoproteins Rhbg and Rhcg are involved in collecting duct ammonia secretion.
3. Which of the following is *true* regarding net acid production by the kidney?
   - **A.** Sulfur-containing amino acids are metabolized to CO_2.
   - **B.** Metabolism of lysine and arginine yield base on metabolism.
   - **C.** Animal foods are high in protein and organophosphates and provide a net acid diet.
   - **D.** Daily volatile acid production is approximately 1 mmol H^+.

Metabolic Acidosis

Biff F. Palmer

DEFINITION

Metabolic acidosis is defined as a low arterial blood pH in conjunction with a reduced serum bicarbonate concentration [HCO_3^-]. Respiratory compensation results in a decrease in arterial carbon dioxide tension ($Paco_2$). A low serum [HCO_3^-] alone is not diagnostic of metabolic acidosis because it also results from the kidney compensation to chronic respiratory alkalosis. Measurement of the arterial pH differentiates between these two possibilities. Box 13.1 shows the expected compensatory responses for metabolic and respiratory acid-base disorders.[1]

After the diagnosis of metabolic acidosis is confirmed, the first step in the examination of the patient is to calculate the serum anion gap. The *anion gap* equals the difference between the serum concentrations of the major cation sodium ([Na^+]) and the major measured anions chloride and bicarbonate ([Cl^-] and [HCO_3^-]) and is given by the following formula:

$$\text{Anion gap} = [Na^+] - ([Cl^-] + [HCO_3^-])$$

In healthy individuals, the normal value of the anion gap is approximately 12 ± 2 mmol/L. Because many of the unmeasured anions consist of albumin, the normal anion gap is decreased by approximately 2.5 mmol/L for each 1 g/dL decrease in the serum albumin concentration below normal. The total number of cations must equal the total number of anions, so a decrease in the serum HCO_3^- concentration must be offset by an increase in the concentration of other anions. If the anion accompanying excess H^+ is Cl^-, the decrease in serum [HCO_3^-] is matched by an equal increase in serum [Cl^-]. This acidosis is classified as a normal anion gap, a non–anion gap, or a hyperchloremic metabolic acidosis. In contrast, if excess H^+ is accompanied by an anion other than Cl^-, the decreased [HCO_3^-] is balanced by an increase in the concentration of the unmeasured anion. [Cl^-] remains the same. In this setting, the acidosis is said to be a high anion gap or anion gap metabolic acidosis.

The normal value for the anion gap has tended to fall over time because of changes in how serum Na^+ and Cl^- are measured.[2] Flame photometry for Na^+ measurement and a colorimetric assay for Cl^- have been replaced by the use of ion-selective electrodes, with which the serum Na^+ values have largely remained the same, whereas the serum Cl^- values have tended to be higher. As a result, the normal value for the anion gap has decreased to as low as 6 mmol/L in some reports. Recognizing this change, some laboratories have adjusted the calibration set point for Cl^- to return the normal value for the anion gap to the 12 ± 2 mmol/L range. The clinician needs to be aware that the average anion gap and range of normal values will vary across different facilities.

Fig. 13.1 provides a recommended approach to a patient with metabolic acidosis and lists the common causes of metabolic acidosis according to the anion gap.

NON–ANION GAP (NORMAL ANION GAP) METABOLIC ACIDOSIS

A non–anion gap metabolic acidosis can result from either kidney or extrarenal causes. Kidney causes of metabolic acidosis occur when renal bicarbonate generation, which results from net acid excretion, does not balance the loss of bicarbonate and other alkali buffers consumed in the buffering of normal endogenous acid production. This failure of net acid excretion is termed *renal tubular acidosis* (RTA). Extrarenal causes occur when exogenous acid loads, endogenous acid production, or endogenous bicarbonate losses are elevated and exceed kidney net acid excretion. The most common extrarenal cause of non–anion gap metabolic acidosis is chronic diarrhea.

Kidney and extrarenal causes of metabolic acidosis can be distinguished by measuring urinary ammonia excretion.[3] The primary response of the kidney to metabolic acidosis is to increase urinary ammonia excretion, each millimole of urinary ammonia excreted resulting in the generation of 1 mmol of "new" bicarbonate. Thus, kidney causes of metabolic acidosis are characterized by low urinary ammonia excretion rates. In contrast, in extrarenal metabolic acidosis, urinary ammonia excretion is elevated. Because most laboratories do not measure urinary ammonia, one can indirectly assess ammonia excretion by measuring the *urinary anion gap* (UAG):

$$\text{UAG} = (U_{Na+} + U_{K+}) - U_{Cl-}$$

The UAG is normally a positive value, ranging from +30 to +50 mmol/L. A negative value for the UAG suggests increased kidney excretion of an unmeasured cation (i.e., cation other than Na^+ or K^+). One such cation is NH_4^+. With chronic metabolic acidosis because of extrarenal causes, urinary ammonia concentrations, in the form of NH_4Cl, can reach 200 to 300 mmol/L. As a result, the measured cation concentration will be less than the measured anion concentration, which includes the increased urinary Cl^-, and the UAG will be less than zero and frequently less than −20 mmol/L.

The UAG only indirectly reflects the urinary ammonia concentration and, if other unmeasured ions are excreted, can give misleading results. Examples include diabetic ketoacidosis, associated with substantial urinary excretion of sodium ketoacid salts, and toluene exposure (discussed later), associated with increased urinary excretion of sodium hippurate and sodium benzoate. In these settings, the UAG value may remain positive despite an appropriate increase in urinary ammonia excretion because of the increased urinary excretion of Na^+ acid-anion salts. A similar situation occurs when urinary NH_4^+ is excreted with an anion other than Cl^-, such as β-hydroxybutyrate, acetoacetate, bicarbonate, or hippurate. In these settings, and even when NH_4^+ is excreted with Cl^-, the urine osmolal gap (UOG) can be used as a surrogate for NH_4^+

BOX 13.1 Expected Compensatory Responses to Acid-Base Disorders

Acute Respiratory Acidosis
For every 10 mm Hg rise in P_{CO_2}, HCO_3^- increases by 1 mmol/L

Chronic Respiratory Acidosis
For every 10 mm Hg rise in P_{CO_2}, HCO_3^- increases by 3.5 mmol/L

Acute Respiratory Alkalosis
For every 10 mm Hg fall in P_{CO_2}, HCO_3^- decreases by 2 mmol/L

Chronic Respiratory Alkalosis
For every 10 mm Hg decrease in P_{CO_2}, HCO_3^- decreases by 5 mmol/L

Metabolic Acidosis
1.2 mm Hg decrease in P_{CO_2} for each 1 mmol/L fall in HCO_3^-
$P_{CO_2} = HCO_3^- + 15$
P_{CO_2} = Last digits of pH

Metabolic Alkalosis
P_{CO_2} increases by 0.7 for each mmol/L HCO_3^-

concentration. The UOG is the difference between the measured and the calculated urine osmolality (mOsmol/kg):

$$(2 \times [Na^+ + K^+]) + [\text{Urea nitrogen (mg/dL)}/2.8] + [\text{Glucose (mg/dL)}/18]$$

In SI units, the formula is:

$$2 \times [Na^+ + K^+]\ \text{mmol/L} + \text{Urea (mmol/L)} + \text{Glucose (mmol/L)}$$

The normal value of the UOG is approximately 10 to 100 mOsmol/kg. $NH4^+$ salts are generally the only other major urinary solute that contributes importantly to the urine osmolality, so values appreciably greater than 100 mOsmol/kg reflect increased excretion of NH_4^+ salts.

Urine pH, in contrast to the UAG or UOG, does not reliably differentiate acidosis of kidney origin from that of extrarenal origin. For example, an acid urine pH does not necessarily indicate an appropriate increase in net acid excretion. If renal ammonia metabolism is inhibited, as occurs with chronic hyperkalemia, there is decreased ammonia available in the distal nephron to serve as a buffer, and small amounts of distal H^+ secretion can lead to significant urine acidification. In this setting, the urine pH is acid, but net acid excretion is low because of the low ammonia excretion. Similarly, alkaline urine does not necessarily imply a renal acidification defect. In conditions in which ammonia metabolism is stimulated, distal H^+ secretion can be massive and yet the urine remains relatively alkaline because of the buffering effects of ammonia.

Metabolic Acidosis of Renal Origin

An overall approach to patient assessment for workup of metabolic acidosis of kidney origin is shown in Fig. 13.2.

Proximal Renal Tubular Acidosis (Type 2)

Normally, 80% to 90% of the filtered load of HCO_3^- is reabsorbed in the proximal tubule. In proximal (type 2) RTA, the proximal tubule has a decreased capacity to reabsorb filtered bicarbonate. When serum bicarbonate concentration is normal or nearly normal, the amount of bicarbonate filtered by the glomerulus exceeds proximal tubule bicarbonate reabsorptive capacity. When this happens, there is increased bicarbonate delivery to the loop of Henle and distal nephron that

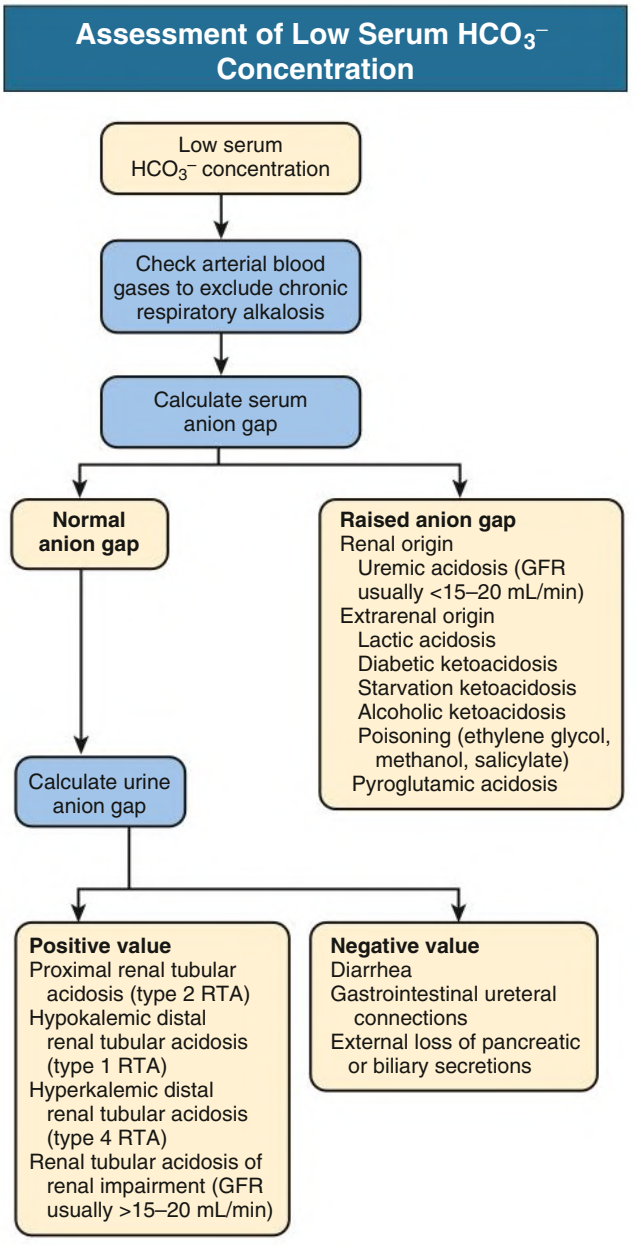

Fig. 13.1 Approach to the patient with low serum HCO_3^- concentration. *GFR,* Glomerular filtration rate; *RTA,* renal tubular acidosis.

exceeds their capacity to reabsorb bicarbonate. As a result, some filtered bicarbonate appears in the urine. The net effect is that serum $[HCO_3^-]$ decreases. Eventually, the filtered bicarbonate load decreases to the point at which the proximal tubule is able to reabsorb sufficient filtered bicarbonate that the bicarbonate load to the loop of Henle and the distal nephron is within their reabsorptive capacity. When this occurs, no further bicarbonate is lost in the urine, net acid excretion normalizes, and a new steady-state serum $[HCO_3^-]$ develops, although at a lower-than-normal level.

Hypokalemia is present in proximal RTA. Kidney $NaHCO_3$ losses lead to intravascular volume depletion, which in turn activates the renin-angiotensin-aldosterone system. Distal Na^+ delivery is increased as a result of the impaired proximal reabsorption of $NaHCO_3$. Because of the associated hyperaldosteronism and increased distal nephron Na^+ reabsorption, there is increased K^+ secretion. The net result is kidney potassium wasting and the development of hypokalemia. In the

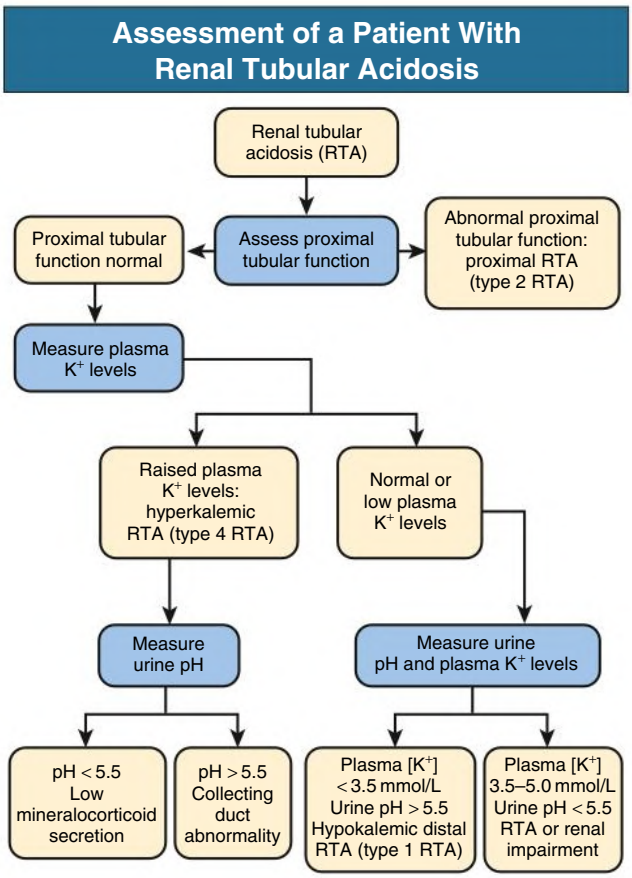

Fig. 13.2 Approach to the patient with renal tubular acidosis.

steady state, when virtually all the filtered HCO_3^- is reabsorbed in the proximal and distal nephron, kidney potassium wasting is less, and the degree of hypokalemia tends to be mild.

Proximal RTA may occur as an isolated defect in acidification but more commonly occurs in the setting of widespread proximal tubule dysfunction (Fanconi syndrome). In addition to decreased HCO_3^- reabsorption, patients with Fanconi syndrome have impaired reabsorption of glucose, phosphate, uric acid, amino acids, and low-molecular-weight proteins. Various inherited and acquired disorders have been associated with the development of Fanconi syndrome and proximal RTA (Box 13.2). The most common inherited cause in children is cystinosis (see Chapter 50). Most adults with Fanconi syndrome have an acquired condition that is related to an underlying dysproteinemic condition, such as multiple myeloma.

Skeletal abnormalities are common in these patients. Osteomalacia can develop from chronic hypophosphatemia caused by renal phosphate wasting if Fanconi syndrome is present. These patients also may have a deficiency in the active form of vitamin D because of an inability to convert 25-hydroxyvitamin D_3 to 1,25-dihydroxyvitamin D in the proximal tubule.

In contrast to distal RTA, proximal RTA is not associated with nephrolithiasis or nephrocalcinosis. One exception is the use of topiramate,[4,5] an antiepileptic drug that is increasingly used to treat a variety of neurologic and metabolic disorders. The drug exerts an inhibitory effect on kidney carbonic anhydrase activity, resulting in a proximal acidification defect similar to that observed with acetazolamide. Topiramate also is associated with hypocitraturia, hypercalciuria, and elevated urine pH, leading to an increased risk for kidney stone disease.

Proximal RTA should be suspected in a patient with a normal anion gap acidosis and hypokalemia who has an intact ability to acidify the urine to below 5.5 while in a steady state.[6] Proximal tubular dysfunction, such as euglycemic glycosuria, hypophosphatemia, hypouricemia, and mild proteinuria, helps support this diagnosis. The UAG is

BOX 13.2 Causes of Proximal (Type 2) Renal Tubular Acidosis

Not Associated With Fanconi Syndrome
- Sporadic
- Familial

Disorder of Carbonic Anhydrase
- Drugs: acetazolamide, sulfanilamide, topiramate
- Carbonic anhydrase II deficiency

Associated With Fanconi Syndrome
- Selective (no systemic disease present)
- Sporadic

Familial
- Autosomal recessive proximal RTA with ocular abnormalities: Na^+-HCO_3^- cotransporter (NBCe1) defect
- Autosomal recessive proximal RTA with osteopetrosis and cerebral calcification: carbonic anhydrase II defect
  - Generalized (systemic disorder present)
  - Genetic disorders
    - Cystinosis
    - Wilson disease
    - Hereditary fructose intolerance
    - Lowe syndrome
    - Metachromatic leukodystrophy

Dysproteinemic States

- Medullary cystic disease

Others
- Bone fibroma
- Osteopetrosis
- Paroxysmal nocturnal hemoglobinuria

RTA, Renal tubular acidosis.

greater than zero, indicating the lack of increase in net acid excretion. The metabolic acidemia in the steady state is maintained by a low rate of NH_4^+ excretion. The lesion causing impaired reabsorption of HCO_3^- in the proximal tubule leads to a more alkaline intracellular pH exerting an inhibitory effect on glutamine metabolism and suppressing ammoniagenesis.

Treatment of proximal RTA is difficult. Administration of alkali increases serum [HCO_3^-], which increases urinary bicarbonate losses and thereby minimizes subsequent increases in the serum [HCO_3^-]. Moreover, the increased distal sodium load, in combination with increased circulating plasma aldosterone, results in increased kidney potassium wasting and worsening hypokalemia. As a result, substantial amounts of alkali, often in the form of a potassium salt, such as potassium citrate, are required to prevent worsening hypokalemia. Children with proximal RTA should be aggressively treated to normalize their serum [HCO_3^-] to minimize growth retardation. These children may require large amounts of alkali therapy, typically 5 to 15 mmol/kg/day.

Adults with proximal RTA are frequently not treated as aggressively as children are because of the lack of systemic metabolic abnormalities or bone disease. Many clinicians administer alkali therapy if serum [HCO_3^-] is less than 18 mmol/L to prevent severe acidosis. Whether more aggressive therapy to normalize serum [HCO_3^-] is beneficial remains unknown. However, the large amounts of alkali required, about 700 to 1000 mmol/day for a 70-kg individual, make this approach problematic.

Hypokalemic Distal Renal Tubular Acidosis (Type 1)

In contrast to proximal RTA, patients with distal RTA are unable to acidify their urine, either under basal conditions or in response to metabolic acidosis.[7,8] Type 1 RTA results from a reduction in net H^+ secretion in the distal nephron and prevents urinary acidification, thereby minimizing titratable acid excretion and urinary ammonia excretion. As a result, these patients are unable to match net acid excretion to endogenous acid production, and acid accumulation ensues. The subsequent metabolic acidosis stimulates reabsorption of bone matrix to release the calcium alkali salts present in bone. During prolonged periods, this can result in progressive osteopenia in adults and in osteomalacia in children.

Distal RTA can be caused by either impaired H^+ secretion (secretory defect) or an abnormally permeable distal tubule, resulting in increased backleak of normally secreted H^+ (gradient defect); it may be genetic or acquired. Certain medications, especially amphotericin, result in increased backleak of protons across the apical plasma membrane, leading to a gradient defect form of distal RTA.

For patients with a secretory defect, the inability to acidify the urine below pH 5.5 results from abnormalities in any of the proteins involved in collecting duct H^+ secretion. Some patients may have an isolated defect in the H^+-K^+-ATPase that impairs H^+ secretion and K^+ reabsorption.[9] A defect confined to the vacuolar H^+-ATPase also results in kidney potassium wasting.[10] The development of systemic acidosis tends to diminish net proximal fluid reabsorption with an increase in distal delivery, resulting in volume contraction and activation of the renin-aldosterone system. Increased distal Na^+ delivery coupled to increased circulating levels of aldosterone then leads to increased kidney K^+ secretion.[11] Defects in the basolateral anion exchanger (AE1) also can cause distal RTA. In this case the lack of basolateral HCO_3^- exit leads to intracellular alkalinization, which inhibits apical proton secretion.

Patients with distal RTA have low ammonia secretion rates. The decreased secretion is caused by the failure to trap ammonia in the tubular lumen of the collecting duct as a result of the inability to lower luminal fluid pH. In addition, there is often impaired medullary transfer of ammonia because of interstitial disease. Interstitial disease is frequently present in such patients through an associated underlying disease or as a result of nephrocalcinosis or hypokalemia-induced interstitial fibrosis.

In contrast to proximal RTA, nephrolithiasis and nephrocalcinosis are common.[12] Urinary Ca^{2+} excretion is high secondary to acidosis-induced bone mineral dissolution. Luminal alkalinization also inhibits calcium reabsorption, resulting in further increases in urinary calcium excretion.[13] Calcium phosphate solubility is also greatly lowered at alkaline pH, and calcium phosphate stone formation is accelerated. Stone formation is further enhanced as a result of low urinary citrate excretion. Citrate is metabolized to HCO_3^-, and its kidney reabsorption is stimulated by metabolic acidosis, thereby minimizing the severity of metabolic acidosis. Urinary citrate also chelates urinary calcium, decreasing ionized calcium concentrations. Accordingly, the decreased citrate excretion that occurs in chronic metabolic acidosis as a result to distal RTA further contributes to both nephrolithiasis and nephrocalcinosis.

Distal RTA may be a primary disorder, either idiopathic or inherited, but it most often occurs in association with a systemic disease, one of the most common of which is Sjögren syndrome (Box 13.3). Hypergammaglobulinemic states as well as drugs and toxins also may cause this disorder.

A common cause of acquired distal RTA is glue sniffing. Inhalation of toluene from the fumes of model glue, spray paint, and paint thinners can give rise to hypokalemic normal anion gap acidosis through multiple mechanisms. First, toluene inhibits collecting duct proton secretion. Second, metabolism of toluene produces the organic acids hippuric and benzoic acid. These are buffered by sodium bicarbonate, resulting in metabolic acidosis and the production of sodium hippurate and sodium benzoate. If plasma volume is normal, these salts are rapidly excreted in the urine, and a non–anion gap metabolic acidosis develops. If plasma volume is decreased, urinary excretion is limited, these salts accumulate, and an anion gap metabolic acidosis develops.

Distal RTA should be considered in all patients with a non–anion gap metabolic acidosis and hypokalemia who have an inability to lower the urine pH maximally. A urine pH above 5.5 in the patient with systemic acidosis suggests distal RTA, and a UAG value greater than zero or lack of an increase in the UOG is confirmatory. Depending on the duration of the distal RTA, the metabolic acidosis can be mild or very severe, with a serum [HCO_3^-] as low as 10 mmol/L. Urinary potassium losses lead to the development of hypokalemia. Severe hypokalemia (<2.5 mmol/L) may result in musculoskeletal weakness and nephrogenic diabetes insipidus. The latter occurs because hypokalemia decreases aquaporin 2 (AQP2) expression in the collecting duct, thereby minimizing the ability to concentrate urine. An abdominal ultrasound scan or radiograph may reveal nephrocalcinosis.

In patients with minimal disturbances in blood pH and plasma [HCO_3^-], a test of urinary acidification is required. Traditionally, such a test involved oral NH_4Cl administration to induce metabolic acidosis with assessment of the kidney response by serial measurement of urine pH. Many patients poorly tolerate NH_4Cl ingestion because of gastric irritation, nausea, and vomiting. An alternative way to test the capacity for distal acidification is to administer furosemide and the mineralocorticoid fludrocortisone simultaneously.[14] The combination of both increased distal Na^+ delivery and mineralocorticoid effect will stimulate distal H^+ secretion by both an increase in the luminal electronegativity and a direct stimulatory effect on H^+ secretion. Unaffected individuals will have urine pH lowered below 5.5 with either maneuver.

Correction of the metabolic acidosis in distal RTA can be achieved by administration of alkali in an amount only slightly greater than daily acid production, usually 1 to 2 mmol/kg/day. In patients with

BOX 13.3 Causes of Hypokalemic Distal (Type 1) Renal Tubular Acidosis (RTA)

Primary
- Idiopathic
- Familial

Secondary

Autoimmune Disorders

severe K^+ deficits, correction of the acidosis with HCO_3^-, particularly if it is done with sodium alkali salts such as $NaHCO_3$, can lower serum potassium concentration to dangerous levels. In this setting, potassium replacement should begin before the acidosis is corrected. In general, a combination of sodium alkali and potassium alkali is required for long-term treatment of distal RTA. For patients with recurrent kidney stone disease caused by distal RTA, treatment of the acidosis increases urinary citrate excretion, which slows the rate of further stone formation and may even lead to stone dissolution.

Hyperkalemic Distal Renal Tubular Acidosis (Type 4)

Type 4 RTA is characterized by distal nephron dysfunction, resulting in impaired kidney excretion of both H^+ and K^+ and causing hyperchloremic normal gap acidosis and hyperkalemia.[15] (Note that the term *type 3 RTA* is most often applied to a rare autosomal recessive syndrome resulting from carbonic anhydrase II deficiency with features of both proximal and distal RTA.)

Type 4 RTA occurs most frequently with mild to moderate impairment in kidney function; however, the magnitude of hyperkalemia and acidosis is disproportionately severe for the observed glomerular filtration rate (GFR). Whereas hypokalemic distal (type 1) RTA is also a disorder of distal nephron acidification, type 4 is distinguished from type 1 RTA on the basis of several important characteristics (Table 13.1). Type 4 RTA is also a much more common form of RTA, particularly in adults.

Hyperkalemic distal RTA results from deficient circulating aldosterone or abnormal cortical collecting duct (CCD) function, or is related to hyperkalemia. In either case, a defect in distal H^+ secretion develops. Impaired Na^+ reabsorption by the principal cell leads to a decrease in the luminal electronegativity of the CCD, which impairs distal acidification as a result of the decrease in driving force for H^+ secretion into the tubular lumen. The H^+ secretion is further impaired in this segment as well as in the medullary collecting duct as a result of either the loss of the direct stimulatory effect of aldosterone on H^+ secretion or an abnormality in the H^+-secreting cell.

TABLE 13.1 Differentiation of Renal Tubular Acidosis Types

Factor	Type 1	Type 2	Type 4
Serum K^+	Low	Low	High
Kidney function	Normal or near normal	Normal or near normal	Stage 3, 4, or 5 chronic kidney disease
Urine pH during acidosis	High	Low	Low or high
Serum HCO^-_3 (mmol/L)	10–20	16–18	16–22
Urine citrate	Low	High	Low
Fanconi syndrome	No	May be present	No

A consequence of the decrease in luminal electronegativity in the CCD is impaired kidney K^+ excretion. In addition, a primary abnormality in CCD transport can also impair K^+ secretion. The development of hyperkalemia adds to the defect in distal acidification by decreasing the amount of ammonia available to act as a urinary buffer. Some studies suggest that hyperkalemia itself, through its effects on ammonia metabolism, is the primary mechanism by which metabolic acidosis develops in type 4 RTA.

The etiology of type 4 RTA includes disorders associated with decreased circulating levels of aldosterone and conditions associated with impaired CCD function. The most common disease associated with type 4 RTA in adults is diabetes mellitus. In these patients, primary NaCl retention leads to volume expansion and suppression and atrophy of the renin-secreting juxtaglomerular apparatus. Several common drugs, such as nonsteroidal antiinflammatory agents (NSAIDs), angiotensin-converting enzyme (ACE) inhibitors, and high doses of heparin, as used for systemic anticoagulation, can lead to decreased mineralocorticoid synthesis. Impaired function of the CCD can be a feature of structural damage to the kidney, as in interstitial renal diseases such as sickle cell nephropathy, urinary tract obstruction, and lupus. CCD function also may be impaired from use of drugs such as amiloride, triamterene, spironolactone, and finerenone.[16]

Type 4 RTA should be suspected in a patient with a normal gap metabolic acidosis associated with hyperkalemia. The typical patient is in the fifth to seventh decade of life with a long-standing history of diabetes mellitus with a moderate reduction in the GFR. Plasma $[HCO_3^-]$ is usually 18 to 22 mmol/L and serum $[K^+]$ between 5.5 and 6.5 mmol/L. Most patients are asymptomatic; however, the hyperkalemia may occasionally be severe enough to cause muscle weakness or cardiac arrhythmias. The UOG is not increased and the UAG value is slightly positive, indicating minimal ammonia excretion in the urine. When the disorder is caused by a defect in mineralocorticoid activity, patients typically have urine pH below 5.5, reflecting a more severe defect in ammonia availability than occurs with a defect in H^+ secretion (Fig. 13.3). In patients with structural damage to the collecting duct, the urine pH may be alkaline, reflecting both impaired H^+ secretion and decreased urinary ammonia excretion.

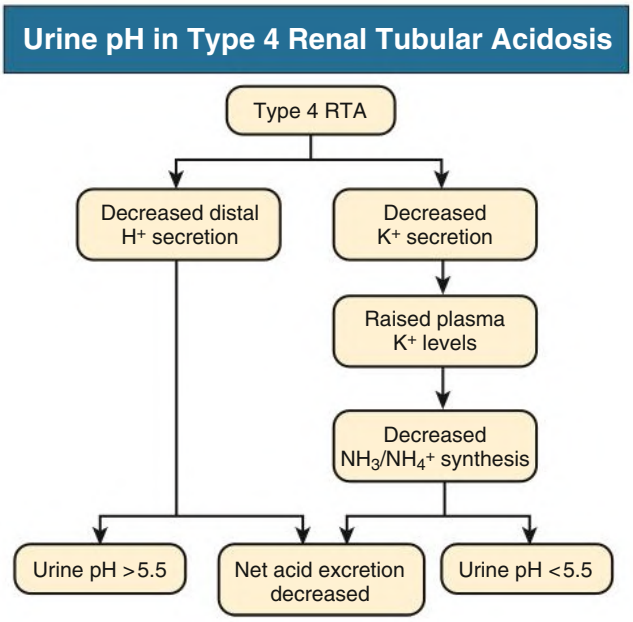

Fig. 13.3 Urine pH in Hyperkalemic Distal (Type 4) Renal Tubular Acidosis. Net acid excretion is always decreased; however, the urine pH can be variable. In structural disease of the kidney, the predominant defect is usually decreased distal H^+ secretion and the urine pH is >5.5. In disorders associated with decreased mineralocorticoid activity, urine pH is usually <5.5.

Treatment of patients with type 4 RTA is directed at both the hyperkalemia and the metabolic acidosis. In many patients, lowering serum $[K^+]$ will simultaneously correct the acidosis.[17] Correction of the hyperkalemia allows kidney ammonia production to increase, thereby increasing the buffer supply for distal acidification. The first consideration in treatment is to discontinue any nonessential medication that might interfere in either the synthesis or activity of aldosterone or the ability of the kidneys to excrete potassium (Box 13.4). ACE inhibitors and angiotensin receptor blockers usually should be continued because of the beneficial effects on cardiovascular disease and their renoprotective benefits in patients with chronic kidney disease (CKD). In patients with aldosterone deficiency who are neither hypertensive nor fluid overloaded, administration of a synthetic mineralocorticoid such as fludrocortisone 0.1 mg/day can be effective. In patients with hypertension or volume overload, particularly in association with CKD, administration of either a thiazide or a loop diuretic is frequently effective. Loop diuretics are required in patients with estimated GFR below 30 mL/min. Loop and thiazide diuretics increase distal Na^+ delivery and thus stimulate K^+ and H^+ secretion in the collecting duct. Alkali therapy (e.g., $NaHCO_3$) also can be used to treat the acidosis and hyperkalemia, but the patient must be closely monitored to avoid volume overload and worsening hypertension. One can also consider chronic use of a gastrointestinal K^+ binding drug such as patiromer or sodium zirconium cyclosilicate.[18]

Renal Tubular Acidosis in Chronic Kidney Disease

Metabolic acidosis in advanced CKD is caused by failure of the tubular acidification process to excrete the normal daily acid load. As functional kidney renal mass is reduced by disease, there is an adaptive increase in ammonia production and H^+ secretion by the remaining nephrons. Despite increased production of ammonia from each remaining nephron, overall production may be decreased secondary to the decrease in total kidney mass. In addition, less ammonia is delivered to the medullary interstitium secondary to disrupted medullary anatomy.[19] The ability to lower the urinary pH remains intact, reflecting the fact that the impairment in distal nephron H^+ secretion is less than that in ammonia secretion. Quantitatively, the total amount of H^+ secretion is small, and the acidic urine pH is the consequence of very little buffer in the urine. The lack of ammonia in the urine is reflected by a positive value for the UAG and lack of an increase in the UOG. Differentiation of RTA from type 4 RTA can be difficult because it is based on the clinician's determination of whether the severity of metabolic acidosis is out of proportion to the degree of kidney dysfunction.

Patients with CKD may develop a hyperchloremic normal gap metabolic acidosis associated with normokalemia or mild hyperkalemia as GFR decreases to less than 30 mL/min. With more advanced CKD (GFR <15 mL/min), the acidosis may change to an anion gap metabolic acidosis, reflecting a progressive inability to excrete phosphate, sulfate, and various organic acids. At this stage, the acidosis is commonly referred to as *uremic acidosis*.

Correction of the metabolic acidosis in patients with CKD is achieved by treatment with $NaHCO_3$, 0.5 to 1.5 mmol/kg/day, beginning when the HCO_3^- level is less than 22 mmol/L. In some patients, non–sodium citrate formulations can be used. Loop diuretics are often used in conjunction with alkali therapy to prevent volume overload. If the acidosis becomes refractory to medical therapy, dialysis needs to be initiated. Recent evidence suggests that metabolic acidosis in the patient with CKD should be aggressively treated because chronic acidosis is associated with metabolic bone disease, is associated with faster progression of kidney disease, and may lead to an accelerated catabolic state in patients with CKD.[20,21]

BOX 13.4 Causes of Hyperkalemic Distal (Type 4) Renal Tubular Acidosis

Mineralocorticoid Deficiency

Low Renin, Low Aldosterone

- Diabetes mellitus
- Drugs
  - NSAIDs
  - Cyclosporine, tacrolimus
  - β-Blockers

High Renin, Low Aldosterone

- Adrenal destruction
- Congenital enzyme defects
- Drugs
  - ACE inhibitors
  - ARBs
  - Heparin
  - Ketoconazole

Abnormal Cortical Collecting Duct

- Absent or defective mineralocorticoid receptor
- Drugs
  - Spironolactone, eplerenone
  - Triamterene
  - Amiloride
  - Trimethoprim
  - Pentamidine
- Chronic tubulointerstitial disease

ACE, Angiotensin-converting enzyme; *ARB,* angiotensin II receptor blocker; *NSAIDs,* nonsteroidal antiinflammatory drugs.

Metabolic Acidosis of Extrarenal Origin

Diarrhea

Intestinal secretions from sites distal to the stomach are rich in HCO_3^-. Accelerated loss of this HCO_3^- rich solution can result in metabolic

acidosis. The resultant volume loss signals the kidney to increase NaCl reabsorption; this combined with the intestinal $NaHCO_3$ losses generates a normal anion gap metabolic acidosis. The kidney response is to increase net acid excretion by increasing urinary excretion of ammonia.[22] Hypokalemia, as a result of gastrointestinal losses, and the low serum pH both stimulate the synthesis of ammonia in the proximal tubule. The increase in availability of ammonia to act as a urinary buffer allows a maximal increase in H^+ secretion by the distal nephron.

The increase in urinary ammonia excretion associated with an extrarenal normal anion gap acidosis results in a negative UAG value and an increase in the UOG. Urine pH can be misleading and in chronic diarrhea may be above 6.0 because of substantial increases in renal ammonia metabolism that result in increased urine pH from the buffering ability of the ammonia. Although the clinical history should distinguish between these two possibilities, in a patient with surreptitious laxative abuse, this may not be helpful because diarrhea may not be reported. Colonoscopy may be required to demonstrate characteristic findings of laxative abuse (e.g., melanosis coli) if this diagnosis is being considered.

Treatment of diarrhea-associated metabolic acidosis is based on treatment of the underlying diarrhea. If this is not possible, alkali treatment, possibly including potassium alkali to treat hypokalemia and metabolic acidosis simultaneously, is indicated.

Ileal Conduits

Surgical diversion of the ureter into an ileal pouch is used in the treatment of the patient with neurogenic bladder or after cystectomy. The procedure may be associated rarely with development of a hyperchloremic normal anion gap metabolic acidosis. Acidosis in part is caused by reabsorption of urinary NH_4Cl by the intestine. The ammonia is transported through the portal circulation to the liver or is metabolized to urea to prevent hyperammonemic encephalopathy. This metabolic process consumes equimolar amounts of bicarbonate and therefore can result in the development of metabolic acidosis. Metabolic acidosis also may develop because urinary Cl^- can be exchanged for HCO_3^- through activation of a Cl^--HCO_3^- exchanger on the intestinal lumen. In some patients, a kidney defect in acidification can develop and exacerbate the degree of acidosis. Such a defect may result from tubular damage caused by pyelonephritis or high colonic pressures, secondarily causing urinary obstruction.

The severity of acidosis relates to the length of time the urine is in contact with the bowel and the total surface area of bowel exposed to urine. In patients with a ureterosigmoid anastomosis, these factors are increased and the acidosis tends to be more common and more severe than in patients with an ileal conduit. The ileal conduit was designed to minimize the time and area of contact between urine and intestinal surface. Patients with surgical diversion of the ureter who develop metabolic acidosis should be evaluated for an ileal loop obstruction because this would lead to an increase in contact time between the urine and intestinal surface.

ANION GAP METABOLIC ACIDOSIS

Lactic Acidosis

Lactic acid is the end product in the anaerobic metabolism of glucose and is generated by the reversible reduction of pyruvic acid by lactic acid dehydrogenase and reduced nicotinamide adenine dinucleotide (NADH), as shown in the following formula:

$$\text{Pyruvate} + \text{NADH} + H^+ \leftrightarrow \text{Lactate} + NAD^+$$

Under normal conditions, the reaction is shifted toward the right and the normal lactate-to-pyruvate ratio is approximately 10:1. The reactants in this pathway are interrelated, as shown in the following equation:

$$\text{Lactate} = K[(\text{pyruvate})(\text{NADH})(H^+)]/NAD^+$$

where K is the equilibrium constant.

On the basis of this relationship, it is evident that lactate can increase for three reasons.[23] First, lactate can increase because of increased pyruvate production alone. In this situation, the normal 10:1 lactate-to-pyruvate ratio will be maintained. An isolated increase in pyruvate production can be seen in the setting of intravenous glucose infusions, intravenous administration of epinephrine, and respiratory alkalosis. Lactate levels in these conditions are minimally elevated, rarely exceeding 5 mmol/L. Second, lactate can increase as a result of an increased NADH:NAD^+ ratio. Under these conditions, the lactate-to-pyruvate ratio can increase to very high values. Third, lactate can increase with a combination of increased pyruvate production and increased NADH:NAD^+ ratio. This is common in severe lactic acidosis.

Lactic acidosis occurs when there is an imbalance between the production and the use of lactic acid. The net result is an accumulation of serum lactate and development of metabolic acidosis. The accumulation of the non–chloride anion lactate accounts for the increase in anion gap. Severe exercise and grand mal seizures are examples of lactic acidosis developing as a result of increased production. The short-lived nature of the acidosis in these conditions suggests that a concomitant defect in lactic acid use is present in most conditions of sustained and severe lactic acidosis.

Some of the disorders associated with the development of lactic acidosis are listed in Box 13.5. Type A lactic acidosis is characterized by underperfusion of tissue or acute hypoxia, such as hypotension, sepsis, acute tissue hypoperfusion, cardiopulmonary failure, severe anemia, hemorrhage, and carbon monoxide poisoning. Type B lactic acidosis occurs in the absence of overt hypoperfusion or hypoxia, such as with congenital defects in glucose or lactate metabolism, diabetes mellitus, liver disease, effects of drugs (especially overdose of isoniazid) and toxins, and neoplastic diseases.[24-29]

BOX 13.5 Causes of Lactic Acidosis

Type A (Tissue Underperfusion or Hypoxia)

Cardiogenic shock
Septic shock
Hemorrhagic shock
Acute hypoxia
Carbon monoxide poisoning
Anemia

Type B (Absence of Hypotension and Hypoxia)

Hereditary enzyme deficiency (glucose 6-phosphatase)
Drugs or toxins
- Phenformin, metformin
- Cyanide
- Salicylate, ethylene glycol, methanol
- Propylene glycol[26]
- Linezolid[24]
- Propofol[25]
- Nucleoside reverse transcriptase inhibitors: stavudine, didanosine[24]
- Clenbuterol[27]
- Isoniazid

Thiamine deficiency
Systemic disease
- Liver failure
- Malignancy

Thiamine deficiency is increasingly recognized as a cause of type B lactic acidosis in subjects with alcoholism, persistent vomiting, and severe malnutrition. In clinical practice, many patients will often exhibit features of type A and type B lactic acidosis simultaneously.

Therapy is aimed at correction of the underlying disorder. Restoration of tissue perfusion and oxygenation is attempted if these are compromised. The role of alkali in the treatment of patients with lactic acidosis is controversial; some experimental models and clinical observations suggest that administration of HCO_3^- may depress cardiac function and exacerbate the acidemia. In addition, such therapy may be complicated by volume overload, hypernatremia, and rebound alkalosis after the acidosis has resolved.[30] In general, HCO_3^- should be given when the systemic pH decreases to below 7.1 because hemodynamic instability becomes much more likely with severe acidemia. In such patients, alkali therapy should be directed at increasing the pH above 7.1; attempts to normalize the pH or [HCO_3^-] should be avoided. Acute hemodialysis is rarely beneficial for lactic acidosis induced by tissue hypoperfusion. The hemodynamic instability that can occur with hemodialysis in these critically ill patients may worsen the underlying difficulty in tissue oxygenation.

Diabetic Ketoacidosis

Diabetic ketoacidosis results from the accumulation of acetoacetic acid and β-hydroxybutyric acid. The development of ketoacidosis is the result of insulin deficiency and a relative or absolute increase in glucagon.[31] These hormonal changes lead to increased fatty acid mobilization from adipose tissue and alter the oxidative machinery of the liver such that delivered fatty acids are primarily metabolized into ketoacids. In addition, peripheral glucose use is impaired, and the gluconeogenic pathway in the liver is maximally stimulated. The resultant hyperglycemia causes an osmotic diuresis and volume depletion.

Ketoacidosis results when the rate of hepatic ketoacid generation exceeds renal excretion, causing increased blood ketoacid concentrations. The H^+ accumulation in the extracellular fluid (ECF) decreases HCO_3^- concentration, whereas the ketoacid anion concentration increases. An anion gap metabolic acidosis is the more common finding in the patient with diabetic ketoacidosis, but a normal gap metabolic acidosis also can be seen. In early stages of ketoacidosis, when the ECF volume is almost normal, ketoacid anions that are produced are rapidly excreted by the kidney as Na^+ and K^+ salts. Excretion of these salts is equivalent to the loss of potential HCO_3^-. This loss of potential HCO_3^- in the urine at the same time the kidney is retaining NaCl results in a normal gap metabolic acidosis. As volume depletion develops, kidney ketoacid excretion cannot match production rates and ketoacid anions are retained within the body, thus increasing the anion gap.[32]

During treatment, the anion gap metabolic acidosis transforms once again into a normal gap acidosis. Treatment leads to a termination in ketoacid production. As the ECF volume is restored, there is increased kidney excretion of the Na^+ salts of the ketoacid anions. The loss of this potential HCO_3^-, combined with the retention of administered NaCl, accounts for the redevelopment of the hyperchloremic normal gap acidosis. In addition, K^+ and Na^+ administered in solutions containing NaCl and KCl enter cells in exchange for H^+. The net effect is infusion of HCl into the ECF. The reversal of the hyperchloremic acidosis takes several days as the HCO_3^- deficit is corrected by the kidney.

Diabetic ketoacidosis can result in a severe metabolic acidosis with serum bicarbonate levels below 5 mmol/L. This diagnosis should be considered in patients with simultaneous metabolic acidosis and hyperglycemia. Diagnosis is confirmed by demonstration of retained ketoacids with nitroprusside tablets or reagent strips in the urine. However, these tests detect only acetone and acetoacetate and not β-hydroxybutyrate. In the patient with lactic acidosis or alcoholic ketoacidosis, acetoacetate may be converted to β-hydroxybutyrate to an extent that depends on the NADH/NAD^+ ratio. With treatment of the diabetic ketoacidosis, acetoacetate is generated as this ratio falls, and the nitroprusside test result may suddenly become strongly positive.

The limitations of the nitroprusside test can be prevented by direct measurement of β-hydroxybutyrate. With uncontrolled diabetes, a serum β-hydroxybutyrate level above 3.0 mmol/L in adults and above 3.8 mmol/L in children confirms diabetic ketoacidosis.[33] Compared with urinary ketone measurements, capillary blood levels of β-hydroxybutyrate better correlate with both the degree of acidosis and the response to therapy.[34]

Treatment consists of insulin and intravenous fluids to correct volume depletion. Deficiencies in K^+, Mg^{2+}, and phosphate are common; therefore these electrolytes are typically added to intravenous solutions, especially after the initial fluid resuscitation. However, diabetic ketoacidosis typically manifests with hyperkalemia secondary to the insulin deficiency. Potassium should be administered only as hypokalemia develops, usually during insulin treatment of diabetic ketoacidosis. If there is significant hypokalemia at presentation, potassium supplementation may be needed before insulin administration to avoid life-threatening worsening of hypokalemia. Alkali therapy is generally not required because administration of insulin leads to the metabolic conversion of ketoacid anions to HCO_3^- and allows partial correction of the acidosis. However, HCO_3^- therapy may be indicated in patients who present with severe acidemia (pH < 7.1).[35]

D-Lactic Acidosis

D-Lactic acidosis is a form of metabolic acidosis that can occur in the patient with small bowel resections or in patients with a jejunoileal bypass. Such short bowel syndromes create a situation in which carbohydrates that are normally extensively reabsorbed in the small intestine are delivered in large amounts to the colon. In the presence of colonic bacterial overgrowth, these substrates are metabolized into D-lactate and absorbed into the systemic circulation. Accumulation of D-lactate produces an anion gap metabolic acidosis in which the serum lactate concentration is normal because the standard test for lactate is specific for L-lactate. These patients typically present after ingestion of a large, high-carbohydrate meal, with neurologic abnormalities including confusion, slurred speech, and ataxia. Ingestion of low-carbohydrate meals and antimicrobial agents to decrease the degree of bacterial overgrowth are the principal treatments.

Starvation Ketosis

Abstinence from food can lead to a mild anion gap metabolic acidosis secondary to increased production of ketoacids. The pathogenesis of this disorder is similar to that of diabetic ketoacidosis in that starvation leads to relative insulin deficiency and glucagon excess. As a result, there is increased mobilization of fatty acids while the liver is set to oxidize fatty acids to ketoacids. With prolonged starvation, the blood ketoacid level can reach 5 to 6 mmol/L. The serum [HCO_3^-] is rarely less than 18 mmol/L. More fulminant ketoacidosis is aborted because ketone bodies stimulate the pancreatic islets to release insulin and lipolysis is held in check. This break in the ketogenic process is notably absent in patients with insulin-dependent diabetes.[36] No specific therapy is indicated in starvation ketosis.

Alcoholic Ketoacidosis

Ketoacidosis develops in patients with a history of chronic ethanol abuse, decreased food intake, and often a history of nausea and vomiting. As with starvation ketosis, a decrease in the insulin-to-glucagon ratio leads

to accelerated fatty acid mobilization and alters the enzymatic machinery of the liver to favor ketoacid production. However, features unique to this disorder differentiate alcoholic ketoacidosis from simple starvation ketosis. First, the alcohol withdrawal combined with volume depletion and starvation greatly increases the levels of circulating catecholamines. As a result, the peripheral mobilization of fatty acids is much greater than typically found with starvation alone. This sometimes-massive mobilization of fatty acids can lead to marked ketoacid production and severe metabolic acidosis. Second, the metabolism of ethanol leads to accumulation of NADH. The increase in NADH/NAD^+ is reflected by a higher ratio of β-hydroxybutyrate to acetoacetate. As mentioned previously, the nitroprusside reaction may be diminished by this redox shift despite the presence of severe ketoacidosis. Treatment of patients with alcoholic ketoacidosis focuses on glucose administration, which leads to the rapid resolution of the acidosis; stimulation of insulin release leads to diminished fatty acid mobilization from adipose tissue, as well as decreased hepatic output of ketoacids.[37]

Ethylene Glycol and Methanol Intoxications

Ethylene glycol and methanol intoxications are characteristically associated with the development of a severe anion gap metabolic acidosis. Metabolism of ethylene glycol by alcohol dehydrogenase generates various acids, including glycolic, oxalic, and formic acids. Ethylene glycol is present in antifreeze and solvents and is ingested by accident or as a suicide attempt. The initial effects of intoxication are neurologic and begin with drunkenness but can quickly progress to seizures and coma. If left untreated, cardiopulmonary symptoms such as tachypnea, noncardiogenic pulmonary edema, and cardiovascular collapse may appear. From 24 to 48 hours after ingestion, patients may develop flank pain and acute kidney injury, often accompanied by abundant calcium oxalate crystals in the urine (Box 13.6). A fatal dose of ethylene glycol is approximately 100 mL.

Methanol is also metabolized by alcohol dehydrogenase and forms formaldehyde, which is then converted to formic acid. Methanol is found in a variety of commercial preparations, such as shellac, varnish, and deicing solutions, and is also known as wood alcohol. As with ethylene glycol, methanol can be ingested either by accident or as a suicide attempt. Clinically, methanol ingestion is associated with an acute inebriation followed by an asymptomatic period lasting 24 to 36 hours. Abdominal pain caused by pancreatitis, seizures, blindness, and coma may develop. The blindness is caused by direct toxicity of formic acid on the retina. Methanol intoxication is also associated with hemorrhage in the white matter and putamen, which can lead to the delayed onset of a parkinsonian syndrome (see Box 13.6). The lethal dose of methanol is 60 to 250 mL.

Lactic acidosis is also a feature of methanol and ethylene glycol poisoning and contributes to the elevated anion gap. Together with an elevated anion gap, an osmolar gap is an important clue to the diagnosis of ethylene glycol and methanol poisoning. The osmolar gap is the difference between the measured and calculated osmolality. The formula for the calculated osmolality is as follows:

$$2 \times Na^+ + BUN/2.8 + Glucose/18 + EtOH/4.6$$

where the blood urea nitrogen (BUN), glucose, and ethanol concentrations are in milligrams per deciliter. Inclusion of the ethanol concentration in this calculation is important because many patients ingest ethylene glycol or methanol while inebriated from ethanol ingestion. The normal value for the osmolar gap is less than 10 mOsm/kg. Each 100 mg/dL (161 mmol/L) of ethylene glycol will increase the osmolar gap by 16 mOsm/kg. Methanol contributes 32 mOsm/kg for each 100 mg/dL (312 mmol/L).

In addition to supportive measures, the patient with ethylene glycol and methanol poisoning is treated with fomepizole (4-methylpyrazole), which inhibits alcohol dehydrogenase and prevents formation of toxic metabolites[38] (see Box 13.6). If fomepizole is unavailable, intravenous ethanol can be used to prevent the formation of toxic metabolites. Ethanol has more than a 10-fold greater affinity for alcohol dehydrogenase than that of other alcohols. Ethanol has its greatest efficacy when levels of 100 to 200 mg/dL are obtained. In addition to both fomepizole and ethanol therapy, the patient should receive hemodialysis to remove both the parent compound and its metabolites. Correction of the acidosis is accomplished with an HCO_3^--containing dialysate or by intravenous infusion of $NaHCO_3$.

BOX 13.6 Ethylene Glycol and Methanol Poisoning

Time course of clinical symptoms and signs after ingestion
- Ethylene glycol
  - 0–12 hours: inebriation progressing to coma
  - 12–24 hours: tachypnea, noncardiogenic pulmonary edema
  - 24–36 hours: flank pain, renal failure, urinary calcium oxalate crystals
- Methanol
  - 0–12 hours: inebriation followed by asymptomatic period
  - 24–36 hours: pancreatitis, retinal edema progressing to blindness, seizures
  - >48 hours: putamen and white matter hemorrhage leading to Parkinson-like state

Increased anion gap metabolic acidosis

Increased osmolar gap

Treatment
- Supportive care
- Fomepizole (4-methylpyrazole) is agent of choice (competitor of alcohol dehydrogenase): 15 mg/kg IV loading dose, then 10 mg/kg every 12 hours for 48 hours. After 48 hours, increase dose to 15 mg/kg every 12 hours; increase frequency of dosing to *every* 4 hours during hemodialysis.
- Intravenous ethanol (5% or 10% solution) if fomepizole unavailable: Loading dose of 0.6 g/kg, followed by hourly maintenance dose of 66 mg/kg. Increase maintenance dose when the patient has history of chronic alcohol use and during hemodialysis.
- Hemodialysis to accelerate removal of parent compound and metabolites
- Bicarbonate therapy to treat acidosis

IV, Intravenous.

Salicylate

Aspirin (acetylsalicylic acid) is associated with a large number of accidental or intentional poisonings. At toxic concentrations, salicylate uncouples oxidative phosphorylation and, as a result, leads to increased lactic acid production. In children, ketoacid production also may be increased. The accumulation of lactic, salicylic, keto, and other organic acids leads to the development of an anion gap metabolic acidosis. At the same time, salicylate has a direct stimulatory effect on the respiratory center. Increased ventilation lowers the carbon dioxide tension (P_{CO_2}), contributing to the development of a respiratory alkalosis.[39] Children primarily manifest an anion gap metabolic acidosis with toxic salicylate levels; a respiratory alkalosis is most evident in adults.

In addition to conservative management, the initial goals of therapy for salicylate poisoning are to correct systemic acidemia and increase the urine pH. By increasing systemic pH, the ionized fraction of salicylic acid will increase, resulting in less accumulation of the drug in the central nervous system. Similarly, an alkaline urine pH favors increased urinary excretion because the ionized fraction of the drug is poorly reabsorbed by the tubule. At serum concentrations above 80

mg/dL or in the setting of severe clinical toxicity, hemodialysis can be used to accelerate drug elimination.

Pyroglutamic Acidosis

Pyroglutamic acid, also known as 5-oxoproline, is an intermediate in glutathione metabolism. An anion gap acidosis caused by pyroglutamic acid has been described rarely in critically ill patients receiving therapeutic doses of acetaminophen[40,41] (Fig. 13.4). Patients present with severe anion gap metabolic acidosis accompanied by alterations in mental status ranging from confusion to coma. High concentrations of pyroglutamic acid are found in the blood and urine. Risk factors include malnutrition, infection, antibiotic use, pregnancy, and kidney failure. In these settings, glutathione levels are reduced because of the oxidative stress associated with critical illness. The reduction in glutathione secondarily leads to increased production of pyroglutamic acid. Even therapeutic doses of acetaminophen can precipitate this disorder when risk factors are present. The diagnosis of pyroglutamic acidosis should be considered in patients with unexplained anion gap metabolic acidosis and recent acetaminophen ingestion.

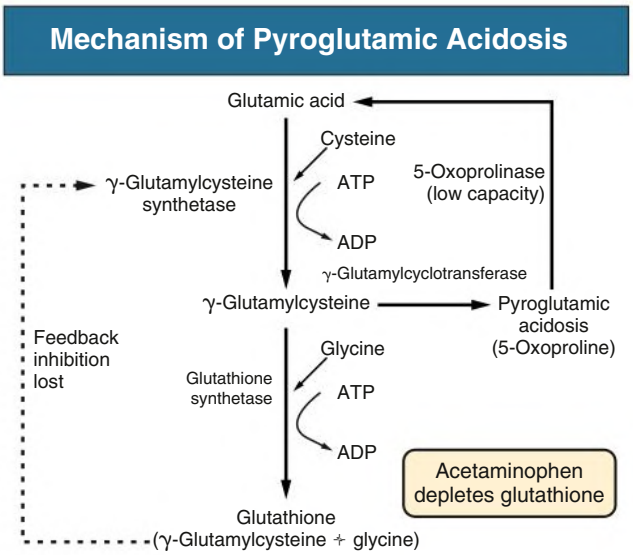

Fig. 13.4 Mechanism of Pyroglutamic Acidosis. Glutathione is formed from γ-glutamylcysteine and glycine in the presence of glutathione synthetase. Glutathione normally regulates the activity of γ-glutamylcysteine synthetase through feedback inhibition. Depletion of glutathione results in increased formation of γ-glutamylcysteine, which in turn is metabolized to pyroglutamic acid (5-oxoproline) and cystine through γ-glutamylcyclotransferase. Pyroglutamic acid accumulates because the enzyme responsible for its metabolism (5-oxoprolinase) is low capacity. *ADP,* Adenosine diphosphate; *ATP,* adenosine triphosphate.

ALKALI TREATMENT OF METABOLIC ACIDOSIS

Treatment of metabolic acidosis usually involves either sodium bicarbonate or citrate[35] (Table 13.2). $NaHCO_3$ can be taken orally as tablets or powder or given intravenously as a hypertonic bolus or an isotonic infusion, which can be created by adding 150 mmol $NaHCO_3$ to 1 L 5% dextrose in water (D5W). This solution is useful if treatment requires both volume expansion and alkali administration.

Citrate may be taken orally as a liquid, as sodium citrate, potassium citrate, or citric acid, or a combination. Many patients find citrate-containing solutions more palatable than oral $NaHCO_3$ as a source of oral alkali therapy. Oral citrate therapy should not be combined with medications that include aluminum. Citrate, which has a −3 charge under normal conditions, can complex with aluminum (Al^{3+}) in the intestinal tract, resulting in an uncharged moiety that is rapidly absorbed across the intestinal tract and then can dissociate to release free aluminum. This can increase the rate of aluminum absorption dramatically and in some patients, particularly those with severe CKD, has resulted in acute aluminum encephalopathy.

The dose of alkali therapy administered is based on both the total body bicarbonate deficit and the desired rapidity of treatment. Under normal circumstances, the volume of distribution (V_D) for bicarbonate is approximately 0.5 L/kg total body weight. Thus, the bicarbonate deficit, in millimoles, can be estimated from the following formula: $(0.5 \times LBW_{kg}) \times (24 - HCO_3^-)$, where LBW_{kg} is the lean body weight in kilograms and *24* is the desired resultant bicarbonate concentration.

Several caveats regarding this equation should be understood. First, edema fluid contributes to the volume of distribution of bicarbonate. Accordingly, an estimation of the amount of edema fluid should be included in this calculation. Second, the volume of distribution for bicarbonate increases as the severity of the metabolic acidosis worsens. When serum $[HCO_3^-]$ is 5 mmol/L or less, the volume of distribution may increase to 1 L/kg or more.

When acute treatment is desired, 50% of the bicarbonate deficit should be replaced during the first 24 hours. If hypertonic $NaHCO_3$ is administered, the increase in serum $[HCO_3^-]$ will be mirrored by an increase in serum $[Na^+]$. After the initial 24 hours of therapy, the response to therapy and the patient's current clinical condition are reevaluated before future therapy is decided. Acute hemodialysis solely for the treatment of metabolic acidosis, other than that associated with kidney failure, is rarely beneficial.

TABLE 13.2 Alkali Treatment Options

Therapy	Route	Usual Dose per Unit	Comments
Sodium bicarbonate tablet	PO	650 mg = 8 mmol	May cause gastric gas
Sodium bicarbonate	IV	50 mmol in 50 mL	Hypertonic, may cause hypernatremia
5% Dextrose with water with $NaHCO_3$	IV	150 mmol/L	Useful for simultaneous intravascular volume expansion and alkali administration
Potassium citrate (tablet)	PO	5 and 10 mmol per tablet	Useful for simultaneous K^+ and alkali therapy
Citric acid/potassium citrate/sodium citrate (liquid)	PO	1 mmol of Na^+ and K^+ and 2 mmol of citrate per milliliter	Avoid concomitant aluminum-containing medications such as antacids and sucralfate 1 mmol citrate equivalent to 3 mmol HCO_3^-
Potassium citrate (liquid)	PO	2 mmol of K^+ and 2 mmol of citrate per milliliter	Avoid concomitant aluminum-containing medications

IV, intravenous; *PO,* oral.

SELF-ASSESSMENT QUESTIONS

1. A 65-year-old man presents with the chief complaint of progressive weakness over the last several months. He is normotensive; physical examination is unremarkable with the following laboratory results (in mmol/L): Na^+ 135, Cl^- 105, K^+ 3.0, HCO_3^- 18, creatinine 1.8, blood urea nitrogen, glucose 110, Pco_2 28 mm Hg, pH 7.33, hematocrit 25%, white blood cells 5600/mm^2, platelets 340,000/mm^3, and urinalysis: trace protein, 1+ glucose, normal sediment, and 4.8 protein g/24 h. Which of the following is characteristic of the renal lesion present in this patient?
   A. Nephrocalcinosis will be shown on a kidney, ureter, bladder radiograph of the abdomen.
   B. Serum HCO_3^- concentration will increase after oral bicarbonate administration but then decrease to 18 mmol/L after therapy is discontinued.
   C. Bicarbonate therapy will cause the serum K^+ to decline slightly because of a shift into cells.
   D. Urine pH will be persistently alkaline.
   E. Urine anion gap will be negative.
2. A 35-year-old woman presents having ingested a large quantity of aspirin after breaking up with her boyfriend. Her medical history is unremarkable, and she is taking no medications. Physical examination shows blood pressure 130/80 mm Hg lying and 110/62 mm Hg standing, pulse 102 beats/min, and respiratory rate 24 breaths/min; the remainder of the examination is normal. Laboratory tests on admission (in mmol/L) are Na^+ 138, K^+ 3.2, Cl^- 100, HCO_3^- 13, pH 7.48, and Pco_2 21 mm Hg; urinalysis is 1+ ketone, normal sediment; and urine chemistry (in mmol/L) is Na^+ 38, Cl^- <10, and K^+ 45. Which of the following statements is *true* regarding salicylate poisoning?
   A. A 5-year-old child who has accidently swallowed an unknown quantity of his mother's aspirin is likely to present with similar acid-base findings.
   B. The cause of hypokalemia is primarily due to a shift of K^+ into cells because of respiratory alkalosis.
   C. Serum uric acid levels are likely to be low in this patient.
   D. The high urine Na^+ is caused by proximal tubular dysfunction as a result of salicylate nephrotoxicity.
   E. Measurement of serum lactic acid in this patient is likely to be normal.
3. A 65-year-old White man with an extensive smoking history and known chronic obstructive pulmonary disease is admitted to the hospital with hematemesis. On the day of admission, endoscopy shows a nonbleeding duodenal ulcer. The procedure was complicated by the development of aspiration pneumonia and respiratory failure. A continuous infusion of intravenous lorazepam was required to control agitation and minimize peak inspiratory pressures. Admission laboratory results (in mmol/L) were Na^+ 142, K^+ 4.3, Cl^- 105, HCO_3^- 22, creatinine 1.4 mg/dL, blood urea nitrogen (BUN) 25 mg/dL, hematocrit 36, pH 7.35, Pco_2 45, and Po_2 75. On hospital day 4, gastrointestinal bleeding recurred, and the patient was taken to the operating room and underwent oversewing of a bleeding duodenal ulcer. The patient remained hemodynamically stable throughout the hospitalization but continued to require intravenous lorazepam for sedation. Laboratory results (in mmol/L) were Na^+ 138, K^+ 4.8, Cl^- 100, HCO_3^- 10, creatinine 1.8 mg/dL, BUN 28 mg/dL, glucose 120 mg/dL, and serum osmolality 330 mOsm/l (osmolar gap = 37). Which of the following is the cause of this patient's anion gap metabolic acidosis and increased osmolar gap?
   A. Propylene glycol toxicity
   B. Diabetic ketoacidosis
   C. Lactic acidosis
   D. Uremic acidosis
   E. Isopropyl alcohol administration

Metabolic Alkalosis

Harold M. Szerlip, Michael Emmett

Metabolic alkalosis is a primary acid-base disorder that increases the serum bicarbonate concentration [HCO_3^-] above 30 mmol/L,[1] causing the arterial blood [H^+] to fall and pH to increase into the alkaline range (>7.45). Most laboratories measure the venous [total CO_2] as a surrogate, which also includes dissolved CO_2 and H_2CO_3. The [total CO_2] exceeds the [HCO_3] by about 1 to 2 mmol/L.

Metabolic alkalosis, a very common acid-base disorder, is especially prevalent in critically ill patients.[2]

RESPIRATORY COMPENSATION

Uncomplicated metabolic alkalosis generates compensatory hypoventilation, which raises P_{CO_2}, thereby reducing the pH toward the normal range. However, the arterial pH generally remains above 7.45. The magnitude of the hypoventilatory response to metabolic alkalosis is proportional to the degree of [HCO_3^-] elevation, but the response is quite variable (Fig. 14.1)[3-6] (M.A. Fallahzadeh et al., unpublished observations). Compensation occurs relatively rapidly, within minutes to hours. Mild metabolic alkalosis generates a modest P_{CO_2} increase (45–50 mm Hg); more severe metabolic alkalosis increases the P_{CO_2} to the 50 to 55 mm Hg range. Although some patients with severe metabolic alkalosis develop higher P_{CO_2} values, these patients are usually also very hypokalemic, which can generate muscle weakness and respiratory acidosis.

SERUM CHLORIDE CONCENTRATION AND METABOLIC ALKALOSIS

Abnormal serum chloride concentration [Cl^-] usually indicates that a water/hydration disorder, an acid/base disorder, or both exist. Water/hydration disorders generate proportional changes of [Cl^-] and [Na^+]. Therefore, the [Cl^-]:[Na^+] ratio remains normal at 1:1.4. [Cl^-] and [Na^+] both increase proportionately with dehydration and decrease proportionately with overhydration. This proportional relationship is disrupted when certain acid-base disorders exist (i.e., metabolic alkalosis, hyperchloremic metabolic acidosis, or chronic respiratory disorders). Metabolic alkalosis elevates [HCO_3^-] and reciprocally reduces [Cl^-]. This disrupts the normal 1:1.4 [Cl^-]:[Na^+] ratio. The "anatomic" electrolyte profile, or "Gamblegram" (Fig. 14.2), shows why the increased [HCO_3^-], which exists with metabolic alkalosis, must be accompanied by an equal reduction of [Cl^-] (independent of [Na+]), a reduction of the anion gap, or both.[7,8] In fact, metabolic alkalosis will commonly slightly increase the anion gap due to increased albumin concentration, increased albumin negative charge density, and accelerated generation of organic acids.[9,10] To the extent this occurs, the relative [Cl^-] decrease must be even greater.

An identical electrolyte pattern (increased [HCO_3^-] and proportionately reduced [Cl^-]) is also generated by compensation for chronic respiratory acidosis. Clinical assessment and blood pH measurement will indicate the correct diagnosis. Blood pH is increased with metabolic alkalosis and low-normal/reduced with chronic respiratory acidosis. Venous blood pH, although less definitive than arterial pH, can be very helpful; add 0.03 pH units to the venous pH to approximate the arterial pH.[11]

PATHOGENESIS: GENERATION AND MAINTENANCE OF METABOLIC ALKALOSIS

Seldin and Rector used an extracellular fluid (ECF) volume–centered approach to explain how metabolic alkalosis develops and is maintained.[12] Subsequently, some have proposed that the "ECF volume–centric" approach should be replaced by a "chloride-centric" model,[13-16] whereas others have challenged this model.[17,18] From a practical and clinically relevant perspective, ECF volume contraction almost invariably equals "chloride depletion" and vice versa. We will use the traditional ECF volume–centered framework to direct the diagnostic and therapeutic approach to the metabolic alkaloses because it remains very useful and easy to understand.

Normal HCO_3^- Reclamation, Regeneration, and Generation

The metabolism of foods and endogenous substrates produces a large amount of nonvolatile organic acids (i.e., lactic, pyruvic, citric acids) that are oxidized to the volatile acid CO_2 and water. In addition, the typical Western European/American diet generates 80 to 100 mmol/day of nonvolatile strong acids, which cannot be metabolically oxidized (mainly sulfuric, phosphoric, and hydrochloric acids). These strong acids dissociate and release protons that mainly react with HCO_3^- to form H_2CO_3, which then rapidly dehydrates to CO_2 and H_2O. To the extent this occurs, the serum [HCO_3^-] falls and is "replaced" by the anions of the generated strong acids, for example, SO_4^{2-}, HPO_4^{2-}, and Cl^-. Acid-base homeostasis must be restored/maintained by the kidney, which filters and/or secretes the anions of these acids, mainly as sodium salts. As the Na salts travel along the tubules, the Na^+ is reabsorbed in exchange for secreted H^+, which either binds to NH_3, forming NH_4^+, or binds to other H^+ binding molecules (i.e., titratable acids), mainly HPO_4^{2-} to generate $H_2PO_4^-$. Excretion of 80 to 100 mmol of H^+ together with the acid anions (e.g., SO_4^{2-}, HPO_4^{2-}, Cl^-) thereby maintains acid-base equilibrium.

However, before this acid-base restorative process can occur, all the $NaHCO_3$ filtered by the glomeruli must first be reclaimed (i.e., removed from the filtrate) and returned to the body fluids. About 80% of the normal filtered HCO_3^- load (about 4000–4500 mmol/day) is reclaimed by the proximal tubules via the process of H^+ secretion. The major features of proximal tubule Na^+ reabsorption and H^+ secretion are shown in Fig. 14.3. A large fraction of proximal Na^+ reabsorption occurs via the Na^+-H^+ exchanger 3 (NHE3) in the proximal luminal membrane. This exchange is energized by basolateral membrane

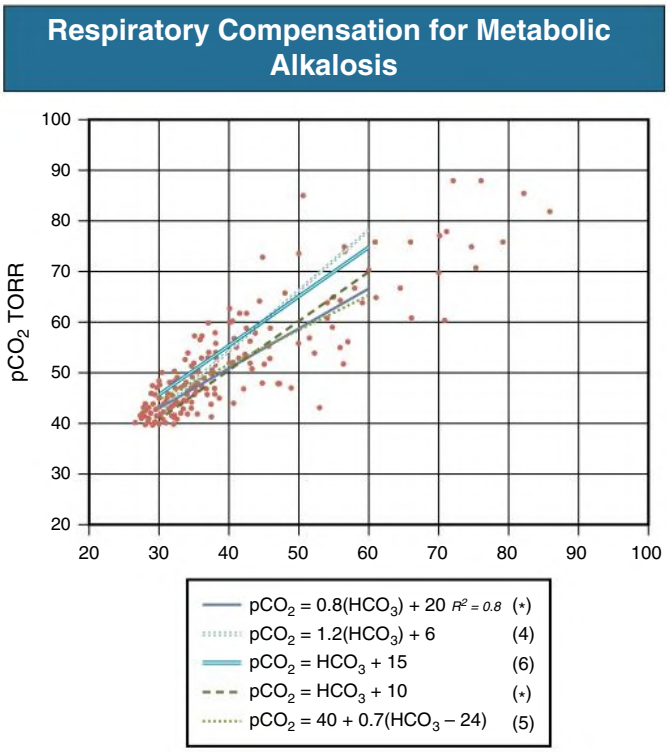

Fig. 14.1 Respiratory Compensation for Metabolic Alkalosis. Simultaneous P_{CO_2} and $[HCO_3^-]$ data points derived from a recent comprehensive literature review shows the best-fit linear regression line. Also shown are several commonly used equations that predict the P_{CO_2} expected for the elevated $[HCO_3^-]$. (The references are indicated.) We show that the equation $P_{CO_2} = [HCO_3^-] + 10$ *(dashed line)* is very similar to the best-fit regression line for the HCO_3 range between 30 and 50 mmo/L. This is a relationship very easy to remember and use. If $[HCO_3^-]$ exceeds 55 mmol/L, the P_{CO_2} may increase markedly. This is likely the result of a coexisting respiratory muscle weakness, very likely due to severe hypokalemia that almost always exists. *P_{CO_2},* Partial pressure of carbon dioxide; 1 Torr = 133.32 Pa. *Asterisk,* Fallahzadeh M.A. et al., unpublished observations. (From Emmet M. Metabolic alkalosis: a brief pathophysiologic review. *Clin J Am Soc Nephrol.* 2020;15[12]:1848–1856.)

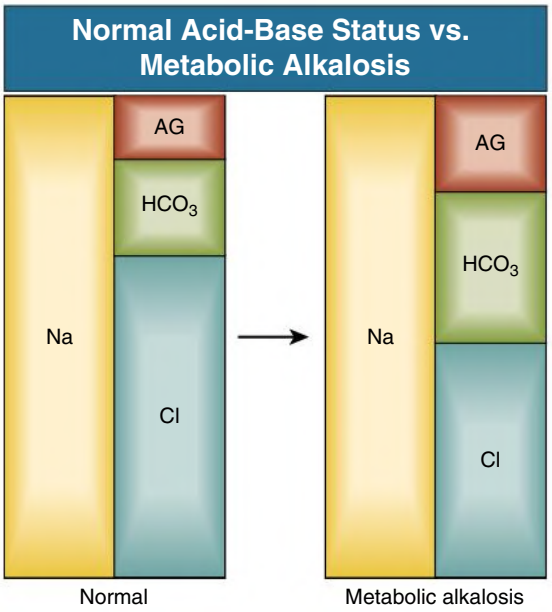

Fig. 14.2 Normal Acid-Base Status and Metabolic Alkalosis. The three major serum electrolytes are shown in the form of Gamblegrams. Note that when $[HCO_3^-]$ increases and the anion gap (AG) also increases slightly (which occurs with most forms of metabolic alkalosis), $[Cl^-]$ must fall, and the $[Cl^-]$:$[Na^+]$ ratio will fall below its normal 1:1.4 relationship.

Na^+,K^+-ATPase, which reduces intracellular Na^+ and generates a negative intracellular electrical charge. The resulting strong electrochemical gradient drives Na^+ from the lumen into the cell in exchange for H^+ entering the lumen. Additionally, ATP-energized H^+ pumps in the luminal membrane of the proximal tubule are responsible for about 30% of proximal H^+ secretion.

Each H^+ that enters the proximal tubule lumen leaves 1 HCO_3^- in the cytoplasm, which moves across the basolateral membrane to enter the ECF. The HCO_3^- movement from within the cell to the ECF occurs largely via the NBCe1A transporter (which moves 1 Na^+ and 3 HCO_3^- ions). The net effect of the secretion of 1 H^+ molecule is the disappearance of 1 HCO_3^- molecule from the luminal fluid and appearance of 1 HCO_3^- molecule in the ECF.

About 20% of the filtered HCO_3^- load escapes proximal tubule reclamation and is delivered downstream, where most is reabsorbed by the thick ascending limb of Henle. Proton secretion here is largely accomplished by the same Na^+-H^+ exchanger (NHE3) as exists in the proximal tubule. The small fraction of HCO_3^- delivered more distally is reabsorbed by mechanisms shown in Fig. 14.4.

After HCO_3^- has largely disappeared from the lumen in distal tubules/collecting ducts, further H^+ secretion generates "new" HCO_3^- that restores, or "regenerates," the HCO_3^- that was decomposed by sulfuric, phosphoric, and hydrochloric acids, for example. Also, the quantity of HCO_3^- that has been lost in the stool must also be regenerated. If 80 to 100 mmol/day of nonvolatile acids have been generated, then 80 to 100 mmol/day of H^+ (plus any HCO_3^- lost in stool) must be excreted by the kidneys to maintain acid-base equilibrium.

As HCO_3^- disappears from the tubular fluid, the pH falls. However, the minimum tubule fluid/urine pH cannot be reduced below about 4.5, which represents only 0.03 mmol/L of free H^+ (and therefore only 0.03 mmol/L of generated HCO_3^-). Therefore, virtually the entire H^+ load excreted in the urine must be bound to buffers in the urine: HPO_4^{2-}, which is titrated to $H_2PO_4^-$, represents most of the titratable acid in urine, and NH_3 binds to H^+ to form NH_4^+.

Metabolic Alkalosis: Source of Excess HCO_3^-

Metabolic alkalosis usually indicates an accumulation of "excess" HCO_3^- in the body. The HCO_3^- source can be exogenous, endogenous, or both.

Exogenous Sources

Exogenous sources include Na^+ or K^+ HCO_3^- or salts of HCO_3^- precursors (organic anions such as lactate, acetate or citrate, which generate HCO_3^- when completely oxidized). These salts may be ingested/absorbed and/or infused. (Box 14.1).

Endogenous Sources

The two most important potential sources of endogenous of HCO_3^- are the stomach and kidney, as described below.

Stomach

HCO_3^- is added to the ECF whenever HCl is secreted into gastric lumen. Essentially, 1 HCO_3^- ion replaces 1 Cl^- in the ECF. However, net HCO_3^- accumulation in the ECF requires the secreted HCl to be lost from the body, usually via vomiting and/or gastric suction (for further explanation, see the section Classic Example: Gastric Alkalosis).

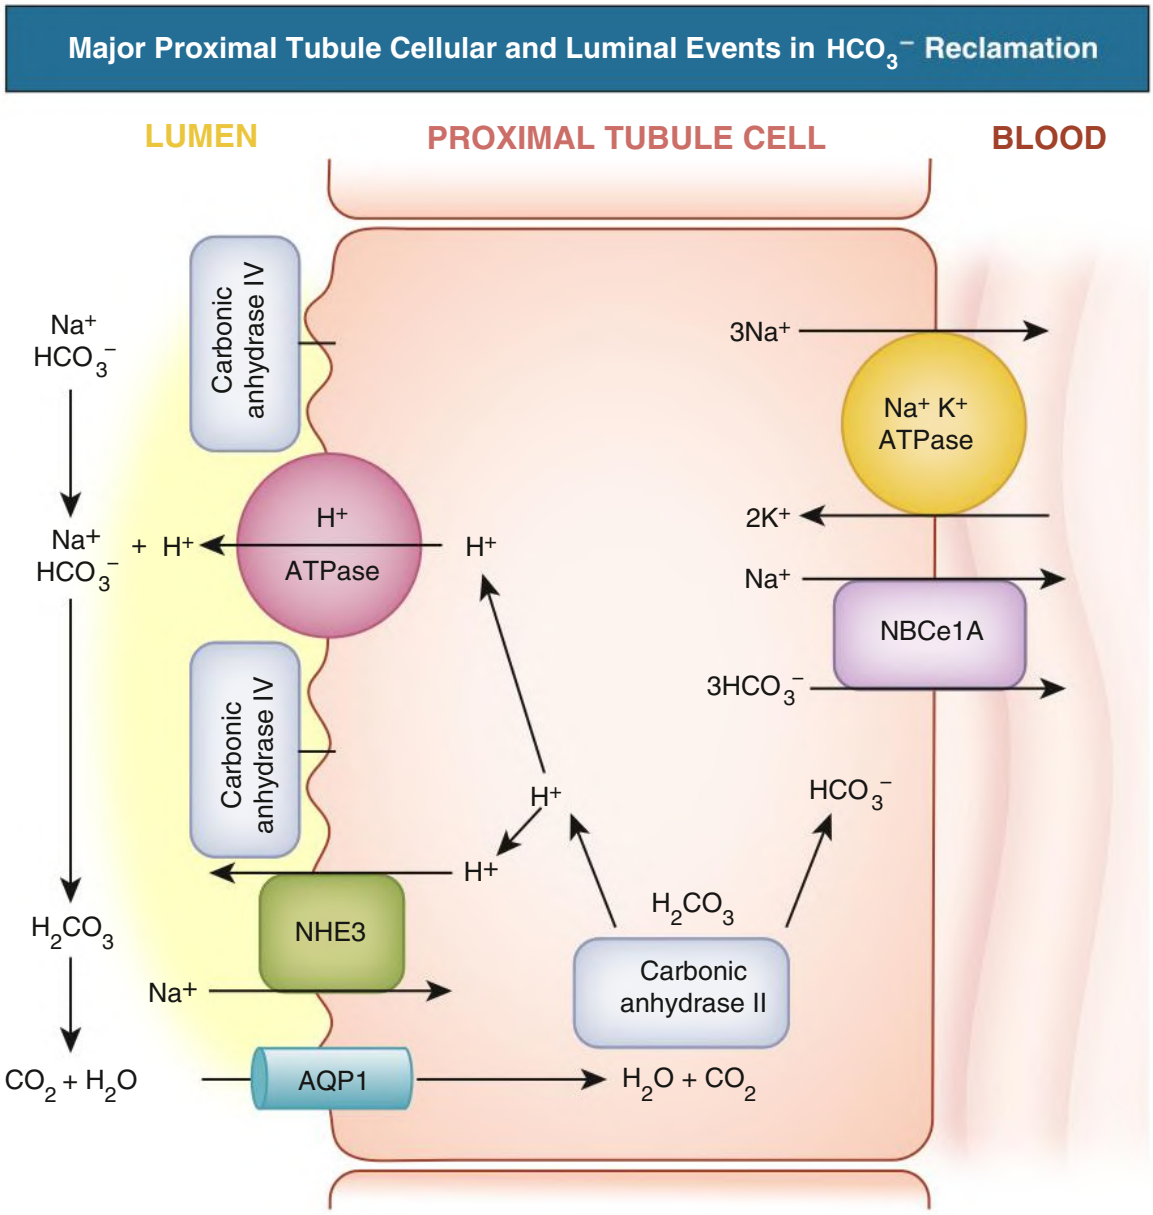

Fig. 14.3 Major Proximal Tubule Cellular and Luminal Events That Participate in HCO_3^- Reclamation. Intracellular H_2O combines with CO_2 to generate H_2CO_3, which rapidly dissociates to H^+ and HCO_3^- ions. These reactions are catalyzed by the cytoplasmic enzyme carbonic anhydrase II. Na^+,K^+-ATPase in the basolateral membrane creates a steep Na^+ electrochemical gradient that energizes Na^+ reabsorption via the Na^+-H^+ exchanger 3 (NHE3). When H^+ moves into the lumen, it reacts with filtered HCO_3^- to form H_2CO_3. The H_2CO_3 dehydrates to H_2O and CO_2, a reaction catalyzed by intraluminal carbonic anhydrase IV (this enzyme is anchored by a glycosylphosphatidylinositol tail to the luminal membrane). The generated CO_2 flows into the cell, largely via the aquaporin 1 (AQP1) channel. The HCO_3^- ions generated within the cells move across the basolateral membrane into peritubular capillaries, primarily via an Na^+-$3HCO_3^-$ cotransporter (the electrogenic NBCe1A transporter is a product of the Solute Carrier Family 4 Member A4 *[SLC4A4]* gene). The net effect of the secretion of 1 H^+ molecule and reabsorption of 1 Na^+ molecule is the addition of 1 $NaHCO_3$ molecule to the extracellular fluid and the disappearance of 1 $NaHCO_3$ molecule from the lumen. In addition, a smaller component of proximal tubule H^+ secretion (HCO_3^- reclamation) is accomplished via a V-type H^+-ATPase pump complex. Under normal conditions, about 80% of the filtered $NaHCO_3$ is reclaimed in the proximal tubule.

Kidney

Normal excretion of H^+ in the urine (as NH_4^+ and titratable acid) generates the quantity of HCO_3^- required to replace the HCO_3^- decomposed by nonvolatile acids derived from dietary metabolism plus any HCO_3^- lost in the stool. To the extent the kidney generates additional HCO_3^- above these replacement requirements, that quantity represents "excess" HCO_3^- and can generate metabolic alkalosis. "Excess" kidney HCO_3^- generation generally occurs when the following conditions coexist:

1. The more distal kidney tubules/ducts are stimulated to avidly reabsorb Na^+ (e.g., because aldosterone activity is high), and

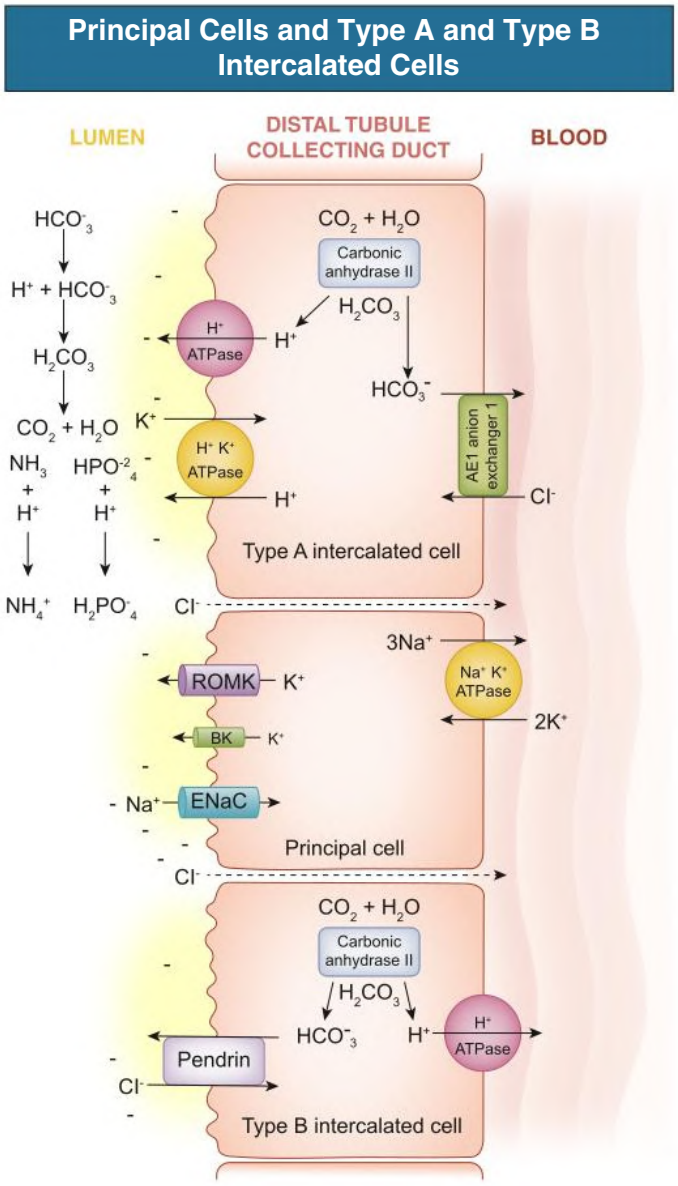

Fig. 14.4 Principal Cells and Type A and Type B Intercalated Cells. These cells are located in the late distal convoluted tubule, the connecting tubule, and cortical collecting duct. Principal cell transport is energized primarily by electrogenic Na^+,K^+-ATPase pumps in the basolateral membrane. The resulting low intracellular [Na^+] and negative intracellular potential difference combine to create a large gradient for Na^+ to move from the lumen into these cells. Flow occurs mainly through the epithelial sodium channel (ENaC, which is composed of α, β, and γ subunits, each a product of a different gene). Inward flow of Na^+ ions is more rapid than the sum of outward movement of K^+ (mainly through the renal outer medullary potassium [ROMK] channel) and inward flow of Cl^- (mainly via the paracellular space). Therefore, the Na^+ influx generates a negative potential difference (PD, approximately −40 mv) in the lumen. The H^+ secreted by the type A intercalated cells into the lumen initially reacts with any HCO_3^- remaining in the lumen; this represents HCO_3^- reclamation. As the luminal fluid pH falls, additional secreted H^+ combines with buffers such as HPO_4^{2-} and NH_3 to generate urine titratable acid (i.e., $H_2PO_4^{2-}$) and NH_4^+, which creates equimolar quantitates of systemic HCO_3^-. See Fig. 14.5 for a more detailed description of intercalated cell ion transport.

BOX 14.1 Metabolic Alkalosis: Bicarbonate Sources and Mechanisms of Generation

- Ingest/absorb and/or infuse $NaHCO_3$ and/or $NaHCO_3$ precursors, such as Na acetate, Na citrate, or Na gluconate.
- Generation of excess HCO_3^- by distal renal tubules/collecting ducts (increased H^+ secretion).
- Generous delivery of NaCl (or other Na salts, such as Na_2SO_4 or Na penicillin) to distal tubules/collecting ducts, which are actively reabsorbing Na^+ (and therefore secreting K^+ and H^+).
- K^+ depletion, shifting H^+ into cells, thereby generating extracellular fluid HCO_3^-.
- Remove HCl from body (vomiting/nasogastric suction/chloride-rich diarrhea).

2. Salt and volume delivery to these distal reabsorbing sites is relatively large.

Several examples of kidney bicarbonate overproduction include:

1. Primary hyperaldosteronism and other disorders, which mimic primary hyperaldosteronism (especially when a high-salt diet is ingested) (Box 14.2)
2. Loop and/or thiazide diuretics
3. Certain inherited kidney salt-wasting syndromes (i.e., Bartter, Gitelman, and related syndromes)
4. The infusion of Na^+ salts of poorly absorbed anions (e.g., HPO_4^{2-}, SO_4^{2-}, penicillin) when distal tubule Na^+ reabsorption is stimulated by mineralocorticoids and/or volume contraction[19,20]

Another important endogenous source of "excess" ECF HCO_3^- is the movement of K^+ out of cells into the ECF (in response to hypokalemia), which is partially balanced by movement of H^+ into cells. This generates HCO_3^- in the ECF.[21,22] The ECF [HCO_3^-] can also increase when ECF volume contracts around a fixed quantity of HCO_3 (see the section Classic Example: Gastric Alkalosis).[23]

Maintenance of Metabolic Alkalosis

If metabolic alkalosis develops and glomerular filtration rate (GFR) is not markedly reduced, correction of the alkalosis should be relatively straightforward: merely excrete a large fraction of the filtered HCO_3^- (which will be supernormal because of the high serum/filtered [HCO_3^-]). A brisk HCO_3^- diuresis would then reduce the [HCO_3^-] and restore normal acid-base status. This obviously has not occurred when metabolic alkalosis persists. Why has a brisk HCO_3^- diuresis not developed to rapidly restore normal acid-base status? The answer to this question depends on the underlying cause of the alkalosis, and the precise explanations continue to be refined and debated. The major mechanisms responsible for the maintenance of metabolic alkalosis are shown in Box 14.3.

Normal individuals can ingest, and their kidneys will efficiently excrete, up to 1000 mmol/day of $NaHCO_3$ over several weeks with only a minimal increase in serum [HCO_3^-].[24] Consequently, when metabolic alkalosis develops and persists despite a relatively normal GFR, this indicates the kidney is avidly reclaiming HCO_3^- at a supernormal rate. Most patients with metabolic alkalosis have both increased proximal and distal HCO_3^- reabsorption. The major factors responsible increasing proximal HCO_3^- are reduced intravascular, or effective intraarterial, blood volume, and hypokalemia.[12] (Metabolic acidosis and chronic respiratory acidosis also stimulate proximal tubule HCO_3^- reabsorption, but these disorders are not relevant to the current discussion.)

Metabolic alkalosis is also usually associated with accelerated distal HCO_3^- reabsorption and generation. Generous distal Na^+ delivery, combined with avid distal Na^+ reabsorption (e.g., because of high aldosterone levels), accelerates distal H^+ and K^+ secretion. This occurs

BOX 14.2 Causes of Metabolic Alkalosis

ECF Volume Contracted: Urine [Cl^-] <20 mmol/L
- Gastric alkalosis: vomiting/nasogastric suction
- Chloride-rich diarrhea (congenital chloridorrhea)
- Status post–chronic hypercapnia (acute reversal of chronic respiratory acidosis)
- Cystic fibrosis with major sweating
- Some villous adenomas
- Thiazide or loop diuretics after their renal tubule diuretic effect has dissipated

ECF Volume Expanded: Urine [Cl^-] >20 mmol/L
- Primary hyperaldosteronism (unilateral adenoma/bilateral hyperplasia/glucocorticoid-sensitive hyperaldosteronism)
- Severe Cushing syndrome (especially with ectopic adrenocorticotropic hormone secretion)
- Exogenous mineralocorticoids
- Reduced 11-β (OH)-steroid dehydrogenase activity
  - Chronic licorice/carbenoxolone ingestion
  - Congenital apparent mineralocorticoid excess syndrome (inactivating mutation of 11-β hydroxysteroid dehydrogenase (type 2)
- Renin-secreting tumors
- Some forms of congenital adrenal hyperplasia
  - 11-β hydroxylase deficiency
  - 17-α hydroxylase deficiency
- Liddle syndrome (persistent open epithelial sodium channel–renal tubule epithelial channels

ECF Volume Contracted: *But* Urine [Cl^-] >20 mmol/L (Generally Indicates a Renal Tubule NaCl Reabsorptive Defect)
- Thiazide and/or loop diuretics actively inhibiting renal tubule NaCl reabsorption
- Bartter syndromes (defective Na reabsorption in loop of Henle, a furosemide-like lesion)
- Gitelman syndrome (defective Na reabsorption by the neutral NaCl transporter, a thiazide-like lesion)

Metabolic Alkalosis: Other
- Very severe potassium deficiency
- Milk (calcium) alkali syndrome
- $NaHCO_3$ loads in patients with markedly reduced glomerular filtration rate.
- Refeeding after prolonged fasting

ECF, Extracellular fluid.

BOX 14.3 Metabolic Alkalosis: Mechanisms of Maintenance

- Increased proximal renal tubule HCO_3 reclamation
  - True extracellular fluid contraction or "effective intraarterial" volume contraction
  - K^+ depletion
- Continuous or intermittent generation of new HCO_3
  - In the distal kidney tubules and collecting ducts
  - Gastric HCl losses
- Exogenous alkali
- Reduced $NaHCO_3$ filtration due to kidney failure

in large part because distal tubule Na^+ reabsorption, mainly via the epithelial sodium channel (ENaC) in principal cells, generates a lumen negative electric potential (potential difference [PD] = −40 mv), which drives paracellular and transcellular anion (mostly Cl^-) reabsorption and enhances the secretion of H^+ and K^+. Also, multiple neurohormonal stimuli that increase distal Na^+ absorption also increase type A intercalated cell activity[25] (Fig. 14.4).

Three different types of intercalated cells are shown in Fig. 14.5. The type B intercalated cell secretes HCO_3^- in exchange for Cl^- and therefore contributes to the correction of metabolic alkalosis. However, generous distal delivery of Cl^- is required to enable this cell to secrete major quantities of HCO_3^-, and Cl^- delivery is usually reduced when ECF, or effective intraarterial volume, is reduced. Intercalated cells also contribute to NaCl reabsorption and volume regulation as discussed in Fig. 14.5.[25-31]

Of course, if GFR is markedly reduced, the filtered HCO_3^- load will fall sharply. However, metabolic alkalosis does not usually develop in patients with very low GFR. These patients more often develop metabolic acidosis. Nonetheless, occasionally metabolic alkalosis does develop, and under these conditions the reduced GFR impairs excretion of the HCO_3^- load. A reduced GFR is a major contributor to the maintenance of metabolic alkalosis in patients with milk-alkali or calcium-alkali syndrome[32,33] and when patients with severe kidney dysfunction ingest bicarbonate salts, bicarbonate generating salts, vomit, or require nasogastric (NG) suction.[34]

METABOLIC ALKALOSES: ETIOLOGIC CLASSIFICATION BASED ON ECF VOLUME STATUS

The generation, maintenance, and resolution of several prototypical types of metabolic alkalosis in each ECF volume status category are described.

ECF Volume Contracted With Persistently Reduced Urine [Cl^-]

Classic Example: Gastric Alkalosis

Generation. Gastric fluid osmolality is about 300 mOsm/L with a [Cl^-] of about 150 mmol/L and a similar total cation concentration of about 150 mmol/L. The [H^+] varies between 40 and 140 mmol/L, [K^+] between 10 and 15 mmol/L, and [Na^+] makes up the balance.[35] Secretion of HCl (via gastric type H^+/K^+ ATPase and Cl^- channels) into the gastric lumen adds an equal quantity of HCO_3^- to the ECF. (The net effect of HCl secretion is the "replacement" of ECF Cl^- by HCO_3^-.) Normally, gastric HCl secretion does not result in metabolic alkalosis because the secreted HCl is not externally lost from the body. The HCl secreted into the gastric lumen usually enters the small bowel where the H^+ reacts with HCO_3^-, mainly secreted by the pancreas (with a small component derived from bile and intestinal epithelium). This reaction generates CO_2 and water in the small bowel lumen. Because the quantity of HCO_3^- that enters the small bowel lumen and reacts with H^+ equals the quantity of H^+ delivered from the stomach, these two processes neutralize one another so that neither alkalosis nor acidosis develops. However, if the HCl secreted into the stomach is removed from the body, via vomiting or aspiration, this prevents the HCl from reaching the small bowel. Consequently, HCO_3^- is either not secreted into the intestinal lumen, for neutralization by HCl, or is reabsorbed. The net effect is the addition of a gastric derived load of HCO_3^- to the ECF and loss of an equal quantity of Cl^- from the body. This represents the initial source of HCO_3^- in patients with "gastric alkalosis."

Later in the development of gastric alkalosis, hypokalemia (generated by renal K^+ loss) results in systemic K^+/H^+ cell shifts, which generate additional ECF HCO_3^- (described later).

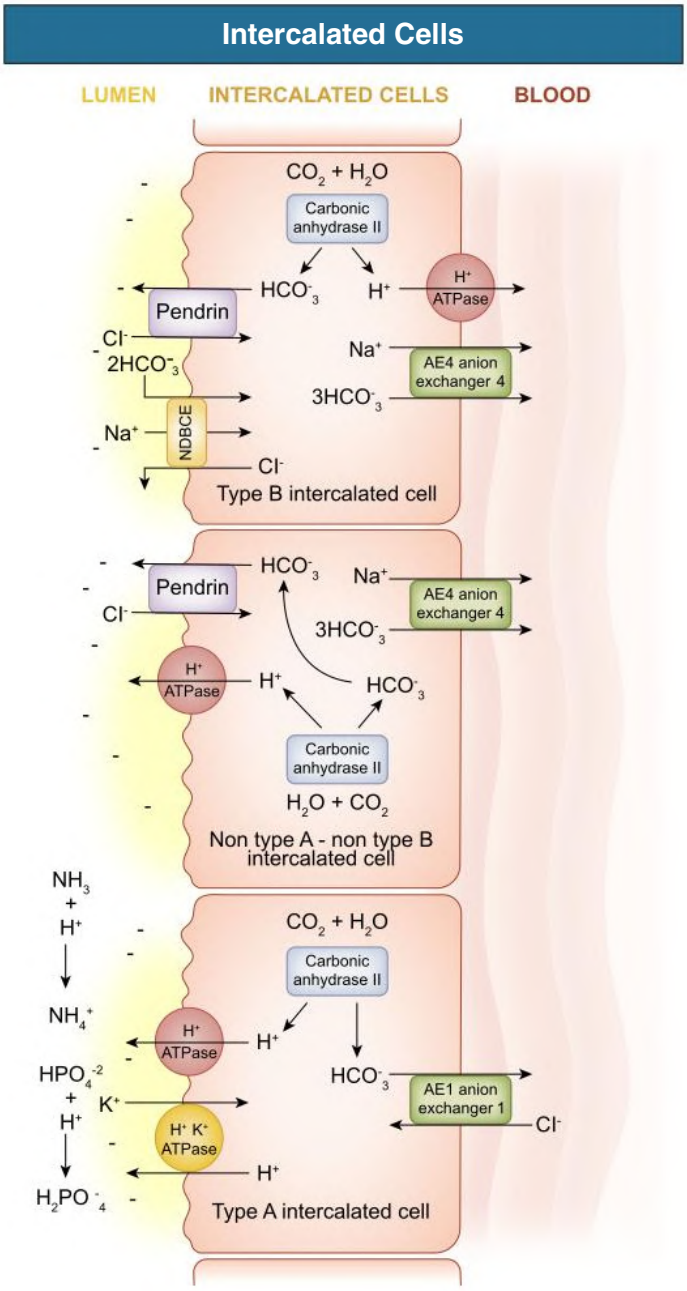

Fig. 14.5 **Intercalated Cells:** Three different intercalated cell types have been identified: type A intercalated cells, type B intercalated cells, and non–type A/non–type B intercalated cells. Each is rich in carbonic anhydrase II and is capable of generating abundant HCO_3^- and H^+ from H_2CO_3. **Type A intercalated cells:** H^+ is secreted into the lumen mainly via V-type H^+-ATPase and to a smaller extent via H^+-K^+-ATPase. The generated cytoplasmic HCO_3^- moves into the peritubular capillary in exchange for Cl^-, via anion exchanger 1 (AE1; a product of the Solute Carrier Family 4 Member 1 *[SLC4A1]* gene). This transporter is also called the *erythrocyte membrane protein band 3* when it is located in red blood cells. **Type B intercalated cells:** H^+ is secreted into the peritubular capillary by V-type H^+-ATPase in the basolateral membrane (the same proton transporter as found in type A intercalated cells but in the opposite, or luminal, membrane). The HCO_3^- generated in this cell is secreted into the lumen via an anion exchanger named pendrin (a product of the Solute Carrier Family 26 Member A4 *[SLC26A4]* gene), which exchanges 1 HCO_3^- for 1 Cl^-. Pendrin is a distinct and different exchanger than the AE1 present in the basolateral membrane of the type A cells. A Na^+/3 HCO_3^- cotransporter *AE4* (anion exchanger 4; a product of the Solute Carrier Family 4 Member A4 *or [SLC4A4]* gene) is present in the basolateral membrane. These cells also have the sodium-driven bicarbonate chloride exchanger (*NDBCE;* a product of the Solute Carrier Family 4 Member A8 *[SLC4A8]* gene) in the luminal membrane (see later discussion). **Non–type A/non–type B intercalated cells:** this is the third type of intercalated cell. Both a V-type H^+-ATPase, pumping H^+, and pendrin, exchanging HCO_3^- for Cl^- coexist in the lumen membrane. AE4 is a major Na^+/3 HCO_3^- transporter in the basolateral membrane, moving these ions into the peritubular capillary. Although intercalated cells were originally identified as major kidney acid-base–regulating cells, it is now clear that these cells also play an important role in salt and volume regulation.[32,33] The NDBCE in the luminal membrane of the type B intercalated cells is an electrically neutral ion exchanger moving 1 Na^+ and 2 HCO_3^- ions into the cell while moving 1 Cl^- into the lumen. The net effect of two pendrin cycles (2 HCO_3^- ions enter the lumen in exchange for uptake of 2 Cl^- ions) and 1 NDBCE cycle (2 HCO_3^- ions and 1 Na^+ ion enter the cell and 1 Cl^- ion enters the lumen) has the net effect of the reabsorption on 1 NaCl molecule. These acid-base and salt reabsorption interactions of intercalated cells may explain why some patients with Pendred syndrome, a genetic defect of pendrin, develop severe salt depletion and metabolic alkalosis when treated with thiazide diuretics.[34] (Pendrin is also a major transporter in the ear, and patients with Pendred syndrome are usually congenitally deaf.)

Maintenance. Initially, as HCO_3^- is added to the ECF and slightly raises the [HCO_3^-], as a result of vomiting or gastric suction, most is filtered and excreted by the kidneys largely as $NaHCO_3$. The loss of gastric fluid combines with kidney loss of $NaHCO_3$ and fluid to produce ECF volume contraction, and this activates a neurohormonal cascade that stimulates the kidneys to avidly retain salt and fluid. Secondary hyperaldosteronism develops and results in the conversion of much of the $NaHCO_3$ delivered to the distal tubules to $KHCO_3$.[36]

Systemic hypokalemia develops causing K^+ to shift out of cells in exchange for ECF H^+ entering cells. This generates ECF HCO_3^-.[21,22] This K^+/H^+ shift acidifies kidney tubule cells, which further stimulates H^+ secretion and thereby drives kidney HCO_3^- reclamation and generation. Systemic hypokalemia also reduces pendrin activity and type B intercalated cell density, which reduces HCO_3^- secretion and contributes to the maintenance of metabolic alkalosis.[30,31]

Extracellular fluid volume contraction stimulates both proximal and distal Na^+ reabsorption. In the proximal tubules, this increases HCO_3^- reclamation. In the distal tubules, Na^+ reabsorption increases both H^+ and K^+ secretion. K^+ depletion further increases H^+ secretion by type A intercalated cells via both H^+ ATPase and H/K ATPase pumps (Figs. 14.3 and 14.4) and increases kidney NH_3 generation and excretion.[37,38] These effects all combine to increase kidney HCO_3^- reclamation and generation.

During the maintenance phase of gastric metabolic alkalosis, the urine electrolyte pattern typically fluctuates. Extracellular fluid volume contraction stimulates avid reabsorption of filtered Na^+, HCO_3^-, Cl^-, and water. This usually generates concentrated urine (an antidiuretic hormone effect) with low Na, Cl, and K concentrations and a relatively acid pH (denoted as *paradoxical aciduria* because systemic metabolic alkalosis exists). However, intermittently (e.g., immediately after loss of a bolus of HCl-rich gastric fluid), serum [HCO_3^-] acutely increases, and for a limited period of time, the larger load of filtered HCO_3^- cannot be completely reclaimed despite the multiple neurohormonal factors generated by volume contraction. When this occurs, the urine excretion of [HCO_3^-], [Na^+], [K^+], and pH all temporarily increase. This reduces the serum [HCO_3^-] and further contracts ECF volume, and after a brief period of time the filtered load of Na^+ and HCO_3^- can again be completely reabsorbed. The urine electrolyte concentrations and urine pH again fall. However, it is very important to note that throughout these cyclic variations in urine [Na^+], [K^+], [HCO_3^-], and pH, urine [Cl^-] remains persistently low (because the intermittent loss of HCO_3^- in the urine mandates loss of Na^+ and/or K^+ but not Cl^-). Thus, a low urine [Cl^-] (<20 mmol/L) generally indicates the ongoing response to reduced ECF/intraarterial blood volume (or very low Cl^- intake). Development of these urine electrolyte profiles presume that kidney tubule function is relatively intact and the absence of exogenous diuretic activity.

Resolution. The factors responsible for kidney HCO_3^- retention in these forms of metabolic alkalosis are largely reversed by adequate ECF volume expansion (NaCl infusion) and K^+ repletion. Restoration of ECF volume is associated with a rising urine [Cl^-] and the development of a $NaHCO_3$ diuresis. Increased distal Cl^- delivery also stimulates HCO_3^- secretion in exchange for Cl^- via the pendrin exchanger in Type B intercalated cells. Systemic K^+ replacement is required to restore K^+ homeostasis. Some of the administered K^+ moves into cells in exchange for H^+ moving into the ECF. This simultaneously reduces the ECF [HCO_3^-] and increases intracellular pH.

The term *contraction alkalosis* has been used to describe several different conditions in which the ECF "contracts" around a relatively fixed quantity of HCO_3^-. Although gastric alkalosis is an ECF volume contracted condition and the ECF contraction contributes importantly to both its generation and maintenance, the major origin of the increased blood [HCO_3^-] is not contraction of the ECF per se but rather generation of HCO_3^- owing to gastric HCl loss and cellular H^+-K^+ shifts.[21-23,36]

Conversely, although ECF expansion with NaCl-rich fluids does directly dilute the ECF [HCO_3^-] to a small degree, the corrective action of NaCl in these patients is mainly the result of ECF volume expansion and resultant kidney HCO_3^- excretion.

Reducing or stopping the loss of gastric HCl is of course required to reverse the process at its initiation point. If the exogenous loss of gastric fluid losses cannot be stopped, then reducing the gastric fluid [HCl] concentration with an H^+ blocker or proton pump inhibitor can be helpful.[39]

Box 14.2 lists the most common forms of metabolic alkalosis associated with ECF volume contraction. The urine [Cl^-] is typically reduced to less than 20 mmol/L in each of these disorders.

ECF Volume Expanded

Classic Example: Primary Mineralocorticoid Excess Syndromes

Primary hyperaldosteronism is a condition of autonomous, or inappropriately upregulated, aldosterone secretion. This usually generates ECF volume expansion, hypertension, hypokalemia, and metabolic alkalosis. A unilateral adrenal adenoma secreting aldosterone is the prototypical cause of this disorder, but many conditions can duplicate or mimic the clinical and electrolyte and acid-base pathophysiology of a primary aldosterone-secreting adenoma (Box 14.2) (see Chapter 39).

ECF Volume Regulation of Renin and Aldosterone (Normal Physiology)

Extracellular fluid volume contraction in normal individuals reduces the GFR and sharply increases the reabsorption of NaCl and $NaHCO_3$ in the proximal tubules. Volume contraction also generates secondary hyperaldosteronism (high aldosterone activity driven by high renin and angiotensin II activity). Reabsorption of Na^+ in late distal tubules/collecting ducts is largely accomplished by the principal cells via ENaC channels in the luminal membranes (Fig. 14.4). When these channels are present in the luminal membrane and in an open state, the electrochemical gradient favors reabsorption of Na^+, and this cation flux generates a lumen negative electrical potential (about −40 mv) that drives both Cl^- reabsorption and also secretion of K^+ and H^+. Normally, ECF volume contraction generates a coordinated series of proximal and distal actions so that the potent aldosterone-driven stimulus to reabsorb Na^+ in the distal tubules and collecting ducts is linked to a fall in GFR and increased proximal tubule salt reabsorption. These proximal tubule events sharply reduce distal salt and water delivery. The net effect is that reduced Na^+ and volume delivery to the distal aldosterone-sensitive tubule sites acts to blunt the magnitude of distal Na^+ reabsorption and the indirectly linked secretion of K^+ and H^+. Thus, metabolic alkalosis and hypokalemia do not usually develop despite physiologic secondary hyperaldosteronism.

An opposite series of events develop in response to ECF volume expansion in normal individuals. The GFR increases, proximal salt and water reabsorption fall, and distal delivery of salt and water is generous. Volume expansion reduces renin, angiotensin II, and aldosterone levels. Now generous distal salt and water delivery exists while aldosterone activity is minimal. Distal Na^+ reabsorption, and indirectly linked K^+ and H^+ secretion, is moderate. Thus, metabolic

acidosis and hyperkalemia do not develop despite physiologic secondary hypoaldosteronism.

These coordinated interactions describe the normal reciprocal physiologic balance that exists between the magnitude of proximal tubule salt and water reabsorption, distal delivery of salt and water, and the neurohormonal stimulation (largely via aldosterone) of distal Na^+ reabsorption and indirectly linked K^+ and H^+ secretion. This exquisite normal reciprocal balance is disrupted by autonomous hypersecretion of aldosterone.[12,40]

Generation. Autonomous hyperaldosteronism generates an inappropriate degree of distal Na^+ reabsorption, which expands the ECF, raises the GFR, and reduces proximal tubule salt and water reabsorption. This results in generous distal salt and water delivery. This occurs in the setting of persistently high aldosterone activity. These conditions result in the unphysiologic combination of high aldosterone activity linked with high distal tubule salt and water delivery. This pathophysiologic combination generates a high rate of distal Na^+ reabsorption and indirectly linked generous K^+ and H^+ secretion. Excess excretion of K^+ and H^+ exceeds physiologic requirements and produces hypokalemia and metabolic alkalosis.

The development of hypokalemia and K^+ depletion contribute importantly to additional systemic and kidney HCO_3^- generation. K^+ shifts out of cells in exchange for H^+ generating ECF HCO_3^-.[22] Systemic K^+ depletion also increases kidney H^+ secretion and ammonia generation and excretion (in part by reducing the pH of kidney tubule cells).[25,27] All these effects enhance kidney HCO_3^- reclamation and generation.

Maintenance phase. Expansion of the ECF usually increases the GFR, reduces proximal tubule salt and volume reabsorption, and decreases HCO_3^- reclamation. ECF expansion normally also reduces renin, angiotensin II, and aldosterone levels. Consequently, with "physiologic" ECF volume expansion, distal Na^+ reabsorption and K^+ and H^+ secretion remain modest despite high delivery rates. However, autonomous aldosterone secretion combines generous distal salt delivery with inappropriately high levels of distal Na^+ reabsorption and indirectly linked K^+ and H^+ excretion. Hypokalemia and K^+ depletion develop and contribute importantly to both ongoing kidney HCO_3^- reclamation and both kidney and systemic HCO_3^- generation and via K^+/H^+ cell shifts and cellular acidification. Hypokalemia also increases H^+/K^+-ATPase activity in type A intercalated cells (Figs. 14.4 and 14.5).[25,27] Additionally, aldosterone increases distal salt reabsorption via a sequence of pendrin-related events as described in Fig. 14.5.[28]

During the maintenance phase of various states of autonomous hyperaldosteronism, and related pathophysiologic conditions, urine electrolytes reflect the individual's salt intake. Thus, the urine $[Cl^-]$ will generally be greater than 20 mmol/L, unless the patient is ingesting a very low NaCl diet.

Recovery phase. Successful resection of an adrenal aldosterone-secreting adenoma should theoretically reverse the entire syndrome. In lieu of surgery, drugs that block the action of aldosterone can be very helpful. The physical and biochemical manifestations of primary hyperaldosteronism can also be markedly ameliorated by ingestion of a low-salt diet. This reduces distal salt delivery and thereby blunts H^+ and K^+ secretion and excretion. Conversely, the physical findings and electrolyte abnormalities are exacerbated by a high-salt diet.[40,41] Analogously, other mineralocorticoid excess syndromes and mineralocorticoid excess-like syndromes are improved or "cured" by eliminating the source of the problem and/or treated by blocking the downstream pathophysiology. However, when hypertension has existed for a long period of time, this may persist as a result of the development of structural vascular pathology.

ECF Volume Contracted With Intermittently Reduced Urine $[Cl^-]$

Classic Example: Thiazide and/or Loop Diuretics

Thiazide and/or loop diuretics often generate hypokalemia and metabolic alkalosis. Despite a relatively contracted ECF and effective arterial blood volume, the generation and maintenance mechanisms of these conditions have many similarities to the ECF volume-expanded condition of primary hyperaldosteronism.[40] That is because distal tubule salt and volume delivery are high when diuretics are inhibiting reabsorption. Therefore, they generate the pathophysiologic combination of high distal salt/volume delivery and high levels of aldosterone activity (in this case due to secondary hyperaldosteronism).

Generation. Inhibition of the neutral Na/K/2Cl cotransporter in the thick limb of Henle by loop diuretics and/or inhibition of the neutral Na/Cl cotransporter in the diluting segment by thiazide diuretics increases NaCl and volume delivery to more distal sites. Diuretics also increase renin, angiotensin II, and aldosterone levels, generating secondary hyperaldosteronism. In the absence of diuretics, secondary hyperaldosteronism is typically associated with reduced distal salt and volume delivery, and this limits the magnitude of distal Na^+ reabsorption (and thereby H^+ and K^+ secretion). However, diuretic activity combines secondary hyperaldosteronism with generous distal tubule NaCl and volume delivery. Therefore, enhanced distal Na^+ reabsorption via principal cell ENaCs is linked with generous distal Na^+ and volume delivery, accelerating distal H^+ and K^+ secretion. This pathophysiologic combination generates metabolic alkalosis and hypokalemia. Hypokalemia also adds additional ECF HCO_3^- via cellular H^+/K^+ exchange described above.

During periods of diuretic activity, urine $[Na^+]$ and $[Cl^-]$ are both high. However, diuretics are typically administered intermittently, so that periods of diuretic activity cycle with periods of inactivity and recovery. During the "off-diuretic" phases, avid proximal kidney salt and water reabsorption markedly reduces distal NaCl delivery. This minimizes principal cell Na^+ reabsorption and distal K^+ and H^+ secretion. During these off-diuretic periods, urine $[Cl^-]$ and $[Na^+]$ fall to low levels, reflecting the patient's relatively contracted ECF volume status. Then, when the diuretic is again ingested or administered, the urine $[Cl^-]$ and $[Na^+]$ increase. Thus, the concentration of these urine electrolytes cycles up and down depending on the presence or absence of diuretic activity.

Recovery phase. When diuretics are discontinued, distal delivery of salt and volume fall, and this reduces kidney tubule HCO_3^- generation. However, metabolic alkalosis will not resolve until the potent stimuli, which are accelerating proximal and distal salt reabsorption, are eliminated. Therefore, if diuretics were initiated to treat avid salt retention (e.g., due to heart failure, hepatic cirrhosis), the metabolic alkalosis will generally persist until the underlying pathology can be ameliorated. Reversing hypokalemia and K^+ depletion is also critical for the amelioration or reversal of metabolic alkalosis. If the clinical situation mandates continuing diuretics despite metabolic alkalosis, the addition or substitution of diuretics, which blunt distal tubule/collecting duct Na^+ reabsorption (i.e., potassium sparing diuretics such as triamterene or spironolactone) and/or "acidifying" diuretics, which block proximal tubule HCO_3^- reclamation (acetazolamide), can be very helpful. However, acetazolamide will generate marked K^+ wasting, so aggressive K^+ supplementation is often required when this diuretic is initiated.[42]

All three types of intercalated cells located in the distal tubule/collecting ducts play a major role in both acid/base regulation and also

volume regulation and salt balance.[43,44] These cells may be especially important in moderating the development of metabolic alkalosis in patients receiving thiazide diuretics[45] (Fig. 14.5).

OTHER METABOLIC ALKALOSES

Bartter and Gitelman syndromes and their related disorders are genetic diseases that result in impaired kidney tubule salt reabsorption. Therefore, these diseases have many similarities to persistent diuretic action. However, unlike patients who receive diuretics, these patients never experience an "off-drug" period. Therefore, these disorders are characterized by persistent, high urine [Cl^-] because an "off-diuretic–like" period never occurs.[46,47]

If large amounts of alkali are ingestion or infused in a patient with acute or chronic kidney disease, this can produce metabolic alkalosis, which may sometimes be of extreme severity.[48] The "milk alkali" or "calcium alkali" syndrome is generated by the ingestion of large quantities of $NaHCO_3$ or other alkalinizing salts together with excess calcium (in milk or $CaCO_3$) intake.[32,33] In these patients, kidney damage is partially generated by kidney calcium deposition, facilitated by high urine calcium concentrations in alkaline urine. Vomiting often also develops and will exacerbate the metabolic alkalosis. Citrate is an anticoagulant that is used in many blood products and is a HCO_3^- precursor. Each mole of Na_3Citrate that is oxidized yields 3 moles of $NaHCO_3$. Therefore, metabolic alkalosis can occur after massive blood transfusions and when blood products, such as fresh frozen plasma, are infused in large volumes during procedures such as plasma exchange. These metabolic alkaloses are usually maintained because GFR is reduced, which impairs kidney HCO_3 excretion.

Compensation for chronic respiratory acidosis elevates plasma [HCO_3^-] and reduces the [Cl^-]. However, arterial pH remains acid due to the elevated P_{CO_2}. If the chronically elevated P_{CO_2} is rapidly reduced, usually by mechanical ventilation, the plasma [HCO_3^-] concentration may remain elevated for a period of time and generate metabolic alkalosis. This is especially likely if the patient has a low effective arterial blood volume or reduced GFR. This is "posthypercapnic" metabolic alkalosis. This alkalosis will persist until enough NaCl is ingested or infused to replete the extracellular fluid volume.[49]

DIAGNOSTIC APPROACH TO METABOLIC ALKALOSIS

Most metabolic alkaloses are due to diuretics or external loss of gastric fluid. When the cause is not apparent from the history, drug review, and physical examination, it is helpful to categorize the disorder based on the kidney function and ECF or effective intraarterial volume status. If the GFR is reduced and major acidic gastrointestinal fluid losses do not exist, a source of exogenous bicarbonate should be sought. If the GFR is not markedly reduced, then it will be helpful to assess volume status integrating the history, physical examination, and spot urine [Cl^-] measurement. Urine [Cl^-] less than 20 mmol/L is consistent with a reduced ECF or effective intraarterial volume. Urine [Cl^-] greater than 20 mmol/L suggests a volume expanded state, or defective kidney salt reabsorption (i.e., diuretic activity or kidney tubule reabsorption defect). Consider the diagnoses listed in Box 14.2. If the patient exhibits signs of volume expansion, such as hypertension, then consider the ECF volume–expanded disorders in Box 14.2. Measurements of plasma renin and aldosterone levels can be helpful. If the patient appears volume contracted, yet has relatively high urine [Cl^-], kidney salt wasting may be responsible. Many of the genetic mutations responsible for Bartter and Gitelman syndromes can be identified by commercial laboratories. Recognize that diuretic-generated metabolic alkalosis is generally characterized by cyclic changes in urine [Cl^-] as the diuretic effects wax and wane, and widely varying urine [Cl^-] generally indicates intermittent diuretic use (which some patients may deny). Fig. 14.6 shows this diagnostic approach.

TREATMENT

Treatment of the volume-contracted metabolic alkaloses, such as those due to the external loss of HCl from vomiting or NG suction, was discussed earlier. Intravenous NaCl is required to expand the contracted ECF and KCl to replete K^+ stores (the K^+ deficit is usually in the 200–400 mmol range). If the HCl losses continue, proton pump inhibitors can be used to reduce the acid loss. Treatment of metabolic alkalosis generated by loop and/or thiazide diuretics include stopping (or reducing the dose of) diuretics whenever feasible, administering KCl to replete K deficits, and adding blockers of distal tubule Na reabsorption (which also reduce H and K loss), such as triamterene or amiloride, or blocking mineralocorticoid activity with spironolactone or eplerenone. Adding or switching to acetazolamide, a diuretic that increases kidney bicarbonate excretion, can also rapidly correct the metabolic alkalosis but will increase kidney K loss. The combination of volume contraction, metabolic alkalosis, and hypokalemia, which characterizes Bartter and Gitelman syndromes, is difficult to manage. In addition to generous oral NaCl and KCl intake, drugs that blunt distal Na+ reabsorption/K+ and H+ exchange (e.g., spironolactone, eplerenone, or amiloride) are helpful, and nonsteroidal antiinflammatory drugs may be useful. The Gitelman phenotype usually also generates marked urine magnesium wasting and hypomagnesemia requiring aggressive magnesium replacement.

Management of metabolic alkalosis and hypokalemia due to excessive (and physiologically inappropriate) mineralocorticoid activity can be definitively treated by removing the source of mineralocorticoid (i.e., resect an adenoma when present). If this is not possible (i.e., bilateral adrenal hyperplasia), then spironolactone or eplerenone are very helpful. For disorders that mimic physiologically inappropriately excessive mineralocorticoid activity (i.e., Liddle syndrome), triamterene or amiloride are used (the excessive mineralocorticoid-like activity in these disorders is independent of aldosterone activity; therefore, spironolactone or eplerenone are not effective). All the physiologically inappropriate increased mineralocorticoid activity disorders, and the disorders that mimic this pathophysiology, are exacerbated by high NaCl intake and ameliorated with low NaCl intake. Administration of KCl to treat K depletion is also important.

Alkalosis driven by alkali ingestion is best treated by discontinuation of oral alkali and/or adjustment of dialysate bicarbonate in dialysis-dependent patients.

When severe metabolic alkalosis develops and cannot be corrected (e.g., dialysis or continuous kidney replacement cannot be initiated), then HCl can be infused. The HCl solution is prepared at a concentration of 100 to 150 mmol/L and must be infused into a central vein to avoid hemolysis and vein damage/sclerosis. The volume of distribution of the HCl is about 50% of body weight.

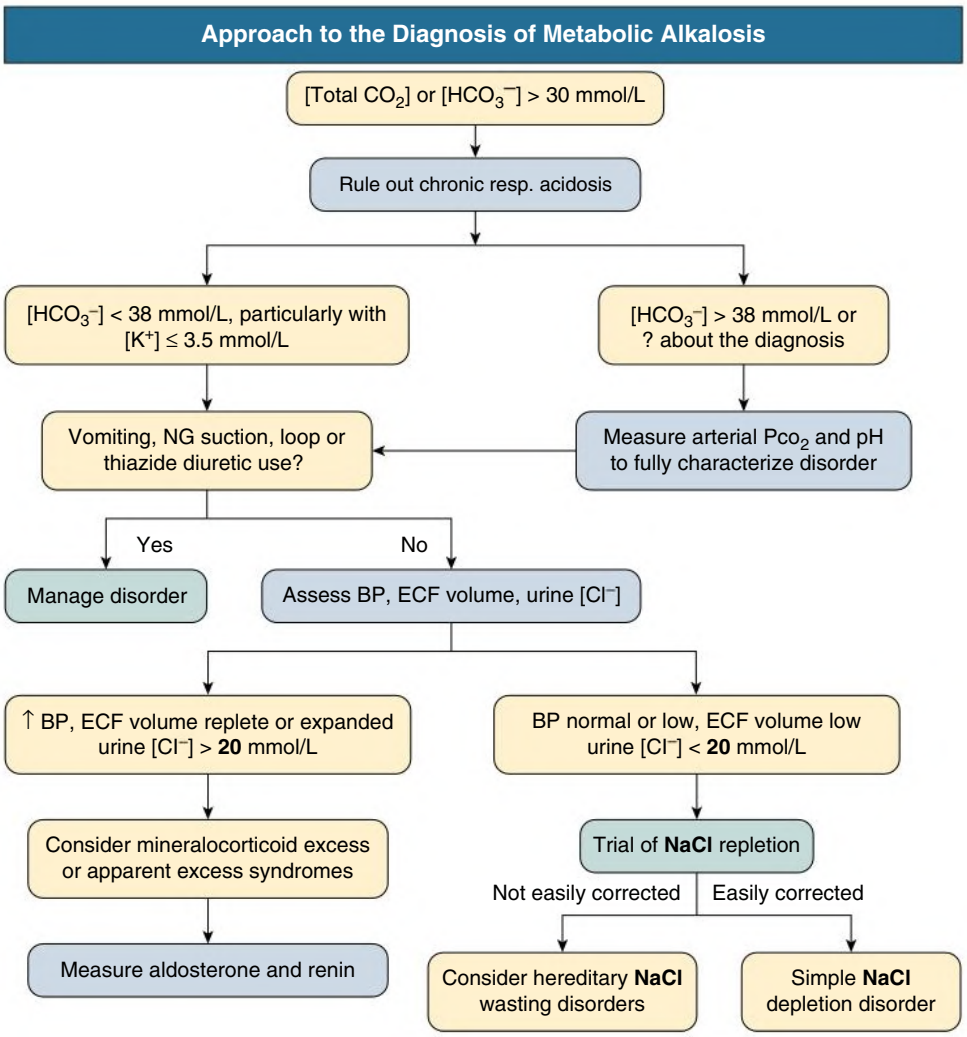

Fig. 14.6 Diagnostic approach to the causes of metabolic alkalosis. *BP,* Blood pressure; *ECF,* extracellular fluid; *NG,* nasogastric tube; *Pco_2,* partial pressure of carbon dioxide.

SELF-ASSESSMENT QUESTIONS

1. A 56-year-old man with a history of hypertension and chronic kidney disease stage 3b has required nasogastric suction for 2 days following right hemicolectomy for colonic carcinoma. His blood pressure (BP) is 110/70 mm Hg and pulse is 105 beats/min. There is no jugular venous distention. There are no bowel sounds noted and no leg edema. Laboratory values are Na 138, K 2.9, Cl 92, and total CO_2 36 (all mmol/L). Creatinine is 2.4 mg/dL, and venous pH is 7.52. Which of the following laboratory studies would *most* help define the mechanism of his alkalosis?
   A. Low urine chloride concentration
   B. Low urine potassium concentration
   C. Low urine sodium concentration
   D. Urine pH greater than 6.0
2. In addition to recommending intravenous 0.9% saline for correction of metabolic alkalosis in the patient in question 1, he will also require which one of the following?
   A. Addition of a proton pump inhibitor
   B. HCl infusion
   C. KCl infusion
   D. Kidney replacement therapy
3. A 26-year-old woman presents to the emergency department reporting weakness. She has no significant past medical history. Examination reveals BP 112/76 mm Hg, pulse 96 beats/min, and 3/5 strength in both legs. Laboratory values are Na 142, K 2.6, Cl 96, and total CO_2 34 (all mmol/L). Urine pH is 7, and urine electrolytes are Na 40, K 45, and Cl 10 (all mmol/L). The *most likely* cause of her illness is:
   A. primary hyperaldosteronism.
   B. Gitelman syndrome.
   C. surreptitious vomiting.
   D. diuretic use.

