Neurologic Complications of Chronic Kidney Disease

Julian L. Seifter, Li Li, Martin A. Samuels

Disorders of the nervous system may coexist with kidney disease in patients with systemic disorders (e.g., hypertensive encephalopathy, thrombotic microangiopathies, atheroembolic and atherosclerotic disease, vasculitides) and fluid and electrolyte abnormalities. Neurologic complications accompany acute kidney injury (AKI) in the intensive care setting and in outpatients with chronic kidney disease (CKD). A recent meta-analysis revealed that cognitive impairment is evident across the stages of CKD independent of age-related changes.[1] Furthermore, patients with CKD are at increased risk for toxin- and pharmacologic agent–induced neurotoxicity. This chapter focuses on the direct neurologic consequences of CKD.

UREMIC ENCEPHALOPATHY

The syndrome of uremic encephalopathy (UE) involves a spectrum of brain abnormalities that may range from nearly imperceptible changes to coma.

Pathogenesis

The brain in CKD has decreased metabolic activity and oxygen consumption.[2,3] As long as the underlying kidney disease has not affected cerebral hemodynamics and responsiveness to carbon dioxide, these functions appear intact, but subtle disturbances have been detected after dialysis.

Among the known uremic toxins listed in the European (EUTox) database, 9% (7 of 75 solutes) are associated with neurologic effects.[4] The balance of excitatory and inhibitory neurotransmitters may be disrupted by organic substances,[5] in particular guanidino compounds, which are increased in cerebrospinal fluid.[6,7] These compounds antagonize γ-aminobutyric acid ($GABA_A$) receptors and at the same time have agonistic effects on *N*-methyl-D-aspartate glutamate receptors, leading to enhanced cortical excitability. Asymmetric dimethylarginine,[8] which is increased in CKD, inhibits endothelial nitric oxide synthase, and levels correlate with cerebrovascular complications in uremia. The serum level of neuropeptide Y (NPY), a peptide associated with orexigenic (hyperphagic) food intake, was found to be elevated in CKD patients. NPY can diffuse across the blood-brain barrier, and elevated NPY levels in blood promote endothelial dysfunction and regulate neural progenitor cells.[9,10] Disturbances in monoamine metabolism include a depletion of norepinephrine and suppression of central dopamine, which has been linked to the impairment of motor activity in uremic rats. Myoinositol, carnitine, indoxyl sulfate, and polyamine content, as well as disrupted solute transport and permeability, have been implicated in the neuronal dysfunction of uremia. Metabolites of drugs such as cimetidine and acyclovir are increased in uremia because of inhibition of organic anion transporter 3 (OAT3) and may result in neurotoxic syndromes.[11] Levels of opiates, in particular metabolites of meperidine, are increased in plasma because of decreased excretion through renal cation secretory transport, with subsequent neurotoxicity.[12]

Secondary hyperparathyroidism also may play a role in UE[13,14] because brain calcium is increased in CKD, and calcium transporters within neurons are sensitive to parathyroid hormone (PTH). Increased cellular calcium may play a role in neuroexcitation, while PTH may increase alkaline phosphatase levels in the brain, therefore indirectly causing cognitive impairment in CKD patients. High levels of alkaline phosphatase in the brain might promote the binding of tau protein to muscarinic receptors in the hippocampus, leading to a significant increase in cellular calcium level and neuronal cell death.[15] High fibroblast growth factor (FGF)-23, directly through its interaction with α-klotho, was associated with a higher risk of dementia in the Framingham study.[16] On the other hand, low α-klotho levels were associated with increased risk of dementia.[17]

Appetite regulation is abnormal in uremia (see Chapter 90). A high rate of tryptophan entry across the blood-brain barrier may increase the synthesis of serotonin, a major appetite inhibitor.[18] High levels of cholecystokinin, a powerful anorectic, and low levels of NPY, an appetite stimulant, have been observed. Cachexia may result from anorexia, acidosis, and inflammation. Inflammatory cytokines such as leptin, tumor necrosis factor-α, and interleukin-1 may signal anorexigenic neuropeptides such as proopiomelanocortin and α-melanocyte–stimulating hormone in the arcuate nucleus of the hypothalamus.

Clinical Manifestations

Whereas 20% of critically ill patients with AKI developed neurologic impairment in a study,[19] the syndrome in CKD is more subtle, not correlating closely to the level of kidney function.[20] Numerous studies with long-term follow-up in CKD patients suggest that cognitive impairment is greater in patients with albuminuria.[21,22] Cross-sectional studies in hemodialysis (HD) patients found cognitive impairment in 30%, with about 10% exhibiting severe impairment. Neurocognitive deficits may have special implications for CKD in early childhood, adversely affecting development of the brain.[23]

UE can manifest as complex mental changes or motor disturbances (Box 89.1). The full-blown syndrome is a risk factor for morbidity and mortality.[2,3] Mental findings include emotional changes, depression, disturbing and disabling cognitive and memory deficits, and, in the most severe form, a generalized disorder characterized by delirium, psychosis, seizures, coma, and ultimately death. Severe motor symptoms or signs are rare. Depression, anxiety, and even suicide are important underdiagnosed and undertreated aspects of uremia and may be related to metabolic or poor nutritional state and fear of dialysis or death. Other known causes of depression should always be sought.

Stable UE manifests with fine action tremor, myoclonus, asterixis, and hyperreflexia. Asterixis is characterized by intermittent loss of

muscle tone in antigravity muscles. It is distinguished from tremor by the fact that it is not an oscillation but rather an intermittent loss of tone. Myoclonus is also seen in patients with UE. It is similar in timing to asterixis (10–100 ms) but is caused by activation of antigravity muscles. For this reason, some consider asterixis to be a form of negative myoclonus. The distinction between asterixis and myoclonus is not as important as once thought, because both or either may be present in many metabolic encephalopathies and some structural brain diseases as well. Asterixis and myoclonus may be elicited with the hands outstretched but detection may be enhanced by looking at the protruded tongue or the index finger raised with the hand resting on a firm surface. Asterixis and myoclonus may be seen in patients with kidney impairment who have received drugs such as metoclopramide, phenothiazines, antiepileptic drugs including gabapentin, and opioids, especially meperidine. It is imperative for the treating physician to understand the life-threatening complications of such drugs for the patient with CKD before and after initiation of dialysis[12] (Table 89.1). Metabolic acidosis may produce an indistinguishable encephalopathy, as can aluminum toxicity. Therefore, a careful search for other causes is required before features potentially consistent with UE are attributed to advanced uremia requiring kidney replacement therapy (KRT).

Advanced UE is usually characterized by a reduced level of consciousness, anorexia, asterixis, myoclonus, and upper motor neuron signs such as spasticity, dysarthria, and gait disturbance.

BOX 89.1 Clinical Manifestations of Uremic Encephalopathy

Early Encephalopathy

Mental Changes

- Mood swings
- Impaired concentration, loss of recent memory
- Insomnia, fatigue, apathy

Motor Changes

- Hyperreflexia
- Tremor, asterixis
- Dysarthria, altered gait, clumsiness, unsteadiness

Late Encephalopathy

Mental Changes

- Altered cognition and perception
- Illusions, visual hallucinations, agitation, delirium
- Stupor, coma

Motor Changes

- Myoclonus, tetany
- Hemiparesis
- Seizures

Diagnosis and Differential Diagnosis

Severe UE is unlikely to occur in patients with CKD who are followed closely before initiation of KRT (see Chapter 95). UE is more likely to occur in patients who initially present with kidney failure or dialysis patients after missing many treatments. The blood urea nitrogen concentration most commonly exceeds 200 mg/dL. Hypertension is often present, and the manifestation may be mistaken for hypertensive encephalopathy. The diagnosis of UE is based on clinical findings and their improvement after adequate therapy (see next section). If the patient develops more insidious signs of cognitive impairment while undergoing dialysis, inadequate dialysis treatment must be distinguished from dialysis-associated dementia, Alzheimer disease, or other causes of chronic cognitive impairment. Lumbar puncture, electroencephalography, and imaging procedures largely serve to exclude other causes in patients in whom the clinical diagnosis is doubtful. In UE the cerebrospinal fluid is often abnormal, sometimes demonstrating a modest pleocytosis (usually <25 cells/μL) and increased protein (usually <100 mg/dL). The electroencephalogram is usually abnormal but nonspecific. Generalized slowing in the theta and delta wave ranges is found.[24] Brain imaging often shows cerebral atrophy and enlargement of the ventricles (Fig. 89.1).

The differential diagnosis of UE is shown in Table 89.2. Seizure activity may be secondary to UE, hypertensive encephalopathy, cerebral embolism, cerebral venous thrombosis, or electrolyte and acid-base abnormalities. Tetany can develop when treatment involves alkalinization of an acidemic patient with kidney disease and hypocalcemia. Severe electrolyte abnormalities, including hypocalcemia, hypomagnesemia, hyponatremia, and hypophosphatemia, may manifest with delirium.

Treatment

Most nephrologists consider advanced cognitive or memory impairment an indication for initiation of KRT. Most of the manifestations of central nervous system (CNS) involvement are reversible with dialysis within days or weeks, but mild signs of UE may persist. Patients who do not manifest severe signs of encephalopathy often notice improvement in cognitive function once they start KRT. Some may describe this as a "fog lifting." In dialyzed patients with persistent or recurrent

TABLE 89.1 Opioid Use in End-Stage Kidney Disease

Drug	Active Metabolites	Comments
Codeine Hydrocodone Meperidine	Morphine Hydromorphone Normeperidine	Active metabolites accumulate in patients with kidney failure; should avoid in dialysis. Meperidine should not be used in chronic kidney disease because normeperidine causes central nervous system toxicity (seizures, opisthotonos) in kidney disease.
Morphine	Morphine-3-glucuronide, Morphine-6-glucuronide	Active metabolites accumulate in patients with kidney failure; can cause myoclonus and respiratory depression; mostly replaced by hydromorphone.
Hydromorphone	Hydromorphone-3-glucuronide	Mostly metabolized in liver. Active metabolites removed by dialysis, but small amounts accumulate in patients with kidney failure.
Oxycodone	Oxymorphone Noroxycodone	
Fentanyl	No active metabolites	Metabolized in liver; not removed by dialysis.
Methadone		Fecal excretion; not removed by dialysis.

symptoms, increasing the delivered dialysis dose may improve clinical findings. Successful kidney transplantation usually results in resolution of the UE syndrome within days.

Correction of anemia with recombinant erythropoietin in the dialysis patient (see Chapter 86) may be associated with improved cognitive function[25] and decreased slowing on the electroencephalogram.[26] Too rapid overcorrection of anemia may be associated with seizures. Treatment of psychosis in kidney disease must consider the pharmacokinetics of the specific agent. For example, risperidone may be useful, but dose reduction is necessary because of the prolonged half-life in CKD.

Of note, intensive blood pressure (BP) control may not improve cognitive impairment in CKD patients. A subset of patients ($n = 670$) in the large SPRINT study received magnetic resonance imaging follow-up. Surprisingly, there was an increase in white-matter lesion volume and a decrease in total brain volume in the intensive antihypertensive treatment group compared with the standard treatment group.[27]

Fig. 89.1 Magnetic Resonance Imaging Findings in Uremic Encephalopathy. Axial T2-weighted (fluid-attenuated inversion recovery) scan from a 40-year-old woman. The extensive hyperintense lesion involves the cortical and subcortical areas of both occipital lobes and, in a more focal distribution, the basal ganglia and the frontal white matter *(arrows)*. The volume of the affected brain parenchyma is increased. Reversibility of the MRI changes was noted 2 weeks after the initiation of regular dialysis. (Courtesy A. Thron, Aachen, Germany.)

PERIPHERAL NEUROPATHY

Patients with CKD are susceptible to both polyneuropathies and mononeuropathies. The pathophysiologic process of polyneuropathy involves axonal degeneration in a length-dependent fashion. Primary demyelinating neuropathies are rare in the context of CKD except when the underlying kidney disease also causes demyelination (e.g., multiple myeloma). Mononeuropathies in CKD may be caused by nerve entrapment with compression of metabolically weakened nerves, particularly in wheelchair users or bed-bound patients. Mononeuritis multiplex should raise the possibility of vasculitic neuropathy, especially when systemic vasculitis (e.g., antineutrophil cytoplasmic antibody–positive small-vessel vasculitis or polyarteritis nodosa) is causing the CKD. Functional sparing of small-diameter axons in uremia is suggested by relatively intact thermal thresholds (hot and cold thermal threshold testing is a surrogate for pain threshold). The modestly slowed nerve conduction velocities in the polyneuropathies of uremia may be related to the reversible inhibition of the sodium-potassium adenosine triphosphatase by a uremic toxin. According to the middle molecule hypothesis, accumulated toxins in the range of 300 to 12,000 Da, including peptide hormones and polyamines, may lead to progression of neuropathy in HD patients.[6,13,14] Lower limb motor axons in uremic patients are depolarized before but not after dialysis, consistent with a role of hyperkalemia in the development of altered nerve excitability.[28] Elevated magnesium levels will also slow nerve conduction velocity. In vitro, extracellular acidosis contributes to decreased sodium conductance in large sensory neurons. Very slow nerve conduction velocities (i.e., less than half normal) suggest a demyelinating

TABLE 89.2 Differential Diagnosis of Uremic Encephalopathy

Differential Diagnosis	Comment
Hemodynamic or Vascular Encephalopathy	
Systemic inflammatory response syndrome	Observed in septic patients.
Systemic vasculitis	Vasculitis or lupus with cerebral involvement.
Cerebral atheroembolic disease	Follows recent aortic or cardiac angiography; associated with peripheral manifestations, including lower extremity cyanosis, livedo reticularis, and eosinophilia.
Drug-Induced Neurotoxicity	
Analgesics	Meperidine, codeine, morphine, gabapentin.
Antibiotics	High-dose penicillins (may cause seizures), acyclovir, ethambutol (optic nerve damage), erythromycin and aminoglycosides (may cause ototoxicity), nitrofurantoin and isoniazid (peripheral neuropathy).
Psychotropics	Lithium, haloperidol, clonazepam, diazepam, chlorpromazine.
Immunosuppressants	Cyclosporine, tacrolimus.
Chemotherapeutics	Cisplatinum, ifosfamide.
Others	High doses of loop diuretics (ototoxic), ephedrine, methyldopa, aluminum metoclopramide (myoclonus, dystonia).
Subdural Hematoma	
Posterior reversible encephalopathy syndrome	Observed particularly after kidney transplantation as a result of reversible, abnormal permeability of the blood-brain barrier. Often manifests with headache followed by mental depression, visual loss, and seizures in the context of volume expansion, acute hypertension, and often treatment with corticosteroids or calcineurin inhibitors. Lesions in the parietal, temporal, and occipital lobes may be seen on imaging studies.

neuropathy, a finding that should lead the physician to seek a specific cause (e.g., a paraprotein).

Uremic neuropathy may progress rapidly in advanced CKD.[2,28,29] Characteristic symptoms and signs are sensory loss, pain, paresthesias, and insensitivity to temperature, particularly cold. Motor findings such as foot drop can also occur. Phrenic neuropathy may cause dyspnea because of poor diaphragmatic movement, whereas hiccups are more likely a result of the CNS effects of uremia. The distal lower extremities are usually affected first because axonal polyneuropathies are length dependent. Decrease in vibratory sensation and position sense and Romberg sign (i.e., greater instability of stance with eyes closed than with eyes open) are common signs. Muscle stretch reflexes are reduced or absent. In the patient with diabetes who is on dialysis and has progressive neuropathy, it is important to establish adequacy of dialysis, as well as glucose control. Uremic polyneuropathy is aggravated by malnutrition, inadequately controlled hypertension, certain comorbid conditions (e.g., diabetes mellitus, alcohol use, atherosclerotic vascular disease), and medications (e.g., nitrofurantoin, isoniazid, hydralazine).

The diagnosis of uremic polyneuropathy can usually be made from clinical findings. If electromyography and nerve conduction tests are performed, they should not be done in an extremity bearing an arteriovenous fistula because vascular access surgery may cause local nerve injury, which can complicate the interpretation of these studies.[28] Nerve conduction velocity is modestly reduced, and needle electromyography shows evidence of chronic denervation and sometimes reinnervation.

Lead polyneuropathy should be considered, particularly when there is a known exposure history. A lower motor neuron syndrome caused by lead toxicity may be mistaken for amyotrophic lateral sclerosis. A bone lead scan using K-line x-ray fluorescence spectroscopy of the tibia is a promising new noninvasive test that may become useful. Serum lead values and red cell protoporphyrin levels may be normal if exposure is remote. There may be associated depression, the so-called *saturnine temperament,* which takes its name from the ancient belief that Saturn was made of lead and was associated with a melancholy disposition. Gout, hypertension, glycosuria, and microcytic anemia also may be caused by lead toxicity.

Other conditions in the differential diagnosis of mixed polyneuropathy include other heavy metals (e.g., arsenic, mercury), nutritional deficiencies (e.g., pyridoxine, folate, thiamine, niacin), HIV-related neuropathy, amyloid, vasculitis, sarcoid, lupus, and a paraneoplastic syndrome.

Progressive polyneuropathy may be an indication for initiation of dialysis or kidney transplantation. Symptoms usually will not deteriorate further or may even show a slow improvement thereafter. If polyneuropathic symptoms worsen in a dialysis patient, the dialysis dose should be increased. Physical therapy is an important component of the management. Patients experiencing neuropathic pain may be treated with tricyclic antidepressants (e.g., amitriptyline 10–25 mg, increasing to 75–150 mg at bedtime) or antiepileptic drugs (e.g., carbamazepine 200–400 mg initially, increasing to 1200 mg maximally; phenytoin 100–200 mg initially, maximally 600 mg).[2,3] Gabapentin may result in sedation and myoclonus in CKD because of marked prolongation of the drug's half-life, and should be prescribed at reduced doses. Deficiencies of cobalamin (vitamin B_{12}), folate, and pyridoxine may be reflected in an elevated serum homocysteine level. Methylmalonic acid may be elevated in vitamin B_{12} deficiency, and it is critical to promptly diagnose this deficiency because irreversible changes to the nervous system may develop within months. Loss of balance and position sense may be mistaken for neuropathy in pernicious anemia. Vitamin B_{12} deficiency and folate deficiency manifest with a megaloblastic or macrocytic anemia. If folate is given to a patient deficient in vitamin B_{12}, acute posterior and lateral column findings of subacute combined degeneration of the spinal cord may develop as the low store of vitamin B_{12} is used to correct the anemia. Thiamine deficiency, often associated with malnutrition, can aggravate neuropathy, but whether replacement of any of these vitamins is effective in preventing or curing polyneuropathy in uremic patients is not well established. Thiamine deficiency is the cause of Wernicke encephalopathy in dialysis or malnourished patients. This syndrome is suspected when the triad of mental change (often amnesia), ataxia (most often affecting gait), and oculomotor disturbances (most often abducens palsies with gaze-evoked nystagmus) is seen in any patient whose diet is deficient in B vitamins. When amnesia is combined with a polyneuropathy, the term *Korsakoff syndrome* applies. In malnourished patients, the cause of Korsakoff syndrome is usually multiple subclinical attacks of Wernicke encephalopathy, hence the term *Wernicke-Korsakoff disease.*

Specific mononeuropathic syndromes include ulnar nerve entrapment, associated with uremic tumoral calcinosis and subsequent ischemia, and carpal tunnel syndrome, for example, caused by β_2-microglobulin–derived amyloidosis (see Chapter 88) or by an arteriovenous fistula.[2,29] These syndromes may be treated with antiinflammatory agents, antiepileptic drugs, and surgical decompression. It is important to ensure adequacy of dialytic treatment.

Pruritus in the uremic patient may be severe and is not primarily a skin disorder (see also Chapter 91). Rather, it may represent a form of sensory neuropathy. This symptom usually improves with KRT. Antihistamines, with their sedating effect, are not always effective. Gabapentin and carbamazepine block the afferent pathway in uremic neuropathic itch. Gabapentin and pregabalin inhibit calcitonin gene–related peptide from primary afferent neurons by inhibiting GABA and opioid receptor antagonists (naloxone and naltrexone) and may antagonize transmission of itch. Antidepressants also have been successful, possibly by interfering with reuptake of serotonin and norepinephrine to reduce pruritus perception.[30]

AUTONOMIC NEUROPATHY

Autonomic neuropathy is also very common in patients with advanced CKD, probably because diabetes is a common cause of CKD. Hyperglycemia may be more difficult to control in CKD because glucose filtration is decreased. Amyloidosis, a less common cause of CKD, is associated with autonomic neuropathy. A typical manifestation is orthostatic hypotension, which is most severe in patients with diabetes mellitus or amyloidosis as a cause of CKD. Some dopaminergic drugs used in Parkinson disease or parkinsonism itself may cause orthostasis. Some patients have peripheral neuropathy and may manifest hyporeninemic hypoaldosteronism with hyperkalemia and renal tubular acidosis. Hypotension or orthostasis may preclude treatment with angiotensin antagonists and may complicate fluid removal during dialysis. CKD patients were thought to have decreased baroreceptor function, but normal baroreceptor responses to graded decrements in mean arterial BP have been described.[31] Instead, CKD patients have sympathetic hyperactivity, which contributes to hypertension, more rapid progression to kidney failure in the predialysis patient, and greater cardiovascular (CV) risk. Accordingly, α- and β-adrenergic blockade has been advocated in CKD.[31] Autonomic neuropathy is caused by axonal disease and thus is length dependent. For that reason, the longest autonomic nerve, the vagus nerve, is usually the first affected, resulting in the loss of the normal sinus arrhythmia, significant reductions of day-night BP variation, and possibly sudden cardiac death related to the loss of the balance between the sympathetic and parasympathetic limbs of the autonomic nervous system. Reports of gastrointestinal problems include gastroparesis, which is particularly problematic for the diabetic patient. In the

predialysis patient, nausea and early satiety associated with gastroparesis may be confused with uremia. Several medical regimens have been used for the uremic patient with gastroparesis; they include erythromycin, which can activate the gastric motilin receptor. Levodopa-carbidopa, as a dopamine agonist, may be effective, as may metoclopramide 10 mg before sleep or domperidone 10 to 20 mg. Nocturnal diarrhea is another consequence of vagal neuropathy. Erectile dysfunction and incontinence (urinary more commonly than fecal) also may be related to autonomic neuropathy.

CRANIAL NEUROPATHIES

Cranial nerve involvement is most often vestibulocochlear. Hearing loss needs to be distinguished from drug-induced ototoxicity or the neurosensory deafness of hereditary nephropathy.[2,3] Bilateral vestibular failure leads to inability to stand or to walk normally without vertigo or nystagmus. It is often related to the use of aminoglycoside antibiotics in the patient with CKD. *N*-Acetylcysteine given with aminoglycosides may reduce the risk for cochlear toxicity. Sulfa-based loop diuretics, often used at high doses in patients with CKD, may cause vestibular or cochlear damage. Decreased olfactory function, especially a reduced ability to discriminate among and identify odors, and dysgeusia are commonly seen in patients with CKD.

SLEEP DISORDERS

Sleep disorders in CKD include daytime sleepiness, insomnia, sleep apnea and restless legs syndrome.[32] Many HD and peritoneal dialysis patients exhibit obstructive sleep apnea that is independent of obesity.[33] The associated sleep deprivation contributes to fatigue and cognitive impairment and increases the risk for CV complications.[33] Both obstructive and central sleep apnea are prevalent in patients with CKD,[34] but the clinical predictive scores used to screen for sleep apnea have poor specificity in CKD patients[32]; diagnostic testing with polysomnography and actigraphy systems may be preferable. Obstructive sleep apnea is a condition in which blockage of the upper airway can interfere with nocturnal breathing. Nighttime oxygen and continuous positive airway pressure (CPAP) may help. Treatment of obstructive sleep apnea is effective, including use of CPAP (as in nonuremic individuals)[35] and conversion to nocturnal HD.[36,37] Central sleep apnea, often accompanied by heart failure, causes prolonged apneic episodes[38] and may respond to oxygen. Initiation of dialysis may be helpful.

Daytime sleepiness is common and underdiagnosed in patients with CKD and contributes not only to worsened hypertension and increased CV risk but also to social dysfunction. Whether obstructive sleep apnea and its associated excessive daytime sleepiness is an independent risk factor for the progression of kidney failure is not yet settled. It is assessed by a multiple sleep latency test; that is, the duration of time from "lights out" to the onset of sleep. Sleep latency less than 5 minutes is consistent with sleep deprivation. There was also a reduced proportion of rapid eye movement sleep. An increased arousal frequency is related to periodic limb movements during sleep and the presence of sleep apnea.

Sleep-wake complaints are common in patients on dialysis, with an incidence of up to 80%. Contributors include peripheral neuropathy, pain, and pruritus.

RESTLESS LEGS SYNDROME (EKBOM SYNDROME)

Restless legs syndrome (RLS), described by K.A. Ekbom in 1944, is frequent in CKD, particularly in women. It may result from a decrease in dopaminergic modulation of intracortical excitability, with reduced supraspinal inhibition and increased spinal cord excitability. RLS is characterized by unpleasant "creeping" sensations in the extremities and a compulsive need to move the limbs, usually the legs.[39,40] The movement is worsened by periods of rest or inactivity and is relieved by walking or stretching. Symptoms are worse at night and may lead to insomnia and consequent daytime sleepiness and reduced quality of life. Nocturnal muscle cramps are common in CKD and should be distinguished from RLS. The Ekbom syndrome consists of restless legs plus other obsessive-compulsive–like disorders including various pica behaviors, such as pagophagia (ice eating), geophagia (clay eating), and amylophagia (starch eating).

Periodic limb movement disorder is characterized by episodes of involuntary repetitive extension of the big toe and dorsiflexion of the ankle, as well as flexion of the knee and hip.[40] This disorder is more likely to occur in those with RLS.

Iron deficiency or iron transport into the CNS plays a central role in RLS. Iron is a cofactor for the enzyme tyrosine hydroxylase, the rate-limiting step in the biosynthesis of dopamine, possibly explaining the link between iron deficiency and dopamine deficiency in RLS. Overt iron deficiency is easily diagnosed and should be treated.[40] In patients with normal red blood cell indices and serum iron and total iron-binding capacity, serum ferritin should be tested. Transferrin saturation ratio may be an even more sensitive indicator of iron deficiency. Although not clinically indicated for RLS, analysis of spinal fluid ferritin may reveal a subtle CNS iron deficiency syndrome. RLS often persists after initiation of dialysis but may improve after transplantation and has been linked to abnormalities in calcium and phosphorus metabolism as well as to anemia. Iron replacement should be initiated if there is any indication of iron deficiency. Intravenous iron may be required (see Chapter 86). Dopaminergic treatment is often helpful, usually starting with the dopamine receptor agonists pramipexole and ropinirole. Levodopa combined with decarboxylase inhibitors (e.g., carbidopa-levodopa) may be used as well as gabapentin, opioids, and benzodiazepines.[39,40] As mentioned earlier, gabapentin should be used cautiously. Older dopamine receptor agonists, such as bromocriptine and pergolide, are rarely used now for RLS.

NEUROLOGIC SYNDROMES ASSOCIATED WITH KIDNEY REPLACEMENT THERAPY

KRT is associated with an increased incidence of subdural hematoma and intracranial hemorrhage, presumably connected to hypertension and anticoagulation with HD as well as Wernicke encephalopathy (see earlier discussion).[2,3] A syndrome of muscle weakness has been attributed to L-carnitine depletion from dialysis, leading to decreased mitochondrial fatty acid usage.

Dialysis disequilibrium syndrome is a rare complication of rapid metabolic changes occurring with HD, usually affecting patients in whom HD is being initiated (see Chapter 100).[41] It is most common in patients with severe uremia of long duration and with severe hypertension. Characterized by acute onset of headache, nausea, vomiting, disorientation, a state of confusion, and seizures, it is a diagnosis of exclusion. It usually results from acute changes in osmolality during HD, in which the rapid decrease in urea in the extracellular fluid favors water movement into brain cells, resulting in cerebral edema. Alternatively, other intracellular osmolytes within brain cells may draw water from the extracellular fluid. The syndrome normally reverses spontaneously after a period of regular HD. If no improvement is seen after a month of HD, one should investigate for other possible causes of the clinical syndrome by imaging the brain, obtaining an electroencephalogram, and examining the spinal fluid. Dialysis disequilibrium syndrome may be prevented by decreasing HD length to 2 to 3 hours, dialyzing daily, providing mannitol during

the dialysis run (such as 25 g IV every 90 minutes) and reducing HD efficacy during the first sessions.

Dialysis encephalopathy (formerly called *dialysis dementia*) is probably a multifactorial syndrome occurring in sporadic-endemic and epidemic types. In particular, in the epidemic type, aluminum-based phosphate binders and exposure to dialysate containing more than 20 μg of aluminum per liter are considered to be major causes.[42,43] Aluminum transferred to the nervous system by transferrin results in a characteristic clinical condition with prominent stuttering that usually worsens toward the end of a dialysis session and encephalopathy, initially responding well to IV benzodiazepines but then becoming unresponsive, leading to severe encephalopathy and death. With the almost universal preparation of dialysate water by reverse osmosis and the marked reduction in aluminum-containing phosphate binder use, aluminum-induced encephalopathy has virtually disappeared. If it is present, aluminum toxicity is treated with deferoxamine (see Chapter 88). Kidney transplantation is an effective treatment for dialysis dementia.

SELF-ASSESSMENT QUESTIONS

1. A 50-year-old man with chronic hypertension, CKD, and eGFR of 8 mL/min/1.73 m^2 who is not yet on dialysis presents with confusion, lethargy, and myoclonus. Which of the following factors may contribute to these neurologic changes?
   - **A.** Use of gabapentin for neuropathic pain
   - **B.** Poorly controlled secondary hyperparathyroidism
   - **C.** Poorly controlled anemia with iron deficiency
   - **D.** Poor dietary protein intake resulting in decreased blood urea level
   - **E.** A and D
   - **F.** All of the above
2. A 25-year-old woman has hypertension, seizures, and encephalopathy believed to be caused by uremia. Her blood pressure is 200/120 mm Hg. Her blood chemistry reveals Na 120 mEq/L, K 4 mEq/L, Cl 80 mEq/L, and HCO_3^- 15 mEq/L. The anion gap is 25 mEq/L, glucose 70 mg/dL, and BUN 200 mg/dL. Which of the following is the *best* answer?
   - **A.** Hypotonic hyponatremia may contribute to the altered neurologic picture.
   - **B.** The seizures may be from severe hypertension.
   - **C.** This presentation is characteristic of uremic encephalopathy.
   - **D.** The BUN should be decreased to normal promptly with dialysis.
   - **E.** Both A and D are incorrect.
   - **F.** A, B, and C are correct.
3. Findings associated with restless legs syndrome include all of the following *except:*
   - **A.** obsessive-compulsive behavior.
   - **B.** amylophagia (starch craving).
   - **C.** iron overload and deposition in the basal ganglia.
   - **D.** response to dopaminergic medication.
   - **E.** commonly, improvement during daytime hours and with exercise.

Nutrition in Chronic Kidney Disease

Gemma Bircher, Kamyar Kalantar-Zadeh

LIFESTYLE ADVICE: NUTRITION

In the early stages of chronic kidney disease (CKD), the emphasis of disease management is on lifestyle interventions. This includes maintaining or achieving a healthy body weight, ensuring good blood glucose control if diabetes is present, and providing dietary interventions to improve blood pressure (BP) and lipid levels. A healthy diet as set out by the World Health Organization (WHO) encourages:

- A variety of vegetables, fruits, legumes, nuts, and whole grains
- Limiting energy intake from fats (with unsaturated fats being preferable to saturated fats)
- Limiting total energy intake from free sugars
- Reducing salt intake

There has been much discussion about reducing protein in the diet and the extent to which it may help slow progression of CKD. Although most would promote moderating protein intake (0.8–1 g/kg body weight/day), opinions differ regarding the ideal level of protein intake as CKD advances.

Multiple levels of protein restriction have been proposed for patients with CKD stages 3 to 5 not on dialysis, with different recommendations for those with or without diabetes[1–4] (Table 90.1). However, a Cochrane review outlines the complexity of this evidence and highlights the need for further research before these dietary approaches can be recommended for widespread use.[5] This therefore remains under discussion.

In people with a solitary kidney (e.g., after nephrectomy) or at high risk for CKD, consider moderating protein to 0.8 to 1.0 g/kg body weight as indicated in the International Society of Nutrition and Metabolism (ISRNM) Commentary.[3,6] Certain patient populations, such as patients with polycystic kidney disease, appear to benefit less from a low protein diet,[1] but even these patients should avoid high dietary protein intake greater than 1.0 g/kg/day.[6] A higher protein intake of 1.0 to 1.2 g/kg body weight/day is recommended for dialysis-dependent patients.[1]

When advising patients with CKD about their protein requirements, factors to consider include diagnosis, CKD stage, comorbidity, nutritional status, food preferences, motivation, cooking skills, and dietetic resources. Lower levels of protein may be advised for those who are motivated, otherwise well/stable, and able to be closely monitored. Low-protein diets can be difficult to implement, in practice requiring adequate resourcing of specialist renal dieticians to allow clinical judgment to be exercised. Individuals need careful monitoring of nutritional status to help prevent malnutrition while acknowledging patient preferences and adherence.

More recently, a plant-dominant (PLADO) low-protein diet has also been proposed, where more than 50% of protein is sourced from plants with a total daily protein intake in the range of 0.6 to 0.8 g/kg body weight/day. This diet was designed for people with CKD who do not need dialysis and may be of interest for the future.[7]

The determination of body weight for diet prescription, whether it be ideal body weight, body mass index (BMI), usual or current, or adjusted depends on clinical judgment because adjustment must be considered for people who are severely underweight or obese.[1]

Malnutrition: Protein-Energy Wasting

Protein-energy wasting (PEW) is defined as a state of nutritional and metabolic derangements in patients with CKD that may negatively affect nutritional status and lean body mass, leading to frailty.[8] Inflammation often coexists, and nutrition intervention in isolation may not successfully reverse the loss of skeletal muscle and fat mass.[9]

PEW is common among patients with CKD, especially those undergoing maintenance dialysis,[10,11] and is associated with increased morbidity and mortality. Several factors contribute to the high incidence of PEW:

- Inadequate dietary protein and energy intake: There is a spontaneous reduction in nutrient intake that parallels the decrease in glomerular filtration rate (GFR) and is largely driven by anorexia.[12] Anorexia in CKD may be caused by impaired taste acuity and diminished olfactory function, medications, autonomic gastroparesis, psychological and socioeconomic factors, and inadequate dialysis. Suboptimal intake can be further compounded by frailty, poverty, advanced age, and multiple acute or chronic comorbidities.
- Inappropriate or overzealous dietary restrictions may have been recommended, which is particularly relevant for patients with end-stage kidney disease (ESKD).[13,14]
- Protein and amino acid losses occur during dialysis treatment. For those on peritoneal dialysis (PD), these losses may increase during episodes of peritonitis.
- Metabolic acidosis and periods of acute or chronic illnesses may induce protein catabolism. This is mediated in large part through the ubiquitin-proteasome pathway of protein degradation.[15]
- Protein catabolic effects that can further compromise patients early after transplantation include large doses of corticosteroids, the stress response to surgery, and delayed graft function.
- Chronic inflammation may contribute to both an increase in nutritional needs and anorexia. Alterations in intestinal microbiota and increased permeability of the intestinal barrier may contribute to the pathogenesis of inflammation (see Chapter 83).[16]
- Endocrine disorders, such as insulin resistance (associated with increased muscle breakdown), vitamin D deficiency, and increased parathyroid hormone concentrations have long been considered contributors to protein energy wasting, although the data remain inconclusive regarding the exact mechanisms involved. There is

TABLE 90.1 Guidelines for Levels of Dietary Protein Intake for Chronic Kidney Disease (Stages 3–5) Not on Dialysis

Protein (g/kg BW/day)[a]	Comments
0.8–1.0 g/kg/day	Widely adopted to moderate protein for CKD patients
0.8 g/kg/day	KDIGO 2012 Clinical Practice Guideline for the Evaluation and Management of Chronic Kidney Disease[4] (CKD [stages 4–5] patients with or without diabetes)
	KDIGO 2020 Clinical Practice Guideline for Diabetes Management in Chronic Kidney Disease[2] (CKD patients with diabetes)
0.6–0.8 g/kg/day	KDOQI clinical practice guideline for nutrition in CKD:2020 update[1] (CKD patients with diabetes under close supervision)
	ISRNM Commentary on the KDOQI clinical practice guideline for nutrition in CKD 2020[3] (suggests a more streamlined target for CKD patients with or without diabetes under close supervision)
0.55–0.6 g/kg/day or 0.28–0.43 g/kg/day (supplemented with essential keto acid/amino acid analogs to meet protein requirements (0.55–0.60 g/kg body weight/day)	KDOQI clinical practice guideline for nutrition in CKD:2020 update[1] (CKD patients without diabetes who are metabolically stable and under close supervision)

[a]Determination of body weight depends on clinical judgment.[1]

some evidence of an association between fibroblast growth factor-23 (a phosphate-regulating hormone) and inflammation in CKD.[17]

Obesity Paradox in Chronic Kidney Disease

Although there is a high prevalence of PEW in patients with CKD, which is associated with poorer outcomes, paradoxically, a higher BMI is associated with better survival in patients receiving hemodialysis (HD). This is termed *reverse epidemiology* (see Chapter 84). This relationship does not hold for morbid obesity in patients receiving HD, which may be used as a predictor of higher mortality.[1]

Of note, obesity in some centers can prevent a patient being activated on the transplant list, and support to achieve an acceptable BMI is often needed.

Assessment of Nutritional Status

The measurement of nutritional status does not lend itself to one simple test, and a panel of measures is required. Table 90.2 summarizes some of the methods used for the assessment of nutritional status.

TABLE 90.2 Assessment of Nutritional Status

Area	Assessments
Physical Examination	
Assessment of dietary intake	Diet history, food diaries, appetite assessment questionnaires
Anthropometric measurements	Body weight, height, body mass index Percentage weight change Skinfold thickness Mid arm muscle circumference Waist circumference
Body composition	Bioelectrical impedance DEXA Near-infrared reactance Neutron activation Total body potassium
Biochemical determinations	Serum electrolytes Serum proteins PNA, PCR Serum cholesterol Creatinine index[a]
Nutritional scoring systems	Subjective Global Assessment, Malnutrition Inflammation Score (MIS), Dialysis Malnutrition Score (DMS) Geriatric Nutritional Risk Index (GNRI)
Immunologic assays	Blood lymphocyte count Delayed cutaneous hypersensitivity tests
Functional tests	Grip strength

[a]The creatinine index is measured as the sum of creatinine removed from the body (measured from the creatinine removed in dialysate, ultrafiltrate, and/or urine), any increase in the body creatinine pool, and the creatinine degradation rate. See also www.kidney.org/professionals/kdoqi/pdf/KDOQI2000NutritionGL.pdf.
DEXA, Dual-energy x-ray absorptiometry; *PCR,* Protein catabolic rate (mathematically identical to PNA); *PNA,* protein equivalent of total nitrogen appearance.

ESTIMATION OF INTAKE

Diet history, recall, and food diaries are the mainstays for estimation of dietary nutrient intake. In dialysis-dependent patients, a gradual decrease in blood urea nitrogen (BUN) and reduced phosphate and potassium levels may indicate a decrease in protein intake, and a low serum cholesterol level may indicate a poor calorie intake.

In HD, the protein catabolic rate (PCR), also known as the protein equivalent of total nitrogen appearance (PNA), can be estimated from interdialytic changes in BUN concentration in serum. The interdialytic appearance of urea is determined by measuring the BUN at the end of one dialysis session and just before the start of the next dialysis session. Among patients who have low BUN, measuring the change in BUN between dialysis sessions distinguishes adequate dialysis as a cause of low BUN from poor intake resulting from inadequate dialysis. The PCR is expressed as g/day. Usually, the PCR is normalized to the patient's body weight (nPCR), which is expressed as g/kg/day.

Assuming that nitrogen excretion equals nitrogen intake in steady state, nPCR can be used to approximate dietary protein intake in the short term but results should be interpreted with caution. The PCR in patients treated with HD is calculated by various urea kinetic modeling software programs. (Urea kinetic modeling and adequacy of dialysis are further discussed in Chapters 99 and 101.)

The use of PCR to estimate protein intake has a number of limitations. It may be considered as a complementary tool to assess

nutritional status but should not be interpreted in isolation because it can be influenced by nonnutritional factors.[1]

If a computer program is not available, the following simple formula will give a good estimate of the nPCR:

$$\text{nPCR (g/kg/day)} = 0.22 + \frac{(0.036 \times \text{interdialytic rise in BUN [mg/dL]} \times 24)}{\text{interdialytic interval (hours)}}$$

Among patients with residual kidney function, total urea lost in the urine must also be measured from urine collected during the interdialytic period. Using this measurement, the following term is added to the equation for nPCR[17a]:

$$+ \frac{\text{Urinary urea nitrogen (g)} \times 150}{\text{Interdialytic interval (hours)} \times \text{Weight (kg)}}$$

where the urinary urea nitrogen is all of the urea nitrogen excreted in a urine collection obtained from the end of one dialysis to the beginning of the next (i.e., in the interdialytic interval).

Body Mass Index

BMI (weight [kg]/height^2 [m^2]), also known as the Quetelet index, is the most commonly used parameter for nutritional assessment; however, because weight does not distinguish between muscle and fat mass or acknowledge hydration status, it may not be representative.

Body Composition

A range of techniques can distinguish body compartments based on physical characteristics providing information about nutritional state (body lean tissue and fat content) and hydration. Some are costly, less accessible, and used more for research purposes, and the usefulness of the results depends on the availability of reference data from a population of same age, race, sex, and disease status. A few of the more widely available techniques are mentioned in the following discussion.

Triceps skinfold thickness can be used as an indicator of fat mass, and mid-arm muscle circumference (MAMC) as a surrogate measure of fat-free mass. The midpoint of the upper dominant arm is used because this is the arm less likely to have an arteriovenous fistula (Fig. 90.1).

$$\text{MAMC (cm)} = \text{Mid-arm circumference (cm)} - [3.14 \times \text{Triceps skinfold (cm)}]$$

The measurement is taken after dialysis for patients on HD. Although these anthropometric parameters are inexpensive and relatively easy to measure, they are limited by relatively wide ranges of inter- and intrapatient variability. An estimation of BMI can be made from the mid–upper arm circumference and there are reference values available, but caution is needed because these are not disease specific. Nevertheless, serial measures over time can be useful to track changes in the same patient when they are used in conjunction with other nutritional indices.

An unintentional weight loss of 5% to 10% would be interpreted as a greater than normal intraindividual variation and an earlier indicator of increased risk of undernutrition, and greater than 10% would be interpreted as clinically significant.[18]

Observation of trends using serial measures of bioelectrical impedance are increasingly being used as an adjunct to the day-to-day clinical assessment of hydration status and body composition management of dialysis patients. Assessments are best obtained after dialysis treatment when fluid compartment levels are balanced. Bioelectrical impedance is not routinely available in all facilities and is not without its limitations. Further prospective controlled trials are required to determine the best role for this technology in clinical practice.[19–21]

Fig. 90.1 Routine Measurement of Skinfold Thickness. The dominant arm, which does not have an arteriovenous fistula or graft, is used in patients with kidney failure.

Fig. 90.2 White Nails in Hypoalbuminemia. The white band grew during a transient period of hypoalbuminemia caused by nephrotic syndrome.

Serum Albumin, Prealbumin, and Transferrin

Serum albumin, prealbumin, and transferrin represent the so-called *visceral protein*. Fluid status, impaired liver function, age, and acute inflammatory conditions can affect serum albumin levels; however, despite its relatively long half-life (20 days), albumin remains an important measure of the nutritional status and health of the patient. Clinically, it may be possible to observe the growth of white nails when there has been a transient period of hypoalbuminemia (Fig. 90.2). Other serum protein markers of nutritional status are difficult to interpret because of the influence of factors other than nutrition. Serum transferrin is linked to body iron stores and may be altered with changes in iron status. Serum prealbumin (transthyretin) levels can be increased by CKD because of impaired metabolism in the kidney but also decline rapidly during episodes of acute inflammation.

Tools to Diagnose Protein-Energy Wasting and Assess Nutritional Status

Given the low specificity and sensitivity of many of the anthropometric and biochemical markers, a range of measurements is needed to assess nutritional status in addition to the evaluation of the subjective well-being of the patient (Table 90.3).

Four main established categories are recommended for the screening for PEW: serum biochemistry, body mass, muscle mass, and dietary intake.[8] Subjective global assessment (SGA) is a reliable nutritional

TABLE 90.3 Some Indices of Malnutrition

Assessment	Indices
Biochemical parameters	Serum albumin below the normal range
	Serum prealbumin < 300 mg/L (30 mg/dL) (for maintenance dialysis patients only because levels may vary according to GFR level for CKD stages 2–5)
	Low predialysis serum creatinine, phosphate, potassium, urea levels
	Serum total cholesterol < 150 mg/dL (3.8 mmol/L)
	Low creatinine index
	Low PNA, PCR
Anthropometric parameters	Continuous decline in weight, skinfold thickness, mid-arm muscle circumference
	WHO classification for BMI:
	<18.5 kg/m^2 underweight (<20 kg/m^2 for some classification systems; note that ISRNM suggests a lower threshold of 23 kg/m^2)[7]
	<18.5–24.9 kg/m^2 normal weight
	<25–29.9 kg/m^2 overweight
	>25 kg/m^2 obese
	Body weight < 90% of ideal
	Abnormal muscle strength

assessment tool for patients on dialysis.[22] Questions about recent changes in nutrient intake are used alongside simple observations of the patient's body weight and muscle mass to assess the nutritional status of the individual; patients are classified as well nourished, mild to moderately malnourished, or severely malnourished. Figs. 90.3 and 90.4 show muscle wasting in a patient on HD who was classified by SGA as severely malnourished. The Kidney Disease Outcomes Quality Initiative (KDOQI) recommends the use of the 7-point SGA for assessing nutritional status in adults on dialysis.[1] The dialysis malnutrition score (DMS) and the malnutrition inflammation score (MIS), which are fully quantitative adaptations of the SGA, as well as the International Society of Renal Nutrition and Metabolism (ISRNM) PEW definition criteria and the geriatric nutritional risk index, are alternative tools used by some centers and continue to be evaluated and refined.

Fig. 90.3 Severely malnourished hemodialysis patient.

Nutritional Guidelines, Monitoring, and Treatment

Renal dieticians, or their equivalent in different regions of the world, have the unique knowledge and skills to nutritionally assess, tailor advice, and prioritize goals according to the patient's clinical condition. The renal dietician is trained in behavioral methods to help reduce barriers, can impart practical information, and may have an extended role, such as with the management of CKD-related bone disease. Latest guidance from KDOQI recommends that a registered dietician, nutritionist, or regional equivalent collaborate closely with the multiprofessional team to help tailor nutrition advice to patients with CKD.[1]

Guidelines are useful, but it is important that dietary restrictions are not unnecessarily imposed and that advice is tailored to the individual and altered as circumstances dictate. Table 90.4 summarizes the nutritional recommendations for CKD.

Historically, dietary advice for patients with CKD has focused on individual nutrients, such as phosphorus, potassium, salt, and protein, which can be complex, challenging to adhere to, and may lead to unbalanced diets. Consequently, particular dietary patterns, including the Mediterranean diet, the Dietary Approach to Stop Hypertension (DASH), and plant-based diets that are high in fruit and vegetables, are increasingly of interest because they are linked with reduced chronic cardiovascular (CV) disease (CVD) and mortality risk in the healthy population.[23] A recent meta-analysis looked at seven studies where healthy dietary patterns (generally higher in fruit, vegetables, fish, legumes, whole grain, and fiber and lower in red meat, salt, and refined sugars) were consumed by adults with CKD and demonstrated that these eating patterns were consistently associated with lower mortality.[24] Although traditionally there has been fear of hyperkalemia from plant-based foods, recent studies suggest that a higher intake of dietary fibers from more plant-based sources can enhance bowel movement and gastrointestinal (GI) potassium loss and have an alkalizing affect, which may reduce hyperkalemia.[6]

The safety and acceptability of various diet patterns must be determined on an individual basis in the advanced stages of CKD, especially with regard to serum potassium control and adequacy of protein and energy. More large-scale clinical trials implementing DASH/Mediterranean style and plant-based diets, including PLADO diet, in people with CKD are needed.

Monitoring of patients with CKD involves a combination of nutritional assessment, noting relevant biochemistry (potassium, phosphate, and lipids), checking dialysis adequacy, and observing fluid status. The challenge comes in balancing the potential dietary restrictions of CKD

Fig. 90.4 Severely Malnourished Hemodialysis Patient. There is marked wasting of the quadriceps and calf muscles. In addition, note skin lesions from scratching because of uremic pruritus.

against the risk for compromising nutritional status. When anorexia is present, compromising food intake, nutrient intake may be maximized by one or more of the methods discussed in the following sections.

Enteral Supplementation

If food fortification advice is insufficient, supplements, in the form of high-protein, high-calorie drinks, powders, and puddings, should be considered when there are signs of PEW or its high-risk factors, especially in dialysis patients.[1] Enteral tube feeding is an option if nutrient intake cannot be increased sufficiently using oral supplements.[1] Kidney-specific tube feeds and supplements are available that are lower in fluid and electrolytes. A systematic review suggested that enteral multinutrient support increases serum albumin concentration and improves total dietary intake in patients receiving maintenance dialysis.[25] In addition, where maintenance HD patients with albumin levels of up to 3.5 g/dL received intradialytic oral nutritional supplements in a large retrospective matched-cohort study, despite limitations, significantly better survival was seen in the supplemented group versus similarly matched patient controls.[26,27]

Supplementation of Intradialytic Parenteral Nutrition and Dialysate Fluids

The GI route is the preferred choice for nutritional supplementation; however, intradialytic parenteral nutrition (IDPN), where a concentrated hypertonic solution is infused into the venous blood line three times weekly over approximately 4 hours during HD treatments, has been used to provide intensive parenteral nutrient therapy for patients who cannot tolerate oral or enteral administration of nutrients. IDPN typically provides 800 to 1200 kcal three times weekly, in the form of glucose and fat emulsion and 30 to 60 g of protein, and so will be only supplementary rather than providing full nutritional needs.

A systematic review concluded that there was insufficient evidence to demonstrate either a net benefit or a net harm associated with providing IDPN to malnourished HD patients,[28] but a more recent RCT demonstrated IDPN therapy increased prealbumin levels and was superior to nutrition counseling after 16 weeks.[29] Further clinical research is needed in this area, although the high cost of the therapy is a barrier to performing adequately powered clinical trials.

Intraperitoneal amino acids (IPAAs) can be used in PD. A 1.1% amino acid solution is substituted for glucose in PD fluid, and about 80% of the amino acids are absorbed in a 4-hour period.[30] Because the long-term effects of IPAAs on nutritional status and clinical outcomes are not known, the solution is often used to reduce glucose exposure.

Expert opinion on the use of these approaches is inconsistent. KDOQI has suggested that IPAAs (for PD) or IDPN (for HD) should be considered for patients who are unable to tolerate adequate oral supplements or tube feeding and have evidence of protein or energy malnutrition.[1] The European Society of Enteral and Parenteral Nutrition (ESPEN) has provided criteria for use of IDPN.[31] Conversely, the American Society for Parenteral and Enteral Nutrition (ASPEN) recommends that IDPN not be used as a nutritional supplement in malnourished HD patients because studies so far are not convincing.[32]

Appetite Stimulants

Despite megestrol acetate, a progesterone derivative, improving appetite moderately in HD patients in small studies, it can have adverse effects, and larger trials are required before recommendations can be made for CKD patients.[33]

In some countries, mirtazapine, an antidepressant with the side effect of increasing appetite, and cannabis-based agents can be considered, but research data in their support are insufficient. It is important to note that the licensing and restrictions of these drugs/agents plus ethical considerations are likely to vary between countries, which will affect their usage and suitability for recommendation.

More studies are also required for ghrelin, an orexigenic hormone, and melanocortin-receptor antagonists.

Vitamins, Minerals, and Trace Elements

Vitamin, mineral, and trace element abnormalities in CKD are related to dietary restriction, dialysate losses, and the necessity of intact kidney function for normal metabolism; however, the dietary requirements for patients with CKD are not clear-cut.

Protein and potassium restrictions can lead to inadequate intakes of pyridoxine, vitamin B_{12}, folic acid, vitamin C, iron, and zinc. The use of recombinant human erythropoietin may increase the requirement for iron and folic acid (see Chapter 86).

Elevated total homocysteine levels have been identified as a risk factor for CVD in the general population. Homocysteine levels in the blood are influenced by blood levels of folic acid; however, evidence from randomized trials does not support supplementation in secondary prevention. Hyperhomocysteinemia is common in patients with ESKD. As observed in those with normal kidney function, lowering homocysteine levels with folic acid, vitamin B_{12}, and pyridoxine supplements had no effect on mortality or risk of CV events in dialysis patients.[34]

A variety of available vitamin preparations contain a recommended water-soluble vitamin profile for dialysis patients. In the absence of firm guidance, it is prudent to have a low threshold for commencing such a water-soluble vitamin preparation. The European Best Practice (www.european-renal-best-practice.org) on nutrition gives opinion-based recommendations for patients on HD[35] and KDOQI give a statement of guidance:

> *In adults with CKD 3 to 5D or post transplantation, it is reasonable for the registered dietician, nutritionist, or international equivalent, in close collaboration with a physician*

TABLE 90.4 Nutritional Recommendations in Chronic Kidney Disease[a]

Daily Intake	CKD Not on Dialysis	Hemodialysis	Peritoneal Dialysis
Protein (g/kg BW/day)	0.6–1.0 Level depends on the view of the nephrologist. 1.0 for nephrotic syndrome (see Table 90.1)	1.0–1.2[1] Recommendations are in conjunction with an adequate energy intake. Requirements may be higher during illness because of multiple comorbidities or during acute periods of infection, including peritonitis.	1.0–1.2[1]
Energy (kcal/kg BW)	25–35[1]	25–35[1]	25–35[1]
Sodium (mmol)	<100[1] (more if salt wasting)	<100[1]	<100[1]
Potassium	Reduce if hyperkalemic	Reduce if hyperkalemic	Reduce if hyperkalemic; potassium restriction is generally not required. May need to increase potassium intake if hypokalemic.
	If hyperkalemic, patients will be advised to moderate intake of certain foods (e.g., some fruits and vegetables) and given information about cooking methods.		
Phosphorous	Adjust dietary phosphate intake to maintain serum phosphate levels in the normal range. Patients will be advised to moderate intake of certain foods (e.g., dairy, offal, some shellfish) as well as processed foods with high content of added phosphates, and given information about the timing of binders with high-phosphorus meals and snacks.		

[a]Recommendations are for typical patients but always should be individualized on the basis of clinical, biochemical, and anthropometric indices.
BW, Body weight; *CKD,* chronic kidney disease.
Determination of body weight depends on clinical judgment.[1]

or physician assistant, to assess dietary vitamin intake periodically and to consider multivitamin supplementation for individuals with inadequate vitamin intake. In adults with CKD 5D who exhibit inadequate dietary intake for sustained periods of time, it is reasonable to consider supplementation with multivitamins, including all the water-soluble vitamins, and essential trace elements to prevent or treat micronutrient deficiencies.[1]

High-dose vitamin C supplements should not be taken by people with CKD because of the increased risk for secondary tissue oxalate deposition.

A review on fat-soluble vitamins in advanced CKD concluded that supplementation with vitamin A is generally not recommended (unless a patient is receiving total parenteral nutrition) because deficiencies are rare, dialysis losses are minimal, and accumulation leading to toxicity can occur.[36] Vitamin E may have antioxidant properties and beneficial effects for patients with CKD,[37] but appropriately powered studies with longer follow-up are needed for confirmation.

Vitamin K is a cofactor for the enzyme γ-glutamyl carboxylase and may inhibit vascular calcification (see Chapters 84 and 88). Evidence suggests most dialysis-dependent patients have subclinical vitamin K deficiency, and there is no known toxicity. Research is ongoing to determine whether vitamin K supplementation may prevent vascular calcification and reduce mortality in patients with advanced CKD.[38] KDOQI suggests that patients receiving anticoagulant medicines known to inhibit vitamin K activity (e.g., warfarin compounds) should not receive vitamin K supplements.[1]

Guidelines for vitamin D, phosphorus, and calcium are summarized in the Kidney Disease: Improving Global Outcomes (KDIGO) guidelines (see Chapter 88).

Recommendations for sodium, potassium, and phosphorus are shown in Table 90.4.

Gut-Targeted Therapeutics

There is accumulating evidence that the GI tract may be a major source of chronic inflammation in CKD. It is hypothesized that altered diets (low potassium, phosphorus, and fiber) may affect the gut microbiome, resulting in overgrowth of bacteria that produce uremic toxins and a leaky epithelial barrier, allowing toxins into the circulation, whereas plant-based diets may have a salutary effect.

Prebiotic and probiotic formulations may lower serum levels of uremic toxins, but more trials investigating gut-targeted therapeutics are needed before they can be recommended for use in clinical practice.

Metabolic Acidosis

Although some trials have shown no detrimental effect of mild metabolic acidosis, many others have reported that normalization of serum bicarbonate concentration (see Chapter 13) is beneficial for nutritional status and bone metabolism. Current guidelines recommend the correction of acidosis in dialysis-dependent patients[9,39,40] and KDOQI states that in adults with CKD 3 to 5D, it is reasonable to maintain serum bicarbonate levels at 24 to 26 mmol/L.[1]

Exercise

There is a large body of research on exercise training for adults with CKD that shows significant benefits on physical fitness, CV parameters, well-being, and nutritional markers.[41] Trials are ongoing, and the future is likely to hold more guidance in this area for clinical practice.

SELF-ASSESSMENT QUESTIONS

1. A 60-year-old woman began hemodialysis 6 years ago. At a recent outpatient appointment, she reported breathlessness. Predialysis BP was 150/80 mm Hg.
   - Dialysis: 4 hours three times per week
   - Target weight: Stable for last 2 years at 55 kg
   - Height: 1.47 m
   - Body mass index (BMI): 25 kg/m^2
   - Intradialytic weight gain average: 0.9 kg
   - Passes small amounts of urine

Monthly laboratory testing reveals blood results as follows:

	Creatinine (mg/dL)	Urea (mg/dL)	Phosphate (mg/dL)	Potassium (mmol/L)	Albumin (g/dL)	Cholesterol (mg/dL)	Hemoglobin (g/dL)
Predialysis	5.3	27	3.16	4.5	3.5	100	13.85
Postdialysis	1.54	7.86	1.30	2.9			

What would your next course of action be?

A. Reduce the dialysis time because she is receiving more dialysis than required.
B. Investigate dietary intake, in particular protein and calorie intake, and assess target weight.
C. Increase target weight.
D. Start diuretics and fluid restriction.

2. A 38-year-old White man with progressive CKD is feeling tired and reporting weight loss, nausea, and a metallic taste in the mouth. His BP is 156/90 mm Hg, and urinalysis reveals +++ protein and traces of blood. There are no signs of peripheral edema. He trains at the gym three times per week.

- Weight: 78 kg
- Height: 1.7 m
- BMI: 27 kg/m^2
- Amlodipine 5 mg/day begun
- Sodium bicarbonate begun
- Diet history reveals an average daily protein intake of 120 g, an approximate calorie intake of 2600 kcal, and sodium intake of 190 mmol/day.Laboratory findings are as follows:

Glomerular filtration rate (mL/min)	Creatinine (mg/dL)	Urea (mg/dL)	Phosphate (mg/dL)	Calcium (mg/dL)	Potassium (mmol/L)	Bicarbonate (mEq/L)
13	5.1	74	4.96	10.02	5.1	16

What would your next course of action be?

A. Put the patient on a reduced-calorie diet.
B. Start dialysis.
C. Moderate protein and salt intake.
D. Start a low-potassium diet.

3. A 59-year-old man with ESKD resulting from type 1 diabetes has been treated with continuous ambulatory peritoneal dialysis for 12 months. He reports reduced appetite, occasional nausea, and feeling full only midway through modest-sized meals; he has lost 3.3 kg over the previous 2 months. He weighs 79.2 kg and has a BMI of 34 kg/m^2. He dialyzes with four exchanges of volume, 2 L each. Measurement of dialysis clearances shows a weekly Kt/V for urea of 1.8 (target minimum 1.7). What would your next course of action be?

A. Reduce dialysis fluid volumes in case they are contributing to his gastrointestinal symptoms.
B. Advise weight reduction because BMI may be contributing to feelings of fullness.
C. Start amino acid-containing peritoneal dialysate.
D. Start a prokinetic agent.

Dermatologic Manifestations of Chronic Kidney Disease

Pieter Evenepoel, Dirk R. Kuypers

Cutaneous disorders are common in patients with chronic kidney disease (CKD). Many of these cutaneous disorders are caused by the underlying kidney disease, whereas others relate to the severity and duration of uremia. CKD patients have a high incidence of skin lesions associated with cutaneous aging, including wrinkling, senile purpura, actinic keratoses, and hair loss.

Improved treatments in dialysis patients have resulted in changes in the frequency and types of skin disorders observed in conjunction with end-stage kidney disease (ESKD). Dermatologic conditions such as uremic frost, erythema papulatum uremicum, uremic roseola, and uremic erysipeloid now rarely occur. Pigmentary alterations, xerosis, ichthyosis, half-and-half nails, acquired perforating dermatosis, bullous dermatoses, pruritus, and calcific uremic arteriolopathy (CUA) remain prevalent, whereas nephrogenic systemic fibrosis (NSF) is a rare and waning entity now that the causative agent has been identified (Fig. 91.1). The last four prevalent skin disorders are the focus of this chapter because they are associated with significant morbidity or mortality and/or represent an ongoing diagnostic or therapeutic challenge.

UREMIC PRURITUS

Clinical Manifestations

Uremic pruritus (UP) is a frequent symptom of ESKD, with a prevalence ranging from 22% to 48%. Although its incidence in adult dialysis patients declined as a result of improved dialysis efficacy and the introduction of so-called "biocompatible" dialysis membranes, UP still causes serious discomfort and skin damage, often associated with disturbance of day and night rhythm, sleeping disorders, depression, anxiety, and diminished quality of life.[1,2] The intensity and spatial distribution of UP vary significantly among patients and over time throughout the course of kidney disease. Excoriations, induced by uncontrollable scratching with or without superimposed infection, occur in severely affected patients and, rarely, lead to prurigo nodularis—a treatment-resistant lichenified or excoriated papulonodular chronic skin eruption (Fig. 91.2). The most frequently involved body areas are the back, limbs, chest, and face; 20% to 50% of patients report generalized pruritus.[3]

Pathogenesis

Factors thought to contribute to UP include parathyroid hormone (PTH) and divalent ions (calcium, phosphate, magnesium) because itching is a frequent symptom accompanying severe secondary hyperparathyroidism and elevated calcium-phosphate product. However, the lack of consistent correlations between serum and skin levels of PTH, calcium, phosphorus, and magnesium with the severity of UP indicates that other factors also contribute to its development. The number of dermal mast cells is increased in uremic patients, and higher tryptase and histamine plasma concentrations are reported in severe cases. Histamine release is triggered by substance P, a neurotransmitter involved in itch sensation. The role of elevated serotonin (5-hydroxytryptamine [5-HT_3]) levels in dialysis patients with UP is debated; clinical trials using a selective inhibitor of 5-HT_3 have yielded conflicting results (see later discussion). Xerosis is a common skin problem in dialysis patients (60%–90%) that predisposes to UP. Skin dryness is caused by primary dermal changes associated with uremia, such as atrophy of sweat glands with impaired sweat secretion, disturbed stratum corneum hydration, sebaceous gland atrophy, and abnormal arborization of free cutaneous nerve fiber endings.

There are two major hypotheses concerning the pathogenesis of UP. The opioid hypothesis proposes that UP is caused by overexpression of opioid μ-receptors and decreased κ opioid receptor expression in dermal cells and lymphocytes. Consistent with this hypothesis, activation of the κ opioid system using a κ-receptor agonist was efficient in reducing UP in a mouse model. In contrast, the immune hypothesis considers UP an inflammatory systemic disease rather than a local skin disorder. Studies examining the beneficial effects of ultraviolet B (UVB) light exposure on pruritus showed that UVB attenuates the development of Th1 helper cells in favor of Th2 helper cells. Indeed, the number of CXCR3-expressing and interferon-γ–secreting $CD4^+$ cells (indicating Th1 differentiation) is significantly increased in the circulation of dialysis patients with UP compared with those without. Levels of serum markers of inflammation, such as (high sensitivity) C-reactive protein, interleukin (IL)-2, IL-31, and IL-6, are also higher in patients with UP.

Treatment

Common causes of UP in CKD and dialysis patients, such as primary skin disorders (e.g., urticaria, psoriasis, atopic and contact dermatitis), liver disease (e.g., hepatitis), and endocrine diseases (e.g., hypothyroidism, diabetes mellitus) should be ruled out and adequately treated. The treatment approach to UP is shown in Fig. 91.3.

Optimizing Dialysis and Mineral Metabolism Therapy

Optimizing dialysis biocompatibility and efficacy, using medium cut-off dialyzers, and improving nutritional status may reduce the prevalence and severity of UP. Controlling calcium and phosphorus serum concentrations by short-term use of dialysate with low calcium and magnesium concentrations has sometimes ameliorated UP symptoms but may lead to worsening of renal osteodystrophy in cases of prolonged use. Parathyroidectomy is not advocated for relief of UP because no consistent beneficial effects have been demonstrated.

Skin Emollients

Emollients continue to be the primary treatment given by nephrologists, although the overall efficacy of this approach is uncertain. Simple emollients without perfumes or other additives are preferred. Continuous bath oil therapy containing polidocanol, a mixture of

Fig. 91.1 Cutaneous Disorders in Patients With End-Stage Kidney Disease. (A) A spectrum of pigmentary alterations occurs in dialysis patients, with brownish hyperpigmentation in sun-exposed areas being the most prevalent. (B) Xerosis, a dry or roughened skin texture, is seen in up to 75% of dialysis patients. (C) Acquired perforating dermatosis affects approximately 10% of the dialysis population. The lesion is usually asymptomatic and consists of grouped dome-shaped papules and nodules, 1 to 10 mm in diameter. The trunk and the extremities are most commonly involved. (D) Half-and-half nails (also termed *red and white nails*) occur in as many as 40% of patients on dialysis. The nails exhibit a whitish or normal proximal portion and an abnormal brown distal portion.

monoether compounds of lauryl alcohol and macrogol, seems to help some patients. Sericin, a biopolymer protein from the silkworm *(Bombyx mori)*, contains 32% serine, is the main amino acid of the natural moisture factor in human skin, and suppresses the release of proinflammatory cytokines. Sericin effectively reduced UP in a randomized, double-blind, placebo-controlled 6-week study in 50 dialysis patients.[4]

Antihistaminic Drugs

Classic antihistamines have similar efficacy compared with emollients; newer, second-generation antihistamines (e.g., desloratadine) might have some effect in UP. Ketotifen (2–4 mg/day), a putative mast cell stabilizer, was beneficial in one small study.

Phototherapy

UV light, especially UVB (wavelength 280–315 nm), is effective for treatment of UP and is well tolerated except for occasional sunburn. The duration of the antipruritic effect of thrice-weekly total body UVB therapy (total of 8–10 sessions) is variable but may last for several months. Potential carcinogenic effects of UV radiation require serious consideration, and its prolonged use (>12 weeks) is contraindicated in patients with a fair complexion (skin phototypes I and II).

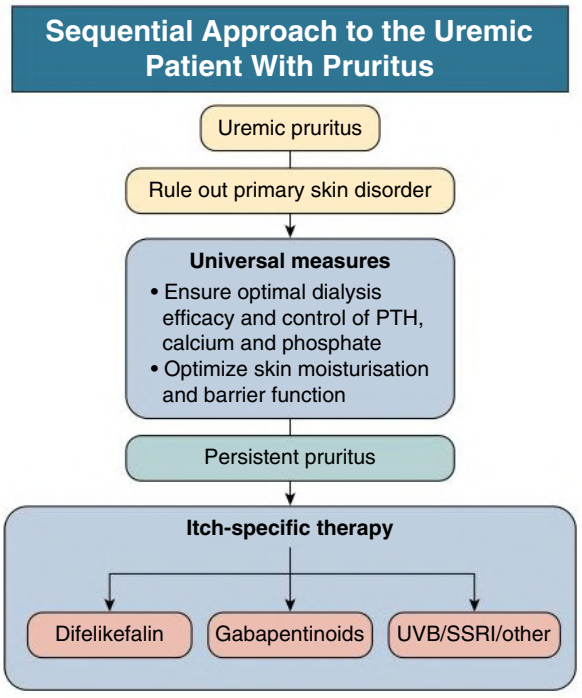

Fig. 91.3 Sequential approach to the uremic patient with pruritus. *PTH*, Parathyroid hormone; *SSRI*, Selective serotonin reuptake inhibitor; UVB, Ultraviolet B.

5-Hydroxytryptamine Antagonist

Ondansetron, a selective 5-HT_3 antagonist, was used successfully in a small study in peritoneal dialysis patients. However, a subsequent larger randomized, placebo-controlled study failed to show superiority over placebo in patients on hemodialysis (HD).

Opioid Receptor Agonists

A κ-opiate receptor agonist, nalfurafine, given intravenously after HD, was tested in two randomized, double-blind, placebo-controlled trials involving 144 patients. Itching intensity, excoriations, and sleep disturbances were significantly reduced in patients receiving the active compound without an excess of drug-related side effects compared with placebo.[5] Oral daily doses of 2.5 to 5 mg nalfurafine were equally effective in reducing UP scores compared with placebo during a 2-week treatment period in 337 dialysis patients.[6] A subsequent 1-year study ($n = 211$) confirmed the sustained beneficial effect of 5 mg nalfurafine on UP, with the most frequently reported adverse events being insomnia (19%), constipation (7%), and increased blood prolactin concentrations.[7] Difelikefalin, a peripherally restricted and selective kappa opioid receptor agonist, has been approved for treatment of moderate to sevier pruritus associated with CKD in adults undergoing hemodialysis. This drug reduced UP intensity in a significantly larger proportion of dialysis patients (51.9% vs. 30.9% in controls) than placebo when administered thrice-weekly intravenously for 12 weeks.[8] UP-related quality of life improved in the active treatment arm, but diarrhea, dizziness, and vomiting were more commonly observed.[8]

Gabapentin

Gabapentin, an anticonvulsant drug administered after dialysis (300 mg), was effective in reducing UP. A reduced dose is required if it is given chronically to patients with ESKD because it has a narrow therapeutic window and can accumulate and cause neurotoxic side effects.[9] The UP score was significantly reduced in two controlled studies after 4 weeks of gabapentin therapy at a dose of 100 to 300 mg administered thrice weekly after dialysis. Gabapentin was well tolerated; no patients stopped therapy because of side effects, which were limited to dizziness, somnolence, fatigue, and nausea. Similar effects were demonstrated in a smaller study using pregabalin and recent randomized trials comparing gabapentin with doxepin and ondansetron.[10,11]

IMMUNOMODULATORS AND IMMUNOSUPPRESSIVE AGENTS

A 7-day course of thalidomide reduced the intensity of UP by up to 80% in a placebo-controlled crossover study of 29 HD patients. Because of its strong teratogenic properties, thalidomide should be reserved for therapy-resistant severe UP in individuals outside the reproductive-age category. Adverse effects of thalidomide, such as peripheral neuropathy and cardiovascular side effects, limit its longer use. A prospective single-center study of 25 chronic dialysis patients with UP demonstrated that 6 weeks of treatment with tacrolimus ointment (0.1%) significantly reduced the severity of UP. Tacrolimus was well tolerated in this trial and caused no detectable systemic exposure or side effects.[12] However, a subsequent, smaller vehicle-controlled trial showed equal relief of UP with vehicle and tacrolimus. The risks of long-term topical use of these agents are currently unknown, and their prolonged use is not recommended until more data are available.

Long-Chain Essential Fatty Acids

Oral administration of γ-linoleic acid (GLA)-rich primrose oil resulted in significant improvement of UP in chronic dialysis patients. Supplementation of GLA-rich primrose oil is thought to augment synthesis of antiinflammatory eicosanoids. Similar effects could be obtained through use of fish oil, olive oil, and safflower oil.

Capsaicin

Capsaicin (*trans*-8-methyl-*N*-vanillyl-6-nonenamide) is a natural alkaloid found in the pepper plant that depletes the cutaneous type C sensory nerve endings of substance P. Two clinical studies showed that application of 0.025% capsaicin cream significantly alleviated UP in dialysis patients, who exhibited no side effects.

Oral Activated Charcoal

UP symptoms completely disappeared or were significantly reduced in chronic dialysis patients treated with activated charcoal (6 g/day) for 8 weeks. In two different clinical studies, comparable results were obtained with this inexpensive and well-tolerated compound, rendering it a valuable alternative for patients with UP.

Miscellaneous

Various other therapies have been examined for the treatment of UP; some may be effective but are not first-line treatments in chronic HD patients because of undesirable side effects, cumbersome use, or incompatibility with kidney replacement therapy (sauna, cholestyramine, nicergoline). Other therapies that have not reduced UP convincingly in controlled studies include acupuncture, turmeric, low-protein diet, intravenous (IV) lidocaine, melatonin, sertraline, oral montelukast, zinc sulfate, topical vitamin D, and mexiletine.

BULLOUS DERMATOSES

Bullous dermatoses are reported in up to 16% of patients on maintenance dialysis. This skin disease entity mainly includes pseudoporphyrias (e.g., secondary to nonporphyrinogenic drugs and chemicals) and other photodermatoses, whereas true porphyrias (e.g., porphyria cutanea tarda [PCT], variegate porphyria) remain rare.[13] Pseudoporphyrias, true porphyrias, and photodermatoses are clinically and histologically similar and are characterized by a blistering photosensitive skin rash. The dorsal hands and the face are the most affected areas (Fig. 91.4).

PCT is caused by abnormalities in the porphyrin-heme biosynthetic pathway, leading to an accumulation of highly carboxylated uroporphyrins in the plasma and skin. Phenotypic expression of the disease also requires one or more of a number of external contributory factors, including alcohol, estrogens, iron overload, and infection with hepatitis B and C viruses. It is important to distinguish PCT from other porphyrias in which patients are at risk for development of potentially fatal neurologic attacks if they are exposed to porphyrinogenic drugs and other precipitants. Therapeutic options include avoidance of environmental triggers, HD with high-flux membranes, repeated small-volume phlebotomies, and iron chelators.

The term *pseudoporphyria* was originally used for patients with normal plasma porphyrins who exhibited PCT-like skin lesions secondary to drugs and chemicals. However, some dialysis patients also develop similar skin lesions that spontaneously heal and leave a hypopigmented area; this entity is known as *dialysis porphyria;* a proportion of these patients have raised plasma porphyrins but without the disturbances in porphyrin metabolism classically found in the porphyrias. In rare patients, an offending medication can be identified. However, in most dialysis patients, protection from sun exposure appears to be the only preventive measure.

Fig. 91.4 Porphyria Cutanea Tarda. Tense bullae, erosions, and crusts of the dorsal hands. (From Kuypers DR, Claes K, Evenepoel P, et al. A prospective proof of concept study of the efficacy of tacrolimus ointment on uraemic pruritus [UP] in patients on chronic dialysis therapy. *Nephrol Dial Transplant.* 2004;19[7]:1895–1901.)

CALCIFIC UREMIC ARTERIOLOPATHY (CALCIPHYLAXIS)

Definition

CUA, or calciphylaxis, is a devastating and life-threatening ischemic vasculopathy seen primarily among patients with CKD.[14,15] The ischemia may be so severe that frank infarction of downstream tissue develops. The most common and most noticeable damage is in the skin and subcutaneous tissues.[12,13] CUA should be distinguished from benign nodular calcification (calcinosis cutis), which can develop in patients with very high serum calcium-phosphate product (Fig. 91.5).

Epidemiology, Pathogenesis, and Risk Factors

Although hard epidemiologic data are lacking, it is generally believed that the incidence of CUA is increasing. This might, in part, result from increased physician awareness and the high-risk profile of contemporary dialysis patients.[15] The estimated incidence ranges from 1 to 4 per 100 patient-years. The pathogenesis of CUA is complex and incompletely understood.[14,16] Recent data suggest that CUA involves a cell-mediated, bone morphogenetic protein-2–driven osteogenic process with extensive subcutaneous extracellular matrix remodeling and deposition of hydroxyapatite.[17] A cascade consisting of matrix remodeling, calcification, endothelial damage and thrombus formation, luminal obstruction, and finally full-blown CUA has been postulated.[17] Female sex, white ethnicity, obesity, diabetes mellitus, long dialysis vintage, and vitamin K deficiency are established risk factors.[15] In a case control study, the incidence of CUA was 10-fold higher in dialysis patients treated with vitamin K antagonists (warfarin or coumarins). Endogenous inhibitors of vascular calcification, such as matrix Gla protein, are dependent on vitamin K for their activation. Patients treated with warfarin or coumarins may thus not be able to appropriately inhibit vascular calcification. CUA prevalence is higher in patients with hyperphosphatemia and/or hypercalcemia. In acute CUA, serum calcium and phosphate levels can be low. Although data from the Evaluation of Cinacalcet HCl Therapy to

Fig. 91.5 Benign nodular calcification (calcinosis cutis). Firm subcutaneous nodule adjacent to the elbow.

Fig. 91.6 Proximal (A) and distal (B–C) calcific uremic arteriolopathy.

Lower Cardiovascular Events (EVOLVE) trial indicate cinacalcet may reduce the incidence of CUA in HD patients who have moderate to severe secondary hyperparathyroidism,[18] registry data fail to confirm a key role for uncontrolled hyperparathyroidism in the pathogenesis of CUA.[19] Finally, both low- and high-turnover bone disease have been associated with CUA.

Clinical Manifestations

CUA is typically characterized by areas of zoster-like tenderness and ischemic necrosis of the dermis, subcutaneous fat, and, less often, muscle.[14] These ischemic changes lead to livedo reticularis or violaceous, painful, plaque-like subcutaneous nodules on the trunk, buttocks, or proximal extremity—that is, in areas of greatest adiposity (proximal CUA; Fig. 91.6A). The early purpuric plaques and nodules progress to ischemic or necrotic ulcers with eschars that often become infected. Proximal CUA is frequently precipitated by a specific event, such as local skin trauma or a hypotensive episode. CUA also can affect the hands, fingers, and lower extremities, thereby mimicking atherosclerotic peripheral vascular disease (distal CUA; Fig. 91.6B). Peripheral pulses are preserved distal to the area of necrosis. Myopathy, hypotension, fever, dementia, and infarction of the central nervous system, bowel, or myocardium have been described in association with cutaneous necrosis. This condition is termed *systemic CUA*.

Pathology

Characteristic histologic features of CUA include calcification, fibrointimal hyperplasia, and thrombosis in microvessels in the subcutaneous adipose tissue and dermis, often accompanied by necrosis and adipose tissue, dermal-epidermal separation, panniculitis, proliferation of dermal epithelial cells, and interstitial depositis[15] (Fig. 91.7). Calcified lesions consist of hydroxyapatite, typically occupy the entire circumference of the vessel, and are mainly located in the intima.[20]

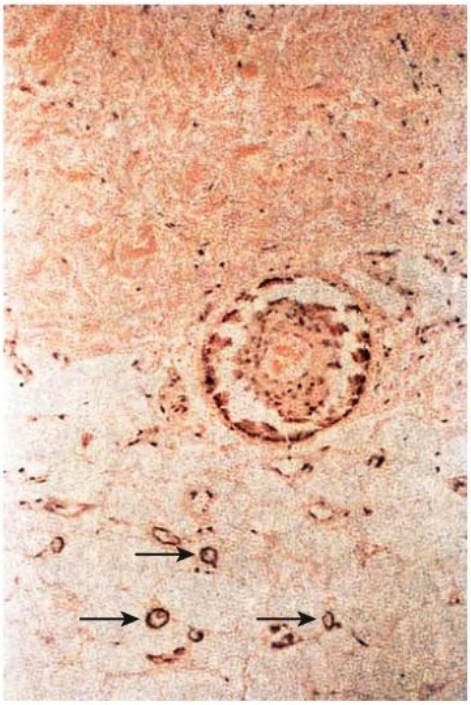

Fig. 91.7 Histopathologic Features of Calcific Uremic Arteriolopathy. Medial calcification and intimal hyperplasia of an arteriole at the dermal-subcutaneous junction. Note calcification of interlobular capillaries *(arrows)* in the subcutaneous tissue. (Van Kossa stain.) (From Kuypers DR, Claes K, Evenepoel P, et al. A prospective proof of concept study of the efficacy of tacrolimus ointment on uraemic pruritus [UP] in patients on chronic dialysis therapy. *Nephrol Dial Transplant.* 2004;19[7]:1895–1901.)

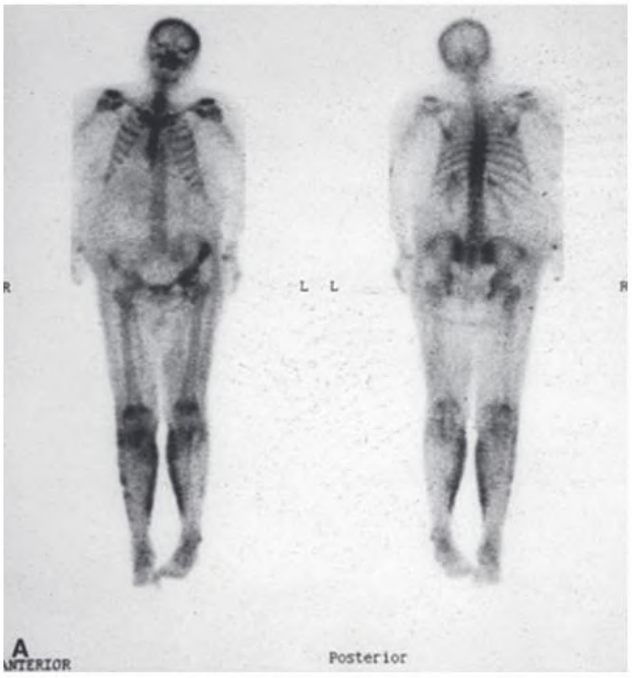

Fig. 91.8 Bone Scintigraphic Abnormalities in Calcific Uremic Arteriolopathy. Calf calcification in a patient with gross ulcerations in both legs from the popliteal fossae to the ankles. (From Nigwekar SU, Thadani R, and Brandenburg V. Calciphylaxis. *N Engl J Med.* 2018;378:1704–1714.)

Diagnosis and Differential Diagnosis

Many clinicians base the diagnosis of CUA on physical examination findings only. Although ulceration is an obvious presentation of CUA, increasing awareness of the condition should allow diagnosis at an earlier, nonulcerative stage when a distinct subcutaneous tenderness can be felt below the early skin lesions. Biopsies are discouraged by most but not all experts because of potential ulceration in the region of the incision and the risk for sampling error. Other potentially useful diagnostic procedures include measurements of transcutaneous oxygen saturation, bone scintigraphy (commonly with Tc-99m-methylene diphosphonate) (Fig. 91.8), and xeroradiography.[21]

The following conditions should be considered in the differential diagnosis: herpes zoster, systemic vasculitis, peripheral vascular disease, pyoderma gangrenosum, atheroemboli, cryoglobulinemia, and systemic oxalosis.[15] Skin biopsy is the standard method for confirmation of clinically suspected calciphylaxis; however, its role in practice is debated, given the risk of provoking new, nonhealing ulcers and infection. A skin biopsy should therefore be performed only when clinical circumstances do not suggest CUA or when clinical and laboratory examinations, including the assessment of coagulation and immunologic parameters, point to an alternative diagnosis.[15]

Natural History

Despite intensive combined treatments, the prognosis of patients with CUA remains poor; the overall 1-year survival is 45% and the 5-year survival is 35%, with a relative risk for death of 8.5 compared with that for other dialysis patients. Patients with ulcerative or proximal CUA have the worst prognosis. Infection accounts for up to 60% of the mortality.[14]

Prevention and Treatment

Preventive approaches include controlling bone and mineral metabolism and optimizing nutritional state.[14] Specific therapeutic regimens have been limited to uncontrolled case series (Box 91.1). Intervention should include an aggressive program of wound care and prevention of superinfection, adequate pain control, and correction of underlying abnormalities in serum calcium and phosphorus concentrations. This includes cessation of vitamin D supplementation, intensification of the dialysis regimen, and use of a low-calcium dialysate and non–calcium-containing phosphate binders. Furthermore, local tissue trauma, including subcutaneous injections, should be avoided. Parathyroidectomy or calcimimetic agents should be reserved for patients with severe hyperparathyroidism. Vitamin K (preferentially vitamin K_1) supplementation is advised, especially in patients with warfarin- or coumarin-associated CUA. Beneficial outcomes have been reported with bisphosphonates in case reports and small series. Sodium thiosulfate has been licensed as an orphan drug for CUA by the European Medicines Agency and is also approved for use in the U.S. It enhances the solubility of calcium deposits[22] because exchange of calcium for sodium results in extremely soluble calcium thiosulfate. Besides being a chelator of calcium, sodium thiosulfate is also a potent antioxidant. Sodium thiosulfate is given via IV at the end of every HD session (12.5–25 g over 30–60 minutes). Apart from nausea and vomiting, the therapy is well tolerated. Major side effects of sodium thiosulfate infusion include metabolic acidosis, volume overload, hypocalcemia, and QT-interval prolongation. The optimal duration of treatment and potential effects of long-term treatment on bone are unknown. Efficacy has been suggested by several case-series, but definite proof by a randomized controlled trial is lacking.

BOX 91.1 Treatment Options in Patients With Calcific Uremic Arteriolopathy

1. Reduction of procalcifying factors
   - Intensified dialysis (e.g., daily hemodialysis, switch from peritoneal dialysis to hemodialysis, low-calcium dialysate)
   - Avoidance of vitamin D and calcium supplements; administration of calcium-free phosphate binders; bisphosphonate administration (caution if adynamic bone disease is suspected)
   - Parathyroidectomy (in the case of hyperparathyroidism) or administration of cinacalcet
2. Improving the status of calcification inhibitors
   - Halt vitamin K antagonists (warfarin)
   - Aggressive treatment of infections or other proinflammatory stimuli to increase fetuin-A levels
   - Experimental:
     - Administration of high-dose vitamin K2, and, if unavailable, vitamin K1?
     - Administration of fetuin-A (e.g., by fresh frozen plasma or plasma exchange?)
3. Prevention or reversal of calcium-phosphate precipitation
   - Administration of sodium thiosulfate
4. Supportive measures
   - Avoidance of additional local tissue trauma by atraumatic wound care with gentle debridement of necrotic tissue and avoidance of subcutaneous injections
   - Anticoagulation (heparin and low molecular weight heparin)
   - Adequate pain management
   - Adequate infection control

Modified from Colboc H, Moguelet P, Bazin D, et al. Localization, morphologic features, and chemical composition of calciphylaxis-related skin deposits in patients with calcific uremic arteriolopathy. *JAMA Dermatol.* 2019;155[7]:789-796.

SNF472, an IV formulation of myoinositol hexaphosphate, is currently being investigated in CUA patients (NCT04195906). SNF472 acts through a novel pathway to selectively and directly inhibit the formation and growth of hydroxyapatite crystals, the final common step in the pathophysiology of vascular calcification. SNF472 significantly attenuates the progression of coronary artery calcium and aortic valve calcification in patients with ESKD receiving HD.[23]

NEPHROGENIC SYSTEMIC FIBROSIS

Definition

NSF, formerly known as *nephrogenic fibrosing dermopathy*, is a scleroderma-like fibrosing disorder that develops in the setting of kidney failure. The fibrotic process affects the dermis, subcutaneous tissues, fascia, and other organs, including striated muscles, heart, and lungs.[24]

Pathogenesis

Gadolinium-based contrast (GBC) agents have been identified as the cause of NSF; exposure to gadolinium before the onset of disease was confirmed in more than 95% of reported cases. Free gadolinium ions are highly toxic to tissues. The toxic effects of gadolinium are circumvented by sequestration of the metal by chelates, large organic molecules that form a stable complex with gadolinium and make the ion biochemically inert and nontoxic. Under normal circumstances, GBC agents are eliminated by the kidney through glomerular filtration. Evidence points toward aberrant activation of circulating fibrocytes as a central event in the genesis of NSF. Other investigators have suspected that the strongly profibrotic mediator transforming growth factor-β may be involved in the pathogenesis of NSF.

Epidemiology

NSF is a rare disorder. Since the identification of the first patients with NSF in 1997, the NSF registry (www.icnfdr.org) has confirmed more than 380 patients from medical centers worldwide. NSF equally affects males and females. The risk for development of NSF after GBC agent exposure is related to the degree of kidney failure and stability of the chelate. The incidence of NSF in patients with severe kidney dysfunction (glomerular filtration rate [GFR] < 30) varies from 0.2% to 4%. Gadodiamide (marketed as OmniScan in the United States), the linear nonionic chelate–based formulation, appears to be associated with the highest risk for NSF. Gadopentetate, the linear ionic chelate–based product, probably has a medium risk, less than linear nonionic chelates but more than macrocyclic chelates. Other factors reported to be associated with NSF (without definitive proof) include coagulation abnormalities and deep venous thrombosis, recent surgery (particularly vascular surgery), hyperphosphatemia, and the use of high doses of recombinant erythropoietin. Angiotensin-converting enzyme inhibitors might protect against NSF. After warnings issued by the U.S. Food and Drug Administration (in 2007) and European Medicines Agency regarding the association of linear GBC agents with NSF in individuals with kidney dysfunction, the incidence of NSF declined and in recent years, no new cases of NSF have been reported.[25]

Clinical Manifestations and Natural History

The lesions of NSF are typically symmetric and develop on limbs and trunk. A common location is between the ankles and midthighs and between the wrists and mid-upper arms bilaterally. On occasion, swelling of the hands and feet, sometimes associated with bullae, is noted. The primary lesions are skin-colored to erythematous papules that coalesce into erythematous to brawny plaques with a peau d'orange appearance (Fig. 91.9A). These plaques have been described as having an ameboid advancing edge. Nodules are sometimes also described. Involved skin becomes markedly thickened and woody in texture. Joint contractures may develop rapidly, with patients becoming wheelchair-dependent within days to weeks of onset (see Fig. 91.9B). Patients often report pruritus, causalgia, and sharp pains in the affected areas.[24] Although NSF has not been reported as a cause of death, this disorder has led to reduced mobility and/or superinfection that ultimately resulted in a protracted hospital course and death.

Pathology

The histopathologic changes in affected skin include marked proliferation of spindle cells, the presence of numerous dendritic cells, and the accumulation of mucinous material and thick collagen bundles (Fig. 91.10). Most dermal spindle cells in NSF have the immunophenotype of a circulating fibrocyte, a recently characterized circulating cell that expresses markers of both connective tissue cells and circulating leukocytes. Metastatic calcification and NSF may be found in the same lesion.

Diagnosis and Differential Diagnosis

The gold standard of diagnosis is histopathologic examination of skin biopsy specimens from an involved site. Skin lesions also can be visualized by [^{18}F]-fluorodeoxyglucose whole-body positron emission tomography (PET). NSF resembles other fibrosing skin disorders, including scleromyxedema, scleroderma, eosinophilic fasciitis, eosinophilia-myalgia syndrome, and Spanish toxic oil syndrome. The specific distribution of cutaneous involvement, the occurrence in the

Fig. 91.9 Nephrogenic Systemic Fibrosis. (A) Peau d'orange appearance. (B) Swelling of the hands, accompanied by palmar erythema, blisters, and contracture of the fingers.

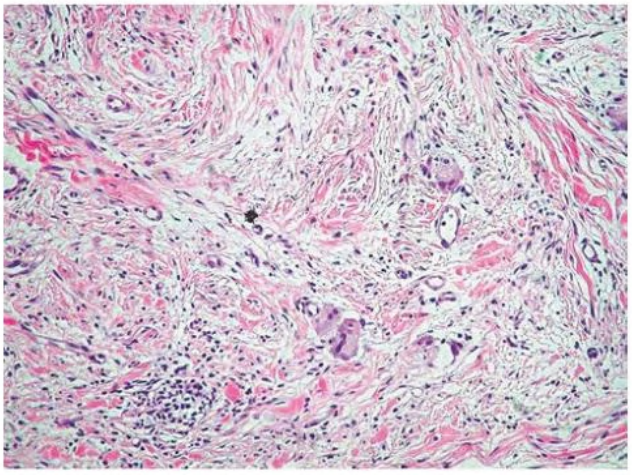

Fig. 91.10 Histopathologic Features of Nephrogenic Systemic Fibrosis. Haphazardly arranged dermal collagen bundles with surrounding clefts and a strikingly increased number of similarly arranged spindled and plump fibroblast-like cells.

setting of kidney failure, the history of recent exposure to linear GBC agents, and the unique histopathologic features distinguish NSF from the other fibrotic disorders.

Treatment and Prevention

There is variable evidence for the efficacy of plasma exchange. Other therapeutic modalities that have been used (or are under investigation) include imatinib, oral and topical corticosteroids, selective histamine blockade, calcipotriene ointment, cyclophosphamide, cyclosporine, thalidomide, interferon-α, photopheresis, and psoralen ultraviolet A therapy. Intensive physiotherapy is advised in every patient to prevent or to reverse contractures of the joints. At present, prevention of NSF seems more important than any of the currently available interventions, and widespread clinical awareness of this condition is required. Avoidance of linear GBC agents in high-risk patients (acute kidney injury and patients with CKD with estimated GFR [eGFR] rate < 30 mL/min/1.73 m^2) is the best measure to prevent this catastrophic complication.[25] According to current guidelines, group II GBC agents, including three macrocyclic agents with 100% kidney excretion (gadoteridol, gadoterate meglumine, and gadobutrol) and one linear ionic agent with approximately 95% kidney and 5% hepatobiliary excretion (gadobenate dimeglumine) can be administered safely independent of preprocedural kidney function screening. Dialysis initiation or alteration is likely unnecessary based on group II or group III GBC administration.[26]

SELF-ASSESSMENT QUESTIONS

1. UP in dialysis patients is:
   - **A.** a local skin disorder.
   - **B.** a systemic disorder caused by uremia.
   - **C.** a neurologic disorder caused by overexpression of opioid skin receptors.
   - **D.** an inflammatory systemic disorder caused by dysregulation of the immune system.
   - **E.** all of the above.
2. Skin emollients in dialysis patients should be used:
   - **A.** only in patients without underlying primary skin diseases.
   - **B.** only in patients with proven xerosis.
   - **C.** only in patients without skin defects.
   - **D.** only in patients with therapy failure.
   - **E.** in all patients.
3. Treatment of UP with oral nalfurafine:
   - **A.** is limited to patients with proven overexpression of μ receptors in their skin.
   - **B.** is limited to patients free from sleeping disturbances.
   - **C.** is limited to patients with therapy failure.
   - **D.** is limited to patients with baseline normal blood prolactin concentrations.
   - **E.** is not limited to any subgroup of patients with UP.

4. Which of the following drugs predisposes to calcific uremic arteriolopathy?
   A. Acetylsalicylic acid
   B. Heparin
   C. β-Blocker
   D. Warfarin and coumarins
   E. Calcium-free phosphate binders

5. Nephrogenic systemic fibrosis:
   A. is a self-limiting disease with benign prognosis.
   B. is related to exposure to linear gadolinium chelates.
   C. is painless.
   D. is especially prevalent in kidney transplant recipients.
   E. is related to exposure to iodine radiocontrast agents.

Acquired Cystic Kidney Disease and Malignant Neoplasms

Anja S. Mühlfeld, Peter Boor

DEFINITION

Acquired cystic kidney disease (ACKD) was first recognized in 1847 by John Simon in patients with chronic Bright disease. He described the development of cystic kidney changes with cysts ranging from "mustard seed to as large as cocoa nuts" and also noted that they "run a slow and insidious progress during life, and often leave in the dead body no such obvious traces as would strike the superficial observer." ACKD was "rediscovered" by Dunnill and colleagues[1] in 1977 in kidneys from dialysis patients.

ACKD is a specific entity of chronic kidney disease (CKD) of any etiology and has to be differentiated from other types of cystic kidney disease (see Chapters 46 and 47). It is usually defined as more than three macroscopic cysts in each kidney of a patient who does not have a hereditary cause of cystic disease. Some researchers consider ACKD to be preneoplastic.[2,3]

PATHOGENESIS

The exact mechanisms of tubule transformation into cysts in ACKD are unknown. Responses to acute or chronic kidney injury with parenchymal (nephron) loss are believed to be involved. Progressive nephron loss results in initial tubular hypertrophy followed by hyperplasia and is likely aggravated by tubular distortion and distal tubular outflow obstruction, such as by advanced tubular atrophy, interstitial fibrosis, or calcium oxalate crystals, which are all common in ACKD (Fig. 92.1).[4] ACKD can appear before dialysis is started and does not correlate with dialysis modality or underlying kidney disease. The cysts seem to develop from various tubular segments. Most cysts are lined not only by a single layer of flat to cuboidal epithelial cells but also by cuboidal cells with eosinophilic, foamy, and occasionally also clear cytoplasm, some of which are considered precursor lesions of renal cell carcinomas (RCC).[2,3,5]

With the continuing presence of mitogenic stimuli, the intracystic epithelium becomes multilayered or forms micropapillary proliferates. Further accumulation of mutations, activated protooncogenes, or chromosomal abnormalities, in conjunction with additional factors such as genetic background, environmental chemicals, and sex hormones, most likely accounts for the transition to RCC (see Fig. 92.1).[6] Next-generation sequencing revealed a gain of chromosome 16 and recurrent mutations in the *KMT2c* and *TSC2* genes, which might act as oncogenic drivers in the specific subtype of RCC found in ACKD (i.e., ACKD-associated RCC). So far, these mutations have no implications for therapy, but testing for these mutations in kidney tumors or cysts might in the future be developed into a tool for planning surveillance.[7] ACKD-associated RCC also show a high expression of proximal tubular cell marker genes indicating this segment of the nephron as a potential origin.[8]

EPIDEMIOLOGY

Among adult and pediatric patients starting maintenance dialysis treatment, the prevalence of ACKD ranges from 5% to 20%. In both chronic hemodialysis (HD) and peritoneal dialysis (PD) patients, prevalence then increases at a similar rate and reaches 80% to 100% after 10 years of treatment (Fig. 92.2).[9–11] The rate of progression appears to slow after 10 to 15 years of dialysis.

The frequency of ACKD and kidney tumors in dialysis patients may be underestimated based on imaging alone. Kidney cysts are detectable by ultrasound, with a minimum size of 0.5 cm. Data obtained in native nephrectomy specimens at the time of transplantation identified ACKD in 33%, kidney adenomas in 14%, and RCCs in 4% of the cases.[12] In unselected series of chronic dialysis or transplant patients, the cumulative incidence of RCC complicating ACKD as demonstrated by imaging is less than 1%, although rates up to 7% have been reported in some small studies. These data indicate an up to 40- to 100-fold increased risk for RCC in ACKD patients compared with RCC in the general population. Risk factors include male sex (male-to-female ratio, 7:1), Black ethnicity, long duration of dialysis, and severe ACKD with marked organ enlargement.

CLINICAL MANIFESTATIONS

ACKD can manifest as unilateral or bilateral cysts, which are mostly cortical and variable in size and number. Rarely, severe ACKD can become macroscopically indistinguishable from adult polycystic kidney disease (PKD). In contrast to hereditary cystic diseases, the cysts of ACKD are strictly confined to the kidneys. The disease is usually asymptomatic and discovered accidently during abdominal imaging procedures. Alternatively, it may be manifested by the following potential complications or consequences of ACKD[13]:

- Cystic hemorrhage with or without hematuria; bleeding may occur with cyst rupture with subsequent perinephric hemorrhage or retroperitoneal hemorrhage, which can rarely lead to hypovolemic shock.
- Calcifications in or around cysts and in rare cases stone formation (calcium-containing stones or β_2-microglobulin stones).
- Cyst infection, abscess formation, or sepsis.
- Erythrocytosis in advanced cases, similar to the erythrocytosis observed in PKD.
- Malignant transformation.

Acquired Cystic Kidney Disease: Associated Renal Cell Carcinomas

About 85% of RCCs in ACKD are asymptomatic at diagnosis. The remainder mostly manifest with bleeding, usually gross hematuria. In cases in which nephrectomy was done in dialysis patients for intractable

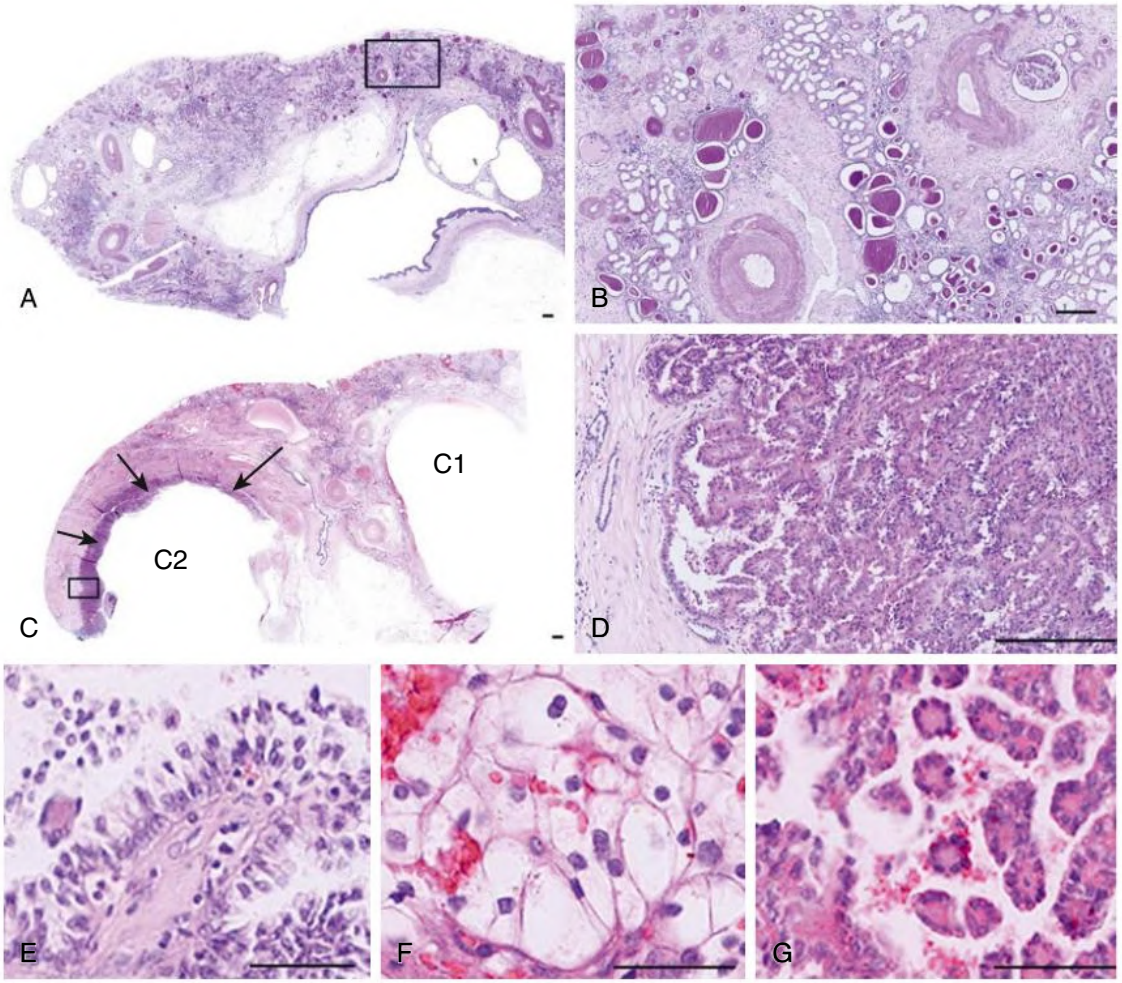

Fig. 92.1 Typical Histomorphologic Appearance of Acquired Cystic Kidney Disease (ACKD) and Commonly Found Renal Cell Carcinoma (RCC) in ACKD. (A) The kidney shows numerous cysts of different sizes and prominent atrophy of kidney parenchyma. (B) At higher magnification global glomerulosclerosis, tubular atrophy with typical focal areas of thyroidization (i.e., intratubular periodic acid–Schiff [PAS]-positive casts), interstitial fibrosis, and arteriosclerosis (PAS-stained section) are noted. (C) Another area of the same kidney specimen as shown in part A, with two cysts. The right cyst is lined by inconspicuous and at this magnification invisible single-layered epithelium *(C1).* The left cyst *(C2)* is lined by a thick cell-dense layer *(arrows),* which at higher magnification (D) is characterized by tubular and papillary proliferation of atypical epithelial cells, characteristic for intracystic ACKD-associated RCC (H&E stained section). (E) Another tumor often found in ACKD is composed of well-differentiated clear cells in a papillary arrangement, characteristic for clear cell papillary RCC. (F) A clear cell RCC, a tumor commonly found in ACKD and the most common kidney tumor in the general population. It is composed of nests and sheets of atypical cells with clear cytoplasm. (G) Papillary RCC, another tumor commonly found in ACKD and the second most common RCC in the general population. It is composed of eosinophilic epithelial cells in a papillary arrangement. In this case the tumor size was 3 cm; therefore the diagnosis of papillary RCC (type 1) was made; if the size were less than 1.5 cm, the same histologic tumor pattern would be classified as papillary adenoma. In the presented cases and typical for ACKD, most clear cell and papillary RCCs in ACKD are well-differentiated, that is, the nuclei show little or no nucleoli and little nuclear pleomorphism. The scale bars in A–D represent 250 μm and in E–G represent 50 μm. The insets in A and C represent areas shown in higher magnification in B and D, respectively.

hematuria, previously undetected RCCs were diagnosed in about one-third of the patients. Compared with sporadic RCCs, ACKD-associated RCCs are characterized by younger age of the patient, male predominance, more frequent multicentric and bilateral manifestation, and less frequent metastases.[2]

PATHOLOGY

Cystic changes in ACKD are typically bilateral but may vary between kidneys. Most ACKD kidneys are smaller than normal, and all show advanced parenchymal atrophy and chronic injury. An increase in the size of the ACKD kidneys above normal may result from cyst hemorrhage or malignant transformation. The cysts are usually restricted to the kidney cortex. The size of the cysts ranges from microscopic to about 2 cm; about 60% of the cysts are smaller than 0.2 cm.[2] Several types of the epithelial lining of cysts can be observed, some of which are likely the earliest precursor lesions of RCCs in ACKD.[14]

Up to 25% of kidneys with ACKD harbor tumors when examined histologically. About one-quarter to one-third of these are carcinomas. Adenomas are only defined for well-differentiated papillary tumors and

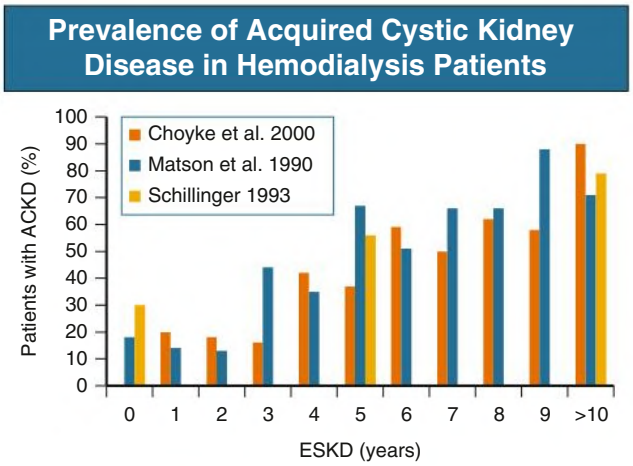

Fig. 92.2 Prevalence of Acquired Cystic Kidney Disease (ACKD) in Hemodialysis Patients. Summary of reported ACKD prevalence in chronic hemodialysis (HD) patients in relation to the length of HD treatment. *ESKD,* End-stage kidney disease. (Modified from Choyke PL. Acquired cystic kidney disease. *Eur Radiol.* 2000;10:1716–1721; Matson MA, Cohen EP. Acquired cystic kidney disease: occurrence, prevalence, and renal cancers. *Medicine (Baltimore).* 1990;69:217–226; and Schillinger F. Acquired cystic kidney disease in renal insufficiency: a multicentre study. Group of Nephrologists of the East of France. *Eur J Med.* 1993;2:457–460.)

are arbitrarily considered adenomas when less than 1.5 cm, whereas those greater than 1.5 cm are considered carcinomas, given the higher metastatic probability of larger tumors. All other tumors showing typical histology of RCCs regardless of size (e.g., invasive groups of clear cells) are diagnosed as RCCs.

The most common type of RCC that is specific for ACKD is ACKD-associated RCC, which accounts for about 36% of RCCs found in ACKD. The histologic appearance of ACKD-associated RCCs varies from tubular, papillary, acinar, microcystic, to solid. They are mostly composed of eosinophilic tumor cells with prominent nucleoli and frequent intratumoral calcium oxalate crystals (see Fig. 92.1).[5] The second most common RCC (24%) that is relatively specific for ACKD (but can be also observed in non-ACKD kidneys) is clear cell papillary RCC, which shows papillary, tubular, or cystic arrangement of relatively well-differentiated clear cells.

Other commonly observed RCCs in ACKD are the same as those in the general population (i.e., papillary [18%], clear cell [10%], and chromophobe RCCs [6%]), with some studies showing that the majority of RCCs in ACKD are clear cell (45%), ACKD-associated (32%), and papillary (13%).[15] RCCs arising from ACKD are multicentric in about 50% of cases and bilateral in about 10%. Multiple histologic subtypes may occur in the same kidney. Clear cell RCCs contain cells in solid, tubulocystic, or alveolar arrangements, whereas papillary RCCs show eosinophilic, papillary arranged tumor cells (see Fig. 92.1). In difficult cases with overlapping histologic appearance, immunohistochemistry helps differentiate between these entities. The precise diagnosis is important because ACKD-associated RCCs and clear cell papillary RCCs seem to be more indolent than clear cell RCCs but can also metastasize. All RCCs in ACKD tend to have a better clinical course most likely as a result of early detection given close follow-up of these patients. Compared with other RCCs, ACKD-associated RCCs less frequently showed unfavorable pathologic findings such as sarcomatoid differentiation, lymphovascular invasion, or necrosis, which might be other reasons for a more favorable prognosis.[15]

RCCs in native kidneys of kidney transplant patients tend to be smaller and exhibit a lower T stage and a lower grade at diagnosis compared with RCCs in patients with end-stage kidney disease (ESKD). Tumors are more often multifocal, bilateral, and papillary.[16,17] Likely because of the earlier stage at detection, the prognosis of RCCs after kidney transplantation is generally more favorable.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnostic approach to ACKD usually involves ultrasound (Fig. 92.3).[4,9] However, the differentiation between simple cysts and RCCs can be difficult given the echogenicity of end-stage kidney parenchyma and the complexity of cysts in ACKD. Computed tomography (CT) scanning, in particular with early contrast enhancement, is superior to ultrasound in detecting small malignant lesions (see Fig. 92.3).[4,9,18] A classification of kidney cysts (Fig. 92.4) based on their appearance in CT scans, introduced by Bosniak,[19,20] is now widely accepted and is also applied to ultrasound and magnetic resonance imaging (MRI; see Table 63.6). Criteria that favor the diagnosis of RCC as opposed to a simple cyst include thickened and irregular walls, the presence of septa or kidney tissue within the lesions, contrast enhancement, multilocularity, and large size (≥ 4 cm). MRI scan can be an alternative to contrast-based CT scans. Although the risk for nephrogenic fibrosis after exposure to gadolinium-containing contrast agents is not a concern anymore in early stages of CKD, caution is still recommended in dialysis patients (see Chapter 6). For these cases, a MRI protocol without contrast enhancement has been developed and has been shown in a pilot study in kidney transplant recipients to be superior to kidney ultrasound alone.[21] Another small study found that ^{11}C-choline-positron emission tomography (PET)/CT was more sensitive to detect RCC in ACKD compared with fluorodeoxyglucose (FDG)-PET/CT and contrast-enhanced CT, but this method is not broadly available.[22]

Because of the risk for malignant transformation, testing for ACKD and follow-up imaging when ACKD is detected have both been advocated (Fig. 92.5). However, the cost of testing has to be weighed against the risk-to-benefit ratio of nephrectomy in dialysis patients. A decision analysis[23] concluded that testing for ACKD (by either ultrasound or CT scanning) in young patients with a life expectancy of 25 years offers as much as a 1.6-year gain in life expectancy. In contrast, in ACKD patients older than 60 years, no significant gain in life expectancy is achieved by regular testing.[24] In a different analysis of 797 dialysis patients who had developed RCCs (90% identified by regular testing), testing provided a mean survival benefit of 3.3 years after adjustment for age and dialysis vintage.[24] Testing during transplant evaluation by ultrasound followed by CT in the case of suspicious lesions is recommended based on recent data showing a prevalence of kidney cancer in up to 4% of the patients and concerns about the role of immunosuppression in accelerating tumor growth.[25]

NATURAL HISTORY

Cystic dilations of kidney tubules may develop at a glomerular filtration rate (GFR) lower than 70 mL/min.[26] ACKD thereafter progresses and reaches a prevalence of nearly 100% after more than 10 years of dialysis (see Fig. 92.2). The constant increase in kidney volume seems to reach a plateau after about 20 years of HD, and at least partial regression may occur after very-long-term HD.[27] In malignant transformation, tumor growth rates are highly variable. Death is usually associated with widespread metastases and accounts for about 2% of the deaths in kidney transplant patients.

It is not established whether kidney transplantation affects the natural history of RCC complicating ACKD, although immunosuppression has been suggested as a risk factor for RCC in transplant patients

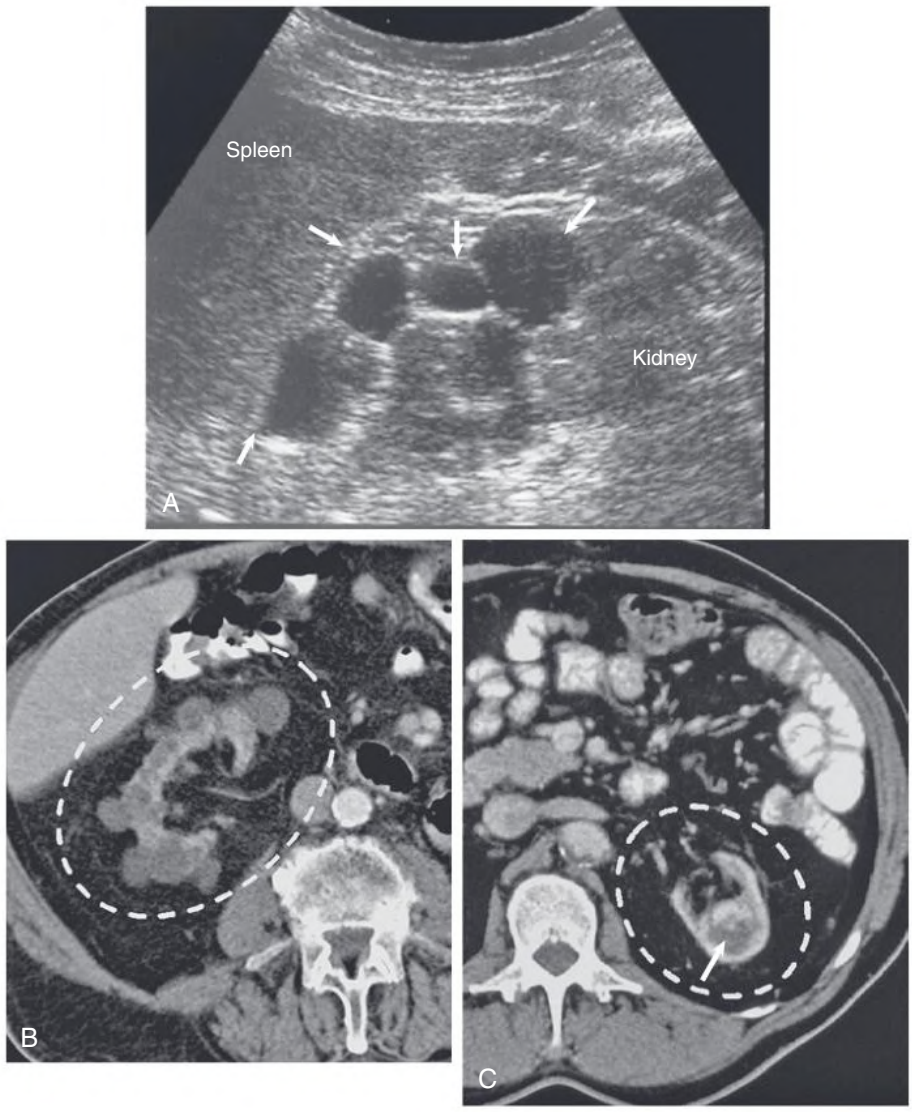

Fig. 92.3 Imaging Studies in Acquired Cystic Kidney Disease (ACKD). (A) Ultrasound image of the left native kidney of a patient after 16 years of chronic hemodialysis (HD). Multiple cysts are present in the kidney cortex *(arrows).* (B) Computed tomography (CT) image of a patient after 5 years of chronic HD demonstrating multiple cysts within the right kidney *(dashed circle).* (C) Contrast-enhanced CT image of a kidney transplant patient who developed a renal cell carcinoma *(arrow)* originating from the left native kidney with ACKD *(dashed circle).*

with ACKD.[13] A prospective, single-center study in which 561 kidney transplant recipients were imaged with ultrasound identified ACKD in 23%.[28] The mean duration of dialysis was 4 to 5 years, and the mean time after transplantation was 9 years. In this cohort, ACKD was slightly less frequent than had been reported in dialysis patients, possibly indicating that kidney transplantation might inhibit the development of ACKD.[28] The prevalence of RCCs among all 561 patients was 4.8%. However, among patients with ACKD, RCCs were detected in almost 20%, but in only 0.5% of patients without ACKD.[28]

TREATMENT

Treatment of ACKD is warranted only when complications such as hemorrhage, cyst infection, or malignant transformation develop. Although the first two complications may be handled conservatively and only rarely require surgery, malignant transformation should raise the question of nephrectomy. Given the perioperative morbidity and mortality of nephrectomy, in particular in multimorbid dialysis or transplant patients, it is not surprising that the threshold for surgical intervention in cases of RCC is still controversial.

Most agree that tumors larger than 3 cm in diameter justify biopsy or surgical treatment (either tumor enucleation or nephrectomy) because, above this size, RCCs in the general population frequently metastasize (for details on urologic evaluation and treatment for kidney masses, refer to Chapter 63).[11] However, this strategy is based on an extrapolation from otherwise healthy persons, and a more aggressive approach may be required under certain circumstances. A Japanese study found that surgically treated RCCs in patients with ESKD seem to have a comparable stage-specific recurrence-free survival, but poorer cancer-specific and overall survival compared with non-ESKD RCC.[29]

For tumors of less than 3 cm in diameter with no complications, the slow tumor growth may justify observation with repeated imaging studies. Patients with high life expectancy or listed for transplantation should

be considered for nephrectomy also in case of tumors with diameters less than 3 cm. In general, tumor enlargement should be used as an indication for nephrectomy if it is permitted by the patient's status.

In patients with unilateral tumors, prophylactic contralateral nephrectomy is not recommended because of the morbidity associated with the procedure, the worsening of anemia, and the loss of residual kidney function in those who are not considered transplant candidates. A delay of transplantation is not typically required in patients who have had an asymptomatic RCC associated with ACKD in their nephrectomy.

We recommend imaging transplant recipients yearly using ultrasound. In suspicious cases, contrast-enhanced CT scanning or MRI might help differentiate blood-filled cysts from solid tumors. In the case of a suspicious mass or RCC in the native kidneys, a nephrectomy should be performed. However, although immunosuppression is possibly associated with the development of RCC, it does not seem to diminish the likelihood of cure, especially because RCCs in transplant patients tend to be detected at an earlier stage, possibly due to frequent imaging in this population.[30]

CANCER IN DIALYSIS PATIENTS

Dialysis patients have a slightly higher cancer risk compared with the general population. Analysis of more than 800,000 dialysis patients in three registries from the United States, Europe, and Australia/New Zealand revealed that most of the increased risk was because of cancers of the kidney, bladder, and endocrine organs (see Fig. 92.5).[31] Besides the specific risk associated with malignant transformation of ACKD, some of the increased risk is directly related to the

underlying kidney disease or to the immunosuppression that may have been administered to patients with immune-mediated kidney disease. For example, cyclophosphamide may predispose to bladder and ureteral cancer that manifests after patients have been initiated on dialysis. Kidney disease or immunosuppressive therapy may underlie the apparent risk in dialysis patients for the development of multiple myeloma (see Fig. 92.5). In addition, patients with analgesic nephropathy or aristolochic acid nephropathy are at high risk for the development of urothelial carcinoma of the upper urinary tract.[32] Other malignancies that are more common in dialysis patients include carcinoma of the cervix, thyroid, and other endocrine neoplasias (see Fig. 92.5), and, at least in the U.S. Renal Data System database, a 1.5- to two fold increase in the risk for non-Hodgkin lymphoma, Hodgkin disease, and leukemias.[31]

SELF-ASSESSMENT QUESTIONS

1. A 52-year-old White man comes to your clinic with new-onset hematuria. He is receiving chronic hemodialysis (HD) treatment for ESKD because of diabetic nephropathy. Ultrasound of his kidneys reveals four cysts on the left side and five cysts on the right. On the right side, two of the cysts are not echo free and have a thickened wall with multiple calcifications. Which of the following statements is *correct?*
   - **A.** His previous diagnosis of diabetic nephropathy causing ESKD is false. Kidney ultrasound clearly depicts the typical picture of autosomal dominant polycystic kidney disease.
   - **B.** ACKD is a common finding in patients on maintenance HD treatment and is a possible cause of hematuria.
   - **C.** This patient needs to be carefully evaluated for the presence of RCC because kidney cysts in patients on RRT almost always undergo malignant transformation.
   - **D.** Most patients with ACKD have cystic disease outside of the kidneys (liver, pancreas) and need to be screened for cerebral aneurysms.
   - **E.** ACKD is associated with exposure to toxic compounds such as benzidine and 2-naphthylamine.
2. A 45-year-old Black woman on maintenance HD for lupus nephritis is asking for your advice. She has heard about an increased risk for malignant tumors in HD patients. Which of the following statements is *false?*
   - **A.** The increase in risk for tumor development in patients on RRT is, in part, related to the underlying kidney disease or to the immunosuppression that may have been administered to patients with immune-mediated kidney disease.
   - **B.** Most of the increased risk is because of cancers of the kidney, bladder, and endocrine organs.
   - **C.** Cyclophosphamide therapy may predispose to cancer of the bladder.
   - **D.** Patients with analgesic nephropathy or Chinese herbs/aristolochic acid nephropathy are at increased risk for development of transitional cell carcinoma (TCC) of the upper urinary tract.
   - **E.** Data from large registries reveal a nearly 10-fold increase in the risk for colorectal cancer in patients on HD treatment.
3. A kidney transplant recipient with ESKD secondary to focal segmental glomerulosclerosis presents for a regular checkup. He reports that his primary care physician had ordered an abdominal ultrasound because of recurrent right upper quadrant pain. As an incidental finding, multiple cysts in his native kidneys were noted. Which of the following statements about his condition is *false?*
   - **A.** ACKD is a common finding in patients with ESKD.
   - **B.** Up to 25% of kidneys with ACKD harbor tumors, about one-third of which are carcinomas.
   - **C.** ACKD is mostly asymptomatic; however, clinical manifestations include cyst hemorrhage, cyst infection, and malignant transformation.
   - **D.** Bilateral nephrectomy is the treatment of choice for asymptomatic ACKD in kidney transplant recipients because malignant transformation occurs in almost 90% of cases.
   - **E.** Contrast-enhanced computed tomography (CT) and magnetic resonance imaging (MRI) are the methods of choice to detect small malignant lesions in patients on RRT.

Geriatric Nephrology

Mitchell H. Rosner, Monica Zanella, Kambiz Kalantari

Aging is a natural and progressive process where there is a slow decline in cellular function that ultimately may become manifest as changes in overall organ function. These inevitable changes that occur with aging need to be distinguished from diseases that are more common among older people, such as heart failure, hypertension, and diabetes mellitus (DM), all of which usually have more dramatic effects on organ function. Although it is often hard to distinguish age-related from disease-mediated changes in organ function, it is generally true that they can act synergistically to alter the rate of functional decline of the kidney and to make the kidney more susceptible to injury and less likely to fully recover. In addition, the age-related decline in kidney function has important implications for medication dosing.

AGING-ASSOCIATED CHANGES IN THE KIDNEY

Anatomic Changes

The human kidney reaches a maximum size of approximately 400 g (12 cm in length) in the fourth decade of life. A natural decline of approximately 10% in kidney mass per decade then follows. This natural decline is associated with cortical thinning and a decrease in the number of functional nephrons. An analysis of kidney tissue from healthy living donors examined the changes in nephron number and structure over time.[1] The number of nonsclerotic glomeruli was 48% lower in the oldest age groups (70–75 years) compared with those aged 18 to 29 years. In contrast, cortical volume was only 16% lower and the proportion of globally sclerotic glomeruli was only 15% higher. This incomplete representation of nephron loss with aging by either increased glomerulosclerosis or cortical volume decline is consistent with atrophy and reabsorption of globally sclerotic glomeruli and hypertrophy of remaining nephrons.

Other anatomic changes with aging include an increase in simple parenchymal and parapelvic kidney cysts and in angiomyolipomas.[2]

Glomerular Changes

Structural glomerular changes with age include basement membrane thickening and development of focal or global glomerulosclerosis, which increases to 10% to 30% and in some studies even exceeds 70% of glomeruli by the eighth decade (Figs. 93.1 [unchanged] and 93.2 [unchanged]).[3] The cross-sectional area of the tuft among preserved glomeruli in older people is often larger than average, consistent with glomerular hypertrophy. Neither kidney function nor chronic kidney disease (CKD) risk factors explain the strong association between age and glomerulosclerosis in healthy adults.

Tubular and Interstitial Changes

Tubulointerstitial injury associated with aging is most pronounced in the outer medulla, with tubular dilation and atrophy, mononuclear cell infiltration, and interstitial fibrosis. Some tubules (especially in the distal tubule and collecting duct) may develop small diverticuli; these diverticuli may play a role in the development of upper urinary tract infections (pyelonephritis) by harboring bacteria.[4]

Vascular Changes

Arterioles often develop hyalinosis with aging. Thickening of the arterioles with an increase in the ratio of medial thickness to lumen diameter is common with aging but is observed almost exclusively in hypertensive individuals.[4] The arcuate arteries become more angulated and irregular with aging, and there is increased tortuosity and spiraling of the interlobar vessels. These changes occur independently of hypertension but are augmented in its presence. With aging, some afferent arterioles, particularly of juxtamedullary glomeruli, develop vascular shunts to the efferent arterioles, thereby bypassing glomeruli, leading to "aglomerular arterioles."[5]

Nephrosclerosis

Thus, the aging kidney develops some combination of glomerulosclerosis, tubular atrophy, interstitial fibrosis, and arteriosclerosis. In one study, the presence of two or more of these abnormalities was found in 2.7% in young kidney donors and increased to 73% in the oldest group of donors.[6]

AGING-ASSOCIATED CHANGES IN KIDNEY FUNCTION

Glomerular Filtration Rate

Inulin clearance studies document a progressive fall in glomerular filtration rate (GFR) after the age of 40 years, with a relatively greater decline in males (Fig. 93.3 [unchanged]).[7] However, the fall in GFR does not appear to be inevitable; in as many as one-third of patients who remain normotensive, there is no decrease in creatinine clearance with age.[2] Studies of potential kidney donors show that the rate of decline of GFR is between 6.3 and 7.5 mL/min per decade.[8] Of note, the GFR assesses the function of all nephrons, and the single-nephron GFR assesses the function of individual nephrons. Single-nephron GFR does not vary significantly according to age (among kidney donors <70 years).[9] Thus, the fall in GFR is likely because the number of nephrons declines with age.[10]

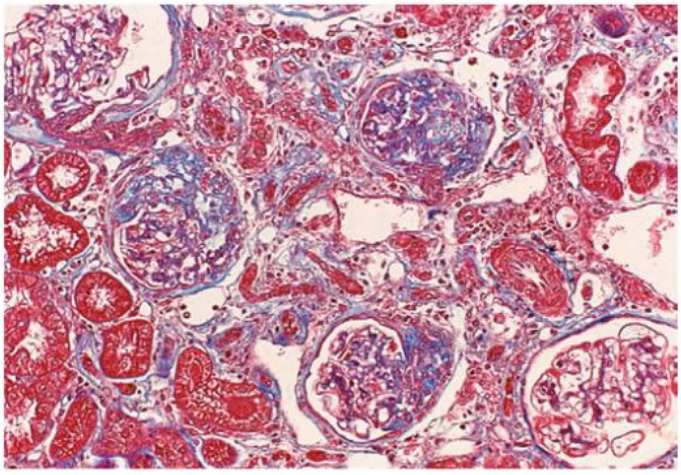

Fig. 93.1 Glomerulosclerosis and Tubulointerstitial Fibrosis in an Aging Rat. Similar changes, consisting of focal segmental glomerulosclerosis, tubular atrophy, and interstitial fibrosis, occur in humans. (Trichrome stain; original magnification ×400.)

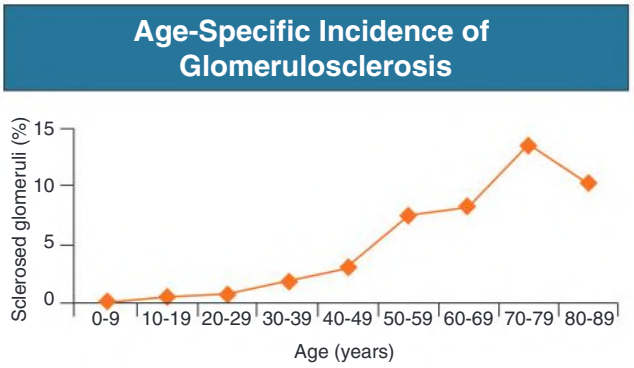

Fig. 93.2 The incidence of glomerulosclerosis increases with aging. (Modified from Rule AD, Sasiwimonphan K, Lieske JC, et al. Characteristics of renal cystic and solid lesions based on contrast-enhanced computed tomography of potential kidney donors. *Am J Kidney Dis.* 2012;59[5]:611–618.)

In addition to the decrease in GFR with aging, there may be a reduction in kidney "reserve." Although some studies suggest that aging humans show a normal increase in GFR after amino acid infusion, others have shown a marked reduction in increases in kidney plasma flow (KPF) and GFR in response to concurrent infusion of amino acids and dopamine in healthy older individuals.[11,12]

Kidney Plasma Flow

KPF also decreases from a mean of 650 mL/min in the fourth decade to 290 mL/min by the ninth decade, with increasing kidney vascular resistance (Fig. 93.4).[4] Because KPF decreases relatively more than GFR, filtration fraction (defined as GFR/KPF) increases with age. Studies have demonstrated that there is a true reduction in kidney blood flow when it is factored for kidney mass.[13] The decrease in kidney blood flow especially involves the cortex, and blood flow to the medulla is relatively preserved.

Albuminuria

The prevalence of albuminuria increases progressively after the age of 40 years. The increased prevalence is most marked in diabetic and hypertensive patients but is also observed in patients lacking these risk factors. However, whether age per se is associated with proteinuria is debatable.[14]

Hematuria

Malignancies of the urinary tract are more common in older patients, and so the diagnostic workup for hematuria in patients aged 50 years

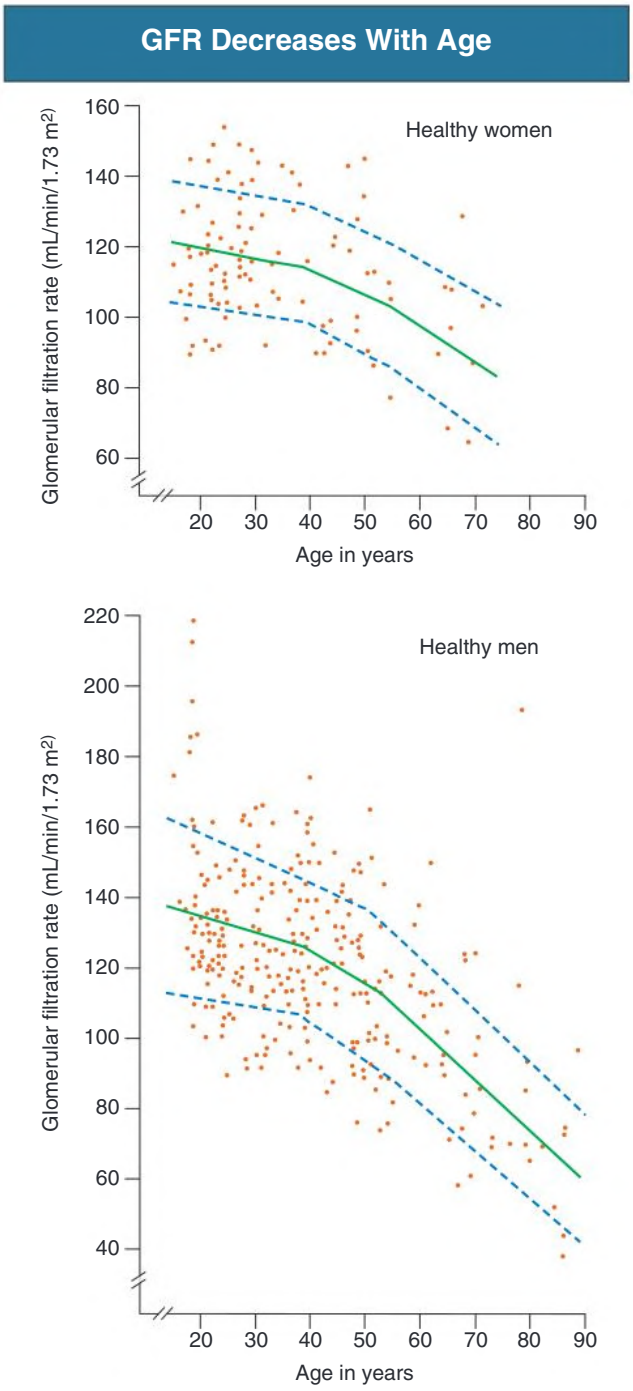

Fig. 93.3 Glomerular Filtration Rate (GFR) Decreases With Age. GFR (inulin clearance) begins to fall at age 40 years, and the rate of decline is more rapid in males than in females. (Modified from Takazakura E, Sawabu N, Handa A, et al. Intrarenal vascular changes with age and disease. *Kidney Int.* 1972;2:224–230.)

should include cystoscopy and urinary tract imaging. Renal cell carcinomas (RCCs) are most commonly diagnosed after the fifth decade of life. RCCs may be more aggressive in the elderly, and treatment decisions can be difficult, especially in the setting of significant CKD in which nephrectomy may lead to dialysis dependence.[15] However, increased use of biopsy to determine whether a mass lesion is cancer and localized resection of the mass alone or surveillance over time have become more common and preserve kidney function. Other causes of hematuria may need to be considered, as discussed in Chapters 4 and 63.