Respiratory Acidosis, Respiratory Alkalosis, and Mixed Acid-Base Disorders

Anip Bansal

RESPIRATORY ACIDOSIS

Respiratory acidosis is defined by a decrease in arterial pH that is primarily because of an increase in whole body carbon dioxide (CO_2) stores, which are indirectly assessed by the partial pressure of CO_2 in arterial blood ($Paco_2$). The $Paco_2$ is the same as the Pco_2 in alveolar air but is usually lower than in the capillaries (which reflects the Pco_2 in both the interstitial fluid and in the cells surrounding these capillaries).[1] At high altitude (i.e., above 4000 m or 13,000 feet), the underlying adaptation with chronic respiratory alkalosis usually causes a slight lowering of the $Paco_2$ at baseline so a respiratory acidosis may be present even with apparently normal $Paco_2$ levels.[2] Pseudorespiratory alkalosis refers to the presence of arterial eucapnia (or hypocapnia) with severe venous hypercapnia in patients with profound circulatory failure with preserved respiratory function.[3,4]

PATHOPHYSIOLOGY OF RESPIRATORY ACIDOSIS

The quantity of CO_2 in the body remains constant if the lungs can excrete the amount of CO_2 produced from metabolism. This is reflected by the amount of dissolved CO_2 and in the partial pressure of CO_2 (Pco_2) in equilibrium with it. Although CO_2 is not an acid per se, it becomes a proton (H^+) donor when a portion of the dissolved CO_2 combines with water to form carbonic acid as follows:

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow [H^+] + [HCO_3^-]$$

For any acid, the tendency to donate H^+ is defined by the following Henderson-Hasselbalch equation:

$$pH = pKa + \log_{10}(A^-/AH)$$

where pKa is the acid dissociation constant *[A–]* and *[AH]* are the concentrations of dissociated base and undissociated acid, respectively. When simplified, the following relationship arises for carbonic acid:

$$pH \propto \frac{[HCO_3^-]}{[Paco_2]}$$

The following relationship determines the $Paco_2$, which is a function of alveolar ventilation (VA) and CO_2 production (VCO_2)

$$Paco_2 = (VCO_2 \times K)/VA$$

where *K* is a proportionality constant.

When the $Paco_2$ increases above its usual physiologic levels (i.e., above 40–45 mm Hg [5.33–6 kPa]), acidemia usually develops.

$$\frac{[HCO_3^-]}{\uparrow [Paco_2]} \text{ results in } \downarrow pH$$

A decrease in VA or an increase in VCO_2 can increase $Paco_2$ and cause respiratory acidosis. CO_2 is the major end product of oxidative metabolism of carbohydrates and fatty acids. Normally, the amount of CO_2 produced metabolically is approximately 10 mmol/min, corresponding to an acid load of 13,000 to 16,000 mmol/day. Titration of HCO_3^- by nonvolatile acids leads to additional production of CO_2, which can be substantially increased in certain acidoses (e.g., lactic acidosis in septic shock). CO_2 production can also be increased by up to 30% to 100% of this basal production in conditions associated with increased metabolism (e.g., vigorous exercise, increased caloric intake with parenteral nutrition, or increased catabolism, such as in burns, trauma, and infection).[5] Similarly, low metabolic states such as coma, anesthesia, paralysis, or a switch to nonoxidative metabolism (e.g., with ketogenesis) lead to decreased CO_2 production.

Bicarbonate retention by the kidney in response to hypercapnia is slow; thus a sudden increase in $Paco_2$ leads to a rapid lowering of the systemic pH. Total minute ventilation (MV) is the sum of VA and dead space ventilation; hence either a decrease in MV or an increase in dead space ventilation can decrease VA. Dead space can be either anatomic or alveolar (the latter refers to the fraction of alveolar ventilation ventilating unperfused alveoli). Dead space ventilation increases in the following situations[6]:

1. When the alveolar-capillary interface is destroyed (e.g., emphysema)
2. When blood flow is reduced (i.e., low cardiac output)
3. When alveoli are overdistended (e.g., during positive-pressure ventilation)

The maintenance of eucapnia depends on the ability of the ventilator system to match VCO_2 by adjustment of the VA. Thus, respiratory acidosis (primary hypercapnia) results from an abnormality of either ventilatory effort (i.e., patients who will not breathe because of a lack of respiratory drive) and/or ventilatory output (i.e., patients who cannot breathe because of ventilator pump failure).[1] The causes of respiratory acidosis (acute or chronic) are listed in Table 15.1.

RESPONSE TO RESPIRATORY ACIDOSIS

The timing of different responses to respiratory acidosis is shown in Fig. 15.1. This includes buffering by intracellular and extracellular buffers and renal compensation.

BICARBONATE BUFFERING SYSTEM

Of the 15,000 to 30,000 mmol of protons delivered daily to the extracellular fluid (ECF), only 40 to 60 nmol/L are found free in the blood. The remainder are bound by the various buffer systems that are present in ECF and intracellular fluid (ICF), which can bind or release H^+, thus preventing large changes in free H^+ concentration. Quantitatively important buffers are the proteins present in the ECF (albumin and

TABLE 15.1 Causes of Respiratory Acidosis

Type of Defect	Mechanism or Type	Examples of Acute Etiologies	Examples of Chronic Etiologies
Depressed ventilatory drive	Congenital Acquired	Drug overdose (opiates, sedatives, alcohol), general anesthesia, cerebrovascular accident, head trauma, acute meningoencephalitis, hypothermia	Primary hypoventilation (Ondine's curse), obesity, hypoventilation syndrome, central sleep apnea, myxedema, brain tumor (primary or metastatic)
Neuromuscular disorders Spinal cord Peripheral nerves Neuromuscular junction	Trauma Vascular Tumors Demyelinating Other Phrenic nerve paralysis Autoimmune Iatrogenic Infections/toxins	Cervical spinal cord injury, vascular accident, Guillain-Barré syndrome, traumatic cardiac surgery, myasthenia gravis, neuromuscular blocking agents, botulism, tetanus, tick paralysis	Vascular accident, primary or metastatic tumor, amyoltrophic lateral sclerosis, compression because of tumor, myasthenia gravis, multiple sclerosis, poliomyelitis
Ventilatory muscle weakness	Congenital Autoimmune Acquired	Hypokalemia, hypomagnesemia, hypophosphatemia, ciguatera, organophosphate and shellfish poisoning	Muscular dystrophy poliomyelitis, dermatomyositis
Chest wall pleural diseases		Flail chest, right bandages, pneumothorax, hemothorax	Kyphoscoliosis, morbid obesity, abdominal distension from ascites/organomegaly, pleural effusion, malignancy, fibrosis
Upper airways Lower airways	Obstruction	Epiglottitis, foreign body, angioedema, acute exacerbation of COPD, acute severe asthma	Tumor, tracheomalacia, goiter, COPD
Lung disease (parenchymal or vascular)	High V/Q Low V/Q (shunt)	Shock, pulmonary embolism, acute exacerbation of COPD, pneumonia, pulmonary edema, atelectasis	Emphysema, interstitial lung disease
Miscellaneous	Increased CO_2 production Exogenous CO_2 inhalation	Fever, sepsis, burns, severe trauma, seizures, accident, rebreathing	

COPD, Chronic obstructive pulmonary disease; V/Q, ventilation/perfusion.

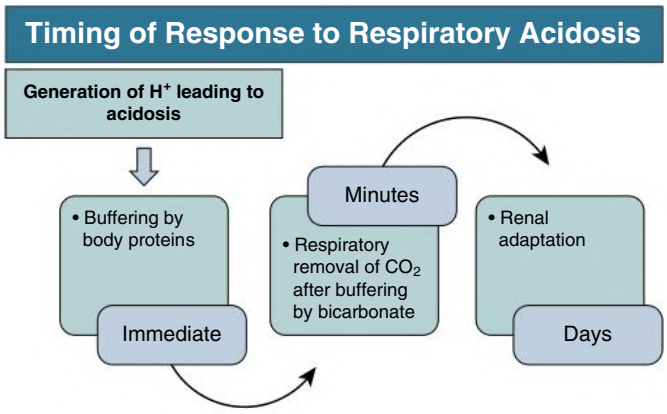

Fig. 15.1 Timing of response to respiratory acidosis.

immunoglobulins); bone; and amino acid side groups such as carboxylates, amines, and the histidines.

The main buffer is the bicarbonate buffering system that forms carbonic acid and then CO_2, as follows:

$$[H^+] + [HCO_3^-] \leftrightarrow H_2CO_3 \leftrightarrow CO_2 + H_2O \quad \textbf{Eq.1}$$

This process converts H^+ released from a nonvolatile acid anion to CO_2, allowing it to be expelled from the ECF by the respiratory actions of the lungs. If CO_2 is effectively eliminated, this reaction continues from left to right. In fact, acidemia stimulates ventilation, further lowering the $Paco_2$ and allowing more hydrogen ions to be buffered by bicarbonate. However, in some circumstances CO_2 accumulates at the tissue level, preventing the previous equation from going from left to right and may even drive the equation to the left. The accumulation of CO_2 occurs when there is a rise in tissue (e.g., muscle) metabolic rate without a reciprocal increase in blood flow to the tissue. It may also occur when there is a decrease in tissue blood flow without a reciprocal decrease in the metabolic rate of the tissue.

KIDNEY RESPONSE TO RESPIRATORY ACIDOSIS

In respiratory acidosis, Equation 1 is driven to the left, leading to accumulation of H^+ and acidemia. The overall response is shown in Fig. 15.2. At first, when CO_2 levels in the extracellular fluid (ECF) become elevated, HCO_3^- levels rise because of mass-action conversion of CO_2 to HCO_3^-. This process is comparatively rapid (i.e., follows the onset of hypoventilation closely in time) and is not compensatory, but rather results in acidification of the plasma and the ECF because each mass action-produced HCO_3^- is also accompanied by one H^+.

After the induction of acidosis, the kidney responds via the increased expression of H^+ pumps in the apical membrane of tubular cells (largely in intercalated cells of the collecting duct). This process occurs over the course of several days, resulting in increased H^+ secretion. Because at this early stage all filtered HCO_3^- has been reabsorbed proximally, these additional hydrogen ions are derived from CO_2 entering from the ECF (i.e., resulting in the synthesis of additional HCO_3^-). More importantly, this secreted H^+ is excreted in the urine.

However, this mechanism of compensation is ultimately limited by the fact that for each compensating H^+ secreted, a HCO_3^- is synthesized. Also adding to the HCO_3^- pool is the bicarbonate formed by the original retention of CO_2, adding to the filtered load of HCO_3^-. Thus, in the final phase of the renal response, most of the additional secreted H^+ now goes to reabsorb this newly added HCO_3^-, and the H^+ excretion returns toward normal.

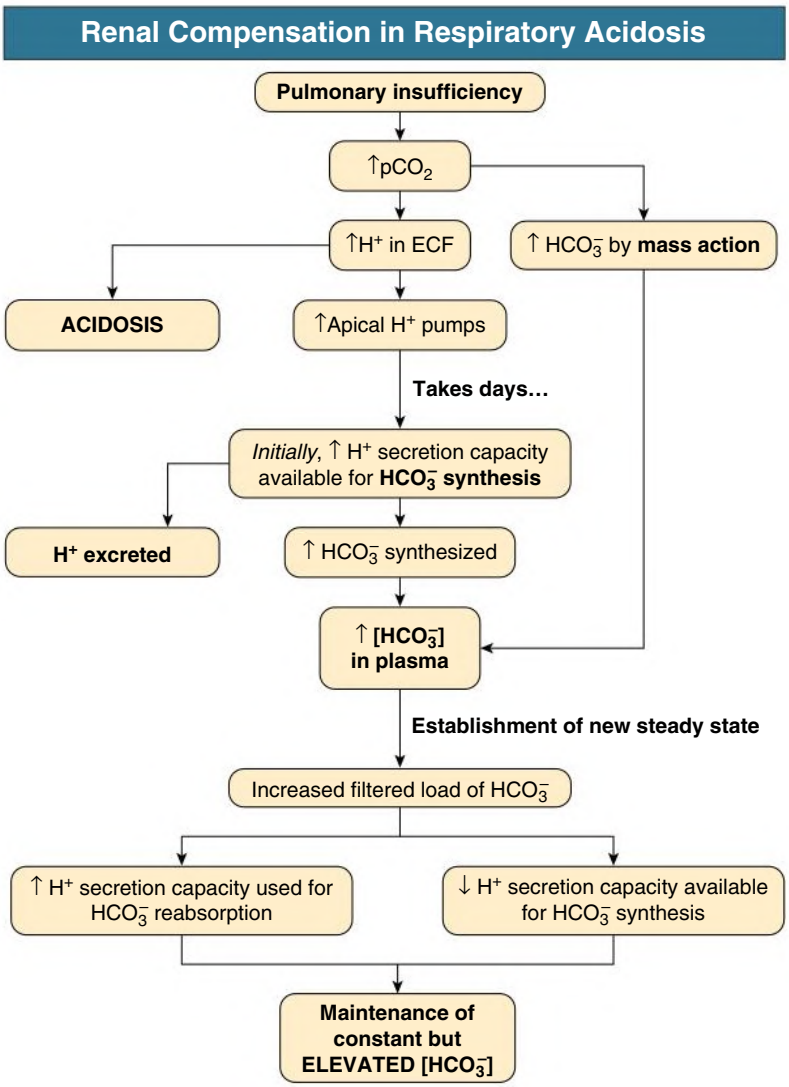

Fig. 15.2 Renal compensation in respiratory acidosis.

In summary, the kidneys initially respond to a respiratory acidosis by increasing the excretion of H^+. Eventually, however, this compensation is limited by the increased filtered load of HCO_3^-. Thus, in the case of a prolonged respiratory acidosis, one generally sees a partial renal compensation with elevated HCO_3^-. Complete renal adaptation takes 3 to 5 days, and the expected change quantitatively is summarized in Table 15.2. The renal response to chronic hypercapnia is not altered by dietary sodium, chloride changes, or potassium changes, but in the presence of a chloride-deficient diet, recovery from chronic hypercapnia leads to a posthypercapnic metabolic alkalosis.[7]

Clinical Manifestations

Patients with acute failure of the ventilatory pump are usually dyspneic and tachypneic with overt respiratory distress, whereas patients with failure of ventilatory drive are usually hypoventilating or apneic. Hypercapnia has deleterious pulmonary and extrapulmonary consequences (Fig. 15.3). In the lungs, hypercapnia leads to pulmonary artery vasoconstriction, increases in right ventricular afterload, and right ventricular failure. In addition, hypercapnic acidosis may cause additional lung damage by increasing both nitric oxide production and inflammation and altering alveolar epithelial cells.[8] Acute hypercapnia is associated with warm and flushed skin, sweating, and a bounding pulse because of increased cardiac output.[9] This, however, can progress to shock because of depressed cardiac output and decreased systemic vascular resistance in severe hypercapnia.[10]

Hypercapnia increases cerebral blood flow and thus causes increased intracranial pressure. This is usually manifested by dyspnea, anxiety, disorientation, headache, and irritability, which can progress to somnolence, confusion, and coma (hypercapnic encephalopathy). Physical findings can include abnormal involuntary movements, including myoclonus, asterixis, tremors and, rarely, findings of increased intracranial pressure as evident by the finding of papilledema on retinal examination. Coma can occur in patients with acute exacerbations of conditions associated with chronic respiratory acidosis (e.g., chronic obstructive pulmonary disease [COPD]) because of treatment with high-flow oxygen.

Diagnosis

Whenever a respiratory acidosis is suspected, an arterial blood gas (ABG) should ideally be obtained to assess the overall acid-base status and pulmonary gas exchange. Appropriate compensatory responses should be assessed to rule out a component of respiratory acidosis in apparent metabolic disorders (see Table 15.2). However, an arterial puncture can be associated with complications, such as pain, infection, nerve injury, bleeding/hematoma, arterial aneurysm/pseudoaneurysm, dissection, thrombosis, and limb ischemia. Thus, there has been an increased use of venous blood gas (VBG) to replace frequent ABGs for diagnosis of

TABLE 15.2 Rules of Compensation in Acid-Base Disorders

Primary Acid-Base Disorder	Change in Laboratory Parameter	Compensatory Response	Expected Change in Laboratory Parameter with Compensatory Response
Metabolic acidosis	↓ HCO_3^-	Respiratory alkalosis	↓ $Paco_2$ 1–1.5 mm Hg for each mEq/L decrease in HCO_3^- *or* Expected $Paco_2 = 1.5 \times [HCO_3^-] + 8 \pm 2$
Metabolic alkalosis	↑ HCO_3^-	Respiratory acidosis	↑ $Paco_2$ 0.6–0.7 mm Hg for each mEq/L increase in HCO_3^-
Respiratory acidosis	↑ $Paco_2$	Metabolic alkalosis	↑ HCO_3^- Acute: 1 mEq/L for each 10 mm Hg ↑ in $Paco_2$ Chronic: 4 mEq/L for each 10 mm Hg ↑ in $Paco_2$
Respiratory alkalosis	↓ $Paco_2$	Metabolic acidosis	↓ HCO_3^- Acute: 2 mEq/L for each 10 mm Hg in ↓ $Paco_2$ Chronic: 5 mEq/L for each 10 mm Hg in ↓ $Paco_2$

acid-base disorders in the emergency setting. Based on meta-analyses of studies looking at the correlation of results between ABG and VBG, venous and arterial pH and bicarbonate agree reasonably at all values, but the agreement is highest at normal values. However, peripheral venous CO_2 ($Pvco_2$) cannot be relied on as an absolute representation of $Paco_2$. Despite this, a normal peripheral $Pvco_2$ has a good negative predictive value for normal arterial Pco_2, and a normal $Pvco_2$ can be used as a screen to exclude hypercapnic respiratory disease.[11]

The overall assessment of the ABG helps differentiate between acute and chronic respiratory acidosis. Acute respiratory acidosis is usually caused by an abrupt decline in ventilation that causes the $Paco_2$ to rise and pH to fall. In contrast, chronic respiratory acidosis is associated with elevated $Paco_2$ values but only slight decreases in pH because of effective renal compensation. Sometimes an acute respiratory acidosis can be superimposed on a chronic respiratory acidosis. In this case, the change in the pH is not as much as would be expected for a similar acute change in the $Paco_2$ (in a person with baseline normal respiratory status). In this situation, the chronically elevated HCO_3^- reduces the fall in the pH and the kidney rapidly increases H^+ secretion when an acute rise in $Paco_2$ is superimposed on a chronic rise in $Paco_2$.[12]

Hypercapnia is usually present along with hypoxemia because alveolar hypoventilation causes a proportional fall in alveolar oxygen pressure (PAO_2), according to the alveolar gas equation:

$$PAO_2 = PiO_2 - [Paco_2 / R]$$

where arterial Pco_2 is assumed to be nearly the same as alveolar Pco_2, PiO_2 is the inspired Po_2 (i.e., the inspired oxygen fraction [Fio_2] multiplied by the difference of barometric pressure and 47 [water vapor pressure at body temperature]), and *R* is the respiratory exchange ratio

(ratio between the amount of CO_2 produced in metabolism and O_2 used). At sea level with 21% Fio_2, this can be simplified to the following:

$$PAO_2 = 150 - [1.25 \times Paco_2]$$

Calculating alveolar Po_2 using this relationship permits determination of the alveolar-arterial oxygen pressure difference (commonly called the "A–a gradient"). The normal A–a gradient is estimated by the following (Age + 10)/4 (i.e., ranges between 5 and 25 mm Hg). This calculation distinguishes between pure hypoventilation as an explanation for hypoxemia (in which case the A–a gradient is normal) and other mechanisms such as low ventilation-perfusion (V/Q) ratios and right-to-left shunt (in which case the A–a gradient is increased). The use of the alveolar gas equation is demonstrated in Box 15.1.

Management

An overview of the management of acute respiratory acidosis is presented in Fig. 15.4. The management of respiratory acidosis is dependent on the cause of the acidosis, and treatment of the underlying cause can often reverse the respiratory acidosis in acute ventilatory failure. However, supportive treatment is often necessary, especially when the etiology is not rapidly or fully reversible. Immediate treatment involves restoring the patency of the airway (if compromised) and delivery of oxygen to maintain a Pao_2 of greater than 60 mm Hg and a peripheral oxygen saturation of greater than 90%. Several oxygen delivery devices are available (Table 15.3).

If appropriate oxygenation cannot be achieved with these oxygen delivery devices or if increased work of breathing is leading to impending respiratory fatigue, either noninvasive ventilation (NIV) or invasive mechanical ventilation can be used. NIV is delivered via tight-fitting face masks and is used for patients with acute respiratory failure who will benefit from ventilatory support but may not need conventional mechanical ventilation (which requires endotracheal intubation). Ideally, NIV is reserved for patients without altered mentation and who are hemodynamically stable. There are three modes of ventilation available for NIV: (1) continuous positive airway pressure (CPAP), (2) bilevel positive airway pressure (BiPAP), and (3) pressure support ventilation (PSV). The latter two modes of ventilation (i.e., BiPAP and PSV) are also referred to as noninvasive positive pressure ventilation (NIPPV). Endotracheal intubation is necessary when airway protection is paramount or with failure of NIV.

In patients with inadequate ventilatory drive despite a presumably normal ventilatory pump, management focuses on restoring normal alveolar ventilation. In the setting of acute central hypoventilation, invasive mechanical ventilation is usually more rapid and protects the airway reliably versus NIV. In chronic neuromuscular disorders, NIV is often used (e.g., elective initiation of noninvasive ventilation is becoming a standard of care in motor neuron disease patients with progressive ventilatory impairment).[5]

In acute respiratory distress syndrome (ARDS), normal tidal volumes can cause regional overdistension (so-called *volutrauma*) and repetitive opening and closing of alveoli can cause lung injury (sometimes called *atelectrauma*). Lung-protective ventilation using lower tidal volumes (less than 6 mL/kg predicted body weight) to maintain a plateau pressure less than 30 mm Hg prevents barotrauma and has been shown to reduce mortality.[13] Because of this, the respiratory rate is set at a higher rate on the ventilator to maintain minute ventilation. This often requires a strategy of "permissive" hypercapnia, which

BOX 15.1 Examples Showing Use of the Alveolar Gas Equation

At sea level, $PAO_2 = 150 - [1.25 \times Paco_2]$

Normal A–a gradient = 5 to 25 mm Hg

Pao_2	$Paco_2$	PAO_2	A–a Gradient	Possible Cause
70	40	100	30	V/Q mismatch
70	60	75	5	Hypoventilation

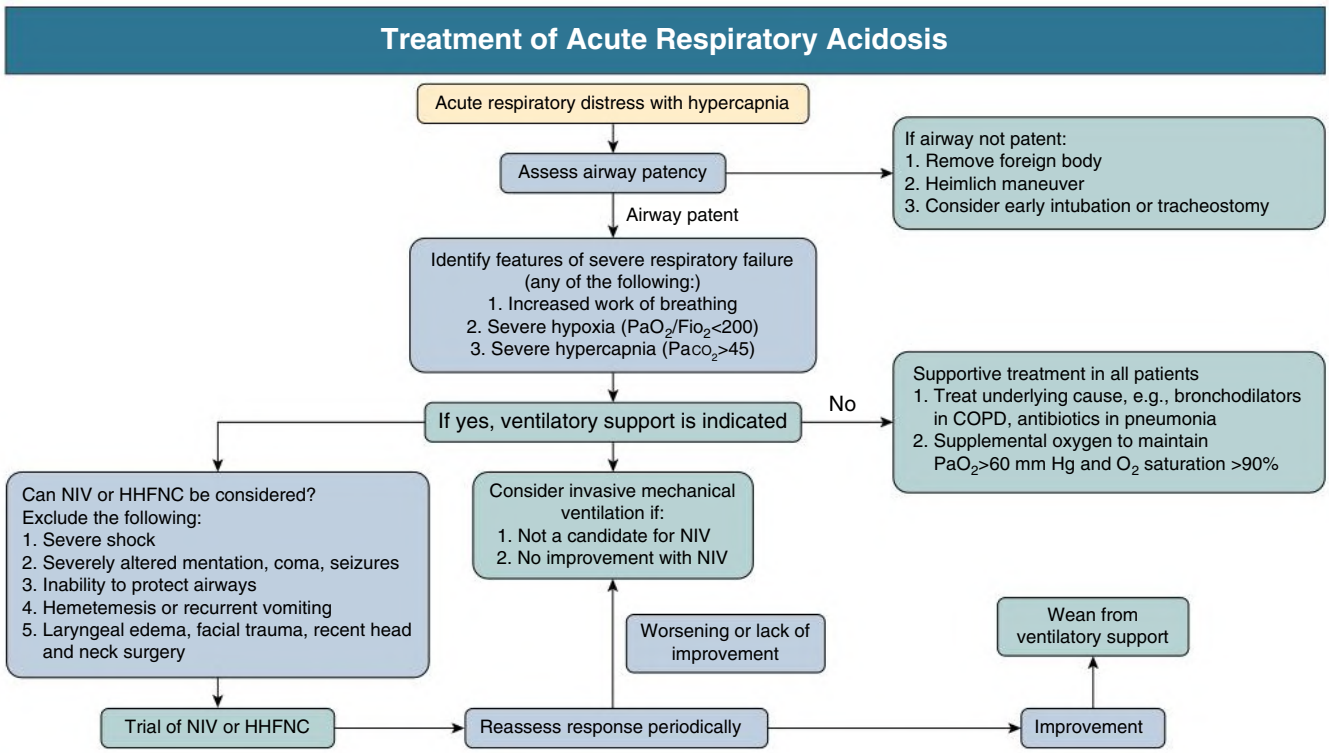

Fig. 15.4 Treatment of acute respiratory acidosis. *HHFNC,* Humidified high-flow nasal cannula; *NIV,* noninvasive ventilation.

TABLE 15.3 Oxygen Delivery Devices

System or Device	Flow Rates (L/min)	Reservoir Volume (mL)	Fi_{O_2} (%)
Low-flow nasal canula	1–6	None	Each L/min adds 4% Fi_{O_2} above room air
Standard face mask	6–12	100–200	35–60
Venturi mask	Fixed flow based on adapter	600–1000	24–40
Nonrebreather mask	>10	600–1000	80–100
High-flow nasal canula	40–60	None	30–100

can lead to a persistent respiratory acidosis with a pH of less than 7.3. In this setting, if the kidneys are not able to generate a compensatory metabolic alkalosis, bicarbonate infusions or renal replacement therapy have been used to keep the pH at least greater than 7.15. Detailed protocols are available to guide this ventilatory strategy.[14] Although permissive hypercapnia was previously thought to be benign, it has several physiologic consequences, and alternative interventions, including prone ventilation, ultralow tidal volume ventilation, extracorporeal membrane oxygenation (ECMO), and extracorporeal CO_2 removal ($ECCO_2R$), are being used to minimize hypercapnia or even aim for normocapnia.[8] Permissive hypercapnia can be dangerous in patients with traumatic brain injury or in those with cerebrovascular disease because it can trigger increased cerebral blood with increased intracranial pressure.

ECMO is reserved for patients with refractory severe ARDS (Pao_2:Fio_2 ratio < 60 mm Hg) after adequate lung-protective ventilation and correction of volume overload have failed to improve oxygenation.[15]

$ECCO_2R$ is a novel extracorporeal technique whose objective is the decarboxylation of blood. This leads to correction of hypercapnia and resolution of respiratory acidosis. This therapy is being tested in clinical trials of acute severe exacerbations of COPD to prevent intubation, to minimize invasive mechanical ventilation, and to facilitate weaning from mechanical ventilation. Additional clinical scenarios where it may be useful are in ARDS and as a bridge to lung transplantation.[16]

It is often not possible to reverse the cause of chronic respiratory acidosis. Adequate airway drainage, relief of bronchospasm, treatment of pulmonary infections, and treatment of heart failure may lead to improvement in the hypercapnia. In some situations (e.g., in advanced COPD or chronic neuromuscular diseases causing ventilator pump failure), patients may require long-term use of NIV or invasive mechanical ventilation.[17,18]

RESPIRATORY ALKALOSIS

In respiratory alkalosis, the arterial pH increases primarily because of a decrease in whole body CO_2 stores, which are indirectly assessed by the $Paco_2$. Respiratory alkalosis is diagnosed by the finding of a $Paco_2$ less than 35 mm Hg (4.7 kPa) in patients with an increased arterial pH (>7.45). Respiratory alkalosis is commonly associated with a compensatory metabolic acidosis. This relationship, as reflected by the simplified Henderson Hasselbalch equation, is as follows:

$$\frac{[HCO_3^-]}{\downarrow [Paco_2]} \text{ results in } \uparrow \text{pH}$$

Failure to measure the systemic pH commonly leads to mislabeling of patients with respiratory alkalosis as having a primary metabolic acidosis when only the HCO_3^- level as measured in the blood chemistries is reviewed. As discussed earlier, pseudorespiratory alkalosis refers to the presence of arterial eucapnia (or hypocapnia) with severe venous hypercapnia in patients with profound circulatory failure with preserved respiratory function. This can also be seen because of hyperventilation when such patients are placed on mechanical ventilation.

TABLE 15.4 Causes of Respiratory Alkalosis

Mechanism	Causes
Hypoxia	High altitude, cyanotic congenital heart disease, congestive heart failure, intrinsic lung disease, laryngospasm
Pulmonary receptor stimulation	Pneumonia, asthma, pulmonary edema, pulmonary embolism, pulmonary fibrosis
Drugs	Salicylates, alkaloids, theophylline, progesterone, catecholamines
Central nervous system stimulation	Primary hyperventilation syndrome, subarachnoid hemorrhage, cerebrovascular accident, pain, trauma
Miscellaneous	Pregnancy, cirrhosis, sepsis, fever, anxiety-hyperventilation syndrome

Modified from Halperin, ML, Goldstein MB, Kamel KS. *Fluid, Electrolyte, and Acid-Base Physiology: A Problem-Based Approach*, 4th ed. Elsevier; 2010:222–239.

PATHOPHYSIOLOGY

Respiratory alkalosis is the most common acid-base disorder but often is not considered a serious clinical problem even though the mortality rate in patients with respiratory alkalosis is higher than the elderly general population.[19]

$Paco_2$ is normally maintained in the normal range by control of the ventilatory drive. Chemoreceptors in the brain (central chemoreceptors) and in the carotid bodies (peripheral chemoreceptors) sense H^+ in the blood and adjust the ventilation to regulate $Paco_2$ and pH. Respiratory alkalosis is usually induced by a process involving hyperventilation. This leads to the shifting of Equation 1 to the right, effectively reducing the H^+ concentration and causing an increase in the systemic pH. The causes of respiratory alkalosis include central causes, hypoxemic causes (leading to stimulation of peripheral chemoreceptors), pulmonary causes (leading to stimulation of peripheral afferent receptors), drugs, and some miscellaneous causes (Table 15.4). Common conditions associated with respiratory alkalosis include pregnancy (in which progesterone-induced hyperventilation leads to a mild respiratory alkalosis most evident in the third trimester)[20]; cirrhosis (characterized by both hypoxemia and stimulation of respiratory drive via progesterone, ammonia, vasoactive intestinal peptide, and glutamine); and iatrogenic hyperventilation in patients on mechanical ventilation.

Hyperventilation syndrome is a type of dysfunctional breathing in which an inappropriate increase in minute ventilation beyond metabolic needs leads to a respiratory alkalosis and is associated with a wide range of symptoms without a clear organic precipitant. It is caused by stress and anxiety, both of which act on the behavioral respiratory control system. The hyperventilation ceases during sleep, when the behavioral control system is inactive and only the metabolic system is controlling breathing. The diagnosis of hyperventilation syndrome should be a diagnosis of exclusion.

RESPONSE TO RESPIRATORY ALKALOSIS

An increase in the pH because of respiratory alkalosis can be acute or chronic. Excess HCO_3^- levels are initially buffered by release of H^+ from intracellular sources to reduce HCO_3^- levels. This buffering is complete in minutes and persists for at least 2 hours.[21] Within 2 to 3 days, there is progressive decrease in renal H^+ secretion (which leads to reduced generation of new HCO_3^- to replace the amount used for buffering the daily acid load) and increased HCO_3^- secretion by reduced reclamation of filtered HCO_3^-, both of which lead to reductions in serum HCO_3^- aimed at restoring physiologic pH. Therefore, acute respiratory alkalosis is associated with high bicarbonate levels because there has not been sufficient time to lower the HCO_3^- levels, and chronic respiratory alkalosis is associated with low to normal HCO_3^- levels. The stimulus for renal compensation is not pH, but rather Pco_2.[22]

Clinical Manifestations

Because the primary cause of all respiratory alkaloses is hyperventilation, most patients present with dyspnea. The specific clinical features depend on its duration, its severity, and the underlying disease process.

Acute respiratory alkalosis can cause light-headedness, confusion, peripheral and circumoral paresthesias, cramps, and syncope. The mechanism of these symptoms is cerebral vasoconstriction causing decreased cerebral blood flow.[23] Carpopedal spasm (which can often be elicited as the Trousseau sign or the Chvostek sign) may occur in severe cases because of decreased levels of ionized calcium in the blood (because of change in the degree of protein binding with change in the pH). Additional physical examination findings may include tachycardia, tachypnea, diaphoresis, hypertension or hypotension, and altered mental status. Chronic respiratory alkalosis is usually asymptomatic and has no distinctive signs.

Cardiovascular effects of hypocapnia in healthy and alert patients are minimal but can be significant in patients who are anesthetized, critically ill, or receiving mechanical ventilation. Cardiac output and systemic blood pressure may fall in these passively hyperventilated patients because of the effects of sedation and positive-pressure ventilation on venous return, systemic vascular resistance, and heart rate. Cardiac rhythm disturbances can also occur because of leftward shift of the hemoglobin-oxygen dissociation curve causing tissue hypoxia.

High altitude illness, which is usually associated with acute respiratory alkalosis, includes a spectrum of disorders that are important to recognize. Acute mountain sickness (AMS) is diagnosed clinically based on the appearance of typical symptoms in a person who ascends to a high altitude (generally >2000 m). Symptoms include headache, fatigue, light-headedness, anorexia, nausea, vomiting, frequent awakening, and dyspnea with exertion. This can progress to high altitude cerebral edema (HACE), which is heralded by the onset of generalized neurologic symptoms.[24]

Diagnosis

A suspicion of respiratory alkalosis based on clinical features should lead to the measurement of an ABG. Failure to measure the systemic pH commonly leads to mislabeling of patients with respiratory alkalosis as having a primary normal anion gap metabolic acidosis when only the HCO_3^- level as measured in the blood chemistries is reviewed. This is very common in pregnancy and cirrhosis, which are usually associated with a respiratory alkalosis without overt respiratory distress.

Treatment

The treatment of respiratory alkalosis is primarily directed at correcting the underlying cause. Respiratory alkalosis itself is rarely life threatening and correcting significant hypoxemia (if present) is more critical. If the $Paco_2$ is corrected rapidly in patients with chronic respiratory alkalosis, metabolic acidosis may develop because of persistence of the renal compensatory drop in serum bicarbonate.

In mechanically ventilated patients who have respiratory alkalosis, the minute ventilation can be decreased by lowering the tidal volume and/or the respiratory rate. Inadequate sedation and pain control may contribute to respiratory alkalosis in patients breathing over the set ventilator rate.

Acute management of patients who are hyperventilating includes reassurance, removal of any stressors, and breathing retraining with a focus on abdominal (diaphragmatic) breathing. Rebreathing of carbon dioxide (CO_2) by breathing into a paper bag is not recommended because it can cause significant hypoxemia, especially in the presence of underlying respiratory or cardiovascular disease. If conservative treatment is not successful, small doses of short-acting benzodiazepines can be used to decrease hyperventilation. Long-term management requires identification and treatment of underlying conditions and precipitants and cognitive behavioral therapy.

MIXED ACID-BASE DISORDERS

Mixed acid-base disorders refer to the presence of more than one acid-base disorder concomitantly. Careful analysis of the ABG is essential to uncover the presence of a mixed acid-base disorder because they can be an important clue to the underlying etiology. An appropriate compensatory response to a primary acid-base disorder is not considered as indicative of a mixed acid-base disorder (see Table 15.2 for the expected compensatory response to the primary acid-base disorders). The effect of a mixed acid-base disorder on the systemic pH can either be additive or can help limit the change in pH (e.g., the presence of both a metabolic acidosis and respiratory acidosis leads to a more severe acidosis, whereas the presence of a concomitant metabolic acidosis and respiratory alkalosis could lead to a minimal change in systemic pH). Triple acid-base disorders can also be seen and involve a combination of two or more independent processes causing metabolic acidosis (leading to a combined high anion gap metabolic acidosis and normal anion gap metabolic acidosis) in the presence of a respiratory disorder.

Diagnosis

Using the following approach to acid-base analysis can help correctly identify mixed acid-base disorders:

Step 1: Look at the pH to classify if the person is acidemic or alkalemic.

Step 2: Determine whether the primary disorder is metabolic or respiratory.

Step 3: If the primary disorder is respiratory, is it chronic or acute? If the primary disorder is metabolic, is the anion gap elevated?

Step 4: Is the compensation for the primary disorder appropriate (using Table 15.2)? If not, a mixed acid-base disorder is present.

Step 5: In cases with a high anion gap metabolic acidosis, is there an additional metabolic disorder?

A simplified approach to the identification of mixed acid-base disorders is presented in Fig. 15.5, and the common mixed acid-base disorders are discussed later.

METABOLIC ACIDOSIS AND RESPIRATORY ACIDOSIS

In the presence of metabolic acidosis, the expected compensatory respiratory response is assessed using the Winters formula (Expected $Paco_2 = 1.5 \times [HCO_3^-] + 8 \pm 2$). If the measured $Paco_2$ exceeds the expected $Paco_2$ by 5 mm Hg, this indicates a concomitant respiratory acidosis. Common clinical scenarios where this is seen include

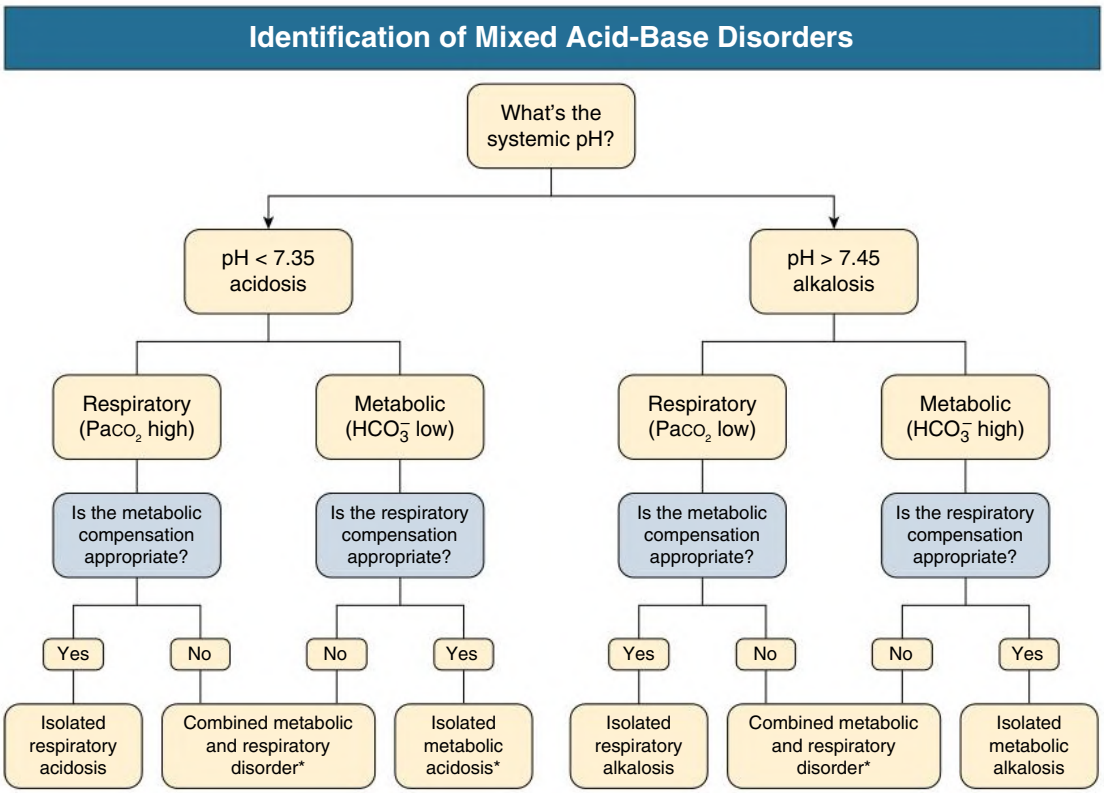

Fig. 15.5 Approach to identification of mixed acid-base disorders. *Evaluate for the presence of concomitant normal gap and high anion gap metabolic acidosis in every case of high anion gap metabolic acidosis.

cardiopulmonary arrest, severe kidney injury in patients with hypercapnic respiratory failure, shock with lactic acidosis in severe respiratory failure, respiratory muscle fatigue with septic shock, and in respiratory muscle weakness because of severe electrolyte disturbances (hypokalemia, hypophosphatemia) caused by prolonged diarrhea. The treatment should be focused on addressing the causes of the respiratory acidosis and the metabolic acidosis.

METABOLIC ACIDOSIS AND RESPIRATORY ALKALOSIS

In the presence of a metabolic acidosis, the expected compensatory respiratory response is assessed using the Winters formula (as above). If the measured $Paco_2$ is lower than this expected $Paco_2$ by 5 mm Hg, it indicates the presence of a concomitant respiratory alkalosis. Because of the opposing effects on systemic pH, the concomitant presence of these two disorders leads to a minimal change in pH. A classic condition associated with this pattern is salicylate intoxication, which leads to central stimulation of the ventilatory drive associated with a high anion gap metabolic acidosis because of a shift from oxidative phosphorylation to anerobic metabolism and increased production of lactic acid and ketoacids. Thus, salicylate toxicity should always be ruled out in patients who present to the hospital with this mixed acid-base disorder. This combination is also commonly seen in critically ill patients with metabolic acidosis caused by lactic acidosis or severe kidney injury in combination with hyperventilation caused by fever, sepsis, hypoxia, and/or mechanical hyperventilation. Another common scenario is hepatic failure in which situation hyperventilation leads to respiratory alkalosis and metabolic acidosis is caused by lactic acidosis or acute kidney injury (AKI) or both.

METABOLIC ALKALOSIS AND RESPIRATORY ALKALOSIS

Metabolic alkalosis is associated with a compensatory respiratory acidosis. The expected increase in $Paco_2$ is 0.6 to 0.7 mm Hg for each mEq/L increase in HCO_3^-. If the measured $Paco_2$ is less than this expected $Paco_2$, a concomitant respiratory alkalosis is present. A marked rise in the pH may result in this mixed acid-base disorder. Common conditions associated with respiratory alkalosis like cirrhosis, pregnancy, and mechanically hyperventilated patients can often develop a metabolic alkalosis in the setting of vomiting, prolonged nasogastric suction, diuretic use, severe hypokalemia, or with alkali administration (e.g., citrate in blood products, exogenous bicarbonate supplements).

METABOLIC ALKALOSIS AND RESPIRATORY ACIDOSIS

Metabolic alkalosis is associated with a compensatory respiratory acidosis. The expected increase in $Paco_2$ is 0.6 to 0.7 mm Hg for each mEq/L increase in HCO_3^-. If the measured $Paco_2$ is higher than this expected $Paco_2$, a concomitant respiratory acidosis is present. Common scenarios that present with this mixed disorder include acute exacerbations of COPD with cor pulmonale, or decompensated heart failure leading to acute respiratory acidosis and then metabolic alkalosis because of aggressive diuresis. Alternatively, metabolic alkalosis with prolonged vomiting or diuretic use can be complicated by respiratory muscle paralysis because of severe electrolyte disturbances (hypokalemia, hypophosphatemia).

MIXED METABOLIC ACIDOSIS

The approach to the evaluation of a metabolic acidosis begins with evaluation of the anion gap. In the setting of a high anion gap (AG) acidosis, further characterization of the metabolic acid-base disorder is important. For this, the relationship between the increment in the anion gap (delta AG) and the decrement in the serum bicarbonate concentration (delta HCO_3) is reviewed. When the delta HCO_3 is greater than the delta AG, it suggests that a mixed high AG and hyperchloremic normal gap metabolic acidosis is present. Common causes of a mixed high AG and normal gap acidosis include severe AKI or chronic kidney disease, ketoacidosis or lactic acidosis with concomitant diarrhea, and recovery phase of diabetic ketoacidosis.

METABOLIC ACIDOSIS AND METABOLIC ALKALOSIS

As discussed previously, in the setting of a high AG acidosis, the delta AG and the delta HCO_3 are calculated to look for an additional metabolic disorder. When the delta HCO_3 is less than the delta AG, a mixed metabolic alkalosis and high AG metabolic acidosis is likely to be present. Common causes for this mixed disorder include metabolic alkalosis induced by vomiting or diuretic use in patients with diabetic ketoacidosis or lactic acidosis because of liver cirrhosis. Prolonged nasogastric suction in patients with uremia or diabetic ketoacidosis can also present with the same problem.

TRIPLE ACID-BASE DISORDERS

Typical triple acid-base disorders involve the presence of a mixed metabolic disorder along with either a respiratory acidosis or a respiratory alkalosis. In the example previously cited, vomiting or diuretic use in patients with diabetic ketoacidosis or lactic acidosis because of liver cirrhosis can lead to a mixed metabolic acidosis and metabolic alkalosis—if such patients then develop a hypercapnic ventilatory failure, this will lead to a triple disorder with additional respiratory acidosis. Another scenario involves the presence of an acute or chronic respiratory disorder in combination with a metabolic disorder (e.g., a COPD patient with chronic respiratory acidosis who gets intubated and mechanically ventilated then develops a sudden decrease in $Paco_2$). In the presence of an underlying compensatory metabolic alkalosis, a new metabolic alkalosis caused by vomiting or nasogastric suction could lead to a rapid elevation in the pH.

Treatment of Mixed Acid-Base Disorders

The management of mixed acid-base disorders involves treating the underlying cause of the acid-base disorder and treating individual components (i.e., each simple acid-base disorder). Figs. 15.6 to 15.9

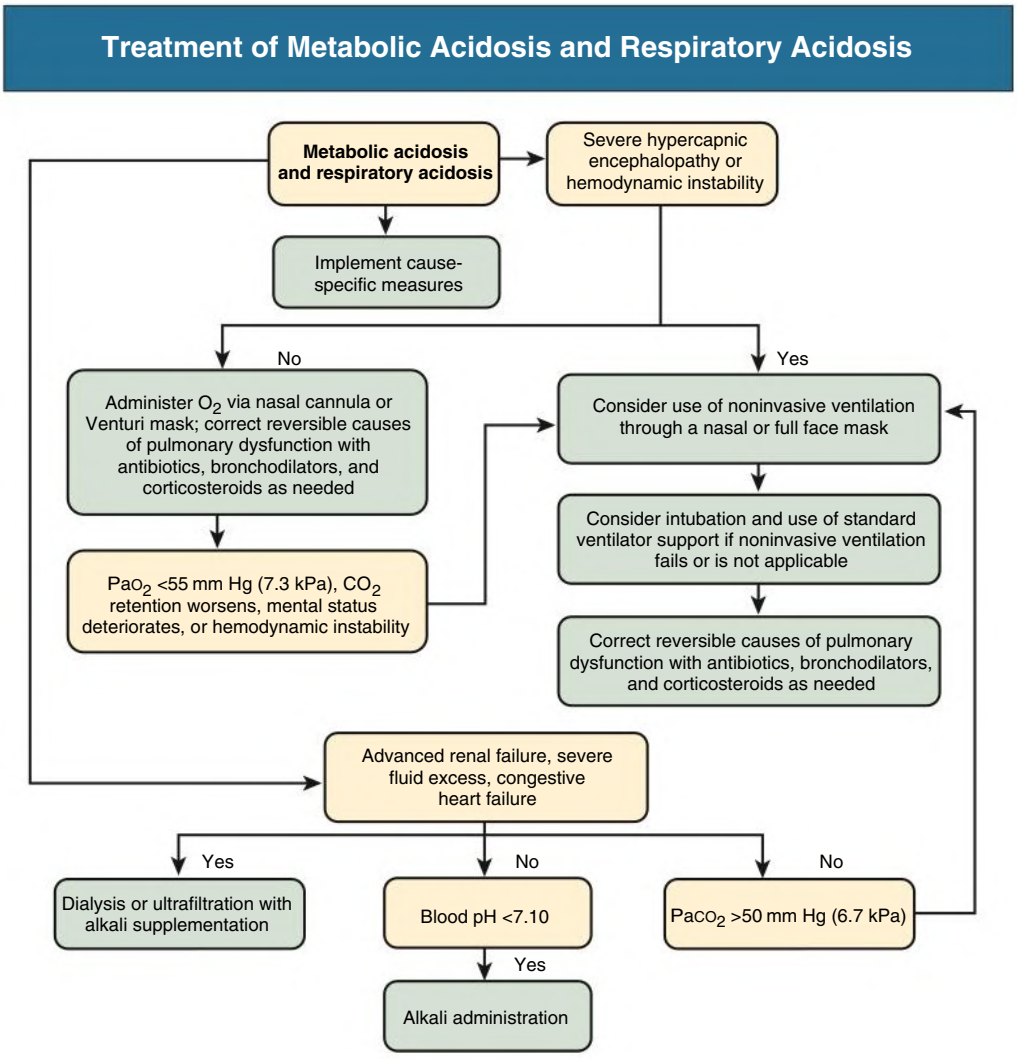

Fig. 15.6 Treatment of metabolic acidosis and respiratory acidosis.

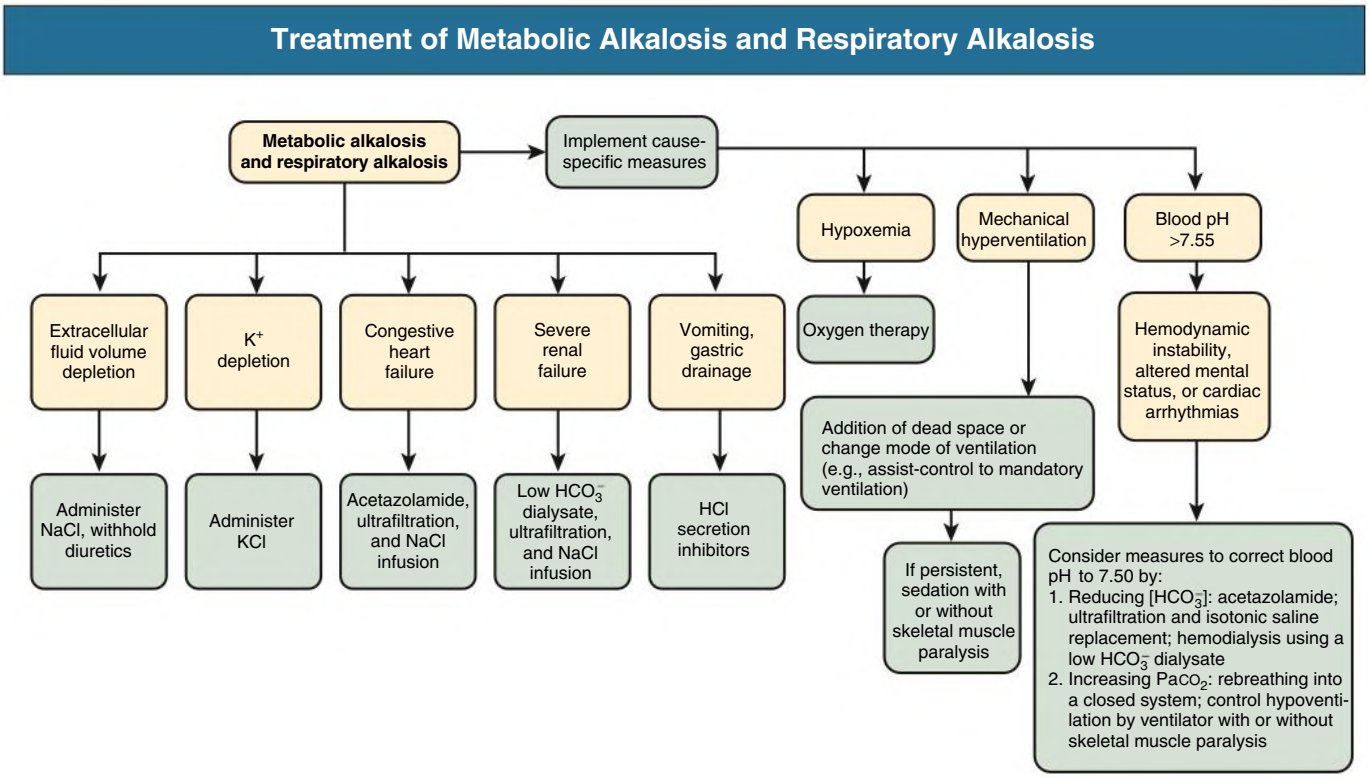

Fig. 15.7 Treatment of metabolic alkalosis and respiratory alkalosis.

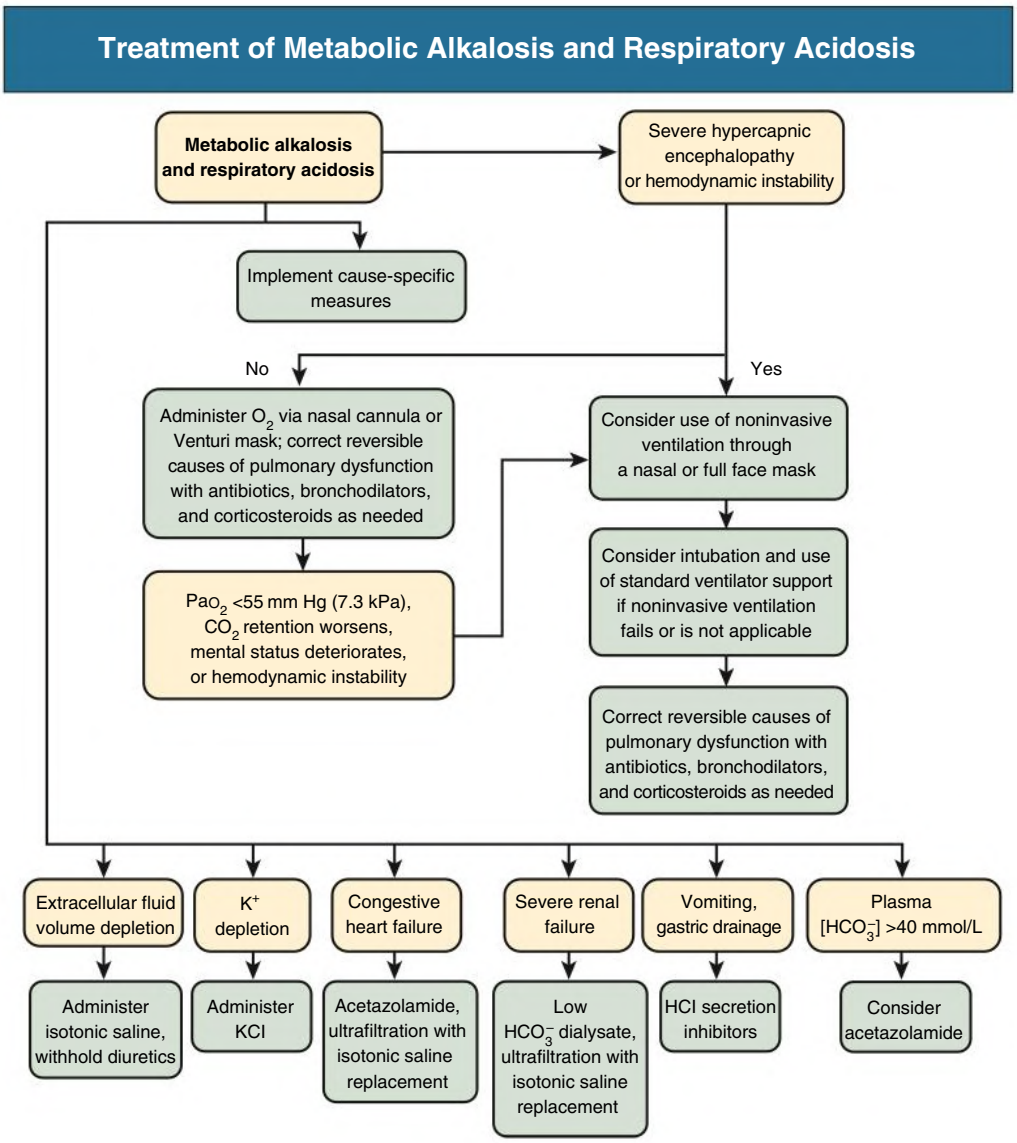

Fig. 15.8 Treatment of metabolic alkalosis and respiratory acidosis.

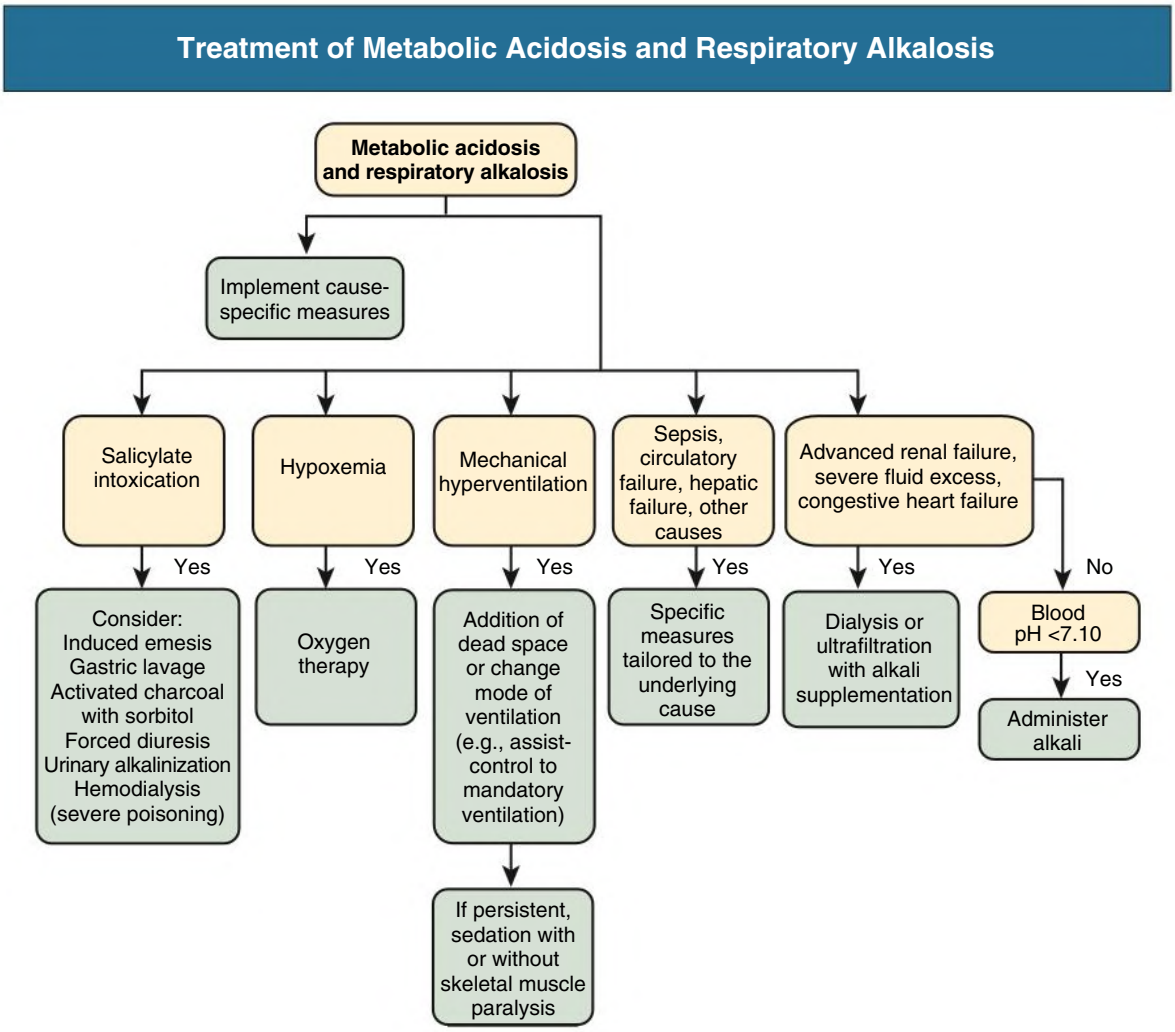

Fig. 15.9 Treatment of metabolic acidosis and respiratory alkalosis.

provide algorithms for the management of some of the more common mixed disorders. Certain disorders (e.g., combined metabolic and respiratory acidosis) lead to a severe change in the pH, and treatment of just one of the simple acid-base disorders can restore the pH to an acceptable level. On the other hand, disorders that have components with opposing effects on the pH should be approached with caution (e.g., although a mixed metabolic acidosis and respiratory alkalosis may have a minimal effect on the pH, complete correction of one of the simple acid-base disorders could lead to a severe acid-base disorder).

SELF-ASSESSMENT QUESTIONS

1. A 26-year-old woman with asthma was brought to the emergency department for severe shortness of breath and appeared to be struggling for air. Her examination was notable for tachypnea with very shallow breaths. She had extensive wheezing throughout both lung fields and audible stridor. Her lab results are as follows:

	ARTERIAL				VENOUS	
pH	Pco_2	Pao_2	Na	K	Cl	HCO_3^-
7.24	61	55	138	4.5	104	26

   A. What acid-base disturbance is present?
   B. Is compensation appropriate?
   C. What is the underlying disorder that caused this problem?

2. A 77-year man is brought to the ICU after being found unresponsive. His initial lab results are as follows:

	ARTERIAL				VENOUS	
pH	Pco_2	Pao_2	Na	K	Cl	HCO_3^-
7.07	28	59	135	2.5	100	8

   What is the acid-base disturbance?

Introduction to Glomerular Disease: Clinical Presentations

Jürgen Floege, Richard J. Johnson

DEFINITION

Glomerular disease has clinical presentations that vary from the asymptomatic individual who is found to have hypertension, edema, hematuria, or proteinuria at a routine medical assessment to a patient who has fulminant illness with acute kidney injury (AKI) possibly associated with life-threatening extrarenal disease (Fig. 16.1). The most dramatic symptomatic presentations are uncommon. Asymptomatic urine abnormalities are much more common but may also indicate a wide range of nonglomerular urinary tract diseases.

CLINICAL EVALUATION OF GLOMERULAR DISEASE

The history, physical examination, and diagnostic investigations are aimed at excluding nonglomerular disease, finding evidence of associated multisystem disease, and establishing kidney function.

History

The majority of glomerular diseases do not lead to symptoms that patients will report. However, specific questioning may reveal edema, hypertension, foamy urine, or urinary abnormalities noted during routine testing (e.g., during scheduled medical examinations). Multisystem diseases associated with glomerular disease include diabetes, hypertension, amyloid, lupus, and vasculitis. Classic genetic causes of kidney disease may include Alport syndrome, especially if associated with hearing loss (see Chapter 48); familial forms of immunoglobulin A (IgA) nephropathy (see Chapter 24); focal segmental glomerulosclerosis (FSGS) secondary to mutations in podocin or other molecules involved in glomerular permeability (see Chapters 19 and 20); complement-mediated glomerulonephritis (GN) (see Chapter 23); thrombotic microangiopathies (see Chapter 30); and other rare conditions (see Chapter 29). Morbid obesity can be associated with FSGS. Certain drugs and toxins may cause glomerular disease, including nonsteroidal antiinflammatory drugs (NSAIDs) and interferon in minimal change disease (MCD); penicillamine, NSAIDs, and mercury (e.g., skin-lightening creams) in membranous nephropathy; pamidronate and heroin in FSGS; smoking in nodular glomerulosclerosis; and cyclosporine, tacrolimus, mitomycin C, and oral contraceptives in hemolytic uremic syndrome (HUS). Recent or persistent infection, especially streptococcal or staphylococcal infection, endocarditis, and certain viral infections (see Chapters 22, 57, and 58) also may be associated with a variety of glomerular diseases.

Malignancies associated with glomerular disease include lung, breast, and gastrointestinal (GI) adenocarcinoma in membranous nephropathy; Hodgkin disease in MCD; non-Hodgkin lymphoma in membranoproliferative GN; and renal cell carcinoma in amyloid disease (see Chapter 28). Kidney disease is occasionally the first manifestation of a tumor.

Physical Examination

The presence of dependent pitting edema suggests nephrotic syndrome, heart failure, or cirrhosis. In the nephrotic patient, edema is often periorbital in the morning (Fig. 16.2), whereas the face is not affected overnight in edema associated with heart failure (edema distributes by gravity, and patients with heart failure often cannot lie flat due to orthopnea or cirrhosis (because of pressure on the diaphragm from ascites). Severe nephrosis can lead to edema of genitals and the abdominal wall, ascites, and pleural effusions. Edema is unpleasant, leading to feelings of tightness in the limbs and a bloated abdomen, with practical problems of clothes and shoes no longer fitting. Surprisingly, however, edema may become massive in nephrotic syndrome before patients seek medical help; fluid gains of 20 kg (44 lb) or more are not unusual (Fig. 16.3). The edema becomes firm and stops pitting only when it is long-standing. In children, fluid retention may be striking with acute GN (nephritic syndrome). Chronic hypoalbuminemia is also associated with white nails or white bands if nephrotic syndrome is transient (Muehrcke lines; Fig. 16.4). Xanthelasmas may be present as a result of the hyperlipidemia associated with long-standing nephrotic syndrome (Fig. 16.5).

Pulmonary signs suggest one of the so-called pulmonary-renal syndromes (see Boxes 25.3 and 25.4). Palpable purpura may be seen in vasculitis, systemic lupus, cryoglobulinemia, or endocarditis.

Laboratory Studies

Assessment of kidney function and careful examination of the urine are critical (see Chapters 3 and 4). The quantity of urine protein and the presence or absence of dysmorphic red cells and casts help classify the clinical presentation (see Fig. 16.1).

Useful serologic tests include antiphospholipase A2 receptor and other autoantibodies (see Chapter 21) for membranous GN, antinuclear and anti-DNA antibodies for lupus, cryoglobulins and rheumatoid factor suggesting cryoglobulinemia, anti–glomerular basement membrane (anti-GBM) antibodies for Goodpasture disease, antineutrophil cytoplasmic autoantibody (ANCA) for vasculitis, and

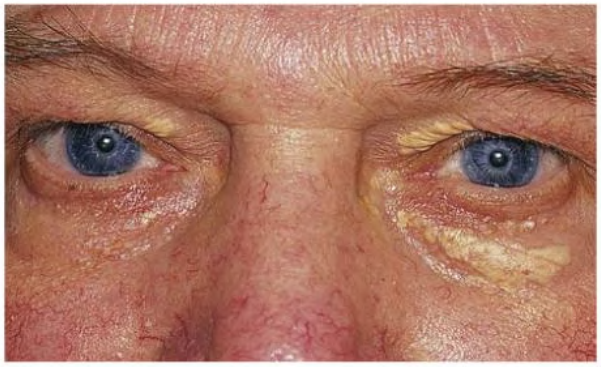

Fig. 16.5 Xanthelasmas in Nephrotic Syndrome. These prominent xanthelasmas developed within 2 months in a patient with recent onset of severe nephrotic syndrome and serum cholesterol level of 550 mg/dL (14.2 mmol/L).

antistreptolysin O titer or streptozyme test for poststreptococcal GN. Serum and urine electrophoresis will detect monoclonal light chains or heavy chains, and assays for free light chains in serum or urine may aid in their quantification, as in myeloma-associated amyloid or light-chain deposition disease.

Blood cultures and testing for hepatitis B, hepatitis C, and human immunodeficiency virus (HIV) infection are also useful.

Measurement of systemic complement pathway activation by testing for serum C3, C4, and CH50 (50% hemolyzing dose of complement) is often helpful in limiting the differential diagnosis (Table 16.1).

The importance of genetic evaluation in patients with GN is discussed in Chapters 20 and 23.

TABLE 16.1 Hypocomplementemia in Glomerular Disease

Pathways Affected	Complement Changes	Glomerular Disease	Nonglomerular Disease
Classical pathway activation	C3↓, C4↓, CH50↓	Lupus nephritis (especially class IV) Cryoglobulinemia Membranoproliferative GN type 1	
Alternative pathway activation	C3↓, C4 normal, CH50↓	Poststreptococcal GN GN associated with other infection[a] (e.g., endocarditis, shunt nephritis) HUS	Atheroembolic renal disease
	plus C3 nephritic factor	Dense deposit disease

	Hereditary C2 or C4 deficiency Factor H deficiency	Lupus nephritis Familial HUS Dense deposit disease	

[a]GN with visceral abscesses is generally associated with normal or increased complement (elevations occur because complement components are acute-phase reactants).
CH50, 50% hemolyzing dose of complement; *GN,* glomerulonephritis; *HUS,* hemolytic uremic syndrome.

Imaging

A kidney ultrasound is recommended in the workup to ensure the presence of two kidneys, to rule out obstruction or anatomic abnormalities, and to assess kidney size. Kidney size is often normal in GN, although large kidneys (>14 cm) are sometimes seen in nephrotic syndrome associated with diabetes, amyloid disease, or HIV infection. Large kidneys also can occasionally be seen with any acute severe GN and acute interstitial nephritis. Small kidneys (<9 cm) and/or severe cortical thinning suggests advanced chronic kidney disease (CKD) and should limit enthusiasm for kidney biopsy or aggressive immunosuppressive therapies.

Kidney Biopsy

Kidney biopsy is generally required to establish the type of glomerular disease and to guide treatment decisions (see Chapter 7). In some patients, however, kidney biopsy is not performed. If nephrotic children (ages 2–12) have no unusual clinical features, the probability of MCD is so high that corticosteroids can be initiated without biopsy (see Chapter 18). In patients with acute nephritic syndrome, if all features point to poststreptococcal GN, especially in an epidemic, biopsy can be reserved for those without early spontaneous improvement (see Chapter 57). In Goodpasture disease (see Chapter 25), the presence of lung hemorrhage and rapidly progressive kidney failure with urinary red cell casts and high levels of circulating anti-GBM antibody establishes the diagnosis without the need for a biopsy. In patients with systemic features of vasculitis, a positive ANCA titer, negative blood cultures, and a biopsy specimen from another site showing vasculitis are sufficient to secure a diagnosis of renal vasculitis. However, even when kidney biopsy is not needed for diagnosis, it may provide important clues to disease activity and chronicity. Biopsy is also not generally performed in patients with long-standing diabetes with characteristic findings suggestive of diabetic nephropathy and other evidence of microvascular complications of diabetes (see Chapter 31). Biopsy may not be indicated in many patients with glomerular disease presenting with minor, asymptomatic urine abnormalities and well-preserved kidney function because the prognosis is excellent and histologic findings will not alter management.

ASYMPTOMATIC URINE ABNORMALITIES

The random nature of urine testing in most communities inevitably means that much mild glomerular disease remains undetected. In some countries, symptomless individuals may have a urine test only if they require medical approval for some key life event, such as obtaining life insurance, joining the armed forces, or sometimes for employment purposes. In other countries, such as Japan, urinalysis is performed routinely in school or for employment. These different practices may partly account for the apparently variable incidence of certain diseases, such as IgA nephropathy, which often manifests as asymptomatic proteinuria and microhematuria. Asymptomatic low-grade proteinuria and microhematuria and the combination of the two also increase in prevalence with age[1] (Fig. 16.6). Nevertheless, there is no evidence to justify routine population-wide screening for asymptomatic urine abnormalities as kidney biopsy and therapeutic intervention are rarely required when kidney function is preserved. For certain high-risk populations, such as patients with diabetes or hypertension, searching for albuminuria ("case-finding") may be useful as it carries increased risk for cardiovascular disease.

Asymptomatic Microhematuria

Microhematuria is defined as the presence of more than two red blood cells (RBCs) per high-power field in a spun urine sediment (3000 rpm for 5 minutes) or more than 10×10^6 RBCs/L. Microhematuria is common in many glomerular diseases, especially IgA nephropathy and thin basement membrane nephropathy, although there are many other causes of hematuria (see Chapters 48 and 63). A glomerular origin should be assumed if more than 5% of RBCs are acanthocytes or dysmorphic (see Chapter 4) or if the hematuria is accompanied by RBC casts or proteinuria (Fig. 16.7).

Pathogenesis

Glomerular hematuria results from small breaks in the GBM that allow extravasation of RBCs into the urinary space. This may occur in the peripheral capillary wall but more often occurs in the paramesangial basement membrane, particularly in diseases involving injury to the mesangium (mesangiolysis). As long as the kidney tubules are intact, low amounts of serum proteins lost together with RBCs in damaged glomeruli can be fully reabsorbed, resulting in "isolated" microhematuria.

Evaluation

The evaluation of microhematuria, discussed further in Chapters 48 and 63, begins with a thorough history. Urine culture should

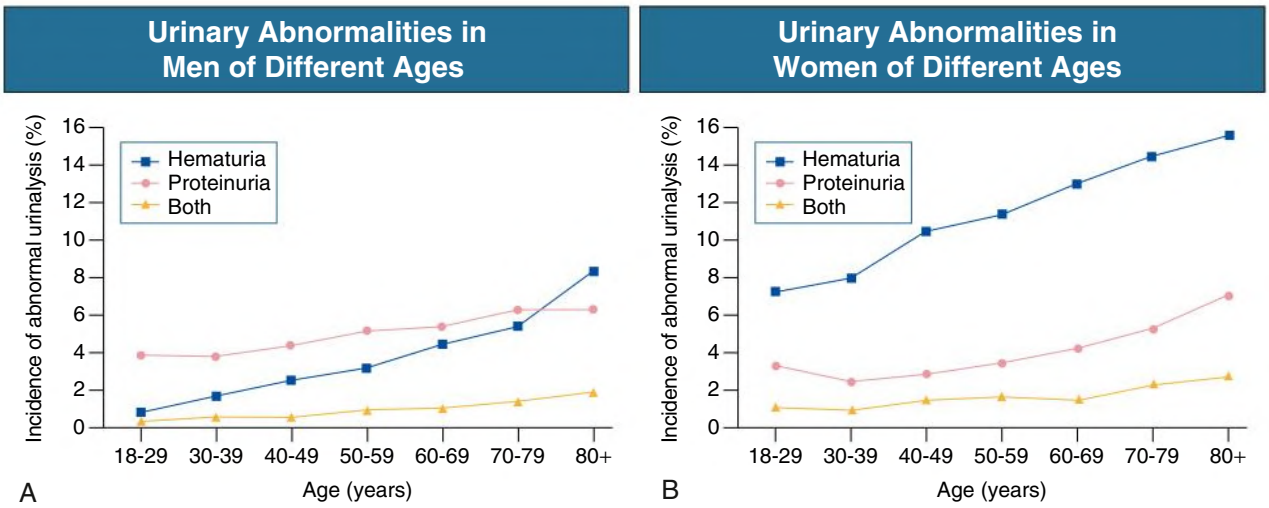

Fig. 16.6 Prevalence of Asymptomatic Proteinuria and Hematuria With Age. Mass screening of a population of 107,192 adult men (A) and women (B) in Okinawa, Japan. Hematuria is more common in women. (Modified from Iseki K, Iseki C, Ikemiya Y, Fukiyama K. Risk of developing end-stage renal disease in a cohort of mass screening. *Kidney Int.* 1996;49:800–805.)

Fig. 16.7 A red blood cell cast typical of glomerular hematuria.

exclude urinary or prostatic infection. Phase contrast microscopy should follow in cases of persistent microhematuria to search for dysmorphic RBCs and RBC casts. In the absence of urine infection or a bladder catheter, any detectable albuminuria (>0.3 g/24 h) in the patient with microhematuria virtually excludes "urologic" bleeding and strongly suggests a glomerular origin. If this evaluation is nondiagnostic, kidney imaging is performed to exclude anatomic lesions such as stones, tumors, polycystic kidneys, or arteriovenous malformations.

In individuals older than 40 years with persistent isolated microhematuria without evidence of a glomerular origin (see previous discussion), cystoscopy is mandatory to exclude uroepithelial malignant disease. In people younger than 40 years, malignancy is so rare that cystoscopy is not recommended. If all the prior study results are normal, a glomerular cause is likely.[2] The glomerular cause can be determined only by kidney biopsy, but this is rarely done because the prognosis is excellent in patients with normal kidney function, normal blood pressure, and low-grade proteinuria (<0.5 g/day). However, repeated evaluation and prolonged follow-up are mandatory for as long as the urinary abnormality persists.

Asymptomatic Nonnephrotic Proteinuria

The hallmark of glomerular disease is the excretion of protein in the urine. Normal urine protein excretion is less than 150 mg/24 h, consisting of 20 to 30 mg of albumin, 10 to 20 mg of low-molecular-weight proteins that undergo glomerular filtration, and 40 to 60 mg of secreted proteins (e.g., Tamm-Horsfall, IgA). Proteinuria is identified and quantified by dipstick testing or by assay in timed urine collections (see Chapter 4).

An albumin excretion rate of 30 to 300 mg of albumin per day (previously termed *microalbuminuria*), equivalent to a urine albumin-to-creatinine (gram/gram) ratio of 0.03 to 0.3, is detected by quantitative immunoassay or by special urine dipsticks because this is below the sensitivity of the normal dipstick (see Chapter 31). This measurement is primarily used to identify diabetic individuals at risk for development of nephropathy and to assess cardiovascular risk, for example, in patients with hypertension.

Nonnephrotic proteinuria is usually defined as a urine protein excretion of less than 3.5 g/24 h or a urine protein/creatinine ratio of less than 3 g/g. Whereas nephrotic-range proteinuria is absolutely characteristic of glomerular disease, lower levels of proteinuria (<3.5 g/24 h) are much less specific and may occur with a wide range of nonglomerular parenchymal diseases as well as other conditions that must be excluded by clinical evaluation and investigation.

Increased urine protein excretion may result from alterations in glomerular permeability or tubulointerstitial disease, although only in glomerular disease will it be in the nephrotic range. Protein excretion also can increase if there is greater filtration through normal glomeruli (overflow proteinuria).

Overflow Proteinuria

Overflow proteinuria is typical of urinary light chain excretion. It is seen in myeloma but can occur in other settings (e.g., release of lysozyme by leukemic cells) and should be suspected when the urine dipstick is negative for albumin despite detection of large amounts of proteinuria by other tests.

Tubular Proteinuria

Tubulointerstitial disease can be associated with low-grade proteinuria (usually <2 g/day). In addition to the loss of tubular proteins such

as α_1- or β_2-microglobulin, there will also be some albuminuria secondary to impaired tubular reabsorption of filtered albumin. Tubular proteinuria accompanying glomerular proteinuria is an adverse prognostic sign in various glomerular diseases because it usually indicates advanced tubulointerstitial damage.

Glomerular Proteinuria

Glomerular proteinuria is further classified into transient or hemodynamic (functional) proteinuria, proteinuria that is present only during the day (orthostatic), and persistent or fixed proteinuria.

Functional proteinuria. Functional proteinuria refers to the transient nonnephrotic proteinuria that can occur with fever, exercise, heart failure, and hyperadrenergic or hyperreninemic states. Functional proteinuria is benign, usually assumed to be hemodynamic in origin, and the result of increases in single-nephron flow or pressure.

Orthostatic proteinuria. In children and young adults, low-grade glomerular proteinuria may be orthostatic, meaning that proteinuria is absent when urine is generated in the recumbent position. If there is no proteinuria in early-morning urine, the diagnosis of orthostatic proteinuria can be made. In patients with fixed orthostatic proteinuria, renal plasma flow and glomerular filtration rate (GFR) decrease in the upright position because of a lower systemic blood pressure. As recently proposed, the decreased GFR translates into a lower *streaming potential* across the filtration barrier, which under physiologic conditions retains albumin within the blood. When GFR and filtration pressure are reduced beyond a certain threshold, albumin is no longer excluded efficiently from the filter by electrophoresis and consequently leaks through the filter, explaining reversible low-grade proteinuria in the upright position in these patients.[3]

Total urine protein in the patient with orthostatic proteinuria is usually less than 1 g/24 h; hematuria and hypertension are absent. Kidney biopsy usually shows normal morphology or occasionally mild glomerular change. The prognosis is uniformly good, and kidney biopsy is not indicated.[4]

Fixed nonnephrotic proteinuria. Fixed nonnephrotic proteinuria is usually caused by glomerular disease. If GFR is preserved and proteinuria is less than 0.5 to 1 g/day, biopsy is not indicated but prolonged follow-up is necessary if significant proteinuria persists, to rule out the possibility of disease progression. Previous studies indicate that the biopsy findings in these patients can be similar to those seen in nephrotic syndrome (most commonly FSGS or membranous nephropathy), although milder lesions are more common, particularly mesangial proliferative GN or IgA nephropathy. In general, other than regular monitoring and blood pressure control as needed, no treatment is necessary.

While controversial, some nephrologists perform a kidney biopsy in patients with normal GFR if nonnephrotic proteinuria exceeds 1 g/day, in particular if it persists after initiation of angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB) therapy.

Fig. 16.8 summarizes the evaluation of isolated asymptomatic proteinuria.

Asymptomatic Proteinuria With Hematuria

Patients with coincident asymptomatic hematuria and proteinuria have a much greater risk for significant glomerular injury, hypertension, and progressive kidney dysfunction. Minor histologic changes are less common. Kidney biopsy is often performed even if urine protein is only 0.5 to 1 g/24 h if there is also persistent microhematuria with casts and/or declining kidney function.

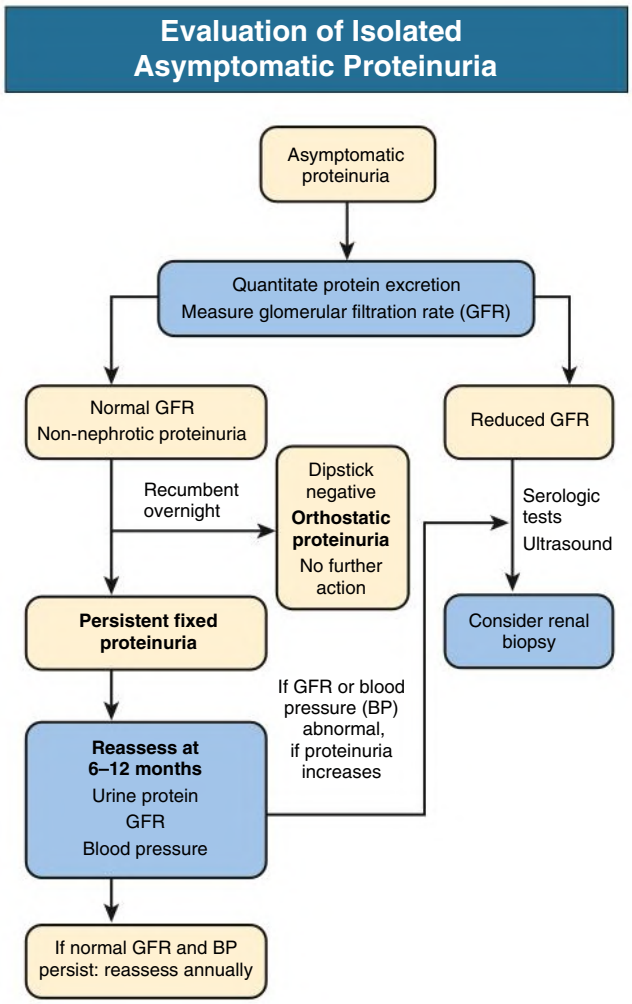

Fig. 16.8 Evaluation of patients with isolated asymptomatic proteinuria.

MACROHEMATURIA

Episodic painless macrohematuria associated with glomerular disease is often brown or "smoky" rather than red, and clots are unusual. Macrohematuria must be distinguished from other causes of red or brown urine, including hemoglobinuria, myoglobinuria, porphyrias, consumption of food dyes (particularly beetroot), and intake of drugs (especially rifampin/rifampicin).

Macrohematuria caused by glomerular disease is seen mainly in children and young adults and is rare after age 40 years. Most cases are caused by IgA nephropathy, but hematuria may occur with other glomerular and nonglomerular kidney diseases, including acute interstitial nephritis. Although macrohematuria is typically painless, the patient may have an accompanying dull loin ache that suggests other diagnoses, such as nephrolithiasis or loin-pain hematuria syndrome (see Chapter 60). In IgA nephropathy, the frank hematuria is usually episodic, occurring within a day of an upper respiratory tract infection. There is a clear distinction between this history and the 2- to 3-week latency between an upper respiratory tract infection and hematuria that is highly suggestive of postinfectious (usually poststreptococcal) GN; furthermore, patients with poststreptococcal disease usually will have other features of nephritic syndrome.

Macrohematuria requires urologic evaluation, including cystoscopy, at any age unless the history is characteristic of glomerular hematuria.

TABLE 16.2 Common Glomerular Diseases Presenting as Nephrotic Syndrome in Adults

Disease	Associations	Serologic Tests
MCD	Allergy, atopy, NSAIDs, Hodgkin disease	None*
FSGS	African American race	—
	HIV infection	HIV antibody
	Heroin, pamidronate	—
MN	Idiopathic drugs: gold, penicillamine, NSAIDs	Antibodies to PLA2R and other new autoantigens (see Chapter 21)
	Infections: hepatitis B and C; malaria	Hepatitis B surface antigen, anti–hepatitis C virus antibody
	Lupus nephritis	Anti-DNA antibody
	Malignancy: breast, lung, gastrointestinal tract	—
MPGN type I	C4 nephritic factor	C3↓, C4 ↓
Dense deposit disease	C3 nephritic factor	C3↓, C4 normal
Cryoglobulinemic MPGN	Hepatitis C	Anti–hepatitis C virus antibody, rheumatoid factor, C3↓, C4 ↓, CH50 ↓
Amyloid disease	Myeloma	Plasma free light chains
	Rheumatoid arthritis, bronchiectasis, Crohn disease (and other chronic inflammatory conditions), familial Mediterranean fever	Serum protein electrophoresis, urine immunoelectrophoresis C-reactive protein
Diabetic nephropathy	Other diabetic microangiopathy	None

*Possibly anti-nephrin antibodies in the future.
CH50, 50% Hemolyzing dose of complement; *FSGS,* focal segmental glomerulosclerosis; *HIV,* human immunodeficiency virus; *MCD,* minimal change disease; *MN,* membranous nephropathy; *MPGN,* membranoproliferative glomerulonephritis; *NSAIDs,* nonsteroidal antiinflammatory drugs; *PLA_2R,* phospholipase A_2 receptor.

TABLE 16.3 Age-Related Variations in the Prevalence (%) of Nephrotic Syndrome

		YOUNG ADULT		MIDDLE AND OLD AGE	
	Child (<15 yr)	Whites	Blacks	Whites	Blacks
Minimal change disease	78	23	15	21	16

NEPHROTIC SYNDROME

Definition

Nephrotic syndrome is pathognomonic of glomerular disease. It is a clinical syndrome with a characteristic pentad[5] (see Fig. 16.1). Patients may be nephrotic with preserved renal function, but in many, progressive kidney failure will become superimposed when nephrotic syndrome is prolonged.

Independent of the risk for progressive loss of kidney function, the nephrotic syndrome has far-reaching effects on the general health of the patient. Some episodes of nephrotic syndrome are self-limited, and a few patients respond completely to specific treatment (e.g., corticosteroids in MCD), but for most patients it is a relapsing or chronic condition. Not all patients with proteinuria above 3.5 g/24 h will have full nephrotic syndrome; some have a normal serum albumin concentration and no edema. This difference presumably reflects the varied response of protein metabolism; some patients sustain an increase in albumin synthesis in response to heavy proteinuria that may even normalize serum albumin.

Etiology

Table 16.2 shows the major causes of nephrotic syndrome. Proteinuria in the nephrotic range in the absence of edema and hypoalbuminemia has similar causes. The relative frequency of the different glomerular diseases varies with age (Table 16.3). Although it is predominant in childhood, MCD remains common at all ages.[6] The prevalence of FSGS in African Americans is increased, which may explain why FSGS is becoming more common in US adults but not in European adults.[7,8]

Hypoalbuminemia

Hypoalbuminemia is mainly a consequence of urinary losses. The liver responds by increasing albumin synthesis, but this compensatory mechanism appears to be blunted in nephrotic syndrome.[9] The end result is that serum albumin falls further. White bands in the nails

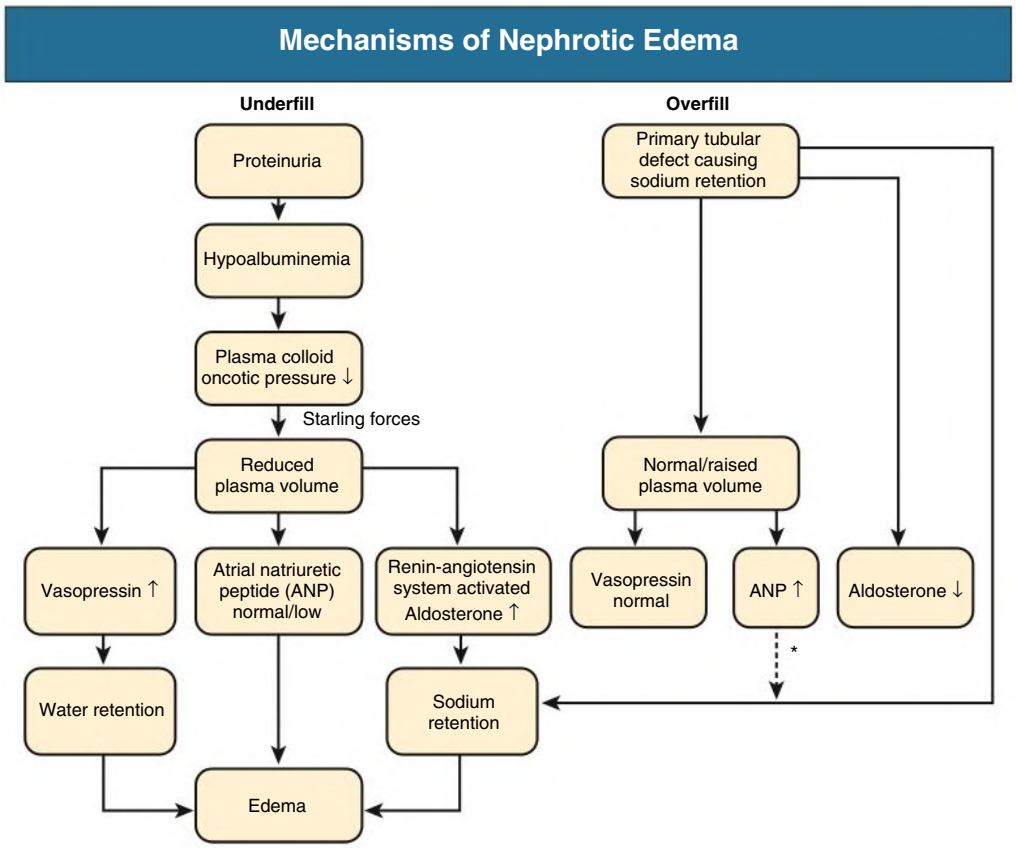

Fig. 16.9 Mechanisms of Nephrotic Edema. *The kidney is relatively resistant to ANP in this setting, so ANP has little effect in countering sodium retention.

(Muehrcke lines) are a characteristic clinical sign of hypoalbuminemia (see Fig. 16.4). The increase in protein synthesis in response to proteinuria is not discriminating; as a result, proteins not being lost in the urine may actually increase in concentration in plasma. This is chiefly determined by molecular weight; large molecules are not lost in urine and will increase in plasma, whereas smaller proteins will enter urine and will decrease in plasma. These variations in plasma proteins are clinically important in two areas: hypercoagulability and hyperlipidemia (see later discussion).

Edema

At least two major mechanisms are involved in the formation of nephrotic edema: underfill and overfill[10] (Fig. 16.9; see Chapter 8). In the first, the edema appears to result from the low serum albumin, producing a decrease in plasma oncotic pressure, which allows increased transudation of fluid from capillary beds into the extracellular space. The consequent decrease in circulating blood volume *(underfill)* results in a secondary stimulation of the renin-angiotensin system (RAS), resulting in aldosterone-induced sodium retention in the distal tubule. This attempt to compensate for hypovolemia merely aggravates edema because the low oncotic pressure alters the balance of forces across the capillary wall in favor of hydrostatic pressure, forcing more fluid into the interstitial space rather than retaining it within the vascular compartment.

However, a much more common mechanism for edema, occurring in most nephrotic patients, is a primary defect in the ability of the distal nephron to excrete sodium, possibly related to activation of the epithelial sodium channel (ENaC) by proteolytic enzymes that enter the tubular lumen in heavy proteinuria.[11] As a result, there is an increased blood volume; suppression of renin, angiotensin, and vasopressin; and a tendency to hypertension rather than to hypotension. The kidney is also relatively resistant to the actions of atrial natriuretic peptide. An elevated blood volume results *(overfill)*, which, in association with the low plasma oncotic pressure, provokes transudation of fluid into the extracellular space and edema. In addition to activation of the ENaC (see earlier discussion), it has been hypothesized that inflammatory leukocytes in the interstitium, which are found in many glomerular diseases, may impair sodium excretion by producing angiotensin II and oxidants (oxidants inactivate local nitric oxide, which is natriuretic).[12]

Metabolic Consequences of Nephrotic Syndrome

Negative Nitrogen Balance

The heavy proteinuria leads to marked negative nitrogen balance, usually measured in clinical practice by serum albumin. Nephrotic syndrome is a wasting illness, but the degree of muscle loss is masked by edema and not fully apparent until the patient is rendered edema free. Loss of 10% to 20% of lean body mass can occur. Albumin turnover is increased in response to the tubular catabolism of filtered protein rather than merely to urinary protein loss. Increasing protein intake does not improve albumin metabolism because the hemodynamic response to an increased intake is a rise in glomerular pressure, increasing urine protein losses. A low-protein diet will reduce proteinuria, but it also reduces the albumin synthesis rate and in the longer term may increase the risk for a worsening negative nitrogen balance.

Hypercoagulability

Multiple proteins of the coagulation cascade have altered levels in nephrotic syndrome; in addition, platelet aggregation is enhanced.[13] The net effect is a hypercoagulable state that is enhanced further by immobility, coincidental infection, and hemoconcentration if the

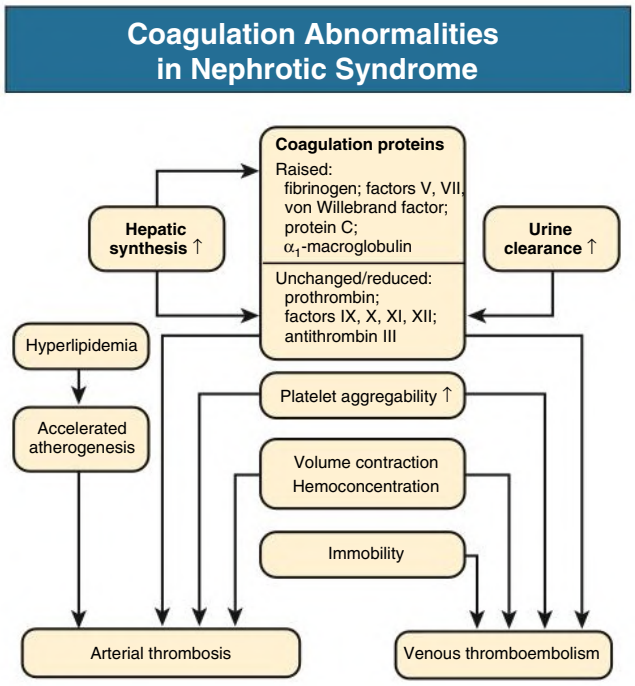

Fig. 16.10 Coagulation abnormalities in nephrotic syndrome.

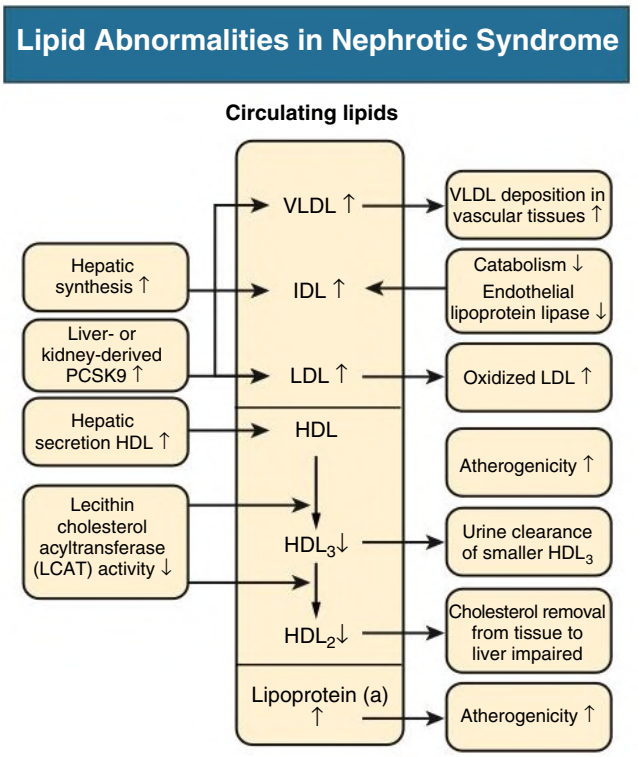

Fig. 16.11 Lipid Abnormalities in Nephrotic Syndrome. Changes in high-density lipoprotein (HDL) are more controversial than those in very-low-density lipoprotein (VLDL). *IDL,* Intermediate-density lipoprotein; *LDL,* low-density lipoprotein; *PCSK9,* proprotein convertase subtilisin/kexin type 9.

patient has a contracted plasma volume (Fig. 16.10). Not only is venous thromboembolism common at any site, but spontaneous arterial thrombosis may rarely occur. Arterial thrombosis may occur in adults, promoting coronary and cerebrovascular events in particular, but it also occurs in nephrotic children, in whom spontaneous thrombosis of major limb arteries can rarely occur. Up to 10% of nephrotic adults and 2% of children will have a clinical episode of thromboembolism. For unexplained reasons, the risk appears particularly high in those with membranous nephropathy.[14] Individual levels of coagulation proteins are not helpful in assessing the risk for thromboembolism, and serum albumin is mostly used as a surrogate marker. Thromboembolic events increase greatly if the serum albumin concentration decreases to less than 2 g/dL.

The hypoproteinemia and dysproteinemia produce a marked increase in erythrocyte sedimentation rate (ESR), which is not a useful marker of an acute phase response in nephrotic patients.

Renal vein thrombosis is an important complication of nephrotic syndrome (see Chapter 43) and presents clinically in up to 8% of nephrotic patients; when sought systematically by ultrasound or contrast venography, the frequency increases to 10% to 50%. Symptoms when the thrombosis is acute may include flank pain and hematuria; rarely, AKI can occur if the thrombosis is bilateral. However, the thrombosis often develops insidiously with minimal symptoms or signs because of the development of collateral blood supply. Pulmonary embolism is an important complication.

Hyperlipidemia and Lipiduria

Hyperlipidemia is so frequently associated with heavy proteinuria that it is regarded as an integral feature of nephrotic syndrome.[15] Clinical stigmata of hyperlipidemia, such as xanthelasmas, may have a rapid onset (see Fig. 16.5). Serum cholesterol concentration can be above 500 mg/dL (13 mmol/L), although serum triglyceride levels are highly variable. The lipid profile in nephrotic syndrome is known to be highly atherogenic in other populations (Fig. 16.11). Many patients who are nephrotic for more than 5 to 10 years will develop additional cardiovascular risk factors, including hypertension and uremia, so it is difficult to separate these influences. However, it is now generally accepted that nephrotic patients have about a fivefold increased risk for coronary death, except for those with MCD, presumably because the nephrotic state is transient before remission with corticosteroid treatment and does not subject the patient with MCD to prolonged hyperlipidemia.

Experimental evidence shows that hyperlipidemia contributes to progressive kidney disease by various mechanisms, with protection afforded by lipid-lowering agents. However, clinical evidence to support a role of statins in slowing CKD progression is inconclusive,[16] so lipid-lowering drugs are indicated in nephrotic syndrome primarily to prevent cardiovascular disease.

Several mechanisms account for the lipid abnormalities in nephrotic syndrome. These include increased hepatic synthesis of low-density lipoprotein (LDL), very-low-density lipoprotein (VLDL), and lipoprotein(a) secondary to the hypoalbuminemia; defective peripheral lipoprotein lipase activity resulting in increased VLDL; and urinary losses of high-density lipoprotein (HDL; see Fig. 16.11). More recently, kidney and hepatic overexpression of proprotein convertase subtilisin/kexin type 9 (PCSK9) has been identified in nephrotic syndrome, which is the basis for a possible new therapeutic intervention using PCSK9 antibodies.[17]

Lipiduria, the fifth component of the nephrotic syndrome, is manifested by the presence of refractile accumulations of lipid in cellular debris and casts (oval fat bodies and fatty casts; Fig. 16.12). However, the lipiduria appears to be a result of the proteinuria and not the plasma lipid abnormalities.

Other Metabolic Effects of Nephrotic Syndrome

Vitamin D–binding protein is lost in the urine, resulting in low plasma 25-hydroxyvitamin D levels, but plasma free vitamin D is usually normal, and overt osteomalacia or uncontrolled hyperparathyroidism is

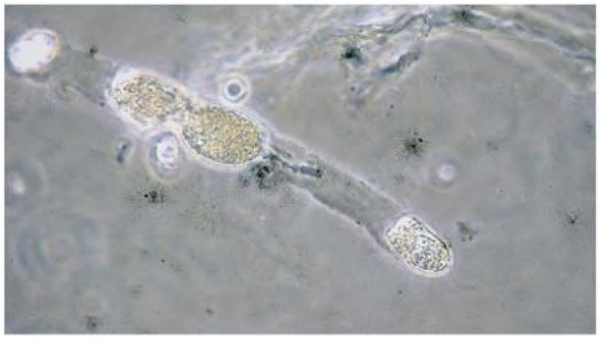

Fig. 16.12 Fat in the Urine. This hyaline cast contains oval fat bodies, which are tubular epithelial cells full of fat. Oval fat bodies often appear brown.

very unusual in nephrotic syndrome in the absence of kidney impairment. Thyroid-binding globulin is lost in the urine and total circulating thyroxine reduced, but again free thyroxine and thyroid-stimulating hormone are normal, and there are no clinical alterations in thyroid status. Occasional patients have been described with copper, iron, or zinc deficiency caused by the loss of binding proteins in the urine.

Drug binding may be altered by the decrease in serum albumin, but most drugs do not require dose modifications. Reduced protein binding also may reduce the dose of vitamin-K antagonists (e.g., warfarin [Coumadin]) required to achieve adequate anticoagulation or the dose of furosemide required to achieve adequate fluid loss (see later discussion).

Infection

Nephrotic patients are prone to bacterial infection. Before corticosteroids were shown to be effective in childhood nephrotic syndrome, sepsis was the most common cause of death, and it remains a major problem in the developing world. Primary peritonitis, especially that caused by pneumococci, is particularly characteristic of nephrotic children. It is less common with increasing age; by 20 years of age, most adults have antibodies against pneumococcal capsular antigens. Peritonitis caused by both β-hemolytic streptococci and gram-negative organisms occurs, but staphylococcal peritonitis is not reported. Cellulitis, especially in areas of severe edema, is also common, most frequently caused by β-hemolytic streptococci.

The increased risk for infection has several explanations. Large fluid collections are sites for bacteria to grow easily; nephrotic skin is fragile, creating sites of entry; and edema may dilute local humoral immune factors. Loss of immunoglobulin G (IgG) and complement factor B (of the alternative pathway) in the urine impairs host ability to eliminate encapsulated organisms such as pneumococci. Zinc and transferrin are lost in the urine, and both are required for normal lymphocyte function. Neutrophil phagocytic function is impaired in patients with nephrotic syndrome, and several forms of in vitro T cell dysfunction are described, although their clinical significance is unclear.

Acute and Chronic Changes in Kidney Function

Acute Kidney Injury

Patients with nephrotic syndrome are at risk for AKI[18] through a variety of mechanisms (Box 16.1). These include volume depletion or sepsis, resulting in prerenal AKI or acute tubular necrosis[19]; transformation of the underlying disease, such as crescentic nephritis in a patient with membranous nephropathy; bilateral renal vein thrombosis; increased disposition to prerenal AKI from NSAIDs and ACE inhibitors or ARBs; and increased risk for allergic interstitial nephritis secondary to drugs, including diuretics. AKI may rarely result from intrarenal edema with compression of tubules and, as with nephrotic patients with prerenal azotemia, may respond with diuresis to albumin infusions combined with a loop diuretic.

BOX 16.1 Causes of Acute Kidney Injury in Nephrotic Syndrome

- Prerenal failure caused by volume depletion
- Acute tubular necrosis caused by volume depletion and/or sepsis
- Intrarenal edema
- Renal vein thrombosis
- Transformation of underlying glomerular disease (e.g., crescentic nephritis superimposed on membranous nephropathy)
- Adverse effects of drug therapy
- Acute allergic interstitial nephritis secondary to various drugs, including diuretics
- Hemodynamic response to NSAIDs and ACE inhibitors or ARBs

ACE, Angiotensin-converting enzyme; *ARBs,* angiotensin receptor blockers; *NSAIDs,* nonsteroidal antiinflammatory drugs.

The influence of heavy proteinuria *(Uprot)* on long-term renal function in 253 patients with primary glomerular disease at Manchester Royal Infirmary, United Kingdom. Heavy proteinuria at any time during long-term follow-up substantially worsens the prognosis even without frank nephrotic syndrome. (Courtesy Dr. C.D. Short.)

Chronic Kidney Disease

With the exception of MCD, most causes of nephrotic syndrome are associated with progressive kidney failure. A major risk factor for progression is the degree of proteinuria (see Chapters 81 and 82). Progression is uncommon if there is sustained proteinuria of less than 2 g/day. The risk increases in proportion to the severity of the proteinuria, with marked risk for progression when protein excretion is more than 5 g/day (Fig. 16.13). Proteinuria identifies patients with severe glomerular injury; however, experimental and clinical evidence also suggests that proteinuria itself may be toxic, especially to the tubulointerstitium.[20] In experimental models, measures that reduce proteinuria (e.g., ACE inhibitors) also prevent tubulointerstitial disease and progressive kidney failure.

NEPHRITIC SYNDROME

In *nephrotic* syndrome, the glomerular injury is manifested primarily as an increase in permeability of the capillary wall to protein. By contrast,

TABLE 16.4 Differentiation Between Nephrotic Syndrome and Nephritic Syndrome

Typical Features	Nephrotic	Nephritic
Onset	Insidious	Abrupt
Edema	++++	++
Blood pressure	Normal	Raised
Jugular venous pressure	Normal/low	Raised
Proteinuria	++++	++
Hematuria	May/may not occur	+++
Red blood cell casts	Absent	Present
Serum albumin	Low	Normal/slightly reduced

in *nephritic* syndrome, there is evidence of glomerular inflammation resulting in a reduction in GFR, nonnephrotic proteinuria, edema and hypertension (secondary to sodium retention), and hematuria with RBC casts.

The classic nephritic syndrome presentation is seen with acute poststreptococcal GN in children, but this complication has become rare. These children usually present with rapid onset of oliguria, weight gain, and generalized edema over a few days. The hematuria results in brown rather than red urine, and clots are not seen. The urine contains protein, RBCs, and RBC casts. Because proteinuria is rarely in the nephrotic range, serum albumin concentration is usually normal. Circulating volume increases with hypertension, and pulmonary edema follows without evidence of primary cardiac disease.

The distinction between typical nephrotic syndrome and nephritic syndrome is usually straightforward on clinical and laboratory grounds (Table 16.4). The use of these clinical descriptions for patients with suspected GN at first presentation helps narrow the differential diagnosis. However, the classification systems are imperfect, and patients with certain glomerular disease patterns, such as a membranoproliferative GN pattern on biopsy, may present with nephrotic syndrome, nephritic syndrome, or a combination of both syndromes.

Etiology

Table 16.5 lists the primary glomerular diseases associated with nephritic syndrome and the serologic tests helpful in diagnosis. The classification is even more challenging than for nephrotic syndrome, because some diseases are identified by histology (IgA nephropathy), some by serology and histology (ANCA-associated vasculitis and lupus nephritis), and others by etiology (postinfectious GN).

RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS

In rapidly progressive glomerulonephritis (RPGN), glomerular injury is so acute and severe that kidney function deteriorates markedly over days or weeks. The patient may present as a uremic emergency, with nephritic syndrome that rapidly progresses to kidney failure, or with rapidly deteriorating kidney function when being investigated for extrarenal disease (many of the GN associated with RPGN occur as part of a systemic immune illness).

The histologic counterpart of RPGN is crescentic GN. The proliferative cellular response seen outside the glomerular tuft but within Bowman's space is known as a "crescent" because of its shape on histologic cross section (see Fig. 17.8). Typically, the glomerular tuft also

TABLE 16.5 Common Glomerular Diseases Presenting as Nephritic Syndrome

Disease	Associations	Serologic Tests
Poststreptococcal glomerulonephritis	Pharyngitis, impetigo	Antistreptolysin titer, streptozyme antibody
Other postinfectious disease		
Endocarditis	Cardiac murmur	Blood cultures, C3↓
Abscess	—	Blood cultures, C3, C4 normal or increased
Shunt	Treated hydrocephalus	Blood cultures, C3↓
IgA nephropathy	Upper respiratory or gastrointestinal infection	Serum IgA↑
Lupus nephritis	Other multisystem features of lupus	Antinuclear antibody, anti–double-stranded DNA antibody, C3↓, C4↓

IgA, Immunoglobulin A.

shows segmental necrosis or focal segmental necrotizing GN, especially in the vasculitis syndromes.

The term *rapidly progressive* GN is therefore often used to describe acute deterioration in kidney function in association with crescentic nephritis. Unfortunately, not all patients with a nephritic urine sediment and AKI will fit this syndrome. For example, AKI may also occur in milder glomerular disease if it is complicated by accelerated hypertension, renal vein thrombosis, or acute tubular necrosis. This emphasizes the need to obtain histologic confirmation of the clinical diagnosis.

Etiology

Table 16.6 shows the primary glomerular diseases associated with RPGN and helpful serologic tests. As with nephritic syndrome, different assessment methods are useful for different diseases causing RPGN.

PROGRESSIVE CHRONIC KIDNEY DISEASE

In most types of chronic GN, between 25% and 50% of patients will have slowly progressive kidney impairment. Patients may present late with established hypertension, proteinuria, and kidney impairment. In long-standing GN, the kidneys shrink but remain smooth and symmetric. Kidney biopsy at this stage is more hazardous and less likely to provide diagnostic material. Light microscopy often shows nonspecific features of end-stage kidney disease (ESKD), consisting of focal or global glomerulosclerosis and dense tubulointerstitial fibrosis, and it may not be possible to confirm that a glomerular disease was responsible, let alone define the glomerular pattern more precisely. Immunofluorescence may be more helpful; in particular, mesangial IgA may be present in adequate amounts to diagnose IgA nephropathy. However, when kidney imaging shows small kidneys, only rarely will biopsy be appropriate, and so chronic GN often has been a presumptive diagnosis in patients presenting late with shrunken kidneys, proteinuria, and kidney impairment. This in turn may have led to an overestimate of the frequency of GN as a cause of ESKD in registry data. GN should be diagnosed only if there is confirmatory histologic evidence.

TABLE 16.6 Glomerular Diseases Presenting as Rapidly Progressive Glomerulonephritis

Disease	Associations	Serologic Tests
Goodpasture Syndrome		
	Lung hemorrhage	Anti–glomerular basement membrane antibody (occasionally ANCA present)
Vasculitis		
Granulomatosis with polyangiitis	Upper and lower respiratory tract involvement	Mostly PR3 ANCA
Microscopic polyangiitis	Multisystem involvement	Mostly MPO ANCA
Pauci-immune crescentic glomerulonephritis	Renal involvement only	MPO or PR3 ANCA
Immune Complex Disease		
Systemic lupus erythematosus	Other multisystem features of lupus	Antinuclear antibody, anti–double-stranded DNA antibody, C3↓, C4 ↓
Poststreptococcal glomerulonephritis	Pharyngitis, impetigo	Antistreptolysin titer, streptozyme antibody C3 ↓, C4 normal
IgA nephropathy; IgA vasculitis (HSP)	Characteristic rash ± abdominal pain in IgA vasculitis	Serum IgA ↑ (30%) C3 and C4 normal
Endocarditis		
	Cardiac murmur; other systemic features of bacteremia	Blood cultures ANCA (occasionally) C3 ↓, C4 normal

Note the overlap between these diseases and those in Table 16.5. A number of glomerular diseases may present with either nephritic syndrome or RPGN.
ANCA, Antineutrophil cytoplasmic antibody; *HSP,* Henoch-Schönlein purpura; *IgA,* immunoglobulin A; *MPO,* myeloperoxidase; *PR3,* proteinase 3; *RPGN,* rapidly progressive glomerulonephritis.

TREATMENT OF GLOMERULAR DISEASE

General Principles

Before any therapeutic decisions, it should always be ascertained that glomerular disease is *primary* and that no specific therapy is indicated. For example, treatment of an underlying infection or tumor may result in remission of GN. In the remaining cases, both general supportive treatment (see Chapter 82) and disease-specific therapy should be considered. Supportive treatment includes treatment of hypertension, proteinuria, edema, and other metabolic consequences of nephrotic syndrome. If successful, these relatively nontoxic therapies can prevent the need for immunosuppressive drugs, which have multiple potential side effects. Supportive therapy is usually not necessary in corticosteroid-sensitive MCD with rapid remission or in patients with IgA nephropathy, Alport syndrome, or thin basement membrane nephropathy, provided the patient exhibits no proteinuria above 0.5 g/day, loss of GFR, or hypertension.

Hypertension

Hypertension is very common in GN; it is virtually universal as chronic GN progresses toward kidney failure and is the key modifiable factor in preserving kidney function. Sodium and water overload is an important part of the pathogenetic process, and high-dose diuretics with moderate dietary sodium restriction are usually an essential part of the treatment. As in other chronic kidney diseases, the blood pressure control reduces cardiovascular risk and also delays progressive kidney function loss. In the Modification of Diet in Renal Disease (MDRD) study, patients with proteinuria (>1 g/day) had a better outcome if their blood pressure was reduced to 125/75 mm Hg rather than to the previous standard of 140/90 mm Hg.[21,22] The recent Kidney Disease: Improving Global Outcomes (KDIGO) CKD guideline recommends a blood pressure target of 130/80 mm Hg in proteinuric patients,[23] but the SPRINT trial and some other studies suggest that a systolic blood pressure target in the 120s may reduce cardiovascular complications in nondiabetic subjects compared with a higher target (140 mm Hg; see Chapters 35 and 82). Clinical trial data strongly supports the use of ACE inhibitors and ARBs as the first-choice therapy.[24-26] Nondihydropyridine calcium channel blockers may also have a beneficial effect on proteinuria as well as on blood pressure. In contrast, dihydropyridine calcium channel blockers may exacerbate proteinuria because of their ability to dilate the afferent arteriole, but these agents are considered relatively safe to use if the patient is receiving either an ACE inhibitor or an ARB. As in primary hypertension, lifestyle modification (salt restriction, weight normalization, regular exercise, and smoking cessation) should be an integral part of the therapy.[23] If target blood pressure cannot be achieved with these measures, antihypertensive therapy should be stepped up according to current guidelines (see Chapter 37).

Treatment of Proteinuria

Besides hypertension, proteinuria represents the second key modifiable factor to preserve GFR in patients with glomerular disease (see Chapters 81 and 82). Most studies suggest that progressive loss of kidney function can be minimized if proteinuria can be reduced to levels below 0.5 g/d. This may be because many of the measures to reduce protein excretion (e.g., ACE inhibitors, ARBs) also reduce glomerular hypertension, which contributes to progressive kidney failure. However, there is also increasing evidence that proteinuria or factors present in proteinuric urine may be toxic to the tubulointerstitium.[23] In nephrotic patients, a reduction of proteinuria to a nonnephrotic range can induce serum proteins to rise, with alleviation of many of the metabolic complications of nephrotic syndrome.

Most of the agents used to reduce urinary protein excretion do so by blocking efferent arteriolar constriction (ACE inhibitors or ARBs) or reducing preglomerular pressure (most other classes of antihypertensive drugs). As mentioned, dihydropyridine calcium antagonists are the exception because they preferentially dilate the afferent arteriole and thereby can increase intraglomerular pressure and thus exacerbate

Fig. 16.14 Treatment of Nephrotic Edema before the Availability of Diuretics. Edema in nephrotic syndrome was very difficult to treat. In 1953 this child with anasarca stands in a bowl while edema fluid drips out through small tubes placed through needles in the skin of the feet. Nevertheless, this was effective treatment. The two pictures of the same child were taken 4 days apart, during which time the child lost 4.5 kg (10 lb), or 18% of body weight. (Courtesy Dr. Robert Vernier.)

proteinuria. Some of the agents, such as ACE inhibitors and ARBs, also may directly reduce the increased glomerular capillary wall permeability. A consequence of this type of therapy is a reduction in GFR; in general, however, the decrease in GFR is of a lower magnitude than the decrease in protein excretion. ACE inhibitors and ARB reduce proteinuria by an average of 40% to 50%, particularly if the patient is on dietary salt restriction. There is little clinical evidence to suggest that ACE inhibitors differ from ARBs in this respect. The combination of ACE inhibitors and ARBs does not appear to provide additional benefit and increases the risk for AKI and hyperkalemia, in particular when used in older people with vascular disease and diabetes.[27,28] Similar concerns relate to the combination of an ACE inhibitor or ARB with a direct renin inhibitor.[29]

In addition, whereas other classes of antihypertensive agents will reduce proteinuria coincident with a decrease in systemic blood pressure, particularly the nondihydropyridine calcium channel blockers such as diltiazem, both ACE inhibitors and ARBs usually reduce proteinuria independent of blood pressure. If doses are increased slowly to minimize symptomatic hypotension, treatment with ACE inhibitors and ARBs is usually possible in the normotensive proteinuric patient. Common side effects include hyperkalemia in patients with advanced CKD, which may necessitate a loop diuretic but rarely should lead to cessation of ACE inhibitors and ARBs, and cough with ACE inhibitors, in which case ARBs should be used instead. Because both agents lower GFR, a 10% to 30% increase in serum creatinine concentration may be observed. Unless serum creatinine continues to increase, this moderate increase reflects the therapeutic effect of ACE inhibitors and ARBs and should not prompt their withdrawal. Finally, if proteinuria persists despite maximum allowed or tolerated doses of ACE inhibitors or ARBs, a low dose of an aldosterone antagonist may overcome so-called aldosterone breakthrough and further reduce proteinuria (see Chapter 82). Hyperkalemia is an important safety aspect, similar to the ACE inhibitor and ARB combination mentioned earlier.

The NSAIDs lessen proteinuria by reducing intrarenal prostaglandin production and dipyridamole through adenosine-mediated afferent arteriolar vasoconstriction. However, they are generally contraindicated as their use can cause profound decreases in GFR, salt retention, and diuretic resistance.

A low-protein diet will lessen proteinuria but must be advised with great care because of the risk for malnutrition.[23] Adequate compensation must be made for urine protein losses,[30] and the patient must be carefully monitored for evidence of malnutrition (see Chapter 90). Whether a low-protein diet is still antiproteinuric in patients treated with a full dose of ACE inhibitor or ARB is not established.

Treatment of Hyperlipidemia

Treatment of hyperlipidemia (or hypercholesterolemia) in patients with glomerular disease should usually follow the guidelines that apply to the general population to prevent cardiovascular disease. A statin or statin/ezetimibe combination is recommended in adults older than 50 years with CKD stage 3 to 5. Statins alone are also recommended in adults over 50 years with earlier-stage CKD. In younger adults, statins should be considered if the patient has significant comorbidity (coronary disease, diabetes mellitus, stroke; see Chapter 85). Statins may protect from a decrease in GFR, although this is not firmly established. Dietary restriction alone has only modest effects on hyperlipidemia in glomerular disease, particularly nephrotic syndrome. Side effects of some medications, such as rhabdomyolysis provoked by fibrates, occur more frequently in patients with kidney failure.

Avoidance of Nephrotoxic Substances

Apart from NSAIDs, which may induce AKI, particularly in patients with preexisting kidney impairment and dehydration, other nephrotoxic substances, such as radiocontrast agents, some cytotoxic drugs, and antibiotics (e.g., aminoglycosides), also should be used with caution in patients with glomerular disease and kidney impairment or nephrotic syndrome. There is also increasing concern that proton pump inhibitors may be associated with increased risk for both acute interstitial nephritis and CKD, and thus their use should be restricted to documented indications when histamine-2 blockers are not effective.

Special Therapeutic Issues in Patients With Nephrotic Syndrome

Treatment of Nephrotic Edema

In contrast to the lack of therapies in the past (Fig. 16.14), the mainstay of current treatment of nephrotic edema is diuretic therapy accompanied by moderate dietary sodium restriction (60–80 mmol/24 h).

Nephrotic patients are diuretic resistant even if GFR is normal. Loop diuretics must reach the kidney tubule to be effective, and transport from the peritubular capillary requires protein binding, which is reduced in hypoalbuminemia. When the drug reaches the kidney tubule, it will become 70% bound to protein present in the urine and therefore be less effective. Oral diuretics with twice-daily administration are usually preferred, given the longer therapeutic effect compared with intravenous diuretics. However, in severe nephrosis, GI absorption of the diuretic may be uncertain because of intestinal wall edema, and intravenous diuretic by bolus injection or infusion may be necessary to provoke an effective diuresis. Alternatively, combining a loop diuretic with a thiazide diuretic or with metolazone may overcome diuretic resistance (see Chapter 8). A third alternative is adding amiloride to loop diuretics because nephrotic syndrome is associated with activation of the ENaC channel. Significant hypovolemia is not often a clinical problem, provided fluid removal is controlled and gradual. Daily weight should decrease by no more than 1 to 2 kg/day. Nephrotic children are much more prone to hypovolemic shock than adults. A stepwise approach to diuretic use is required, aiming at fluid removal in adults of no more than 2 kg daily, moving on to the next drug level if this is not achieved (Fig. 16.15).

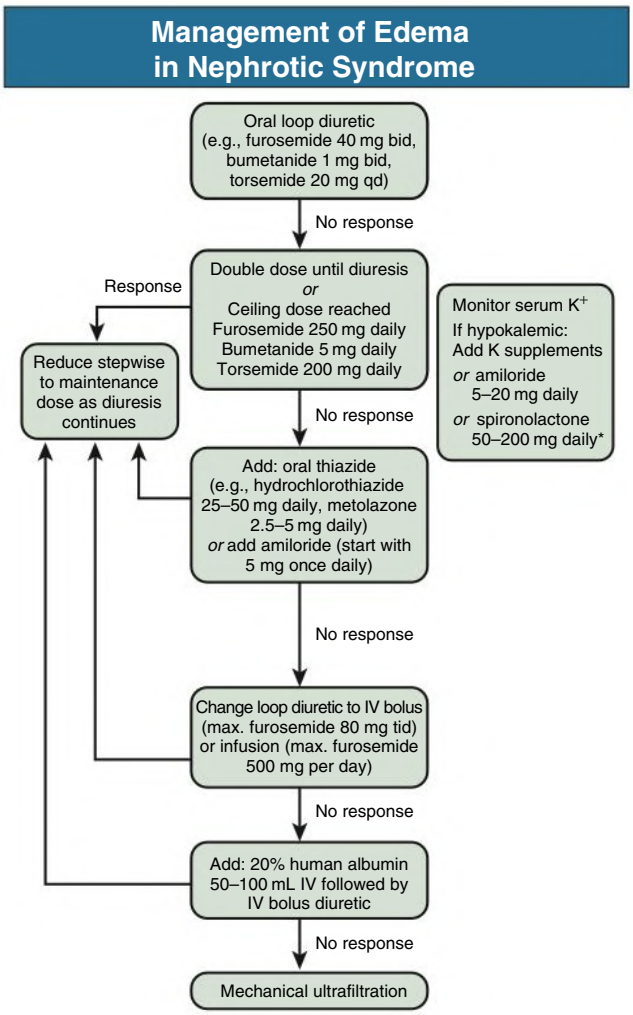

Fig. 16.15 Management of Edema in the Patient With Nephrotic Syndrome. Edema is often diuretic resistant, but the response is not predictable. Therefore, stepwise escalation of therapy is appropriate until diuresis occurs. Even when there is anasarca, diuresis should not proceed faster than 2 kg/day in adults to minimize the risk for clinically significant hypovolemia. Mechanical ultrafiltration is rarely required for nephrotic edema unless there is associated renal impairment. *Spironolactone is less effective in nephrotic syndrome than in cirrhosis and is often poorly tolerated because of gastrointestinal side effects. Spironolactone should be used with great caution if the glomerular filtration rate is very low. *bid,* Twice daily; *IV,* intravenous.

Correction of Hypoproteinemia

Adequate dietary protein should be ensured in nephrotic patients (0.8–1 g/kg/day) with a high carbohydrate intake to maximize use of that protein. In patients with heavy proteinuria, the amount of urinary protein loss should be added to dietary protein intake.

In the very rare setting of proteinuria so severe that the patient is dying of the complications of nephrotic syndrome, the physician may need to resort to medical nephrectomy to prevent continued protein losses: the deliberate use of NSAIDs combined with ACE inhibitors and diuretic to lessen proteinuria by provoking AKI. If medical nephrectomy alone does not adequately reduce proteinuria, bilateral renal artery embolization can be considered. It is a painful procedure and is not always as successful (perhaps because of collateral arterial supply to the kidneys, which is not blocked by embolization). A final alternative is bilateral nephrectomy, which can be performed by laparoscopic surgery with reduced morbidity compared with classical surgical removal. Bilateral nephrectomy is commonly used in the management of infants with congenital nephrotic syndrome.

Treatment of Hypercoagulability

The risk for thrombotic events increases as serum albumin values decrease to less than 2.5 g/dL. Immobility as a consequence of edema or intercurrent illness further aggravates the risk. Prophylactic low-dose anticoagulation (e.g., heparin 5000 U subcutaneously twice daily) is indicated at times of high risk, such as relative immobilization in the hospital and albumin levels between 2 and 2.5 g/dL. Full-dose anticoagulation with low-molecular-weight heparin or warfarin should be considered if serum albumin decreases to less than 2 g/dL,[13,31] and this is mandatory if a thrombosis or pulmonary embolism is documented. Heparin is used for initial anticoagulation, but an increased dose may be needed because part of the action of heparin depends on circulating antithrombin III, which is often reduced in nephrotic patients. Warfarin (target international normalized ratio [INR] 2 to 3) is the long-term treatment of choice but should be adjusted with special care because of altered protein binding, which may require dose reductions. Newer oral anticoagulants have not been systematically tested so far in this situation.

Management of Infection

A high degree of clinical suspicion for infection is vital in nephrotic patients. Especially in nephrotic children, ascitic fluid should be examined microscopically and cultured if there is any suspicion of systemic infection. Bacteremia is common even if clinical signs are localized. ESR is unhelpful, but an elevated C-reactive protein level may be informative. Parenteral antibiotics should be started once culture specimens are taken, and the regimen should include coverage for pneumococci. If repeated infections occur, serum immunoglobulins should be measured. If serum IgG is less than 600 mg/dL, an uncontrolled study suggested that infection risk is reduced by monthly administration of intravenous immune globulin (10–15 g) to keep the IgG levels above 600 mg/dL.[32]

Disease-Specific Therapies

Specific treatments for glomerular diseases are discussed in the subsequent chapters; the general principles are discussed here. Most glomerular diseases have an immune pathogenesis, and treatment has generally consisted of immunosuppressive therapy. In the patient with

glomerular disease resulting from ineffectual elimination of a foreign antigen, treatment aims at eliminating this antigen, such as antibiotics in endocarditis-associated GN or antiviral therapy for cryoglobulinemia resulting from hepatitis C viral infection.

In general, the more severe and acute the presentation of GN, the more successful is immunosuppressive treatment. Immunosuppression in chronic GN has had minimal success. When kidney function is declining rapidly, as in RPGN, the toxicity of intensive regimens becomes acceptable for a short period, although it would be unacceptable if prolonged. Furthermore, the nonspecific nature of most immunosuppressive treatments results in widespread interruption of immune and inflammatory events at multiple levels. Despite great increases in the understanding of immune mechanisms in glomerular disease since the 1970s, most immunosuppressive therapies are not yet much more specific or precise. The mainstays of treatment include corticosteroids, cyclosporine, tacrolimus, cyclophosphamide, mycophenolate mofetil, and/or rituximab. Novel agents, including some that modify inflammation (e.g., complement antagonists) or B cell immunity (e.g., inhibitors of B cell activation factor), are now being studied in clinical trials in glomerular disease but as yet have no proven indications.

The use of immunosuppressive therapies to treat patients with GN has drawbacks. In many diseases, good prospective controlled trials are often lacking. If sufficient glomerular damage is present, proteinuria and progressive deterioration of kidney function may occur by nonimmune pathways that may not be responsive to immunosuppressive therapies. This is particularly relevant in patients in whom the GN has already resulted in advanced CKD. Unfortunately, good noninvasive markers to assess disease activity are missing in most clinical circumstances. Given the frequent uncertainty of the response to immunosuppressive therapy, it becomes mandatory to weigh the potential benefits against the risks of therapy.

Immunosuppression may be associated with reactivation of tuberculosis and hepatitis B infection and also can lead to a hyperinfection syndrome in patients with *Strongyloides* infection. Therefore, high-risk patients should be tested for these diseases before embarking on therapy.

Alkylating agents such as cyclophosphamide have considerable toxicity. In the short term, leukopenia is common, as is alopecia, although hair will regrow within a few months with discontinuation of therapy. These agents can cause infertility (observed in adults with cumulative doses of cyclophosphamide >200 mg/kg). There is also an increased incidence of leukemias (observed with total doses of cyclophosphamide >80 g). Cyclophosphamide is also a bladder irritant, and treatment can result in hemorrhagic cystitis and bladder carcinoma, particularly after therapy lasting more than 6 months.[33] Irritation of the bladder is caused by a metabolite, acrolein. The effect can be minimized in patients receiving intravenous cyclophosphamide by enforcing a good diuresis and administering mesna. The dose of mesna (milligrams) should equal the dose of cyclophosphamide (milligrams); 20% is given intravenously with the intravenous cyclophosphamide, and the remaining 80% should be given in two equal oral doses at 2 and 6 hours. Cyclophosphamide also requires dose reduction in the setting of impaired kidney function. Given all these concerns, oral treatment with cyclophosphamide should ideally be limited to 12 weeks.

The modes of action and potential adverse effects of corticosteroids, azathioprine, and other immunosuppressive agents occasionally used in glomerular disease are discussed further in Chapter 106.

SELF-ASSESSMENT QUESTIONS

1. Which of the following statements regarding proteinuria is *correct?*
   - **A.** Tubular proteinuria is characterized by equal amounts of α_1-microglobulin and immunoglobulins.
   - **B.** Proteinuria exceeding 3.5 g/day (i.e., "nephrotic" proteinuria) inevitably results in hypoalbuminemia.
   - **C.** In orthostatic proteinuria, urinary protein is typically increased with the patient lying down.
   - **D.** Overflow proteinuria is typical of urinary light chain excretion.
   - **E.** Functional proteinuria typically occurs after heavy meals with high protein intake.
2. Which of the following statements regarding general treatment of glomerular disease is *incorrect*?
   - **A.** The KDIGO CKD guideline recommends a blood pressure target below 130/80 mm Hg in proteinuric patients.
   - **B.** ACE inhibitors and ARBs may directly reduce the increased glomerular capillary wall permeability.
   - **C.** Common side effects of ACE inhibitors and ARBs in patients with advanced CKD include hyperkalemia, which may necessitate a loop diuretic.
   - **D.** A statin or a statin-ezetimibe combination is recommended in all adults younger than 50 years with CKD.
   - **E.** A low-protein diet will lessen proteinuria but must be advised with great care because of the risk of malnutrition.
3. Which statement regarding the treatment of nephrotic syndrome is *correct?*
   - **A.** Nephrotic patients are diuretic resistant only if GFR is greatly impaired.
   - **B.** Patients with heavy proteinuria should be advised to consume a high-protein diet of about 2 to 3 g/kg/day.
   - **C.** Full-dose anticoagulation with low-molecular-weight heparin or warfarin should be considered if serum albumin decreases to less than 2 g/dL.
   - **D.** Ascitic fluid should be examined regularly by microscopy and culture independently of a suspicion of systemic infection.
   - **E.** Nephrotic children are no more prone to hypovolemic shock than are adults.

Introduction to Glomerular Disease: Histologic Classification and Pathogenesis

Jürgen Floege, Peter Boor

HISTOLOGIC CLASSIFICATION

Glomerular disease has a wide variety of etiologies and clinical presentations (see Chapter 16). Some glomerular diseases are given the generic title of glomerulonephritis (GN), which implies an immune or inflammatory pathogenesis. Although a specific diagnosis is sometimes possible based on clinical presentation and laboratory tests, in most patients a kidney biopsy is useful for both classification and prognosis. Ideally, the kidney biopsy should be examined by light microscopy, immunohistology or immunofluorescence, and electron microscopy (EM), which allows description of the underlying histopathological pattern. Using this approach, an etiologic classification or specific diagnosis can often be made, particularly when integrating the biopsy results with clinical features and other laboratory tests. One useful example of an etiologic classification is the Mayo/Renal Pathology Society consensus report on the classification of GN,[1] distinguishing five major disease etiologies: immune-complex GNs, pauci-immune GNs, anti–glomerular basement membrane (GBM) antibody GNs, monoclonal gammopathy–associated GNs, and complement-related GNs. In some cases the exact condition might remain idiopathic, but in the vast majority of cases one of these GN classes can be assigned. However, because treatments are often developed for specific histologic patterns, a histology-based approach is currently favored in the management of most patients with glomerular disorders.

HISTOPATHOLOGY

The full assessment of a kidney biopsy requires light microscopy, EM, and examination for deposits of complement and immunoglobulin by immunofluorescence (IF) or immunoperoxidase (IP) techniques.

Light Microscopy

In GN the dominant, but not the only, histologic lesions are in glomeruli (Fig. 17.1). GN is described as *focal* (<50% of glomeruli are involved) or *diffuse* (>50% of glomeruli are involved). In any individual glomerulus, injury may be *segmental* (affecting <50% of any glomerulus) or *global* (>50%). Sampling error is possible in a kidney biopsy; the extent of a focal lesion may be misjudged in a small biopsy specimen, and sections through glomeruli may miss segmental lesions. Therefore, the number of glomeruli in a biopsy is an essential quality parameter, and serial sections may be necessary for the biopsy workup. In general and for most lesions and pathologies, 10 to 15 glomeruli are considered optimal and 8 to 10 necessary, albeit in a few cases a diagnosis can be made even on a single glomerulus. Lesions may be hypercellular (termed *proliferative*) because of an increase in endogenous cells or infiltration of inflammatory leukocytes, and based on localization (extracapillary, endocapillary, mesangial or combinations thereof). Severe acute inflammation may produce glomerular necrosis, which is often segmental. Multiple processes can cause thickening of the walls of the glomerular capillaries, including an increase in GBM material and immune deposits. Segmental sclerosis (scarring) may occur and is characterized by segmental capillary collapse with the accumulation of hyaline material and extracellular matrix, often with attachment of the capillary wall to Bowman's capsule (synechiae or adhesion formation).

The classic stains used in light microscopy include hematoxylin-eosin (HE) and the periodic acid–Schiff (PAS) reaction, the latter being particularly effective for evaluating the overall histological pattern. More specific stains include methenamine silver, which stains GBM and other matrix black and which is particularly helpful in revealing GBM abnormalities (such as double contours or spikes of the GBM), which are not easily detected with other techniques. Trichrome staining is also useful to show areas of scarring (blue) and immune deposits or thrombi (red).

Extracapillary proliferations, or *crescents*, are defined as increased number of cells in Bowman's space. Crescents develop when severe glomerular injury results in local rupture of the capillary wall or Bowman's capsule, allowing plasma proteins and inflammatory material to enter into Bowman's space. Crescents mainly consist of proliferating parietal cells, probably some visceral epithelial cells, and infiltrating fibroblasts; lymphocytes and monocytes/macrophages might be also involved, often with local fibrin deposition. They are called crescents because of their appearance when the glomerulus is cut in one plane for histology. Crescents are destructive, may rapidly increase in size, and may lead to glomerular tuft occlusion (see Fig. 17.1). If the acute injury is stopped, the crescents may probably either resolve with restitution of normal morphology or, more likely, heal via fibrosis (i.e., via transformation to fibrocellular and later fibrous crescents, which in turn may contribute to irreversible loss of renal function). Crescents are most frequently observed in vasculitis and in Goodpasture disease but also in severe acute GN of any cause.

Tubulointerstitial injury, inflammation, and tubular atrophy and fibrosis can accompany GN, particularly the latter, which is usually strongly correlated with prognosis (see Chapter 81).

Immunofluorescence and Immunoperoxidase Microscopy

Indirect IF and IP staining are both used to identify immune reactants (Fig. 17.2 and Table 17.1), particularly for immunoglobulins (IgG, IgA, and IgM), for components of the complement system (usually C3 and C1q in native and C4d in transplant biopsies), and for the presence of fibrin, which is typically observed in crescents and in capillaries in thrombotic disorders such as hemolytic uremic syndrome (HUS) and antiphospholipid syndrome. For diagnostic purposes, not only the composition of the deposits is important but also their localization; that is, in the mesangium or along capillary loops (distinguishing subepithelial, subendothelial, or combined localization) and in the staining pattern (i.e., continuous [linear] or discontinuous [granular]).

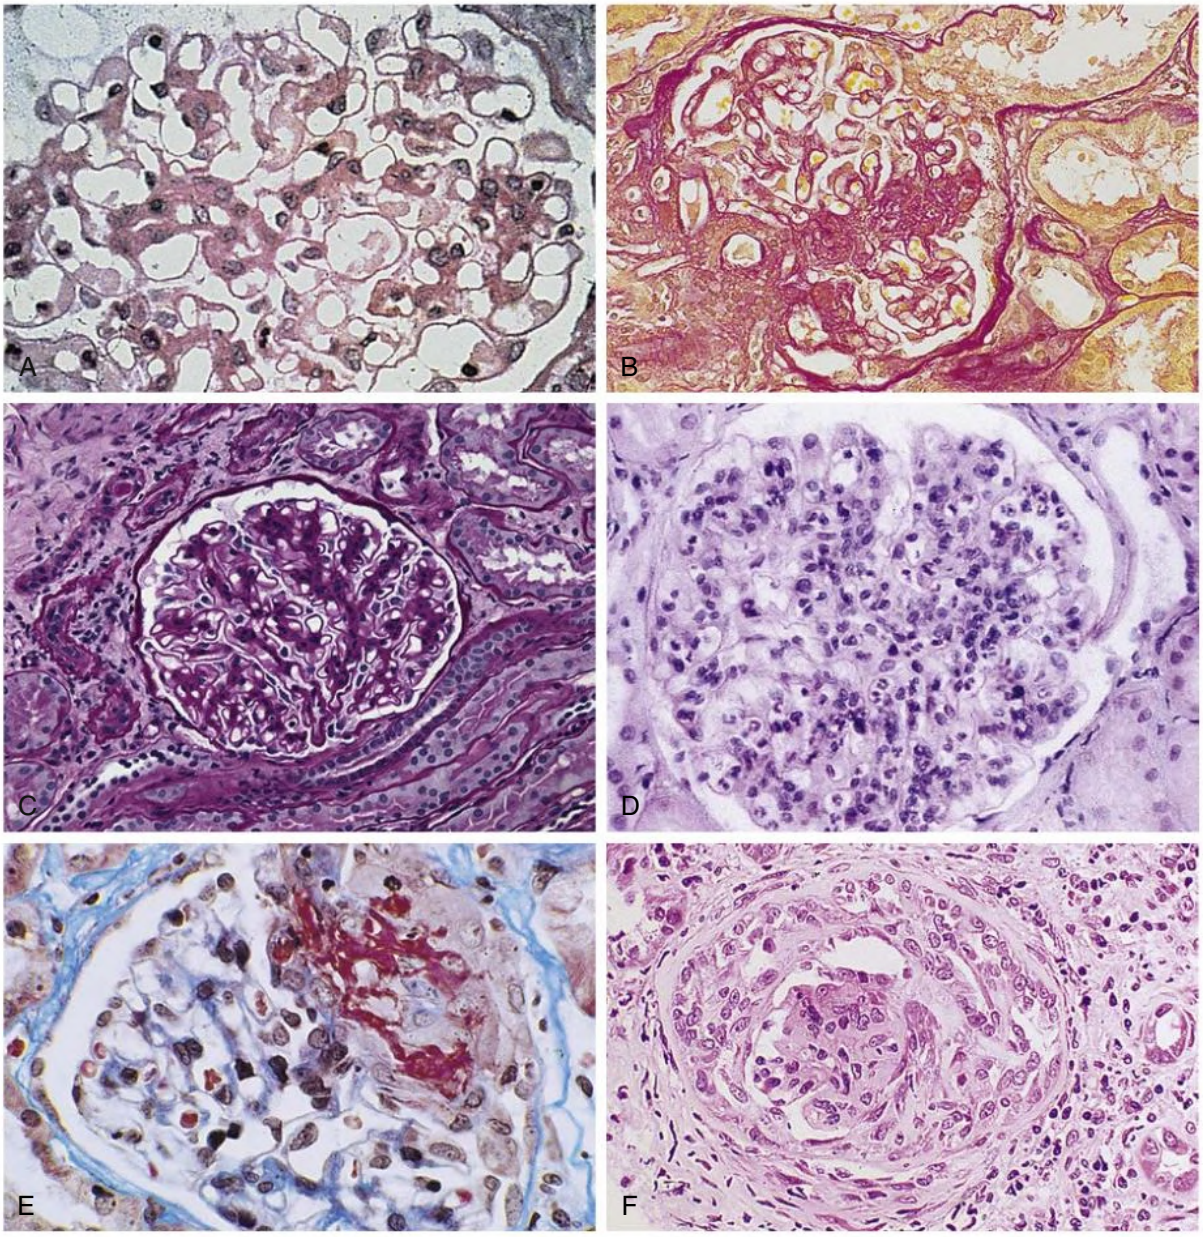

Fig. 17.1 Pathology of Glomerular Disease: Light Microscopy. Characteristic patterns of glomerular disease illustrating the range of histologic appearances and the descriptive terms used. (A) Normal glomerulus: minimal change disease. (B) Segmental sclerosis: focal segmental glomerulosclerosis. (C) Diffuse mesangial hypercellularity: immunoglobulin A nephropathy. (D) Diffuse endocapillary hypercellularity: poststreptococcal glomerulonephritis. (E) Segmental necrosis: renal vasculitis. (F) Crescent formation: anti–glomerular basement membrane disease. (A–B, hematoxylin-eosin; C–D and F, periodic acid–Schiff; E, trichrome.)

Electron Microscopy

Electron microscopy (EM) is valuable for defining the morphology of the GBM, which is abnormal in some forms of hereditary nephropathy (e.g., Alport syndrome and thin basement membrane nephropathy; see Chapter 48) and for identifying fibrils (e.g., in amyloidosis) or tubuloreticular intracellular structures (e.g., in lupus nephritis). EM is also useful for localizing the site of immune deposits, which are usually homogeneous and electron dense (Fig. 17.3). Electron-dense deposits are seen in the mesangium or along the capillary wall on the subepithelial or subendothelial side of the GBM. Infrequently, the electron-dense material follows a linear pattern within the GBM. The sites of immune deposits are helpful in the classification of the types of GN.

GENERAL MECHANISMS OF GLOMERULAR INJURY

Proteinuria

Proteinuria, accompanied by variable degrees of hematuria, is the hallmark of glomerular disease. The endothelial glycocalyx and the GBM may repel proteins in part through their highly negative charge (proteins are mostly negatively charged as well) and prevent them from entering Bowman's space. The key barrier for protein is the slit diaphragm between the podocyte foot processes[2,3] (Fig. 17.4). The slit diaphragm consists of several transmembrane proteins that extend from adjacent interdigitating foot processes to form a zipper-like scaffold on the outer side of the GBM (Fig. 20.1 and Chapter 1).

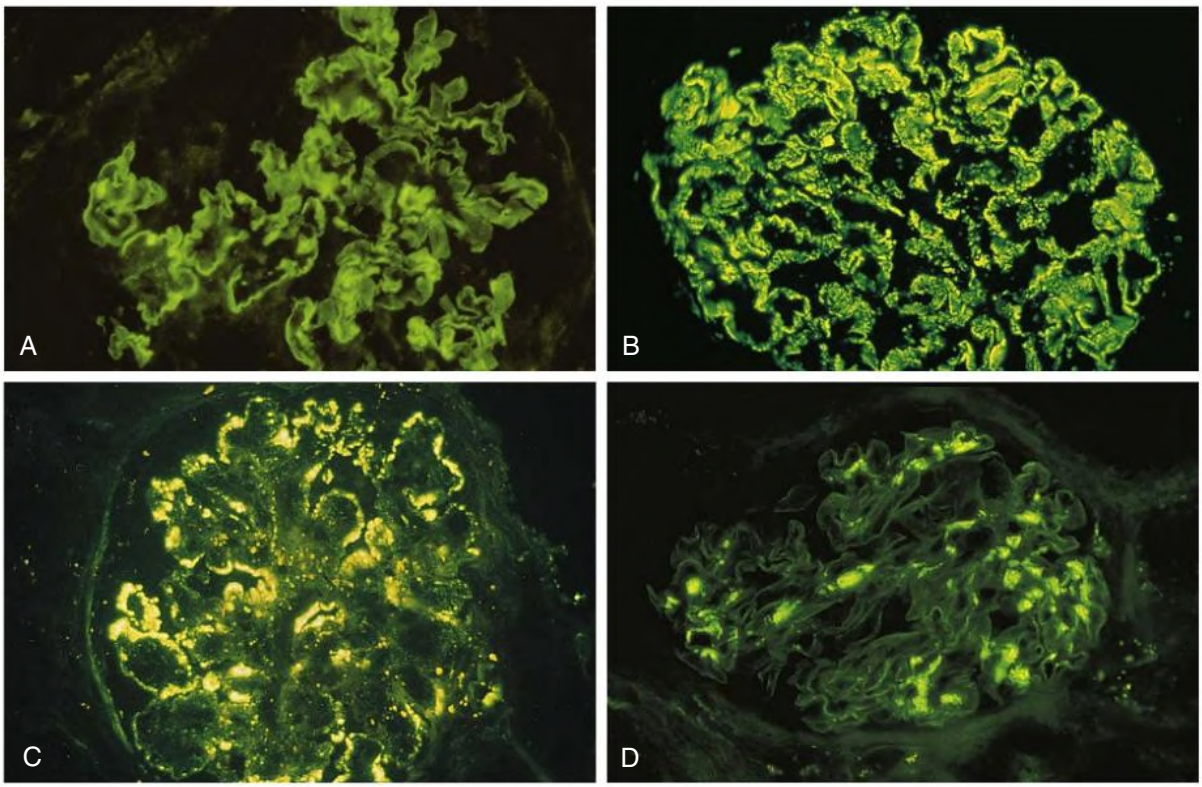

Fig. 17.2 Pathology of Glomerular Disease: Immunofluorescence Microscopy. Common patterns of glomerular staining found by immunofluorescence. (A) Linear capillary wall immunoglobulin (Ig) G: anti–glomerular basement membrane disease. (B) Fine granular capillary wall IgG: membranous nephropathy. (C) Coarse granular capillary wall IgG: membranoproliferative glomerulonephritis type I. (D) Granular mesangial IgA: IgA nephropathy.

The importance of the slit diaphragm in proteinuric states has been documented in numerous hereditary types of nephrotic syndrome in which the mutations involve various slit diaphragm proteins (see Chapter 20). These diseases usually manifest as a type of steroid-resistant minimal change disease (MCD) or focal segmental glomerulosclerosis (FSGS). Whereas most recessive mutations of slit diaphragm or podocyte proteins manifest in childhood or even prenatally, dominant mutations tend to manifest in early adult life.[3] An exception is steroid-resistant autosomal recessive nephrotic syndrome, in which the homozygous mutation in podocin *(NPHS2)* presents in childhood, but the heterozygous mutation, when it coexists with the p.R229Q variant polymorphism, may manifest clinically in young adulthood (age 20–35 years).[4]

Although it may result from injury or mutation of slit diaphragm proteins, proteinuria may be caused by nonspecific injury to the podocyte in many cases. When the podocyte is injured, it may undergo shape changes with swelling and loss or fusion of the foot processes. Filtration is reduced at sites where the foot processes fuse (possibly accounting for the reduction of the filtration coefficient K_f seen in nephrotic syndrome), but there are gaps where the podocytes are detached from the GBM. Massive protein filtration may occur at these sites; structurally, the capillary wall defects are likely to correspond to the large pores noted in functional studies[5] (Fig. 17.5). Podocyte immaturity also can result in nephrotic syndrome, perhaps from incomplete differentiation and slit diaphragm development. Congenital nephrotic syndrome with mesangial sclerosis has been linked with mutations in the phospholipase C epsilon gene *(PLCE1),* which is important in podocyte development.[6]

In addition to podocyte damage, and in particular slit diaphragm defects, proteinuria also can result from changes in the glomerular endothelium, especially its glycocalyx, as well as from changes in the GBM and altered electrical forces across the GBM.

Severe albuminuria reflects a glomerular defect, but some albumin is normally filtered but then endocytosed and metabolized in the proximal tubule or is transcytosed intact through the tubular cell. Proximal tubular dysfunction can therefore result in albuminuria if endocytosis is impaired, although this is generally in the nonnephrotic range.

Antibody and Antigen

Many glomerular diseases are associated with deposition or glomerular trapping of immunoglobulins, often with components of the complement system, and with the presence of electron-dense deposits by EM. These findings likely represent immune complexes. Experimentally, immune complexes can localize in glomeruli by two major mechanisms. In some conditions, such as mesangial proliferative GN, diseases associated with a membranoproliferative GN (MPGN) pattern, or lupus nephritis, the immune complexes are thought to originate in the circulation and to be passively trapped in the mesangium or subendothelial areas. However, circulating immune complexes cannot readily pass across the GBM. Therefore, the presence of immunoglobulin G (IgG) on the subepithelial aspect of the basement membrane, such as occurs in membranous nephropathy (MN), either results from the direct binding of podocyte antigens by an antibody (e.g., phospholipase A2 receptor antibody) or represents binding of an antibody to an antigen that was temporarily "trapped" or bound at this site (in situ complex formation).[7] GN also may occur only with complement activation in the glomeruli in the absence of IgG, as occurs in dense deposit disease (DDD), in which ribbon-like deposits replace the basement membrane (see Chapter 23). Some antigens may deposit in

TABLE 17.1 Antibodies Used in Nephropathology Diagnostics

Immunostaining	Example of Diagnostic Use
Standard	
IgG	Diseases with IgG deposits (e.g., MPGN, anti-GBM GN)
IgA	IgA nephropathy and vasculitis
IgM	Mixed cryoglobulinemia or Waldenstrom macroglobulinemia
C3	C3 glomerulopathies
C1q	Lupus nephritis
Specific	
Kappa and light chain	Renal involvement in monoclonal light chain diseases
Fibrinogen	Necrosis, thrombotic microangiopathies
Phospholipase A2 receptor	Primary membranous nephropathy
THSD7A, exostosin 1 and 2	PLA_2R negative membranous nephropathy
IgG1, IgG2, IgG3	Monoclonal IgG deposits
IgG4	Membranous nephropathy, IgG4-associated interstitial nephritis
DNAJB9	Fibrillary GN
Collagen type 4 alpha 3 and 5 chains	Alport syndrome
Specific amyloid antibodies (e.g., amyloid A, transthyretin)	Subtyping amyloidosis

Each nephropathology laboratory uses a different set of antibodies as a standard panel; the five mentioned in this table are considered a "minimal" standard for nontransplant kidney biopsies.
In kidney transplant biopsies, C4d and eventually stains for polyomavirus are used as a standard set, additionally, staining for adenovirus or cytomegalovirus can be used.
DNAJB9, DnaJ homolog subfamily B member 9; *GBM,* glomerular basement membrane; *GN,* glomerulonephritis; *Ig,* immunoglobulin; *MPGN,* membranoproliferative GN pattern; *PLA_2R,* phospholipase A_2 receptor; *THSD7A,* thrombospondin type 1 domain-containing protein 7A.

glomeruli and directly activate the alternative pathway of complement in the absence of IgG, as may occur in poststreptococcal GN (PSGN). Immunoglobulin with aberrant characteristics may also aggregate in glomeruli and activate complement in the absence of antigen, as occurs in IgA nephropathy with aberrantly glycosylated IgA (see Chapter 24) and glomerular diseases associated with monoclonal immunoglobulins (see Chapters 22 and 28).[8]

Normally, immune complexes are removed from the circulation by binding of the complex to the C3b receptors on erythrocytes. The immune complexes are then removed and degraded during transit of the erythrocytes in the liver and spleen. If antigenemia persists or clearance of complexes is impaired (e.g., chronic liver disease), immune complexes may deposit in the glomerulus by binding to Fc receptors on mesangial cells or by passive deposition in the mesangium or subendothelial space. Physical characteristics of the complexes also may favor deposition, including avidity, charge, and size. However, quantification of circulating immune complexes in patients with GN does not correlate reliably with glomerular events and thus is not typically measured.

In some glomerular diseases, the target antigen has been identified (Table 17.2). In other patients, glomerular disease develops as a result of infection with organisms that release superantigens that cause a polyclonal activation of B cells. The classic organism responsible for superantigen-associated GN is *Staphylococcus aureus,* and the pattern of immune deposits often includes the presence of both IgG and IgA. Some infections initiate an immune response that cross-reacts with endogenous antigens. This type of molecular mimicry may be responsible for Goodpasture disease and certain types of vasculitis[9] (see Table 17.2). Once an immune response is initiated, local injury may lead to the release of additional antigens that extend the immune response (epitope spreading). In Goodpasture disease, in which the antigen is an α3 chain of type IV collagen, the antigen is present in the lung alveolar basement membrane but is normally sequestered. In tobacco smokers, however, the inhalation results in oxidative injury with exposure of the α3 chain, allowing the binding of antibodies.[10] This may explain why lung involvement rarely occurs in nonsmokers with Goodpasture disease.

Complement

The complement system is often activated in glomerular disease (Fig. 17.6). Complement can be activated through three pathways. *Classic pathway* activation involves the binding of C1q to the Fc region of antibody in IgG- and IgM-containing immune complexes and can result in reduced serum C4 and C3. This is common in lupus nephritis, immune complex–induced GN, and cryoglobulinemic MPGN. Complement may be activated by the *alternative pathway,* which is activated independently of immune complexes and can be triggered by polysaccharide antigens, polymeric IgA, injured cells, bacterial products (e.g., streptococcal antigens), and antibodies to complement pathway components (C3 convertase). The alternative pathway appears to be activated in IgA nephropathy, DDD, and PSGN. Serum complement levels are generally normal in IgA nephropathy; in DDD and PSGN, however, the C3 is typically low but C4 is normal. In DDD as well as in C3-glomerulonephritis (C3GN) (see Chapter 23), the activation of the alternative pathway may not involve an antigen but rather results from continuous activation of the pathway through altered factor H or an IgG autoantibody (nephritic factor) that stabilizes the C3 convertase (see Chapter 23). Complement also can be activated through the mannose-binding lectin (MBL) pathway initiated by MBL, which has a structure similar to that of C1q. The role of the MBL pathway in GN is emerging in IgA nephropathy and idiopathic MN. However, despite evidence for intraglomerular complement activation in these conditions, serum complement components such as C3 and C4 generally remain in the normal range.

Activation of the complement pathway has several consequences. Leukocyte recruitment is facilitated by the chemotactic factor C5a, and C3b binding is important in the binding and opsonization of the immune complexes by the infiltrating leukocytes. The terminal membrane attack complex of the cascade, C5b-9, inserts into cell membranes, where it can kill cells or more commonly activate them to secrete cytokines, oxidants, and extracellular matrix. C5b-9 likely has a role in mediating injury to the glomerular epithelial cell in MN, in which immune deposits and complement activation occur in the subepithelial space. Complement also can be activated in proteinuric urine because of amidation of C3 by ammonia, which may have a role in mediating tubulointerstitial injury even in conditions not associated with immune complex formation. Experimental studies have emphasized the importance of local synthesis of complement components by the tubular cells as a mechanism that may augment this process.[11]

Activation of complement is controlled by complement regulatory proteins (see Fig. 17.6). A genetic absence or malfunction of factor H or other regulatory proteins can result in increased susceptibility to glomerular endothelial injury, resulting in thrombotic microangiopathy (Chapter 30) or less often hereditary forms of GN (see Chapter 23).

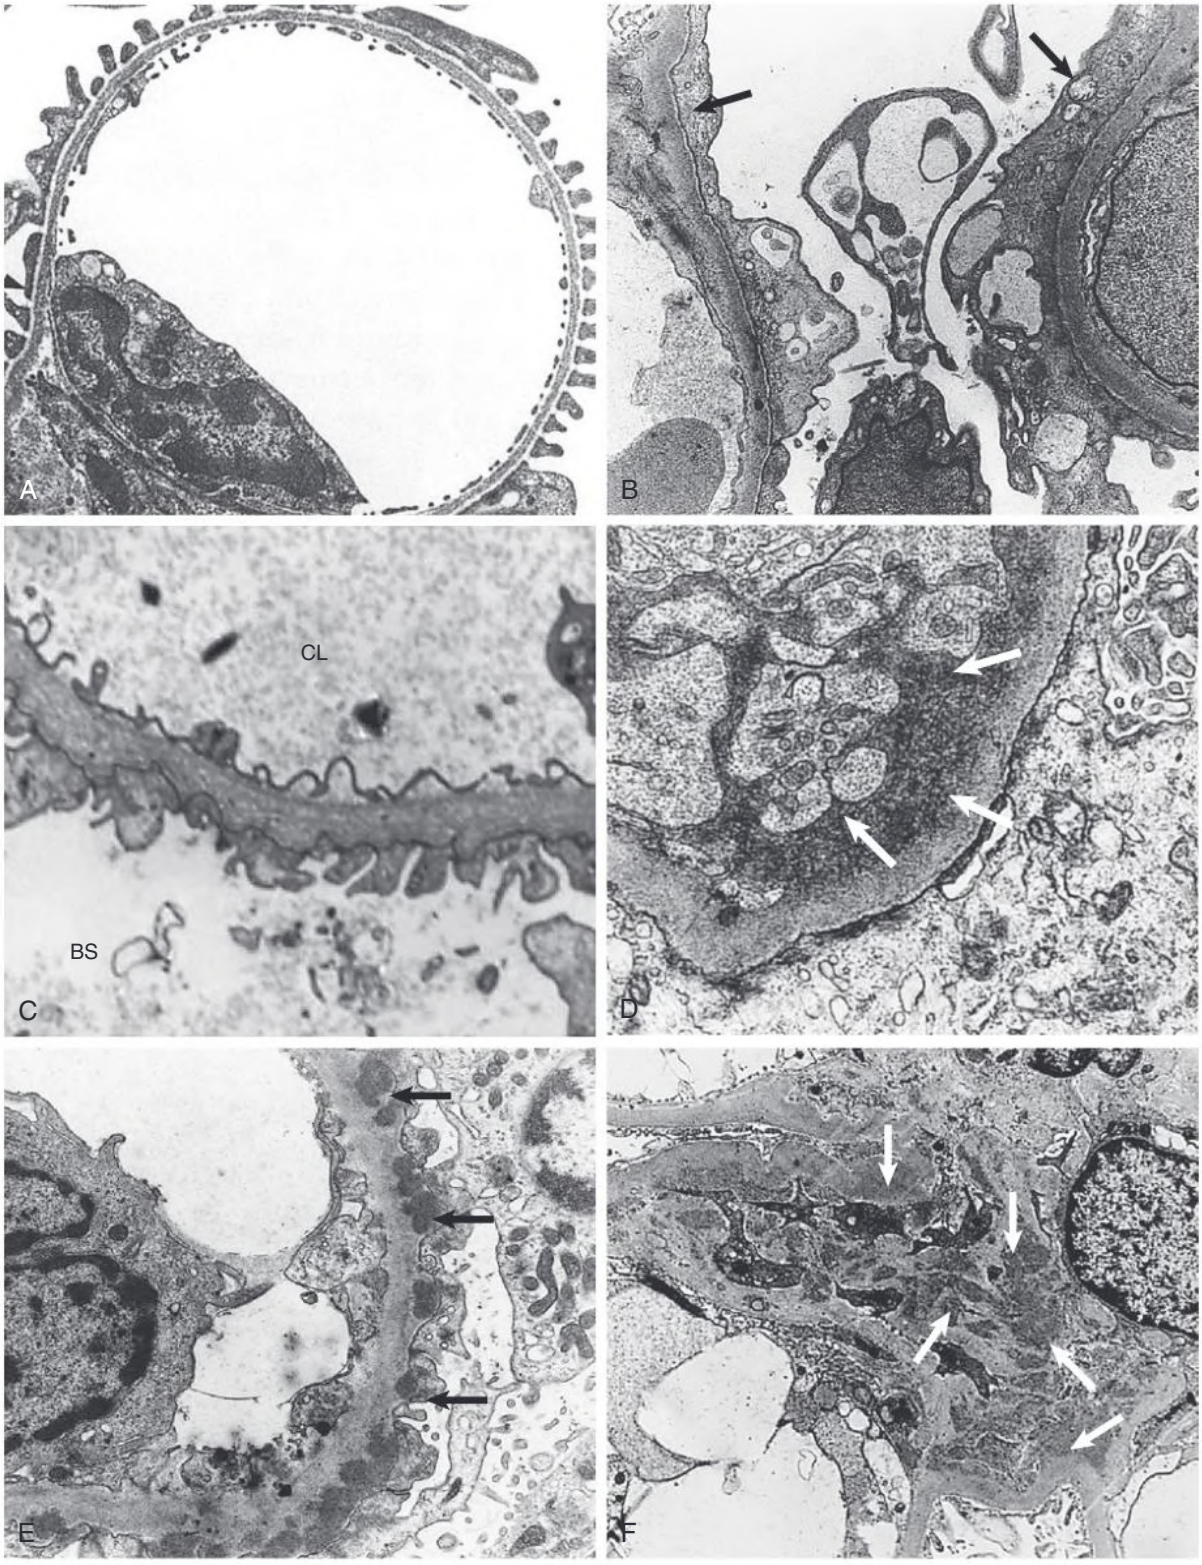

Fig. 17.3 Ultrastructural Pathology of Glomerular Disease. Some characteristic patterns of electron-dense deposits and glomerular basement membrane (GBM) abnormalities seen in glomerular disease. Fig. 17.4 Mechanisms of Proteinuria. Normally, negatively charged proteins such as albumin *(blue circles)* are repelled by the negatively charged proteins in the endothelium (sialoglycoproteins) and basement membrane (heparan sulfate proteoglycans), as well as by a size barrier in the glomerular basement membrane (GBM) and at the slit diaphragm so that only small amounts of albumin pass into the urinary space. In most proteinuric states, the podocytes are injured, leading to foot process swelling and injury to the slit diaphragm; in these situations, large amounts of protein (albumin) can pass through the GBM and the gaps between the fused foot processes *(red arrows)*.

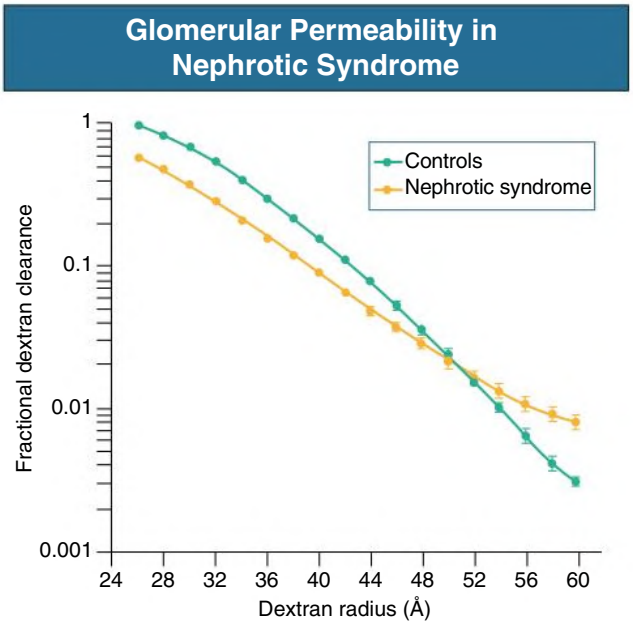

Fig. 17.5 Glomerular Permeability in Nephrotic Syndrome. Dextran sieving curve shows the relative glomerular permeability of different-sized dextrans in normal individuals and nephrotic patients with membranous nephropathy and minimal change disease. Nephrotic patients actually have a lower fractional dextran clearance for small dextrans (26–48 Å [2.6–4.8 nm]) but have an increased clearance for dextrans of larger molecular weight (52–60 Å [5.2–6.0 nm]). This is consistent with large pores appearing in the glomerular basement membrane. (Modified from Machuca E, Hummel A, Nevo F, et al. Clinical and epidemiological assessment of steroid-resistant nephrotic syndrome associated with the NPHS2 R229Q variant. *Kidney Int.* 2009;75:727–735.)

TABLE 17.2 Antigens Identified in Glomerulonephritis

Disease	Antigens
Poststreptococcal GN	Streptococcal pyrogenic exotoxin B (SPEB), plasmin receptor
Anti-GBM disease	α3 type IV collagen (likely induced by molecular mimicry)
IgA nephropathy	Possibly no antigen but rather polymeric polyclonal IgA (? superantigen driven)
MN[a]	Phospholipase A_2 receptor Thrombospondin type-1 domain-containing 7A Neutral endopeptidase in podocyte (congenital) HBeAg (hepatitis B virus associated)
Staphylococcus aureus–associated GN	*Staphylococcus* superantigens induce polyclonal response; not necessarily antigen in glomeruli
MPGN	HCV and HBsAg in hepatitis-associated MPGN

[a]See Chapter 21 for less common newer autoantigens.
GBM, Glomerular basement membrane; *GN,* glomerulonephritis; *HBeAg,* hepatitis B early antigen; *HBsAg,* hepatitis B surface antigen; *HCV,* hepatitis C virus; *IgA,* immunoglobulin A; *MPGN,* membranoproliferative GN pattern; *MN,* membranous nephropathy; *SPEB,* streptococcal pyrogenic exotoxin B.

Mechanisms of Immune Glomerular Injury

Two major mechanisms account for the presence of immune complexes in glomerular diseases. There may be ineffectual clearance of an antigen from an impaired immune response, as in chronic viral infections caused by hepatitis B or hepatitis C virus (HBV or HCV). Despite a strong humoral response, viral infection persists because the cell-mediated response required for elimination of these viruses is impaired. The consequence is a state of persistent antigenemia with circulating antigen-antibody complexes, which predisposes to glomerular injury. Eradication of the virus with antiviral therapy can be associated with remission of the glomerular disease.

More often, glomerular disease results from autoimmunity. In health, a tension exists between the normal immune response to foreign antigen and tolerance, which is the cellular process that prevents an immune response to self-antigen. Tolerance develops because self-reactive T and B cells are clonally deleted during fetal and neonatal life, although small numbers survive outside the thymus or bone marrow, respectively. Under certain conditions, these peripheral self-reactive cells can be stimulated to generate a cellular and humoral response to a self-antigen. Infection or toxins may play a role in initiating the response by releasing antigens from sequestered sites so they have access to dendritic cells, which carry the antigen to lymph nodes for presentation to T cells, by altering host proteins to make them more immunogenic, or by molecular mimicry, in which antibodies to an exogenous antigen (e.g., those present in infecting organism) cross-react with a native protein.[12] Activation of T cells may be further enhanced by the release of cytokines or endogenous danger-associated molecular patterns, such as toll-like receptor ligands or inflammasome activators, and the conversion of normally innocuous endogenous renal cells into antigen-presenting cells through the upregulated or de novo expression of human leukocyte antigen (HLA) class II molecules and cytokines.

Regulatory T cells ($CD4^+$, $CD25^+$) have a key role in controlling T cell responses and preventing the development of autoimmunity. However, their role is not well understood, and the local regulation of these cells in the kidney by a subset of dendritic cells ($CD103^+$) may be more important than systemic numbers of regulatory T cells.[13]

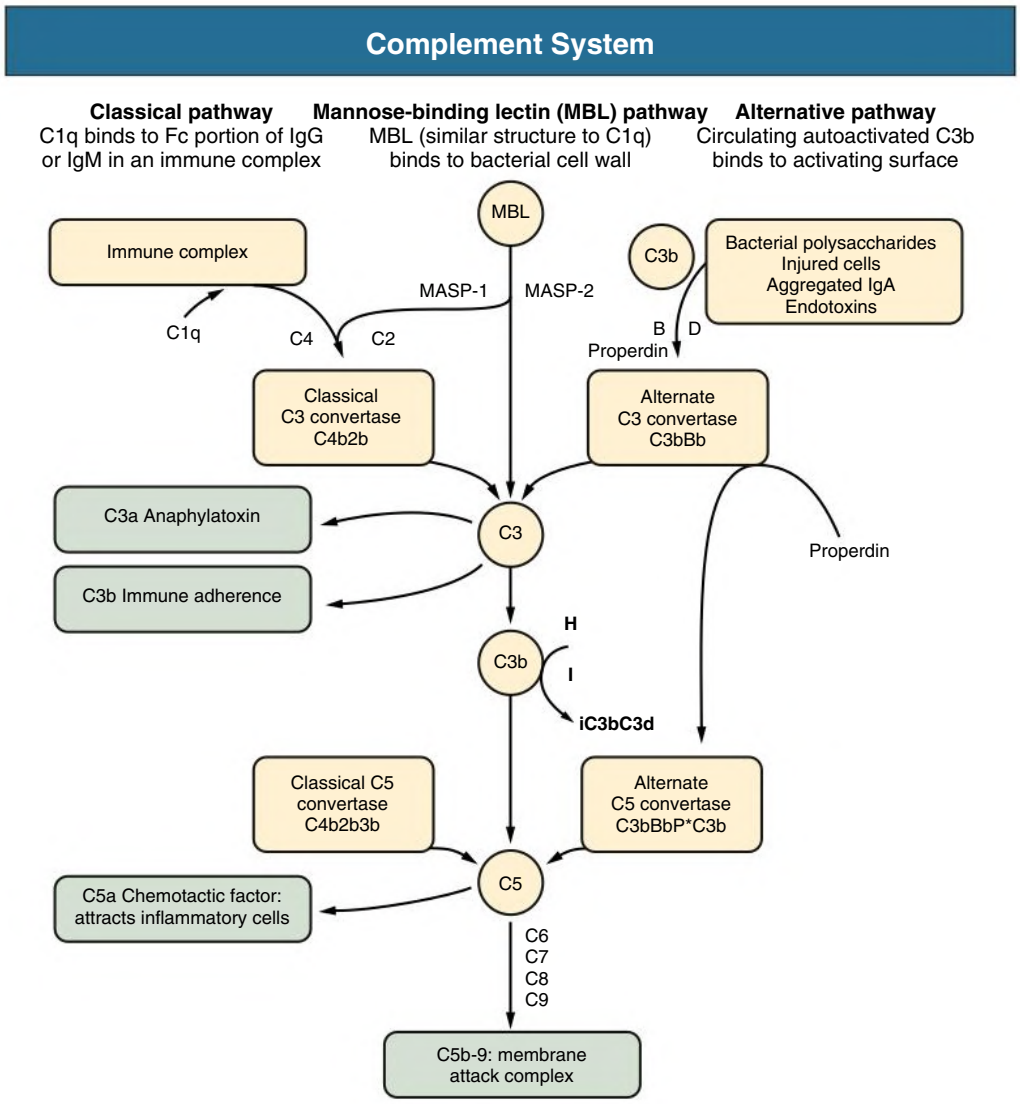

Fig. 17.6 Complement System. The complement system is a self-amplifying cascade of proteins that generates a membrane attack complex, which is cytolytic; the cascade promotes inflammation by the activity of the fragments it produces. The amplifying cascades result from activated fragments of the components combining to make convertase enzymes that degrade C3 and C5. The complement cascade is controlled in part by the short active life of many of its components. There are also inhibitory regulatory proteins, most notably factors H and I inhibiting C3b. Activated fragments of any component are designated *b* (e.g., C3b); anaphylatoxic fragments are designated *a* (e.g., C5a). Inflammatory functions of complement components are shown in green. *IgA,* Immunoglobulin A; *MASP,* MBL-associated serine protease.

Variations in HLA molecules and the T cell receptor are under strong genetic influence. Close immunogenetic associations, particularly between HLA expression and various patterns of GN, have been described in IgA nephropathy, MN, and other glomerular diseases. For example, whereas HLA-DR2 identifies a powerful relative risk for the development of Goodpasture disease, some individuals can develop the disease without HLA-DR2, and the vast majority with HLA-DR2 never develop this rare disease. HLA associations also differ among various ethnic groups. To date, HLA associations have no practical diagnostic or therapeutic implications, and HLA typing is not needed in the clinical management of patients with GN.

Inflammation

The presence of glomerular inflammation is largely determined by the site of immune deposits. Immune deposits with direct access to the circulation (subendothelial and intrabasement membrane locations) are usually associated with leukocyte accumulation. Mesangial deposits elicit an intermediate response, whereas immune deposits in the subepithelial space generally are not associated with inflammatory cells.

In GN associated with subendothelial deposits, such as class III or IV lupus nephritis or MPGN, leukocyte infiltration is common. With acute injury, the predominant infiltrating cells are platelets and monocytes, and occasional neutrophils, and in chronic injury the predominant cells are monocyte/macrophages and T cells. The primary mechanism for attracting these cells is the secretion of chemokines and the expression of leukocyte adhesion molecules by local endothelial and resident cells; local release of complement activation fragments (C5a) is also important.

Although neutrophils are common with immune complex disease, cell-mediated immunity is important in some glomerular diseases. For example, T cells likely have a role in crescentic nephritis, becoming

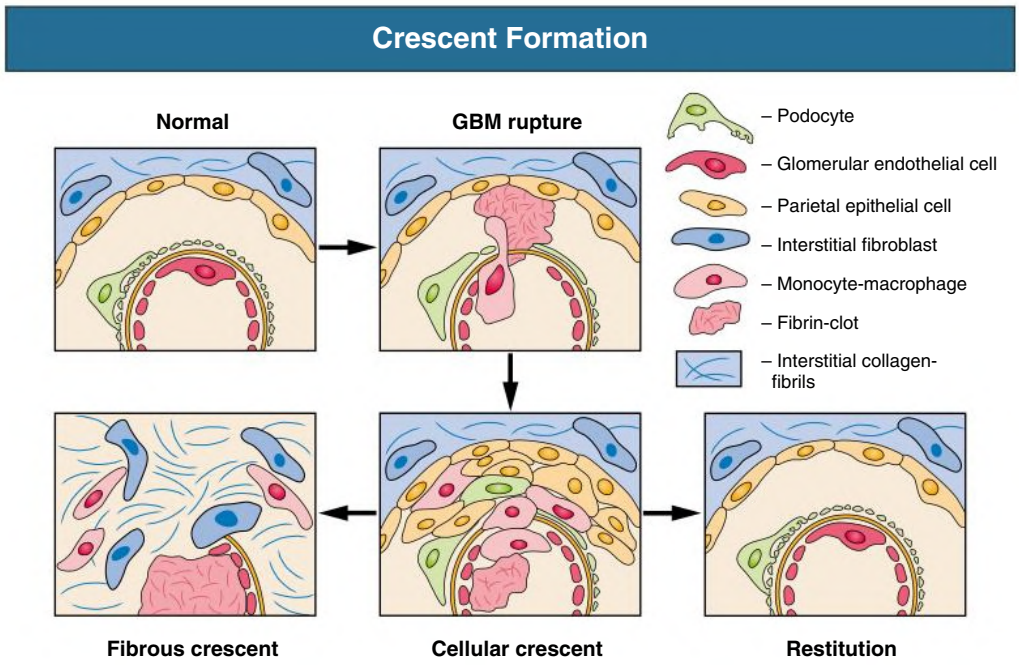

Fig. 17.7 Crescent Formation. In early crescent formation, cytokines and growth factors cross the glomerular basement membrane (GBM) to initiate proliferation of the parietal epithelial cells. Small breaks in the GBM occur secondary to injury from oxidants and proteases from neutrophils and macrophages, thus allowing the macrophage to enter Bowman's space, where it can proliferate. Breaks in Bowman's capsule secondary to the periglomerular inflammation also occur, allowing the entrance of more inflammatory cells, as well as fibroblasts. The proliferation of parietal and visceral epithelial cells and macrophages is associated with fibrin deposition, slowly choking the glomerular tuft until filtration becomes impossible. In the late stages, the crescent becomes fibrotic and the glomerulus end stage. Alternatively, in less severe cases, complete restitution of the glomerular tuft can occur.

sensitized to endogenous or exogenous antigen and then recruiting macrophages that mediate crescent formation.

Proliferation, Apoptosis, and Fibrosis

Intrinsic glomerular cells (epithelial, mesangial, and endothelial) are also activated in various glomerular diseases. Mesangial cells can become myofibroblast-like cells that proliferate and produce excessive extracellular matrix. Endothelial cells produce nitric oxide and other antiinflammatory proteins, and injury to this cell population can result in the expression of leukocyte adhesion molecules and activation of the coagulation system. Podocytes are differentiated epithelial cells that when injured undergo shape change (reorganization of the actin filaments) that can lead to disruption of the slit diaphragm, resulting in proteinuria. Interestingly, podocytes also can be induced to express receptors involved in antigen presentation that are similar to those expressed by dendritic cells. Progressive loss of podocytes by apoptosis is associated with the development of glomerulosclerosis. Important growth factors associated with glomerular injury include transforming growth factor β (TGF-β), which mediates matrix deposition; platelet-derived growth factor (PDGF), which mediates mesangial cell proliferation; and vascular endothelial growth factor (VEGF), required for endothelial health.

Crescent formation represents a severe cellular response and is initiated by cytokine-driven proliferation, particularly of the parietal epithelial cells. Local breaks in the GBM or Bowman's capsule, mediated by activated leukocytes, are followed by macrophage infiltration, proliferation of parietal epithelial cells and podocytes, and local fibrin deposition (Fig. 17.7).

Glomerular scarring (i.e., sclerosis) is characterized by proliferation of mesangial cells with loss (apoptosis) of endothelial cells and podocytes and deposition of extracellular matrix. Tubulointerstitial fibrosis also accompanies progressive glomerular disease and correlates with both renal function and prognosis. Proteinuria has been shown to activate tubular cells and induce toxicity, either directly or through the generation of oxidants (from iron proteins excreted in urine) or from complement activation, which can be shown in proteinuric urine. Tubulointerstitial ischemia after loss of glomerular and peritubular capillaries also may drive fibrosis. Finally, loss of renal function may result from leakage of plasma ultrafiltrate into the peritubular space, resulting in a scarring response (misdirected filtration) or stenosis/occlusion of the opening of the proximal tubule from Bowman's space, resulting in nonfunctional (atubular) glomeruli. A detailed discussion of current mechanisms involved in glomerulosclerosis is presented in Chapter 81. Specific pathogenic mechanisms in the different patterns of glomerular disease are discussed in subsequent chapters in Section IV.

PATHOGENESIS OF SPECIFIC GLOMERULAR SYNDROMES

Minimal Change Disease

Minimal change disease (MCD) is a steroid-sensitive nephrotic syndrome in which the only structural abnormality is podocyte swelling and fusion of foot processes on EM (see Chapter 18). For many years, the podocyte injury in MCD was thought to be caused by a cytokine released from T cells. T cells are activated in MCD, and T cell hybridomas from these patients were reported to secrete a factor that provokes heavy proteinuria in rats.[14] One candidate cytokine is interleukin-13 (IL-13), which is expressed by T cells in patients with MCD; overexpression of IL-13 causes nephrotic syndrome and histologic changes consistent with MCD in rats. However, proteinuria can

be induced in immunodeficient mice using CD34-positive hematopoietic bone marrow cells of patients with MCD and recurrent FSGS but not by their T cells.[15] Thus, the role of T cells in this disorder remains to be clarified.

Evidence also suggests that the podocyte injury is associated with overexpression of angiopoietin-like-4, which is associated with a proteinuric response.[16] This overexpression can be reduced with corticosteroids and *N*-acetyl-D-mannosamine. In addition, patients with MCD show high levels of CD80 (also known as B7.1) in urine and in podocytes, and the level of urinary CD80 correlates with disease activity. CD80 is an antigen that is normally expressed by dendritic cells and B cells.

Finally, two additional discoveries have been recently made. The first is the observation that a subset of patients with MCD have antibodies to nephrin despite IF showing minimal IgG deposition in glomeruli. The other observation is that the majority of individuals with MCD have evidence for mild glomerular endothelial injury with circulating endothelial biomarkers. This has suggested that MCD is not a strict "podocytopathy" as originally proposed.

Focal Segmental Glomerulosclerosis

Focal segmental glomerulosclerosis (FSGS) is a generic term to describe a pattern of glomerular scarring and is therefore nonspecific. Focal segmental sclerosing lesions in the absence of nephrotic syndrome, often termed *secondary FSGS,* can occur in a range of contexts, including GN, chronic hypertension, obesity, and progressive renal disease of any etiology. These lesions are particularly common in African Americans; recent findings suggest this susceptibility relates to increased frequency of a genetic polymorphism in *APOL1,* a gene coding for a circulating lipoprotein.

When the histologic pattern of FSGS is seen in association with the nephrotic syndrome (a podocytopathy often termed *primary FSGS* if there is no associated condition), immune deposits are absent, but as with MCD, there is a generalized foot process fusion (also termed *effacement*) on EM (see Chapter 19). However, unlike MCD, there is segmental scarring (sclerosis) in some glomeruli with FSGS. Some forms of FSGS result from mutations of podocyte proteins (see Chapter 20), whereas others are believed to originate from a circulating factor; cardiotrophin-like cytokine 1 is one candidate molecule, but others are also being investigated as potential circulating factors that may mediate FSGS (see Chapter 19). Although it is unproven, some consider that MCD and FSGS share similar pathogenic mechanisms and are part of a "podocytopathy" spectrum in which MCD has lower levels of the circulating factor and is therefore more sensitive to corticosteroids. These forms of FSGS may be particularly prone to rapid recurrence, sometimes within hours, after renal transplantation.

A variant of FSGS is *collapsing FSGS,* in which there is proliferation of the normally quiescent podocyte, leading to collapse of the glomerular tuft, often in association with massive proteinuria. The pathogenesis may involve production by the podocyte of growth factors such as VEGF or local inhibition of cell cycle proteins that normally maintain the podocyte in a nonproliferative state.[17]

Membranous Nephropathy

In membranous nephropathy (MN), immune deposits are localized to the subepithelial space, representing autoantibody binding to an intrinsic podocyte antigen (see Chapter 21). The major antigen is the M-type phospholipase A_2 receptor (PLA_2R), accounting for as many as 70% of cases of idiopathic MN.[18] Antibodies to PLA_2R are specific for MN. Circulating anti-PLA_2R reflects the immunologic activity of the disease and may be useful to monitor the clinical course, including patient response to treatment. Other autoantibodies have been found, albeit much less frequently, including those against thrombospondin type-1 domain-containing 7A,[19] exostosin-1 and exostosin-2,[20] neutral endopeptidase (in the very rare neonatal MN), or against bovine serum albumin (BSA).[21] Some cases of MN may be caused by low-avidity immune complexes, which may dissociate and then reform at the subepithelial space; this may be a mechanism for some MN caused by viruses such as HBV.

Most cases of idiopathic MN caused by anti-PLA_2 antibodies are associated with IgG4 deposition, which is an isoform of IgG that does not activate the classic complement pathway. However, there is evidence that the IgG4-PLA_2 complex can activate complement through the MBL complement pathway, resulting in local generation of the membrane attack complex (C5b-9), which may insert into the podocyte to cause activation, injury, and proteinuria.

Glomerulonephritis With a Membranoproliferative Pattern on Histology

The term MPGN describes a histologic pattern rather than a single disease entity. The pattern may result from localization of immune deposits to both the mesangium and the subendothelial space (see Chapter 22). One of the diseases causing an MPGN pattern is cryoglobulinemic GN, in which the immune complexes contain a monoclonal IgM or polyclonal IgM that acts as a rheumatoid factor by binding to the IgG in the immune complex. Whether due to cryoglobulinemia or another cause, the MPGN pattern and its clinical consequences are thought to occur by passive deposition from the circulation, and the antigen is often a component of the HCV virus, especially in adults. When this pattern is seen in lupus nephritis, it may be facilitated by the binding of extracellular nucleosomes to the complexes. Nucleosomes are cationic nuclear proteins that can interact with the negatively charged proteins within the glomerulus.

Studies in experimental models suggest that the intraglomerular immune complexes cause local complement activation with the generation of chemotactic factors, including C5a, chemokines, and leukotrienes. Leukocyte adhesion molecules on endothelial cells are upregulated (intracellular adhesion molecule 1) or expressed de novo (E- and P-selectin). Proinflammatory cytokines (IL-1 and tumor necrosis factor-α) are generated locally and augment the inflammatory response. Neutrophils, platelets, and monocytes/macrophages then localize in the glomerulus and release oxidants, particularly hypohalous acids generated by neutrophil myeloperoxidase, and proteases (elastase, cathepsin G, metalloproteinases) that cause local cellular injury and GBM degradation.

Dense Deposit Disease and C3 Glomerulonephritis

In contrast to the MPGN forms described above, immune complexes are absent in glomeruli of patients with DDD and C3-GN. Initiation results from spontaneous intraglomerular activation of the alternative complement pathway. The most common cause is nephritic factor, an autoantibody that activates the alternative pathway. Some cases may be caused by mutations of the complement regulatory factor H, in which case the location of the mutation within the gene determines whether the disease manifests as DDD or atypical HUS.[22]

Mesangial Proliferative Glomerulonephritis

IgA nephropathy is the most common type of GN (see Chapter 24). Production of an abnormally glycosylated IgA, possibly by a bacterial superantigen,[23] or perhaps from an altered mucosal immune system, may lead to IgA polymers that deposit in the mesangium; the glomerular capillary wall is relatively spared. Marked yet usually nonnephrotic proteinuria is a common feature of the clinical presentation. Mesangial cell injury may be mediated by binding of the IgA-containing immune complexes to Fcα or other IgA receptors on the mesangial cell, resulting in the release of chemokines and growth factors that provokes leukocyte infiltration as well as mesangial cell proliferation and mesangial matrix production.

Poststreptococcal Glomerulonephritis

Poststreptococcal GN (PSGN) has long been considered the human equivalent of acute serum sickness in rabbits (see Chapter 57). It is observed only in patients infected with specific (nephritogenic strains) of group A streptococci. One antigen responsible for some cases of PSGN, streptococcal pyrogenic exotoxin B, enters the circulation and localizes to glomeruli, resulting in a brisk inflammatory reaction with local endothelial and mesangial cell proliferation and manifestations of nephritic syndrome. Complement activation occurs through the alternative pathway and may result from direct activation of the pathway by streptococcal antigens. Some deposits ("humps") also form in the subepithelial space and may represent the translocation of immune complexes across the GBM or in situ immune complex formation.

Goodpasture Disease

Goodpasture disease (anti-GBM disease) is caused by an autoantibody to the α3 chain of type IV collagen present in the GBM and alveolar basement membrane (see Chapter 25). The autoantibody develops in genetically susceptible individuals because of molecular mimicry between the type IV collagen antigens and certain bacterial antigens.[9] Binding of antibody results in complement activation with the infiltration of inflammatory cells, causing local capillary wall damage and proteinuria. Crescent formation also usually occurs and may be mediated by both T cells and macrophages.

Antineutrophil Cytoplasmic Antibody–Associated Vasculitis

A severe form of segmental necrotizing glomerular injury, often in association with crescents, can be observed with vasculitis (see Chapter 26). The two most common types of vasculitis causing this type of injury are granulomatosis with polyangiitis (GPA) and microscopic polyangiitis (MPA). Both are associated with circulating antibodies against neutrophil cytoplasmic antigens (ANCAs), with antibodies to endopeptidase (proteinase) 3, which give a cytoplasmic pattern by staining (c-ANCA) in most patients with GPA granulomatosis, and antibodies to myeloperoxidase, which give a perinuclear staining pattern (p-ANCA) in subjects with MPA. Experimental evidence suggests that ANCAs are pathogenic by activating neutrophils within the vasculature. The mechanism responsible for triggering autoantibodies to neutrophil antigens remains unclear, although geographic and temporal clustering suggest a role for infection or antigen exposure that may induce an autoimmune response.[12]

Further discussion of specific pathogenic mechanisms in the different patterns of glomerular disease can be found in Chapters 18 to 30.

SELF-ASSESSMENT QUESTIONS

1. MN may result from all of the following *except:*
   - **A.** Anti–phospholipase A_2 receptor antibodies
   - **B.** Thrombospondin type-1 domain-containing 7A antibodies
   - **C.** Antibodies to cationic bovine serum albumin
   - **D.** Factor H deficiency
   - **E.** Deposition of hepatitis B virus antigens and antibody
2. A low serum C3 level would suggest all the following diseases *except:*
   - **A.** Membranoproliferative glomerulonephritis secondary to hepatitis C virus
   - **B.** Cryoglobulinemic glomerulonephritis accompanying bacterial endocarditis
   - **C.** Class IV lupus nephritis
   - **D.** Goodpasture disease
   - **E.** Class III lupus nephritis
3. Marked proteinuria typically results from damage to which structures?
   - **A.** Mesangial cells
   - **B.** Parietal epithelial cells
   - **C.** Podocytes
   - **D.** Preglomerular arterioles
   - **E.** Loops of Henle
4. Which statement best describes FSGS?
   - **A.** It is typically a disease of the mesangium.
   - **B.** It usually results in nephrotic syndrome.
   - **C.** It can result from a circulating factor.
   - **D.** It is an autoimmune disease.
   - **E.** Most cases result from mutations.

Minimal Change Disease

Charlotte Seneschall, Gabriel Cara Fuentes, Megan Griffith

INTRODUCTION

Minimal change disease (MCD) is the most common cause of nephrotic syndrome in children (approximately 80%) and accounts for 10% to 20% of cases in adults. MCD is so called because on kidney biopsy, glomeruli are normal or near normal on light microscopy, with podocyte foot process fusion or effacement found on electron microscopy. Compared to other causes of nephrotic syndrome, MCD has a higher rate of remission after steroid treatment, with better long-term kidney outcomes. However, MCD still causes significant morbidity, especially in older patients, due to complications such as acute kidney injury (AKI) and thrombosis. A high proportion of patients with MCD relapse, resulting in the need for multiple courses of steroids or alternative immunosuppressive therapy and significant associated side effects.[1]

EPIDEMIOLOGY

The International Study of Kidney Disease in Children (ISKDC) study found that 363 of 471 (77%) children presenting with nephrotic syndrome had MCD as the underlying histologic diagnosis,[2] and MCD accounted for 94% of cases in patients younger than 6 years who responded to an 8-week course of oral steroids. In older children with nephrotic syndrome, the proportion with MCD decreases steadily, reaching about 50% of all cases between ages 8 and 16 years, with a rising proportion secondary to focal segmental glomerulosclerosis (FSGS) relative to MCD.

The incidence of MCD in children ranges from 1.2 to 7 new cases per 100,000 population. It has a higher incidence during winter and shows variability among different populations. The incidence of MCD is reported to be as low as 1 per million population in the United Kingdom and up to 27 per million in the United States. It is less common in Blacks, in whom nephrotic syndrome is much more likely to be caused by FSGS.[3] In adults, MCD is generally rarer than in children, although incidence is less well defined.

ETIOLOGY

Most patients have idiopathic MCD. Secondary MCD is usually clinically indistinguishable from idiopathic MCD[1]; causes include Hodgkin disease and nonsteroidal antiinflammatory drugs (NSAIDs) (see Table 18.1 for full list).

Stimulation of the immune system (e.g., by infections or atopic reactions) has been linked with both onset and relapses of MCD. In children, most exacerbations occur with an upper respiratory infection,[1] and recent reports show an association with SARS-CoV-2. Atopic individuals have a higher risk of MCD, and atopic reactions, such as to pollen, bee stings, and food allergens, have been reported as triggers of MCD relapses. This clinical association led to the introduction of allergen-free diets for patients with MCD, and a gluten-free diet, elemental diets, or skin desensitization may result in a decrease in proteinuria.[4] A link between vaccinations and presentations and relapses of MCD has also been suggested.

Rare cases of familial MCD have been reported but likely represent an underlying mutation in genes encoding for slit diaphragm proteins instead of primary or idiopathic MCD.[5] Certain human leukocyte antigen alleles and other genes have been suggested to lead to an increased risk of MCD.[6]

PATHOGENESIS

Traditionally, MCD has been considered an immune disorder in which circulating T cells release factors that increase the permeability of the glomerular filtration barrier to plasma proteins by altering podocyte shape. However, the pathogenesis remains poorly understood. Fig. 18.1 summarizes proposed pathways involved in MCD.

Circulating Factors as Mediator of Disease

In 1974, Shalhoub postulated that MCD was a T cell–mediated disorder based on the lack of immune deposits in the glomerulus, the rapid response to steroids, the association with Hodgkin disease, and the observation that remission often occurred during resolution of measles infection.[7] This hypothesis was supported by the observations that (1) supernatants from T cell hybridomas from a patient with MCD induced podocyte injury and proteinuria in rats,[8] and (2) proteinuria remitted when kidneys from a patient with active MCD were transplanted into patients without nephrotic syndrome.[9] Several candidate molecules have been considered as possible circulating factors.

Cytokines

Certain T cell cytokines have been proposed as circulating factors, including interleukins IL-4 and IL-13. Some animal studies have shown that IL-13 or IL-4 can lead to increased proteinuria and foot process effacement, although how this translates to human MCD is unclear.[10] Levels of IL-4 and IL-13 are higher in children with nephrotic relapse compared with healthy controls or those in remission, although this is not true for all patients. IL-4 and IL-13 are both produced as part of a Th2 immune response, which underlies atopy. Cytokines from other T cells may also be implicated. IL-17 and IL-23 from proinflammatory Th17 cells are higher in MCD than controls, whereas IL-10 and TGFβ from opposing T-regulatory (Treg) cells are higher in controls. An increased Th17:Treg ratio was found in MCD patients compared with a control group. This ratio normalized with therapy, leading to the hypothesis that MCD may be due to an imbalance of proinflammatory Th17 cells and immune-modulatory Tregs.[11] Other proinflammatory cytokines of the innate immune system may also have a role in MCD. IL-8 has also been shown to increase urine protein creatinine ratio after its infusion into rats.[12] Tumor necrosis factor-α (TNF-α) has also been shown to act directly on podocytes, where it causes nephrin

TABLE 18.1 Secondary Causes of Minimal Change Disease

Causes	Examples
Drugs	NSAIDs, interferon-α, lithium (rare: usually causes chronic interstitial nephritis), tamoxifen, antimicrobials (ampicillin, rifampicin, cefixime), gold (rare: usually causes membranous nephropathy), mercury in skin-lightening products
Allergy	Pollen, house dust, insect stings, poison oak
Hematologic conditions	Hodgkin disease, non-Hodgkin lymphoma, leukemia, hemophagocytic syndrome, myelodysplastic syndrome
Solid organ tumors	Most commonly lung, colorectal, renal cell carcinoma, thymoma (rare: pancreatic, breast, bladder, ovarian)
Other	Immunizations

NSAIDs, Nonsteroidal antiinflammatory drugs.

downregulation, restructuring of the actin cytoskeleton, and altered focal adhesions.[13] However, case studies show that TNF-α blockade with etanercept can also lead to MCD.

Hemopexin

Hemopexin is synthesized in the liver and is present in human plasma of patients with MCD. Mechanistically, hemopexin is thought to mediate podocyte injury in a nephrin-dependent manner, but the role of hemopexin in MCD remains unproven.

Microbial Products

A role for microbial products as circulating factors is attractive because of the association between upper respiratory infections and relapses. Two toll-like receptor (TLR) ligands, lipopolysaccharide (LPS), a component of the outer membrane of gram-negative bacteria, and polyinosinic-polycytidylic acid (polyIC), a viral-like particle, bind to TLR-4 and TLR-3 on podocytes, respectively, and cause proteinuria in animals.[14] However, the relevance of these findings for human MCD remains unknown.

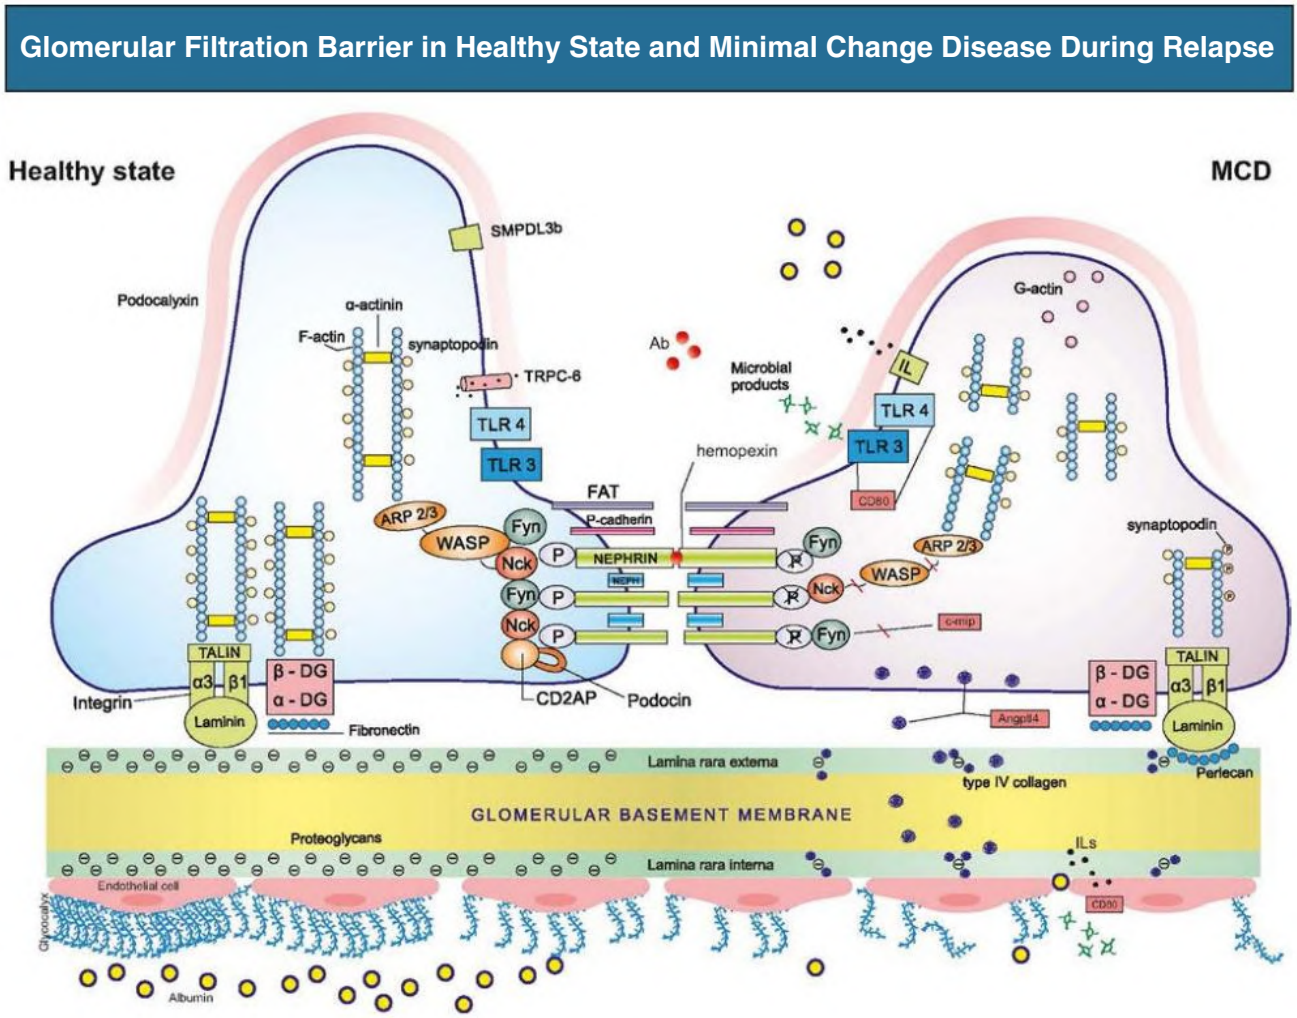

Fig. 18.1 Glomerular Filtration Barrier in Healthy State *(left)* and in Minimal Change Disease (MCD) During Relapse *(right).* In MCD, microbial products, circulating interleukins, hemopexin, and/or antinephrin antibodies (Ab) may target podocytes leading to foot process effacement and proteinuria. Circulating products may target and activate endothelial cells during relapse. Upregulation of CD80, c-mip, and angiopoietin-like 4 (Angptl4) seem to play a role in experimental models of MCD-like injury. *ARP 2/3,* Actin-related protein 2/3 complex; *CD80,* cluster of differentiation 80; *CD2AP,* CD2-associated protein; *c-mip,* c-maf inducing protein; *DG,* dystroglycans; *IL,* interleukin receptor; *SMPDL3b,* sphingomyelin phosphodiesterase acid like 3B; *TLR,* toll-like receptor; *TRPC6,* Transient receptor potential cation channel subfamily C member 6; *WASP,* Wiskott-Aldrich syndrome protein. (Figure created using biorender.com.)

Loss of Anionic Charges in the Glomerular Filtration Barrier

Heparan sulfate proteoglycans (HSPs) represent the major source of anionic sites in the glomerular basement membrane (GBM), and loss of HSP is observed in some MCD patients. Although HSP loss was thought to facilitate the passage of albumin through the GBM, subsequent experimental studies do not support this hypothesis driving proteinuria in MCD.[15] An "electrokinetic model" has been proposed in that the endothelial glycocalyx represents a major site for the generation of a streaming potential that would repel albumin before passing through endothelial fenestration.[16] Scattered reports showed increased circulating markers of endothelial injury in MCD, but their significance is unknown.

Podocyte Dysfunction as a Cause of Minimal Change Disease

In patients with MCD during relapse, podocytes display several molecular changes. An increase in podocyte focal adhesion kinase phosphorylation has been reported in MCD but not in FSGS.[17] Likewise, changes in nephrin expression, phosphorylation, and localization have been reported by several groups.[18] In experimental models, few molecules have been thought to mediate podocyte injury (Fig. 18.1).

CD80. In cultured podocytes, CD80 mediates actin reorganization and podocyte migration by targeting Neph 1 and β1 integrins. In some patients with active MCD, CD80 can be upregulated in glomerular cells, primarily glomerular endothelial cells but also podocytes.[19] In addition, most patients with MCD have higher urinary CD80 levels than patients with other glomerular disease,[20] but the relevance of this finding remains unknown. Anti-CD80 therapy has been associated with remission in two patients with MCD and high urinary CD80, whereas results in patients with FSGS have been contradictory.

Angptl4. This is a glycoprotein that has been proposed as a mediator of proteinuria in MCD. In a transgenic rat model characterized by glomerular overexpression of Angptl4 and podocin, rats had a marked loss of GBM heparan sulfate proteoglycans, podocyte foot process effacement, and albuminuria.[21] However, data on Angptl4 in MCD are scarce and conflicting. A larger study did not confirm that MCD is associated with glomerular overexpression of Angptl4. In addition, urinary Angptl4 levels do not differ between different glomerular diseases.[22]

C-mip. Experimental studies provide evidence for a pathogenic role of podocyte c-mip in proteinuria and podocyte injury. Mechanistically, c-mip impairs nephrin phosphorylation, which is a molecular feature of MCD. C-mip is upregulated in podocytes from patients with MCD but also in patients with other glomerular diseases,[23] so the exact role of c-mip in MCD is yet to be determined.

Role of B cells

The anti-CD20 monoclonal antibody rituximab has been effective for treating some patients with MCD, suggesting that B cells could be implicated in MCD. Recently, some patients with MCD were found to have antinephrin antibodies in circulation and in glomeruli.[23b] Still, the role of B cells in MCD, either secreting antibodies or modulating T cell activation, remains poorly understood. It has been postulated that rituximab exerts a direct protective role in podocytes by binding to sphingomyelin phosphodiesterase acid-like 3 b (SMPDL3B),[24] but this remains controversial.[10]

In summary, the mechanisms of podocyte injury in MCD remain unknown. How findings from experimental studies may translate to human disease remain a matter of debate and clearly require further investigations. It also highlights the need to develop novel animal models of MCD. The observation that glomerular endothelial cells are activated during relapse warrants further investigation, as well as the role of B cells and B cell–T cell interactions in MCD.

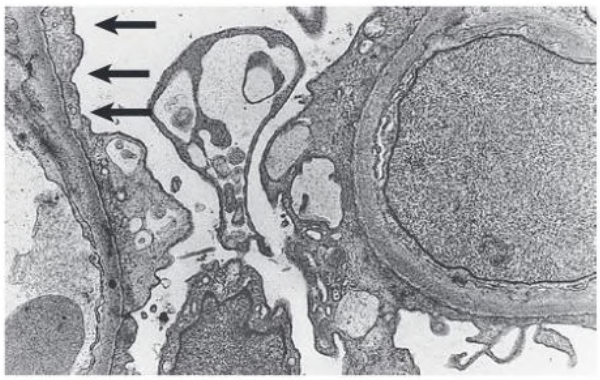

Fig. 18.2 Podocyte Toot Process Fusion and Effacement in Minimal Change Disease. The epithelial cells *(arrows)* are completely effaced along the glomerular basement membranes. (Electron micrograph; magnification ×6000.) The normal appearance of epithelial cell foot processes is shown in Chapter 1, Figs. 1.6 and 1.7.

PATHOLOGY

MCD received its name because of the minimal, if any, glomerular abnormalities present by light microscopy. Mild changes such as a slight increase in mesangial matrix and hypercellularity may occasionally be observed. A small percentage (<10%) of glomeruli may display global, but not segmental, glomerulosclerosis, which may reflect the natural senescence of glomeruli observed in young adults. In a few cases, minor focal tubular atrophy with segmental interstitial fibrosis may be present. Fat and hyaline droplets also may be found in the proximal tubule.

By immunofluorescence, immunoglobulins or complement deposits are rarely found. If present, deposits are limited to the mesangium. There is a small subset of patients who have IgM deposits, which have been considered by some clinicians to represent an entity distinct from MCD known as *IgM nephropathy* and characterized by a poorer clinical outcome. Although mesangial IgM had been considered due to "passive trapping" and of no pathogenic significance, subsequent studies suggested IgM may be directed against mesangial antigens and contribute to proteinuria.[25] Some case series have found mesangial C1q deposits, which may be associated with worse outcomes, leading to the concept of C1q nephropathy (see Chapter 29). However, it remains controversial whether the long-term prognosis is dictated by the presence of C1q deposits or, most likely, by the presence or lack of glomerulosclerosis on light microscopy.

Electron microscopy demonstrates diffuse podocyte foot process effacement or fusion (Fig. 18.2). Although fusion of foot processes is observed in other nephrotic conditions, in the absence of light microscopy glomerular changes, the finding is pathognomonic for MCD. The GBM is normal, and no electron-dense deposits are observed.

CLINICAL MANIFESTATIONS

Rapid onset of pitting edema, worse in the lower extremities, is often the first sign of MCD. Some patients present with bilateral periorbital edema, often misinterpreted as an allergic process. Edema may be mild or severe, presenting as anasarca with pleural effusions and ascites. Bowel edema may manifest as diarrhea. The mechanism(s) of edema formation in MCD is not fully understood but may be due to both a decrease in oncotic pressure and an increase in sodium and water reabsorption in the distal tubule (see Chapter 16).

Abdominal pain and nausea are common manifestations in MCD. Pain is usually dull due to massive ascites and bowel hypoperfusion. This pain resolves after albumin is administered. Severe pain may be due to peritonitis or acute pancreatitis.

MCD usually presents with a normal blood pressure. However, approximately 20% of adult patients are hypertensive on presentation. Some patients may develop transient renin-mediated hypertension during relapse from hypovolemia and renal hypoperfusion. Urinary changes may also be noted. Patients may describe "frothiness" of the urine. Macroscopic hematuria is concerning for renal vein thrombosis.

Less commonly, patients with MCD may develop "white nails," sometimes in bands (Muehrcke lines) correlating with periods of clinical relapse (see Fig. 16.4). Adults may develop xanthomas and xanthelasmas, especially on the eyelids (see Fig. 16.5).

LABORATORY TESTS

Nephrotic syndrome is the combination of nephrotic-range proteinuria, hypoalbuminemia, hyperlipidemia, and edema. In children, nephrotic-range proteinuria is defined as greater than 50 mg/kg/24 h, greater than 40 mg/h/m^2 (urinary specimens collected overnight), 200 mg protein/mmol urine creatinine, or a ratio of urinary protein to creatinine (uPCR) greater than 3 mg/mg.[2] In adolescents and adults, nephrotic-range proteinuria is defined as greater than 3.5 g/24 h or an uPCR greater than 3 mg/mg. In MCD, proteinuria is not only massive but also selectively albuminuria (see Chapter 16). Urine microscopy shows hyaline casts and fat bodies, as well as microscopic hematuria in 20% of patients.

Hypoalbuminemia is defined by a serum level of albumin below 2.5 g/dL, and it is the result of the increased glomerular filtration permeability to plasma proteins. The liver production of albumin is increased in MCD patients, and gastrointestinal losses are minimal. In MCD, massive edema usually develops with serum albumin levels below 2 g/dL.

Hyperlipidemia (elevated total cholesterol and low-density lipoprotein [LDL] cholesterol) is a universal feature of patients with MCD in relapse, and if massive proteinuria is persistent, triglycerides and very-low-density lipoprotein (VLDL) are also elevated. Hyperlipidemia results from increased hepatic synthesis of cholesterol and triglycerides, decreased activity of lipoprotein lipase, and altered expression of proprotein convertase subtilisin/kexin type 9 (PCSK9; see Chapter 16). In addition, urinary losses of lecithin cholesterol acyltransferase lead to a reduction of chylomicrons and VLDL clearance. The hyperlipidemia resolves after resolution of proteinuria.

Kidney function is commonly normal, but acute kidney injury is seen in up to 25% of adults. Oliguria can occur, and some patients may require dialysis, which can be prolonged in some cases. Risk factors for AKI include older age, history of hypertension, and more severe nephrotic syndrome. AKI is also seen in children hospitalized with MCD. AKI in MCD can be due to intravascular depletion, but without excessive diuretic therapy, intravascular volume is not reduced. Despite this, up to 60% of kidney biopsies in MCD patients with AKI show acute tubular injury, suggesting ischemia, the mechanism for which is not understood. One theory is that the nephrotic state in MCD causes local release of the potent vasoconstrictor endothelin-1.[26]

Mild hyponatremia is common during relapse and may represent pseudohyponatremia due to hyperlipidemia. Total serum calcium may be low, as hypoalbuminemia leads to decreased protein-bound calcium. Ionized calcium is usually normal, and no treatment is indicated. Urinary losses of vitamin D–binding proteins can cause low vitamin D levels, and supplementation should be considered, especially if treatment with steroids is being considered.

Other Presentations (Complications)

Infection

Infections are a common complication of MCD, causing 19% of all hospital admissions for pediatric patients and a significant proportion of pediatric deaths. Mechanisms for increased susceptibility to infection are diverse, including disruption of complement, especially in the alternative pathway where urinary losses reduce levels of factors B and I, persistent hypogammaglobulinemia, and immunosuppressive burden. Pneumonia, urinary tract infection, bacteremia, and peritonitis have all been reported. The predominant infective agents are *Streptococcus pneumoniae, Haemophilus* species, and *Escherichia coli*.[27]

Thrombosis

The combination of hypercoagulability (decreased anti–thrombin III and proteins C and S and increased fibrinogen; coagulation factors V, VII, VIII, X, and XII; increased platelet aggregability) with hypovolemia (and resulting thrombocytosis) puts MCD patients at high risk for thrombosis. However, the risk is lower than in membranous glomerulonephritis (see Chapter 16). Thromboses are more common in adults than in children. Predisposing factors for development of thromboembolism include increased severity of the nephrotic syndrome at presentation, concurrent infection, male sex, and central venous catheterization. Presentations include pulmonary emboli, sagittal venous thrombosis, renal vein thrombosis, peripheral venous thrombosis, and less frequently, arterial thrombosis.[27] Children with nephrotic syndrome have a 2.8% chance of thromboembolism, whereas in adults that risk is 26.7%.[28]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Kidney Biopsy

MCD is the most common type of idiopathic nephrotic syndrome in children, and therefore kidney biopsy is not routinely done in children younger than 10 years. However, if there are features that are not characteristic for MCD, such as hypertension, red cell casts, gross hematuria, kidney dysfunction, or lack of response to steroids (4- to 6-week course), a kidney biopsy should be considered at presentation.

In adults, a kidney biopsy is required to establish the diagnosis. Clinical and pathologic findings must be carefully interpreted. A patient with normal-appearing glomeruli who does not respond to immunosuppression could have a hereditary disease associated with a podocyte mutation (e.g., congenital nephrotic syndrome; see Chapter 20). Some patients with FSGS may only have a small percentage of glomeruli affected, which may not be evident on initial kidney biopsy sample due to sampling error. Indeed, there is ongoing debate about whether MCD and FSGS represent different diseases or whether they are the same disease at different stages.[1] MCD patients with steroid resistance often have findings consistent with FSGS in subsequent kidney biopsies.

NATURAL HISTORY OF MINIMAL CHANGE DISEASE

Children and adults with MCD classically present with nephrotic syndrome with normal kidney function, and spontaneous remission is uncommon in the absence of steroid treatment. Steroid treatment is usually effective in inducing remission, and time to remit with steroid therapy is longer with adults than children. In children, 50% of patients remit within 8 days of starting therapy, whereas adults have a median time to remission of over 2 months.

Up to 75% patients with both pediatric- and adult-onset MCD will have one or more relapses. Among children with MCD, 25% never relapse, 25% relapse infrequently, and 50% have numerous relapses. The last group are classified as frequent relapsers if they have at least four relapses per year and steroid dependent if relapse occurs during the steroid taper or soon after it is stopped. In adults, approximately 45% of patients have more than one relapse, a proportion of whom develop steroid dependence.[29] Relapses may occur at any point after

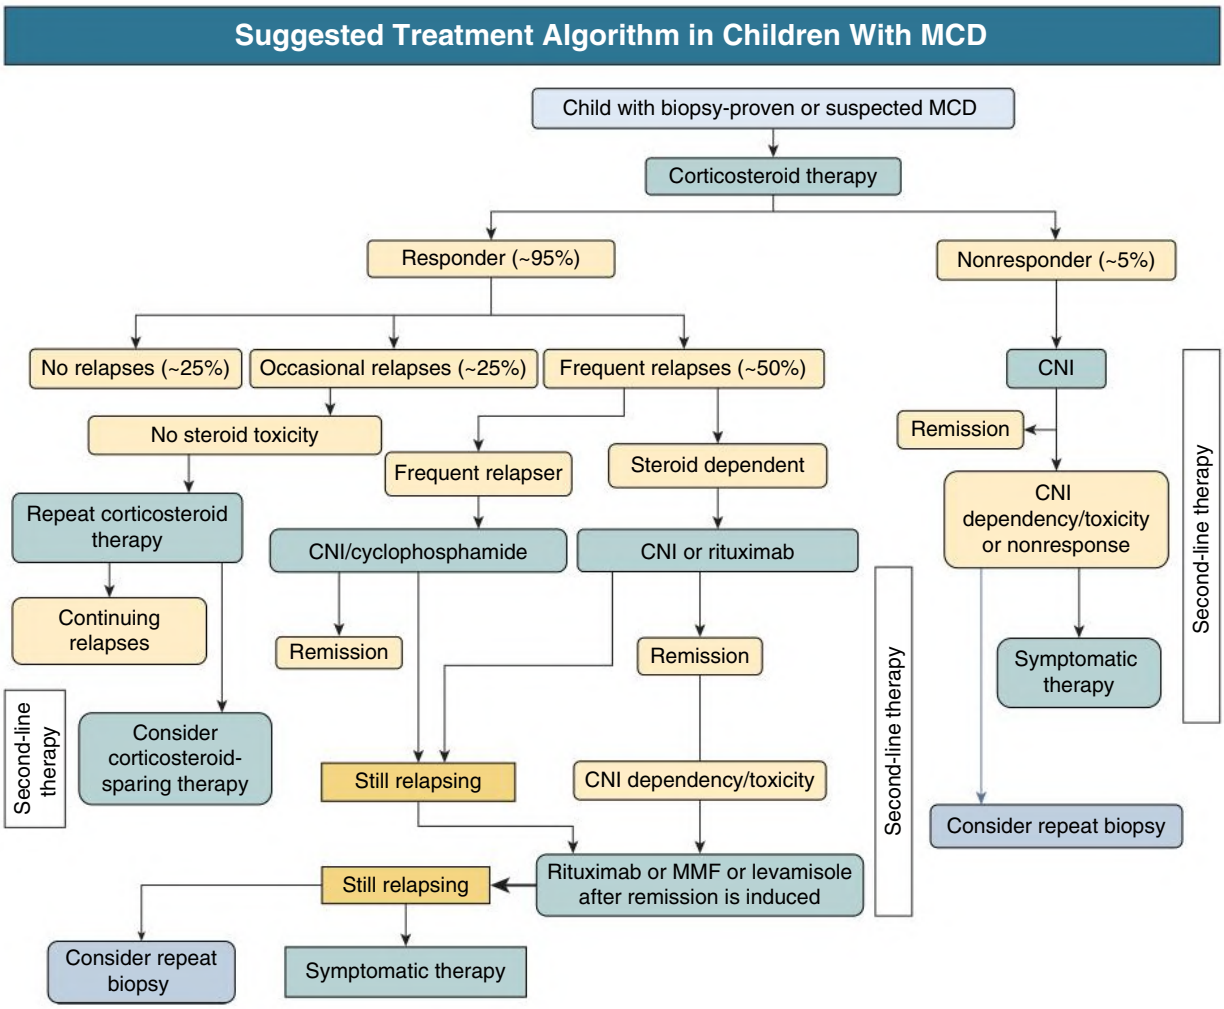

Fig. 18.3 Algorithm for Treatment of Childhood Minimal Change Disease. For definitions, see Table 18.2. The patient or parents should be involved in the decision after the potential side effects of the second-line treatment are considered in the rare patient who is a nonresponder to standard corticosteroid therapy and by definition is corticosteroid resistant. *CNI,* Calcineurin inhibitor; *MMF,* mycophenolate mofetil.

diagnosis, including at more than 15 years after initial presentation. However, patients in remission for more than 5 years may be less likely to relapse. There is no evidence that disease resolves during puberty, and it is not unusual to see children with MCD undergoing relapses during adulthood.

In contrast to FSGS, long-term kidney function in MCD is usually good. However, there is significant morbidity, mortality, and reduced quality of life, from both relapse and treatment, especially in older adults.

TREATMENT

General Considerations

Management of nephrotic syndrome is discussed in Chapter 16, including a low-sodium diet to control edema. Diuretics are infrequently used in children because of potential further volume depletion but are often used to control extracellular fluid volume in adults, in whom hypovolemia before treatment is less common. For patients who are diuretic resistant, intravenous albumin is frequently given, although there is scarce evidence for benefit.[30] Prophylactic anticoagulation should be considered for patients with pronounced hypoalbuminemia (i.e., serum albumin <2 g/dL), particularly in adults whose nephrotic syndrome is likely to be more prolonged. One reported regimen uses daily low-molecular-weight heparin or warfarin if serum albumin is below 2 g/dL, switching to aspirin once serum albumin rises to over 2 g/dL and the thrombosis risk is reduced.[31] There is little data on the use of newer direct oral anticoagulants, such as apixaban and rivaroxaban, in nephrotic syndrome, but these agents are highly protein bound, leading to increased urinary losses that may reduce efficacy.[32]

Management of AKI in MCD is supportive. Patients with persistent AKI should be considered for repeat kidney biopsy.

Treatments for hyperlipidemia are more commonly given in adults than children due to the increased time to remission. Statins are the mainstay of cholesterol-lowering therapy, although these have little effect on triglyceride or lipoprotein levels.

Treatment in Children

A summary of suggested treatment for children with MCD is shown in Fig. 18.3.

Initial Treatment

Steroids are the first-line therapy to induce remission in children with idiopathic nephrotic syndrome and biopsy-proven MCD, because 95% of MCD patients respond to this therapy. The ISKDC recommended

TABLE 18.2 Terms Used in Nephrotic Syndrome in Adults and Children

Classification	Definition
Nephrotic syndrome	Nephrotic-range proteinuria (uPCR ≥2 mg/mg or ≥200 mg/mmol or 3+ protein on urine dipstick for children, or ≥3.5 g/day proteinuria for adults) *and* either hypoalbuminemia ≤3 g/dL (≤30 g/L) or edema when albumin level is not available
Complete remission	uPCR <0.2 mg/mg or <20 mg/mmol or negative or trace dipstick on three or more consecutive occasions (children) Reduction of proteinuria to ≤0.20 g/day and serum albumin >3.5 g/dL (adults)
Partial remission	uPCR >0.2 but <2 mg/mg or >20 and <200 mg/mmol, and, if available, serum albumin≥3 (children) Reduction of proteinuria to between 0.21 g/day and 3.4 g/day ± decrease in proteinuria of ≥50% from baseline (adults)
Relapse	Recurrence of nephrotic-range proteinuria. In children, relapse is commonly assessed by urine dipstick, defined as dipstick≥3+ for 3 consecutive days or ≥1+ for 7 days. In adults, relapse is defined as proteinuria ≥3.5 g/day occurring after complete remission obtained for >1 month.
SSNS	Complete remission after 4 weeks of prednisone or prednisolone at standard dose (children)
IRNS	One relapse per 6 months or less than four relapses per 12 months
FRNS	Two or more relapses per 6 months, or four or more relapses per 12 months
SDNS	Relapses during therapy with prednisone or prednisolone (either at full dose or during tapering) or within 15 days of prednisone or prednisolone discontinuation
SRNS	Lack of complete remission at 4 weeks of therapy with daily prednisone or prednisolone at standard dose (children) Persistence of proteinuria despite prednisone therapy, 1 mg/kg/day for 16 weeks (adults)
Initial responder	Attainment of complete remission within initial 4 weeks of corticosteroid therapy
Late responder	Complete remission at 6 weeks (children)
CNI-responsive SRNS	Partial remission after 6 months of treatment and/or complete remission after 12 months of treatment with a calcineurin inhibitor at adequate doses and/or levels
CNI-resistant SRNS	Absence of partial remission after 6 months of treatment with a calcineurin inhibitor at adequate doses and/or levels
Multidrug-resistant SRNS	Absence of complete remission after 12 months of treatment with two mechanistically distinct steroid-sparing agents at standard doses
Secondary SRNS	A SSNS patient at disease onset who at a subsequent relapse fails to achieve remission after 4 weeks of therapy with daily prednisone or prednisolone at standard dose

CNI, Calcineurin inhibitor; *FRNS,* frequent-relapsing nephrotic syndrome; *IRNS,* infrequent-relapsing nephrotic syndrome; *SDNS,* steroid-dependent nephrotic syndrome; *SRNS,* steroid-resistant nephrotic syndrome; *SSNS,* steroid-sensitive nephrotic syndrome; *uPCR,* urinary protein to creatinine ratio.

an induction phase consisting of prednisone 60 mg/day/m^2 (equivalent to 2 mg/kg, with a maximum of 60 mg/day for children and 80 mg/day for adolescents) for 4 weeks.[2] Most nephrologists administer 2 mg/kg of prednisone as a single morning daily dose based on evidence that it provides equal efficacy than three times a day, and it is associated with less adrenal insufficiency and better adherence.

Although the German Arbeitsgemeinschaft für Pädiatrische Nephrologie reported a greater rate of sustained remission in patients treated with extended versus short (6 vs. 4 weeks) therapy with steroids,[33] this was not confirmed by the Southwest Pediatric Nephrology Study Group.[34] Given these results, the 2021 Kidney Disease: Improving Global Outcomes (KDIGO) guidelines recommend treatment of the initial episode of nephrotic syndrome in children with daily oral prednisone or prednisolone at 60 mg/m^2/day or 2 mg/kg/day (maximum 60 mg/day) as induction therapy for 4 to 6 weeks.[35]

Most children enter remission during the induction phase, but treatment is continued to the 4-week or 6-week time point, and then prednisone is slowly tapered to reduce the risk of side effects. During the tapering phase, prednisone is administered on alternate days, but there is no agreement on the duration or dose.

The 2021 KDIGO guidelines recommended oral prednisone at 40 mg/m^2 or 1.5 mg/kg on alternate days and continued for another 4 to 6 weeks.[35] A Cochrane systematic review in 2015 concluded that a 6-month prednisone course does not reduce the risk of relapse compared with a 2- or 3-month course in children aged 1 to 17 years at presentation. More recently, the PREDNOS study found no difference in time or number of relapses or relapse pattern among children who received standard (4-week course with prednisone 40 mg/m^2 on alternate days) or long taper regimen (12-week therapy starting at 60 mg/m^2 on alternate days and tapering by 10 mg/m^2 every 2 weeks).[36] Thus, the 2020 Cochrane update concluded that there is no benefit of prolonging prednisone therapy beyond 2 to 3 months in the first episode of steroid sensitive nephrotic syndrome (SSNS).[37]

Treatment of Relapses

There is no consensus on the prednisone regimen for induction and tapering phases. The ISKDC recommends prednisone at 60 mg/m^2/day until response (maximum of 4 weeks) followed by prednisone 40 mg/m^2/day for 3 consecutive days in a week for a total of 4 weeks.[2] Recently, the PROPINE trial found no differences in outcomes among patients who, after remission, received a short (18 doses of prednisone 40 mg/m^2 on alternate days) versus extended taper (prednisone at 40 mg/m^2 dose on alternate days tapered over 72 days by steps of six doses).[38] Other groups have studied the efficacy of different doses of steroids. In a prospective study, Borovitz and colleagues showed that children receiving prednisone at 1 mg/kg/day and followed by stepwise taper had similar rate of remission and relapse rate than those treated with a standard regimen (prednisone 2 mg/kg/day until remission followed by slow taper over 10–12 weeks).[39]

The ISKDC and KDIGO provided arbitrary definitions regarding the relapse pattern, grouping patients as steroid dependent (SDNS) and frequent relapsers (FRNS) (see Table 18.2).[2,35] These are widely used, but the distinction between them should be made carefully to

select appropriate therapy based on the available studies because definitions of steroid dependence can vary among different centers.

Steroid-Sparing Therapies

Whereas initial treatment of relapsing patients usually involves repeated courses of steroids, long-term exposure to steroids can cause significant toxicity, including behavioral changes, growth impairment, cataracts, hypertension, and diabetes among others. Therefore, alternative therapies are often required in children with MCD who are steroid dependent and/or relapse frequently. Patients should be ideally in remission prior to the initiation of any steroid-sparing agent. This is particularly important when using cyclophosphamide to minimize the risk of hemorrhagic cystitis. There is no consensus on the best second-line therapy for children with MCD.

Cyclophosphamide

This alkylating agent has been used in MCD for decades and used to be the most common first-line steroid-sparing agent. Cyclophosphamide can induce sustained remission, particularly in patients with FRNS, whereas its efficacy is lower in those with SDNS.[35] The optimal length of cyclophosphamide therapy is debatable and varies from 8 to 12 weeks. The most common side effect is bone marrow suppression, so weekly cell blood count is recommended, with adjustment of dosage or cessation of therapy if necessary. Second courses of cyclophosphamide should not be given (maximum cumulative dose of 168 mg/kg) to minimize gonadal toxicity. Some centers may favor other newer therapies due to a theoretical safer profile.

Calcineurin Inhibitors: Cyclosporine and Tacrolimus

Treatment with cyclosporine results in a similar rate of remission compared with cyclophosphamide and chlorambucil. However, its long-term efficacy is hampered by frequent relapse shortly after calcineurin inhibitor (CNI) withdrawal. Tacrolimus appears to have efficacy similar to that of cyclosporine.[40] The recommended dose for cyclosporin and tacrolimus are 4 to 5 mg/kg/day (in two divided doses) and 0.1 mg/kg/day (in two divided doses) with target 12-hour trough levels of 60 to 150 ng/mL and 5 to 10 ng/mL, respectively, aiming for the lowest levels to maintain remission and avoid toxicity. These recommendations are largely based on the experience in kidney transplantation, but have not been formally validated in MCD. The length of therapy varies from 12 to 24 months.[35] Mild to moderate cyclosporine-associated nephrotoxicity has been reported in up to one-third of MCD patients treated with cyclosporine for more than 3 years.

Rituximab

Rituximab has been used in MCD for over a decade. The 2021 KDIGO Guidelines and the 2020 Cochrane update recommend rituximab as a steroid-sparing agent.[35,37] Iijima and colleagues found a significantly longer relapse-free period and fewer relapses in patients who received rituximab compared with those receiving a placebo.[41] A recent randomized controlled trial (RCT) showed that rituximab was associated with a higher 12-month relapse-free survival rate than tacrolimus (90% vs. 63.3%, respectively) in children with SDNS, suggesting that rituximab could potentially be used as a first-line steroid-sparing agent in these children.[42] Overall, rituximab is well tolerated. Infusion reactions are the most common adverse event. Serious complications include rituximab-associated lung injury, colitis, multifocal leukoencephalopathy, persistent hypogammaglobulinemia, and infections.

Mycophenolate Mofetil

Uncontrolled studies suggested beneficial effects of mycophenolate mofetil (MMF) therapy, but this has not been confirmed in RCT. Dorresteijn and colleagues found that children receiving MMF had a higher risk for relapse than those on cyclosporine, though the difference did not reach statistical significance.[43] In a larger crossover trial using MMF or cyclosporine, patients on MMF suffered more relapses than those on cyclosporine, though patients with higher plasma levels of MMF (area under the curve >50 μg/h/mL) had a similar course to those treated with cyclosporine.[44] MMF is a relatively safe drug that can be associated with mild and dose-dependent side effects (gastrointestinal, bone marrow suppression) but not nephrotoxicity. Therefore, MMF seems a reasonable alternative as a steroid-sparing drug, especially if plasma levels are closely monitored. However, MMF is teratogenic, so caution is required when used in young females.

Other Medications

Levamisole. One RCT showed sustained remission in 26% of patients treated with levamisole compared with 6% in the placebo group.[45] Levamisole was more effective in patients from India than Europe. It is unclear whether this is because SDNS was more common in Europe or because helminthic infections could trigger MCD. Still, the use of levamisole is limited as it is not available in some countries and because it is associated with agranulocytosis and antineutrophil cytoplasmic antibody vasculitis.

Adrenocorticotrophic hormone. The ATLANTIS trial found a similar rate of relapse in children with FRNS and SDNS who received adrenocorticotrophic hormone (ACTH) therapy versus no relapse-preventing treatment,[46] so there is no evidence to support the use of ACTH in children with MCD.

Treatment in Adults

Initial Treatment

A summary of treatment recommendations given here is shown in Fig. 18.4. Although a small proportion of patients with MCD will spontaneously remit, withholding immunosuppression has been shown to be associated with increased risk of acute kidney injury and steroid resistance.[47]

Steroids

Steroids are widely used as the initial therapy for MCD. Studies comparing different steroid regimens in adults with MCD are limited and regimens are extrapolated from successful approaches in children with steroid-sensitive nephrotic syndrome, although often with slightly lower doses of oral prednisolone (1 mg/kg/day, up to maximum 80 mg/day).[48] There is no good evidence that alternate-day steroids (prednisolone 2 mg/kg, up to maximum 120 mg) offer any clinical advantages over daily dosing; however, induction with methylprednisolone pulses may lead to more rapid responses and fewer relapses.[49]

Response is often delayed in comparison with that in children, with a median time to remission of 10 weeks, and 25% fail to remit after 3 to 4 months.[50] Although unclear, the reason may be that adults are often given a relatively lower dose of steroids or that a greater proportion of adults have FSGS, missed on the original biopsy, which is more likely to be steroid resistant (SR). More recent work has shown a correlation between reduced nephron mass and increased time to remission with steroids.[51] The KDIGO guideline recommends that the duration of steroid treatment should be up to 6 months, but this is based on very low-grade evidence.[35] The initial high dose of steroids, if tolerated, should be maintained for a minimum of 2 weeks after complete remission is achieved and for a maximum of 16 weeks if complete remission is not achieved. After this, steroids should be tapered over 24 weeks, although the rate of dose tapering and total length of treatment of the initial episode may need to be reduced if steroid toxicity is significant. If the patient has not responded after 12 to 16 weeks, genetic screening for FSGS or a repeat biopsy should be considered.

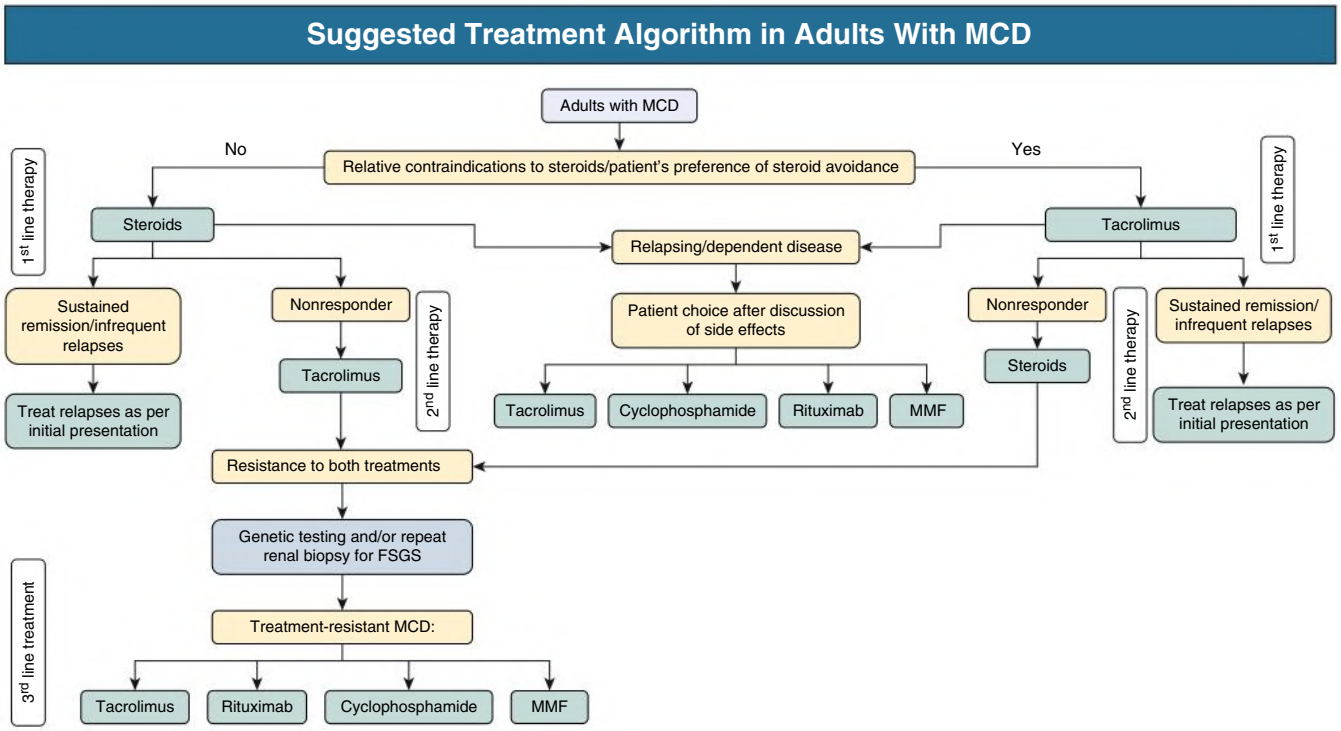

Fig. 18.4 Algorithm for Treatment of Adult Minimal Change Disease *(MCD). FSGS,* Focal segmental glomerulosclerosis; *MMF,* mycophenolate mofetil.

Infrequent relapses should be treated in the same way as the initial presentation, but there is even less evidence that a prolonged course of steroids is beneficial in reducing the frequency of subsequent relapse.

Although steroids are a highly effective treatment for MCD, prolonged courses of steroids often cause significant side effects. Up to 90% of adults taking steroids for more than 60 days report a side effect of steroid therapy; weight gain is the most commonly reported alongside skin changes, muscle weakness, sleep disturbance, cataracts, hyperglycemia, psychiatric disturbance, and bone demineralization leading to pathologic fractures. In other areas of nephrology such as kidney transplantation, steroid avoidance and early withdrawal protocols have led to improved outcomes, and similar strategies have been studied in MCD.

Calcineurin Inhibitors

A large RCT compared intravenous methylprednisolone followed by oral tacrolimus with oral prednisolone as initial therapy for MCD. This study found a similar rate of remission and relapse between both groups, but the oral prednisolone arm had a worse side effect profile.[52] A more recent RCT compared low-dose prednisolone and tacrolimus with higher-dose prednisolone monotherapy. They found comparable rates of complete and partial remission but a significantly lower rate of relapse in the combination therapy group compared with steroids alone. This study showed a comparable rate of adverse events across both groups.[53]

Use of tacrolimus monotherapy with complete avoidance of steroids has also been shown to be effective. The MINTAC trial involved 55 adults who were given either tacrolimus or prednisolone as initial therapy. There was no significant difference in complete or partial remission rates after 8, 16, and 26 weeks of treatment. There was no significant difference in relapse rates and no significant difference in the rate of adverse events.[54] This may be due to the relatively conservative steroid doses used in this trial. A second RCT also comparing tacrolimus with prednisolone as first-line MCD treatment also found similar remission and relapse rates, but adverse events were significantly more common in the steroid-treated group.[55] Tacrolimus may be particularly useful for patients with contraindications to steroids, such as diabetes or psychosis.

Mycophenolate Mofetil

MMF has also been tried as a steroid sparing agent for initial therapy. Rémy and colleagues compared MMF plus low-dose prednisolone (0.5 mg/kg/day) with standard-dose prednisolone (1 mg/kg/day) alone in 116 adult patients and found no significant difference in rates of remission or relapse and no benefit in adverse events between the two treatment arms.[56]

Cyclophosphamide

Cyclophosphamide can also be used as initial therapy in MCD instead of steroids,[48] although there are no RCTs to show efficacy. This may be suitable in older adults, where there is less concern regarding impacts on fertility or increased lifetime malignancy risk.

Rituximab

Other alternatives for first-line therapy include rituximab, although there is still a paucity of evidence relating to this. Fenoglio and colleagues gave rituximab as a first-line therapy to treatment-naive adult patients with MCD who had contraindications to steroid therapy; five out of six patients achieved complete remission and did not relapse until the end of the follow-up period. The remaining patient achieved partial remission.[57] Patients may require enhanced dosing if rituximab is given when nephrotic due to protein binding of the drug.

Treatment of Relapses and Steroid-Sparing Therapies

As in children, some adults have transient nonnephrotic relapses, so it is important to establish that a full relapse has developed with persistent nephrotic range proteinuria before recommencing immunosuppression. Several different immunosuppressant therapies are effective for relapsing MCD; hence the choice of treatment should be tailored to individual patient's needs.

The CNIs cyclosporine and tacrolimus have similar efficacy, inducing remission in up to 75% of patients, but as in children, relapse often follows dose reduction or withdrawal. Due to its side effect profile, tacrolimus may be preferred to cyclosporine.[58] Initial dosing is 0.05 to 0.1 mg/kg, with target tacrolimus levels of 4 to 8 ng/mL, but higher levels may be required to maintain remission. Tacrolimus is suitable for young adults wishing to preserve fertility and is safe in both pregnancy and breastfeeding.[59] Recommended dosing for cyclosporine is 4 to 6 mg/kg/day, aiming for trough whole-blood levels of 150 to 200 ng/mL. KDIGO guidelines recommend CNI therapy should continue for 1 to 2 years,[48] but some patients require longer or repeated courses of therapy.

Rituximab can reduce the frequency of relapses and need for concomitant immunosuppression,[60] although definitive RCTs in adults are awaited. Median time to relapse with rituximab has been reported as 18 months.[61] Longer-term maintenance dosing of rituximab can be guided by B cell monitoring, but relapse can recur quickly after repletion. For these patients, regular six-monthly dosing may be preferable and has been shown to be effective.[62] Rituximab is generally well tolerated in adults with MCD, but patients need to be monitored for hypogammaglobulinemia. For patients who struggle with adherence to a daily oral medication, rituximab may offer some advantage due to its administration by intermittent infusion. Optimal doses and schedule remain to be determined.[24]

A 12-week course of oral cyclophosphamide 2 to 2.5 mg/kg/day induces a longer-term remission more often in adults than children (75% and 66% at 2 and 5 years, respectively).[63] Although there are no satisfactory studies comparing 8-week and 12-week courses in adults, the 12-week course is logical based on the pediatric experience. If this treatment is selected, the opportunity for banking sperm or retrieval of ova should be considered before treatment in appropriate patients. Intravenous cyclophosphamide has been recommended to limit the cumulative dose: intravenous cyclophosphamide 0.5 g/m^2 per month adjusted upward to 1 g/m^2 based on the leukocyte count after 2 weeks with a target nadir of 3000 cells/mm^3.

Several uncontrolled reports suggest that MMF is effective in inducing remission in steroid- and cyclosporine-dependent patients[29] and is generally well tolerated. However, it may not be suitable in young women due to teratogenicity.

Steroid Resistant Disease

For the 10% to 30% adults who do not remit with primary therapy, treatment of MCD may be challenging. For patients not remitting on steroids, tacrolimus can be used as second-line therapy, and vice versa for patients failing to remit on tacrolimus. Patients should be offered genetic testing or repeat biopsy to look for FSGS. For patients with truly SR MCD, case series have shown that CNIs, cyclophosphamide,[64] MMF,[65] and rituximab[66] can all induce remission.

MINIMAL CHANGE DISEASE WITH NONNEPHROTIC PROTEINURIA

It is possible to have MCD with subnephrotic proteinuria. These patients may be treated with antiproteinuric medications such as angiotensin converting enzyme inhibitors or angiotensin receptor blockers. If there is any uncertainty regarding diagnosis, a repeat biopsy should be offered.

Treatment of Secondary Minimal Change Disease

MCD secondary to NSAIDs requires discontinuation of the offending medication. Many patients are treated with a course of steroids for MCD (higher dose) or for acute interstitial nephritis (see Chapter 64), but evidence of benefit is uncertain. Secondary MCD from Hodgkin disease usually responds to treatment of the lymphoma. Some patients will also receive a drug regimen for MCD as adjunctive therapy in addition to the chemotherapy directed at the tumor in particular if MCD remission does not occur quickly with adequate chemotherapy.

SELF-ASSESSMENT QUESTIONS

1. Which of the following statements regarding the presentation of MCD is *correct?*
   - **A.** Less than 1% of adults present with AKI.
   - **B.** Microscopic hematuria excludes a diagnosis of MCD.
   - **C.** Edema is rarely the first presenting feature.
   - **D.** Children may present with abdominal pain, ascites, and diarrhea.
   - **E.** Urinary frothiness indicates a patient has achieved remission.
2. Which of the following statements regarding the natural history of MCD is *correct?*
   - **A.** Seventy-five percent of children presenting with MCD never relapse.
   - **B.** Most patients with MCD will undergo one or more relapses.
   - **C.** End-stage kidney disease is seen in up to 30% patients who present as adults.
   - **D.** MCD resolves with puberty.
   - **E.** Patients requiring kidney replacement therapy in MCD rarely recover kidney function.
3. Which treatment is most appropriate for a 24-year-old woman with relapsing minimal change disease hoping to conceive in the next year?
   - **A.** Tacrolimus
   - **B.** Rituximab
   - **C.** Mycophenolate mofetil
   - **D.** Cyclophosphamide
   - **E.** Adalimumab
4. Which of the following statements regarding complications of MCD is *true?*
   - **A.** Hyperlipidemia is a rare complication of MCD.
   - **B.** Thrombotic events in MCD are usually arterial.
   - **C.** The enhanced risk of infection in MCD is only due to the immunosuppressive therapy seen.
   - **D.** AKI occurs in most adults.
   - **E.** Rituximab can contribute to hypogammaglobulinemia.

Primary and Secondary (Nongenetic) Causes of Focal and Segmental Glomerulosclerosis

Dominick Santoriello, Jai Radhakrishnan

INTRODUCTION

Focal segmental glomerulosclerosis (FSGS) is a histologic pattern of glomerular injury that represents the final common pathway of podocyte injury and depletion. FSGS may be primary (idiopathic) or secondary to diverse causes[1-3] (see also Chapter 20). Early in the disease process, the pattern of glomerulosclerosis is focal, involving a minority of glomeruli, and segmental, involving a portion of the glomerular tuft.[4] As FSGS progresses, more diffuse and global glomerulosclerosis evolves.[4] Although it accounts for only a small proportion of nephrotic syndrome in young children, FSGS represents as many as 35% of cases of primary nephrotic syndrome in adults and is a major cause of end-stage kidney disease (ESKD) in the United States.[5]

FSGS can be caused by a diverse set of pathogenetic mechanisms, some of which manifest as particular histologic subtypes of disease. Although primary (idiopathic) FSGS is potentially treatable and curable in many patients, the optimal type and duration of immunosuppressive, as well as adjunctive therapy, remain controversial. For secondary FSGS, effective therapies exist to slow or modify the disease course (see Chapter 82).

ETIOLOGY AND PATHOGENESIS

FSGS is a pattern of glomerular injury that represents a common final pathway of podocyte depletion. Primary FSGS underlies a subset of idiopathic nephrotic syndrome and is thought to be mediated by circulating permeability factors.[6-8] Distinct causes of secondary FSGS (Box 19.1) include genetic variants in podocyte and glomerular basement membrane components (see Chapter 20), viral infections, drug toxicity, maladaptive responses to a reduced number of functioning nephrons, and hemodynamic stress placed on an initially normal nephron population. In all forms of FSGS, injury directed at or inherent to the podocyte mediates altered cell signaling and reorganization of the actin cytoskeleton resulting in foot process effacement, and eventually podocyte depletion though detachment and apoptosis.[1,9] Podocytes are terminally differentiated, postmitotic cells with limited hypertrophic capacity. Furthermore, regeneration mediated by resident podocyte progenitor cells along Bowman's capsule is inefficient. Therefore, stress placed on the remaining podocytes may lead to local propagation of damage (see Chapter 81). Injury to podocytes may spread to adjacent podocytes by reduction in supportive factors such as nephrin signaling, increased toxic factors such as angiotensin II (Ang II), or mechanical strain on remnant podocytes.[9,10] Cell-to-cell spread of podocyte injury until the entire glomerular lobule is captured could explain the segmental nature of the sclerosing lesions.[10] Repeated and diverse stresses to the podocyte could explain the FSGS pattern of injury in age-related nephrosclerosis and glomerular senescence.[1,9]

CLASSIFICATION OF FOCAL SEGMENTAL GLOMERULOSCLEROSIS

The terms *primary* and *idiopathic* FSGS have been used interchangeably, leading to confusion. Thus, we avoid the term *idiopathic* in this section. The following definitions are suggested by the KDIGO Guideline.[11]

Primary Focal Segmental Glomerulosclerosis

Primary FSGS is diagnosed when the nephrotic syndrome is present (in particular, the presence of hypoalbuminemia) and diffuse podocyte foot process effacement is observed on kidney biopsy without evidence for other causes of FSGS.[11] Primary FSGS, together with minimal change disease (MCD; see Chapter 18), are the main causes of idiopathic nephrotic syndrome and are collectively referred to as *primary podocytopathies*. Compared with MCD, primary FSGS is associated with a higher likelihood of steroid resistance and progression to CKD, leading most experts to conclude that they are separate diseases. Despite these clinical differences, MCD and primary FSGS may represent a disease spectrum in which the severity and duration of podocyte injury, inherent susceptibility of the podocyte to injury, and comorbid conditions all influence the disease phenotype.[12] Indeed, follow-up kidney biopsies from patients with refractory nephrotic syndrome suggest that FSGS may evolve from an initial MCD pattern.[13] In some instances this may be attributed to sampling variability. However, sequential biopsy samples of kidney allografts show that recurrent FSGS may pass through an early stage of podocytopathy with MCD-like pathology.[14] Animal models of persistent nephrotic syndrome also show progression from an initial MCD-like phase to FSGS.[15]

Both MCD and primary FSGS are thought to be mediated by as-yet unidentified circulating permeability factors.[6,16] Alterations in glomerular capillary wall permeability may occur in response to circulating "humoral" substances that act on the podocyte to promote foot process effacement. Circulating permeability factors that enhance in vitro permeability of glomeruli to albumin have been found in some FSGS patients. An in vitro assay of cultured podocytes has been used to detect the presence of circulating permeability factors.[17] Some patients with recurrent FSGS after transplantation achieve remission of nephrotic syndrome after plasma exchange or use of a protein A adsorption column, supporting the role of a circulating factor[8,18] (see Chapter 113). However, none of several candidate proteins, including suPAR, B7-1 (also known as CD-80), or cardiotrophin-like cytokine 1 (CLC1), a member of the interleukin (IL)-6 family, has been consistently shown to be the permeability factor in human FSGS.[19]

Glomerular hypertrophy (or glomerulomegaly) may identify children with MCD at risk for development of FSGS. In early idiopathic FSGS and in many secondary forms of FSGS, such as obesity-related FSGS, there is initially glomerular hypertrophy and high glomerular filtration rate (GFR) associated with glomerular hypertension.[20] Similarly, in secondary forms of FSGS with reduced nephron numbers, maladaptive

BOX 19.1 Etiologic Classification of Focal Segmental Glomerulosclerosis

Primary
- Presumably mediated by circulating/permeability factor(s)

Genetic Causes
- (See Chapter 20)

Secondary

Virus Associated
- HIV-1 (HIV-associated nephropathy)
- SARS-CoV-2 (COVID-19 associated nephropathy)
- Parvovirus B19
- CMV
- EBV

Drug Induced
- Interferon
- Pamidronate
- Sirolimus
- Anabolic steroids

Adaptive Changes to Glomerular Hyperfiltration

Reduced Kidney Mass
- Oligomeganephronia
- Very low birth weight (correlating with low nephron endowment)
- Unilateral kidney agenesis
- Kidney dysplasia
- Reflux nephropathy
- Sequela to cortical necrosis
- Surgical kidney ablation
- Any advanced kidney disease with reduction in functioning nephrons

Initially Normal Kidney Mass
- Hypertension
- Atheroemboli or other acute vasoocclusive processes
- Obesity
- Bodybuilders
- Cyanotic congenital heart disease
- Sickle cell anemia

Uncertain Cause

CMV, Cytomegalovirus; *EBV,* Epstein-Barr virus; *FSGS,* focal segmental glomerulosclerosis; *HIV,* human immunodeficiency virus; *SARS-CoV-2,* severe acute respiratory syndrome coronavirus 2.

hemodynamic alterations may be associated with glomerular hyperfiltration. Intraglomerular coagulation and abnormalities of lipid metabolism may also contribute to glomerulosclerosis in these patients (see Chapter 81). Although immunoglobulin (Ig) M and C3 are regarded as nonspecifically trapped in areas of sclerosis, they may contribute to glomerular injury through activating complement and binding antigens.[21,22] Recent studies document both reparative and sclerosing roles for parietal epithelial cells in FSGS. In vivo microscopy has illustrated that parietal cells can rapidly cover sites of podocyte denudation and depletion in FSGS but make a limited contribution to podocyte regeneration.[23,24] Parietal cells may also directly contribute to glomerulosclerosis by migrating onto the glomerular tufts and synthesizing extracellular matrix proteins.[25]

Genetic Focal Segmental Glomerulosclerosis

Genetic and familial forms of FSGS are covered in detail in Chapter 20. Many cases of apparently primary FSGS may harbor unrecognized variants or polymorphisms in podocyte genes. Genetic predisposition may underlie the susceptibility to second hits, whereby viral factors, immune stimuli, and other insults lead to the initiation or acceleration of disease. For example, *APOL1* gene variants predispose to FSGS, as well as HIV nephropathy, chronic hypertensive nephrosclerosis, and lupus nephritis among African Americans.[26] G1 and G2 variants in *APOL1* protect against infection by *Trypanosoma brucei,* the parasite that causes African sleeping sickness. Similar to the gene for sickle cell disease, which confers protection against malaria, the G1 and G2 variants became prevalent because they protect against infection. Although *APOL1* is expressed by glomerular endothelial cells and podocytes, it is not entirely clear how sequence variations in *APOL1* cause glomerulosclerosis. Various mechanisms have been proposed including increased podocyte membrane pores promoting intracellular potassium depletion and induction of stress-activated protein kinases[27] and impairment of podocyte endocytic functions and autophagy.[28]

Secondary Focal Segmental Glomerulosclerosis

When an FSGS lesion is found together with a process associated with FSGS, we refer to this as secondary FSGS.[11] The known/presumptive etiologies of secondary FSGS include viral infections, drug toxicities, and maladaptive responses to glomerular hyperfiltration and are listed in Box 19.1.