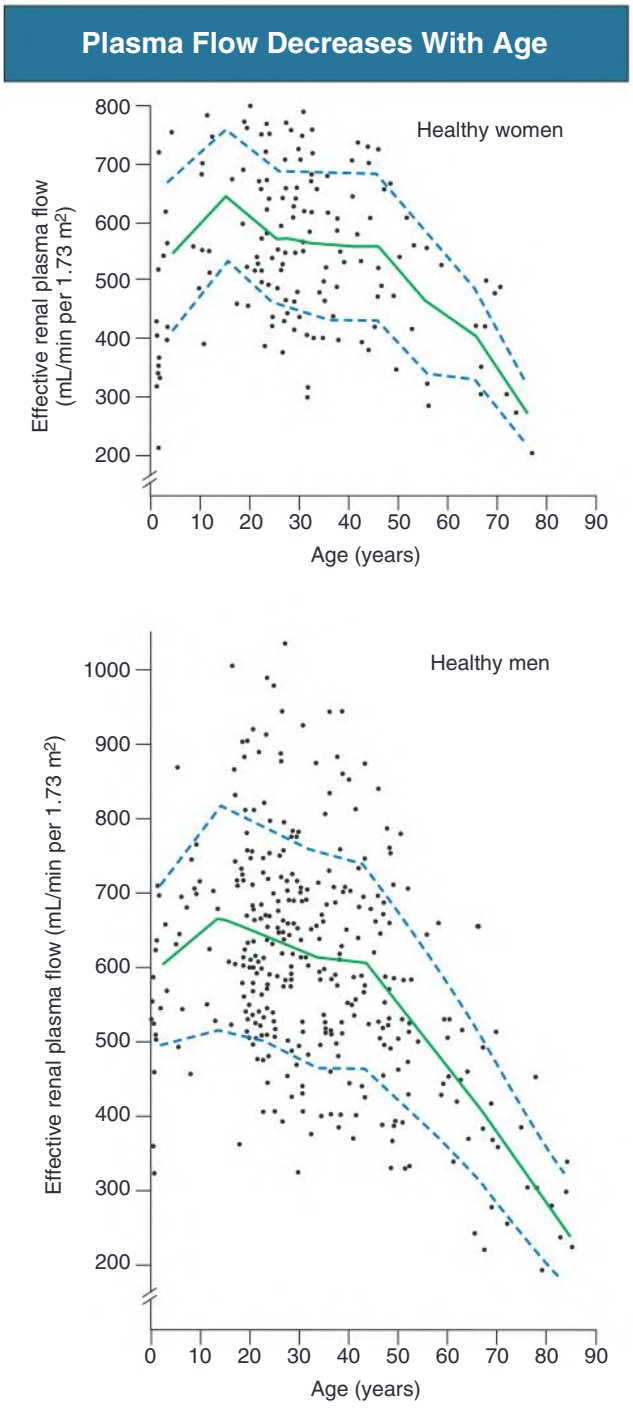

Fig. 93.4 Renal Plasma Flow (RPF) Decreases With Age. RPF (*p*-aminohippurate clearance) begins to fall rapidly after the age of 50 years, and the rate of decline is more rapid in males than in females. (Modified from Takazakura E, Sawabu N, Handa A, et al. Intrarenal vascular changes with age and disease. *Kidney Int.* 1972;2:224–230.)

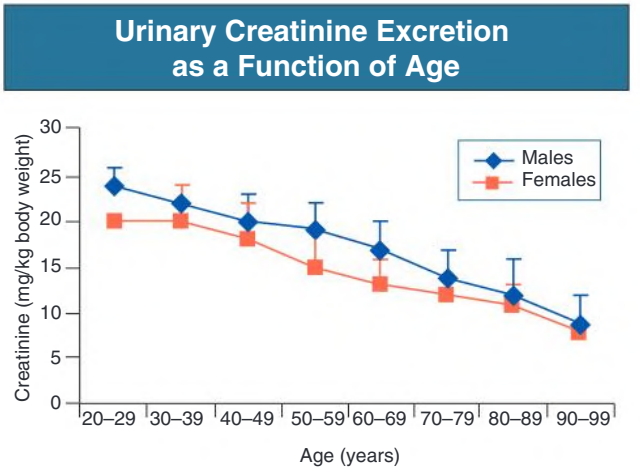

Fig. 93.5 Urinary creatinine excretion (adjusted for body weight) decreases with age. (Modified from Denic A, Mathew J, Lerman LO et al. Single-nephron glomerular filtration rate in healthy adults. *New Engl J Med.* 2017;376[24]:2349–2357.)

ASSESSMENT OF GLOMERULAR FILTRATION RATE IN THE ELDERLY

Serum creatinine becomes a less reliable indicator of GFR after aging because after the age of 60 years, there is a progressive decrease in urinary creatinine excretion, which largely reflects that muscle mass decreases with aging (Fig. 93.5).[16] There is no consensus on the optimal approach to estimation of GFR in elderly people. Although the Modification of Diet in Renal Disease (MDRD) study equation and the Cockcroft-Gault formula for estimating GFR use age in their calculations (see Chapter 3), neither has been validated in people older than 70 years and both underestimate true GFR in those older than 65 years compared with gold standard techniques. Although the MDRD equation may be more accurate than the Cockcroft-Gault formula,[17] serum cystatin C, which is independent of muscle mass, may be superior to both.[18] The Berlin Initiative Study equation for estimating GFR was derived from patients who were older than 70 years using iohexol clearance as the gold standard and is particularly accurate for classifying patients whose true GFR is between 30 and 90 mL/min/1.73m^2.[19] Another equation was recently developed and has improved validity across the full age spectrum, with less bias at the extremes of age and perhaps allowing for better clinical decision making.[20]

The implementation of routine estimated GFR (eGFR) reporting has led to a higher number of older adults diagnosed with CKD, leading to increased referrals to nephrologists and increased anxiety among patients.[9] As discussed later, the clinical significance of this diagnosis (which is largely driven by age in estimation equations) is not clear.

PREVALENCE OF CHRONIC KIDNEY DISEASE IN THE ELDERLY

According to the U.S. Renal Data System's Annual Data Report, the prevalence of CKD defined by eGFR is increasing in people aged 65 years and older with nearly 25% of those older than 85 years showing some level of CKD (Fig. 93.6).[21] Of note, higher increases in the apparent overall prevalence of CKD occurred around 2005 to 2006 and 2015 to 2016 and are likely attributable to the introduction of stage-specific CKD codes and the shift from the International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM) to the ICD-10-CM classification system, respectively.

eGFR is attractive for classifying the severity of CKD because eGFR is an independent predictor of mortality and other adverse events. However, this may not be true in patients older than 65 years of age. For instance, eGFR of 50 to 59 mL/min/1.73 m^2 may not be associated with increased mortality among patients age 65 years or older compared with patients with eGFR of more than 60 mL/min/1.73 m^2.[22] Additionally, cardiovascular mortality begins to increase in those older than 65 years with eGFR less than 45 mL/min/1.73 m^2.[23] However, other studies have shown that both low eGFR and high albuminuria were independently associated with mortality and end-stage kidney disease (ESKD) regardless of age across a wide range of populations.[24]

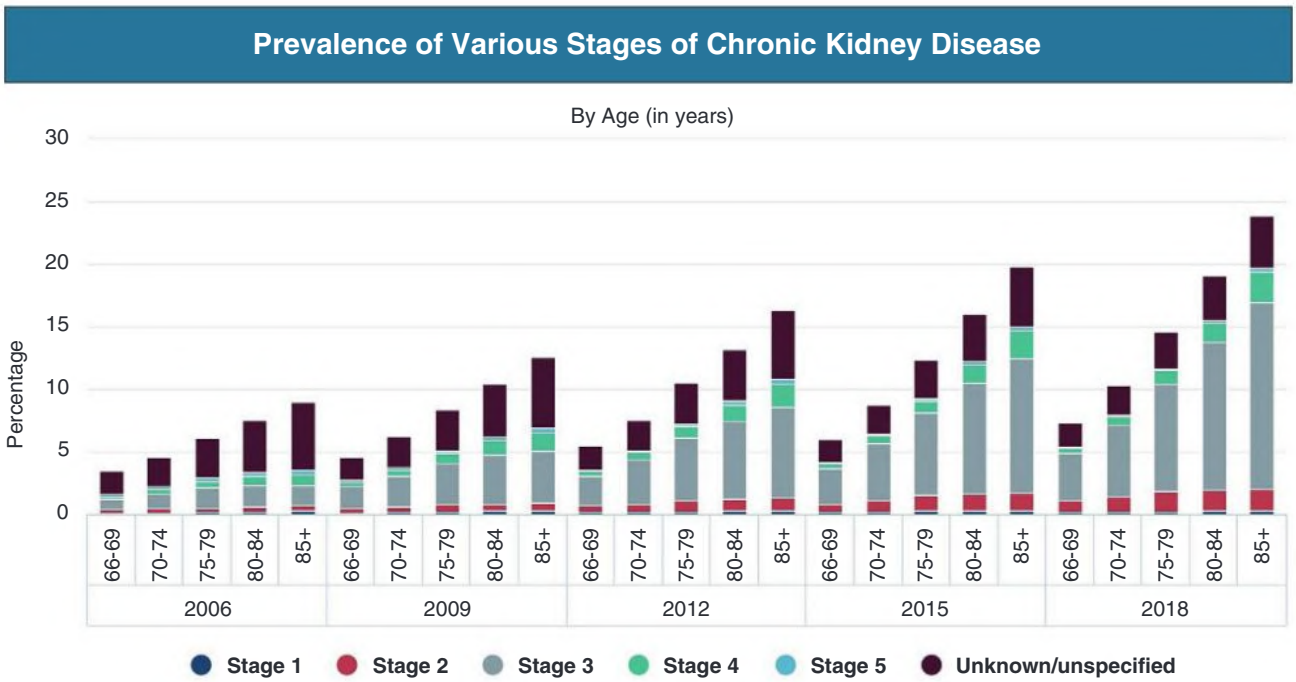

Fig. 93.6 Prevalence of various stages of chronic kidney disease (CKD) in people aged >65 years over 2006 to 2018 demonstrating increases in stage 3 to 5 CKD over time in this population. (Data from U.S. Renal Data System. www.usrds.org.)

The interpretation of small decreases in eGFR in those older than 65 years has led to debate and whether the term *chronic kidney disease* in such cases should be replaced with *age-related reduced kidney function*.[25]

RISK FACTORS FOR CHRONIC KIDNEY DISEASE IN THE ELDERLY

The variability in the severity of aging-related kidney disease in humans has suggested that other factors besides aging per se may contribute to the loss of GFR that is seen in older populations. A recent study found that in a cohort of patients older than 65 years with stage 3A to 5 CKD, up to 60% of patients showed continued declines in kidney function over 2 years.[26] Factors associated with progressive loss of eGFR in prospective and retrospective studies include use of oral analgesics, metabolic syndrome, hyperuricemia, proteinuria, DM, and baseline CKD.[26] In another prospective study, increased levels of physical activity correlated with a lower risk for rapid GFR decline (defined as loss > 3 mL/min/1.73 m^2 per year, based on cystatin C levels) in a general population of older adults.[27]

PATHOGENESIS OF AGE-RELATED CHRONIC KIDNEY DISEASE

A variety of mechanisms have been proposed for the aging-related kidney changes that are reflected in declining GFR, decreased tubular function, progressive fibrosis, and vascular changes (Box 93.1). The kidney is an important source of the antiaging hormone klotho. Klotho is a transmembrane protein and a coreceptor for fibroblast growth factor-23 (FGF-23). Klotho has a role in modulating many aging-related pathways associated with cellular senescence and regeneration, and mice with klotho deficiency recapitulate features of systemic and kidney aging.[28] As klotho levels fall during aging, signaling through the Wnt pathway increases, leading to fibrosis and vascular calcification.[29] Klotho (and its deficiency) may be a future target for antiaging strategies.

BOX 93.1 Proposed Mechanisms for Aging-Associated Kidney Disease

Hemodynamic
- Glomerular hypertension and hyperfiltration
- Intrarenal activation of renin-angiotensin system
- Endothelial dysfunction (loss of nitric oxide)
- Kidney ischemia
- Decreased renalase

Metabolic
- Accumulation of advanced glycation end-products
- Chronic effects of uric acid
- Chronic metabolism of endogenous and exogenous fructose

Cellular Dysfunction
- Oxidative stress
- Decreased klotho
- Senescence (with telomere shortening and loss of mitochondria)

Additional mechanisms of kidney aging may involve telomere shortening of chromosomal DNA, declining levels of peroxisome proliferator-activated receptor-γ, loss of mitochondria, and accelerated apoptosis. Aging-associated kidney disease also may be mediated by activation of the renin-angiotensin system, which may lower kidney klotho expression. Other mechanisms may include hyperfiltration injury and glomerular hypertension as well as vascular changes associated with arteriolar stiffening, progressive reduction in nitric oxide production by endothelial cells, progressive capillary loss with ischemia, and accumulation of advanced glycation endproducts.[29–35] The possibility that sugar intake and/or fructose metabolism may be involved has also been suggested by the finding that mice lacking the ability to metabolize fructose appear to be protected from age-associated kidney injury.[36]

FLUID AND ELECTROLYTES IN AGING

Sodium Balance and Hypertension

Aging is associated with impaired excretion of a salt load and defective conservation in the setting of sodium restriction.[37] Proximal sodium reabsorption is increased in aging, whereas distal sodium reabsorption may be reduced.[38] Because the diet of most individuals in wealthier countries contains excess sodium (8–10 g of salt daily), there is a tendency for total body sodium excess among elderly people. This relative defect in sodium excretion and increased total body sodium may be predisposing factors for the development of hypertension, the prevalence of which increases with age. After the age of 60 years, most people are hypertensive (Fig. 93.7).[39] Salt sensitivity occurs in more than 85% of aging people, and sodium restriction will result in a significant fall (>10 mm Hg) in mean arterial pressure.[40] Populations that ingest low-sodium diets, such as the Yanomami Indians of southern Venezuela, do not show an increase in blood pressure (BP) with age.[41] Loss of vascular compliance also may contribute to aging-associated hypertension, as may endothelial dysfunction, perhaps mediated by oxidative stress. Aging-associated kidney and vascular changes may explain why correction of secondary forms of hypertension (e.g., primary aldosteronism, Cushing syndrome, and renovascular hypertension) is less effective at curing hypertension in older patients. In one study, diastolic BP (DBP) fell to less than 90 mm Hg in 24 of 25 patients younger than 40 years after treatment of the mechanism responsible for the secondary hypertension but in only 38 of 61 patients older than 40 years.[42] Recent data suggest that treatment of hypertension in the elderly (>75 years) should be similar to that in the younger population because treating to a systolic BP (SBP) target of less than 120 mm Hg (compared with an SBP target of <140 mm Hg) resulted in significantly lower rates of fatal and nonfatal major cardiovascular events.[43] Reaching these lower BP goals in the elderly may be more difficult, require more medications, and have risk for orthostatic and diastolic hypotension. Hypotension in the frail elderly patient may be associated with an increased risk of falls and morbidity.

Osmoregulation and Water Handling

The most common electrolyte abnormalities in the elderly are the consequence of impaired water handling with aging. Hyponatremia has been found in up to 11% of the ambulatory geriatric population and 5.3% of hospitalized elderly patients.[44] Hypernatremia is found in about 1% of patients older than 60 years and admitted to the hospital.[44] Both concentration and dilution of the urine are affected by aging and account for part of the susceptibility to dysnatremias.

In the elderly, the maximal urinary osmolality and thirst response to hyperosmolality are reduced, which may predispose to dehydration and hypernatremia. The impairment in urine concentrating ability results from a defect in the concentrating gradient in the medullary region and can lead to nocturia.[45] Compounding the risk for hypernatremia is that the ill elderly patient may not have ready access to water.

The elderly also have an impaired ability to dilute the urine and thus have a decreased ability to excrete a water load, leading to an increased predisposition to hyponatremia that is often compounded by the use of medications such as thiazide diuretics and selective serotonin reuptake inhibitors.[46] Whether age per se is an independent risk factor for the development of hyponatremia has been questioned, because after adjustment for frailty, the relationship between age and sodium disorders is no longer significant.

Other Tubular Defects and Electrolyte Problems

Potassium excretion is impaired in the elderly, and the transtubular potassium gradient is decreased.[47] Hyperkalemia occurs more frequently in elderly patients treated with drugs that interfere with potassium excretion (such as potassium-sparing diuretics or agents that block the renin-angiotensin-aldosterone system). Other factors contributing to hyperkalemia in the elderly include decreased GFR, lower basal levels of aldosterone, and tubulointerstitial scarring. Hypokalemia is also common because of kidney (especially with thiazide diuretics) or extrarenal losses.

Most elderly individuals can maintain acid-base balance under normal conditions. However, during conditions of stress when acid production is increased (sepsis or acute kidney injury [AKI]), an inability to excrete an additional acid load may be uncovered. This is supported by a study demonstrating that elderly patients could not increase net acid excretion to the same level as younger adults in response to a protein meal.[48] This tendency to metabolic acidosis becomes more manifest in the presence of CKD.

Hypercalcemia occurs in 1% to 3% of elderly patients. Causes include malignancy, hyperparathyroidism, immobilization, and use of thiazide diuretics. Many patients with thiazide-associated

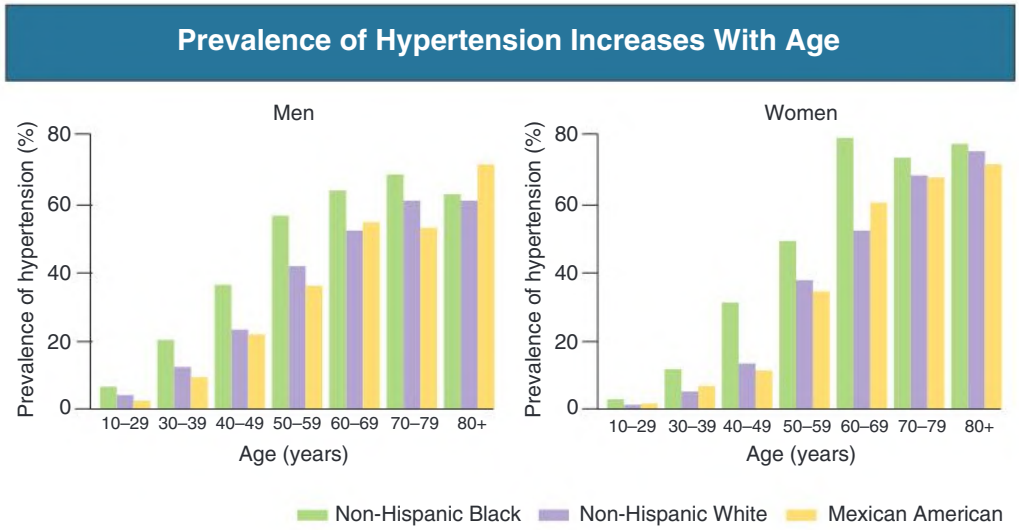

Fig. 93.7 Prevalence of hypertension based on age, sex, and race. (Modified from Burt VL, Whelton P, Roccella EJ, et al. Prevalence of hypertension in the US adult population. Results from the Third National Health and Nutrition Examination Survey, 1988-1991. *Hypertension*. 1995;25:305–313.)

hypercalcemia have underlying primary hyperparathyroidism.[49] Hypocalcemia is less common and is observed mainly in patients with advanced CKD (in association with vitamin D deficiency and hyperphosphatemia), chronic malabsorption, and severe malnutrition. Hypomagnesemia is reported in 7% to 10% of elderly patients admitted to the hospital, most commonly because of malnutrition or laxative or diuretic use. Hypermagnesemia is less common and is found primarily in patients with CKD or who are taking large doses of magnesium-containing antacids. Gout (as well as asymptomatic elevations in serum uric acid levels) is also more common in older people.

ENDOCRINE FUNCTION AND KIDNEY HORMONES

Elderly females with eGFR less than 60 mL/min/1.73m^2 have lower calcium absorption and lower 1,25-hydroxyvitamin D levels, probably because of diminished conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D by the aging kidney.[50]

The kidney removes about 50% of insulin in the peripheral circulation by filtration and proximal tubular uptake and degradation. The decline of kidney function in the elderly leads to a decrease in insulin clearance. This is, in part, offset by diminished glucose tolerance, which may relate to the increasing frequency of obesity observed in aging individuals. However, the risk for hypoglycemia related to insulin use is increased in the elderly.

CLINICAL MANIFESTATIONS

General Considerations

Aging is associated with declines in kidney function that ultimately limit the ability to defend against destabilizing events. Moderate fluid loss (e.g., an episode of diarrhea) and moderate fluid loading (e.g., inappropriate perioperative intravenous fluids) may be poorly tolerated and lead to hypovolemia and fluid overload, respectively. Hypovolemia in those taking multiple medications with impact on kidney hemodynamics, including angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), and nonsteroidal anti-inflammatory drugs (NSAIDs), may lead to AKI. Overzealous administration of water as 5% dextrose or 0.45% saline can result in hyponatremia, especially in patients taking selective serotonin reuptake inhibitors, which may increase levels of antidiuretic hormone. The use of NSAIDs in the elderly is associated with increased risk for hyponatremia, hyperkalemia, hypertension, and impaired kidney function.

Glomerular Diseases

Elderly patients may have treatable kidney diseases identifiable on kidney biopsy.[51] In a study of 235 biopsy specimens in patients older than 80 years, 67% of the patients had treatable lesions.[52] The pathologic spectrum of glomerular disease seen in elderly people is similar to that in the general population, although the prevalence of various pathologies differs. For example, diabetic kidney disease is seen with increasing frequency in the aging population. Among patients with nephrotic syndrome who are older than 60 years, membranous nephropathy is the most common diagnosis, followed by amyloidosis (typically light chain–derived) and minimal change disease (Fig. 93.8).[52] Other important causes of glomerular disease in the elderly include rapidly progressive glomerulonephritis (GN) resulting from pauci-immune (antineutrophil cytoplasmic antibody-associated) GN (accounting for about 30% of elderly patients with AKI who undergo kidney biopsy).[51] A recently described entity, immunoglobulin G4 (IgG4)-related kidney disease is seen with a higher frequency in males older than 65 years.[53] In contrast, certain glomerular disorders, such as lupus nephritis and IgA nephropathy, are uncommon in elderly people. Only 2% of patients with lupus nephritis present after the age of 60 years.[52]

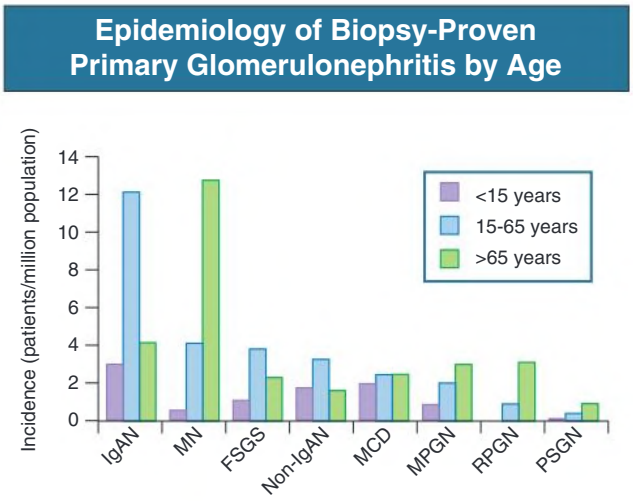

Fig. 93.8 Epidemiology of Biopsy-Proven Primary Glomerulonephritis by Age. Children presenting with nephrotic syndrome are often treated empirically for minimal change disease *(MCD)*; thus diagnosed MCD is likely underrepresented in data derived from biopsy registries. *FSGS,* Focal segmental glomerulosclerosis; *IgAN,* immunoglobulin A nephropathy; *MPGN,* membranoproliferative glomerulonephritis; *non-IgAN,* other mesangial proliferative glomerulonephritis; *PSGN,* poststreptococcal glomerulonephritis; *RPGN,* rapidly progressive glomerulonephritis. (Modified from Vendemia F, Gesualdo L, Schena FP, D'Amico G. Epidemiology of primary glomerulonephritis in the elderly. Report of the Italian Registry of Renal Biopsy. *J Nephrol.* 2001;14: 340–352.)

Renovascular and Atheroembolic Disease

There is an increased frequency of renovascular and atheroembolic disease with aging. In several case series, AKI resulting from atheroembolic disease accounted for 4% to 7% of cases.[54] Atherosclerotic renal artery stenosis is estimated to be present in about 7% of patients older than 65 years and is a major cause of secondary hypertension, ischemic nephropathy, and CKD in the elderly.[54] In elderly people with hypertension, elevated serum creatinine, and a history of vascular disease, testing for renovascular disease with magnetic resonance angiography or renal artery duplex scanning may be considered (see Chapter 43). Percutaneous transluminal renal angioplasty and renal artery stenting are of variable value in the elderly because many patients have significant arteriosclerosis, which may limit the benefits of intervention.[54] Thus, an individualized approach to therapy is warranted that weights the likelihood of improvement in GFR and BP against the potential risks of the procedure.

Diabetic Kidney Disease

Diabetic kidney disease (DKD) is a common disease in the elderly; more than half of all diabetic individuals in the United States are older than 60 years. In type 2 diabetic patients, the prevalence of both eGFR decline and albuminuria increases with age.[55] In patients older than 65 years with type 2 DM, 44.3% had eGFR less than 60 mL/min/1.73 m^2 and 38.7% had albuminuria, with 17.8% having both findings.[55] Relatively healthy older adults with no major comorbidities may benefit from more intense glucose control (target hemoglobin [Hb] $A_{1c} < 7\%$), whereas more lenient targets may be more appropriate for elderly with major comorbidities, established diabetic end-organ damage, or limited life expectancy. The doses of oral hypoglycemic agents and insulin may need to be decreased as the kidney function declines,

especially in the elderly, to avoid hypoglycemia and other side effects.[56] Generally, specific guidelines for the treatment of DM in older people address in a very limited manner the use of more recent therapies, such as sodium-glucose cotransporter-2 inhibitors (SGLT2i), which may have important benefits for older people, such as a low risk of hypoglycemia and reduction of cardiovascular and kidney disease risk. The use of SGLT2i in the elderly must take into account the use of other hypoglycemic medications and drugs such as loop diuretics that may negatively impact volume status.[57] Kidney function should be monitored closely when introducing these agents.

Acute Kidney Injury

Polypharmacy associated with aging greatly increases susceptibility to the development of AKI as a result of drug toxicity.[58] Although the causes of AKI in the elderly patient encompass the same spectrum of prerenal, renal, and postrenal causes that are seen in other age groups, the elderly patient has a higher relative risk for developing AKI from obstructive uropathy or sepsis and associated with cancer and antineoplastic therapies. Decision making about renal replacement therapy (RRT) in elderly patients with AKI and multisystem organ failure will be influenced by comorbidity and the expected likelihood of a good clinical outcome. These discussions require a multidisciplinary approach.

Nephrotoxicity and Drug Dosage

Elderly patients are prone to increased nephrotoxicity because they are often administered medicines on the assumption that normal or nearly normal serum creatinine concentration is consistent with normal kidney function. Thus, eGFR or perhaps creatinine clearance (but not serum creatinine) should be used to determine drug doses. In addition, elderly patients with CKD usually are prescribed multiple medications, and this creates a great risk for drug-drug interactions that can be exacerbated when GFR is low.

End-Stage Kidney Disease and Kidney Replacement Therapy

The mean age for a patient to initiate RRT is currently over 60 years in the United States and Europe. The mean age of patients receiving maintenance dialysis in most low- and middle-income countries is much lower (32–42 years) than that in high-income countries. In the United States there has been a slight decline in the incidence of ESKD in patients older than 65 years, with a continued higher but stable incidence in those older than 75 years.[59] However, the prevalence of RRT continues to rise in patients older than 65 years (Fig. 93.9). Despite the frequency of CKD among elderly patients, kidney replacement therapy is far less common as an outcome than events associated with cardiovascular morbidity or mortality. For example, older patients with CKD stage 3 are more likely to die of cardiovascular disease and less likely to receive RRT than their younger counterparts.[60]

The decision to offer RRT should not be based solely on the age of the individual. It is important to recognize that such a decision involving an elderly patient is more complex and fraught with more challenges than in younger patients and requires a multidisciplinary approach that involves family members. Nonmedical barriers, such as limited transportation, family support, and cost, may be particularly important in the elderly. Of note, nursing home patients who began dialysis experienced sharp and sustained declines in their ability to perform basic daily activities.[61] A year after beginning dialysis, 58% of the patients had died and only 13% still functioned at the same level as they had before beginning dialysis. Thus, although dialysis may extend life, it does not necessarily lead to improvements in functional status in older patients. In fact, the increased longevity associated with institution of dialysis may be entirely accounted for by increased days in the hospital without improvements in quality of life (QOL).[62]

As with other populations, the survival of arteriovenous fistulas (AVFs) in elderly patients is significantly greater than that of arteriovenous grafts.[63]

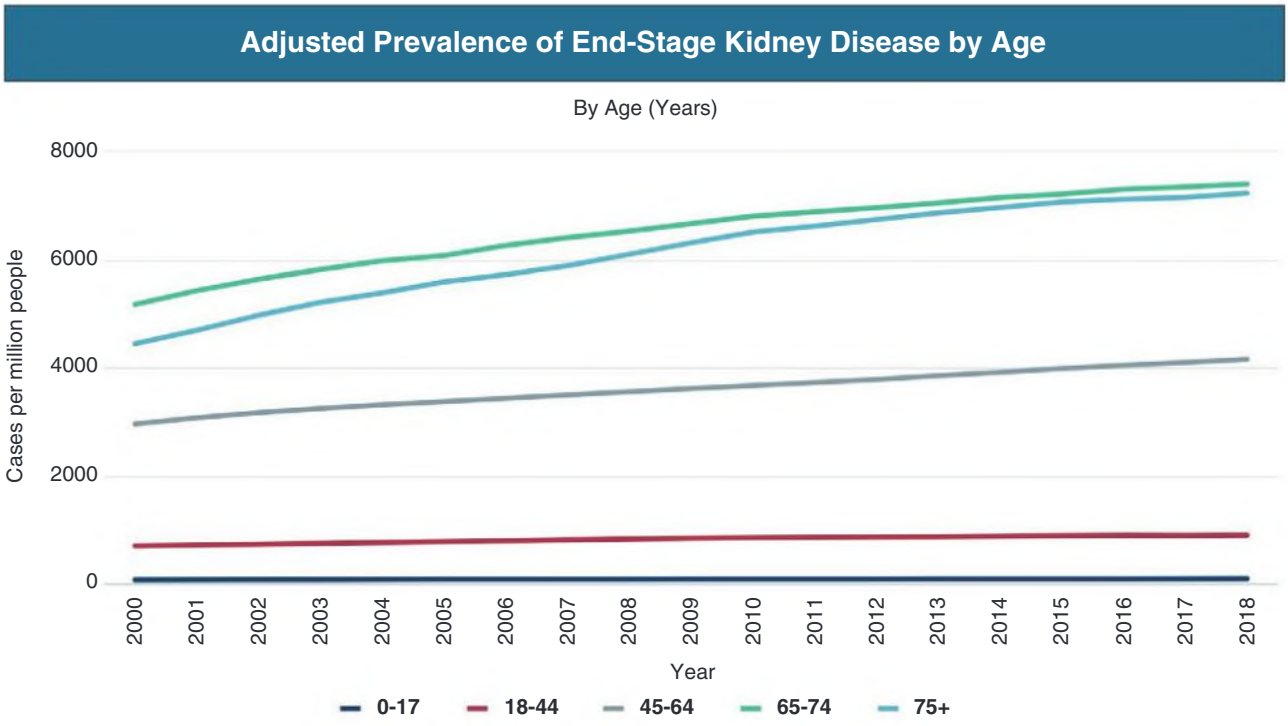

Fig. 93.9 Adjusted Prevalence of End-Stage Kidney Disease (ESKD) by Age. Adjusted ESKD prevalence increased with advancing age, with 7401 cases per million people aged 65 to 74 years and 7233 cases per million people age 75 years or older. (Data from U.S. Renal Data System. www.usrds.org.)

In fact, successful use of an AVF in the elderly has results similar to those in younger people, with prolonged patency and low incidence of infections and thromboses, and thus age alone should not preclude AVF creation. Similarly, use of tunneled hemodialysis (HD) catheters is also associated with increased mortality in older HD patients.[63] However, the high prevalence of comorbidities, particularly DM, peripheral vascular disease, and congestive heart failure, usually make vascular access creation more difficult in the elderly. Furthermore, many of these patients may have an insufficient vasculature for fistula maturation. Finally, many fistulas may never be used because of the competing risk for death before dialysis initiation. In these cases, an arteriovenous graft or a central venous catheter becomes a valid alternative form of vascular access.

Additional limitations of HD in the elderly may include sensitivity to fluid shifts and the presence of significant cardiac dysfunction, leading to poor tolerance of HD sessions; hence peritoneal dialysis (PD) may theoretically offer some advantage by offering a slow, sustained degree of ultrafiltration that leads to greater hemodynamic stability. Unfortunately, inherent functional limitations may provide impediments to broader use of PD in the elderly, especially in those without social support.[64] Studies have demonstrated similar outcomes in elderly patients undergoing HD versus PD.[64] Comprehensive care programs have been designed to support elderly patients to perform PD in their community or at nursing facilities and may offer options to increase the choices that patients have regarding treatment options.[65]

Transplantation should be considered in the management of elderly patients with ESKD because selected elderly transplant recipients have significantly lower mortality compared with otherwise comparable patients who are wait-listed for transplantation.[66] This survival benefit is most striking for patients with kidney failure caused by DM or hypertension, but it declines with longer projected waiting times. Even when expanded-criteria donor kidneys are used, a 25% mortality reduction has been shown in those who undergo transplantation compared with those who are wait-listed.[66] Overall graft survival for the elderly transplant patient is similar to that in younger patients.[66] It has been argued that lower doses of immunosuppression are sufficient in elderly kidney transplant recipients. However, the Eurotransplant Senior Program, allocating kidneys from donors 65 years or older to recipients 65 years or older regardless of human leukocyte antigen (HLA) matching, found 5% to 10% increased rejection rates in this "old to old" group compared with two better HLA-matched groups, the "old to any" and the "any to old," within the Eurotransplant Kidney Allocation System.[67] In a subanalysis of the Efficacy Limiting Toxicity Elimination (ELiTE)-Symphony study, a large prospective randomized trial comparing immunosuppressive regimens in kidney transplant patients, equal rates of rejection in elderly (≥60 years) versus younger (<60 years) recipients were demonstrated.[68] Furthermore, this subanalysis suggested that older recipients who receive a marginal kidney from an older or expanded-criteria donor may fare worse than younger recipients, with an increased likelihood of death, delayed graft function, graft loss, treatment failure, and reduced graft function.

For those who decide not to pursue RRT, symptomatic therapy (supportive management and palliative care) is an option. This concept underscores the importance of individualizing patient goals with a focus on QOL. For those with severe functional or cognitive impairment or for whom complications of dialysis have negatively affected their QOL, dialysis discontinuation is an important consideration. Hospice services remain underused for ESKD patients but may provide an important support mechanism for patients and their families who wish to discontinue dialysis.

SELF-ASSESSMENT QUESTIONS

1. An 82-year-old man has a sudden onset of severe lower extremity edema and weight gain (6 kg in 10 days). He has been taking allopurinol for gout prophylaxis, celecoxib for pain associated with osteoarthritis, losartan for hypertension, and metformin for type 2 diabetes. He has smoked half a pack of cigarettes daily for the past 60 years. His BP is 160/90 mm Hg. Other than the pitting lower extremity edema, the physical examination findings, including findings from a retinal examination, are within normal limits. Chest radiograph shows mild emphysematous changes and small bilateral pleural effusions. A urinalysis reveals 4+ protein and 1+ blood. Serum creatinine is 3.6 mg/dL, and serum albumin is 2.1 g/dL. The erythrocyte sedimentation rate is 90 mm/h (Westergren). Blood glucose is 140 mg/dL (nonfasting). Electrolytes show sodium of 132 mEq/L, potassium of 5.5 mEq/L, bicarbonate of 20 mEq/L, and chloride of 98 mEq/L. A kidney biopsy is performed. Complete blood count is within normal limits. Which one of the following lesions is *most* likely to be present in the kidney biopsy?
   A. Minimal change disease (MCD) with interstitial nephritis
   B. Amyloidosis
   C. Crescentic glomerulonephritis
   D. Membranous nephropathy
   E. Immunoglobulin A nephropathy
2. An 87-year-old woman with hypertensive nephrosclerosis was started on HD 3 months ago. Before dialysis initiation, she had significant weight loss and anorexia, with a serum albumin of 2.8 g/dL. Most recently, her appetite has improved and with this her albumin has improved to 3.2 g/dL, with a serum phosphorus of 5.4 mg/dL and a serum calcium of 9.6 mg/dL. She is currently living in a nursing facility and unable to ambulate without assistance. She appears depressed and apathetic and reports that she has little energy and motivation to participate in any exercise. The family has asked you to meet with them to tell them what they can expect for their mother's health in the future. Which statement is *correct?*
   A. Dialysis will likely continue to improve her energy level and appetite; the family should expect continued improvement over the next few months.
   B. Her inability to ambulate, frailty, and depression will likely not improve with dialysis, and her condition is likely to continue to deteriorate over time.
   C. Home HD should be considered because this modality is associated with improved outcomes in this age group.
   D. Assisted PD should be considered as a way to keep the patient at home; this modality is associated with increased survival over in-center HD.
3. A 79-year-old patient who recently started HD for ESKD secondary to drug-induced interstitial nephritis approaches you to discuss his potential for kidney transplantation. His clinical history includes hypertension, mild angina-like symptoms, and hyperlipidemia. He does not smoke and is very active. In your region, the average time for patients with his blood type to be on the wait list is 5 years before transplantation. Which of the following statements would *most* accurately inform the patient with regard to his candidacy for kidney transplantation?
   A. He is unlikely to gain any benefit from transplantation because there is a high risk for death in the first year postoperatively in patients older than 75 years.
   B. He would likely benefit from transplantation, and he should consider living donation as the best option.
   C. He should seek transplant listing but not seek a living donor.
   D. He should be advised to avoid going on the extended-criteria donor waiting list.

Palliative Nephrology

Edwina A. Brown, Fliss E. Murtagh

Palliative care is defined by the World Health Organization as "an approach that improves the health-related quality of life of patients and their families facing the problem associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial, and spiritual."[1] The term *supportive care* is usually preferred by patients and families and is the term used by the Kidney Disease: Improving Global Outcomes (KDIGO) summary document on supportive care in kidney disease[2] and likewise in this chapter. As shown in Fig. 94.1, supportive care should begin at the time of diagnosis of advanced kidney disease. Fig. 94.2 shows how the different components can be used at different times.

PROGNOSIS

Informing patients accurately about prognosis is key to individualizing dialysis and associated supportive care. Patients with advanced kidney disease often have other comorbidities and complications of treatment; these and increasing age are causes of a high burden of morbidity affecting quality of life (QOL) and shortening length of life. Physicians, however, often are not good at estimating prognosis, with quotes in recent literature such as, "If you're on dialysis you could last 10, 15, 20 years (male, 76 years old)" or "You will probably have 6 years on dialysis (male, 82 years old)."[3] Patients often want to have conversations about life expectancy,[4] and failure to have these discussions can result in high expectations and increased desire for aggressive treatment.[5] Being aware of prognosis is a key part of shared decision making.[6] At the individual level, the surprise question of "Would you be surprised if the patient died in the next 6 or 12 months?" has been shown to enhance prognostic prediction,[7] although it has the limitation of being subjective and depending on clinician perception.

Prognostic tools have therefore been developed to enable clinicians to estimate the prognosis of patients. Factors that can be used to develop tools are summarized in Box 94.1; more detailed information can be found in an overview by Couchoud et al.[6]

Prognostic tools, however, have limitations because they provide an estimate of average survival for a population of similar risk but not for the individual. Before using a particular tool, it is important to know whether the patient concerned is similar to those used for the development of the tool in terms of things such as age, ethnicity, kidney replacement therapy (KRT), and clinical data available. The tool that is most readily accessible is the Analyzing Data, Recognizing Excellence and Optimizing Outcomes (ARO) score, which is based on simple clinical and laboratory data for prevalent European patients on hemodialysis[7]; it can be easily calculated on the ARO Risk Score website.[8] For patients who have not begun KRT, a risk score for mortality in the first 90 days of dialysis has been developed for patients older than 75 years from the French Renal Epidemiology and Information Network (REIN) registry.[9] In routine clinical practice, these tools can inform discussions with patients and families.

The prognostic tools discussed herein are all specific for kidney disease and mostly for patients on dialysis. Clinical tools useful as prognostic indicators in the general population are also applicable in the presence of kidney disease. The concept of frailty is rapidly becoming one of the useful prognostic indicators for hospitalization, complications of procedures, and mortality in the general population.[10] Clinically, frailty manifests as a composite of poor physical function, exhaustion, low physical activity, and weight loss and is associated with an increased risk for falls, cognitive impairment, hospitalization, and death. Frailty is more common in the chronic kidney disease (CKD) population and, not surprisingly, is a strong predictor of mortality.[11] There are various methods of assessing frailty, but the easiest to use clinically is the Clinical Frailty Scale (Table 94.1), which correlates with more complex assessment methods and predicts hospitalization and mortality.[12] Using this scale, prior work has shown that it is frailty, not dialysis modality (assisted peritoneal dialysis [PD] and hemodialysis [HD]), that is associated with symptom score, physical functioning, and better QOL.[13] Routinely determining a frailty score in older patients approaching or on dialysis enhances prognostication both of survival and QOL. Frailty therefore is another factor that should inform discussions with patients and families.

COMMUNICATION AND SHARED DECISION MAKING

Good communication is key to enabling people to optimize QOL and achieve their goals at all stages of a long-term condition. Conversations must include awareness of prognosis and wishes for end-of-life planning. These latter conversations are commonly referred to as "advance care planning," but conversations about prognosis and realistic outcomes of potential treatments and their limitations should ideally be routinely conducted with people at all stages of advanced kidney disease. Treatment decisions should be made *with* and not *for* the patient, using shared decision making. This is a process in which patients, when faced with an important choice about their health care, can review all the treatment options available to them and participate actively with their healthcare professional in making that decision,[14] thereby respecting patient autonomy.[15] Shared decision making is embedded in the U.S. Renal Physicians Association guidelines on dialysis initiation and withdrawal,[16] which state that "clinicians, family members, and others have an ethical duty to accept the decisions regarding medically indicated treatment made by competent patients and, in the absence of competence, to formulate decisions that would respect patients' wishes, or if wishes are unknown, advance the best interest of their patients." To make these decisions, patients and families must be given evidence-based information about what is happening regarding disease process, what is likely to

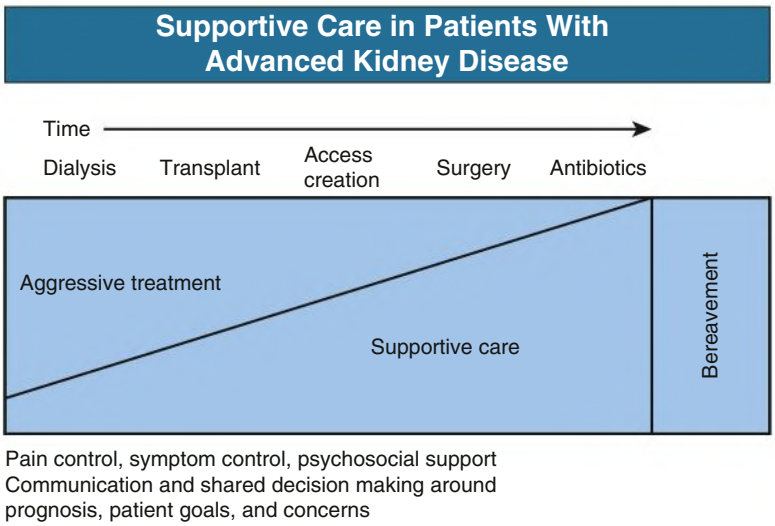

Fig. 94.1 Schematic diagram of how supportive care fits into patient pathway with advanced kidney disease.

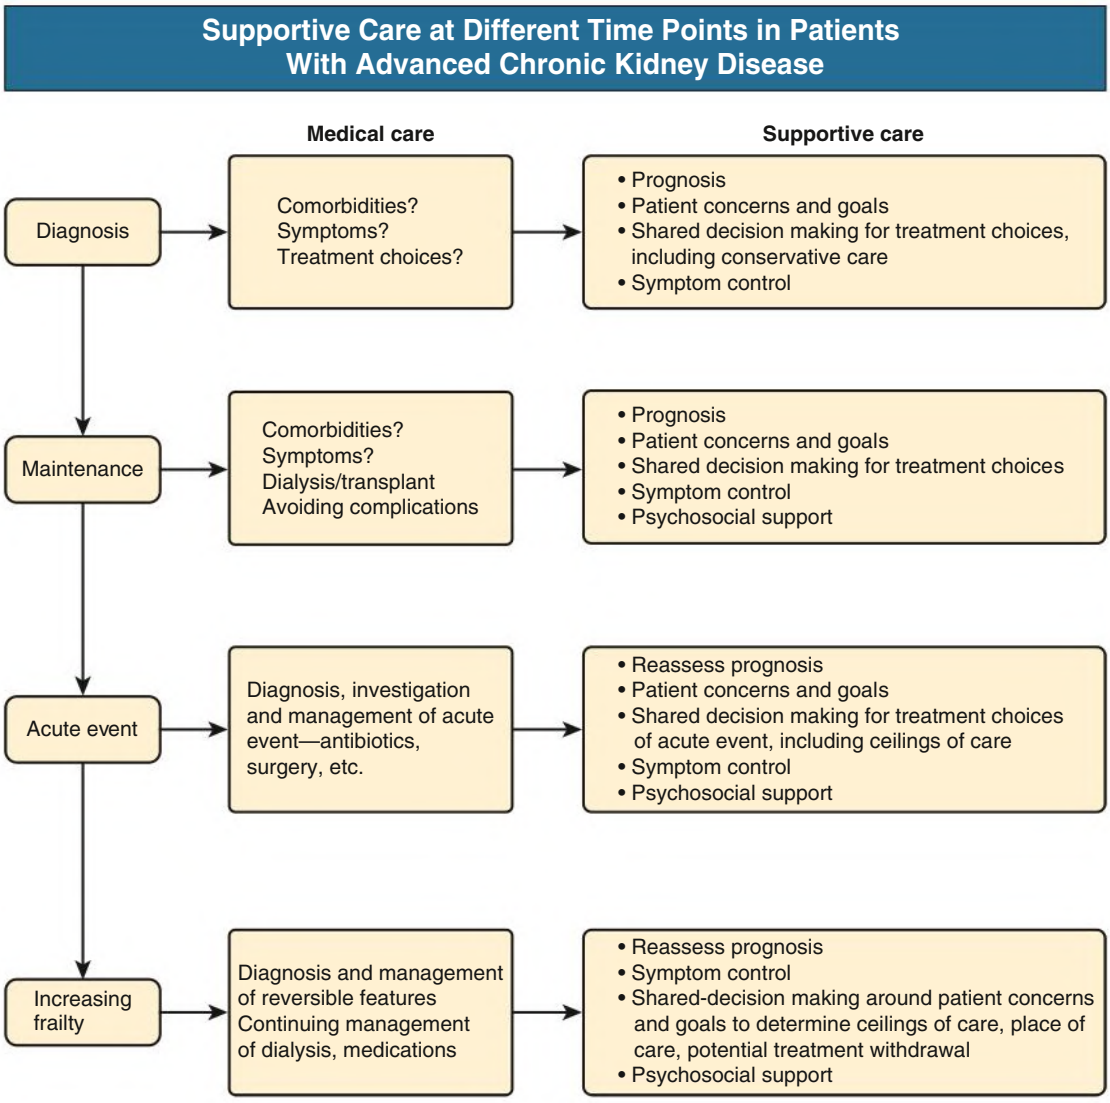

Fig. 94.2 Use of supportive care at different time points in life with advanced kidney disease.

BOX 94.1 Factors Used to Develop Prognostic Tools

Clinical Data
- Age
- Assistance with activities of daily living
- Sex
- Congestive heart failure
- Peripheral vascular disease
- Dysrhythmia
- Active malignancy
- Mobility
- Diabetes
- Body mass index
- Behavioral disorders
- Frequency of hospitalization

Dialysis Related
- Use of central vein dialysis catheter
- Early nephrology referral

Laboratory Values
- Plasma albumin
- Plasma creatinine
- C-reactive protein

TABLE 94.1 Clinical Frailty Scale

Score	Definition
1	*Very fit:* Robust, active, energetic, well-motivated and fit
2	*Well:* No active disease but less fit than people in category 1
3	*Well, with treated comorbid disease:* Disease symptoms are well controlled compared with category 4
4	*Apparently vulnerable:* Although not frankly dependent, commonly complain of being "slowed up"
5	*Mildly frail:* With limited dependence on others for instrumental activities of daily living
6	*Moderately frail:* Help is needed with both instrumental and noninstrumental activities of daily living
7	*Severely frail:* Completely dependent on others for the activities of daily living or terminally ill

BOX 94.2 Time Points for Advance Care Planning Discussions

- As part of kidney replacement therapy planning, particularly if transplant ineligibility or conservative care is discussed.
- Starting or within first few months of starting dialysis.
- Not eligible for transplant and patient does not want dialysis or is anticipated to have poor outcomes on dialysis.
- Not responding to peritoneal dialysis (PD) and patient does not want hemodialysis (HD) or is anticipated to have poor outcomes on HD and transplantation is not feasible.
- Recurrent vascular access problems in HD patient who does not want or cannot transfer to PD, and transplantation is not feasible.
- Patient wants to withdraw from dialysis.
- After intercurrent event that results in worsening of prognosis, such as stroke, fall and bone fracture, worsening cognitive function, or new malignancy.
- Development of intercurrent event needing major surgical intervention, such as coronary artery bypass surgery or major abdominal surgery.
- Increasing frailty and/or cognitive decline.
- Answer of "no" to surprise question: "Would you be surprised if patient died in the next 12 months?"

BOX 94.3 Questions and Statements to Use in Advance Care Planning

- How is your health now compared with a few months ago?
- Would you be surprised if I told you that things are not going well?
- It is always hard to predict the future, but it would not be a surprise if some major acute event occurred or your health deteriorated significantly in the next few months (or other applicable time scale). We should therefore discuss what your wishes would be should this occur.
- It is a good idea to talk about what we can do and how to get help if you proceed to become more unwell.
- Different people make decisions in different ways. Do you make decisions on your own, do you involve your family, or does someone from your family make important decisions for you?
- Do you have a faith or spiritual beliefs that help you in difficult times?
- Have you ever thought how much treatment you would want if you are very ill, unable to communicate to make your own decisions, and unlikely to leave hospital and be independent?
- You know you have a choice about where you would like your end-of-life care to take place. Would you like to talk through the options?
- Some people decide to stop dialysis when their health has deteriorated and they feel that dialysis has become a burden and is no longer of benefit. We do not need to mention that any further now, but it is something you may want to discuss later.

happen regarding prognosis, what treatment options are available, and what the realistic outcomes are from these treatments. Healthcare professionals should seek to understand the patient's concerns and lifestyle priorities and then use these to guide the patient through decision making about, for example, wishes regarding specific treatments, ceilings/limits of care if they are no longer able to make decisions, and place of care at end of life. A summary of when such conversations could and should take place is shown in Box 94.2.

There are challenges to having advance care planning discussions, such as time needed, cultural and linguistic challenges,[17] and overcoming the inhibitions of healthcare professionals to have difficult conversations, particularly when the prognostic future is uncertain.[18] Some useful questions to help with overcoming these challenges are shown in Box 94.3.

Conversations about prognosis and advance care planning should be embedded in nephrologic practice. The timing and frequency of discussions can have a huge influence on patient outcomes. Fig. 94.3 gives the example of a woman who has had a major stroke 5 years after starting dialysis at age 70 years and who has had progressive cognitive impairment in the last 2 years. In the absence of any previous discussions, the family would be unaware of the high probability of stroke and, in all likelihood, would not have had discussions about extent of treatment in such an event; there would then be a high probability of them expecting intensive investigations and management. In reality, for this particular patient, there had been a number of discussions after the onset of cognitive impairment and the patient had made it clear that she did not want continuing active management if she was not going to be independent; this made the final decision making by the family much easier. This has been confirmed by randomized controlled

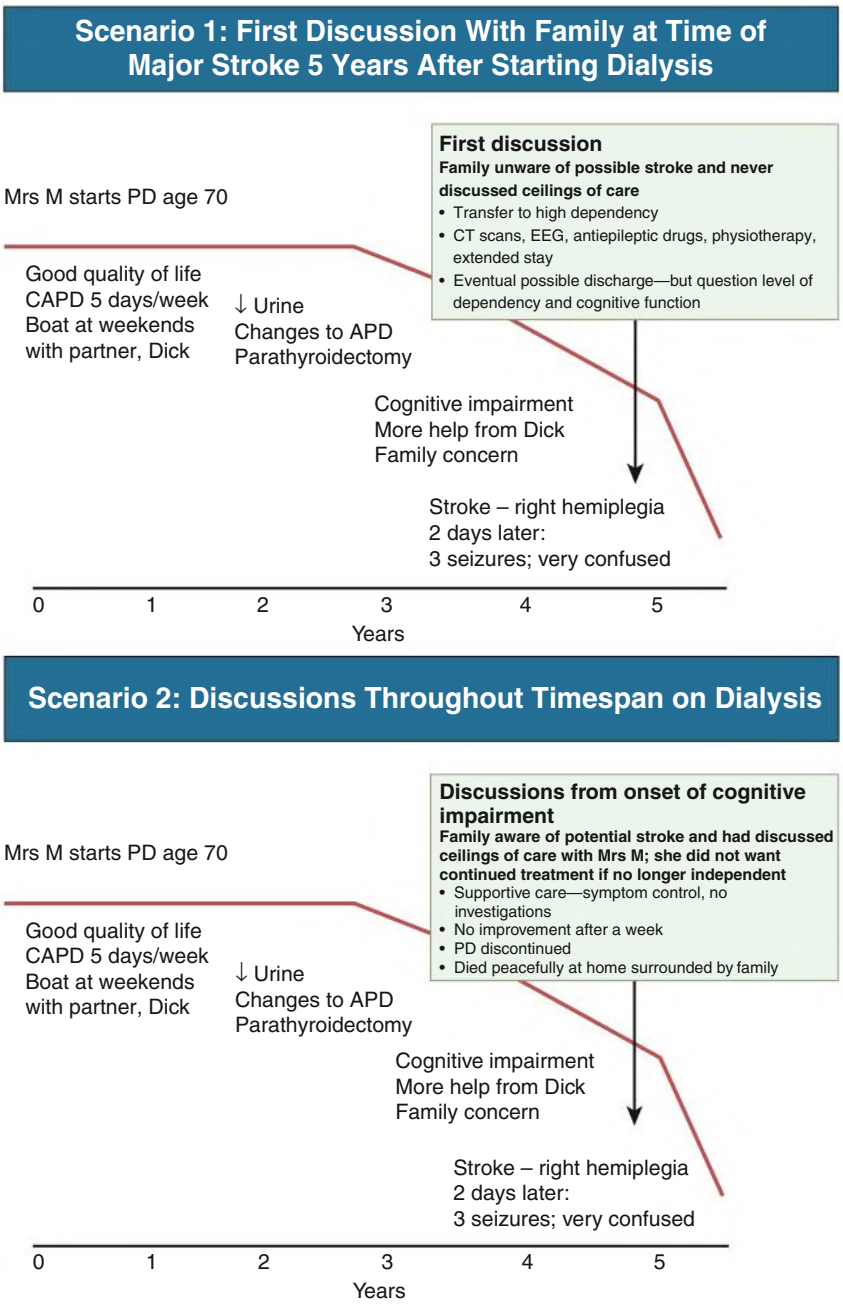

Fig. 94.3 How Communication and Aadvance Care Planning Can Influence Patient Outcomes. *Scenario 1:* First discussion with family at time of major stroke 5 years after starting dialysis. *Scenario 2:* Discussions throughout time span on dialysis. *APD,* Ambulatory peritoneal dialysis; *CAPD,* continuous ambulatory peritoneal dialysis; *CT,* computed tomography; *EEG,* electroencephalogram; *PD,* peritoneal dialysis.

studies in elderly and dialysis populations showing better QOL at end of life and improved certainty about decision making by close family members when these conversations have occurred.[19,20]

CONSERVATIVE CARE

Conservative (nondialytic) kidney care has been defined (Box 94.4), using the term *comprehensive conservative care* and encompassing all the components required for effective comprehensive care.

It has also been proposed that globally there are three distinct groups within the conservative care population (Box 94.5); this reflects limited availability of KRT, the consequent (lack of) options for choice in low-income and middle-income countries, and constraints on diagnosis of stage 5 CKD in resource-poor settings.

Rates of conservative management vary considerably among and within countries, and it is likely that individual nephrology practice is a factor in this variation.[21] It is important therefore to consider all available evidence on survival of those managed conservatively and to contrast this to evidence on survival with dialysis. However, this is challenging, because those who are more fit usually opt for dialysis, and others are advised to follow conservative nondialytic management because of comorbidity or other factors that adversely influence survival. This selection bias makes it hard to meaningfully compare survival between those with dialysis and those managed conservatively.

BOX 94.4 Definition of Comprehensive Conservative Care

Comprehensive conservative care is planned, holistic, patient-centered care for patients with stage 5 (glomerular filtration rate category 5) chronic kidney disease that includes:

- Interventions to delay progression of kidney disease and minimize risk for adverse events or complications
- Shared decision making
- Active symptom management
- Detailed communication, including advance care planning
- Psychological support
- Social and family support
- Cultural and spiritual domains of care

Comprehensive conservative care does not include dialysis.

From Davison SN, Levin A, Moss AH, et al. Executive summary of the KDIGO Controversies Conference on Supportive Care in Chronic Kidney Disease: Developing a roadmap to improving quality care. *Kidney Int.* 2015;88:447–459.

BOX 94.5 Distinct Conservative Care Populations

Comprehensive conservative care: Conservative care that is chosen or medically advised.

Choice-restricted conservative care: Conservative care for patients in whom resource constraints prevent or limit access to kidney replacement therapy; therefore a choice for conservative care cannot be recognized.

Unrecognized stage 5 chronic kidney disease: Chronic kidney disease is present but has not been recognized or diagnosed; therefore a choice for conservative care cannot be recognized.

From Davison SN, Levin A, Moss AH, et al. Executive summary of the KDIGO Controversies Conference on Supportive Care in Chronic Kidney Disease: Developing a roadmap to improving quality care. *Kidney Int.* 2015;88:447–459.

The summary of the evidence by O'Connor and Kumar[22] provides a good overview of current evidence, although further comparative studies[23–27] have since been published. This collected evidence shows that there is a substantial survival advantage with dialysis; however, for older people with end-stage kidney disease (ESKD; >75–80 years) with comorbidity, much of this survival advantage is lost. When time in hospital and receiving dialysis is also considered, there is little or no survival advantage to be gained from dialysis for these older patients with comorbidities. However, there are two notes of caution in interpreting and applying this evidence; first, the evidence from those receiving conservative care remains very limited, and second, the conservative care population is heterogeneous. This makes it much harder to relate to individual circumstances, yet decisions for conservative care always need to be individually tailored.

It is important to also consider symptoms, QOL, illness experience, and survival. There is robust evidence that patients rarely prioritize survival above all else; QOL is equally important and often takes precedence.[28] The systematic review cited previously[29] shows that patients managed conservatively (as do those receiving dialysis) report significant symptom burden, with an average of 9 to 17 symptoms. QOL is generally similar between patients on dialysis and patients receiving conservative care, although there may be some decrease in life satisfaction in relation to dialysis adjustment.[30] Of note, with good supportive care, many of the conservatively managed patients have stable or improved symptoms and QOL.[31]

BOX 94.6 Situations Where Dialysis Withdrawal Is Appropriate

- Patients with decision-making capacity who, being fully informed and making voluntary choices, refuse dialysis or request that dialysis be discontinued
- Patients who no longer possess decision-making capacity
  - Those who have previously indicated refusal of dialysis
  - Those whose legal agents/surrogates request that it be discontinued
- Patients with irreversible, profound neurologic impairment such that they lack signs of thought, sensation, purposeful behavior, and awareness of self and environment

From Davison SN, Levin A, Moss AH, et al. Executive summary of the KDIGO Controversies Conference on Supportive Care in Chronic Kidney Disease: Developing a roadmap to improving quality care. *Kidney Int.* 2015;88:447–459.

DIALYSIS WITHDRAWAL

As already demonstrated in the case discussed in Fig. 94.3, patients may decide to stop dialysis. The median time to death after stopping dialysis is 8 to 9 days[32] but can be considerably longer if there is significant residual kidney function. There is information for patients and caregivers about stopping dialysis on both U.K. and U.S. patient support websites.[33,34] The situations in which dialysis withdrawal is appropriate are shown in Box 94.6.

Studies suggest that the rate of dialysis withdrawal has increased over the years, but this needs to be interpreted with caution because there is no well-accepted definition of dialysis withdrawal.[35] A recent report published from the Scottish Renal Registry[36] has defined death resulting from withdrawal as patients refusing further treatment, therapy ceased for other reasons, and dialysis withdrawn for medical reasons. In this study, dialysis withdrawal was the primary cause of death in 19% of all deaths (a rate of 41 in 1000 patient-years) over a 7-year period; in a further 17% of patients, withdrawal from dialysis was considered to have contributed to death but not to have been the main cause. Using this definition, deaths attributed to dialysis withdrawal accounted for around one-third of deaths; this did not change over the 7 years of the study but did vary significantly across the different kidney centers with dialysis withdrawal accounting for 3.3% to 55.8% of all deaths per center.[36] This variation also has been found on a larger scale between different European countries, with higher reports of dialysis withdrawal if respondents in the survey worked in a public center, if stopping life-supporting treatments was perceived as allowed, if withdrawal decisions were considered shared between patients and doctors, and if palliative care was reimbursed by payers.[37] The patient factors associated with dialysis withdrawal vary in individual studies, but many of the following have been consistently identified: older age, female sex, higher comorbidity burden (particularly cerebrovascular disease), being on HD, early initiation of dialysis, and late referral to nephrologist.[36,38,39] Cultural differences also play an important role in dialysis withdrawal with lower rates of dialysis discontinuation in racial and ethnic minorities reported in studies in English-speaking countries.[38,39,40]

Withdrawal from dialysis is ethically and clinically acceptable only after a process of shared decision making with the patient (and close persons if the patient is no longer able to make decisions). These discussions need to be attuned to the culture (ethnic and religious) of the individual.[17] It is also incumbent on all providers caring for a patient who is contemplating stopping dialysis to address potentially remedial factors contributing to the decision, such as depression, or other

symptoms, such as pain and potentially reversible social factors.[2] *It is essential to ensure access to appropriate supportive and/or hospice care as an integral part of care after any decision to withdraw dialysis.*[2] Details of this are discussed in the following section.

SYMPTOM CONTROL AND MANAGEMENT OF LAST DAYS

Symptoms are as common in those managed conservatively as among those on dialysis, with 3 in 4 reporting weakness and pruritus; 1 in 3 reporting drowsiness, breathlessness, and edema; and more than 1 in 2 patients with ESKD reporting pain.[41] These symptoms are not mild; a high proportion (more than two-thirds) of those with pain, for instance, have moderate or severe pain, often related to comorbid conditions rather than to kidney disease. In addition, symptoms often accumulate, with an average of 12 symptoms experienced by each patient that impair QOL and need optimal management.

Evidence on management of symptoms is often extrapolated from other populations or based on best understanding of the pharmacodynamics and pharmacokinetics in severe kidney impairment. This evidence is limited but is well summarized in a recent series of articles.[42]

In the last days of life, additional symptoms may arise from uremia (nausea, vomiting, drowsiness, myoclonus, pruritus), fluid overload (breathlessness and edema), and immobility and poor tissue perfusion (pain, muscle soreness, pressure sores). It is best practice to prescribe "as required" doses of an analgesic, an antiemetic, a sedative, and an antisecretory agent for all patients with ESKD as they enter the last few days of life, to anticipate any distressing symptoms and ensure they can be rapidly addressed. The actual drugs used will vary between different centers and countries. What is important is involvement with local palliative care team support in determining which drugs to prescribe for the individual patient.

As end of life approaches, both patient and family often need much more information and explanation than is provided by health professionals. Encouragement to ask questions, straightforward but sensitively judged responses, and frequent opportunities for professionals to check on concerns and anxieties can go a long way to provide support to the patient and family at a difficult and challenging time.

SELF-ASSESSMENT QUESTIONS

1. Which of the following factors have been shown to be associated with a poor survival prognosis in an 80-year-old man who has been on dialysis for 2 years?
   - **A.** Being on peritoneal dialysis
   - **B.** Peripheral vascular disease
   - **C.** Use of central venous catheter
   - **D.** Requiring assistance to get dressed
   - **E.** Low plasma albumin
2. Advance care planning should include which of the following?
   - **A.** Legal process resulting in advance decision
   - **B.** Informing the patient that they will not be resuscitated
   - **C.** Discussion about prognosis
   - **D.** Identification of patient concerns
   - **E.** Opportunity for patient to record future wishes
3. Which of the following statements can be made about dialysis withdrawal?
   - **A.** Approximately 20% of deaths of dialysis patients are stated to be because of dialysis withdrawal.
   - **B.** Death invariably occurs within 3 days of stopping dialysis.
   - **C.** Dialysis withdrawal can be viewed as euthanasia.
   - **D.** Shortness of breath is the main symptom after withdrawing dialysis.
   - **E.** Dialysis can be stopped in patients lacking decision-making capacity who have made a previous decision to this effect.
4. Which of the following statements can be made about conservative care?
   - **A.** Survival rates of multimorbid patients older than 80 years are similar on dialysis and conservative care.
   - **B.** Survival of functionally independent patients 70 to 75 years old are the same on dialysis and conservative care.
   - **C.** Patients choosing conservative care should be persuaded to start dialysis if they deteriorate acutely.
   - **D.** Anemia management with erythropoietin is appropriate for patients choosing conservative care.
   - **E.** Conservative care is not "rationing" because patients choose not to have dialysis themselves.

Approach to Kidney Replacement Therapy

Hugh C. Rayner, Chandra M. Thomas

Individuals with advanced chronic kidney disease (CKD) will have one of three fates: stable CKD, progressive loss of kidney function to kidney failure, or death prior to developing kidney failure. The options for treatment for people who progress to kidney failure include kidney replacement therapy (KRT), consisting of transplantation or dialysis, and supportive (nondialysis) care (see Chapter 94).

Broadly there are two types of dialysis: peritoneal dialysis (PD) and hemodialysis (HD).

The number of people starting dialysis for KRT each year varies enormously around the globe (Fig. 95.1).[1] The incidence per million population in most countries has risen steadily over the past decade (Fig. 95.2), although some have seen a decline in recent years (Fig. 95.3). The incidence of dialysis for KRT is influenced by multiple factors: the incidence and prevalence of diseases that may lead to kidney failure, especially diabetes; the ability of health care systems to identify CKD and to slow progression to kidney failure[2,3]; the level of kidney function at which KRT is begun; and the availability of resources to provide dialysis.

Dialysis is costly and time-consuming; once started, it may continue for many years. All individuals likely to reach kidney failure, their families, and their caregivers require physical and psychological preparation, including education about future treatment options, given in a form that they find accessible.

PREDICTION OF KIDNEY FAILURE

Preparation for kidney failure treatment requires two things: identification of those individuals who are at high risk for reaching kidney failure and prediction of the likely time when KRT may be needed.[4]

Diabetes, heavy proteinuria, declining estimated glomerular filtration rate (eGFR), and previous episodes of acute kidney injury make it more likely that an individual will progress to kidney failure. A variety of risk prediction tools can be used. The Kidney Failure Risk Equation (KFRE) performs reasonably well over 2 years and has been extensively studied and validated in a variety of populations (Fig. 95.4).[5] Models making predictions at 5 years or more considerably overestimate the risk of kidney failure because of the competing risk of death.[6] The Grams model, which accounts for this, is suitable for predictions over 4 years.[7]

Predicting when someone may need KRT is made easier by a graphical display of eGFR. The trajectory of the eGFR accurately reflects changes in the true GFR over time[8] and is easier to understand than columns of figures. The graph should be shared with patients to help them understand how their disease is progressing. If individuals with a declining trend in eGFR are systematically identified,[9] the number starting KRT without adequate preparation may be reduced and the rising trend in KRT incidence slowed.[2]

MULTIDISCIPLINARY CARE IN ADVANCED CHRONIC KIDNEY DISEASE

Advanced CKD care aims to address several issues: preservation of remaining kidney function; prevention or treatment of complications of CKD; involvement of the individual, their family, and caregivers in making an informed choice in regard to PD, HD, and conservative kidney management; creation of dialysis access in good time; and, in appropriate individuals, preparation for kidney transplantation ideally before dialysis is started. People who receive consistent predialysis care have better outcomes[10] and incur lower health care costs.

People need time (often months) to understand and make decisions about dialysis and its implications. The best approach is to transfer the care of individuals with a high risk of kidney failure to a multidisciplinary team at least 12 months before dialysis is started. One method of determining who should be referred to multidisciplinary care is to use a risk-based assessment such as the Kidney Failure Risk Equation described earlier. A risk of kidney failure of more than 10% over 2 years has been suggested as a trigger for referral. Alternatively, one can estimate the start date for KRT by extrapolating a trendline of the eGFR forward until it reaches 10 mL/min/1.73 m^2.[11] Using the 12-month prediction rather than an arbitrary value of eGFR to prompt referral avoids older individuals with slowly declining GFR being referred for dialysis preparation unnecessarily.

The trajectory of the eGFR graph may not be linear; intercurrent illness in individuals at stage 5 CKD can cause a sudden drop in GFR and precipitate urgent dialysis. It is therefore prudent to refer all individuals with CKD for multidisciplinary care once the eGFR reaches 15 mL/min/1.73 m^2.

Predialysis Education Programs

Conventional office consultations with a nephrologist may not enable people with advanced CKD to gain sufficient knowledge and understanding to make good decisions about KRT.[12] Individuals receiving additional care from a predialysis multidisciplinary team have better biochemical results, are more likely to start dialysis in a planned way with less hospitalization, and may even have improved survival rates once they have started dialysis. As well as being good clinical practice,

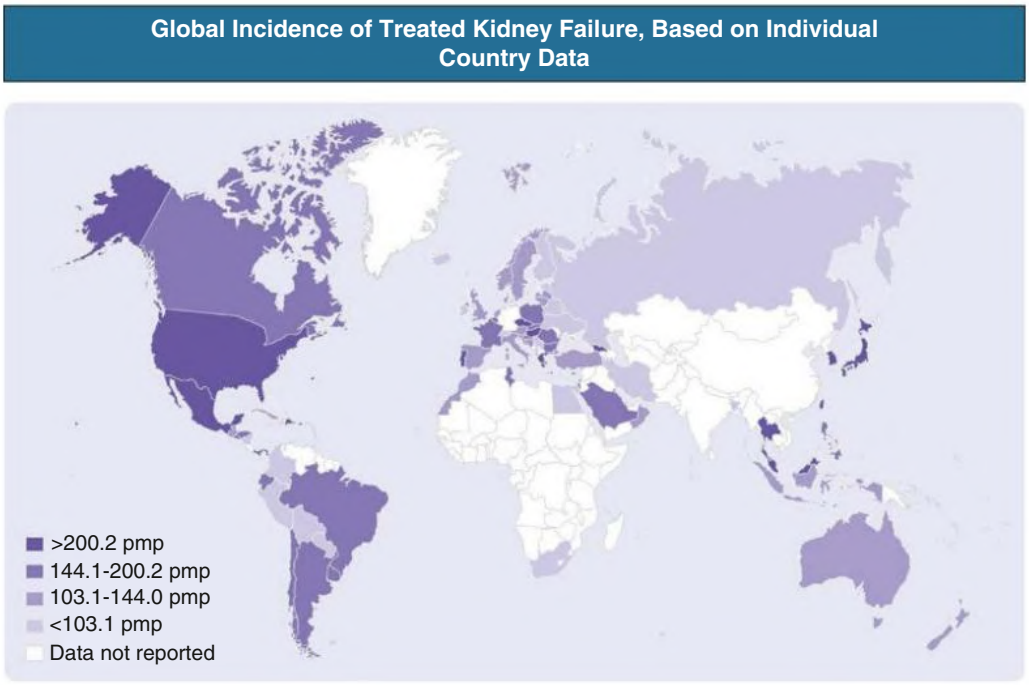

Fig. 95.1 Geographic Variation in the Incidence of Treated Kidney Failure per Million Population (pmp), by Country, 2019. Data presented only for countries from which relevant information was available. All rates are unadjusted. (From Bello AK, Levin A, Lunney M, et al. Status of care for end stage kidney disease in countries and regions worldwide: international cross sectional survey. *BMJ.* 2019;367:l5873.)

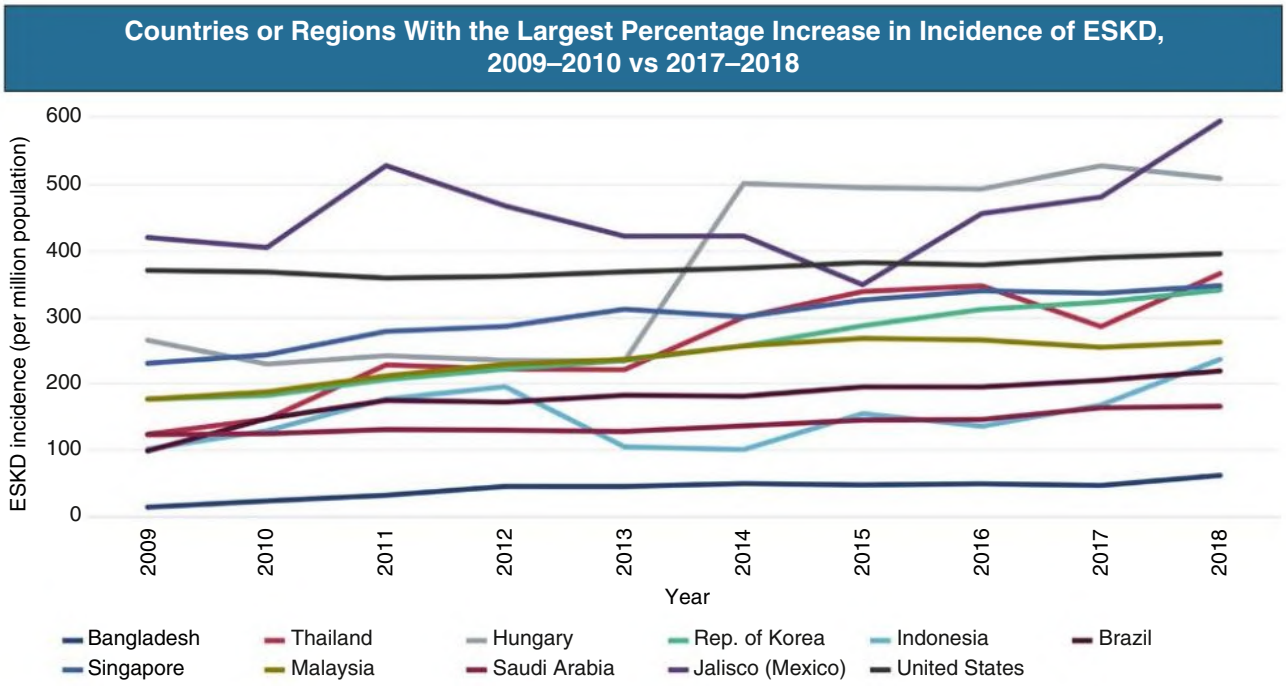

Fig. 95.2 Ten Countries Having the Highest Percentage Increase in the Incidence of End-Stage Kidney Disease (ESKD) From 2009 to 2018. All data are unadjusted. Data for United States are shown for comparison purposes. (From US Renal Data System. 2020 *USRDS Annual Data Report: Epidemiology of Kidney Disease in the United States.* National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases; 2020.)

these programs may make good financial sense because the savings in inpatient costs can exceed those required to run the clinics.[13]

Although clinicians are expert in the technical aspects of dialysis and transplantation, people living with CKD know best about their own needs and preferences and should be encouraged to share in making decisions.

Education should follow the principles of adult learning: first, assess the individual's existing level of knowledge and understanding; second, build on this knowledge by delivering appropriate information in an appropriate form; and third, establish that they have understood and accepted the information given. Education can be delivered both

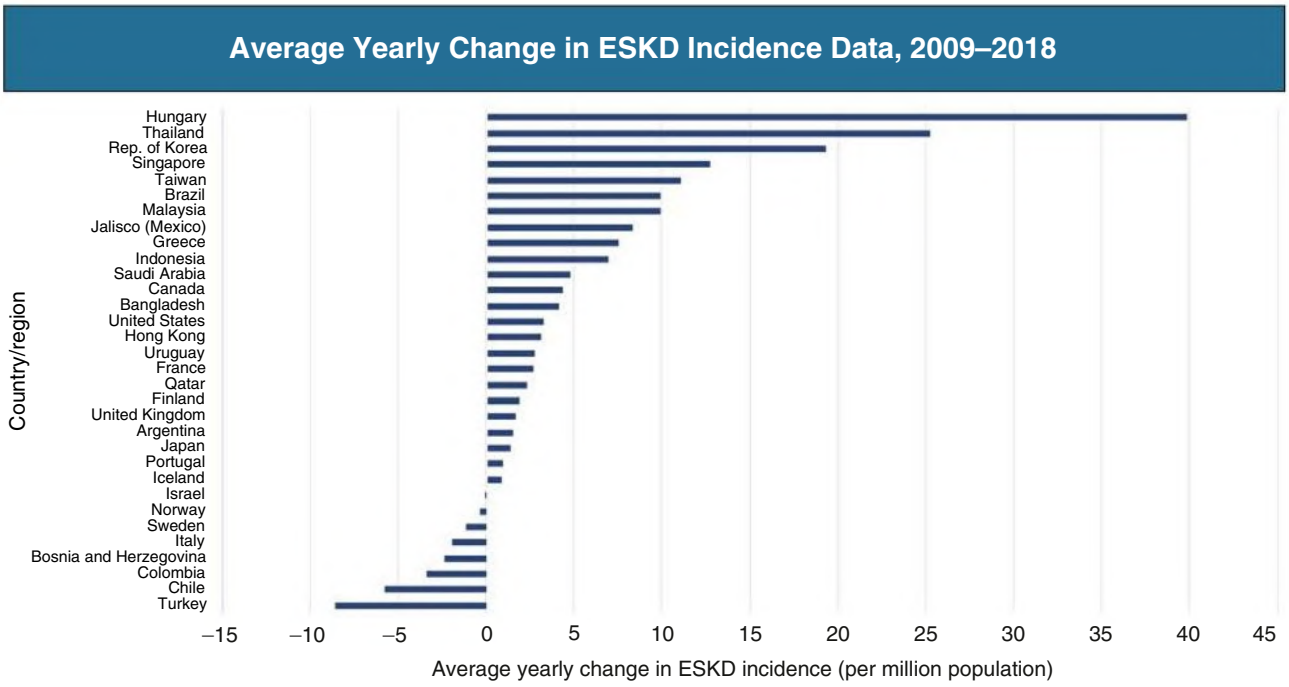

Fig. 95.3 Average Yearly Change in End-Stage Kidney Disease (ESKD) Incidence Data From 2009 to 2018. All data are unadjusted. Predicting the Probability of Kidney Failure

Variables	Patient A	Patient B
Age	70 years old	50 years old
Sex	Male	Male
Estimated glomerular filtration rate	30 mL/min/1.73 m^2	30 mL/min/1.73 m^2
Urine albumin to creatinine ratio	200 mg/g	50 mg/g
Albumin	3.5 g/dL	4.0 g/dL
Bicarbonate	21 mEq/L	26 mEq/L
Calcium	9.0 mg/dL	9.8 mg/dL
Phosphorus	4.5 mg/dL	3.8 mg/dL
Kidney failure risk	**9.2% (2 years) 27.0% (5 years)**	**3.6% (2 years) 11.3% (5 years)**

Fig. 95.4 Predicted Probability of Kidney Failure for Two Patient Profiles Using the 8-Variable Kidney Failure Risk Equation. The Kidney Failure Risk Equation uses eight common variables to estimate the 2- and 5-year risk of kidney failure.

individually and in groups. In a group education session, individuals living with CKD may learn more from fellow participants than from the group's facilitator. Furthermore, support groups help individuals and their relatives appreciate that they are not alone in facing the demands of kidney failure.

The multidisciplinary team may include a dietician, nurse educator, pharmacist, physical therapist, occupational therapist, social worker, and sometimes a trained peer-support volunteer. There is no ideal team composition, and it will vary depending on the local context.[14] A controlled trial in California studied the value of social worker input to the predialysis program in reducing unemployment.[15] In the intervention group, individuals and their relatives met regularly with a licensed social worker both before and after starting dialysis to explore strategies for continuing their current employment. Blue-collar workers in the intervention group were 2.8 times more likely to continue working. People in employment had a better quality of life, greater self-esteem, and a more positive attitude toward work. Because it is difficult for individuals treated with dialysis to regain jobs once they are lost, this result is particularly valuable for long-term rehabilitation.

Individuals living with CKD should be directed to the wide range of educational materials available. Many national organizations, such as Kidney Care UK (https://www.kidneycareuk.org/),[16] provide web-based information and produce printed and audiovisual material. Decision aids can help people think through their options and choose the treatment that suits them best. A good online example is My Kidneys, My Choice (http://mychoice.kidney.org.au).[17] Each consultation should be followed by a letter or report, ideally written directly to the patient[18] and copied to their family doctor.

Education About Transplantation

For many, transplantation offers the best prospect for improved survival and quality of life, especially in younger people. Even in older people with greater comorbidity, transplantation can improve survival and be cost-effective.[19]

The options of transplanting kidneys from a deceased or living donor should be discussed, as well as combined kidney and pancreas transplants for some people with diabetes. Although outcome data from the local transplant center should be made available, published data can be used, such as from the US Scientific Registry of Transplant Recipients[20] or NHS Blood and Transplant in the United Kingdom (https://www.odt.nhs.uk).

The ideal time for the transplant to be performed is before dialysis has begun (preemptive transplantation). This avoids the need for access surgery, and in most studies, survival, graft survival, and acute rejection rates are better.[21]

WHEN SHOULD DIALYSIS BE STARTED?

There is no single measure that can be used to determine the right time to start dialysis. A low eGFR, rising serum phosphate, and falling serum bicarbonate may indicate kidney failure, but these levels are also affected by muscle mass and protein intake. Falling serum albumin may indicate inflammation rather than malnutrition secondary to uremia.

The mean eGFR at the start of dialysis varies across countries. In the United Kingdom, the mean eGFR at dialysis initiation was 7.4 mL/min/1.73 m^2 in 2018. Registry data from USRDS shows 10.6% of individuals starting dialysis with eGFR greater than 15 mL/min/1.73 m^2 and 27.3% with eGFR 10 to 14 mL/min/1.73 m^2.[20] In Canada, 7.9% started dialysis with eGFR greater than 15 mL/min/1.73 m^2 and 19.4% with eGFR 10.5 to 15 mL/min/1.73 m^2.[22] The median eGFR at dialysis initiation in Australia was 7.4 mL/min/1.73 m^2 and 5.6 mL/min/1.73 m^2 in New Zealand.[23]

In the United States, dialysis was started at a consistently lower eGFR within the Department of Veterans Affairs, a non–fee-for-service health system, than with other providers.[24]

Limitations of a Purely Clinical Approach to the Initiation of Dialysis

Waiting for uremic symptoms to develop before starting KRT carries the risk that the individual will be malnourished when they start dialysis, with an increased risk for mortality. The chronic nature of progressive kidney disease means that people may remain unaware of the severity of their illness. Protein intake may fall spontaneously so that symptoms of uremia do not develop, at the expense of a loss of lean body mass. Similarly, people may gradually reduce their activities as their exercise tolerance declines. Many individuals only appreciate how ill they have become once they have rehabilitated on a dialysis program. Lack of awareness can be avoided by seeking insidious symptoms of uremia. For example, people should be asked to compare their current eating habits and level of activity with those 6 to 12 months previously. Close friends and relatives may provide a useful third-party view of their well-being. A validated patient-reported outcome measure (PROM) may help identify changing symptoms as CKD advances.[25]

Limitations of a Purely Laboratory Results–Based Approach to the Initiation of Dialysis

Starting dialysis early must have proven benefits to justify the additional inconvenience, risk of dialysis-related complications, and cost. Dialysis treatment has a finite life, either from loss of peritoneal function or failure of HD access; thus, starting treatment earlier will bring forward the time when further procedures or a change of modality are needed.

Moreover, there is likely to be resistance from many individuals to the suggestion that they should start dialysis if they have no symptoms of uremia. Starting dialysis is the first step in a lifelong commitment to KRT, and people treated with dialysis will be asked to comply with a wide variety of inconvenient and sometimes unpleasant treatments. A high level of compliance is required for a successful outcome. Missed dialysis treatments are associated with increased risk of mortality and health care interventions.[26,27]

A randomized trial comparing individuals who started dialysis at eGFR of 9.0 mL/min/1.73 m^2 with those who started 6 months later at eGFR of 7.2 mL/min/1.73 m^2 showed no difference in survival or quality of life (Fig. 95.5).[28] Starting dialysis earlier was not associated with better quality of life and incurred higher health care costs.[29] The one advantage in the earlier-start group was that a higher proportion of those who had previously chosen PD actually started dialysis with PD (80% vs. 70%, $P = .01$).

Some clinicians advocate an incremental start to hemodialysis. Incremental hemodialysis is the delivery of less than the conventional thrice-weekly sessions of dialysis with adjustments of dialysis prescription informed by changes in residual kidney function.[30] Prescription changes can include frequency of dialysis sessions, session duration, fluid volumes, needle size, dialyzer surface area, blood flow rate, dialysate flow rate. Additionally, dietary intervention can be modified. People with preserved residual kidney function (>500 mL/day), limited weight gain between dialysis sessions (<2.5 kg), and the ability to maintain metabolic parameters in an acceptable range with shorter or fewer sessions would be good candidates for consideration of incremental dialysis. Close monitoring of residual kidney function, interdialytic weight gain, and metabolic parameters are needed to ensure that continuing incremental dialysis is still appropriate. In low-income countries, less frequent dialysis may be all that is available.[31]

CHOICE BETWEEN PERITONEAL DIALYSIS AND HEMODIALYSIS

The mix of PD and HD in the dialysis population varies considerably across countries (Fig. 95.6). In the most recent Global Kidney Health Atlas, only 32% of low-income countries report that PD is available[32] compared with greater than 90% of upper-middle- and high-income countries. Some countries such as Hong Kong and New Zealand have consistently high incidence and prevalence rates of PD.[33,34] In Hong Kong, PD comprises approximately 75% of prevalent dialysis[33] and since 1985 has been provided as first-choice KRT unless absolute medical contraindications to PD are present.[35]

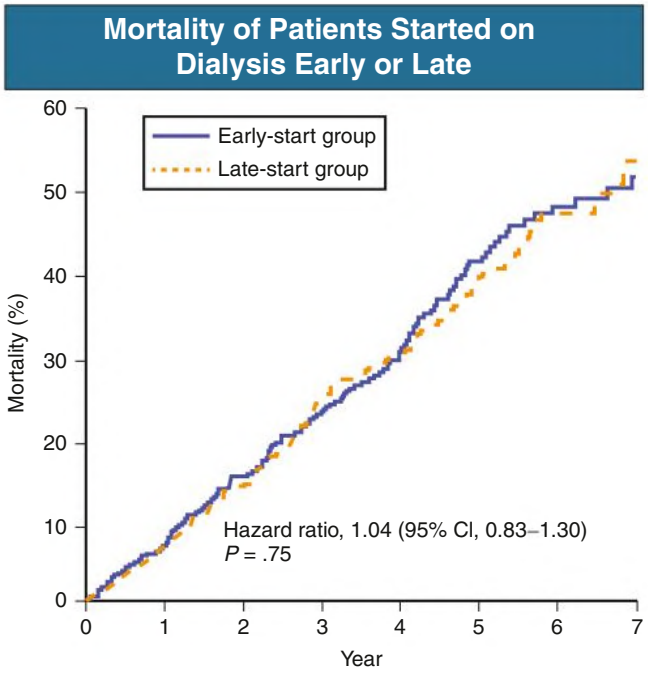

Fig. 95.5 Mortality of Individuals Started on Dialysis Early or Late. Kaplan-Meier curves for the time to death. (From Cooper BA, Branley P, Bulfone L, et al. A randomized, controlled trial of early versus late initiation of dialysis. *N Engl J Med.* 2019;36[7]:609–619.)

Globally, higher expenditure of gross domestic product (GDP) on health care, a larger proportion of private health-care expenditure, and lack of local production of PD consumables and high duty imports on PD supplies are associated with higher costs of PD relative to HD.[36] However, in Hong Kong PD has been shown to be more cost-effective than HD.[37]

Most people with kidney failure are suitable for treatment with either PD or HD. How should we choose between the two? Ideally, we would apply evidence from a randomized clinical trial (RCT) of PD versus HD, but executing such a trial would be difficult. One attempted RCT, the Netherlands Cooperative Study on the Adequacy of Dialysis (NECOSAD), had to be stopped because of low recruitment.

Retrospective and prospective nonrandomized comparative studies have failed to indicate a consistent survival advantage for either modality.[38] Previous evidence suggested that PD may be inferior to HD over the longer term in individuals with coronary heart disease and congestive heart failure.[39] More recent evidence suggests that this may not be the case,[40] and PD is associated with superior health-related quality of life.[41]

PD technique failure can be due to infection, mechanical problems, inadequate dialysis, and social reasons. Late technique failure is associated mainly with social factors.[42] Technique failure due to infection and social reasons are associated with a higher short-term risk of death,[43] most frequently because of cardiac mortality when technique failure is due to infection, and dialysis withdrawal due to social reasons.

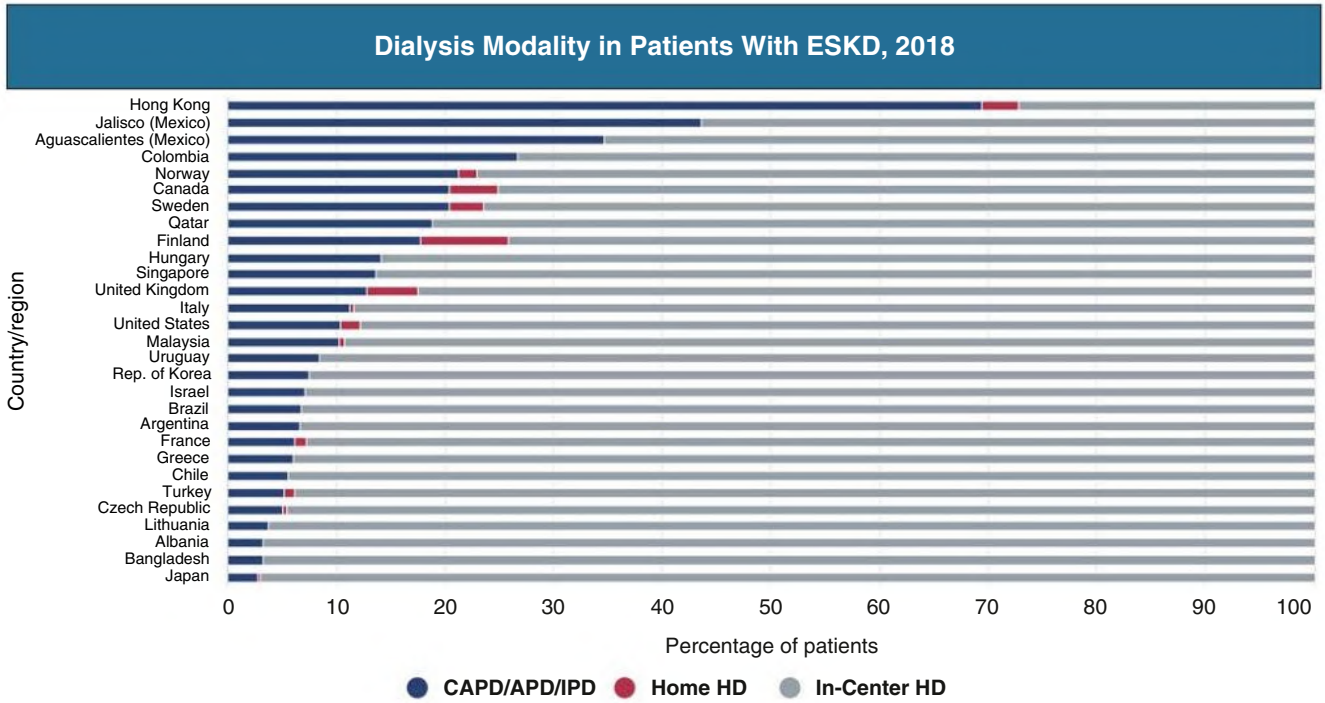

Fig. 95.6 Distribution of the Percentage of Prevalent Patients Using In-Center Hemodialysis (HD), Home HD, or Peritoneal Dialysis (PD), 2018. Denominator is calculated as the sum of patients receiving HD, PD, or home HD; does not include patients with other/unknown modality. *APD,* Automated peritoneal dialysis; *CAPD,* Continuous ambulatory peritoneal dialysis; *IPD,* Intermittent peritoneal dialysis. Contraindications to Peritoneal Dialysis

There are a few situations in which PD is contraindicated (Box 95.1). Relative contraindications to PD include those discussed in the following section.

Fresh Intraabdominal Foreign Body

Individuals with prosthetic aortic grafts have been successfully treated with PD. HD is usually used for up to 16 weeks to allow the graft to be covered with epithelium and so avoid the risk for graft infection via peritoneal dialysate. However, this risk must be balanced against that of bacterial seeding from the HD access.

Body Size Limitations and Intolerance of Intraabdominal Fluid Volume

Both very large and very small body size can be challenging for people treated with PD. Small individuals may be intolerant of the volume of dialysate needed to achieve adequate dialysis, particularly if they have negligible residual kidney function. Alternative methods of fluid exchange, such as automated PD, can be used to overcome this limitation. Larger dwell volumes or automated PD are required to achieve adequate solute clearance and ultrafiltration in people with a body mass index greater than 35 kg/m^2. Discomfort as a result of increased intraabdominal volume can be significant in those with chronic respiratory disease, low-back pain, or large polycystic kidneys. In general, it is hard to predict someone's tolerance of intraabdominal fluid, and so these limitations usually appear after PD has been started.

Bowel Disease and Other Sources of Infection

The presence of ischemic bowel disease, inflammatory bowel disease, or diverticulitis is likely to increase the incidence of peritonitis caused by organisms passing through the bowel wall into the peritoneum. Abdominal wall infection may lead to peritonitis via the exit site and catheter tunnel.

Testing for methicillin-resistant *Staphylococcus aureus* (MRSA) before all elective surgical procedures is good practice. Clearance of nasal *S. aureus* with topical mupirocin cream reduces the risk for staphylococcal infection at the exit site.

Severe Malnutrition or Severe Obesity

Severe malnutrition may lead to poor wound healing and leakage from the catheter tunnel. In addition, peritoneal protein losses during dialysis may exacerbate hypoalbuminemia. At the other end of the spectrum, it may prove difficult to satisfactorily place a peritoneal catheter through the abdominal wall in people with severe obesity, and the risk for infection is greater. Thereafter, absorption of glucose from the dialysate, which may average as much as 800 calories per day, may contribute to further weight gain.

Contraindications to Hemodialysis

Contraindications to HD are few (see Box 95.1). As discussed in Chapter 96, access to the circulation usually can be obtained, even in people with extensive vascular disease or previous surgery. An aversion to needle puncture of the atrioventricular fistula (AVF) is common in the early stages but usually can be overcome by careful use of local anesthetic and nursing encouragement. Severe coagulopathy may make management of anticoagulation in the extracorporeal circuit difficult.

BOX 95.1 Contraindications to Dialysis Modalities

Peritoneal Dialysis

Absolute

- Lack of housing/lodging
- Loss of peritoneal function producing inadequate clearance
- Adhesions blocking dialysate flow
- Surgically uncorrectable abdominal hernia
- Abdominal wall stoma
- Diaphragmatic fluid leak
- Inability to perform exchanges in absence of suitable assistant

Relative

- Recent abdominal aortic graft
- Ventriculoperitoneal shunt
- Intolerance of intraabdominal fluid
- Large muscle mass
- Extreme obesity
- Severe malnutrition
- Skin infection
- Bowel disease

Hemodialysis

Absolute

- No vascular access possible

Relative

- Difficult vascular access
- Needle phobia
- Cardiac failure
- Coagulopathy

Modified from Peritoneal Dialysis Adequacy Work Group. Clinical practice guidelines for peritoneal dialysis adequacy. *Am J Kidney Dis.* 2006;48(suppl 1):S91–S97.

HOME HEMODIALYSIS

In the 1960s, maintenance dialysis was mostly done by the patient and the family at home. Because in-center HD programs were established and then PD became available, people could choose not to have HD at home. This removed the burden of dialysis from the individual and family and avoided the cost of installing a dialysis machine with its associated water treatment. In the United Kingdom the percentage of the adult dialysis population having home HD fell from 35% in 1984 to 1% in 2006.[44]

Home-based HD offers similar clinical outcomes compared with facility-based HD and provides significant benefits: it removes the inconvenience of traveling to and from the dialysis facility, gives individuals the freedom to dialyze at a time that suits them, reduces the cost of nursing and support staff, and gives the individual more opportunities to take part in home and work activities.[45]

People who dialyze at home often perform more than three treatments per week, and some dialyze overnight. More frequent dialysis significantly reduces the time taken to recover after each treatment, reduces dietary restrictions and antihypertensive medications, and leads to improved quality of life and reduced mortality.[46]

In recent years there has been increasing recognition of the benefits of home HD, and this, along with better technology, has increased nephrologists' enthusiasm for it.[47] In 2018, the proportion of individuals treated with KRT (including transplant) receiving home HD was 2.0% in the United Kingdom,[44] 2.1% in the United States,[20] and 2.6% in Canada; the highest proportion in Europe was 3.45% in Denmark.[48] Some countries achieve higher uptake: the proportion in Australia was 4.2% and in New Zealand 8.1%.[19,22]

Hemodialysis or Hemodiafiltration

Hemodiafiltration (HDF) is increasingly used throughout Europe and elsewhere but is not available in the United States because of regulatory restrictions. HDF adds the removal of fluid containing larger molecules by convection to the clearance of smaller molecules by diffusion. For example, β_2-microglobulin levels are lower in individuals treated by HDF than by HD. In this way, HDF theoretically mimics glomerular filtration more closely and potentially may benefit people with little or no residual kidney function.

A number of trials comparing outcomes with HD and HDF have been conducted, yielding conflicting results. Evidence suggests that high convection volumes (>30 L/wk/m^2) need to be used to deliver better outcomes if HDF is selected as the dialysis modality.[49]

CHOICE OF HEMODIALYSIS OR PERITONEAL DIALYSIS

Ideally, everyone with advanced CKD would be given "modality-neutral" counseling and allowed to select their preferred mode of treatment. When provided with modality education, people are more likely to select and be treated with PD.[50] Independent predictors for choosing PD include being married, being counseled before the start of dialysis, and increasing distance from the base unit; predictors for choosing HD are increasing age, comorbidity, and male sex. However, although 45% of patients may choose PD, not all of them start dialysis on this modality. Individuals who require urgent dialysis often receive HD rather than PD, although PD can be started urgently if the necessary resources are available.[51] Once started on HD, only a small proportion transfer to PD, even if this was their original preference. Individuals who do transfer from HD to PD are more likely to have technique failure in the following 12 months.[52] Patients presenting late for dialysis can start PD urgently,[53] and if they do start hemodialysis, they still should have access to an education program about their options for long-term treatment.

Frail individuals can be assisted to have PD at home by a spouse, family member, or trained assistant. This can avoid them having the burden of in-center HD and improve their quality of life,[54] and they may progress to independent PD after a month or two of assistance.[55]

The major differences in dialysis modality across countries (see Fig. 95.6) suggest that the type of dialysis individuals receive is more often determined by physicians and organizational factors than by their preferences.

IMPORTANCE OF DIALYSIS ACCESS

Before starting dialysis, every patient would ideally have made an informed choice between PD and HD after weeks or months of counseling and preparation, and those choosing HD would have a functioning AVF. Unfortunately, dialysis is frequently started in less than ideal circumstances. The percentage of individuals presenting shortly before starting dialysis varies between dialysis units and countries (Fig. 95.7). This is a particular issue in the United States, where in 2015 only 31% of individuals beginning KRT had received 12 months of nephrology care before KRT.[56]

People presenting to a nephrologist shortly before starting dialysis have a longer initial hospital stay and a higher incidence of major complications and death.[10] Late presentation is one reason why HD is started using a catheter rather than an AVF (Fig. 95.8), and increased catheter use is associated with increased mortality.

The timing of AVF placement is complex.[57] If an AVF is created many months before the individual is predicted to reach kidney failure, then the chances that a catheter is used are reduced. However,

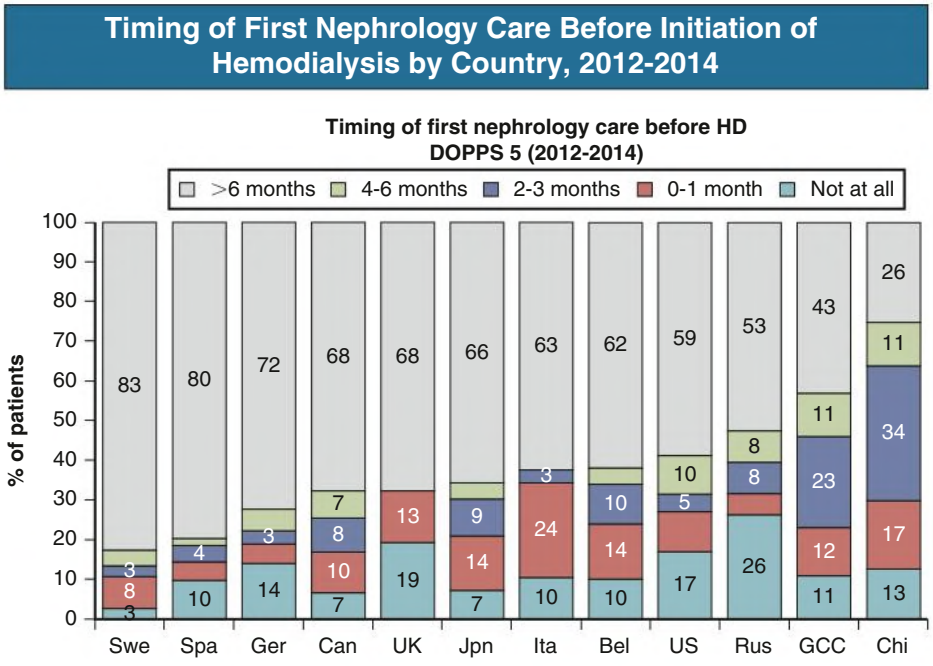

Fig. 95.7 Global Differences in Timing of First Nephrologist Care Before Starting Dialysis Among Individuals Enrolled in the Dialysis Outcomes and Practice Patterns Study (DOPPS) Within 60 Days of Starting Dialysis (2012–2014). elderly individuals may die without the AVF ever being used.[58] AVF placement after dialysis has started is associated with a lower chance of long-term fistula use.[59] International data from the Dialysis Outcomes and Practice Patterns Study show that the risk for death is higher for individuals dialyzing in units that use central venous catheters in a high proportion of patients.[60] The risk is also increased if arteriovenous grafts are commonly used. Catheters can cause complications such as infection, pulmonary embolism, and central venous stenosis.

There is wide variation across countries in the time required for permanent access to be created and used. If a fistula can be created swiftly and used as soon as it is mature, perhaps after only 2 weeks, the need for a catheter may be avoided. Details of HD access surgery are discussed in Chapter 96 and PD catheter placement in Chapter 101.

DECISION WHETHER TO OFFER KIDNEY REPLACEMENT THERAPY

Availability of Dialysis Facilities

Because of its high cost, KRT is not available to most people with kidney failure worldwide. The practice of rationing dialysis has been candidly documented in a report from a South African center,[61] in which more than half the people with kidney failure assessed between 1988 and 2003 were not offered dialysis. Socioeconomic factors such as age, race, employment, and marital status outweighed medical factors in the decision to begin treatment.

The phenomenon of "supply-sensitive care" applies to dialysis as it does to health care in general.[62] KRT incidence is independently associated with a country's GDP, the percentage of GDP spent on health care, and the reimbursement rate relative to GDP for HD dialysis facilities. In more developed countries, those with a greater proportion of private for-profit facilities have a higher incidence of dialysis.[63]

Selection by Physicians and Nephrologists

Although incidence rates of KRT in most countries have increased in recent decades (see Fig. 95.2), not all of this is due to increases in the incidence of kidney failure.[63,64] In other words, physicians have become more willing over time to offer dialysis to people with kidney failure. The practice of starting dialysis in people who are very elderly and dependent on others for their care or who have multiple comorbid conditions varies significantly across countries and among nephrologists within those countries.[65] In the UK only 19% of individuals on hemodialysis were fully independent. In Japan in 2010, 13% of individuals treated with hemodialysis had dementia, and 54% of these individuals spent more than half the day in bed.[66]

Uncertainty about prognosis, lack of palliative care services and training, and financial incentives toward providing dialysis may persuade nephrologists to offer dialysis.[67]

Rationing Versus Rational Dialysis Treatment

How dialysis should be used has raised a range of bioethical issues over the years.[68] In the 1960s, committees would meet to decide who should be offered dialysis, on the grounds that the greatest good should be derived from the limited resources available. Individuals who were expected to survive for only a few months would not be offered dialysis. As resources became more widespread, a rationing approach became unacceptable and was replaced by decisions based on the balance of benefit and harm gained from dialysis for each individual.

Predictive Factors

Are there objective criteria that can be applied to identify individuals for whom the harms of dialysis will outweigh the benefits? One criterion to be dismissed is age. Although advanced age was used as a simple exclusion criterion in the early days of dialysis, the elderly are now the most rapidly growing section of the dialysis population.

There are several mortality risk prediction scores that estimate 6-month mortality for individuals starting dialysis.[69] For older individuals, a high Ramipril Efficacy in Nephrology (REIN) score predicts 6-month mortality with high sensitivity and specificity.[70]

ADVISING ABOUT PROGNOSIS ON DIALYSIS

Despite these uncertainties, individuals should be given an estimate of their likely future on dialysis. The Renal Physicians Association (RPA) has suggested the following criteria to help identify those over 75 years of age who have a poor prognosis on dialysis[71]: (1) clinicians' response of "No, I would not be surprised if my patient died in the next 6 months"; (2) high comorbidity score; (3) significantly impaired functional status (e.g., Karnofsky Performance Status score <40); and (4) severe chronic malnutrition (i.e., serum albumin <2.5 g/dL using the bromocresol green method). Quality of life is also strongly predictive of mortality, even after statistical correction for these comorbid factors.

For individuals whose prognosis is particularly uncertain, or where there is disagreement between the views of the individual and the dialysis team, a time-limited trial of dialysis may be offered. This may give the individual and their family a better understanding of what life on dialysis entails and allow time for further discussion between all parties. The duration of the trial should be judged for each person, and clinical and biochemical parameters such as serum albumin reviewed regularly.

The RPA in the United States has issued guidelines for decisions to not initiate or to discontinue dialysis (Fig. 95.9) and provides a comprehensive toolkit to support shared decision-making.[71]

CONSERVATIVE KIDNEY CARE

Conservative kidney care can be defined as planned, holistic, patient-centered care for individuals with stage 5 CKD including a full range of treatment and support but not dialysis.[72] This modality is increasingly adopted for a subset of individuals with kidney failure and multiple comorbidities.[73] To date, evidence to inform discussions about conservative care as an alternative to dialysis has come from observational studies of varied quality.[74] A meta-analysis found that at 1-year survival was similar for individuals managed with dialysis (73%) and conservative care (71%), but that at 2 years survival diverged to 62% for the dialysis group and 44% for the conservative care group. The Prepare for Kidney Care trial has been undertaken to address this evidence gap.[75] It is an RCT comparing preparing for either dialysis or conservative care in frail, multimorbid older individuals with advanced CKD.

When asked in a survey about their priority between quality of life or extending the length of life if they were faced with a serious illness, Europeans strongly favored quality of life, with only a few expressing a preference for extending life.[76] Individuals who are likely to have an unacceptable quality of life should not be subjected to the discomfort of dialysis. Individuals choosing conservative kidney management are spared surgical procedures and the inconvenience and discomfort of traveling to the HD unit or performing PD. Depending on age and the number of comorbidities, survival with dialysis may be no longer, and much of any additional time is made up of days having or recovering from dialysis treatments.[77] Quality of life is likely to be better without dialysis, and patients are more likely to die at home.

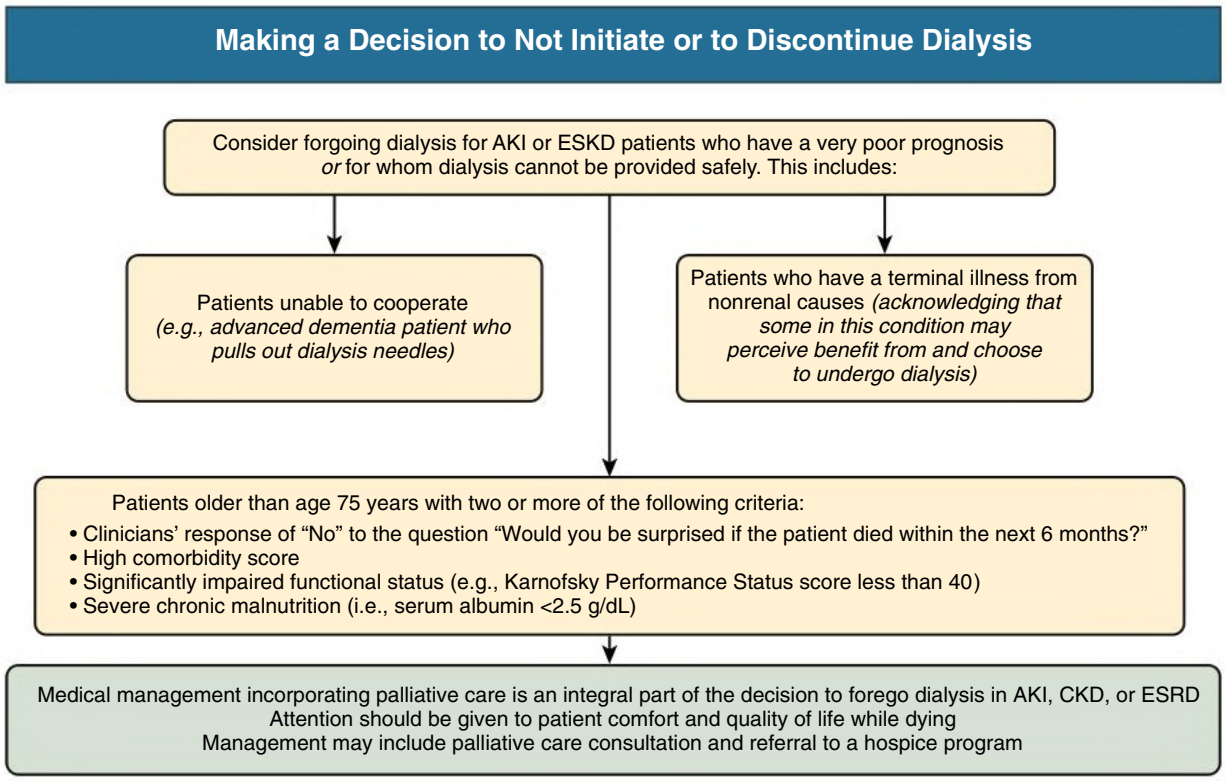

Fig. 95.9 Making a decision to not initiate or to discontinue dialysis. *AKI,* Acute kidney injury; *CKD,* chronic kidney disease; *ESKD,* end-stage kidney disease.

Many of the symptoms and complications of kidney failure, such as anemia, acidosis, itching, insomnia, depression, fluid overload, and hypertension, can be treated with medication and diet. Individuals may not report symptoms such as pain or itching that they do not associate with kidney failure and so should be asked specifically about them.[78] Symptom management tools and other resources for individuals who chose conservative care and their care providers are available at https://www.ckmcare.com/.

Family physicians can be supported to deliver conservative care along with a specialist CKD multidisciplinary team and palliative care specialists.

INDIVIDUALS WHO DO NOT WANT DIALYSIS

Nephrologists may be presented with the dilemma of someone who has decision-making capacity and whom they would normally treat but who does not wish to have dialysis. From an ethical viewpoint, an individual's decision not to start dialysis or to discontinue it is justified on the principle of individual autonomy. Legally, in the United Kingdom this is based on the individual's common law right to self-determination and in the United States on the constitutional right of liberty. Where the individual is able to express a clear wish, the physician is obliged to respect this, because to treat them against their will constitutes an assault.

The physician must nonetheless ensure that all reversible factors have been addressed, such as unfounded fears about what dialysis will entail or a depressive illness affecting the patient's judgment, and ideally request a psychiatric evaluation. It is not uncommon for individuals to express a strong desire not to have dialysis, particularly if they are relatively asymptomatic, only to change their mind when they become more symptomatic. At this late stage, the basic "will to survive" comes to the fore. An advance directive not to have dialysis should never be held as a reason against a change of mind.

DISAGREEMENT ABOUT A DECISION TO DIALYZE

There will inevitably be differences of opinion about the harms and benefits of dialysis to individuals. Dialysis nurses may disagree with the nephrologist's decision to treat someone. If the dialysis nurses and doctors are functioning well as a team, they should feel able to express these reservations and have the issue adequately discussed. It is demoralizing for staff to feel pressured into giving treatment they believe to be inappropriate.

The nephrologist may remain reluctant to offer dialysis despite the insistence of either the individual or, more often, their family or caregivers, the legal agent, or another doctor (see Fig. 95.9). Dialysis must never be given if it is against the individual's clearly expressed wishes, despite the insistence of others. However, if they insist on treatment against the nephrologist's advice, dialysis usually should be given while a resolution is reached.

Extensive discussions and explanations of the treatment options and prognosis may be needed to gain a better understanding of the reasons behind the differing views. Helpful advice may be obtained from another physician, particularly the individual's family doctor, who will have a broader understanding of their circumstances. It may be appropriate to involve a psychologist, social worker, or religious counselor.

It may be necessary to refer the case to a formal ethics committee, if one exists locally, to clarify the issues of disagreement and enable a resolution. A physician cannot be compelled to offer treatment against his or her professional judgment, but the physician is ethically and legally obliged to attempt to transfer the care of the individual to another physician. Only as a last resort, if no alternative dialysis unit can be found and after adequate notice has been given, should dialysis be withdrawn. The RPA Clinical Practice Guideline Toolkit provides a systematic approach to conflict resolution if there is disagreement regarding the benefits of dialysis[71] (Fig. 95.10).

MANAGEMENT OF DISRUPTIVE INDIVIDUALS ON DIALYSIS

Most nephrologists have had experience of treating a small number of individuals who, for one reason or another, will not comply with the discipline required for maintenance dialysis and who become disruptive to the staff and others. This behavior can range from nonadherence with treatment, which harms the individual but is merely inconvenient to the staff, to verbal or even physical aggression toward the staff and others in the unit. The impact of this small number of individuals can be very great.

The strategy for dealing with this situation must be tailored to the individual, particularly their decision-making capacity. Useful suggestions for resolving conflict have been provided by the RPA (Box 95.2). They emphasize the importance of understanding, information, patience, and persistence. However, the bottom line for individuals who have capacity and are aggressive toward staff on the dialysis unit must be that they are taken off dialysis and sent home.

RESUSCITATION AND WITHDRAWAL OF DIALYSIS

Cardiopulmonary Resuscitation

If people are to be fully involved in making decisions about their treatment, two sensitive issues need to be discussed: cardiopulmonary resuscitation (CPR) and the possibility of withdrawal of dialysis. The two are not necessarily linked; individuals may wish to continue with dialysis but express a desire that resuscitation not be attempted should they have a cardiac arrest. The outcome of CPR in patients treated with dialysis is worse than in the general population, the odds ratio for mortality being 1.24 (95% confidence interval, 1.11–1.3; $P < .001$). In 2011 survival after CPR in the United States was 31%, but a greater proportion of people with kidney failure who survived a cardiac arrest were discharged to skilled nursing facilities.[79] In Taiwan in 2012, 18.8% of individuals suffering an in-hospital cardiac arrest were discharged from hospital, with a median survival of 6.8 months.[80] For a witnessed cardiac arrest in an outpatient dialysis unit, fewer than half survive and are admitted to hospital, and only 26% survive to discharge from hospital.[81]

A decision not to attempt CPR must be documented in the individual's medical and nursing records, and all nursing staff must be made aware of it. It is important to be clear what is meant by "cardiac arrest" and for there to be agreement on how the nursing staff should respond to a hypotensive "crash" while on dialysis. These notes may form part of an advance directive, as discussed later.

Withdrawal of Dialysis

It is not possible to predict accurately which individuals will gain prolonged benefit from dialysis; thus, many nephrologists offer dialysis to all individuals with kidney failure who wish to have it. This policy ensures that no one is denied dialysis but has the inevitable consequence that some people are started on dialysis who subsequently have an unacceptable quality of life. The possibility of withdrawing dialysis needs to be addressed if these individuals are not to suffer unreasonably.

Rates of withdrawal vary widely between countries and cultures. Withdrawal rates are much higher in Australia, New Zealand, and

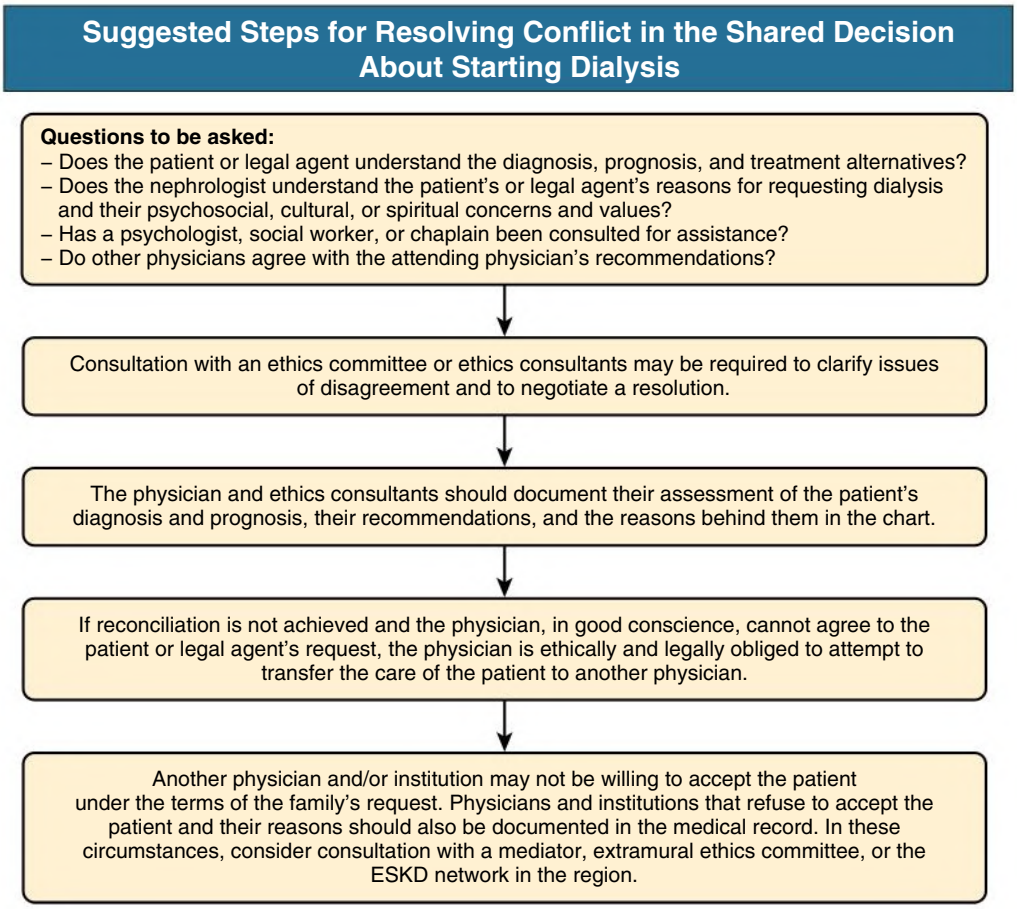

Fig. 95.10 Suggested steps for resolving conflict in the shared decision about starting dialysis. *ESKD,* End-stage kidney disease. (Modified from Shen JI, Mitani AA, Saxena AB, Goldstein BA, Winkelmayer WC. Determinants of peritoneal dialysis technique failure in incident US patients. *Perit Dial Int.* 2013;33[2]:155–166.)

BOX 95.2 Suggested Steps for Dealing With Disruptive Individuals

Identify and document problem behaviors and discuss them with the individual.

- Seek to understand their perspective.
- Identify their goals for treatment.
- Share control and responsibility for treatment with them.
  - Educate them so they can make informed decisions.
  - Involve them in the treatment as much as possible.
  - Negotiate a behavioral contract with them.
- Consult a psychiatrist, psychologist, or social worker for assistance in clinical management or determination of decision-making capacity.
- Be patient and persistent; try not to be adversarial.
- Allow the individual to vent concerns but do not tolerate verbal abuse or threats to staff or others.
- Contact law enforcement officials if physical abuse is threatened or occurs.
- If satisfactory resolution has not occurred with these strategies, contact the local ESKD Network to discuss the situation and ensure due process.
- As a last resort, consider transferring the individual to another facility or discharging them.
- Obtain legal advice before proceeding with plans for discharge, and do not discharge without advance notice and a full explanation of future treatment options.

Modified from Butler CR, Mehrotra R, Tonelli MR, Lam DY. The evolving ethics of dialysis in the United States: a principlist bioethics approach. *Clin J Am Soc Nephrol.* 2016;11(4):704–709.

Canada than in Japan and Italy.[82] For the countries where withdrawal is more common, the rates are much higher in the 4 months after the start of dialysis. Individuals who withdraw from dialysis are more likely to be older and female, require assistance for transferring and eating, reside in an institution, and have multimorbidity. Rates of dialysis withdrawal are higher in units where conservative care is always or usually discussed, which suggests that individuals' wishes are not always fully included in these decisions.

People may be reticent to express a wish to withdraw from dialysis. Many see it as their duty as a patient to go along with the treatment recommended by their physician and do not wish to appear ungrateful for the efforts that are being made to keep them alive. Their physician may be the last member of the team to learn about their views, and it is very important that good communication exists within the multidisciplinary team so that any clues that the individual gives are acted upon. Staff should adopt a proactive approach and raise the issue of withdrawal of dialysis with individuals who are not thriving.

People's willingness to discuss planning for the end of their life will be affected by factors such as age, ethnicity, cultural background, and religious beliefs, as well as the circumstances of their daily lives. Qualitative research suggests that, when done sensitively, raising the subject of death does not destroy hope for the future. Early discussion of these issues can lead to a more satisfactory outcome for patients, relatives, and staff when the individual eventually dies. In the United States, formal advance directives play an important part in these discussions, and helpful guidance on how to conduct sensitive interviews has been published.[83]

In the United Kingdom, dialysis teams may enter individuals on an "at risk" register so they can receive appropriate assessment and care. The dialysis unit should have close links with palliative care specialists so there is a smooth transition from maintenance to palliative dialysis, where priority is given to symptoms and person-centered outcomes. Palliative care for people with kidney disease is discussed further in Chapter 94. Individuals who take a long time to recover after a dialysis treatment may benefit from reducing the number of treatments per week.[84]

When someone is no longer competent to make a decision, an advance directive can provide a clear legal basis for the decision to stop dialysis. Indeed, some US states (e.g., Missouri and New York) insist that dialysis must be continued in the absence of such clear and convincing written evidence. In other US states and the United Kingdom, the physician is given the task of deciding on the individual's behalf. Helpful advice for dialysis staff and individuals wishing to complete an advance directive is available in the RPA Clinical Practice Guideline Toolkit (see Fig. 95.9).[71]

Once someone has expressed a wish for dialysis to be withdrawn, or his or her relatives have raised the issue, the first priority must be to identify any reversible factors that may improve their health sufficiently for the decision to be reversed. In particular, any depression must be identified and treated. Once all these factors have been ruled out, the process of withdrawing dialysis should be managed according to some key principles (Box 95.3).

BOX 95.3 Key Principles Underlying the Process of Withdrawal of Dialysis

- The ultimate responsibility for the decision rests with the physician, not the relatives or caregivers.
- The individual's interests and dignity should be protected at all times.
- The process should not be rushed. If there is any doubt about the correctness of the decision, treatment should continue.
- There should be an open discussion among the multidisciplinary team to avoid any damaging disagreements.
- The psychological needs of the health care team should not be overlooked.
- Palliative care must be given in the most appropriate environment (e.g., a hospice or, ideally, the individual's own home).

Withdrawing dialysis should not be seen as an admission of failure but as a final stage in the process of KRT. The opportunity provided by dialysis to complete unfinished emotional and financial business can make the subsequent bereavement period much less traumatic. Managing this terminal phase can be uniquely rewarding, particularly if it allows an individual and their family and caregivers to prepare themselves for the end of their life.

SELF-ASSESSMENT QUESTIONS

1. Which of the following provides the *best* outcomes in someone with advanced CKD?
   - **A.** Deceased donor transplant
   - **B.** Preemptive living donor transplant
   - **C.** Home hemodialysis
   - **D.** Peritoneal dialysis
2. Early initiation of dialysis is associated with:
   - **A.** improved survival
   - **B.** improved quality of life
   - **C.** decreased morbidity
   - **D.** higher health care costs
3. Dialysis should be started in someone with advanced CKD when:
   - **A.** eGFR is less than 15 mL/min/1.73 m^2 (CKD stage 5)
   - **B.** Urine output is decreased
   - **C.** Clinical and biochemical features of azotemia develop
   - **D.** Serum bicarbonate is less than 20 mEq/L
4. A decision to transfer someone to multidisciplinary renal care should be made when:
   - **A.** symptoms of kidney failure begin
   - **B.** the eGFR reaches 10 mL/min/1.73 m^2
   - **C.** the individual is in CKD stage 4 with stable eGFR
   - **D.** the trajectory of eGFR indicates a likely need to start kidney replacement therapy within the next 12 months
5. The nephrologist may withhold dialysis from someone with end-stage kidney disease:
   - **A.** if they have verbally expressed a wish not to have dialysis.
   - **B.** if it is against the judgment of the nephrologist.
   - **C.** if the individual is disruptive on dialysis.
   - **D.** if the dialysis nurses do not wish to continue dialysis.
6. Which of the following is *not* predictive of a poor prognosis on dialysis?
   - **A.** Karnofsky performance status score less than 40
   - **B.** Severe chronic malnutrition
   - **C.** Age older than 75 years
   - **D.** Physician would not be surprised if the individual died within the next 6 months

Vascular Access for Hemodialysis

Jan H.M. Tordoir, Charmaine E. Lok

Functional vascular access is needed for all extracorporeal dialytic therapies and is the lifeline for patients treated with chronic hemodialysis (HD). The three main forms of vascular access are the arteriovenous fistula (AVF), arteriovenous graft (AVG), and central venous catheter (CVC). Arteriovenous (AV) access refers to either an arteriovenous fistula or graft. The ideal AV access should have a suitable superficial conduit (autogenous or synthetic) that allows for two-needle cannulation that delivers blood flow for effective dialysis (Qb), with intraaccess flows (Qa) usually in the range of 400 to 1500 mL/min. A well-planned vascular access should be functional when needed for dialysis, have good primary patency, have few complications, and align with the patient's end-stage kidney disease (ESKD) Life-Plan.[1] Previously, it had been taught that the ideal access should be an AVF placed peripherally at the wrist. However, because upper arm and lower limb access sites or CVCs are increasingly used due to the patient's limiting anatomy or circumstances (e.g., frail elderly with multiple comorbidities, exhaustion of access sites, future transplant), a more comprehensive approach to vascular access choice was developed that considers the patient's ESKD Life-Plan.

ESKD LIFE-PLAN

The ESKD Life-Plan is an individualized map of kidney replacement modalities (hemodialysis [HD], peritoneal dialysis, transplantation) required during the patient's life with chronic kidney disease (CKD). All patients with progressive CKD and/or with estimated glomerular filtration rate (eGFR) of 15 to 20 mL/min/1.73 m^2 or already on kidney replacement therapy should have a Life-Plan. The Life-Plan is regularly reviewed and revised after considering the patient's unique medical and life circumstances and their informed preferences. The appropriate dialysis access is then chosen to align with and support the patient's ESKD Life-Plan; if done correctly, each patient would then have an individualized PLAN: ***p***atient ***l***ife-plan and their ***a***ccess ***n***eeds.[1] Within "access needs," there are three main components: (1) insertion/creation plan, (2) contingency plan (a plan to manage complications), and (3) succession plan. Concurrently, there must always be a vessel preservation plan to ensure viability for future access as required. Therefore, each vascular access must include four plans: vessel preservation plan, insertion/creation plan, contingency plan, and succession plan.[1]

Vascular access should be created in a timely manner by a surgeon or interventionalist experienced in vascular access creation to avoid unnecessary CVC use and its associated complications.[1] However, vascular access complications are almost inevitable and may require management by endovascular procedures or surgical revision. A multidisciplinary approach to access creation and maintenance (involving nephrologists, interventional radiologists, access surgeons, and dialysis nurses) helps optimize HD access–related outcomes and minimize costs.

EVALUATION OF THE PATIENT FOR VASCULAR ACCESS

CKD patients should be considered for vascular access if they have progressive decline in kidney function and referred when eGFR is 15 to 20 mL/min/1.73 m^2. Earlier referral should occur in patients with unstable and/or rapid rates of GFR decline (e.g., >10 mL/min/1.73 m^2/yr).[1] Patients with a failing kidney transplant or who are not responding to peritoneal dialysis should be assessed for vascular access in a timely manner to avoid CVC use when transitioning to HD. If an AV access is deemed appropriate based on the ESKD Life-Plan, the type and site of the vascular access will be based on the following:

- *Physical examination*, with careful inspection and palpation of arterial pulses and venous vasculature. Particular attention is paid to the venous filling capacity, with use of a blood pressure cuff and variable pressures, and to the presence of venous collaterals and swelling. The nondominant arm is not necessarily the preferred side, and the decision should be based on the quality of the vessels and future access needs.
- *Vascular mapping* is usually done with Duplex ultrasound and provides information about the venous vasculature (particularly in obese patients and in the upper arm) and the diameter of the brachial, radial, and ulnar arteries; detects vascular calcifications; and reveals the blood flow volume in the brachial artery. The resistance index (a measure of arterial compliance) can be calculated from the differences between the high-resistance triphasic Doppler signal with clenched fist and the low-resistance biphasic waveform after the fist is released. A preoperative resistance index of 0.7 or higher in the feeding artery indicates insufficient arterial compliance (often associated with arterial calcification), warning of lower success with AVF creation. Guidelines support vessel mapping in most patients (Table 96.1).
- Additional angiography and/or phlebography is needed only in very difficult cases or in patients with previous ipsilateral CVCs to rule out central vein stenosis or obstruction; the use of radiocontrast media should be minimized in patients with residual kidney function.

Preservation of vessels is crucial for the success of vascular access. Patients should be instructed to protect their veins, restricting blood sampling and intravenous cannulas to the dorsum of the hand whenever possible. Physicians that may access radial arteries for interventional procedures (e.g., cardiac investigations) should be alerted to consider alternate access for these procedures.

VASCULAR ACCESS TYPES

Autogenous Access

Distal Forearm Fistulas

Radiocephalic arteriovenous fistula. A well-functioning distal radiocephalic AVF in the nondominant arm is the ideal permanent

TABLE 96.1 Risk Factors for Which Vessel Mapping May Be Beneficial

Clinical Problem	Risk Factors
Fistula failure	Elderly age; female sex; comorbidities (e.g., peripheral vascular disease; coronary artery disease)
Peripheral vessel damage	PICC insertion; iatrogenic vein damage; radial artery harvesting for coronary artery bypass grafting
Central venous stenosis	Multiple CVC; prolonged CVC duration; cardiac implantable electronic device; PICC; surgery or trauma to neck, chest or upper extremity
Limitations to physical examination	Severe obesity; suboptimal conditions (dehydration or vasoconstriction); poor skin integrity

CVC, Central venous catheter; *PICC,* peripheral inserted central catheter.

access for HD. This usually gives adequate blood flow and a long length of superficial vein for needling. It also leaves proximal sites for further procedures in the event of failure. Although this distal radiocephalic AVF is the aim for incident patients, its creation and success may be compromised if the cephalic and antecubital fossa veins are damaged because of thrombophlebitis and/or thrombosis from previous intravenous cannulas or venipunctures.

A radiocephalic AVF is usually created at the wrist but can be created more proximally in the forearm if distal vessels are inadequate (Fig. 96.1). On occasion, three or four radiocephalic AVFs can be created at progressively more proximal sites in the forearm before a brachiocephalic AVF is created. The radiocephalic AVF at the wrist was initially described as a side-to-side anastomosis, but an end-to-side configuration is preferred to reduce the risk of venous hypertension in the radial aspect of the hand.

The patency of radiocephalic fistulas varies from center to center and from surgeon to surgeon. Reported primary failure rates vary from 5% to 60%, and 1-year patency rates vary from 52% to 71% (Table 96.2),[2-8] primarily due to early thrombosis and AVF nonmaturation. Risk factors for early failure include diminished radial artery or cephalic vein size or quality, female sex, older age, greater and complex comorbidity, and center effect.[9,10] Patients deemed at high risk for distal radiocephalic fistula primary failure should be considered for a proximal elbow or upper arm AVF or forearm graft, depending on the patient's ESKD Life-Plan.

Proximal Forearm and Upper Arm Fistulas

Although a radiocephalic AVF is preferable, the first created vascular access is increasingly an upper arm AVF with use of an autogenous superficially located arm vein,[11] especially in patients with comorbidities such as diabetes mellitus, coronary heart disease, and peripheral vascular disease.[12,13]

The upper limb is preferred to the lower limb for vascular access because of the ease of cannulation, comfort for the patient, and considerably lower incidence of complications. Similarly, autogenous conduits are preferable to the use of prosthetic grafts because of better patency and lower risk of infection.

Forearm cephalic and basilic vein transposition. Vein transposition or elevation increases the possibilities for creating a forearm fistula. The cephalic vein is preferred, but if it is unsuitable, the more deeply located basilic vein can be transposed from the ulnar to the radial side along a straight subcutaneous course from the elbow to the radial artery. Alternatively, an anastomosis from the basilic vein to the ulnar artery can be performed with additional volar transposition to facilitate needling for dialysis.