Virus-Associated Focal Segmental Glomerulosclerosis

Viral infections (particularly HIV) can cause podocytopathies, particularly collapsing FSGS (see Chapter 58). Other potential viral triggers include parvovirus B-19, Epstein-Barr virus (EBV), and cytomegalovirus (CMV) infections. During the COVID-19 pandemic, collapsing FSGS was linked to severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection in patients of African ancestry.[29,30] The heightened cytokine release associated with viral infections may place patients with the high-risk *APOL1* genotype at risk of interferon-mediated podocyte injury, as can occur in other virally mediated, interferon therapy–induced, and HIV-associated forms of collapsing FSGS.[31,32]

Drug-Induced Focal Segmental Glomerulosclerosis

Several drugs and medications are associated with the FSGS phenotype, including heroin, lithium, pamidronate, sirolimus, calcineurin inhibitors (CNIs), tyrosine kinase inhibitors, and interferons α, β, and γ (Box 19.1). Heroin is associated with the nephrotic syndrome and FSGS (heroin nephropathy), although its incidence has diminished markedly in recent years. Pamidronate is a bisphosphonate used to prevent bone resorption in myeloma and metastatic tumors and is associated with collapsing FSGS and MCD.[33] Stabilization of kidney function and resolution of nephrotic syndrome may follow withdrawal of these medications. Long-term anabolic steroid use by bodybuilders is associated with FSGS,[34] although this observation could be confounded by use of high-protein diets and other potential nephrotoxins such as growth hormone. Putative mechanisms of glomerular injury include direct toxic effects of anabolic steroids on glomerular cells, as well as adaptive responses to elevated lean body mass. In a small series, all patients who developed FSGS secondary to interferon therapy have been shown to carry double *APOL1* risk alleles and to activate a viral innate immunity program in podocytes upon interferon exposure, supporting a two-hit model of podocyte injury.[35]

Focal Segmental Glomerulosclerosis From Adaptive Changes to Glomerular Hyperfiltration

Many secondary forms of FSGS are mediated by adaptive structural-functional responses leading to podocyte detachment and subsequent

sclerosis.[36] These adaptive forms include patients with both congenital and acquired reduction in the number of functioning nephrons, whereas other secondary forms are associated with hemodynamic stress placed on an initially normal nephron population (Box 19.1). Obesity-related glomerulopathy is increasingly common worldwide and may be associated with metabolic syndrome, including hypertension, diabetes, and hyperlipidemia.[37] Low birth weight associated with prematurity and reduced nephron endowment also may lead to glomerular hypertrophy, with secondary FSGS developing in adolescence or adulthood.[38] Biopsy specimens with secondary adaptive FSGS typically show glomerulomegaly and perihilar lesions of segmental sclerosis and hyalinosis. These conditions resemble experimental models of kidney ablation in which the surgical reduction in kidney mass causes functional hypertrophy of remnant nephrons with increased glomerular plasma flows and pressures. Although these changes are initially "adaptive," the resultant hyperfiltration and increased glomerular pressure become "maladaptive" and serve as mechanisms for progressive glomerular damage.[36]

Focal Segmental Glomerulosclerosis From Uncertain Cause

FSGS can also occur without a genetic or identifiable secondary cause, in the absence of nephrotic syndrome (NS), and without diffuse foot process effacement on electron microscopy of the kidney biopsy. This form of FSGS is distinct from primary FSGS based on its clinical and histologic manifestations. The KDIGO Guideline proposes calling this entity FSGS of unknown cause.[11] Patients with FSGS of unknown cause may have secondary or genetic forms of FSGS that have not yet been elucidated.

EPIDEMIOLOGY

There is substantial variation in the reported frequency of primary glomerular diseases between different geographic and among racial populations.[39,40] The reasons for these differences may be multifactorial (e.g., bias in referral patterns and who undergoes biopsy, environmental or racial predispositions such as the presence of *APOL1* genetic variants in people of African descent). The prevalence of FSGS varies across countries. In a study from China, FSGS was diagnosed in 2.45% of biopsies.[41] In a Danish kidney biopsy registry study, an incidence of 1.5 to 5.7 patients per million/year was reported.[42] In a single-center study from Germany, FSGS accounted for 6.1% of biopsies, and its frequency rose 3.9-fold over a 24-year period beginning 1990.[43] An analysis of the prevalence of ESKD in the United States caused by FSGS during a 21-year period showed an increase from 0.2% in 1980 to 2.3% in 2000, and FSGS was the most common primary glomerular disease leading to ESKD.[5] Although some changes in prevalence may relate to changes in biopsy practice or disease classification, the true frequency of FSGS has likely increased over time.

Primary FSGS is slightly more common in males than females, and the incidence of ESKD secondary to FSGS in males of all races is 1.5 to 2 times higher than in females. The incidence in both children and adults is higher in African Americans than in Whites and those of Asian descent.[1,44] This most likely relates to the presence of G1 and G2 variants of the apolipoprotein L1 genes in African Americans.[26]

CLINICAL MANIFESTATIONS

Patients with primary FSGS typically present with the full nephrotic syndrome (especially hypoalbuminemia).[11,45] Secondary forms of FSGS associated with hyperfiltration typically have lower levels of proteinuria, and many such patients have subnephrotic proteinuria and normal serum albumin concentration.[37,46] Patients with genetic FSGS may have variable degrees of proteinuria and serum albumin levels.[46]

Hypertension is found in 30% to 65% of children and adults with FSGS at diagnosis. Microhematuria is found in 30% to 75% of these patients, and decreased GFR is noted at presentation in 20% to 50%.[1] Daily urinary protein excretion ranges from less than 1 to more than 30 g/day. Proteinuria is typically nonselective. Complement levels and other serologic test results are normal. Occasional patients will have glycosuria, aminoaciduria, phosphaturia, or a concentrating defect indicating functional tubular damage and glomerular injury.

Different histologic patterns of FSGS may display unique clinical features.[47] The clinical presentation of patients with the tip variant of FSGS resembles MCD.[48] They often present with an abrupt clinical onset of the full nephrotic syndrome (almost 90%), shorter time course from onset to kidney biopsy, more severe proteinuria, and less chronic tubulointerstitial disease than in FSGS not otherwise specified (NOS).[48] The cellular variant also typically manifests with greater proteinuria and higher incidence of nephrotic syndrome than FSGS NOS.[49] The collapsing variant usually manifests with greater proteinuria, severe nephrotic syndrome, and lower GFR.[47,50]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Except for genetic forms of FSGS, a firm diagnosis of FSGS requires a kidney biopsy. Tests for permeability factors are neither reliable nor available in routine clinical practice. In children with FSGS, most of whom present with nephrotic syndrome, the major differential is between MCD and other variants of corticosteroid-resistant nephrotic syndrome. In adults with subnephrotic proteinuria, the differential includes almost all glomerular diseases without positive serologic results. In adults with nephrotic syndrome, MN and MCD may present in an identical manner, and only a kidney biopsy will clarify the diagnosis (except for MN patients, in whom the presence of M-type phospholipase A2 receptor [PLA2R] antibody and possibly other autoantibodies may provide the diagnosis without a biopsy; see Chapter 21). Focal sclerosing lesions caused by other glomerulopathies (e.g., segmental scarring from chronic glomerulonephritis) must be excluded pathologically. Moreover, because the defining glomerular lesion of FSGS is focal and may be confined to deeper juxtamedullary glomeruli early in the disease, it may not be sampled on kidney biopsy. A large sample of more than 20 glomeruli for light microscopy or serial sections of the biopsy core may increase the likelihood of identifying the diagnostic segmental lesions.

Even after the diagnosis of FSGS is established, the primary form must be distinguished from secondary forms by careful clinicopathologic correlation (Box 19.2). In general, many forms of adaptive FSGS have lower levels of proteinuria than primary FSGS, a lower incidence of hypoalbuminemia, and, on biopsy, lesser degrees of foot process effacement.[11,46] In patients younger than 25 years and especially in those with a family history of FSGS, genetic screening for variants in podocin, TRPC6, α-actinin-4, inverted formin 2, or other podocyte genes may be useful (see Chapter 20). Similarly, in young adults with sporadic corticosteroid-resistant FSGS, genetic testing may yield pathogenic variants, albeit in a lower proportion compared with children.[51,52]

PATHOLOGY

The pathologic manifestations of FSGS are heterogeneous.[1,3] A hierarchical classification of FSGS by histologic variants (Table 19.1) can be applied to both primary and secondary forms of FSGS (see Box 19.1).[47] This working classification has been applied successfully to

retrospective and prospective biopsy series. Other, more controversial histologic variants of FSGS include FSGS with diffuse mesangial hypercellularity and C1q nephropathy (see Chapter 29). Some think these are distinct disease entities, whereas others think they are merely subgroups of FSGS.[53,54]

BOX 19.2 Definition of Remission, Relapse, Resistance, and Therapy Dependence for Focal Segmental Glomerulosclerosis

Complete Remission
Reduction of proteinuria to <0.3 g/day or urine PCR <300 mg/g (or <30 mg/mmol), stable serum creatinine, and serum albumin >3.5 g/dL (or 35 g/L)

Partial Remission
Reduction of proteinuria to 0.3–3.5 g/day or urine PCR 300–3500 mg/g (or 30–350 mg/mmol) and a decrease >50% from baseline

Relapse
Proteinuria >3.5 g/day or urine PCR >3500 mg/g (or 350 mg/mmol) after complete remission has been achieved or an increase in proteinuria by >50% during partial remission

Steroid-Resistant
Persistence of proteinuria >3.5 g/day or urine PCR >3500 mg/g (or 350 mg/mmol) with <50% reduction from baseline despite prednisone 1 mg/kg/day or 2 mg/kg every other day for at least 16 weeks

Steroid-Dependent
Relapse occurring during or within 2 weeks of completing glucocorticoid therapy
CNI-resistant FSGS
Persistence of proteinuria >3.5 g/day or urine PCR >3500 mg/g (or 350 mg/mmol) with <50% reduction from baseline despite cyclosporine treatment at trough levels of 100–175 ng/mL or tacrolimus treatment at trough levels of 5–10 ng/mL for >6 months

CNI-Dependent
Relapse occurring during or within 2 weeks of completing cyclosporine or tacrolimus therapy for >12 months

CNI, Calcineurin inhibitor; *FSGS,* focal segmental glomerulosclerosis; *PCR,* polymerase chain reaction.
Modified from KDIGO GN Guideline. *Kidney Int.* 2021;100(4S):S1–S276.

Classic Focal Segmental Glomerulosclerosis Not Otherwise Specified

FSGS NOS requires exclusion of the more specific subtypes described later. This is the most frequent variant and may occur in primary or secondary forms of FSGS, including genetic forms. It is defined by segmental obliteration of the glomerular tuft by matrix accumulation, which may be accompanied by hyalinosis and/or endocapillary foam cells (Fig. 19.1).[47] Adhesions or synechiae to Bowman's capsule are common, and overlying visceral epithelial cells often appear swollen and form a cellular "cap" over the sclerotic segment. Glomerular lobules unaffected by segmental sclerosis appear normal on light microscopy, except for mild podocyte swelling. Tubular atrophy and interstitial fibrosis are commensurate with the degree of glomerulosclerosis. Immunofluorescence (IF) typically reveals focal and segmental granular deposition of IgM, C3, and more variably C1q in the distribution of the segmental glomerular sclerosis (Fig. 19.2). On electron microscopy (EM), segmental sclerotic lesions exhibit increased extracellular matrix (ECM), wrinkling and retraction of the glomerular basement membrane (GBM), accumulation of inframembranous hyaline, and resulting narrowing or occlusion of the glomerular capillary lumina. Electron-dense immune-type deposits should be absent and, if present, should raise suspicion for chronic glomerulonephritis. Overlying the segmental sclerosis, there is often podocyte detachment with parietal cell coverage (Fig. 19.3). The adjacent nonsclerotic glomerular capillaries show foot process effacement with variable microvillous transformation (slender projections resembling villi along the surface of podocytes).

Perihilar Variant of Focal Segmental Glomerulosclerosis

The perihilar variant is defined as hyalinosis and sclerosis at the vascular pole involving more than 50% of glomeruli with segmental lesions (Fig. 19.4).[47] This category requires exclusion of the cellular, tip, and collapsing variants. Although the perihilar variant may occur in primary FSGS, it is particularly frequent in secondary forms of FSGS mediated by adaptive structural-functional responses, accompanied by glomerular hypertrophy (glomerulomegaly) and relatively mild foot process effacement. In this setting, reflex dilation of the afferent arteriole and the greater filtration pressures at the proximal end of the

TABLE 19.1 Morphologic Variants of Focal Segmental Glomerulosclerosis : Columbia Classification

Variant	Defining Features	Clinical Features	Associations
Collapsing	Implosive retraction of capillaries with overlying GEC hyperplasia, severe tubular injury, tubular microcysts, severe FPE	Primary or secondary, severe nephrotic syndrome and AKI, Black racial predominance, worst prognosis	Viral infections (HIV, SARS-CoV-2, CMV), autoimmune SLE, drugs (pamidronate, INF), vasoocclusion, *APOL1*
Tip	Adhesion of tuft at tubular pole with foam cells, severe FPE	Usually primary, abrupt-onset nephrotic syndrome	Usually steroid responsive, favorable prognosis
Cellular	Expansile lesion with endocapillary hypercellularity (foam cells, leukocytes)	Usually primary	
Perihilar	Hyalinosis and sclerosis centered at vascular pole, glomerulomegaly, focal FPE	Usually secondary, adaptation to glomerular hyperfiltration	Obesity, HTN, low nephron number, sickle cell nephropathy
NOS	Does not meet criteria for any above variant	Most common variant, primary or secondary	

AKI, Acute kidney injury; *CMV,* cytomegalovirus; *FPE,* foot process effacement; *FSGS,* focal segmental glomerulosclerosis; *GEC,* glomerular epithelial cell; *HIV,* human immunodeficiency virus; *HTN,* hypertension; *INF,* interferon; *NOS,* not otherwise specified; *SARS-CoV-2,* severe acute respiratory syndrome coronavirus 2; *SLE,* systemic lupus erythematosus.

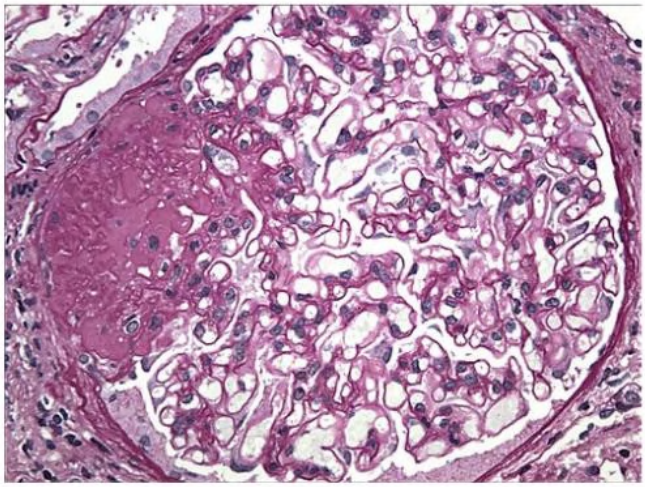

Fig. 19.1 Focal Segmental Glomerulosclerosis Not Otherwise Specified. A glomerulus with discrete lesion of segmental sclerosis involving a portion of the tuft characterized by accumulation of acellular matrix material, hyalinosis, and adhesion of the tuft to Bowman's capsule. (PAS; ×400.)

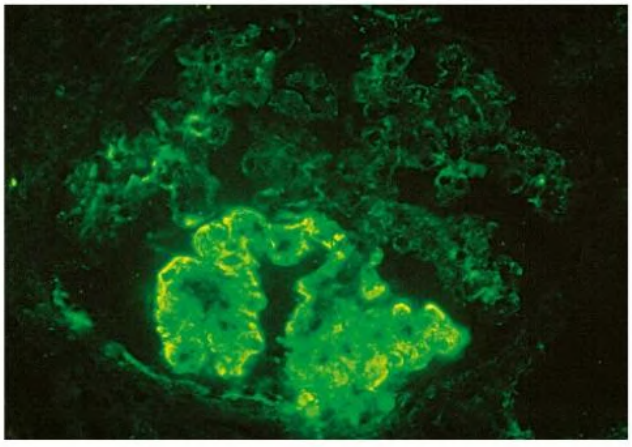

Fig. 19.2 Focal Segmental Glomerulosclerosis Not Otherwise Specified. The lesions of segmental sclerosis contain deposits of immunoglobulin M (IgM) corresponding to areas of increased matrix and hyalinosis. Weaker staining for IgM is also seen in the adjacent mesangium. (Immunofluorescence micrograph; ×400.)

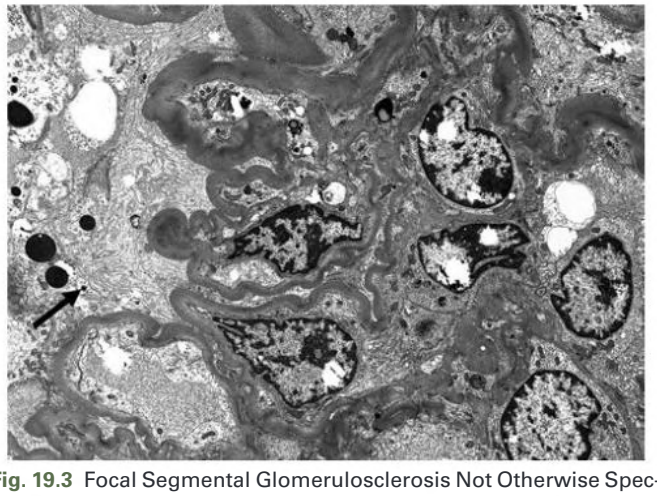

Fig. 19.3 Focal Segmental Glomerulosclerosis Not Otherwise Specified. Electron micrograph illustrates the lesion of segmental sclerosis with obliteration of the glomerular capillaries by increased extracellular matrix with wrinkled and retracted glomerular basement membranes. The overlying podocytes are detached *(arrow)*. (×3000.)

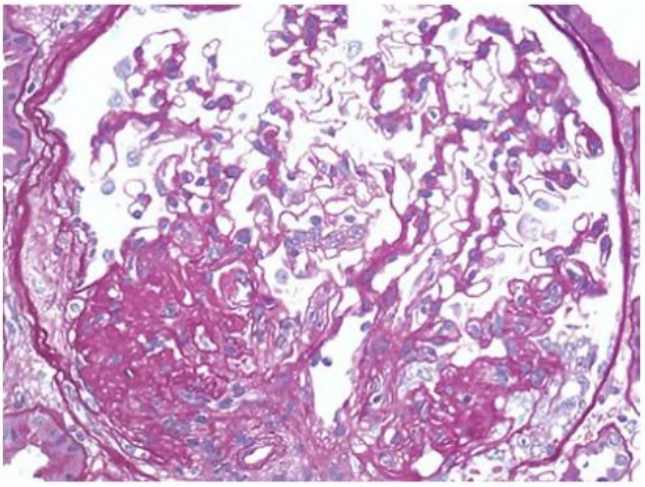

Fig. 19.4 Focal Segmental Glomerulosclerosis (FSGS), Perihilar Variant. A discrete lesion of segmental sclerosis and hyalinosis is located at the glomerular vascular pole (i.e., perihilar). The glomerulus is hypertrophied. The patient had secondary FSGS in the setting of severe obesity. (PAS; ×400.)

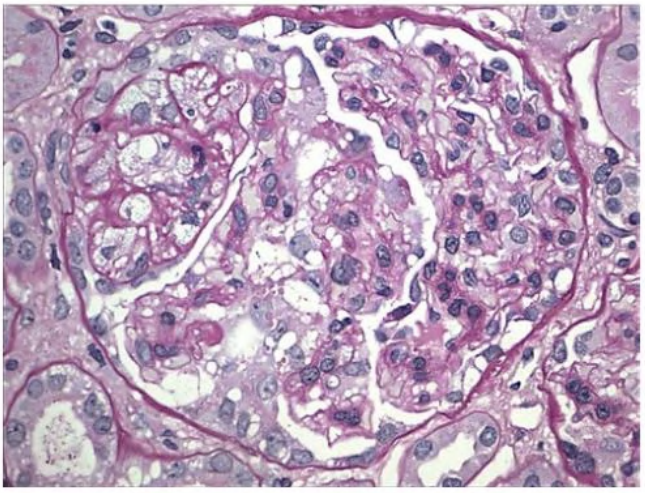

Fig. 19.5 Focal Segmental Glomerulosclerosis, Cellular Variant. The glomerular capillary lumina are segmentally occluded by endocapillary cells, including foam cells, infiltrating mononuclear leukocytes, and pyknotic debris. The findings mimic a proliferative glomerulonephritis because of the hypercellularity and absence of extracellular matrix material. There are hypertrophy and hyperplasia of the overlying visceral epithelial cells, some of which contain protein resorption droplets. (PAS; ×400.)

glomerular capillary bed may favor the development of lesions at the vascular pole.[20,36]

Cellular Variant of Focal Segmental Glomerulosclerosis

The cellular variant is characterized by focal and segmental endocapillary hypercellularity that may mimic a form of focal proliferative glomerulonephritis.[47,49] Glomerular capillaries are segmentally occluded by endocapillary hypercellularity, including foam cells, infiltrating leukocytes, karyorrhectic debris, and hyaline (Fig. 19.5). There is often hyperplasia of the visceral epithelial cells, which may appear swollen, sometimes forming pseudocrescents. Foot process effacement is typically severe. This variant requires that tip lesions and collapsing lesions be excluded. Cellular FSGS is thought to represent an early stage in the development of segmental lesions and is usually primary.

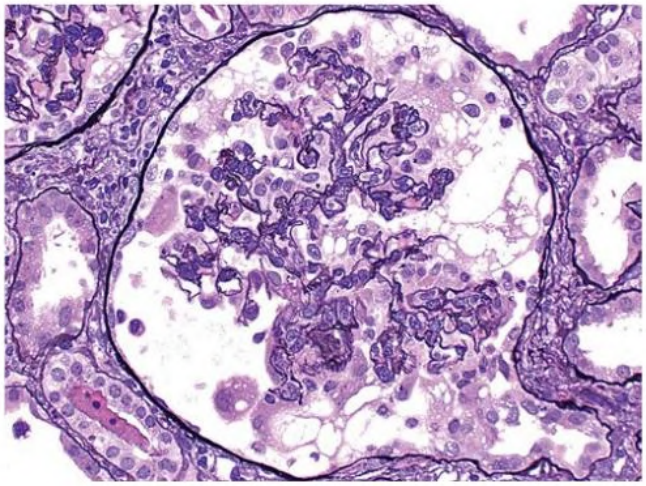

Fig. 19.6 Focal Segmental Glomerulosclerosis, Collapsing Variant. There is global implosive collapse of the glomerular tuft with obliteration of capillary lumina. The overlying visceral epithelial cells appear hypertrophied and hyperplastic, show prominent cytoplasmic vacuolization, and contain enlarged nuclei and nucleoli. There are no adhesions to Bowman's capsule. (Jones methenamine silver; ×400.)

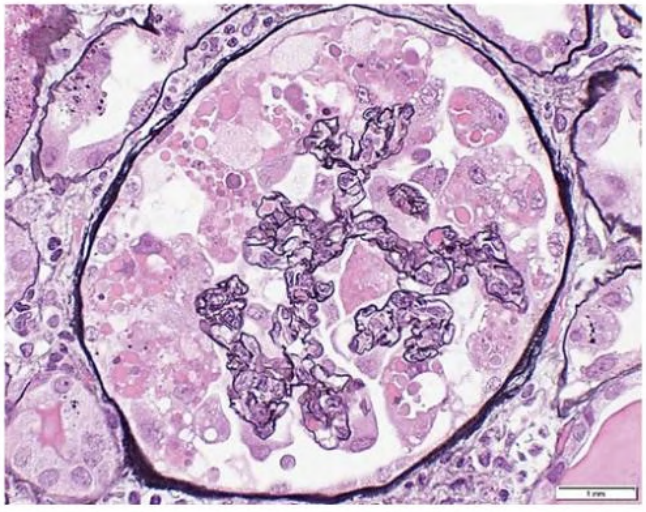

Fig. 19.7 Focal Segmental Glomerulosclerosis, Collapsing Variant. In this example, exuberant proliferation of glomerular epithelial cells forms a pseudocrescent that obliterates the urinary space. The hypertrophied and hyperplastic glomerular epithelial cells contain abundant intracytoplasmic protein droplets. The pseudocrescent lacks the spindle cell morphology, ruptures of Bowman's capsule, or pericellular matrix typically seen in true inflammatory crescents of parietal epithelial origin. (Jones methenamine silver; ×400.)

Collapsing Variant of Focal Segmental Glomerulosclerosis

The collapsing variant is defined by at least one glomerulus with segmental or global collapse and overlying hypertrophy and hyperplasia of visceral epithelial cells (Fig. 19.6). In these areas, there is occlusion of glomerular capillary lumina by implosive GBM wrinkling and collapse.[47,50] The collapsing lesion is more often global than segmental. Overlying visceral epithelial cells display hypertrophy and hyperplasia and express proliferation markers. These glomerular epithelial cells often contain prominent intracytoplasmic protein resorption droplets and may fill Bowman's space, forming pseudocrescents (Fig. 19.7). Attenuated collapsing lesions are characterized by retraction and solidification of the tuft, which is often capped by a layer of reactive glomerular epithelial cells (Fig. 19.8). Studies suggest that dysregulated podocytes, activated parietal cells (expressing claudin and CD44), and progenitor cells (expressing stem cell markers CD133 and CD24) that line Bowman's capsule contribute to the glomerular epithelial cell hyperplasia and glomerulosclerosis.[55]

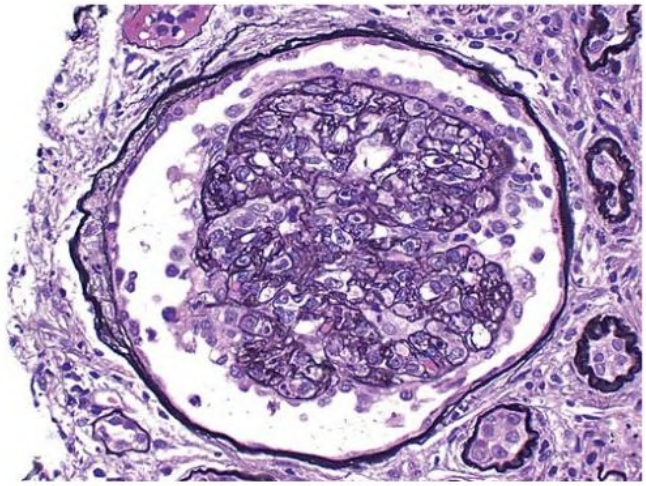

Fig. 19.8 Focal Segmental Glomerulosclerosis, Collapsing Variant. An attenuated lesion of collapsing focal segmental glomerulosclerosis shows global retraction and early solidification of the glomerular tuft, which is capped by reactive-appearing glomerular epithelial cells. (Jones methenamine silver; ×400.)

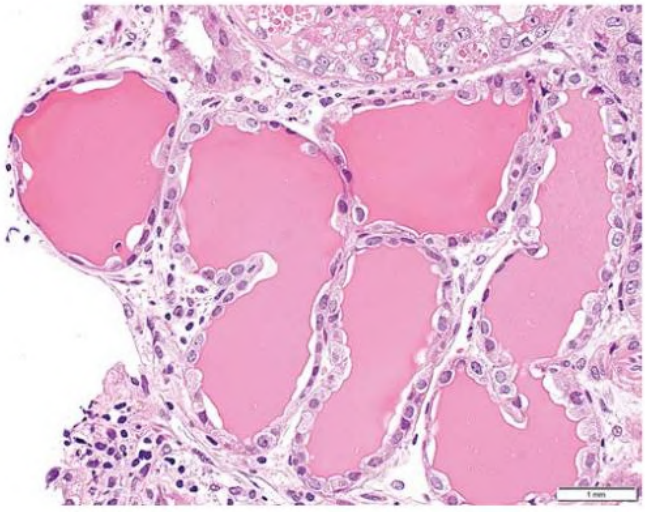

Fig. 19.9 Focal Segmental Glomerulosclerosis, Collapsing Variant. The kidney parenchyma contains abundant tubular microcysts with proteinaceous casts. (H&E; ×200.)

In collapsing FSGS, there is prominent tubulointerstitial disease, including acute tubular injury, tubular atrophy, interstitial fibrosis, interstitial edema, and inflammation. A distinctive feature is the presence of dilated tubules forming microcysts that contain proteinaceous casts (Fig. 19.9). On EM, there is typically severe foot process effacement affecting both collapsed and noncollapsed glomeruli. Collapsing glomerulopathy may occur as a primary form of FSGS.[56] It is also frequently observed in secondary FSGS caused by viral infections (including HIV and SARS-CoV-2), lupus podocytopathy, hemophagocytic syndrome, and interferon therapy in conjunction with high-risk *APOL1* variants.[29,32,57] The presence of endothelial tubuloreticular inclusions helps to identify collapsing glomerulopathy secondary to HIV-associated nephropathy, COVID-19–associated nephropathy

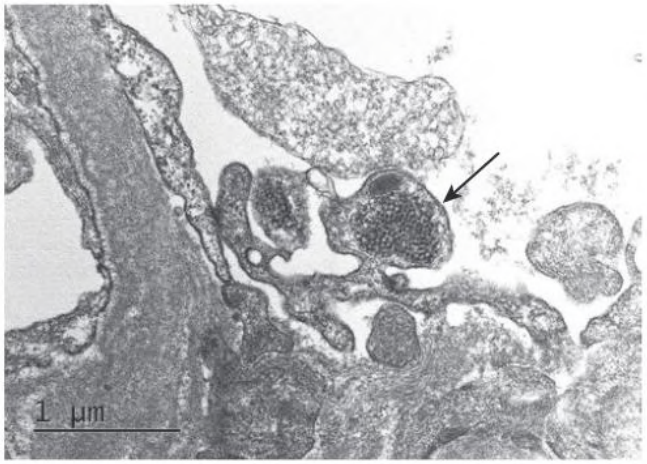

Fig. 19.10 Focal Segmental Glomerulosclerosis, Collapsing Variant, COVID-19–associated nephropathy. A glomerular endothelial cell contains a large intracytoplasmic tubuloreticular inclusion ("interferon footprint"; *arrow*) composed of interanastomosing tubular structures within a dilated cisterna of endoplasmic reticulum. (EM; ×40,000.)

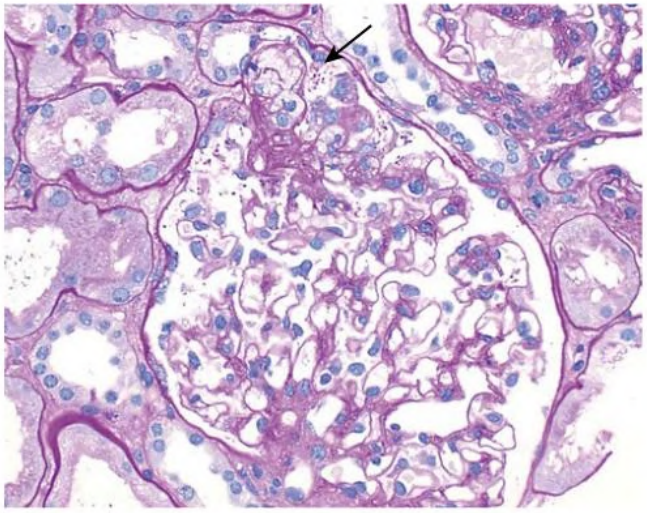

Fig. 19.11 Focal Segmental Glomerulosclerosis, Tip Lesion Variant. A cellular tip lesion displays engorgement of glomerular capillaries by foam cells and adhesion of the involved segment to the origin of the proximal tubule/tubular pole *(arrow)*. (PAS; ×200.)

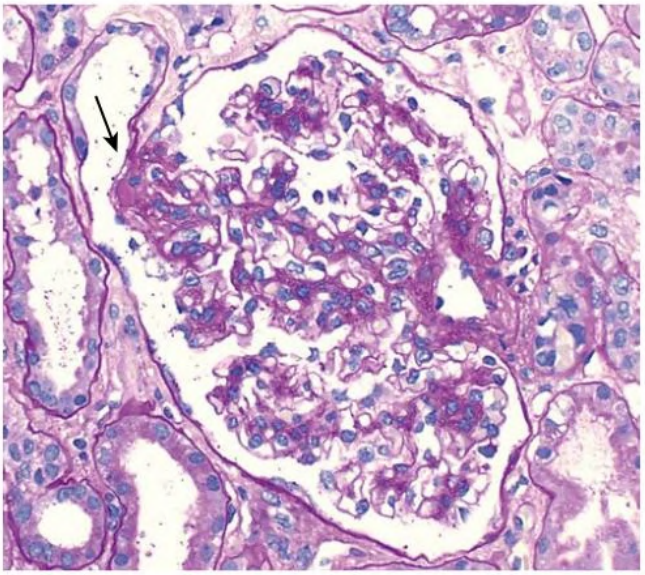

Fig. 19.12 Focal Segmental Glomerulosclerosis, Tip Lesion Variant. A sclerosing tip lesion forms an adhesion to the tubular pole *(arrow)*. (PAS; ×200.)

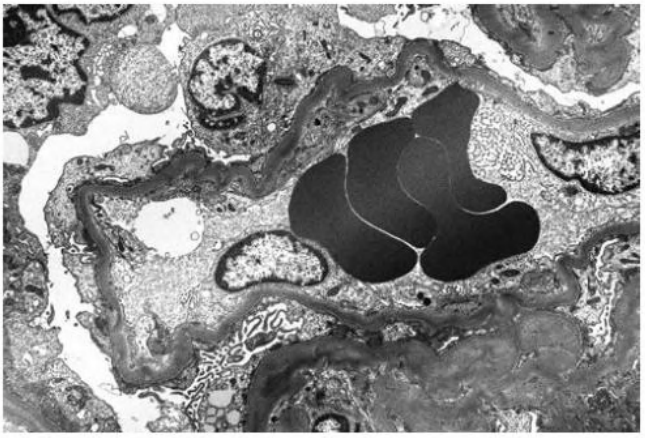

Fig. 19.13 Focal Segmental Glomerulosclerosis, Tip Lesion Variant. Electron microscopy reveals complete podocyte foot process effacement with matting of the actin cytoskeleton, selling of podocyte cell bodies, and focal microvillous transformation of podocyte cytoplasm. (EM; ×3000).

lupus podocytopathy, or interferon therapy. These "interferon footprints" consist of 24-nm interanastomosing tubular structures located within dilated cisternae of endoplasmic reticulum (Fig. 19.10).

Tip Variant of Focal Segmental Glomerulosclerosis

The tip variant is defined by the presence of at least one segmental lesion involving the tip domain, the outer 25% of the tuft next to the origin of the proximal tubule.[47,48,58] There is either adhesion between the tuft and Bowman's capsule or confluence of swollen podocytes with parietal or tubular epithelial cells at the tubular lumen or neck. The segmental lesions may be cellular or sclerosing (Figs. 19.11 and 19.12). The presence of perihilar sclerosis or collapsing sclerosis rules out the tip variant. In one study of FSGS tip lesions, biopsy specimens had glomerular tip lesions alone in 26% and glomerular tip lesions plus other peripheral FSGS lesions in the other 74%.[48] The degree of foot process effacement is usually severe (Fig. 19.13). Most cases are primary and resemble MCD with respect to abrupt onset of full nephrotic syndrome, high likelihood of responsiveness to corticosteroid therapy, and favorable prognosis relative to other FSGS variants. Higher shear stress and tuft prolapse at the tubular pole are likely to play a role in the morphogenesis of this lesion.[4]

Other Variants of Focal Segmental Glomerulosclerosis

Two histologic variants often included within the FSGS spectrum are FSGS with diffuse mesangial hypercellularity and C1q nephropathy (see Chapter 29).[1] FSGS with *diffuse mesangial hypercellularity* has lesions of FSGS on a background of generalized mesangial hypercellularity. By IF, there is often diffuse mesangial positivity for IgM, with more variable mesangial staining for C3. EM reveals extensive foot process effacement. Amorphous hyaline-like electron-dense deposits are variably present in the paramesangial region. This variant occurs almost exclusively in young children.[59,60]

C1q nephropathy is defined by dominant or codominant IF staining for C1q, mesangial electron-dense deposits, and light microscopic findings resembling FSGS or MCD with variable mesangial hypercellularity. In one study, 17 patients had a light microscopic appearance of

BOX 19.3 Risk Factors for Progressive Kidney Disease in Focal Segmental Glomerulosclerosis

Clinical Features at Biopsy
- Severity of nephrotic-range proteinuria
- Elevated serum creatinine
- Black race

Histopathologic Features at Biopsy
- Collapsing variant
- Tubulointerstitial fibrosis

Clinical Features During Disease Course
- Failure to achieve partial or complete remission

FSGS (including six collapsing and two cellular) and three of MCD.[53] In addition to C1q staining, biopsy specimens may show deposition of other immunoglobulins (particularly IgG) and complement components (C3), making it important to exclude other clinical disease such as lupus nephritis. In C1q nephropathy, electron-dense deposits are typically located in the paramesangial region subjacent to the GBM reflection. There is variable foot process effacement. In one series of C1q nephropathy, many cases represented a subgroup of primary FSGS or MCD, whereas in others, an idiopathic immune complex–mediated glomerulonephritis was noted.[54]

Distinguishing Pathologic Features of Secondary Focal Segmental Glomerulosclerosis

Although the pathology of some secondary forms of FSGS closely resembles primary FSGS, there are several noteworthy differences. Collapsing FSGS, particularly when tubuloreticular inclusions are present, should prompt exclusion of viral, autoimmune, or drug-induced causes of disease. In secondary adaptive forms of FSGS, kidney biopsy typically shows glomerulomegaly and predominantly perihilar lesions of segmental sclerosis and hyalinosis. In secondary FSGS resulting from loss of kidney mass, such as from reflux nephropathy or hypertensive arterionephrosclerosis, FSGS is usually seen on a background of extensive global glomerulosclerosis, tubular atrophy, interstitial fibrosis, and arteriosclerosis. In secondary FSGS related to sickle cell disease, glomerular hypertrophy and sclerosis are associated with capillary congestion by sickled erythrocytes and double contours of the GBM resembling those seen in chronic thrombotic microangiopathy.[61,62] In adaptive forms of FSGS, the degree of foot process effacement tends to be relatively mild, affecting less than 50% of the total glomerular capillary surface area. In one study, a cutoff of greater than 1500 nm for mean foot process width was able to distinguish primary from adaptive FSGS.[16]

NATURAL HISTORY AND PROGNOSIS

The natural history of FSGS is varied. Without response to therapy, patients with primary FSGS experience a progressive increase in proteinuria and progression to kidney failure. Spontaneous remission is uncommon.[63] In treatment-refractory patients, ESKD occurs 5 to 20 years from presentation, with approximately 50% of such patients developing kidney failure within 10 years.[64]

Certain epidemiologic, clinical, and histologic findings at diagnosis help predict the long-term course of patients with FSGS (Box 19.3). African Americans with FSGS experience a more rapid progression to ESKD than people of other races.[65] At biopsy, reduced GFR, greater degrees of proteinuria, and greater degrees of interstitial fibrosis predict a more progressive course.[66,67] In general, outcomes are best for tip variant and worst for collapsing variant of primary FSGS, with intermediate outcome in FSGS NOS.[47,68] In a comparative series, the percentage of complete and partial remission was greatest for tip lesion (76%), lowest for collapsing variant (13%), and intermediate for cellular (44%) and FSGS NOS (39%). There was a strong inverse correlation between remission rates and progression to ESKD among these subgroups. Accordingly, the likelihood of ESKD was greatest for collapsing variant (65%), lowest for tip lesion (6%), and intermediate for cellular variant (28%) and FSGS NOS (35%).[47] Although collapsing variant has the worst outcome among the FSGS variants, when patients with collapsing variant are matched with patients with FSGS NOS for baseline levels of kidney function, proteinuria, and immunosuppression, responses to treatment are similar, highlighting the importance of early detection and aggressive therapy.[50] A key predictor of prognosis is remission of proteinuria. Complete remission of the nephrotic syndrome is associated with excellent kidney survival compared with those who do not remit.[64] Even patients with a partial remission of nephrotic syndrome have a lower rate of long-term kidney failure.[64]

TREATMENT

Before considering the treatment of FSGS, it is useful to define remission of proteinuria. There has been considerable variability in the definition of remission, and the KDIGO Guideline has attempted to unify these definitions (Box 19.2).[11] Recently a novel definition of partial remission (40% proteinuria reduction and proteinuria <1.5 g/g) was useful in predicting prognosis.[69]

Although FSGS is common in adults, there are few randomized controlled trials (RCTs) on which to base treatment decisions.[11] However, almost all patients with FSGS will benefit from good supportive care (e.g., blockade of the renin-angiotensin-aldosterone system), as described in Chapter 82. The optimal treatment of FSGS is not well defined. In part, this relates to properly defining primary and secondary forms of the disease, including unrecognized genetic variants (Fig. 19.14). For example, even after biopsy, it is not always clear whether an obese person with glomerulomegaly, FSGS lesions, and nephrotic-range proteinuria has secondary or primary disease. This problem of heterogeneity in the patient population also potentially translates to varying treatment responses in clinical trials.[70] In general, we recommend treating patients with presumed primary FSGS with immunosuppressive medications. In contrast, immunosuppression is not needed in patients with subnephrotic proteinuria, genetic or secondary FSGS, or FSGS of uncertain etiology (Fig. 19.14).[11]

First-Line Therapy for Focal Segmental Glomerulosclerosis

Corticosteroids as Initial Therapy (Table 19.2)

Corticosteroids appear to increase the likelihood of remission[64,71-73] and are considered first-line therapies for primary FSGS.[11] Although earlier reports suggested that primary FSGS is a steroid-resistant disease with poor outcomes,[74] subsequent studies showed that longer treatment duration with higher doses of corticosteroids was associated with improved response rates of 50% to 60%,[63,66,75] and in one study up to 80%.[76] The suggested regimens (as per KDIGO Guideline) are shown in Box 19.2.[11] A suggested maximum duration of high-dose corticosteroid treatment for remission to be achieved is 16 weeks. However, based on available evidence, it is uncertain whether the side effects of 16 weeks of high-dose glucocorticoid treatment outweigh benefits in primary FSGS, as studies have been inconsistent in the reporting of adverse events. The optimal duration of glucocorticoid therapy is

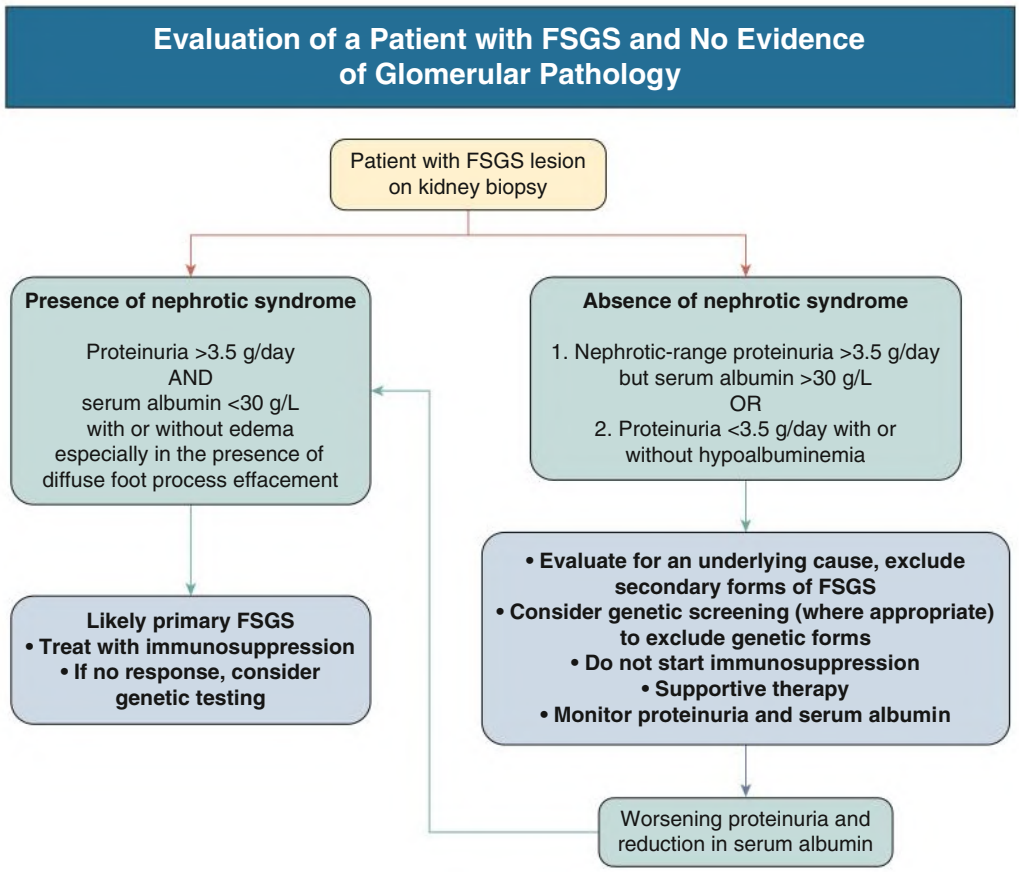

Fig. 19.14 Evaluation of a patient with focal segmental glomerulosclerosis (FSGS) lesion on the kidney biopsy and no evidence of other glomerular pathology. (From KDIGO GN Guideline. *Kidney Int.* 2021;100(4S):S1–S276.)

unknown. A slow taper is suggested after initial response, and for such patients, the suggested total period of glucocorticoid treatment is 6 months as tolerated.[11] If there is no remission in proteinuria, corticosteroids should be tapered off after 16 weeks.

Corticosteroid-Sparing or Noncorticosteroid Regimens as Initial Therapy

Patients may not tolerate high doses of glucocorticoids, and with the need for prolonged treatment regimens for FSGS, adverse effects of corticosteroids may be unacceptable (Table 19.2). Moreover, in patients with obesity, uncontrolled diabetes, psychiatric disease, or severe osteoporosis, corticosteroids may be relatively contraindicated.[77] CNIs (cyclosporine or tacrolimus) and antimetabolites (azathioprine or mycophenolic acid analogs) have been used to avoid or reduce exposure to corticosteroids. In a small observational study, tacrolimus monotherapy achieved partial remission in all six patients after about 6 months.[78] In a randomized study of 33 FSGS patients, mycophenolate mofetil (MMF) 2 g/day for 6 months with prednisolone 0.5 mg/kg/day for 2 to 3 months was compared with conventional therapy with prednisolone 1 mg/kg/day for 3 to 6 months. Remission was similar in the MMF group 70% versus 69% in the conventional corticosteroid group.[79] A retrospective observational study compared high-dose oral prednisone (1 mg/kg/day) for at least 4 months followed by a taper, with lower dose prednisone (0.5 mg/kg/day) in combination with cyclosporine (3 mg/kg/day initially, tapering to 50 mg/day) or azathioprine (2 mg/kg/day initial dose, tapering to 0.5 mg/kg/day). Average duration of treatment was 20 months. Low-dose prednisone was given to 16 patients with obesity, bone disease, or mild diabetes. Remission rates were comparable: 63% for prednisone, 80% for prednisone plus azathioprine, and 86% for prednisone plus cyclosporine.[72] In a large retrospective study, 173 patients were treated with corticosteroids alone and 90 treated with CNIs with or without corticosteroids; the risk of ESKD was similar in the two groups.[80]

Corticosteroid-Resistant Focal Segmental Glomerulosclerosis

For patients with corticosteroid-resistant FSGS, the CNIs (cyclosporine or tacrolimus) are recommended.[11] Other options include MMF, rituximab, and corticotrophin.

Calcineurin Inhibitors (Table 19.3)

In one study, steroid-resistant adult patients with FSGS randomized to either cyclosporine with low-dose corticosteroids or the same low dose of corticosteroids alone for a 6-month period exhibited a much higher remission rate (12% complete and >70% complete or partial) in the group treated with cyclosporine.[81] Despite some relapses after cyclosporine discontinuation, the treated group had significantly more patients in remission and better GFR at long-term follow-up. In another randomized controlled study, cyclosporine monotherapy was used, with similar results.[82] Although data on tacrolimus are more limited, results are similar.[83] Because the major side effects (nephrotoxicity, hypertension, and hyperkalemia) are similar with cyclosporine and tacrolimus, the choice depends on other adverse effects (e.g., gum swelling, tremor, hirsutism with cyclosporine, and diabetes with tacrolimus). Because there is a high relapse rate when cyclosporine is discontinued early,[81] we use a 1-year treatment course with a slow taper in patients with a favorable reduction of proteinuria on CNIs.[11]

TABLE 19.2 Initial Treatment of Primary Focal Segmental Glomerulosclerosis

Treatment	Dose and Duration
Glucocorticoids	**Starting Dose**
	• High-dose glucocorticoid therapy with prednisone at daily single dose of 1 mg/kg (maximum 80 mg) or alternate-day dose of 2 mg/kg (maximum 120 mg)
	High-Dose Glucocorticoid Treatment Duration
	• Continue high-dose glucocorticoid therapy for at least 4 weeks and until complete remission is achieved, or a maximum of 16 weeks, whichever is earlier
	• Patients who are likely to remit will show some degree of proteinuria reduction before 16 weeks of high-dose treatment
	• It may not be necessary to persist with high-dose glucocorticoid therapy until 16 weeks if the proteinuria is persistent and unremitting, especially in patients who are experiencing side effects
	Glucocorticoid Tapering
	• If complete remission is achieved rapidly, continue high-dose glucocorticoid treatment for 2 weeks after the disappearance of proteinuria, whichever is longer. Reduce prednisone by 5 mg every 1–2 weeks to complete a total duration of 6 months.
	• If partial remission is achieved within 8–12 weeks of high dose glucocorticoid treatment, continue until 16 weeks to ascertain whether further reduction of proteinuria and complete remission may occur. Thereafter, reduce the dose of prednisone by 5 mg every 1–2 weeks to complete a total duration of 6 months.
	• If the patient proves to be steroid resistant or develops significant toxicities, glucocorticoids should be rapidly tapered as tolerated and treatment with alternative immunosuppression like a CNI inhibitor should be considered
CNIs	**Starting Dose**
	• Cyclosporine 3–5 mg/kg/day in two divided doses *or* tacrolimus 0.05–0.1 mg/kg/day in two divided doses
	• Target trough levels could be measured to minimize nephrotoxicity
	• Cyclosporine target trough level: 100–175 ng/mL
	• Tacrolimus target trough level: 5–10 ng/mL
	Treatment Duration for Determining CNI Efficacy
	• Cyclosporine or tacrolimus should be continued at doses achieving target trough level for at least 6 months, before considering the patient to be resistant to CNI treatment
	Total CNI Treatment Duration
	• In patients with partial or complete remissions, cyclosporine or tacrolimus should be continued at doses achieving target trough level for at least 12 months to minimize relapses
	• The dose of cyclosporine or tacrolimus can be slowly tapered over a course of 6–12 months as tolerated
	• Consider discontinuing CNI if the eGFR continues to decline to <30 mL/min/1.73 m^2

CNI, Calcineurin inhibitor; *eGFR*, Estimated glomerular filtration rate.

TABLE 19.3 Treatment of Steroid-Resistant Primary Focal Segmental Glomerulosclerosis

Treatment	Dose and Duration
CNIs	**Starting Dose**
	• Cyclosporine 3–5 mg/kg/day in two divided doses *or* tacrolimus 0.05–0.1 mg/kg/day in two divided doses
	• Target trough levels could be measured to minimize nephrotoxicity
	• Cyclosporine target trough level: 100–175 ng/mL
	• Tacrolimus target trough level: 5–10 ng/mL
	Treatment Duration for Determining CNI Efficacy
	• Cyclosporine or tacrolimus should be continued at doses achieving target trough level for at least 6 months before considering the patient to be resistant to CNI treatment
	Total CNI Treatment Duration
	• In patients with partial or complete remissions, cyclosporine or tacrolimus should be continued at doses achieving target trough level for at least 12 months to minimize relapses
	• The dose of cyclosporine or tacrolimus can be slowly tapered over a course of 6–12 months as tolerated
	• Consider discontinuing CNI if the eGFR continues to decline to <30 mL/min/1.73 m^2
Inability to tolerate or contraindications to CNIs	• Lack of quality evidence for any specific alternative agents
	• MMF and high-dose dexamethasone, rituximab, and ACTH have been considered
	• Treatment will need to be personalized and is dependent on availability of drugs and resources, as well as the benefits of further treatment and risks of adverse effects of immunosuppression
	• Patients should be referred to specialized centers with the appropriate expertise and should be evaluated on the appropriate use of alternative treatment agents or to discontinue further immunosuppression

ACTH, Adrenocorticotrophic hormone; *CNI*, calcineurin inhibitor; *eGFR*, estimated glomerular filtration rate; *MMF*, mycophenolate mofetil.

Mycophenolic Acid Analogs

Mycophenolic acid analogs (mycophenolate-MMF and mycophenolic acid) have been used successfully in several uncontrolled series of patients with FSGS.[84,85] One multicenter prospective RCT of cyclosporine versus oral MMF plus dexamethasone in 138 children and adults up to age 40 years who had corticosteroid-resistant FSGS showed no difference in remission rates.[86] However, this trial did not meet recruitment targets and was likely underpowered. Further, as with other clinical trials of FSGS, patients with secondary FSGS were likely included.

Other Therapies

Use of sirolimus has been limited since the drug was reported to induce proteinuria and FSGS lesions in kidney transplant recipients. In one series, sirolimus was associated with worsening of kidney function, episodes of acute kidney injury, and no remissions of the nephrotic syndrome.[87] The addition of plasmapheresis to immunosuppressive medications, which has been successful in treating some patients with recurrent FSGS in the kidney allograft (see Chapter 113), has not been evaluated in patients with native kidney FSGS. Likewise, use of low-density lipoprotein apheresis and galactose (a monosaccharide sugar with a high affinity for CLC1, a putative permeability factor in patients with FSGS) has been anecdotal.[88,89] Rituximab has been used anecdotally in several studies of small numbers of patients with FSGS who have either not responded to other treatments or have become dependent on these therapies. It has proved more successful for steroid-dependent[90] than steroid-resistant patients.[91] Corticotropin (adrenocorticotropic hormone) has shown benefit in small numbers of patients with FSGS resistant to multiple other immunosuppressive agents, but it also has not been studied in large RCTs.[92]

Therapy of Secondary Focal Segmental Glomerulosclerosis

For patients with secondary forms of FSGS, treating the underlying cause should be the initial step. Patients with FSGS secondary to obesity and heroin nephropathy have had remissions of proteinuria after weight reduction or cessation of heroin use, respectively. In HIV-associated nephropathy, therapy with highly active antiretroviral drugs and blockers of the renin-angiotensin system has proven useful (see Chapter 58). The role of immunosuppression has not yet been proven in RCTs in any form of secondary FSGS. In all forms of secondary FSGS, supportive therapy as outlined in Chapter 82 is essential to prevent progressive kidney disease. In patients with primary idiopathic or a secondary form of FSGS who remain nephrotic, fluid retention and edema can be managed with salt restriction and diuretics (see Chapter 16). In general, genetic forms of FSGS are not responsive to immunosuppressive medications. Although blockers of the renin-angiotensin system are commonly used, there are no studies that have reported outcomes. A small proportion of children with genetic FSGS have demonstrated proteinuria reduction with CNIs.[93,94]

KIDNEY TRANSPLANTATION

Approximately 30% of patients with primary FSGS who develop ESKD and undergo kidney transplantation develop recurrent FSGS in the allograft. Risk factors for recurrence include early-onset FSGS, and severe proteinuria with a rapid course to ESKD. Patients who have lost a prior allograft due to recurrent FSGS are at highest risk for recurrence. Treatment protocols include plasmapheresis, rituximab, high-dose CNIs, and renin-angiotensin system blockers.[95] Recurrent FSGS is further discussed in Chapter 113.

SELF-ASSESSMENT QUESTIONS

1. Use of which of the following medications has *not* been associated with proteinuria and the histologic pattern of FSGS?
   - **A.** Interferon β
   - **B.** Pamidronate
   - **C.** Sirolimus
   - **D.** Amlodipine
   - **E.** Lithium
2. Which histologic feature on kidney biopsy suggests a secondary FSGS pattern related to structural-functional adaption?
   - **A.** Adhesions or synechiae to Bowman's capsule
   - **B.** Glomerulomegaly and perihilar segmental sclerosis and hyalinosis
   - **C.** Hypertrophy and hyperplasia of the visceral epithelial cells
   - **D.** Diffuse mesangial hypercellularity
   - **E.** Collapse of part of or all the glomerular tuft
3. Which of the following statements about the prognosis of primary FSGS is *true?*
   - **A.** The outcome is worse for patients with the tip variant versus other patterns.
   - **B.** The outcome is better for patients with the collapsing variant versus other patterns.
   - **C.** Remission of proteinuria is a strong predictor of a favorable outcome.
   - **D.** African Americans have a prognosis similar to that of Whites if controlling for hypertension and degree of proteinuria.
   - **E.** The degree of glomerular sclerosis is the strongest histologic predictor of a poor kidney outcome.

Inherited Causes of Nephrotic Syndrome

Ronen Schneider, Friedhelm Hildebrandt

INTRODUCTION

The discovery of the genes encoding the slit membrane proteins nephrin *(NPHS1),*[1] podocin *(NPHS2),*[2] and phospholipase C epsilon 1 *(PLCE1)*[3] as causing steroid-resistant nephrotic syndrome (NS), if mutated, has stimulated extensive research into monogenic causes of NS. In the last 20 years, acceleration of next-generation sequencing has permitted identification of more than 63 monogenic causes of NS, and this number is rapidly increasing (Fig. 20.1 and references in Table 20.1). Most of these genes are highly expressed in the glomerular podocytes, implicating podocytes as the primary site of injury in NS. The encoded proteins of these genes cluster within functional pathways critical for podocyte biology and cause disruption of the filtration barrier if mutated.

Epidemiology

Steroid-resistant nephrotic syndrome (SRNS) is the second leading cause of pediatric chronic kidney disease (CKD), responsible for 15% of all CKD cases before the age of 25 years. A monogenic cause of SRNS can be found in 10% to 30% of cases. Specific SRNS genes or distinct mutations (alleles) in the same SRNS gene may cause characteristic phenotypes, which may pertain to age of onset of disease.[4,5] Adult-onset NS is of heterogeneous origin and may include causes such as membranous glomerulonephritis, minimal change nephropathy, diabetic nephropathy, and amyloid nephropathy. The majority of these diseases do not seem to have a genetic basis, at least not a monogenic one, and genetic workup for polymorphisms in these diseases (e.g., PLA2R polymorphisms) does not have clinical relevance so far. However, genetic testing should be considered in selected cases of adult-onset focal segmental glomerulosclerosis (FSGS) (see "Diagnosis" section).

A study using next-generation sequencing tested a large international cohort of patients with SRNS manifesting before age 25 years (1783 families).[4] The diagnostic panel included 21 genes with a recessive mode of inheritance and six genes with a dominant mode of inheritance. A genetic diagnosis was established in 526 of 1783 families (29.5%) in whom the condition manifested before age 25 years.[4] Stringent criteria for calling mutations "disease causing" were applied (Box 20.1). The highest rate of mutation detection of 69% was in the youngest group of patients (0–3 months), a percentage that decreased with older age (Fig. 20.2).

A recent study used whole-exome sequencing (WES) analysis and established a genetic diagnosis in 25% of individuals younger than 25 years who had SRNS.[6] This study showed that four genes were major SRNS genes: *NPHS1* (4.3% of 300 individuals with SRNS), *PLCE1* (3.7%), *NPHS2* (2.7%), and *SMARCAL1* (2.7%) (Fig. 20.3). The most prevalent SRNS dominant genes are *INF2, TRPC6,* and *ACTN4* (see Fig. 20.3 and Table 20.1).[6]

Etiology

The proteins encoded by the genes that cause monogenic SRNS map back onto distinct structural protein complexes and signaling pathways that reveal what is essential for glomerular function (see Fig. 20.1). In particular, it has been determined that almost all mutations involve genes/proteins important for the slit diaphragm function or essential pathways in podocytes. Interdigitations of podocyte foot processes form the glomerular slit membrane between them, which is critical for the filtering process and retention of protein in the bloodstream (see also Chapter 1). The integrity of the glomerular slit membrane is lost in NS. Thus, identification of monogenic causes of NS revealed dozens of proteins, each of which is an indispensable component of glomerular function, because loss of their function in a monogenic form of NS inescapably leads to proteinuria and FSGS. Knowledge of these mutations helps to understand the physiology of the glomerular filtration barrier and the pathogenic mechanisms which cause NS. These functional complexes include proteins involved in glomerular slit membrane–associated components, actin-binding proteins, actin-regulating small GTPases of the Rho/Rac/Cdc42 family, coenzyme Q_{10} (CoQ_{10}) biosynthesis, sphingosine-1-phosphate (S1P) metabolism, nuclear transcription factors, nucleoporins, lysosomal proteins, endosomal trafficking regulating proteins, tRNA modification (KEOPS complex), and laminin/integrin receptors (focal adhesions) (see Fig. 20.1).

The power of identification of such single-gene causes of NS lies in the fact that recessive mutations (and to a lesser degree, dominant mutations) almost always convey full penetrance and thereby represent the cause of NS (i.e., the etiology) rather than representing only an increased risk for acquiring disease (see Box 20.1). Thus, mutations in the 63 monogenic genes can be considered causative of NS (see Table 20.1).

CLINICAL PRESENTATION

Mutations in recessive genes tend to cause SRNS in early childhood, whereas there is a tendency for mutations in dominant SRNS genes (e.g., *TRPC6, INF2*) to cause adult-onset SRNS,[7,8] with the exception of *WT1*.[4] In a study, mutations in *WT1* have been shown to exhibit a biphasic distribution for onset of NS with a first peak at 4 to 12 months and a second peak for age of onset beyond 18 years of age (see Fig. 20.2).[4] This difference in age of presentation between recessive and dominant diseases is a well-reported genetic phenomenon that is not completely understood. Perhaps late onset could be explained by molecular mechanisms in dominant diseases that can result in an age-related penetrance. These mechanisms include haploinsufficiency, gain-of-function, and dominant-negative effects that often do not

Proteins That, if Mutated, Can Cause Monogenic Steroid-Resistant Nephrotic Syndrome

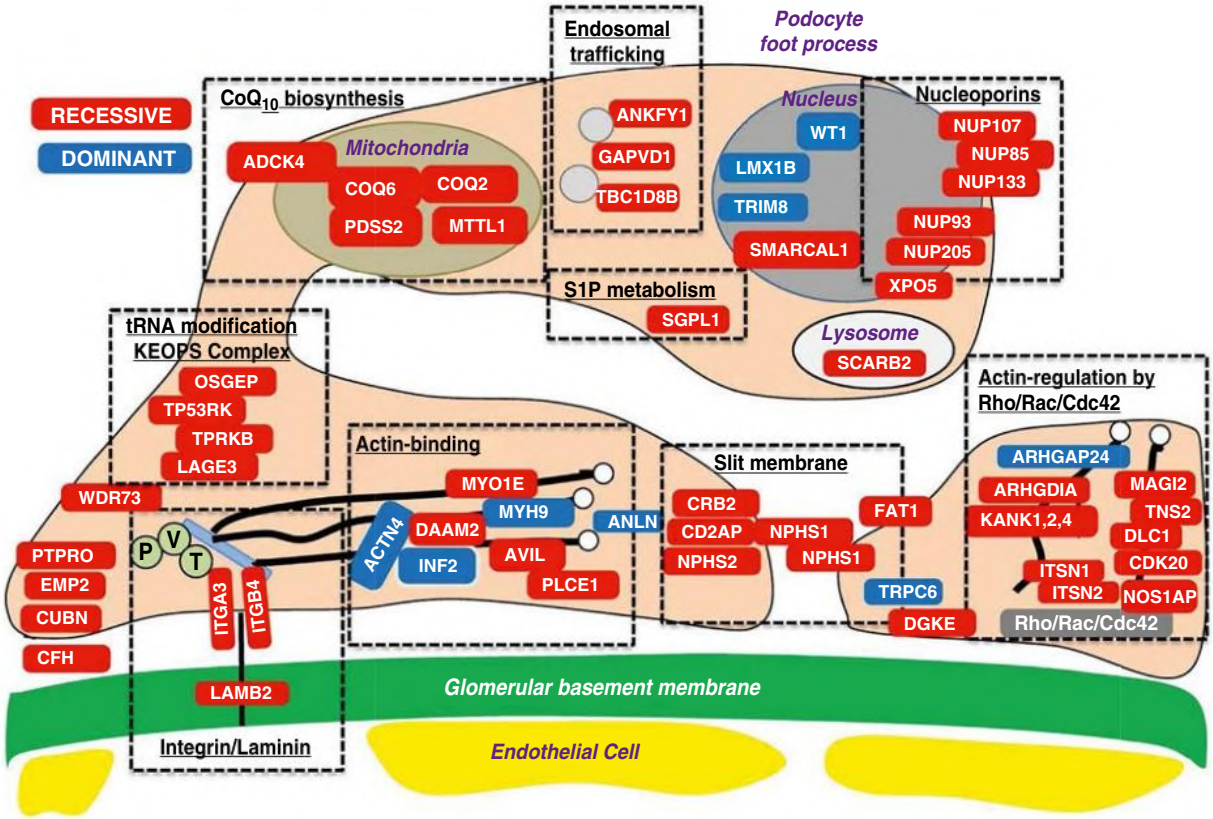

Fig. 20.1 Proteins Whose Genes, if Mutated, Cause Monogenic Steroid-Resistant Nephrotic Syndrome (SRNS) Define Essential Podocyte Functions. Identification of 63 single-gene (monogenic) causes of SRNS has revealed the glomerular epithelial cell, the podocyte, as central to the pathogenesis of SRNS, because almost all of the related genes are relevantly expressed in podocytes. Identification of genes that, if mutated, cause SRNS revealed distinct proteins and functional pathways as essential for glomerular function, because a mutation in any single one of them is sufficient to cause SRNS. This figure depicts a simplified cross section through a podocyte *(tan)* and a neighboring podocyte foot process, which is attached to the glomerular basement membrane *(green)* by laminin-integrin receptors. Fifty-three proteins whose genes, if mutated, cause recessive monogenic forms of SRNS are shown in *red,* and 10 proteins whose genes, if mutated, cause dominant forms of SRNS are shown in *blue* (see Tables 20.1 and 20.2). The 63 SRNS-related proteins were found to be part of protein-protein interaction complexes that participate in defined structural components or signaling pathways of podocyte function (shown within *black dashed boxes*). These proteins include proteins involved in coenzyme Q10 biosynthesis, S1P metabolism, nuclear transcription factors, nucleoporins, lysosomal proteins, actin-regulating small GTPases of the Rho/Rac/Cdc42 family, glomerular slit membrane–associated components, actin-binding proteins, tRNA modification (KEOPS complex), endosomal trafficking regulators, and laminin/integrin receptors (focal adhesions). Proteins that are encoded by recessive NS genes are marked in *red. ADCK4,* aarF domain containing kinase 4; *ANKFY1,* Rabankyrin-5; *ARHGDIA,* Rho GDP dissociation inhibitor (GDI) α; *AVIL,* advillin; *CD2AP,* CD2-associated protein; *CDK20,* cyclin-dependent kinase 20; *COQ2,* coenzyme Q2 4-hydroxybenzoate polyprenyltransferase; *COQ6,* coenzyme Q10 monooxygenase 6; *CRB2,* crumbs family member 2; *CUBN,* cubilin (intrinsic factor-cobalamin receptor); *DAAM2,* disheveled-associated activator of morphogenesis 2; *DGKE,* diacylglycerol kinase; *DLC1,* deleted in liver cancer 1; *EMP2,* epithelial membrane protein 2; *FAT1,* FAT tumor suppressor homolog 1; *GAPVD1,* GTPase-activating protein and VPS9 domain-containing protein 1; *GON7,* EKC/KEOPS complex subunit GON7; *ITGA3,* integrin, α3; *ITGB4,* integrin, β4; *ITSN1,* intersectin 1; *ITSN2,* intersectin 2; *KANK,* KN motif and ankyrin repeat domains 1/2/4; *LAGE3,* L antigen family member 3; *LAMB2,* laminin, β2; *MAGI2,* membrane-associated guanylate kinase, WW and PDZ domain containing 2; *MTTL1,* mitochondrial tRNA leucine 1; *MYO1E,* Homo sapiens myosin 1e; *NOS1AP,* Carboxyl-terminal PDZ ligand of neuronal nitric oxide synthase protein; *NPHS1,* nephrin; *NPHS2,* podocin; *NUP85,* nucleoporin 85 kDa; *NUP93,* nucleoporin 93 kDa; *NUP107,* nucleoporin 107 kDa; *NUP133,* nucleoporin 133 kDa; *NUP205,* nucleoporin 205 kDa; *OSGEP,* O-sialoglycoprotein endopeptidase; *PDSS2,* prenyl (decaprenyl) diphosphate synthase, subunit 2; *PLCE1,* phospholipase C, ε 1; *PTPRO,* protein tyrosine phosphatase, receptor type O; *SCARB2,* scavenger receptor class B member 2; *SGPL1,* sphingosine-1-phosphate lyase 1; *SMARCAL1,* SWI/SNF-related, matrix-associated, actin-dependent regulator of chromatin, subfamily a-like 1; *TBC1D8B,* TBC1 domain family member 8B TNS2, tensin 2; *TP53RK,* TP53-regulating kinase; *TPRKB,* TP53RK-binding protein; *WDR73,* WD repeat domain 73; and *XPO5,* Exportin; *YRDC,* YrdC domain-containing protein, mitochondrial 5. Proteins that are encoded by dominant NS genes are marked in *blue: ACTN4,* actinin, α4; *ANLN,* anillin; *ARHGAP24,* Rho GTPase-activating protein 24; *INF2,* inverted formin, FH2 and WH2 domain containing; *LMX1B,* LIM homeobox transcription factor 1-β; *MYH9,* myosin, heavy chain 9; *TRIM8,* E3 ubiquitin-protein ligase TRIM8; *TRPC6,* transient receptor potential cation channel, subfamily C, member 6; *WT1,* Wilms tumor 1. (Modified from Lovric S, Ashraf S, Tan W, Hildebrandt F. Genetic testing in steroid-resistant nephrotic syndrome: when and how? *Nephrol Dial Transplant.* 2016;31[11]:1802–1813.)

TABLE 20.1 Genes That, if Mutated, Cause Monogenic Steroid-Resistant, Steroid-Sensitive, or Dependent Nephrotic Syndrome[a]

Gene	Mode of Inheritance	Clinical Aspects	Reference
Genetic Causes of Nephrotic Syndrome That First Manifest in Adolescents and Adults			
INF2[b]	AD	Potential neurologic manifestations (Charcot-Marie-Tooth syndrome, see Table 20.2)	8
WT1[b]	AD	Biphasic age of onset Risk for WT/gonadoblastoma (mutation dependent, see Table 20.2)	39
ACTN4[b]	AD	Screen for mutation in family members if kidney donation is considered	40
TRPC6	AD	Familial FSGS, screen for mutation in family members if kidney donation is considered NS onset can present in up to fifth decade of life	7
MYH9	AD	Screen for mutation in family members if kidney donation is considered	41
PAX2	AD	Screen for mutation in family members if kidney donation is considered Variable age of presentation (2–20 years)	42
ANLN	AD	Screen for mutation in family members if kidney donation is considered	43
Genetic Causes of Nephrotic Syndrome That First Manifest in Infancy to Early Childhood			
NPHS[c]	AR	Congenital nephrotic syndrome Common in Finland Infants born prematurely with massive proteinuria and often have low-set ears and a small nose Mutation-dependent prognosis; ESKD in most cases by age 3 years	1
NPHS2[c]	AR	Early childhood or adolescent-adult onset, mutation dependent	2
PLCE1[c]	AR	Incomplete penetrance was observed (very rare for AR disease)	3
LAMB2[c]	AR	Potential eye abnormalities (Pierson syndrome; see Table 20.2)	44
SMARCAL1[c]	AR	Potential skeletal abnormalities (Schimke immuno-osseus dysplasia; see Table 20.2)	45
LMX1B	AD	See Table 20.2	46
ARHGDIA	AR	May be responsive to eplerenone treatment	33
CDK20	AR	May respond to steroid treatment	15
COQ2, COQ6, COQ8/ ADCK4, PDSS2	AR	May respond to CoQ10 supplementation	10, 19, 47
CUBN	AR	Can manifest as proteinuria with no progression to ESKD; may respond to treatment with vitamin B_{12}	31
DGKE	AR	Can present as SRNS in first decade of life or as an acute episode of aHUS during first year of life	48
DLC1	AR	May respond to steroid treatment	15
EMP2	AR	May respond to steroid treatment	20
FAT1	AR	Potential syndromic features (allele dependent): colobomatous microphthalmia, ptosis, syndactyly	49, 50
ITSN1	AR	May respond to steroid treatment	15
ITSN2	AR	May respond to steroid treatment	15
MAGI2	AR	May respond to steroid treatment	51
TNS2	AR	May respond to steroid treatment	15
TRIM8	AD	All mutations described thus far are de novo Extrarenal manifestation: epilepsy	52

[a]Genes for which no clear clinical clues to diagnosis were described, or which are too rare as monogenic SRNS to have clinical considerations concluded, are not shown.
[b]Most common dominant SRNS causing genes.
[c]Most common recessive SRNS causing genes.
AD, Autosomal dominant; *aHUS,* atypical hemolytic uremic syndrome; *AR,* autosomal recessive; *CoQ,* coenzyme Q; *ESKD,* end-stage kidney disease; *FSGS,* focal segmental glomerulosclerosis; *NS,* nephrotic syndrome; *SRNS,* steroid-resistant nephrotic syndrome; *WT,* Wilms tumor.

result in a complete loss of function of the encoded proteins, as in recessive diseases.

SRNS manifests histologically as FSGS, a lesion characterized by segmental sclerosis often with diffuse podocyte foot process effacement.[9] Diffuse mesangial sclerosis (DMS) is a pathogenic finding that may occur in patients with early-onset NS. In DMS, light microscopy shows small, sclerosed glomeruli with a reduced number of capillary loops together with podocyte hypertrophy and mesangial matrix expansion. SRNS may rarely be associated with extrarenal manifestations such as neurologic defects (Table 20.2).[10]

BOX 20.1 Assignment of Mutations as Being Disease Causing

Basic Assumptions

- Defined clinical phenotype
- Known genes with similar phenotype have been excluded
- "Mutation" implies that an allele changes the phenotype
- Full (AR) or incomplete (AD) penetrance (age related)

Include Allele as Disease Causing if:

- Truncating mutation (stop, abrogation of start or stop, obligatory splice, frameshift) in an expressed gene (well-annotated mRNA, conservation, protein expression), *or*
- Missense mutation if:
  - Continuously conserved at least up to *Danio rerio* (zebrafish), *and*
  - Loss of function in human allele is supported by functional data, *and*
  - Allele segregates with the affected status in the family
  - Known genes with similar phenotype have been excluded

Exclude Allele as Disease Causing if:

- Heterozygous allele frequency >1% (for AR) or >0.1% (for AD) or reported homozygous in gnomAD (Genome Aggregation Database) in AR disease, or frequent heterozygously (>20) in AD disease
- AR: nonsegregation (e.g., "compound heterozygous" in cis; affected family member is without the variant; unaffected parent is with homozygous variant)
- AD: nonsegregation (e.g., affected family member is without the variant; but if an affected family member is with the allele, consider incomplete penetrance and variable expressivity)

AD, Autosomal dominant; *AR,* autosomal recessive.

Disease presentation of NS may vary in a gene-specific or even allele-specific manner (i.e., specific mutations within the same gene may determine a phenotypic range) that can affect age of onset, severity of disease, response to steroids, and associated syndromic features. For instance, mutations in *NPHS1* encoding nephrin will most often result in congenital nephrotic syndrome (CNS) characterized by massive proteinuria not responding to steroids and will likely require kidney replacement therapy and bilateral nephrectomy at approximately 1 year of age. Until permissive body weight (>10 kg) is achieved to enable kidney transplantation, these infants are at a high risk of life-threatening complications. However, specific mutations, such as the introduction of a stop codon (non-sense mutation) at position p.1160 of nephrin, tend to cause a milder form of CNS that may respond to steroid treatment.[11] In *NPHS2* (encoding podocin) mutations, which are the most common causative mutations found in monogenic SRNS, the mutation R138Q causes onset in early childhood,[12] whereas the mutation R229Q in compound heterozygosity with specific second mutations causes later-onset SRNS.[13] With *INF2*, a heterozygous mutation will typically result in SRNS and FSGS with adolescent- or adult-onset disease, with or without neurologic manifestations (Charcot-Marie-Tooth syndrome; see Table 20.2).[14] Mutations in recessive genes that cause SRNS/FSGS with syndromic features (see Table 20.2) tend to be of early onset, severe, and carry a poor prognosis. On the other hand, mutations in one of six recently discovered genes may result in partial SSNS[15] (see Table 20.1).

DIAGNOSIS

Next-generation sequencing of a specified panel of genes, such as an SRNS-disease genes panel, or WES of mutations across the entire

Relative Distribution of Nephrotic Syndrome—Causative Genes by Age of Onset

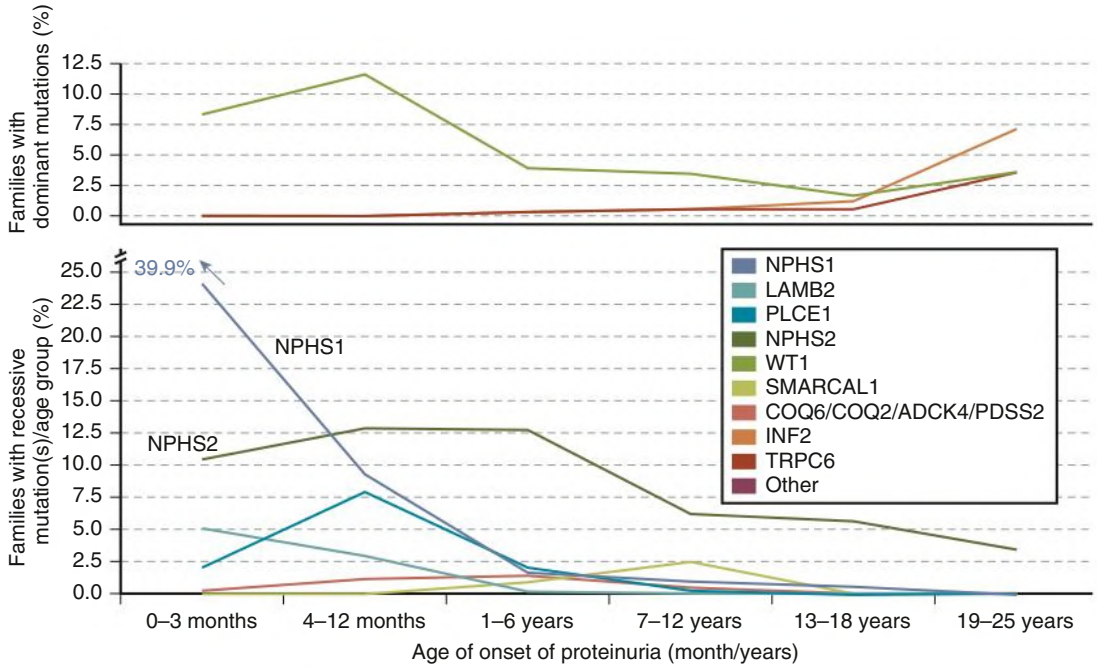

Fig. 20.2 Relative Distribution of Genes that Cause Nephrotic Syndrome, by Age of Onset. Percentages of families in an international cohort with steroid-resistant nephrotic syndrome resulting from mutations in recessive genes are interconnected by lines between age groups and shown in different colors for each causative gene (lower panel for recessive genes, upper panel for dominant genes). *NPHS1* mutations *(red), LAMB2 (orange),* and *PLCE1 (dark blue)* have early age of onset and are rarely found in patients older than 6 years. The dominant genes *INF2 (light blue)* and *TRPC6 (brown)* manifest in early adulthood, and *WT1 (black)* shows a biphasic distribution with a first peak at 4 to 12 months and a second peak for age of onset beyond 18 years (upper panel). These findings are compatible with the notion that mutations in recessive disease genes are found more frequently in early-onset disease, whereas mutations in dominant genes more frequently cause adult-onset disease. (Modified from Sadowski CE, Lovric S, Ashraf S, et al. A single-gene cause in 29.5% of cases of steroid-resistant nephrotic syndrome. *J Am Soc Nephrol.* 2015;26[6]:1279–1289.)

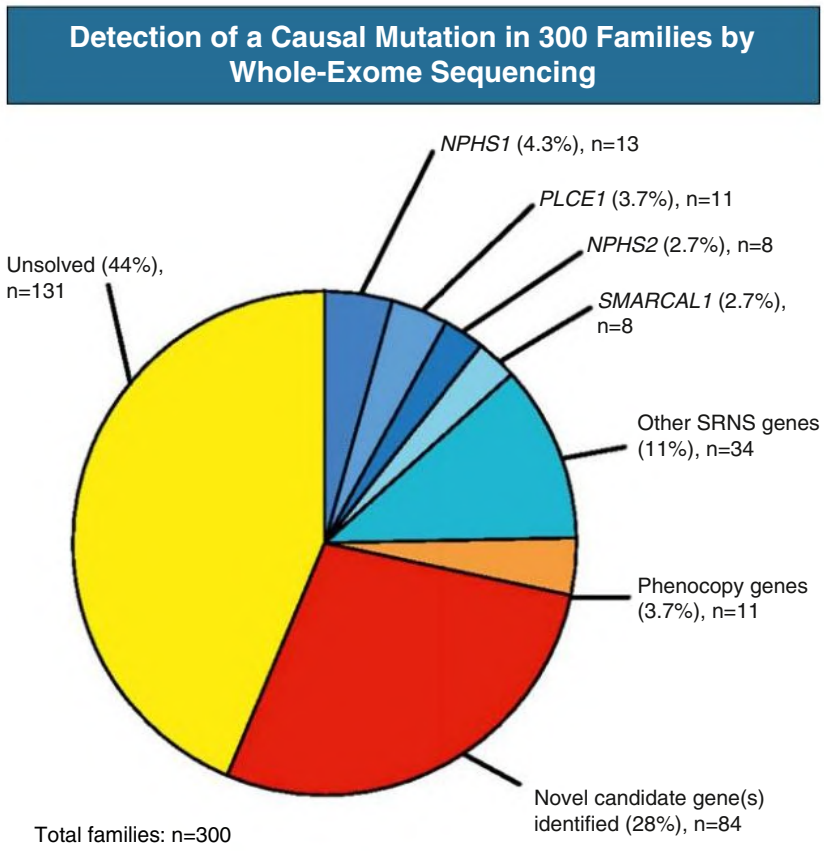

Fig. 20.3 Detection of a Causal Mutation in 300 Families by Whole-Exome Sequencing. In 74 of 300 (25%) families with steroid-resistant nephrotic syndrome (SNRS), a causal mutation was detected in one of 20 genes known to cause steroid-resistant nephrotic syndrome *(shades of blue)*. In 3.7% of families, a mutation was found in genes causing a kidney disease that may represent phenocopies of steroid-resistant nephrotic syndrome *(orange)*. In 28% of families, one or more potential novel candidate genes were identified *(red)*. In 44% of families, no causal mutations or candidate genes were detected. (From Warejko JK, Tan W, Daga A, et al. Whole exome sequencing of patients with steroid-resistant nephrotic syndrome. *Clin J Am Soc Nephrol.* 2018;13[1]:53–62.)

TABLE 20.2 Syndromic Proteinuric Kidney Disease

Syndrome	Gene(s), Mode of Inheritance	CLINICAL FEATURES		Management	Outcome
		Kidney Disease	Extrarenal Manifestations		
AMRF syndrome	*SCARB2*, AR	Collapsing FSGS (tubular proteinuria was also described) Deposition of C1q and IgM and of C3 in capillary loops and mesangium Adolescent to adulthood age of onset	Progressive myoclonus epilepsy	Supportive	Most affected individuals die in third decade of life
CMTDIE	*INF2*, AD	SRNS; FSGS; median onset of proteinuria is 18 years	Sensorineural deafness; skeletal abnormalities; peripheral neuropathy with median age of onset of 13 years	Supportive	ESKD develops at median age of 21 years
Denys-Drash	*WT1*, AD	DMS; high incidence of severe hypertension and rapid progression to ESKD by 3 years of age	Male pseudohermaphroditism, progressive glomerulopathy, development of WT	Bilateral nephrectomy at time of kidney replacement therapy initiation is recommended to prevent WT development/relapse	Dependent on ESKD and WT management Most individuals live to adulthood

TABLE 20.2 Syndromic Proteinuric Kidney Disease—cont'd

Syndrome	Gene(s), Mode of Inheritance	CLINICAL FEATURES		Management	Outcome
		Kidney Disease	Extrarenal Manifestations		
Frasier	*WT1,* AD	FSGS; NS may be slowly progressive, usually over 10 years, and is typically steroid resistant	Male pseudohermaphroditism typically present in phenotypic females with amenorrhea or NS, or both; development of genitourinary tumors	Screening for gonadoblastoma; WT not common Evaluate need for an early gonadectomy to prevent tumorigenesis	ESKD development at second to third decade of life Limited information on life expectancy
Galloway-Mowat	*WDR73; WDR4; KEOPS* complex *(LAGE3, OSGEP, TP53RK, TPRKB, YRDC* and *GON7); PRDM15,* All: AR	Kidney disease generally presents as NS within the first few months of life, with rapid progression to ESKD	Microcephaly, abnormal cerebral gyral patterns, seizures, psychomotor delay, cranial dysmorphia Most affected children die before age 6 years	Supportive	Most affected individuals die in early childhood
Nail-Patella (hereditary onycho-osteodysplasia; Fong syndrome)	*LMX1B,* AD	NS, early childhood	Nail dysplasia, absence of or poorly developed patellas, dysplasia of the iliac horns and elbows, cataracts, glaucoma	Treatment of joint limitations, ocular and kidney complications	Clinical expression variable; cases range from mild with no functional impact to severe leading to disability Kidney involvement reported in 30%–60% of cases; life span is normal
Pierson	*LAMB2,* AR	Congenital NS; DMS on biopsy; rapid progression to ESKD	Hypoplasia of the ciliary body and iris resulting in fixed narrowing of the pupil (microcoria)	Supportive	Most patients progress toward kidney failure within the first year of life Visual prognosis is generally poor
Schimke immuno-osseus dysplasia	*SMARCAL1,* AR	SRNS, FSGS, ESKD	Growth retardation, T cell deficiency, bone dysplasia, cerebrovascular disease	Due to underlying immune disorder, immunosuppressive therapy after kidney transplantation is associated with increased risk of rejection and severe opportunistic infections	Most individuals do not survive beyond early adolescence due to stroke, infections, bone marrow failure, and kidney failure
SPLIS	*SGPL1,* AR	SRNS; FSGS; typically presents at early childhood (age 1–4 years)	Primary adrenal insufficiency, endocrine abnormalities, immunodeficiency, neurologic abnormalities (cranial nerve deficits, peripheral neuropathy, developmental delay), sensorineural hearing loss, ichthyosis	Multidisciplinary, supportive Recent report[32] suggests potential response to treatment with vitamin B_6	Overall prognosis is unclear (variable) Risk of death due to infection complications

AD, autosomal dominant; *AMRF,* action myoclonus-renal failure; *AR,* autosomal recessive; *CMTDIE,* Charcot-Marie-Tooth Dominant intermediate E; *DMS,* diffuse mesangial sclerosis; *ESKD,* end-stage kidney disease; *FSGS,* focal segmental glomerulosclerosis; *IgM,* immunoglobulin M; *NS,* nephrotic syndrome; *SPLIS,* Sphingosine phosphate lyase insufficiency syndrome; *SRNS,* steroid-resistant nephrotic syndrome; *WT,* Wilms tumor.

coding sequence, is increasingly available, albeit often limited to research initiatives (https://www.precisionnephrology.org, http://www.renalgenes.org). WES allows sequencing of all approximately 330,000 exons in the human genome (i.e., the exome).[16] It is currently assumed that WES offers a theoretical likelihood of 86% of detecting the disease-causing mutation in a recessive disease.[17] Besides its use to detect mutations in an established list of known disease-causing genes, WES was also very successfully applied to detecting novel disease-causing genes (e.g., *ADCK4, EMP2, CRB2, FAT1, NUP93,* KEOPS complex, and *TNS2*).[15,18-21]

The indications for genetic testing in individuals with SRNS are based on several considerations:

1. *Age of onset.* Because of the high likelihood (~30%) of finding a causative monogenic mutation in SRNS with onset before age 25 years,[4,5] and because of the many important implications for disease management, it is advisable to suggest genetic testing to *all* individuals with FSGS or with persistent proteinuria that manifests before age 25 years. In adult-onset FSGS, genetic testing should be considered if there is a positive family history[22,23] or if there is clinical suspicion of a disease syndrome that may mimic SRNS by a phenocopy gene (as can be the case with mutations in type 4 collagen forming genes).[24,25] Moreover, recent studies suggest a diagnostic yield for WES of up to 17.1% in adults with a clinical diagnosis of nephropathy of unknown origin,[23] and therefore genetic testing should be considered in these cases as well. Finally, individuals of African ancestry with FSGS should be tested for the presence of the APOL1 risk alleles, at any age of presentation, because mutations in these alleles confer a 10-fold higher risk of end-stage kidney disease (ESKD) due to FSGS and sevenfold higher risk of ESKD due to hypertensive nephropathy.[26]
2. *Consanguinity.* The likelihood of finding a causative (recessive) mutation is higher in individuals with SRNS from consanguineous marriages than in outbred individuals.[6,27]
3. *Family history.* One of the most important genotype-phenotype correlations in SRNS is the distinction between recessive versus dominant SRNS genes (see Table 20.1). In recessive mutations, family history is most likely negative because parents of individuals with recessive mutations will usually be healthy heterozygous carriers, and no one in the ancestry will have had the disease. If there is any inherited mutation, it will have only been heterozygous in ancestors. However, in dominant disease, one of the parents of an affected individual will most likely be affected, and the disease may have been handed down through multiple generations (except for situations of incomplete penetrance or de novo mutations). Therefore, the detection of dominant mutations has important clinical implications, such as in situations of planned living-related donor kidney transplantation (see Table 20.1). Here, it will be important to exclude the presence of the disease-causing mutation in the related donor, in whom SRNS may not yet have manifested because of incomplete penetrance, which can be a feature of autosomal dominant inheritance. Kidney donation from a heterozygous carrier of a recessive gene is essentially harmless.
4. *Syndromic features.* The presence of extrarenal manifestations can suggest a mutation in a known gene that results in specific syndrome (see later) and hence increases the likelihood of detecting a monogenic cause of the disease (see Table 20.2).

Natural History and Management

The identification of causative monogenic mutations may have important therapeutic consequences in some cases:

1. *Response to steroid treatment.* In childhood SRNS, which manifests beyond the first year of life, often one attempt is made at treatment with corticosteroids.[28] If a response is lacking, treatment attempts are made with calcineurin inhibitors, and, more recently, mycophenolate mofetil or rituximab. The majority of the patients with NS, in whom a single-gene cause is detected, do not respond to steroid treatment, and therefore the detection of a monogenic cause of SRNS can save unnecessary ineffective and potentially toxic treatment. Recently, however, six genes *(EMP2, TNS2, DLC1, CDK20, ITSN1, ITSN2)* were identified in which recessive mutations surprisingly cause NS that is partially or fully responsive to steroid therapy or cyclosporine A, for unknown reasons (see Table 20.1).[3,15,20]
2. *Response to CoQ10 supplementation.* In patients who carry mutations in a gene of CoQ_{10} biosynthesis (*COQ2, COQ6, ADCK4,* or *PDSS2*),[19,29,30] treatment with CoQ_{10} may be indicated.[29]
3. *Response to treatment with vitamin B.* The *CUBN* gene encodes the cubilin protein, which functions as a receptor for intrinsic factor–vitamin B_{12} complexes. Mutations in *CUBN* may benefit the treatment with vitamin B_{12},[31] those with sphingosine-1-phosphate lyase 1, encoding a mitochondrial lyase enzyme, may respond to vitamin B_6.[32]
4. *Response to other available drugs.* Individuals with *ARHGDIA* mutations theoretically may be responsive to eplerenone treatment.[33] Finally, *TRPC6* mutations may potentially be amenable to treatment with calcineurin inhibitors.[7,34] However, no systematic studies exist for these theoretical treatment modalities.
5. *Other considerations.* Rare syndromic proteinuric kidney diseases require management of extrarenal manifestations (see Table 20.2). For instance, donor splice-site heterozygous mutations in intron 9 of the *WT1* gene have been reported to alter the alternative splicing leading to two WT1 isoforms, with (+) or without (−) three amino acids, lysine-threonine-serine (KTS), between zinc fingers three and four. The detection of *WT1* mutations often has clinical consequences as, for instance, KTS+ mutations, depending on karyotype, may confer a risk for gonadoblastoma.[35]

RECURRENCE

Childhood-onset SRNS carries a risk of about 33% for relapse in a kidney transplant, thereby causing recurrence of CKD[36] (see Chapter 113). However, kidney transplantation in a child with a known monogenic cause of SRNS carries almost no risk of disease recurrence because the defective gene, which is usually exclusively expressed in the kidney, is now replaced with a normal one. A case of a truncating mutation (resulting in no formation of a functional protein) and the introduction of a novel protein through the donor kidney may rarely elicit an antibody response (such as in Alport posttransplant nephritis) and rejection of the transplanted organ.[37] However, posttransplant immunosuppressive regimens probably protect against such a response in most cases (see Chapter 113).

FUTURE DIRECTIONS

Currently only "strong" mutations are considered as disease causing (see Box 20.1). However, it is very likely that a high percentage of adult-onset SRNS is caused by hypomorphic ("weak") recessive alleles, which have not yet been revealed as deleterious (e.g., the allele R229Q of *NPHS2*). One of the most important tasks in the future for kidney geneticists is to use cell-based and animal model systems to explore whether "weak" recessive mutations (e.g., one hypomorphic heterozygous variant in a compound-heterozygous mutation) may cause adult-onset SRNS.

The recent identification of monogenic causes of NS that manifests before age 25 years in as many as 12% to 45% of individuals

TABLE 20.3 Implications of the Identification of Causative Mutations in Nephrotic Syndrome

Implication	Significance[a]
Unequivocal molecular genetic diagnosis	Avoidance of unnecessary diagnostic procedures; positive psychological impact on the individual and family members
Prediction of treatment response	Avoidance of steroids/immunosuppressive therapy
Establishment of genotype–phenotype correlations	Can assist in management (anticipated extrarenal manifestations or complications); etiologic stratification of participants for therapeutic studies by specific causative gene and mutation
Study of mutations' detrimental effects using genetic animal models	Study the pathogenesis of steroid-resistant nephrotic syndrome as the basis for targeted therapy development
Discovery of distinct mutations that may be amenable to treatment	May offer a curative therapy
Inform clinical decisions	Guide the identity of a living related donor in dominant diseases

worldwide[4] has offered many advantages for future management of NS. With the available sequencing technology and the continuous reduction in sequencing cost, WES on a commercial or research basis should now be offered to every patient with persistent proteinuria occurring before age 25 years, or in patients with FSGS manifesting after age 25 years and positive family history, if the patient consents for clinical genetic testing for the following reasons (Table 20.3): (1) it will provide the patient and families with an unequivocal diagnosis; (2) it will establish genotype–phenotype correlations; (3) it may avoid the need for kidney biopsy; (4) it will further unravel the puzzle of pathogenic pathways of NS and enable etiologic stratification of participants for therapeutic studies by specific causative gene and mutation; (5) it will permit personalized treatment options for NS by discovery of distinct mutations that may be amenable to treatment (e.g., CoQ_{10}-related genes), or on the other hand, support a decision to avoid immunosuppression or corticosteroids; and (6) it will help establish informed clinical decisions (e.g., in kidney transplantation) (see https://www.precisionnephrology.org).[38]

SELF-ASSESSMENT QUESTIONS

1. A 23-year-old man is admitted to the hemodialysis unit after inpatient hemodialysis initiation for ESKD secondary to FSGS. At initial evaluation, you obtain a detailed family history in which the patient discloses that his maternal grandfather, mother, and two brothers have received dialysis. You suspect familial FSGS as the cause of renal disease in this family. Based on the pattern of kidney disease occurrence in his family, what mode of inheritance would you suspect in this patient?
   A. Autosomal recessive
   B. X-linked recessive
   C. Autosomal dominant
   D. X-linked dominant
   E. Both C and D are possible
2. You are called to consult on a patient with newly diagnosed FSGS. Her family history is significant for multiple family members with advanced CKD or ESKD requiring renal replacement therapy. Three family members are known to have had renal transplants without recurrence of disease. You construct a family pedigree that suggests an autosomal dominant inheritance pattern. Of the known genetic mutations to cause autosomal dominant FSGS, which gene may be affected in this patient?
   A. *NPHS1*
   B. *MYO1E*
   C. *INF2*
   D. *NPHS2* (podocin)
3. Genetic mutations affecting which of the following cell populations have been identified as a cause of familial FSGS?
   A. Glomerular epithelial
   B. Glomerular endothelial
   C. Glomerular mesangial
   D. Tubular epithelial
4. What is the approximate likelihood of finding a monogenic cause of steroid-resistant nephrotic syndrome that manifests by age 25 years?
   A. 5%
   B. 30%
   C. 50%
   D. 80%
5. You are consulted on a 5-year-old girl with significant nephrotic range proteinuria. On genetic analysis, she is found to have a homozygous missense mutation in the *COQ6* gene. Which of the following would be the most appropriate treatment that could help improve her condition?
   A. Steroids
   B. Coenzyme Q_{10}
   C. Eplerenone
   D. Calcineurin inhibitors

Membranous Nephropathy

David J. Salant, Laurence H. Beck Jr, Heather N. Reich

DEFINITION

Membranous nephropathy (MN) is an immune complex disease in which deposits of immunoglobulin (Ig) G and complement components develop predominantly or exclusively beneath podocytes on the subepithelial surface of the glomerular capillary wall. Podocyte injury resulting from the immune deposits increases glomerular permeability, which results in proteinuria and potentially in nephrotic syndrome.[1,2] *Primary* (formerly called *idiopathic*) MN is an organ-specific autoimmune disease in which autoantibodies target an intrinsic podocyte antigen. It accounts for about 75% to 80% of patients with MN and typically occurs in the absence of any identifiable initiating event. It is the most common cause of primary nephrotic syndrome in older (>60 years) White adults, but the age range is broad and patients may present for the first time as teenagers.[3] Various conditions have been identified in association with MN, some of which are likely to be causal, and are known as *secondary* MN (Table 21.1). The term "membranous" refers to thickening of the glomerular capillary wall on light microscopy of a kidney biopsy. Currently MN is more often defined by immunofluorescence and electron microscopy showing the pathognomonic diffuse, finely granular or electron-dense immune deposits in the subepithelial space. Consequently, MN is a pathologic diagnosis made in patients with proteinuria whose glomeruli exhibit these immune deposits without associated hypercellularity or inflammatory changes.

ETIOLOGY AND PATHOGENESIS

Experimental Membranous Nephropathy

Much of what we know about the pathogenesis of MN derives from observations in animal models.[4] Studies of the Heymann nephritis model of MN in rats established that the subepithelial immune deposits form in situ when circulating antibodies bind to an intrinsic ("fixed") antigen in the glomerular capillary wall. The antigen in rats was identified as *megalin,* a large transmembrane receptor of the low-density lipoprotein receptor family expressed on the basal surface of rat podocytes. Binding of circulating antimegalin antibodies induces capping and shedding of the antigen-antibody complexes, where they bind to the underlying glomerular basement membrane (GBM), resist degradation, and persist for weeks or months as immune deposits characteristic of MN (Fig. 21.1A). In this model, proteinuria is caused by antibodies in the deposits that overcome local complement regulatory mechanisms and activate complement in situ. Sublethal podocyte injury induced by the complement membrane attack complex C5b-9 triggers a cascade of changes, including oxidative injury, calcium influx, activation of cytosolic phospholipase A_2, production of arachidonic acid metabolites and cytokines, endoplasmic reticulum stress, DNA damage, and alterations in the ubiquitin-proteasome system[4] (Fig. 21.2). Podocyte foot process effacement results from collapse of the actin cytoskeleton and loss of cell-GBM adhesion complexes, and the loss and displacement of slit diaphragms is associated with the onset of severe, nonselective proteinuria. Podocyte injury also leads to the production of new extracellular matrix proteins that are laid down around the immune deposits, giving rise to the characteristic "spikes" and GBM thickening.

Another mechanism of subepithelial immune deposit formation involves planted antigens[2] (Fig. 21.1B). This is best exemplified by animal models immunized with cationized bovine serum albumin (cBSA). The cBSA binds to negatively charged residues in the GBM, where it serves as a target for circulating anti-BSA antibodies. As in the Heymann nephritis model, podocyte injury and proteinuria result from local complement activation.

Human Membranous Nephropathy

The first demonstration that circulating antibodies reactive with an intrinsic podocyte antigen might be involved in human MN (see Fig. 21.1) was provided by an unusual case of antenatal MN induced by the transplacental passage of alloantibodies to podocyte neutral endopeptidase (NEP).[5] The mother of the affected child was deficient in NEP and had been immunized during a previous pregnancy and, like subsequent cases, produced complement-fixing anti-NEP alloantibodies. Although these anti-NEP alloantibodies are distinct from the autoantibodies responsible for adult primary MN, other alloantibodies probably explain the development of de novo MN after kidney transplantation and MN in the setting of chronic graft-versus-host disease after allogeneic hematopoietic stem cell transplantation (see Table 21.1).

Since this initial demonstration of a podocyte-expressed antigen in human MN, several additional target antigens have been identified. The predominant autoimmune system responsible for primary MN is that associated with autoantibodies directed at the M-type phospholipase A_2 receptor (PLA_2R) on podocytes.[4,6] Circulating anti-PLA_2R antibodies are detectable in the serum of 75% to 80% of patients with primary MN from all ethnic groups and are rarely found in secondary MN.[2,7] The antibodies are predominantly IgG4, and the antigen (PLA_2R) and antibodies (anti-PLA_2R) colocalize in the immune deposits in primary (but not in secondary) MN.[8,9] These IgG4 anti-PLA2R autoantibodies are able to initiate complement activation through the lectin pathway,[10] although other subclasses of anti-PLA2R and other complement pathways are likely also involved. PLA_2R is a transmembrane protein of the mannose receptor family[11] (Fig. 21.3) that undergoes constitutive endocytosis between the plasma membrane and internal compartments; its role in podocytes is unknown.

In the 20% or more cases of primary MN not associated with antibodies to PLA_2R, a number of distinct target antigens have been identified that now define subsets of MN, some of which have distinct

TABLE 21.1 Classification of Conditions and Agents Associated With Membranous Nephropathy

Primary

PLA_2R-associated (70%–80%)
Other antigens: NELL1 (5%–10%), THSD7A (1%–5%), Sema3B, PCDH7, HTRA1

Secondary	Common	Uncommon
Autoimmune diseases	Class V lupus nephritis Can be associated with staining for EXT1/EXT2, NCAM1, TGFBR3 in deposits	Rheumatoid arthritis Autoimmune thyroid disease IgG4-related systemic disease Crescentic glomerulonephritis (anti-GBM or ANCA-associated) can co-occur with MN
Infections	Hepatitis B	HCV HIV Syphilis Schistosomiasis
Malignancy	Solid tumors (prostate, breast, lung, colon, stomach, kidney)	Non-Hodgkin lymphoma CLL Melanoma
Drugs or toxins	NSAIDs and COX-2 inhibitors	Mercury-containing compounds Gold salts D-Penicillamine, bucillamine
Miscellaneous		Sarcoidosis Anti-cationic bovine serum albumin

Alloimmune

Graft-versus-host disease following hematopoietic stem cell transplantation

phenotypes or associations. Antibodies to thrombospondin type 1 domain-containing 7A (THSD7A)[12] account for about 5% of cases of primary MN in Western countries but appear to be more prevalent in Japanese patients with primary MN.[13] THSD7A is localized on the basal surface of podocytes and, like PLA_2R, it redistributes to form the subepithelial immune deposits. Neural EGFL-like 1 (NELL1) is the target of IgG1-predominant autoantibodies, and up to one-third of these MN cases may be associated with malignancy.[14,15] Antibodies to semaphorin 3B can be found in some early childhood cases of MN but can rarely occur in adults as well.[16] In all of these subsets of MN, the target antigen becomes localized within the immune deposits, allowing pathologists to query the tissue by immunostaining.

Reactivity to certain intracellular antigens, including aldose reductase, superoxide dismutase 2, and alpha-enolase, has been detected in primary MN and may contribute to the progression of podocyte injury. The best evidence of a planted antigen mechanism is that described in children with MN who have been exposed to cBSA, presumably in bottled milk. In such cases, the cBSA localizes in the GBM, where it forms complexes with circulating anti-BSA.[17] Planted antigens may also be responsible for immune deposition in class V (membranous) lupus nephritis and hepatitis B virus (HBV)-associated MN.

In all forms of MN, injury to the podocyte and glomerular filtration barrier continues as long as there is formation of subepithelial antibody-antigen complexes that can activate complement. In primary autoimmune forms, the persistence of circulating autoantibodies is the main factor causing continued disease activity. Only after these autoantibodies decline and disappear (owing to a spontaneous or treatment-induced remission) can a clinical remission be attained. When immunologic remission occurs before extensive podocyte loss and GBM remodeling, complete recovery is possible, but proteinuria may persist for months. Once there is extensive podocyte loss, proteinuria persists despite immunologic remission, and glomerular sclerosis, tubular atrophy, and interstitial fibrosis may ensue.

EPIDEMIOLOGY AND GENETICS

MN may occur at any age and in all ethnic groups, but primary MN is twice as common in men than in women and is rare in children. Primary MN has its peak incidence during the fourth and fifth decades of life (Box 21.1). MN in childhood is more often secondary (e.g., caused by HBV). Primary MN is the most common cause of nephrotic syndrome in nondiabetic White adults. Estimated annual incidence is 8 to 10 cases per 1 million population in Western countries. Reported variation in incidence may reflect specific country/physician indication for kidney biopsy but could also represent real differences related to socioeconomic status, ethnicity, or environment in particular air pollution. Although association with certain human leukocyte antigen (HLA) class II immune response genes indicated a genetic predisposition, primary MN is typically not a familial disease. Studies from Korea and Taiwan suggested the presence of *PLA2R1* risk variants that were nonsynonymous single-nucleotide polymorphisms (SNPs)[18,19] in the first and seventh C-type lectin-like domains (CTLDs) of PLA_2R (Fig. 21.3). A subsequent

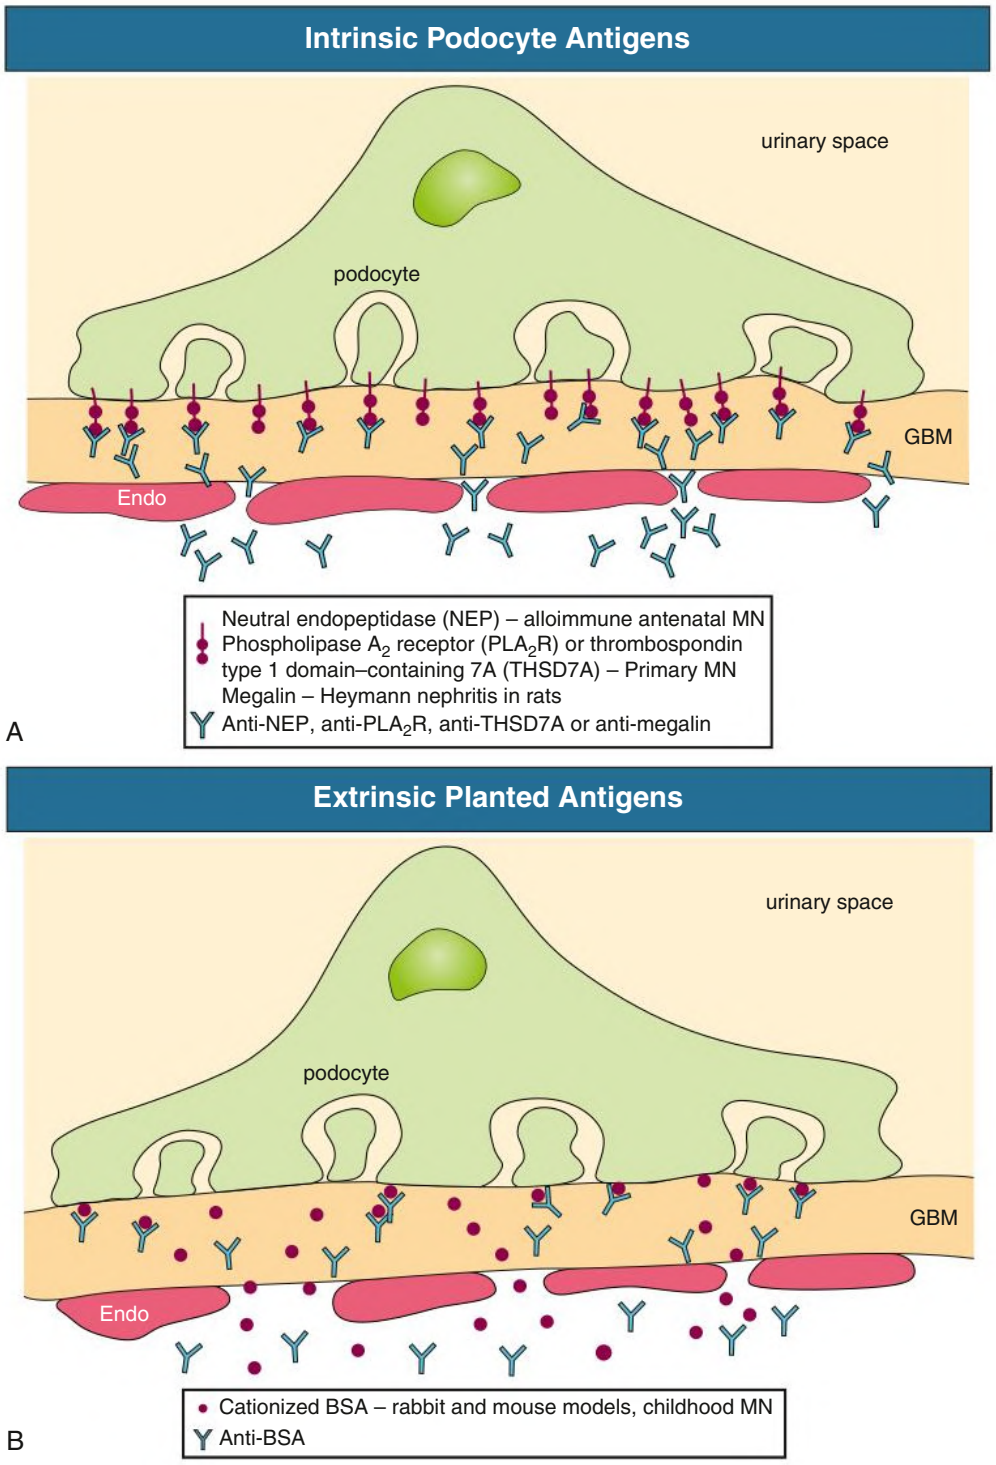

Fig. 21.1 Mechanisms of In Situ Immune Complex Formation in Experimental and Human Membranous Nephropathy (MN). (A) Circulating antibodies may cross the glomerular capillary wall and bind to podocyte antigens exposed on the foot process, as in Heymann nephritis in rats (megalin), alloimmune MN (neutral endopeptidase), and primary MN (PLA_2R or THSD7A). (B) Certain extrinsic antigens such as cationized bovine serum albumin (BSA) may bind to sites in the GBM and serve as planted antigens and form deposits with circulating antibody. *Endo,* Glomerular endothelial cell; *GBM,* glomerular basement membrane.

European genome-wide association study revealed strong associations with a noncoding SNP in *PLA2R1* and another in *HLA-DQA1*, a member of HLA class II that includes isoforms that predispose carriers to autoimmunity.[20] The odds ratio of MN was almost 80 in individuals who were homozygous for both *HLA-DQA1* and *PLA2R1* variants. No unique coding variants have been found in *PLA2R1*, and the risk allele in *PLA2R1* is proposed to lie in a regulatory region that may increase renal expression of the protein.[21]

Higher-resolution analysis of risk variants with MN in the Chinese population suggest that specific HLA molecules may be altered

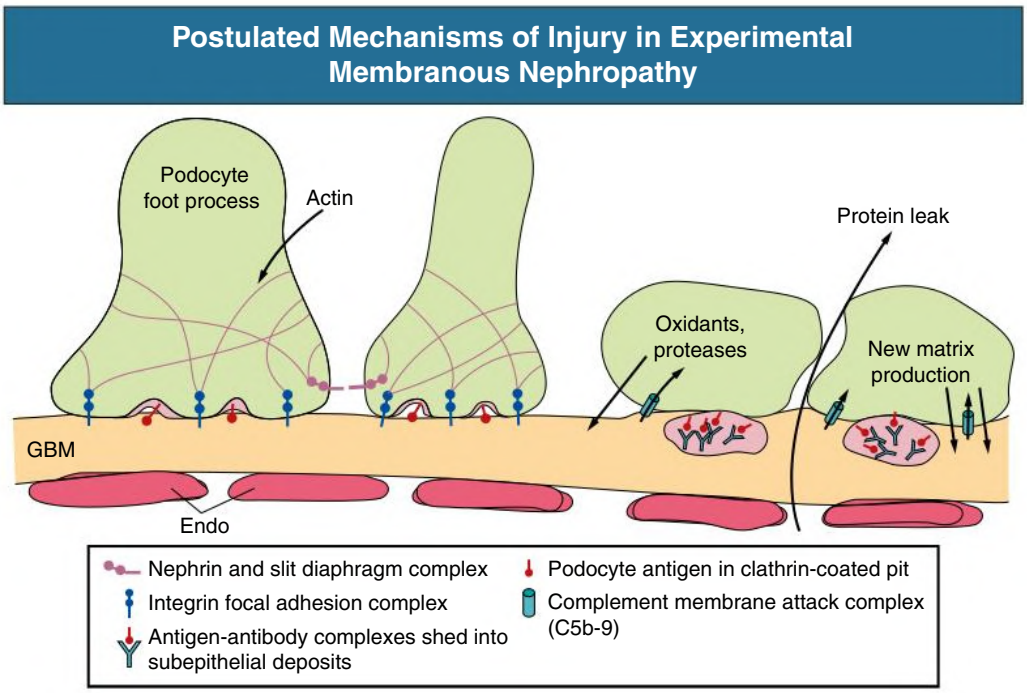

Fig. 21.2 Postulated Mechanisms of Injury in Experimental Membranous Nephropathy. Antibodies against a podocyte antigen in clathrin-coated pits on the foot processes (left podocyte) form complexes that are shed to form deposits in the subepithelial space (right podocytes) and induce complement activation leading to formation of C5b-9. Insertion of C5b-9 is insufficient to cause lysis but stimulates the podocyte to release a host of inflammatory mediators. Disruption of the actin cytoskeleton causes altered cell-matrix adhesion and loss or displacement of slit diaphragms, leading to foot process effacement and loss of the filtration barrier to protein. New matrix production by the damaged podocytes expands the glomerular basement membrane (GBM) between and around the deposits. *Endo,* Glomerular endothelial cells.

BOX 21.1 Clinical Features of Membranous Nephropathy

- Rare in children: <5% of total cases of nephrotic syndrome
- Common in adults: 15%–50% of total cases of nephrotic syndrome, depending on age; increasing frequency after age 40 years
- Males > females in primary forms; SLE-associated forms may be female predominant
- Can occur in all racial and ethnic groups
- Nephrotic syndrome in 60%–70% of cases
- Normal or mildly elevated blood pressure at presentation
- Urinary sediment reflective of lipiduria[a]; trace hematuria possible, but no RBC casts
- Nonselective proteinuria
- Tendency to thromboembolic disease[b]
- Associations to suggest possible secondary MN: infection, drugs, neoplasia, SLE

[a]Fatty casts, oval fat bodies, cholesterol crystals.
[b]Deep venous thrombosis, renal vein thrombosis, and pulmonary embolism.
MN, Membranous nephropathy; *RBC,* red blood cell; *SLE,* systemic lupus erythematosus.

specifically within the peptide binding groove,[22] which may confer the ability to present regions of the PLA_2R protein more effectively to the immune system. *PLA2R1* gene variants may also contribute to the severity or likelihood of MN progression. Alternatively, the interaction of *PLA2R1* with the autoimmune predisposition conferred by HLA class II may set the stage for an external trigger to initiate MN.[1,2] An example of such a trigger might be exposure to environmental pollutants.[23] A second genome-wide association confirmed the risk variants within *PLA2R1* and the HLA region and identified additional risk loci in *IRF4* and *NFKB1*,[21] although the implications of these findings are not yet known.

CLINICAL AND SEROLOGIC MANIFESTATIONS

A majority of patients (70%–80%) with MN present with the nephrotic syndrome. The remaining patients present with asymptomatic subnephrotic, nonselective proteinuria (<3.5 g/24 h) that may be present for months or even years before the diagnosis is made.[24] Microscopic hematuria is common (30%–40%), but red blood cell (RBC) casts are rare and suggest a different or coexistent proliferative glomerular pathologic process. In primary MN, serologic tests for anti-PLA_2R are positive in 75% to 80% of cases,[1,2] whereas serum complement levels are normal despite evidence of intraglomerular complement activation, and serologic markers (e.g., antinuclear antibodies, antineutrophil cytoplasmic antibodies [ANCAs], rheumatoid factor) are normal or absent. At diagnosis, 10% to 20% of MN patients have hypertension and kidney function is usually normal, with only a small fraction (<10%) presenting with kidney impairment (Table 21.2). Hypertension and reduced GFR are more common at presentation in older patients; this may reflect tubulointerstitial and vascular changes on biopsy independent of the severity of the MN.[25] Complications of the nephrotic syndrome including dyslipidemia, infections, thromboembolic events, and cardiovascular events may be present early in the course of the disease (see later).

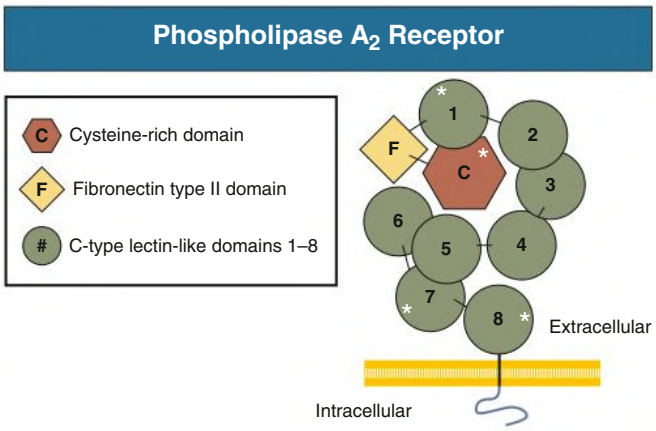

Fig. 21.3 Structural Diagram of Phospholipase A_2 Receptor (PLA_2R), the Major Podocyte Antigen Targeted in Membranous Nephropathy. PLA_2R is composed of 10 extracellular domains, starting with the N-terminal cysteine-rich domain (CysR; *red hexagon*) and followed by a single fibronectin type II domain *(yellow diamond)* and eight C-type lectin-like domains (CTLD; *green circles*). These domains form a compact structure with pH-dependent conformational relationships to each other that likely allow the receptor to release its cargo (such as secreted phospholipase A_2 enzymes) in the more acidic intracellular organelles. A short C-terminal cytoplasmic domain *(blue)* contains a motif that allows for constitutive endocytosis of the receptor. Autoantibodies to PLA_2R target at least four different regions in the extracellular domain (CysR, CTLD1, CTLD7, and CTLD8; *white asterisks*). Within CysR, there is an immunodominant epitope of 31 amino acids that is recognized by all individuals with anti-PLA2R antibodies.[33] (Data from Dong Y, Cao L, Tang H, Shi X, He Y. PATHOLOGY

The earliest pathologic feature of MN is the formation of subepithelial immune complexes of IgG and complement along the outer surface of the capillary wall in which glomeruli may appear histologically normal if only light microscopy is performed. Subsequent changes involve the podocyte, deposition of new extracellular matrix material between and around the immune deposits, thickening of the GBM (membranous change), and in some cases, focal glomerulosclerosis, tubular atrophy, and interstitial fibrosis.

Light Microscopy

In the earliest stages of MN, the glomeruli and interstitium appear normal on light microscopy, and the diagnosis is made by immunohistology and electron microscopy (Fig. 21.4A). The next stage of MN involves a homogeneous thickening of the capillary wall, seen with light microscopy in sections stained with hematoxylin and eosin or with periodic acid–Schiff (PAS) reagent (Fig. 21.4B). On silver methenamine staining, early projections of the GBM between deposits may be detected in a characteristic spike-like configuration (see Fig. 21.4C). Later, lucencies may develop in the GBM as immune deposits are resorbed, resulting in craters within the thickened GBM.

Glomerular leukocyte infiltration and hypercellularity are absent, probably because chemotactic products of complement activation follow filtration forces into the urinary space, and the intervening GBM prevents immune adherence mechanisms from being operative.

The podocyte response to this form of injury includes effacement of foot processes visible only by electron microscopy. There typically are no visible endothelial cell abnormalities. The presence of significant mesangial hypercellularity suggests immune deposit formation in the mesangium and is more consistent with a secondary MN, such as class V lupus nephritis (see Chapter 27). In some patients with heavy proteinuria and progressive disease, glomeruli exhibit reduced podocyte numbers and areas of focal sclerosis that resemble secondary focal segmental glomerulosclerosis (FSGS; see Chapter 19). These patients often have a more rapidly progressive course and a poor response to therapy. These sclerotic lesions may be a consequence of glomerular hypertrophy accompanied by an inability of terminally differentiated podocytes to proliferate leading to areas of denuded GBM, attachment to Bowman's capsule, and subsequent capillary collapse. As in all glomerular diseases, tubulointerstitial injury is common, and its severity correlates with both long-term kidney function and the level of proteinuria.

Immunohistology

Granular glomerular capillary wall staining for IgG in MN is characteristic (Fig. 21.5A). Positive staining for IgG marks the finely granular subepithelial deposits, which are present on the outer surface of all capillary walls. The predominant IgG subclass in many forms of primary MN is IgG4,[6,12] although IgG1 may predominate in other types of MN.[15,16]

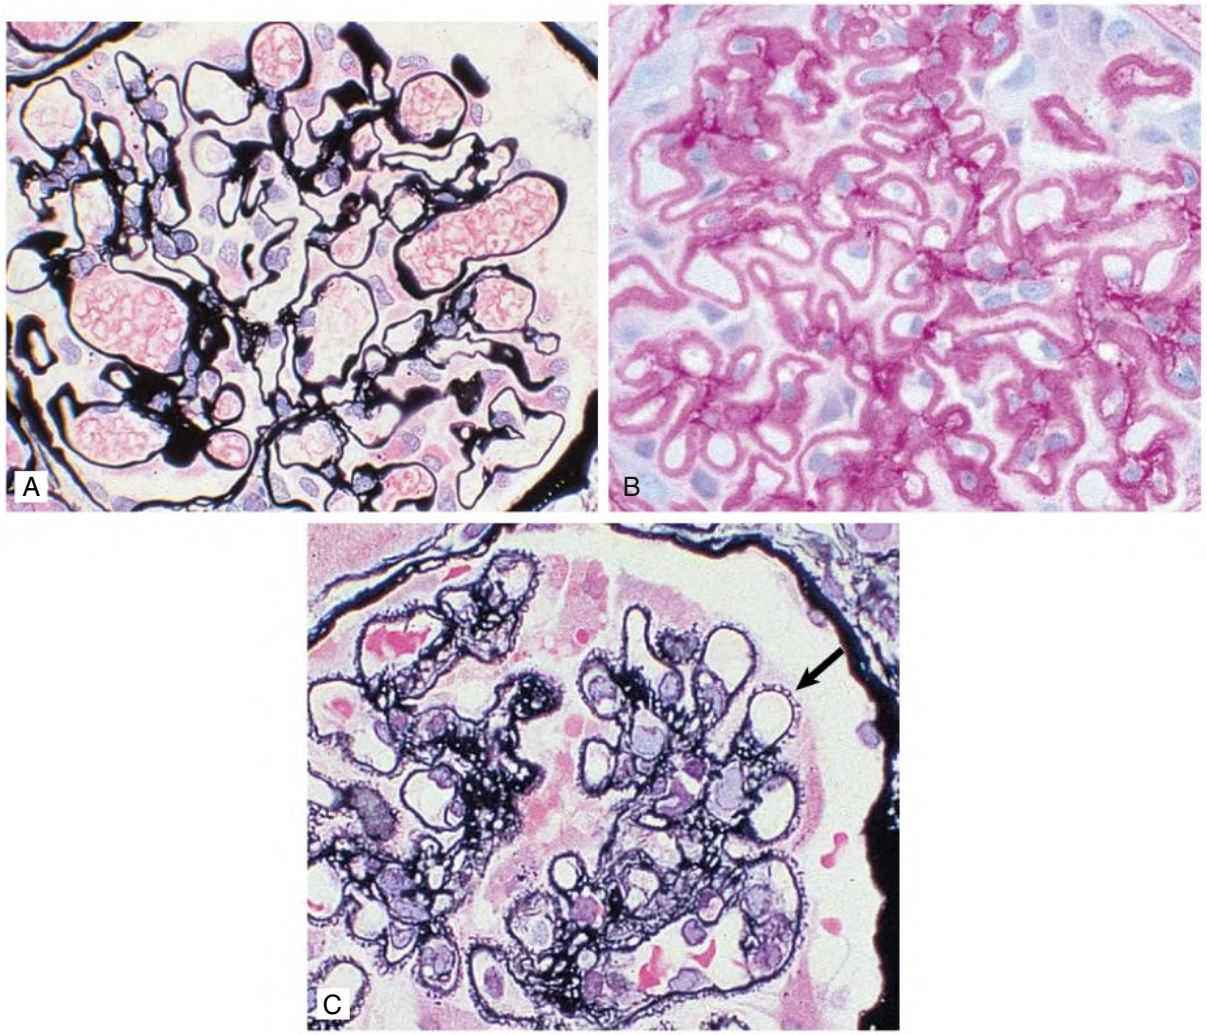

Fig. 21.4 Light Microscopy in Membranous Nephropathy (MN). (A) Early MN. Glomerulus from a patient with severe nephrotic syndrome exhibiting normal architecture and peripheral capillary basement membranes of normal thickness. (B) Morphologically advanced MN. Uniform increase in thickness of glomerular capillary walls throughout the glomerulus with no increase in glomerular cellularity. (C) More morphologically advanced MN, same patient as in (B). Discrete spikes of matrix emanating from outer surface of the basement membrane *(arrow),* indicative of advanced MN. (A and C, Silver methenamine stain, ×400. B, PAS, ×400.) (Courtesy C.E. Alpers.)