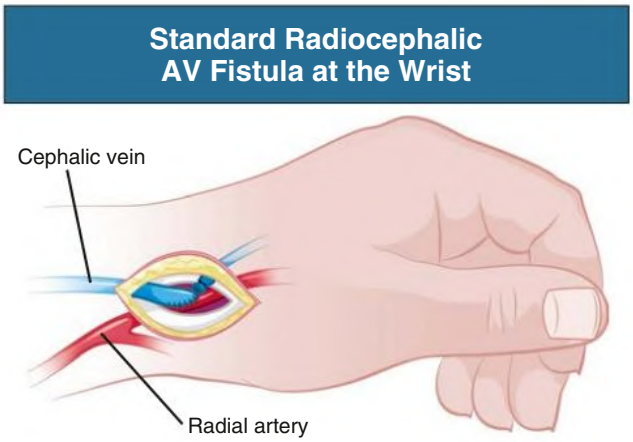

Fig. 96.1 Standard Radiocephalic Arteriovenous (AV) Fistula at the Wrist. Anastomosis of end of vein to side of artery.

Different surgical techniques (with or without vein transposition) have been advocated according to the forearm artery and vein location, with the possibility of achieving 91% fistula maturation[14]; for example, in one study 15% of participants had a straightforward AVF, 33% required vein transposition from dorsal to volar, and 52% required superficial forearm vein transposition before arterial anastomosis. Primary patency rates were 84% at 1 year and 69% at 2 years. Cannulation of radiocephalic and/or brachiocephalic AVFs may be difficult, particularly in obese patients. Preplanned vein elevation or transposition techniques in such patients can be effective and should be considered; the primary failure rate has been reported to be 15%, with a 1-year patency rate of 84%. Alternatively, surgical lipectomy or liposuction can be performed to facilitate cannulation of deeply located AVF.[15]

Elbow and upper arm cephalic vein arteriovenous fistula. The brachiocephalic and antecubital configurations can be used for AV anastomoses in the elbow region. If possible, the anastomosis can be created between the cephalic, cubital, or perforating vein and the brachial artery, typically 2 cm distal to the elbow, which optimizes opportunities for cannulation along the cephalic vein in the upper arm (Fig. 96.2). The outcome of a brachiocephalic AVF is usually good, with high primary function and good long-term patency; studies show a 10% early failure rate caused by nonmaturation and an 80% 1-year patency rate.[16,17] Two-year primary, assisted primary, and cumulative patency rates were 40%, 59%, and 67%, respectively. Primary patency means that the access is functioning without any intervention; assisted primary patency means that the access is functioning but required a preemptive intervention for flow decline. Cumulative or secondary patency refers to accesses that are functioning after intervention for thrombosis. The term *cumulative patency* is preferred to reduce confusion and improve standardization for communication about vascular access.[1,18] The early failure and 1-year patency rates of brachiocephalic AVFs are shown in Table 96.3.[16,17,19-21] Newer endovascular options for creation of antecubital AVF, typically between the perforating vein and ulnar or radial arteries, have recently been described. Early data are promising, demonstrating both technical success and 6-month patencies each greater than 88%.[22-24]

Upper arm basilic vein arteriovenous fistula. The upper arm basilic vein is usually inaccessible or painful for dialysis cannulation because of its medial and deep position. Therefore, the basilic vein needs to be superficialized and transposed to an anterolateral position. In the

two-step approach to creating a brachiobasilic AVF, the anastomosis is first constructed, followed by a second operation, usually 6 weeks later, whereby the arterialized vein is mobilized into a subcutaneous position to enable needling (Fig. 96.3). Alternatively, in the one-step approach to creating the brachiobasilic AVF, the vein is elevated and transposed into position at the time of anastomosis creation. Primary failure rates are 2% to 26%, with 1-year cumulative patencies varying from 69% to 86%.[25]

Brachiobasilic AVF have several advantages over forearm or upper arm AV grafts, such as less infection and thrombosis. A meta-analysis found that brachiobasilic AVFs have superior primary and cumulative patency compared with AV grafts[26] and should be preferentially considered in difficult access cases and when suitable according to the PLAN.[1]

Lower limb vascular access. The main indications for lower limb vascular access are bilateral central venous or caval obstruction,

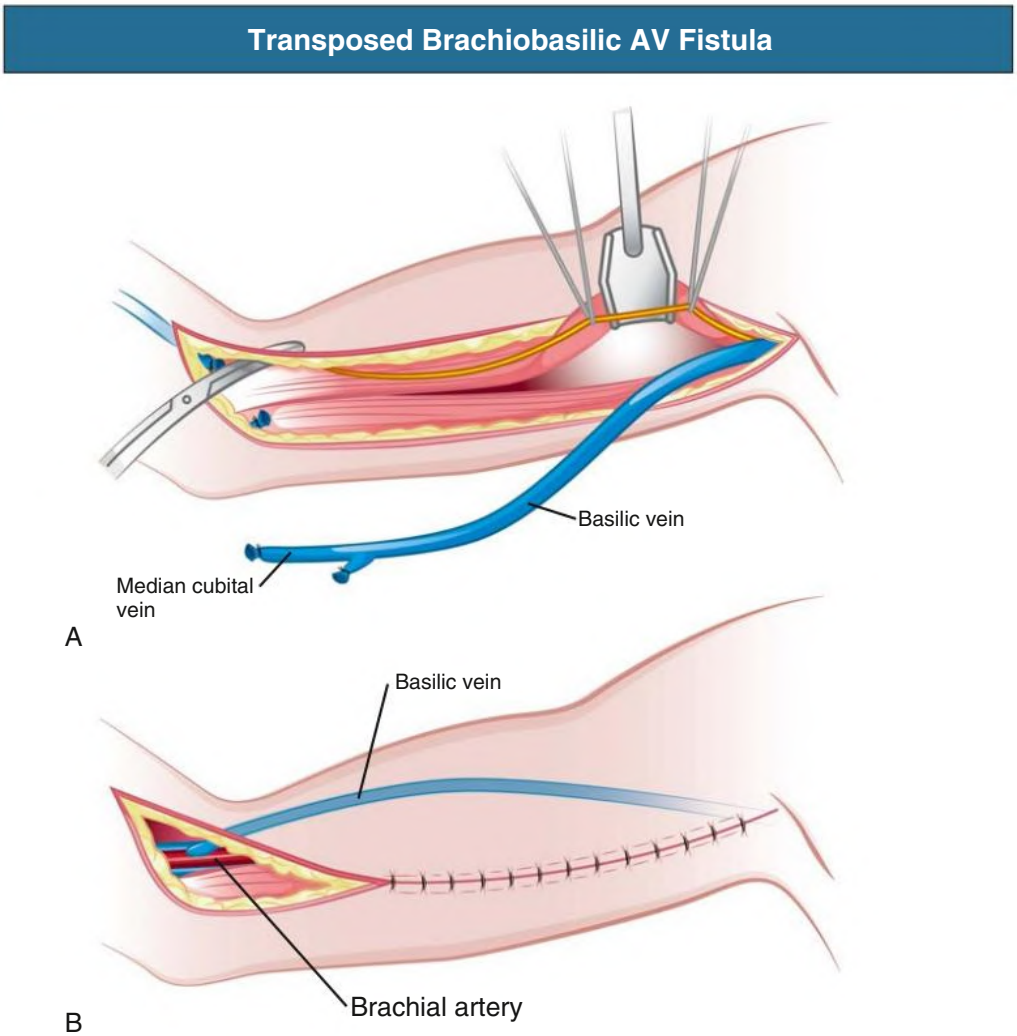

Fig. 96.3 Transposed Brachiobasilic Arteriovenous (AV) Fistula. (A) Dissection of the basilic vein. (B) Anterolateral transposition and brachial artery anastomosis.

which endangers the outflow of upper limb AVFs. Saphenous and superficial femoral vein transposition is a primary option for thigh AVFs, although this carries a relatively high risk for distal ischemia. If clinical evaluation indicates incipient ischemia, primary flow reduction by tapering of the anastomosis is indicated to prevent complications. Synthetic AV graft implantation in the thigh bears a high risk for infection and septicemia.[27]

NONAUTOGENOUS SYNTHETIC VASCULAR ACCESS

Arteriovenous Grafts

An AV access (referring to AVF or AV graft) is preferable to a CVC, whenever feasible. When autogenous AVF creation is impossible, an AV graft should be considered. Xenografts such as the ovine (sheep) graft are an alternative access conduit with acceptable patency and low infection rates. However, the most frequently used synthetic grafts are made of expanded polytetrafluoroethylene (ePTFE) and, less commonly, polyurethane. These prosthetic grafts can be implanted in a wide variety of locations and configurations in the upper and lower limbs (Fig. 96.4). At present, early cannulation of AV grafts (within 24 hours of surgery) is feasible because of newer graft compositions. In randomized controlled trials (RCTs), they have been shown to be catheter sparing and have equivalent patencies to standard AV grafts.[28,29]

The primary patency rates of AV grafts vary from 60% to 80% at 1 year and from 30% to 40% at 2 years of follow-up. Secondary patency ranges from 70% to 90% and from 50% to 70% at 1 and 2 years, respectively.[30-33] The new KDOQI Vascular Access Guidelines 2019 have helpful algorithms for the appropriate use of early cannulation and standard AV grafts.[1]

CENTRAL VENOUS CATHETER ACCESS

CVCs are widely used to initiate HD despite recommendations for AV access use.[1,34,35] Data from the Dialysis Outcomes and Practice Patterns Study (DOPPS)[36] indicate that 15% of HD patients in the United States are dialyzed with catheters; in other countries, CVC use is even more common (Canada, 45%; Belgium, 38%; United Kingdom, 16%). Two types of CVC are used: nontunneled CVC for short-term use, and tunneled cuffed CVC, which can be used for several weeks to months or as permanent access in patients without AV access options. Nontunneled CVCs are associated with higher infectious complications and should be limited to less than 2 weeks duration of use. Box 96.1 provides indications for short- and long-term use of CVCs. Although the physical CVC characteristics (i.e., design and geometry) theoretically influence the performance (blood flow rate, recirculation, and resistance) and affect the overall efficiency of the HD therapy and morbidity risk

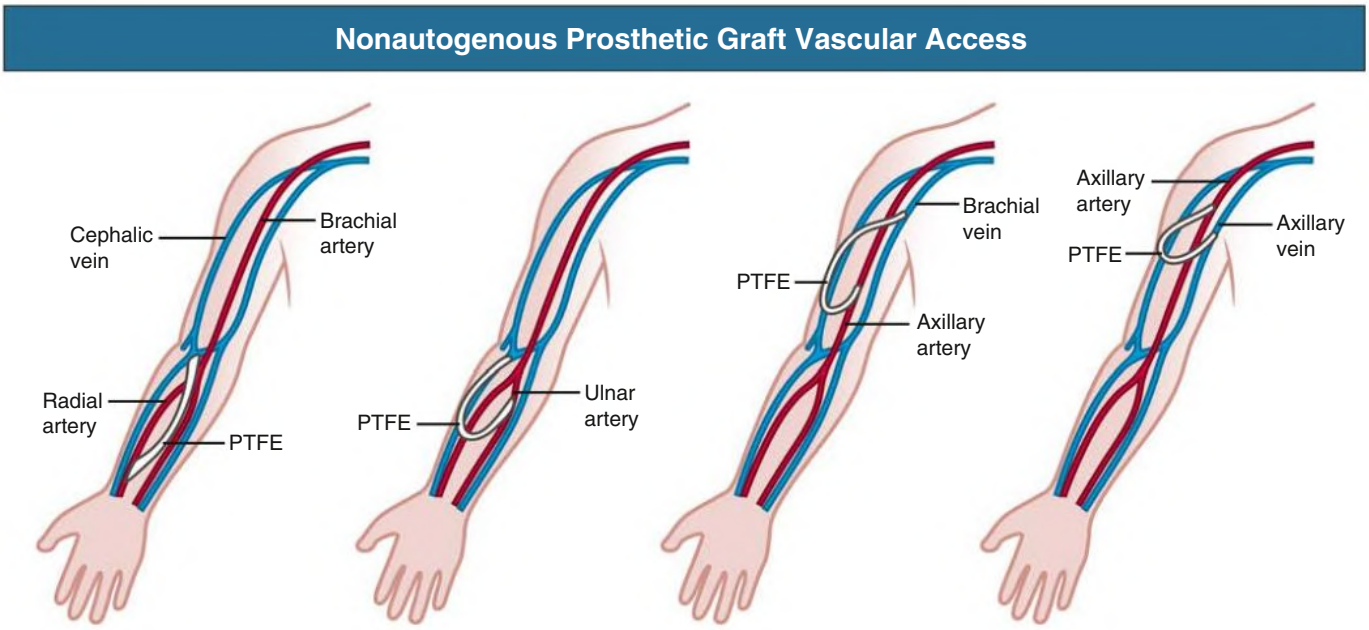

Fig. 96.4 Nonautogenous Prosthetic Graft (Polytetrafluoroethylene [PTFE]) Vascular Access. Straight and loop configuration in upper limb.

BOX 96.1 Indications for Short and Long-Term Use of Central Venous Catheters

- Temporary switch from another modality (PD-related complications; transplant acute rejection)
- Awaiting live-donor kidney transplant with established surgical date
- Short-term use of nontunneled CVC awaiting placement of tunneled CVC
- Temporary use if established AV access is temporarily unusable (e.g., maturing fistula); AV access requiring cannulation-free time due to complication (e.g., significant infiltration injury)
- Limited life expectancy (<6 months)
- Clinical conditions that worsen with AV access (heart failure with ejection fraction <15%; nontreatable skin lesions where cannulation increases infection or rupture risk)
- All other AV access options have been exhausted
- Patient choice after proper informed consent

AV, Arteriovenous; *CVC,* central venous catheter; *PD,* peritoneal dialysis.

(infection, thrombosis), no CVC type has been proven consistently superior to another.[1,37]

Nontunneled Catheters

Single- or double-lumen CVCs are usually made of polymers (polyethylene, polyurethane), which enable easy insertion. The length of the CVC must be appropriately chosen to consider the anatomic insertion site. The femoral route requires catheters of 27 to 35 cm in length for the distal tip to be located in the inferior vena cava. The internal jugular vein route needs shorter catheters of 19 to 25 cm in length, with tip location at the mid–right atrium. The ideal CVC diameter is 12 to 14 Fr to allow sufficient blood flow to achieve adequate dialysis.

Tunneled Catheters

Tunneled CVCs have two lumens, each having a length of 40 cm, 10 cm of which is tunneled under the skin; the cannulae are made of synthetic polymer with a large internal lumen and, typically, a Dacron cuff to ensure subcutaneous anchoring. The CVC characteristics rely on the type of polymer, design, and geometry (e.g., double-lumen CVC, dual CVC, split CVC). The use of tunneled CVCs is associated with reduced morbidity and consistently better performance compared with noncuffed, nontunneled CVC.[38]

Both tunneled and nontunneled CVC are inserted percutaneously by the Seldinger technique with ultrasound guidance and fluoroscopy. The internal jugular vein and femoral vein routes are preferred because of ease of insertion and lower risk of some complications, such as central vein stenosis, compared with subclavian vein insertion (Fig. 96.5). Radiologic placement of tunneled translumbar HD catheters (TLDC) is a safe and technically successful procedure in those with exhausted conventional CVC access. Compared with traditional CVCs, TLDCs have higher complication rates, exchanges, and removals (>30% of patients), usually due to poor blood flow and infection. These catheters function well in the short term but are typically considered a last resort.

VASCULAR ACCESS COMPLICATIONS

Primary Arteriovenous Fistula Problem: Nonmaturation

The AVF needs time to mature, allowing the vein to enlarge and toughen so that it can be needled for dialysis. Depending on the practice pattern and dialysis prescription, typically 6 to 12 weeks for maturation is required. AVF may be successfully cannulated by 2 weeks but can take as long as 9 months.[35,39] Nonmaturation rates vary from 7% to 60%. The essential components of a successful AVF are a sufficient vein diameter of 4 to 5 mm for needling and Qa greater than 500 to 600 mL/min, for a typical dialysis prescription with a Qb of 300 to 400 mL/min, in order to prevent recirculation and achieve dialysis adequacy in a 4-hour time frame. Although these criteria have been used in research studies, clinical practice has informed that usability of AVF for cannulation is best judged by an experienced dialysis nurse with or without ultrasound vein diameter and access flow measurements. The statement of successful cannulators, such as "It's the feel of the integrity and 'toughness' of the fistula, not just the size that determines

Tunneled Cuffed Double-Lumen Central Venous Catheter Inserted in the Right Internal Jugular Vein

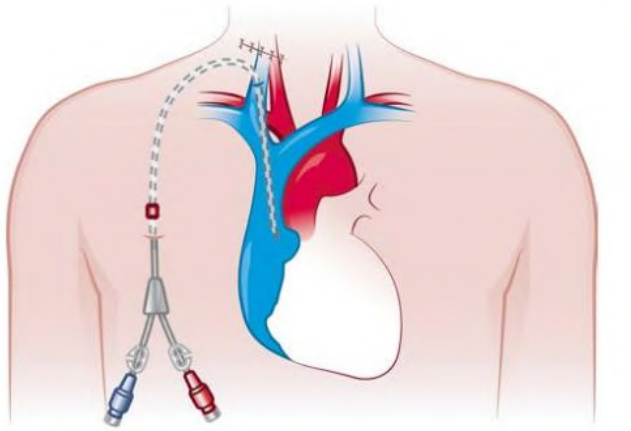

Fig. 96.5 Tunneled cuffed double-lumen central venous catheter inserted in the right internal jugular vein.

successful usability," highlights that objective measurement should support, and not replace, cannulation experience.

Fistulas that fail immediately do so as a consequence of poor selection of vessels, poor surgical technique, or postoperative hemodynamic instability. New AVFs should be assessed by the operator within 2 weeks of creation with 4 to 6 weeks follow-up by the team if there is suspected nonmaturation. Almost all early, non–process-related AVF failures involve vascular abnormalities. Therefore, duplex ultrasound investigation can detect poor flow, stenosis, and accessory branches, guiding the interventional radiologist and surgeon to the appropriate treatment. More than half of the stenoses detected are in the perianastomotic area. Arterial inflow stenoses of more than 50% reduction in vessel diameter are seen in less than 10% of nonmaturing fistulas, but if identified, they should undergo angioplasty. Anastomotic and swing segment (in which the vein has been mobilized and swung over to the artery) stenosis may be treated percutaneously or surgically, depending on local expertise.

Percutaneous intervention includes angioplasty (± drug coated balloons) of stenotic lesions, coil embolization, or ligation of accessory or collateral veins. In patients with residual kidney function (either predialysis or on HD), the risk of further loss of kidney function as a result of radiocontrast load can be mitigated by use of CO_2 angiography or by performance of ultrasound-guided angioplasty of the nonmatured fistula.[1,40] Percutaneous transluminal balloon angioplasty (PTA) is further discussed in Chapter 97.

When a surgical approach is selected, nonmatured AVFs should be reconstructed, usually under regional or local anesthesia. The anastomosis is exposed and ligated; the vein then can be divided, mobilized proximally, and reanastomosed to the proximal radial artery.

Limiting or preventing early failure is difficult, as the physiologic, functional, pathologic, and process of care factors that contribute to AVF failure or nonmaturation remain elusive.[9,41,42] An RCT that compared brachial plexus block (BPB) with local anesthesia for AVF creation showed superiority of BPB, with significant improvement in the primary outcome of patency at 3 months. Consideration may be given to using BPB for AVF creation.[43] Hand and finger exercise may improve maturation and can be considered 2 weeks post AVF creation.[1] The use of far infrared therapy appears promising, but its availability and generalizability is limited.[1,44,45] To date, there are no consistent medical therapies found to improve maturation.

Primary Arteriovenous Graft Problem: Reduced Patency

Numerous studies have evaluated the influence of AV graft material and design on AV graft patency. Theoretically, modulating the distensibility (e.g., polyurethane grafts) or geometry of the arterial inlet or venous outlet of the AV graft may have a beneficial effect on intimal hyperplasia. However, clinical studies of polyurethane grafts and those using tapered (at the arterial side of the graft) AV grafts did not improve patency rates, nor did cuff implantation at the venous anastomosis. Cuff-shaped prosthesis (e.g., Venaflo) may be beneficial.[46,47]

Because ePTFE AVGs are prone to thrombosis, infection, and intimal hyperplasia at the venous anastomosis, tissue-engineered vascular grafts have been developed as a potential solution to these limitations. Preliminary results of human studies suggest these biologic grafts are safe and functional; further phase III studies are underway.[48]

Both Aggrenox and fish oil have been found to improve primary patency of AV grafts.[49,50] Fish oil has also been shown to reduce the rate of thrombosis and interventions. Given its low cost and safety, fish oil can be considered in patients who need AV graft access.[1]

General Arteriovenous Access Problem: Stenosis and Thrombosis

Vessel stenosis is common in both autogenous AVFs and prosthetic AVGs. Intimal hyperplasia, with smooth muscle cell migration, proliferation, and matrix deposition, is the major cause of stenosis formation and thrombosis. The cause of the intimal hyperplasia is multifactorial, with uncertain contributing factors. They range from the uremic environment, the impact of surgery, the high wall shear stress caused by the access flow itself, and the downstream effect of the denuded endothelial cell layer, resulting in platelet adhesion and initiation of a cascade of proteins that stimulate the smooth muscle cells to proliferate and to migrate.[51,52] Progressive stenosis leads to access flow deterioration and subsequently thrombotic occlusion. Prophylactic repair of access stenoses may prevent thrombosis and prolong access patency.

Autogenous Arteriovenous Fistula Stenosis or Thrombosis

AVF stenosis should be suspected if the vessel diameter is reduced by more than 50% and is accompanied by clinical indicators such as difficulties with cannulation or prolonged bleeding time after decannulation (indicating high intraaccess pressure caused by outflow vein stenosis). Box 96.2 discusses clinical indicators. In AVFs, 55% to 75% of the stenoses are close to the AV anastomosis, 25% in the venous outflow tract, and 15% in the arterial inflow. In brachiocephalic and brachiobasilic AVFs, stenosis is typically located (other than the anastomosis) at the junction of the cephalic with the subclavian vein (cephalic arch) and the basilic with the axillary vein (junctional stenosis). Initial evaluation of suspected access stenosis is by ultrasound; angiography is used subsequently when intervention is planned.

Endovascular treatment by PTA is the first option for arterial inflow and venous outflow stenoses and junctional stenoses, with the option of stent or stent-graft placement.[53] These techniques are discussed further in Chapter 97. Use of stents or stent grafts should avoid cannulation segments.[1] Some stenoses may not be sufficiently dilated by conventional balloons (12–16 atm), and in these accesses, cutting balloons or ultra-high-pressure balloons (up to 36 atm) may be applied. Drug-eluting balloons have shown to be beneficial in preventing restenosis; however, data are conflicting.[54,55] Surgical revision may be appropriate, depending on the nature and location of the lesion; for

BOX 96.2 Clinical Indicators of Vascular Access Stenosis

Physical Examination

- Ipsilateral extremity edema
- Alterations in pulse, with a weak or resistant pulse, difficult to compress in the area of the stenosis
- Abnormal thrill (weak and/or discontinuous) with only a systolic component in the region of the stenosis
- Abnormal bruit (high pitched with a systolic component in the area of stenosis)
- Failure of the fistula to collapse when the arm is elevated (outflow stenosis) and lack of pulse augmentation (inflow stenosis)
- Excessive collapse of the venous segment upon arm elevation

Dialysis

- New difficulty with cannulation when previously not a problem
- Aspiration of clots
- Inability to achieve the target dialysis blood flow without any other cause
- Prolonged bleeding beyond usual for that patient from the needle puncture sites for three consecutive dialysis sessions
- Unexplained decrease in the delivered dialysis dose (Kt/V) on a constant dialysis prescription without prolongation of dialysis duration, and other variables excluded

example, a more proximal reanastomosis for swing segment stenosis is indicated after failed PTA of a radiocephalic AVF.

Fistula thrombosis should be treated as soon as possible because timely declotting allows immediate use of the AVF without the need for a CVC. Fistula intervention is ideal within 6 hours, and success is greatly reduced after 72 hours (grafts should be intervened on within 72 hours but can be salvaged up to 5–7 days). The duration and site of AV access thrombosis, as well as the type of AV access, are important determinants of treatment outcome. Thrombi become progressively fixed to the vein wall, which makes surgical removal more difficult. When the clot is localized at the anastomosis in radiocephalic and brachiocephalic AVFs, the outflow vein may remain patent because of continuing flow in its tributaries, making it possible to create a new proximal anastomosis.[56]

Thrombolysis can be performed mechanically or pharmacomechanically. Whereas the immediate success rate is higher in AVGs than in AVFs (99% vs. 93% in forearm AVFs), the primary patency rate of the forearm AVF at 1 year is much higher (49% vs. 14%). One-year secondary patency rates are 80% in forearm and 50% in upper arm AVFs.[57]

Nonautogenous Arteriovenous Graft Stenosis or Thrombosis

The most common cause of AV graft dysfunction and thrombosis is venous anastomotic stenosis. Because AV grafts are typically created in patients with exhausted peripheral veins, vein-saving procedures such as PTA or patch angioplasty are preferred to AV graft extensions to more central venous segments. When a stent or a patch fails, AV graft extension is still possible. Clinical monitoring of an AV graft is recommended (see Box 96.2) and can be supplemented with surveillance, such as access flow (Qa) measurement[1]; ultrasound detection of stenoses with preemptive endovascular treatment may diminish AV graft thrombosis but does not extend AV graft patency.

Intragraft (or midgraft) stenoses are found in the cannulation segment of AV grafts. They result from excessive ingrowth of fibrous tissue through puncture holes. These stenoses can be treated by PTA, AV graft curettage, or segmental AV graft replacement. When only a part of the cannulation segment is replaced, the access can be used immediately for HD without the need for a CVC. When restenosis occurs in a nonexchanged part of the AV graft, this can be replaced after healing of the new segment.

AV graft thrombosis can be treated with various percutaneous techniques and tools, including combinations of thromboaspiration, thrombolytic agents such as urokinase, tissue plasminogen activator (tPA), and mechanical thrombectomy. An initial success rate of 73% and primary patency rates of 32% and 26% at 1 and 3 months, respectively, are reported.[57] It is ideal to perform thrombolysis as soon as possible to avoid CVC use and as an outpatient procedure for best clinical outcomes and cost containment. Postprocedural angiography to detect and correct inflow, intraaccess, or venous outflow stenosis is mandatory.

When endovascular treatment fails or is not possible, surgical thrombectomy may be performed with a Fogarty catheter after venotomy, with correction of the underlying obstruction. On-table angiography should be performed after completion of thrombectomy of both the arterial and venous limbs of the graft.

Central Venous Obstruction

In the majority of patients, central vein obstruction is a result of previously inserted CVCs or pacemaker wires. In 40% of patients with subclavian vein catheters and in at least 20% with jugular vein catheters, central venous stenosis or occlusion will develop. Chronic swelling of the access arm is the most obvious sign, usually with prominent superficial collateral veins around the shoulder. The indications for intervention by PTA and stent placement are severe and disabling arm swelling, pain, finger ulceration, and inadequate HD. Contrast angiography of the access and complete venous outflow tract must be performed; ultrasound is not suitable for examining the central veins because of their retroclavicular location.

The benefits and risks of AVF, AVG, and CVCs are listed in Table 96.4.

Interventions to Manage Patency Complications

Endovascular intervention. Endovascular intervention is the first treatment option for central venous obstruction. PTA alone results in patency rates of only 10% or less at 1 year, and numerous restenoses may develop. Primary or additional stent implantation is associated with a better outcome, with 1-year patency rates up to 56% or higher.[58] Reinterventions are usually required to maintain patency and achieve long-term clinical success.

Stent placement should avoid overlapping the ostium of the internal jugular vein because this vein is essential for future placement of CVCs. Similarly, a stent placed in the innominate vein should not overlap the ostium of the contralateral vein; otherwise, contralateral stenosis may occur and preclude future creation of a contralateral AV access.

A percutaneous approach to bypass central venous obstruction with the "inside out" technique using the Surfacer System Inside-Out Access Catheter System is a novel and daring method for gaining central venous access.[59]

Surgical intervention. When endovascular treatment of central venous obstruction fails, surgical revision with bypass grafting is indicated. Surgical bypass to the ipsilateral jugular vein or contralateral subclavian or jugular vein is the first option in these patients. Alternative surgical approaches for upper limb vascular accesses with compromised venous outflow are axillary vein to femoral, saphenous, or popliteal vein and right atrial bypasses.[60] In case of bilateral obstruction of the mediastinal veins, including the superior vena cava, it will not be possible to sustain upper limb access, and lower limb access will be required.

TABLE 96.4 General Benefits and Risks of AV Fistula, AV Graft, and CVC

AV Fistula	AV Graft	CVC
high maturation failure	low maturation failure	no maturation needed
difficult cannulation	easy cannulation	easy connection to dialysis machine
low-moderate infection rate	low-moderate infection rate	moderate-high infection rate
low-moderate revision rate	moderate-high revision rate	high revision rate
good long-term patency if maturation with few facilitative interventions	moderate long-term patency	short long-term patency
low thrombosis rate	moderate thrombosis rate	high thrombosis rate

AV, Arteriovenous; *CVC,* central venous catheter.

Ultimately, ligation of the upper limb access can be considered, which will relieve local symptoms but sacrifices a valuable dialysis access.

Pharmacologic approaches for access patency. Based on clinical trials, there is insufficient evidence to determine whether medical treatments such as ticlopidine, aspirin, fish oil, clopidogrel, dipyridamole, warfarin, and sulfinpyrazone improve the patency of AV accesses compared with placebo treatment; the quality of the evidence is low because of short follow-up periods, the small number of studies for each comparison, heterogeneity among trials, and incomplete reporting.[61] Warfarin may reduce AVG thrombosis but increases the risk for hemorrhage and vascular calcification.[62] A large trial showed that dipyridamole plus aspirin had a statistically significant but modest clinical effect in prolonging the duration of primary unassisted patency of newly created AVGs.[49] Fish oil reduced AVG thrombosis and also improved unassisted patency of newly created AVG in RCTs.[63,64] In a large randomized study, clopidogrel improved fistula thrombosis but not functional maturation and usability.[65]

Clinical trials in patients undergoing AVF and AVG creation, who had perivascular biodegradable collagen wraps with sirolimus placed at the anastomosis, demonstrated safety and feasibility of the sirolimus wrap. A phase III RCT is ongoing to assess the safety, efficacy, and patency outcomes of a perivascular sirolimus-eluting implant placed at the AVF anastomosis in HD patients receiving new AVFs.[66]

Vascular Access–Induced Ischemia

Vascular access–induced upper limb ischemia is a serious complication that without prompt intervention may lead to amputation. The incidence of symptomatic ischemia varies from 2% to 8% of the HD population.[67] Elderly patients, diabetics, patients with prior ipsilateral AV access, and those with peripheral or coronary arterial occlusive disease are most at risk for ischemia. Access-induced ischemia occurs more often with proximally located AVFs and high flow rates; such AVFs can induce a steal phenomenon with lowering of distal perfusion pressures, and when collateral circulation is inadequate, symptoms may occur. Pain during HD is a characteristic early symptom. A grade 1 to 4 classification for access-induced ischemia can be used to outline the severity of the disease; this ranges from minor symptoms to finger necrosis.[68]

- Grade 1: Pale and blue or cold hand without pain
- Grade 2: Pain during exercise or HD
- Grade 3: Ischemic pain at rest
- Grade 4: Ulceration, necrosis, and gangrene

For grades 1 and 2, conservative treatment of ischemia is advocated. With grades 3 and 4, interventional treatment is mandatory.

Diagnosis of Ischemia

Physical examination, including observation and palpation of peripheral vessels, may be inadequate and misleading for the diagnosis of symptomatic ischemia. Additional noninvasive testing with measurement of digital pressures and calculation of the digit-brachial index, transcutaneous oximetry ($TcPo_2$), ultrasound of forearm arteries, and access blood flow measurement are important steps in the diagnosis and decision-making process.[69] Finally, contrast angiography with visualization of the upper extremity arterial tree from the proximal subclavian artery to the distal palmar arches with and without AVF compression to enhance distal flow is obligatory to outline the strategy for treatment and determine whether endovascular or surgical options are preferred.

Endovascular and Surgical Management of Ischemia

The treatment strategy depends on the cause of the ischemia. Inflow arterial obstruction and distal arterial lesions are recanalized with small-caliber balloons or stent placement[70]; high-flow AVFs are suitable for flow-reducing procedures such as access banding and arterial inflow reduction by an interposition graft to a smaller forearm artery (revision using distal inflow [RUDI]) (Fig. 96.6).[71,72] Steal in itself may be corrected by ligation of the artery distal to the AV anastomosis or revascularization procedures such as the distal revascularization–interval ligation (DRIL) procedure (Fig. 96.7) or other procedures.[73]

Intraoperative digital pressure measurement (or $TcPo_2$) is mandatory to guarantee an adequate surgical intervention with acceptable outcome. A digital-brachial pressure index above 0.60 or $TcPo_2$ above 40 mm Hg is indicative of sufficient distal hand perfusion. In some patients, AVF ligation and transition to chronic CVC access or a change of dialysis modality to peritoneal dialysis may be the only solution.

Catheter-Related Infection

Catheter-related bloodstream infections are a significant cause of morbidity and mortality in HD patients. CVC use is associated with a higher risk of mortality compared with AV access.[1] Switching from CVCs to an AV access is associated with a lower risk of mortality compared with continuing CVC use.[74] CVC-related infections include bacteremia, tunnel infections and exit site infections. Any of these types of infection can progress to metastatic complications of osteomyelitis, septic arthritis, epidural abscess, and endocarditis. Nontunneled CVC have a higher rate of infection compared with tunneled CVC.[38] Each facility should track and monitor CVC-related infection rates, with a goal bacteremia rate of less than 1.5 per 1000 CVC days.[1]

Prevention of Catheter-Related Infection

The most important measure to prevent CVC infection is meticulous handling of the CVC at all times. The CVC should be inserted with use of maximal infection control precautions, per local facility guidelines. The dialysis nurses, technicians, or patient/caregiver (if home dialysis) needs to access the CVC under strict aseptic or sterile conditions; it is of the utmost importance that CVCs are never accessed by untrained

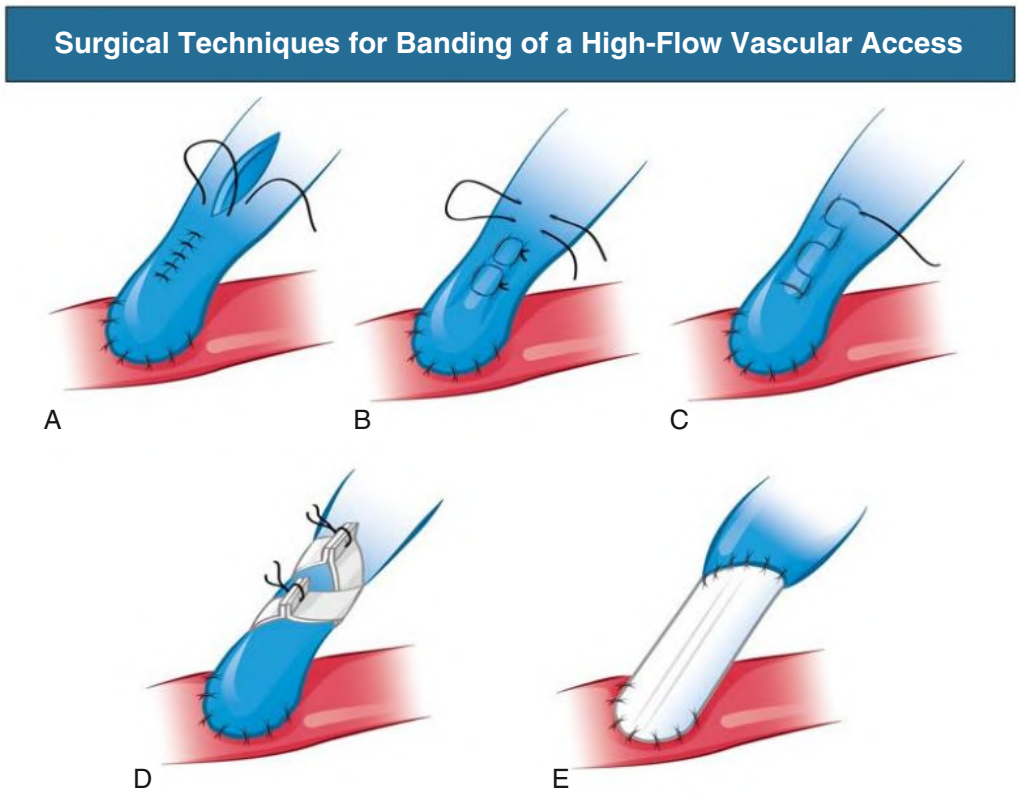

Fig. 96.6 Surgical Techniques for Banding of a High-Flow Vascular Access. (A) Open venoplasty. (B) Interrupted mattress suturing. (C) Continuous mattress suturing. (D) Polytetrafluoroethylene (PTFE) banding. (E) PTFE interposition graft. The choice of technique is made by the surgeon on a case-by-case basis.

personnel. An exemplar protocol for safe connection and disconnection of CVCs can be found in the KDOQI Vascular Access Guidelines 2019.[1] Catheter locking with trisodium citrate solutions appears to reduce bleeding and may reduce bacteremia compared with locking with heparin solutions.[75] However, it is unclear whether citrate alone has the same protective effect against systemic infection as it does when combined with other antimicrobial agents[76,77] and may depend on the concentration of citrate used.[77] Mupirocin ointment applied to the exit site may reduce the incidence of CVC-associated bacteremia, but there are concerns of CVC material breakdown and mupirocin resistance. Topical application of povidone, medi-honey, and Polysporin triple ointment to exit sites has been shown in multicenter RCTs to reduce the rate of CVC-related bacteremia. Polysporin triple has sustained efficacy with no demonstrated resistance after long-term follow-up.[1,78]

Treatment of Catheter-Related Infection

Managing catheter-related infections involves treating the patient and managing the catheter. Patients should have appropriate culture and sensitivities obtained and treated with antibiotics according to the results of the sensitivities. Until they return, the infected patient should be treated with empiric broad-spectrum antibiotics to cover both gram-positive and gram-negative organisms.

Various societies have issued recommendations for the management of catheter infections.[1,79] A recommended treatment algorithm is shown in Fig. 96.8. A more detailed algorithm can be found in the KDOQI Vascular Access Guidelines 2019, including durations of antibiotic use and special management considerations depending on the infecting organism. For example, if the infecting organism is *Staphylococcus aureus* causing bacteremia, an infectious disease consult may be considered. All such patients should undergo a 2D echocardiogram to evaluate for the presence of vegetations or endocarditis, and antibiotic treatment should be at least 4 weeks in duration.

Infections Involving Temporary Nontunneled Catheters

When a temporary nontunneled CVC becomes infected, it should always be removed. There is no role for trying to salvage temporary nontunneled catheters.[1]

Exit Site Versus Tunnel Tract Infections

An exit site infection is a localized cellulitis confined to the 1 to 2 cm where the catheter exits the skin. The majority of these infections respond well to oral antibiotics and meticulous exit site care, and the removal of the CVC is generally not required.[1,78] However, exit site infections can progress to tunnel tract infections, which involve the potential space surrounding the CVC more than 2 cm from the exit site (Fig. 96.9). Tunnel infections should be treated with intravenous antibiotics. Patients with a tunnel infection sometimes but not always have an associated exit site infection; untreated, they can rapidly develop bacteremia. Patients with a tunnel infection present with fever and local signs of pain, swelling, fluctuance, and erythema along the tract of the catheter. There may be purulent discharge from the exit site. Because tunnel infections involve a potential space in an area with limited vascular supply and an implanted synthetic device, they respond poorly to antibiotics alone and require catheter removal.[1,78]

Catheter-Associated Bacteremia

When a patient with a dialysis catheter has a fever, CVC-related bacteremia must be considered but other causes ruled out. If the patient does not have a clear and convincing alternative explanation for the fever, blood cultures should be obtained peripherally (e.g., dialysis circuit), as well as through the catheter hub[80]; as indicated earlier, the

Distal Revascularization-Interval Ligation (DRIL) for Ischemia in an Upper Arm Vascular Access

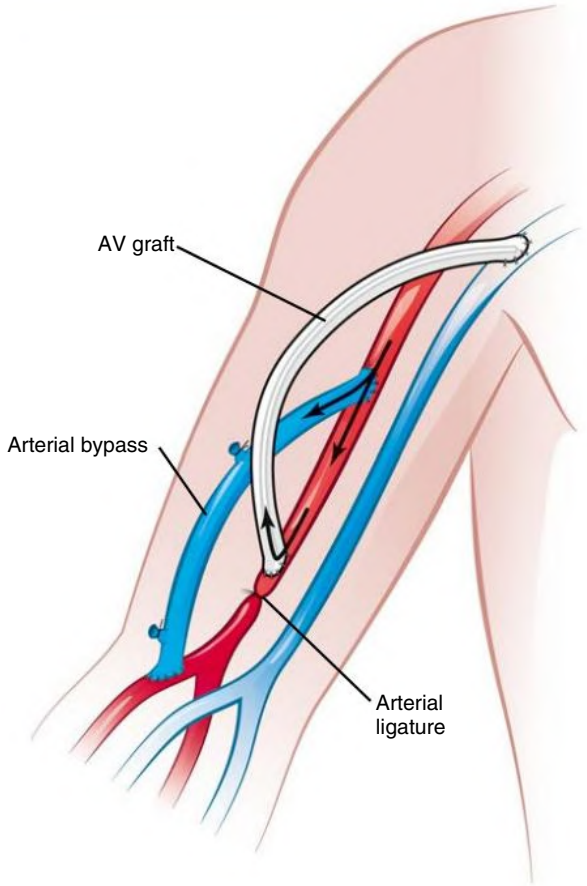

Fig. 96.7 Distal revascularization–interval ligation for ischemia in an upper arm vascular access. *AV,* Arteriovenous.

patient should be started on empiric antibiotics and adjusted based on culture results.[1] The most common organism is *S. aureus,* although a wide range of gram-positive and gram-negative organisms have been reported. An aminoglycoside or a cephalosporin is a good choice for gram-negative coverage; however, the presence of residual kidney function and local microbiologic epidemiology must be considered, especially with regard to antibiotic resistance.

Management of Catheter-Related Infection

The decision to remove a tunneled cuffed CVC because of an episode of CVC-associated bacteremia is not straightforward. The clinical condition of the patient and response to initial therapy, the presence of an infected fibrin sheath, metastatic complications, the infecting organism, and the availability of other vascular access sites must be taken into consideration (see Fig. 96.8).

The conventional approach is to remove the CVC with interval replacement at a different site after the infection has resolved. The efficacy of this approach is uncertain, and it requires temporary CVC insertion before a new CVC is placed. Further, if the CVC is removed without identifying and disrupting an infected fibrin sheath, a nidus of continual infections remains. A new CVC may inadvertently be placed back into the infected sheath. The ineffectively treated nidus of infection may explain why attempts to salvage an infected CVC with systemic antibiotic therapy is only successful in about 30% of patients. Another treatment option is to combine systemic antibiotics with antibiotic "lock" solutions. Many different combinations of antibiotics mixed with either heparin or citrate have been tested; the appropriate antibiotic lock depends on the culture sensitivities. A suitable broad-spectrum regimen is vancomycin 2.5 mg/mL, gentamicin 1 mg/mL, and heparin 2500 U/mL. Infection clearance rates of 50% to 70% are reported with antibiotic locking.

CVC exchange over a guidewire after 48 hours of antibiotic treatment can be more effective than treatment with antibiotics alone and is at least as effective as removal of the CVC and delayed replacement, with the advantages of only one invasive procedure and preservation of the venous access site.[76,81] This also has the advantage of disrupting a fibrin sheath, if present.[82,83]

Management of Central Venous Dialysis Catheter Infections

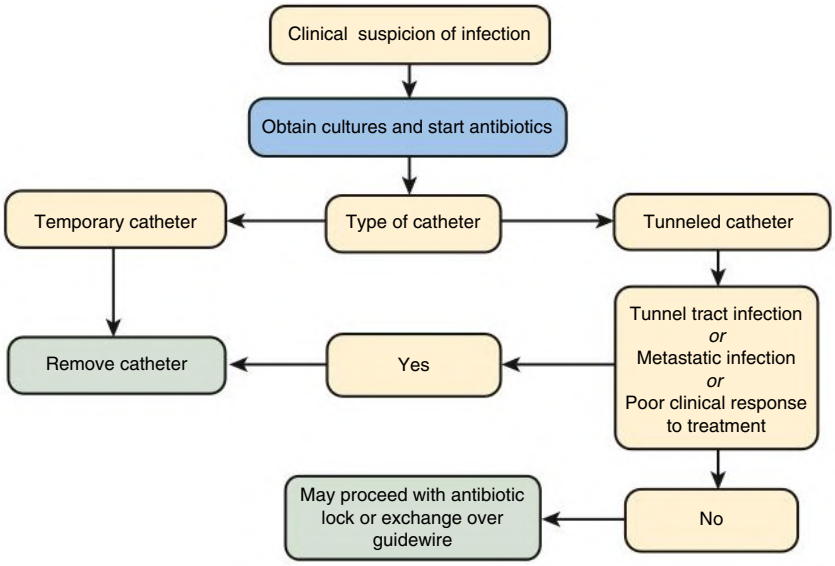

Fig. 96.8 Algorithm for the management of central venous dialysis catheter infections. (Modified from Manian FA. IDSA guidelines for the diagnosis and management of intravascular catheter-related bloodstream infection. *Clin Infect Dis.* 2009;49[11]:1770–1772.)

Catheter Thrombotic Obstruction

Catheter obstruction may be caused by endoluminal fibrin deposits, restricting the CVC lumen or obstructing CVC side holes or at the tip, or external fibrin sleeves surrounding the CVC, resulting in inadequate flow and excessive extracorporeal blood pressure alarms during the dialysis session. Depending on the location of the fibrin clot (arterial or venous line), there may be high negative arterial pressure (obstruction at the arterial CVC) or high positive venous pressure (obstruction at the venous CVC).

Prevention of clot formation in the CVC lumen and tip during the interdialytic period is crucial. This is achieved by installing an anticoagulant lock solution (heparin or trisodium citrate).[1] Catheter malfunction might be treated with regular thrombolytic locking (e.g., urokinase or tPA); further, routine prophylactic locking was found to reduce CVC malfunction and CVC-related bacteremia in a multicenter RCT.[84] RCTs have shown that regular use of low-dose warfarin or antiplatelet agents does not improve CVC function but increases the risk of major bleeding in HD patients.[1,62]

There are few established maneuvers to prevent CVC-related malfunction beyond the use of regular tPA, as demonstrated in the PRECLOT study[84]; however, the latter may become cost prohibitive. If a patient depends on CVC for HD access, the CVC may require multiple exchanges over guidewires. It is therefore critical to properly lay out the patient's ESKD Life-Plan and have a PLAN for each patient in order to appropriately limit CVC use and maximize safe, complication-free vascular access options for each patient.

SELF-ASSESSMENT QUESTIONS

1. The PLAN includes which of the following components?
   - **A.** The patient's ESKD Life-Plan only
   - **B.** A plan for the patient's individualized vascular access care only
   - **C.** The patient's ESKD Life-Plan and corresponding access needs (insertion/creation plan, contingency plan, succession plan, vessel preservation plan)
   - **D.** The plan for the hemodialysis access (insertion/creation plan, contingency plan, succession plan, vessel preservation plan)
2. AV access (fistulas and grafts) is preferred to CVCs because of:
   - **A.** the lower rate of thrombotic complications.
   - **B.** the lower rate of infections.
   - **C.** the lower rate of nonthrombotic complications.
   - **D.** all the above.
3. Ischemia in elbow fistulas with adequate access flow (800 mL/min) is best treated by:
   - **A.** access banding.
   - **B.** the DRIL procedure.
   - **C.** the revision using distal inflow procedure.
   - **D.** distal radial artery ligation.
4. Tunneled cuffed CVCs are preferred over nontunneled catheters because of:
   - **A.** ease of insertion.
   - **B.** lower occlusion rate.
   - **C.** higher dialysis flows.
   - **D.** lower infection rate.
5. The primary treatment option for symptomatic central vein occlusion is:
   - **A.** percutaneous transluminal angioplasty.
   - **B.** stent placement.
   - **C.** surgical bypass.
   - **D.** vascular access ligation.

Diagnostic and Interventional Nephrology

Haimanot Wasse, Stephen R. Ash

A variety of procedures are essential to the care of nephrology patients and include ultrasound, kidney biopsy, insertion of hemodialysis (HD) and peritoneal dialysis (PD) catheters, creation of arteriovenous fistulas (AVF), and diagnostic and interventional procedures to maintain HD access function. These procedures have traditionally been performed by other specialists but are increasingly performed by nephrologists. The field of diagnostic and interventional nephrology is most developed in the United States, where the American Society of Diagnostic and Interventional Nephrology (ASDIN) (https://www.asdin.org) has established training standards and certification procedures. This chapter covers insertion of dialysis catheters and interventions in vascular access, focusing on the applications of these procedures and their performance by nephrologists. Kidney biopsy is covered in Chapter 7, and placement of AVF and arteriovenous grafts (AVG) in Chapter 96. The role and interpretation of ultrasound are further covered in Chapters 5 and 6.

PERITONEAL DIALYSIS CATHETERS

Successful PD depends on proper catheter insertion and management, which can be done safely and successfully by nephrologists,[1-3] thus facilitating uptake of PD. Tenckhoff catheters are the most popular chronic peritoneal access devices; they are constructed of silicone rubber with a 5-mm external diameter and internal diameters of 2.6 to 3.5 mm and numerous intraperitoneal side holes. The intraperitoneal portion can be straight, straight with perpendicular silicone disks, or curled. Several design modifications have been developed in attempts to diminish outflow obstruction, including a version sold in Europe with a weighted tip. The subcutaneous portion is either straight or bent and has one or two extraperitoneal Dacron cuffs that prevent fluid leaks and bacterial migration around the catheter. One type of catheter has a silicone ball and Dacron disc at the parietal peritoneal surface. The subcutaneous portion is curved to give a lateral or downward direction of the exit site. An upward-directed exit site collects debris and fluid, increasing the risk for exit site infection. The method of catheter placement has more effect on the outcome than does the catheter type.

Catheter Insertion

There are four techniques for PD catheter insertion: dissection (surgical), the Seldinger technique (blind or with fluoroscopy), peritoneoscopic, and laparoscopic.[4] The Seldinger technique with fluoroscopy is the procedure used by most nephrologists, because it uses the same fluoroscope and some disposables used in placement of central venous catheters and angioplasty of AVGs and AVFs. Peritoneoscopic insertion is a single-puncture technique using a small (2.2-mm diameter) optical peritoneoscope for direct inspection of the peritoneal cavity and identification of a suitable site for the optimal intraperitoneal portion of the catheter. Peritoneoscopic placement is performed using local anesthesia (sometimes with conscious sedation) and manual infusion of about 1 L of air to allow visualization of the anterior peritoneal surfaces. This technique is not used by many nephrologists because it involves specialized training and equipment including the peritoneoscope, a video camera to display images, and a table allowing Trendelenburg positioning of the patient.

Laparoscopic techniques are performed with the patient under general anesthesia using larger scopes, multiple insertion sites, and automated gas infusion (usually CO_2). Both peritoneoscopic and laparoscopic techniques allow direct visualization of anterior peritoneal surfaces, to identify adhesions and hernias, and to choose the optimal location of the PD catheter. Laparoscopic placement allows advanced techniques for improving catheter function including omentopexy, correction of hernias, and removal of adhesions, which improve the long-term success of PD catheters.[5,6]

Any of the methods for PD catheter placement can be successful if the physician performing placement has sufficient experience with the technique. Randomized and nonrandomized studies have documented that the peritoneoscopic and fluoroscopic Seldinger techniques can result in fewer catheter complications (infection, outflow failure, pericatheter leak) and improved catheter survival compared with surgical placement.[2,7] The superior results with peritoneoscopic placement may relate to direct visualization of the abdominal cavity, less tissue dissection, and avoidance of general anesthesia. Because tissue dissection is minimal during placement, the catheter can be used for intermittent dialysis immediately, although there is an increased risk of peri-catheter leaks if the catheter is used immediately and continually for fluid exchange.[8,9]

For peritoneoscopic insertion (Fig. 97.1), a small skin incision (2–3 cm) is made and dissection of subcutaneous tissue down to the rectus muscle.[10] The anterior rectus sheath is identified but not incised. A preassembled cannula with trocar and a spiral sheath is then inserted at a 45-degree angle into the abdominal cavity through the rectus muscle toward the pelvis (see Figs. 97.1A and 97.2). The trocar is then removed and replaced by the 2.2-mm diameter peritoneoscope to confirm the intraabdominal position of the cannula (see Fig. 97.1B). Air is then infused (600–1000 mL) to separate the visceral peritoneum and parietal peritoneum, using a sterile syringe or rubber bulb. Alternatively, a Veress needle can be used for first insertion to the peritoneum, but this needle does not allow inspection of the peritoneal surfaces before gas infusion.[11] During peritoneoscopy, bowel loops, mesentery, the dome of the bladder, and intraabdominal adhesions are identified. The cannula and surrounding spiral sheath are advanced toward the pelvis, avoiding any areas of peritoneal adhesions (see Fig. 97.1C). The cannula and the peritoneoscope are then removed, the spiral sheath is dilated to 6-mm diameter (see Fig. 97.1D), and the catheter is inserted through the sheath while stiffened by a stylet (see Fig. 97.1E).

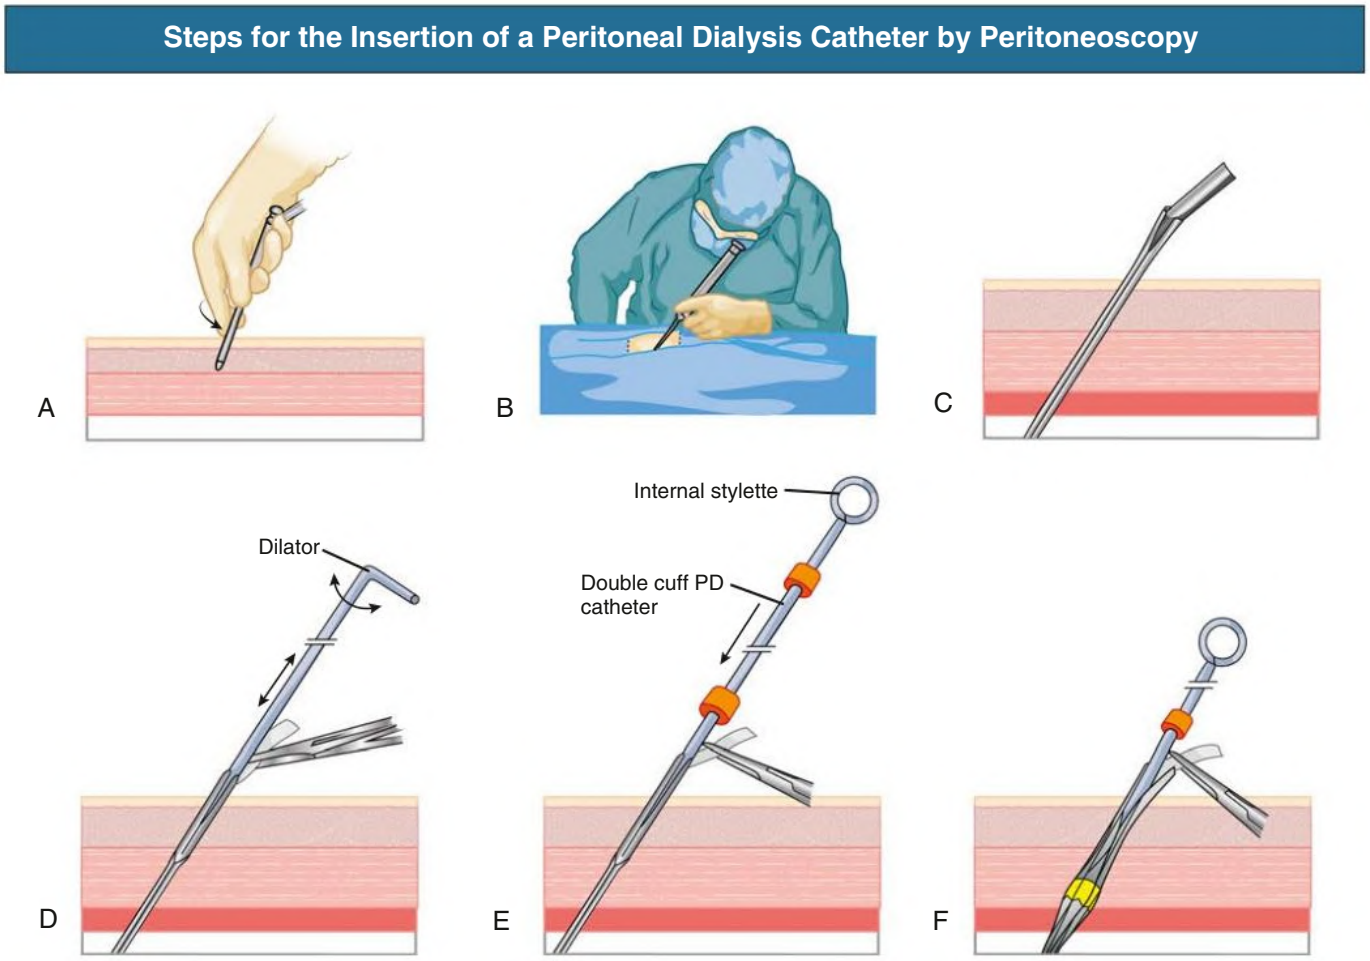

Fig. 97.1 Steps for the Insertion of a Peritoneal Dialysis (PD) Catheter by Peritoneoscopy. (A) A trocar and cannula with a sheath are inserted into the abdominal cavity. (B) A peritoneoscope is passed through and locked into the cannula. (C) The sheath has been passed into the abdominal cavity and the peritoneoscope and cannula removed sequentially. (D) The sheath is secured with forceps while it is being dilated. (E) A PD catheter (with double cuff) is passed through the dilated sheath by use of an internal stylet. (F) The deep cuff is implanted into the rectus muscle. (Modified from Y-Tec Instructions. *Laparoscopic and Peritoneoscopic Placement of Peritoneal Dialysis Catheters*. Medigroup Inc. [division of Janin Group, Inc.]; 2004:1–5.)

The deep cuff is implanted into the rectus muscle using an implanter tool without dissection of the anterior rectus sheath or the muscle (see Fig. 97.1F). A tunnel and an exit site are created, and the superficial cuff is implanted into the subcutaneous tissue. The dermis is sutured with absorbable material, and the epidermis is closed with nylon. No sutures are placed on the external rectus sheath or at the skin exit site. Instead of using a trocar, the cannula can be advanced into the peritoneal space over a 0.035-inch guidewire by placing a 7-mm dilator inside the cannula. This step is useful to inspect the peritoneum during a fluoroscopic placement, in case the guidewire does not progress as expected within the peritoneum.

The Seldinger technique using fluoroscopy begins with blunt dissection down to the level of the lateral border of the rectus sheath. An 18-gauge needle with internal blunt stylet or a 22-gauge needle from a 5-French micropuncture set is inserted at an angle of 45 degrees, directed toward the lower pelvis into the peritoneum (ultrasound is helpful to identify thickness of the rectus muscle and presence of adhesions to the parietal peritoneum).[12] The location of the needle within the peritoneal cavity is confirmed by injecting 1 to 5 mL of contrast material, which forms a classic "spider web" appearance on fluoroscopy as dye moves into small spaces between bowel loops and

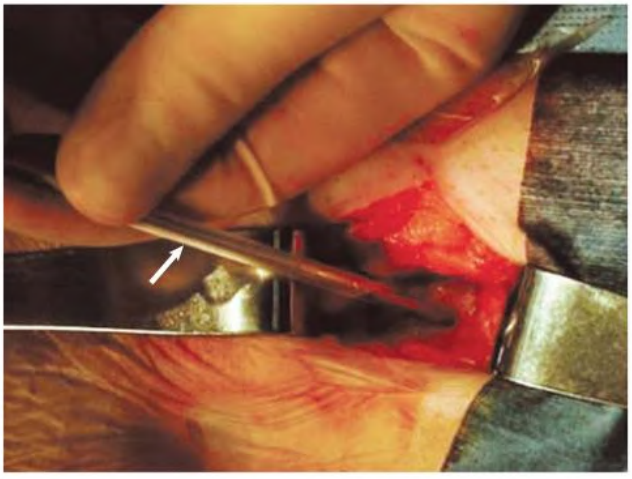

Fig. 97.2 Peritoneoscopic Insertion of a Peritoneal Dialysis Catheter. During peritoneoscopic insertion of a peritoneal dialysis catheter, a Quill guide trocar and cannula *(arrow)*, with its wrapped spiral sheath, is being inserted through the rectus muscle under local anesthesia.

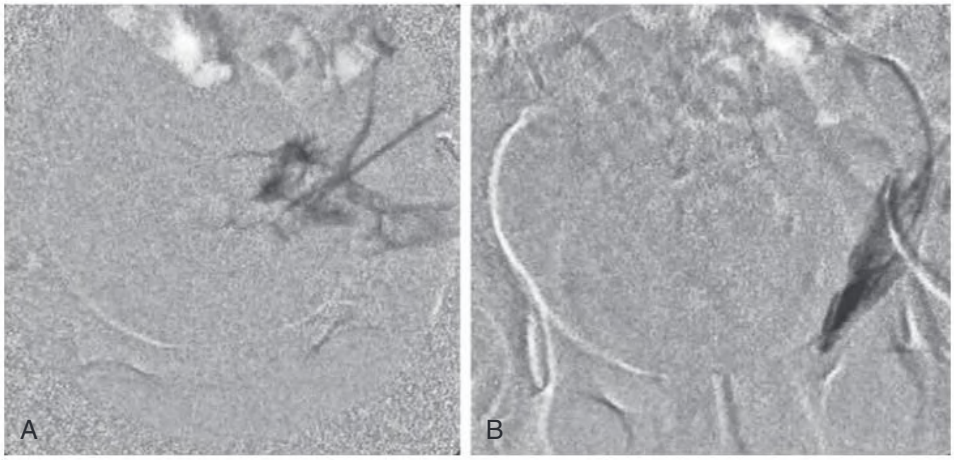

Fig. 97.3 (A) Fluoroscopic image after injecting a few milliliters of radiopaque dye through an 18-gauge needle after insertion through the rectus muscle and into the peritoneal space. Dye moves quickly away from the needle, and the image is not static. (B) Image after injecting a few milliliters of dye into an 18-gauge needle after insertion through the rectus muscle, with the tip of the needle in the preperitoneal space. Dye collects around the tip of the needle, at least one flat surface outlines the parietal peritoneum, and the image changes very little with time. (From Ash S, Sequeira A, Narayan R. Imaging and peritoneal dialysis catheters. *Semin Dial*. 2017;30[4]:338–346.)

parietal peritoneum (Fig. 97.3A).[12] If the tip of the needle is in the preperitoneal space, the dye collects around the tip of the needle, forms an outline of the parietal peritoneum, and appears static over a minute or so (Fig. 97.3B). If the tip of the needle appears to be preperitoneal, advancing the needle under fluoroscopic visualization allows the tip to penetrate the parietal peritoneal surface as confirmed by injection of a few milliliters of dye. If a micropuncture needle is used, an 0.018-inch guidewire is then inserted through the needle under fluoroscopy. Once the wire is in the lower pelvis, a 5-French catheter and internal dilator are advanced over the wire. Contrast material is again injected through the catheter to confirm the position. If an 18-gauge needle is used, a 0.035-inch guidewire is passed directly through the needle. Dilators are advanced sequentially over the guidewire up to the final 18-French dilator and peel-away sheath. The guidewire is removed, and the PD catheter with an internal metal stylet is advanced through the sheath, splitting the sheath as the deep cuff advances. This cuff is pushed into the rectus muscle while the sheath is in place, and the sheath is then removed around the cuff and catheter. The catheter is tunneled laterally with a tunneling tool (Fig. 97.4).[13,14] (For additional details, see reference[15].)

Fig. 97.4 Subcutaneous Tunnel Being Created for a Peritoneal Dialysis Catheter. With use of a disposable tool, a subcutaneous tunnel is created for the catheter. The superficial cuff (shown) will be implanted in the subcutaneous tunnel.

Burying (Embedding) the Peritoneal Dialysis Catheter

If the catheter will not be used immediately, the external portion can be buried under the skin for weeks to months before it is exteriorized and used. The catheter is placed in the usual manner, tunneled through a 1-cm skin exit site, filled with heparin solution (1000 U/mL), and blocked with a plug. The outside tip is then directed back into the exit site and tunneled through the subcutaneous space in a direction toward midline, caudal to the umbilicus. In the original publications, the catheter was tied off with silk suture and coiled into a pouch under the exit site.[16] Direct line tunneling of the external portion of the catheter (described earlier) avoids creation of a pocket just below the exit site and creates a normal exit site anatomy when exteriorized.

The primary incision and exit site are closed over the catheter. Embedding the catheter allows ingrowth of tissue into the cuffs of the catheter with less chance of bacterial colonization. This diminishes the incidence of early pericatheter infections and peritonitis.[16,17] Exteriorization of the catheter is done by making a small incision (1 cm) through the original exit site and using hemostats to locate and bring the catheter and surrounding tunnel to the exit site. The tunnel is incised and the catheter exteriorized.

Catheters buried in this fashion have been successfully exteriorized and used several years after insertion.[18] We recommend embedding the catheter when the catheter will not be used for at least a month, which obviates the need for care of the exit site and flushing the catheter after placement. The procedure allows time for ingrowth of fibrous tissue to the catheter cuffs and allows PD catheter placement to be performed electively rather than urgently (similar to creation of an AVF or AVG).

Complications of Peritoneal Dialysis Catheter Insertion

Bowel perforation is the most feared complication of peritoneal catheter insertion. The incidence is 1% to 1.4% with surgical insertion[2,3] and up to 0.8% with peritoneoscopic or fluoroscopic insertion.[1,3,19] During peritoneoscopic insertions, the diagnosis of bowel perforation is established by direct visualization of bowel mucosa or bowel contents, discharge of fecal material, or emanation of foul-smelling gas through the cannula. In fluoroscopic procedures it is recognized by a characteristic pattern of

injected dye outlining the bowel mucosa. Some physicians suggest this complication should be treated surgically,[20] but successful conservative management with bowel rest and intravenous antibiotics is possible if the perforation is recognized early in the procedure (before dilation of the tract or insertion of the catheter).[13,21] To minimize risk for perforation, a needle with a blunt and self-retracting stylet (such as a Veress needle or a Hawkins 18-gauge needle with obturator) can be used instead of a trocar or sharp needle to gain access to the abdominal cavity.[11] Previous abdominal surgery is a relative contraindication to PD catheter placement because of risk of bowel perforation due to intraperitoneal adhesions.[22,23] However, with careful ultrasound examination before needle placement, an area free of adhesions can be identified in almost every patient. If the visceral peritoneal surface moves freely versus the parietal peritoneal surface with each inspiration, then there are no major adhesions in that area of the peritoneum the risk of bowel perforation is low.

Peritoneoscopy or laparoscopy is useful for patients at high risk for adhesions. The scope can be used to identify intraperitoneal adhesions, assess their extent, and locate another site more suitable for catheter placement. With either fluoroscopic or peritoneoscopic techniques, the incidence of bowel perforation is no higher than with surgery, and the early success rate of catheters exceeds 95%.[1,24]

Catheter Repositioning

Outflow failure of a PD catheter occurs whenever the outflow fluid volume is less than the inflow volume. Peritonitis that fails to resolve is the number one reason for removal of PD catheters, but outflow failure is a close second in causes of PD catheter failure. Outflow failure is caused principally by omental attachment to the catheter. If omentum attaches to only a few side holes of the PD catheter, the omentum then acts as a "flap valve" limiting outflow through the PD catheter. As the omentum retracts and moves, the tip of the catheter often migrates to the upper abdomen. However, outflow failure due to adhesions can occur without catheter migration.

A variety of techniques have been used for repositioning PD catheters, including guidewire or stylet insertion, manipulation using a Fogarty catheter, and laparoscopy. Several techniques for catheter repositioning are feasible for nephrologists to perform. Fogarty catheter manipulation is the simplest method and works best with straight Tenckhoff catheters rather than coiled catheters. A Fogarty catheter is advanced past the tip of the catheter, the balloon is inflated, and tugging movements are used to reposition the catheter into the pelvis. Infusion and drainage of dialysate and fluoroscopy are performed to determine patency and position of the PD catheter. Peritoneal catheters can also be repositioned using stiff guidewires or stylets. Fluoroscopic images are helpful in determining the degree of catheter entrapment and the progress of the repositioning procedure.[12] The long-term success rate of repositioned catheters is only 27% to 48%,[25,26] probably because the primary problem is attachment of omentum to the catheter rather than migration of the catheter. Insertion of a new catheter is the most effective therapy in many patients.

Removal of Peritoneal Dialysis Catheters

A Tenckhoff curled or straight PD catheter can be safely removed in an outpatient procedure room; an operating room and general anesthesia are not required.[8] Local anesthetic is infiltrated at the site of the original primary incision, and the incision is incised. Dissection is carried down to the subcutaneous portion of the catheter, which is elevated while the surrounding fibrous sheath is opened. The catheter is clamped with a hemostat, and a nylon suture is placed through the catheter just outside the hemostat. The catheter is cut between the tag and hemostat. Dissection is continued toward the deep cuff by incising the fibrous tunnel adjacent to the catheter (Fig. 97.5). Additional anesthetic is infiltrated around the deep cuff. For catheters that have been in place for less than a month, blunt dissection is usually sufficient to free the deep cuff. Catheters in place for more than a month require sharp dissection, clamping and cautery to free the deep cuff from the rectus muscle. Before removing the deep cuff from the musculature, a purse-string suture is placed into the rectus sheath around the cuff. The deep cuff is then separated from the surrounding tissue, the intraperitoneal portion of the catheter is gently withdrawn from the peritoneal cavity, and the defect in the rectus sheath is closed by tying purse-string suture. The nylon tag is then pulled to expose the remaining subcutaneous portion of catheter segment within the primary incision, and dissection is performed in the direction of the superficial cuff. Once the superficial cuff is free, the external portion of the catheter is cut off at the skin level, and the outer portion of the catheter is removed through the primary incision site. Absorbable suture material in the dermis is used to close the skin incision, reinforced by nylon sutures in the epidermis or sterile adhesive strips if needed. The exit site is not sutured to allow drainage of fluid or pus if it develops.

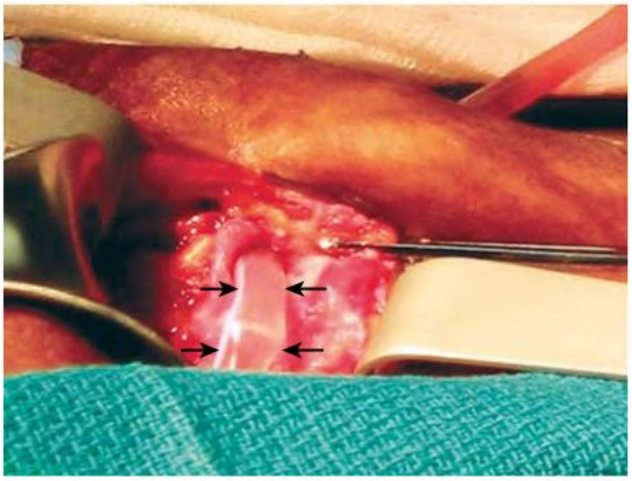

Fig. 97.5 Peritoneal Dialysis Catheter Removal. The catheter (*arrows* show lateral margins of catheter) has been exposed by dissection of the subcutaneous tunnel.

Training and Certification

ASDIN has established training guidelines and criteria for certification of physicians in the insertion of PD catheters by fluoroscopy or peritoneoscopy.[27] In addition to appropriate didactic training, there should be two practice insertions (into models, animals, or human cadavers), observation of two insertions into patients, and then six successful PD catheter insertions into patients with the physician as primary operator.

TUNNELED HEMODIALYSIS CATHETERS

Central venous catheters are used as a temporary HD access, as a bridge to AVF or AVG use, and when all other permanent access sites have been exhausted. Nontunneled catheters are used when a limited number of dialysis sessions is anticipated or there are contraindications to tunneled catheters (systemic infection, risk for bleeding), but they are more appropriate for use in inpatients. Tunneled catheters can be placed in both inpatient and outpatient settings, can be inserted at multiple vein locations, are relatively low in cost, and provide immediate access. However, there are significant disadvantages, including morbidity from infection and thrombosis and the risk of central vein stenosis or occlusion[28,29] (see Chapter 96).

Tunneled Catheter Insertion

The right internal jugular vein is the preferred catheter location compared with the left internal jugular and subclavian vein sites; it provides

a straight route to the right atrium, thereby reducing the risk for central vein stenosis. Catheters also may be placed in the femoral veins.

Catheter insertion should be performed in a sterile setting, ideally in an operating room environment with fluoroscopy available or at a minimum in a dedicated procedure room with cardiac monitoring. Before cannulation the vein should be located by ultrasound to detect anatomic variation or venous thrombosis. The patient's neck is then prepared and draped in sterile fashion; under ultrasound guidance, the vein is cannulated with a micropuncture needle (18–22 gauge), and a micropuncture guidewire is inserted and positioned in the superior vena cava. The needle is then removed, and the micropuncture dilator is inserted over the guidewire so it can be replaced with a standard guidewire. The use of the smaller needle rather than the standard 15-gauge needle minimizes trauma to the vein. A small subcutaneous incision is made adjacent to the dilator or guidewire, additional dilation is performed, and the catheter is placed over the guidewire, with care taken to hold the guidewire in place. If a tunneled catheter is to be placed, a catheter exit site is selected inferior to the clavicle and sufficiently lateral to the venotomy to avoid a kink in the catheter. A 1-cm superficial incision is made at this point, and a subcutaneous tract adjacent to the venotomy is infiltrated with lidocaine. A double-lumen catheter, generally 24 or 28 cm in length, is attached to the tunneling device and pulled through the subcutaneous tunnel in a curved path. A guidewire is passed through the dilator and into the inferior vena cava. The venotomy site is then serially dilated over the guidewire. The catheter can then be inserted over the guidewire through the venous port. When a split-tip catheter is used, the guidewire is passed in and out of the two venous ports and through an arterial port or through a hollow intracatheter stiffener. Alternatively, a peel-away sheath is placed over the guidewire and the catheter inserted through the sheath after the removal of the guidewire; however, this method has greater potential for blood loss and air embolism. Fluoroscopy is used to confirm tip placement at the level of the right atrium, with the arterial port facing away from the atrial wall, and to ensure there are no kinks in the catheter (Fig. 97.6). Each port of the catheter is then flushed with saline and locked with the appropriate amount of heparin based on catheter length and priming volume designation, followed by placement of the catheter hub caps.

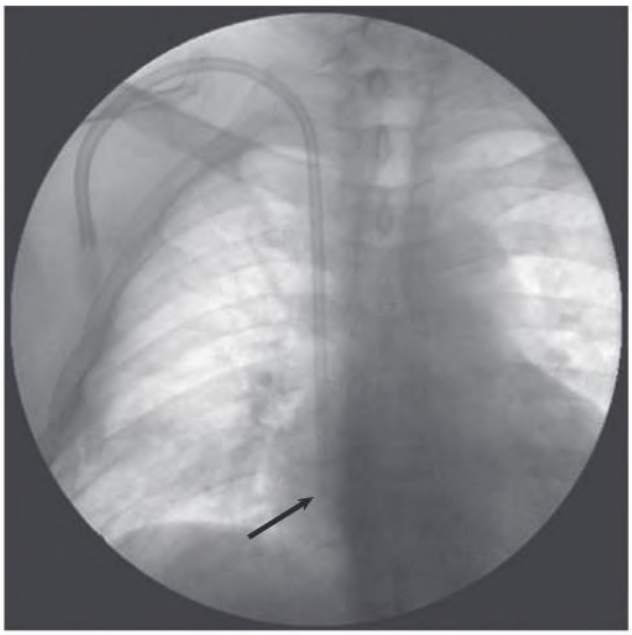

Fig. 97.6 Insertion of a Venous Catheter for Hemodialysis. Chest radiograph confirming that the tip of the catheter *(arrow)* is at the junction of the superior vena cava and the right atrium.

Catheter Dysfunction

Catheter dysfunction is the failure to maintain a blood flow sufficient to perform HD without significantly extending treatment time; this is usually 300 mL/min or greater for conventional dialysis.[30] Causes of immediate dysfunction include a kink in the catheter, incorrect position or orientation (e.g., arterial port against the vessel wall), and errant venous cannulation. These problems should be ascertained and corrected at the time of catheter placement. Catheter thrombosis is the most common cause of late dysfunction. Extrinsic thrombosis is less common than intrinsic thrombosis and is caused by central vein, mural, or right atrial thrombosis. Intrinsic obstruction results from thrombus within the catheter lumen or tip or most commonly from a fibrin sheath. Fibrin sheaths typically develop weeks to months after catheter insertion and result when a sleeve of connective tissue forms at the venotomy site and extends and encases the catheter tip, creating a flap valve. First-line treatment of catheter thrombosis includes forceful flush of the catheter with saline. If flow is not restored, a fibrinolytic agent should be instilled. Tissue plasminogen activator (tPA) is commonly used and appears more effective than urokinase in restoring patency and adequate flow.[31,32] Typically, 2 mg of tPA is instilled per occluded catheter lumen with 0.9% sodium chloride without preservative to fill the internal volume of each lumen and is allowed to dwell 30 minutes or until the next dialysis session. If this fails, the catheter should be exchanged. Strategies to minimize dialysis catheter thrombosis are discussed in Chapter 96.

Catheter Exchange and Fibrin Sheath Removal

Catheter exchange over a guidewire is useful in the setting of catheter thrombosis or bacteremia and allows the preservation of the venotomy, tunnel, and exit sites. The tunnel and exit sites must appear free of infection if the same sites are to be used. Catheter exchange should take place within 72 hours of the initiation of antibiotic therapy.[30] Under sterile conditions, the exit site is anesthetized and the cuff is freed. Once the catheter is pulled back 8 to 10 cm, contrast material is injected through the catheter under fluoroscopy to check for a fibrin sheath (Fig. 97.7). To obliterate a sheath, a guidewire is passed down the venous port of the catheter and into the inferior vena cava. The catheter is then removed, and a balloon catheter is inserted over the guidewire to the sheath location and inflated to disrupt the sheath. A new catheter is then inserted over the guidewire. When the catheter tip is beyond the venotomy site, near the superior vena cava, contrast material can be injected again to check for sheath removal before proceeding with catheter insertion.

Training and Certification

The ASDIN guidelines for HD vascular access procedure certification specify formal didactic training in central venous anatomy, sonographic examination of central veins, fluoroscopy, and catheter design and complications. Practical training for certification includes satisfactory insertion of 25 tunneled long-term catheters (see https://www.asdin.org).

PROCEDURES ON ARTERIOVENOUS FISTULAS AND ARTERIOVENOUS GRAFTS

The most common indications for intervention are inadequate flow during dialysis, thrombosis, and failure of AVFs to mature. Specific interventions include angiography, thrombectomy, angioplasty, and stenting. All of these procedures require a dedicated facility, either

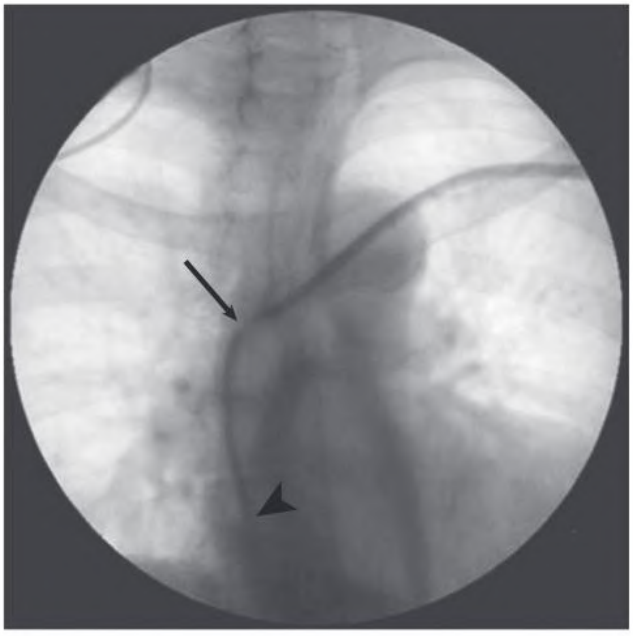

Fig. 97.7 Fibrin Sheath on a Tunneled Venous Catheter. Contrast material has been injected into a tunneled catheter after the tip *(arrow)* has been pulled back into the innominate vein. The contrast material fills a sheath that extends from the catheter tip as far as the *arrowhead.*

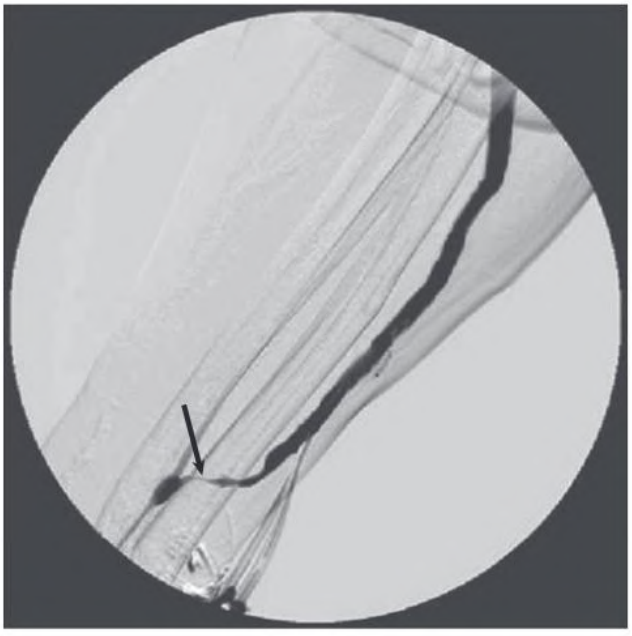

Fig. 97.8 Juxtaanastomotic Stenosis in a Radiocephalic Arteriovenous Fistula. Contrast material was injected at the arterial anastomosis *(bottom left)* and demonstrates a narrowing in the initial portion of the fistula *(arrow).*

inpatient or outpatient, with fluoroscopy, monitoring equipment, and staff to assist with the procedures and deliver conscious sedation. There are many different techniques for AV access procedures and few data to indicate superiority of one method over the other, so the choice is generally one of personal preference and cost. However, the first step always should include careful physical and ultrasound examination of the access. An examination will generally identify the problem and allow detection of access infection, an absolute contraindication to intervention. Appropriate intervention then can be planned. Monitoring and management of vascular access to minimize stenosis, thrombosis, and failure are discussed further in Chapter 96.

Percutaneous Balloon Angioplasty

Stenosis in AVG and AVF is routinely managed by percutaneous balloon angioplasty, which causes minimal discomfort and allows immediate use of the access. Not all stenotic lesions are responsive, however, and some require repeated treatment. In fistulas, the stenosis is most commonly located at the "swing point," including the portion of the native vein mobilized during creation of the AV anastomosis (Fig. 97.8), during vein transposition, or at the cephalic arch; in grafts, the venous anastomosis is the most common site of stenosis.[33-37] Angioplasty is indicated if the stenosis is 50% or more and is associated with clinical or physiologic abnormalities.[30] Treatment of stenosis increases access blood flow and longevity and reduces access thrombosis and access-related hospitalization.[37-39] A relative contraindication to angioplasty is a newly created access (less than 4–6 weeks old).

The access is cannulated with an introducer needle, a sheath is inserted, and initial angiography is performed. This should include views of the access, draining veins (peripheral and central), and arterial anastomosis and is used to confirm the location and degree of stenosis. Unless contraindicated, short-acting sedation and analgesia are given once a lesion has been identified on initial angiography, because angioplasty is painful.

A guidewire is passed through the sheath and across the stenosis. An angioplasty balloon catheter is passed over the guidewire,

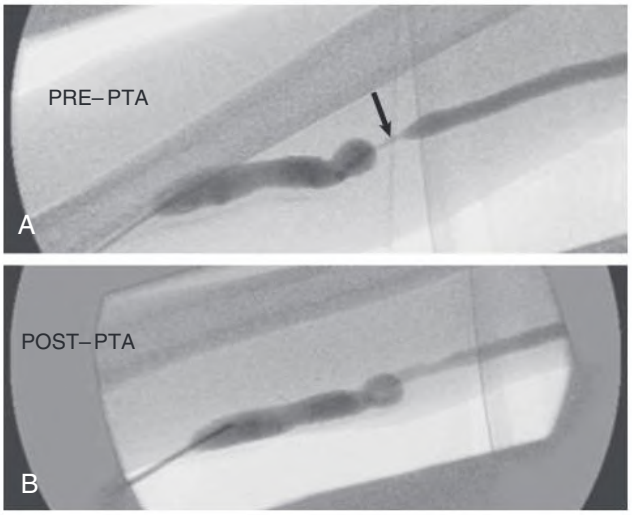

Fig. 97.9 Arteriovenous Graft Stenosis. (A) Stenosis in the outflow vein of an upper arm arteriovenous graft *(arrow).* (B) Angiogram performed immediately after percutaneous angioplasty. *PTA,* Percutaneous transluminal angioplasty.

positioned at the stenotic site, and inflated with a syringe or inflation device (Fig. 97.9). A variety of sheaths, guidewires, balloon sizes, and maximum pressures are available. The guidewire is left in place, and angiography is repeated to identify residual stenosis or any complications. Angioplasty is repeated for residual stenosis or when multiple lesions are present and may require a second cannulation of the access in the opposite direction for inflow stenoses. After removal of all devices, hemostasis at the cannulation site is achieved by manual pressure or suture placement. There is no evidence to support the use of antiplatelet agents or anticoagulation after intervention. According to Kidney Disease Outcomes Quality Initiative guidelines, a successful angioplasty is achieved when there is no more than 30% residual stenosis and physical indicators of stenosis have resolved.[30]

Percutaneous Thrombectomy

A variety of techniques are used for thrombus removal. In thromboaspiration—the least costly method, and as effective and efficient as mechanical and pharmacomechanical thrombolysis—low-dose tPA is instilled into the thrombosed access, the clot is manually macerated, flow returns, and angioplasty is used to dilate access stenoses.[40] Thrombectomy by thromboaspiration combines angiography with balloon angioplasty and thrombectomy by clot aspiration. Absolute contraindications to thromboaspiration include access infection and known right-to-left cardiac shunt; relative contraindications include a large clot burden and long-standing access occlusion.

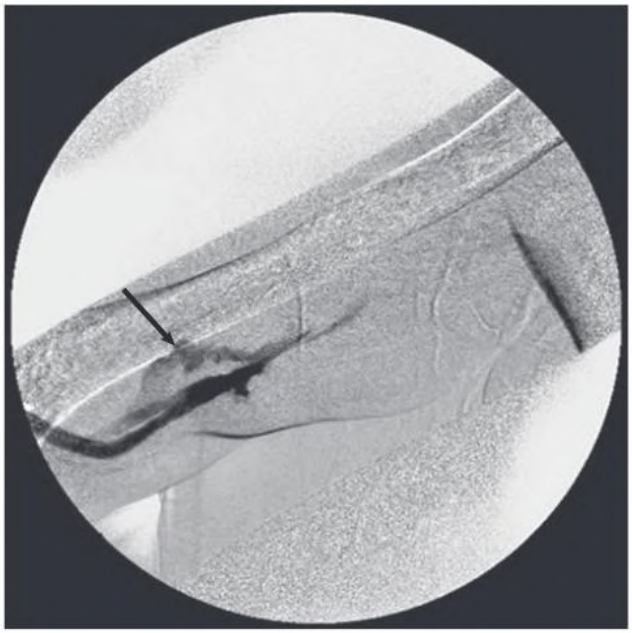

Fig. 97.10 Vein Rupture. Postangioplasty angiogram of an arteriovenous fistula showing extravasation of dye *(arrow),* indicative of a vein rupture. (Courtesy Dr. G. Beathard, Austin, TX.)

The access is cannulated in an antegrade direction, and a guidewire is passed to the level of the central veins. A straight catheter is inserted over the wire to the central veins, and angiography is performed to confirm central venous patency. Anticoagulation and short-acting sedative and analgesic medications are administered in the central circulation. An angiogram is then obtained as the catheter is pulled back to identify the location of stenosis. The guidewire is then inserted beyond the stenotic lesion, followed by an angioplasty balloon catheter. The balloon catheter is insufflated by hand with a syringe or inflation device, and the stenotic lesion is dilated. The access is then cannulated in the retrograde direction, a sheath is inserted, and a Fogarty catheter is passed across the arterial anastomosis, inflated, and pulled back through the entire length of the access while clot fragments are aspirated. On return of flow through the access, angiography is performed to evaluate the inflow and the arterial anastomosis, and angioplasty is repeated if necessary. Hemostasis is achieved by manual pressure or a suture at the cannulation sites.

Stents

Stents are considered in the setting of failed balloon angioplasty (an elastic lesion), when there are few remaining access sites, if the patient is not a surgical candidate for a new access, or when an outflow vein ruptures after balloon angioplasty (Figs. 97.10 and 97.11).[41,42] Results of randomized studies designed to demonstrate stent graft noninferiority to conventional angioplasty for AVG venous anastomotic stenosis show an increased primary patency for stent grafts.[43-45] Further, data suggests improved patency with stent grafts used to treat outflow vein restenosis in AVG, AVF, and central veins.[46-49,50] Finally, a stent may be useful in the setting of an expanding pseudoaneurysm.[51,52]

Despite these encouraging findings, stents should be used judiciously, particularly when surgical options may provide greater enduring patency. Stents should be avoided in situations in which their use will not extend the life of the access.

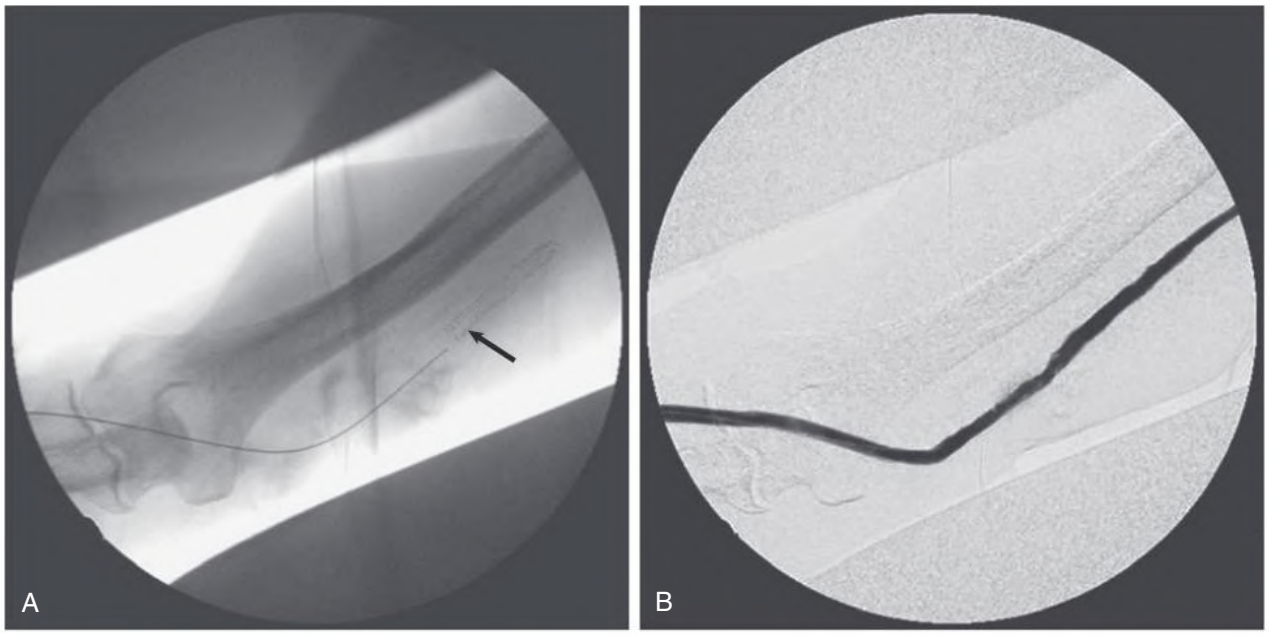

Fig. 97.11 Treatment of Vein Rupture With an Intraluminal Stent. (A) Placement of the stent *(arrow).* (B) An angiogram obtained after stent placement showing that venous outflow has been reestablished. (Courtesy Dr. G. Beathard, Austin, TX.)

Training and Certification

The ASDIN guidelines for HD vascular access procedure certification specify didactic training in venous anatomy, fluoroscopy, procedural equipment, and sedation and analgesia. Requirements for practical training include 125 procedures in both fistulas and grafts of each of the following: angiography, angioplasty, and thrombectomy as primary operator (refer to https://www.asdin.org for more information). In general, several hundred procedures as secondary operator are required before one can become a primary operator.

SELF-ASSESSMENT QUESTIONS

1. tPA is generally effective in treating poor blood flow in tunneled central venous catheters resulting from fibrin sheath formation.
   A. True
   B. False
2. A 57-year-old man with ESKD with a mature left brachiocephalic AVF is referred for evaluation of prolonged bleeding from the AVF on removal of the dialysis needles. The AVF is pulsatile on examination and does not collapse when the left arm is raised above the heart. An angiogram identifies a 75% stenosis at the cephalic arch, and an angioplasty is performed. According to the National Kidney Foundation's Kidney Disease Outcomes Quality Initiative guidelines, what defines a successful percutaneous angioplasty of an arteriovenous access?
   A. Less than 10% residual stenosis at the angioplasty site
   B. Ability to receive eight uncomplicated, consecutive dialysis sessions after the procedure
   C. Less than 30% residual stenosis and resolution of physical indicators of stenosis
   D. A and B
   E. B and C
3. Embedding (or burying) a newly placed PD catheter under the skin:
   A. allows ingrowth of tissue into the cuffs of the catheter without an opportunity for bacterial colonization.
   B. diminishes the incidence of early pericatheter infections.
   C. results in better catheter function in the future.
   D. A and B.
   E. is of no benefit other than cosmetic.
4. Which of the following statements about ultrasound of the renal and urinary tract is *false?*
   A. For examination of the kidneys, a renal ultrasound is always indicated in the workup of chronic kidney disease.
   B. A renal ultrasound is not indicated in every patient with acute kidney injury.
   C. Ultrasound is not useful in the diagnosis of bladder outlet obstruction.
   D. The ureters are usually visible only when dilated.
5. Insertion of PD catheters is commonly performed using:
   A. laparoscopy.
   B. surgical dissection.
   C. peritoneoscopy.
   D. the guidewire (Seldinger) technique.
   E. all the above.

Hemodialysis: Principles and Techniques

Peter Kotanko, Martin K. Kuhlmann, Christopher Chan, Nathan W. Levin

Hemodialysis (HD) has been in practice for more than 50 years and has extended the lives of millions of patients with kidney failure worldwide. Although the basic principles of HD are still being applied today, dialysis technology has improved markedly. The main components of the dialysis system are the extracorporeal blood circuit, the dialyzer, the dialysis machine, and the water purification system.

DIALYZER DESIGNS AND MEMBRANES

The dialyzer provides countercurrent transfer of solutes and fluid across a semipermeable membrane. The semipermeable dialysis membrane separates the blood compartment from the dialysate compartment (Table 98.1). Most current membranes are made of entirely synthetic materials, such as polyacrylonitrile, polysulfone, polycarbonate, polyamide, and polymethylmethacrylate, and are more biocompatible than cellulose-based membranes.

Transport of molecules across the dialysis membrane is driven by (1) the concentration gradient (diffusive transport) and (2) the hydrostatic pressure gradient across the membrane (convective transport). In the case of protein-bound solutes, only their free fraction is transported across the membrane, unless so-called albumin-leaky membranes are used. The flux of solutes is also affected by their charge and the protein concentration on the blood side (Gibbs-Donnan effect). Dialyzer efficiency increases with surface area (usually between 0.8–2.1 m^2; smaller dialyzers with surface areas between 0.075–0.245 m^2 are used for treatment of neonates). The dialyzer mass transfer area coefficient (KoA) for urea is a measure of the theoretically maximal possible urea clearance (mL/min). Dialyzer efficiency can be categorized based on KoA for urea as low (<500 mL/min), moderate (500–700 mL/min), and high (>700 mL/min). High-flux and medium cut-off membranes have pores large enough to allow some passage of molecules such as β_2-microglobulin (molecular weight 11,800 Da), tumor necrosis factor (TNF)-α (17 kDa), and beyond.

Water permeability is defined by the ultrafiltration coefficient (Kuf) that describes the transmembrane ultrafiltration volume per hour and unit of hydrostatic transmembrane pressure in millimeters of mercury. In high-flux dialyzers, Kuf can be as high as 80 mL/h/mm Hg. High-flux and medium cut-off membranes demonstrate substantial internal ultrafiltration at the proximal part of the dialyzer and backfiltration of dialysate into the blood at the distal end of the dialyzer blood compartment. Therefore, water quality is of paramount importance when high-flux and medium cut-off dialyzers are used (see later).

SAFETY MONITORS

Safety monitors are integral parts of the dialysis machine.

Pressure monitors measure hydrostatic pressures in critical positions (Fig. 98.1)[1]:

- Between the arterial needle and the blood pump (prepump pressure): Overly negative values may signal reduced arterial inflow and access problems.
- Between the blood pump and the dialyzer inlet (postpump): A high pressure may signal dialyzer clotting.
- Between the dialyzer outlet and the air trap (venous pressure): A high pressure may point toward an obstruction in the venous limb; it is important to recognize that in the event of venous needle displacement, with external bleeding, the venous pressure will remain positive.

Venous air detectors and *air trap* are located downstream of the venous pressure monitor. A positive signal at the air detector automatically clamps the venous line and stops the blood pump.

A *blood leak detector* is placed in the dialysate outflow line. Dialysate temperature is constantly monitored. Dialysate is produced by a proportioning system that mixes acid and bicarbonate concentrates with highly purified water. The concentration of ions in the dialysate translates into conductivity, which is measured by a *dialysis conductivity monitor*.

DIALYSATE FLUID

Water and Water Treatment

A standard 4-hour HD session exposes the patient to 120 to 160 L of water at a rate of 600 to 800 mL/min. A typical water purification plant is shown in Fig. 98.2. Water from municipal sources is filtered to remove particulate matter. Activated carbon devices, which need regular replacement, adsorb substances such as endotoxins, chlorine, and chloramines. Downstream water softeners use a resin coated with sodium ions, which are exchanged for calcium and magnesium ions before the water enters the reverse osmosis (RO) system. During RO, water is pumped at high pressure (15–20 bar) through a membrane with pores of less than 1.0 nm diameter, providing an absolute barrier for molecules larger than 100 to 300 Da. Depending on the technology used, 20% to 60% of water is rejected by the RO, meaning that water requirements are much higher than the final dialysate volume.

Standards for chemical quality of water are widely accepted, but there is less consensus regarding acceptable levels of bacterial and endotoxin contamination. The microbiologic standards for HD water, dialysis fluid, and substitution fluid vary across countries (Table 98.2).[2] Municipal water supplies may contain undesirable added substances such as aluminum and chloramines. Aluminum accumulation may result in neurologic disorder, bone disease, and erythropoietin-resistant anemia. Plasma aluminum levels should be less than 1 μmol/L. Chloramines have been associated with hemolysis and methemoglobinemia. Copper and zinc may leach from plumbing components and may cause hemolysis. Lead has been associated with abdominal pain and muscle weakness. Nitrate and nitrite may cause nausea and

TABLE 98.1 Dialysis Membrane Properties

Membrane	Membrane Name (Example)	High or Low Flux	Biocompatibility
Cellulose	Cuprophan	Low	Low
Semisynthetic cellulose			
Cellulose diacetate	Cellulose acetate	High and low	Intermediate
Cellulose triacetate	Cellulose triacetate	High	Good
Diethylaminoethyl-substituted cellulose	Hemophane	High	Intermediate
Synthetic polymers			
Polymethylmethacrylate	PMMA	High	Good
Polyacrylonitrile methacrylate copolymer	PAN	High	Good
Polyacrylonitrile methallyl sulfonate copolymer	PAN/AN-69	High	Good
Polyamide	Polyflux	High and low	Good
Polycarbonate-polyether	Gambrane	High	Good
Ethylene vinyl alcohol copolymer	EVAL	High	Good
Polysulfone	Polysulfone	High and low	Good

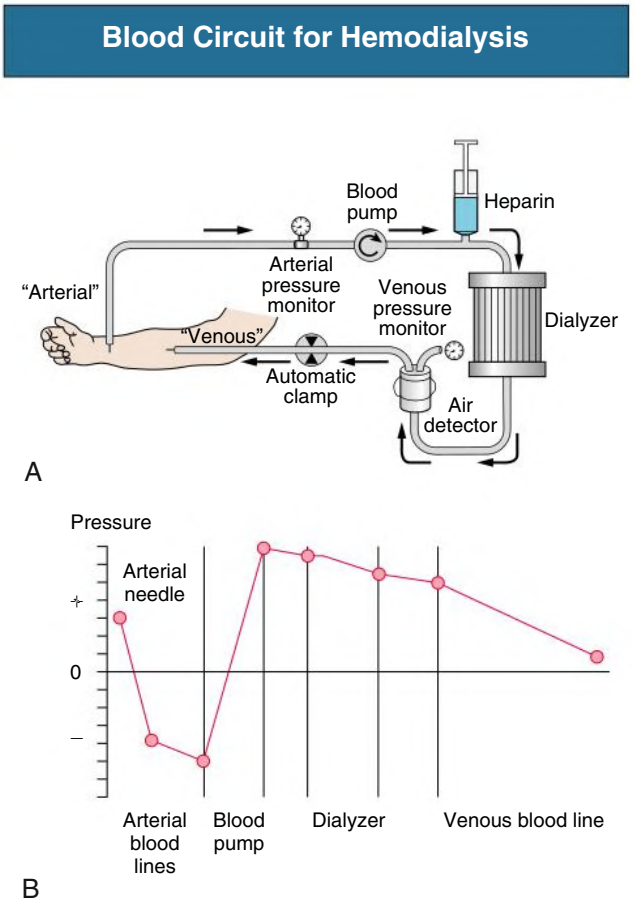

Fig. 98.1 Blood Circuit for Hemodialysis. (A) The blood circuit. (B) The pressure profile in the blood circuit with an arteriovenous fistula as the vascular access.

seizures. High concentrations of calcium may cause the so-called *hard water syndrome,* a condition characterized by nausea, vomiting, blood pressure instability, and fatigue during and after dialysis.

Gram-negative bacteria produce endotoxins, and fragments of these endotoxins may be responsible for some dialysis-related symptoms. Exposure to endotoxin is associated with rigors, hypotension, and fever. Use of a polysulfone or polyamide filter in the dialysate line may be adequate to remove endotoxins. Liquid bicarbonate dialysis fluid concentrate distributed in a central distribution system may be a source of bacterial growth and should be replaced daily; acid concentrates in canisters and bicarbonate powder represent no bacterial growth risk.

Ultrapure water is recommended for use with high-flux dialyzers. Water used for online hemodiafiltration (HDF) must be virtually sterile and nonpyrogenic, thus fulfilling major criteria for ultrapure water.

Dialysate Solution

Dialysate is made by mixing two components, which may be provided as liquid or dry (powder) concentrates (Table 98.3). The *base concentrate* contains sodium bicarbonate and sodium chloride. The *acid concentrate* typically contains chloride salts of sodium, calcium, magnesium, and potassium, glucose monohydrate, and an organic acid, the latter in the form of acetic acid, citric acid, or lactic acid. The acid concentrate may contain the salt of an organic acid, such as sodium acetate. The purpose of the acid is to lower the dialysate pH to less than 7.3 so that calcium and magnesium do not precipitate when bicarbonate is added. Base and acid components are mixed simultaneously with purified water to make the dialysate. Dialysate proportioning pumps ensure proper mixing. One typical mixing relationship is 1:1.72:42.28 (acid concentrate to base concentrate to water; the so-called *45X preparation*). Some dry acid concentrates contain sodium diacetate (8 mmol/L), which is composed of equal parts of acetic acid and sodium acetate. After mixing with bicarbonate, the final dialysate contains 8 mmol/L sodium acetate.[3] Dialysate composition can be modified by small changes in the mixing ratio and adding salt solutions; potential advantages and disadvantages of dialysate modifications are shown in Table 98.4.

BIOCOMPATIBILITY

The contact of blood with some lines and membranes triggers an inflammatory response. Although many components of the dialysis procedure contribute to the degree of biocompatibility, it is the membrane itself that is most important. Biocompatibility is especially important when cellulose membranes are used, whereas synthetic and reused membranes activate complement to a much lesser extent (Fig. 98.3). Activation of complement peaks at 15 minutes after the start of dialysis and lasts up to 90 minutes. Symptoms associated with activation of complement system and proinflammatory pathways include shortness of breath, chest pain, headache, nausea, vomiting, and hypotension.

Water Purification Plant

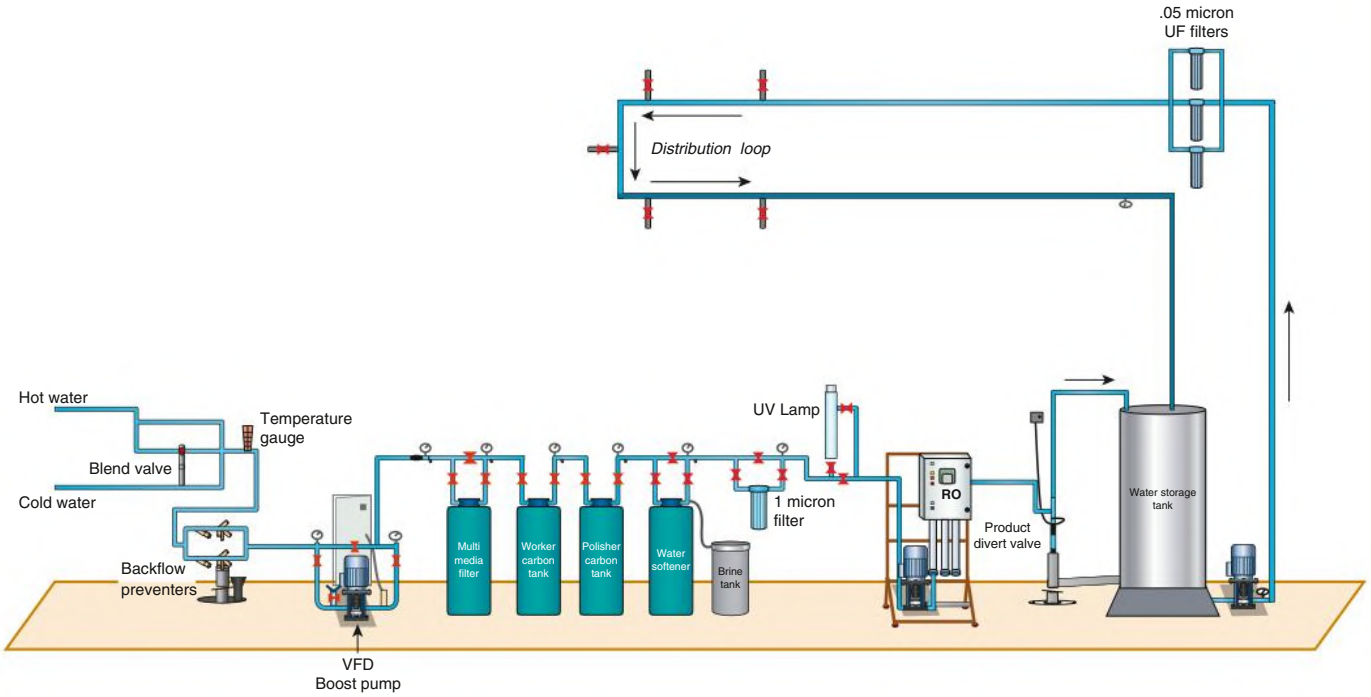

Fig. 98.2 Water Purification Plant. The four main functional domains are water supply, water pretreatment, primary purification, and delivery to the loop. A series of filters and water softeners are the key technical pretreatment components, whereas reverse osmosis is the main component of the primary purification. Note that several features are optional, such as the water storage tank. *UF,* Ultrafiltration; *UV,* ultraviolet light; *VFD,* variable frequency drive. HEMOFILTRATION, HEMODIAFILTRATION, AND INTERNAL FILTRATION AND BACKFILTRATION

Hemofiltration (HF) and HDF involve the removal of large fluid volumes from the patient, with the removed fluid replaced by substitution fluid. It is the use of substitution fluid that sets these techniques apart from simple ultrafiltration.

TABLE 98.3 Composition of Dialysates for Bicarbonate Dialysis

	CONCENTRATION	
Component	**Range**	**Typical**
Electrolytes (mmol/L)		
Sodium	135–145	138
Potassium	1.0–4.0	2.0
Calcium	1.0–1.75	1.25
Magnesium	0.5–1.0	0.75
Chloride	87–124	105
Buffers (mmol/L)		
Acetate	2–4	3
Bicarbonate	20–40	35
pH	7.1–7.3	7.2
P_{CO_2} (mm Hg)	40–100	
Glucose	0–11 (0–200 mg/dL)	5.5 (100 mg/dL)

HF (Fig. 98.4) is a convective elimination technique by which water and solutes from the blood compartment are driven solely by positive hydrostatic pressure across the dialyzer membrane into the filtrate compartment without the use of dialysate. As a result of solvent drag effects, small and larger solutes are eliminated at a rate depending on membrane characteristics.

HDF (Fig. 98.5) combines diffusive (HD) and convective (HF) solute transport using a high-flux membrane. Fluid is removed by ultrafiltration (convective volume) and the volume of filtered fluid exceeding the volume to achieve target weight loss is replaced by ultrapure infusion solution (substitution volume). *Online* HDF refers to the online production by the dialysis machine of ultrapure, nonpyrogenic dialysate, which is also used as infusion solution. *High-volume* HDF refers to an effective convection volume of more than 23 L per dialysis. HDF modalities are further characterized by the site of infusion of substitution fluid.

Postdilution Hemodiafiltration

The substitution fluid is infused to the patient downstream of the dialyzer. Filtration is limited by hemoconcentration in the dialyzer. Postdilution HDF is most efficient in terms of increasing solute removal.

Predilution Hemodiafiltration

Substitution fluid is added upstream of the dialyzer and immediately removed by convection. For an identical substitution volume, the efficiency of this mode is lower than that of postdilution HDF because of the dilution of solute blood concentrations before the dialyzer and consecutive and thus a reduction of in the transmembrane gradient.

TABLE 98.4 Advantages and Disadvantages of Modifications in the Dialysate Composition

Component	Advantage	Disadvantage
Sodium		
Increased	Hemodynamic stability	Postdialytic thirst; increased postdialytic serum sodium levels; increased intradialytic weight gain; high blood pressure
Decreased	Reduced osmotic stress in the presence of predialytic hyponatremia	Intradialytic hemodynamic instability
Potassium		
Increased	Fewer arrhythmias in digoxin intoxication with hypokalemia; may improve hemodynamic stability	Hyperkalemia
Decreased	Increased dietary potassium intake	Arrhythmias; risk for sudden death
Calcium		
Increased	Suppresses PTH, increased hemodynamic stability	Hypercalcemia, vascular calcification, adynamic bone disease resulting from PTH suppression
Decreased	Permits more liberal use of calcium-containing phosphate binders	Stimulation of PTH, reduced hemodynamic stability
Bicarbonate		
Increased	Acidosis control improved	Postdialytic alkalosis; increased mortality
Decreased	No postdialytic alkalosis	Promotes acidosis; increased mortality
Magnesium		
Increased	Hemodynamic stability, fewer arrhythmias, suppresses PTH	Altered nerve conduction, pruritus, renal bone disease
Decreased	Permits use of magnesium-containing phosphate binders; improved bone mineralization; less bone pain	Arrhythmias, muscle weakness and cramps, elevated PTH
Glucose		
Decreased	Avoidance of intradialytic hyperglycemia and hyperinsulinemia	Increased risk for disequilibrium (rare), hypoglycemia
Increased	Lower risk for disequilibrium	Intradialytic hyperglycemia and hyperinsulinism
Citrate	Heparin-sparing effect	High blood citrate levels in liver failure

PTH, Parathyroid hormone.

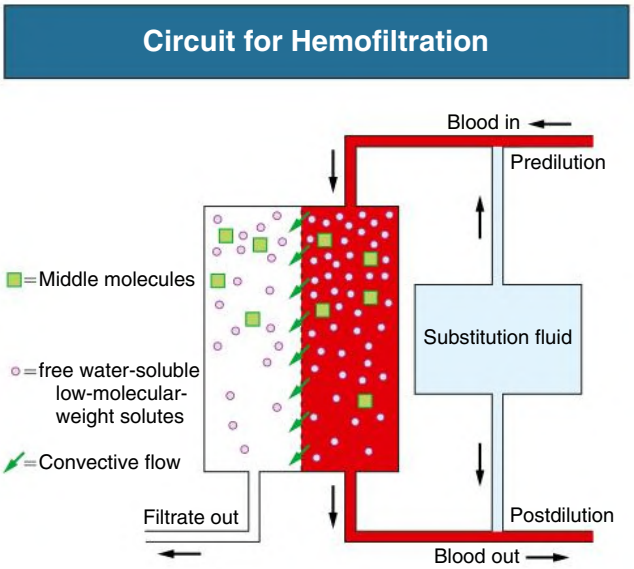

Fig. 98.4 Circuit for Hemofiltration. Substitution fluid is typically administered either predilution or postdilution but not both.

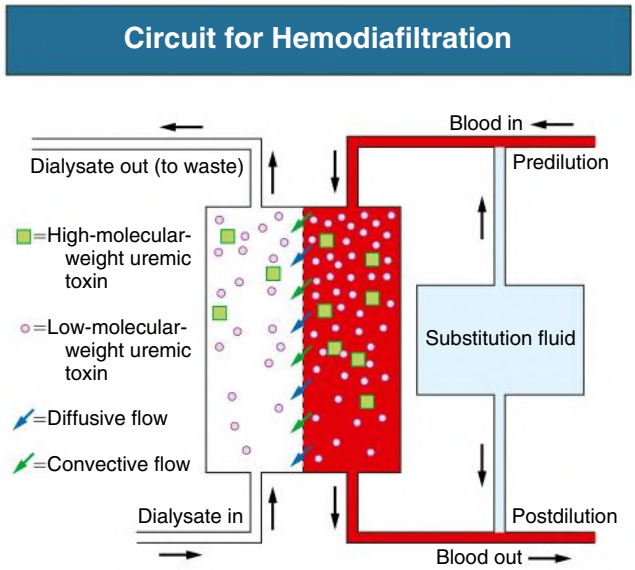

Fig. 98.5 Circuit for Hemodiafiltration. Substitution fluid is typically administered either predilution or postdilution but not both.

To achieve comparable efficiency to postdilution HDF, substitution volume needs to be doubled.

Mixed Dilution Hemodiafiltration

Replacement fluid is infused both upstream and downstream of the dialyzer. The ratio of upstream and downstream infusion rates can be varied to achieve the optimal compromise between maximizing clearance and avoiding the consequences of a high transmembrane pressure and hemoconcentration.

Mid-Dilution Hemodiafiltration

Replacement fluid is infused within specifically designed dialyzers partway down the blood pathway so that the first part of the blood circuit is operated in postdilution and the second part in predilution mode.

Internal Filtration and Backfiltration

Ultrafiltration does not occur in a uniform manner across the entire length of a dialyzer. Several characteristics such as blood and dialysate flows, membrane characteristics, and dialyzer geometries define the internal flow characteristics. In high-flux dialyzers, ultrafiltration dominates in the proximal (upstream) part, whereas backfiltration of dialysate takes place more distally (downstream). The backfiltration has raised concerns in the absence of ultrapure dialysate because endotoxin fragments and other bacterial substances may enter from the dialysate into the patient's blood, possibly aggravating inflammatory response. Medium cut-off membranes were designed for high rates of filtration and backfiltration with the expectation that their use would enhance clearance of middle molecules. A recent randomized controlled trial (RCT) showed larger reduction ratios for complement factor D, free k light chains, TNF-α, and β_2-microglobulin with a medium cut-off membrane versus a high-flux dialyzer.[4] In a cross-over RCT, after 3 months of medium cut-off membrane use, a significant decrease in serum levels of albumin, 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D was seen,[5] possibly related to the loss of vitamin D–binding protein (52 kDa).

UREMIC TOXINS AND THEIR REMOVAL BY HEMODIALYSIS

Uremic toxins have been traditionally categorized based on their molecular weight and binding properties (Table 98.5). Recent research has identified the gut, in particular the colon, as an important source of uremic toxins and their precursors. These colon-derived toxins are products of bacterial metabolisms, such as phenols, indoles, and amines.

Low-molecular-weight compounds not bound to protein: These include urea and guanidines such as asymmetric dimethylarginine (ADMA), purines, pyrimidines, oxalate, phosphorus, and uric acid. Modern dialysis membranes achieve maximal removal of these compounds.

Low-molecular-weight compounds bound to protein: These include indoxyl and cresyl compounds, advanced glycation

end-products, TNF-α, and phenolic compounds. Clearances of the unbound fraction may be increased by use of HDF, especially postdilutional modes. "Leaky" dialysis membranes and possibly medium cut-off membranes increase the clearance of protein-bound solutes in relationship to the pore size distribution of the membrane.

Middle molecule compounds: Traditionally, middle molecules encompass substances with a molecular weight between 5 and 32 kDa. Their removal is increased when using high-flux dialyzers, high-volume HDF, and medium cut-off membranes.

The clinical benefits of increased removal of protein-bound solutes and specific middle molecules have not been evaluated in appropriate clinical trials.

ADDITIONAL DEVICES AND TECHNOLOGIES

Relative Blood Volume Monitoring

Blood volume monitors provide continuous noninvasive monitoring of relative changes in blood volume by continuously measuring plasma protein concentration using ultrasound or hematocrit by optical scattering. A sharp decline in relative blood volume (RBV) may precede intradialytic hypotension. In the RCT Crit-Line Intradialytic Monitoring Benefit (CLIMB) study, mortality was higher in patients using RBV monitoring compared with conventional monitoring. However, because of an atypically low mortality rate in the conventional monitoring group, the authors pointed out that these findings should be generalized to the HD population in the United States with caution.[6] In an observational study of 842 maintenance hemodialysis patients, specific ranges of RBV ranges have been shown to be associated with improved all-cause mortality.[7] In this study, two-thirds of patients showed a decline of RBV by less than 8% 3 hours into the treatment, possibly indicating fluid overload. In clinical practice, flat RBV curves may prompt a re-evaluation of the target weight. In some dialysis machines, the rate of blood volume change is used to automatically adjust ultrafiltration rates and dialysate sodium concentration (feedback control). This approach has been shown to reduce the frequency of symptomatic intradialytic hypotension in some, but not all, studies.[8,9]

Ultrafiltration Profiling

The ultrafiltration rate is usually kept constant but can be changed during the dialysis session in a preprogrammed manner (ultrafiltration profiling). It may be advantageous to remove a large proportion, such as two-thirds of the prescribed total ultrafiltration volume, in the first half of the HD session. The clinical benefits of ultrafiltration profiling are under debate.

Sodium Profiling

Normally, the dialysate sodium concentration is kept constant throughout the dialysis treatment. The variable sodium option allows dynamic changes of the dialysate sodium concentration during the treatment (sodium profiling). Typically, such treatments would start with a high dialysate sodium concentration (e.g., 145 mmol/L) and end with a lower one (e.g., 135 mmol/L). Some patients with hemodynamic instability may benefit from this option in which the initial sodium concentration is kept high and then slowly reduced to avoid sodium loading. Stepwise profiling was shown to be effective in reducing intradialytic hypotensive episodes.[10] Sodium profiling may result in dialytic sodium loading that may manifest itself in increased thirst, interdialytic weight gain, and blood pressure. In patients presenting with these signs and symptoms, the need for sodium profiling should be critically re-evaluated. Using conductivity measurements of dialysate, some modern dialysis machines allow the user to target a specific dialytic sodium balance.

Online Clearance Monitoring

Sodium and urea clearances are identical for practical purposes. The conductivity of the dialysate is largely a function of the dialysate sodium concentration, and online clearance monitors use this feature to compute the urea clearance (K) of a dialyzer during a dialysis treatment.

Blood Temperature Monitoring and Dialysate Cooling

In most patients, HD exerts a net positive thermal balance that may affect hemodynamic stability. "Cool" dialysate has been shown to improve vascular stability during dialysis. An RCT showed cardiac and brain white matter protection with individualized cooling at 0.5°C below body temperature.[11,12] The most precise control of a patient's temperature during dialysis is enabled by a body temperature monitor (BTM) that adjusts in a feedback loop the dialysate temperature to attain a prescribed thermal balance and core temperature. Alternatively, tympanic temperature can be used to prescribe the dialysate temperature (e.g., 0.5°C below tympanic temperature). In some studies, the dialysate temperature was set to 35°C irrespective of the patient's body temperature.

Intradialytic Oxygen Measurement

Blood coming from a functioning arteriovenous access resembles arterial blood. Some devices and dialysis machines measure predialyzer blood oxygen saturation. In an observational study, patients with prolonged intradialytic hypoxemia showed greater morbidity and mortality.[13] In HD patients with central venous catheter as vascular access, a low central venous oxygen saturation is associated with intradialytic hypotension.[14]

HOME HEMODIALYSIS

Home HD (HHD) offers several clinical benefits compared with conventional renal replacement therapies, such as better survival, enhanced blood pressure control and left ventricular geometry, normalization of phosphate balance, augmentation of kidney-specific quality of life scores, and improved fertility.[15] HHD also provides greater patient autonomy in a cost-effective manner.[16] There are variations in HHD prescription and practices (Table 98.6). Additionally, conventional HD platforms and low dialysate flow systems may be used in the home.

Several considerations should be addressed before starting patients on HHD. Routinely, a home visit should be conducted before

TABLE 98.6 Home Hemodialysis Prescription and Practices

	Conventional	Short Daily	Nocturnal	Low Dialysate Flow Systems
Treatments per week	3	6	5–6	6
Treatment time (hours)	4	2–3	6–8	2.5–3.5
Blood flow rate (mL/min)	400	400	200	400
Dialysate flow rate (mL/min)	500	800	300	130

starting home dialysis to assess for feasibility and the potential need for renovations and modifications. The Advancing American Kidney Health Initiative was announced in 2019, which aimed to ensure that 80% of incident patients with end-stage kidney disease will receive home-based dialysis or a kidney transplant by 2025. Given the change in policy, it is anticipated that there will be a global growth in home therapies.

DIALYSIS MACHINE CHOICE AND OTHER EQUIPMENT

The choice of machine should be tailored to the patient's individual requirements and preference, and it will also determine the ease of dialysis fluid preparation. Additionally, the availability of appropriate water, electrical supply, and space may influence the choice of HD machine. Conventional HD platforms will require water filtration systems, whereas others (i.e., low-dialysate flow systems) may use prepackaged dialysate or generate online dialysis solutions. Premixed bags are available with bicarbonate-buffered or lactate-buffered dialysate. All types of vascular accesses may be used for HHD. Registry data suggest that permanent vascular access has superior outcomes compared with tunneled HD catheters. Moreover, the use of buttonhole cannulation (compared with the stepladder technique) is associated with higher infectious complications and hence should be reserved for selected patients only.

WATER PREPARATION, STANDARDS, AND PLUMBING

As for in-center HD, prevailing standards for water quality should be adhered to (see previous discussion). Depending on the local water conditions and regulations, water softener, backflow preventers, and blending devices may be necessary in the home. In certain circumstances, feeder tanks may be necessary to provide the water pressure necessary for the RO unit and dialysis machine to function properly.

SAFETY

All dialysis machines are equipped with monitors, as described earlier. Leak and moisture detectors should be placed around vascular access cannulation sites, under the dialysis machine, and at the water treatment system. For central venous catheters, special connectors or catheter safety lock boxes can be used. Telemonitoring systems have been employed for HHD, but they are not a prerequisite. Practically, most HHD users continue to rely on an "on-call" system for troubleshooting. Typically, arterial and venous pressure alarms are the most common type of alarms. The average number of alarms per night decreased significantly over time as patients gained experience with HHD (from a maximum of 1.98 ± 3.31 alarms/night to a low of 0.74 ± 1.63 alarms/night) according to the London Ontario experience.

BOX 98.1 Activities to Reduce the Environmental Footprint of Hemodialysis

Electricity
- Reporting of energy consumption
- Energy-efficient dialysis machine implementation
- Use of light sensors and lighting timers
- Switch to LED bulbs
- Reduced facility size
- Integration of dialysis unit into a high environmental-quality building
- Change or tuning of air treatment systems

Water
- Reporting of water usage
- Water-efficient dialysis machine implementation
- Change in water treatment system

Care-Related Waste
- Reporting of waste produced
- Regular audits of waste management
- Caregiver training for waste sorting

LED, Light-emitting diode.

WEARABLE ARTIFICIAL KIDNEY

Wearable artificial kidneys (WAKs) have been successfully tested in clinical trials, proving that this technology is safe and a potential future form of renal replacement therapy. At their current stage, however, WAKs are not yet suitable for routine use, facing formidable challenges such as anticoagulation, toxin clearance, and fluid removal.

"GREEN" HEMODIALYSIS

Hemodialysis is a resource-intensive treatment that uses substantial amounts of energy and water and produces plastic and other waste. The annual per-patient carbon footprint of 6-chair satellite dialysis unit has been calculated to be 10.2 tonnes of CO_2 equivalents. Importantly, environmental responsibility awareness, staff education, and improved technology can substantially improve the environmental footprint of hemodialysis. By implementing systemwide changes (Box 98.1), between 2005 and 2018, a French dialysis network was able to reduce water use from 801 to 382 L/session, power use from 23.1 to 16.3 kWh/session, and waste from 1.8 to 1.1 kg/session.[17] Additional measures call for recycling reverse osmosis water, renewable energy use, commingled recycling, polyvinyl chloride plastic recycling, secured bicycle parking, shower and changing facilities for bike riders, videoconferencing, and telemedicine. Little is known about the ecological impact of peritoneal dialysis. "Green" dialysis is likely to evolve as a major topic in the years to come.

SELF-ASSESSMENT QUESTIONS

1. Which statement is *correct?*
   - **A.** Bacterial endotoxin in the HD fluid cannot pass through the dialysis membrane.
   - **B.** An increase in HD fluid sodium concentration will always raise the serum sodium level.
   - **C.** HD fluid buffers include anions such as bicarbonate diacetate, chloride, and citrate.
   - **D.** HD fluid potassium concentrations of 1 mEq/L are safer than 3 mEq/L.
2. Which statement is *correct?*
   - **A.** A high-protein diet will eventually reduce the level of uremic toxins in the blood.
   - **B.** Urea is considered a powerful uremic toxin.

C. Some uremic toxins are synthesized in the colon and absorbed into the bloodstream.
D. HDF is highly efficient in removing protein-bound uremic toxins.

3. Which statement is *correct?*
A. A typical symptom of hard water syndrome is spiking fever during hemodialysis.
B. Medium cut-off membranes showed significantly improved survival in a randomized controlled trial.
C. Predilution HDF is most efficient in terms of increasing solute removal.
D. Dialysate cooling is an effective means to increase hemodynamic stability.

4. Which statement is *correct?*
A. Intradialytic hypoxemia is associated with poor outcomes.
B. Sodium profiling is a preferred way to treat patients with intradialytic hypertension.
C. In patients with predialysis serum potassium levels greater than 6.2 mEq/L, a dialysate potassium concentration of 0 mEq/L is warranted.
D. Home HD is not advised in patients with diabetes mellitus.

5. Which statement is *correct?*
A. A positive venous pressure is a reliable indicator of correct needle placement.
B. Water treatment is key to the preparation of adequate dialysis fluid.
C. Intradialytic hypoxemia is associated with poor outcomes.
D. Modern dialyzer membranes combine polysulfone with cellulose.

Hemodialysis: Dialysis Prescription and Adequacy

Martin K. Kuhlmann, Christopher T. Chan, Peter Kotanko, Nathan W. Levin

From an idealistic perspective, an adequately treated hemodialysis (HD) patient is physically active, well nourished, and euvolemic with a maintained good quality of life and a life expectancy comparable to that of similarly aged persons with normal kidney function. The HD treatment remains a critical aspect of the multifactorial management necessary to achieve these goals. Adequacy of HD treatment today encompasses more than just the fractional replacement of excretory kidney function (dialysis dose) and extends to the prevention of intradialytic and interdialytic complications, particularly the maintenance of hemodynamic stability and symptom control. Elderly patients, the largest group of prevalent and incident dialysis patients worldwide, are especially vulnerable to hemodynamic and osmotic effects of dialysis treatment and therefore require a special approach in dialysis prescription.

ASSESSMENT OF DIALYSIS DOSE

Similar to native kidney function, the delivered dose of dialysis is conventionally assessed by the mass removal of selected uremic solutes from the patient's body. For decades, small solute clearance, assessed solely by urea as a surrogate marker, has been emphasized in clinical practice guidelines and used as measure for quality assessment and/or payment. However, evidence for relationships between small solute clearance, plasma levels of these solutes, and clinical outcomes and symptomatology is weak. Small solute clearance reflects only one of many aspects of dialysis care that are likely to affect outcomes.

Markers of Uremic Toxin Removal by Kidney Replacement Therapy

Urea Removal

Among all potential uremic toxins, only urea, a 60-Da water-soluble compound, is established as a marker of uremic solute retention and removal. Urea, which itself causes little toxicity, is a metabolite of amino acid metabolism, and urea generation therefore depends on protein intake and the balance between protein anabolism and catabolism. Urea removal was originally considered to be a good proxy for removal of pathogenic water-soluble solutes. However, it is now known that urea removal does not closely parallel the removal of other small water-soluble compounds and correlates poorly with removal of middle molecules and protein-bound solutes.[1] Nevertheless, detailed knowledge of urea kinetics is essential for the general understanding of the physics and basic principles of solute accumulation and removal in dialysis.

In a state of homeostasis, urea is evenly distributed throughout whole body water. Urea easily transfers across cell membranes by diffusion and specific urea transporters, allowing for rapid equilibration within its distribution volume after dialytic removal from the blood compartment. For almost all other water-soluble small and middle molecular weight toxins, the intercompartmental transfer rate is much slower, leading to protracted equilibration between the various compartments and thus different removal kinetics during dialysis.[2] Urea removal from the body during dialysis is expressed either by urea reduction ratio (URR) or by the treatment index Kt/V. Although urea removal alone is not a sensitive marker of dialysis adequacy, it is still the standard measure to quantify removal of low molecular weight solutes during dialysis treatment. The dialysis dose ideally should be evaluated in conjunction with residual kidney function (RKF) assessed with the same uremic toxin.

Intradialytic Urea Kinetics

Dialyzers are highly efficient at removing urea from the blood, reducing plasma urea concentration during one dialyzer passage by over 90%. However, the urea clearance of the dialyzer itself is only a marker of dialyzer efficiency but not of dialysis dose, which is based on the fractional removal of urea from the whole body. The kinetics of plasma urea concentration during dialysis is satisfactorily described by a two-compartment model in which the intravascular blood compartment is replenished with urea through redistribution from extravascular compartments. The dynamics of urea redistribution depend on the urea gradient between the two compartments and on blood flow in the various tissue regions. Because intercompartmental redistribution is not immediate, urea concentration in the blood compartment during dialysis is lower than in the extravascular compartment. After a dialysis treatment, urea rebound occurs, which takes 30 to 60 minutes until full equilibration between all compartments is achieved.

Mathematical models based on the difference in predialysis and postdialysis serum urea concentration have been applied to describe intradialytic urea kinetics including URR, single-pool Kt/V (spKt/V), equilibrated Kt/V (eKt/V), and weekly standard Kt/V (stdKt/V). The classic single-pool urea kinetic model (spKt/V) assumes single-compartment characteristics where full equilibration between blood and tissue compartments occurs immediately and the change in serum urea follows first-order kinetics, with a linear decline and no urea rebound (see Fig. 99.1, *dashed line*).[3] The more physiologic "equilibrated" double-pool urea kinetic model (eKt/V) considers the urea redistribution kinetics between the two compartments (Fig. 99.1, *solid line*).

Urea Reduction Ratio

URR, which refers to the treatment-related reduction of serum urea concentration, is a simple but rather imprecise way to quantify dialysis dose because it does not consider intradialytic urea generation and convective urea removal by ultrafiltration, and it is a single-pool measurement (Table 99.1). Despite these limitations, URR correlates quite well with dialysis outcome and is an accepted method for assessment of dialysis dose. A minimum URR of 65% to 70% is considered an adequate dialysis dose.[2]

Single-Pool Kt/V and Equilibrated Kt/V

The treatment index Kt/V is the most widely used parameter to assess dialysis dose. Kt/V is a dimensionless number representing the total plasma volume cleared (K × t, in liters) in relation to the individual volume of distribution (V, in liters). The concept of Kt/V may be applied to any substance but in clinical practice is almost exclusively used for urea, where K is the dialyzer blood water urea clearance (in liters/hour), t is dialysis session length (hours), and V is the distribution volume of urea (in liters), which equates closely to total body water. A delivered Kt/V of 1.0 implies that the volume of plasma cleared of urea (K × t) during a dialysis session is equal to urea distribution volume (V). However, because of the multicompartment kinetics of urea equilibration, and constantly ongoing urea generation, clearing a plasma volume equivalent to 1 unit of total body water (V) does not mean that all urea has been removed from body water.

In daily clinical practice, single-pool Kt/V (spKt/V) is computed from the Daugirdas equation, which is based on URR but also accounts for intradialytic urea generation and ultrafiltration volume.[3] The Daugirdas equation is validated for an spKt/V range between 0.8 and 2.0 and is widely used because of its simplicity and accuracy. However, spKt/V somewhat overestimates the delivered dialysis dose because nonequilibrated postdialysis urea concentration is used for computation. The magnitude of the difference between equilibrated and nonequilibrated postdialysis urea concentration depends on the intensity of dialysis; the shorter and more intense a treatment, the higher is the postdialysis urea rebound and the larger the difference. Using eKt/V formulas, which include an estimate of equilibrated postdialysis urea concentration, grants a more accurate estimate of delivered dialysis dose. Because equilibrated post-HD serum urea concentrations are higher than nonequilibrated concentrations, eKt/V is always lower than spKt/V for any treatment (Table 99.1).

Correct assessment of Kt/V requires accurate timing of blood collections. Predialysis blood samples are collected right at the start of the treatment and postdialysis samples immediately before termination of treatment after slowing the blood flow rate to reduce any potential effect of recirculation. Blood sampling procedures should be standardized.[2] URR, spKt/V, or eKt/V should be assessed regularly and the dialysis prescription adjusted accordingly. In large observational studies, mortality was higher at spKt/V of less than 1.2, and a target spKt/V of 1.4 is recommended as the minimum dose for conventional thrice-weekly dialysis schedules.[2] Many HD machines today provide some option to monitor spKt/V online during each single dialysis session without the need for pre- or postdialysis blood sampling. However, a weakness of online methods remains the inability to measure the volume of urea distribution directly.