Positive staining for IgA, or IgM or significant staining in the glomerular mesangium suggests lupus or other causes of secondary MN.[26] Kappa and lambda light chain staining are typically equal, but rare cases of MN due to monoclonal IgG, including anti-PLA_2R, have been reported.[26] Complement C3 is present in most cases of active disease and usually reflects staining for C3c, a breakdown product of C3b that itself is rapidly cleared. Consequently, positive C3 staining probably reflects active, ongoing immune deposit formation. When sought, staining for C5b-9 is generally present as well, consistent with the proposed pathogenetic role of C5b-9 in this disease.[4,27,28] Strong C1q staining is uncommon in primary MN (<20% of cases) but common in lupus-associated MN.[29] Positive staining for C4d in the absence of C1q is characteristic of primary MN.[30]

The identification of target antigens (or specific biomarkers associated with types of MN) now allows immunohistologic subtyping of MN biopsies. These antigens accumulate within immune deposits where they can demonstrate the same fine granular capillary wall pattern as IgG and C3 (because they all reside within the immune deposits). Many pathologists stain the biopsy for PLA_2R and, if negative, may send the slides to be stained for other autoantigens at specialized centers. PLA_2R staining in the immune deposits in a pattern that colocalizes with IgG is another feature that helps distinguish PLA_2R-associated MN from secondary MN (Fig. 21.5B) (Table 21.3).[6,8,9]

Electron Microscopy

The finding of subepithelial electron-dense deposits by electron microscopy (EM) parallels IgG staining. In primary MN, immune deposit formation occurs in a subepithelial distribution; subendothelial deposits are not seen and mesangial deposits are rare (Table 21.3). These deposits in early stages of the disease process are homogeneous and may even be confluent in some areas, with overlying podocyte foot process effacement and little change in the underlying GBM (stage I). As the disease persists, basement membrane material is laid down between the deposits and corresponds to the spikes seen on light microscopy and are easily visible by EM (stage II; Fig. 21.6A). Later, the spikes extend and the deposits may become surrounded by new basement membrane–like material (stage III; Fig. 21.6B). In stage IV disease, the basement membrane is overtly thickened, the deposits incorporated in it become more lucent, and the spikes are less apparent

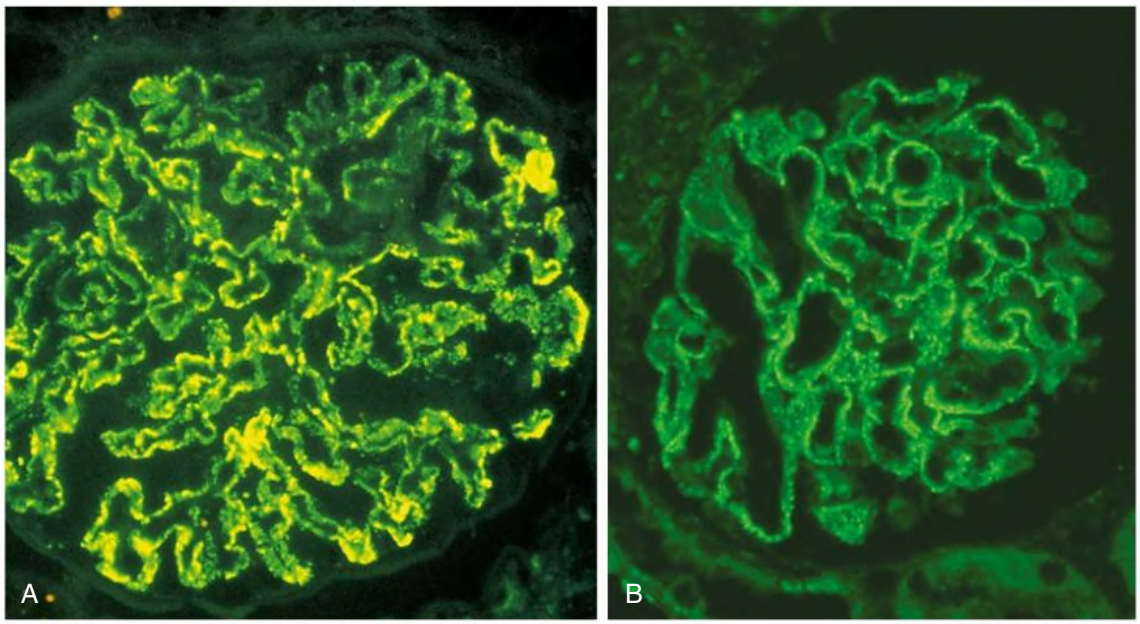

Fig. 21.5 Immunofluorescence in Membranous Nephropathy. (A) Glomerulus with diffuse, finely granular deposits of Immunoglobulin (Ig) G along outer surface of all capillary walls. In primary membranous nephropathy, the antibodies eluted from the glomeruli are reactive with PLA_2R. (B) Glomerulus stained for PLA_2R with diffuse, finely granular deposits of the antigen along outer surface of all capillary walls in a similar distribution as IgG. (Original magnification ×400.) TABLE 21.3 Histopathologic Features That Help Distinguish Primary From Secondary Membranous Nephropathy

Primary	Secondary
Immunofluorescence Microscopy	
IgA and IgM absent	IgA and/or IgM may be present
IgG4 is predominant or codominant	IgG1, IgG2, or IgG3 predominant
Mesangial Ig staining absent	Mesangial Ig staining may be present
C1q negative or weak	C1q positive
PLA_2R positive and colocalizes with IgG	PLA_2R negative EXT1/EXT2, NCAM1, or TGFBR3 can colocalize with IgG in MN associated with lupus
Electron Microscopy	
Subepithelial deposits only ± rare mesangial or paramesangial deposits	Subepithelial deposits ± mesangial and subendothelial deposits Tubuloreticular inclusions in endothelial cells

EXT1/EXT2, Exostosin 1/exostosin 2; *Ig,* immunoglobulin; *MN,* membranous nephropathy; *NCAM1,* neural cell adhesion molecule 1; *PLA2R,* phospholipase A2 receptor; *TGFBR3,* transforming growth factor beta receptor 3.

(stage IV; Fig. 21.6C). Although clearly reflecting the duration of disease, these GBM changes do not correlate well with clinical manifestations at time of biopsy or ultimate outcome. The overlying podocyte foot processes are effaced with condensation of the actin cytoskeleton; the filtration slits between the foot processes may be occluded; and in those still open, the slit diaphragms may be displaced or disrupted. Microvillous changes of the podocyte membrane are common, as are protein reabsorption droplets within podocytes and proximal tubular cells. The presence of tubuloreticular inclusions in the endothelial cells is strongly suggestive of lupus-associated MN, although these may rarely be found in primary MN as well.[31]

Diagnosis and Differential Diagnosis

When the initial presentation includes the nephrotic syndrome, the differential diagnosis includes minimal change disease (MCD), FSGS, the membranoproliferative glomerulonephritis (GN) spectrum of diseases (including C3 glomerulopathies and immune complex GN; see Chapters 22 and 23), amyloidosis, light-chain deposition disease, lupus nephritis, and diabetic nephropathy. In the 20% to 25% of patients whose initial presentation is asymptomatic nonnephrotic proteinuria, the differential is even more extensive. Although clinical clues in proteinuric patients may increase the likelihood of one specific histologic pattern over another, confirmation that MN is the underlying cause of nephrotic syndrome generally requires a kidney biopsy.

In the presence of proteinuria and a positive anti-PLA_2R antibody test measured by both enzyme-linked immunosorbent assay and immunofluorescence assay, estimated GFR (eGFR) greater than 60 mL/min/1.73m^2, and negative screening for autoimmune and infectious causes as well as malignancy, alternate diagnoses are rarely encountered and a biopsy is not necessary for diagnosis.[32] Also, when a biopsy cannot be performed, such as when uninterrupted anticoagulation is required, the diagnosis can be confidently made with a positive serologic test for anti-PLA_2R or anti-THSD7A. On the other hand, negative tests for anti-PLA_2R and anti-THSD7A do not exclude primary MN, as some patients may have positive glomerular staining for PLA_2R or THSD7A despite negative serology early in the course of disease or during remission.[1] In addition, some patients have all the features of primary MN but may have MN associated with one of the other minor antigens noted above.[1,33]

Secondary MN represents 20% to 30% of all cases (see Table 21.1); the most common causes are systemic lupus, hepatitis B, malignant neoplasms, and drugs. In addition to a careful history and physical

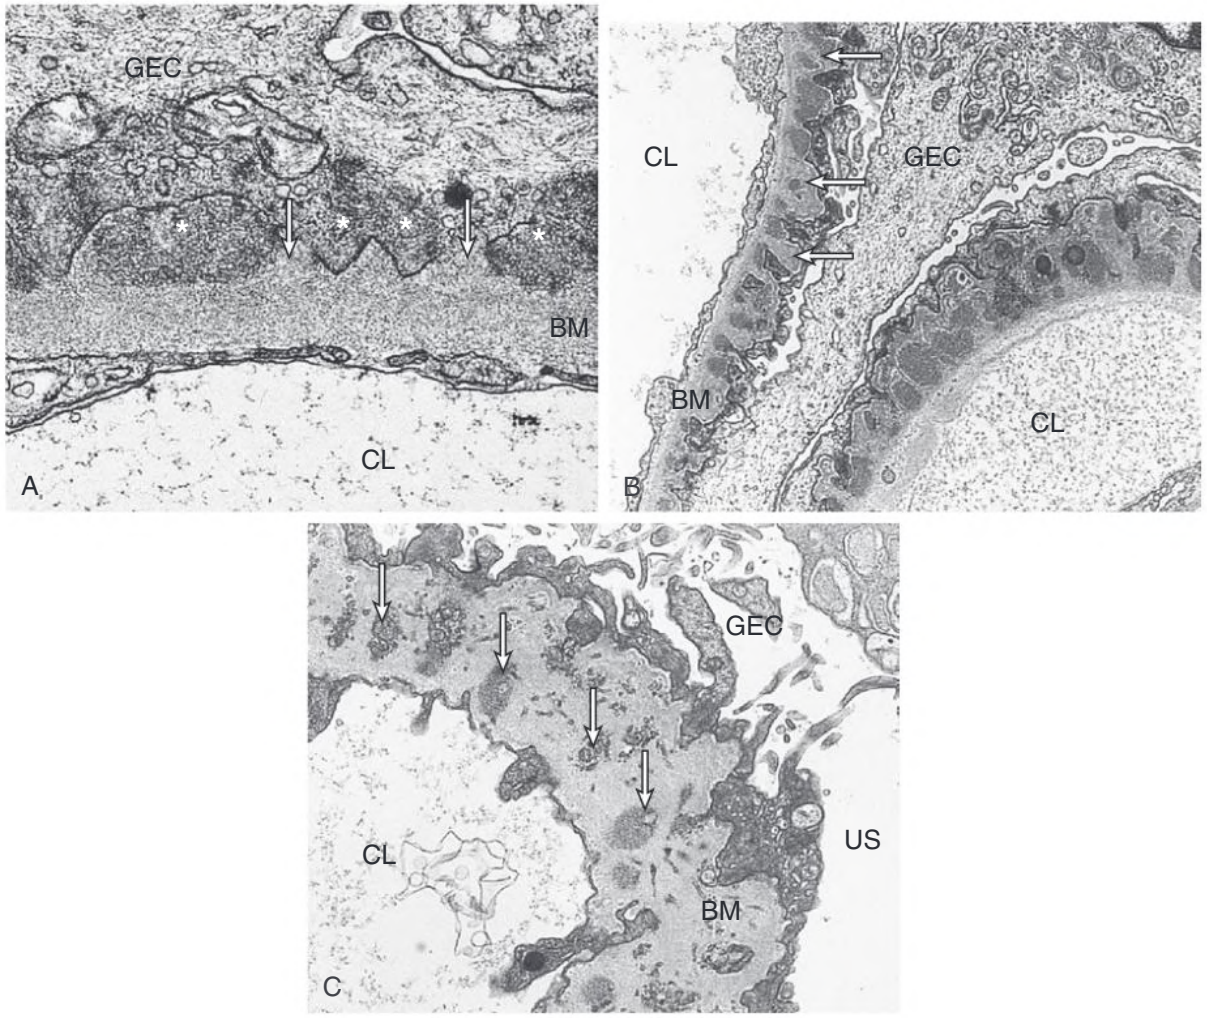

Fig. 21.6 Electron Microscopy in Membranous Nephropathy (MN). (A) Early (stage II) MN. Glomerular capillary wall with discrete, electron-dense deposits on the subepithelial surface of the basement membrane *(BM)* corresponding to granular deposits of IgG detected by immunofluorescence microscopy (corresponding to light micrograph in B). There are diffuse, granular immune complex deposits *(white asterisks)* along outer surface of the capillary wall, with effacement of overlying podocyte foot processes. Small extensions of BM between deposits *(arrows)* are also evident and represent the projections that are seen as spikes by light microscopy with silver methenamine staining. (B) More advanced (stage III) MN. Two glomerular capillary loops show involvement of the BM by the immune complex deposition *(arrows).* There is prominent membrane synthesis surrounding and incorporating these deposits into the BM (corresponding to spikes seen on silver-stained histologic preparations). Overlying cells continue to demonstrate widespread effacement of foot processes. (C) Morphologically advanced (stage IV) MN. Capillary BM is diffusely thickened; scattered electron-dense immune deposits *(arrows)* are present throughout its thickness, in addition to scattered subepithelial deposits. Overlying GECs continue to demonstrate effacement of foot processes. *CL,* Capillary lumen; *GEC,* glomerular epithelial cell; *US,* urinary space. (Original magnification ×18,000.) (Courtesy C.E. Alpers.)

examination, appropriate laboratory evaluation should include a complement profile, antinuclear antibodies, hepatitis and human immunodeficiency virus (HIV) serology, chest radiography, stool testing for occult blood, mammography in women, and prostate-specific antigen testing with digital rectal examination in men. In women aged 20 to 50 years, a high index of suspicion is warranted for underlying lupus. This diagnosis can be particularly difficult to make because most of these patients have no systemic symptoms, and serologic markers of systemic lupus erythematosus are often absent. Membranous lupus accounts for 8% to 27% of cases of lupus nephritis (see Chapter 27).

In adults, regardless of age, malignancy is an important secondary cause of MN (see Table 21.1) and in some patients, the tumor may not be evident at presentation. Although the diagnosis of anti-PLA_2R-associated MN renders an associated underlying malignancy unlikely,[34] given the therapeutic implications regarding immunosuppression affecting cancer growth and therapy, each case should still be carefully assessed and evaluations beyond routine age-appropriate testing considered if patients have risk factors for cancer. All anti-PLA_2R-negative cases merit a more thorough search for a malignant tumor.[14,35]

HBV-associated MN is also a common secondary cause in countries where HBV is endemic and can occur with or without overt liver disease. It can affect both adults and children who are chronic carriers of HBV (positive HBsAg, HBcAg, and usually HBeAg). The presence of anti-PLA_2R-antibodies is well documented in HBV-associated MN.[9,36]

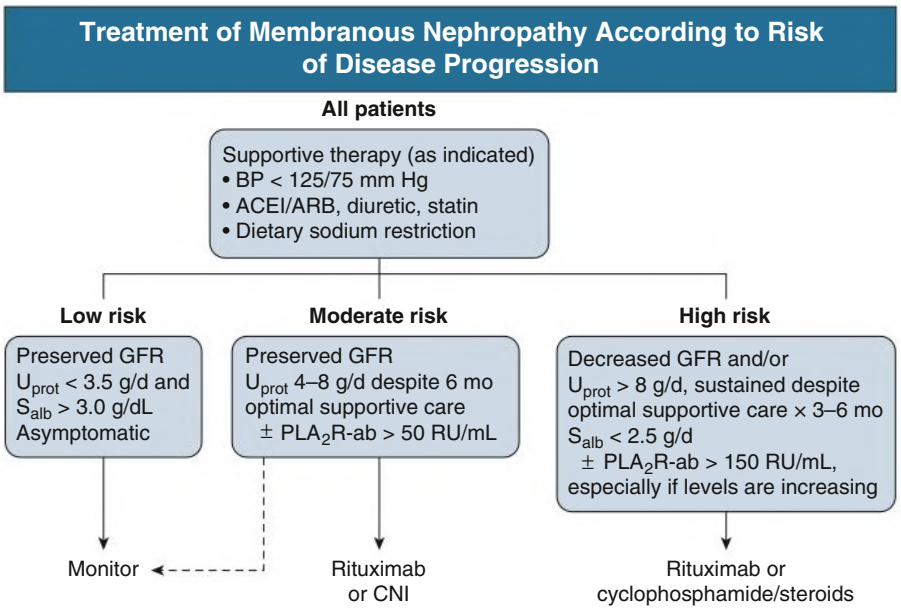

Fig. 21.7 Algorithm for Treatment of Membranous Nephropathy According to Risk of Disease Progression. All patients should receive supportive therapy. Low-risk patients can continue to be monitored on supportive therapy but should be periodically reassessed if they become symptomatic or their clinical parameters worsen. Close monitoring may also be appropriate for moderate-risk patients *(dashed arrow),* especially if they exhibit declining titers of anti-PLA2R. Rituximab or calcineurin inhibitors (CNIs) are appropriate for moderate-risk patients, whereas higher-risk patients may require cytoxic agents such as cyclophosphamide and corticosteroids, or extended durations of rituximab. Very high-risk patients (not shown), such as those with life-threatening complications of nephrotic syndrome or rapidly deteriorating kidney function, may warrant cytotoxic agents as first-line therapy. There are no threshold anti-PLA2R levels to dictate initiation of immunosuppressive treatment but, if present, they should be followed to see if they are increasing or decreasing before starting or modifying therapy. *ACEI,* Angiotensin-converting enzyme inhibitor; *ARB,* angiotensin receptor blocker; *BP,* blood pressure; *GFR,* glomerular filtration rate; *PLA2R-ab,* anti-PLA2R antibodies; *Salb,* serum albumin (g/dL); *Uprot,* urine protein in grams/day.

In children, HBV-associated MN most often presents as the nephrotic syndrome and usually follows a benign course.[37] In adults, progressive loss of GFR is a more common outcome, and a controlled trial to assess the utility of combined therapy with antiviral therapy and tacrolimus has been proposed (https://www.clinicaltrials.gov, NCT03062813).

MN secondary to drugs usually resolves after discontinuation of the offending agent. The time to resolution, however, varies significantly from as early as 1 week for the drugs more commonly implicated (e.g., for nonsteroidal antiinflammatory drugs and proton pump inhibitors), compared with several years for the more classic but rarely used drugs such as gold and D-penicillamine. Many other kidney disorders have been seen in association with or superimposed on MN, including IgA nephropathy, FSGS, anti-GBM disease, ANCA vasculitis, acute interstitial nephritis, and diabetic nephropathy.

NATURAL HISTORY AND PROGNOSIS

The clinical course of MN varies widely. Spontaneous remissions in proteinuria occur in up to 30% of patients. Female gender and lower-grade (nonnephrotic) proteinuria at presentation are the only two features associated with a higher likelihood of spontaneous remission.[38] Inclusion of such patients with nonnephrotic-range proteinuria in natural history studies is likely to have produced a bias in kidney survival. For example, one study of untreated patients reported 72% kidney survival at 8 years, although more than one-third did not have nephrotic-range proteinuria at presentation and more than 50% had less than 5 g/day.[39] Despite this, the rate of end-stage kidney disease (ESKD) was 25% at 8 years and almost 50% by 15 years. Patients presenting with less than 3.5 g/day of proteinuria, no RBC casts, no hypertension, normal kidney function, and no systemic features suggestive of a secondary cause have a generally favorable prognosis. However, these patients must be monitored, because up to 50% will develop nephrotic-range proteinuria at some time in the disease course, often within 2 years after presentation.

Traditional clinical variables including sustained proteinuria and kidney function are associated with long-term kidney outcome and can be used to classify patients into low, moderate, or high risk for progression to kidney failure (Fig. 21.7). One validated model to calculate risk in MN takes into consideration the initial creatinine clearance, the slope of the creatinine clearance during a fixed period, and the lowest level of proteinuria during that observation period.[40] The model predicts that patients with a normal creatinine clearance at presentation that remains stable during a 6-month period and persistent proteinuria of less than 4 g/24 h have a less than 5% chance of progression, and only conservative treatment is recommended. In contrast, patients with proteinuria of 4 to 8 g/24 h during the same time frame have a 55% probability for development of kidney impairment, and those with persistent proteinuria greater than 8 g/24 h have a 66% to 80% probability of progression to chronic kidney impairment within 10 years.

Anti-PLA_2R-antibody titer at the time of diagnosis can assist in prognostication (Table 21.4), although serum anti-PLA_2R titers have yet to be fully incorporated into prediction models. Testing for circulating anti-PLA_2R antibody can detect increases in MN immunologic activity before changes in classic laboratory parameters become apparent[1,41] (Fig. 21.8). The presence and titer of anti-PLA_2R antibody

TABLE 21.4 Risk Factors Associated With Loss of Kidney Function in Membranous Nephropathy

Factors	Predictor
Clinical Features	
Age	Older > younger
Sex	Male > female
Hypertension	Present
Nephrotic syndrome	Present
Traditional Laboratory Parameters	
Albumin	<1.5 g/dL
Creatinine (eGFR)	Above normal (reduced)
Proteinuria	Sustained high-grade proteinuria
Kidney Biopsy Features	
Glomerulosclerosis (focal or global)	Present
Interstitial fibrosis	Present
Autoantibodies	
Anti-PLA_2R titer	Highest tertile > lowest tertile
Epitope spreading	Spreading > No epitope spreading
Antibodies to intracellular antigens	Present
Treatment and Response	
Immunosuppression	Not used > used, if indicated
Response to treatment	No response > partial or complete remission

eGFR, Estimated glomerular filtration rate; *PLA2R,* phospholipase A2 receptor.

can help diagnose primary MN, predict who might have spontaneous remission, monitor disease activity and response to therapy, identify those at risk for progression, and, most significantly, decide when to minimize or stop treatment.[42]

A low or decreasing serum anti-PLA_2R antibody titer is associated with a greater likelihood of spontaneous and complete remission,[43,44] but with a lag time that reflects the time required to stop forming deposits and allow the podocyte to recover from the complement-mediated injury. Conversely, an initially high or increasing trajectory of anti-PLA_2R suggests that the clinical manifestations will continue and may worsen in the short-term. The anti-PLA_2R antibody titers cannot be regarded on their own as indication to postpone or initiate immunotherapy, as clinical parameters such as serum albumin and degree of proteinuria and kidney impairment also must factor into decisions.

Other factors relating to the repertoire of circulating autoantibodies have been proposed as negative prognostic factors. The presence of "epitope spreading," that is, autoantibodies to portions of PLA_2R in addition to the immunodominant N-terminal epitope (see Fig. 21.3), has been associated with worse clinical outcomes in some studies[45] but not others.[46] The presence of additional autoantibodies to intracellular antigens has been suggested to independently convey worse prognosis.[47]

Beyond anti-PLA_2R, other biomarkers, including urinary α_1-microglobulin, β_2-microglobulin, IgM, and IgG, are also associated with MN progression.[48,49] These markers measured together at a single time point have a higher positive predictive value than proteinuria alone, but independent prediction value beyond clinical variables and anti-PLA_2R antibodies requires further exploration.

The severity of chronic changes seen on the biopsy specimen (i.e., degree of glomerulosclerosis, tubulointerstitial fibrosis, and vascular disease) is associated with a poor prognosis but more closely reflects initial GFR than the subsequent rate of decline in GFR.[25,50,51] Other pathologic features, including the percentage of glomeruli with glomerulosclerosis and the configuration of the immune deposits (synchronic/single stage or heterogeneous/multistage) on EM, have also been suggested as predictors of outcome and response to treatment, although these features did not add independent prognostic value in a larger cohort study.[25]

Importance of Complete or Partial Remission

Relapse from a complete remission (CR) occurs in approximately 25% to 40% of MN cases, but the timing is unpredictable. Relapses have been reported up to 20 years after the primary remission. However, most patients relapsing after CR only develop subnephrotic-range proteinuria and will maintain stable long-term kidney function with conservative management alone.[52] In contrast, the relapse rate is as high as 50% in those achieving only a partial remission (PR).

Ten-year kidney survival in patients with CR is 100%; with PR, 90%; and with no remission, only 45%.[53] CR was defined by proteinuria of 0.3 g/day or less, and PR was defined by a proteinuria value less than 3.5 g/day plus a 50% reduction from its peak value. A recent update in this cohort suggested that the durability of CR or PR, whether drug induced or spontaneous, is closely related to the long-term outcome.[54] This suggests that CR and PR may become acceptable shorter-term surrogate endpoints for kidney failure for clinical trials rather than reduction in GFR, which commonly takes years to evolve in MN.[55]

TREATMENT

Nonimmunosuppressive Therapy

Conservative management of MN is directed at control of edema, hypertension, hyperlipidemia, and proteinuria and is similar to that used for nephrotic syndrome of any etiology (see Chapter 16). For patients with proteinuria of greater than 1 g/day, the target for blood pressure is 125/75 mm Hg unless contraindicated for clinical reasons. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) can reduce proteinuria and slow progression of kidney disease (see Chapter 82). A meta-analysis of the largest kidney protection trials using ACE inhibitors showed that the degree of protection is closely correlated to the degree of proteinuria reduction. None of these studies has focused on the specific effect of renin-angiotensin system (RAS) blockade in MN. In secondary analyses, the number of patients with MN has been small, and although the use of ACE inhibitors has been associated with significant improvement in some series, their antiproteinuric effect was modest (<30% reduction in proteinuria) in others. When effective, the benefit of RAS blockade occurs early, usually within the first 3 months of initiation of treatment. Even patients at low risk for progression (proteinuria <4 g/24 h) should be treated with ACE inhibitors or ARBs because this may reduce proteinuria and offer additional kidney protection, with minimal risk of significant adverse effect. Patients must also follow a low-salt diet (1.5–2 g sodium/day) to achieve the maximum benefit from RAS blockade.

When the proteinuria is in the nephrotic range, there is a clear increase in cardiovascular risk, with a threefold to fivefold increase in both coronary events and death rates in this population.[56] Patients with significant proteinuria almost always have pronounced hyperlipidemia. Although not proven, we recommend the use of statins to reduce low-density lipoprotein cholesterol to less than 100 mg/dL (<2 mmol/L), especially if proteinuria remains in the nephrotic range (see Chapters 82 and 85). Both RAS blockade and lipid control should be initiated early in these nephrotic MN patients at higher risk of progression.

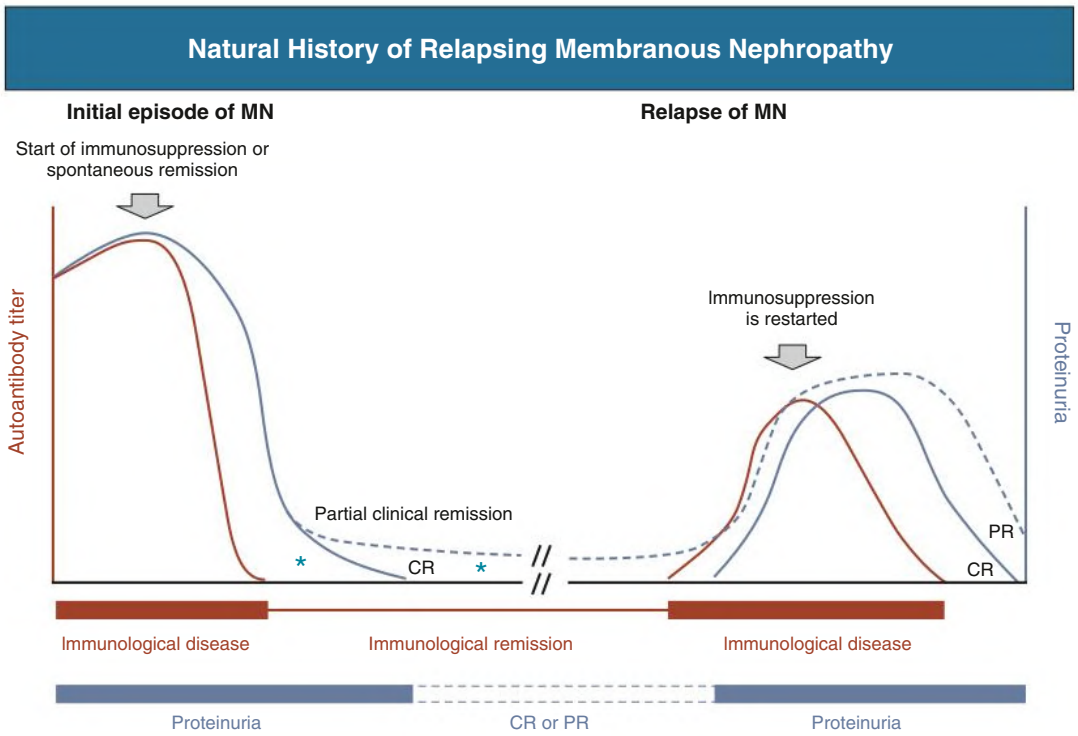

Fig. 21.8 Relationship of Immunologic and Clinical Courses of Disease in Membranous Nephropathy During Initial Disease and Relapse. Autoantibody (e.g., anti-PLA2R) titer is depicted in *red* and reflects the time course of immunologic (or serologic) disease. The start of the immunologic disease typically predates the clinical detection of MN by many months. Autoantibodies start to decline after successful immunosuppressive therapy or the onset of a spontaneous remission. Once the antibodies have disappeared, the patient is in an immunologic remission. The proteinuria *(blue)* lags behind the autoantibody curve and requires more time for the patient to achieve a partial remission (PR) and then a complete remission (CR). In some patients *(dashed blue line),* due to prolonged disease and more permanent damage to the kidney, levels of proteinuria may remain elevated in the subnephrotic range despite immunologic remission. Note that there are periods *(asterisks)* when proteinuria may still be present in the absence of detectable autoantibody. In 25% to 30% of patients, an immunologic and clinical relapse may occur, requiring another round of immunosuppression.

Persistent nephrotic syndrome, especially when caused by MN, is associated with an important risk of thromboembolic events.[57] Hypoalbuminemia appears to be a more robust predictor of venous thromboembolic events (VTEs) than the level of proteinuria. The risk of VTE increases dramatically if serum albumin is less than 2.5 g/dL.[58] These events tend to occur within the first 6 months of diagnosis but may occur up to 2 years from initial presentation. Patients with MN are also at significant risk of arterial thrombotic and cardiovascular events. Early in the disease course, these events occur at a rate that is commensurate to or exceeding that of ESKD.

Prophylactic anticoagulation seems beneficial in reducing fatal thromboembolic episodes in nephrotic patients with MN, without a concomitant increase in the risk of bleeding.[59] No randomized controlled trial (RCT) has ever been done, however, and thus there is no current consensus about prophylactic anticoagulation and no laboratory test that can predict with any accuracy such an event. Using VTE risk data informed by retrospective cohorts, and bleeding risk estimates based upon data from a large trial of warfarin in atrial fibrillation (ATRIA), a decision analysis balanced the risk of thrombosis versus bleed, considering risk thresholds for adverse events (https://www.med.unc.edu/gntools/).[60] The benefits of prophylactic anticoagulant therapy with warfarin appear to outweigh the risks in patients with serum albumin less than 2 or 2.5 g/dL in patients with a low to intermediate risk of bleeding, according to criteria outlined in the ATRIA study.[61] An independent retrospective cohort supported use of an alternate regimen of anticoagulation with low-molecular-weight heparin in patients with nephrotic syndrome due to a spectrum of glomerular pathologies.[62] A shortcoming of the available data is the challenge of quantifying bleeding risk in patients with nephrotic syndrome, which can impact stability of anticoagulation with warfarin and some formulations of low-molecular-weight heparin. There are little data regarding safety of direct oral anticoagulants in this patient population.

Immunosuppressive Therapy

Several regimens using a variety of immunosuppressive agents can successfully reduce proteinuria in MN patients. Many unresolved questions are discussed in the Kidney Disease: Improving Global Outcomes (KDIGO) clinical practice guidelines for glomerulonephritis, including duration of conservative therapy while awaiting a spontaneous remission, when to initiate immunosuppressive therapy, the most effective and safest of the available agents, and duration of treatment before treatment is considered futile.[62a]

Specific immunosuppressive drug therapy should not be considered unless the patient has had persistent nephrotic-range proteinuria (>4 g/day) and the proteinuria has not declined by more than 50% from baseline, over a minimum observation period of 6 months, despite maximum antihypertensive and antiproteinuric therapy. Other suggested criteria for early intervention are the presence of severe disabling or life-threatening symptoms related to the nephrotic syndrome or a rise in serum creatinine of more than 30% within 12 months, which would define a very high risk patient per the KDIGO guidelines. Worsening GFR should be documented as related to disease progression and not a complication, such as renal vein thrombosis,

transformation to crescentic MN variant, hemodynamic or volume-related changes from medications, or drug-induced interstitial nephritis. Low and/or declining titers of the PLA_2R antibody are associated with a higher likelihood of spontaneous remission, and very high levels of the anti-PLA_2R might be an indication for early intervention.[8,41]

Corticosteroids

Three RCTs of corticosteroids in primary MN treatment showed no significant long-term beneficial effect on proteinuria, rate of disease progression, or kidney survival.[63,64] The use of oral corticosteroids as a single agent for the treatment of MN is therefore not recommended. The one exception may be the Japanese population, in whom long-term observational studies have indicated improvement in both proteinuria and kidney function preservation with use of corticosteroids as monotherapy.[65]

Cytotoxic Agents Combined With Corticosteroids

In patients at moderate risk of progression, a significant benefit has been described with a regimen beginning with methylprednisolone pulses 1 g intravenously for 3 days at the start of months 1, 3, and 5 followed by oral prednisone 0.5 mg/kg/day for 27 days, and each cycle followed by 1 month of treatment with an oral cytotoxic agent (cyclophosphamide or chlorambucil).[66] CR or PR was seen in almost 80% of treated patients, and both progression rate and kidney survival were significantly improved versus the supportive care group. Few adverse events were reported in this study, although relapses were seen within 2 years in 30% of the treatment group. Similar results were obtained in an RCT using the same cyclophosphamide-corticosteroid regimen to treat MN patients of Asian (East Indian) ethnicity.[67] Because the results of a cyclophosphamide-based regimen were similar to one based on chlorambucil, cyclophosphamide is most often used because of a better safety profile.

The safe use of cytotoxic agents in patients with deteriorating kidney function remains a challenge, even with appropriate adjustments in dose. One trial enrolled participants with a greater than 20% decline in GFR from baseline and demonstrated that the combination of corticosteroids and a cytotoxic drug (chlorambucil) offered marginally better protection against progressive kidney disease than placebo or cyclosporine but was associated with a high proportion of severe adverse events and a high study dropout rate.[68] Another study followed 65 high-risk patients with serum creatinine greater than 1.5 mg/dL treated with oral cyclophosphamide for 12 months plus corticosteroids.[69] Most patients achieved PR and had good kidney survival at 5 years, but two-thirds of participants had treatment-related complications such as bone marrow suppression and infections. Most adverse events could be managed by dose reduction, although some required permanent discontinuation of treatment.

In summary, cyclophosphamide used in combination with corticosteroids appears to be effective in the treatment of patients with nephrotic-range proteinuria due to primary MN, especially if GFR is well preserved at initiation of therapy. This combination may work even in those with impaired kidney function, but the supporting evidence is much less compelling, adverse effects are higher, and the likelihood of benefit is reduced, especially in patients with advanced kidney failure (GFR <30 mL/min/1.73m^2).[69] The adverse effects of long-term cyclophosphamide therapy are the major drawbacks to the universal application of this treatment. These include increased susceptibility to infections, anemia, thrombocytopenia, nausea, vomiting, sterility, and, over time, malignant disease. Evidence from the MN literature suggests that the incidence of cancer is increased at a much lower level of exposure than previously considered; the number of malignant neoplasms increased with total cyclophosphamide exposure as low as 10 to 20 g (~100 mg/day for 6 months).[70] Therefore, the use of cytotoxic agents should be limited to those patients with the highest risk of progression or with life-threatening complications of the nephrotic syndrome.

Calcineurin Inhibitors

Early uncontrolled studies using the calcineurin inhibitor (CNI) cyclosporine suggested an initial benefit but a high relapse rate. Cyclosporine may reduce proteinuria through its immunosuppressive effects but also by direct effects on the podocyte. In a single-blinded RCT, patients with corticosteroid-resistant MN were treated for 6 months with cyclosporine plus low-dose prednisone and compared with placebo plus prednisone.[71] Cyclosporine was started at 3.5 mg/kg/day and titrated to reach a 12-hour trough level of 125 to 225 μg/L, with a mean trough level of approximately 150 μg/L ultimately achieved in the cyclosporine group. CR or PR was seen in 75% of cyclosporine-treated patients versus 22% of the controls. Cyclosporine was well tolerated. However, 38% relapsed within 6 months of discontinuation of treatment.

Only one RCT has used cyclosporine in patients with high-grade proteinuria and progressive decline in GFR, and both proteinuria and rate of kidney function loss were reduced with cyclosporine compared with placebo.[72] This improvement in proteinuria was sustained for up to 2 years after cyclosporine was discontinued. In contrast to the UK study,[68] cyclosporine was introduced at a lower dose and slowly increased to minimize toxicity (treatment started at 3.5 mg/kg/day compared to 5 mg/kg/day in the UK study; target trough levels were similar). Treatment with longer-term cyclosporine (i.e., 12 months) has resulted in a higher rate of PR/CR (84%). Persistence of remission was maintained with doses of cyclosporine as low as 1 to 2 mg/kg, although relapses were still common if the cyclosporine level fell below 100 ng/mL.

Significant adverse effects seen with cyclosporine include hypertension, gingival hyperplasia, gastrointestinal complaints, muscle cramps, and, most important, nephrotoxicity. The latter depends on both dose and duration of treatment.

In a 12-month RCT (n = 48), monotherapy with tacrolimus was compared with a control group (conservative therapy only).[73] Proteinuria remission was 76% with tacrolimus versus 35% in the control group, and progression rate was also substantially slowed by the CNI. The relapse rate after stopping of the drug, however, approached 50% by the end of 2 years of follow-up.

In summary, both cyclosporine and tacrolimus reduce proteinuria in MN. Although relapses are common after short exposure (6–12 months), a longer duration and lower maintenance doses of CNI can maintain partial remission. No studies using CNIs have been of sufficient duration to confirm that maintenance of remission in proteinuria prolongs kidney survival. Side effects are substantial, with the major concern being nephrotoxicity, particularly if the CNI is not introduced at a low dose and slowly increased until an effective drug level is reached. The potential for nephrotoxicity with the CNIs increases if GFR is less than 40% of normal or rapidly deteriorating, or if there is a high degree of interstitial or vascular pathology accompanying the membranous lesion.

Mycophenolate Mofetil

Studies using mycophenolate mofetil (MMF) in MN patients report conflicting results. However, even in the most optimistic study, although initial response was high (used in combination with prednisone), the relapse rate within months approached 50%.[74] A comparison of MMF to a historical control group receiving cyclophosphamide showed no benefit of MMF in terms of effect or tolerability.[75] The addition of MMF to CNI therapy also does not appear to improve efficacy or relapse rate.[76]

Rituximab

A favorable remission rate of 60% to 70% in patients treated with rituximab as a primary or salvage therapy prompted the design of larger RCTs to evaluate efficacy of this drug in MN.[77,78] Furthermore, rituximab was shown to cause early reduction in anti-PLA_2R antibodies, a finding consistent with a favorable kidney prognosis.[79] Although the first RCT comparing rituximab plus conservative therapy to conservative therapy alone did not achieve a significant primary endpoint of remission at 6 months, anti-PLA_2R levels were significantly reduced by rituximab.[80] During the extended follow-up, remission rates after a mean of 17 months of observation increased to 65% in those treated with rituximab compared with 34% in those treated conservatively.

The largest RCT in primary MN (n = 130) was MENTOR (Membranous Nephropathy Trial of Rituximab), designed to test the hypothesis that rituximab was not inferior to cyclosporine for inducing and maintaining a complete or partial remission of proteinuria.[81,82] Patients assigned to rituximab received 1 g on days 1 and 15. At 6 months, if proteinuria was reduced by more than 25% but there was no CR, a second course of rituximab was administered. In the cyclosporine group, trough levels of 125 to 175 ng/mL were targeted. If CR was observed at 6 months, cyclosporine was tapered and discontinued over 2 months. If proteinuria was reduced by more than 25%, cyclosporine was continued for an additional 6 months and then tapered and discontinued after 2 months. Sixty percent of patients in the rituximab group achieved the primary outcome PR/CR at 24 months versus only 20% in the cyclosporine group, supporting both noninferiority and statistical superiority for rituximab. At 12 months, 60% in the rituximab group and 52% in the cyclosporine group achieved PR/CR, demonstrating noninferiority for rituximab at this time point. The duration of action of rituximab in terms of B cell depletion may have extended the period of immunosuppression well beyond the 12-month treatment period. An important additional finding was a higher creatinine clearance at all time points in patients in remission within the rituximab group. In patients achieving remission, the anti-PLA_2R titer declined more rapidly in those who received rituximab. The rate of serious adverse events was 17% in the rituximab group and 31% in the cyclosporine group. Thus, the MENTOR study suggests that rituximab is at least as efficacious as cyclosporine at inducing remission, and is associated with a lower risk of relapse, with better preservation of creatinine clearance at 24 months, and a trend toward less serious adverse events.

The Sequential Treatment with Tacrolimus and Rituximab Versus Alternating Corticosteroids and Cyclophosphamide in Primary MN (STARMEN) trial evaluated the cyclical cyclophosphamide-corticosteroid regimen versus a combination of tacrolimus with rituximab added prior to tapering in order to potentially affect the rate of relapse after CNI withdrawal.[83] One group received the regimen with alternating months of corticosteroids and oral cyclophosphamide. The second group received tacrolimus targeted to achieve a trough level of 5 to 7 ng/mL for 6 months, followed by a single dose of 1 g of intravenous rituximab and a tacrolimus taper through the end of month 9. The primary outcome of PR/CR at 24 months was achieved in 84% in the corticosteroid-cyclophosphamide arm and 58% in the tacrolimus-rituximab arm. Patients treated with cyclophosphamide had a shorter time to PR/CR and immunologic remission and a trend toward better preservation of eGFR at 24 months. Patients in the cyclophosphamide group experienced more adverse events, including leukopenia and associated infections. Of note, two patients in the cyclophosphamide arm experienced reactivation of tuberculosis.

Although the STARMEN study provides important information, the short duration of tacrolimus therapy and the single dose of rituximab used in this trial do not allow clear comparison of either of these agents to the known efficacy of standard alkylating agent-based therapy. The Rituximab or Cyclophosphamide in the Treatment of Membranous Nephropathy (RI-CYCLO) study directly compared the standard alternating corticosteroid-cyclophosphamide regimen to a single rituximab cycle (two 1 g doses given on days 1 and 15).[84] There was no significant difference in terms of PR/CR at 24 months between the groups, and adverse event rates were also similar. However, because longer-term adverse effects such as infertility or late malignancies, which could occur following treatment with cytotoxic agents, were not captured here, we still recommend consideration of rituximab as first-line treatment.

Complement Inhibition

Although products of complement activation are present in the glomeruli in a high fraction of cases of primary and secondary MN, presently there is no data from clinical trials to indicate if complement is a therapeutic target. An early 16-week RCT of the humanized anti-C5 monoclonal antibody, eculizumab, was terminated prematurely for lack of efficacy; however, there were concerns about adequate dosing because of proteinuria, and the results might be considered inconclusive. Given that complement inhibition would appear to be an appealing strategy during an early window of opportunity until effective immunosuppression lowers circulating autoantibody levels, various clinical trials have been initiated in patients with MN using LNP023 (iptacopan), a small molecule inhibitor of factor B of the alternative pathway; of OMS721 (narsoplimab), a neutralizing human monoclonal antibody targeting mannan-binding lectin-associated serine protease-2 (MASP-2) of the lectin pathway; and of APL-2 (pegcetacoplan), a small molecule C3 activation inhibitor.[85]

Adrenocorticotropic Hormone

Two small studies have reported the use of a synthetic form of adrenocorticotropic hormone (ACTH) in MN. The exact mechanism of action of this agent in MN is unknown but likely unrelated to corticosteroid effects because corticosteroids alone are not beneficial in MN. An early dose escalation study of synthetic ACTH showed improved lipid profiles, with a small subgroup who received therapy for 1 year demonstrating sustained reduction in proteinuria.[86] In a small RCT, ACTH was compared with a standard cytotoxic plus corticosteroids regimen. The remission rate was the same in the two groups (80% vs. 90%), but the relapse rate in the ACTH group was lower (14% vs. 30%), after a follow-up of 1 year. Side effects of ACTH were few and included fluid retention, sleep disturbances, and bronze skin discoloration.[87]

A dose escalation study found that natural ACTH gel significantly reduces proteinuria in proportion to drug exposure among most MN patients, and has an acceptable adverse event profile.[88] In contrast, a subsequent nonrandomized study using the synthetic agent found a substantially lower response rate and an incidence of adverse events approaching 95%, prompting the authors to suggest this agent not be used in MN.[89] Therefore, the most effective formulation of ACTH must be assessed in a larger RCT before it is recommended as standard therapy.

Treatment Approach

Achieving either CR or PR of the nephrotic syndrome is associated with prolonged kidney survival and a slower rate of kidney disease progression in patients with MN. Supportive or conservative care should be provided to all patients first, including diuretics, antihypertensive agents such as ACE inhibitors and ARBs, and lipid-lowering agents, with lifestyle modifications such as salt restriction and efforts toward smoking cessation (see Chapter 82).

Decisions regarding initiation of immunosuppression can be guided by stratifying patients into categories based on the risk of progression to kidney failure. Although persistent proteinuria is a key factor informing risk stratification, severe hypoalbuminemia places patients at significant risk of life-threatening complications of nephrotic syndrome and should be evaluated in parallel with proteinuria and factored into clinical decisions. Fig. 21.7 outlines a suggested management algorithm based on the level and persistence of proteinuria and incorporates information such as serum albumin and anti-PLA_2R antibody titer into risk stratification.

The traditional 6-month period of observation on optimized conservative therapy continues to be recommended. This might also include prophylactic anticoagulation in the setting of severe hypoalbuminemia and low bleeding risk, as described previously. In patients with high-grade proteinuria (>8 g/day), with hypoalbuminemia and persistently elevated or rising anti-PLA_2R antibody titer, initiation of immunotherapy can be considered after a shorter observation period (e.g., 3 months). Life-threatening complications of nephrotic syndrome such as thrombosis or worsening kidney function may also prompt earlier consideration of immunosuppression.

For patients at moderate risk of disease progression, evidence supports the use of either rituximab or a calcineurin inhibitor, although the MENTOR study supports a lower risk of relapse and better preservation of kidney function with rituximab. Cytotoxic/corticosteroid combinations are effective in moderate-risk or high-risk MN patients. This regimen, however, may be associated with important toxicity, and therefore is often reserved for patients at high risk of disease progression. Side effect profile, cost, and availability of these agents are important factors that will influence treatment selection for the individual patient.

Although beyond the scope of this discussion, bone protection and prophylaxis against *Pneumocystis jiroveci* pneumonia should be coadministered with corticosteroids and/or cytotoxic and rituximab therapy.

A reduction in anti-PLA_2R antibody titer will often occur prior to improvement in serum albumin or proteinuria, and the first evidence of clinical response may not be evident for 3 to 4 months. In the case of resistance to a treatment regimen or untenable adverse effects, an attempt at a second treatment regimen is often explored. Ideally, the approach should leave 2 to 3 months between treatment regimens to help immune system recovery.

Patients with severely reduced eGFR (<30 mL/min/1.73 m^2) are less likely to benefit from immunosuppressive therapy (especially if the MN course has been slowly progressive and histopathology indicates significant interstitial fibrosis and glomerular obsolescence), and conservative therapy may be the best option for such patients.

FUTURE DIRECTIONS

The ongoing identification of novel MN antigens continues to highlight new mechanisms of disease development and will help elucidate additional biomarkers that can be used for prognostication and to assist in treatment decisions and monitoring of treatment response. Although great strides have been made in the design and execution of multicenter RCTs in this disease, the rate of adverse events in these trials has remained significant. Furthermore, the response rate remains modest, with 30% to 40% of study participants having no response to the allocated treatment regimen. This highlights the need to continue to search for personalized, novel, and safe treatment strategies for this important cause of kidney failure.

SELF-ASSESSMENT QUESTIONS

1. Which statement on autoantigens in patients with membranous glomerulonephritis is *true?*
   - **A.** Phospholipase A2 receptor is the dominant autoantigen in Whites but not Asians.
   - **B.** THSD7A is a more common autoantigen in those of Japanese ancestry compared with Whites.
   - **C.** NELL1 is the autoantigen in most cases associated with malignancy.
   - **D.** Semaphorin 3B is the autoantigen in lupus-associated membranous glomerulonephritis.
   - **E.** Alpha-enolase is a membrane bound autoantigen, which is commonly shed into the glomerular basement membrane.
2. Which statement on MN is *false?*
   - **A.** Primary MN has its peak incidence during the fourth and fifth decades of life.
   - **B.** Estimated annual incidence is 8 to 10 cases per 1 million population in Western countries.
   - **C.** The odds ratio of MN is almost 80 in individuals who are homozygous for particular HLA-DQA1 and PLA2R1 variants.
   - **D.** A majority of patients (70%–80%) with MN present with the nephrotic syndrome.
   - **E.** Microscopic hematuria is uncommon (5%–10%).
3. Which statement on MN is *false?*
   - **A.** The predominant IgG subclass in many forms of primary MN is IgG3.
   - **B.** In earliest stages of MN, the glomeruli and interstitium appear normal on light microscopy.
   - **C.** In some patients with progressive disease, glomeruli exhibit areas that resemble secondary focal segmental glomerulosclerosis.
   - **D.** Granular glomerular capillary wall staining for IgG in MN is characteristic.
   - **E.** Phospholipase A2 receptor staining in the immune deposits exhibits a pattern that colocalizes with IgG.
4. Which statement on the therapy of patients with membranous glomerulonephritis (MN) is *true?*
   - **A.** For patients with proteinuria of greater than 1 g/day, the target for blood pressure is 140/90 mm Hg.
   - **B.** Prophylactic anticoagulation should be given to all patients with MN.
   - **C.** Immunosuppressive drug therapy should not be considered unless the patient has had persistent nephrotic-range proteinuria.
   - **D.** Oral corticosteroids as a single agent for the treatment of MN are often effective.
   - **E.** Rituximab should not be first-line treatment because of longer-term adverse effects, such as late malignancies.

Immunoglobulin-Mediated Glomerulonephritis With a Membranoproliferative Pattern of Injury and Cryoglobulinemic Glomerulonephritis

Sanjeev Sethi, An S. De Vriese, Fernando C. Fervenza

IMMUNOGLOBULIN-MEDIATED GLOMERULONEPHRITIS WITH A MEMBRANOPROLIFERATIVE PATTERN OF INJURY

Definition and Classification

Membranoproliferative glomerulonephritis (MPGN) is a pattern of glomerular injury resulting from subendothelial and mesangial deposition of immune complexes and/or complement factors and their products, along with proliferative changes in the glomeruli. This pattern does not represent a disease entity per se. We therefore prefer to use terminology that refers to the underlying disease, such as immune-complex glomerulonephritis, monoclonal Ig glomerulonephritis, and C3 glomerulopathy.[1] Other terms, such as lobular glomerulonephritis and mesangiocapillary glomerulonephritis, should be avoided.

Former Classification

Previously, MPGN was classified as MPGN type I, MPGN type II, and MPGN type III based on ultrastructural characteristics. MPGN type I was defined by the presence of mesangial and subendothelial deposits. MPGN type II, also referred to as *dense deposit disease* (DDD), was characterized by mesangial and intramembranous highly electron-dense deposits. MPGN type III was defined by the presence of subendothelial, intramembranous, and subepithelial electron-dense deposits. However, some cases had glomerular deposition of immunoglobulins and complement components, whereas in others, only complement deposition was present. This insight engendered a new classification. Older publications regarding epidemiology, therapy, and transplantation may be difficult or impossible to interpret because, with the exception of DDD, immune-complex and complement-mediated MPGN were included together (see later discussion).

Newer Classification Based on Etiology and Pathogenesis

The Mayo Clinic classification of MPGN[2,3] divides MPGN based on two broad pathogenetic pathways: (1) immune complex or monoclonal immunoglobulin deposition in the glomeruli with or without complement deposition and (2) complement deposition subsequent to dysregulation of the complement system.

The MPGN pattern of injury secondary to deposition of immune complexes in the glomeruli can occur when there are persistent circulating antigen-antibody immune complexes resulting from chronic infections or autoimmune diseases. MPGN with immunoglobulin and complement deposits may also be observed in the setting of a monoclonal gammopathy.

On light microscopy, a proliferative glomerulonephritis is seen in the acute phase with initial influx of neutrophils followed by mononuclear inflammatory cells. In the repair phase, the injured mesangial cells and endothelium produce new basement membrane, and there is expansion of the mesangial matrix. As a result of remodeling, the glomerular basement membrane (GBM) thickens and glomeruli acquire a lobular appearance typical of MPGN pattern. The immune-complex and monoclonal immunoglobulin–mediated MPGN are differentiated by the presence of immunoglobulins on immunofluorescence (IF); in the former the deposits are polyclonal, whereas in the latter they are monoclonal. C3 is also usually present, indicating activation of the complement pathway.

Complement-mediated MPGN is less common than immune complex–mediated MPGN and results from dysregulation of the complement alternative pathway (see Chapter 23).

A third pathogenic pathway with an MPGN pattern despite the absence of immune complex or complement deposition can occur with chronic thrombotic microangiopathy or chronic endothelial injury (Table 22.1).

Epidemiology

MPGN is decreasing in frequency in high-income countries (possibly because of better control of infectious diseases) but remains common in patients presenting with nephrotic syndrome in low- and middle-income countries in South America, Asia, and Africa. The incidence of MPGN in most high-income countries is less than 1 to 2 cases per million population per year.[4] Only about 4% to 5% of kidney biopsy samples showing an MPGN pattern have underlying C3 glomerulonephritis (see Chapter 23).

Clinical Presentation and Pathology

Infection-Associated MPGN

Chronic viral infections such as hepatitis C (HCV) and B (HBV) are important causes of immune complex–mediated MPGN (cryoglobulinemic glomerulonephritis; see later discussion and Chapter 57).[5,6] The exact mechanism of HCV-related glomerular disease is unknown. Toll-like receptors, particularly TLR3, might play a role in HCV-related MPGN.[7] HBV most frequently causes a membranous nephropathy pattern of injury but can more rarely be associated with MPGN. The pathology of HBV-related MPGN is likely related to the trapping of circulating immune complexes in the mesangium and subendothelial regions.[8] It is also possible that mesangial cells are directly infected by HBV virions. Uncommonly, MPGN may be seen with acute viral infections, such as with Puumala hantavirus.[9]

Chronic bacterial infections can cause MPGN as a result of continuous low-grade antigenemia.[10,11] Potential causative agents include *Staphylococcus, Mycobacterium tuberculosis, Streptococcus,*

TABLE 22.1 Causes of a Membranoproliferative Pattern of Glomerular Injury

Immune complex mediated, monoclonal immunoglobulin mediated	Deposition of immune complexes as a result of an infection	Viral: hepatitis B and C Bacterial: endocarditis, infected ventriculoatrial shunt, visceral abscesses, leprosy, meningococcal meningitis Protozoa/other infections: malaria, schistosomiasis, mycoplasma, leishmaniasis
	Deposition of immune complexes as a result of an autoimmune disease	Systemic lupus erythematosus Sjögren syndrome Rheumatoid arthritis
	Deposition of monoclonal immunoglobulin as a result of a monoclonal gammopathy	Plasma cell or B-cell disorder
Complement-mediated (C3 glomerulonephritis and dense deposit disease)	Mutations in complement-regulating proteins CFH, CFI, CFHR5 Antibodies to complement regulating proteins C3/C4 nephritic factor, antibodies against CFH, CFI, or CFB Mutations in complement factors C3, CFB Monoclonal gammopathy	
Non–immunoglobulin mediated, non–complement mediated	Healing phase of HUS/TTP Antiphospholipid (anticardiolipin) antibodies syndrome POEMS syndrome Radiation nephritis Nephropathy associated with bone marrow transplantation Drug-associated thrombotic microangiopathies Sickle cell anemia and polycythemia Dysfibrinogenemia and other prothrombotic states Transplant glomerulopathy	
Idiopathic	None of the conditions previously mentioned present	

CFB, complement factor B; *CFH*, complement factor H; *CFI*, complement factor I; *CFHR5*, complement factor H related 5; *HUS*, Hemolytic uremic syndrome; *POEMS*, polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, skin; *TTP*, thrombotic thrombocytopenic purpura. Modified from Fervenza FC, Sethi S, Glassock RJ. Idiopathic membranoproliferative glomerulonephritis: Does it exist? *Nephrol Dial Transplant*. 2012;27(12):4288–4294.

Propionibacterium acnes, Mycoplasma pneumoniae, Coxiella burnetii, Nocardia, Brucella, and *Meningococcus.*[12,13] So-called "shunt nephritis," as may be seen with ventriculoatrial or ventriculocaval shunts for hydrocephalus or as a result of catheter infections (e.g., parenteral nutrition), is caused most commonly by coagulase-negative staphylococci. Fungal and parasitic infections less frequently cause an MPGN pattern of injury.[14,15]

In the setting of viral infections, IF typically shows granular deposition of immunoglobulin M (IgM), C3, and both kappa and lambda light chains (Fig. 22.1). IgG may or may not be present, and C1q is typically negative. The presence of IgG staining stronger than IgM and C3 is more often seen in bacterial infections, although in some cases with chronic infections the immunoglobulin staining may be weak compared with the C3 staining. Electron microscopy (EM) shows mesangial and subendothelial deposits. The capillary walls are thickened with entrapment of cellular elements, subendothelial electron-dense deposits, matrix-like material, and new GBM formation manifested as double contours on light microscopy.

Additional information on the glomerular diseases associated with infection can be found in Chapter 57.

Autoimmune-Associated MPGN

An MPGN pattern of injury is commonly seen in patients with autoimmune diseases such as systemic lupus erythematosus (SLE), rheumatoid arthritis (RA), primary Sjögren syndrome, undifferentiated connective tissue disease, primary sclerosing cholangitis, and Graves disease.[16,17] The majority of patients with Sjögren syndrome and glomerulonephritis (80%) have type II monoclonal cryoglobulinemia and low complement C4 levels.[18] Sjögren syndrome is one of the most common causes of non–HCV-related cryoglobulinemia.[19]

On IF, a full house pattern with positive staining for IgG, IgA, IgM, C1q, C3, and kappa and lambda light chains is frequently seen, particularly in the setting of SLE. IgM may be the dominant immunoglobulin in MPGN associated with RA and primary Sjögren syndrome. EM shows mesangial and subendothelial capillary wall electron-dense deposits. Subepithelial deposits may also be present. In such cases, an exostosin 1/exostosin 2–associated membranous nephropathy should be considered.[20] Tubuloreticular inclusions are often present in the endothelial cells.

Monoclonal Immunoglobulin–Associated MPGN

Monoclonal gammopathies encompass disorders characterized by clonal proliferation of immunoglobulin-producing B lymphocytes or plasma cells. In most patients with monoclonal immunoglobulin-associated MPGN, a monoclonal immunoglobulin cannot be detected in the blood or urine[21,22] with routine serum electrophoresis and immunofixation examination, and evidence of overt malignancies such as lymphoma, multiple myeloma, or Waldenström macroglobulinemia is absent. In those cases, the term *monoclonal gammopathy of renal significance* (MGRS) is used.[23] The glomerular diseases included in this group are proliferative glomerulonephritis with monoclonal immunoglobulin deposits (PGNMID), amyloidosis, fibrillary glomerulonephritis (DNAJB9 positive), immunotactoid glomerulopathy, and monoclonal immunoglobulin deposition disease (see Chapter 28).[24–26] Although each of these entities may have a varied morphologic appearance, the common pattern of glomerular injury is MPGN.

On kidney biopsy (Fig. 22.2), glomerular deposition of the monoclonal immunoglobulin usually results in an MPGN pattern. Less common patterns of proliferative glomerulonephritis include mesangial proliferative, diffuse proliferative, crescentic, necrotizing,

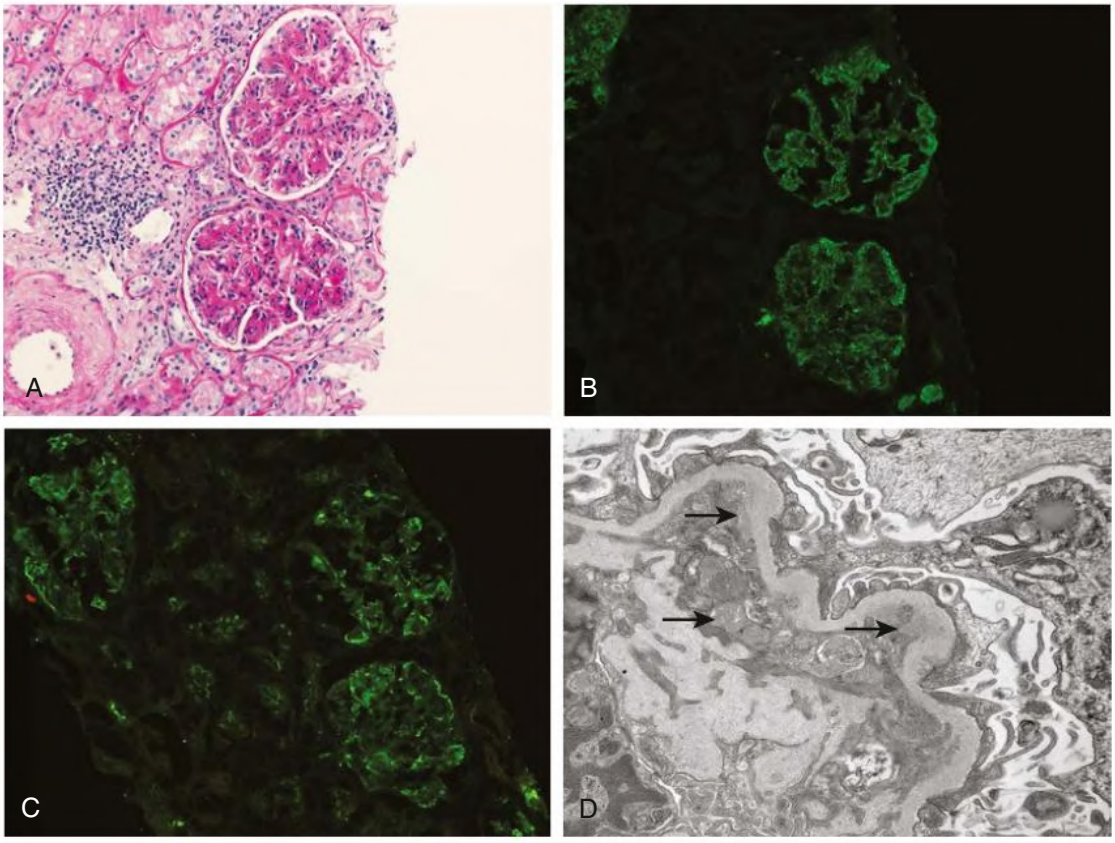

Fig. 22.1 Membranoproliferative Glomerulonephritis (MPGN) Associated With Hepatitis C. (A) Light microscopy showing two glomeruli with an MPGN pattern of injury (PAS ×20). (B–C) Immunofluorescence microscopy showing bright granular staining for immunoglobulin M (B), and C3 (C). There was equal staining for kappa and lambda light chains (not shown). (D) Electron microscopy showing subendothelial electron-dense deposits and double contour formation. *Black arrows* point to subendothelial deposits. (D, ×13,000.)

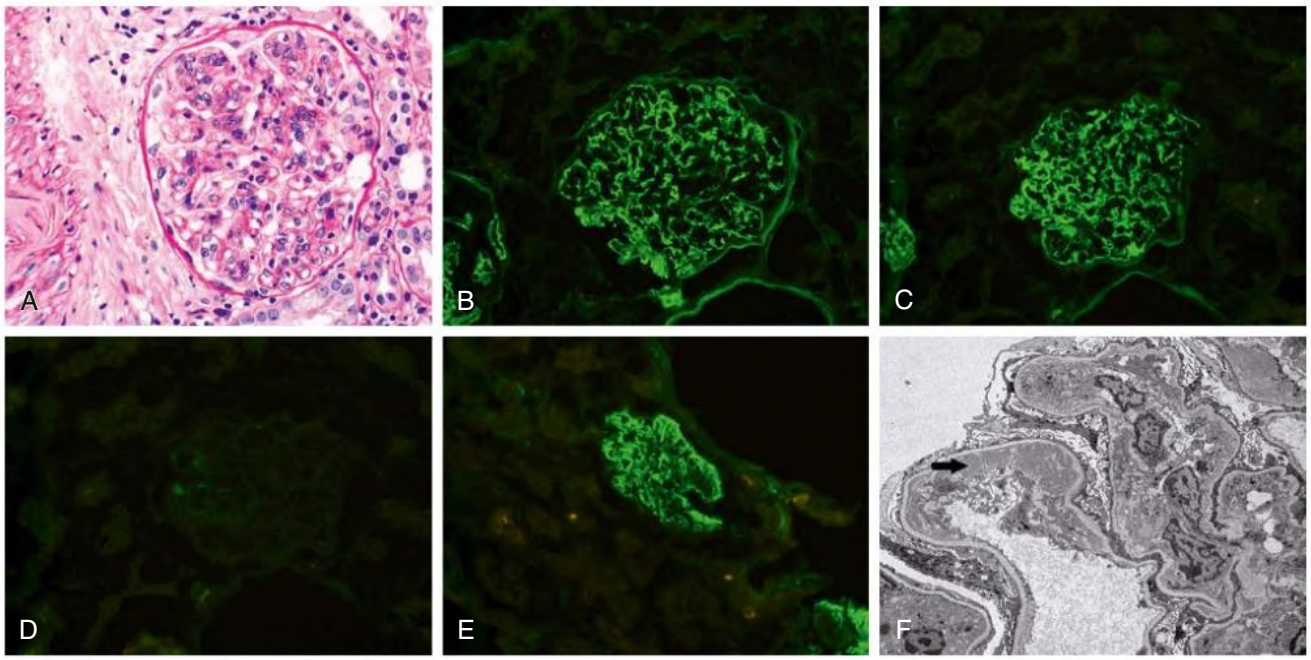

Fig. 22.2 Proliferative Glomerulonephritis With Monoclonal Immunoglobulin Deposits. (A) Light microscopy showing a membranoproliferative glomerulonephritis (MPGN) pattern of injury (PAS, ×40). (B–E) Immunofluorescence microscopy showing bright granular staining for immunoglobulin G (IgG) (B), kappa light chains (C), negative staining for lambda light chains (D), and positive staining for IgG3 subtype (E). (F) Electron microscopy showing subendothelial electron-dense deposits and double contour formation. *Black arrows* point to subendothelial deposits (F, ×4000.)

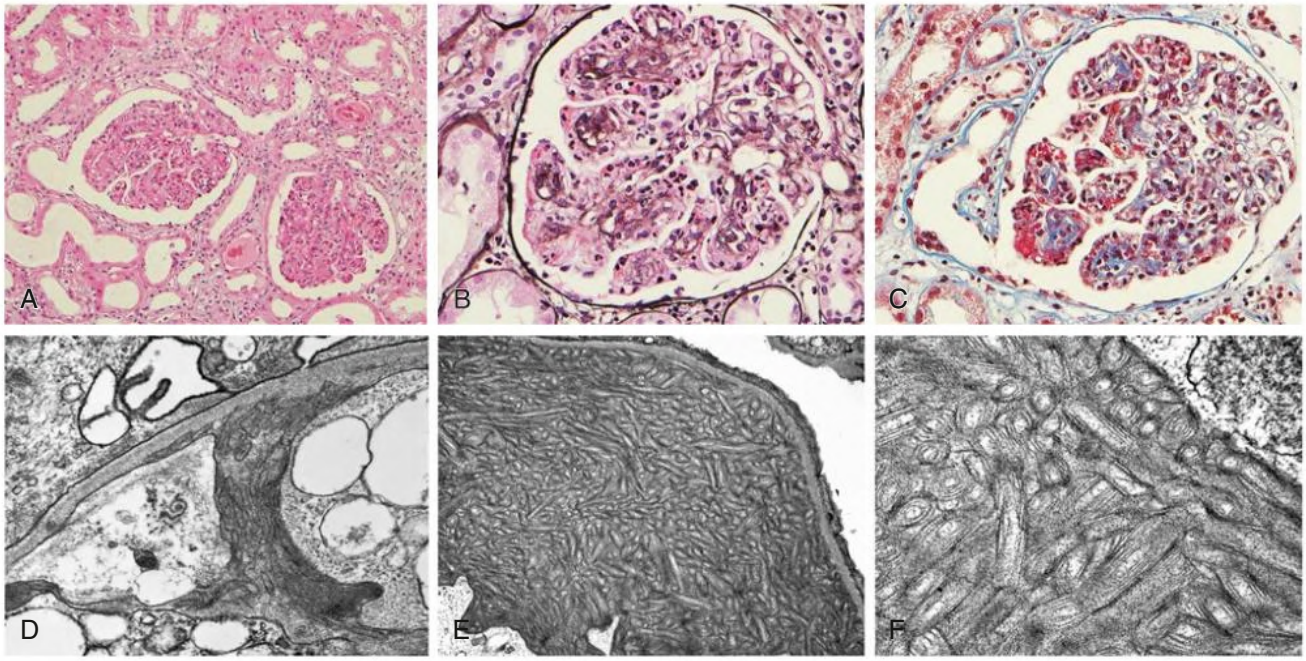

Fig. 22.3 Cryofibrinogen Glomerulopathy With a Membranoproliferative Pattern of Injury. (A–C) Light microscopy showing a membranoproliferative glomerulonephritis pattern of injury. Scattered fuschinophilic material can be seen with some capillary loops in part C. Immunofluorescence microscopy was negative for immune deposits. (D–F) Electron microscopy showing randomly arranged and loosely arranged subendothelial fibrillary deposits with tubular substructures (D) and aggregates of intraluminal tubular deposits with large central bore with double and triple layering (E–F). (A, H&E, ×20. B, Silver methenamine silver, ×40. C, Masson trichrome stain, ×40. D, ×30,000. E, ×9300. F, ×3000.)

and sclerosing glomerulonephritis.[21,22] IF studies are crucial for the diagnosis and show mesangial and capillary wall monoclonal immunoglobulin deposits. The monoclonal immunoglobulin most often contains heavy chain IgG, less commonly IgM or, rarely, IgA, with kappa or lambda light chain restriction. Sometimes, only heavy or light chains may be present.[27] EM shows mesangial and subendothelial electron-dense deposits, and, rarely, subepithelial and intramembranous deposits. Glomerular capillary wall remodeling with double contour formation is often present.

In cases in which the heavy chain consists of IgG, the IgG3 subclass is the most common subclass. Interestingly, this class of deposits is most likely to have undetectable circulating monoclonal immunoglobulin by routine serum and urine electrophoresis studies.[28]

In monoclonal immunoglobulin-associated MPGN, 30% of patients have a monoclonal or biclonal band on serum immunofixation studies. Of these, bone marrow studies revealed 16 cases of MGRS, of which two converted to multiple myeloma; two cases of chronic lymphocytic leukemia (CLL); one case of lymphoplasmacytic lymphoma/Waldenström macroglobulinemia; three cases of low-grade B-cell lymphoma not further classifiable; and six cases of multiple myeloma.[25] Thus, all patients with MPGN associated with monoclonal immunoglobulin should be evaluated for an underlying plasma cell or B-cell proliferative disorder.

MPGN With Masked Immune Deposits

MPGN with isolated C3 deposits rarely occurs in the setting of monoclonal gammopathy.[29] Hypocomplementemia is common. IF on formalin-fixed, paraffin-embedded tissue after protease digestion unmasks monoclonal immunoglobulin glomerular deposits. The immunoglobulin on the glomerular deposits matches the monoclonal protein on serum immunofixation. It is important that these cases are not misdiagnosed as C3 glomerulopathy because most are associated with a low-grade lymphoma or plasma cell dyscrasia. A C4d stain can be helpful in detecting masked immune deposits.[30,31]

Complement-Mediated MPGN

Complement-mediated MPGN is also the most common MPGN pattern seen in C3 glomerulopathy, a lesion that is characterized by dominant C3 staining with minimal or no immunoglobulin deposits (see Chapter 23).

MPGN Without Immunoglobulins or Complement

Glomeruli may demonstrate membranoproliferative-like changes in the absence of immunoglobulin or complement deposits in chronic thrombotic microangiopathy (see Chapter 30).

Uncommon Causes of MPGN

Cryofibrinogen-related MPGN. Cryofibrinogenemia is a rare disease resulting in an MPGN pattern of injury (Fig. 22.3). Cryofibrinogen is a cryoprecipitate that develops after refrigeration of plasma but not serum (when both serum and plasma form a precipitate on refrigeration, the responsible proteins are called cryoglobulins). Cryofibrinogenemia may be asymptomatic but can be associated with thromboembolic disease, particularly affecting the skin.

C4 glomerulopathy. C4 glomerulopathy is characterized by glomerular deposits of predominantly C4 with little or no immunoglobulin or C3 deposition. This glomerulopathy encompasses C4 DDD and C4 glomerulonephritis[32] and may be caused by an overactive lectin pathway of complement. Kidney biopsy shows a membranoproliferative pattern of injury with extremely thick glomerular capillary walls.

Collagen type III glomerulopathy. Collagen type III (collagenofibrotic) glomerulopathy is a rare disorder characterized by massive accumulation of atypical type III collagen fibrils in the mesangium and subendothelial space (see Chapter 29).

BOX 22.1 Patient Evaluation in Cases of MPGN Pattern of Injury on Biopsy[a]

Immune Complex MPGN

Infection

- Viral serology for HBV, HCV, HIV, COVID-19
- Quantification of viral load
- Blood cultures
- Imaging studies for deep-seated abscesses and vegetations by echocardiogram
- QuantiFERON-Tb Gold
- Parasitic and fungal infections are investigated only in the appropriate clinical situation (history of recent travel to endemic regions, prolonged fever of unknown origin, atypical pulmonary infiltrates)

Autoimmune

- Antinuclear antibodies, anti-ds-DNA antibodies, extractable nuclear antigen antibodies (anti-ribonucleoprotein, anti-SSA, [Ro], anti-SSB, [La], anti-Smith [Sm], Scl-70, Anti-Jo-1)

Monoclonal Immunoglobulin–Associated MPGN

Serum and urine protein electrophoresis and immunofixation
Serum M-protein isotype by mass spectrometry
Serum free light chains
Bone marrow biopsy

MPGN Without Immunoglobulin and Complement Deposition

Evaluate for thrombotic microangiopathy

[a]C3/C4, cryoglobulins, rheumatoid factor, C-reactive protein, serum albumin, urinalysis, quantified proteinuria and kidney function should be performed at baseline in all patients.
HBV, Hepatitis B virus; *HCV*, hepatitis C virus; *HIV*, human immunodeficiency virus; *MPGN*, membranoproliferative glomerulonephritis.

Evaluation

The evaluation for MPGN should be guided by the suspected cause, based on clinical presentation and biopsy findings. A standard workup for MPGN is presented in Box 22.1. Low serum C3 and C4 are more typical of classic pathway activation, as in immune complex–mediated glomerulonephritis. A low C3 with a normal C4 suggests abnormalities of the alternative complement pathway. These findings, along with the biopsy results (particularly IF and EM), can guide further detailed evaluation.

Infections

Workup in the evaluation of infection-related MPGN depends on the suspected pathogen (see Chapter 57). In the case of viral infection–related MPGN, tests should include viral serology and quantification of viral load. The workup for parasitic infection–related MPGN should include blood tests for malaria, urine and stool tests for schistosomiasis, and serologic tests for schistosomiasis and leishmaniasis. Blood cultures, cultures of indwelling catheter tips, imaging studies for deep-seated abscesses, and transthoracic echocardiograms for valvular vegetations should be performed in the case of suspected fungal and bacterial infections.

Autoimmune Diseases

The diagnostic tests for autoimmune diseases should follow the established criteria, such as those of the American College of Rheumatology.

Monoclonal Gammopathy

The workup should include serum protein electrophoresis, urine protein electrophoresis, serum and urine immunofixation, and serum free light chain assays. Urine free light chains have no diagnostic utility and should not be assessed. Bone marrow evaluation should be performed to rule out an underlying plasma cell dyscrasia and/or lymphoproliferative disorder. In patients in whom a clone is identified (approximately 20%–30%), the underlying clonal process is plasmacytic in 50% of patients and derives from B-cell lymphocytes in the other 50%.[33] In our experience, in the absence of a circulating monoclonal protein, the probability of finding an underlying plasma cell dyscrasia is limited.[28]

Treatment

Therapy should be directed to treatment of the underlying condition, such as chronic infection, autoimmune disease, and malignancy (e.g., myeloma, lymphoma, CLL). Treatment of monoclonal immunoglobulin–associated MPGN is complex and depends on the type of the immunoglobulin. In patients with IgM monoclonal proteins, we suggest employing a regimen used to treat Waldenström macroglobulinemia as initial therapy: rituximab 4 doses of 375 mg/m^2, weekly for 4 weeks, with an identical regimen repeated 6 months later. More intense regimens include bendamustine plus rituximab; bortezomib, dexamethasone, and rituximab; or bortezomib plus rituximab with or without dexamethasone.

For patients with non-IgM monoclonal proteins, conservative and immunosuppressive therapy with the use of corticosteroids (alone or in combination with an alkylating agent), thalidomide, and mycophenolate mofetil (MMF) have been used in a small number of patients with variable outcomes.[34] A recent case series suggests that clone-directed therapy with the use of rituximab; bortezomib plus dexamethasone; or bortezomib, cyclophosphamide, and dexamethasone, similar to that used in myeloma, results in a good chance of partial or complete proteinuria remission.[33] In nontransplant patients who were treated empirically with these regimens, the rate of complete or partial remission of proteinuria was 75%. These regimens are well tolerated and safe for use in kidney failure, with minimal dose adjustments needed. We typically treat patients for at least 6 months and then reassess. Some patients may also respond with disappearance of the moncolonal gammopathy after a 3- to 6-month combined course of prednisone and cyclophosphamide.

Daratumumab is an IgG1-kappa human monoclonal antibody that binds to the CD38 transmembrane glycoprotein on the surface of tumor cells and induces apoptosis. It has shown promise in the treatment of refractory multiple myeloma. In a phase II trial in patients with proliferative glomerulonephritis and monoclonal immune deposits (PGNMID), the overall response rate at 12 months was 100% (60% partial and 40% complete remission of proteinuria).[35] Autologous stem cell transplantation has been reported to be successful in MGRS and light chain proximal tubulopathy, but little information is available on its use regarding monoclonal immunoglobulin–associated MPGN.[36]

There is no strong evidence to guide treatment in patients with "idiopathic" MPGN.[37] Corticosteroids have been widely used as monotherapy and/or in combination with other immunosuppressives. In a randomized trial, 80 children with nephrotic-range proteinuria and preserved estimated glomerular filtration rate (eGFR) were assigned to either prednisone or lactose 40 mg/m^2 every other day for a mean duration of 41 months.[38] Prednisone therapy had a significantly lower rate of treatment failure (40% vs. 55%) but was associated with significant toxicity, particularly hypertension, and it is uncertain whether the findings (published in 1992) are applicable to contemporary practice. No randomized studies with corticosteroids have been performed in adults with idiopathic MPGN.

Cytotoxic agents have been tried, with unimpressive results and significant side effects. Calcineurin inhibitors have also been used in

TABLE 22.2 Cryoglobulin Classification and Associated Diseases

Cryoglobulin Type	Immunoglobulin Class	Associated Diseases
I. Monoclonal immunoglobulins	M > G > A > BJP	Myeloma, CLL, Waldenström macroglobulinemia
II. Mixed cryoglobulins with monoclonal immunoglobulins	M/G ≫ G/G	Infection (hepatitis C), Sjögren syndrome, CLL, lymphoma
III. Mixed polyclonal immunoglobulins	M/G	Infection (hepatitis B/C), SLE, RA, vasculitis, neoplasia

BJP, Bence Jones protein (light chains); *CLL,* chronic lymphocytic leukemia; *RA,* rheumatoid arthritis; *SLE,* systemic lupus erythematosus.

uncontrolled studies, suggesting a modest decline of proteinuria in patients with MPGN not otherwise characterized.

Data on the use of MMF in patients with MPGN are limited.[39–41] An observational study compared five adults treated with MMF and oral prednisolone to six patients on no immunosuppressive agents.[39] At 18 months, proteinuria had declined and GFR was preserved or improved in the MMF group, compared with no change in proteinuria and a 40% decline in GFR in patients who were not treated. Whether the benefit was derived from MMF or prednisone cannot be ascertained from the study.

Our experience with rituximab (1 g on days 1 and 15) in four patients with idiopathic MPGN showed a 65% reduction in proteinuria and preserved GFR over 1 year.[42]

The KDIGO 2021 Clinical Practice Guideline on Glomerular Diseases recognized difficulties in interpreting previous information because, in many instances, historical controls were used, studies antedated the use of angiotensin II blockade, statistical significance was marginal, or the power to detect substantial differences was small.[37] More importantly, in these studies, the underlying pathogenic processes that lead to MPGN were not taken into account. It also recognizes that truly "idiopathic" MPGN is an exceptional condition in adults. As such, KDIGO 2021 only provides practice points based on very low-quality evidence, clinical experience, and expert opinion. We have taken a pragmatic approach based on our clinical experience, as follows:

- Patients with normal kidney function, no active urinary sediment, and nonnephrotic range proteinuria can be treated conservatively as outlined in Chapter 82 because the long-term outcome is relatively benign in this setting. Frequent follow-up is required initially to detect early deterioration in kidney function. If there is no disease progression, follow-up every 6 months should suffice.
- Patients with nephrotic syndrome and preserved kidney function could be treated with a regimen similar to that used in primary (permeability factor-related) focal segmental glomerulosclerosis, such as prednisone 1 mg/kg/day (maximum dose 60–80 mg/day) for 12 to 16 weeks (see Chapter 19). If the patient responds, prednisone is gradually tapered to alternate-day therapy over 6 to 8 months. If there is less than a 30% reduction in proteinuria after 12 to 16 weeks, we recommend tapering and discontinuing the prednisone. Calcineurin inhibitors may be considered in patients who do not respond to or tolerate glucocorticoids.
- Patients who present with impaired kidney function (eGFR < 60 mL/min/1.73m^2), with or without nephrotic syndrome, but without crescents or severe tubulointerstitial fibrosis on kidney biopsy, and an active urinary sediment (arbitrarily defined as >10 red blood cells per high-power field) can also be considered for treatment with corticosteroids, as mentioned previously. For patients who cannot or do not wish to receive high-dose glucocorticoids, treatment with MMF, with or without low-dose prednisone (10 mg/day), for 6 to 12 months is a reasonable alternative. If there is no improvement in GFR, proteinuria, or hematuria after 6 to 12 months of therapy, we discontinue these agents and consider repeating a kidney biopsy to reevaluate disease activity and chronicity. If the repeat kidney biopsy shows mainly chronic damage without mesangial proliferation and/or endocapillary hypercellularity, we do not give additional immunosuppressive therapy because it is unlikely to be beneficial. If the repeat kidney biopsy shows evidence of ongoing active glomerulonephritis, rituximab (1 g on day 1 and 1 g on day 15) or cyclophosphamide 2 mg/kg/day (reduced to 1.5 mg/kg/day in patients with a serum creatinine >2.5 mg/dL or age >60 years) for 3 to 6 months could be added, realizing that the efficacy of rituximab or cyclophosphamide in these patients is unknown. Patients who do not respond to treatment with either cyclophosphamide or rituximab are considered to have resistant disease and we recommend stopping immunosuppressive therapy, continuing general supportive measures, and referring them for kidney transplantation when appropriate.
- Patients presenting with rapidly progressive disease and crescents on biopsy can be treated as in other forms of crescentic glomerulonephritis with pulse methylprednisolone followed by oral corticosteroids and cyclophosphamide (see Chapter 26).
- Patients who present with eGFR less than 30 mL/min/1.73m^2 and severe tubulointerstitial fibrosis on kidney biopsy are unlikely to benefit from immunosuppressive therapy.

Transplantation

Recurrent MPGN after kidney transplantation is discussed in Chapter 113.

CRYOGLOBULINEMIC GLOMERULONEPHRITIS

Definition

Cryoglobulins are immunoglobulins that precipitate at cold temperatures and dissolve when rewarmed. Cryoglobulins usually present in the setting of infections, autoimmune diseases, and monoclonal gammopathy, but, in rare instances, they can be idiopathic. All of the aforementioned causes can present with an MPGN pattern of injury with intraluminal deposits (immune microthrombi) suggestive of cryoglobulins.

Cryoglobulins are often divided into three types (Table 22.2). Type I cryoglobulinemia is characterized by the presence of a single monoclonal immunoglobulin, most often resulting from an underlying B-cell hematologic malignancy, typically Waldenström macroglobulinemia or multiple myeloma. In the absence of overt malignancy, the diagnosis of MGRS should be established. The cryoglobulins are usually IgM or IgG, but IgA and monoclonal free light chains also may occur.

In type II mixed cryoglobulinemia, there is a mixture of monoclonal IgM with rheumatoid factor activity directed against a polyclonal IgG. It is most commonly caused by chronic infections, generally HCV, but also HBV and HIV. It can also occur in the context of autoimmune diseases, particularly Sjögren syndrome. In patients with HCV infection, cryoglobulinemia may be the first manifestation of liver disease.[6,43]

In type III mixed cryoglobulinemia, the IgG and IgM are polyclonal. Type III cryoglobulinemia is most commonly seen in HCV

Fig. 22.4 Purpura in a Patient with Hepatitis C Virus–associated Cryoglobulinemia. (A) Palpable nonpruritic purpura affecting the lower extremities in a patient with hepatitis C virus infection and cryoglobulinemia. Raised purpuric lesions are present on the legs. Differential diagnosis for patients with dermatorenal syndromes includes IgA vasculitis and antineutrophil cytoplasmic antibody–associated vasculitis. (B) Purpuric lesions are present on the patient's buttocks and thigh. Note the purpuric lesions along the superior and inferior elastic border of the undergarment line.

infection, in chronic inflammatory and autoimmune disease (e.g., SLE and Sjögren syndrome), and in lymphoproliferative malignancies. Thus, there is a significant overlap between the underlying causes of type II and III cryoglobulins.

Clinical Presentation

The syndrome of cryoglobulinemia is caused by deposition of antigen-antibody complexes in capillaries and small arterioles and occasionally in small arteries.[44] Most cases are associated with HCV. In the majority of patients with HCV infection, the immune complexes consist of HCV, anti-HCV IgG, and monoclonal IgM anti-IgG (with rheumatoid factor activity) (type II mixed cryoglobulinemia). Clinical presentation of mixed cryoglobulinemia includes weakness, palpable nonpruritic purpura (Fig. 22.4), symmetric arthralgias (arthritis is rare), peripheral neuropathy, and kidney involvement.[45] The purpura is usually painless and mainly localized to the extremities and buttocks, similar to patients with IgA vasculitis (see Chapter 24). Other manifestations include digital necrosis (Fig. 22.5), congestive heart failure, pulmonary infiltrates, and mesenteric ischemia. The clinical syndrome and dominant symptoms may evolve over time.

On the other hand, patients with type I cryoglobulinemia are usually asymptomatic. Kidney disease occurs in approximately 20% to 60% of the patients, ranging from microscopic hematuria with low-grade proteinuria to a full-blown nephrotic or nephritic syndrome or both. Hypertension is common and can be severe. Kidney disease is a major determinant of long-term prognosis and substantially increases mortality.

Evaluation

Laboratory data suggestive of a cryoglobulin are low C4 levels (and normal or mildly decreased C3 levels) and a positive rheumatoid factor. It is crucial that blood is drawn into collection tubes that have been prewarmed to 37°C without anticoagulants because anticoagulants

Fig. 22.5 Necrosis of the fingertips in a patient with cryoglobulinemia.

can produce false-positive results due to cryofibrinogen or heparin-precipitable complexes. However, in as many as 40% of patients with type II and in occasional patients with type III mixed cryoglobulinemia, circulating cryoglobulins may not be detected. In some cases, kidney disease presents in the absence of detectable cryoglobulins or other manifestations of mixed cryoglobulinemia such as purpura or arthritis. There is a poor correlation between the clinical manifestations and the cryocrit.

On kidney biopsy, an MPGN lesion is seen in more than 80% of cases (Fig. 22.6). Light microscopy findings that point toward a cryoglobulinemic MPGN include a greater number of macrophages than seen in other forms of proliferative glomerulonephritis and the presence of intraluminal thrombi composed of precipitated cryoglobulins. On IF, there is diffuse IgM deposition in capillary loops, and EM may show subendothelial deposits that often have a characteristic "fingerprint" pattern of cryoprecipitates. MPGN with features of cryoglobulins should prompt evaluation for infections (especially HCV),

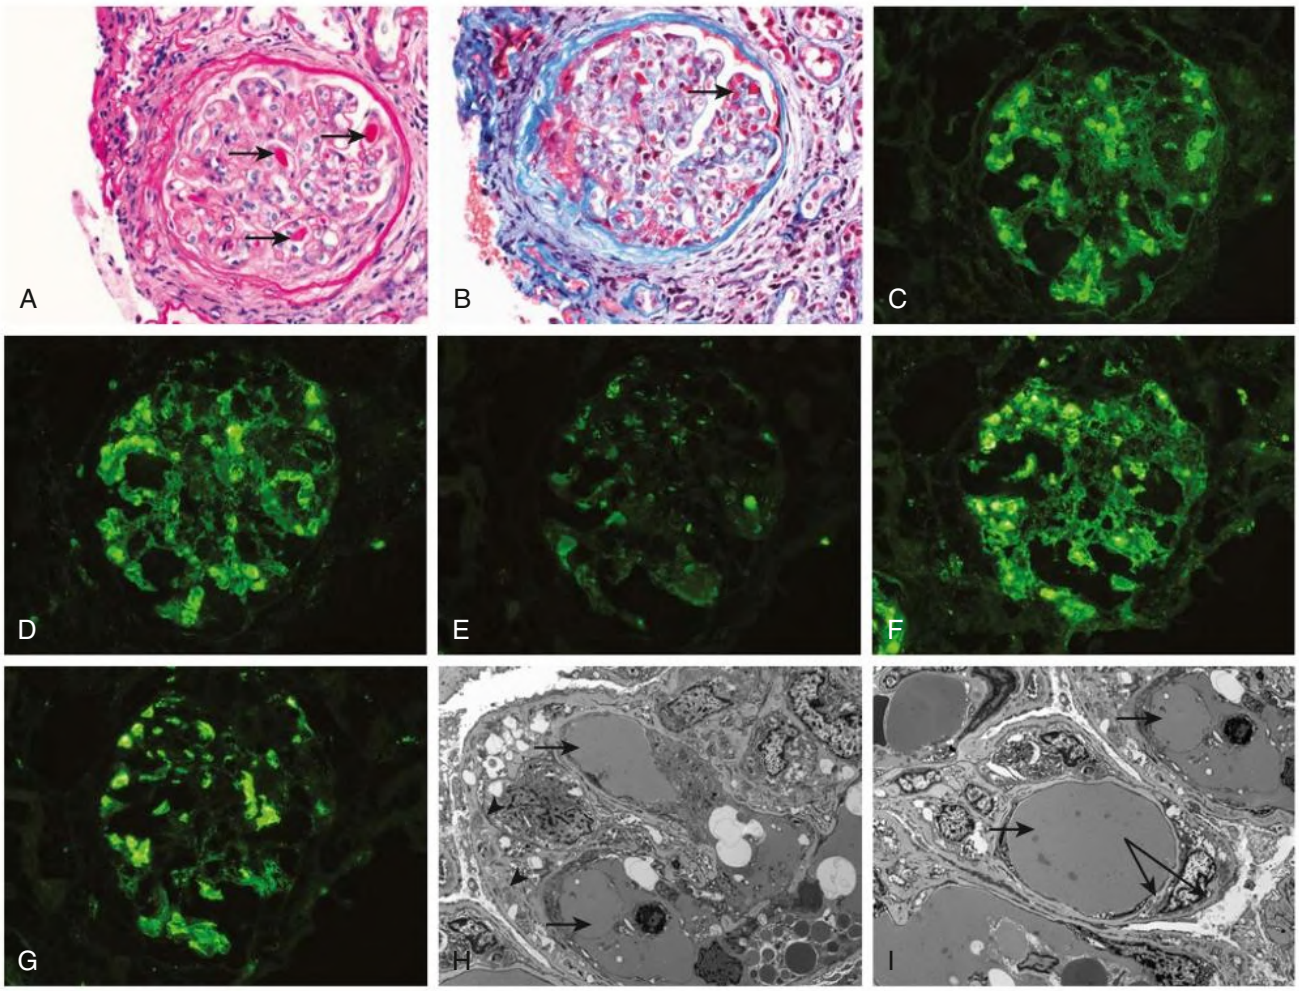

Fig. 22.6 Membranoproliferative Glomerulonephritis and Cryoglobulins Associated With Sjögren Syndrome. (A–B) Light microscopy showing a membranoproliferative glomerulonephritis pattern of injury. Immunofluorescence microscopy showing bright granular staining for immunoglobulin (Ig) G (C), IgM (D), C3 (E), kappa chains (F), and lambda light chains (G). (H–I) Electron microscopy showing numerous intraluminal deposits (*arrowheads* in H); subendothelial deposits and double contours (*double arrow* in I) are also present. *Black arrows* point to intraluminal deposits representing cryoglobulins. (A, PAS, ×40. B, Masson trichrome stain, ×40. H and I, ×2900.)

autoimmune diseases (especially Sjögren syndrome), and monoclonal gammopathies. Features that suggest glomerulonephritis because of monoclonal immunoglobulin–associated cryoglobulins (type I cryoglobulins) include intraluminal periodic acid–Schiff (PAS) positive (hyaline-like) deposits on light microscopy, intraluminal monoclonal immunoglobulin on IF microscopy, and substructures (microtubules, fibrillary, fingerprints) on EM.

Treatment

Patients with mixed cryoglobulinemia who have mild disease (i.e., petechial rash without necrotizing lesions, mild sensory neuropathy, arthralgias) typically do not require immunosuppressive therapy, and management of such patients should focus on treating the underlying disease. Patients with a rapidly progressive, organ-threatening, or life-threatening cryoglobulinemic syndrome such as rapidly progressive glomerulonephritis, severe digital ischemia, gastrointestinal vasculitis, rapidly progressive neuropathy, central nervous system vasculitis, and heart failure should be treated with immunosuppressive therapy, regardless of the cause of the mixed cryoglobulinemia.[46] This typically involves a short course of corticosteroids combined with rituximab. If rituximab is unavailable, fails to produce a response, or is not tolerated, cyclophosphamide can be used instead.

In patients with life-threatening disease (e.g., acute respiratory failure with pulmonary hemorrhage); cryoglobulinemia-associated hyperviscosity syndrome; severe, refractory skin ulcers because of cutaneous vasculitis; or a high cryocrit level (i.e., ≥10%), we suggest adding plasmapheresis to immunosuppressive therapy. We typically perform daily plasma exchange for 10 to 14 sessions or three exchanges per week for 2 to 3 weeks. After disease stabilization, therapy should be directed at the underlying disease. Patients with HCV infection (without decompensated cirrhosis) and mixed cryoglobulinemia should receive antiviral therapy as per current guidelines.[47]

Patients with severe manifestations of cryoglobulinemic vasculitis associated with HCV infection and not yet treated with antiviral therapy should receive immunosuppression first, with antiviral therapy delayed for 1 to 4 months.[44] The rationale is based on the fact that immunosuppression can rapidly improve inflammation and resolve target-organ damage, although no randomized trials have evaluated immediate versus delayed timing of antiviral therapy. However, in

patients with cryoglobulinemic vasculitis associated with infection with HIV or HBV, antiviral therapy should always be initiated before or concurrently with immunosuppressive therapy because these patients are at high risk for enhanced viral replication as a result of rituximab or cyclophosphamide therapy.

The specific antiviral drugs and therapy schemes depend on the HCV genotype, kidney function, prior treatment response, type of antiviral agent used, tolerance to treatment, and clinical and laboratory response to treatment.

Patients with a lymphoproliferative disorder should receive disease-specific therapy.

Patients treated with immunosuppressive therapy should receive opportunistic infection (i.e., *Pneumocystis jirovecii*) prophylaxis. The frequency of monitoring is determined by the severity of disease.

SELF-ASSESSMENT QUESTIONS

1. A 50-year-old woman is referred for sudden onset of edema and hypertension. Past medical history is unremarkable. Apart from a blood pressure of 155/95 mm Hg and 2+ edema, the physical examination is unremarkable. Serum creatinine is 1.8 mg/dL and proteinuria is 3.2 g/24 h. Urinalysis shows 50 to 100 red blood cells per high-power field, of which more than 25% are dysmorphic. C3/C4 complement levels, antineutrophil cytoplasmic antibody, antinuclear antibody, and anti-GBM are all normal or negative. A kidney biopsy is performed. Light microscopy shows an MPGN pattern of injury on immunofluorescence (IF) IgG (+++), IgM (+), IgA (–) C3 (+++), C1q (–), kappa (+++), lambda (–) chains, and EM duplication of the GBM with subendothelial deposits. The most likely diagnosis is:
   A. MPGN secondary to monoclonal gammopathy
   B. MPGN secondary to underlying infection
   C. MPGN secondary to abnormalities in the alternative pathway of complement
   D. MPGN type I (idiopathic)
2. A 65-year-old man undergoes orthotopic liver transplantation for liver failure secondary to HCV infection. The immediate posttransplantation course is uneventful. However, 1 year later he presents with recurrence of HCV infection, blood pressure of 150/90 mm Hg, proteinuria of 3 g/24 h, a rising serum creatinine up to 1.8 mg/dL, and a serum albumin of 3.9 g/dL. Urinalysis shows 40 to 50 red blood cells per high-power field, of which more than 25% are dysmorphic. C3 complement is 101 mg/dL (normal 75–115 mg/dL), C4 complement is 2 mg/dL (normal 10–40 mg/dL), and rheumatoid factor is positive. In this patient, a kidney biopsy is most likely to show:
   A. Focal segmental glomerulosclerosis
   B. Minimal change disease
   C. Membranous nephropathy
   D. Cryoglobulinemic glomerulonephritis
3. Which of the following causes of glomerulonephritis is typically associated with low serum complement C4?
   A. Mixed cryoglobulinemia
   B. Henoch-Schönlein purpura nephritis
   C. Anti-GBM disease
   D. Poststreptococcal glomerulonephritis
4. A 52-year-old woman with a long history of rheumatoid arthritis and Sjögren syndrome is evaluated for new onset of a skin rash on the lower extremities and impaired kidney function. Blood pressure is 150/90 mm Hg. Serum creatinine is 1.8 mg/dL. Urinalysis shows more than 50% red blood cells per high-power field, of which more than 25% are dysmorphic. Proteinuria is 2.8 g/24 h. C3 complement is 82 mg/dL (normal 75–115 mg/dL), and C4 complement is less than 5 mg/dL (normal 10–40 mg/dL). Antineutrophil cytoplasmic antibody, antinuclear antibody, and anti-GBM serologic results are all negative. In this patient a kidney biopsy is most likely to show:
   A. MPGN with IgA (+++), C3 (++), IgG (+), kappa (+), lambda (++).
   B. MPGN with linear IgG.
   C. MPGN with C3 (+++), IgG (neg), IgM (neg), IgA (neg).
   D. MPGN with IgG (++), IgM (+++), IgA (+), C3 (++), kappa (++), lambda (++).

Glomerulonephritis Associated With Complement Disorders

Joshua M. Thurman, H. Terence Cook, Matthew C. Pickering

Glomerular diseases associated with abnormalities of the complement system include thrombotic microangiopathy (see Chapter 30) and glomerulonephritides. Activation of complement in most cases of glomerulonephritis is secondary to deposition of immune complexes. Rarely, a genetic or acquired abnormality of the complement system itself causes glomerulonephritis. Deficiencies of early components of the classic pathway of complement are associated with autoimmunity and glomerulonephritis.[1] This is most clearly seen in the very rare individuals with C1q deficiency, almost all of whom have a lupus-like illness. This is thought to be because of the failure of clearance of immunogenic apoptotic bodies and other cellular debris in the absence of normal classic pathway complement activation. The largest group of patients with complement abnormalities and glomerulonephritis (C3 glomerulopathy) exhibits abnormal control of the alternative pathway of complement activation (Box 23.1).

C3 GLOMERULOPATHY

C3 glomerulopathy encompasses glomerular disease characterized by the predominant accumulation of complement component C3 in glomeruli particularly associated with abnormal control of the alternative pathway of complement activation (Fig. 23.1).[2] Glomeruli show strong staining for C3 with much less intense or absent staining for immunoglobulins or for components of the classic pathway of complement activation, C1q and C4. C3 glomerulopathy is distinct from atypical hemolytic uremic syndrome (aHUS; see Chapter 30), which is also associated with alternative pathway activation, because in aHUS, complement activation is on the kidney endothelium and is not associated with well-defined deposits on electron microscopy (EM). On light microscopy, C3 glomerulopathy may manifest with mesangial proliferation, a membranoproliferative pattern (see Chapter 22), endocapillary proliferation, and crescents. Many cases that were previously classified morphologically as membranoproliferative glomerulonephritis (MPGN) types I, II, or III are actually cases of C3 glomerulopathy. Indeed, it appears that most cases that have previously been called MPGN type III (see Chapter 22) are examples of C3 glomerulopathy. However, monoclonal gammopathy–associated MPGN also may be misclassified as C3 glomerulopathy if the glomerular immunoglobulin deposits are masked and only become detectable after protease digestion of the histologic section (see later and Chapter 22).

On EM, C3 glomerulopathy also may have a variety of appearances. Common is dense deposit disease (DDD), which is characterized by replacement of the glomerular basement membrane (GBM) by dense bands on EM (Fig. 23.2). In some cases, the light microscopic appearance in DDD shows a membranoproliferative pattern, which explains the older term MPGN type II (see Chapter 22). However, most cases of DDD do not have MPGN morphology on light microscopy.

Cases of C3 glomerulopathy that do not manifest as DDD may show a range of appearances on EM with deposits that may be mesangial, subendothelial, or subepithelial and may be more or less well defined (Fig. 23.3). The relevance of the site of the deposits has not been defined, although it is likely, by analogy with diseases such as lupus nephritis, that capillary wall deposits are associated with more glomerular inflammation and higher levels of proteinuria. These cases of non-DDD C3 glomerulopathy have been given the collective name of *C3 glomerulonephritis* (C3GN).[3,4]

Etiology and Pathogenesis

C3 glomerulopathy involves dysregulation of the alternative pathway of complement (see Fig. 23.1). In health, the alternative pathway is constantly activated at a very low rate. This means there is a constant generation of activated C3 (C3b), which allows the pathway to be rapidly amplified when needed. In the presence of pathogens, C3b amplification occurs through a positive feedback loop (C3b amplification loop) that generates millions of C3b molecules within minutes. Because amplification can progress rapidly, efficient systems are needed to prevent inappropriate activation. The most important regulator of the alternative pathway is factor H (CFH). CFH has three key functions: (1) to block the formation of alternative pathway C3 convertases by binding to C3b and inhibiting interaction between C3b and factor B, (2) to promote the spontaneous dissociation of these convertases, and (3) to work together with factor I to cleave C3b to iC3b. Mice genetically engineered to lack factor H have undetectable circulating C3 because C3 is constantly consumed by the uncontrolled alternative pathway.[5]

CFH is a glycoprotein predominantly made in the liver composed of protein subunits known as short consensus repeat (SCR) domains. The activity of CFH can be modulated by a group of closely related proteins called factor H–related (CFHR) proteins.[6] There are five CFHR proteins in humans (CFHR1–5) encoded by individual genes downstream from the *CFH* gene. The CFHR proteins, like CFH, are composed of SCR domains and share considerable sequence similarity with CFH. This has led to genomic rearrangements (i.e., polymorphisms and mutations) within the *CFH-CFHR* locus, most commonly a combined deletion of the *CFHR1* and *CFHR3* genes. This is present in homozygosity in 5% to 20% of healthy individuals depending on ethnic origin. It is now clear that some CFHR proteins are able to compete with the binding of CFH to C3b.[7] Unlike CFH, the CFHR proteins cannot inhibit complement activation. Furthermore, the CFHR-C3b interaction prevents CFH from negatively regulating C3b production. Consequently, the CFHR-C3b interaction promotes C3b amplification, termed CFH deregulation (Fig. 23.4).

In many cases of C3 glomerulopathy, the failure of CFH to control the activation of the alternative pathway in the circulation is associated with low circulating C3 because of uncontrolled consumption.

Up to 80% of patients with DDD and up to half of patients with C3GN have low serum C3.[3] Many of these patients have a C3 nephritic factor (C3Nef). C3Nefs are autoantibodies that stabilize the alternative pathway C3 convertase, preventing CFH regulation. C3Nef likely plays an etiologic role in these patients. C3Nefs can be identified in 40% to 60% of cases of C3GN and 80% to 90% of cases of DDD.[3,8] However, C3Nefs also may be found in patients with immune complex–associated MPGN, lupus nephritis, and poststreptococcal glomerulonephritis and even in healthy patients. Nephritic factors that stabilize the classical pathway C3 convertase (C4Nef) or the C5 convertase (nephritic factor of the terminal pathway, or Nft) have also been detected in some patients.[9] In some patients, failure of alternative pathway control is associated with autoantibodies directed against factor H that target its regulatory domain.

In other cases, genetic mutations lead to failure of alternative pathway control. These cases include patients with complete CFH deficiency,[10,11] mutations in CFH that interfere with its binding to C3b,[12,13] and mutations in C3 that change its structure so that it cannot be inhibited by CFH.[14] In cases of C3 glomerulopathy without activation of circulating C3, it can be assumed that there is a failure to control the alternative pathway locally within the glomerulus. This might be because of a failure to control activation or inappropriate handling of the fragments of C3 generated by alternative pathway activation. There is a familial C3 glomerulopathy (now called CFHR5 nephropathy) without systemic C3 activation. This disease is endemic in Cyprus, and the mutation is a duplication of the first 2 exons of the *CFHR5* gene.[15] This leads to an abnormal protein that forms multimers that are able to deregulate the activity of CFH on surfaces.[7] It appears that the abnormal protein interferes with the action of CFH locally within the glomerulus and enhances alternative pathway activation.

Several other mutations and polymorphisms in complement genes have been associated with C3 glomerulopathy, but their role is uncertain. Complement mutations are only detected in a minority of patients,[16] and the frequency of rare variants in complement genes was

BOX 23.1 Definitions

C3 glomerulopathy—A *disease process* secondary to abnormal control of complement activation, deposition, or degradation characterized by predominant glomerular C3 fragment deposition with electron-dense deposits on electron microscopy.

Dense deposit disease—A form of C3 glomerulopathy with a characteristic electron microscopy appearance of intensely osmiophilic transformation of the glomerular basement membrane.

C3 glomerulonephritis—C3 glomerulopathy without the characteristic appearances of dense deposit disease.

Glomerulonephritis with dominant C3—A morphologic term for cases of glomerulonephritis with dominant staining for C3c. Dominant is defined as C3c intensity 2 or more orders of magnitude more than any other immune reactant on a scale of 0 to 3 (including 0, trace, 1+, 2+, 3+). Many, but not all, of these will represent cases of C3 glomerulopathy.

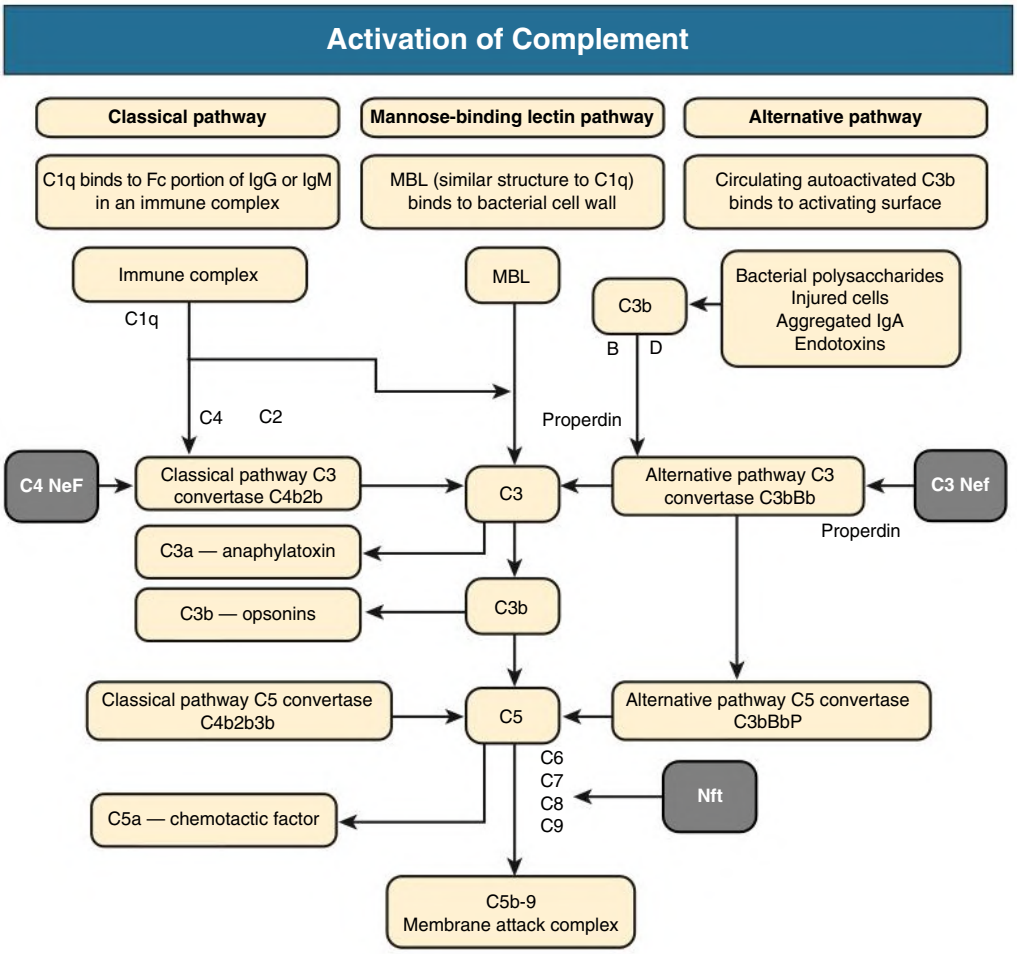

Fig. 23.1 Mechanisms of Activation of the Complement Pathways. These activators include nephritic factors (NeF, Nef). *MBL,* Mannose-binding lectin; *Nft,* Nephritic factor of the terminal pathway.

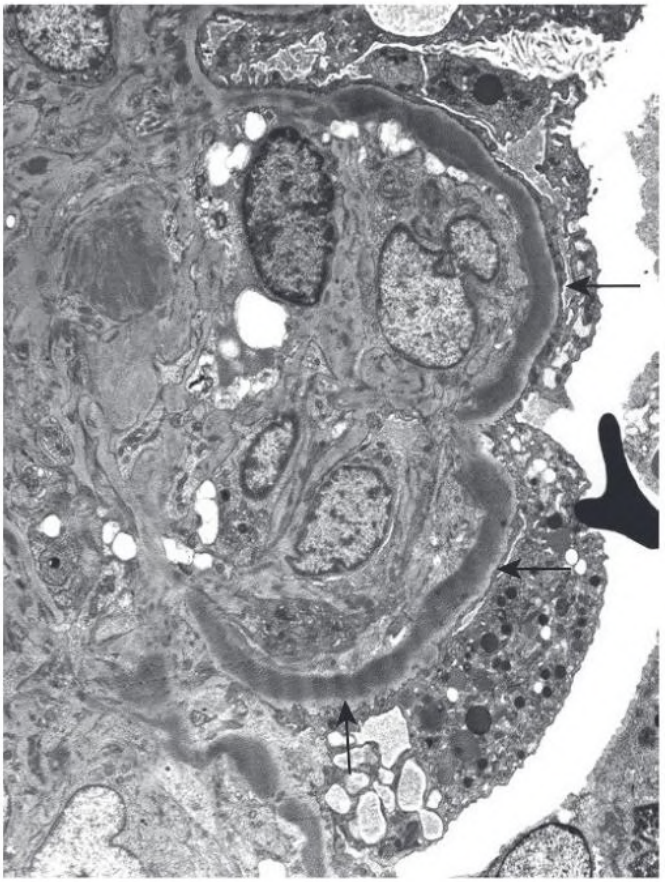

Fig. 23.2 Electron micrograph of a glomerulus showing typical appearances of dense deposit disease with very osmiophilic transformation of the basement membrane *(arrows)*.

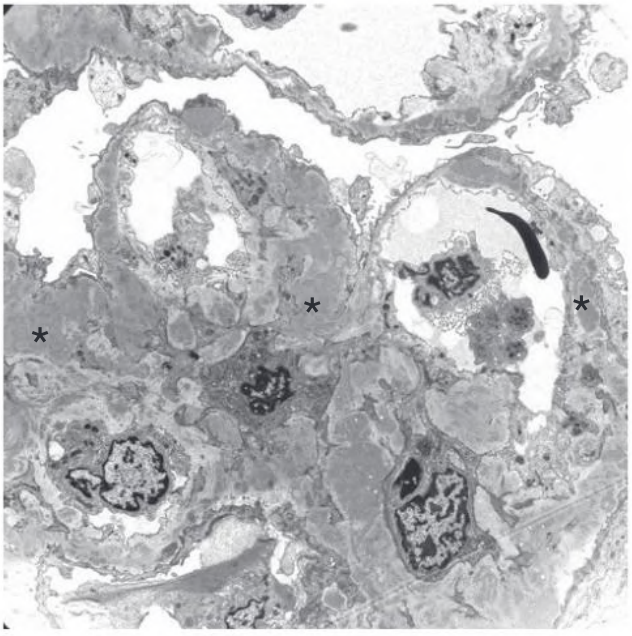

Fig. 23.3 Electron micrograph of a glomerulus in a case of C3 glomerulonephritis. There is a complex pattern of thickening of the glomerular basement membrane with intramembranous electron-dense material. Similar deposits are also seen in the mesangium *(asterisks)*.

no higher in MPGN or C3G patients than in controls.[17] There appears to be an association between monoclonal gammopathy and C3 glomerulopathy, particularly in patients who are older than 50 years.[18–20] In some cases, the monoclonal immunoglobulin may act as a C3Nef, but this has only rarely been demonstrated.[21,22]

Epidemiology

DDD has been reported to have a prevalence of 2 to 3 per million population and to be primarily a disease of children and young adults. However, in a 2009 series from New York, 39% of the adult patients were older than 60 years.[23] Some, but not all, studies have shown a female DDD predominance. In a French series, the ratio of C3GN to DDD was approximately 2:1 and patients with C3GN were significantly older, with a mean age at diagnosis of 30 years.[3] In the United Kingdom and Ireland, the ratio was approximately 3:1 and the incidence of C3 glomerulopathy 1 to 2 per million population per year.[24] The apparent incidence of C3GN may increase as the entity becomes better recognized. There is no reliable information on geographic variation in incidence, with the notable exception of C3GN resulting from a specific mutation in *CFHR5,* apparently originating in Cyprus several hundred years ago.[15]

Clinical Manifestations

Dense Deposit Disease

At presentation, almost all patients have proteinuria, usually with hematuria. Nephrotic range proteinuria is present in two-thirds of patients[23,25] and frank nephrotic syndrome in 12% to 65% in different series. In 98 patients from North America,[26] about 20% of patients did not suspect a problem and kidney disease was detected as part of a routine examination. Many patients have initial signs and symptoms of acute nephritic syndrome. In some cases, there may be episodes of acute kidney injury that show complete clinical resolution.[27] Decreased kidney function is common at presentation, particularly in adults. Hypertension is commonly found either at presentation or in follow-up. In about half of patients, clinical onset of DDD is preceded by acute infection.

Patients with DDD may develop ocular drusen (Fig. 23.5), lipoproteinaceous deposits of complement-containing debris within the Bruch membrane beneath the retinal pigment epithelium. This pathology is similar to that in age-related macular degeneration (AMD), but, in contrast to AMD, drusen in DDD may be found as early as the second decade of life. Complete visual loss is rare, but in late disease both peripheral and central vision can be affected.[28] There is no correlation between the severity of the disease in the kidney and that in the eye. A small minority of patients with DDD have acquired partial lipodystrophy (APL), a condition with symmetric loss of adipose tissue from the face, arms, and upper portions of the trunk (see Fig. 23.5).

The overall long-term outcome in DDD is poor and 50% of the patients progress to end-stage kidney disease (ESKD) within 10 years of diagnosis; young women appear to be at especially high risk.[26]

C3 Glomerulonephritis

C3GN has only recently been recognized, and thus clinical manifestations are less well defined. In a French series, 27% of patients with C3GN had nephrotic syndrome, two-thirds had microhematuria, and one-third had hypertension at presentation.[3] In that series, the rate of progression to ESKD was similar to that in the patients with DDD.

In CFHR5 nephropathy in Cyprus, the major clinical feature in young patients is microhematuria, which is present in 90%, and 20% of patients reported episodes of macrohematuria often associated with upper respiratory tract infection.[29] Proteinuria became more common with increasing age and was seen in 80% of males and 20% of females over the age of 50 years. Impaired kidney function was more common with increasing age, particularly in men, and of 18 patients who reached ESKD, 78% were male.

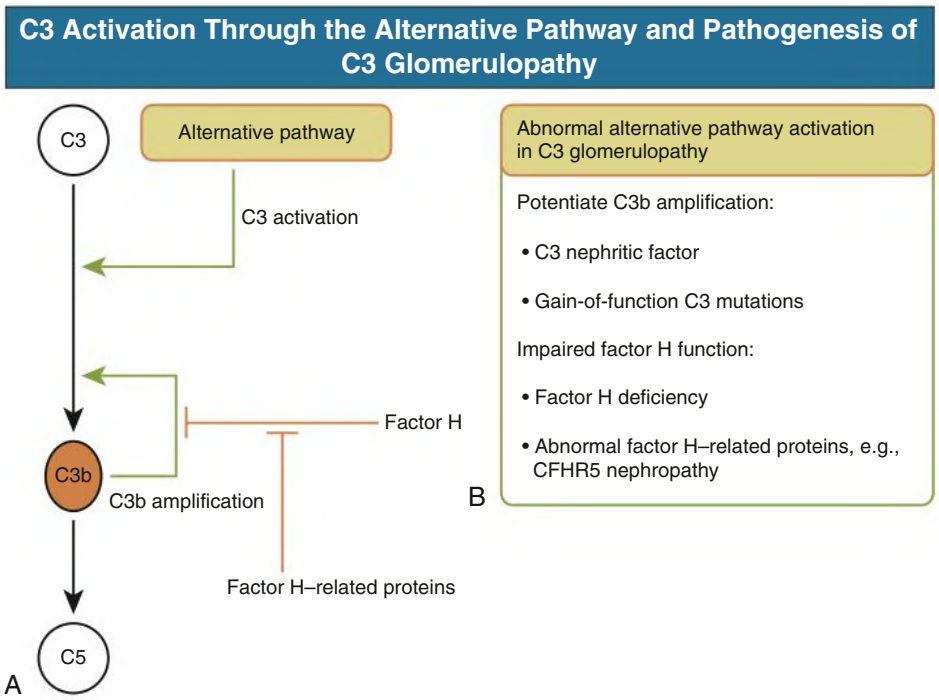

Fig. 23.4 C3 Activation through the Alternative Pathway and Pathogenesis of C3 Glomerulopathy. (A) Activation of C3 results in the formation of C3b and then C5 activation. C3b production is amplified through a positive feedback loop. Factor H inhibits this amplification (depicted). Some factor H–related proteins (e.g., complement factor H–related protein 5 [CFHR5]) interact with C3b and, unlike factor H, allow C3b amplification to proceed. In this way, they antagonize the actions of factor H in a process termed factor H deregulation. (B) C3 glomerulopathy is associated with abnormal (increased) activation of the alternative pathway. These include situations in which there is enhanced C3b amplification despite normal factor H function, such as in the presence of C3 nephritic factor, and where there is a defect in the ability of factor H to negatively regulate the alternative pathway. Examples include cases of factor H deficiency (extremely rare) and abnormal factor H–related proteins associated with familial C3 glomerulonephritis (e.g., CFHR5 nephropathy).

Fig. 23.5 Dense Deposit Disease. (A) Partial lipodystrophy. Note the absence of subcutaneous fat from the face. (B) Drusen bodies in the retina. (Courtesy Dr. C.D. Short, Manchester, UK.)

Laboratory Findings

Low levels of serum C3 are found in approximately 80% of patients with DDD and up to 50% of patients with C3GN. In C3GN secondary to CFHR5 nephropathy, serum C3 levels are typically normal. Serum levels of the early components of the classic pathway (C1q and C4) are usually normal. Most patients with DDD are positive for serum C3Nef, and in more than 50% of patients C3Nef persists throughout the clinical course.[30] However, C3Nef is not a specific serologic marker (see earlier). C3Nef can be identified in 40% to 60% of cases of C3GN.[3,8] However, methods for measuring C3Nef and the other nephritic factors are not standardized.

Box 23.2 shows a list of investigations that may be helpful in C3 glomerulopathy.[31,32] It is recommended that investigations in the

BOX 23.2 Serologic and Genetic Evaluation of C3 Glomerulopathy

Tests Recommended in All Patients With C3 Glomerulopathy

- Measurement of serum levels of C3 and C4
- Measurement of C3 nephritic factor
- CH50—classic pathway hemolytic assay, and AH50—alternative pathway hemolytic assay
- Measurement of factor H and factor I
- Serum paraprotein detection
- Testing for the genetic mutation of CFHR5 nephropathy
- Anti–factor H autoantibodies

Tests That Should Be Considered on a Case-by-Case Basis

- Measurement of serum factor B and C5
- Measurement of markers of C3 and C5 activation (e.g., C3d, Bb, soluble C5b9)
- Detection of autoantibodies to factor B
- Mutation testing of complement regulatory genes (e.g., CFH, CFI, CD46), activation protein genes *(C3, CFB),* and assessment of copy number variation across the *CFH-CFHR* locus

second category be discussed with experts and performed in laboratories with experience in complement assays. Complement laboratories in Europe are listed on the European Complement Network website (www.ecomplement.org). Parameter selection should consider the clinical scenario. For example, in patients with C3 glomerulopathy and low serum C3 levels in the absence of C3Nef, it is important to test for anti-CFH autoantibodies. In familial cases of C3 glomerulopathy, a search for genetic mutations may be important. It is important to test for a circulating paraprotein in adult patients. C3 glomerulopathy patients who have a detectable paraprotein in the absence of an underlying malignancy are classified as having a monoclonal gammopathy of renal significance (MGRS).[33]

Pathology

The defining feature of C3 glomerulopathy is the presence of C3 (usually detected with an antibody to C3c) in glomeruli by immunohistology (Fig. 23.6). In most cases, C3 is seen on capillary walls and in the mesangium. In some cases, particularly in DDD, C3 also may be found on Bowman's capsule or on tubular basement membranes.

The light microscopic appearances are quite variable. In both DDD and C3GN, membranoproliferative changes are common with increased glomerular lobulation, an increase in mesangial matrix and cells, and capillary wall thickening with double contour formation (Fig. 23.7). In patients with C3GN, 71% showed an MPGN pattern.[3] Other cases may exhibit a mesangial proliferative pattern or endocapillary hypercellularity, in part as a result of influx of macrophages or neutrophils. Sometimes this endocapillary hypercellularity may affect almost all the glomeruli, giving an appearance of diffuse endocapillary proliferative glomerulonephritis similar to that typically seen with postinfectious glomerulonephritis (PIGN). Crescent formation may be sufficiently prominent to merit the designation of crescentic glomerulonephritis (>50% crescents). In DDD, the distribution of different histologic patterns was membranoproliferative (25%), mesangial proliferative (45%), crescentic (18%), and acute proliferative and exudative (12%).[34]

The EM appearances of C3 glomerulopathy are also variable, but in many cases the diagnosis of C3 glomerulopathy can be suspected from the EM changes. By definition, DDD shows the presence of osmiophilic dense transformation of the GBM (see Fig. 23.2), with similar features often seen in Bowman's capsule and tubular basement membranes. These changes may be segmental within glomeruli, in some cases making it difficult to define DDD with certainty. In DDD, there are typically large electron densities in the mesangium.

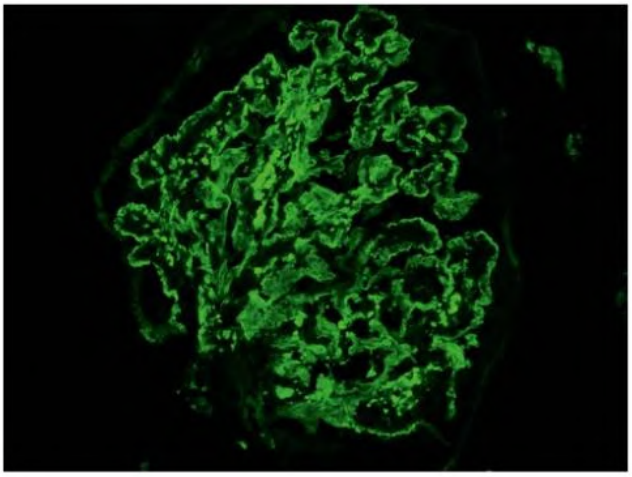

Fig. 23.6 Immunofluorescence for C3c in a case of dense deposit disease. There is widespread staining of capillary walls and focal granular mesangial staining.

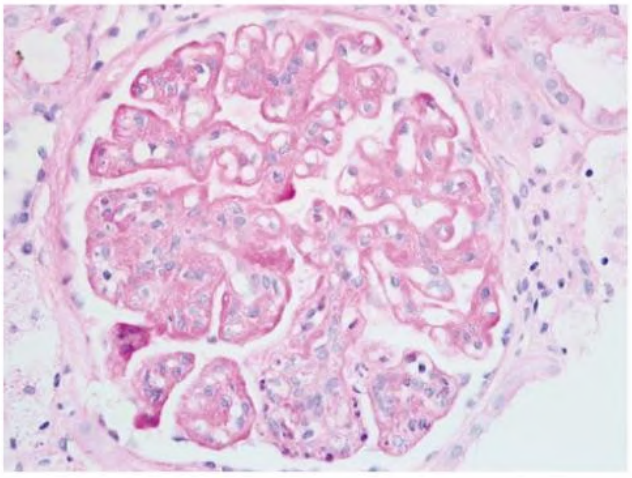

Fig. 23.7 C3 Glomerulonephritis. Light microscopy in a case of C3 glomerulonephritis. The glomerulus shows a membranoproliferative pattern of injury, with increased mesangium, capillary wall thickening, and segmental endocapillary hypercellularity (PAS stain).

In some cases of C3GN, electron-dense material expands the GBM, similar to the changes in DDD but without such marked electron density; the distinction between these cases and DDD may not be clear cut and are subjective (see Fig. 23.3).[35] Other cases have more distinct subendothelial and mesangial electron-dense deposits reminiscent of those seen in immune complex MPGN. Some cases show a complex pattern of intramembranous deposits that was previously designated as a form of MPGN type III (see Fig. 23.3).

In both DDD and C3GN, subepithelial hump-shaped deposits, identical to those characteristically seen in PIGN, occur. Their significance is unclear, although they may be more common in infectious exacerbations of the disease.

In one study the presence of crescents was associated with adverse kidney outcomes.[16] In that study, activity and chronicity scores (analogous to those used in lupus nephritis) also correlated with kidney disease progression.

Differential Diagnosis

The diagnosis of C3 glomerulopathy is relatively straightforward if there is isolated C3 deposition with typical deposits on EM. However, some patients have otherwise typical appearances of DDD or C3GN but also have small amounts of immunoglobulin in glomeruli, which presents a diagnostic challenge. The criterion with the best balance of sensitivity and specificity is the presence of dominant C3 staining with the intensity of C3 staining at least two orders of magnitude greater than any other immunoreactant (i.e., immunoglobulin [Ig] G, IgM, IgA, and C1q).[31,36] This is referred to as glomerulonephritis with dominant C3 (see Box 23.1). Cleavage of C3c generates the C3d fragment, which remains bound within the glomerulus. Antibodies that detect C3d may be useful for diagnosing C3 glomerulopathy in biopsies where C3c deposits appear faint.[37] In some cases, the initial kidney biopsy may not show C3-dominant GN, but it may appear in subsequent biopsies,[36,38,39] suggesting that repeat biopsy may be useful in cases with an atypical clinical course.