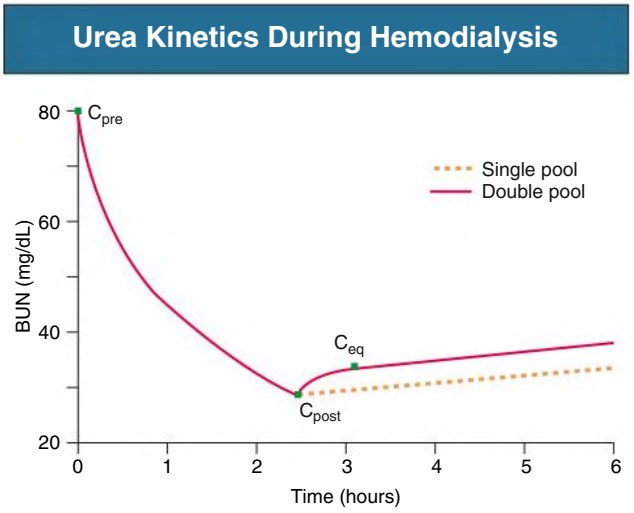

Fig. 99.1 Urea Kinetics During Hemodialysis. Urea kinetics is determined by the difference between predialysis (C_{pre}) and postdialysis (C_{post}) blood urea nitrogen (BUN). The single-pool Kt/V model assumes no relevant change in BUN concentration after termination of dialysis except for a slow constant increase as a result of BUN generation *(orange dashed line).* The double-pool Kt/V model *(red line)* more accurately describes the in vivo situation, in which intercompartmental urea redistribution leads to a urea rebound until full equilibration between blood and tissue compartments is reached. Equilibrated postdialysis BUN concentration (C_{eq}) can be mathematically predicted from postdialysis BUN (C_{post}).

Weekly Dialysis Dose and Weekly Standard Kt/V

A useful way to compare native kidney function with dialysis dose across a wide variety of dialysis modalities and frequencies is by looking at an average clearance (in milliliters per minute) of a given solute achieved over a unifying period, such as 1 week. The established parameter developed for this comparison is the weekly standard Kt/V for urea (stdKt/V). With this concept, a thrice-weekly *intermittently* provided dialysis urea clearance (e.g., 250 mL/min for 4 hours thrice weekly and 0 mL/min for the remaining 6.5 days per week) is converted to an equivalent *continuous* extracorporeal urea clearance (in mL/min) related to urea distribution volume *V* (in milliliters).[4] The resulting dimensionless stdKt/V value is directly compatible with the continuous native residual kidney clearance expressed as kidney Kt/V and peritoneal clearance (weekly peritoneal Kt/V). The principle of stdKt/V is visualized in Fig. 99.2, in which on the *x*-axis the eKt/V of a representative dialysis session is plotted onto a curve representing the prescribed treatment frequency, and the resulting stdKt/V is then derived from the intercept with the *y*-axis. The frequency curves are not linear because the decreasing transmembrane urea gradient over time results in decline of the efficiency in dialysis urea mass removal. Independent of the treatment schedule, a minimum stdKt/V of 2.1

TABLE 99.1 Computation of Dialysis Dose[a] Results Derived From Different Model Equations

Formula	Result	Comment
$URR = (1 - C_t/C_0) \times 100\%$	67%	Urea rebound, urea generation, and ultrafiltration not taken into account
$K_t/V = \ln(C_0/C_t)$	1.10	Urea rebound, urea generation, and ultrafiltration not taken into account
$spKt/V = -\ln(R - 0.008 \times t) + (4 - 3.5R) \times UF/W$	1.33	Single-pool model; urea rebound not taken into account
$eKt/V = spKt/V - 0.6 \times spKt/V/t + 0.03$	1.16	Double-pool model for arteriovenous access, including urea rebound
$eKt/V = spKt/V - 0.47 \times spKt/V/t + 0.02$	1.20	Double-pool model for central venous access, including urea rebound

accounting for kidney Kt/V is recommended for all patients.[2,5] In anuric patients this is achieved with a thrice-weekly delivered spKt/V of 1.2 per treatment.

MIDDLE MOLECULE REMOVAL

It is widely held that retention solutes of middle molecular size may play an important role in the pathogenesis of uremia and contribute significantly to the high mortality of dialysis patients. Because of higher membrane porosity, high-flux dialyzers can remove larger amounts of middle molecules than low-flux dialyzers, and this is further increased using convective dialysis strategies, such as hemodiafiltration (HDF) and expanded HD (HDx).[6] Because of slow intercompartmental redistribution rates, middle molecule removal is limited during conventional 4-hour dialysis sessions, and β_2-microglobulin, a surrogate for uremic middle molecules, is more effectively removed by high-flux dialysis. Predialysis β_2-microglobulin levels were found to be related to mortality in patients randomly assigned to high-flux or low-flux dialyzers,[7] and certain vulnerable patient groups (e.g., those with diabetes) may gain some extra benefit from high-flux dialysis, although this is controversial.[8,9] The European Best Practice Guidelines recommend the use of synthetic high-flux membranes to reduce cardiovascular risk and improve control of hyperphosphatemia and anemia.[10]

High-volume online HDF provides the largest removal of the widest range of low and middle molecular size solutes. Diffusive and convective solute elimination are maximized to the benefit of the removal of larger molecular size solutes. Because diffusive urea clearance during standard HD treatment is already high and increases by less than 10% when convective clearance is added, urea removal is not an adequate marker of treatment dose in convective dialysis modes. In HDF, mass removal of middle molecules is directly related to ultrafiltration volume, which is also referred to as *convection volume* (CV) (see Chapter 98). The *effective* CV is used as key quantifier for HDF dosing, where the term *effective* principally relates to the undiluted blood water volume removed by filtration. Thus, in postdilution mode, the effective CV is identical to total CV, whereas in predilution or mixed-dilution mode, the effective CV is considerably lower than total CV.[11]

Various randomized controlled studies failed to demonstrate an overall survival advantage with postdilution high-volume online HDF to conventional low-flux or high-flux HD. However, an individual patient data analysis of these trials demonstrated a significantly reduced mortality risk for patients receiving more than 23 L of effective CV normalized to a body surface area of 1.73 m^2 in postdilution HDF mode.[12] Adjustment of target HDF dose to some measure of body size makes sense because the generation rate and distribution volume of uremic toxins are both related to body mass.

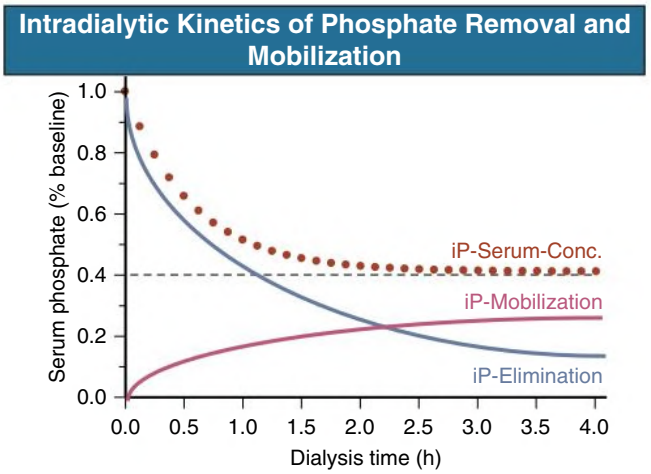

Fig. 99.3 Intradialytic kinetics of phosphate removal and mobilization. *iP,* Inorganic phosphate.

Phosphate Removal

Because hyperphosphatemia is a strong risk factor for cardiovascular mortality, predialysis serum phosphate levels should be lowered toward the normal range in all patients (see Chapter 88).[13] Management of hyperphosphatemia is based on phosphate removal by dialysis, dietary phosphate restriction, and intestinal phosphate binding with use of phosphate binder medication. Despite its low molecular weight, the effective molecular size of phosphate (because of a rather stable coating with several water moieties) is much bigger than that of other low molecular weight solutes, which impairs intercompartmental and transmembrane phosphate redistribution during dialysis. Intradialytic phosphate kinetics resembles much more those of middle molecules, with serum phosphate levels steeply falling during the first 90 to 120 minutes into dialysis, driven by removal primarily from plasma and extracellular volumes and stabilizing thereafter (Fig. 99.3). This latter intradialytic plateau is explained by phosphate mobilization from extravascular compartments at a rate similar to that of dialyzer phosphate removal.[14] Phosphate removal is improved by high-flux HD and HDF, by the use of larger dialyzer surface area, and, most dramatically, by longer or higher frequency dialysis schedules, such as short daily or daily nocturnal HD. Long, frequent dialysis schedules, such as daily nocturnal HD, offer the highest phosphate mass removal and may even result in hypophosphatemia so that phosphate needs to be added to the dialysate.

PRESCRIPTION OF HEMODIALYSIS

Hemodialysis Dose

The National Kidney Foundation's KDOQI guidelines recommend a target spKt/V of 1.4 per HD session for patients treated thrice weekly, with a minimum delivered spKt/V of 1.2. In patients with significant residual native kidney function, a lower dose of HD may be appropriate (termed *incremental dialysis*), provided RKF is measured periodically to avoid inadequate dialysis. For HD schedules other than thrice weekly, a target stdKt/V of 2.1 per week including residual kidney function is recommended.[2]

Delivered dialysis dose depends on dialyzer efficiency (Kd), effective treatment time (t), and distribution volume (V). Dialyzer clearance Kd depends on the flow rates within the blood and dialysate compartments (Qb and Qd), dialyzer KoA, effective membrane surface area, hematocrit, and anticoagulation. Effective treatment time is essential for reaching the Kt/V target and can be substantially shorter than prescribed treatment time because of intermittent pump stops or patient demand. Urea distribution volume V does not substantially change during a single HD session but may change over time. Therefore, dialysis dose needs to be adjusted when lean body mass and thus V increases. On the contrary, if there is a loss in muscle mass, which is associated with a decrease in V, dialysis dose should not be reduced but rather based on a higher (ideal) patient V to support gains in body mass.[2]

A standard dialysis prescription should consist of a high-flux dialyzer, a minimum treatment time of 4 hours, a blood flow rate of at least 250 mL/min, and a dialysate flow rate of 500 to 800 mL/min. The prescription is then adjusted to meet the target spKt/V of 1.4 volumes. In severe and long-standing uremia, the target dose is approached slowly over the course of several sessions to avoid the dialysis disequilibrium syndrome. Confronted with an inadequate URR or Kt/V, it is sensible to check whether the studied session was representative of the average session, because unusual problems may have occurred (e.g., shortened time, vascular access recirculation, single-needle HD). Frequent causes of inadequately low delivered dialysis dose with recirculation are vascular access problems, particularly of arterial supply. Blood sampling errors also should be considered because delayed post-HD blood sampling results in falsely low Kt/V results. If a low Kt/V remains unexplained, treatment time should be increased and a more efficient dialyzer and higher blood and dialysate flow rates should be considered (Fig. 99.4). Delivered Kt/V should be checked whenever the dialysis prescription has been modified substantially.

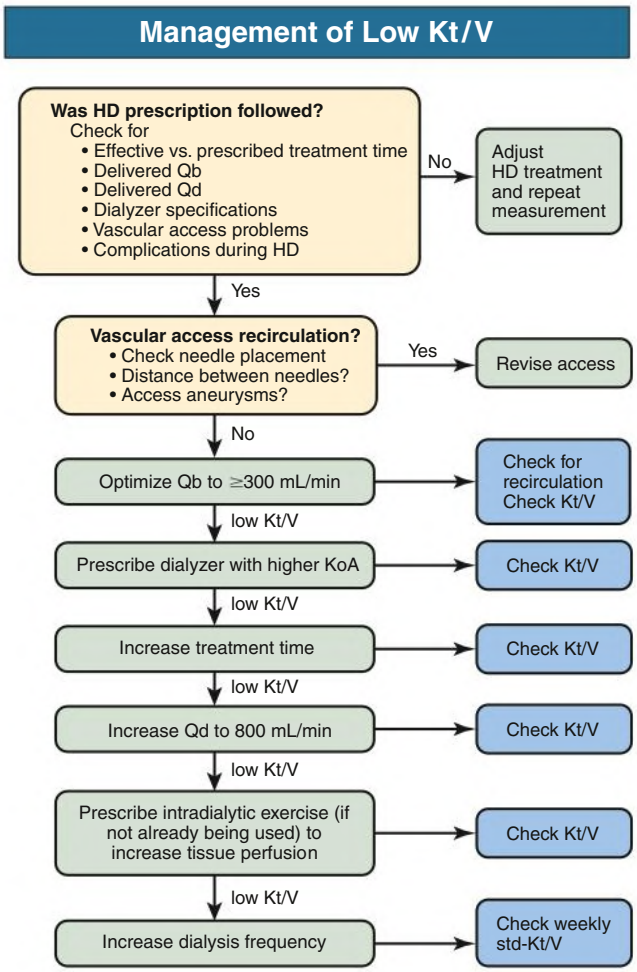

Fig. 99.4 Management of low and inadequate treatment index (Kt/V). *HD,* Hemodialysis; *KoA,* the dialyzer urea mass transfer area coefficient; *Qb,* blood flow rate; *Qd,* dialysate flow rate; *stdKt/V,* equilibrated Kt/V.

Hemodiafiltration Dose

The two major aims governing the prescription of high-volume online-HDF dose are adequate delivery of the target effective CV and the prevention of excess hemoconcentration. High-flux membranes offering high hydraulic permeability, as well as high middle-molecule clearance, are required for effective HDF. Hydraulic permeability is reflected by the membrane ultrafiltration coefficient, whereas membrane permeability is defined by the sieving coefficients for selected middle molecules. For high-volume online HDF a high-flux membrane with an ultrafiltration coefficient greater than 20 mL/h/mm Hg/m^2 and a sieving coefficient for β_2-microglobulin of 0.6 is required.[15] The major determinants of achieving a prescribed target CV in postdilution HDF are blood flow rate (Qb), ultrafiltration rate (UFR), and treatment time (t). Because ultrafiltration is applied to undiluted blood, hemoconcentration necessarily occurs together with a lowering of blood flow rate within the dialyzer. Under certain circumstances, this leads to the deposition of plasma proteins on the membrane surface, clogging of membrane pores, and occlusion of dialyzer capillaries. To prevent excessive hemoconcentration, UFR and Qb need to be individually adjusted so that the filtration fraction (FF), which is defined as the ratio of UFR to Qb, does not exceed 25%. Higher FF up to 30% can be safely achieved only with modern HD machines designed to optimize filtration rate based on constant assessment and optimization of transmembrane pressure. Effective treatment time in high-volume HDF with a fixed target CV will thus always depend on achievable Qb and UFR.

Treatment Time and Frequency

The European best practice guidelines recommend that dialysis should be delivered at least 3 times per week and the total duration should be at least 12 h/wk, unless supported by significant residual kidney function with GFR greater than 3 mL/min.[10] Conventional thrice-weekly dialysis remains the standard of care in most countries, where treatment time is typically governed by dialysis dose (Kt/V), with the consequence of longer dialysis in patients with higher urea distribution volumes. Acknowledging the difficulties in removing adequate amounts of fluid and low/middle molecular uremic solutes during short dialysis sessions, a minimum treatment time of 4 hours per HD session is recommended in many countries. More frequent in-center dialysis and longer dialysis hours delivered by in-center or home HD are increasingly used alternatives to conventional thrice-weekly treatment. Both modalities offer the opportunity for improved solute clearance and complete removal of interdialytic weight gain (IDWG) with fewer intradialytic problems, particularly hypotension.

Several epidemiologic studies in larger patient populations suggested a survival advantage for patients treated with extended time and/or frequency dialysis schedules, such as daily in-center or nocturnal HD 4 to 6 times a week. The randomized controlled Frequent Hemodialysis Network (FHN) study was designed to compare short daily (6 times weekly) HD vs. thrice-weekly in-center HD and, separately, nocturnal home HD 5 to 6 times weekly vs. conventional thrice weekly home HD. After 12 months of follow-up, daily in-center HD resulted in lower phosphate levels, a reduction in left ventricular mass, and an improvement in self-reported physical health.[16] Analysis of patient survival over a median of 3.6 years after randomization suggested that short daily in-center HD reduced long-term mortality.[17]

No such benefit was observed in the nocturnal FHN trial, but this may have been due to inadequate statistical power and unexpectedly low patient recruitment.[18,19]

Dialysate Composition

During a standard HD treatment session, a patient's blood is exposed to 120 to 200 L of dialysate. The several ingredients of dialysate composition should therefore be prescribed with great care. Generation of near-sterile dialysate and prescription of dialysate temperature are addressed in Chapter 98.

Sodium

A positive sodium balance is a typical feature of end-stage kidney disease (ESKD) and an important factor in the pathogenesis of hypertension and fluid overload in HD patients. Chronic sodium accumulation may be associated with increased nonosmotic tissue sodium storage and left ventricular hypertrophy.[20-22] Judicious control of interdialytic sodium intake to approximately 5 to 6 g salt (2300 mg or 100 mmol sodium) per day is effective in normalizing blood pressure. Sodium movement during dialysis depends on the transmembrane sodium gradient between dialysate and plasma water. To avoid a positive intradialytic sodium balance, dialysate and plasma sodium concentrations should be aligned or care should be taken that dialysate sodium does not exceed the patient's average predialysis serum sodium concentration by more than 2 to 3 mmol/L. A positive intradialytic sodium balance may lead to increased interdialytic fluid intake and higher ultrafiltration volumes. However, the associations between serum and dialysate sodium levels and morbidity and mortality require further studies.

Potassium

Potassium removal during dialysis ideally should be equal to the amount accumulated during the interdialytic period. The dialysate potassium concentration must be set at a level that avoids pre-HD hyperkalemia, as well as intradialytic hypokalemia, which may provoke dialysis-induced arrhythmia. Postdialysis hypokalemia less than 3.0 mmol/L is associated with increased risk of mortality, especially in patients presenting with predialysis potassium levels less than 4.0 mmol/L.[23] The typical dialysate potassium concentration is set between 2.0 and 4.0 mmol/L. Prescription of potassium dialysate concentrations less than 2.0 mmol/L is associated with an increased risk for tachyarrhythmia and sudden cardiac death[24] and should be avoided.

Calcium

In light of accelerated vascular calcification in ESKD, intradialytic calcium delivery to the patient should be minimized, and in patients using calcium salts as phosphate binders, a negative intradialytic calcium mass balance is desirable.[25] A dialysate calcium concentration of 1.25 to 1.50 mmol/L is recommended by KDIGO, but many patients will be in positive balance even at 1.25 mmol/L. A positive calcium balance may be associated with tissue calcium accumulation, whereas lower dialysate calcium will stimulate parathyroid hormone (PTH) secretion. In most patients a dialysate calcium concentration of 1.25 mmol/L is now used.

Bicarbonate

Chronic metabolic acidosis is associated with decreased protein synthesis and increased protein catabolism and contributes to mineral and bone disorders. Pre-HD bicarbonate levels in the range of 20 to 23 mmol/L are associated with improved survival. Dialysate bicarbonate concentration is typically set between 35 and 40 mmol/L to generate a transmembrane concentration gradient favoring bicarbonate delivery to the patient. Data from the Dialysis Outcomes and Practice Patterns Study (DOPPS) indicate that both high (>27 mmol/L) and low (<17 mmol/L) predialysis serum bicarbonate levels are associated with increased risk for mortality and hospitalization.[26]

Magnesium

In the past, dialysate magnesium levels of 1.5 mmol/L were used frequently. Currently recommended levels are between 0.5 and 1.0 mmol/L. Whereas observational studies suggested an inverse association between serum magnesium levels and mortality,[27] other studies showed that magnesium dialysate does not improve intradialytic hemodynamics or abrogate myocardial stunning.[28] It is unclear to what extent dialysate magnesium levels have a sustained effect on serum levels.

Ultrafiltration Rate

Fluid overload is an established risk factor for the development of left ventricular hypertrophy and cardiovascular mortality. Similarly, predialysis extracellular fluid depletion is also associated with increased mortality.[29] Adequate HD aims to normalize body water homeostasis and extracellular volume to a postdialysis level comparable with that of patients of similar age and normal kidney function. This ideal, near-normal postdialysis body weight is frequently termed *dry weight,* which often differs substantially from the target weight prescribed. Because of the difficulties in detecting fluid overload of 2 to 3 L clinically, technical methods, such as bioimpedance, relative blood volume monitoring, and imaging (ultrasound, chest radiograph) for assessing volume status should be applied regularly.[30] A successful clinical approach to define dry weight has been the gradual and stepwise reduction in postdialysis weight by 0.2 to 0.5 kg per session until some cramps occur and blood pressure is in the normal range. Postdialysis target weight is then set at 0.5 kg above cramping level. UFRs above 10 mL/kg/h are associated with higher odds of intradialytic hypotension and a greater risk for mortality.[31] It is important to realize that IDWG and fluid overload are not synonymous, and that postdialysis fluid depletion may result in high IDWG.

DIALYSIS ADEQUACY AND GOAL-DIRECTED DIALYSIS

Dialysis adequacy used to be defined as prescribing and delivering a dialysis dose that is associated with the best long-term outcome, but it has meanwhile become evident that the outcome and quality of life of HD patients cannot be influenced by dialysis prescription alone. Therefore, multiple measures and goals should be considered when prescribing dialysis, including small solute clearance, residual kidney function, volume status, biochemical measures, nutritional status, cardiovascular function, intra- and interdialytic symptoms and complications and the patient's individual experiences and goals. Patients may interpret adequacy different than clinicians, and therefore treatment goals should be individualized and reassessed over time while recognizing accepted minimums for small solute removal during dialysis.[1]

The term *goal-directed dialysis* specifically refers to using shared decision-making between patient, their family/delegate, and the care team to establish realistic care goals to allow patients to meet their own life goals and allow the clinician to provide individualized, high-quality dialytic care. The aim of goal-directed dialysis is to provide the best health outcome possible for an individual on dialysis (HD or peritoneal dialysis [PD]) in terms of maintaining their clinical well-being, quality of life, and ability to meet life goals and also minimize patient and caregiver treatment burden. The components of goal-directed dialysis include those directly affected by the dialysis prescription and

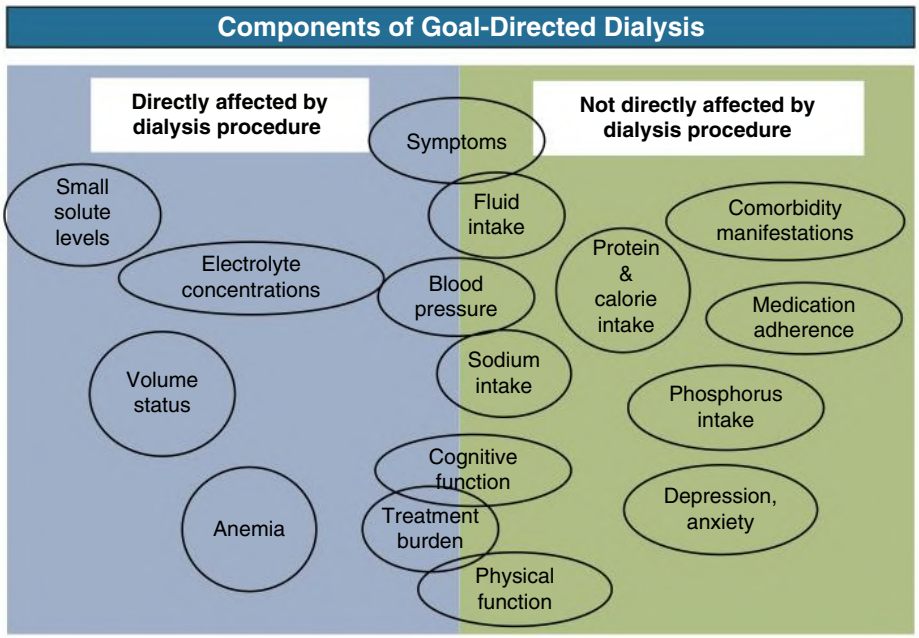

Fig. 99.5 Components of Goal-Directed Dialysis. Some individual goals can be directly affected by dialysis procedure *(left),* whereas others cannot be directly affected by dialysis procedure *(right).* Most goals, however, are overlapping the zones and can only partly be affected by dialysis procedure.

procedure, such as solute clearance electrolyte concentrations, volume status, and intradialytic symptoms, as well as those only indirectly affected by the dialysis procedure, such as symptom burden, nutritional status, activity level, work capacity, and social engagement (Fig. 99.5).[32]

Prevention of Intradialytic Hypotension

Depending on the definition, intradialytic hypotension (IDH) occurs in 10% to 30% of treatments and is associated with damage to the brain, gut, heart, kidney, and poor outcome.[33] Early IDH occurring during the first half of a dialysis session is associated with particularly poor outcome and may be triggered independent of intravascular volume changes.[34] In contrast, IDH occurring later during dialysis is often due to high rates of ultrafiltration occasioned by the necessity to remove large IDWGs during a relatively short treatment.[31] In addition, an individual inability to preserve organ perfusion in the face of dialysis-related hypotension or intravascular hypovolemia (e.g., secondary to uremic and/or diabetic autonomic dysfunction) may lead to short-term changes (e.g., intradialytic cardiac stunning) and long-term consequences (e.g., heart failure and cardiac mortality outcomes).[35] Prevention of high IDWG may help: potential strategies include dietary counseling to reduce sodium intake, lengthening of dialysis duration, dialysate cooling, use of α-sympathetic agonists such as midodrine, and avoidance of food during dialysis. In addition, prevention and management of postural hypotension immediately after dialysis is essential to prevent falls. Intradialytic hypotension is also discussed in Chapter 100.

Preservation of Residual Kidney Function

Most patients starting dialysis still have considerable RKF, but by the end of the first year, the majority may have lost RKF completely. Only 10% to 20% of patients still have RKF after more than 3 years of dialysis. A kidney clearance of 2 to 3 mL/min, which for a patient with total body water of 40 L is equivalent to a stdKt/V of 0.5 to 0.75/wk, contributes significantly to the elimination of uremic toxins with lower β_2-microglobulin, phosphate, potassium, urea, creatinine, and uric acid levels, as well as maintained endocrine, metabolic, and antioxidative stress functions; higher hemoglobin concentration; enhanced nutritional status; better quality of life scores; and a reduced need for dietary and fluid restrictions.[36]

Loss of RKF is associated with left ventricular hypertrophy. Risk factors for the loss of RKF include activation of the immune system by cellulose-based membranes and dialysate water impurities; intradialytic hypotension and kidney hypoperfusion; use of angiotensin-converting enzyme inhibitors or nephrotoxic agents (e.g., radiocontrast media, aminoglycosides, and nonsteroidal antiinflammatory drugs); and hypercalcemia. Loss of RKF may be delayed by adequate target post-HD weight prescription and prevention of intradialytic hypotensive episodes.[37]

Maintenance or Improvement of Nutritional Status

HD patients are at risk for malnutrition secondary to protein-energy wasting, decreased appetite, infection, intercurrent illnesses, hospital admissions, and missed meals after dialysis.[38] The recommended daily intake of 1.2 g protein per kilogram of ideal body weight and 30 to 35 kcal per kilogram of ideal body weight are often not met. The nutritional status of dialysis patients should be assessed regularly by clinical and biochemical means and by technical means such as bioimpedance. Eating during dialysis or intradialytic oral nutritional supplements including supplemental vitamins may be beneficial in patients with low spontaneous energy and protein intake. Nutrition in HD patients is also discussed in Chapter 90.

Goal-Directed Dialysis in the Elderly

Patients older than 75 years represent the largest incident and fastest-growing prevalent patient population in HD worldwide, and the unique medical and social needs of these patients require consideration. Studies in this population show that the parameters that correlate with clinical outcomes are not the traditional markers of HD dose, such as Kt/V and treatment time, but rather cardiovascular comorbidity, nutritional status, functional capacity, and frailty.[39] Therefore, the focus of dialysis adequacy in elderly patients should shift

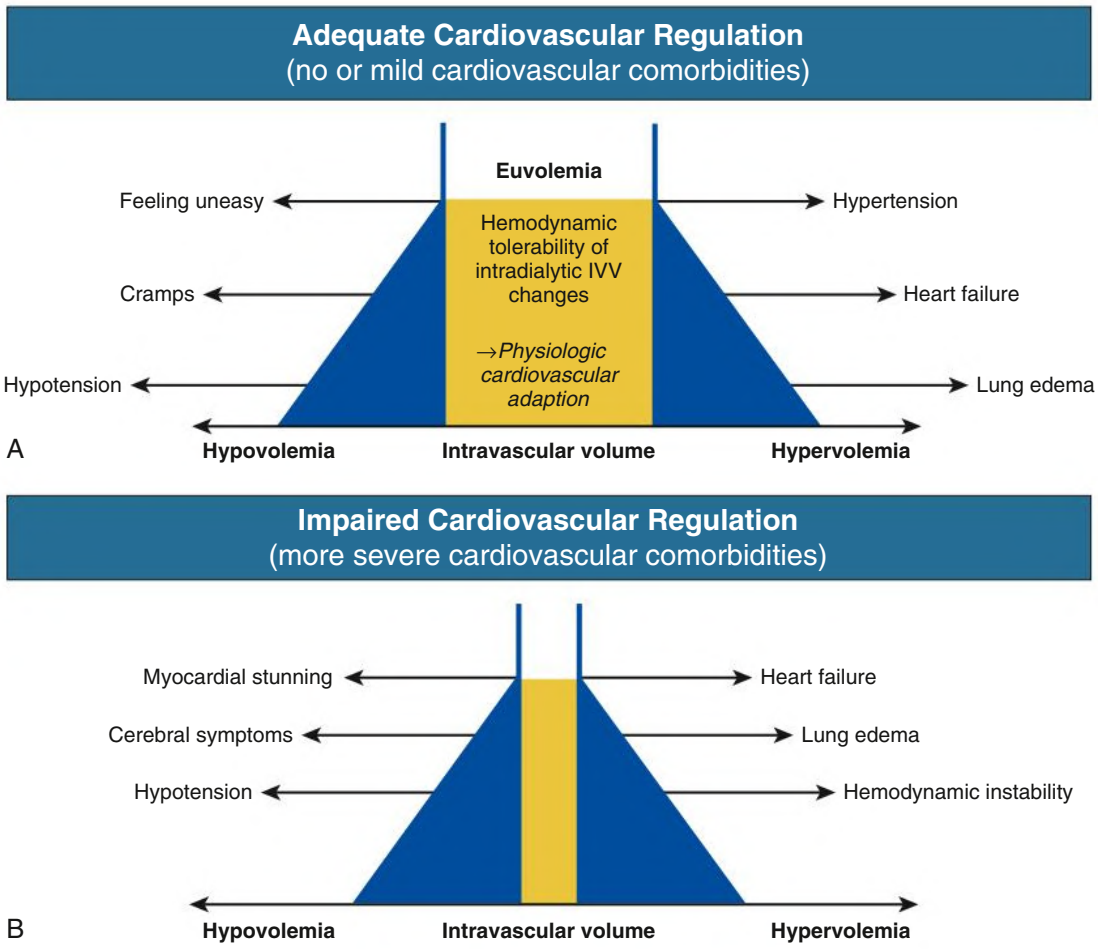

Fig. 99.6 Intradialytic Vulnerability. The occurrence of complications *(arrows)* in response to intradialytic changes in intravascular volume (IVV) depends on the functionality of physiologic cardiovascular (CV) adaptation mechanisms, such as an increase in heart rate and constriction of arterioles and venous capacity vessels. The individual hemodynamic tolerability of intradialytic IVV changes *(yellow field)* is higher in patients on hemodialysis (HD) with no or mild CV comorbidities and intact CV responses (A) than in typically older and multimorbid HD patients with impaired cardiovascular regulation (e.g., secondary to diabetic autonomous neuropathy; B). (Modified from Chauveau P, Combe C, Laville M, et al. Factors influencing survival in hemodialysis patients aged older than 75 years; 2.5-year outcome study. *Am J Kidney Dis.* 2001;37:997–1003.)

from urea-based assessment of dialysis dose to the use of a more multidimensional measure.[32] Elderly dialysis patients with multiple comorbidities tolerate HD treatments less well than younger patients. Typical complications, such as intradialytic hypotension, cramps, atrial fibrillation, and postdialysis fatigue contribute to the rapid loss of independence occurring in this vulnerable patient population. The underlying etiology is reduced tolerance to intravascular volume reduction during dialysis, which is at least partially caused by impaired cardiovascular hemodynamic responses in combination with uremic and/or diabetic autonomic neuropathy (Fig. 99.6). Significant reductions in organ perfusion occurring in the gut, liver, kidneys, heart, and brain contribute to the development of inflammation, malnutrition, heart failure, loss of RKF, frailty, depression, and dementia.[33] To protect vulnerable elderly patients from the dramatic short- and long-term consequences of intradialytic tissue hypoxia, the HD prescription should be individualized. The following list provides some interventions that may help make HD treatments more tolerable in elderly patients, with the goal to reduce cardiovascular complications, sustain nutritional status, and slow the development of frailty.

- Carefully evaluate individual susceptibility to intradialytic hypotension in relation to UFR.
- Assess vascular refilling capacity by monitoring intradialytic changes in blood volume.
- Individualize maximum UFR (ideally <10 mL/kg body weight/h).
- Consider ultrafiltration profiling and/or the use of dialysis machines with biofeedback control of UFR.
- Lower dialysate temperature to prevent the intradialytic increase in body core temperature associated with an increased risk for intradialytic hypotension.
- Reduce IDWG (dietary counseling regarding salt intake, prescribe adequately dosed diuretics).
- Avoid intradialytic positive sodium balance (individualize dialysate composition).
- Increase dialysis frequency in case the patient does not tolerate a long interdialytic interval.
- Reduce β-blocker medication to allow cardiac compensation for changes in intravascular volume.
- Reduce or pause antihypertensive medication before dialysis in hypotension-prone patients.
- Assess the effect of food intake during dialysis on hemodynamic stability.
- Regularly adjust postdialysis target weight (bioimpedance).

- If hypertensive, gradually reduce postdialysis weight, avoiding intradialytic hypotensive episodes.
- Consider supine position during dialysis.
- Consider online HDF.
- Consider peritoneal dialysis in patients with otherwise intractable IDH.
- Treat intradialytic hypoxia by intradialytic oxygen application.
- Ensure three meals per day, including the dialysis day.
- Prescribe oral nutritional supplements during and between dialysis treatments.
- Prevent immobilization by early rehabilitation and physical therapy.

SELF-ASSESSMENT QUESTIONS

1. Which of the following factors related to the hemodialysis prescription in a patient without much residual kidney function is likely to result in the *worst* outcome?
   A. Kt/V of 1.15 over months
   B. Use of low-flux dialyzers
   C. 3-hour dialysis times
   D. Dialysate potassium of 2 mEq/L
2. Hypertension is very common in dialysis patients. Which factor alone is *least* likely to reduce BP?
   A. Use of antihypertensive drugs
   B. Longer dialysis times with fluid removal
   C. Postdialysis weight reduction
   D. Dietary sodium restriction
3. Which action is *not* useful when the BP falls frequently during dialysis?
   A. Decrease dialysate temperature
   B. Apply abdominal pressure
   C. Reduce the ultrafiltration rate
   D. Increase postdialysis target weight
4. The recommended target convective volume in high-volume online hemodiafiltration is 23 L/1.73 m^2/treatment. Which of the following actions is *not* useful to increase the convective volume?
   A. Increase ultrafiltration rate
   B. Increase filtration fraction
   C. Increase blood flow rate
   D. Increase dialysate flow rate
   E. Increase treatment time
5. In patients with residual kidney function, an intrinsic urea clearance of 3 mL/min is approximately equivalent to a weekly standard KtV of:
   A. 0.10.
   B. 0.25.
   C. 0.75.
   D. 1.05.
   E. 1.50.

Acute Complications During Hemodialysis

Kevan R. Polkinghorne, Peter G. Kerr

Although technical advances in hemodialysis (HD) have made the procedure increasingly safe and well tolerated, important acute complications can occur in patients receiving HD in both acute and chronic clinical settings. These complications, etiology, and their management are discussed in this chapter.

CARDIOVASCULAR COMPLICATIONS

Intradialytic Hypotension

Intradialytic hypotension occurs in 15% to 50% of treatments depending on the definition and ranges from asymptomatic episodes to marked compromise of organ perfusion, resulting in myocardial ischemia, cardiac arrhythmias, vascular thrombosis, loss of consciousness, seizures, or death.[1-3] Furthermore, in patients with acute kidney injury, intradialytic hypotension may reduce the likelihood of recovery. Recurrent HD-induced ischemic cardiac injury (myocardial stunning) is a prominent cause of intradialytic hypotension and is more common at higher ultrafiltration rates and less frequent with longer and more frequent dialysis treatments.[4] Like intradialytic hypotension and postdialysis orthostatic hypotension, myocardial stunning is an independent risk factor for mortality.[5] The pathogenesis of intradialytic hypotension is complex and is summarized in Fig. 100.1. Most commonly, intradialytic hypotension results from the need to deal with excessive fluid weight gain between dialysis treatments. The subsequent rate of fluid removal required exceeds the achievable rate of intravascular filling, resulting in relative intravascular volume depletion. Recent data demonstrate an increased risk for death as the ultrafiltration rate increases, regardless of the threshold used.[6]

The immediate treatment for intradialytic hypotension is to restore the circulating blood volume by placing the patient in the Trendelenburg position, reducing or stopping ultrafiltration, and infusing boluses of 0.9% isotonic saline (≥100 mL, as necessary). Salt-poor albumin and other hypertonic solutions offer no proven advantage over isotonic saline and are more expensive.[7] Blood flow rate should not be routinely reduced to manage hypotension, as this has not been shown to be beneficial and will compromise overall solute clearance. Of course, in the setting of excessive weight gain, the administration of boluses of saline or cessation of ultrafiltration makes achieving the target dry weight more difficult. Because cardiac factors can precipitate intradialytic hypotension, the clinician should maintain a high index of suspicion for cardiac ischemia, especially if hypotension is accompanied by chest pain or dyspnea, and an electrocardiogram and serum troponin values should be obtained. Similarly, recurrent and unexplained episodes of hypotension might warrant echocardiography to rule out pericarditis or pericardial effusion.

Preventive strategies include correction of anemia, treatment of congestive heart failure or arrhythmias, avoidance of antihypertensive drugs on the day of or at least in the hours before dialysis (especially those that reduce arteriolar tone), and avoiding food before and during dialysis, as these may result in shunting of blood to the gut. Patients should be counseled to avoid excessive interdialytic weight gain (IDWG), because this is the predominant cause of intradialytic hypotension and particular attention should be given to ensuring minimal salt intake. Finally, an accurate assessment of the patient's dry weight is required. Midodrine, an oral selective α1-agonist, 5 to 10 mg before dialysis, can be a useful preventive therapy if the earlier-mentioned strategies fail.

Preventive strategies through modification of the dialysis procedure include use of bicarbonate dialysate (as opposed to acetate buffered dialysate) and volumetric control of ultrafiltration. Subsequently, reducing the ultrafiltration rate by increasing either treatment time or the frequency of dialysis can be tried.[2,8] The strategy of isolated ultrafiltration followed by HD (i.e., sequential dialysis) has been recommended for many years, although there is limited evidence to support it.[2] A higher dialysate sodium may improve single-treatment blood pressure but at the expense of higher IDWG and volume overload in the longer term[2] (see Chapter 42). The data to support sodium profiling or modeling are limited, with one study suggesting that the routine use of sodium modeling/profiling to limit or prevent intradialytic hypotension is associated with increased all-cause mortality.[9] Online blood volume monitoring and biofeedback techniques have been developed in an attempt to improve intradialytic cardiovascular (CV) stability.[10] Although online blood volume devices may decrease the incidence of intradialytic hypotension in an at-risk population, there is limited evidence that blood volume monitoring can predict intradialytic hypotension in individual patients or produce a long-term morbidity and mortality benefit, especially in the wider HD population.[10] A recent small crossover study failed to show a benefit of ultrafiltration profiling in preventing intradialytic hypotension or treatment-related cardiac stress.[11] Cooling of dialysate to 35.5°C to 36°C (95.9–96.8° F), a measure that induces release of catecholamines, resulting in vasoconstriction or at least preventing vasodilation, may lessen hypotension. Modulation of dialysate temperature is achieved by measuring the blood temperature in the arterial and venous circuits and feeding back the information to the arterial and venous thermostats in the dialysis machine. The machine can be programmed to allow a constant body temperature and a negative overall energy transfer, so-called *isothermic* or *thermoneutral* HD, which aims to prevent energy transfer between the dialysate and extracorporeal blood. A recent systematic review of the randomized controlled trials using biofeedback-modulating dialysate temperature demonstrated significant reductions in the incidence of intradialytic hypotension compared with conventional dialysis.[12] However, large multicenter randomized trials are needed to determine whether reduced temperature dialysis reduces CV events and patient death.

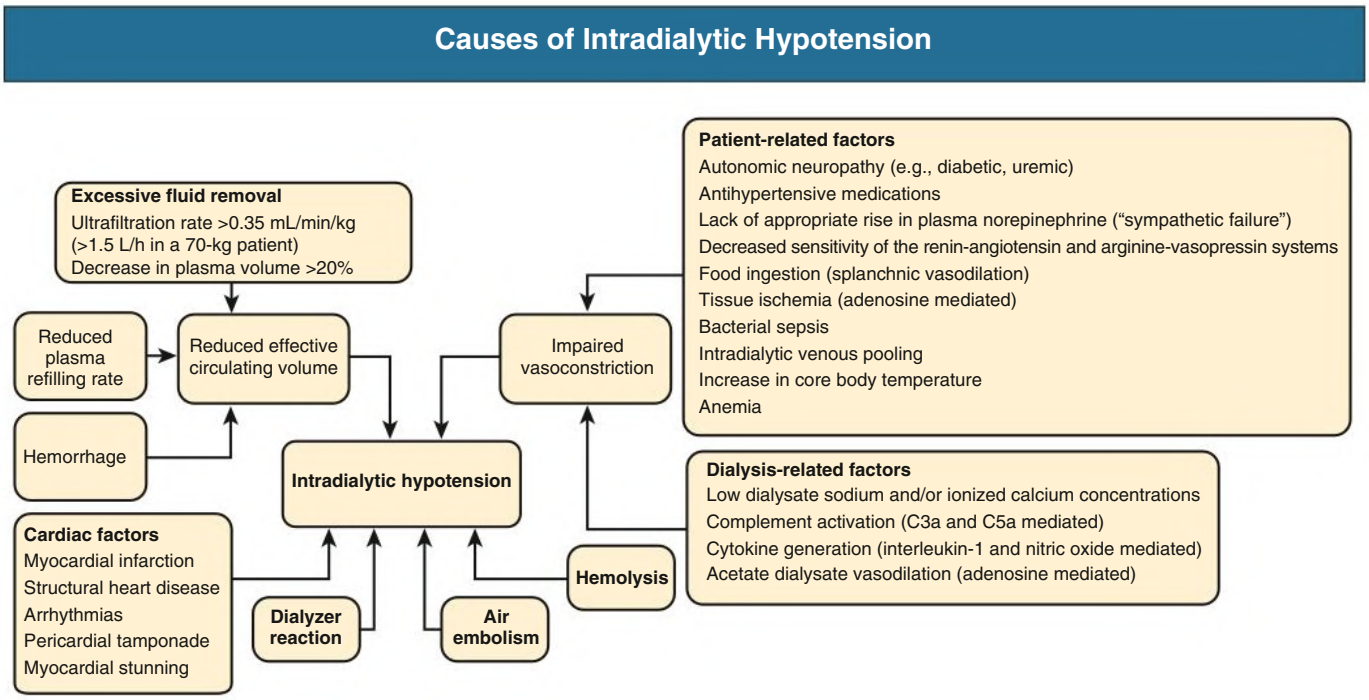

Fig. 100.1 Pathogenesis and causes of intradialytic hypotension.

Across Europe and many other countries, hemodiafiltration (HDF) has become a common mode of dialytic therapy. Although claims of improved mortality with this modality remain a matter of debate, most accept that HDF is associated with improved intradialytic CV stability and less frequent hypotension, but this is also disputed by some.[13]

Intradialytic Hypertension

Intradialytic hypertension (IDH) occurs in 5% to 30% of treatments depending on the definition used.[2,14] Hypertension during or immediately after HD constitutes an important risk factor for CV mortality. Moreover, an intradialytic increase in systolic blood pressure (BP) is associated with an increased risk for hospitalization or death.[15]

In most circumstances, an intradialytic elevation of BP indicates significant volume overload. However, in a number of patients BP remains elevated despite fluid removal, a syndrome called *dialysis-refractory hypertension*. These patients are usually young, with preexisting hypertension, and have excessive IDWG and a hyperactive renin-angiotensin system in response to fluid removal.[16] In these patients the hypertension is still mediated by the previous volume expansion, but there is often a lag of days to 2 or more weeks before the BP becomes normal after reduction of the dry target weight (known as the dialysis "lag phenomenon"). Often patients can discontinue most of their antihypertensive agents once this period has elapsed. Chapter 42 presents more details on the diagnosis and management of hypertension associated with hemodialysis.

Erythropoietin (EPO) and other erythropoiesis-stimulating agents have been associated with a 20% to 30% incidence of new-onset hypertension or exacerbation of hypertension. Furthermore, among patients receiving intravenous (not subcutaneous) EPO, elevated levels of endothelin-1 (a potent vasoconstrictor) have been shown to correlate with increased BP. Such EPO-induced rises in BP are usually associated with a rapid rise in hemoglobin and can be avoided by a more conservative approach to correcting the hemoglobin.

IDH can be precipitated by the use of high-sodium dialysate, which is intended to mitigate the intradialytic decrease in serum osmolality that occurs with the diffusive removal of urea and sodium.[17] Although this approach stabilizes BP during dialysis by improving intravascular filling, high-sodium dialysate results in a positive intradialytic sodium balance and is associated with increased postdialysis thirst, resulting in significant weight gain in the interdialytic period. To circumvent these problems, sodium modeling has been adopted as an approach that uses variable sodium concentrations in the dialysate, generally with sodium reduced in a continuous or stepwise manner from an initial level of 150 to 154 mmol/L to 138 to 142 mmol/L. Although sodium modeling has been widely promoted, results from both randomized and nonrandomized crossover studies do not suggest any definitive benefit.[9,18] Other hypothesized mechanisms of IDH include hyperactivity of the sympathetic nervous system[19] and increased cardiac output resulting from fluid removal, particularly in patients with cardiomyopathy.[20] Clinicians also should be aware of possible dialytic removal of certain antihypertensive drugs, such as angiotensin-converting enzyme (ACE) inhibitors and β-blockers.

Increasing hypertension during a dialysis session requires intervention if systolic BP is greater than 180 mm Hg. This is best treated with a short-acting agent, such as the ACE inhibitor captopril. Successful treatment of hypertension for a longer period requires an accurate determination of the patient's dry weight and its achievement by gradual ultrafiltration over several weeks of dialysis. Once dry weight is achieved, optimization of antihypertensive drug therapy is warranted, potentially including the use of minimally dialyzable or nondialyzable medications such as angiotensin receptor blockers, calcium channel blockers, clonidine, and carvedilol. However, use of antihypertensive agents may make achievement of dry weight difficult because of induced intradialytic hypotension. Evidence from the Dry-Weight Reduction in Hypertensive Hemodialysis Patients (DRIP) trial[21] suggests that optimal control of BP in HD patients is via control of extracellular fluid volume (salt and water) and not the use of antihypertensive agents. One common error in management is to treat dialysis hypertension with increasing BP medications as opposed to opting to achieve dry weight. The use of vasodilator drugs (hydralazine, minoxidil) can lead to increased fluid retention that worsens volume overload. Minoxidil

also can cause pleural and pericardial effusions and should be avoided in dialysis patients if at all possible.

Cardiac Arrhythmias

Intradialytic arrhythmias are common and are often multifactorial in origin.[22,23] Left ventricular hypertrophy, congestive cardiomyopathy, uremic pericarditis, silent myocardial ischemia, and conduction system calcification are frequently encountered in adult dialysis patients. In addition, polypharmacy coupled with the constant alterations in fluid, electrolyte, and acid-base homeostasis may precipitate intradialytic arrhythmias. Intradialytic hypotension is also associated with intradialytic cardiac arrhythmias.[24] The range of electrocardiographic abnormalities that may be encountered in kidney failure is shown in Table 100.1. QTc dispersion, the difference between maximum and minimum QTc interval on a standard 12-lead electrocardiogram, is prolonged after HD and has been proposed as a prognostic indicator of cardiac complications in dialysis patients.

Preventive measures include the use of bicarbonate dialysate and careful attention to dialysate potassium and calcium levels as well as careful attention to preventing intradialytic hypotension (see earlier). There are very few trials of the most appropriate dialysate potassium level, although recent observational evidence suggests that dialysate potassium levels below 2 mmol/L should be avoided in most patients.[25] Zero potassium dialysate should be avoided in the hyperkalemic individual because of its arrhythmogenic potential, particularly in patients receiving digoxin. Serum digoxin levels should be regularly monitored and the need for the drug regularly reassessed.

Sudden Death

Cardiac arrest occurs in 7 per 100,000 HD sessions and is more common in the elderly, patients with diabetes, and patients using central venous catheters.[26] Sudden deaths during dialysis are observed more frequently after the 3-day (classically weekend) interdialytic interval in patients receiving dialysis three times per week.[27,28] The etiology is complex but likely related to cardiac structural abnormalities related to long-standing hypertension and uremia coupled with the more marked fluid and solute accumulation seen in the long interdialytic period. Both peritoneal dialysis patients and patients undergoing frequent long-hours HD do not show this high event rate on a particular day of the week.[28] Recent analysis of data from implantable cardiac monitors in HD patients with sudden cardiac death found that the vast majority were due to bradycardia and asystole, rather than malignant ventricular arrhythmias, raising uncertainty regarding β-blocker use in this population.[29]

Although coronary heart disease increases the risk for sudden death, other catastrophic intradialytic events need to be ruled out. The prompt recognition and treatment of hyperkalemia, as a reversible cause of cardiac dysfunction, is imperative. Profound generalized muscle weakness may be a warning sign of imminent life-threatening hyperkalemia.

When cardiopulmonary arrest occurs during dialysis, an immediate decision must be made as to whether the collapse is the result of an intrinsic disease or technical errors, such as air embolism, unsafe dialysate composition, overheated dialysate, line disconnection, or sterilant in the dialyzer. Air in the dialysate, grossly hemolyzed blood, and hemorrhage caused by line disconnection can be easily detected. However, if no obvious cause is identifiable, blood should not be returned to the patient, particularly if the arrest occurred immediately on initiation of dialysis. A patient exposed to formaldehyde may have reported earlier burning at the access site; fortunately, this agent is rarely used today. If the possibility of a problem with dialysate composition is remote, blood may be returned to the patient. However, blood and dialysate samples should be immediately sent for electrolyte analysis, the dialyzer and blood lines saved for later analysis, and the dialysis machine replaced until all its safety features have been thoroughly evaluated for possible malfunction. It should be standard practice to have defibrillators in dialysis units. The management of cardiopulmonary arrest during dialysis should follow the standard principles of cardiopulmonary resuscitation; the diagnosis and management of technical errors are discussed later. All dialysis units should have established protocols for managing cardiac arrest and other common dialysis emergencies.

Prevention of sudden cardiac death in HD patients, including the role of implantable defibrillators, is discussed further in Chapter 85.

TABLE 100.1 Electrocardiographic Abnormalities in Kidney Failure

Function	Abnormality
PR interval	Usually normal; prolongation in long-term HD. Calcification of mitral valve annulus may involve His bundle, resulting in complete heart block.
QRS interval	
Amplitude	Increases during ultrafiltration (correlates with reduction in LV dimensions). LVH on voltage criteria found in up to 50%.
Duration	Prolonged (within normal range) by hemodialysis. Late potentials increased only in patients with preexisting coronary heart disease. Prolonged in hyperkalemia.
ST segment	Depression during HD does not predict coronary artery disease. Depression or elevation may occur in hyperkalemia. Depression during ambulatory monitoring poorly predictive of coronary artery disease.
QTc interval	Increases during HD (correlates with reduction in K^+ and Mg^{2+}). Increased QT dispersion reported in patients on dialysis.
T wave	Peaking or inversion may occur in hyperkalemia. Inversion in anterolateral leads in LVH with strain pattern.
Rhythm	Bradycardia and asystole in long intradialytic break and during HD. Atrial and ventricular arrhythmias during HD.

Risk factors include LV dysfunction, wall motion abnormalities, known coronary artery disease, abnormal perfusion scans (even without coronary artery disease), use of cardiac glycosides, and low dialysate potassium concentration.
HD, Hemodialysis; *LV,* left ventricle; LVH, left ventricular hypertrophy.

Dialysis-Associated Steal Syndrome

The clinical presentation, differential diagnosis, and evaluation of dialysis-associated steal syndrome are discussed further in Chapter 96.

NEUROMUSCULAR COMPLICATIONS

Muscle Cramps

Muscle cramps occur in 5% to 20% of patients late during dialysis and frequently involve the legs. They account for 15% of premature discontinuations of dialysis.[30] Electromyography shows increased tonic muscle electrical activity throughout dialysis, and serum creatine kinase may be elevated.

Although the pathogenesis is unknown, dialysis-induced volume contraction and hypoosmolality appear to be common predisposing factors. Indeed, the onset of muscle cramps may give an indication that

the target weight has been reached. However, hypomagnesemia and carnitine deficiency also may play a role.

The acute management is directed at increasing plasma osmolality. Cessation of ultrafiltration is not useful. Parenteral infusion of 23.5% hypertonic saline (15–20 mL), 25% mannitol (50–100 mL), or 50% dextrose in water (25–50 mL) is equally effective. However, hypertonic saline may result in postdialytic thirst, and both hypertonic saline and mannitol cause transient warmth and flushing during the infusion. Furthermore, large and repetitive infusions of mannitol may lead to increased thirst, IDWG, and fluid overload. Overall, dextrose in water is preferred, particularly in nondiabetic patients.

Preventive measures include dietary counseling about excessive IDWG, in particular reducing dietary sodium intake. In patients without clinical signs of fluid overload, it is reasonable to increase the dry weight by 0.5 kg and to observe the clinical response. Quinine sulfate (250–300 mg) or oxazepam (5–10 mg) given 2 hours before dialysis also may be effective. Although the US Food and Drug Administration regards quinine sulfate as unsafe and ineffective for the prevention of cramps, this drug works well in some patients and is used freely in most parts of the world. Some reports also promote the use of vitamin E in this role.[31] The use of sodium gradients during dialysis may have some benefit as well. Proposed strategies include starting with a dialysate sodium concentration of 145 to 155 mmol/L and a linear decrease to 135 to 140 mmol/L by the completion of the treatment. A comparison of sodium modeling with an exponential, linear, or step program has yielded similar results.[18,32] In anecdotal reports, 5 mg of enalapril twice weekly may be effective, presumably by inhibiting angiotensin II–mediated thirst. Stretching exercises, magnesium, creatine monohydrate (12 mg before dialysis), and L-carnitine supplementation (20 mg/kg per dialysis session) also may be beneficial. An intradialytic blood volume biofeedback control system has been shown to reduce the incidence of muscle cramps.[33]

Restless Legs Syndrome

Restless legs syndrome is common in dialysis patients. The typical report is of crawling sensations in the legs that occur with inactivity, and symptoms may worsen during dialysis. The etiology, prevention, and management of restless legs syndrome are discussed in Chapter 89.

Dialysis Disequilibrium Syndrome

Despite a decline in its incidence, dialysis disequilibrium syndrome (DDS) is still observed sporadically in patients who are initiated on HD on high-flux dialyzers with large surface areas and short dialysis time. Risk factors (Table 100.2) include young age, severe uremia, rapid and marked intradialytic falls in urea at dialysis initiation, low dialysate sodium concentration, and preexisting neurologic disorders (see Chapter 89).

DDS commonly manifests with restlessness, headache, nausea, vomiting, blurred vision, muscle twitching, disorientation, tremor, and hypertension. More severe manifestations include obtundation, seizures, and coma. DDS usually develops toward the end of dialysis but may be delayed for up to 24 hours. Although cerebral edema is a consistent finding on computed tomographic scanning, DDS remains a clinical diagnosis because laboratory tests, including electroencephalography, are nonspecific. It is usually self-limited, but full recovery may take several days. The differential diagnoses for DDS are detailed in Table 100.2.[34]

The pathogenesis of DDS is still a subject of debate. The reverse urea effect theory, which proposes that a transient osmotic disequilibrium occurs during dialysis as a result of a more rapid removal of urea from blood than from cerebrospinal fluid, has been disputed.[35] In animals undergoing rapid dialysis, despite the correction of systemic acidosis, a paradoxical cerebrospinal fluid acidosis develops that is aborted by slower dialysis. An additional mechanism is the intracerebral accumulation of idiogenic osmoles, such as inositol, glutamine, and glutamate.

TABLE 100.2 Dialysis Dysequilibrium

Differential diagnosis	Subdural hematoma Uremia Nonketotic hyperosmolar coma Acute cerebrovascular event Dialysis dementia Excessive ultrafiltration and seizure Hypoglycemia Malignant hypertension Hyponatremia
Risk factors	Younger age Severe uremia Rapid and marked intradialytic fall in urea at dialysis initiation Low dialysate sodium concentration Preexisting neurologic disorders
Prevention	Early recognition of uremia states Stepped initiation of dialysis with short initial treatment times Use of volumetric-controlled hemodialysis machines Low blood flow rates Utilize small surface area dialyzers Targeted reduction in blood urea ~30% Sodium profiling, high not low sodium dialysate concentration

In high-risk patients (see Table 100.2), preventive measures include the use of volumetric-controlled machines, bicarbonate dialysate, sodium modeling, earlier recognition of uremic states, and stepped initiation of dialysis (short initial treatment times with lower blood pump speeds). To this end, short and more frequent dialysis treatments are recommended with use of small surface area dialyzers and reduced blood flow rates. The target reduction in blood urea should initially be limited to 30%. The prophylactic use of mannitol or anticonvulsants is not recommended.

An extension of this syndrome may be one that mimics osmotic demyelination syndrome, similar to that seen with rapid correction of hyponatremia. Several cases have been reported in association with dialysis initiation, with clinical manifestations similar to those of the locked-in pontine picture of central demyelination. The difference is that with the dialysis-related condition, patients appear to recover over the ensuing 5 to 7 days, and the condition seems to be related to edema rather than demyelination.[36]

Seizures

Intradialytic seizures occur in fewer than 10% of patients and tend to be generalized but easily controlled. However, focal or refractory seizures warrant evaluation for focal neurologic disease, particularly intracranial hemorrhage. Causes of seizures are summarized in Fig. 100.2 and are discussed further in Chapter 89.

Treatment of established seizures requires cessation of dialysis, maintenance of airway patency, and investigation for metabolic abnormalities. Intravenous diazepam, alprazolam, or clonazepam, and phenytoin may be required. Intravenous 50% dextrose in water should be administered promptly if hypoglycemia is suspected.

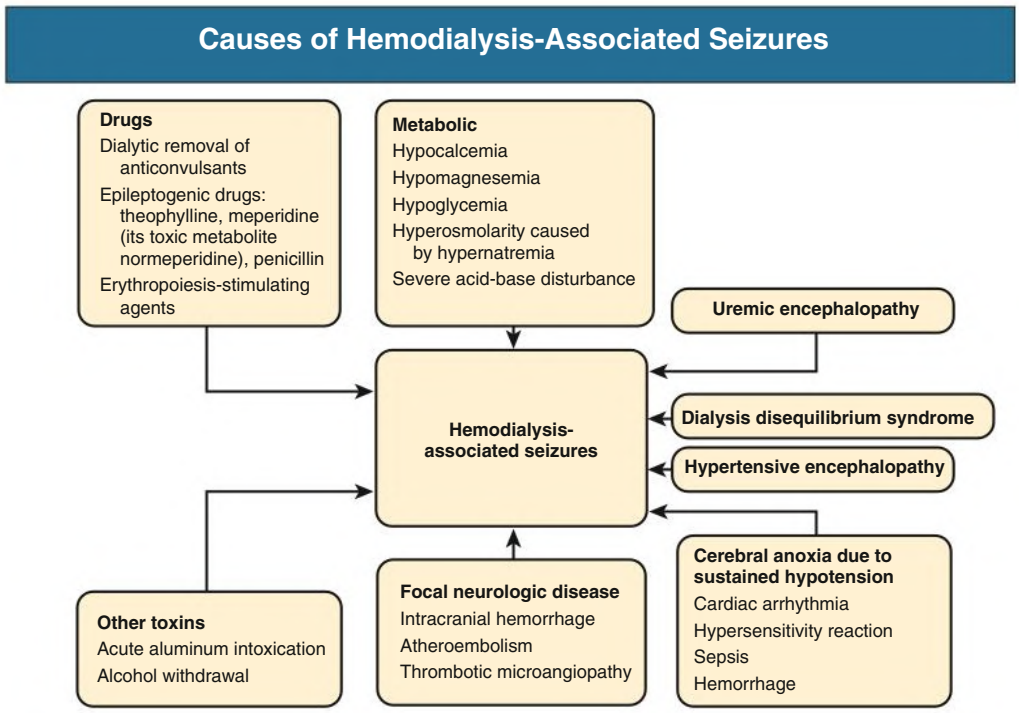

Fig. 100.2 Causes of hemodialysis-associated seizures.

Headache

Dialysis headache is common and typically consists of a bifrontal discomfort that develops during dialysis and may become intense and throbbing, accompanied by nausea and vomiting. It is usually aggravated by the supine position, but there are no visual disturbances.[37]

Although its cause is unknown, dialysis headache may be a subtle manifestation of DDS or may be related to accumulation of acetate, which is present in low concentrations (3–4 mmol/L) in almost all dialysate fluid. A role for nitric oxide also has been postulated. Alternatively, it may be a manifestation of caffeine withdrawal caused by dialytic removal of caffeine.

Management consists of oral analgesics (e.g., acetaminophen [paracetamol]). Preventive measures include slow dialysis with reduced blood flow rates; change to bicarbonate dialysate, sodium, and ultrafiltration modeling; coffee ingestion during dialysis; and use of reprocessed dialyzers. Attention should also be paid to adequate flushing of the lines and dialyzer before commencement of dialysis. Changing the dialyzer (especially to a synthetic membrane or an alternative synthetic membrane) is sometimes useful in refractory cases.

HEMATOLOGIC COMPLICATIONS

Complement Activation and Dialysis-Associated Neutropenia

Complement activation and neutropenia, first seen with unsubstituted cellulose dialyzers that are now not used, can occur with widely used dialyzer membranes, including cellulose acetate and "synthetic" membranes such as polysulfone. However, this is very uncommon, especially in the case of the synthetic membranes, and the long-term clinical relevance of this phenomenon remains speculative. Its contribution to acute intradialytic morbidity is discussed later.

Intradialytic Hemolysis

Acute hemolysis can be caused by faulty dialysis equipment, chemicals, drugs, toxins, or patient-related factors (Fig. 100.3).[38] With the advent of better dialysis equipment design and the widespread use of reverse osmosis and/or deionization systems and carbon filters, traumatic red blood cell (RBC) fragmentation caused by poorly designed blood pumps and methemoglobinemia caused by water contamination with chloramine or copper are rarely seen today. However, nitrate or nitrite intoxication causing methemoglobinemia still occurs sporadically in patients on home HD who use well water contaminated with urine from domesticated animals. Furthermore, during dialyzer reprocessing, formaldehyde retention can result in hemolysis by inducing formation of cold agglutinins or inhibiting RBC metabolism.

The diagnosis of acute hemolysis is evident when grossly translucent hemolyzed blood is observed in the tubing. Patients with methemoglobinemia have nausea, vomiting, hypotension, and cyanosis, and oxygen therapy does not improve the black blood present in the extracorporeal circuit. Copper contamination should be suspected in the presence of skin flushing and abdominal pain or diarrhea.

Evaluation should include reticulocyte count, haptoglobin, lactate dehydrogenase, blood smear, Coombs test, and measurement of methemoglobin. Chromium 51 (^{51}Cr)-labeled RBC survival and bone marrow examination may occasionally be indicated if there is recurrent hemolysis. More important, analysis of tap water for chloramines and assessment of the status of charcoal filtration (which removes chloramines) and metal contaminants and thorough analysis of the dialysis equipment for clues of increased blood turbulence are recommended.

Hemorrhage

Bleeding complications are commonly related to the use of intradialytic anticoagulation, which exacerbates the uremic bleeding diathesis (see Chapter 87). In addition, dialysis patients are prone to spontaneous bleeding at specific sites, such as gastrointestinal arteriovenous malformations; subdural, pericardial, pleural, retroperitoneal, and hepatic subcapsular spaces; and the ocular anterior chamber. Despite its limitations, the bleeding time remains the best indicator of hemorrhagic tendency.

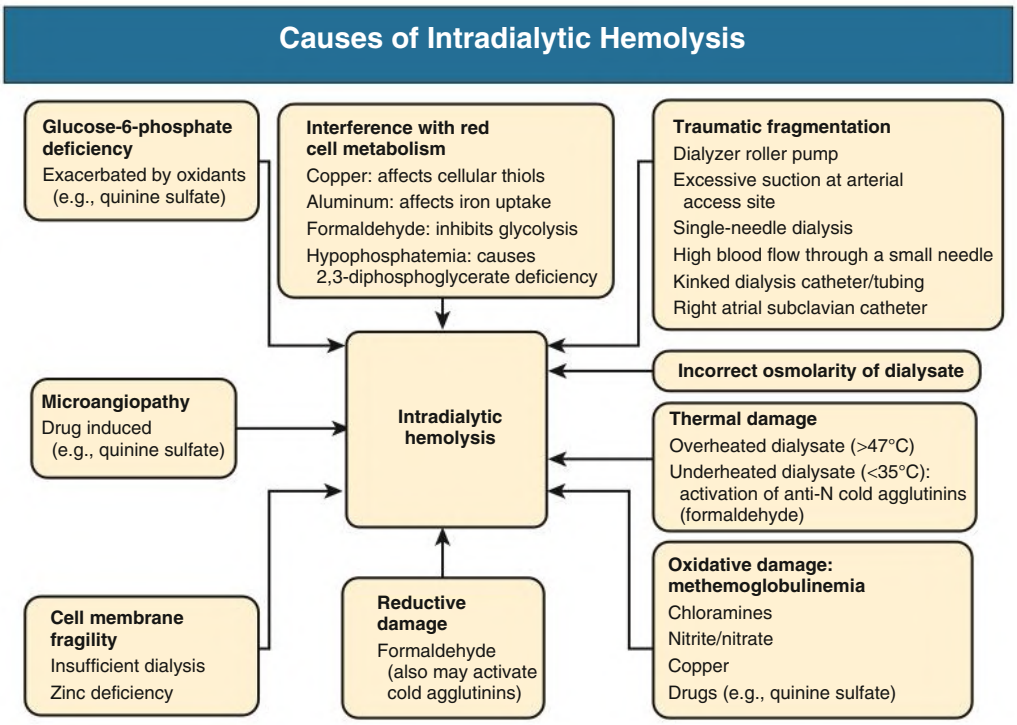

Fig. 100.3 Causes of intradialytic hemolysis.