Some patients with monoclonal gammopathies have glomerular immunoglobulin deposits that are not detected by standard immunofluorescence and only after tissue digestion with pronase.[40,41] It is recommended that screening for monoclonal gammopathy be performed in all patients presenting with C3G.

Another problem is the distinction of C3 glomerulopathy from PIGN. PIGN may show markedly reduced serum C3, and glomeruli may stain for C3 without immunoglobulin. In some cases, the distinction from C3 glomerulonephritis may be possible only by following the patient for resolution of clinical glomerulonephritis.[31] It has been suggested that PIGN could be considered a self-limiting form of C3 glomerulopathy. Some patients who have been diagnosed with atypical PIGN have C3 glomerulopathy.[42] Cryoglobulinemia also should be considered in the differential diagnosis because cases may present with prominent C3 with only sparse IgG staining. Anti–Factor B autoantibodies are transiently detectable in a high proportion of children with acute PIGN.[43] If validated, this may represent a means of distinguishing PIGN from C3G at presentation.

Treatment

The optimal treatment for C3 glomerulopathy remains undefined. In addition, in many studies DDD was grouped with forms of MPGN, which makes it difficult to make specific statements about DDD. Treatments that have been tried include renin angiotensin system blockade, corticosteroids and other immunosuppressants, anticoagulants, and plasma exchange.[44] Several case series have found that mycophenolate mofetil (MMF) may be effective in C3 glomerulonephritis.[45,46] Nephritic factors are a form of autoantibody, and patients with nephritic factors may be more likely to respond to treatment with immunosuppression than patients with genetic causes of complement dysregulation. Nevertheless, some patients with complement gene mutations still respond to treatment, and there are not yet any lab tests that can be used to select or exclude patients for treatment. A Kidney Disease: Improving Global Outcomes (KDIGO) controversies conference[31] recommended that all patients should receive optimal blood pressure control and patients with moderate disease—defined as urine protein greater than 500 mg/24 h despite supportive therapy, moderate inflammation on kidney biopsy, or recent rise in creatinine—should receive prednisone or MMF. In severe disease with proteinuria more than 2 g/24 h, severe disease on biopsy, or progressive creatinine increase, the KDIGO conference suggested the use of methylprednisolone pulse dosing and other immunosuppressants.[31]

In many cases of C3 glomerulopathy, the deposition of C3 in glomeruli leads to subsequent activation of C5, and there are a number of case series reporting on use of the anti-C5 antibody eculizumab to treat C3 glomerulopathy.[47,48] Some, but not all, patients have shown clinical improvement, and in some there was reduction of glomerular inflammation on repeat biopsy. Patients with rapidly progressive disease and glomerular crescents may be more likely to respond to treatment.[49] In the patients who underwent repeat biopsy, IgG-κ was found, consistent with binding of the monoclonal eculizumab to C5 in glomeruli.[50] However, the KDIGO conference concluded, "Data are insufficient to recommend eculizumab as a first-line agent for the treatment of rapidly progressive disease."[31] Rational treatment of C3 glomerulopathy would involve inhibition of C3 activation, and a number of drugs are in clinical trials that may achieve that and allow more targeted therapy in the future.

In patients with an underlying monoclonal gammopathy, treatment of the hematologic process with B-cell or plasma cell–directed therapies can lead to improvement of the kidney disease.[51] Transplantation is a reasonable option for patients who progress to ESKD, particularly because so many of these patients are children. Disease recurrence is seen in the majority of patients, however, and recurrence of C3 glomerulopathy after transplantation is higher than recurrence of other causes of primary glomerulonephritis (see Chapter 113).[52,53]

SELF-ASSESSMENT QUESTIONS

1. Which of the following are *not* features of C3 glomerulopathy?
   - **A.** Subendothelial electron-dense deposits
   - **B.** Full house of immunoglobulins and complement on immunofluorescence
   - **C.** Subepithelial electron-dense humps
   - **D.** Mesangial C3 on immunofluorescence
   - **E.** Glomerular crescents
2. Which of the following *best* describes C3 nephritic factor?
   - **A.** A paraprotein
   - **B.** An autoantibody against ADAMTS13
   - **C.** An autoantibody against complement factor H
   - **D.** An abnormal factor H-related protein
   - **E.** An autoantibody against the alternative pathway C3 convertase
3. Which of the following *best* describes CFHR5 nephropathy?
   - **A.** C3 glomerulopathy associated with C3 nephritic factor
   - **B.** C3 glomerulopathy associated with complete absence of CFHR5
   - **C.** C3 glomerulopathy associated with intramembranous electron-dense deposits
   - **D.** C3 glomerulopathy associated with heterozygous mutation of *CFHR5*
   - **E.** C3 glomerulopathy associated with autoantibodies against CFHR5
4. Which of the following is an evidence-based therapy for C3 glomerulopathy?
   - **A.** CFHR5 replacement
   - **B.** Alternate-day glucocorticoid treatment
   - **C.** Anti-C5 antibody therapy (eculizumab)
   - **D.** Ponticelli regimen
   - **E.** None of the above

Immunoglobulin A Nephropathy and Immunoglobulin A Vasculitis (Henoch-Schönlein Purpura)

Jürgen Floege, Jonathan Barratt, Hong Zhang

IgA NEPHROPATHY

Definition

Immunoglobulin A (IgA) nephropathy (IgAN) is a mesangial proliferative glomerulonephritis (GN) characterized by diffuse mesangial deposition of IgA. IgAN was first recognized in 1968 by Jean Berger when immunofluorescence (IF) techniques were introduced for the study of kidney biopsy specimens. IgAN is unique among glomerular diseases in being defined by the presence of an immune reactant rather than by any other morphologic feature on kidney biopsy, and the light microscopy changes are variable. IgAN is the most prevalent pattern of glomerular disease seen in most Western and Asian countries where kidney biopsy is widely practiced. It is likely that IgAN is not a single entity but rather a common response to various injurious mechanisms.

Etiology and Pathogenesis

Although there has been much recent progress in understanding the pathogenesis of IgAN, it is not certain that all subjects with IgAN share a single common process leading to mesangial IgA deposition. Fig. 24.1 summarizes some key elements involved in the pathogenesis of IgAN.[1]

IgA Immune System

IgA is the most abundant immunoglobulin in the body and is chiefly concerned with mucosal defense.[2] It has two subclasses, IgA1 and IgA2. Mucosal antigen challenge provokes *polymeric* IgA (pIgA) production by plasma cells of the mucosa-associated lymphoid tissue (MALT); the pIgA is then transported across epithelium into mucosal fluids, where it is released after coupling to secretory component as *secretory* IgA (sIgA). The function of circulating IgA is less clear; it is derived from bone marrow and mostly is *monomeric* IgA1 (mIgA1). Circulating IgA1 is cleared by the liver through hepatocyte asialoglycoprotein receptors and Kupffer cell Fcα receptors.

The regular recurrence of IgAN after kidney transplantation in patients with prior underlying IgAN implies an abnormality in the host IgA immune system (see Chapter 113). Serum IgA levels, both mIgA and pIgA, are increased in only one-third of patients with IgAN and not useful for diagnosing IgAN. However, high serum IgA itself is not sufficient to cause IgAN. High circulating levels of monoclonal IgA in myeloma or polyclonal IgA in acquired immunodeficiency syndrome (AIDS) only infrequently provoke mesangial IgA deposition and thus in IgAN, changes to the physicochemical properties of IgA, rather than the absolute amount in the circulation, probably cause mesangial deposition and glomerular injury.

IgA Glycosylation

A striking feature of IgAN is altered glycosylation of the hinge region of IgA1. IgA1 carries distinctive *O*-linked sugars at its hinge region; IgA2 has no hinge and carries no such sugars. There is good evidence that circulating IgA1 in IgAN is enriched for IgA1 *O*-glycoforms with reduced galactosylation of the IgA1 hinge region; these glycoforms are collectively named galactose-deficient IgA1 (gd-IgA1).[1] *O*-galactosylation of IgA1 has a clear genetic basis, but it is unclear whether these same genes are linked to the development of IgAN.[3] This enrichment of gd-IgA1 in the serum is because of an excess of mucosal IgA1 entering the systemic circulation, either directly from the MALT or after translocation of mucosal lymphocytes to the bone marrow. The latter is consistent with experiments in which immortalized lymphocytes from patients with IgAN continued to produce dimeric and polymeric IgA with altered galactosylation.[4]

Mesangial IgA1 in IgAN also has increased gd-IgA1.[5,6] IgA and IgG antibodies with specificity for gd-IgA1 have been identified in IgAN, promoting formation of circulating immune complexes.[7] Mesangial IgA1 may result from deposition of these circulating IgA1 immune complexes or of altered IgA1 interactions with matrix proteins and mesangial cell or monocyte Fc receptors. There also may be impaired clearance of gd-IgA1 through inhibition of its interactions with hepatic and circulating myeloid cell IgA receptors.

Increased serum gd-IgA1 is also found in the unaffected relatives of subjects with IgAN, suggesting that gd-IgA1 is necessary but not sufficient for the development of IgAN, which requires a "second hit," such as an event that provokes induction of autoimmunity or an encounter with microbial pathogens that triggers a humoral immune response, resulting in IgA cross-reactive antibodies.

Origin of Mesangial IgA

Evidence supporting the importance of mucosal-derived IgA as a major source of mesangial IgA in IgAN includes the close association between mucosal inflammation and episodes of nephritis. In addition, mesangial IgA in IgAN is predominantly pIgA1. IgAN patients exhibit elevated serum levels of sIgA and levels of IgA antibodies specific for food antigens, mucosal vaccines, and gut-associated bacteria. Mucosal hyperresponsiveness to a variety of food antigens has been noted in patients with IgAN.[1,2] Furthermore, the composition of the gut microbiome appears different in IgAN, and gut bacteria are capable of modulating IgA class switching, the amount of mucosal IgA production, and IgA1 *O*-galactosylation in the MALT. Genome-wide association studies have identified a number of risk alleles that are either directly associated with risk of inflammatory bowel disease, maintenance of the intestinal epithelial barrier, or response to mucosal pathogens and which converge on the intestinal immune network for IgA production.[8,9]

Role of Infection

The clinical association of visible hematuria with upper respiratory tract infection in IgAN indicates the mucosa may be a site of entry

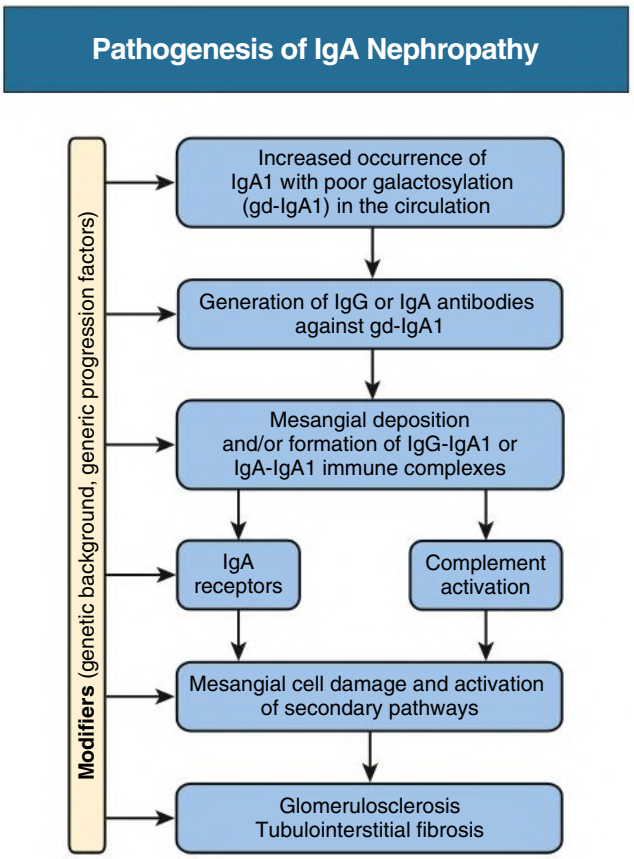

Fig. 24.1 Pathogenesis of Immunoglobulin A (IgA) Nephropathy. Proposed mechanisms leading to mesangial deposition of abnormally glycosylated IgA1 and mesangial injury. (Modified from Floege J. The pathogenesis of IgA nephropathy: what is new and how does it change therapeutic approaches? *Am J Kidney Dis.* 2011;58:992–1004.)

for foreign antigens or alternatively may be a site for nonspecific activation of the innate immune system that enhances kidney injury. There have been occasional reports of IgAN in association with infection, both bacterial (e.g., *Campylobacter, Yersinia, Mycoplasma, Haemophilus*) and viral (e.g., cytomegalovirus, adenovirus, coxsackievirus, Epstein-Barr virus). A severe form of IgAN has been reported in association with staphylococcal infection (see Chapter 57). However, no organism has been consistently implicated in typical cases of IgAN. It is likely that exposure to a variety of microbial pathogens can result in the development of IgA cross-reactive antibodies, which, in subjects with a propensity for high serum gd-IgA1 levels, results in IgA immune complex formation and mesangial IgA deposition.

Glomerular Injury After IgA Deposition

Polymeric IgA deposition in the mesangium is typically followed by mesangial proliferative GN. Co-deposition of IgG and complement are not necessary for development of GN, but when present have been associated with greater glomerular injury. Complement deposits are usually C3 without C1q. Complement activation occurs via both the mannose-binding lectin pathway and alternative pathway.

Once deposited, pIgA binds to and activates mesangial cells, leading to a cascade of molecular events that result in the histopathologic features making up the MEST-C classification (see later).[10] Importantly, each of these features independently associates with progressive disease. In brief, mesangial cell IgA binding triggers the release of proinflammatory and chemotactic mediators, which act locally in the glomerulus, leading to mesangial cell proliferation (M) and recruitment of inflammatory cells into the glomerulus (E), occasionally resulting in crescent formation (C). These mediators also cross the glomerular basement membrane (GBM) and directly influence podocyte function, altering podocyte gene expression and glomerular permeability, increasing filtration of pIgA, podocyte damage (glomerular cell crosstalk), and segmental glomerulosclerosis (S).[11] In addition to effects within the glomerulus, glomerular-derived cytokines, along with filtered pIgA, are capable of activating tubular epithelial cells (glomerulotubular crosstalk), driving tubulointerstitial inflammation and fibrosis (T) via generic biochemical pathways (see Chapter 81).

Animal Models of IgA Nephropathy

Animal IgA does not have the same characteristics as human IgA1, and some animals also have IgA clearance mechanisms distinct from those in humans. Therefore, animal models, even if they provoke mesangial IgA deposits, are not particularly informative about the mechanisms that underlie human mesangial pIgA1 deposition, although they have provided many insights into events after IgA deposits have developed.

Genetic Basis of IgA Nephropathy

Urine abnormalities increase in frequency among the relatives of patients with IgAN, although IgAN is rarely found in multiple generations of the same pedigree. More than 90% of all cases of IgAN appear to be sporadic.

Large worldwide genome-wide association studies have identified genetic modulators that seem to affect the prevalence of sporadic IgAN and modulate its course.[8,9] Variations in major histocompatibility gene loci (HLA-DR, -DQ, -DP, and HLA-B) have consistently been identified. Other gene loci are less consistent and include inflammatory mediators (tumor necrosis factor and α-defensin), gene loci affecting complement factor H, innate immunity, IgA-regulating cytokines, and mucosal integrity.[8,9]

Other Modulators of the Course of IgA Nephropathy

Many cases of IgAN never come to medical attention, and among those in whom the diagnosis is obtained by kidney biopsy, only a minority develop end-stage kidney disease (ESKD). Thus, in addition to genetic factors, there must be potent further modulators of the course of IgAN, such as essential hypertension, obesity, or smoking (see Fig. 24.1; see also Natural History).

Epidemiology

IgA nephropathy is typically the most prevalent pattern of glomerular disease in countries where kidney biopsy is widely available. The incidence rate has been estimated at 2 to 10 per 100,000 person-years. The prevalence of IgAN is higher in Asian populations (45 cases per million population/year in Japan) than in Whites (31 cases per million population/year in France).[12,13] The geographic variation has been associated with the presence of particular gene alleles that protect from IgAN[8,9] (Fig. 24.2). This racial predisposition is maintained in other locations; in the United States, IgAN is less common in Blacks than in Whites of European origin. Perceived prevalence of IgAN also may be influenced by attitudes to the investigation of microhematuria. A country with an active program of routine urine testing will inevitably identify more individuals with urine abnormalities, but IgAN will be identified only if kidney biopsy is performed. Even then, the prevalence of IgAN will be underestimated; a study of kidney donors suggests that the prevalence of IgAN with mesangial proliferative changes and glomerular C3 deposits in the general population in Japan may be 1.6%.[14] This suggests that the vast majority of patients with IgAN never come to medical attention and spontaneously remit.

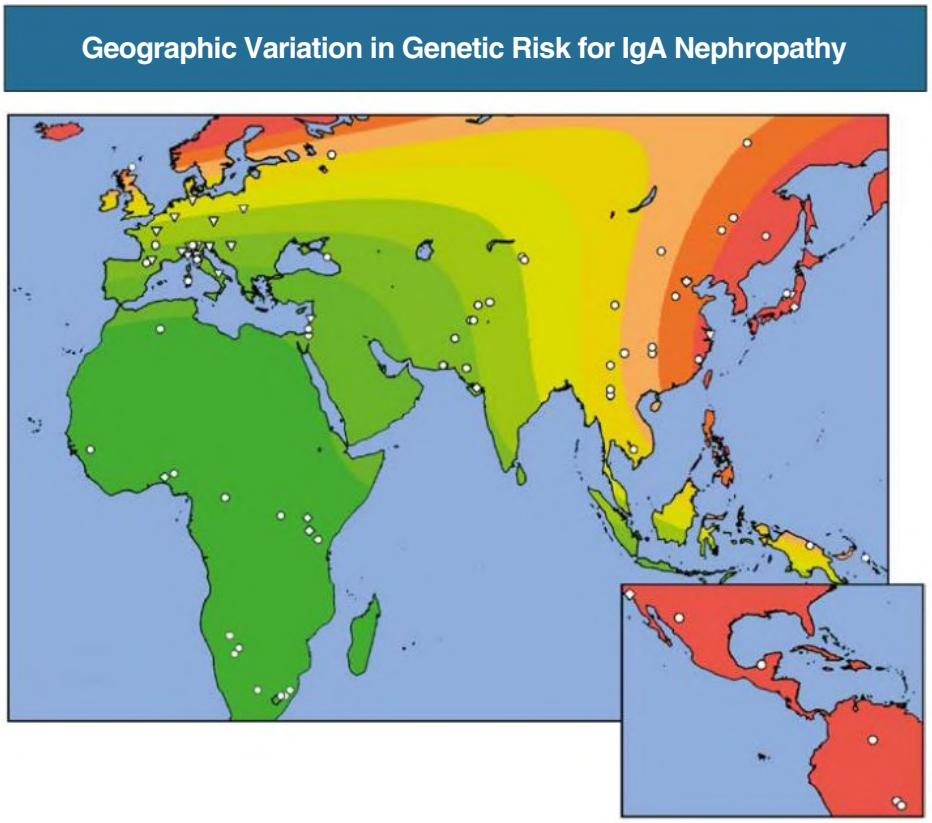

Fig. 24.2 Geographic Variation in Genetic Risk for Immunoglobulin A (IgA) Nephropathy. Genome-wide association studies indicate a geographic gradient of risk from *green* (low risk) to *red* (high risk). (From Kiryluk K, Li Y, Sanna-Cherchi S, et al. Geographic differences in genetic susceptibility to IgA nephropathy: GWAS replication study and geospatial risk analysis. *PLoS Genet.* 2012;8:e1002765.)

Clinical Manifestations

IgA Nephropathy

The wide range of clinical presentations of IgAN varies in frequency with age (Fig. 24.3). No clinical pattern is pathognomonic of IgAN. In populations of White descent, IgAN is more common in males than females by a ratio of 2:1 or 3:1, whereas the ratio approaches 1:1 in most Asian populations.

Macroscopic Hematuria

In 40% to 50% of patients with IgAN, the clinical presentation is episodic macroscopic hematuria, most frequently in the second decade of life. The urine is usually brown rather than red, and clots are unusual. There may be loin pain caused by kidney capsular swelling. Hematuria usually follows intercurrent mucosal infection, typically in the upper respiratory tract (the term *synpharyngitic hematuria* has been used) or occasionally in the gastrointestinal (GI) tract. Hematuria is usually visible within 24 hours of the onset of the symptoms of infection, differentiating it from the 2- to 3-week delay between infection and subsequent hematuria in postinfectious (e.g., poststreptococcal) GN. The macroscopic hematuria resolves spontaneously over a few days. Microscopic hematuria persists between attacks. Most patients have only a few episodes of frank hematuria, which become less frequent and resolve over a few years or sooner. Such episodes may be associated with acute kidney injury (AKI) characterized by tubular injury that is usually reversible.

Asymptomatic Hematuria and Proteinuria

As many as 30% to 40% of cases of IgAN are identified by detection of microhematuria with or without albuminuria (usually <2 g/24 hours)

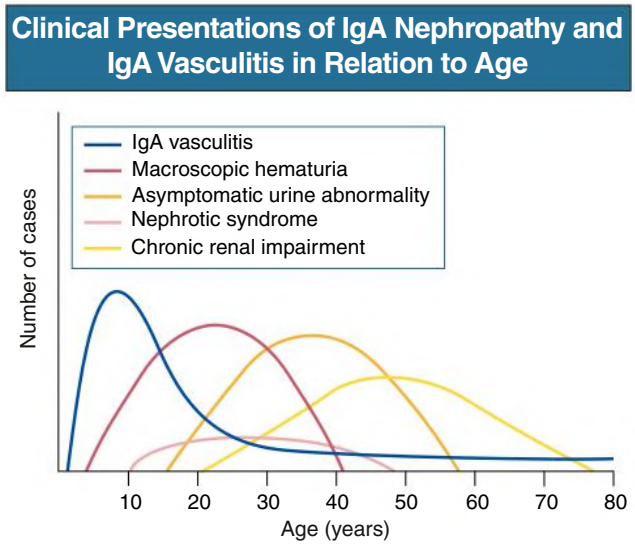

Fig. 24.3 Age in Clinical Presentation of Immunoglobulin A Nephropathy (IgAN) and IgA Vasculitis (IgAV). IgAV is most common in childhood but may occur at any age. Macrohematuria is very uncommon after age 40 years. The importance of asymptomatic urine abnormality as the presentation of IgAN will depend on attitudes to routine urine testing and renal biopsy. It is unclear whether patients presenting late with chronic renal impairment have a disease distinct from that of those presenting younger with macrohematuria. (Data from patients presenting in Leicester, UK, 1980–1995.)

TABLE 24.1 Diseases Reported in Association With IgA Nephropathy

Disease Group	Common	Reported	Rare
Rheumatic and autoimmune disease	Ankylosing spondylitis Rheumatoid arthritis Reiter syndrome Uveitis	Behçet syndrome,[a] Takayasu arteritis,[b] myasthenia gravis	Sicca syndrome
Gastrointestinal disease	Celiac disease	Ulcerative colitis	Crohn disease Whipple disease
Hepatic disease	Alcoholic liver disease Nonalcoholic cirrhosis Schistosomal liver disease		
Lung disease	Sarcoid		Pulmonary hemosiderosis
Skin disease	Dermatitis herpetiformis		
Malignancy		IgA monoclonal gammopathy	Bronchial carcinoma, renal carcinoma, laryngeal carcinoma, mycosis fungoides, Sézary syndrome
Infection	HIV, hepatitis B (in endemic areas)	Brucellosis	Leprosy
Miscellaneous		Wiskott-Aldrich syndrome[c]	

Rare associations have been made in one or two reported cases only. In a disease as common as IgA nephropathy, it is therefore uncertain whether these are truly related.

[a]Behçet syndrome: systemic vasculitis typified by orogenital ulceration and chronic uveitis.

[b]Takayasu arteritis: systemic vasculitis involving the aorta and its major branches, most often found in young women.

[c]Wiskott-Aldrich syndrome: X-linked disorder in which increased serum IgA is associated with the triad of recurrent pyogenic infection, eczema, and thrombocytopenia.

HIV, Human immunodeficiency virus; *IgA,* immunoglobulin A.

during routine urine testing among asymptomatic individuals. The number of patients identified in this way will depend on local attitudes to urine testing and on the use of kidney biopsy in patients with isolated microscopic hematuria. Most patients with IgAN are asymptomatic and would be identified only when the urine is tested. If such patients with very early or mild IgAN are identified by kidney biopsy, their 20-year prognosis for kidney survival is very good, but 5% will progress to chronic kidney disease (CKD) stages IV to V,[15] stressing the need for very long-term follow-up.

Proteinuria and Nephrotic Syndrome

It is rare for proteinuria to occur without microscopic hematuria. Although nephrotic-range proteinuria may occur, in particular in the presence of uncontrolled hypertension or marked obesity, full-blown nephrotic syndrome is uncommon, occurring in only 5% of all patients with IgAN. Nephrotic syndrome may occur early in the course of the disease, with minimal glomerular change (in such cases, IgAN may coexist with minimal change disease [MCD]) or with active mesangial proliferative GN. Alternatively, it may occur as a late manifestation of advanced chronic glomerular scarring.

Acute Kidney Injury

Although AKI is uncommon in IgAN (<5% of all cases), one study reports that it may be the manifestation in up to 40% of patients older than 65 years.[16] The proportion of patients who progressed to ESKD was significantly higher in those presenting with AKI than in patients presenting without AKI. AKI develops by three distinct mechanisms. There may be acute severe immune and inflammatory injury with necrotizing GN and crescent formation (crescentic IgAN); this may be the first presentation of IgAN, or it may be superimposed on established, less aggressive disease. Alternatively, AKI can occur with mild glomerular injury when heavy glomerular hematuria leads to tubule occlusion by red blood cells (RBCs). Third, especially in elderly patients, chronic IgAN will predispose to AKI from a variety of incidental kidney insults, including drug-induced acute tubulointerstitial nephritis (see Chapter 64).

Chronic Kidney Disease

Some patients already have kidney impairment and hypertension when they are first diagnosed with IgAN. These patients tend to be older, and they probably have longstanding disease that previously remained undiagnosed because the patient did not have frank hematuria or undergo routine urinalysis. Hypertension is common, as in other chronic glomerular disease; accelerated hypertension occurs in 5% of patients.

Clinical Associations With IgA Nephropathy

Mesangial IgA deposition, which does not necessarily equal IgAN, is a frequent finding in autopsy studies in chronic liver disease. Although particularly associated with alcoholic cirrhosis, mesangial IgA deposition can occur in other chronic liver diseases, including those caused by hepatitis B and schistosomiasis. It is thought to result from impaired clearance of IgA by the Kupffer cells, which express Fcα receptors, and hepatocytes, which express the asialoglycoprotein receptor. Secondary IgAN is described as a form of IgAN associated with other diseases (e.g., liver cirrhosis, human immunodeficiency virus [HIV], and inflammatory bowel disease). There are no established definitions or different histologic findings in secondary IgAN cases, so the basis for the term is questionable.[17] Clinical evidence of kidney disease is more common than previously appreciated, but patients rarely develop ESKD.

A number of case reports have associated IgAN with HIV infection and AIDS. It is not clear whether the polyclonal increase in serum IgA, which is a feature of AIDS, is the predisposing factor.

There are case reports associating IgAN with many other conditions, particularly with a number of immune and inflammatory diseases (Table 24.1). Their relationship to abnormalities of the IgA immune system is not always clear, and some may represent the coincidental development of unrelated but relatively common conditions. In a Swedish population-based cohort study, it was observed that patients with IgAN had an increased risk of inflammatory bowel disease both before and after their nephropathy diagnosis; the presence of inflammatory bowel disease increased the risk of progression to ESKD.[18]

Boor.)

Pathology

Immune Deposits

Diffuse mesangial IgA is the defining hallmark of IgAN (Fig. 24.4A). C3 is co-deposited in up to 90% of cases. IgG in 40% and IgM in 40% of cases also may be found in the same distribution. IgA also may deposit along capillary loops, a pattern more common in IgA vasculitis (IgAV); in IgAN, this pattern is associated with a worse prognosis. Mesangial deposits of terminal pathway complement complex C5b-9 are commonly observed in IgAN. Evidence of classical pathway activation, such as C1q deposits, is usually lacking in kidney biopsy specimens of patients with IgAN. Properdin co-deposits with IgA and C3 in 75% to 100% of patients and factor H in 30% to 90% of patients, indicating alternative complement pathway activation. MBL co-deposits with IgA in 17% to 25% of IgAN biopsies, and glomerular and arteriolar C4d as an indicator of the lectin pathway activation has been associated with more severe kidney damage.[19] Disappearance of IgA deposits after prolonged clinical remission has been documented in both children and adults. About one-third of the patients also have deposits of sIgA in the mesangium and are characterized by more severe disease.[20]

Light Microscopy

Light microscopy changes are remarkably variable and do not correlate topographically with the IgA deposits. There can be almost normal glomerular architecture, mesangial hypercellularity that may be diffuse (see Fig. 24.4B) or segmental, or, in rare cases, focal segmental necrotizing GN with extracapillary proliferation. Typical cases are characterized by an increase in mesangial cells and mesangial matrix with normal-appearing capillary loops, although endocapillary hypercellularity can occur (see Fig. 24.4C). Focal segmental or global glomerular sclerosis indicates that the disease has been ongoing for some time (see Fig. 24.4D). In addition to glomerular changes, the preglomerular arterial vessels often exhibit wall hyalinosis and subintimal fibrosis even in patients with only mild arterial hypertension. In longstanding disease, tubulointerstitial inflammation leads to interstitial fibrosis and tubular atrophy in a pattern no different from that of other progressive glomerular diseases. On occasion, IgAN and minimal change nephrotic syndrome coincide (see Differential Diagnosis), in which case light microscopy is normal but there are mesangial IgA deposits.

Morphology helps to predict prognosis in patients with slowly progressive disease. The Oxford (MEST-C) classification of IgAN is now widely accepted.[10] This classification identifies five features of prognostic value and can be easily scored on light microscopy: mesangial hypercellularity (M1 when present, M0 when absent), endocapillary hypercellularity (E1), segmental sclerosis (S1), three degrees of tubular atrophy and interstitial fibrosis (T0, T1, T2), and three degrees of cellular and/or fibrocellular crescents (C0, C1, C2). Examples of these glomerular features are shown in Fig. 24.4.

Histologic patterns of injury in AKI include tubular occlusion by RBCs with acute tubular epithelial injury in AKI associated with macroscopic hematuria (Fig. 24.5) or necrotizing GN and cellular crescent formation. Such crescentic IgAN may develop on a histologic background of established chronic kidney injury caused by IgAN or may be the first presentation of IgAN. Small numbers of crescents may be seen in hypertensive patients with stable kidney function and no other pathologic evidence of severe glomerular inflammation; the term *crescentic IgAN* should not be used for such patients, in whom the prognosis is often favorable.

Electron Microscopy

Electron-dense deposits correspond to the mesangial (or capillary loop) IgA (see Fig. 24.4E). Typically, electron-dense deposits are confined to mesangial and paramesangial areas, although subepithelial and subendothelial deposits also can be seen. Up to one-third of patients will have some focal thinning of the GBM. On occasion, there

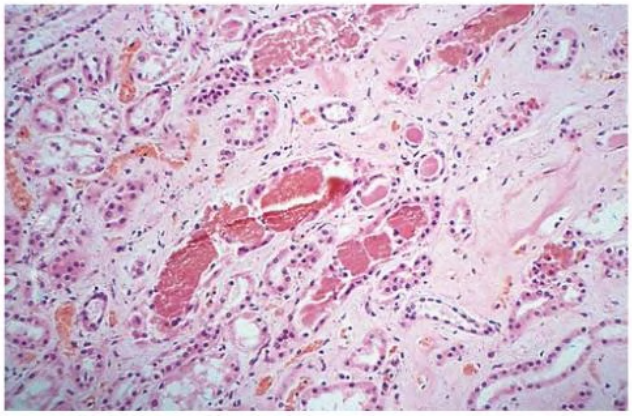

Fig. 24.5 Acute Kidney Injury in Immunoglobulin A Nephropathy. Tubular occlusion by red blood cells. This appearance may be associated with only minor glomerular changes. (H&E, ×300.)

will be extensive GBM thinning, suggesting a coincident diagnosis of thin basement membrane nephropathy (see Chapter 48).

Differential Diagnosis

The diagnosis of IgAN or IgAV nephritis requires identification of mesangial IgA in the glomeruli. Therefore, it cannot be made without a kidney biopsy, no matter how suggestive the clinical presentation. Serum IgA is often increased, and there may be IgA in cutaneous blood vessels in IgAN and in both affected and unaffected skin in IgAV. Neither finding, however, is reliable enough to support the diagnosis without a kidney biopsy. Serum complement components are normal in most patients.

Mesangial IgA occurs in other conditions and can usually be differentiated by clinical, serologic, and histologic criteria (Box 24.1). The light microscopic features alone are not diagnostic of IgAN.

An important differential diagnosis is IgA-dominant acute postinfectious GN (APIGN), in which IgA is the dominant immunoglobulin in glomerular deposits (see Chapter 57). It usually occurs in association with staphylococcal infections. Diabetes is a key risk factor. Compared with IgAN, patients with IgA-dominant APIGN are more likely to be older and have AKI, documented staphylococcal infection, hypocomplementemia, diffuse glomerular endocapillary hypercellularity with prominent neutrophil infiltration on light microscopy, stronger IF staining for C3 than IgA, and the presence of subepithelial humps on electron microscopy (EM).[21] This entity has a poor prognosis.

Hematuria

Nonglomerular causes of hematuria, particularly stones and neoplasia, must be excluded by appropriate investigations (see Chapter 63). In its most characteristic clinical setting—recurrent macroscopic hematuria coinciding with mucosal infection in a man in the second or third decade of life—the diagnosis can be strongly suspected. Such a diagnosis, however, cannot be made without a biopsy because recurrent macroscopic hematuria also occurs in other glomerular diseases (e.g., Alport syndrome and membranoproliferative GN), particularly in children and young adults. In young adults, thin basement membrane nephropathy is the most important differential diagnosis for isolated microhematuria.

Nephrotic Syndrome

Patients with IgAN occasionally develop nephrotic syndrome, which is indistinguishable from that in MCD. There is a sudden onset of nephrosis, with biopsy evidence of glomerular epithelial cell foot process effacement and a prompt complete remission of proteinuria in response to corticosteroids. Only hematuria and mesangial IgA deposits persist after treatment. This pattern occurs particularly in children. These patients are usually regarded as having two separate common glomerular diseases: IgAN and MCD.

Other patients with IgAN may develop nephrotic syndrome with more structural glomerular damage and lack the response to corticosteroids. The clinical differential diagnosis includes common causes of nephrotic syndrome appropriate for the age of the patient (see Chapter 16).

Chronic Kidney Disease: Hypertension, Proteinuria, Kidney Impairment

In this context, IgAN is clinically indistinguishable from many forms of CKD. The kidney biopsy may be diagnostic by identifying mesangial IgA, even when structural damage is so advanced on light microscopy that it has the nonspecific features of ESKD.

Acute Kidney Injury

When AKI occurs in a patient known to have IgAN, kidney biopsy should be performed unless there is rapid improvement in kidney function, after at least 5 days from the onset of kidney function worsening, in response to supportive care and vigorous hydration. Kidney biopsy may be required to differentiate the tubular occlusion and acute tubular necrosis that occasionally follow heavy glomerular hematuria from crescentic IgAN or other coincidental causes of AKI (see Fig. 24.5).

BOX 24.1 Differential Diagnosis of Immunoglobulin A (IgA) Nephropathy: Conditions Associated With Mesangial IgA Deposition

- IgA nephropathy
- IgA vasculitis
- Lupus nephritis[a]
- Alcoholic liver disease
- IgA monoclonal gammopathy
- Schistosomal nephropathy
- IgA-dominant *Staphylococcus*-associated glomerulonephritis (more common in diabetics)

[a] Distinguishing lupus nephritis (especially International Society of Nephrology/Renal Pathology Society classes II and III) may cause difficulty. The finding of C1q deposition is useful. It indicates classical pathway involvement found in lupus nephritis but not in IgAN.

Natural History

IgA Nephropathy

The overall prognosis of IgAN differs based on the clinical presentation. If diagnosed very early, only about 5% will develop CKD stages 4 to 5 after 20 years.[15] In the more typical clinical presentation, where many patients already exhibit some degree of GFR decline, at 20 years later one-fourth of patients will have ESKD and a further 20% will have progressive impairment of kidney function.[22,23] A Swedish study suggested that patients with IgAN died 6 years earlier than people without the disease; most deaths were from cardiovascular causes.[24]

Although active investigation of microhematuria will increase the size of the cohort of patients found to have IgAN, it will include more with a good prognosis,[15] thus altering the perceived risk for disease progression. Episodes of macrohematuria do not confer a worse prognosis. This may indicate that such episodes occur only early in the natural history of the disease and patients doing less well from the point of diagnosis in fact were identified at a later stage in their disease. This is also suggested by the adverse prognosis associated with older age at diagnosis.

The risk for ESKD is not uniform. As in any chronic glomerular disease, hypertension, proteinuria, and reduced glomerular filtration rate

BOX 24.2 Prognostic Markers Used to Calculate the Risk of Progressive GFR Loss in Immunoglobulin A Nephropathy

(GFR) at presentation, as well as histologic evidence of glomerular and interstitial fibrosis, are all associated with worse prognosis (Box 24.2). Hyperuricemia, smoking, and increased body mass index are also independent risk factors for progression. However, during follow-up, only hypertension and proteinuria, in particular time-averaged proteinuria, are reliable predictors of risk for progression. Risk for progression is low when proteinuria remains below approximately 0.2 g per 24 hours with normal blood pressure.[15,22,23,25,26] Another risk predictor for kidney disease progression is persistent hematuria, whereas hematuria remission was associated with improved kidney outcomes in IgAN among patients with persistent proteinuria.[27]

If a kidney biopsy documents IgAN in patients with mild disease (i.e., those manifesting with isolated microhematuria, little or no proteinuria, normotension, and normal GFR), the 7- to 10-year prognosis is mostly good.[15,25,26] However, up to 40% of patients will develop increasing proteinuria and up to 5% will lose GFR over this period, implying the need for regular follow-up in such patients. Large studies with long-term follow-up indicate a slow attrition.

Pathologic findings and clinical findings together inform prognosis.[28] The MEST-C classification of IgAN identified mesangial hypercellularity, endocapillary proliferation, segmental sclerosis, tubular atrophy and interstitial fibrosis, as well as crescents, as adding prognostic information even when adverse clinical features (proteinuria, hypertension, GFR) are known at presentation and during follow-up.[10]

The International IgAN Prediction Tool (available at www.qxmd.com) includes two validated Cox survival models that predict a 50% decline in estimated GFR (eGFR) or ESKD using clinical risk factors and Oxford MEST histology scores.[29]

Transplantation

Recurrent IgA Nephropathy

Patients with IgA nephropathy are ideal candidates for kidney transplant because they are often relatively young and with few comorbidities. Transplant registry data show that transplant outcome is not affected for the first 10 years if IgAN is the patient's primary kidney disease; thereafter, however, recurrent disease may lead to accelerated graft loss (see Chapter 113). Mesangial IgA deposits recur in the donor transplant kidney in up to 60% of patients with IgAN.[30] They may occur within days or weeks, but the risk increases with the duration of the transplant. The deposits seem benign in the short term and are not often associated initially with light microscopy changes. In pooled series, recurrent IgAN is 30% in living related transplants versus 23% in cadaveric grafts, but this does affect graft survival only beyond 10 years after transplantation.[30] Living related donation should not be discouraged. However, any urinary abnormality in a potential related donor requires thorough evaluation, including kidney biopsy if necessary. Recurrence of crescentic IgAN with rapid graft failure occurs infrequently and is generally resistant to treatment.

In a few unwitting experiments, cadaver kidneys with IgA deposits have been transplanted into recipients without IgAN. In all cases, the IgA rapidly disappeared, supporting the concept that abnormalities in IgAN lie in the IgA immune system and not in the kidney.

Treatment

Although specific early treatment intervention might influence the IgA immune system abnormalities that underlie IgAN, the mechanisms of chronic disease progression are unlikely to be unique. Therefore, studies of such patients with IgAN may provide information applicable to many forms of chronic GN for which IgAN is the paradigm.

The balance of risk to benefit for immunosuppressive therapy is often unfavorable in patients with IgAN, except in the unusual circumstance of crescentic IgAN.

Fig. 24.6 provides a treatment algorithm for IgAN that is based on the current Kidney Disease: Improving Global Outcomes (KDIGO) guidelines.[30a] The approach distinguishes among the following[31]:

- The "low-risk" patient, with minor urinary abnormalities, normal GFR, and normotension, who needs only sporadic follow-up for a prolonged period (>10 years)
- The "intermediate-risk" patient, with significant proteinuria, hypertension, and slow reduction of GFR, who particularly benefits from comprehensive supportive care

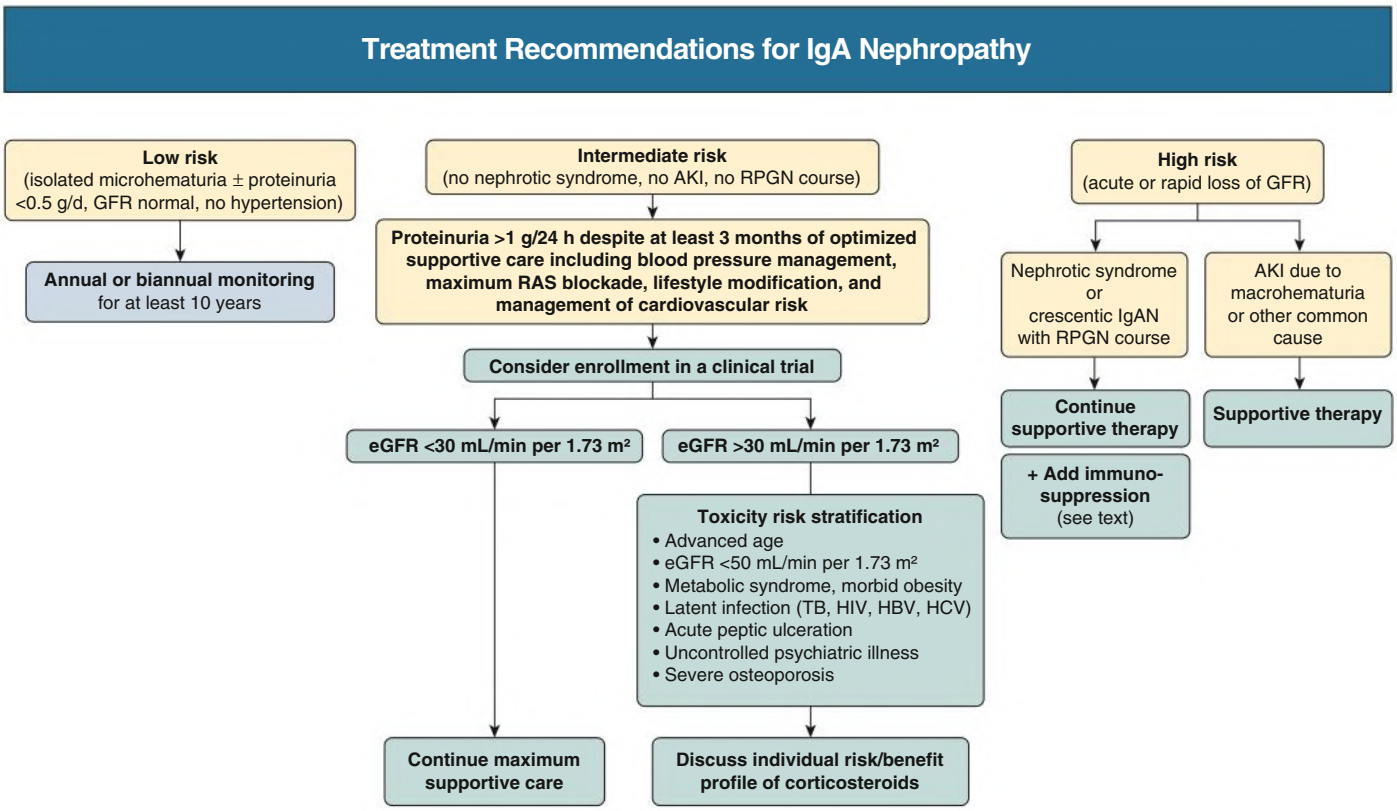

Fig. 24.6 Treatment Recommendations for Immunoglobulin A Nephropathy (IgAN). *AKI,* Acute kidney injury; *GFR,* glomerular filtration rate; *HBV,* hepatitis B virus; *HCV,* hepatitis C virus; *HIV,* human immunodeficiency virus; *RPGN,* rapidly progressive glomerulonephritis; TB, tuberculosis. (Modified from Floege J, Feehally J. Treatment of IgA nephropathy and Henoch-Schonlein nephritis. *Nat Rev Nephrol.* 2013;9:320–327.)

- The "high-risk" patient, with rapid loss of GFR, who may require more aggressive immunosuppression

Slowly Progressive IgA Nephropathy (Intermediate Prognosis)

Minimal evidence exists to suggest the events of progressive glomerular injury are unique to IgAN. Comprehensive supportive therapy following the strategies outlined in Chapter 82 therefore remains central in the therapeutic approach to patients at risk for progressive IgAN (see Fig. 24.6).

Antihypertensives and proteinuria-lowering drugs. There is compelling evidence for the benefit of lowering blood pressure (BP) in the treatment of chronic progressive glomerular disease such as IgAN. In patients with IgAN, there is also evidence that casual clinic BP readings underestimate BP load, as judged by ambulatory monitoring and echocardiographic evidence of increased left ventricular mass.[32] Two controlled trials strongly support the use of angiotensin-converting enzyme (ACE) inhibitors in patients with IgAN as first-choice hypotensive agents to lower BP.[33,34] In a randomized study of IgAN, achieving a mean BP of 129/70 mm Hg prevented the decrease in kidney function over 3 years seen in patients achieving mean BPs of 136/76 mm Hg.[35]

Observational studies indicate that the risk for progression in IgAN decreases significantly if proteinuria can be reduced to less than 1 g/day by any therapeutic maneuver.[23] Another compelling indication for the role of lowering proteinuria in IgAN is based on the superior effectiveness of ACE inhibitors over other antihypertensive agents.[33,34] There is no good evidence to recommend dual renin-angiotensin system (RAS) blockade with ACE inhibitors plus angiotensin receptor blockers over monotherapy with either agent alone.[36]

Fish oil. The favorable effects of omega-3 fatty acids in the form of fish oil include reductions in eicosanoid and cytokine production, changes in membrane fluidity and rheology, reduced platelet aggregability, and reduced proliferation of kidney cells in response to platelet-derived growth factors (PDGF). The evidence for a benefit of fish oil in IgAN is weak; the 2021 KDIGO guidelines no longer support its use.[30a] However, fish oil is safe except for a decrease in blood coagulability, which is not usually a practical problem, and an unpleasant taste, with flatulence, which may make compliance difficult. Some fish oil preparations contain significant amounts of cholesterol.

Dipyridamole and warfarin. Two randomized controlled trials (RCTs) with dipyridamole and warfarin showed mutually inconsistent results. There was no benefit in one and preserved kidney function in the other. Neither drug is currently recommended in IgAN patients.[30a]

Newer nonimmunosuppressant approaches. A major reduction in renal endpoints (40% GFR loss, dialysis, death) was observed in IgAN patients treated with dapagliflozin.[30b] It is likely that inhibition of sodium glucose transporter-2 (SGLT-2) will become standard of care after RAS-blockade has been optimized in high-risk patients with IgAN. Empagliflozin is currently being evaluated in IgAN as well (EMPA-Kidney trial). A Chinese RCT suggested that hydrochloroquine (100–400 mg/day depending on GFR) may be useful to reduce albuminuria, potentially related to the mild antiinflammatory actions of the drug.[37] Various other novel treatment approaches, including dual angiotensin plus endothelin receptor blockade (PROTECT trial), endothelin A receptor blockade on top of RAS blockade (ALIGN trial), and various approaches to complement inhibition (e.g., the narsoplimab ARTEMIS or iptacopan APPLAUSE trials) are currently in phase II to III testing.

Immunosuppressive Regimens

Corticosteroids. A meta-analysis and retrospective data suggest that corticosteroids are beneficial in IgAN, in particular in adults with proteinuria exceeding 3 g/day.[38,39] However, several trials have failed to demonstrate benefit from corticosteroids, and dosage was somewhat lower in two of the three negative trials versus the positive trials.[31] Several trials did not optimize supportive therapy, in particular RAS blockers, or required that such drugs be temporarily halted before the trial.[31]

The role of corticosteroid therapy has been investigated in two large prospective trials of oral corticosteroids in IgAN added to optimized supportive care (STOP-IgAN and TESTING). In the German STOP-IgAN trial, an extensive 6-month optimization of supportive measures abolished any subsequent short- or long-term benefit from high-dose corticosteroids in adult patients with IgAN with an average baseline GFR of 60 mL/min/1.73 m^2 and baseline proteinuria around 1.7 g/d.[40,41] The largely Southeast Asia–based TESTING trial on high-dose corticosteroids in adults with a baseline GFR of 58 mL/min and a baseline proteinuria of approximately 2 g/day was terminated early after an excess of severe, sometimes fatal infections was noted in the corticosteroid arm.[42] The trial was continued using a 50% lower corticosteroid dosage and demonstrated a considerable yet transient benefit on kidney function, but at the expense of more serious adverse events in the steroid arm.[42a] These two trials strongly emphasize the value of comprehensively optimizing supportive measures in high-risk patients with IgAN and suggest that corticosteroids may slow loss of renal function, particularly high-risk Asian IgAN patients.

Accordingly, the 2021 KDIGO guidelines suggest that corticosteroids should be initiated in high-risk patients only if proteinuria remains greater than 1 g/day after supportive care has been optimized for 3 to 6 months and only after a thorough discussion of potential adverse events with patients.[30a] At present, no evidence supports combined intravenous (IV) and oral corticosteroid therapy over a purely oral prednisolone regimen, starting with 1 mg/kg/day for 2 months, then reduced by 0.2 mg/kg/day per month or low dose at 0.4 mg/kg/day methylprednisolone with tapering over 6 months.[31,42a] KDIGO also points out that corticosteroids should be used very restrictively or be avoided in obese patients (body mass index > 30 kg/m^2) or in patients with a GFR of less than 30 to 50 mL/min/1.73 m^2, diabetes mellitus, latent infection, secondary IgAN, active peptic ulcers, or psychiatric illness.[30a]

Full-blown nephrotic syndrome may occur when MCD and IgAN coincide, in which case the nephrotic syndrome will be fully and promptly corticosteroid responsive. A trial of high-dose corticosteroid therapy analogous to that used in MCD (see Chapter 18) is therefore justified in patients with IgAN who have nephrotic syndrome associated with minimal glomerular injury.

An alternative approach to corticosteroid dosing has been evaluated. An enteric release corticosteroid (budesonide) preparation administered to patients with intermediate-risk IgAN led to a reduction in proteinuria and better preservation of kidney function in the treated patients.[43] Based on the phase III NEFIGARD trial, enteric release budesonide has now obtained a conditional approval for use in high-risk IgAN patients in some countries.

Cyclophosphamide and azathioprine. Cyclophosphamide has been used in combination with warfarin and dipyridamole in two RCTs, with inconsistent results. Both showed modest reduction in proteinuria, but only one preserved kidney function. Cyclophosphamide followed by azathioprine combined with prednisolone preserved kidney function in patients with poor prognosis, although BP control was suboptimal.[44] The same regimen, however, was ineffective in the STOP-IgAN trial and led to a death from pulmonary sepsis.[45] In another recent study, adding azathioprine to corticosteroids in patients with proteinuric IgAN with GFR greater than 50 mL/min/1.73 m^2 had no added benefit and only increased side effects.[46] Neither agent is therefore recommended by the 2021 KDIGO guidelines in patients with intermediate-risk IgAN.[30a]

Other immunosuppressive approaches. Mycophenolate mofetil (MMF) has been used in several RCTs in high-risk patients. Three trials in White patients failed to demonstrate a benefit, whereas studies in Chinese patients noted reduced proteinuria and preserved GFR.[31,47,48] Whether ethnic differences underlie these discrepant results remains to be clarified. In another Chinese trial, 4 of 32 patients with IgAN receiving MMF plus corticosteroids died of *Pneumocystis* pneumonia.[49] MMF is not recommended by the 2021 KDIGO guidelines in non-Chinese patients with intermediate-risk IgAN.[30a]

Cyclosporine has been used in one RCT in IgAN.[50] Patients showed a reversible decrease in proteinuria along with a decrease in creatinine clearance, suggesting the changes were a hemodynamic effect of cyclosporine rather than an immunomodulating effect.

Rituximab (two infusions of 1 g) failed to reduce levels of undergalactosylated IgA and autoantibodies against this IgA in a small open-label trial in adult patients with high-risk IgAN and did not affect proteinuria over the course of 1 year.[51]

Pooled human immunoglobulin has yielded encouraging preliminary results in patients with IgAN who have an aggressive clinical course. Proteinuria was reduced, deterioration of GFR slowed, and histologic activity lessened on repeated kidney biopsies.[52] No RCT is available for this approach.

Newer immunosuppressive approaches targeting B-cell activation (e.g., B-cell activating factor [BAFF] and/or a proliferation-inducing ligand [APRIL] or using BAFF/APRIL inhibitors such as atacicept) are being studied in patients with IgAN.

Rapidly Progressive IgA Nephropathy (Poor Prognosis)

In this uncommon situation of rapidly progressive kidney failure associated with crescentic IgAN (i.e., not crescentic IgAN associated with stable GFR), the risk-to-benefit ratio most strongly favors intensive immunosuppressive therapy because untreated patients will rapidly progress to ESKD. Treatment has often combined plasma exchange with prednisolone and cyclophosphamide.[53] Early clinical response is favorable, as in other crescentic nephritis. Medium-term results, however, are disappointing; kidney survival at 5 years was only 30% and not different in immunosuppressed and nonimmunosuppressed patients.[54]

A subset of patients with circulating IgG-antineutrophil cytoplasmic antibody (ANCA) may have a more favorable response to immunosuppressive therapy similar to that seen in other ANCA-positive crescentic nephritis.[55] With no RCTs of treatment, it is impossible to be certain which elements of the regimen (corticosteroids, cyclophosphamide, or plasma exchange) are mandatory.

Other Therapeutic Approaches to Progressive IgA Nephropathy

Reduction of IgA production. Tonsillectomy reduces the frequency of episodic hematuria when tonsillitis is the provoking infection. In all other patients with IgAN, tonsillectomy is not routinely recommended[30a]; there is no role for prophylactic antibiotics. Dietary gluten restriction, used to reduce mucosal antigen challenge, has not been shown to preserve kidney function.[2]

Prevention and removal of IgA deposits. The ideal treatment of patients with IgAN would remove IgA from the glomerulus and prevent further IgA deposition. This remains a remote prospect while the pathogenesis remains incompletely understood.

Transplant recurrence. There is no evidence that newer immunosuppressive agents have modified the frequency of recurrent

IgA deposits or are of value in recurrent disease. There is, however, registry evidence that transplant outcome is improved if corticosteroids are continued long term and if the immunosuppression includes MMF.[56,57] In patients with established IgAN recurrence, most clinicians merely optimize supportive care. When crescentic IgAN recurs with rapidly deteriorating graft function, treatment as for primary crescentic IgAN has been used, although evidence of its success is sparse.

IgA VASCULITIS

Definition

IgAV, previously termed Henoch-Schönlein purpura, is a small-vessel vasculitis that predominantly affects children and affects the skin, joints, gut, and kidneys. It is defined by tissue deposition of IgA. Typically, there is clinical involvement in the skin, gut, and kidneys. The nephritis associated with IgAV is characterized by diffuse mesangial IgA deposition. Indeed, the kidney histologic features of IgAV are indistinguishable from those of IgAN.

Epidemiology

In children, IgAV is usually diagnosed on clinical grounds without biopsy confirmation of tissue IgA deposition. Transient urine abnormalities are common in the acute phase. However, only those with persistent urine abnormalities or with more overt kidney disease will come to kidney biopsy. Therefore, the incidence of IgAV is almost certainly underestimated, with many unidentified mild and transient cases. There is no information on geographic variations in IgAV.

Despite some differences in age at onset and natural history of IgAN and IgAV,[58] there is much evidence to support a close link between the two conditions. Monozygotic twins who developed IgAN and IgAV, respectively, at the same time have been described. The evolution of IgAN into IgAV in the same patient is described in both adults and children, and patients with IgAV and ESKD receiving a kidney transplant may experience recurrent disease in the form of IgAN.

Pathogenesis

Many of the abnormalities of IgA production and handling reported in IgAN are also detected in IgAV, including circulating IgA-rheumatoid factors in 55% of cases, and increased serum gd-IgA1, which is found in IgAV when there is nephritis, but it is not clear whether gd-IgA1 is also predictive of extrarenal manifestations of IgAV. No studies have investigated whether gd-IgA1 is in mesangial deposits in IgAV. There is no animal model for IgAV to facilitate studies of pathogenesis.

Although infection precedes IgAV in up to 50% of cases, no evidence indicates a role for any specific antigen.

Genetics

Subjects with IgAV have been excluded from recent large-scale genome-wide association studies in IgAN, and the genetic background to IgAV has not been systematically studied.

Clinical Manifestations

Although most prevalent in the first decade of life, IgAV may occur at any age. A palpable purpuric rash, which may be recurrent, occurs on extensor surfaces (Fig. 24.7). There may be polyarthralgia (usually without joint swelling) and abdominal pain caused by gut vasculitis. This may be severe, with bloody diarrhea if intussusception develops. In practice, the diagnosis is made by clinical criteria in the great majority of children, in whom IgAV is often a self-limiting illness. In adults, clinical features include purpura, arthritis, and GI symptoms in 95%, 60%, and 50% of patients, respectively.[59] Kidney involvement in adults with IgAV does not differ from that in isolated IgAN. Tissue confirmation of IgA deposition by kidney or skin biopsy is necessary to establish the diagnosis of IgAV.

Fig. 24.7 Immunoglobulin A Vasculitis. The rash is a palpable purpuric vasculitis on the lower limbs spreading on extensor surfaces to the buttocks and occasionally to the upper limbs. Histology shows leukocytoclastic vasculitis with immunoglobulin A deposits in blood vessel walls.

BOX 24.3 Treatment Recommendations for Nephritis in IgA Vasculitis

Crescentic nephritis: regimen is as for crescentic IgA nephropathy (see Fig. 24.6).

All other nephritis in IgA vasculitis (including nephrotic syndrome): regimen as for IgA nephropathy (see Fig. 24.6).

Hypertension: angiotensin-converting enzyme inhibitors and angiotensin receptor blockers are agents of first choice; target blood pressure: 130/80 mm Hg if proteinuria is <1 g/24 h, 125/75 mm Hg if proteinuria is >1 g/24 h.

Transplantation: Cadaveric donor may be preferable to living-related donor in children (controversial).

Much kidney involvement in IgAV is transient. Urine abnormalities are noted during the acute presentation but may disappear. Of those referred to a nephrologist, asymptomatic urine abnormality is still the most frequent clinical manifestation. Nephrotic syndrome occurs in 20% to 30% of patients. AKI may develop as a result of crescentic GN.

Pathology

The kidney histopathologic findings in IgAN and IgAV nephritis may be indistinguishable (see Fig. 24.4). The predictive value of the MEST score has not been shown for IgAV with kidney involvement.

Differential Diagnosis

In children, the diagnosis of IgAV is usually made on the basis of clinical criteria; not all patients have a kidney biopsy to confirm tissue IgA deposition. In adults, the differential diagnosis is much wider and includes other forms of systemic vasculitis, requiring diagnosis by clinical, serologic, and histologic characteristics (see Chapter 26).

Natural History

The natural history for IgAV is less clear than for IgAN. Observations are restricted to patients referred for kidney biopsy, which excludes the majority of patients with minor transient kidney involvement, who have an excellent prognosis. The kidney prognosis is worse in adults than in children with IgAV. In adults, up to 40% will have CKD or

ESKD 15 years after biopsy. One series reports an increased mortality from lung and GI malignancy.[59]

Transplantation

IgAV can recur as isolated IgA deposits in the graft (~50% of transplants), as full-blown yet isolated IgAN, or, rarely, as a full recurrence of systemic involvement, including a rash. The clinical and pathologic characteristics of kidney recurrence are similar to those of recurrent IgAN.[30] Delay of transplantation after initiation of dialysis does not reduce the risk for IgAV recurrence.

Treatment

Many patients have transient nephritis during the early phase of IgAV, which spontaneously remits and requires no treatment. No RCTs guide the treatment of IgAV. Most therapeutic studies of IgAN exclude those with IgAV, so it is unclear whether the potential treatments for IgAN have a role in IgAV.[30a] Commonly used treatments for IgAV are shown in Box 24.3.

Rapidly Progressive Chronic Kidney Disease Caused by Crescentic Nephritis

Crescentic nephritis is more common in IgAV than in IgAN, particularly early in the course of the disease. There is little specific information on treatment in adults or children, but regimens based on those for other forms of systemic vasculitis are widely used. These include corticosteroids and cyclophosphamide, with the addition of plasma exchange or pulse methylprednisolone in some cases. However, a French RCT in adults with severe IgAV failed to detect a benefit of cyclophosphamide plus steroids over steroids alone.[60]

Active IgA Vasculitis Without Kidney Failure

There is little information about less aggressive IgAV. Corticosteroids alone, although often considered more effective than in IgAN, have never been shown to be beneficial for prevention or treatment of kidney involvement in IgAV, although are apparently beneficial for extrarenal manifestations.[30a] Promising findings with combination therapy of corticosteroids, cyclophosphamide, and antiplatelet agents have been reported in only small, nonrandomized studies.[30a] A nonrandomized study reported that prednisolone and azathioprine preserved kidney function and improved histologic appearances, but it relied on historical controls.[61]

Slowly Progressive Chronic Kidney Disease

Although the kidney histology and clinical course of slowly progressive IgAV and IgAN may be indistinguishable, patients with IgAV have not been included in studies of slowly progressive IgAN. Therefore, there is no evidence that fish oil is beneficial in IgAV. Tight BP control with ACE inhibitors or angiotensin receptor blockers (ARBs) is recommended for proteinuric IgAV as for IgAN. The 2021 KDIGO guidelines recommend a similar indication for corticosteroids in slowly progressive IgAV as in patients with intermediate-risk IgAN.[30a]

Transplant Recurrence

No treatment is known to reduce the risk for recurrence. There is some evidence that recurrence is more common and more likely to lead to graft loss in children receiving kidneys from living rather than deceased donors, although this is not confirmed in adults.[62,63] If crescentic IgAV recurs, intensive immunosuppression may be justified as for primary disease. This, however, has not been thoroughly evaluated.

SELF-ASSESSMENT QUESTIONS

1. Based on the 2021 KDIGO guidelines, which treatment is recommended for all patients at risk for progressive loss of *GFR*?
   - **A.** Fish oil
   - **B.** Mycophenolate mofetil
   - **C.** Prednisolone
   - **D.** Renin angiotensin aldosterone system inhibitor
   - **E.** Tonsillectomy
2. The Oxford (MEST-C) classification includes pathologic features predictive of outcome. Which of the following is *not* one of the predictive features?
   - **A.** Endocapillary hypercellularity
   - **B.** Capillary vascular changes (nephrosclerosis)
   - **C.** Mesangial hypercellularity
   - **D.** Segmental glomerulosclerosis
   - **E.** Tubulointerstitial damage and fibrosis
3. Which of the following statements for IgA nephropathy is *true?*
   - **A.** IgAN is more common in Europe than any other part of the world.
   - **B.** Measurement of abnormally glycosylated serum IgA is a diagnostic test for IgAN.
   - **C.** The renal pathologic features can be identical to those in IgA vasculitis.
   - **D.** Acute kidney injury with macrohematuria in IgA nephropathy is almost always caused by crescentic IgAN.
   - **E.** The risk for recurrence after kidney transplantation is reduced when MMF is part of the immunosuppressive regimen.
4. In IgA vasculitis, which of the following statements is *true?*
   - **A.** IgA vasculitis never occurs after age 40 years.
   - **B.** There is altered glycosylation of serum IgA1.
   - **C.** Delay in transplantation reduces the risk for recurrence.
   - **D.** Cyclophosphamide is of proven benefit for slowly progressive IgA vasculitis.
   - **E.** Corticosteroids given at the onset of the rash reduce the risk for subsequent nephritis.

Anti–Glomerular Basement Membrane Disease and Goodpasture Disease

Richard G. Phelps, A. Neil Turner

The syndrome of kidney failure and lung hemorrhage was associated with the name of Ernest Goodpasture by Stanton and Tange in their description of nine cases in 1958.[1,2] All nine patients presented with lung hemorrhage and acute kidney failure and died within hours or days. These features had been prominent in the case of a young man who died during the influenza pandemic of 1919, whose postmortem findings were memorably reported by Goodpasture[1]: "The lungs gave the impression of having been injected with blood through the bronchi so that all the air spaces were filled" (Fig. 25.1).

Several diseases are now recognized as being associated with alveolar hemorrhage and rapidly progressive glomerulonephritis (RPGN). Nevertheless, this remains a striking clinical entity with relatively few causes and few pathogenetic mechanisms.

Because the first recognized mechanism was anti–glomerular basement membrane (anti-GBM) antibody formation and deposition, Goodpasture's name is firmly associated with anti-GBM disease (Goodpasture disease), even though this is responsible for only a proportion of patients with Goodpasture syndrome of lung hemorrhage and RPGN. The terminology used in this chapter is defined in Table 25.1.

ETIOLOGY AND PATHOGENESIS

Autoimmunity to a Component of Glomerular Basement Membrane

Goodpasture disease is caused by autoimmunity to the carboxyl terminal, noncollagenous (NC1) domain of a type IV collagen chain, α3(IV)NC1, also known as the Goodpasture antigen[3,4] (Fig. 25.2). Type IV collagen is an essential constituent of all basement membranes. In most tissues, it is composed of trimers including two α1 chains and one α2 chain, but there are also four tissue-specific chains, α3 through α6.[5,6] Three of these, α3 through α5, are found in GBM and in the basement membranes of the alveolus, the cochlea, parts of the eye (including corneal basement membrane and Bruch's membrane), the choroid plexus of the brain, and some endocrine organs.

All patients with RPGN, lung hemorrhage, and anti-GBM antibodies have antibodies to α3(IV)NC1, usually binding predominantly to a single or a very restricted set of epitopes. Some patients also have antibodies to other basement membrane constituents, including other collagen IV chains, usually in low titer.

Predisposing Factors

Both environmental and genetic factors appear to be important in etiology. There are strong associations between Goodpasture disease and human leukocyte antigen (HLA) class II alleles, including *DRB1∗1501* and *DR4* alleles, whereas *DR1* and *DR7* confer strong and dominant protection.[7] Some diseases and treatments predispose, as described in the following section.

Precipitating Factors

Theories of pathogenesis include precipitating factors that alter antigen processing to generate peptides that are usually destroyed or hidden, and to which tolerance is therefore deficient,[8,9] and molecular mimicry.[10] None of these is proved. Reports of temporal and geographic clustering of cases suggest an environmental trigger but no specific infectious agent has been consistently identified, leading to speculation that autoimmunity could be triggered (or amplified) by infection in general (or the response to infection), rather than the consequence of an aberrant immune response to a particular infectious agent.[11,12] Hydrocarbon exposure has been linked to disease onset in several striking case reports, but such exposure may simply trigger lung hemorrhage in patients who already have the disease. Furthermore, exposures of this kind are very common in the modern world. Similarly, cigarette smoking may precipitate lung hemorrhage in patients who already have circulating autoantibodies, but there is no evidence for a role in causation.

In several cases, kidney trauma or inflammation has preceded the development of the disease (Box 25.1). This may alter α3(IV)NC1 turnover and metabolism qualitatively or quantitatively, providing an opportunity for self-tolerance to be broken. Qualitative changes in the basement membrane epitopes presented to T cells could be a result of overloading of the usual or recruitment of alternative processing pathways, such as extracellular processing by proteases released into inflamed glomeruli. The quantity of α3(IV)NC1 presented to T cells may be greater where there has been damage to the basement membrane, as occurs in small-vessel vasculitis (see Chapter 26). Some features suggest that an anti-GBM response may be a secondary phenomenon in some patients with vasculitis.[13,14] The association with membranous nephropathy (MN) is interesting because the thickened GBM in that disease contains increased amounts of the tissue-specific type IV collagen chains, including the Goodpasture antigen. The same could apply to a possible association with long-standing type 1 diabetes mellitus.[15]

Mechanisms of Kidney Injury

The α3(IV)NC1 autoantibodies are central in the pathogenesis of Goodpasture disease[16,17] (Fig. 25.3). Antibodies eluted from the kidneys of patients who had died of Goodpasture disease rapidly bind to the GBM and cause glomerulonephritis (GN) when they are injected into monkeys.[18] The deposited antibodies are predominantly immunoglobulin G1 (IgG1). Contributions to kidney injury mediated by such antibodies come from complement and from neutrophil and macrophage infiltration. T cells are essential for driving autoantibody production by T cell–dependent B cells, and, in experimental kidney disease, they are critical in producing glomerular crescents,[16,19] which are a usual feature of Goodpasture disease. Moreover, in mice engineered to express the human susceptibility HLA allele *DRB1∗1501*,

α3(IV)NC1-specific CD4 T cells are sufficient to transfer disease between animals.[20]

Agents that downregulate inflammation by inhibiting interleukin-1 (IL-1) or tumor necrosis factor (TNF), or that inhibit recruitment of inflammatory cells by blockade of adhesion molecules or chemoattractants, suppress injury in experimental models of anti-GBM disease. Evidence in humans and in experimental animals supports the severity of kidney injury being increased by proinflammatory cytokines or by stimuli likely to elicit them, such as bacteremia.[19] Crescent formation is seen in aggressive inflammatory GN, as described in Chapter 17 (see Fig. 17.7).

Lung Hemorrhage

Lung hemorrhage in Goodpasture disease (but not in small-vessel vasculitis, the other major cause of Goodpasture syndrome) occurs only if there is an additional insult to the lung, which is usually cigarette smoke. However, infection, fluid overload, toxicity from inhaled vapors or other irritants, and the systemic effects of some cytokines are also possibilities. The higher risk of kidney disease compared with lung hemorrhage may be because alveolar capillary endothelial cells more effectively block circulating immunoglobulin from reaching the underlying basement membrane. In the glomerulus, antibodies have more direct access to the GBM via the diaphragm-free fenestrations of glomerular endothelium. Other sites at which the Goodpasture antigen is found are not involved in Goodpasture disease, except possibly the choroid plexus, where the endothelium is again fenestrated, and more rarely the eye.

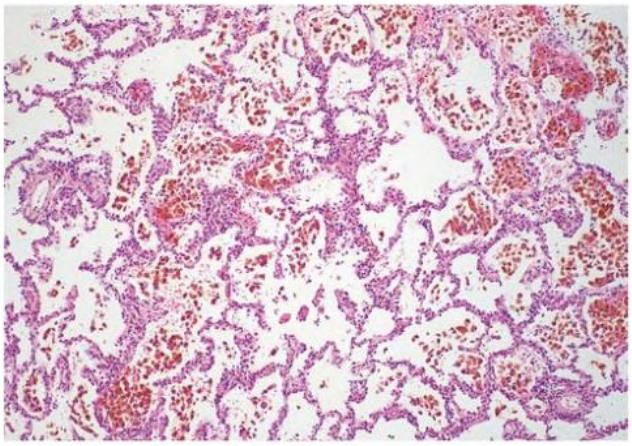

Fig. 25.1 Alveolar Hemorrhage. Open lung biopsy sample in a patient with Goodpasture disease shows alveolar hemorrhage. (Courtesy Dr. E. Mary Thompson, St Mary's Hospital, London.)

EPIDEMIOLOGY

Goodpasture disease is rare, with an incidence in both White and Chinese populations approaching 1 case per 1 million population per year.[15] The incidence in Black populations appears to be lower. The incidence in other racial groups is uncertain. There is a slight male predominance. Lung hemorrhage is more common in younger patients. Age incidence is bimodal, with peaks in third and sixth decades.[15]

CLINICAL MANIFESTATIONS

Between 50% and 75% of patients present with acute symptoms of lung hemorrhage and advanced kidney failure. Symptoms are usually confined to the preceding few weeks or months, but rapid progression (during days) or much slower progression (during many months) may occur. A lack of systemic symptoms, other than those related to anemia, is typical, although an apparently minor infection often triggers the clinical presentation.

Lung Hemorrhage

Lung hemorrhage may occur with kidney disease or in isolation. Presenting symptoms may include cough and hemoptysis, but lung hemorrhage may result in marked iron-deficiency anemia and exertional dyspnea, even in the absence of hemoptysis. Examination findings may include pallor, dry inspiratory crackles, signs of consolidation, or respiratory distress. Recent lung hemorrhage typically is shown on the radiograph as central shadowing that may traverse fissures and give rise to the appearance of an air bronchogram (Fig. 25.4). However, even lung hemorrhage sufficient to reduce the hemoglobin concentration may cause only minor or transient radiographic changes, and these cannot be distinguished radiologically from other causes of alveolar shadowing, notably edema or infection. The most sensitive indicator of recent lung hemorrhage is an increased uptake of inhaled carbon monoxide (DLCO). Patients with lung hemorrhage are usually current cigarette smokers.

In apparently isolated lung disease, progressive alveolar or fibrotic disease or pulmonary hemosiderosis may be suspected, although hematuria is usually found to be present if sought. This may continue for months or, in rare cases, recurrently for years before significant kidney disease occurs.

Glomerulonephritis

Patients with GN may notice dark or red urine, but progression to oliguria is sometimes so rapid that this phase, if it occurs, is missed. In a third to half of patients, GN occurs in the absence of lung hemorrhage.

TABLE 25.1 Definition of Terms Associated With Anti-GBM Disease and Goodpasture Syndrome

Term	Definition	Pathogenesis
Pulmonary-renal syndrome	Kidney and respiratory failure	Many causes (see Box 25.3)
Goodpasture syndrome	RPGN and alveolar hemorrhage	Several causes (see Box 25.4)
Anti-GBM disease	Disease associated with antibodies specific for (any) components of GBM	Most important are Goodpasture disease and Alport syndrome posttransplant anti-GBM disease
Goodpasture disease	Disease associated with autoantibodies specific for α3(IV)NC1 May include RPGN, lung hemorrhage, or both	Autoimmunity to α3(IV)NC1
Alport syndrome posttransplant anti-GBM disease	Glomerulonephritis associated with anti-GBM antibodies developing after kidney transplantation in patients with Alport syndrome	Immunity to foreign collagen IV chains not expressed in patients with Alport syndrome, usually α3 or α5(IV)NC1

GBM, Glomerular basement membrane; *RPGN,* rapidly progressive glomerulonephritis.

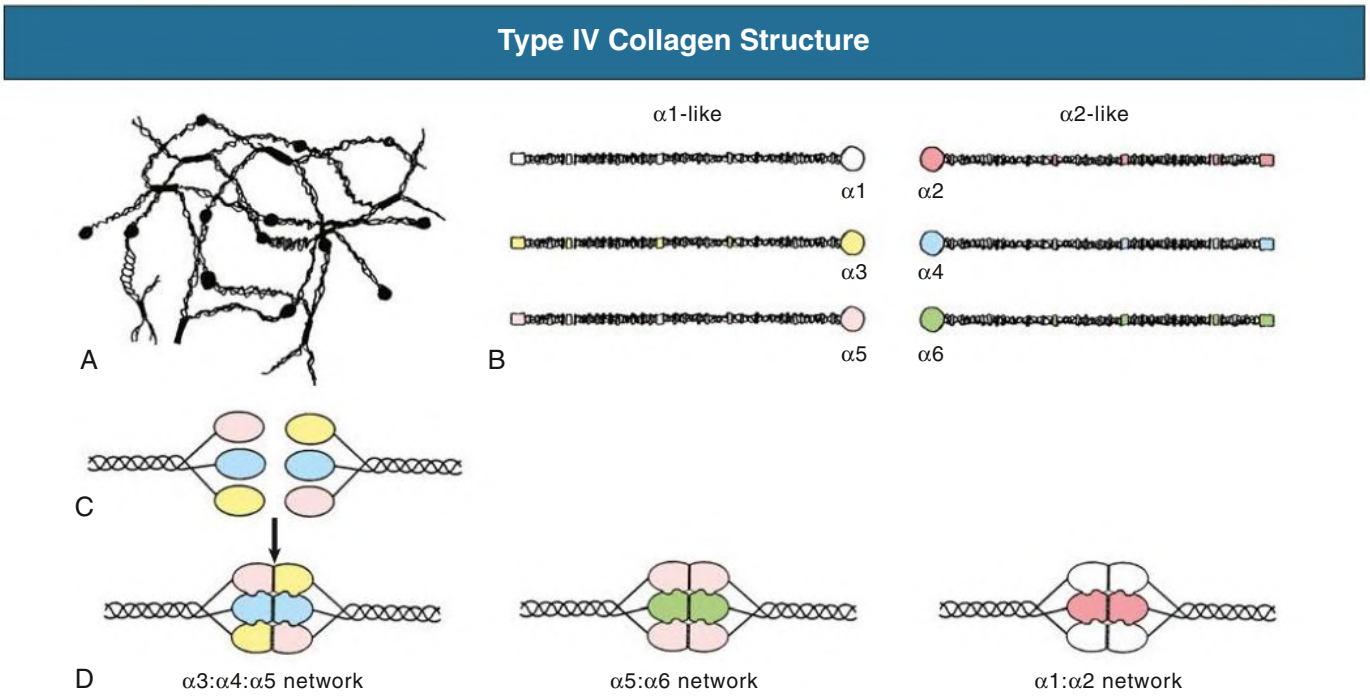

Fig. 25.2 Type IV Collagen Structure. (A) The type IV collagen network makes a "chicken wire" structure in the glomerular basement membrane (GBM). (B) Six paired type IV collagen genes, *COL4A1* to *COL4A6,* encode type IV collagen monomers α1 to α6. (C) These associate in two or three defined monomer types per protomer (carboxyl terminal domains of α3:α4:α5) to form three recognized networks (D). α1:α2 is present in almost all basement membranes; α3:α4:α5 is the major constituent of GBM and is a significant component of alveolar basement membrane and other locations; and α5: α6 is found in Bowman's capsule, skin, esophagus, and other locations.

BOX 25.1 Predisposing Events Associated With the Presentation of Goodpasture Disease

Possibly Induce Autoimmune Response and Disease

- Systemic small-vessel vasculitis affecting glomeruli
- Membranous nephropathy
- Lithotripsy of kidney stones
- Urinary obstruction
- Alemtuzumab therapy for multiple sclerosis

Precipitate Pulmonary Hemorrhage

- Cigarette smoke
- Hydrocarbon exposure
- Pulmonary infection
- Fluid overload

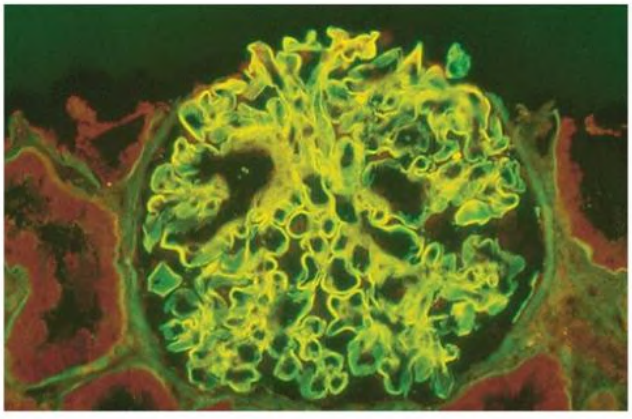

Fig. 25.3 Autoantibodies to Goodpasture Antigen Bound to a Normal Glomerulus. Direct immunofluorescence of normal kidney with sera from a patient with Goodpasture disease shows the antigen in a patient with lung hemorrhage and hematuria. (Courtesy Dr. Richard Herriot, Aberdeen Royal Infirmary, UK.)

In this subgroup, because systemic symptoms are generally not prominent, presentation is often late with kidney failure.

Whatever the early pattern of disease, once significant kidney impairment has occurred, further deterioration in kidney function is usually rapid. Presentation at or shortly after acceleration of the disease process is common, and patients may demonstrate very rapid loss of kidney function and life-threatening lung hemorrhage. Urinalysis always reveals hematuria (even in apparently isolated pulmonary disease), usually modest proteinuria, and dysmorphic red blood cells (RBCs) and RBC casts on microscopy. The kidneys are generally of normal size but may be enlarged. Hematuria may be substantial or associated with loin pain in acute disease.

PATHOLOGY

Kidney biopsy is essential because it provides diagnostic and prognostic information. Typical appearances are of diffuse proliferative GN with variable degrees of necrosis, crescent formation, glomerulosclerosis, and tubular loss (Fig. 25.5). The degree of crescent formation and tubular loss correlates with kidney prognosis. Characteristically, the crescents all appear to be of similar age and cellularity. When biopsy is performed earlier in the disease, changes may be limited to focal and segmental mesangial expansion, with or without necrosis.

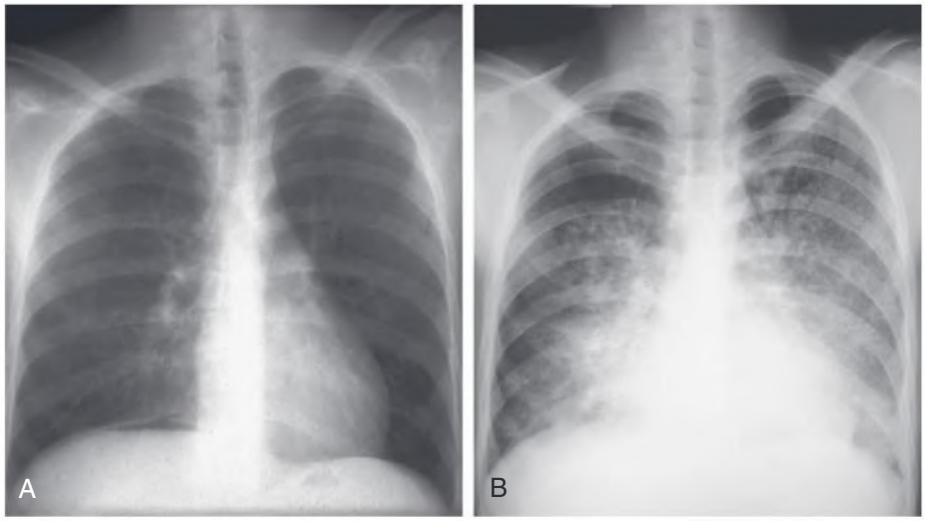

Fig. 25.4 Lung Hemorrhage. (A) Patient with early pulmonary hemorrhage. The chest radiograph still appears normal. (B) Radiograph taken 4 days later shows the evolution of alveolar shadowing caused by lung hemorrhage.

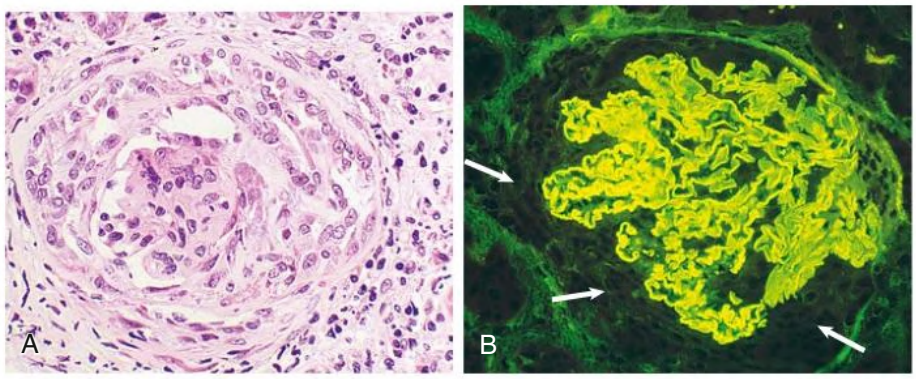

Fig. 25.5 Kidney Biopsy in Goodpasture Disease. (A) Glomerulus from a patient with Goodpasture disease showing a recent, mostly cellular crescent. (B) Direct immunofluorescence study showing ribbon-like linear deposition of immunoglobulin G along the glomerular basement membrane. The glomerular tuft is slightly compressed by cellular proliferation (exhibiting no immunofluorescence), forming a crescent *(arrows)*. (Courtesy Dr. Richard Herriot, Aberdeen Royal Infirmary, UK.)

This progresses to hypercellularity and then to more general changes, including fractures of the GBM and Bowman's capsule, neutrophils in the glomeruli, and glomerular capillary thrombosis.[21]

Immunohistology

In the presence of severe glomerular inflammation, linear deposition of Ig along the GBM is pathognomonic. The immunoglobulin is usually IgG, sometimes with IgA or IgM (10%–15%), but IgA alone is rarely detected. Linear deposition of C3 is detectable in about 75% of biopsies. Linear immunofluorescence (IF) with anti-immunoglobulin reagents is occasionally seen in other conditions, usually without glomerular inflammation (Box 25.2). In most such cases, the deposited immunoglobulin is less abundant than in Goodpasture disease and is either nonspecifically deposited or bound to GBM components other than type IV collagen chains.

Circulating IgG anti-GBM antibodies are almost invariably present and may be detected and quantified by use of immobilized Goodpasture antigen in an immunoassay. The titer of anti-GBM antibody at presentation correlates with the severity of nephritis, but sometimes is at a very low level despite significant disease; interpretation may require knowledge of the local laboratory's approach to classifying assay results. Treatment and relapse are often mirrored by changes in titer.

BOX 25.2 Conditions Associated With Linear Binding of Immunoglobulin to the GBM

Specific Binding to GBM
- Goodpasture syndrome
- Alport syndrome after kidney transplantation

Nonspecific Binding to GBM
- Diabetes
- Cadaver kidneys
- Light chain disease
- Fibrillary glomerulopathy
- Systemic lupus erythematosus (possibly specific but not considered directly pathogenic)

GBM, Glomerular basement membrane.

Pathology in Other Tissues

Pathologic changes in lung tissue can be difficult to interpret because the changes, including Ig deposition, are often patchy and may be missed.

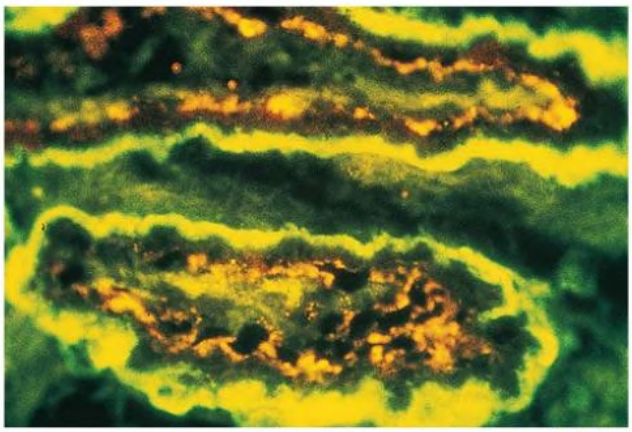

Fig. 25.6 Immunoglobulin G (IgG) Binding to Choroid Plexus. Direct immunofluorescence study showing binding of IgG to the choroid plexus of a patient who died of Goodpasture disease. (Courtesy Dr. Stephen Cashman, Imperial College, London.)

Frequently, the only findings are mild, chronic inflammation and hemosiderin-laden macrophages, which are consistent with other more common pathologic diagnoses. This makes negative bronchoscopic or open-lung biopsy findings unhelpful in excluding the diagnosis.

Other tissues in which α3(IV)NC1 is expressed are rarely available for pathologic analysis, but even if antibody is deposited in these other sites, it is rarely associated with clinical disease. A number of case reports describe neurologic syndromes, particularly seizures, that may be related to antibody deposition in the choroid plexus but may have other explanations in patients with acute kidney injury (Fig. 25.6). Other reports have described retinal detachment, in one case with antibody deposition, but again, this is rare. Placental tissue also contains the Goodpasture antigen and has been reported in a single case to act as a "sink" that binds anti-GBM antibody during pregnancy, resulting in exacerbation of GN after delivery.

DIFFERENTIAL DIAGNOSIS

Diagnosis of Goodpasture disease in patients who present with Goodpasture syndrome does not usually present difficulties once the possibility has been raised, although the urgency is often not appreciated. Direct IF on kidney tissue and assay for circulating anti-GBM antibodies are the most rapid techniques, and kidney biopsy is always indicated. Diagnosis is often delayed when patients present with subacute disease affecting the lung or the kidney in isolation. Patients with subacute lung hemorrhage may not report hemoptysis and may present with diffuse lung disease, which has many causes. Dipstick testing for hematuria is important.

Detection of Anti–Glomerular Basement Membrane Antibodies

Direct immunohistology is very sensitive for detection of anti-GBM antibody production because the GBM selectively adsorbs and concentrates low levels of circulating antibody. However, in some circumstances, GBM may also adsorb antibody nonspecifically (see Box 25.2). Detection of anti-GBM antibodies in serum requires immunoassays based on preparations of human or animal GBM or recombinant antigen. The performance of these assays is variable. False negatives may be encountered with low titers of antibody (typically in apparently isolated pulmonary disease) and, rarely, with antibodies targeting unusual epitopes or unusual types (e.g., IgA or monoclonal proteins). Confirmation of the specificity of anti-GBM antibodies may be obtained by Western blotting of serum onto solubilized human GBM or recombinant α3(IV)NC1, usually at a reference laboratory. Indirect immunohistology (putting patient serum onto normal kidney sections) is too insensitive for reliable diagnostic use.

False-positive results may be encountered in sera from patients with inflammatory diseases that often exhibit increased nonspecific binding. This places greater emphasis on the purity of antigen used for anti-GBM assays. False-negative results are usually encountered in patients with low titers of antibodies in association with isolated lung disease or with very early or subacute kidney disease. Low titers also may be associated with anti-GBM disease that occurs after kidney transplantation in patients with Alport syndrome (see later discussion).

In very advanced disease, linear antibody deposition may not be seen because of extensive destruction of GBM structure. Otherwise, deposited Ig remains detectable for some months after immunoassays have become negative.

Patients With Anti-GBM Antibodies and Other Diseases

Antineutrophil Cytoplasmic Antibody and Systemic Small-Vessel Vasculitis

Anti-GBM antibodies are sometimes detected in patients with antineutrophil cytoplasmic antibodies (ANCAs), especially ANCAs with specificity for myeloperoxidase (see Chapter 26). Such "double-positive" patients may have a clinical course and response to treatment more typical of vasculitis than of Goodpasture disease and have possibly developed anti-GBM antibodies secondary to vasculitic glomerular damage.[8–11] Anti-GBM titers tend to be lower in ANCA-positive anti-GBM antibody–positive patients than in patients with anti-GBM antibodies alone. Recovery of kidney function may be more likely if ANCAs are present, even if patients are dialysis dependent when treatment is started, although newer series have failed to detect the differences described in early reports.

Membranous Nephropathy

Anti-GBM antibodies are occasionally identified in patients with MN, usually coincident with an accelerated decline in kidney function and the formation of glomerular crescents.[5,15,22] About two-thirds of studies report evidence of evolution from preexisting nephrotic syndrome, and about half report that a previous kidney biopsy showed typical MN. Progression to end-stage kidney disease (ESKD) has usually been rapid, but the diagnosis has rarely been made at a stage early enough to expect intensive treatment to be successful. Three patients with Goodpasture disease later developed typical MN.

Alemtuzumab Treatment

Treatment of multiple sclerosis (MS) with alemtuzumab, a monoclonal antibody targeting CD52 on B and T cells, is associated with the development of new autoimmunity in approximately 30% of patients, including rare cases of anti-GBM disease, sometimes as late as 4 years after treatment.[23] It remains to be established whether carriage of *DRB1∗1501,* which is overrepresented in MS, influences the risk for developing anti-GBM disease after alemtuzumab therapy.

Pulmonary-Renal Syndromes

A wide variety of conditions may cause simultaneous pulmonary and kidney disease. The term *pulmonary-renal syndrome* implies failure of both organs, the most common cause being fluid overload in a patient with kidney failure of any cause (Box 25.3). Then there are diseases associated with pulmonary hemorrhage and RPGN, sometimes called Goodpasture syndrome (Box 25.4).

BOX 25.3 Nonimmune Causes of Pulmonary-Renal Syndrome

With Pulmonary Edema
- Acute kidney injury with hypervolemia
- Severe cardiac failure

Infective
- Severe bacterial pneumonia (e.g., *Legionella*) with kidney failure
- Hantavirus infection
- Opportunistic infections in the immunocompromised patient

Other
- Acute respiratory distress syndrome with kidney failure in multiorgan failure
- Paraquat poisoning
- Renal vein/inferior vena cava thrombosis with pulmonary emboli

BOX 25.4 Causes of Lung Hemorrhage and Rapidly Progressive Glomerulonephritis

Diseases Associated With Antibodies to the GBM (20%–40% of Cases)
- Goodpasture disease (spontaneous anti-GBM disease)

Diseases Associated With Systemic Vasculitis (60%–80% of Cases)
- Granulomatosis with polyangiitis (common)
- Microscopic polyangiitis
- Systemic lupus erythematosus
- Eosinophilic granulomatosis with polyangiitis (Churg-Strauss)
- IgA vasculitis (Henoch-Schönlein purpura)
- Henoch-Schönlein purpura
- Behçet syndrome
- Essential mixed cryoglobulinemia
- Rheumatoid vasculitis
- Drugs: Penicillamine, hydralazine, propylthiouracil

GBM, Glomerular basement membrane; *IgA*, immunoglobulin A.

The two classes of disease in Box 25.4 can sometimes be differentiated clinically, but serology and kidney biopsy are usually required. Kidney biopsy also provides valuable prognostic information.

NATURAL HISTORY

There is some variability in the pattern of early disease. Most patients present acutely with lung hemorrhage or advanced kidney failure and report that the illness developed over weeks or a few months. However, there are several reports of patients presenting with mild respiratory symptoms or incidental microhematuria, with disease progressing much more slowly during months or years; some have abruptly developed the full acute syndrome. Microhematuria preceded kidney failure in all the patients who developed anti-GBM disease while being monitored after alemtuzumab treatment of MS. A study of US veterans showed a similarly long delay between first appearance of antibodies and clinical presentation.[24]

Once RPGN has developed, kidney function is rapidly and often irretrievably lost. Progression is often much more rapid than in RPGN occurring in other contexts, such as microscopic polyangiitis, perhaps because more glomeruli are simultaneously affected. Consequently, there is a much narrower window of opportunity for effective treatment than when other diseases cause the syndrome.

Although a severe exacerbation of lung disease usually coincides with deterioration of kidney function, the natural history of isolated lung disease critically depends on continued exposure to pulmonary irritants.

TREATMENT

Immunosuppressive Regimens

Before the introduction of immunosuppressive treatment, most patients died shortly after the development of renal impairment or lung hemorrhage.[19] Lung hemorrhage now usually can be arrested within days. Kidney function can be protected if impairment is mild, and even severe kidney impairment can be reversed in some patients. However, dialysis-dependent patients rarely recover kidney function despite immunosuppression and should probably be immunosuppressed only if lung hemorrhage occurs.

Fig. 25.7 shows a chart recording the treatment of a patient with Goodpasture disease. Treatment recommendations for acute severe disease were devised to reduce levels of circulating pathogenic antibodies as rapidly as possible and to lessen their contribution to rapid glomerular destruction (Table 25.2). However, this regimen is almost certainly effective through a much broader range of mechanisms, including T-cell depletion. Once the disease is controlled, immunosuppression usually can be tapered off over 3 months, and subsequent relapse is uncommon. The immune response is self-limited in the absence of immunosuppression, with antibodies disappearing over 1 to 2 years. Spontaneous remissions and effectiveness of relatively brief periods of immunosuppression are in striking contrast to the more prolonged immunosuppression generally required to prevent relapse of vasculitis and suggest a greater capacity for restoration of usual tolerance to α3(IV)NC1[25] than to targets in vasculitis (see Chapter 26).

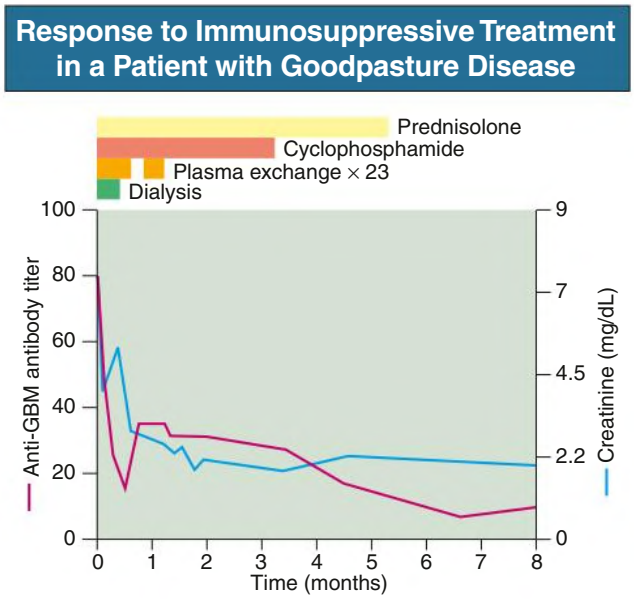

Fig. 25.7 Response to Immunosuppressive Treatment in Goodpasture Disease. The patient required dialysis but had no lung hemorrhage. The good response to treatment was unusual but not unique. The kidney biopsy showed that 85% of glomeruli contained recent (mostly cellular) crescents, suggesting very acute disease, which may be indicative of a more favorable response to treatment. *GBM*, Glomerular basement membrane.

TABLE 25.2 Treatment Regimen for Acute Goodpasture Disease

Therapy	Recommendation
Prednisolone	1 mg/kg/24 hr orally. Reduce at weekly intervals to achieve one-sixth of this dose by 8 wk. For a starting daily dose of 60 mg, use weekly reductions to 45, 30, 25, 20, and 15 mg; then alternate weekly reductions to 12.5 and 10 mg. Maintain this dose to 3 months; then taper to stop by 4 months.
Cyclophosphamide	3 mg/kg/24 h orally, rounded down to the nearest 50 mg. Patients >55 years receive a reduced dose of 2.5 mg/kg. Discontinue after 3 months.
Plasma exchange	Daily exchange of 1 volume of plasma for 5% human albumin for 14 days or until the circulating antibody is suppressed. In the presence of pulmonary hemorrhage or within 48 hours of invasive procedure, 300–400 mL of fresh-frozen plasma is given at end of each treatment or according to coagulation tests.
Monitoring	Daily blood count during plasma exchange and while antibody titer remains elevated. At least twice weekly during first month, weekly thereafter. If white blood cell count decreases to $<3.5 \times 10^9$/L, stop cyclophosphamide until the count recovers. Resume at lower dose if cessation has been necessary. Baseline D_{LCO}, with further measurements as indicated. Daily coagulation tests during plasma exchange to monitor for significant depletion of clotting factors. Initially, daily checks of kidney and hepatic function and glucose.
Prophylaxis against complications of treatment	Oral antifungal lozenges or rinse; proton pump inhibitor. Cotrimoxazole prophylaxis against *Pneumocystis jirovecii*. Avoid nonessential lines and catheters.

D_{LCO}, Diffusing capacity of lung for carbon monoxide.

In RPGN with no evidence of an infective cause, immunosuppressive therapy should be started immediately, sometimes before the kidney biopsy findings are available. If therapy is stopped after a few days, the patient will have incurred minimal risk (as long as pulse high-dose corticosteroids are avoided) but may have much to gain from earlier treatment.

Plasma Exchange and Immunosuppression

The regimen described in Table 25.2 dramatically improved the outlook for patients when it was introduced in the 1970s. An early randomized trial suggested some additional benefit of plasma exchange, but the interpretation was complicated by the recipient group's less severe disease at presentation.[26] It showed that milder disease can be effectively treated with corticosteroids and cyclophosphamide alone, although the overall outcomes for all patients were not as good as described with more intensive regimens.[26] Historical evidence suggests that treatment with corticosteroids alone, or corticosteroids with azathioprine, is less effective. Plasma exchange is of value only if it is accompanied by adjunctive immunosuppressive therapy.

Plasma exchange is likely to benefit kidney outcome by removing circulating auto-antibody so there is interest in new treatments that are more specific or more potent in their capacity to remove autoantibody. More specific is immunoadsorption to protein A, which also lowers anti-GBM antibodies rapidly and does not deplete complement components or clotting factors: A few reports suggest that it is as effective as plasma exchange. More effective is treatment with IdeS, a bacterial IgGase, which has been shown to rapidly and profoundly deplete circulating IgG anti-GBM autoantibody in patients with refractory anti-GBM disease.[27] The place of IdeS in therapy is yet to be worked out, but on current understanding of the immunopathogenesis of anti-GBM disease, it could well replace plasma exchange offering more rapid, more complete, and more selective depletion of circulating anti-GBM IgG and possibly reducing the deleterious effects of autoantibody that is already bound to the GBM. [28]

Information is lacking on the effectiveness of newer immunosuppressive agents such as mycophenolate mofetil (MMF) or anti–B cell antibodies, which tend to have only a slow effect on antibody production but may affect antigen presentation. Therefore, it is difficult to justify their use over proven therapy in the acute phase of this often rapidly progressive disease, but there may be a role in particular circumstances. Rituximab has anecdotally led to reductions in antibody titer in patients with autoimmune responses persisting or relapsing after usual therapy.[29]

Lung hemorrhage occurring alone tends to be relapsing and remitting, so there have been many reports of treatments (e.g., bilateral nephrectomy) that may help. Pulse methylprednisolone has been advocated, but high doses of corticosteroids fail to alter the underlying pathogenetic immune response and put the patient at increased risk for infectious and other complications. We recommend treating seriously ill patients with moderate doses of corticosteroids plus plasma exchange and cyclophosphamide. In contrast to advanced kidney failure, in which treatment is unlikely to lead to recovery of kidney function, even severe lung hemorrhage is likely to respond to treatment with full or almost full recovery of lung function.

In other acute severe diseases, daily administration of cyclophosphamide often has been superseded by pulse administration. We still prefer to use daily oral administration because it is known to work and requires only 3 months of therapy. Patients unable to take the drug orally can be given daily intravenous therapy at the usual oral dose. Dose does not need to be reduced in severe kidney failure, provided the white blood cell (WBC) count is monitored closely, but reductions for older patients are important (see Table 25.2) and close monitoring of leukocyte counts is imperative in all patients. If pulsed therapy were chosen, the CYCLOPS (Randomised Trial of Daily Oral Versus Pulse Cyclophosphamide as Therapy for ANCA-Associated Systemic Vasculitis) regimen would be a reasonable, if untested, option (see Chapter 26).

Results from all series show that recovery of kidney function is unlikely if, at initiation of treatment, the patient is oliguric, has a very high proportion of glomeruli with circumferential crescents, or has a serum creatinine level greater than 5.5 to 6.5 mg/dL (~500–600 µmol/L).[30] This is a notably different experience from that encountered in systemic vasculitis or idiopathic RPGN (see Chapter 26), in which kidney disease of apparently similar severity (using histology and serum creatinine) can be salvaged by similar treatment protocols.[31] This has led to the suggestion that immunosuppressive treatment should be withheld from patients with only slight chance of recovery (Table 25.3).

Supportive Treatment

The most likely cause of death in the first few days is respiratory failure caused by lung hemorrhage. Lung hemorrhage may be precipitated or exacerbated by the following:

- Fluid overload
- Smoking and other pulmonary irritants, possibly including high inspired oxygen concentration (Fio_2)
- Local or distant infection

TABLE 25.3 Factors to Consider in Aggressive Treatment of Goodpasture Disease

	Factors Favoring	Factors Against
Pulmonary hemorrhage	Present	Absent
Oliguria	Absent	Present
Creatinine	<5.5 mg/dL (~500 µmol/L)	>5.5–6.5 mg/dL (~500–600 µmol/L) and ANCA negative Severe damage on kidney biopsy No desire for early kidney transplantation
Other factors	Creatinine >5.5–6.5 mg/dL (~500–600 µmol/L) *but* rapid and recent progression ANCA positive Glomerular damage less severe than expected Crescents recent, nonfibrous Early kidney transplantation desired	
Associated disease	Absent	Unusually high risk from immunosuppression

ANCA, Antineutrophil cytoplasmic antibody.

- Anticoagulation used during dialysis or plasma exchange
- Thrombocytopenia, defibrination, and depletion of clotting factors as a consequence of plasma exchange

It is therefore advisable to ensure correct fluid balance, to prohibit smoking, to use the lowest fractional Fio_2 that gives adequate oxygenation, and to minimize the use of heparin.

Plasma exchange (see Table 25.2) should be monitored by daily blood counts, calcium concentration (if regional citrate anticoagulation is used), and coagulation tests. Diminished clotting factor levels should be replenished by administration of fresh-frozen plasma or clotting factor preparations at the end of each plasma exchange session, as required.

After the first few days, the major cause of morbidity and mortality is infection. Infection carries the added risk for potentiating glomerular and lung inflammation and injury, so precautions to reduce risk, such as minimizing indwelling cannulas, are important. If leukopenia less than 3.5×10^9/L or neutropenia develops, cyclophosphamide should be discontinued and resumed at a lower dose when the neutrophil count recovers, if necessary with the assistance of granulocyte colony-stimulating factor.

Monitoring Effect of Treatment on Disease Activity

The effect of treatment on the kidney disease is monitored by following serum creatinine values. Indicators of recent lung hemorrhage include hemoptysis, decreases in hemoglobin concentration, chest radiograph changes, and increases in the DLCO, with the last being the most sensitive. Any worsening of symptoms during treatment may indicate inadequate immunosuppression, but it is frequently a consequence of intercurrent infection exaggerating immunologic injury or fluid overload or other factors precipitating lung hemorrhage.

Monitoring of anti-GBM titers during, and particularly 24 hours after, the last planned plasma exchange treatment is useful for confirming effective suppression of autoantibodies. They should be undetectable within 8 weeks, but even without treatment, autoantibodies generally become undetectable by an average of 14 months.

Duration of Treatment and Relapses

Corticosteroid treatment may be gradually reduced and cyclophosphamide discontinued at 3 months. In contrast to treatment of small-vessel vasculitis, immunosuppression longer than this is usually not necessary. Longer treatment is appropriate for patients who are positive for both anti-GBM antibody and ANCA (see later discussion). Late increases in anti-GBM level may predict clinical relapse, although antibodies are generally permanently suppressed in patients who have completed the immunosuppressive regimen. If there is recurrence, success has been achieved by treating as at first presentation.

Electing Not to Treat

Advanced kidney failure, frequently already established at presentation, is generally not salvaged by any current treatment.[30,32,33] Furthermore, the immunosuppressive regimen outlined carries significant risks and careful monitoring is required. For these reasons, it may be reasonable not to initiate immunosuppression in patients who present with advanced kidney failure without lung hemorrhage. The decision not to treat is strengthened if the kidney biopsy specimen shows widespread glomerulosclerosis and tubular loss and the patient is dialysis dependent at presentation (see Table 25.3). The risk for development of late lung hemorrhage in these patients seems to be low but warrants particular care to avoid the major precipitating factors, smoking and pulmonary edema, in at least the first few months. However, patients who are dialysis dependent usually should be treated if the kidney histopathologic changes are unexpectedly mild or very recent (highly cellular crescents, even if 100% of glomeruli are involved, or acute tubular necrosis). Several reports describe good outcomes in these patients even after prolonged oliguria.

Treatment of Double-Positive Patients

Patients with both ANCA and anti-GBM antibodies may have other extrarenal disease requiring treatment (see Table 25.3). There is conflicting evidence as to whether their kidney prognosis is the same as or better than that of other patients with anti-GBM antibodies. Earlier series suggested a better prognosis, but this was not confirmed in two later reports.[13,14] Because of the risk for serious disease in other organs, double-positive patients should usually receive an immunosuppressive regimen similar to that given for small-vessel vasculitis, with continuing immunosuppression with azathioprine after 3 months of cyclophosphamide (see Chapter 26).

TRANSPLANTATION

Kidney transplantation in patients who have had Goodpasture disease carries the additional risk for disease recurrence. Recurrence with consequent loss of the graft has been reported and appears more likely when circulating anti-GBM antibodies are still detectable at transplantation. Therefore, it is reasonable to delay transplantation until circulating anti-GBM antibodies have been undetectable for 6 months and to monitor graft function, urinary sediment, and circulating anti-GBM antibody levels to detect recurrent disease (see Chapter 113). Biopsy samples of well-functioning grafts sometimes show linear deposition of Ig on the GBM without clinical or histologic disease or apparently an adverse prognosis.

ALPORT SYNDROME POSTTRANSPLANT ANTI–GLOMERULAR BASEMENT MEMBRANE DISEASE

Patients with Alport syndrome have mutations in a gene encoding one of the tissue-specific type IV collagen chains, usually α5. Because these chains assemble with each other during biosynthesis, the resulting phenotype in the case of most mutations often has all the tissue-specific chains (α3–α5) missing from the basement membranes, where they are normally coexpressed. Altered expression may lead to absent or inadequate immunologic tolerance to these proteins and to preservation of the capacity to mount a powerful (allo)immune response to the type IV collagen chains expressed in a normal donor kidney after kidney transplantation. Most patients with Alport syndrome accommodate kidney transplants with conventional immunosuppression without development of anti-GBM nephritis. However, development of low titers of anti-GBM antibodies is shown by many such patients having linear deposition of IgG on the GBM of the transplanted kidney on direct IF, without disease. This alone does not justify treatment.

Up to 2% of patients with Alport syndrome have been reported to develop RPGN in the transplanted kidney, although anecdotally this is much less common than historically. It is clinically indistinguishable from spontaneous anti-GBM disease but without lung hemorrhage. This is more likely if the patient has a large gene deletion causing the disease rather than a point mutation, with the inference that the immune system has never been exposed to the mature protein. Typically, graft function is lost despite treatment for presumed acute rejection. Disease is usually encountered some months or longer after a first kidney transplant, after weeks in a second, and after days in a third.[32] However, regrafting has been successful in two cases known to us and in two further cases in the literature. If the disease is recognized early, there are sound theoretical reasons for treating with the regimen recommended for Goodpasture disease, but there are few data on its effectiveness.[34]

In contrast to spontaneous Goodpasture disease, the specificity of anti-GBM antibodies in Alport syndrome posttransplant anti-GBM disease is not always to α3(IV)NC1. In many patients, possibly in most, the autoantibodies are specific for α5(IV)NC1, encoded by the *COL4A5* gene usually implicated in causation of the disease.[35] This is important because immunoassays for anti-GBM antibodies are optimized for detection of the anti-α3(IV)NC1 antibodies of spontaneous Goodpasture disease, and they may have low sensitivity for anti-α5(IV)NC1 antibodies. In the absence of widely available assays for these uncommon antibodies, kidney biopsy with immunohistology is the only reliable method of diagnosis.

SELF-ASSESSMENT QUESTIONS

1. A 65-year-old man presenting with acute kidney failure and pulmonary hemorrhage was diagnosed after appropriate investigation as having Goodpasture disease and was treated with plasma exchange (10 × 4 L over 2 weeks), oral cyclophosphamide (150 mg/day), and prednisolone (week 1: 60 mg/day; week 2: 45 mg/day; week 3: 30 mg/day; week 4: 25 mg/day; week 5: 20 mg/day; week 6: 15 mg/day; weeks 7–8: 20 mg alternate days). Cyclophosphamide (CYP) had to be omitted for 5 days, then restarted at 100 mg/day in week 4 because of neutropenia. At review 3 months after treatment commenced, the patient is entirely well with estimated glomerular filtration rate of 36 mL/min, hemoglobin of 110 g/L, and white blood cell count of 2.4×10^3 per μL. Anti-GBM antibodies remain detectable just above the reporting threshold of the local assay. How should his immunosuppression be managed?
   - **A.** Replace CYP with azathioprine or MMF and maintain with steroids to at least 1 year.
   - **B.** Discontinue CYP and steroids with close outpatient monitoring.
   - **C.** Continue CYP at a reduced dose with prednisolone (10 mg/day) or equivalent to at least 1 year.
   - **D.** Reinstitute plasmapheresis.
2. A 45-year-old nonsmoking executive collapses at a meeting and in the emergency department is found to have a serum creatinine of 1800 μmol/L, hemoglobin of 90 g/L, potassium of 7.2 mmol/L, blood pressure (BP) 165/92 mm Hg, and normal-sized unobstructed kidneys on ultrasound scan. After appropriate acute dialysis and BP control, a kidney biopsy sample is taken, which shows severe crescentic GN affecting 32/32 sampled glomeruli. On silver staining, breaks could be seen in multiple capillary loops and in Bowman's capsule of most glomeruli. Linear deposition of IgG along the residual GBM and strong positivity for serum anti-GBM antibodies establishes a diagnosis of Goodpasture disease. ANCA testing is negative, and there is no evidence of lung hemorrhage. What treatment would you recommend for this patient with Goodpasture disease?
   - **A.** Plasma exchange, CYP, and oral prednisolone for at least 3 months
   - **B.** Plasma exchange, CYP, and oral prednisolone with plan for early discontinuation in the event of continuing dependence on dialysis
   - **C.** Close monitoring with a goal of avoiding immunosuppression
   - **D.** CYP and oral prednisolone for at least 3 months
3. A 26-year-old man has a deceased donor renal transplant after 10 months on hemodialysis. His kidney failure is of unknown cause. Eight months posttransplant, kidney function is found to have deteriorated dramatically, with creatinine rising from 130 to 800 μmol/L at routine clinic visits 3 weeks apart. A biopsy shows 100% crescentic nephritis with strong linear binding of IgG to the GBM. Serum anti-GBM titers are negative. The most likely diagnosis is:
   - **A.** Anti-GBM (Goodpasture) disease
   - **B.** Alport anti-GBM disease
   - **C.** Antibody-mediated rejection
   - **D.** Polyomavirus infection

Renal and Systemic Vasculitis

Meghan Free, J. Charles Jennette, Ronald J. Falk, Koyal Jain

DEFINITION

The large number and variety of kidney vessels make the kidneys targets for a variety of systemic vasculitides, especially those affecting small vessels.[1–4] Vasculitis involving the kidneys produces a variety of clinical manifestations, depending on the type of kidney vessel affected. Vasculitides are categorized as large-, medium-, and small-vessel vasculitis (Figs. 26.1 and 26.2). The 2012 Chapel Hill Consensus Conference definitions are used throughout this chapter (Table 26.1).[4]

Several vasculitides in Fig. 26.2 are reviewed in other chapters and are discussed here only in the context of differential diagnosis. Nephrologists often encounter patients with small-vessel vasculitides because these frequently cause glomerulonephritis (GN). Therefore, small-vessel vasculitis (SVV) is the primary focus of this chapter.

Small-Vessel Vasculitis

SVV is necrotizing vasculitis affecting predominantly vessels that are smaller than arteries, including capillaries, venules, and arterioles; however, small arteries can be involved.[4] The most common renal target for SVV is glomerular capillaries and the most common kidney clinical manifestation is GN.

Medium-Vessel Vasculitis

Medium-vessel vasculitis is necrotizing arteritis affecting predominantly major visceral arteries.[4] In the kidneys, interlobar arteries and arcuate arteries are most affected, although any arteries from the main renal artery to the smallest interlobular arteries may be affected. Arterial inflammation and necrosis may result in thrombosis or rupture, causing kidney infarction and hemorrhage, respectively.

Large-Vessel Vasculitis

Large-vessel vasculitis is chronic granulomatous arteritis affecting the aorta and its major branches more often than other forms of vasculitis.[4] With kidney involvement, the ostia of the renal arteries and the main renal arteries are most often affected. The most common clinical kidney manifestation is renovascular hypertension.

SMALL-VESSEL PAUCI-IMMUNE VASCULITIS

SVV can be divided into *immune complex* SVV with moderate to marked vessel wall deposits of immunoglobulin and *pauci-immune* SVV with few or no immune deposits in vessel walls.[4] Pauci-immune SVV often is associated with circulating antineutrophil cytoplasmic autoantibodies (ANCAs).[1] The ANCA-associated vasculitides share an indistinguishable form of necrotizing SVV that affects capillaries, venules, arterioles, and small arteries.[1–5] Some patients with *ANCA-associated vasculitis* (AAV) have no evidence of arterial involvement, although they have involvement of glomerular capillaries, causing GN; pulmonary alveolar capillaries, causing pulmonary hemorrhage; or dermal venules, causing purpura. The clinicopathologic variants of pauci-immune SVV are categorized based on clinical, laboratory, and pathologic findings, as follows[4]:

- *Microscopic polyangiitis* (MPA) is pauci-immune SVV in the absence of evidence for necrotizing granulomatous inflammation.
- *Granulomatosis with polyangiitis* (GPA) is pauci-immune vasculitis associated with necrotizing granulomatous inflammation, most often affecting the respiratory tract.
- *Eosinophilic granulomatosis with polyangiitis* (EGPA; formerly called Churg-Strauss syndrome) is pauci-immune vasculitis associated with asthma, eosinophilia, and necrotizing granulomatous inflammation.

MPA, GPA, and, less frequently, EGPA share an indistinguishable pattern of GN that is expressed as vasculitis in glomerular capillaries.[1] In the acute phase, the GN usually has necrosis and crescents, an absence or paucity of immunoglobulin deposition, and is designated *pauci-immune crescentic glomerulonephritis.* In the absence of systemic vasculitis, pauci-immune crescentic GN is sometimes referred to as *renal-limited vasculitis.*

Pathogenesis

MPA, GPA, EGPA, and renal-limited pauci-immune crescentic GN are all associated with ANCAs.[4–6] The most common antigen targets of ANCAs are proteinase 3 (PR3) and myeloperoxidase (MPO).[7,8]

The association of ANCAs with this form of SVV suggests that ANCAs are involved in disease pathogenesis.[4–6] Correlation of ANCA titers with disease activity in some individuals suggests a pathogenic role; however, this correlation is not strong and some patients with clinically and pathologically typical MPA, GPA, or renal-limited pauci-immune crescentic GN are negative using conventional serologic ANCA testing. MPO-ANCA epitope specificity determines the pathogenicity, detectability, and clinical predictive value of circulating MPO-ANCA.[9] For example, ANCAs with certain epitope specificities occur only during active disease, whereas other MPO-ANCA epitope specificities occur regardless of disease status and in healthy controls (natural ANCAs), although at very low titers.[10,11] Some patients with AAV who are negative by conventional serologic testing have MPO-ANCA with restricted epitope specificity that can be detected with unmasking techniques.[10]

The pathogenic potential of ANCAs is supported by the observation that certain drugs, such as propylthiouracil, hydralazine, and penicillamine, can induce AAV.[12] Cocaine adulterated with levamisole can induce AAV with high titer MPO-ANCA, PR3-ANCA, and ANCA specific for elastase.[12] Levamisole-induced vasculitis has frequent cutaneous leukocytoclastic angiitis and upper respiratory tract involvement but rarely kidney or lung involvement.

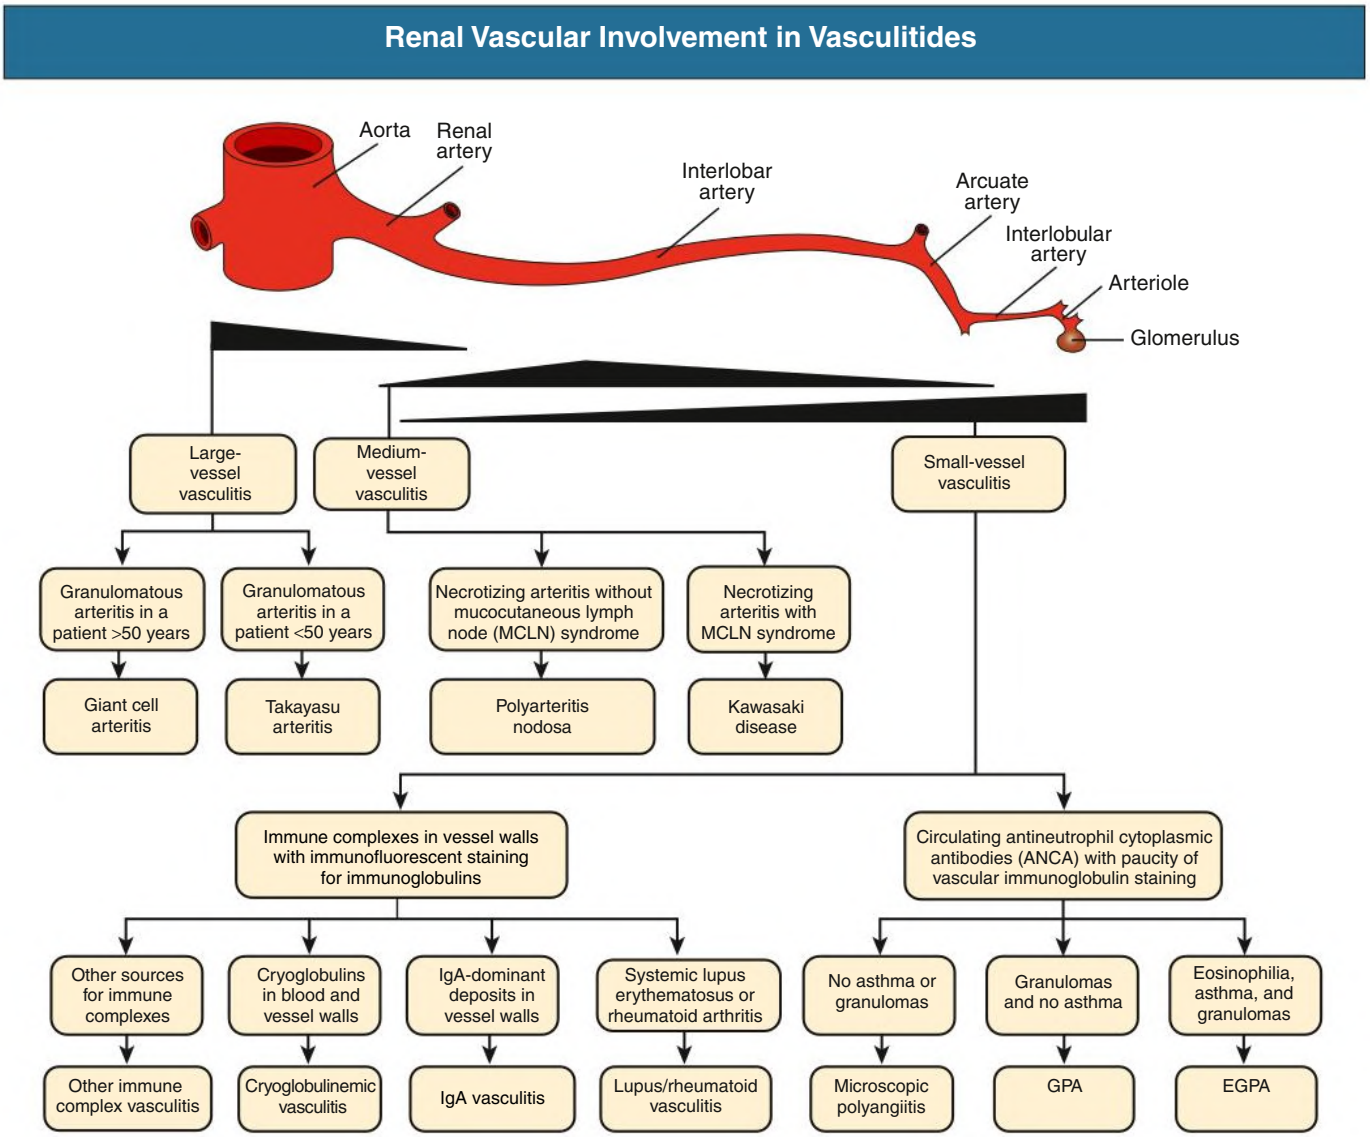

Fig. 26.1 Renal Vasculitis. Predominant distribution of kidney vascular involvement by a variety of vasculitides. The heights of the trapezoids represent the relative frequency of involvement of different portions of the renal vasculature by the three major categories of vasculitis. *EGPA,* Eosinophilic granulomatous polyangiitis; *IgA,* immunoglobulin A.

In vitro observations suggest mechanisms by which ANCAs cause vascular injury.[5,6] Cytokine priming causes neutrophils to increase expression of ANCA antigens on their surfaces where ANCAs can bind. Cytokine-primed neutrophils activated by ANCAs release lytic enzymes from granules, generate toxic oxygen metabolites, and kill cultured endothelial cells. ANCA-antigen complexes adsorb onto endothelial cells where they could participate in in situ immune complex formation. ANCA activation of neutrophils is mediated by $F(ab')_2$ binding to neutrophils and to a greater degree by FcR engagement. These events cause vasculitis as a result of neutrophils adhering to, penetrating, and destroying vessel walls (Fig. 26.3).

The ability of ANCA to cause pauci-immune necrotizing and crescentic GN and vasculitis is demonstrated in animal models induced with MPO-ANCA. No widely accepted model of PR3-ANCA disease has been developed because of differences in murine PR3 expression and limited homology between mice and humans.[6] Wild-type or immunodeficient mice intravenously (IV) injected with anti-MPO antibodies develop pauci-immune focal necrotizing crescentic GN.[13] A rat model of pauci-immune necrotizing crescentic GN developed by immunizing rats with human MPO developed antibodies that cross-react with rat MPO.[14] MPO-ANCA GN in mice is mediated by neutrophil activation, modulated by the FcγR repertoire, and is prevented by neutrophil depletion.[6,13] Alternative complement pathway activation plays a role in amplifying ANCA-induced inflammation.[15] ANCA-activated neutrophils release factors that activate the alternative complement pathway, resulting in C5a generation, which is chemotactic for neutrophils and primes for further activation by ANCAs.[16] Patients with active AAV (as defined by the Birmingham Vasculitis Activity Score [BVAS]) have increased plasma levels of C3a, C5a, soluble C5b-9, and Bb, and plasma levels of Bb correlated with percentage of cellular crescents in kidney biopsy samples and BVAS.[17] Further studies concluded that complement cascade activation differs with disease activity and serotype.[18]

Clinical and experimental data indicate that ANCAs can activate neutrophils and cause vasculitis, especially if there are synergistic proinflammatory stimuli. The synergistic neutrophil-priming

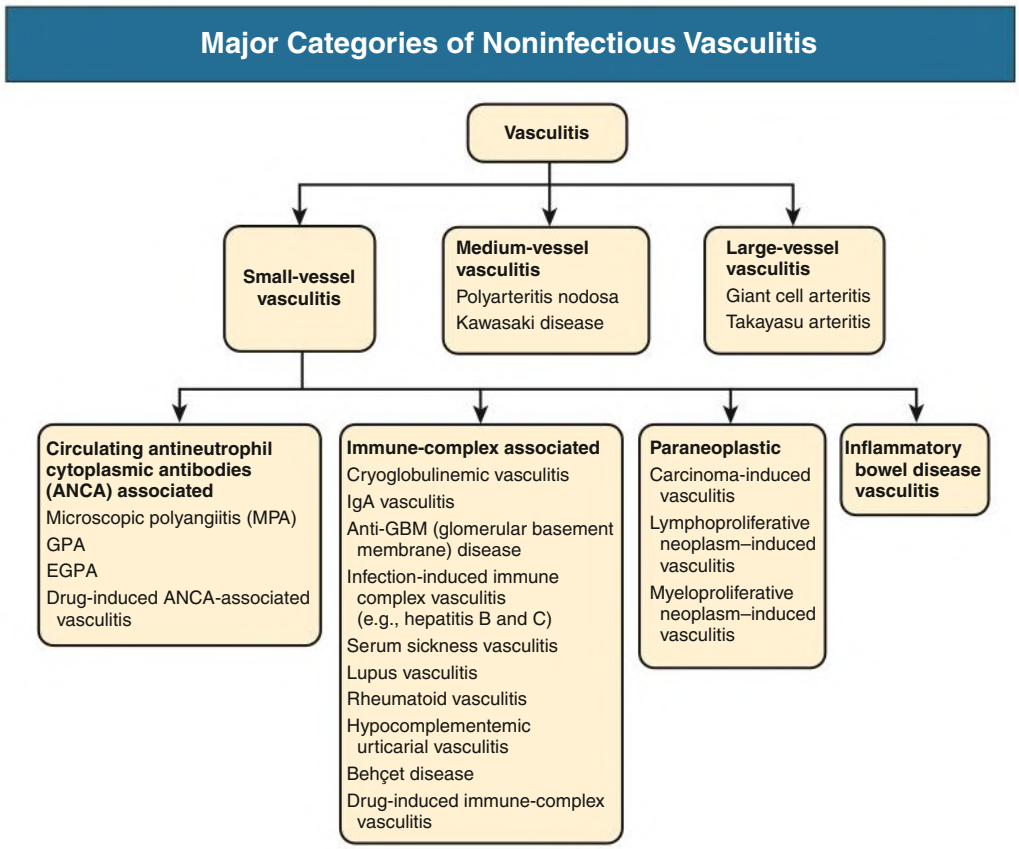

Fig. 26.2 Major Categories of Noninfectious Vasculitis. Not included are vasculitides that are known to be caused by direct invasion of vessel walls by infectious pathogens, such as rickettsial vasculitis and neisserial vasculitis. *EGPA,* Eosinophilic granulomatous polyangiitis; *GPA,* granulomatous polyangiitis.

inflammatory process may be reflected in the frequent association of AAV onset with an influenza-like syndrome.[19]

Initiation of the ANCA autoimmune response is less understood but involves human leukocyte antigen (HLA) with specific molecular recognition capabilities.[20,21] Genome-wide association studies have identified associations between HLA alleles and AAV (HLA-DP for PR3-ANCA and HLA-DQ for MPO-ANCA).[20–22] Because certain HLA have a greater predilection for binding autoantigenic peptides, it is logical that HLA associated with AAV has a higher propensity to bind MPO or PR3 peptides. Within the MPO-ANCA serotype, a small number of MPO peptides bind specific HLA, and T cells react to these same peptides.[11] These autoreactive T cells are capable of shaping the B-cell response, leading to ANCA production.

Epidemiology

GPA, MPA, and EGPA occur at any age but usually begin during the fifth through seventh decades of life, with a peak incidence of 65 to 75 years. There is a slight male predominance. AAV has geographic and race/ethnicity differences in prevalence.[23] In the United Kingdom, GPA (148 per 1 million) is more common than MPA (65 per million), and MPA is more common than EGPA (46 per 1 million). In France, AAV prevalence is twice as high in Europeans (105 per 1 million) compared with non-Europeans (53 per million). In the United States, the incidence is disproportionately greater in Whites than in Blacks, which may be caused by HLA differences.[24]

In the United Kingdom and northern Europe, PR3-ANCA (usually associated with GPA) is more common than MPO-ANCA; however, in Southern Europe, Asia, and India, MPO-ANCA and MPA are more common.[23] In the United States, there is a similar trend with more PR3-ANCA and GPA in northern states and more MPO-ANCA and MPA in southern states. Geographic and racial differences may be related to HLA differences.[20,21]

Clinical Manifestations

Generalized nonspecific manifestations of systemic inflammatory disease (fever, malaise, anorexia, weight loss, myalgias, and arthralgias) often are present. Many patients trace the onset of their vasculitic disease to a flu-like illness.[19]

Clinical manifestations of GPA, MPA, and EGPA are extremely varied because they are influenced by the organs affected. The three categories of vasculitis share features caused by SVV, and patients with GPA and EGPA have additional defining features.[4,25,26]

Kidney involvement occurs often in GPA and MPA and is uncommon in EGPA (Table 26.2). Most common kidney manifestations are hematuria, proteinuria, and kidney failure. Kidney failure often has the characteristics of rapidly progressive glomerulonephritis (RPGN) in GPA and MPA but is less severe in EGPA. A cohort of more than 300 patients with pauci-immune crescentic GN evaluated at kidney biopsy had a mean age of 56 years (range, 2–92 years), male-to-female ratio of 1.0:0.9, mean serum creatinine concentration of 6.5 mg/dL (range, 0.8–22.1 mg/dL; 69–1900 μmol/L), and proteinuria of 1.9 g/day (range, 0.1–18g/day).[27]

TABLE 26.1 Names and Definitions of Vasculitis

Category/Name	Definition
Large-Vessel Vasculitis	
Takayasu arteritis	Arteritis, often granulomatous, predominantly affecting the aorta and/or its major branches. Onset usually in patients younger than 50 years.
Giant cell arteritis	Arteritis, often granulomatous, usually affecting the aorta and/or its major branches, with predilection for branches of carotid and vertebral arteries; often involves temporal artery. Onset usually in patients older than 50 years and often associated with polymyalgia rheumatica.
Medium-Vessel Vasculitis	
Polyarteritis nodosa	Necrotizing arteritis of medium or small arteries without GN or vasculitis in arterioles, capillaries, or venules and not associated with ANCA.
Kawasaki disease	Arteritis associated with mucocutaneous lymph node syndrome and predominantly affecting medium and small arteries; coronary arteries are often involved; aorta and large arteries may be involved. Usually occurs in infants and young children.
Small-Vessel Vasculitis	
ANCA-Associated Small-Vessel Vasculitis	
Necrotizing vasculitis, with few or no immune deposits, predominantly affecting small vessels (capillaries, venules, arterioles, small arteries), associated with MPO-ANCA or PR3-ANCA. Not all patients have ANCA. Add prefix indicating ANCA reactivity (e.g., PR3-ANCA, MPO-ANCA, ANCA-negative).	
Microscopic polyangiitis (MPA)	Necrotizing vasculitis, with few or no immune deposits, predominantly affecting small vessels (capillaries, venules, arterioles). Necrotizing arteritis involving small and medium arteries may be present. Necrotizing GN is common. Pulmonary capillaritis often occurs. Granulomatous inflammation is absent.
Granulomatosis with polyangiitis (GPA)	Necrotizing granulomatous inflammation usually involving upper and lower respiratory tract and necrotizing vasculitis affecting predominantly small to medium vessels (capillaries, venules, arterioles, arteries, veins). Necrotizing GN is common.
Eosinophilic granulomatosis with polyangiitis (EGPA)	Eosinophil-rich and necrotizing granulomatous inflammation often involving the respiratory tract, and necrotizing vasculitis predominantly affecting small to medium vessels and associated with asthma and eosinophilia. ANCA is more common when GN is present.
Immune Complex Small-Vessel Vasculitis	
Vasculitis with moderate to marked vessel wall deposits of immunoglobulin and/or complement components predominantly affecting small vessels (capillaries, venules, arterioles, small arteries). GN is common.	
Anti–glomerular basement membrane (anti-GBM) disease	Vasculitis affecting glomerular capillaries, pulmonary capillaries, or both, with basement membrane deposition of anti–basement membrane autoantibodies. Lung involvement causes pulmonary hemorrhage, and renal involvement causes GN with necrosis and crescents.
Cryoglobulinemic vasculitis	Vasculitis with cryoglobulin immune deposits affecting small vessels (predominantly capillaries, venules, or arterioles) and associated with cryoglobulins in serum. Skin, glomeruli, and peripheral nerves are often involved.
IgA vasculitis (IgAV)	Vasculitis with IgA1-dominant immune deposits affecting small vessels (predominantly capillaries, venules, or arterioles). Often involves skin and gastrointestinal tract and frequently causes arthritis. GN indistinguishable from IgA nephropathy may occur.
Hypocomplementemic urticarial vasculitis (anti-C1q vasculitis)	Vasculitis accompanied by urticaria and hypocomplementemia affecting small vessels (capillaries, venules, arterioles) and associated with anti-C1q antibodies. GN, arthritis, obstructive pulmonary disease, and ocular inflammation are common.

Adopted by the 2012 Chapel Hill consensus conference on the nomenclature of systemic vasculitis. Note that all three categories affect arteries, but only small-vessel vasculitis has a predilection for vessels smaller than arteries.
ANCA, Antineutrophil cytoplasmic antibody; *GN,* glomerulonephritis; *IgA,* immunoglobulin A.
Modified from Charles P, Terrier B, Perrodeau E, et al. Comparison of individually tailored versus fixed-schedule rituximab regimen to maintain ANCA-associated vasculitis remission: Results of a multicentre, randomised controlled, phase III trial (MAINRITSAN2). *Ann Rheum Dis.* 2018;77:1143–1149.

Cutaneous involvement, manifesting as purpura, occurs frequently in all types of SVV (Fig. 26.4). Purpura is most common on the lower extremities, tends to occur as recurrent crops, and may be accompanied by areas of ulceration. Nodular cutaneous lesions are more frequent in GPA and EGPA than MPA. Nodules can be caused by dermal or subcutaneous arteritis and granulomatous inflammation.

Upper respiratory tract involvement is most common in GPA and EGPA but also occurs in MPA.[28] In all three categories, patients can have pulmonary hemorrhage caused by alveolar capillaritis. Patients with GPA, and to a lesser extent EGPA, can have pulmonary injury caused by necrotizing granulomatous inflammation, which may be detected radiographically as nodular or cavitating lesions. By definition, patients with MPA do not have granulomatous respiratory tract lesions.[4]

Manifestations of upper respiratory tract disease include subglottic stenosis, sinusitis, rhinitis, nasal septal collapse, otitis media, and ocular inflammation. The upper respiratory inflammation in MPA is caused by angiitis alone, without granulomatous inflammation. Destruction of bone, resulting in septal perforation and saddle nose, results from necrotizing granulomatous inflammation and does not occur in MPA.

Cardiac disease is identified in approximately 50% of patients with EGPA (usually myocarditis) but in less than 20% of patients with GPA or MPA. Cardiac manifestations in GPA and MPA are predominantly transient heart block and ventricular hypokinesis that respond to immunosuppressive treatment, although infarction, endocarditis, pericarditis, and severe life-threatening myocarditis may occur.

TABLE 26.2 Organ System Involvement in Small-Vessel Vasculitis

	FREQUENCY OF INVOLVEMENT (%)				
Organ System	Microscopic Polyangiitis	GPA	EGPA	IgA Vasculitis	Cryoglobulinemic Vasculitis
Kidney	90	80	20	50	55
Skin/cutaneous	40	40	40	90	90
Lungs	50	90	90	<5	<5
Ear, nose, throat	35	90	70	<5	<5
Musculoskeletal	60	60	50	75	70
Neurologic	30	50	40	10	40
Gastrointestinal	50	50	40	60	30

EGPA, Eosinophilic granulomatosis with polyangiitis; *GPA,* granulomatosis with polyangiitis; *IgA,* immunoglobulin A.

Peripheral neuropathy, usually mononeuritis multiplex, is the most common neurologic manifestation. Central nervous system involvement is less common, most often resulting from vasculitis within the meninges. Gastrointestinal (GI) involvement typically causes abdominal pain and hematochezia, with mesenteric ischemia and rarely intestinal perforation. Vasculitis in the pancreas and liver can mimic pancreatitis and hepatitis symptomatically and cause elevated serum pancreatic and liver enzymes.

Antineutrophil Cytoplasmic Autoantibody

Serologic testing for ANCAs is useful for diagnosing SVV and pauci-immune crescentic GN but should be interpreted in the context of patient characteristics and performance qualities of the assay.[29–32] Antigen specificity of ANCA for PR3 versus MPO is helpful for diagnosis and has predictive value in clinical course and outcome.[8,32] Laboratory testing for ANCA should include indirect immunofluorescence microscopy assay (IFA) and enzyme immunoassay (EIA).[31] IFA using normal human neutrophils as substrate produces two major staining patterns (Fig. 26.5): cytoplasmic (c-ANCA), and perinuclear (p-ANCA). By EIA, most c-ANCAs have specificity for proteinase 3 (PR3-ANCA) and most p-ANCAs have specificity for myeloperoxidase (MPO-ANCA). For diagnostic accuracy, serologic testing for ANCAs should include an immunochemical analysis for antigen specificity, such as an EIA.[7,31,32] High-quality EIA can be used alone as a screening test for AAV.[32] Although positive results are rare in healthy individuals, one-fourth of patients with other inflammatory kidney diseases

Fig. 26.4 Cutaneous Vasculitis. Ankle of a patient with small-vessel vasculitis, showing purpura and a few small ulcers.

TABLE 26.3 Antineutrophil Cytoplasmic Antibody in Small-Vessel Vasculitis

	FREQUENCY (%)		
Disorder	Proteinase 3 (PR3, Usually c-ANCA)	Myeloperoxidase (MPO, Usually p-ANCA)	Negative
Granulomatosis with polyangiitis	70	25	5
Microscopic polyangiitis	40	50	10
Eosinophilic granulomatosis with polyangiitis	5	40	55
Renal-limited pauci-immune crescentic GN	20	70	10

Approximate frequency of antibody in small-vessel vasculitis (ANCA) with specificity for proteinase 3 (PR3/c-ANCA) and for myeloperoxidase (MPO/p-ANCA) in patients with different categories of pauci-immune small-vessel vasculitis and crescentic glomerulonephritis.
GN, Glomerulonephritis.

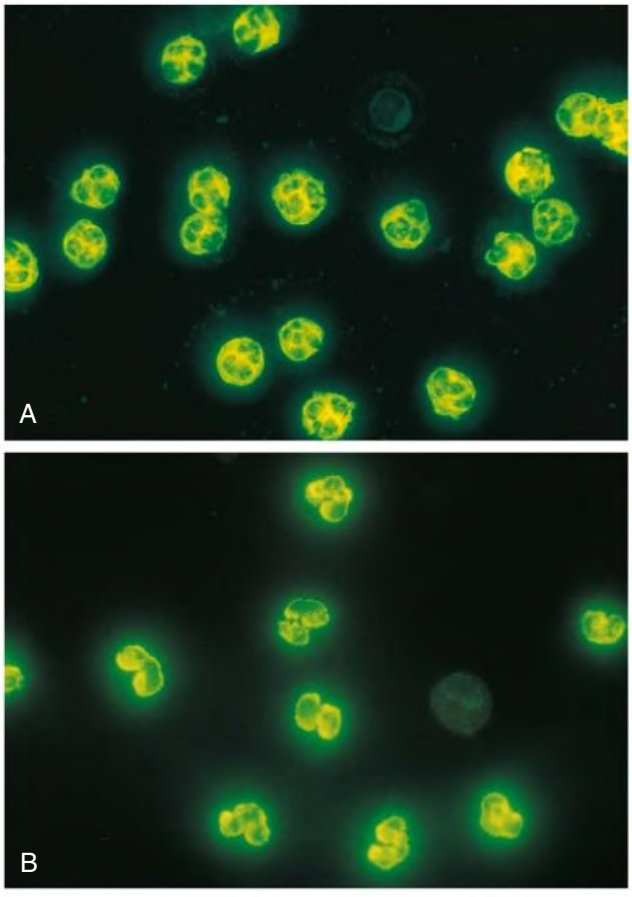

Fig. 26.5 Antineutrophil Cytoplasmic Antibodies (ANCAs). Indirect immunofluorescence staining pattern of alcohol-fixed normal human neutrophils. (A) Cytoplasmic pattern caused by ANCAs with specificity for proteinase 3. (B) Perinuclear pattern caused by ANCAs with specificity for myeloperoxidase (anti–immunoglobulin G). (Original magnification, ×250.)

(especially lupus) have a false-positive IFA result (usually p-ANCA) and approximately 5% have a false-positive EIA result (usually low titer).[31]

ANCA testing has good sensitivity for AAV (80%–90%). The specificity and predictive value depend on the patient population and the assay quality.[7] Although ANCAs are most frequent in patients with pauci-immune crescentic GN, one-fourth to one-third of patients with anti–glomerular basement membrane (GBM) crescentic GN and one-fourth of those with idiopathic immune complex crescentic GN with 50% or more crescents are ANCA-positive.[27,33] Some patients have well-recognized types of immune complex GN complicated by ANCAs, such as membranous nephropathy and IgA nephropathy; others have non-lupus IgG-dominant immune complex disease that cannot be categorized further. Patients with concurrent ANCAs and anti-GBM antibodies have a worse prognosis than patients with ANCAs alone. This is complicated by antiperoxidasin antibodies in some patients with anti-GBM exhibiting pulmonary-renal syndrome.[34] Peroxidasin and MPO have antigenic overlap, which may be implicated in the autoimmune process. Anti-GBM antibodies typically disappear after treatment without recurrence, whereas ANCAs and associated vasculitis may recur.

Table 26.3 estimates the relative frequencies of PR3-ANCA/c-ANCA and MPO-ANCA/p-ANCA in the different clinical phenotypes of AAV, although this has geographic and racial influences.[5,23] PR3-ANCA/c-ANCA are most prevalent in GPA, and MPO-ANCA/p-ANCA are most prevalent in renal-limited pauci-immune crescentic GN and EGPA. Patients with MPA have a more equal distribution of PR3-ANCA/c-ANCA and MPO-ANCA/p-ANCA, although this varies geographically.[23] Patients with EGPA have the lowest overall frequency of ANCAs, but the frequency of ANCAs is much higher in EGPA patients with GN (75%) than in those without GN (26%).[35] ANCA specificity correlates with clinical symptoms, with PR3-ANCA having the highest frequency (~90% when ANCA present) in patients who have destructive upper respiratory tract disease, especially saddle nose.[28]

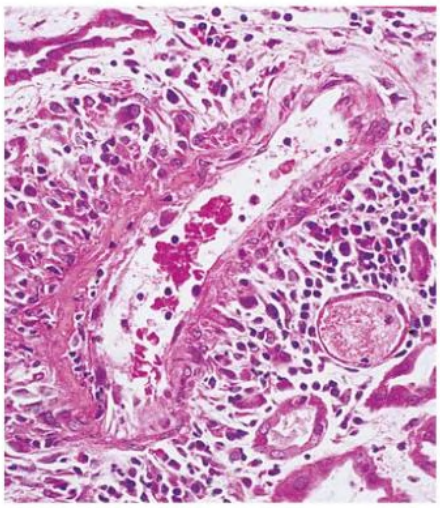

Fig. 26.6 Necrotizing Arteritis of Interlobular Artery in Patient with Antineutrophil Cytoplasmic Antibody–Associated Small-Vessel Vasculitis. There is segmental fibrinoid necrosis with adjacent perivascular leukocyte infiltration. (H&E, ×50.)

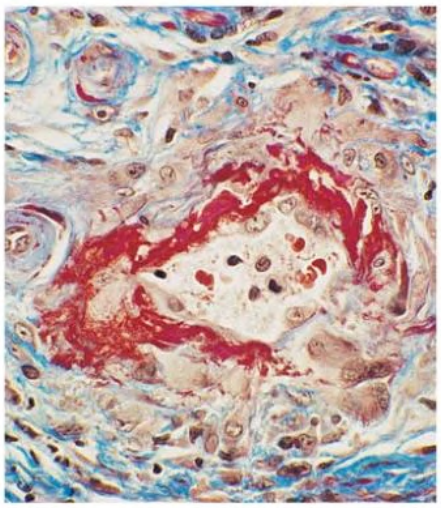

Fig. 26.7 Necrotizing Arteritis of Interlobular Artery in Patient with Antineutrophil Cytoplasmic Antibody–Associated Small-Vessel Vasculitis. The fibrinoid necrosis is indicated by the red staining. (Masson trichrome, ×100.)

Changes in ANCA titers over time may correlate with disease activity but are not dependable and must be interpreted with caution.[7,31,32,36] Titers generally decrease with treatment and increase before or at disease recurrence. Increased ANCA titers should prompt careful patient evaluation for corroborating evidence of exacerbation, but most physicians do not modify treatment based on increased titer without accompanying clinical signs. Epitope-specific assays may provide better correlation with and prediction of disease outcome.[10] MPO-ANCAs with certain epitope specificities occur only in patients with active disease, disappear with remission, and reappear during relapse.[10]

From 10% to 20% of patients with pauci-immune necrotizing and crescentic GN and SVV are ANCA negative. The clinicopathologic and outcome characteristics of these patients are indistinguishable from ANCA-positive patients.[37] In the epitope-specific assays previously mentioned, some patients with AAV who are negative by clinical assays have MPO-ANCA with restricted epitope specificity that can be detected with sensitive assays.[10]

ANCAs may be positive but not associated with vasculitis in inflammatory conditions other than vasculitis, including inflammatory bowel disease (IBD), rheumatoid disease, chronic inflammatory liver disease, bacterial endocarditis, and cystic fibrosis. In IBD, specificity of the ANCAs usually is not against PR3 or MPO but against other neutrophil antigens, including lactoferrin, cathepsin G, and anti–bactericidal/permeability-increasing protein (BPI).[31,32]

Pathology

The acute vascular lesion of pauci-immune SVV is segmental fibrinoid necrosis, often accompanied by leukocyte infiltration and leukocytoclasia[1,38–40] (Figs. 26.6 and 26.7). The earliest vasculitic lesions have infiltrating neutrophils quickly replaced by predominantly mononuclear leukocytes. The acute necrotizing lesions evolve into sclerotic lesions and may be complicated by thrombosis.

These focal necrotizing lesions can affect many different vessels, producing varied signs and symptoms. For example, involvement of glomerular capillaries causes nephritis; of alveolar capillaries, pulmonary hemorrhage; of dermal venules, purpura; of upper respiratory tract mucosal venules, rhinitis and sinusitis; of abdominal visceral arteries, abdominal pain; and of epineural arteries, mononeuritis multiplex.

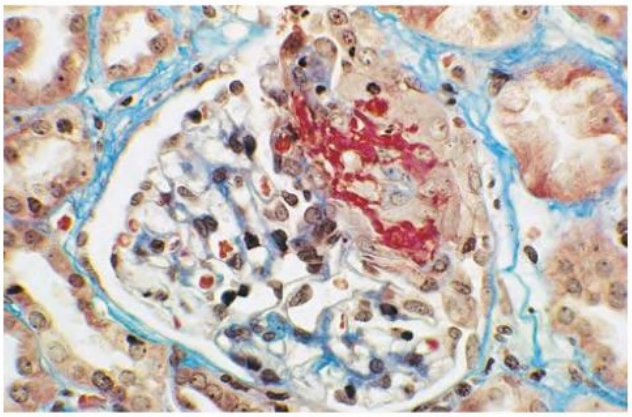

Fig. 26.8 Segmental Glomerular Necrosis and Crescent Formation in Patient with Antineutrophil Cytoplasmic Antibody–Associated Small-Vessel Vasculitis. The fibrinoid material is *red*. The uninvolved segments appear normal. (Masson trichrome, ×150.)

Pauci-immune SVVs present as necrotizing GN, usually with resultant crescent formation.[1,38–40] Early mild lesions have segmental fibrinoid necrosis with or without adjacent small crescent (Fig. 26.8). Severe acute lesions may have global necrosis with large circumferential crescents (Fig. 26.9). In a cohort of 181 kidney biopsy specimens from patients with ANCA-associated GN, 90% had glomerular crescents affecting 50% of glomeruli, with half having crescents in more than 50% of glomeruli.[27] Nonnecrotic segments within segmentally injured glomeruli (see Fig. 26.8) and glomeruli without necrosis have slight or no histologic abnormalities.

Approximately one-fourth of patients with anti-GBM crescentic GN and one-fourth of patients with immune complex–mediated crescentic GN are ANCA positive,[27] but less than 5% of patients with immune complex GN who do not have crescents are ANCA positive. Even in patients with immune complex GN, the presence of ANCAs is associated with an increased incidence of crescents (and inflammation in vessels other than glomerular capillaries). A histopathologic classification has been proposed for AAV GN: sclerotic class (≥50% globally sclerotic glomeruli), focal class (≥50% normal glomeruli), crescentic class (≥50% of glomeruli with cellular crescents), or mixed class if

none of these features predominated.[40] Kidney survival at 5 years was 93% for the focal class, 76% for crescentic class, 61% for mixed class, and 50% for sclerotic class.

In addition to GN, patients with AAV may have renal arteritis, most often affecting interlobular arteries (see Figs. 26.6 and 26.7), and medullary angiitis affecting the vasa recta (Fig. 26.10). Medullary angiitis rarely causes papillary necrosis.

Patients with GPA and EGPA have pathologic lesions in addition to necrotizing SVV.[1,3,4] The necrotizing granulomatous inflammation of GPA occurs most often in the respiratory tract, characterized by necrotic zones surrounded by infiltrates of neutrophils, lymphocytes, monocytes, and macrophages, including scattered multinucleated giant cells. In patients with GPA and EGPA, extravascular granulomatous inflammation is rare in kidney biopsy specimens. Varying numbers of eosinophils may be present in the lesions of GPA, but these are more conspicuous in the necrotizing granulomatous inflammation of EGPA. Eosinophils are typically conspicuous in the vasculitic lesions of EGPA, but this is not a pathognomonic observation because eosinophils may be present in the vasculitic lesions of GPA, MPA, polyarteritis nodosa (PAN), and other vasculitides.

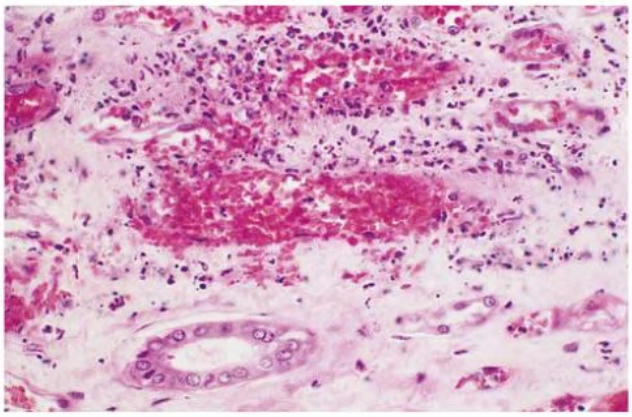

Fig. 26.10 Medullary leukocytoclastic angiitis involving vasa recta in a patient with granulomatosis with polyangiitis. (H&E, ×150.)

Differential Diagnosis

AAV must be differentiated from other forms of SVV that can produce similar signs and symptoms.[1,3,4] An attempt should be made to distinguish MPA, GPA, and EGPA, although in some patients this cannot be accomplished conclusively and is not required for initiation of therapy. Patients should be categorized as MPO-ANCA, PR3-ANCA, or ANCA-negative because serotype has independent predictive value about clinical course and outcome.[5,8,28] Pathologic confirmation of the granulomatous inflammation in ANCA disease is difficult because biopsy specimens often show nonspecific acute and chronic inflammation and necrosis. Findings such as nodular or cavitating lung lesions observed radiographically or destructive bone lesions in the nasal septum often are markers of necrotizing granulomatous inflammation to categorize patients. Because of treatment toxicity, even in patients with substantial clinical and serologic evidence of ANCA disease, pathologic confirmation of vasculitis is warranted. This can be accomplished with biopsy of different involved sites, including skin, muscle, nerve, gut, and kidney. In patients with substantial kidney involvement, kidney biopsy findings can be useful for predicting treatment response and clinical outcome.[38–40]

All forms of SVV in Fig. 26.2 are capable of producing clinically indistinguishable overlapping features of disease, such as nephritis, purpura, peripheral neuropathy, myalgias, arthralgias, and abdominal pain. Table 26.4 lists features that help distinguish categories of SVV.[3] Accurate differentiation is important for proper patient management because the natural histories and treatments vary greatly. For example, a patient with nephritis, arthralgias, and abdominal pain could have IgA vasculitis (IgAV, formerly Henoch-Schönlein purpura), MPA, cryoglobulinemic vasculitis, or several other small-vessel vasculitides. Serologic and pathologic observations are useful for reaching the correct diagnosis (see Table 26.4). A positive ANCA assay (confirmed by EIA to be MPO- or PR3-ANCA) supports a diagnosis of MPA or one of the other pauci-immune SVV. A negative ANCA assay and positive

TABLE 26.4 Differential Diagnostic Features of Select Forms of Small-Vessel Vasculitis

Features	Microscopic Polyangiitis	GPA	EGPA	IgA Vasculitis	Cryoglobulinemic Vasculitis
Vasculitic signs and symptoms[a]	+	+	+	+	+
IgA-dominant immune deposits	–	–	–	+	–
Cryoglobulins in blood and vessels	–	–	–	–	+
ANCAs in blood	+	+	+	–	–
Necrotizing granulomas	–	+	+	–	–
Asthma and eosinophilia	–	–	+	–	–

[a]These vasculitides can manifest any of the shared features of small-vessel vasculitides, such as nephritis, purpura, abdominal pain, peripheral neuropathy, myalgias, and arthralgias. Each is distinguished by the presence and, just as important, by the absence of certain specific features.
ANCAs, Antineutrophil cytoplasmic antibodies; *EGPA,* eosinophilic granulomatosis with polyangiitis; *GPA,* granulomatosis with polyangiitis.
Modified from Jennette JC, Falk RJ. Small-vessel vasculitis. *N Engl J Med.* 1997;337:1512–1523.

cryoglobulin assay (especially accompanied by hypocomplementemia and positive hepatitis C serology) support a diagnosis of cryoglobulinemic vasculitis. A negative ANCA assay, negative cryoglobulin assay, and normal complement levels support a diagnosis of IgAV, especially in a patient younger than 21 years. Patient age influences the likelihood of a specific diagnosis, so approximately 80% of children younger than 10 years who have purpura, nephritis, and arthralgias will have IgAV, but approximately 80% of adults older than 60 years with the same symptoms will have an AAV. However, each disease can occur at any age.

Drug exposures that may provoke AAV must be considered, including penicillamine, hydralazine, propylthiouracil,[12] and cocaine adulterated with levamisole.[12] Cholesterol embolization can mimic the clinical features of SVV with lower extremity rash or livedo reticularis, but ANCA assay is negative. The differential diagnosis of lung hemorrhage and nephritis includes anti-GBM disease, alone or with ANCA disease.

Natural History

Before the advent of immunosuppressive therapy, patient survival in MPA and GPA was poor, with most dying in less than 1 year. With adequate immunosuppressive therapy, 5-year kidney and patient survival is 65% to 75%.[5,41,42] The success of long-term maintenance of kidney function is inversely correlated with the serum creatinine concentration when therapy begins, indicating the importance of early diagnosis and prompt therapeutic intervention. Patient survival increases with early treatment of pulmonary hemorrhage and sepsis and avoidance of overimmunosuppression leading to life-threatening infections. Adverse events from therapy, including infections, are the leading cause of death in the year after diagnosis.[41] Older age, higher serum creatinine at presentation, pulmonary hemorrhage, and dialysis-dependent kidney failure correlate with an overall poor outcome; however, dialysis-dependent kidney failure may resolve with aggressive early therapy. Respiratory tract disease and PR3-ANCA are predictors of higher relapse rates.[42] Pathologic features correlating with kidney outcome include histologically normal glomeruli, glomerular sclerosis, interstitial leukocyte infiltration, tubular necrosis, and tubular atrophy.[40] Increased histologically normal glomeruli or glomeruli with cellular crescents correlate with a better prognosis than higher proportions of globally sclerotic glomeruli, suggesting that active inflammatory lesions may be suppressed if not reversed by treatment, whereas chronic injury at initiation of treatment may be irreversible.

When severe GN is present, the kidney prognosis is similar for patients with MPA, GPA, or EGPA, and renal-limited pauci-immune crescentic GN. Kidney involvement is less common and usually less severe in patients with EGPA. Cardiac involvement is the most frequent cause of death in patients with EGPA but rarely causes mortality in MPA or GPA. GPA has a broad spectrum of clinical manifestations, from localized indolent disease to fulminant multisystem disease. Some patients have disease limited to the upper respiratory tract or the upper and lower respiratory tract. Limited disease may have a more benign natural history than systemic disease with substantial kidney involvement and may warrant less aggressive treatment.

Patients with MPO-ANCA have a slightly better kidney outcome than those with PR3-ANCA, although they have more kidney impairment and more chronic kidney pathologic changes at presentation. Patients with PR3-ANCA have more extrarenal organ manifestations (especially respiratory tract disease), more frequent relapse, and higher mortality than patients with MPO-ANCA. Regardless of the category of AAV, the best clinical predictor of kidney outcome is the glomerular filtration rate (GFR) at diagnosis.

Treatment

In patients with AAV affecting the kidneys, the goal is to avoid overtreating mild disease or undertreating severe disease. GN resulting in kidney impairment is an indication for immunosuppressive treatment in patients with GPA, MPA, EGPA, and renal-limited pauci-immune crescentic GN. Patients with AAV and concurrent immune complex disease should be treated similarly to patients with AAV alone. Patients with AAV and concurrent anti-GBM disease should be treated similarly to patients with anti-GBM disease alone. Treatment involves three phases: induction of remission, maintenance of remission, and treatment of relapse (Fig. 26.11).

Induction Therapy

Standard induction therapy for AAV combines corticosteroids with an immunomodulatory agent, usually cyclophosphamide or rituximab.[5,42–55] Combined corticosteroid and cyclophosphamide induces remission in approximately 75% of patients at 3 months and 90% at 6 months. Combined induction regimens vary with respect to agents, doses, route of administration, and duration. One approach begins with methylprednisolone 7 mg/kg/day IV for 3 days, followed by oral prednisone 1 mg/kg/day, tapering to an alternate-day regimen and discontinuing within 3 to 6 months.[44] Alternatively, corticosteroids can be administered as prednisolone 1 mg/kg/day tapered to 0.25 mg/kg/day by 3 months.[48] Most trials used an IV methylprednisolone dose of 1 to 3 g followed by oral prednisone 1 mg/kg/day (max 80 mg).

Early steroid withdrawal is possible using combination therapy; 49 patients were successfully induced with a short course of oral glucocorticoids (1–2 weeks) while receiving combination cyclophosphamide (3 months) and rituximab (2 doses) therapy.[56] The Plasma Exchange and Glucocorticoids in Severe ANCA-Associated Vasculitis (PEXIVAS) trial demonstrated noninferiority of reduced corticosteroid dosing (60% less exposure) compared with standard dosing in end-stage kidney disease (ESKD) and all-cause mortality.[57] Novel complement-based strategies are being evaluated to reduce cumulative corticosteroid exposure. In a phase II trial, avacopan (CCX168; selective C5a receptor inhibitor) was as effective as prednisone in patients with newly diagnosed or relapsing vasculitis.[58] The phase III Avacopan Development in Vasculitis to Obtain Corticosteroid Elimination and Therapeutic Efficacy (ADVOCATE) trial for safety and efficacy of avacopan compared with prednisone showed that 72.3% of patients achieved remission with avacopan compared with 70.1% with prednisone.[59,60] Other complement-based trials are underway with IFX-1, an anti-C5a antibody (NCT03712345, NCT03895801).

Because of the morbidity with long-term corticosteroid use, a reduced-dose corticosteroid regimen and discontinuation by 16 weeks in most patients is recommended. Utilization of cyclophosphamide or combination of cyclophosphamide and rituximab can help taper steroids faster.

Corticosteroid treatment is combined with oral cyclophosphamide 2 mg/kg/day or cyclophosphamide at 0.35 to 0.5 g/m^2 IV per month adjusted upward to 1 g/m^2, based on the leukocyte count after 2 weeks, with a target nadir of 3000 cells/mm^3. Oral cyclophosphamide dose can be reduced by 25 mg for patients older than 60 years. A comparison by the European Vasculitis Study Group (CYCLOPS trial) indicated that IV cyclophosphamide has similar remission rates as oral cyclophosphamide while reducing the total cyclophosphamide dose.[52]

The US Food and Drug Administration (FDA) and European Medicines Agency (EMA) approved rituximab for AAV induction therapy based on the results of two randomized controlled trials (RCTs), noting that rituximab-based cyclophosphamide-sparing strategies were comparable to traditional cyclophosphamide induction protocols.[50,51] The Rituximab for ANCA-Associated Vasculitis (RAVE) trial[51] noted no difference in remission off all therapy in 6

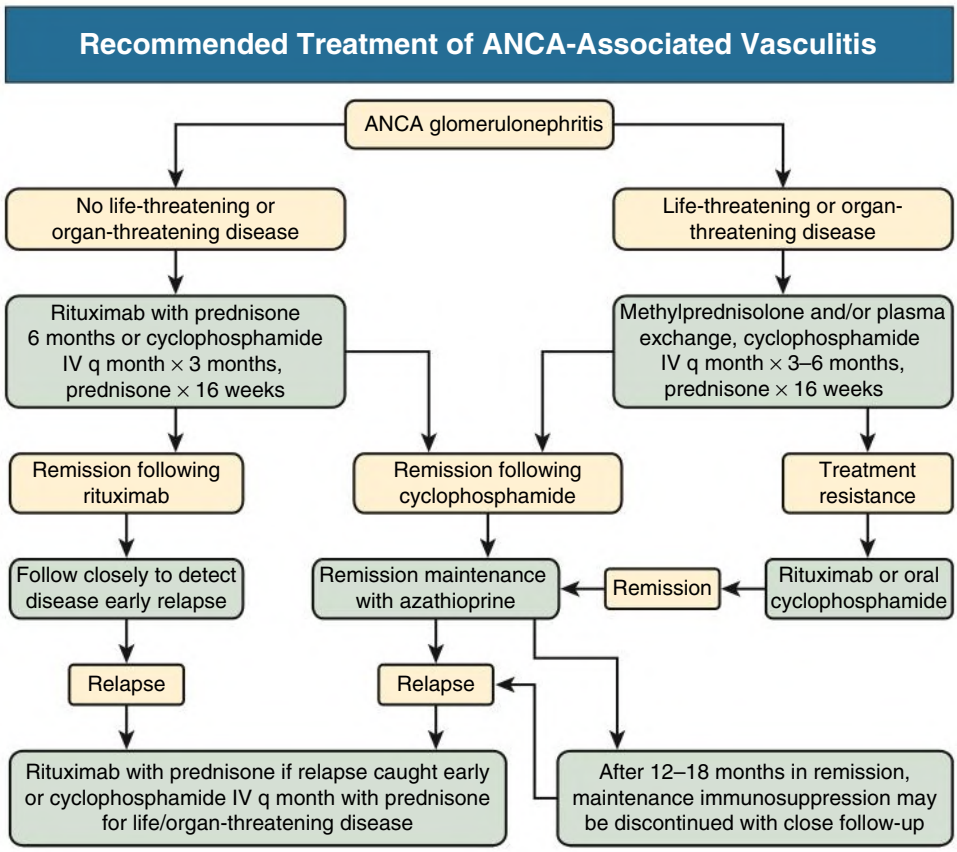

Fig. 26.11 Recommended treatment for antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis.

months between patients treated with prednisone and four infusions of 375 mg/m^2 rituximab versus oral cyclophosphamide (64% in rituximab arm, 55% in cyclophosphamide arm). The RITUXVAS trial[61,62] compared 6 to 10 infusions of cyclophosphamide followed by azathioprine to 4 infusions of 375 mg/m^2 rituximab in combination with 2 infusions of cyclophosphamide without maintenance therapy. There was no difference in remission rates at 12 months between the groups. In RAVE and RITUXVAS, there were no significant differences in adverse events between rituximab and cyclophosphamide. Compared with cyclophosphamide, rituximab is more effective in PR3-ANCA disease.[63] Our approach uses two 1-g doses 14 days apart.

Combination of cyclophosphamide-rituximab allows a rapid steroid taper and reduces mortality, relapses, and ESKD compared with propensity-matched patients from European Vasculitis Study Group (EUVAS) trials.[64] We recommend combination IV cyclophosphamide-rituximab in patients with severe kidney or pulmonary involvement to decrease cumulative cyclophosphamide exposure.

Plasma exchange (PLEX) has come under much scrutiny. Prior studies showed benefit in patients with life-threatening pulmonary hemorrhage[53] and patients who have dialysis-dependent kidney failure at presentation.[54] With pulmonary hemorrhage, 20 of 20 patients treated with early PLEX had resolution of pulmonary bleeding compared with a 50% mortality in historical controls.[53] A EUVAS trial (MEPEX) evaluated the efficacy of IV methylprednisolone as induction therapy or PLEX in patients who had a serum creatinine of more than 500 µmol/L.[54] Patient survival and adverse events were similar in patients who did or did not receive PLEX. PLEX was associated with a 24% reduced risk for progression to ESKD, from 43% to 19% at 1 year.[54] Conversely, the PEXIVAS trial noted no reduction in mortality or ESKD with the use of PLEX in patients with severe AAV. The PEXIVAS trial enrolled 704 patients with severe AAV (an eGFR rate of <50 mL/min/1.73 m^2 or diffuse pulmonary hemorrhage). ESKD or death occurred in 28.4% patient in the PLEX group versus 31% patients in control group.[57] One drawback of PEXIVAS was the lack of kidney biopsy data on interstitial fibrosis and tubular atrophy. PLEX had a trend for benefit in subgroup analyses of patients with pulmonary hemorrhage. Hence, we still consider PLEX in patients with acute kidney injury (estimated GFR [eGFR] < 30 mL/min/1.73 m^2) without significant chronic changes of interstitial fibrosis. We also use PLEX in patients presenting with severe pulmonary hemorrhage requiring mechanical ventilation or supplemental oxygen.

Maintenance Therapy

Duration of induction therapy and intensity of maintenance therapy should be decreased as much as possible to reduce toxic side effects. This is difficult because of the tendency for AAV to recur. Various approaches to reduce the cyclophosphamide dose include using IV cyclophosphamide rather than oral, substituting a less toxic maintenance drug after 3 to 6 months, and discontinuing therapy earlier in patients with lower risk for relapse. IV cyclophosphamide regimens afford one-third to one-half the total dose of cyclophosphamide given in oral regimens. Long-term follow-up notes longer time to relapse in the oral cyclophosphamide treated group, at the cost of increased leukopenia.[55] Azathioprine after 3 to 6 months of therapy can reduce cyclophosphamide dose.[48] In another EUVAS trial (CYCAZAREM), cyclophosphamide was replaced with azathioprine 2 mg/kg/day after 3 to 6 months with no change in the relapse rate at the end of the study.[48] When azathioprine 2 mg/kg/day was compared with mycophenolate mofetil (MMF) 2 g/day in a randomized control fashion, relapses were more common in the MMF group compared with the azathioprine group (unadjusted hazard ratio [HR] for MMF, 1.69; 95% confidence interval [CI] 1.06–2.70). Adverse events, disease activity score, GFR,

and proteinuria did not differ between groups, but two instances of bladder cancer and three of skin cancer were noted in the azathioprine group compared with one instance of skin cancer in MMF group (HR, 0.25; 95% CI, 0.02–2.62).[65]

The French Vasculitis Study Group compared methotrexate with azathioprine as maintenance therapy in patients with GPA and MPA.[66] Methotrexate was as effective as azathioprine for maintenance of remission, but methotrexate did not have fewer side effects. Methotrexate should not be used in patients with eGFR less than 30 mL/min/1.73 m^2. Karras et al. compared 24 versus 48 months of azathioprine remission maintenance therapy. Although 48 months of azathioprine therapy had fewer relapses (22% vs. 63%), more severe adverse events were noted (9 vs. 3 events).[67] An alternative is to stop all immunosuppressive therapy at 6 to 12 months if the patient is in full remission, especially if the patient is at lower risk for relapse.

Rituximab is another option for maintenance of remission.[66,67] The MAINRITSAN trial compared rituximab with azathioprine for maintenance in patients with MPA and GPA in remission after induction treatment with cyclophosphamide and glucocorticoids. Rituximab was more effective than azathioprine for preventing relapse, including renal relapse,[66] for up to 60 months.[68] The rituximab versus azathioprine in remission maintenance (RITAZAREM) trial is evaluating patients with relapsing ANCA vasculitis after achieving remission with rituximab induction. Preliminary results suggest a lower relapse rate with rituximab as opposed to azathioprine (18% vs. 38%).[69,70]

Dose and frequency of rituximab infusion and duration of therapy have been controversial. Tailored rituximab dosing of 500 mg based on reappearance of $CD19^+$B cells or ANCA or rise in ANCA titer had similar relapse rates compared with fixed 500 mg rituximab dose every 6 months in the MAINRITSAN2 study (17.3% vs. 9.9%, $P = .22$).[71] The tailored group had fewer infusions of rituximab (median 3 vs. 5), suggesting that dose and frequency of rituximab infusion can be successfully modified. The MAINRITSAN3 trial treated patients in remission from MAINRITSAN2 with placebo versus rituximab 500 mg biannually. The rituximab group had more major relapse-free survival compared with placebo group (100% vs. 87%, $P = .009$).[72] Although the adverse events were similar, the trial included patients who had previously tolerated rituximab.

Because rituximab is a biologic agent that has immunogenic mouse protein in its structure, many patients have become sensitized and some have developed serum sickness–like disease. If sensitivity develops during maintenance therapy, rituximab may not be an option for recurrent clinical disease. Fully humanized anti-CD20 antibodies, ofatumumab, obinutuzumab, and ocrelizumab may have a lower risk of sensitization but efficacy data is lacking. The expense of rituximab may be prohibitive for some patients. Because of these concerns and the risk of hypogammaglobulinemia, we suggest using a rituximab maintenance dose of 500 mg. Additionally, because of ease of reinduction,[73] we recommend discontinuing rituximab if patients are in long-term remission (>2 years).

The role of antimicrobial agents such as trimethoprim-sulfamethoxazole (TMP-SMX) in maintenance of remission is controversial. Some studies suggest a benefit, but others do not because of an increased likelihood of relapse.[74] TMP-SMX may be useful adjunct therapy, especially in patients with upper respiratory tract disease but should not be used in the absence of immunosuppressive drugs with more proven efficacy (e.g., cyclophosphamide, azathioprine) for induction or maintenance therapy for systemic vasculitis or GN. We often use TMP-SMX as prophylaxis in patients receiving prednisone at 20 mg or higher dose.

Relapse Therapy

One-fourth to one-half of patients with AAV will experience a relapse within several years. Relapses are diagnosed by clinical and pathologic evidence of recurrent disease, not by increase in ANCA titer alone.[36] Increase in ANCA titer does increase the likelihood of a relapse, and some advocate preemptive immunosuppressive therapy if the titer increases by at least fourfold.[36] We prefer identifying clear-cut clinical or pathologic evidence of relapse before increasing or resuming immunosuppressive therapy.[44]

Observational data suggest that rituximab is the best treatment for relapses and is superior to cyclophosphamide.[50] Reinstitution of treatment similar to an induction regimen is used most often, but less intensive or less toxic therapy may be adequate.[44] Lifetime exposure to cyclophosphamide is a consideration when selecting treatment for relapses. In addition to rituximab or cyclophosphamide, other therapies can be used for treating relapse, including azathioprine, MMF, methotrexate, or combinations of these drugs tailored to the individual patient with recalcitrant disease.

The MAINRITSAN and RITAZAREM trials suggest rituximab may be more effective in reducing relapse rates compared with azathioprine.[66,69,70] Long-term therapy may not be required, especially when there is a low risk for relapse. In our Glomerular Disease Collaborative Network (GDCN) cohort, 277 patients (65%) of 427 patients stopped immunosuppressive therapy. Some patients (23%) stayed off therapy for 5 or more years, suggesting long-term remission off therapy is possible. Additionally, 197 patients never relapsed with no difference between those who were on therapy or off.[73] In prospective observational studies from the GDCN, the relative risk for relapse was increased in individuals who had PR3-ANCA and respiratory tract disease.[42] Patients had more than a threefold risk for relapse compared with individuals having MPO-ANCA and without lung or ear, nose, and throat disease. This model of relapsing disease was investigated in a separate registry in France in which the combination of PR3-ANCA and lung disease was the most important predictive marker.[75]

Comparison of the major rituximab-based trials (RAVE, RITUXVAS, MAINRITSAN1, MAINRITSAN2, and RITAZAREM) shows a significant underrepresentation of MPO-ANCA patients compared with PR3-ANCA. There were 2 to 3 times as many PR3-ANCA patients compared with MPO-ANCA patients in the major rituximab-based trials. Because PR3-ANCA predominates in these trials (232 vs. 111), it is likely that the number of flares seen was higher than what would have been expected with MPO-ANCA patients. Thus, in patients having a much smaller risk for relapse, all therapy may be stopped, provided the patient is closely monitored (e.g., home urinary dipstick testing to monitor for recurrence of hematuria). The risk for relapse is about 10% to 15% even with maintenance therapy.

Transplantation

Kidney transplantation is not contraindicated in patients with ESKD caused by AAV. In a multicenter experience, the vasculitis relapse rate was 0.02 per patient per year[76] (see Chapter 113). Although a positive ANCA titer at the time of transplantation is not thought to increase the risk for recurrent disease in the transplant,[77] a study of 16 patients suggested a higher likelihood of relapse with PR3-ANCA compared with MPO-ANCA (OR, 2.19; $P = .71$).[78] An increase in ANCA titer and an active urine sediment suggest recurrent GN, but the diagnosis requires pathologic confirmation. Recurrent ANCA GN in a kidney transplant responds similarly to recurrent disease in native kidneys and usually is treated with cyclophosphamide and corticosteroids. Rituximab has been used successfully and avoids the risk for cyclophosphamide toxicity.[79]

POLYARTERITIS NODOSA

PAN is a systemic necrotizing arteritis that affects predominantly main visceral arteries and their intraparenchymal branches.[2,26,80] The Chapel

Hill nomenclature system limits the diagnosis of PAN to patients who have only arteritis.[4] The presence of vasculitis in capillaries and venules excludes a diagnosis of PAN and indicates SVV. Thus, GN excludes a diagnosis of PAN. When PAN is distinguished from MPA, the two categories of vasculitis have different pathologic characteristics, clinical features, and natural histories.[81]

Pathogenesis

The etiology and pathogenesis of PAN are unknown and probably are diverse.[2] When PAN is separated from MPA, the latter is associated with ANCAs. An immune complex trigger for PAN has been proposed but not confirmed. A minority of patients have hepatitis B virus (HBV) infection, suggesting that the HBV infection is producing immune complexes that localize in arterial walls and induce inflammation, ultimately leading to narrowing and weakening of vessel walls, thereby predisposing to aneurysms.[2] However, evidence that HBV infection is causing vascular immune complex deposition is stronger in certain forms of GN and SVV than in PAN.

Epidemiology

When defined by the Chapel Hill nomenclature system, PAN has a low prevalence of 1.5 per million.[23] Prevalence is higher in regions with higher levels of endemic HBV infection. PAN affects males and females equally and is found in all races. Onset occurs most frequently between ages 40 and 60 years.

Clinical Manifestations

The usual clinical presentation of PAN includes nonspecific constitutional symptoms: fever, malaise, arthralgias, myalgias, weight loss, and manifestations of arteritis.[39,81,82] Peripheral neuropathy, typically in the form of mononeuritis multiplex, is common. This is caused by inflammation of small epineural arteries and is clinically indistinguishable from the peripheral neuropathy caused by other forms of vasculitis affecting epineural arteries, such as MPA, GPA, and EGPA. GI involvement occurs in about half of patients, usually manifesting as abdominal pain and hematochezia. Bowel infarction is uncommon and perforation is rare. Kidney involvement produces infarction and hemorrhage, as indicated by flank pain and hematuria. Rupture of an arterial aneurysm with retroperitoneal or peritoneal hemorrhage is an uncommon but potentially lethal renal complication. Approximately one-third of patients develop hypertension, rarely reaching the malignant range. Red, tender inflammatory nodules are the most common cutaneous manifestation. Infarction, ulceration, and livedo reticularis may be present.

Arterial aneurysms may be detected by angiography in patients with PAN (Fig. 26.12). This is not a completely specific determination because any necrotizing arteritis that affects arteries large enough to be seen by angiography can produce this finding.

Pathology

Any artery in the kidney can be affected by PAN, although the interlobar and arcuate arteries are affected most often.[17] Nodular inflammatory lesions and aneurysms (pseudoaneurysms) can be observed grossly when medium-sized arteries are involved. Inflammation in small arteries can be observed only by microscopy.

The characteristic acute lesion is segmental transmural fibrinoid necrosis of arteries, usually accompanied by infiltrating leukocytes with leukocytoclasia[3] (Fig. 26.13). The earliest lesions have numerous neutrophils, and later lesions have predominantly mononuclear leukocytes. Acute lesions may be complicated by thrombosis or hemorrhage. Older lesions develop fibrosis and end-arterial remodeling. The aneurysms of necrotizing arteritis are not true aneurysms but rather inflammatory pseudoaneurysms—the walls of the arteries are not dilated but have been eaten away by the necrotizing inflammation, which then erodes into the surrounding perivascular tissue to create an enlarged lumen. This explains the propensity for such lesions to induce thrombosis or rupture.

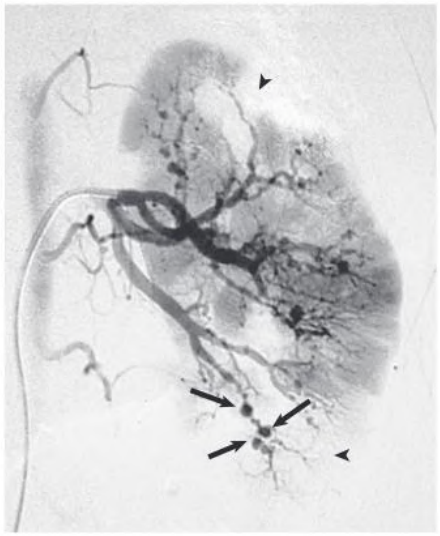

Fig. 26.12 Renal Angiogram in Polyarteritis Nodosa. Angiogram shows patchy kidney perfusion defects *(arrowheads)* and aneurysms *(arrows)*.

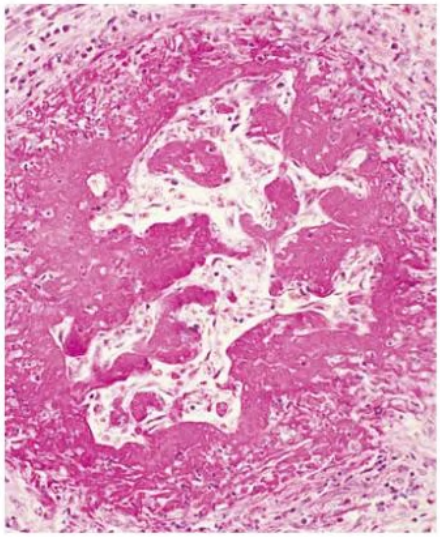

Fig. 26.13 Necrotizing Arteritis in Arcuate Artery of Patient With Polyarteritis Nodosa. The lumen is partially occluded by thrombotic material that is continuous with the fibrinoid material that has replaced the entire wall of the artery. (H&E, ×50.)

The necrotizing arteritis of PAN is indistinguishable by light microscopy from arteritis caused by other necrotizing vasculitides affecting arteries.[2,3] For example, necrotizing arteritis in a skeletal muscle biopsy specimen or a peripheral nerve biopsy specimen is histologically identical whether caused by PAN, MPA, GPA, or EGPA. For these vasculitides to be distinguished, additional clinical and serologic information is required.

Differential Diagnosis

Clinical features may assist in distinguishing PAN from other forms of vasculitis, especially other forms of necrotizing vasculitis that can affect arteries, such as MPA[2,3,83] (Table 26.5). A positive ANCA test supports

TABLE 26.5 Clinical Differences Between Polyarteritis Nodosa and Microscopic Polyangiitis

Clinical Feature	Polyarteritis Nodosa	Microscopic Polyangiitis
Microaneurysms by angiography	Yes	No (rare)
Rapidly progressive nephritis	No	Yes (very common)
Pulmonary hemorrhage	No	Yes
Renovascular hypertension	Yes (10%–33%)	No
Peripheral neuropathy	Yes (50%–80%)	Yes (10%–20%)
Positive hepatitis B serology	Uncommon	No
Positive ANCA	Rare	Frequent
Relapses	Rare	Frequent

ANCA, Antineutrophil cytoplasmic antibody.
Modified from Scott DGI, Watts RA. Epidemiology and clinical features of systemic vasculitis. *Clin Exp Nephrol.* 2013;17:607–610.

the diagnosis of one of the AAVs rather than PAN. The presence of GN indicates some form of SVV rather than PAN. Vasculitic pulmonary disease is rare in PAN but common in MPA, GPA, and EGPA. Peripheral neuropathy or muscle tenderness with arteritis in epineural or skeletal muscle arteries is not a useful differentiating feature because it often occurs in PAN and in AAV. Kawasaki disease (KD) causes necrotizing arteritis but is distinguished from PAN by the presence of the mucocutaneous lymph node syndrome.

Natural History

The natural history of PAN is muddled because early studies grouped MPA with PAN. PAN with multisystem involvement has a poor prognosis without therapy.[26] The 10-year survival with appropriate treatment is approximately 80%. Approximately 15% of patients who enter remission do relapse, which is much less frequent than with MPA. Relapse is more likely if treatment is delayed.

Treatment

PAN in patients without HBV infection is treated with corticosteroids and cytotoxic drugs (usually cyclophosphamide) if there is life-threatening major organ involvement.[26,81,82] Regimens vary and include treatments similar to those described earlier for MPA and GPA. In patients with no risk factors for poor outcome (e.g., age > 50 years; cardiac, gut, or kidney involvement), corticosteroids alone may be adequate and are less toxic than corticosteroids combined with cytotoxic agents.[82] In patients without major organ involvement, azathioprine or methotrexate can be used to reduce steroid exposure.

Aggressive immunosuppressive therapy without initial antiviral therapy is contraindicated in patients with HBV-associated PAN because of potential adverse effects on the outcome of the HBV infection. Patients with hepatitis B viremia should be treated with effective hepatitis B therapy. Often additional immunosuppression is needed, but short-term corticosteroid treatment combined with antiviral agents and possibly PLEX should precede more extensive immunosuppression in such patients.

KAWASAKI DISEASE

Definition

KD is an acute febrile illness that usually occurs in young children, often under 1 year, and is characterized by the mucocutaneous lymph node (MCLN) syndrome (see later discussion).[2,4,84–86] Necrotizing arteritis is a complication of KD that is present in some patients. Clinically significant kidney involvement is rare and KD is seldom encountered by nephrologists. If untreated, approximately 20% to 25% of children develop coronary artery aneurysms that may cause myocardial infarction.[85] Most patients undergoing autopsy after fatal myocardial infarction (MI) caused by coronary artery arteritis also have vasculitis in renal arteries.[84]

Pathogenesis

The occasional occurrence of KD as an endemic or epidemic disease suggests that the cause may be an infectious agent or environmental toxin.[2] Both cell-mediated and antibody-mediated mechanisms have been incriminated, as well as dysregulated innate immunity, possibly mediated by innate immune pathogen-associated molecular patterns.[86] At present, the etiology and pathogenesis of KD are unknown.

Epidemiology

KD usually occurs in children younger than 5 years (median, 2–3 years).[85] First described in Japan, it occurs worldwide but is more common in Asians and Polynesians than in Whites and Blacks. In Japan, the incidence is 50 in 100,000 children younger than 5 years, with 50% of the children younger than 2 years.[23,85] KD occasionally occurs in an endemic or epidemic pattern but usually is sporadic (with the COVID-19 pandemic, there have been cases of a Kawasaki-like disease in children after COVID-19 infection). KD is not transmitted person to person and does not occur in clusters within households, schools, or nurseries.[86]

Clinical Manifestations

MCLN syndrome is the characteristic clinical manifestation of KD.[4,85,86] This includes fever (temperature of 38°C to 40°C), mucosal inflammation, swollen red tongue (strawberry tongue), polymorphous erythematous rash, indurative edema of the extremities, erythema of palms and soles, desquamation from the tips of digits, conjunctival injection, and enlarged lymph nodes. Frequency of active arteritic lesions peaks during the first week of the illness and greatly reduces after 1 month. Arteritis often manifests as cardiac disease. Thrombosis of inflamed coronary arteries in patients with KD is the most common cause of childhood MI. Clinically significant kidney disease is surprisingly uncommon given that autopsy reveals arteritis in kidney vessels in up to three-fourths of patients.[84]

Pathology

KD involves small- and medium-sized arteries. The acute histologic lesion is necrotizing inflammation with less fibrinoid necrosis and more vessel wall edema than usually observed with PAN[84] (Fig. 26.14). Aneurysm (pseudoaneurysm) formation and thrombosis may occur. The most frequent site of arteritis is the coronary arteries, followed by the kidney arteries.[84] Arteritis most often affects interlobar arteries, occasionally arcuate arteries, and rarely interlobular arteries.

Differential Diagnosis

KD is sometimes misdiagnosed as childhood PAN. The differentiation of KD from PAN is important because corticosteroid treatment may increase the risk for coronary artery aneurysms in KD. Arteritis in a child younger than 5 years should always raise the possibility of KD. The presence or absence of the MCLN syndrome is the basis for distinguishing between KD and other forms of arteritis.[4]

Natural History

KD usually is self-limited, with an uneventful recovery if treated promptly with IV gamma globulins.[84,85] Recurrence occurs in less than 5% of patients.[85]

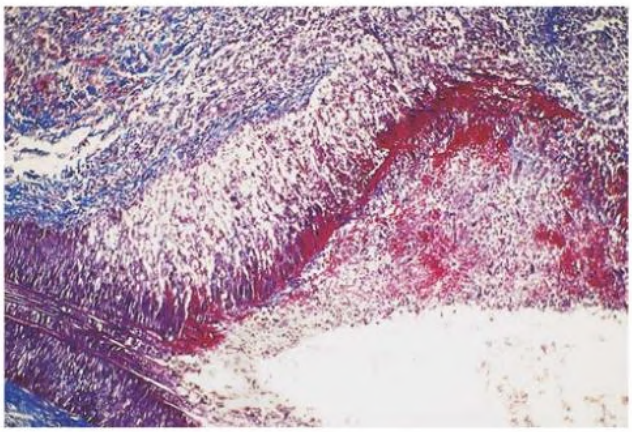

Fig. 26.14 Kawasaki Disease Arteritis Affecting Renal Interlobar Artery in a Young Child. The artery wall is intact on the *far left.* The remainder of the wall has extensive edema, infiltration by mononuclear leukocytes, and a band of fuchsinophilic *(red)* fibrinoid material roughly at the junction between the inflamed intima and muscularis. (Masson trichrome, ×25.)

Treatment

Aspirin and single IV immunoglobulin infusion (2 g/kg) within 10 days of fever onset are the standard therapy for KD.[84,85] Moderate to high doses of aspirin are used until resolution of fever followed by low-dose for antiplatelet effect. The role of corticosteroid treatment is controversial but may be beneficial in patients with severe disease that does not respond well to aspirin and intravenous immunoglobulin.

TAKAYASU ARTERITIS AND GIANT CELL ARTERITIS

Takayasu arteritis and giant cell arteritis (GCA) affect the aorta and its major branches more often than other forms of vasculitis.[4,87,88] GCA has a predilection for the extracranial branches of the carotid artery but can affect arteries in almost any organ. Takayasu arteritis has a predilection for major arteries supplying the extremities. Both diseases cause chronic vascular inflammation, often with a granulomatous appearance that may include multinucleated giant cells. GCA, but not Takayasu arteritis, is associated with polymyalgia rheumatica (PMR). The relation of Takayasu arteritis and GCA is not known. The striking demographic differences suggest that they are distinct pathophysiologic entities.

Pathogenesis

The etiology and pathogenesis of GCA and Takayasu arteritis are unknown.[2] Because of the histologic changes and the nature of the infiltrating leukocytes, cell-mediated immune mechanisms are incriminated. The inciting antigen or autoantigen has not been identified.

Epidemiology

Takayasu arteritis is seen most frequently in Asia. GCA occurs most often in individuals of northern European ancestry. Takayasu arteritis has a female-to-male ratio of approximately 9:1 and GCA of 4:1. Takayasu arteritis usually is diagnosed in those between ages 10 and 20 years and is rare after age 50 years. GCA is rare before age 50 years. Takayasu arteritis has uniform global incidence of 1 to 2 per million.[23] Race and ethnicity affect the vascular distribution of Takayasu arteritis, with the aortic arch and its branches affected mainly in Japanese patients, abdominal aorta and its branches affected mainly in Indian patients, lower abdominal aorta affected mainly in African

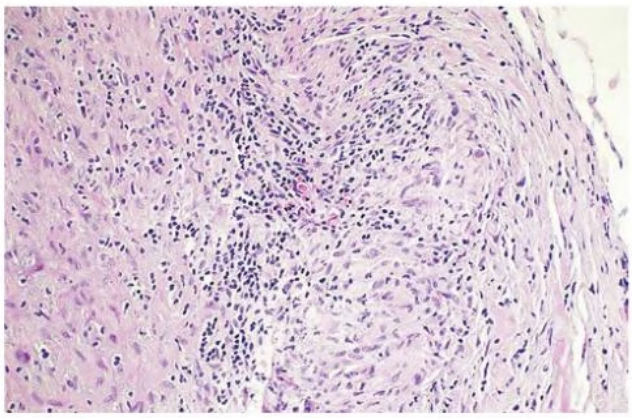

Fig. 26.15 Severe Giant Cell Arteritis Affecting a Main Renal Artery. This caused marked renal atrophy and renovascular hypertension. (H&E, ×50.)

populations, and kidney involvement most common in Asian and African populations.[88]

GCA is the most common form of vasculitis, with an incidence highest in populations of Scandinavian descent, with an annual incidence of 15 to 35 per 100,000 older than 50 years.[23]

Clinical Manifestations

In addition to constitutional symptoms, such as fever, arthralgias, and weight loss, the major clinical manifestations of Takayasu arteritis and GCA are caused by arterial narrowing and resultant ischemia.[2,87] Major clinical manifestations of Takayasu arteritis are reduced pulses (95% of patients), vascular bruits, claudication, and renovascular hypertension. Renovascular hypertension results from kidney ischemia caused by renal artery stenosis or aortic coarctation.[89] Reduced aortic elasticity and impairment of carotid artery baroreceptors also may play a role in some patients. The European League Against Rheumatism (EULAR) recommends thorough imaging assessment (see later discussion) of the entire major arterial tree when a diagnosis of Takayasu arteritis is suspected.[90]

Headache is the most common presenting symptom in patients with GCA. Temporal artery tenderness, nodularity, or decreased pulsation is present in half of patients. Other symptoms include blindness, deafness, jaw claudication, tongue dysfunction, extremity claudication, and reduced pulses. More than half of patients with GCA have PMR, characterized by stiffness and aching in the neck and the proximal muscles of the shoulders and hips. Clinically significant kidney disease is less common in GCA than in Takayasu arteritis. Case reports of necrotizing and crescentic GN associated with GCA may represent examples of GPA or MPA with temporal artery involvement.

Computed tomography (CT), magnetic resonance angiography (MRA), fluorodeoxyglucose positron emission tomography/CT (FDG-PET/CT), and contrast-enhanced ultrasonography are used to diagnose and assess the activity of vascular inflammation in Takayasu arteritis and GCA.[88] CT and MRA identify structural changes (e.g., stenosis, aneurysms). FDG-PET/CT detects active inflammation even in vessels that show no overt structural changes by other imaging techniques.

Pathology

The aortitis and arteritis of Takayasu arteritis and GCA cannot be confidently differentiated by pathologic examination.[4] Both are characterized in the active phase by inflammation with a predominance of mononuclear leukocytes, often with scattered multinucleated giant cells (Fig. 26.15). The chronic phase is characterized by progressive

fibrosis that may cause severe narrowing of vessels, with resultant ischemia. Major renal arteries are often found to be involved at autopsy in patients with Takayasu arteritis and those with GCA. However, clinically significant kidney disease is relatively common in Takayasu arteritis but rare in GCA. A glomerular lesion characterized by nodular mesangial matrix expansion and mesangiolysis may occasionally be a component of Takayasu arteritis.[91]

Differential Diagnosis

There is overlap between the clinical manifestations and pathologic features of Takayasu arteritis and GCA. Patient age and presence or absence of PMR are the best factors for distinguishing between these vasculitides.[4] GCA has been called temporal arteritis, but not all patients have temporal artery involvement, and patients with other types of vasculitis (PAN, GPA, MPA) can have involvement of the temporal arteries.

Treatment

Corticosteroids are the usual treatment of GCA and Takayasu arteritis.[90] EULAR recommends initial daily therapy with prednisolone 1 mg/kg until disease control followed by tapering over several months to over a year.[90,92] Prolonged treatment may be dictated by persistent disease activity. Rapid steroid taper is associated with increased risk of relapse.[93] Tocilizumab, an interleukin (IL)-6 inhibitor, has been a successful adjunct to corticosteroids in patients at high risk for corticosteroid-related adverse events or with life- or organ-threatening disease.[92–94] Methotrexate is an alternative. Cytotoxic agents such as cyclophosphamide may be required in patients with recalcitrant disease. Patients with GCA are at a higher risk of thrombotic vascular events. Antiplatelet or anticoagulant therapy is not recommended unless indicated for another reason.[92]

Management of kidney disease is typically not an issue with GCA, although rare patients have ischemic kidney manifestations. Renovascular hypertension is the major kidney problem in Takayasu arteritis.[88,89] When bilateral renal artery involvement occurs, angiotensin-converting enzyme (ACE) inhibitors may precipitate kidney failure in patients with Takayasu arteritis.[95] When medical management fails, the renovascular hypertension in patients with Takayasu arteritis may be controlled by vascular surgery or endovascular angioplasty.[88,89] Reconstructive vascular surgery should be performed during a quiescent phase of the disease.[90] The management of renovascular hypertension is discussed in Chapter 43.

COVID AND MANAGEMENT OF VASCULITIS

Although only case reports exist on development of vasculitis in patients with COVID-19,[96–98] the impact is substantial. There are scarce data on treatment in patients with concurrent vasculitis and COVID-19, and controversy on whether immunosuppression is protective or harmful. In some cases immunosuppression was discontinued during active infection,[99] and steroids were used for treatment in others.[98] It is unclear if one immunosuppression is superior or if rituximab is safe in patients with vasculitis flare and COVID-19. The question about vaccination is unanswered. How does the COVID-19 vaccine affect management, especially around time of vaccination? Some groups suggest avoiding overimmunosuppression,[100] but the question remains whether we are adequately treating our patients with vasculitis.

SELF-ASSESSMENT QUESTIONS

1. In a patient who has systemic vasculitis affecting multiple organs, a kidney biopsy showing GN that is a component of the systemic vasculitis is definitive evidence that the systemic vasculitis is a:
   A. large-vessel vasculitis.
   B. small-vessel vasculitis.
   C. medium-vessel vasculitis.
   D. variable-vessel vasculitis.
2. If pathologic and serologic studies in a patient with crescentic GN are diagnostic for anti-GBM disease, ANCA testing is:
   A. unnecessary because it is unlikely to be positive.
   B. unnecessary because it would not change the prognosis if positive.
   C. necessary because it is positive in one-fourth to one-third of patients and changes the prognosis.
   D. necessary because a positive ANCA result rules out anti-GBM disease.
3. Which of the following is *most* common in patients with PAN?
   A. Glomerulonephritis
   B. Pulmonary hemorrhage
   C. Polymyalgia rheumatica
   D. Hepatitis B infection
4. Which of the following is the *most* common clinical sign or symptom caused by Takayasu arteritis?
   A. Flank pain caused by kidney infarction
   B. Acute kidney failure
   C. Hematuria
   D. Hypertension
5. Is targeted B-cell therapy with rituximab an acceptable component of induction therapy for ANCA-associated vasculitis and glomerulonephritis?
   A. Yes, because induction with rituximab has fewer adverse events than induction with cyclophosphamide.
   B. Yes, because clinical trials have shown noninferiority between induction therapy with rituximab compared with cyclophosphamide.
   C. No, because clinical trials have shown that induction therapy with rituximab is inferior to induction with cyclophosphamide.
   D. No, because rituximab is not approved by the FDA for induction therapy.

Lupus Nephritis

Ana Malvar, Valeria Alberton, Brad H. Rovin

DEFINITION

Lupus nephritis (LN), the prototypical immune complex glomerulonephritis (GN), occurs commonly in patients with systemic lupus erythematosus (SLE) and can be very severe. SLE is defined by specific clinical and laboratory features (Table 27.1).[1] To be considered as having SLE, a patient must demonstrate antinuclear antibody (ANA) positivity of 1:80 or more using a Hep2 cell or equivalent assay. Other clinical and serologic parameters are assigned points and, in addition to a positive ANA, a patient must have sufficient clinical and laboratory findings to achieve a score of at least 10. Importantly, proteinuria and kidney biopsy findings are heavily weighted. A kidney biopsy showing an immune complex GN consistent with an International Society of Nephrology/Renal Pathology Society (ISN/RPS) class III or IV LN will receive a score of 10, so this plus a positive ANA are together sufficient to establish a diagnosis of SLE and LN.

EPIDEMIOLOGY

The incidence and prevalence of lupus and LN are influenced by age, sex, ethnicity, geographic region, diagnostic criteria used, and method of ascertainment. Clinically important kidney disease occurs in about 50% of patients with SLE, mostly between the ages of 15 and 45 years, with women outnumbering men 8:1 to 15:1.[2] Female predominance is less pronounced in children and older individuals. Among patients with lupus, LN affects both sexes equally, is more severe in children and men, and is less so in older adults. The incidence of LN is about 30% in White, 60% in Black and Hispanic, and 40% to 80% in Asian patients with SLE.[3,4] The higher frequency of LN in Black patients is independent of socioeconomic status.[5] Black and Hispanic patients with SLE develop LN earlier and have worse outcomes than White patients. The prevalence of LN in a Medicaid population was 31 in 100,000.[5]

A pragmatic review found the 5- and 10-year cumulative incidence of end-stage kidney disease (ESKD) to be 11% and 19%, respectively,[2] but this depends on histologic class and the population sampled. The risk for ESKD over 15 years was up to 44% in class IV LN.[6] In a Medicaid population with a new diagnosis of LN between 2000 and 2010, the 5-year cumulative incidence of ESKD was about 22%.[7]

SLE patients with LN die earlier than those without nephritis and have a standardized mortality ratio of 6 to 6.8 versus 2.4 in lupus without kidney involvement.[8,9] This increases to 14 for those with chronic kidney disease and 63 for those with ESKD.[10] However, if LN remission is achieved through treatment, 10-year survival doubles to 95%.[11]

ETIOLOGY AND PATHOGENESIS

Genetics and Environment

A genetic predisposition to SLE is supported by disease clustering in families, twin concordance, racial differences in susceptibility, and the high frequency of autoantibodies and other autoimmune disorders in healthy family members.[12] In Taiwan the relative risk for lupus in families of those with SLE was 316 for twins, 24 for siblings, 11 for parents, 14 for children of patients, and 4.4 for nonrelated spouses, suggesting that heritability contributed 44% to the risk for SLE, shared environmental exposures contributed 26%, and nonshared environmental exposures 30%.[13]

Homozygous deficiency of early complement cascade components (C1q, C2, C4) is associated with a high risk of SLE, as are certain FcγRIII receptor polymorphisms. Genome-wide association studies have identified over 100 loci associated with an increased risk for SLE. Genetic risk scores are lowest in Europeans, higher in Asians, and highest in those of African ancestry.[14] Genes involved in lupus risk include those affecting B-cell signaling, neutrophil function, interferon regulation, immune-complex clearance, toll-like receptors (TLRs), and the B-cell survival factor BAFF.[12,15] The BAFF variant results in higher levels of BAFF and contributes to the rationale of treating lupus and LN with a monoclonal antibody against BAFF. A disproportionate number of transcription factors have been identified, suggesting an important contribution of gene dysregulation to lupus.[16] HLA genes are also strongly associated with lupus risk, at least in Europeans.[17] In Whites and Asians, four HLA class II DR allele families confer increased susceptibility or resistance to the development of LN.[18] Independent of causation, other polymorphisms in genes such as *MYH-9, ACE, TNIP-1,* and *APOL-1* (in Blacks) confer a worse prognosis for LN. Having even one *APOL-1* kidney risk allele was associated with progressive chronic kidney disease (CKD) and more chronicity, especially interstitial fibrosis and tubular atrophy, in nonwhite Brazilian patients.[19]

External environmental factors, such as ultraviolet light exposure and smoking, play a role in the onset and exacerbation of SLE and LN.[20] Viral infections may be triggers for lupus, but conclusive evidence for a viral pathogenesis of SLE or LN is lacking. Exposure to certain medications (e.g., procainamide, hydralazine, quinidine, and anti-tumor necrosis factor [TNF] biologics) has been linked to SLE or SLE-like syndromes, but LN occurs infrequently in such individuals.

The internal environment also appears to be relevant in SLE given the strong female predominance, disease exacerbations during or shortly after pregnancy, and the effects of hormone treatment and ablation in animal models of LN. The gut microbiome may also contribute to lupus disease pathogenesis and activity. For example, orthologs of the RNA binding autoantigen Ro60 have been found in gut, skin, and oral commensal bacteria.[21] Autoantibodies to Ro60 are seen early in patients who develop SLE. The Ro60 orthologs could trigger autoimmunity in genetically susceptible individuals. Dysbiosis of the gut microbiome occurs in lupus patients. In some patients with active LN, circulating antibodies against overrepresented bacterial species have been found.[22] Anti-double stranded DNA (dsDNA) antibodies can recognize an antigen from these bacteria, again supporting a link

TABLE 27.1 ACR/EULAR and SLICC Criteria for the Diagnosis of SLE

ACR/EULAR Criteria	SLICC Criteria	
Sensitivity: 96.1%	Sensitivity: 96.7%	
Specificity: 93.4%	Specificity: 83.7%	
Classification as SLE requires 10 points plus a positive ANA at any time	Classification as SLE requires four or more of the following (with at least 1 clinical and 1 immunologic criteria) **OR** biopsy-proven lupus nephritis with positive ANA or anti-dsDNA	
	Clinical Criteria	**Immunologic Criteria**
Acute cutaneous (2 points) SCLE (4 points)	Acute *or* subacute cutaneous lupus	Positive ANA
Discoid rash (4 points)	Chronic cutaneous lupus	Positive anti-dsDNA antibody
Nonscarring alopecia (2 points)	Nonscarring alopecia	Positive anti-Sm antibody
Oral ulcers (2 points)	Oral *or* nasal ulcers	Positive antiphospholipid antibody (includes presence of a lupus anticoagulant, false-positive RPR, anticardiolipin antibody, or anti-β_2 glycoprotein antibody)
Nonerosive arthritis (involving ≥2 joints, characterized by tenderness, swelling, or effusion) (6 points)	Synovitis ≥2 joints (swelling or effusion) *or* tenderness in ≥2 joints and ≥30 min of morning stiffness	Low complement (C3, C4, or CH50)
Serosal effusion (5 points) Acute pericarditis (6 points)	Serositis	Direct Coombs test (in the absence of hemolytic anemia)
Kidney disease Proteinuria (4 points) ISN/RPS class II/V (8 points) ISN/RPS class III/IV (10 points)	Kidney disease (RBC casts *or* proteinuria ≥500 mg/day on 24-h urine collection *or* spot ratio of urine protein to creatinine ratio ≥0.5)	
Neurologic disorder Neuropsychiatric seizure (5 points) Psychosis (3 points) Delirium (2 points)	Neurologic disorder	
Hematologic disorder Coombs+ hemolytic anemia (4 points) Leukopenia (3 points) Thrombocytopenia (4 points)	Hemolytic anemia	
Serology Anti-dsDNA (6 points) Anti-Sm (6 points) Antiphospholipid (2 points) Low C3 or C4 (3 points) Low C3 and C4 (4 points)	Leukopenia *or* lymphopenia	
	Thrombocytopenia

between gut flora and autoimmunity. Finally, pathobionts may traverse the intestinal wall and trigger autoimmune responses in susceptible individuals.[23]

Autoimmunity in Systemic Lupus Erythematosus

Patients with SLE typically develop multiple autoantibodies, many directed against nucleic acids and proteins involved in transcription and translation, such as nucleosomes (DNA-histone), chromatin antigens, and small nuclear and cytoplasmic ribonuclear proteins.[24] Early in disease, clearance of apoptotic cells is impaired and nuclear autoantigens released from these cells stimulate expression of interferon-α (IFN-α), which facilitates the generation of antigen-presenting cells, promotes the differentiation of autoreactive B cells into plasma cells, and fosters the development of T helper cells. Antigen mimicry (i.e., exposure to viral or bacterial peptides with sequences similar to those of native antigens) also may lead to induction of autoantibody-producing cell lines. Both autoreactive B and T cells clonally expand in lupus, facilitated by failure of apoptotic mechanisms to silence autoreactive cells (i.e., loss of tolerance and an increased expression of B cell trophic factors). The nature of antigen presentation also may be important, with certain nuclear antigens capable of triggering an immunogenic response through interactions with a variety of intracellular TLRs.

The number and type of autoantibodies present in SLE reflects the patient's ancestry and may be associated with disease severity.[25] Patients of any ancestry, but in particular those of African ancestry, who displayed multiple autoantibodies simultaneously and in association with anti-RNP antibodies, have increased transcriptomic signatures for interferon, plasma cells, T regulatory cells, and myeloid inflammation.

In addition to antibodies against nuclear antigens, patients with LN often have other autoantibodies: Up to 18% of LN patients may have

antinuclear cytoplasmic antibodies (ANCA), which occur more often in proliferative than membranous LN and are associated with worse baseline kidney function.[26]

PATHOGENESIS OF KIDNEY INJURY IN LUPUS NEPHRITIS

The hallmark of LN is the accumulation of immune complexes in glomeruli.[27] Patients with LN have autoantibodies against dsDNA, Sm antigen, C1q, nucleosomes, and other antigens. There is direct binding of dsDNA antibodies to the glomerular basement membrane (GBM), and cross-linking of positively charged nucleosome components such as chromatin between autoantibodies and GBM.[27] In proliferative LN, immune complexes are found in the subendothelial space, whereas in membranous LN, they localize to the subepithelial space.

Glomerular immune complexes, especially in the subendothelial space, activate proinflammatory mechanisms, including the complement pathway, leukocyte Fc receptors, cytokines that regulate cell proliferation and matrix formation, and procoagulant factors.[27–29] Nucleosomes also can activate resident dendritic cells through binding to TLR-2 and -9.[30] These activated pathways result in kidney damage, intraglomerular hypertension and coagulation, and leukocyte infiltration with release of proteolytic enzymes. Subepithelial immune complexes are associated with less inflammation but increased production of GBM components and more podocyte injury.

T cells contribute to the progression of LN by facilitating B cell differentiation and expansion. Additionally, T helper cell (Th1) cytokines are overexpressed in kidneys of patients with LN and promote intrarenal inflammation by activation of macrophages, complement, and the Fc receptor pathway. Kidney biopsies of LN patients also contain Th17 cells, which secrete interleukin-17 (IL-17), which is thought to sustain kidney inflammation by driving T cells away from maturing into a regulatory phenotype ($CD4^+CD25^{hi}FoxP3^+$) capable of suppressing autoantibody production and attenuating the immune response.[31] $CD8^+$ T cells may gradually lose effector function and express inhibitory receptors under persistent antigen exposure and become "exhausted." Exhaustion may, however, explain, why LN patients whose peripheral T cells displayed an exhausted phenotype had a nonrelapsing disease course.[32]

In SLE and LN, neutrophils undergo a form of cell death called NETosis, in which a chromatin meshwork (or NET) is released.[30] These NETs are a source of autoantigens and are not properly degraded in lupus patients. In addition, lupus patients have an increased number of low-density granulocytes that are more susceptible to NETosis. NET material has been found in LN biopsy samples, and the subset of SLE patients with LN often do not degrade NETs well. The NETs induce production of IFN-α by plasmacytoid dendritic cells, which are also found in LN kidneys.[30]

Within the tubulointerstitial compartment, T and B cells are often found in close proximity to each other and appear to be interacting, in some cases even forming germinal centers.[33] Interstitial B cells aggregating with T cells may show clonal expansion and somatic hypermutation, suggesting intrarenal autoantibody production against kidney-specific antigens, such as vimentin. Such interactions may contribute to interstitial inflammation, a major determinant of long-term kidney survival.[33]

Single-cell RNA sequencing (scRNA-seq) identified 21 clusters of immune cells in the LN kidney,[34] all displaying an interferon signature, much as is seen in the peripheral blood of patients with SLE and LN. Of the three clusters of $CD8^+$ T cells found in the kidney, none had an exhaustion signature, in contrast to that found in the peripheral blood of some patients. This demonstrates the complex and sometimes unexpected relationships among intrarenal immune cells and between tissue and peripheral blood immune cells.

TABLE 27.2 Frequency of Kidney Manifestations in Patients With Lupus and Kidney Involvement

Manifestation	Prevalence (%)
Proteinuria	100
Nephrotic syndrome	45–65
Hematuria	
Microscopic	80
Gross	1–2
Red blood cell casts	10
Cellular casts	30
Reduced kidney function	40–80
Rapidly progressive glomerulonephritis	10–20
Acute kidney injury	1–2
Hypertension	15–50
Hyperkalemia	15

CLINICAL MANIFESTATIONS

Immune complex kidney involvement (LN) is usually heralded by proteinuria and active urinary sediment with microhematuria, acanthocytes, and erythrocyte casts (Table 27.2). More severe LN, usually with proliferative histology, may present with hypertension and a decline in the glomerular filtration rate (GFR). Less frequently, kidney disease in lupus presents as a tubulointerstitial disorder such as renal tubular acidosis (see Chapter 13), isolated interstitial nephritis, or as a thrombotic microangiopathy with or without an antiphospholipid antibody syndrome (see Chapters 29 and 30).

Extrarenal Manifestations

Patients with active SLE often present with nonspecific complaints of malaise, low-grade fever, poor appetite, and weight loss. Other common features include patchy alopecia, oral or nasal ulcerations, arthralgias, nondeforming arthritis, and a variety of skin findings, including photosensitivity, Raynaud's phenomenon, and a "butterfly" (malar) facial rash. Livedo reticularis is seen in up to 15% of cases and may be associated with miscarriage, thrombocytopenia, and antiphospholipid antibodies. Neuropsychiatric involvement presents with headache, nerve palsies, psychoses, or frank coma. Serositis, in the form of pleurisy or pericarditis, affects up to 40% of patients. Pulmonary hypertension can develop silently as a result of multiple pulmonary emboli or intravascular coagulation in association with antiphospholipid antibodies or may be caused by nonthrombotic pulmonary arterial disease. Mitral valve prolapse, and less commonly Libman-Sacks endocarditis, may both be seen in SLE. Splenomegaly and lymphadenopathy are present in about one-fourth of patients, and hematologic abnormalities can affect all three cell lines. SLE-associated anemia can result from impaired erythropoiesis, autoimmune hemolysis, or bleeding. Thrombocytopenia and leukopenia may occur as part of lupus or as complications of therapy. Thrombotic events are common and should prompt a search for antiphospholipid antibodies and other procoagulant abnormalities.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Although the diagnosis of lupus may be obvious in a young woman with classic manifestations and serologic markers, less typical presentations are common and often result in diagnostic delay. This is, in

part, a result of the varied features of the disease and because signs and symptoms evolve over time.

Several autoimmune diseases mimic the extrarenal manifestations of SLE, including fibromyalgia, Sjögren syndrome, thrombotic microangiopathies, primary antiphospholipid syndrome, dermatomyositis, systemic sclerosis, and mixed connective tissue disease. Adding complexity to diagnosis, many of these autoimmune diseases can involve the kidney and, in some cases, are associated with GN. Conversely, several common forms of GN must be distinguished from LN because of similar clinical features, including vasculitides (see Chapters 24 and 26), bacterial endocarditis, and cryoglobulinemia. ANCAs of uncertain significance are detected in 20% of LN patients.

Immunologic Tests in Lupus

ANAs are found in more than 90% of untreated patients with lupus. Although highly sensitive, neither the presence nor pattern (e.g., diffuse, speckled) are specific for SLE. Autoantibodies against dsDNA are more specific but less sensitive, being present in 75% of untreated lupus patients. Whereas high titers of anti-dsDNA antibodies correlate with the presence of SLE and are often used to follow the course of LN, antibodies to single-stranded DNA (ssDNA) are found in many rheumatologic conditions and do not correlate with the course of LN. Sm antibodies are strongly associated with the diagnosis of lupus and LN but are present in only about 25% to 30% of patients. Antibodies to C1q (anti-C1q) have been more closely associated with the activity of LN than anti-dsDNA antibodies and may have a prognostic role in the follow-up.[35]

Serum levels of total hemolytic complement and complement components C3 and C4 are often depressed in untreated SLE and especially in LN. In general, both C3 and C4 are depressed. Preferential C4 depression in lupus patients may reflect activation of the classic complement pathway. In some cases, low C4 with normal C3 in a patient with lupus may reflect genetic C4 deficiency or the presence of cryoglobulins. Preferential depression of C3 is observed in patients with postinfectious glomerulonephritis (PIGN) and the C3 glomerulopathies (see Chapters 23 and 57) rather than in SLE/LN.

KIDNEY BIOPSY IN SYSTEMIC LUPUS ERYTHEMATOSUS

Although lupus nephritis may be suspected based on clinical symptoms and laboratory markers, a kidney biopsy is required for confirmation, subclassification, prognosis, and management decisions. A biopsy should be done in patients with a persistent urine protein/creatinine ratio greater than 0.5 g/g (equivalent to proteinuria of about 0.5 g/day), with or without an active urine sediment (i.e., glomerular hematuria and/or leukocyturia in the absence of urinary tract infection). Although a fall in GFR because of LN is usually accompanied by proteinuria and hematuria, a biopsy should be done if kidney function declines in an SLE patient in the absence of urinary abnormalities if no other reason (e.g., infection, nephrotoxic medications) for the falling GFR can be found.

The proteinuria cutoff of 0.5 g/g is not an absolute threshold. A kidney biopsy should be considered for individual patients in the context of their overall disease characteristics. For example, proliferative LN can be found in lupus patients with proteinuria less than 0.5 g/g who have glomerular hematuria with or without impaired kidney function. In one cohort, over 80% of such patients had class III or IV LN on kidney biopsy.[36]

After LN treatment, a second kidney biopsy can be considered for patients who have not responded adequately, have persistently elevated markers of kidney disease activity, or who deteriorate and in whom future treatment is unclear.

PATHOLOGY

Glomerular involvement is the dominant finding in LN. LN is currently classified by the revised ISN/RPS system (Table 27.3)[37] and is based mainly

TABLE 27.3 ISN/RPS Classification of Lupus Nephritis and Associated Clinical Correlations

Class	Definition	Urine Findings	Clinical Findings
I: Minimal mesangial LN	Normal glomeruli by LM but mesangial immune deposits by IF	Usually unremarkable	None relevant to kidney; excellent kidney prognosis[a]
II: Mesangial proliferative LN	Mesangial hypercellularity (4 or more nuclei fully surrounded by matrix in the mesangial area excluding the hilar region) with mesangial immune deposits	Microscopic hematuria; proteinuria, if present, is usually low grade	Preserved kidney function; hypertension infrequent; excellent kidney prognosis[a]
III: Focal LN	Segmental or global, active endocapillary or extracapillary, or inactive glomerulonephritis affecting <50% of glomeruli with mesangial and subendothelial immune deposits	Microscopic hematuria; proteinuria	Hypertension possible; kidney failure and nephrotic syndrome not unusual; variable kidney prognosis
IV: Diffuse LN	Segmental or global active endocapillary or extracapillary, or inactive glomerulonephritis affecting ≥50% of glomeruli with mesangial and subendothelial immune deposits	Microscopic hematuria; proteinuria	Hypertension; kidney failure and nephrotic syndrome frequent; variable kidney prognosis
V: Membranous LN	Glomerular basement membrane thickening with subepithelial and mesangial immune deposits; can occur alone or in combination with class III or IV	High-grade proteinuria; microscopic hematuria possible	Preserved kidney function; nephrotic syndrome common; kidney prognosis good[a] Anti-PLA2R antibody negative
VI: Advanced sclerosing LN	≥90% of glomeruli globally sclerosed without residual disease activity	Microscopic hematuria; proteinuria not unusual	Kidney failure expected

[a]As long as there is no transformation to a proliferative class.

on glomerular histology (examples are shown in Figs. 27.1 through 27.5). Less common glomerular pathologies omitted from the ISN/RPS system include lupus podocytopathy (see later discussion) and pauci-immune crescentic GN (analogous to ANCA-associated renal vasculitis).

Although IgG is generally the dominant glomerular immunoglobulin in LN, IgA, and IgM, along with the complement components C1q and C3, are often co-deposited, giving the "full-house" pattern that is highly suggestive of LN. Strong glomerular C1q staining is also suggestive of LN. Fibrin staining, corresponding to active lesions, is often noted in the glomerular tuft, especially in crescents.

On electron microscopy (EM), the distribution of electron dense, immune complex deposits corresponds to the pattern of immunoglobulins seen by immunofluorescence or immunohistology. Some electron-dense deposits have an organized substructure known as *fingerprinting*, corresponding to the presence of curvilinear microtubular or fibrillar structures. Tubuloreticular inclusions, which are tubular structures located in the endoplasmic reticulum of kidney endothelial cells, are often found in biopsy specimens of LN patients and are thought to reflect a high interferon milieu.

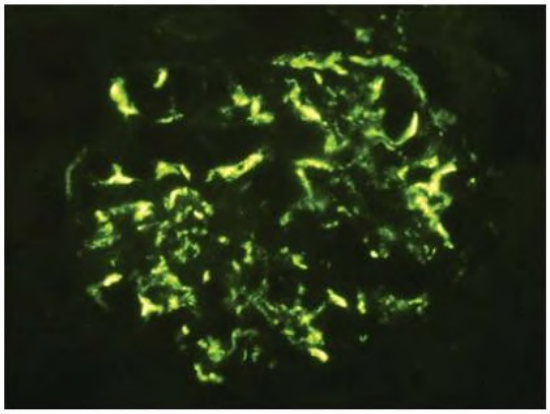

Fig. 27.1 International Society of Nephrology/Renal Pathology Society Class I: Minimal Mesangial Lupus Nephritis. Light microscopy is normal *(not shown)*, but direct immunofluorescence shows C1q deposits in the mesangial area. No capillary walls are involved. (Magnification ×400.)

Tubulointerstitial and Vascular Disease

The original ISN/RPS classification does not assess the kidney tubulo-interstitial or vascular compartments, even though interstitial and vascular damage contribute to poor kidney outcomes.[38] The updated ISN/RPS classification includes activity and chronicity scores for glomerular and tubulointerstitial lesions, and vascular lesion grading along the lines of the Banff classification for transplant biopsies.[37]

About 50% of patients with LN, predominantly those with proliferative glomerular lesions, have immune aggregates along tubular basement membranes. Interstitial inflammatory cell infiltrates, including T cells, B cells, and monocytes, are frequently found, and tubulitis can be seen in active disease (Fig. 27.6). In chronic disease, the interstitium is often expanded by fibrosis and sparser infiltrates. Infrequently, tubulointerstitial nephritis is seen in the absence of glomerular disease and may result in acute kidney injury (AKI) or renal tubular acidosis.

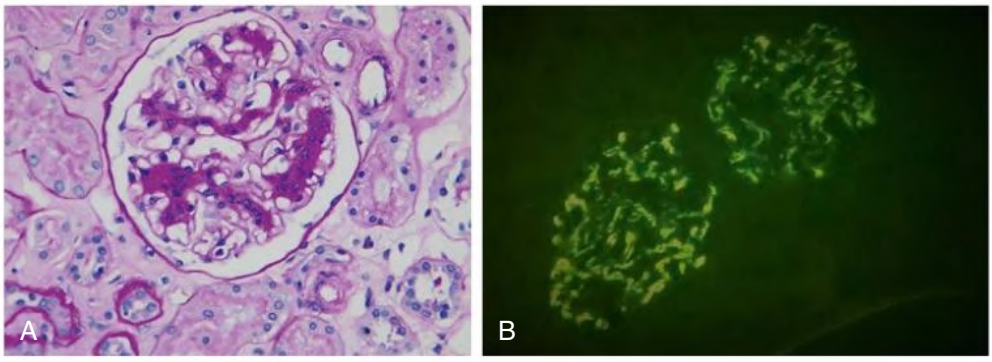

Fig. 27.2 International Society of Nephrology/Renal Pathology Society Class II: Mesangial Proliferative Lupus Nephritis. (A) Mesangial expansion with hypercellularity, normal capillary walls, and no endocapillary hypercellularity (PAS stain, ×400). (B) Diffuse mesangial immunoglobulin G deposits shown by direct immunofluorescence (×200).

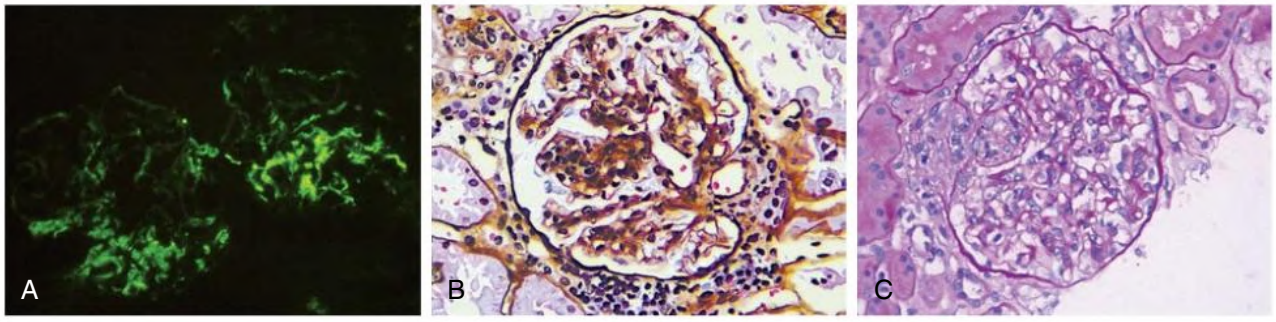

Fig. 27.3 International Society of Nephrology/Renal Pathology Society Class III: Focal Proliferative Lupus Nephritis. (A) Segmental deposits of immune complexes in the mesangial areas and in some capillary walls (C1q, direct immunofluorescence, ×200). (B) Glomerulus showing segmental endocapillary hypercellularity (silver methenamine stain, ×400). (C) Area of endocapillary hypercellularity with karyorrhexis and a segmental fibrocellular crescent with focal disruption of Bowman's capsule (PAS stain, ×400).

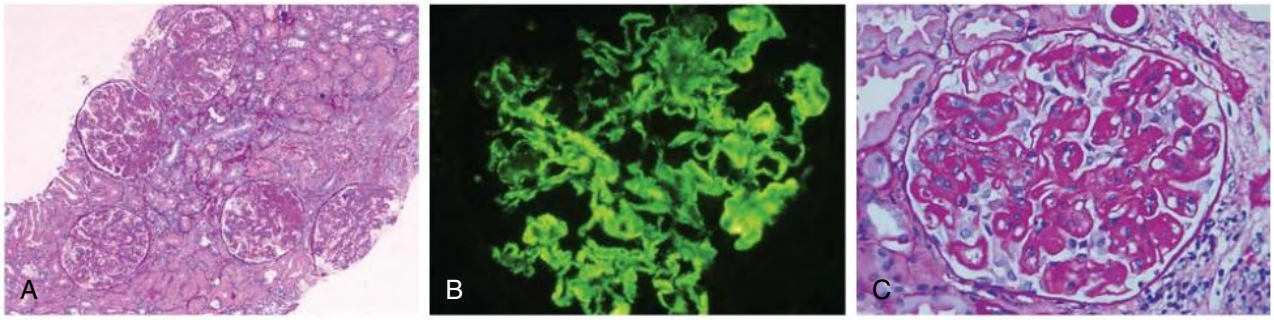

Fig. 27.4 International Society of Nephrology/Renal Pathology Society Class IV: Diffuse Proliferative Lupus Nephritis. (A) Active diffuse proliferative lupus nephritis showing the presence of endocapillary hypercellularity with lobular accentuation of the glomerular capillaries and hyaline deposits that compromise the majority of the capillary walls (PAS stain, ×40). (B) Prominent global subendothelial deposits, accompanied by immune deposits in the mesangium (direct immunofluorescence for immunoglobulin, ×400). (C) Extensive subendothelial immune deposits thickening almost all the capillary walls, generating a wire loop appearance and hyaline thrombi that occlude capillary lumens (PAS stain, ×400).

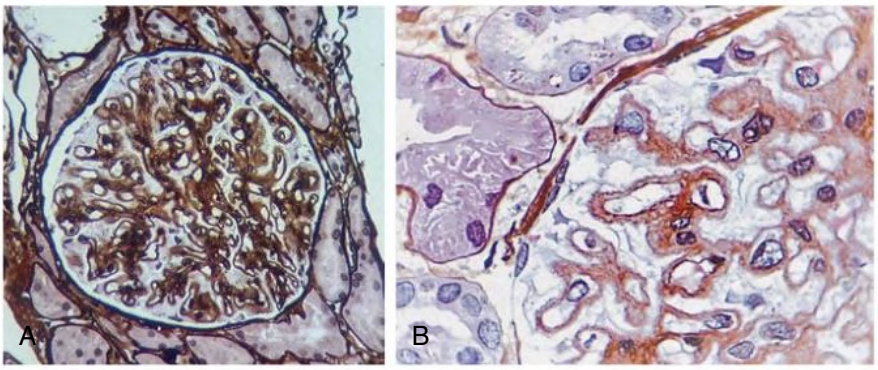

Fig. 27.5 International Society of Nephrology/Renal Pathology Society Class V: Membranous Lupus Nephritis. (A) Global subepithelial deposits with spike formation (silver methenamine stain, ×400). (B) Presence of extensive subepithelial deposits and segmental subendothelial deposits that generate double contours and indicates membranous lupus nephritis with a proliferative component (class V + III/IV) (silver methenamine stain, ×400).

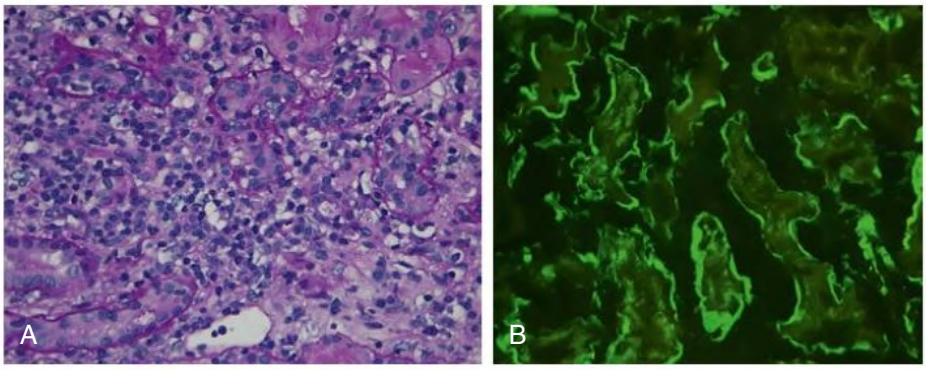

Fig. 27.6 Tubular Injury in Lupus Nephritis. (A) Interstitial lupus nephritis: mononuclear cells invading and destroying the tubular basement membranes (tubulitis and tubulorrhexis). Interstitial nephritis should not be related to chronic lesions such as tubular atrophy or glomerular scarring to contribute to the activity index. (PAS stain, ×400). (B) Direct immunofluorescence showing immunoglobulin G deposits in the tubular basement membrane (×400). Such tubular basement membrane aggregates are common in lupus nephritis, being found in 60% to 65% of biopsy specimens overall and with increasing frequency from class II (20%) to class IV (75%).

Vascular lesions are common in LN (Fig. 27.7). Five main pathologic types of kidney microvascular injury are seen: (1) vascular immune-complex deposits, (2) arteriosclerosis, (3) thrombotic microangiopathy, (4) noninflammatory necrotizing vasculopathy and, less frequently, (5) true vasculitis.[39]

Transformation of Histologic Appearance and "Silent" Lupus Nephritis

The ISN/RPS class found for LN is not fixed for an individual's entire clinical course. Those treated for proliferative (class III/IV) LN may transform to a less serious histology, such as class II, or have resolution

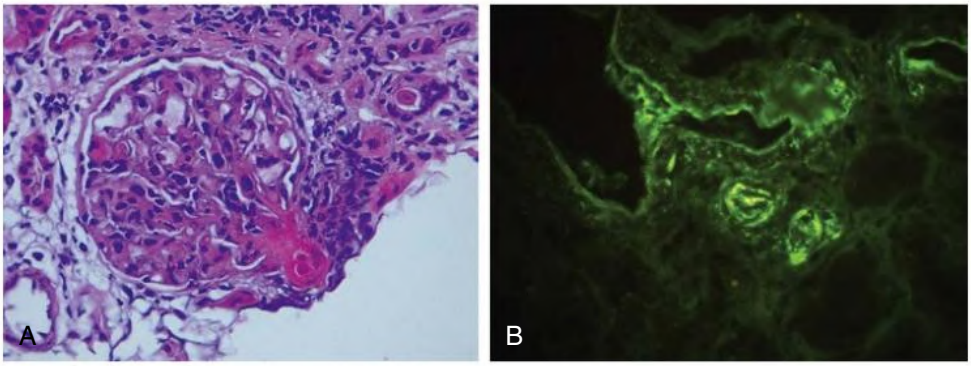

Fig. 27.7 Vascular Injury in Lupus Nephritis. (A) Lupus vasculopathy: luminal narrowing of arterioles by intramural immune deposits with fibrinoid changes but without inflammation of the vessel wall. (B) Demonstration of C1q deposits along the arterial walls, confirming that the hyaline deposits seen by light microscopy correspond to immune complexes and the diagnosis of lupus vasculopathy (direct immunofluorescence, ×400).

TABLE 27.4 Modified NIH Lupus Nephritis Activity and Chronicity Scoring System[a]

	ACTIVITY INDEX						CHRONICITY INDEX			
Semiquantitative Lesion Score[a]	Cellular/ Fibrocellular Crescents	Fibrinoid Necrosis	Neutrophils/Karyorrhexis	Endocapillary Hypercellularity	Hyaline Deposits	Interstitial Inflammation	Total Glomerulosclerosis Score (Segmental or Global)	Fibrous Crescent	Tubular Atrophy	Interstitial Fibrosis
None	0	0	0	0	0	0	0	0	0	0
Mild (<25%)	2	2	1	1	1	1	1	1	1	1
Moderate (25%–50%)	4	4	2	2	2	2	2	2	2	2
Severe (>50%)	6	6	3	3	3	3	3	3	3	3

[a]Maximum activity index is 24; maximum chronicity index is 12.
NIH, National Institutes of Health.

of inflammatory lesions with scarring and move from an active to a chronic histologic pattern. Conversely, patients initially diagnosed with class II or V LN may transform to proliferative LN, often heralded by increasing proteinuria and activity of the urine sediment.[40]

Kidney biopsies have been done in patients with SLE but no clinically obvious kidney involvement[41]; glomerular immune complexes were seen in some cases, most often consistent with class I/II LN but sometimes consistent with class III, IV, or V LN. This has been termed *silent LN* and may represent a preclinical stage in the evolution of LN.

Clinical, Laboratory, and Histopathologic Correlations and Outcomes

Kidney biopsy remains the gold standard for diagnosis and subsequent management of LN. Table 27.3 summarizes the typical clinicopathologic correlations of LN. Lupus membranous nephropathy is distinguished from the most frequent type of primary membranous nephropathy by the absence of circulating anti-PLA2r autoantibodies and by the presence of all IgG isotypes in the intrarenal immune deposits, although restriction to the IgG4 isotype has been rarely observed in LN patients.

The importance of the kidney biopsy is underscored by patients with SLE and kidney injury who do not have classic LN. For example, up to 24% of patients may have a renal thrombotic microangiopathy, either alone or associated with immune-complex GN.[42] A small (1.3%) but important subset of patients with SLE present with nephrotic syndrome, with or without AKI, but their kidney biopsies either mimic minimal change disease (MCD) or show mild mesangial expansion, proliferation and segmental sclerosis, mimicking focal segmental glomerulosclerosis (FSGS).[43] EM shows diffuse podocyte effacement, without immune complexes, or with mesangial deposits but no peripheral capillary deposits of immunoglobulins or complement components. These patients, although not classified by ISN/RPS, have lupus podocytopathy and like MCD or FSGS, most respond to corticosteroids alone.[44] However, in a Chinese study, the risk for relapse exceeded 50%, and at repeat kidney biopsy, half of the relapsed patients had transformed to class IV or V LN.[44] Although these results may not be generalizable to a non-Asian population, they underscore the importance of histology-driven treatment decision analysis.

Long-Term Prognosis and Kidney Histology

Features of reversible (active) or irreversible (chronic) damage on kidney biopsy are captured by the National Institutes of Health (NIH) activity and chronicity indices now adapted to the proposed revisions of the ISN/RPS classification (Table 27.4; Fig. 27.8).[37] Similar to other types of GN, long-term kidney prognosis is poor if the biopsy sample shows extensive glomerulosclerosis or interstitial fibrosis and tubular atrophy. In patients with less extensive scarring, the activity and chronicity indices at diagnostic biopsy may not correlate with the course of

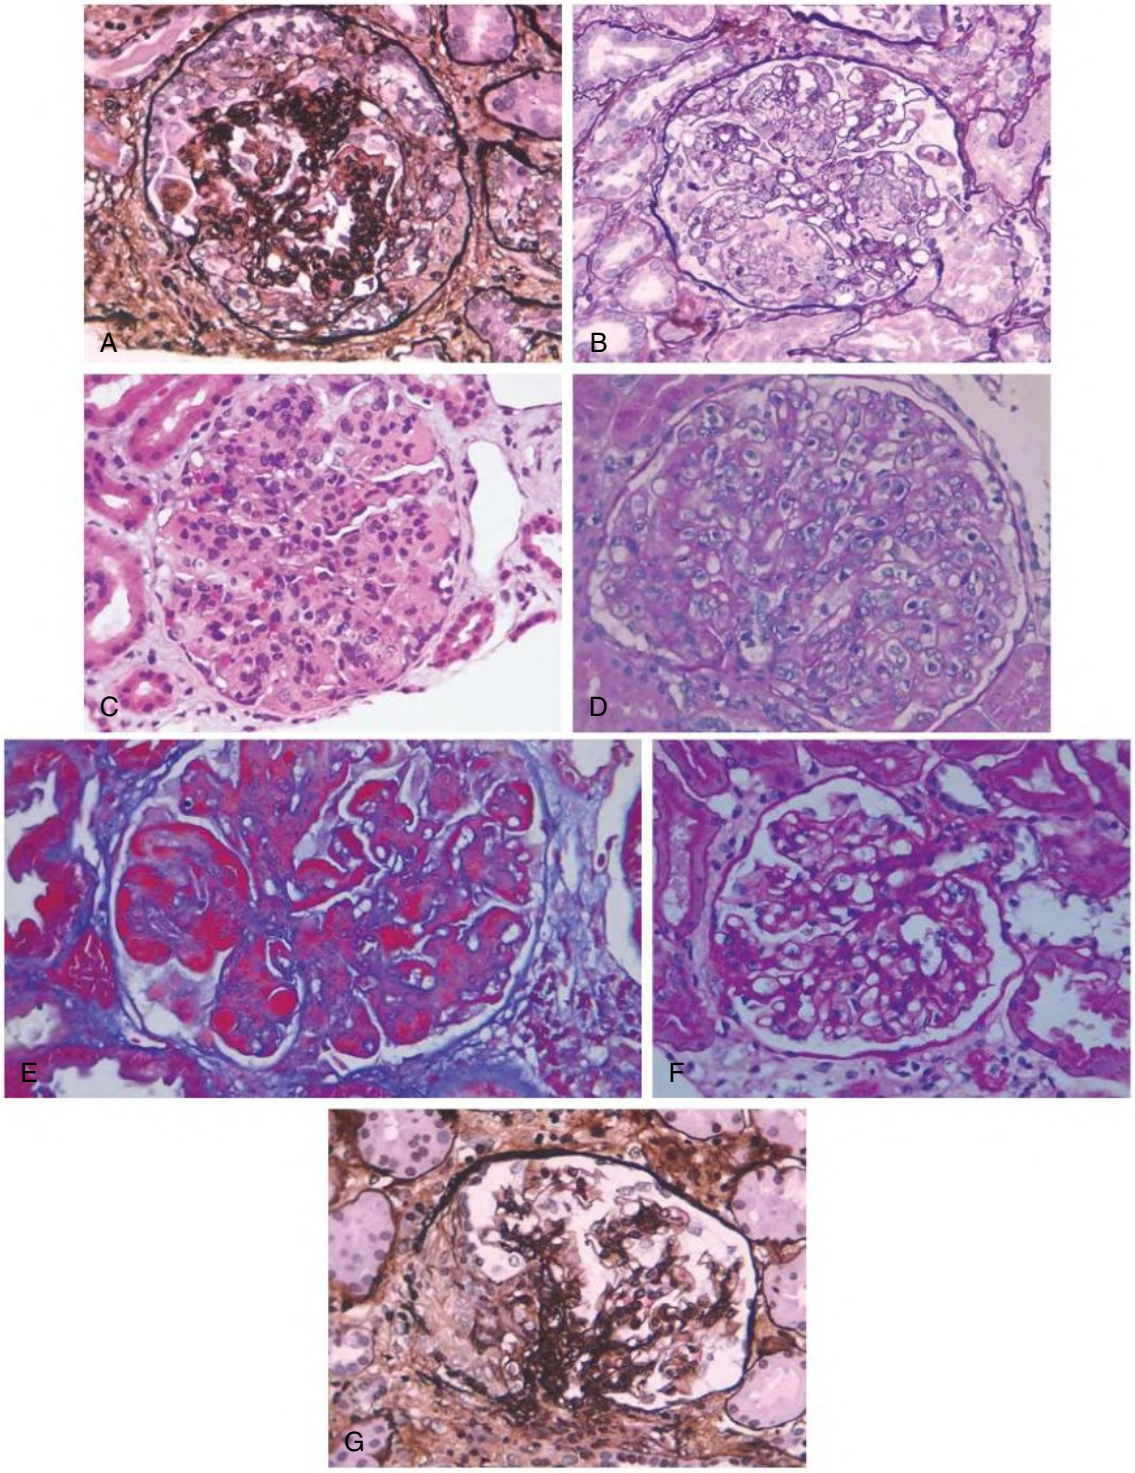

Fig. 27.8 Histologic Components of the Activity and Chronicity Indices. (A) Fibrocellular crescent. A crescent is defined by the presence of extracapillary hypercellularity, composed of more than two cell layers that make up 10% or more of the circumference of Bowman's capsule. Fibrocellular crescents have 25% to 75% cells and fibrin, and the remainder of fibrous matrix, and should be considered in the activity index (silver methenamine stain, ×400). (B) Fibrinoid necrosis. Fibrin associated with glomerular basement membrane disruption; this lesion does not require the presence of karyorrhexis (silver methenamine stain, ×400). (C) Neutrophils/karyorrhexis. Presence of neutrophils in the capillary lumina and karyorrhexis; defined as the presence of apoptotic, pyknotic, and fragmented nuclei (H&E, ×400). (D) Endocapillary hypercellularity. Increased number of infiltrating monocytes causing narrowing of the glomerular capillary lumina (PAS stain, ×400). (E) Hyaline deposits. Wire loop lesions and hyaline thrombi that represent the presence of massive subendothelial deposits that occlude the capillary lumina (Masson's trichrome stain, ×400). (F) Glomerulosclerosis. Segmental sclerosis with fibrous adhesions to Bowman's capsule (PAS stain, ×400). For the chronicity index, segmental and global glomerulosclerosis are considered together. (G) Fibrous crescent. Extracapillary proliferation with more than 75% fibrous matrix and less than 25% cells and fibrin (Silver methenamine stain, ×400).

LN.[40] In contrast, persistent activity (activity index > 2) despite treatment on repeat kidney biopsy is associated with a worse long-term kidney prognosis, as is high chronicity (chronicity index > 6).[40]

TREATMENT

The management of patients with SLE (including those with LN but no systemic disease) should include an antimalarial agent such as hydroxychloroquine. Antimalarials are TLR antagonists (specifically TLR-7, -8, and -9) and reduce flare rates (including LN flares), decrease organ damage, and enhance responsiveness to immunosuppression, among other beneficial effects.[44] Patients should be monitored for retinal toxicity.

The treatment of patients with active proliferative LN is traditionally divided into induction and maintenance phases, although these distinctions are blurred by the design of novel therapeutic trials (discussed later). The *initial* or *induction phase* may be thought of as the first step in controlling kidney inflammation to allow healing of kidney injury. This translates clinically into stabilization or improvement of kidney function, attenuation of proteinuria, and reduction in urine sediment activity. The *maintenance phase* focuses on consolidating clinical remissions and preventing relapses while reducing exposure to potentially toxic medications.

The ISN/RPS biopsy classification should guide initial therapy (see Table 27.3). In general, the immunosuppressive treatment of extrarenal lupus manifestations is sufficient for class I and II LN. The combination of high-dose glucocorticoids plus an immunosuppressive agent is mainly used for patients with active focal and diffuse proliferative LN (classes III and IV) and membranous lupus (class V).

A complete kidney response is achieved in only 30% to 40% of LN patients by 12 months.[45] Most studies define complete kidney response as a reduction in proteinuria to less than 0.5 g/day or a urine protein to creatinine ratio less than 0.5 g/g, absence of glomerular hematuria and red blood cell casts, and normal or stable GFR. However, long-term kidney survival is best predicted by reducing proteinuria to less than 0.7 to 0.8 g/day after 1 year of treatment.[46–48] Importantly this cutoff is starting to be incorporated into phase III clinical trials of novel LN therapies.[49] The term *partial response* requires a 50% reduction in proteinuria to subnephrotic levels, and stability or improvement in GFR and is usually achieved before complete response criteria are met.

In addition to immunosuppressive regimens, the kidney protective measures outlined in Chapter 82 should be used as appropriate.

Proliferative Lupus Nephritis: Initial Treatment

Glucocorticoids

The administration of glucocorticoids is fundamental to the treatment of LN. The goal of initial steroid therapy is to quickly control intrarenal inflammation and halt ongoing injury, thereby allowing time for coadministered immunosuppressive agents to attenuate the autoimmune mechanisms that initiated and perpetuate LN. Most regimens start with one to three consecutive intravenous (IV) pulses of methylprednisolone at up to 1000 mg/pulse, followed by oral prednisone or prednisolone, often starting at 1 mg/kg/day with slow tapering. There is considerable variability in cumulative glucocorticoid dosing.

There has been a concerted effort to reduce the cumulative steroid burden for LN patients. The original Euro-Lupus Nephritis Trial (ELNT) initiated oral prednisolone at 0.5 mg/kg/day for 1 month, followed by tapering after three 750 mg pulses of methylprednisolone.[50] The RITUXILUP trial used rituximab plus two 500 mg pulses of IV methylprednisolone followed by maintenance with mycophenolate mofetil (MMF) in the absence of oral steroids.[51] After a median of 36 weeks, 72% of patients had achieved a complete response. During follow-up, 22% of patients had a LN flare 65 weeks (median) after remission and 64% were managed without oral steroids. A phase II study compared the novel calcineurin inhibitor (CNI) voclosporin to placebo on a background of immunosuppression with MMF and low-dose glucocorticoids.[52] Patients were given two IV pulses of 500 mg methylprednisolone, followed by 20 to 25 mg/day prednisone that was tapered to 2.5 mg/day by 4 months. A complete kidney response was achieved by 49% of patients in the voclosporin group and 24% of patients in the placebo group after 48 weeks. Taken together, high-dose steroids for all LN patients may not be necessary, oral steroid dosing may be lowered after IV pulses of methylprednisolone, and some therapeutic regimens could be steroid-sparing.

Current LN guidelines recommend initiating steroid treatment with IV methylprednisolone at a total cumulative dose of 250 to 2500 mg (depending on disease severity), followed by oral prednisone at 0.3 to 1 mg/kg/day, and tapered to 7.5 mg/day or less after 3 to 6 months.[53,54]

Immunosuppressive Agents

Long-term kidney function is better preserved, and LN relapses after 3 to 5 years are reduced if glucocorticoids are combined with cyclophosphamide during initial therapy.[55] Both daily oral and IV pulses of cyclophosphamide are effective in LN, although IV cyclophosphamide given as 6-monthly pulses of 0.5 to 1 g/m^2 (NIH protocol) has been the standard of care for several years. The ELNT trial compared low-dose IV cyclophosphamide (500 mg/infusion) bimonthly for 3 months to the NIH protocol. Similar efficacy with less toxicity and fewer infections, and similar 5- and 10-year kidney outcomes were demonstrated.[50,56] The Euro-Lupus low-dose IV cyclophosphamide regimen achieved similar rates of remission induction in Black, Hispanic, and Southeast Asian patients.[57,58] Therefore, LN guidelines now recommend low-dose cyclophosphamide as the first choice if a cyclophosphamide-based regimen is to be used.[53] However, because low-dose cyclophosphamide studies have not included patients with serum creatinine levels 2.5 mg/dL or higher or those with extensive crescents or necrosis on kidney biopsy, high-dose IV cyclophosphamide remains an option for such patients.[57,58]

Oral MMF plus glucocorticoids for 6 months followed by maintenance therapy is as effective as 6-monthly pulses of cyclophosphamide (NIH protocol) plus glucocorticoids followed by maintenance therapy.[45] MMF also showed similar treatment response rates to the Euro-Lupus cyclophosphamide regimen at 24 weeks.[58] High-dose (NIH protocol) cyclophosphamide has been favored in patients presenting with marked kidney impairment or severe proliferative LN on biopsy, but there are no convincing differences in outcome between MMF and cyclophosphamide induction for such patients.[59] No improvement in overall mortality or severe infection has been seen with MMF; gastrointestinal disturbances are more frequent, but the risk for amenorrhea is lower than with cyclophosphamide.

Optimal MMF dosing and adjustment for different patient subgroups remains unclear. Although concentration-time curve ($AUC_{0\text{-}12}$) of the active MMF metabolite mycophenolic acid (MPA) may provide accurate overall measurements,[60] $AUC_{0\text{-}12}$ measurement is expensive and difficult to apply clinically. MPA trough levels correlate poorly with total drug exposure by AUC. A 4-hour AUC ($AUC_{0\text{-}4}$) has been proposed to follow MMF exposure, but targets for efficacy and toxicity still need to be established.[60] To date, a dosing range of 2 to 3 g/day for MMF has been recommended for initial treatment of proliferative LN with dose reduction for intolerance.

Long-term kidney outcomes of patients treated with MMF versus cyclophosphamide are not different, although one study reported a nonsignificant increase in LN flares in patients induced with MMF.[61] Differences in response between ethnic and geographic subgroups

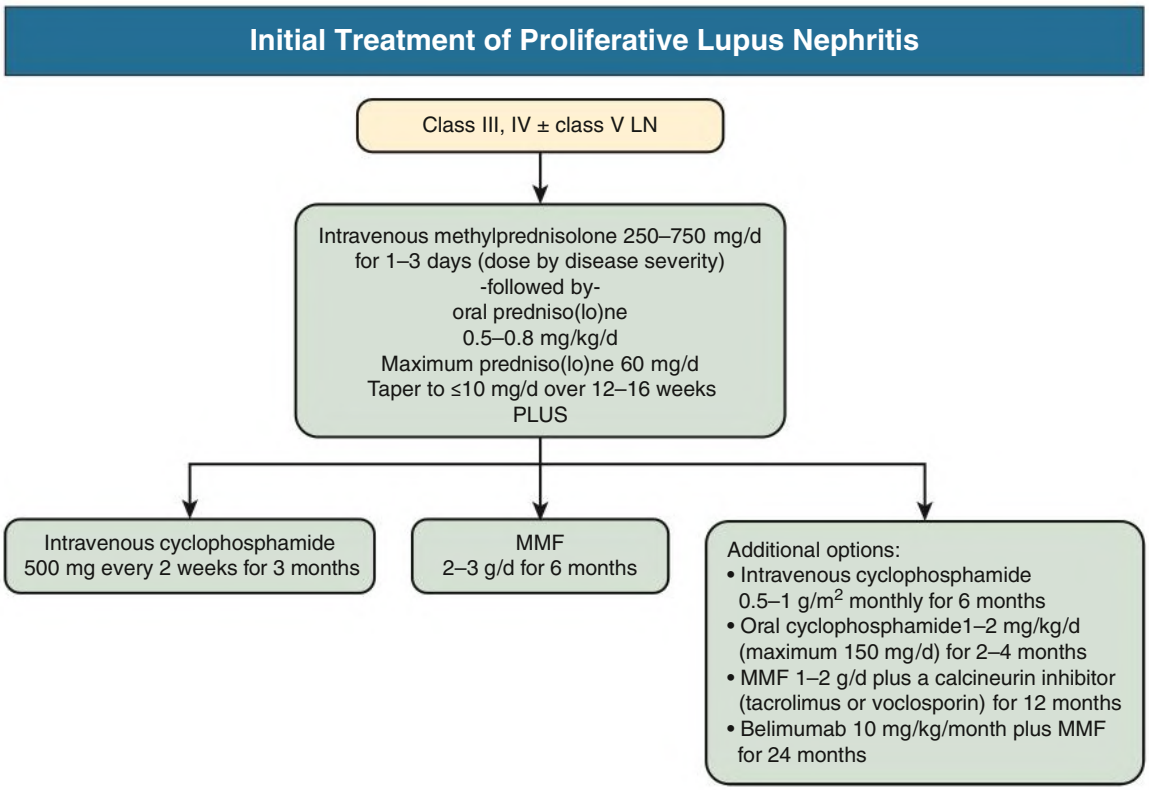

Fig. 27.9 Approach to the initial treatment of proliferative lupus nephritis *(LN) AZA,* Azathioprine; *MMF,* mycophenolate mofetil.

have been suggested but not confirmed.[62] However, a retrospective analysis of a Korean cohort showed similar remission rates for MMF and cyclophosphamide but more relapses and a higher incidence of ESKD in the MMF group.[63]

Guidelines for immunosuppressive therapy from the nephrology and rheumatology societies have been updated.[53,54] Our approach to the initial treatment of proliferative LN is given in Fig. 27.9.

Other Immunosuppressive Strategies

Azathioprine (AZA) has been used in combination with glucocorticoids for the induction of remission in proliferative LN. A randomized controlled trial (RCT) comparing AZA with cyclophosphamide found no difference in nonsustained doubling of initial serum creatinine, but more relapses, worse kidney function, and more chronicity on repeat biopsy in the AZA group.[64] Although AZA is not recommended as first-line therapy, it remains an option when MMF or cyclophosphamide are unavailable, undesirable, or contraindicated (including during pregnancy).

CNIs in combination with glucocorticoids or as part of a three-drug regimen consisting of prednisone, MMF, and a CNI have been used primarily in Asia for the initial treatment of LN. In the largest Chinese three-drug combination study, tacrolimus plus MMF and glucocorticoids were compared with high-dose cyclophosphamide plus glucocorticoids. The CNI-based regimen resulted in a greater complete kidney remission rate than cyclophosphamide at 6 months for all LN classes.[65] A CNI-based approach was also tested in a phase II trial in a highly diverse patient population that compared MMF, prednisone, and placebo with MMF, prednisone, and voclosporin.[52] The addition of voclosporin resulted in significantly more complete kidney responses at 6 and 12 months. In a phase III study (AURORA) of 357 patients with class III, IV, or V LN, the additive benefit of voclosporin was confirmed.[66] Long-term preservation of kidney function and improvement in kidney histology in CNI-treated LN patients will be addressed to some extent through the extension phase of AURORA.

The AURORA trial design did not distinguish between induction and maintenance. Other than a tapering of low-dose glucocorticoids, patients remained on the same medications and doses for 12 months.

Biologic Agents

Rituximab, an anti-CD20 monoclonal antibody that depletes B cells, was tested in the LUNAR trial, a randomized prospective study of patients with active LN. LUNAR failed to detect a difference in complete kidney responses at 1 year when rituximab was added to MMF and glucocorticoids compared with MMF and glucocorticoids alone.[67] In subsequent clinical trials, other biologics, such as Abatacept, an inhibitor of T- and B-cell costimulation, an anti-interleukin 6 monoclonal antibody, and an anti-TWEAK monoclonal antibody, also failed to improve the proportion of LN patients achieving a complete kidney response.[57,68,69]

Despite the trial's failure, follow-up of LUNAR participants beyond 12 months suggested that the rituximab and placebo groups need more time to show differences.[67] Additionally, a post hoc analysis of LUNAR showed that complete kidney responses correlated with complete peripheral B cell depletion that occurred early and was sustained.[70] Using this information to inform trial design, the humanized anti-CD20 monoclonal antibody obinutuzumab was tested in NOBILITY, a 2-year, phase II LN RCT. Like rituximab, obinutuzumab depletes peripheral B cells, but compared with rituximab, depletion is more complete and sustained, there is more antibody-dependent cytotoxicity, and there is less reliance on complement-dependent cytotoxicity.[71,72] NOBILITY compared obinutuzumab to placebo on a background of MMF and prednisone. Besides being longer than LUNAR, overall glucocorticoid dosing was less, and there was little separation into induction and maintenance phases in NOBILITY,

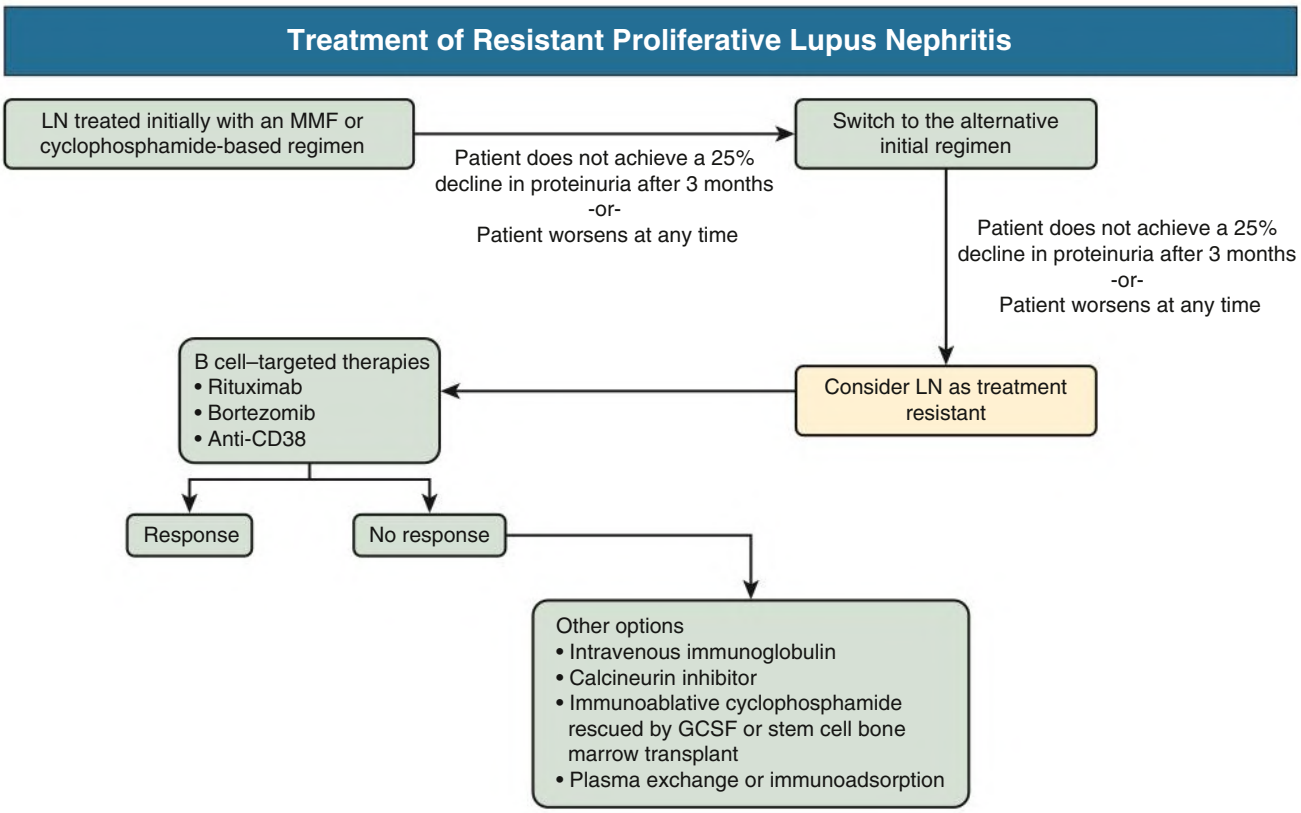

Fig. 27.10 Treatment of resistant proliferative lupus nephritis (LN). *GCSF,* Granulocyte colony-stimulating factor; *MMF,* mycophenolate mofetil.

other than the last infusion of obinutuzumab or placebo at month 6. Significantly more patients who received obinutuzumab achieved complete kidney response at week 76 and week 104 compared with placebo.[73,74] Adverse events were comparable between the two groups.

Belimumab, a monoclonal antibody that targets the B-cell growth and survival factor BAFF (also called BLyS), was tested in a large (n = 448) phase III trial (BLISS-LN).[49] BLISS-LN was a 2-year study that allowed investigators to choose background immunosuppression, and the primary endpoint was primary efficacy renal response (PERR), whereas complete kidney response was a secondary endpoint. For PERR, the urine protein to creatinine ratio was 0.7 or less compared with less than 0.5 for complete response, and estimated GFR (eGFR) had to be at least 60 mL/min/1.73 m^2 and no more than 20% below its preflare value, whereas complete response required an eGFR of at least 90 mL/min/1.73 m^2 and no more than 10% below its preflare value. Belimumab was added to MMF plus glucocorticoids followed by MMF or to low-dose cyclophosphamide plus glucocorticoids followed by azathioprine. Glucocorticoids had to be tapered to 10 mg/day or less by week 24 and could only be increased briefly to treat a non-renal SLE manifestation, and not at all between week 76 and week 104 or the treatment was considered a failure. At 104 weeks, patients who received belimumab had significantly more PERRs and complete kidney responses than those given placebo.[49] Belimumab-treated patients had significantly fewer kidney-related events and better preservation of kidney function over the 2 years of the trial. Adding belimumab to background immunosuppression did not increase adverse events compared with placebo.

In summary, although the early experience with biologics for the treatment of LN was discouraging, longer trial duration, a blurring of the line between induction and maintenance therapy, and lower exposure to glucocorticoids allowed for successful trials. B cell–targeted biologics do not appear to act quickly, consistent with the fact that B cells do not produce autoantibodies but are precursors to autoreactive plasma cells and plasmablasts. Antibodies to type 1 interferon and to complement system components are currently being assessed for the treatment of LN.

Renal Response to Initial Therapy

LN patients who achieve a complete kidney response during treatment generally have 5-year patient and kidney survival of more than a 90% compared with only 69% (patient) and 45% (kidney) for those not achieving complete remission.[11] Partial responses are also associated with improved outcomes compared with no response. It is also clear that complete kidney responses take time. About half of LN patients treated with MMF or cyclophosphamide achieve a complete or partial response by 1 year, with an additional 25% by 2 years.[75] To avoid prolonged exposure to inflammatory injury, a 25% reduction in proteinuria should be targeted during the first 3 months of therapy and proteinuria should be reduced by 50% by 6 months.[53] At 12 months, patients would ideally have a proteinuria level less than 0.7 g/day. Using these metrics, consider switching medications if a patient has not demonstrated a 25% decline in proteinuria at 3 months. If the patient had been started on an MMF-based regimen, a switch to a cyclophosphamide-based regimen is appropriate, or vice versa. After another 3 months, if the patient has not shown a 25% decline in proteinuria, they could be considered as treatment resistant, at least to usual therapies (Fig. 27.10). A critical caveat before calling a patient treatment resistant is to verify adherence to therapy.[76]

Resistant Proliferative Lupus Nephritis

There is no high-quality RCT evidence to suggest an optimal approach to patients with resistant LN. In uncontrolled trials, cohort studies, and

observational studies in resistant LN, rituximab was added to, or given after, intense conventional immunosuppression and converted 40% to 50% of nonresponders to complete responders.[77,78] Rituximab also has been combined with belimumab for refractory LN.[79] Plasma cells have been targeted in a small number of resistant LN patients with bortezomib or anti-CD38 antibodies with some success.[80,81]

Other possible beneficial approaches tested in small series of patients with resistant LN include plasma exchange, IV immunoglobulin, and CNIs.[82,83,84] Infusion of allogeneic mesenchymal stem cells derived from umbilical cord or bone marrow has been tested in refractory LN.[85] At 12 months, about 23% of patients had a complete renal response, but 40% of patients were considered to have treatment failures. Finally, for patients with life-threatening resistant disease, small pilot studies have tested total lymphoid irradiation and immunoablation by high-dose cyclophosphamide and antithymocyte globulin, with or without autologous stem cell reconstitution. These approaches have led to sustained treatment-free remissions, but toxicity and treatment-related mortality are considerable.[86]

Proliferative Lupus Nephritis: Subsequent Therapy

The high adverse event rate from intense cytotoxic treatment can be mitigated with no loss of efficacy if cyclophosphamide is discontinued after 3 to 6 months and drugs such as azathioprine or MMF are substituted in for long-term disease control.[87] The concept of induction followed by maintenance therapy has been challenged (see earlier), and LN is thought of as a chronic disease for which preservation of kidney function is the most important outcome.

MMF is the drug of choice for long-term immunosuppression after initial therapy with cyclophosphamide or MMF, based on a trial that demonstrated MMF was superior to azathioprine at preventing renal flares, preserving kidney function over 3 years, and delaying progression to ESKD.[61] If MMF is not tolerated, or in specific circumstances such as pregnancy, azathioprine or a CNI may be used for long-term immunosuppression.

The optimal duration of immunosuppression in patients with LN is unknown. Patients generally remain on immunosuppression for several years, and the longer the duration of therapy, the less chance of flare.[88] The concern with withdrawing therapy too early is that LN will flare (relapse) and that every flare will increase the risk of progressive kidney disease. On the other hand, continuing immunosuppression increases the risk for adverse events.

Protocol kidney biopsies may help decide whether immunosuppressive therapy can be safely withdrawn. In patients with proliferative LN, a protocol biopsy done after 36 months of immunosuppression and at least 12 months of complete clinical renal remission showed that 30% of patients still had ongoing immunologic activity. Immunosuppression was withdrawn from all patients in clinical remission and LN relapsed almost exclusively in patients with a residual histologic activity index of at least 2.[89] Using a similar approach,[90] if a 42-month protocol biopsy showed a histologic activity index of 0, immunosuppression was discontinued, but if the activity index was 1 or greater, immunosuppression was continued. After 24 months, biopsies were performed again in the patients who remained on immunosuppression, and if the activity index was 0, the immunosuppressives were discontinued. Using this approach, the observed flare rate was fivefold less than that expected after discontinuation of immunosuppression based only on clinical data. Thus, performing a kidney biopsy can help inform the decision to withdraw immunosuppression. It is conceivable that lower cumulative immunosuppression may be sufficient for some patients, perhaps those with no histologic activity on kidney biopsy after 1 or 2 years of treatment.

The long-term management of immunosuppression for patients with persistent proteinuria who have achieved only partial remission is even less certain. Persistent proteinuria may be because of ongoing inflammatory disease activity or chronic damage and nephron loss. It has been found that a proportion of patients with persistent proteinuria no longer has histologic activity on kidney biopsy.[91] Such patients may not need ongoing immunosuppression.

Membranous Lupus Nephropathy

Membranous nephropathy is often diagnosed together with proliferative forms of LN. In these patients, treatment is directed at the proliferative component. Alternatively, the combination of low doses of glucocorticoids, MMF, and a CNI has shown considerable success in an Asian cohort of mixed membranous and proliferative LN.[92]

Immunosuppressive therapy should be used for patients with nephrotic syndrome and/or impaired kidney function. The only RCT in patients with pure class V LN was small and compared cyclophosphamide or cyclosporine with glucocorticoids alone.[93] The patients studied had preserved kidney function and a mean proteinuria of almost 6 g/day. Complete and partial remissions were more frequent in the cyclophosphamide and cyclosporine-treated patients. Cyclosporine induced remission more rapidly than the other drugs, but LN relapses were fewer in the cyclophosphamide group. Two trials of MMF versus cyclophosphamide as initial therapy of LN included 84 patients with pure membranous nephropathy, among others.[94] Remissions, relapses, and courses were similar in the class V patients treated with MMF and cyclophosphamide. Pure class V LN with subnephrotic proteinuria can be treated with renoprotective and antiproteinuric therapies and immunosuppression dictated by extrarenal lupus symptoms. Our approach to treatment of class V LN is outlined in Fig. 27.11.

Long-Term Monitoring of Lupus Nephritis Patients

The relapse (flare) rate for LN ranges from 35% to 60%, depending on the population studied, the criteria for relapse, and the maintenance therapy used.[90] In LN patients in remission, quarterly monitoring (including blood pressure, kidney function, proteinuria, urinary sediment, and serum C3 and C4) is recommended, with anti-dsDNA measured at least biannually. Changes in serology alone do not warrant therapeutic action, although some investigators report lower flare rates when modest preemptive treatment is given to such patients.[95] At the very least, patients should be watched even more closely for flare. If LN does flare, a repeat biopsy should be considered if a change in histologic class is suspected. Patients with proliferative LN tend to remain proliferative at flare, but patients with class II and V not infrequently develop a proliferative component.

ANTIPHOSPHOLIPID ANTIBODY SYNDROME, ATHEROSCLEROSIS, AND PREGNANCY IN LUPUS NEPHRITIS

Intrarenal thrombosis caused by the antiphospholipid antibody syndrome is found in 30% of patients with SLE and may occur in the presence or absence of LN (see Chapter 29). The mainstay of treatment for antiphospholipid nephropathy is anticoagulation plus an antimalarial, although immunosuppressive agents have also been used. Vitamin K antagonists such as warfarin (VKAs) are the anticoagulants of choice for arterial thromboses; the choice between VKAs and direct oral anticoagulants for patients with venous thrombosis remains controversial.[96]

Patients with lupus have markedly elevated risk for atherosclerotic cardiovascular disease and a greater atherosclerotic plaque burden compared with age-matched controls.[97,98] Reduction of atherosclerotic

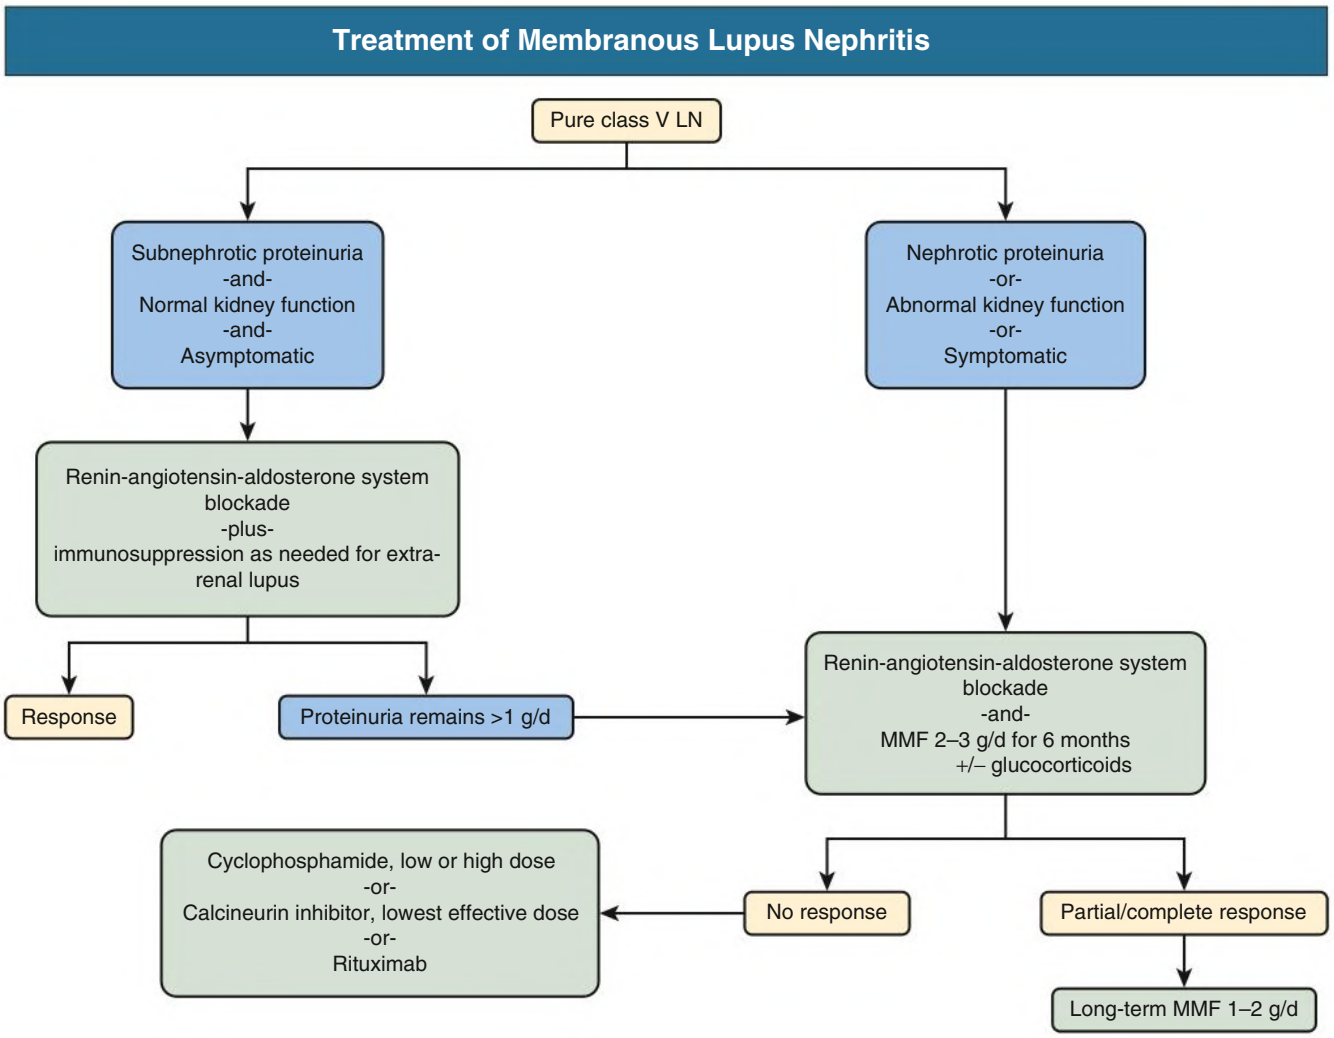

Fig. 27.11 Treatment of membranous lupus nephritis *(LN). MMF,* Mycophenolate mofetil.

risk should focus on blood pressure control (goal of <130/80 mm Hg), use of statins and hydroxychloroquine,[99] and reduction of inflammatory disease activity.

The effects of SLE and LN on pregnancy and fetal outcomes and the effects of pregnancy on LN activity are discussed in Chapter 45.

END-STAGE KIDNEY DISEASE AND KIDNEY REPLACEMENT THERAPY

Although survival of LN patients on dialysis was noted to be similar to patients with other causes of ESKD,[100] a study from Australia suggested worse survival.[101] LN patients who received a kidney transplant had significantly better survival than those who did not,[102] suggesting that kidney transplantation is the kidney replacement modality of choice for LN patients with ESKD. Extrarenal lupus is often quiescent by the time patients reach ESKD, but those with active extrarenal disease may still require immunosuppression. It has been suggested that patients with LN defer transplantation for 3 to 6 months to allow SLE to become inactive; however, an increased risk for allograft failure was found when LN patients waited more than 3 months before transplantation.[103] Recurrent LN after kidney transplantation may occur but is generally not the cause of allograft loss.[104]

SELF-ASSESSMENT QUESTIONS

1. A 21-year-old African-American woman presents for initial therapy of LN. She was diagnosed with SLE 1 year ago, when she was found to have alopecia, malar rash, and arthralgias with ANAs and dsDNA antibodies. At that time, urine sediment was unremarkable, serum creatinine was 0.6 mg/dL, and she had no proteinuria. She was treated with low-dose glucocorticoids and hydroxychloroquine, with resolution of her symptoms. Over the past month, she noticed foamy urine and mild ankle swelling. Evaluation showed blood on her urine dipstick, 24-hour urine with 4 g protein, serum creatinine of 1 mg/dL, and a rising dsDNA titer with both C3 and C4 now newly decreased. A kidney biopsy revealed class IV LN, without crescents or glomerular capillary necrosis. The patient wants children in the future. Considering options for initial therapy for this patient's LN, which of the following statements is *incorrect?*
   A. She could be treated with MMF and glucocorticoids.
   B. She could be treated with a calcineurin inhibitor in combination with MMF and glucocorticoids.
   C. She could be treated with low-dose cyclophosphamide and receive ovarian protection.
   D. She could be treated with belimumab alone.

2. A 24-year-old Hispanic woman has been treated for the last 6 months with MMF 3 g/day and a tapering dose of glucocorticoids for active focal proliferative class III LN. Her initial proteinuria decreased from 3.4 g/day to 1.2 g/day, urine sediment became inactive, serum creatinine decreased from 1.6 to 0.9 mg/dL over the 6 months of therapy, anti-dsDNA titer declined, and serum complement values returned to normal. She has tolerated her treatment well and reports no side effects. What should be done with her immunosuppression?
   - **A.** Continue the current dose of MMF, follow patient for a complete renal remission, and when achieved, reduce MMF to 2 g/day and continue for at least 36 months of total immunosuppressive therapy, with ongoing monitoring for any evidence of LN relapse.
   - **B.** Change to intravenous cyclophosphamide at 500 mg every 2 weeks for 6 doses and then administer azathioprine at 2 mg/kg daily.
   - **C.** Add a calcineurin inhibitor to her current regimen.
   - **D.** Add rituximab to her current regimen.
3. A 32-year-old White woman with a past history of LN wants to become pregnant and is concerned about flares during the pregnancy. Which of the medications listed should NOT be used during pregnancy?
   - **A.** Glucocorticoids
   - **B.** Calcineurin inhibitor
   - **C.** Hydroxychloroquine
   - **D.** Azathioprine
   - **E.** Mycophenolate mofetil
4. A 28-year-old White man had been diagnosed 4 years ago with class IV LN by kidney biopsy. He was treated with MMF and glucocorticoids, and his kidney function improved to an eGFR of 89 mL/min/1.73 m^2. Proteinuria fell from 2.7 g/day to 950 mg/day. His anti-dsDNA antibody titer fell by 75% and his C3 complement increased to the normal range, but C4 remained low. He has been on MMF 2 g/day for 3 years. He has been on 5 mg of prednisone every other day for 2 years. He has had no extrarenal signs or symptoms of lupus for over 3 years. He wants to know if he needs to stay on immunosuppression or can safely come off. What should be done?
   - **A.** Continue his MMF and prednisone until the anti-dsDNA antibody is no longer detectable and then stop immunosuppression.
   - **B.** Order a kidney biopsy to determine whether there is any residual histologic activity.
   - **C.** Continue his MMF and prednisone until his C4 level is in the normal range and then stop immunosuppression.
   - **D.** Continue his MMF and prednisone until his proteinuria is less than 250 mg/day.

Monoclonal Immunoglobulin–Related Glomerular Diseases and Renal Amyloidosis

Frank Bridoux, Jean-Paul Fermand, Nelson Leung, Pierre Ronco, Guy Touchard

MONOCLONAL GAMMOPATHY OF RENAL/CLINICAL SIGNIFICANCE

The glomerulus is a favorite site for the deposition of aggregated, misfolded, or abnormal proteins. Among these, monoclonal immunoglobulins (Igs) are increasingly recognized as a major cause of glomerular disorders (see also Chapter 22). Monoclonal Ig is produced by an abnormal B-cell clone, which most commonly does not cause cancerous symptoms but is quiescent or indolent, corresponding to a monoclonal gammopathy of undetermined significance (MGUS) or to an indolent lymphocytic or plasmacytic disorder. The association of such a "dangerous small B-cell clone" with related kidney manifestations is now recognized as monoclonal gammopathy of renal significance (MGRS).[1] Recently, the concept has been extended to monoclonal gammopathy of clinical significance (MGCS) to encompass the involvement of other organs.[2] Importantly, in patients with MGR(C)S-related organ lesions, current treatment is based on targeting the underlying B-cell clone, although it is not malignant per se.

Overt hematologic malignancies, such as symptomatic myeloma, B-cell lymphoma, or Waldenström macroglobulinemia (WM), may be complicated by the same kidney diseases as in MGR(C)S. More frequently, kidney disorders occurring during these malignant lymphoid and/or plasmacytic proliferations are related to tumor mass, including light chain (LC) cast nephropathy, kidney infiltration by malignant cells, and intracapillary thrombi of monoclonal IgM.[3,4] In these cases, treatment is directed at the hematologic malignancy.

Kidney disorders related to MGRS are classified into three categories according to the composition and appearance of deposits by immunofluorescence (IF) and electron microscopy (EM), respectively (Table 28.1).[5] The first category includes diseases with deposition of monoclonal Ig organized ultrastructurally into fibrils (immunoglobulinic amyloidosis) or microtubules (cryoglobulinemic glomerulonephritis [GN] and immunotactoid GN). The second category includes disorders characterized by nonorganized electron-dense granular monoclonal Ig deposits (i.e., monoclonal Ig deposition disease) and proliferative GN with monoclonal Ig deposits. In the third category, encompassing C3 glomerulopathy and thrombotic microangiopathy, no Ig deposits are present and glomerular lesions are thought to derive from local or systemic complement activation by the monoclonal Ig. This chapter focuses on glomerular diseases with organized and nonorganized monoclonal Ig deposits, except for cryoglobulinemic GN (Chapter 22), fibrillary GN (Chapter 29), monoclonal Ig-associated C3 glomerulopathy (Chapter 23), and renal thrombotic microangiopathy (Chapter 30).

Pathophysiology

The large spectrum of MGR(C)S-related diseases reflects the diversity of pathogenic mechanisms and affected tissues or organs. Kidney lesions most commonly result from deposition of all or part of the monoclonal immunoglobulins as aggregates, amorphous, crystalline, microtubular, or fibrillar forms. Other identified mechanisms include autoantibody activity directed against a tissue antigen or resulting in the deposition of immune complexes and complement activation.[2,5,6] Of note, monoclonal Ig-mediated activation of the alternative pathway of the complement system has been documented recently in monoclonal Ig-associated C3 glomerulopathy (see Chapter 23).[7]

Only a minority of monoclonal immunoglobulins produced in clonal B-cell disorders are nephrotoxic. Pathogenicity appears mostly due to sequence peculiarities in the variable (V) domain that govern monoclonal Ig toxicity, including their propensity to aggregate and deposit.[6] In light chain amyloidosis (AL), there is a strong prevalence for λ LC isotype, and two germline Vλ genes are implicated in half of λ-LC-associated AL amyloidoses.[8] In light chain deposition disease (LCDD), κLC isotypes are predominant, with overrepresentation of the *Vκ4-1* gene. The LC V domain features frequent glycosylation, hydrophobic residues, and high isoelectric point (pI) that could account for propensity to deposit along the anionic proteoglycans of the basement membranes.[6,9]

Diagnostic Considerations

In any patient with proteinuria, serum and urine protein electrophoresis must be performed. In addition, serum and urine immunofixation and serum free light chain (FLC) assay should be considered, particularly in the 40- to 80-year age range.[1,2,5]

In Patients With Known Monoclonal Gammopathy and Kidney Manifestations

The first step is to rule out symptomatic multiple myeloma (MM), WM, chronic lymphocytic leukemia (CLL), or other B-cell lymphoma, which would per se require specific hematologic treatment.

In patients with monoclonal gammopathy and no evidence of symptomatic hematologic disease, the diagnosis of MGRS-related kidney disease should be considered.

Regarding kidney disease, immunologic investigations should include serum complement studies and tests for cryoglobulins. In the absence of contraindications, a kidney biopsy should be performed in most patients. Exceptions are AL amyloidosis already proven on an extrarenal biopsy (see later), and any condition including age and comorbidities that would question the benefits of chemotherapy. If a concurrent cause of kidney disease such as diabetes is present, kidney biopsy should be considered only if presentation or clinical course is

TABLE 28.1 Classification of Glomerular Disorders With Monoclonal Immunoglobulin Deposits and Comparison With Fibrillary Glomerulonephritis

Glomerular Disease	Renal Symptoms	Light Microscopic Findings	Immunohistology	Ultrastructural Findings	Extrarenal Involvement	Identification of a Monoclonal Immunoglobulin	Hematologic and Immunologic Characteristics
Organized Monoclonal Ig Deposits							
Amyloid: AL, AH, AHL	Proteinuria, NS CKD Hypertension and hematuria uncommon	Congo red–positive mesangial and CW deposits Vascular and tubulointerstitial deposits common	AL: LC deposits (mostly λ) AH: HC deposits (γ1, or γ4, or α), with CH1 deletion AHL: LC and HC deposits	7–14 nm fibrils randomly arranged	Frequent: heart, liver, peripheral nerves	EP/IFIX: 70%–90% FLC: 80%–90%	MGR(C)S Symptomatic MM uncommon WM
Immunotactoid glomerulopathy/ glomerulonephritis with organized microtubular immunoglobulin deposits	Proteinuria, NS CKD Microhematuria Hypertension	Mesangial proliferative GN Atypical MN MPGN pattern Interstitial tumoral infiltrate common (CLL)	Granular/smudgy deposits in mesangium and CW (predominantly subepithelial). Monotypic IgG deposits (IgG_1 most common) (κ > λ) C3, C4, C1q deposits	10–60 nm microtubules with hollow core, arranged in parallel; similar microtubules in leukemic lymphocytes (if present)	Rare (peripheral nerve, skin)	EP/IFIX: 40%–70% FLC: 20%	CLL (common) B-cell lymphoma MGRS MM Hypocomp. ~30%
Type I cryoglobulinemic GN	Proteinuria, NS CKD Microhematuria Hypertension Possible nephritic syndrome, AKI	MPGN pattern Endocapillary GN Glomerular thrombi common Intrarenal vasculitis occasional	Deposits in mesangium, CW (predominantly subendothelial), vascular walls. Glomerular thrombi IgG, IgM, or IgA (κ > λ) C3, C4, C1q deposits	10–90 nm microtubules with hollow core Extra + intracellular crystals (crystal-cryoglobulinemia)	Frequent: skin ++, peripheral nerve, joints	EP/IFIX: 80% FLC: unknown	MGR(C)S MM B-cell lymphoma WM Hypocomp. common
Nonorganized Monoclonal Ig Deposits							
Monoclonal Ig deposition disease	Proteinuria, NS CKD Microhematuria Hypertension	Nodular glomerulosclerosis (constant in HCDD) Less often mesangial proliferative GN, crescents rare (<10%) and focal Thickened TBM and vascular walls	Linear deposits along TBM, GBM, and arteriolar myocytes LCDD: LC deposits only (mostly κ) HCDD: HC deposits only (γ or α), with CH1 deletion LHCDD: LC + HC deposits	Amorphous, finely granular deposits in TBM, GBM, mesangium, and arteriolar walls	Frequent (often oligosymptomatic): heart, liver, peripheral nerve	EP/IFIX: 70%–100% FLC: ~100%	MGR(C)S Symptomatic MM WM Hypocomp. common in γ1 and γ3 HCDD

Glomerular Disease	Renal Symptoms	Light Microscopic Findings	Immunohistology	Ultrastructural Findings	Extrarenal Involvement	Identification of a Monoclonal Immunoglobulin	Hematologic and Immunologic Characteristics
Proliferative GN with monoclonal Ig deposits	Proteinuria, NS CKD Microhematuria Hypertension	MPGN pattern Endocapillary GN Membranous GN Mesangial proliferative GN	Granular mesangial and CW deposits IgG deposits (mostly IgG3), (κ> λ), rarely IgM, IgA, or LC alone C3 + C1q deposits	Nonorganized granular deposits in mesangium, subendothelial, and/or subepithelial zone	None	EP/IFIX: 30% FLC: unknown	Usually none MGRS MM, B-cell lymphoma WM rare Hypocomp. ~30%
Fibrillary GN (See Chapter 29): Not Related to Monoclonal Ig Deposits							
Fibrillary GN	Proteinuria, NS CKD Microhematuria Hypertension Acute nephritic syndrome rare	Mesangial proliferative GN MPGN pattern Crescents in 10–20% Positive DNAJB9 staining in 100% Congo red negative[a]	IgG deposits (almost always polyclonal, mostly IgG4)[b] C3 ± C4, C1q	12–24 nm fibrils randomly arranged	None	EP/IFIX <10% (fortuitous association in most cases)	HCV, autoimmune diseases, nonhematologic malignancy Hematologic disease very rare

[a]Rare fibrillary GN cases with Congo red weakly positive glomerular deposits have been described.[46]
[b]Rare cases of IgG-negative fibrillary GN have been described.[47]
AH, Amyloid with immunoglobulin heavy chains; *AL,* amyloid with immunoglobulin light chains; *AKI,* acute kidney injury; *CLL,* chronic lymphocytic leukemia; *CKD,* chronic kidney disease; *CW,* glomerular capillary walls; *DNAJB9,* DnaJ homolog subfamily B member 9; *EP/IFIX,* electrophoresis/immunofixation; *FLC,* serum free light chains; *GN,* glomerulonephritis; *HC,* immunoglobulin heavy chains; *HCDD,* heavy chain deposition disease; *Hypocomp.,* hypocomplementemia; *Ig,* immunoglobulin; *LC,* immunoglobulin light chains; *LCDD,* light chain deposition disease; *LHCDD,* light and heavy chain deposition disease; *ITGP,* immunotactoid glomerulopathy; *MGR(C)S,* monoclonal gammopathy of renal (clinical) significance; *MM,* multiple myeloma; *MN,* membranous nephropathy; *MPGN,* membranoproliferative glomerulonephritis; *NS,* nephrotic syndrome; *TBM,* tubular basement membrane; *WM,* Waldenström macroglobulinemia.

atypical. Importantly, when a kidney biopsy is performed, a sample should be processed for EM. Light microscopy (LM) should include Congo red staining. Immunofluorescence studies are crucial to determine the composition of deposits, to assess their monotypic nature and their concordance with the circulating monoclonal Ig. They should be performed using antibodies specific for κ and λ LCs, and, when deposits are composed of an entire IgG, heavy chain subclass typing is recommended. Except for most cases of AL amyloidosis, EM is required to assess the diagnosis of MGRS-related lesions to demonstrate the distribution and ultrastructural pattern of organization of deposits. When the diagnosis remains uncertain, additional techniques including paraffin IF after pronase digestion, proteomic analysis, and immuno-EM are required, preferentially after expert advice from a reference center.[5]

Careful attention should be paid to extrarenal manifestations. Tests for liver function and cardiac biomarkers (NT-proBNP and troponin) are mandatory.

Hematologic workup is the cornerstone of the management of MGR(C)S. It must include bone marrow examination with flow cytometric characterization of lymphocytic and plasmacytic populations and serum FLC (sFLC) measurement. Interpretation of FLC assays may be difficult in patients with impaired kidney function. Physiologically, FLCs undergo renal elimination, and the level of polyclonal κ and λ FLCs increases as glomerular filtration rate decreases. With the Freelite test, the "normal" FLC ratio is 0.26 to 1.65 in patients with preserved kidney function but is 0.34 to 3.10 in patients with severe kidney failure (chronic kidney disease [CKD] stage 5 or greater). Of note, several different assays for measuring FLC are now available but results from different assays cannot be directly compared so the same FLC assay must be used to monitor a particular patient throughout follow-up. The nature of the clone is usually in accordance with the isotype of the monoclonal Ig: plasmacytic when the monoclonal Ig is IgG, IgA, or LC only; and lymphoplasmacytic or lymphocytic when it is IgM.[1,2,5,10] Exceptions exist, such as plasma cell clones harboring translocation t(11;14) and producing monoclonal IgM. Considering the high prevalence of monoclonal immunoglobulins after age 50 years (>3%), it is crucial to exclude a chance association between the kidney disease and the monoclonal gammopathy and obtain support for a causal link between the two. For example, demonstrating tissue deposition or precipitation of all or part of the circulating monoclonal Ig is a strong argument for clone toxicity. In the absence of such evidence, an indication for chemotherapy is more uncertain and should be validated by multidisciplinary evaluation.[1,2,5,10]

In Patients Without Known Monoclonal Gammopathy but Monotypic Deposits/Inclusions or C3 Deposits/Thrombotic Microangiopathy on Kidney Biopsy

In this situation, the main concern is detecting and characterizing the pathogenic clone. The monotypic nature of renal deposits should be carefully assessed. Detailed immunologic hematologic investigations are required to identify a small monoclonal Ig, including serum and urine immunofixation, measurement of sFLC, and sensitive techniques (flow cytometry) to detect a small blood or bone marrow B-cell population.[5,10]

Principles of Treatment

General Considerations

In patients with MGRS-related glomerulopathies, targeting the underlying B-cell clone is the only therapeutic option and requires collaboration between nephrologists and hematologists. Treatment is based on chemotherapy, either conventional or with high-dose melphalan (HDM) supported by autologous stem cell transplantation (ASCT), and anti–B-cell monoclonal antibodies (Mabs).[2,10]

No strategy is available to limit monoclonal Ig toxicity by reducing its secretion, inhibiting its deposition, or other interventions. In AL amyloidosis, approaches aimed at eliminating amyloid deposits have been developed, using antibodies directed against conformational fibril epitopes, or agents targeting amyloid P component. However, none has been approved yet for use.[8,11,12]

The choice of chemotherapy should consider kidney metabolism of drugs and their potential renal and extrarenal toxicity. Bortezomib can be used without dose adjustment, even in patients with end-stage kidney disease (ESKD). Thus, bortezomib-based regimens are often recommended because of their favorable benefit/risk profile.[13] HDM/ASCT is feasible with acceptable toxicity in carefully selected patients with kidney failure due to AL amyloid or monoclonal Ig deposition disease (MIDD).[8-10,14] The administration of rituximab raises no concerns in patients with reduced glomerular filtration rate (GFR). Current experience regarding the use of antiplasma cell Mabs, such as anti-CD38 Mabs in AL amyloidosis, is encouraging.[8,15]

Indication for treatment and its modalities rely upon a benefit-to-risk approach considering natural history of kidney disease, extrarenal involvement, and comorbidities. It is reasonable to consider polychemotherapy and even HDM/ASCT in a patient with MGR(C)S and potential life-threatening clone-related lesions. In contrast, these strategies are not appropriate in a frail patient with MGRS and kidney-limited disease who already progressed to ESKD and is not eligible for kidney transplantation. In patients on maintenance dialysis, chemotherapy should be considered if extrarenal manifestations are present or if the patient is a candidate for kidney transplantation, given the high recurrence rate of MGRS-related kidney diseases in the allograft (see later).[10]

Treatment should be adapted to the nature of the clone. If the clone is plasmacytic, treatment is based on antimyeloma agents, particularly bortezomib-based regimens. Anti-CD38 Mabs are increasingly used in all MGR(C)S types. Treatment with an anti-CD20 Mab, such as rituximab, is usually not appropriate in patients with a plasmacytic clone, whose cells are commonly CD20 negative. If the clone is lymphoplasmacytic or corresponds to CLL or B-cell lymphoma, treatment should be adapted accordingly, usually based on anti-CD20 Mabs. The place of new agents, such as Bruton kinase inhibitors, remains to be assessed.[2,5,8,10]

Evaluation of Response to Treatment

Achievement of the best hematologic response is the goal of treatment and the primary criterion for determining its optimal duration.[2,5,8,10,16] In the most frequent types of MGC(R)S, AL amyloidosis, and MIDD, the quality of hematologic response is the main prognostic factor for both kidney and patient survival.[8,9,13-18]

Accordingly, assessment of hematologic response to treatment is crucial. It depends on repeat evaluations of the pathogenic monoclonal Ig component, usually based on FLC variations. International response criteria have been validated in AL amyloidosis (see later).[8,16] The validity of these criteria in MIDD is currently under evaluation. When the causal monoclonal Ig is not detectable or difficult to measure, evaluating the hematologic response is challenging. Repeated bone marrow examination, including molecular studies, may be considered.[10]

For kidney (and extrarenal) outcomes, hematologic response is necessary but not sufficient. The probability of improving organ function is also governed by the severity and chronicity of tissue damage. When a complete or near complete hematologic response has been achieved, chemotherapy should be stopped even if kidney symptoms persist, because organ response is usually delayed. For example, in AL amyloidosis, remission of nephrotic syndrome may require up to 1 year after hematologic remission.[14] At least

partial regression of monoclonal Ig deposits and associated lesions after deep hematologic response has been documented histologically in animal models and in few patients with MIDD or AL amyloidosis.[6,19]

Symptomatic Measures and Kidney Replacement Therapies

Supportive measures in MGRS-related glomerulopathies are generally similar to that recommended in glomerular diseases (see Chapter 82). In AL amyloidosis, blockers of the renin-angiotensin system and anticoagulants should be used cautiously due to the risk of severe hypotension and bleeding, respectively. Monitoring of side effects of chemotherapy includes prophylactic antibiotics.[8,10]

Indications and modalities of chronic dialysis are similar to that in patients with other causes of ESKD. Patients with AL amyloidosis are more frequently exposed to complications due to multisystemic organ involvement.[8,10,20]

Kidney transplantation may be proposed to selected patients with MGC(R)S without severe extrarenal disease. Transplantation should be performed preferentially in those who have achieved sustained deep hematologic remission (for at least 6 months) prior to the procedure.[9,21-23] Recurrence occurs after variable delay depending on the type of kidney disease, leading to rapid graft loss in proliferative GN with monoclonal Ig deposits (PGNMID),[23] or after several years in AL amyloidosis.[21,22] The recurrence rate is mostly determined by the quality of hematologic response prior to transplantation. In AL amyloidosis and MIDD, achievement of very good partial hematologic response or more is associated with acceptable long-term allograft and patient outcomes.[9,21,22] Compared with the broader population of kidney transplant recipients, recipients with AL amyloidosis or MIDD are exposed to an increased risk of neoplastic and infectious complications.[9,21] In contrast, as in all patients with MGRS, the risk of progression to overt symptomatic myeloma is low.[9,21-23]

GLOMERULOPATHIES WITH ORGANIZED MONOCLONAL IMMUNOGLOBULIN DEPOSITS

On EM examination, glomerular monoclonal Ig deposits may be organized into fibrils, crystals, or microtubules.

Fibrillar Deposits

Fibrillar deposits nearly always correspond to LC (AL) amyloidosis, which is the main type of renal AL amyloidosis (see later). Nonamyloid fibrillary GN is nearly always characterized by deposition of polyclonal IgG (see Chapter 29).[5,24,25]

Crystalline Deposits

Type I cryoglobulins (usually IgG) sometimes display a crystalline pattern defining crystalglobulinemia.[5] LC crystalline inclusions within glomerular cells have been rarely described, mostly in patients with Fanconi syndrome or crystal-storing histiocytosis[5] (see Chapter 50).

Microtubular Deposits

Microtubular deposits are observed in type I and type II cryoglobulinemic GN (see Chapter 22).[5] They also characterize immunotactoid glomerulopathy, also referred to as GN with organized microtubular monoclonal Ig deposits (GOMMID).[24-27]

IMMUNOTACTOID GLOMERULOPATHY (GOMMID)

Immunotactoid glomerulopathy (ITGP/GOMMID) is extremely rare, representing less than 0.05% of all kidney biopsies.[25,26] Diagnosis is usually made between age 50 and 60 years. Kidney manifestations include proteinuria often of nephrotic range, microscopic hematuria, and mild to severe CKD.[24-27] Extrarenal deposits in the skin or peripheral nerves have been very rarely reported.[24]

Histologically, ITGP/GOMMID usually shows atypical membranous glomerulopathy with segmental mesangial proliferation, or a membranoproliferative GN (MPGN) pattern. Interstitial infiltration with clonal lymphocytes is common in patients with an underlying CLL. On IF, glomerular deposits stain for IgG (most commonly IgG_1) and C3 and exhibit LC restriction in most cases. Electron microscopy is mandatory for diagnostic confirmation, showing glomerular deposition of microtubules of 10 to 90 nm in external diameter, with a distinct hollow core at magnification of less than 50,000, and arranged at least focally in parallel arrays (Fig. 28.1).[24-27]

As in all glomerulopathies with monotypic Ig deposits, hematologic investigations searching for an underlying monoclonal B-cell clone are required. Two-thirds of patients have detectable serum and/or urine monoclonal gammopathy matching kidney deposits. ITGP/GOMMID complicates CLL or small lymphocytic lymphoma in about half of cases, and MGRS in the remaining cases.[24-27] Intracytoplasmic microtubules, identical to those found in glomeruli, are commonly observed in clonal lymphocytes from these CLL patients (Fig. 28.1).[24,27]

Data regarding treatment and outcomes in ITGP/GOMMID are limited. Kidney response to clone-targeted chemotherapy, using alkylating agents, rituximab-based, or bortezomib-based regimens, appears to be frequent and often sustained. When it occurs, renal relapse often precedes hematologic recurrence.[26,27]

GLOMERULOPATHIES WITH NONORGANIZED MONOCLONAL IMMUNOGLOBULIN DEPOSITS

Glomerulopathies with nonorganized monoclonal immunoglobulins include two distinct entities: Randall-type MIDD and PGNMID.

Randall-Type Monoclonal Immunoglobulin Deposition Disease

Monoclonal Ig deposition disease encompasses three subtypes, depending on the composition of deposits. LCDD, in which the deposits contain monoclonal LC only (κ in 80% of cases) is by far the most common subtype. Heavy chain deposition disease (HCDD), with deposits derived from monoclonal heavy chains only (most frequently γ and always lacking the first constant [CH1] domain) is rare. Light and heavy chain deposition disease (LHCDD), in which the deposits are composed of monoclonal light and heavy chains (most commonly γ and κ) is even rarer.[9,28-31]

Epidemiology

Monoclonal Ig deposition disease occurs with a slight male predominance and a wide range of age distribution, but predominantly in the sixth decade. Its diagnosis is made in around 0.3% to 0.5% of native kidney biopsies, representing a 10-fold lower prevalence compared with AL amyloidosis.[28,29]

Clinical Manifestations

Monoclonal Ig deposition disease is due to MGRS in around two-thirds of cases but noticeably complicates symptomatic myeloma in more than 30% of cases. Abnormal LFC level and κ/λ ratio is a nearly constant finding in all types of MIDD.[9] Monoclonal Ig deposition disease rarely occurs during WM, CLL, or non-Hodgkin lymphoma.[9,29]

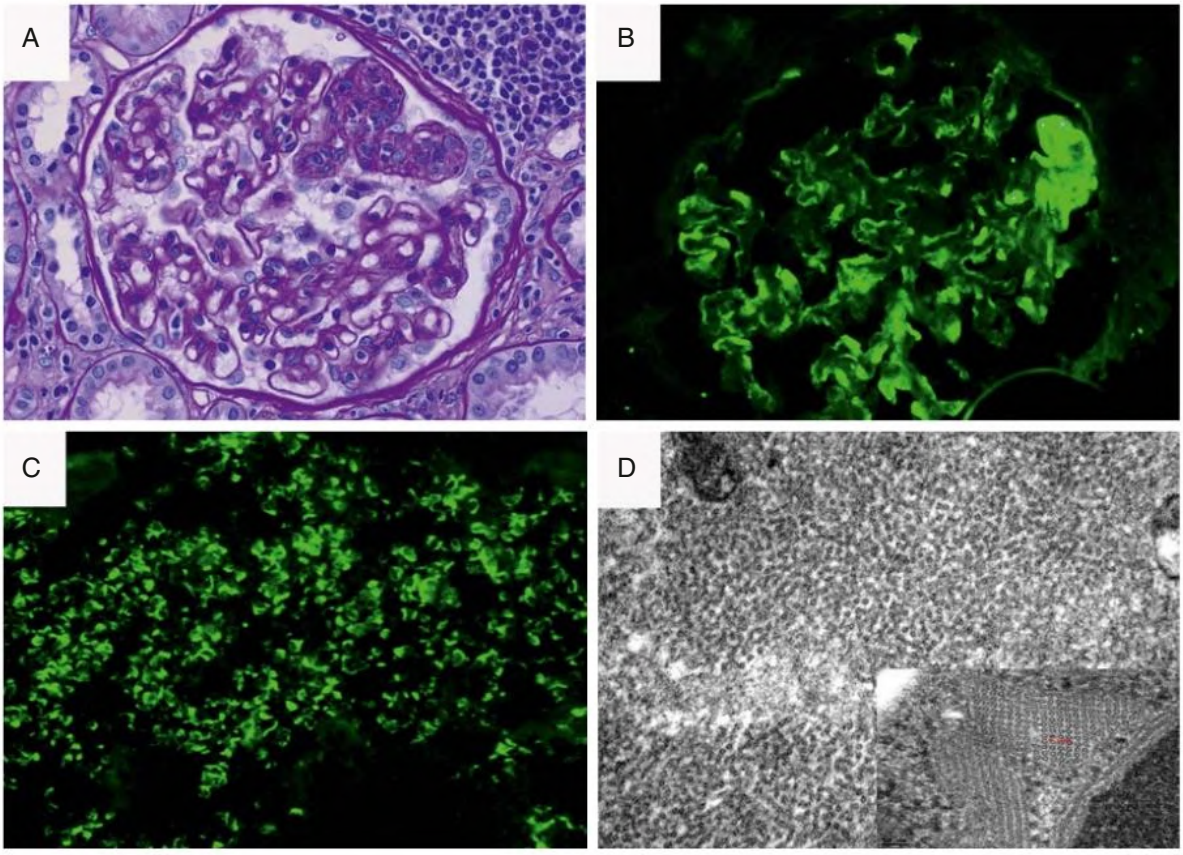

Fig. 28.1 Immunotactoid Glomerulopathy/Glomerulonephritis With Organized Microtubular Monoclonal Immunoglobulin (Ig) Deposits in a Patient With Underlying Chronic Lymphocytic Leukemia. (A) Endocapillary proliferative glomerulonephritis with segmental double contour appearance of capillary walls. Interstitial infiltration with malignant B cells (PAS ×400). (B). Immunofluorescence microscopy. Glomerular granular deposits stained with anti-IgG2 and anti-κ (not shown) antibodies (×400). (C). Interstitial malignant B cells showing same positivity with anti-IgG2 antibody (×400). (D) Ultrastructurally, glomerular deposits are organized into microtubules of 10 nm in external diameter, with a distinct hollow core (electron microscopy ×100,000). *Inset:* similar microtubules within the endoplasmic reticulum of clonal B-lymphocytes (electron microscopy ×100,000).

Kidney involvement is an almost constant feature of MIDD. Heavy proteinuria is present in about 90% of cases, with hematuria and hypertension in around half of the patients. Nephrotic syndrome is more frequent in HCDD. High prevalence, early appearance, and rapid progression of CKD are other characteristics of kidney disease in MIDD.[9,28-31] Around 10% of LCDD cases have prominent kidney arteriolar involvement and present with slowly progressive CKD and low-grade proteinuria (<0.5 g/day).[9]

Extrarenal monoclonal Ig deposition is frequent, particularly in LCDD. Liver, cardiac, and peripheral nerve manifestations have been reported in up to 30% of patients. Liver deposits may be confined to the sinusoids and basement membranes of biliary ducts, without associated parenchymal lesions. They are sometimes massive, with dilation and ruptures of sinusoids, resembling peliosis. Hepatomegaly with mild isolated cholestasis is the main presentation. Rarely, life-threatening hepatic insufficiency and portal hypertension may occur. Cardiac involvement results in hypertrophic cardiomyopathy, resembling AL amyloidosis cardiopathy, with potential development of diastolic dysfunction, arrhythmias, conduction blocks, and heart failure. Neuropathy due to deposits along peripheral nerve fibers or in the choroid plexus has been described. Deposits may affect a variety of other organs and tissues, including spleen, pancreas, salivary glands, thyroid, gastrointestinal tract, lungs, and skin.[9]

Kidney Pathology

By LM, the most characteristic lesion is nodular mesangial sclerosis, resembling diabetic nodular glomerulosclerosis (see Chapters 29 and 31), found in two-thirds of patients with LCDD and in almost all patients with HCDD. Mesangial nodules are composed of periodic acid–Schiff–positive material, with bitonal appearance, often accompanied by mild mesangial hypercellularity. Occasionally prominent endocapillary cellularity and mesangial interposition are present, mimicking MPGN. Crescents are uncommon, except in α-HCDD.[9,30] Milder forms of LCDD may feature increased mesangial matrix or cellularity, with modest thickening of glomerular basement membranes (GBMs), often with abnormal brightness and rigidity. In early stages, glomerular deposits may be detected only by IF or EM.[9,28-30]

The most characteristic and almost constant feature of MIDD is the presence of tubular lesions, predominantly in distal tubules, and characterized by the deposition of a refractile eosinophilic, ribbon-like material along tubular basement membranes (TBM). Deposits are commonly found in arterioles and peritubular capillaries. Variable degrees of tubular atrophy and interstitial fibrosis are present.[9,28-30]

Immunofluorescence study is the cornerstone of diagnosis, which relies on the demonstration of diffuse linear TBM staining of monotypic LC only (LCDD), heavy chain only (HCDD), or both (LHCDD).

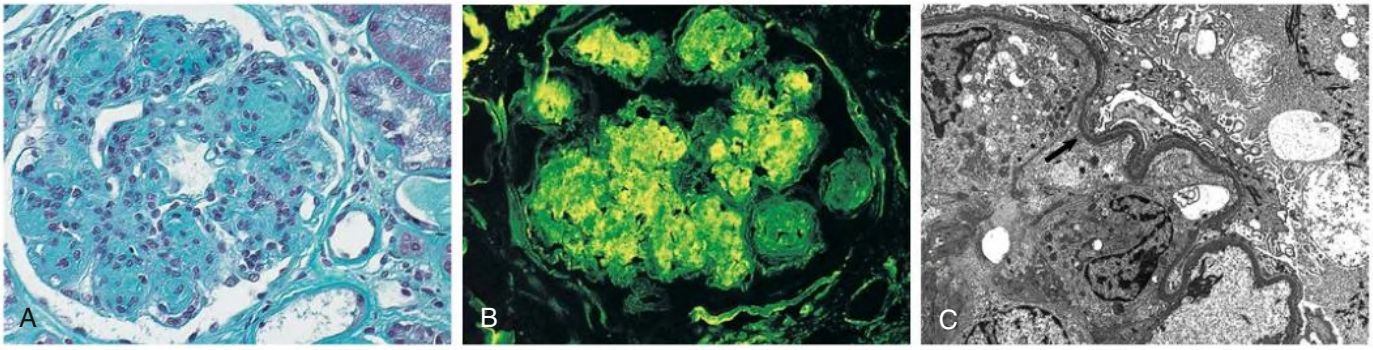

Fig. 28.2 Light Chain Deposition Disease. (A) Nodular glomerulosclerosis with mesangial matrix accumulation (Masson trichrome stain, ×312). (B) Staining of mesangial nodules and tubular basement membranes with anti-κ antibody (immunofluorescence, ×312). (C) Electron micrograph showing a layer of dense granular deposits *(arrow)* along the inner aspect of the glomerular basement membrane (×2500). (Courtesy Dr. Béatrice Mougenot, Paris.)

Similar deposits are common along GBMs, within the mesangium, and around vascular myocytes (Fig. 28.2).[9,28-30] In γ-HCDD, diagnostic confirmation requires not only the absence of staining for κ and λ LCs, but also confirmation of monotypic γ–heavy chain deposits using antibodies specific for IgG subclasses. In addition, the use of antibodies specific for the constant domains invariably demonstrates deletion of the first (CH1) domain in HCDD. In most cases of γ1 and γ3 HCDD, codeposition of complement components C4 and C1q is present, associated with activation of the complement classical pathway in the serum.[9,30]

By EM, the most characteristic feature is the presence of linear, finely granular punctate ("powdery") electron-dense deposits along the inner aspect of GBMs and the outer aspect of TBMs.[9,28-30]

A pattern of LCDD may be observed in patients with symptomatic myeloma and LC cast nephropathy. In this situation, glomerular lesions are typically absent, and linear deposits along glomerular and tubular basement membranes are identified by IF, defining the so-called LCDD by IF only.[28] LCDD with concurrent glomerular AL amyloidosis has been also described.[9]

Management and Outcomes

The outcome of patients with MIDD has improved with earlier diagnosis and development of efficient chemotherapy. In LCDD, before the era of novel antiplasma cell agents, kidney and overall median survivals were 2 and 4 years, respectively.[28] Currently 80% of patients are dialysis-free at 2 years from diagnosis. Median overall survival is estimated at more than 10 years in patients achieving hematologic response, who account for more than 70% of cases. Predictors of kidney response and survival include baseline GFR greater than 30 mL/min/1.73 m^2 and achievement of very good partial response (difference between involved and noninvolved sFLC <40 mg/L). In addition to hematologic and renal responses, factors influencing patient survival are age, presence of symptomatic myeloma, and extrarenal LC deposition.[9,31]

Proliferative GN With Monoclonal Immunoglobulin Deposits

Epidemiology

PGNMID is a rare disorder with biopsy incidence around 1%. The mean age at presentation is 55 years, but PGNMID more commonly affects young patients than the other MGRS-related glomerulopathies.[32-35]

Clinical Manifestations

Proliferative GN with monoclonal Ig deposits is a renal-limited disorder, without any known description of extrarenal monoclonal Ig deposits. Kidney manifestations are nonspecific, with constant proteinuria and full-blown nephrotic syndrome in nearly half of patients. Hematuria, sometimes macroscopic, is found in 80% of cases. Two-thirds of patients have reduced GFR, but less than 10% require dialysis at the time of diagnosis. Rapidly progressive GN is uncommon. Low C3 and/or C4 serum levels are observed in around 20% of patients, and tests for cryoglobulins are negative.[32-35]

Diagnosis

Histologically, PGNMID mimics immune complex GN, with the association of proliferative glomerular lesions and deposits of immunoglobulins and complement.[32-35] Predominant LM patterns are MPGN, endocapillary proliferative GN, or mesangial proliferative GN. In contrast to immune complex–type GN, glomerular deposits on IF appear monotypic, with staining for single LC isotype and a single γ–heavy chain subclass, admixed with C3 and C1q. There is a striking overrepresentation of the IgG3 κ isotype, particularly in young patients. The deposits are restricted to glomeruli (without extraglomerular or extrarenal involvement). PGNMID rarely features deposits made of other isotypes than IgG, including IgM, IgA, or LCs only.[5,32,35] Electron microscopy shows granular, nonorganized deposits, typically in a subendothelial and mesangial distribution, with or without subepithelial deposits (Fig. 28.3).[32-35]

In contrast with most types of MGRS-related nephropathies, an underlying clone is infrequent, particularly in patients with IgG_3 deposits.[32-35] A monoclonal Ig is found in around 30% using immunofixation and sFLC measurement. The diagnostic rate of bone marrow studies is also low, even using sensitive techniques such as flow cytometry.[33,35] Accordingly, whereas some cases of PGNMID are actually MGRS-related, others, particularly those featuring IgG3 deposits, might involve oligoclonal production of nephrotoxic Ig, secondary to skewed B-cell repertoire induced by viral or other putative antigenic stimulation.

Management and Outcomes

The specific management of PGNMID remains unclear, currently based on data from small cohorts. The frequent absence of a detectable clonal disorder affects both the choice of treatment and evaluation of its efficacy, which in many cases relies on kidney response only. Renin-angiotensin system blockade alone can be a reasonable strategy

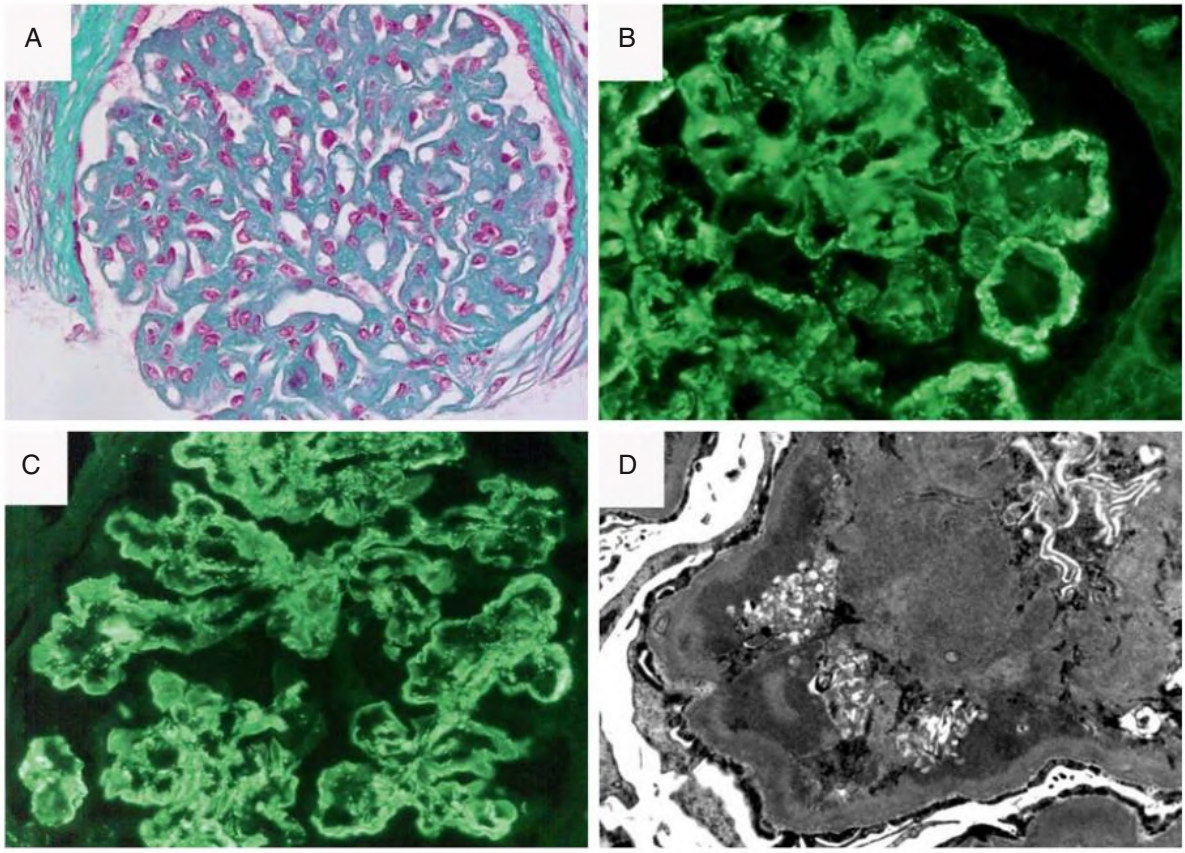

Fig. 28.3 Proliferative Glomerulonephritis (GN) with Monoclonal Immunoglobulin (Ig) Deposits. (A) Mesangial proliferative GN (trichrome staining ×400). (B–C) Immunofluorescence microscopy showing glomerular granular deposits stained with anti-IgG3 (B) and anti-κ LC (light chain) (C) antibodies (×400). (D) By electron microscopy, discontinuous electron dense deposits appear nonorganized and have predominant subendothelial distribution (×10,000).

in patients without nephrotic syndrome and stable mild CKD, particularly if they are frail.[10,32] Because PGNMID is a renal-limited disease, chemotherapy is not indicated in patients who have reached ESKD and are not candidates for kidney transplantation. In other situations, chemotherapy may be recommended, adapted to the underlying clone when identified, or empirically chosen and most often rituximab or bortezomib based.[32,35]

RENAL AMYLOIDOSIS

The term *amyloidosis* refers to a heterogeneous group of diseases due to extracellular deposition of a protein material in an abnormal fibrillar conformation. Amyloidosis is classified according to the nature of the precursor protein that composes the fibrils. To date, more than 30 different types have been described in humans. Amyloidosis is most often an acquired disorder resulting from overproduction of a normal precursor protein. It may also be an inherited condition deriving from an abnormal genetically modified precursor. Most types of amyloidosis are systemic disorders, often with predominant kidney involvement[8,36] (Table 28.2).

Common Properties to All Types of Amyloidosis

Whatever the protein precursor, amyloid deposits are composed of randomly arranged, rigid, nonbranching aggregated fibrils of indefinite length. Each amyloid fibril is composed of 4 to 6 twisted protofilaments, each displaying the typical "cross-β" structure, where antiparallel β-sheets are perpendicular to the filament axis. This configuration accounts for the affinity for Congo red staining that colors all amyloid deposits in a sensitive and specific manner, with a characteristic yellow-green birefringence under polarized light. All types of amyloid fibrils are associated with common nonfibrillar components. Most important is the amyloid P component, a glycoprotein that represents up to 15% of deposits and accounts for their incapacity to be solubilized in an organic milieu. It derives from serum amyloid P protein (SAP), a member of the pentraxin family (as C-reactive protein), synthesized by the liver. Serum amyloid P protein is resistant to proteolytic digestion, and its coating to amyloid fibrils results in their reduced tissue catabolism.[8,11] Another constant component of amyloidosis are glycosaminoglycans (GAGs), which are linear polysaccharides made of repeating units of hyaluronic acid. Linked to a protein core, they form proteoglycans, mostly of the heparan sulfate type. Serum amyloid P protein easily binds to GAGs, which appear to induce and stabilize the β-pleated amyloid structure.[8,36]

Amyloid formation results from abnormal folding of the precursor protein, which modifies its structure leading to the formation of intermolecular β-sheets. Amyloidogenesis involves a nucleation-dependent polymerization process. Formation of an ordered nucleus is the initial and thermodynamically limiting step, followed by addition of monomers and elongation of the fibrils. This process depends on (1) the natural propensity of the precursor to adopt an abnormal configuration (e.g., chronic accumulation of native transthyretin with aging, leading to wild-type transthyretin amyloidosis); (2) overproduction or

TABLE 28.2 Main Characteristics of Systemic Amyloidoses

Type	Acquired or Hereditary	Underlying Disorder	Precursor Protein	ORGAN INVOLVEMENT					Treatment
				Kidneys	Heart	Liver	PN (AN)	Other	
AL, AH	Acquired	Plasma cell clone (usually MGR(C)S)	Monoclonal Ig LC Monoclonal Ig heavy chain	+++	+++	++	+(+)	Soft tissue, GI	Chemotherapy ± anti-CD38 Mab HDM/ASCT
AA	Acquired	Chronic inflammatory disorders (infections, chronic arthritis, FMF, other periodic fever syndromes)	SAA	+++	± (late)	+ (late)	–	GI, adrenal glands, thyroid	Suppression of inflammation Anti-TNF and anti-IL1 agents Colchicine
ATTR	Acquired	Aging	Wild-type TTR	–	+++	–	–	Carpal tunnel syndrome	Supportive treatment of heart failure Tafamidis
	Hereditary	Mutations in *TTR* gene	TTR variant	+	++	–	+++(+++)	Eye	Supportive treatment of heart failure Tafamidis, RNA interference Liver transplantation (in selected patients)
Aβ2M	Acquired	Long-term dialysis	Wild-type Aβ2M	–	–	–	–	Arthropathy Carpal tunnel	Efficient hemodialysis, renal transplant
	Hereditary	Mutation in *Aβ2M* gene	Aβ2M variant	–	+	+	+(+)	GI, salivary glands, spleen, adrenal glands	Supportive
ALECT2	Acquired	Unknown	Wild-type Lect2	+++	–	++	–	–	Supportive

accumulation of the precursor (e.g., serum amyloid A protein [SAA] or β-2 microglobulin, resulting in acquired amyloid A [AA] amyloidosis or β-2 microglobulin amyloidosis, respectively); (3) genetic mutation generating or increasing amyloidogenicity of a precursor protein in hereditary amyloidosis; and (4) modification of the precursor through proteolytic cleavage or other mechanisms. In AL amyloidosis the LC variable domain (VL) is the main component of the fibrils, its polymerization being favored by proteolysis of the constant domain. In AA amyloidosis, macrophages seem to enhance fibril formation through C-terminal proteolysis of the precursor SAA.[8,36]

Diagnosis of Amyloidosis

General Considerations

Amyloidosis should be considered in any patient with suggestive presentations, including heart failure with preserved ejection fraction, albuminuria, or peripheral neuropathy, particularly if a monoclonal gammopathy is present. However, this diagnosis requires histologic confirmation. Whenever possible, noninvasive biopsies of abdominal fat and minor salivary glands should be performed initially. If necessary (i.e., when tissue biopsies fail to demonstrate amyloid deposition or are insufficient for amyloid typing), biopsy of a clinically affected organ (usually the kidney) should be considered. The diagnosis of amyloid is based on light microscopic examination, showing amorphous extracellular Congo red–positive deposits (Fig. 28.4). Congo red staining may be falsely negative if tissue sections are less than 5 μm in thickness. When a kidney biopsy is performed in patients with kidney involvement, it allows identification of Ig LC amyloid deposits in more than 80% of cases.[5,8,36]

Rapid identification of the nature of the amyloid precursor is crucial, as it dictates therapeutic management. It relies primarily on immunohistochemistry on paraffin-embedded tissue sections, or preferably on IF microscopy on frozen sections, using a panel of reactive antibodies that should include at least conjugates specific for κ and λ LC, Ig heavy chains, SAA, and transthyretin. Immunofluorescence is associated with higher rate of successful typing than immunohistochemistry (Fig. 28.4C). However, even IF has limitations due to local proteolysis, inaccessibility of the epitopes, or lack of commercial antibodies. Considerable progress has been achieved with the development of novel techniques, such as immuno-EM and laser capture microdissection combined with tandem mass spectrometry. Due to their high sensitivity and specificity, they allow correct typing in nearly 100% of cases. Although available only in a few specialized centers, they should be systematically considered when routine antibody-based techniques are inconclusive.[37,38]

Kidney Pathology

On LM, extracellular eosinophilic deposits appear faintly red after Congo red staining (Fig. 28.4A) and show characteristic apple-green birefringence under polarized light (Fig. 28.4B). The earliest lesions are located in the mesangium (Fig. 28.4A), on the external aspect of GBMs, and in blood vessels. Mesangial deposits may be sparse or more diffuse, sometimes featuring a lobular distribution. When glomeruli

become massively sclerotic (or at the opposite, in the very early stages), the deposits may be difficult to demonstrate by Congo red staining. In this situation, EM may be useful to confirm the presence of amyloid deposits that typically display the ultrastructural appearance of randomly arranged fibrils 7 to 10 nm in external diameter (Fig. 28.4D).[5]

Main Types of Systemic Amyloidosis With Kidney Involvement

Acquired systemic AL, AA, and leukocyte cell-derived chemotaxin 2-associated amyloidosis (ALECT2) are the most frequent causes of amyloid kidney disease. Rarely, amyloidosis-associated kidney disease is inherited, induced by a mutation of the precursor protein (Table 28.1).

Clinical Presentation

Whatever its type, amyloidosis-associated kidney disease most commonly manifests with chronic glomerular symptoms, including heavy proteinuria (usually around 5 g/day at presentation) predominantly composed of albumin. Proteinuria is sometimes massive (>20 g/day), and about half of patients have full-blown nephrotic syndrome, often accompanied by diffuse edema. Fluid retention is of variable severity, sometimes resulting in anasarca. Nephrotic syndrome due to amyloidosis increases the risk of thromboembolic complications including renal vein thrombosis, particularly in AA amyloidosis. The prevalence of hematuria and hypertension varies according to the type of amyloidosis, being uncommon in AL whereas observed in around 30% in patients with AA. Kidney failure appears more frequent and usually more severe in AA compared with AL, reported in 50% to 75% and less than 50% in newly diagnosed patients, respectively.[39] Classically, enlarged kidneys on imaging studies are suggestive of amyloidosis, but kidneys of normal or even reduced size should not exclude the diagnosis, particularly in patients with kidney failure.[15,35,36]

Rarely, amyloid deposits predominantly or exclusively involve the tubulointerstitial compartment, manifesting with low-grade tubular proteinuria, slowly progressive chronic kidney failure, and impaired urine concentration with polyuria. This misleading presentation has been mostly reported in AA and in AL amyloidosis, and more specifically in hereditary apoA1 amyloidosis related to the Leu75Pro variant.[40] Amyloid deposits may predominantly affect intrarenal vessels, inducing severe hypertension, as in apoC3 hereditary amyloidosis (Table 28.2).

Immunoglobulinic Amyloidosis (Light Chain and Heavy Chain)

In the vast majority of cases, the main component of amyloid fibrils derives from the VL of a monoclonal LC. Heavy chain (AH) amyloidosis, made of a peptide derived from an Ig heavy chain, is rare. The incidence of AL amyloidosis is 9 to 12 cases per million inhabitants per year. AL is always due to a LC-secreting clonal population of cells belonging to the B-cell lineage. The abnormal population rarely causes an overt lymphoid disorder, such as symptomatic MM or WM. In over 80% of cases, it corresponds to a MG(R)CS, as defined earlier.[8,36] The plasma cell clone that usually characterizes these MGCS-related ALs is featured by similar cytogenetic abnormalities as in symptomatic MM, except for a striking overrepresentation of the translocation t(11–14) (more than 50% compared with 15%, respectively). This translocation is associated with relative resistance to apoptosis and may predict high efficacy of BCL2 inhibitors and less sensitivity to bortezomib and immunomodulatory drugs.[8]

Physicochemical and structural characteristics determining the amyloidogenic potential of monoclonal LC remain poorly understood. The λ LC isotype is up to fourfold more frequent than the κ isotype, whereas in other monoclonal gammopathies, κ accounts for two-thirds of cases. The tropism of organ involvement is influenced both by the germline gene used for the light-chain VL and by somatic mutations occurring in the secreting clone. Thus, the usage of genes belonging to the rare Vλ6 family is constantly associated with kidney involvement, whereas κ LCs of the Vκ1 family are more likely to induce dominant hepatic involvement. In addition, organ-specific environmental factors are also involved. Independently of deposition as fibrils, circulating free amyloid LCs may also participate in organ damage, as documented in the heart and suspected in the kidney.[6,8]

TABLE 28.3 Main Clinical and Laboratory Features at Presentation in 816 Patients With Proven Light Chain (AL) Amyloidosis

Median age (years)	63
Male sex	59.9%
Organ involvement	
Median number of involved organs	2
Kidney	68.1%
Heart	64.8%
Peripheral nerves	18.7%
Liver	16.0%
eGFR value (mL/min/1.73 m^2)	
30–59	25.1%
15–29	8.5%
<15 or dialysis	6.9%
Median proteinuria (g/day)	2.9
NYHA class III or IV	26.8%
Cardiac staging	
I	30.9%
II	43.7%
III	25.4%
Involved LC type	
κ	24.6%
λ	75.4%
Positive serum/urine immunofixation	94.2%
Monoclonal gammopathy	
IgG	38.8%
IgA	10.0%
IgM	3.0%
LC only	47.6%
Serum FLCs	
Abnormal κ/λ ratio	84.8%
Median involved FLC concentration (mg/L)	178
Median dFLC (mg/L)	157
Median bone marrow plasma cell infiltration	10%

Modified from Palladini G, Dispenzieri A, Gertz MA, et al. New criteria for response to treatment in immunoglobulin light chain amyloidosis based on free light chain measurement and cardiac biomarkers: impact on survival outcomes. *J Clin Oncol.* 2012;30:4541–4549.

Clinical Manifestations

The median age at diagnosis is 64 years, with a slight male predominance (Table 28.3). About 10% of the patients are younger than 50 years. The clinical presentation of AL amyloidosis depends on the pattern and severity of organ involvement. Amyloid deposits may affect virtually any organ or tissue. Except for the combination of macroglossia (Fig. 28.5) and periorbital purpura (Fig. 28.6), which is rare but pathognomonic of AL amyloidosis, clinical features are not specific, with weakness being the most frequent initial symptom. Thus the

Fig. 28.5 Macroglossia in patient with light chain amyloidosis.

Fig. 28.6 Periorbital purpura in patient with light chain amyloidosis.

clinical diagnosis may be challenging, and when facing a patient with glomerular symptoms, it is crucial to carefully search for extrarenal manifestations.

Kidney disease is present in up to 70% of patients. Cardiac involvement is as frequent, and it is the major cause of mortality through arrhythmia, conduction blocks, and congestive heart failure. It is typically featured by restrictive hypertrophic cardiomyopathy, which should be systematically detected with measurement of sensitive cardiac biomarkers (troponin and brain natriuretic peptide [BNP] or NT-proBNP) and Doppler echocardiography showing increased septum ventricular wall thickness and decreased left ventricular longitudinal strain. Magnetic resonance imaging is useful in difficult cases. AL amyloidosis may infiltrate articular structures, such as carpal tunnel. Peripheral nerve involvement may result in a sensory polyneuropathy, often associated with dysautonomia including orthostatic hypotension, impotence, and bladder dysfunction. Involvement of the liver, spleen, and gastrointestinal tract is common and usually pauci-symptomatic. The most common skin manifestation is purpura, secondary to amyloid infiltration of capillaries. This implies a hemorrhagic risk, sometimes increased by an acquired deficiency of Factor X, thought to occur through adsorption on amyloid fibrils. Accordingly, coagulation and hemostasis screening tests are particularly important before biopsy of the kidney or any other deep organ.[8,36]

Management and Outcomes

The diagnostic workup of AL amyloidosis is similar to that of other MG(R)CS (see earlier). As already mentioned, the presence of a monoclonal gammopathy is not sufficient for the diagnosis, which should be secured by histologic identification of the Ig nature of amyloid deposits. AL amyloidosis is a systemic disease, and once the diagnosis has been confirmed, biopsies of other potentially involved sites are unnecessary and should be avoided because of the bleeding risk.

Elevation of NT-proBNP and cardiac troponin strongly correlate with prognosis and are therefore used for risk assessment according to the Mayo staging system. This prognostic score identifies 3 stages: stage 1, normal serum levels of troponin T and NT-proBNP; stage 2, increase in a single marker level; and stage 3, increase in both markers with thresholds at 332 ng/L for NTproBNP and 0.035 µg/L for troponin, respectively.[8,16,36] Of note, NT-proBNP serum levels are influenced by eGFR. This limitation can be partly overcome by using BNP in patients with severe kidney failure.

Patients presenting with very high concentrations of NT-proBNP (>8500 ng/L) with systolic hypotension less than 100 mm Hg (Mayo Clinic stage IIIb) have a median survival of only 4 months. Cardiac transplantation may be considered in selected patients. Kidney involvement has a lesser impact on survival.[8] Proteinuria greater than 5 g/24 h with eGFR of 50 mL/min/1.73 m^2 or less at diagnosis have been associated with a high risk for progression to ESKD (up to 85% at 3 years).[16]

Regarding clone-targeted chemotherapy, pioneering studies established a modest efficacy of the oral melphalan and prednisone (MP) regimen. An important progress was achieved by using high-dose dexamethasone instead of prednisone (MDex combination), which significantly increased both frequency and rapidity of hematologic response. From the early 1990s, HDM/ASCT has been performed in selected patients with AL. Even in reference centers and after careful patient selection, HDM/ASCT is associated with significant morbidity and an early mortality rate of around 5%.[8,36] A randomized controlled trial performed in a multicenter setting did not provide evidence for a survival benefit of HDM/ASCT compared with MDex.[41] However, some centers still offer HDM/ASCT to highly selected young Mayo stage 1 individuals, who represent a minority of AL patients. Other investigators consider that the results of HDM/ASCT are biased by the selection process.

A decisive step has been the introduction of novel antimyeloma agents, particularly the proteasome inhibitor bortezomib. To date, bortezomib-melphalan-dexamethasone (BMDex) or cyclophosphamide-bortezomib-dexamethasone (CyBorD) regimens are the backbone of initial treatment.[13] The use of antiplasma cell monoclonal antibodies, such as anti-CD38 Mabs, is likely to further increase hematologic response rate, which remains the key prognostic factor.[15] Results of a recent phase III trial indicate that addition of subcutaneous daratumumab to CyBorD results in hematologic response rate of more than 90%, compared with 77% with CyBorD alone. In addition, deep responses were significantly more frequent in the daratumumab arm, and this translated into increased organ improvement.[42]

Hematologic response should be regularly evaluated to assess treatment efficacy and to rapidly detect disease relapse. It is based on repeat sFLC measurements, using the difference between serum level of involved and noninvolved light chains (dFLC). Current response criteria are defined as complete response (negative serum and urine

immunofixation with normalized FLC ratio), very good partial response (reduction of dFLC <40 mg/L), and partial response (50% reduction of dFLC). Regarding organ response, the modification of serum NT-ProBNP and troponin levels is an important prognostic factor in patients with cardiac amyloidosis. Because improvement in kidney parameters is usually delayed by several months following hematologic remission, treatment modifications should be based on FLC response.[8,16-19] Although several agents developed to increase clearance of amyloid deposits have failed to demonstrate a clinical benefit,[11] this approach is still under evaluation, particularly using novel antifibril antibodies.[8,12]

AA Amyloidosis

General Considerations

AA amyloid fibrils derive from SAA, which is produced by the liver during inflammatory reaction, where its serum concentration may increase by a factor of 1000. Among the different SAA isotypes, whose function is unknown, only SAA1 and SAA2 are amyloidogenic.

AA amyloidosis is consecutive to chronic inflammation, either of infectious origin or due to chronic inflammatory diseases, most commonly acquired and represented by rheumatoid disorders. AA amyloidosis sometimes complicates a genetic disorder due to mutation in a factor involved in the control of inflammatory reaction. These disorders, referred to as hereditary periodic fever syndromes, are increasingly recognized as the underlying condition in AA amyloidosis.

Patients at risk for of AA amyloidosis are those with long duration of chronic inflammatory disease (median 17 years), high serum SAA levels, homozygosity for the SAA1 genotype, familial Mediterranean fever (FMF) trait (heterozygosity for variant pyrin), or other family history of AA amyloidosis (e.g., periodic fever syndromes).[39,43]

AA Amyloidosis Due to Acquired Inflammation

AA amyloidosis is rare in high-income countries, where it mostly complicates chronic inflammatory arthritis, particularly rheumatoid arthritis and systemic juvenile idiopathic arthritis, less commonly poorly controlled inflammatory bowel disease, or chronic infections such as in bronchiectasis and osteomyelitis. Rarely, AA amyloidosis complicates neoplasia, Castleman disease, and WM. AA is still frequent in lower-income countries and is commonly observed during granulomatous infections such as tuberculosis and pyogenic infections, particularly chronic osteomyelitis.

The usual clinical presentation of these forms of AA amyloidosis is proteinuria, often in the nephrotic range, with or without reduced glomerular filtration rate, in the context of a chronic infectious process or poorly controlled inflammatory arthritis.

Compared with AL amyloidosis, kidney disease in AA amyloidosis is more frequent and severe and is the main prognostic factor for survival. In contrast, symptomatic cardiac involvement is observed in less than 10% of cases. Gastrointestinal tract infiltration, hepatomegaly, and spleen enlargement are common, often asymptomatic, but hyposplenism may occur resulting in infectious complications. Marked cholestasis is rare, but associated with poor outcomes. Endocrine manifestations, including adrenal and thyroid dysfunction may occur. Peripheral neuropathy is rarely reported (Table 28.4).

Amyloid load and clinical outcomes relate to circulating concentrations of SAA. The risk for death among patients with an SAA concentration of 4 mg/L or less is almost 18 times lower than in those with an SAA concentration of 155 mg/L or greater. Even a very modest elevation in the SAA concentration of 4 to 9 mg/L is associated with a fourfold increased risk for death. These data emphasize the importance of vigorous treatment of the underlying inflammatory disease.

TABLE 28.4 Characteristics at Presentation of 374 Patients With Systemic Secondary (AA) Amyloidosis

Age, years (range)	50 (9–87)
Male sex	210 (56%)
Race or Ethnic Group	
White	307 (82%)
South Asian	27 (7%)
Other	40 (11%)
Duration of Inflammatory Disease at Diagnosis (Years)	
Median	17
Range	0–68
Kidney Dysfunction	
Proteinuria >500 mg/day or serum creatinine >133 µmol/L	363 (97%)
End-stage kidney disease	41 (11%)
Proteinuria, g/day median (range)	3.9 (0–26.0)
Liver Involvement	
Hepatomegaly, n (%)	35 (9%)
Deposits on SAP scintigraphy	85 (23%)
Splenic Involvement	
Deposits on SAP scintigraphy	370 (99%)
Cardiac Involvement	
Cardiac failure (n)	1
Cardiac infiltration (n)	2

From Lachmann HJ, Goodman HJ, Gilbertson JA, et al. Natural history and outcome in systemic AA amyloidosis. *N Engl J Med.* 2007;356:2361–2371.

Antibiotic treatment or surgical resection of an infectious site efficiently prevents and may even cure infection-related AA amyloidosis by suppressing its cause. The increasing use of effective disease-modifying treatments for chronic inflammatory arthritis, such as anti–tumor necrosis factor and anti–interleukin-1 agents, accounts for the decline of AA in developed countries.[39]

AA Amyloidosis in Autoinflammatory Syndromes

Familial Mediterranean fever, also referred to as periodic fever, is the most frequent auto-inflammatory syndrome complicated by AA amyloidosis. Familial Mediterranean fever is an autosomal recessive disorder occurring most often in Sephardic Jews and Armenians. It is caused by mutations of the Mediterranean fever (MEFV) gene encoding a protein called pyrin (also known as marenostrin). Clinically, there are two independent phenotypes. In the first, brief episodic, febrile attacks of peritonitis, pleuritis, or synovitis occur in childhood or adolescence and precede the kidney manifestations. In the second phenotype, kidney symptoms appear first and may long be the only manifestation of the disease. The attacks are accompanied by dramatic elevations of acute phase reactants, including SAA. Amyloid deposits are responsible for severe kidney lesions with prominent glomerular involvement, leading to ESKD at a young age. When given early, colchicine can prevent the development of proteinuria. It is less effective in preventing eGFR decline in patients with nephrotic syndrome or kidney impairment. The minimum daily dose of colchicine for prevention of amyloidosis is 1 mg, but doses of 1.5 to 2 mg are required in patients with symptomatic amyloid nephropathy. In patients unresponsive or intolerant to colchicine, or noncompliant, interleukin-1 receptor antagonists should be considered.[43]

Other autoinflammatory syndromes associated with specific genetic mutations have been identified. All may be complicated by

AA amyloidosis. The main are TNF-α receptor–associated periodic fever syndrome (TRAPS), Muckle-Wells syndrome, familial cold autoinflammatory syndrome, and hyperIgD syndrome. Most can be efficiently controlled by anti–interleukin-1 or anti–tumor necrosis factor-α agents.[39,43]

Other Types of Amyloidosis With Kidney Involvement

Leukocyte Cell–Derived Chemotaxin 2–Associated Amyloidosis

Recently identified, ALECT2 is currently the third most common type of kidney amyloidosis in the United States. It preferentially affects certain ethnic groups, particularly Hispanic Americans. LECT2 is a chemotactic factor to neutrophils mainly produced by the liver. ALECT2 manifests around 60 years of age, without family history. Kidney disease is predominant, including proteinuria and CKD that progresses to ESKD in 40% of cases. Nephrotic syndrome is rare. Kidney deposits predominate in the cortical interstitium, with variable glomerular and vascular distribution. Deposits may involve the liver and adrenal glands. The pathophysiology remains unknown. There is no mutation in LECT2 but affected individuals show homozygous polymorphism for the G allele, suggesting the disease may be favored by environmental factors on a predisposing genetic background.[44]

Hereditary Kidney Amyloidoses

The kidney is the major site of organ involvement in most types of hereditary amyloidosis, including fibrinogen A-α, apolipoprotein A-I, apoliprotein A-II, apolipoprotein C2, apolipoprotein C3, gelsolin, and lysozyme amyloidosis. The exception is hereditary transthyretin amyloidosis (ATTR), the most frequent type of genetically transmitted amyloidosis, in which cardiac disease and peripheral neuropathy with dysautonomia are prominent, whereas proteinuria and kidney failure develop in 30% to 50% of patients only. All hereditary amyloidoses are autosomal dominant conditions, but due to variable penetrance, a relevant family history may be absent. Thus, kidney hereditary amyloidosis should be suspected whenever IF studies of the kidney biopsy fail to type amyloid deposits. In this situation, the diagnosis is established by proteomic and/or immuno-EM completed by genetic studies to confirm an amyloidogenic mutation of the precursor protein. Careful clinical investigation of extrarenal manifestations is required to guide diagnosis and to evaluate organ involvement.[36]

Fibrinogen A-β Amyloidosis

Fibrinogen A-α Amyloidosis (AFib) is the most frequent hereditary kidney amyloidosis, deriving from a single mutation in the fibrinogen A-α-chain gene. It clinically manifests with chronic glomerular disease, usually around age 58 years. A family history is often lacking, resulting in delayed diagnosis. Age at diagnosis and severity of presentation vary according to the type of mutation. Symptomatic extrarenal manifestations are uncommon, although liver and spleen involvement may occur. In the kidney, amyloid deposits have a characteristic distribution, because they massively infiltrate the glomerulus but almost always spare the interstitial and vascular compartments. Kidney disease progresses to ESKD after a median time of 4.6 years. Kidney transplantation is usually associated with acceptable graft survival, despite disease recurrence. In the most severe forms (juvenile onset, hepatic failure) combined liver and kidney transplantation should be considered because it prevents amyloid recurrence by removing the source of the amyloidogenic fibrinogen variant, taking into account the increased risk of perioperative complications.[45]

SELF-ASSESSMENT QUESTIONS

1. Which of the following applies to heart involvement in AL (light chain) amyloidosis?
   - **A.** A contraindication to cardiac transplantation
   - **B.** Less common than in AA amyloidosis
   - **C.** Primarily responsible for valve dysfunction
   - **D.** A contraindication to hemodialysis
   - **E.** A major prognostic factor for patient survival
2. Regarding renal disease in monoclonal immunoglobulin deposition disease (MIDD), which of the following is *true?*
   - **A.** A contraindication to kidney transplantation
   - **B.** Characterized by crescent formation
   - **C.** Frequently responsible for nondiabetic glomerulosclerosis
   - **D.** Characterized by microtubular deposits
   - **E.** Caused by deposition of cryoglobulin
3. Which of the following is the key investigation for the diagnosis of immunotactoid glomerulopathy?
   - **A.** Immunofixation of serum proteins
   - **B.** Immunofixation of urinary proteins
   - **C.** Bone marrow aspiration
   - **D.** Immunofluorescence examination of kidney biopsy sample
   - **E.** Electron microscopy
4. Which of the following is the *most* common clinical sign or symptom caused by MIDD?
   - **A.** Renal failure
   - **B.** Hematuria
   - **C.** Hypertension
   - **D.** Jaundice
   - **E.** Heart failure

Rare Glomerular Disorders

Cynthia C. Nast, Sharon G. Adler, Richard J. Glassock

This chapter describes several uncommon or rare glomerular disorders and the clinical syndromes that tend to affect adults and infrequently have glomerular disease as a major clinical manifestation. These disorders must be recognized and differentiated from other more common glomerular diseases to determine whether a familial disorder is present, estimate the prognosis, plan therapy, or determine the risk for recurrence in a transplanted kidney. The chapter also describes primary and secondary antiphospholipid antibody syndromes in detail.

MESANGIAL PROLIFERATIVE GLOMERULONEPHRITIS WITHOUT IMMUNOGLOBULIN A DEPOSITS

Mesangial proliferative glomerulonephritis (MesPGN) encompasses a heterogeneous collection of disorders with a largely unknown etiology. The common feature is a light microscopy (LM) histologic glomerular pattern of injury characterized by diffuse mesangial proliferation[1–4] (Fig. 29.1). MesPGN has a diffuse and global increase in mesangial cells, often with an increase in mesangial matrix. Other cells (e.g., neutrophils and monocytes) may contribute to the hypercellularity. Thus, MesPGN is a glomerular pattern of injury, *not a specific disease entity.*

On the other hand, mesangial cellular proliferation can also occur as focal and segmental lesions, often accompanied by segmental glomerular necrosis and very localized crescents. This phenotype may accompany the evolution of pure MesPGN but often signifies the presence of systemic disease, including systemic lupus erythematosus (SLE), immunoglobulin A (IgA) vasculitis (Henoch-Schönlein purpura), IgA nephropathy, infection-related glomerulonephritis (i.e., postinfectious glomerulonephritis [GN] or human immunodeficiency virus [HIV]),[5] microscopic polyangiitis, granulomatous polyangiitis, Goodpasture disease (anti–glomerular basement membrane [GBM] disease), rheumatoid vasculitis, mixed connective tissue disease, and monoclonal immunoglobulin-associated glomerular diseases (see disease-specific chapters). On occasion, focal and segmental proliferative GN is discovered without any associated identifiable multisystem disease process or IgA deposits (i.e., idiopathic focal and segmental proliferative GN). Such patients have a clinical presentation, course, and response to treatment similar to those described for pure MesPGN but are not discussed further in this section.

In "pure" MesPGN, the peripheral capillary walls are thin and delicate, without obvious deposits, reduplication, focal disruptions, or necrosis. The visceral and parietal epithelial cells, although occasionally enlarged, have not undergone proliferation, and there are no crescents or segments of sclerosis. Large mesangial deposits staining with periodic acid–Schiff (PAS) or fuchsin are absent; such deposits suggest IgA nephropathy (see Chapter 24), lupus nephritis (LN; see Chapter 27), C3 glomerulonephritis (see Chapter 23), or, less often, HIV-associated glomerular diseases (see Chapter 58), which commonly manifest as a mesangial proliferative lesion. Postinfectious GN may also cause MesPGN (see Chapter 57). The tubulointerstitium and vasculature are usually normal, unless reduced kidney function or hypertension is present or the patient is of advanced age.

On immunofluorescence (IF) microscopy, a wide variety of immunoglobulin and complement deposition is observed (Table 29.1). Most often, diffuse and global granular immunoglobulin M (IgM) and C3 deposits are scattered throughout the mesangium (so-called *IgM nephropathy*; see later discussion), but isolated C3, C1q, or even IgG deposits may be seen.[6–8] If IgA is the predominant immunoglobulin, the diagnosis is IgA nephropathy. Occasionally, no immunoglobulin deposits are found. Prominent C3 deposits without immunoglobulin deposition should suggest C3 glomerulopathy.[6] Extensive C1q deposits, with or without immunoglobulin deposits, should suggest C1q nephropathy (see later discussion).[9] On electron microscopy (EM), the number of mesangial cells is increased, with an occasional leukocyte. Mesangial matrix material is frequently, but not invariably, diffusely increased. Mesangial electron-dense deposits often can be seen but there are no subendothelial, intramembranous, or subepithelial deposits. In the absence of glomeruli for IF, very large mesangial or paramesangial electron-dense deposits suggest IgA nephropathy. Deposits in locations other than the mesangium suggest a postinfectious etiology or an underlying disease, such as LN or C3 glomerulopathy. Deposits of multiple immunoglobulin classes and EM identification of numerous tubuloreticular inclusions suggest underlying LN.

The clinical presentation of MesPGN is varied, but persistent or recurring microscopic or macroscopic hematuria with mild proteinuria is most common. It commonly affects young adults,[1,2] with a slight male predominance. Nephrotic syndrome is a less frequent initial presentation but more often occurs with diffuse mesangial IgM deposits (IgM nephropathy; see later discussion),[3] C1q deposits (C1q nephropathy[9]), or C3 glomerulonephritis.[6] Pure MesPGN is uncommon (<5%) in patients with idiopathic nephrotic syndrome. In some countries, such as India and China, MesPGN is found in 10% to 15% of kidney biopsy samples, but the frequency is much less in wealthy countries with a lower burden of infectious diseases. MesPGN also has been observed in acute parvovirus B19 disease and in association with Castleman disease.

Kidney function and blood pressure are usually normal, at least initially. Serologic studies are generally unrewarding but should be performed in most patients to exclude known causes. Serum C3 and C4 and hemolytic complement activity (CH50) are typically normal. A low C3 and normal C4 level suggest C3 glomerulopathy or poststreptococcal GN. Antinuclear antibody (ANA), antineutrophil cytoplasmic autoantibody (ANCA), anti-GBM autoantibody, and cryoimmunoglobulins are negative. MesPGN can indicate resolving postinfectious (poststreptococcal or nonpoststreptococcal) GN, often with isolated C3 deposits with scanty, subendothelial, intramembranous, or

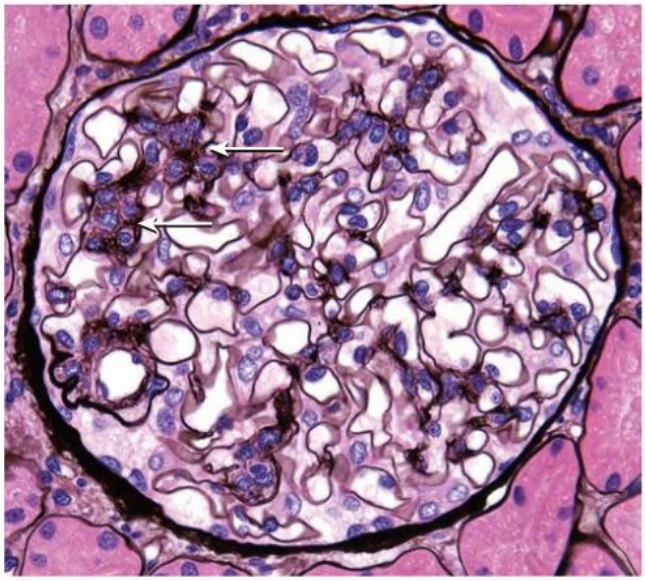

Fig. 29.1 Pure Mesangial Proliferative Glomerulonephritis. There is segmental increase in mesangial cellularity *(arrows)* with single contoured capillary walls and no sclerosis or epithelial cell hypertrophy.

TABLE 29.1 Immunofluorescence Microscopy Patterns in Mesangial Proliferative Glomerulonephritis

Pattern	Associated Disorders
Predominantly mesangial IgA deposits (± IgM, C3)	IgA nephropathy
Predominantly mesangial IgG deposits (± IgM, C1q, C3)	Often associated with lupus nephritis
Predominantly mesangial IgM deposits (± C3)	IgM nephropathy
Mesangial C1q deposits (± IgG, IgM, C3)	C1q nephropathy If IgG present, need to exclude lupus nephritis
Isolated mesangial C3 deposits	Often associated with resolving poststreptococcal GN or C3 GN
Negative for immunoglobulin or complement deposits	Idiopathic MesPGN

Ig, Immunoglobulin; *GN,* glomerulonephritis; *MesPGN,* mesangial proliferative glomerulonephritis.

subepithelial (hump-like) deposits on EM. Urinary protein biomarkers may help determine prognosis.[7]

The prognosis of non-IgA MesPGN depends on the IF findings (see later discussion of IgM and C1q nephropathy) but is often benign. The 30-year kidney survival has been estimated to be 50%.[2] Severe and persistent nephrotic syndrome indicates a poor prognosis, particularly in males.[2] Patients with nephrotic syndrome may evolve to typical focal and segmental glomerulosclerosis (FSGS) over time.

The treatment of pure MesPGN, unaccompanied by other underlying diseases or lesions, such as SLE, minimal change disease (MCD) lesion, or IgA nephropathy, is not well defined.[1,2] The prognosis for patients with isolated hematuria or hematuria combined with mild proteinuria (<500 mg/day) is generally benign, and only supportive measures are needed (see Chapter 82) unless a distinct change in the course is observed. Repeat kidney biopsy may be indicated in such circumstances. For patients with nephrotic syndrome (with or without impaired kidney function), a more aggressive approach is recommended in addition to supportive therapy, especially in the presence of diffuse IgM deposits (IgM nephropathy), as discussed later. Even in the absence of randomized controlled trials (RCTs), an initial course of corticosteroid therapy is justified in most patients with nephrotic-range proteinuria, such as prednisone 60 mg/day or 120 mg every other day for 2 to 3 months, followed by lower doses on an alternate-day regimen for 2 to 3 additional months. About 30% to 50% of these patients experience a decrease in proteinuria to subnephrotic levels, and complete remissions may occur. Relapses of proteinuria are common when steroids are tapered or discontinued. Such relapsing, partially corticosteroid-responsive patients may benefit from the addition of cyclophosphamide, calcineurin inhibitor agents (cyclosporine, tacrolimus, voclosporin), mycophenolate, or rituximab, although information on the efficacy and safety of these agents in pure MesPGN is limited.

Persistent treatment-unresponsive nephrotic syndrome almost invariably progresses to end-stage kidney disease (ESKD), accompanied by a conversion to FSGS over several years. Although transplantation is not contraindicated, patients who rapidly progress to ESKD with superimposed FSGS have a high risk for recurrence of proteinuria and FSGS in the transplanted kidney (see Chapters 19 and 113).

Immunoglobulin M Nephropathy

IgM nephropathy is characterized by diffuse and generalized glomerular deposits of IgM often accompanied by C3[3,8] with mesangial electron-dense deposits. On LM, pure MesPGN is usually observed, sometimes with superimposed FSGS[8] or crescentic disease. A proposed consensus definition of IgM nephropathy includes (1) dominant mesangial staining for IgM by IF, (2) mesangial electron-dense deposits by EM, and (3) absence of any identifiable systemic disease.[9] Patients with only IgM deposits by IF but MCD by LM and EM do not have IgM nephropathy, according to this definition. IgM deposits in steroid-sensitive MCD or FSGS do not have any clinical significance.[10] Patients may present with recurring macrohematuria and proteinuria, the latter in the nephrotic range in up to 40% to 50% of patients.[8] Middle-aged adults are most commonly affected, with a slight male predominance.[8]

Glomerulosclerosis (but not the extent of mesangial proliferation), persisting nephrotic syndrome, and a poor response to corticosteroids or immunosuppressive therapy connote a poor prognosis. As many as 80% of patients with IgM nephropathy and nephrotic syndrome will eventually progress to typical FSGS lesions and, if unresponsive to corticosteroids, will slowly develop progressive chronic kidney disease (CKD). Thus, IgM nephropathy may be an early form of primary FSGS. Patients with IgM deposition accompanying MesPGN but without nephrotic syndrome tend to have a benign course. IgM nephropathy can coexist with IgA nephropathy, diabetic nephropathy, and Fabry disease.[11–13]

Treatment of IgM nephropathy with nephrotic syndrome is uncertain, although steroid therapy may be associated with a complete or partial remission in as many as 50% of patients. Anecdotal reports of success with rituximab also have appeared. The etiology and pathogenesis are unknown, but IgM deposition itself is believed to be an important pathogenic factor acting to augment complement-mediated injury.

C1q Nephropathy

C1q nephropathy is characterized by IF showing diffuse dominant or codominant mesangial C1q deposition, often accompanied by IgG, IgM, or both,[4,9] and, much less frequently, by C3 deposits. These immunopathologic features resemble those seen in LN; however, these

BOX 29.1 Rheumatic Diseases Associated With Glomerular Lesions

- Systemic lupus erythematosus (see Chapter 27)
- Rheumatoid arthritis
- Mixed connective tissue disease
- Rheumatic fever
- Ankylosing spondylitis
- Reiter syndrome
- Dermatomyositis/polymyositis
- Scleroderma
- Relapsing polychondritis
- Psoriasis/psoriatic arthritis
- Systemic or renal-limited polyangiitis (see Chapter 26)

patients lack the clinical features of SLE and usually do not develop SLE even after prolonged follow-up. Anti-C1q vasculitis (also known as hypo-complementemic urticarial vasculitis or McDuffie syndrome) can resemble C1q nephropathy, although urticarial lesions and systemic symptoms are more common in anti-C1q vasculitis with low levels of serum C1q and elevated anti-C1q autoantibodies.

LM findings of C1q nephropathy are heterogeneous, including MesPGN (the mesangial proliferative variant), MCD, and FSGS.[9,14] Electron-dense deposits are seen in mesangial regions often initially near the arteriolar pole and less frequently in subepithelial and subendothelial areas. Nephrotic-range proteinuria occurs, often with hematuria. Males predominate and African Americans are often affected. Serum C3 components, ANA, and anti–double-stranded DNA (anti-dsDNA) antibodies are normal or negative. The response to treatment is poor, and progression to ESKD may occur, particularly when nephrotic syndrome is present, when FSGS lesions predominate, and when the biopsy displays significant tubular atrophy and interstitial fibrosis.[9,15] Anecdotal reports of success with immunosuppressive agents, including rituximab, have appeared. Patients with C1q deposits and MCD appear to respond well to conventional steroid therapy.

Mesangial Proliferative Glomerulonephritis Associated With Minimal Change Disease

MesPGN may be a part of the spectrum of MCD-FSGS lesions (see Chapters 18–20). Distinct mesangial hypercellularity superimposed on MCD (diffuse foot process effacement seen on EM) suggests a greater likelihood for the presence of hematuria, corticosteroid unresponsiveness, and an eventual evolution to FSGS.

GLOMERULONEPHRITIS WITH RHEUMATIC, COLLAGEN-VASCULAR, OR CONNECTIVE TISSUE DISEASE

Several collagen vascular diseases other than SLE may be complicated by GN[16] (Box 29.1), including rheumatoid arthritis (RA), mixed connective tissue disease, polymyositis and dermatomyositis, acute rheumatic fever, scleroderma, relapsing polychondritis, and psoriatic arthritis. IgA nephropathy also may be seen in association with the seronegative spondyloarthropathies. Toxic or hypersensitivity reactions to nonsteroidal antiinflammatory drugs (NSAIDs) can contribute to glomerular disease.[17]

Rheumatoid Arthritis

A wide variety of glomerular, tubulointerstitial, and renovascular lesions may complicate RA (Box 29.2).[16] Clinical abnormalities, including hematuria, leukocyturia, proteinuria, and reduced kidney function are

BOX 29.2 Kidney Disease in Rheumatoid Arthritis

Glomerular Lesions That May Be Direct Complications of the Disease

- MN
- MesPGN (± IgA or IgM deposits)
- Diffuse proliferative GN
- Necrotizing and crescentic GN (rheumatoid vasculitis)
- Amyloidosis (AA type)

Glomerular Lesions Associated With Agents Used to Treat Rheumatoid Arthritis

- Gold: MN, MCD, acute tubular necrosis
- Penicillamine: MN, crescentic GN, MCD
- NSAIDs: acute TIN with MCD, acute tubular necrosis, MCD without TIN
- Cyclosporine: chronic vasculopathy and TIN, focal and segmental glomerulosclerosis
- Azathioprine/6-mercaptopurine: TIN
- Pamidronate: collapsing glomerulopathy
- TNF-α inhibitors: lupus-like lesions, crescentic GN

common in patients with severe or longstanding RA. Membranous nephropathy (MN; see Chapter 21) is the most common glomerular lesion. Possibly because of the underlying disease, the presence of human leukocyte antigen (HLA)-DR3 increases the risk for MN in a patient with RA, which is not associated with anti–phospholipase A_2 receptor (anti-PLA_2R) autoantibodies. RA-associated MN has a course similar to that of idiopathic disease, although spontaneous remissions are less likely to occur. Secondary (AA) amyloidosis (see Chapter 28) is found in up to 30% of patients with RA, of which 56% have proteinuria. Half of these have nephrotic syndrome, which commonly progresses to kidney failure.[18]

NSAIDs may produce tubulointerstitial nephritis alone, or with MCD or MN (more commonly the former; see Chapters 18 and 64). A severe, necrotizing polyangiitis may complicate the course of longstanding RA (rheumatoid vasculitis). These patients may have profoundly reduced C3 levels, striking elevation of rheumatoid factors, and marked polyclonal hypergammaglobulinemia. Kidney involvement in rheumatoid vasculitis is now relatively uncommon. Tumor necrosis factor (TNF)-α inhibitors used to treat RA can evoke a picture resembling LN (see Chapter 27).

Mixed Connective Tissue Disease

Mixed connective tissue disease is characterized by overlapping features of SLE, scleroderma, and polymyositis. Typically, the serum of such patients contains high-titer autoantibodies to extractable nuclear antigens (ribonucleoprotein-extractable nuclear antigen, U1 ribonucleoprotein antigen) and may have low titers of anti-dsDNA antibody. Kidney disease, originally thought to be quite rare, is found in 10% to 50% of patients, most frequently MN and MesPGN. Steroid treatment is generally effective, but some patients exhibit progressive CKD. Patients with severe GN may respond to treatment regimens similar to those used for LN (see Chapter 27).

Polymyositis and Dermatomyositis

The related collagen vascular diseases polymyositis and dermatomyositis are characterized by inflammatory lesions in muscle with variable

skin lesions and often include Raynaud phenomenon. Patients may have proteinuria and hematuria secondary to MesPGN with IgM deposits. Acute kidney injury (AKI) may rarely supervene when severe muscle injury and myoglobinuria are present. Treatment with steroids may ameliorate the kidney manifestations and improve the muscle and skin manifestations.

Acute Rheumatic Fever

Acute rheumatic fever secondary to a pharyngeal infection with a rheumatogenic strain of group A β-hemolytic streptococci is seldom accompanied by kidney disease (see Chapter 57). Cutaneous streptococcal infections are never associated with acute rheumatic fever sequelae. Poststreptococcal GN and acute rheumatic fever almost never coexist because of distinct differences between nephritogenic and rheumatogenic strains of streptococci. Nevertheless, MesPGN is rarely associated with acute rheumatic fever. MesPGN usually manifests with hematuria and scant proteinuria and often resolves with appropriate treatment of acute rheumatic fever.

Ankylosing Spondylitis and Reiter Syndrome (Seronegative Spondyloarthropathies)

The seronegative spondyloarthropathies and oligoarticular arthropathies may be associated with mesangial IgA deposition or MesPGN. Clinical manifestations are usually mild and nonprogressive. AA amyloidosis may complicate longstanding ankylosing spondylitis.

Scleroderma (Systemic Sclerosis)

Scleroderma is a heterogeneous disorder of unknown etiology characterized by uncontrolled expansion of connective tissue in the skin and other visceral organs,[19] as well as vascular thickening and narrowing. Clinical manifestations vary from increased connective tissue in localized patches of skin (morphea) to diffuse and generalized disease (systemic sclerosis). The latter leads to skin thickening of the face and hands, telangiectasia, Raynaud phenomenon, tendon friction rubs, and sclerodactyly. Nail beds display a characteristic pattern of blood vessel abnormalities. Visceral involvement causes interstitial pulmonary fibrosis, loss of esophageal and other gastrointestinal motility, restrictive cardiomyopathy, and kidney disease. Limited forms of the disease (CREST syndrome: calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia) occur but are seldom associated with kidney disease. The disorder is more frequent in females, with an onset usually in young adults. Approximately 90% of patients will have a speckled pattern of fluorescent ANA, and 30% will have detectable antibody to topoisomerase I (Scl-70). Anticentromere antibody is strongly associated with the CREST syndrome. Anti–RNA polymerase III, antitopoisomerase, and anticentromere antibodies are associated with more systemic and kidney involvement and a poor prognosis. Rarely, the visceral abnormalities occur without cutaneous lesions (systemic sclerosis *sine* scleroderma).

Kidney involvement in scleroderma ranges from low-grade proteinuria and slight impairment of glomerular filtration rate to a more marked reduction in renal blood flow leading to a greatly elevated filtration fraction secondary to mild MesPGN to severe AKI.[20,21] The last is referred to as scleroderma renal crisis (SRC), affecting 5% to 10% of patients with scleroderma and consisting of severe (hyperreninemic) hypertension, encephalopathy, systolic and diastolic congestive heart failure, and AKI. Posterior reversible encephalopathy has been reported. Rare cases of SRC may occur without cutaneous features and even with relatively normal blood pressure. These patients are often positive for anti-RNA polymerase III antibody, and complement activation can be observed.[22] There is often accompanying microangiopathic hemolytic anemia with schistocytes and elevated serum lactate dehydrogenase. AKI results from primary involvement of the arcuate and interlobular arteries (Fig. 29.2). It may be superimposed on lesions of hypertensive emergencies (e.g., fibrinoid necrosis of the afferent arterioles) and ischemic glomerular changes (e.g., wrinkling of the capillary wall and thickening of the basal lamina).

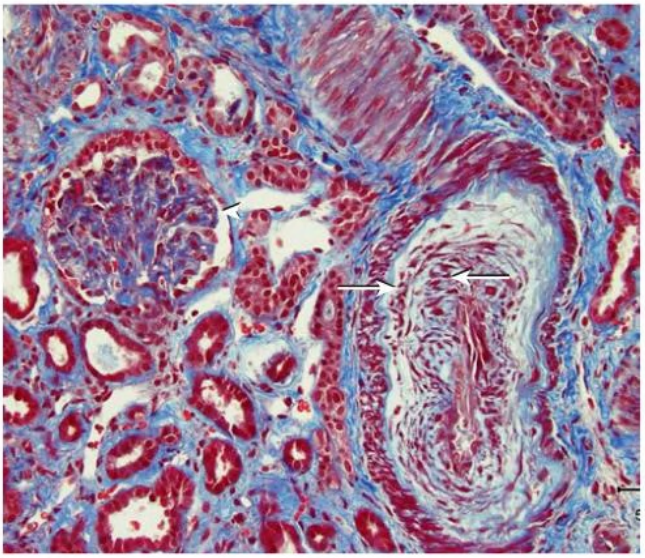

Fig. 29.2 Scleroderma. An interlobular artery shows pronounced mucoid edematous subendothelial thickening with myofibroblasts on Masson trichrome stain *(arrows),* with endothelial cell swelling and luminal narrowing. The process is limited to the intima with preservation of the internal elastic lamina. Note the ischemic glomerulus *(arrowhead)* with severely wrinkled and retracted capillary walls.

The prognosis of patients with SRC has improved remarkably with the use of angiotensin-converting enzyme (ACE) inhibitors.[20,21] In one study, ACE inhibitor treatment was associated with better patient survival at 1 year (75% vs. 15%) and with significant preservation or recovery of kidney function.[22] Captopril is the preferred therapeutic agent; there is wide experience with it in SRC and its short half-life facilitates rapid dosing uptitration.[22] Various biologic agents, including transforming growth factor (TGF)-β inhibitors, anti-CD20 (rituximab), interleukin 6 (IL-6) monoclonal antibodies, eculizumab, and tyrosine kinase inhibitors are undergoing evaluation as therapies for scleroderma or SRC.[23]

In an observational analysis of patients with scleroderma in 19 European kidney registries, the annual incidence of ESKD was 0.11 to 0.26 per 1 million population and the adjusted prevalence was 0.73 to 0.95. Recovery of kidney function occurred in 7.6% (compared with 0.6% for diabetes and 2.1% for nondiabetic kidney diseases). Recovery time may be prolonged. ACE inhibitor treatment should continue during dialysis therapy. Posttransplant 5-year patient survival is 88.2% and allograft survival is 72.4%, but disease in other visceral organs may limit life expectancy.[24]

Relapsing Polychondritis

Relapsing polychondritis is a chronic, often repetitive, episodic or continuous disorder characterized by destructive inflammation of cartilage (ear, nose, trachea, costal cartilage). Reports have associated it rarely with crescentic GN, MesPGN, MN, or tubulointerstitial IgG4 related disease.[25] In one international study of relapsing polychondritis, kidney injury was uncommon and the authors suggested that kidney involvement should raise the possibility of an alternative primary disorder.[26]

Cartilage lesions may cause deformities (saddle nose, floppy ears, tracheal collapse or stenosis, cardiac valvular disease). When kidney disease occurs, it may be severe and progressive, particularly with crescentic disease. Although corticosteroids may be adequate to treat the nonrenal manifestations, patients with refractory relapsing polychondritis may require additional agents such as azathioprine, methotrexate, cyclophosphamide, infliximab, tocilizumab, abatacept, or occasionally rituximab. For progressive kidney disease, cytotoxic agents (e.g., cyclophosphamide) may be indicated, particularly for crescentic GN.

Psoriasis/Psoriatic Arthritis

Psoriasis is an autoimmune inflammatory disease with a strong familial component, with excessive and rapid growth of the skin epidermal layer. Up to 30% of affected patients also develop psoriatic arthritis. Psoriasis (especially if severe or associated with arthritis) is associated with IgA nephropathy, MN, MesPGN, and, very rarely, with membranoproliferative glomerulonephritis (MPGN) pattern of injury on histology.[27–29] Treatment for psoriasis with glomerular disease may include steroids, methotrexate, calcineurin inhibitors, and TNF-α antagonists, the latter having some success in patients with psoriasis-associated IgA nephropathy.

Non-Lupus "Full House" Glomerulonephritis

Patients can present with findings indicative of an immune-complex mediated glomerulonephritis resembling LN, with deposition of C1q, C3, IgG, IgA, IgM by IF ("full-house"), and a typical MPGN or MN pattern of injury, without the typical clinical and serologic features required for diagnosis of SLE.[30] The pathogenesis of this uncommon disorder is unknown, but it may follow certain infections such as COVID-19, parvovirus, HIV, or syphilis.[31,32] A subset of such patients may evolve to typical SLE over many years. The prognosis seems to be poor,[30] and treatment is not well understood, but management similar to that used for LN is often recommended.

Podocyte Infolding Glomerulopathy

This clinicopathologic entity was first recognized in Japan in 2006.[33] It is commonly associated with autoimmune phenomena and connective tissue disease, such as LN or Sjögren syndrome.[34–36] Proteinuria, including nephrotic syndrome, is universal. The lesion is characterized on EM by microspheres and microtubular structures (likely representing remnants of infolded podocyte cytoplasm) incorporated into thickened GBMs (Fig. 29.3) and can resemble MN or FSGS by LM. There may be concomitant immunoglobulin deposition and subepithelial electron dense deposits in some, but not all, cases.[34] The natural history and treatment are largely unknown, but partial remissions of proteinuria can occur.

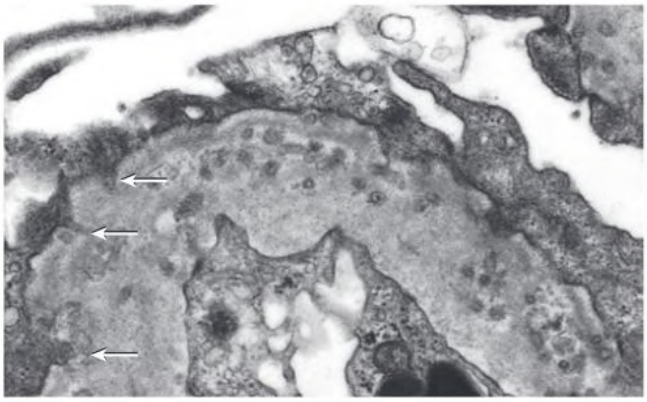

Fig. 29.3 Podocyte Infolding Disease. Electron microscopy shows a thickened glomerular capillary basement membrane (GBM) containing microspheres and microtubular structures. These likely represent entrapped podocyte cytoplasm and, in areas, podocyte cytoplasm is extending into the GBM *(arrows)*.

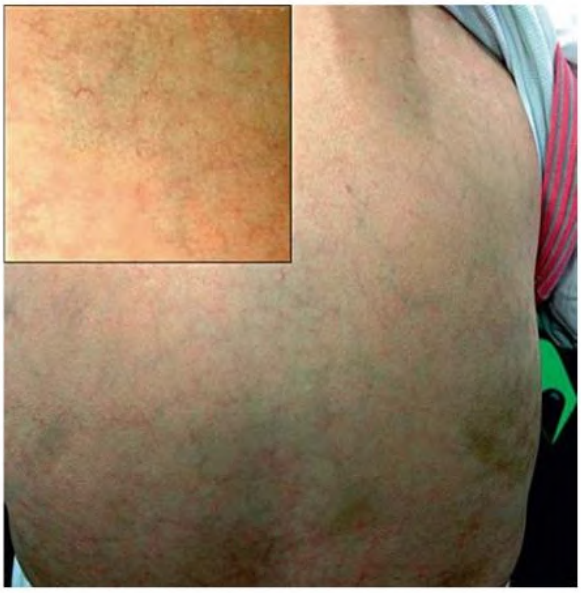

Fig. 29.4 Livedo Reticularis in Patient with Antiphospholipid Antibody Syndrome. Note reticulated skin changes (*inset,* higher magnification) on the patient's back, in addition to hematomas related to her warfarin therapy. (Courtesy J. Floege, Aachen, Germany.)

ANTIPHOSPHOLIPID ANTIBODY SYNDROME

The antiphospholipid antibody syndrome (aPLA syndrome) is characterized by venous and arterial thrombosis and circulating autoantibodies to phospholipid-protein complexes, including those of the coagulation cascade.[37,38] The syndrome was first recognized by Hughes in 1983[37] and has protean manifestations ranging from migraine headaches to multiple thrombosis and multiorgan failure (catastrophic aPLA syndrome [CAPS]).[37,38] The frequency of thrombotic episodes is about 7.5 per 100 patient years for 5 years after the first thrombotic event and often can be the presenting feature.[39] Neurologic symptoms and signs are common, including transient cerebral ischemic attacks (TIAs), strokes, migraine headaches, seizures, myelitis, and balance and sensory disturbances (often resembling multiple sclerosis).[37,38] Cardiovascular problems, such as pulmonary hypertension, premature atheromatous disease, renal artery stenosis, and myocardial infarction, are common.[37,38] Livedo reticularis is an important diagnostic clue (Fig. 29.4). Adrenal infarction or hepatic venous thrombosis may lead to acute adrenal insufficiency or Budd-Chiari syndrome, respectively. Visual loss, visual field defects, anosmia, aseptic bone necrosis, fracture, spinal claudication, and autonomic dystrophy are less frequent complications. Pulmonary hemorrhage or fibrosing alveolitis can be a presenting feature.[40] Repeated pregnancy loss is common.

The kidneys are frequently involved with a thrombotic microangiopathy (TMA; see Chapter 30).[41] CAPS is a rare but often fatal form of aPLA syndrome frequently associated with SLE or infections. It involves many organ systems, including the brain, kidneys, heart, and lungs.[42]

aPLA syndrome may occur without known systemic disease or may accompany SLE (see Chapter 27) or infection with SARS-CoV-2 (see Chapter 59). In the latter, antibodies are directed at different

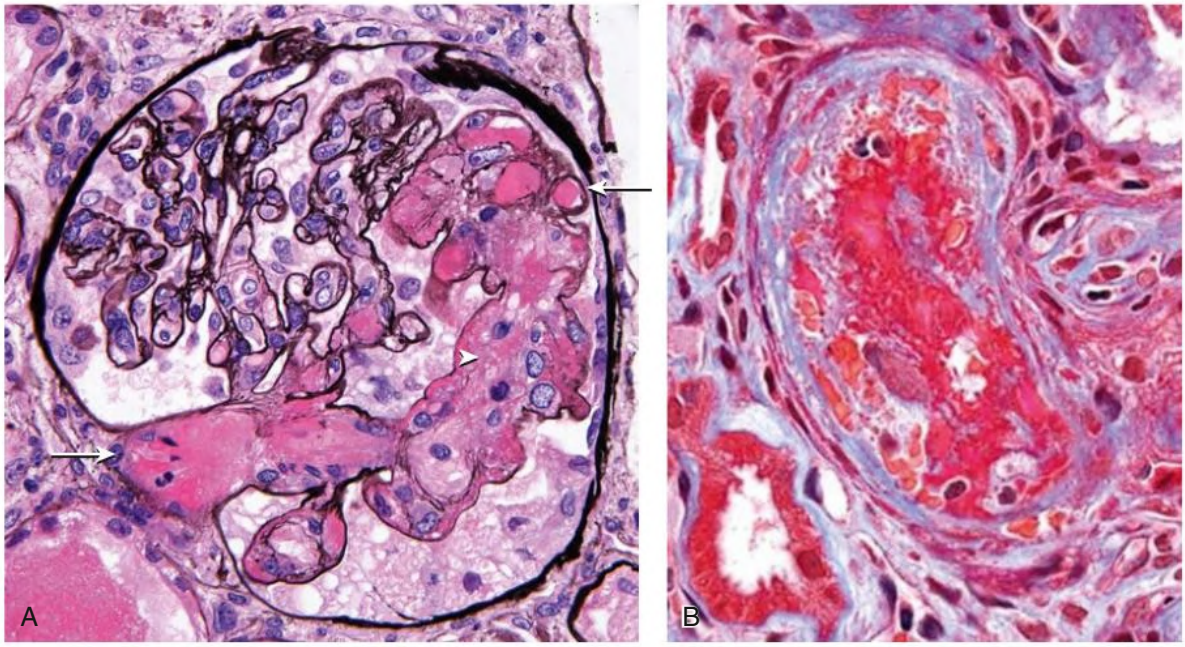

Fig. 29.5 Antiphospholipid Syndrome. (A) Thrombosis of the peri- and intraglomerular arteriole and segmental glomerular capillaries *(arrows)* with associated mesangiolysis characterized by mesangial matrix dissolution *(arrowhead)*. The adjacent glomerular capillaries show ischemic wrinkling and retraction. (B) Arteriole with luminal fibrin-platelet thrombus and endothelial cell loss. Note the muscular wall is intact and without inflammation.

β2-glycoprotein 1 epitopes than in SLE or the primary syndrome, and titers correlated poorly with clinically significant thrombotic events.[43] The presence of aPLA syndrome in SLE confers a much worse prognosis and greater risk for neuropsychiatric and cardiovascular complications. aPLA syndrome (primary or SLE related) should always be suspected with a history of migraine headache, TIA or stroke, multiple pregnancy loss, arterial or venous thrombosis, or a family history of autoimmune disease. Diagnosis of aPLA syndrome requires at least one clinical criterion plus one laboratory criterion.[44] Clinical criteria are (1) thrombosis (arterial or venous) or (2) spontaneous abortions or stillbirths. Laboratory criteria (two or more occasions at least 6–12 weeks apart)[44] are (1) lupus anticoagulant, (2) anticardiolipin antibody, or (3) anti–β_2 glycoprotein 1 antibody. The pathogenic antibodies in aPLA syndrome appear to be primarily directed against the domain I of β_2-glycoprotein 1.[45] Antibodies to prothrombin, thrombin, or phosphatidylserine may predict severe thrombophilia and/or pregnancy loss.

The pathogenesis of aPLA is probably multifactorial.[46] The thrombotic state seems to involve generation of reactive oxygen species leading to alterations in β_2-glycoprotein 1 function, impaired function of endothelial nitric oxide synthase, activation of prothrombotic receptors by autoantibodies, increased expression/activation of tissue factor, increased modified forms of prothrombotic factor XI, disruption of annexin A5 shield, and antibody-mediated activation of C3 and/or C5.[46] There is prominent involvement of the mammalian target of rapamycin complex (mTOR) in aPLA syndrome.[47] Transplanted patients with aPLA syndrome who receive the mTOR inhibitor sirolimus for prevention of allograft rejection have a lower risk for recurrence of vascular lesions. Complement and toll-like receptor (TLR) activation have also been reported.