In addition to specific measures directed to the site of hemorrhage, reversal of uremic platelet dysfunction is imperative. Strategies include the use of erythropoiesis-stimulating agents or RBC transfusions to achieve a hematocrit above 30% to improve rheologic platelet–vessel wall interactions, intravenous conjugated estrogens at 0.6 mg/kg/day for 5 consecutive days, intravenous or subcutaneous 1-deamino-8-D-arginine-vasopressin (DDAVP) at 0.3 μg/kg administered over 15 to 30 minutes, and intravenous infusion of cryoprecipitate (see Chapter 87). For patients experiencing severe bleeding, it is advisable to consider heparin-free dialysis with use of normal saline flushes every 15 to 30 minutes with ultrafiltration adjustments. An alternative approach is to utilize predilution HDF, which provides dialysate infusion prior to entry of the blood into the dialyzer. However, this approach requires high ultrafiltration volumes and does not have a proven benefit over normal saline flushes.[39,40] Other alternatives may include regional heparin or citrate anticoagulation, and in the long term the use of low molecular weight heparin, heparin modeling, or prostacyclin may be considered. More recently, the use of heparin-bound dialyzers (such as hemophan or AN69ST)[41] or citrate-containing dialysate have been advocated in patients at risk for bleeding, although they may not decrease the need for routine circuit anticoagulation.[42] In patients scheduled for elective surgery or invasive procedures, cessation of aspirin should be considered a week in advance, the dose of anticoagulant reduced to a minimum, and the hematocrit maintained above 30%. In some patients, intravenous DDAVP to reverse the uremic platelet defect also may be required, although its efficacy has been questioned. Tranexamic acid, a potent fibrinolytic inhibitor, can be used as an adjuvant treatment to control hemorrhage in dialysis patients.[43]

Thrombocytopenia

Heparin-induced thrombocytopenia is an increasingly important cause of thrombocytopenia in dialysis patients. The diagnosis and management, including alternative strategies for anticoagulation for HD, are discussed in Chapter 87.

PULMONARY COMPLICATIONS

Dialysis-Associated Hypoxemia

In most patients, the arterial Pao_2 decreases by 5 to 20 mm Hg (0.6–4.0 kPa) during dialysis, reaching a nadir at 30 to 60 minutes, and resolves within 60 to 120 minutes after discontinuation of dialysis. This decrease is usually of no clinical significance to patients unless there is preexisting chronic cardiopulmonary disease.

Hypoventilation is the main implicated factor and is primarily central in origin as a result of a decrease in carbon dioxide production after acetate metabolism (specific to acetate-containing dialysate), loss of carbon dioxide in the dialyzer (with both acetate and bicarbonate dialysate), and rapid alkalinization of body fluids (particularly with large surface area dialyzers).[44] In addition, acetate-induced respiratory muscle fatigue can lead to hypoventilation, especially in acutely ill patients. Furthermore, ventilation-perfusion mismatch may be caused by pulmonary leukocyte agglutination (in part resulting from complement activation) or impaired cardiac output (e.g., from myocardial stunning).

In high-risk patients with fluid overload, preventive measures consist of using intradialytic oxygen supplementation, biocompatible membranes, and avoiding acetate dialysate. Optimizing hematocrit/hemoglobin values and performing sequential ultrafiltration followed by HD may further reduce the likelihood of hypoxemia.

TECHNICAL MALFUNCTIONS

Air Embolism

The most vulnerable source of air entry into the extracorporeal circuit is the prepump tubing segment, in which significant subatmospheric pressures prevail. However, other sources need to be considered, including intravenous infusion circuits especially with glass bottles, air bubbles from the dialysate, and dialysis catheters. High blood flow rates may allow rapid entry of large volumes of air despite small leaks.

Clinical manifestations depend on the volume of air introduced, the site of introduction, the patient's position, and the speed at which air is introduced.[45] In the sitting position, air entry through a peripheral vein bypasses the heart and causes venous emboli in the cerebral circulation. The acute onset of seizures and coma in the absence of precedent symptoms such as chest pain and dyspnea is highly suggestive of air embolism. In the supine position, air introduced through a central venous line will be trapped in the right ventricle, where it forms foam, interferes with cardiac output, and, if it is large enough, leads to obstructive shock. Dissemination of microemboli to the pulmonary vasculature results in dyspnea, dry cough, chest tightness, or respiratory arrest. Furthermore, passage of air across the pulmonary capillary bed can lead to cerebral or coronary artery embolism. In the left Trendelenburg position, air emboli migrate to the lower extremity venous circulation, resulting in ischemia as a result of increased outflow resistance. Foam may be visible in the extracorporeal tubing, and cardiac auscultation may reveal a peculiar churning sound, the so-called "millwheel murmur."

The immediate management of clinically suspected air embolism is summarized in Fig. 100.4. Prevention depends primarily on dialysis machines equipped with venous air bubble traps and foam detectors located just distal to the dialyzer and a venous pressure monitor at the venous end. The detector is attached to a relay switch that simultaneously activates an alarm, shuts off the blood pump, and clamps the venous blood line if air is detected. Therefore, dialysis should never be performed in the presence of an inoperative air detection alarm system. Glass bottles should be avoided because they create vacuum effects that can permit air entry into the extracorporeal system. Dialysis catheters should be aspirated and flushed with saline before connection. Extra care should be taken to ensure occlusion of catheters at two points at the end of treatment (clamp and line cap). Dialyzer rinsing, before use, should expand all compartments to remove residual air bubbles.

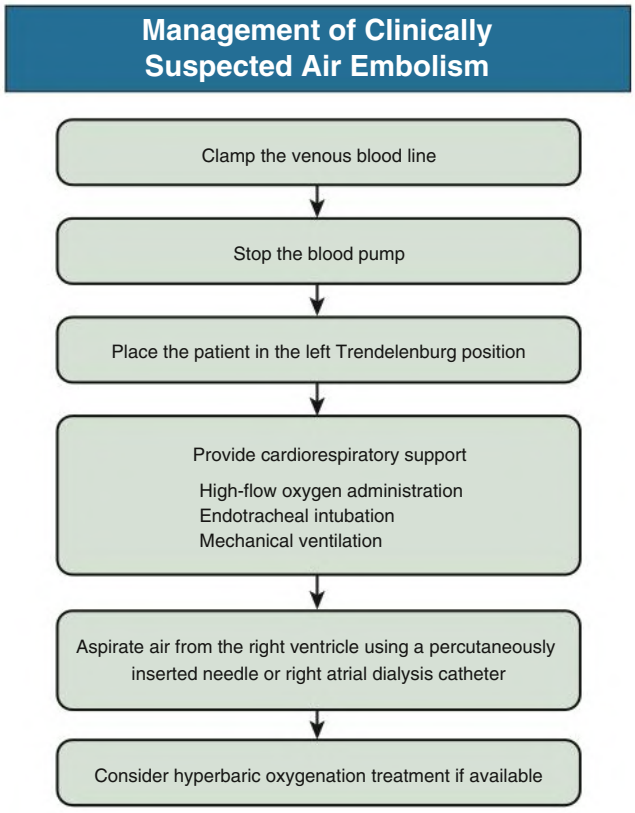

Fig. 100.4 Management of clinically suspected air embolism.

Incorrect Dialysate Composition

Incorrect dialysate composition results from technical or human errors. Because the primary solutes constituting the dialysate are electrolytes, the dialysate concentration will be reflected by its electrical conductivity. Therefore, proper proportioning of concentrate to water can be achieved by the use of a meter that continuously measures the conductivity of the dialysate solution as it is being fed to the dialyzer. Life-threatening electrolyte and acid-base abnormalities are avoidable if the conductivity alarm is functioning properly and the alarm limits are set correctly. However, in dialysis machines that are equipped with conductivity-controlled mixing systems, the system automatically changes the mixing ratio of the concentrates until the dialysate solution conductivity falls within the set limits. This may inadvertently lead to dialysate without any bicarbonate, with apparently acceptable conductivity. Therefore, if conductivity-controlled systems are used, it is safer to also check the dialysate pH before dialysis. Conductivity monitors can fail or can be improperly adjusted due to human error. Therefore, it is important to add human monitoring of dialysate composition before every treatment, whenever a machine has been sterilized or moved about, or whenever a new concentrate is used. Furthermore, as many nonstandard solutions are available, some of which may be used with an inappropriate proportioning system, it is also essential that the supplies match the machine-proportioning ratio for which they were prepared for the appropriate final dialysate composition to be obtained (note that different machine manufacturers use different proportioning ratios). Double checking of concentrate variations (e.g., potassium and calcium concentration) should be practiced, as it is for intravenous drug administration.

Hypernatremia

Intradialytic hypernatremia occurs when concentrate or the ratio of concentrate to water is incorrect and the conductivity monitors or the alarms are not functioning properly. Hyperosmolality results in intracellular water depletion. Clinical manifestations include thirst, headache, nausea, vomiting, seizures, coma, and death. Aggressive treatment is mandatory and includes cessation of dialysis, hospitalization, and infusion of 5% dextrose in water. Dialysis should be resumed with a different machine; the dialysate sodium level should be 2 mmol/L lower than the plasma level, and isotonic saline should be concurrently infused. Dialysis against a sodium level 3 to 5 mmol/L lower than the serum level may increase the risk for disequilibrium. Ultrafiltration with equal volume replacement with normal saline is another option.

Hyponatremia

Failure to add concentrate, inadequate concentrate-to-water ratio, or conductivity monitor or alarm malfunction can cause intradialytic hyponatremia. Hyponatremia also can occur during the course of dialysis with a proportioning system if the concentrate container runs dry and the conductivity set limits are inappropriate. Acute hypoosmolality causes hemolysis with hyperkalemia and hemodilution of all plasma constituents. Symptoms include restlessness, anxiety, pain in the vein injected with the hypotonic hemolyzed blood, chest pain, headache, nausea, and occasional severe abdominal or lumbar cramps. Pallor, vomiting, and seizures may be observed. Treatment consists of clamping the blood lines and discarding the hemolyzed blood in the extracorporeal circuit. High-flow oxygen and cardiac monitoring are imperative because of hyperkalemia and potential myocardial injury. Dialysis should be restarted with a new dialysate batch containing

low potassium, and high transmembrane pressure should be applied to remove excess water. Correction of serum sodium concentration should be achieved by no more than 1 to 2 mmol/L/h. Anticonvulsants are indicated for seizures and blood transfusions for severe anemia. Successful correction of severe hyponatremia has been reported in a single 3-hour HD session with a dialysate sodium concentration of 135 mmol/L without any adverse neurologic consequences despite a serum sodium correction rate of 3 mmol/L/h.[46] This suggests that elevated blood urea levels might protect uremic patients from the development of demyelinating syndromes when hyponatremia is rapidly corrected.

Metabolic Acidosis

Although acute intradialytic metabolic acidosis can be a manifestation of improper mixing of concentrates or failure of pH monitors, other causes need to be ruled out, including diabetic or alcoholic ketoacidosis, lactic acidosis, ischemic tissues, toxic ingestions, and dilutional acidosis.[47] The diagnosis is usually suggested by the acute onset of hyperventilation during HD and confirmed by laboratory evaluation. In most circumstances, correction of the underlying cause and use of bicarbonate dialysate at the appropriate concentration (32–35 mmol/L) are adequate measures.

Metabolic Alkalosis

Severe intradialytic metabolic alkalosis is rare and may be caused by errors in dialysate concentrates, reversed connection of bicarbonate and acid concentrate containers to the entry ports of the dialysis machine, pH monitor malfunction, or use of regional citrate anticoagulation. The most common cause, however, is hydrochloric acid loss as a result of vomiting or nasogastric suction. Attention should also be directed to identification of sources of added alkali.[48]

Acute treatment is rarely necessary unless a technical error has occurred. Removal of the alkali source is usually sufficient, and H_2-antagonists or proton pump inhibitors may be successful if there is gastric acid loss. The administration of sodium chloride to anephric patients with chloride-sensitive alkalosis will not repair the alkalosis. If a more rapid reduction in serum bicarbonate is desired, modification of the dialysate bath by replacement of alkali with chloride, substitution of bicarbonate with acetate dialysate, use of acid dialysate, and infusion of hydrochloric acid are effective but cumbersome measures. The use of conventional or low-bicarbonate (25–30 mmol/L) dialysate is probably as effective.

Temperature Monitor Malfunction

Malfunction of the thermostat in the dialysis machine can result in the production of excessively cool or hot dialysate. Whereas cool dialysate is not dangerous and may have beneficial hemodynamic effects (see discussion regarding intradialytic hypotension), overheated dialysate can cause immediate hemolysis and life-threatening hyperkalemia, particularly if the dialysate temperature increases to more than 51°C. In such an event, dialysis must be stopped immediately and blood in the system discarded. The patient should be monitored for hemolysis and hyperkalemia. Dialysis should be resumed to cool the patient by use of a dialysate temperature of 34°C to treat hyperkalemia and allow blood transfusions if necessary. Visual and audible alarms are mandatory to prevent this complication.

Blood Loss

Intradialytic blood loss can result from arterial or venous needle disengagement from the access, separation of the venous or arterial line connections, femoral or central line dialysis catheter perforation or dislodgment, or rupture of a dialysis membrane with or without malfunction of the blood leak detector. Care should be taken to ensure needle insertion sites and line connection points are and remain visible during a dialysis treatment. Clinical findings include hypotension, loss of consciousness, and cardiac arrest. In addition, after traumatic insertion of a dialysis catheter, blood loss can result in pain or mass from a rapidly expanding hematoma; chest, shoulder, or neck pain from intrapericardial blood loss; back, flank, groin, or lower abdominal pain or distention from retroperitoneal bleeding; or hemoptysis from pulmonary bleeding. Acute management includes the discontinuation of HD, pressure application for local hemostasis, reversal of anticoagulation (e.g., protamine sulfate for heparin), hemodynamic support, oxygen administration, and surgical intervention if needed.

In the home dialysis setting, especially nocturnal HD, venous needle dislodgement is potentially catastrophic. A number of devices have been developed for early detection of blood leak resulting from needle dislodgment, including bed-wetting incontinence pads, Red-Sense and HEMOdialert blood detectors, and other proprietary techniques. However, the most important component is prevention by comprehensive and repeated patient education about adequate taping of dialysis needles and lines.

Clotting of Dialysis Circuit

Clotting of the extracorporeal circuit during dialysis is a common practical problem, has many underlying causes, and warrants a thorough investigation. Technical factors include an inadequate or poor priming technique, resulting in retention of air in the dialyzer, and lack of or inadequate priming of the heparin infusion line. Such operator-induced errors are corrected through ongoing staff education and competency assessment. Incorrect heparin loading dose, insufficient time lapse after loading dose of heparin for systemic anticoagulation to occur, incorrect pump setting for constant heparin infusion, delayed start of the heparin pump, and failure to release the heparin line clamp are important correctible causes of clotting that also should be considered. Low molecular weight heparin is often used as a single bolus at the commencement of dialysis but may not maintain anticoagulation for extended hours of treatment (e.g., nocturnal HD). Vascular access–related problems from inadequate blood flow caused by needle or catheter positioning or clotting, excessive access recirculation, and frequent interruption of blood flow also can result in clotting. Immediate management requires prompt recognition of the underlying cause and implementation of corrective actions, including ongoing heparin dose adjustment and, if indicated, vascular access revision.

Heparin-free dialysis is sometimes medically indicated, such as in an actively bleeding patient or postoperatively. Although traditional approaches to avoid circuit clotting in this circumstance involve frequent saline flushes, an alternative approach is to employ predilution HDF as outlined earlier.

DIALYSIS REACTIONS

During HD, blood is exposed to surface components of the extracorporeal circuit, including the dialyzer, tubing, sterilization processes, and other foreign substances related to the manufacturing and reprocessing procedures. This interaction between the patient's blood and the extracorporeal system can lead to various adverse reactions (Fig. 100.5).

Anaphylactic and Anaphylactoid Reactions

Clinical Presentation

Anaphylaxis is the result of an immunoglobulin E (IgE)-mediated acute allergic reaction in a sensitized patient, whereas anaphylactoid reactions result from the direct release of mediators by host cells. Symptoms usually develop within the first 5 minutes of dialysis,

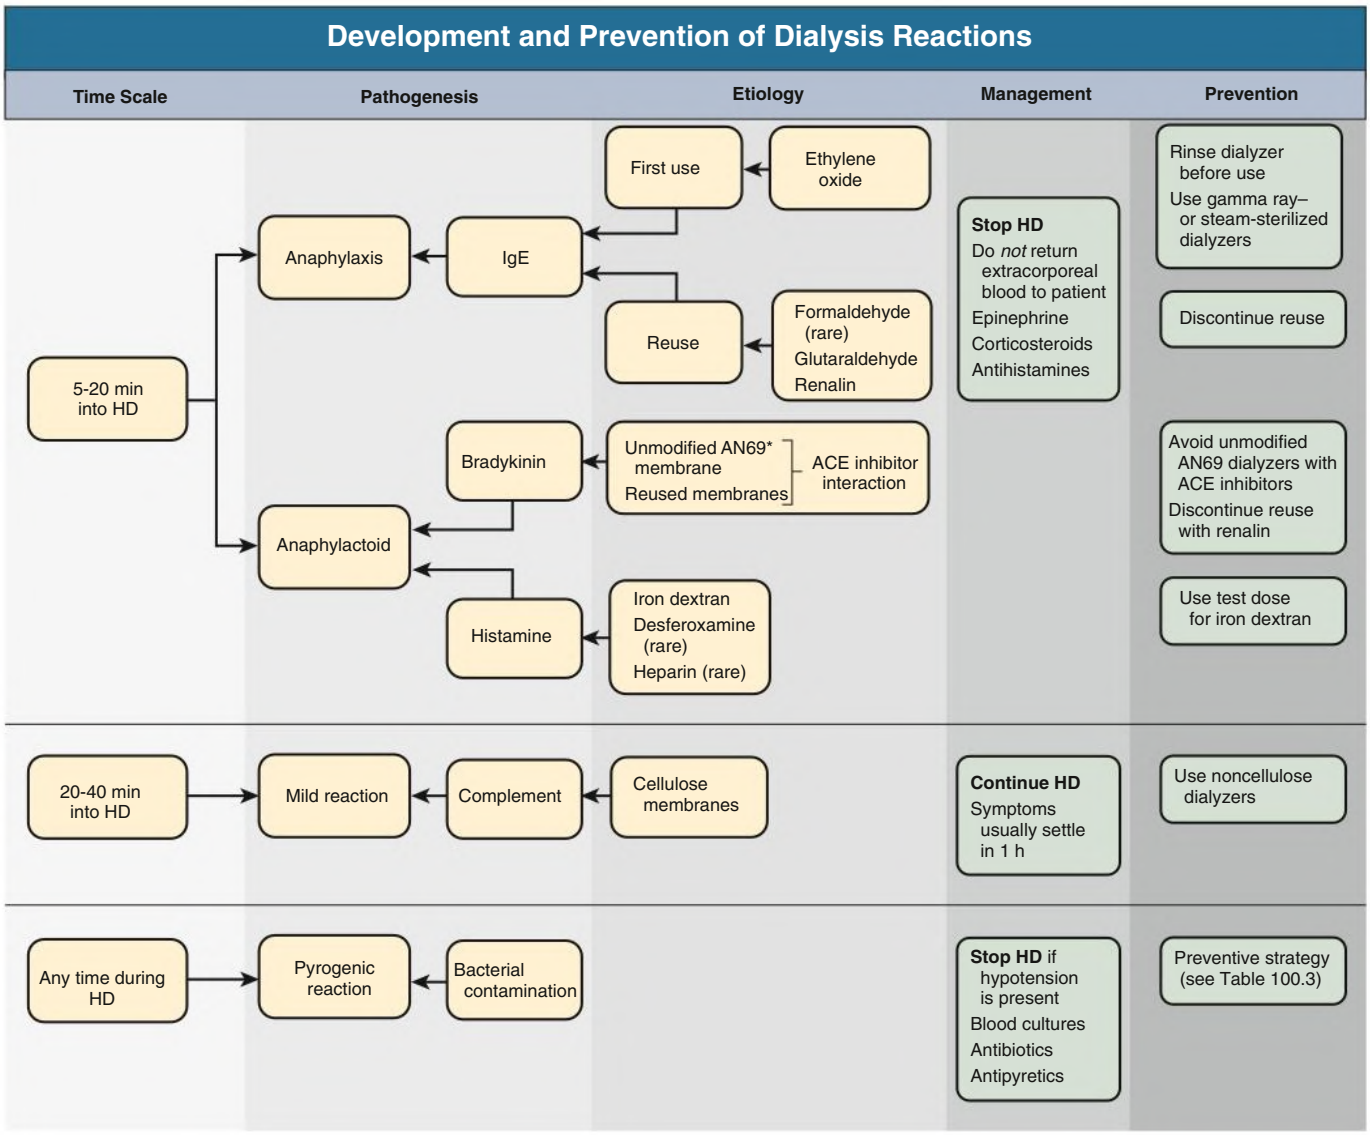

Fig. 100.5 Development and prevention of dialysis reactions. *Acrylonitrile and sodium methallyl sulfonate copolymer. *ACE,* Angiotensin-converting enzyme; *AN69,* acrylonitrile; *HD,* hemodialysis; *IgE,* immunoglobulin E.

although a delay of up to 20 minutes is possible. Symptoms vary from subtle to severe and include burning or heat throughout the body or at the access site; dyspnea, chest tightness, and angioedema or laryngeal edema; paresthesias involving the fingers, toes, lips, or tongue; rhinorrhea, lacrimation, sneezing, or coughing; skin flushing; pruritus; nausea or vomiting; abdominal cramps; and diarrhea. Predisposing factors include a history of atopy, elevated total serum IgE, eosinophilia, and the use of ACE inhibitors. The etiology of dialysis reactions is diverse, and a thorough investigation is required.

First-Use Reactions

The majority of first-use reactions were ascribed to the manufacturer's dialyzer sterilant ethylene oxide (ETO), which is now rarely used. The potting compound that anchors the hollow fibers in the dialyzer housing acts as a reservoir for ETO and may impede its washout from the dialyzer, leading to sensitization. When it is conjugated to human serum albumin (HSA), ETO acts as an allergen. By use of a radioallergosorbent test (RAST), specific IgE antibodies against ETO-HSA are detected in two-thirds of patients with such reactions. However, 10% of patients with no history of dialysis reactions have a positive RAST result.

Reuse Reactions

Because most residual ETO is washed out of the dialyzer during first use, reuse reactions are likely to be a result of the disinfectants used for dialyzer reprocessing. These agents include formaldehyde, glutaraldehyde, and peracetic acid–hydrogen peroxide in allergic patients; specific IgE antibodies against formaldehyde are occasionally detectable.

Bradykinin-Mediated Reactions

In the early 1990s, anaphylactoid reactions appeared in Europe among patients dialyzed with modified acrylonitrile (AN69) dialyzers who were also taking ACE inhibitors. Investigation of these incidents revealed that binding of factor XII to this sulfonate-containing, negatively charged membrane resulted in the formation of kallikrein and release of bradykinin, which in turn led to the production of prostaglandin and histamine, with subsequent vasodilation and increased vascular permeability. ACE inactivates bradykinin, and therefore ACE inhibitors can prolong the biologic activities of bradykinin.[49] These membranes have since been chemically modified, thereby reducing this risk, but are still in use for plasmapheresis.

Anaphylactoid reactions also have been observed in patients taking ACE inhibitors who were dialyzed with membranes that had been reprocessed with peracetic acid–hydrogen peroxide; these reactions abated once reprocessing was discontinued, despite continued use of ACE inhibitors. It has been speculated that Renalin may oxidize cysteine-containing proteins that are adsorbed on the dialyzer membrane, leading to the formation of cysteine sulfonate and contact activation of factor XII. Bradykinin-mediated reactions are rarely observed during contemporary hemodialysis treatments.

Drug-Induced Reactions

Anaphylactoid reactions to parenteral iron dextran occur in 0.6% to 1% of HD patients. Significantly higher rates of anaphylactoid reactions have been observed among users of higher molecular weight compared with lower molecular weight iron dextran. In vitro, dextran produces a dose-dependent basophil histamine release. The Kidney Disease Improving Global Outcomes Guidelines recommend that resuscitative medication and personnel trained to evaluate and resuscitate anaphylaxis should be available whenever a dose of iron dextran is administered.[50] Alternative preparations of iron provoke fewer anaphylactoid reactions than iron dextran and are discussed further in Chapter 86.

Hypersensitivity to heparin formulations is rare and usually responds to substitution of beef with pork heparin or vice versa. An alternative is to substitute low molecular weight heparin. A nationwide outbreak in the United States of severe adverse reactions in HD patients was attributed to vials of heparin contaminated with oversulfated chondroitin sulfate.[51]

Treatment and Prevention

Treatment of anaphylactic and anaphylactoid reaction requires the immediate cessation of HD without returning the extracorporeal blood to the patient. Epinephrine, antihistamines, corticosteroids, and respiratory support should be provided, if needed. Specific preventive measures include rinsing the dialyzer immediately before first use, substituting ETO with dialyzers sterilized with gamma ray or steam, avoiding unmodified AN69 membranes in patients taking ACE inhibitors, and discontinuing reprocessing procedures in selected patients.

Mild Reactions

Mild reactions particularly occur 20 to 40 minutes after initiation of dialysis, predominantly with first use of unsubstituted cellulosic dialyzers, and consist of chest or back pain. Dialysis can be continued because symptoms usually abate after the first hour, suggesting a relation to the degree of complement activation. Indeed, these reactions decrease with the use of substituted and reprocessed unsubstituted cellulose membranes. Administration of oxygen and analgesics is usually sufficient. Preventive measures include automated cleansing of new dialyzers and use of noncellulose dialyzers.

Fever and Pyrogenic Reactions

Fever during dialysis can be due to infection or excessive microbial contamination of the dialysis apparatus. The latter, known as *pyrogenic reaction,* is usually a diagnosis of exclusion. Several factors during dialysis place patients at risk for exposure to bacterial products, including contaminated water or bicarbonate dialysate, improperly sterilized dialyzers, use of central venous dialysis catheters, and cannulation of infected arteriovenous fistulas or arteriovenous grafts.[52] Soluble bacterial products such as endotoxin fragments can diffuse across the dialyzer into the blood, resulting in cytokine production and, consequently, pyrogenic reactions. Whereas high-flux dialyzers have larger pores that may potentially allow larger fragments to cross from the dialysate to the patient, the synthetic high-flux membranes have a thick wall that tends to be very adsorptive for endotoxin fragments, thus mostly preventing this phenomenon.[53] Similarly, although HDF potentially has a higher risk for pyrogenic reactions because of the infusion of 10 to 25 L of dialysate, the customary use of two serial ultrafilters in the dialysate circuit make this an uncommon occurrence. Strategies for the prevention of pyrogenic reactions are summarized in Table 100.3.[54]

When fever develops during HD, the first step is to address hemodynamic stability. If the patient is hypotensive, administration of fluids, cessation of ultrafiltration, and discontinuation of dialysis are often required, and refractory hypotension suggesting severe sepsis should trigger hospitalization.

TABLE 100.3 Strategies to Prevent Bacterial Contamination

Fluid Type	Microbial Count (cfu/mL)	Endotoxin (EU)
Water products	<100	<0.25
Dialysate	<100	<0.50
Ultrapure dialysate (e.g., for HDF)	<0.1	<0.03
Reprocessed dialyzers	No growth	—
Use appropriate germicide: • 4% formaldehyde[a] • 1% formaldehyde heated to 40°C[a,b] • Glutaraldehyde[b] • Hydrogen peroxide–peracetic acid mixture[b] • Heat sterilization (105°C for 20 hours) for reprocessing of polysulfone membranes[b]		
Wash and rinse the vascular access arm with soap and water.		
Before cannulation, inspect vascular access for local signs of inflammation.		
Scrub the skin with povidone-iodine or chlorhexidine and allow to dry for 5 minutes before cannulation.		
Record temperature before and after dialysis.		
When central delivery system is used: • Clean and disinfect connecting pipes regularly. • Remove residual bacteria or endotoxin by additional filtration.		
When single-patient proportioning dialysis machine is used: • Freshly prepare bicarbonate dialysate on a daily basis. • Discard unused solutions at the end of each day. • Rinse and disinfect containers with fluids that meet AAMI standards. • Air dry containers before dialysate preparation.		
Follow manufacturer's guidelines for use of preservative-free medications.		

Strict adherence to AAMI/ISO 11663:2014 standards.
[a]A minimum of 11- or 24-hour exposure to peracetic acid or formaldehyde is required, respectively.
[b]These germicides are equivalent or superior to 4% formaldehyde. The action level for the total viable microbial count in the product water and conventional dialysate is 50 cfu/mL, and the action level for the endotoxin concentration is 50% of the relevant standard.

From Lata C, Girard L, Parkins M, James MT. Catheter-related blood stream infection in end-stage kidney disease: a Canadian narrative review. *Can J Kidney Health Dis.* 2016;3:24.

The next step is to identify a potential source of infection. The dialysis vascular access should be carefully examined. If an infectious source related to non–vascular access is identified, specific therapy should be instituted on the basis of the working diagnosis. Nontunneled and tunneled central venous dialysis catheters always should be suspected as a likely cause of infection, even in the absence of local signs of infection such as erythema and exit site drainage. Catheters with evident signs of infection at the insertion site should be removed and the tip cultured (detailed management is outlined in Chapter 96).

Antipyretics should be administered, and blood culture specimens should be obtained before initiation of antibiotic therapy; this should include cultures from temporary access devices. The initial choice of antibiotics should include gram-positive and gram-negative bacterial coverage, and the regimen should be adjusted according to the culture results and local guidelines.

In the presence of a dialysis catheter, paired blood culture specimens should be obtained from a peripheral vein and the catheter lumen, and a broad-spectrum antibiotic regimen should be initiated. Catheter lock solutions that use either antibiotics or sterilants such as calcium citrate have been demonstrated to significantly reduce the rate of catheter-related bacteremia.[55,56] In the case of catheter-related bacteremia, removal of the dialysis catheter is strongly indicated, as is transesophageal echocardiography to rule out endocarditis, particularly with staphylococcal sepsis. A regimen of at least 14 days of antibiotic therapy after removal of the catheter is also recommended.

An outbreak of bacteremia among several dialysis patients involving a similar organism should prompt a thorough search for bacterial contaminants in the dialysis equipment.[52] Attention should also be paid to multiuse vials that are punctured several times, such as vials of epoetin, which has been linked to an outbreak of bloodstream infection. Single-use vials are preferred, when available.

Investigation of a Dialysis Pyrogenic Outbreak

Although causes of dialysis outbreaks are usually easily identifiable, often the reason for the outbreak is less clear, such as water contamination with bacterial toxins,[57] medication chemical impurities,[51] bacterial contaminants, systemic embolization of degraded dialyzer membrane polymer after prolonged or improper storage,[58] and hemolysis from faulty blood tube sets.[59] Investigation of a dialysis outbreak requires a methodical approach, including a critical review of the medical records and the various steps of the dialysis procedure (Box 100.1).

MISCELLANEOUS COMPLICATIONS

Postdialysis Fatigue

An ill-defined "washed-out" feeling or malaise during or after HD is a common nonspecific symptom that is observed in about one-third of patients and has multifactorial origins. Reduced cardiac output, peripheral vascular disease, depression, poor conditioning, postdialysis hypotension, hypokalemia or hypoglycemia, mild uremic encephalopathy, myopathy caused by carnitine deficiency, and dialysis-induced cytokine generation have all been incriminated. The use of bicarbonate dialysate with or without additional glucose (5–10 mmol/L) and L-carnitine supplementation (20 mg/kg/day) have been shown to improve postdialysis well-being. A trial of thrice-weekly L-carnitine at 20 mg/kg for 6 months resulted in a marked decrease in C-reactive protein level, which was paralleled by an increase in body mass index.[60] To date, however, there is no conclusive evidence that L-carnitine improves quality of life in unselected dialysis patients.[50]

Compared with thrice-weekly HD, more frequent dialysis, including short daily and nocturnal HD, has been associated with a marked shortening in the time it takes for patients to recover from a dialysis session and to resume their daily activities, which is a surrogate for postdialysis fatigue.

Pruritus

Pruritus is common and can be a very troubling symptom. The cause is often multifactorial, including xerosis, hyperparathyroidism, neuropathy, derangements in the immune system, and inadequate dialysis. In many patients, pruritus is more severe during or after dialysis and may be a manifestation of an allergic reaction to heparin, ETO, formaldehyde, acetate, or the dialysis membrane. In this subgroup of patients, use of gamma ray–sterilized dialyzers, discontinuation of formaldehyde use, switching to bicarbonate dialysate, use of low-dialysate calcium and magnesium might result in cessation of itching. Difelikefalin, a peripherally restricted and selective agonist of kappa opioid receptors, has recently shown significant promise in the treatment of uremic pruritus and depending on availability should be considered.[61] A detailed discussion of the management of uremic pruritus can be found in Chapter 91 (see Fig. 91.3).

Finally, eczematous reactions to antiseptic solutions, rubber gloves or puncture needle components, puncture needles, or adhesive tapes used to secure dialysis needles also should be considered.[62]

Genitourinary Problems

Priapism occurs in less than 0.5% of male HD patients. It is not related to sexual activity and occurs while the patient is on dialysis. The patient is usually awakened from sleep by a painful erection. Although the majority of cases are idiopathic, secondary causes include hyperviscosity; high hematocrit from androgen or epoetin therapy; dialysis-induced hypoxemia and hypovolemia from excessive ultrafiltration, particularly in men with sickle cell disease; and use of α-blockers, such as prazosin, or an antidepressant, such as trazodone.[63]

Urgent urologic referral is mandatory. Acute treatment consists of corporal aspiration and irrigation. Although surgical bypass

provides venous egress from the corpora cavernosa, secondary impotence commonly develops but may be effectively treated by a penile prosthesis.

An unusual case of testicular angina occurring during excessive ultrafiltration has been described. The patient was diabetic and had extensive vascular calcification evident on imaging. He eventually required orchidectomy.[64] A similar mechanism for this type of "angina" also has been described for the mesentery and right colon.

Hearing and Visual Loss

Intradialytic hearing loss may be caused by bleeding in the inner ear as a consequence of anticoagulation, cochlear hair cell injury from edema, or flux of fluid and electrolytes across cochlear cell membranes.

Intradialytic visual loss is rare but can be caused by central retinal vein occlusion, retinal hemorrhage secondary to heparin exposure in diabetics, precipitation of acute glaucoma, ischemic optic neuropathy secondary to hypotension, or Purtscher-like retinopathy secondary to leukocyte embolization.

SELF-ASSESSMENT QUESTIONS

1. The most common cause of intradialytic hypotension is:
   - **A.** new-onset sepsis.
   - **B.** cardiac ischemia.
   - **C.** intravascular volume depletion.
   - **D.** altered thermal balance.
   - **E.** use of antihypertensive medications.
2. The most appropriate preventive strategy to avoid intradialytic hypotension is:
   - **A.** isothermic dialysis.
   - **B.** sodium modeling.
   - **C.** hematocrit-controlled volume removal.
   - **D.** avoidance of excessive interdialytic weight gain.
   - **E.** use of agents such as midodrine.
3. Intradialytic hemolysis may be caused by all of the following *except:*
   - **A.** copper in the dialysate.
   - **B.** residual formaldehyde.
   - **C.** chloramine spillover.
   - **D.** faulty dialysis pumps.
   - **E.** heparin exposure.
4. Severe dialyzer reactions may occur as a result of exposure to:
   - **A.** new synthetic dialysis membranes.
   - **B.** potting compound.
   - **C.** sterilant effects related to steam or gamma radiation.
   - **D.** angiotensin-converting enzyme inhibitors.
   - **E.** peracetic acid.
5. Management options for intradialytic cramps include:
   - **A.** intravenous hypertonic saline.
   - **B.** oral magnesium salts.
   - **C.** oral carnitine supplementation.
   - **D.** intravenous 50% dextrose.
   - **E.** all the above.

Peritoneal Dialysis: Principles, Techniques, and Adequacy

Joanne M. Bargman, Bourne L. Auguste

INTRODUCTION

The prevalence of peritoneal dialysis (PD) continues to grow steadily worldwide. It is estimated that more than 272,000 patients worldwide are treated with PD, accounting for about 11% of the total global dialysis population.[1] Patients on PD can have numerous fluid exchanges through a permanent indwelling silicone-based catheter. The exchange of PD fluid involves three important steps: filling, dwelling, and draining. Sterile dialysate provided in plastic bags is instilled into the peritoneal cavity with each exchange. The peritoneal membrane and surrounding capillaries function as a semipermeable membrane, which allows removal of waste and fluid. The removal of waste from the blood occurs by diffusion. Fluid is removed by a process called ultrafiltration (UF), in which an osmotic gradient generated by glucose or by another osmotic agent leads to water flux across the membrane.

PD can be prescribed up to 24 hours/day and 7 days/wk to patients in the form of continuous ambulatory peritoneal dialysis (CAPD) or continuous cyclic peritoneal dialysis (CCPD). In CCPD, patients receive treatment with an automated PD (APD) cycler, allowing for nighttime exchanges followed by a long dwell called a "last fill" that remains in the peritoneum during the daytime. There is significant geographic variation in the use of PD cyclers, driven in part by local resources and reimbursement policies. For example, in lower-resource settings, the overall PD uptake, prevalence, and cycler use are reduced compared with countries where reimbursement is greater.[2] CAPD is the preferred dialysis modality in low- and middle-income countries as it is cost-effective and does not require more expensive equipment such as automated PD cyclers.[3]

ADVANTAGES AND LIMITATIONS OF PERITONEAL DIALYSIS

PD can be offered to many patients with kidney failure barring a few absolute contraindications. These contraindications include abdominal hernias that cannot be corrected surgically, abdominal adhesions not amenable to adhesiolysis, recurrent intraabdominal infections, and large hiatal hernias. Furthermore, severe cognitive impairment is another contraindication, unless a helper or visiting health care worker is available.

Patients with residual kidney function (RKF) may have greater benefit from PD compared with anuric patients. PD prescriptions can be adjusted easily to ensure effective clearance when RKF declines. However, if adequate dialysis or UF cannot be achieved or maintained with PD, patients may need to be transferred to hemodialysis (HD).

PD offers numerous advantages to patients. First, PD can be initiated in an incremental manner, which allows incident patients to become comfortable in the early phases of their treatment while minimizing treatment burden. Second, PD allows for slow and gentle removal of fluid without significant hemodynamic changes. Third, PD can preserve RKF better than HD.[4] Fourth, PD does not require vascular access and, unlike HD, there is no blood-membrane contact, which has been suggested as a cause of accelerated decline in RKF.[2] Observational data suggests that PD can effectively remove excess fluid in patients with refractory volume overload due to cardiorenal syndrome.[5]

PD patients have better self-reported quality of life than patients receiving other types of dialysis. PD offers flexibility in schedule and travel while reducing the frequency for hospital visits. In patients receiving kidney transplants, PD is associated with better 5-year overall patient survival and a lower risk of delayed graft function compared with patients previously treated with HD.[3]

There are, however, some important disadvantages of PD that must be considered by patients, caregivers, and practitioners. PD is usually offered in the home, where the burden of care for patients and family members can be overwhelming, especially among patients who are frail or unable to safely perform PD without daily assistance. PD also increases hyperglycemia risk, particularly when using high-concentration glucose-based solutions. There is also an increased risk of dyslipidemia along with volume overload. Volume overload risk can be reduced by prescribing high-dose diuretics in patients with RKF.

PRINCIPLES OF PERITONEAL DIALYSIS

The fundamental principles of solute and fluid transport across the peritoneal membrane in PD include diffusion, osmosis, and convection. The peritoneal membrane consists of two major layers, the mesothelial monolayer and submesothelial compact zone (Fig. 101.1A). The compact zone contains peritoneal capillaries that allow for solute clearance and fluid removal. Over time, changes in the peritoneal membrane can occur, leading to neovascularization of capillaries and fibrosis, and ultimately to changes in membrane transport characteristics (Fig. 101.1B).

Three-Pore Model

Peritoneal membrane transport occurs through three distinct pores of varying sizes, in what is described as the three-pore model (Fig. 101.2). Small pores allow small-solute and fluid exchange between the plasma and peritoneal cavity through the capillary wall in spaces called interendothelial clefts. These clefts have a radius of 40 to 50 Å, preventing the movement of larger macromolecules such as immunoglobulins and other macromolecules.[6] Larger molecules can move between the plasma and peritoneal cavity via very large pores (radius ~250 Å) in the capillaries and postcapillary venules. Very large pores only account for 0.01% of the total capillary pores, and transport across these pores is mainly driven by hydrostatic pressure.[6] The smallest pore, also called aquaporin-1 (AQP-1, radius < 4 Å), is

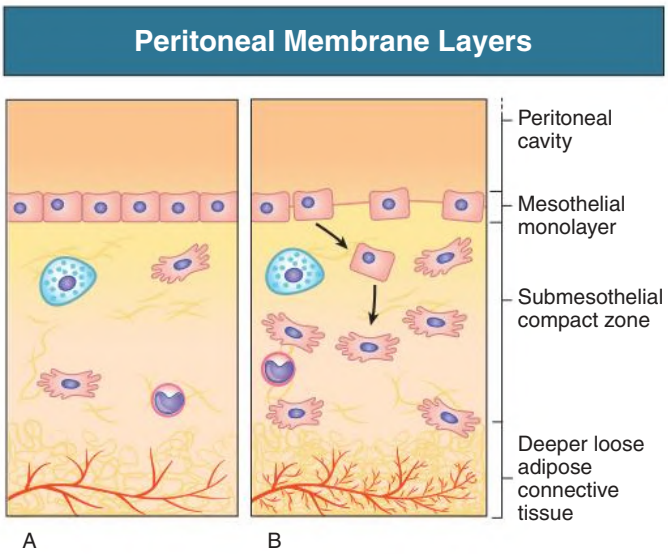

Fig. 101.1 (A) various layers of the peritoneal membrane. (B) Changes occurring over time with peritoneal dialysis in peritoneal membrane layers with the submesothelial compact zone increasing in thickness due to extracellular matrix expansion along with neovascularization of capillaries in the deep layers. (From Nessim SJ, Perl J, Bargman JM. The renin-angiotensin-aldosterone system in peritoneal dialysis: is what is good for the kidney also good for the peritoneum? *Kidney Int.* 2010;78[1]:23–28.)

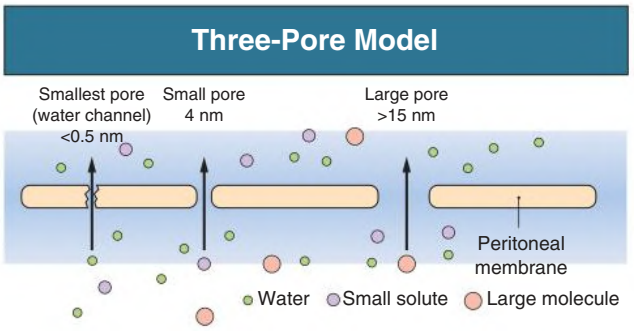

Fig. 101.2 Three-Pore Model. Small pores (4 nm) represent the major pathway across the peritoneum through which small solutes move by diffusion and water by convection driven by hydrostatic, colloid osmotic, and crystalloid osmotic pressure differences. Across large pores (>15 nm), macromolecules move out slowly by convection from plasma to the peritoneal cavity. The smallest pores (<0.5 nm) are represented by aquaporins permeable to water but are impermeable to solutes. Water moves here exclusively by crystalloid osmotic pressure.

responsible for nearly 50% of osmotically driven water movement in PD[7] (Fig. 101.1).

Effective Peritoneal Surface Area

The effective peritoneal surface area represents an area of the peritoneum that is perfused by capillaries and remains in direct contact with dialysate. Peritoneal blood flow through the capillaries can vary depending on vasodilation and vasoconstriction but is estimated to be 50 to 100 mL/min.[8] Variations in peritoneal capillary vascular resistance can also influence the permeability-surface area product (PS), also known as the mass transfer area coefficient. For example, inflammation from peritonitis can potentiate capillary vasodilation, increasing the capillary surface area and in turn enhancing small solute PS. Although small solute clearance may be enhanced with an increase in capillary recruitment, the same cannot be said about fluid permeability. Alterations in peritoneal blood flow do not directly translate to changes in peritoneal fluid permeability. The peritoneal fluid permeability is also known as hydraulic conductance (L_pS) and is dependent on the distribution and density of AQP-1 and small pores across the peritoneum.[9] L_pS varies from individual to individual such that in some cases of peritonitis, there is an increase in the L_pS, leading to increased fluid transport across all pores. The opening of large pores may increase the leakage of macromolecules such as albumin into the peritoneum from the plasma. Enhanced peritoneal absorption of fluid from the dialysate can occur with peritonitis, resulting in reduced fluid removal due to rapid dissipation of the osmotic gradient between peritoneum and plasma.

Changes in patient positioning and fill volume can have significant variation in the dialysate-peritoneal surface area. Most adult patients will tolerate a maximum fill volume of 2 to 2.5 L or an intraperitoneal hydrostatic pressure (IPP) of less than 18 cm of H_2O without much discomfort.[10] However, at higher pressures (≥18 cm of H_2O), patients normally highlight discomfort even in a supine position. IPP is highest when patients are sitting compared with standing and is lowest in the supine position. A common misconception is that IPP elevations could result in high transcapillary hydrostatic pressure gradients that may lead to an increased loss of fluid from the peritoneal cavity. However, approximately 80% of the change in IPP (ΔIPP) will transmit to large veins surrounding the peritoneal cavity, causing increased intracapillary hydrostatic pressure.[11,12] As a result, the transcapillary hydrostatic pressure gradient is reduced, and the impact of ΔIPP on fluid absorption is minimal.

Fluid Kinetics

In PD, small pores account for over 95% of all pores in the peritoneal membrane. Only 2% of all pores in the peritoneal membrane are AQP-1, but they account for about 50% of water transport that is driven by the osmotic gradient created by intraperitoneal hyperosmolar dialysate.[13] Glucose-based dialysate solutions generate water transport through both AQP-1 and small pores. On the other hand, colloid osmotic agents such as icodextrin remove fluid primarily through small pores (~90%). The movement of electrolyte-free water via AQP-1 results in a fall in dialysate concentration of sodium during the first 2 hours of the dialysate dwell, a process referred to as sodium sieving. As dwell duration extends beyond 2 hours, sodium diffuses from plasma to dialysate through the small pores along its concentration gradient, and the dialysate concentration of sodium approaches the level in plasma.

Computer models have simulated the variation in UF over a 12-hour dwell time (Fig. 101.3A). The osmotic gradient is greatest in the initial phase of the dwell, resulting in a large initial UF volume that diminishes with time as the osmotic gradient is lost. As the osmotic gradient dissipates, fluid absorption occurs through small pores (60%–80%) and lymphatics (20%–40%) in the surrounding tissues. Fig. 101.4 demonstrates the partial flows in the peritoneal membrane modeled across the various fluid conductive pathways in the three-pore model for 3.86% glucose PD solution. In "rapid transporters" (high and high-average transporters), the osmotic gradient created by glucose dissipates rapidly with UF occurring early in the dwell and fluid reabsorption in the latter part of the dwell. Conversely, "slow transporters" have prolongation of the glucose osmotic gradient, and thus better and more prolonged UF. Glucose has a low osmotic efficiency (osmotic reflection coefficient [σ] = 0.03), indicating that the osmotic gradient is more rapidly lost compared with many other solutes. On the other hand, glucose has an osmotic efficiency of 100% across AQP-1 (σ = 1).[14] As a result of this increased efficiency across AQP-1, glucose exerts about a 30-fold increase in the transport of fluid through aquaporins and leads to movement of solute-free water across the membrane. Fig. 101.3B demonstrates that for 4.25% glucose solution, the dialysate concentration of sodium will drop from 132 mmol/L to

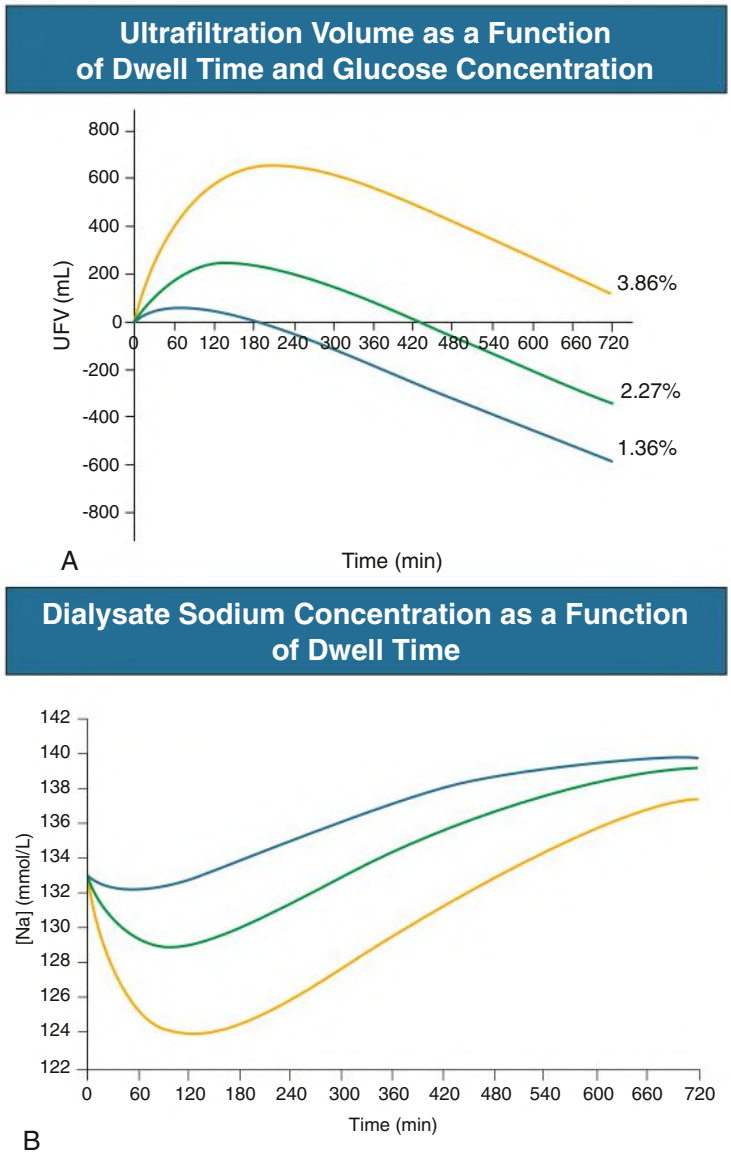

Fig. 101.3 (A) Ultrafiltration as a function of dwell time. Net ultrafiltration volume (UFV) as a function of dwell time for 3.86% *(yellow line),* 2.27% *(green line),* and 1.36% *(blue line)* glucose, computer simulated using the three-pore model of peritoneal transport. (B) Dialysate sodium as a function of dwell time. Dialysate sodium as a function of dwell time for 3.86% *(yellow line),* 2.27% *(green line),* and 1.36% *(blue line)* glucose, computer simulated according to the three-pore model of peritoneal transport.

123 mmol/L within 90 minutes, followed by a gradual increase toward the serum sodium concentration. On the other hand, icodextrin (see later) has an average molecular weight between 13 and 19 kDa with a higher osmotic efficiency (σ ~0.5) compared with glucose across the small pores and is inefficient across aquaporins.[15] This inefficiency of icodextrin across aquaporins results in minimal UF across these channels and explains why this solution does not result in sodium sieving (Fig. 101.5B). The important clinical implication is that the volume of ultrafiltrate induced by icodextrin will contain more sodium than the volume induced by a dextrose-based solution.

TYPES OF PERITONEAL DIALYSIS FLUID

PD fluid is usually packaged in clear polyvinyl chloride bags containing lactate-buffered, tightly regulated electrolyte levels without much variation between manufacturers. The solutions are potassium free, which allows for easier clearance of potassium down a concentration gradient. The primary osmotic agents used in PD fluids are glucose, amino acids, and icodextrin. Traditionally, solutions were prepared using a lactate-buffer instead of bicarbonate, as Ca^{2+} and Mg^{2+} may precipitate to form calcium carbonate and magnesium carbonate, respectively, at an elevated pH during storage. Commercially available solutions now include multichambered PD delivery systems that replace lactate with bicarbonate. In dialysis bags with multiple chambers, the glucose is stored under conditions of low pH (the buffer is in another chamber that is admixed before inflow), and the production of glucose degradation productions during sterilization or storage is delayed by this low pH (see biocompatible solutions).[16]

Glucose-Containing Solutions

Glucose-based solutions are the primary osmotic agents used in the management of PD. Options include solutions of low concentration (1.36% or 1.5%), intermediate concentration (2.27% or 2.5%), and high concentration (3.86% or 4.5%). The approximates in osmolarities

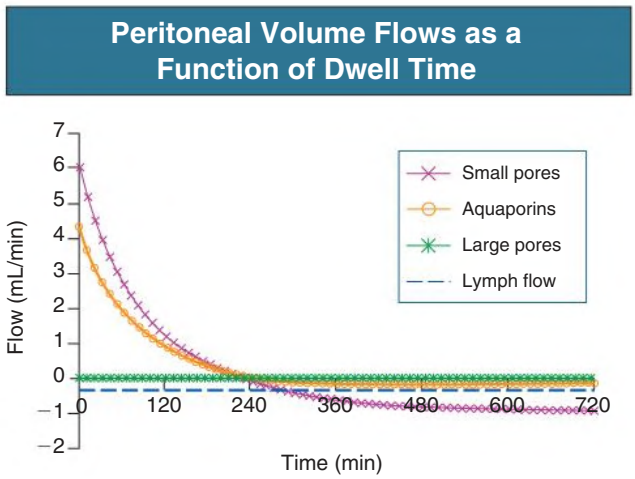

Fig. 101.4 Peritoneal Volume Flows as a Function of Dwell Time. Peritoneal volume flows as a function of dwell time for 3.86% glucose partitioned among aquaporins, small pores, large pores, and lymphatic absorption. The small-pore volume flow is initially approximately 60% of total volume flow and becomes negative after peak time (220 min). The aquaporin-mediated water flow becomes slightly negative after approximately 250 minutes. The large-pore volume flow is negligible and remains constant throughout the dwell, as does lymphatic absorption (0.3 mL/min). (Modified from Venturoli D, Rippe B. Validation by computer simulation of two indirect methods for quantification of free water transport in peritoneal dialysis. *Perit Dial Int.* 2005;25[1]:77–84.)

are 345 mOsm/L (low concentration), 395 mOsm/L (intermediate concentration), and 484 mOsm/L (high concentration). A very-low-concentration solution (0.5%) is less readily available and can be offered to patients with hypotension or intravascular volume contraction. The 0.5% solution leads to water and electrolyte absorption from dialysate to plasma and can sometimes be used to avoid intravenous fluid resuscitation.

There are, however, important drawbacks associated with the chronic use of glucose-based solutions. These include hyperglycemia, dyslipidemia as a result of continuous glucose absorption, and declining osmotic gradient ($\sigma = 0.03$) over time (Fig. 101.3A). Additionally, heat sterilization of glucose can lead to the generation of glucose degradation products (GDPs) (~5.5), which could have detrimental effects on the peritoneal membrane.[17] These reactive carbonyl compounds have also been shown to have toxic effects on various cells in vitro and in vivo.[18,19]

Non–Glucose-Based Solutions

Given the highlighted drawbacks of glucose-based solutions, alternative osmotic agents including amino acids and icodextrin are available. Icodextrin is an isoosmolar glucose polymer (~280 mOsm/L) that is manufactured as a 7.5% solution with the same electrolyte constituents as glucose-based solutions. It has a molecular weight averaging between 13 and 19 kDa that generates UF by its oncotic effect.[20] The large molecules greatly enhance the osmotic efficiency of this solution ($\sigma = 0.5$) compared with glucose solutions, leading to more sustained UF over a 12-hour period (Fig. 101.5A), and so icodextrin is preferred for long dwell exchanges (daytime dwell for patients on APD and overnight dwell for CAPD). Although icodextrin can be slowly absorbed into the plasma and metabolized to produce maltose, there have been no reported events of maltose toxicity. However, maltose can interact with glucose dehydrogenase pyrroloquinoline quinone assays used for capillary glucose measurement, leading to falsely elevated results for glucose. Therefore, alternative strategies for blood glucose monitoring must be considered in patients being treated with icodextrin, or it must be ensured that the glucometer being used is compatible with use of icodextrin and does not read out maltose as glucose.[21]

Amino acid–based solutions are available as a 1.1% amino acid mixture that has a similar osmolality to 1.36% glucose solution.[22] Like icodextrin, these solutions have the theoretical benefit of reducing the overall glucose exposure for the peritoneal membrane. Amino acid–based solutions are used primarily to enhance nutrition, but the results have been disappointing.[23,24] These solutions are limited to one exchange per day, as the absorbed amino acids can lead to acidosis and increase plasma urea levels. The access to amino acid–based solutions is now limited to European countries and a few other countries in compassionate use programs.

"Biocompatible" Solutions

The previously mentioned multicompartment systems are mixed just before instillation, thus addressing two potential limitations of traditional single-compartment lactate-buffered solutions. First, mixing just before instillation allows bicarbonate to be used as the buffer instead of lactate. The pH of lactate-buffered solutions is acidic (~5.5), whereas the pH of bicarbonate-buffered solutions is approximately neutral (~7.4),[19,25-27] which may reduce infusion pain while still correcting metabolic acidosis.[28] Second, the use of two compartments allows glucose to be stored at very low pH during heat sterilization, which protects it from caramelization and GDP formation. Experimental and observational data suggest that these solutions should reduce the patient's exposure to GDPs and that this should lead to clinical benefit.

However, clinical data has shown conflicting results in terms of overall benefits with the use of these "biocompatible" solutions. For example, one study demonstrated an improvement in RKF among patients receiving PD solutions with low GDP concentration.[25] However, more recent randomized trials have not supported such findings.[28,29] The balANZ study was a small randomized controlled trial (RCT) that suggested biocompatible solutions had lower incidence of peritonitis compared with conventional solutions.[30] There have been other small RCTs with conflicting results with regards to peritonitis and RKF. Systematic reviews have also shown inconclusive findings, and as a result the overall benefit of biocompatible solutions remains unclear.[26,27]

In commercial PD solutions the concentration of Na^+, Cl^-, Ca^{2+}, and Mg^{2+} are provided at levels similar to their respective plasma concentrations.[11] As a result, the diffusive capacity of these electrolytes is greatly reduced, and their transport across the peritoneal membrane is mostly dependent on convective transport (with UF). Computer simulations demonstrate that for an average patient with a plasma concentration of 140 mmol/L, approximately 10 mmol of Na^+ is removed with every 100 mL of UF volume produced.[11] Na^+ concentration in the solution is usually 132 to 134 mmol/L, as higher concentrations would reduce the diffusive gradient for sodium removal from the plasma.

Similarly, Ca^{2+} transport is primarily driven by convective transport, a UF-dependent process. The concentration of Ca^{2+} in PD solutions usually ranges from 1.25 to 1.75 mmol/L. In reducing the risk of hypercalcemia in PD patients who commonly use calcium-based phosphate binders, a calcium concentration of 1.25 mmol/L in the dialysate is recommended to achieve a "calcium neutral" state,[11] in which calcium is neither lost nor gained during a dwell. In commercial solutions, the concentration of Ca^{2+} does not vary with glucose concentrations, and so solutions with 1.25 mmol/L of Ca^{2+} may be preferable for patients treated with calcium-based phosphate binders to reduce the risk of hypercalcemia. Net peritoneal calcium removal can be obtained by intermediate- and high-concentration solutions with a Ca^{2+} concentration of 1.25 mmol/L,

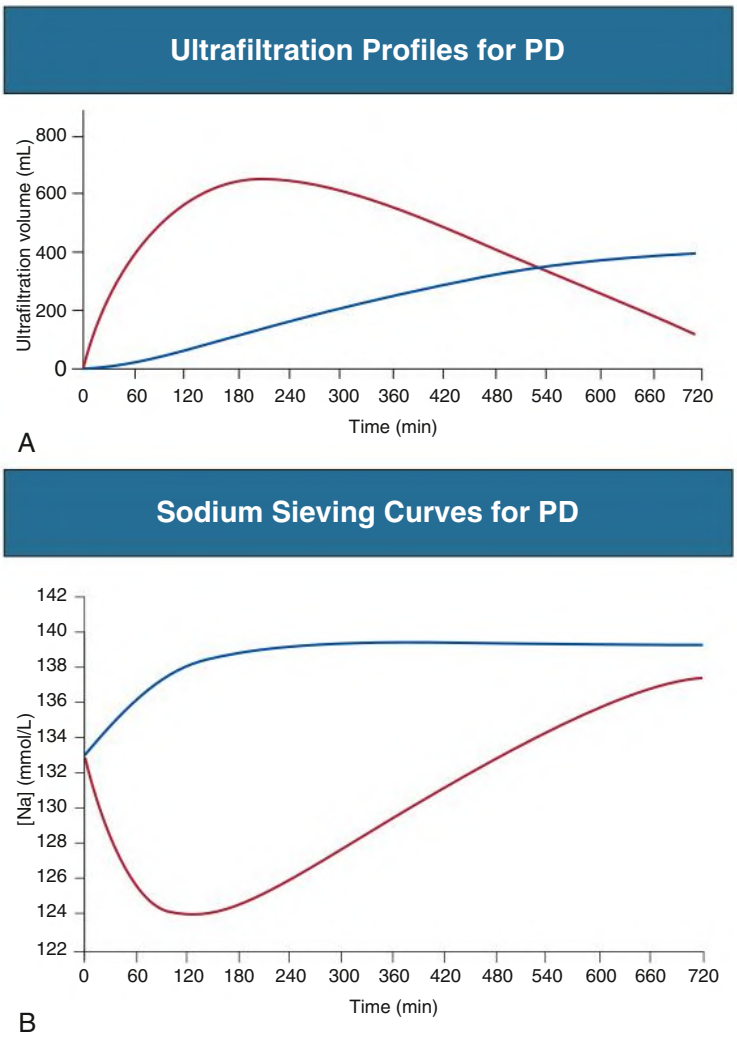

Fig. 101.5 (A) Ultrafiltration (UF) profiles for peritoneal dialysis (PD). UF profile for 7.5% icodextrin *(blue line),* computer simulated according to the three-pore model in an average patient who is not naive to icodextrin, in comparison with the computer-simulated UF curve for 3.86% glucose *(red line).* (B) Sodium-sieving curves for PD. 7.5% icodextrin *(blue line)* and 3.86% glucose *(red line)* (see Fig. 101.3). *Na,* Sodium. as convective transport results in 0.1 mmol of Ca^{2+} for every 100 mL of UF.[11]

The other important divalent cation in PD solutions is magnesium. The concentration of Mg^{2+} in manufactured solutions ranges from 0.25 to 0.75 mmol/L. In 1.5% (1.36%) glucose solutions, the concentration of Mg^{2+} at 0.25 mmol/L would maintain a net neutral magnesium level during the dwell,[31] whereas net losses of Mg^{2+} would be seen with PD fluid with higher glucose concentrations due to larger convective flux driven by UF.

PERITONEAL ACCESS

Peritoneal Dialysis Catheters

A well-functioning PD catheter is critical for sustainable treatment with PD, because approximately 20% of PD withdrawal is due to catheter dysfunction.[32] The Tenckhoff catheter is a Silastic tube with numerous holes along the intraperitoneal segment.[33] Modern catheters typically have two Dacron (polyester) cuffs that limit catheter migration and reduce risks of pericatheter leaks and infection. The deep cuff is best placed in the rectus muscle of the abdominal wall, which allows the tissue ingrowth to encapsulate the catheter, reducing the risk of migration. On the other hand, the superficial cuff is best placed about 2 to 4 cm from the exit site. This functions as a barrier against the entry of bacteria into the subcutaneous tunnel.[34]

Catheters are available in coiled-tip and straight-tip types, with further variation existing in some catheters whereby there is a preformed bend in the intercuff segment called a "swan neck" (Fig. 101.6). Reported benefits of less inflow pain associated with coiled-tip variants due to better dispersion of dialysate fluid rather than a rapid jet flow with straight-tip variants remain hypothetical. Numerous studies comparing outcome and complication rates between the two catheter-tip variants have produced conflicting results,[35-37] and thus either is acceptable.

Insertion of Peritoneal Dialysis Catheters

PD catheters should be inserted under sterile conditions by a skilled operator. Laparoscopic insertion is the preferred method, as it allows the operator to incorporate interventions to enhance the overall success rate of functioning catheter. Operators can insert catheters with laparoscopically guided rectus sheath tunneling directed toward the pelvis,

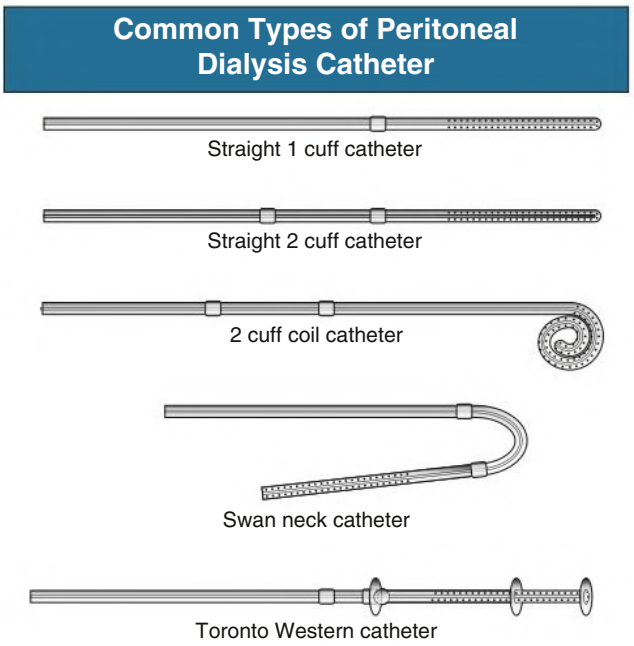

Fig. 101.6 Various types of peritoneal dialysis catheter.

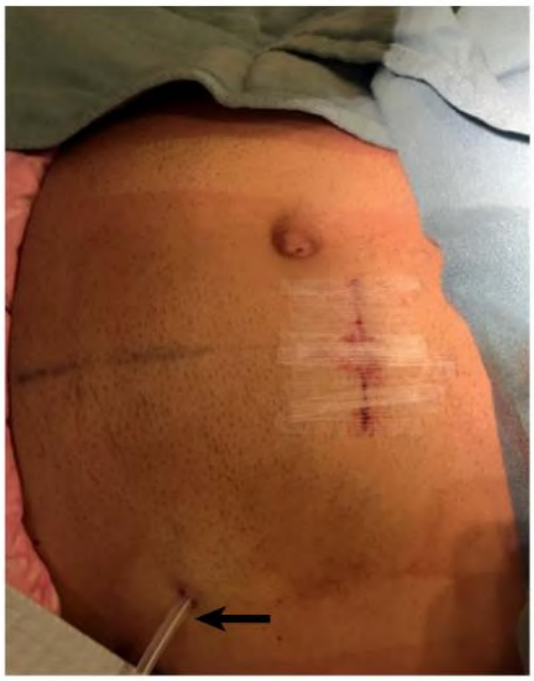

Fig. 101.7 Peritoneal Dialysis Catheter Inserted at the Bedside. Note the insertion in the left paramedian portion of the abdomen through which the catheter was inserted using a Seldinger technique *(arrow).*

which reduces the likelihood of catheter tip migration. Furthermore, laparoscopic insertion allows operators to visualize redundant omentum that may compromise catheter function; redundancy is reduced by suturing it to a nearby organ or upon itself in a procedure referred to as an omentopexy. Alternatively, percutaneous insertion using needle with guidewire and the assistance of ultrasound is a technique that can be performed at the bedside (Fig. 101.7). This technique uses a modified Seldinger technique and is useful in low-resource settings in patients who do not have abdominal hernias and previous surgical abdominal history.[34]

Before catheter insertion, patients should undergo a complete abdominal assessment to identify any prior surgical scars or hernias and to plan for the catheter exit site. It is important that the exit site be planned with the patient sitting rather than when lying on the table so as to account for any pannus that could obscure the site. Antibiotic prophylaxis should be given to patients before catheter insertion to reduce the risk of peritonitis.[38] A single preoperative dose of a first- or second-generation cephalosporin is recommended depending on local resistance patterns and patient allergic history.

PERITONEAL DIALYSIS TECHNIQUES

Historically, transporter status guided prescriptive strategies for PD patients. For example, high transporters would have a rapid dissipation of their glucose gradient and theoretically were deemed best suited for APD. On the other hand, patients with low transporter status were deemed best suited for CAPD, allowing for dwells of longer duration in effort to maximize diffusive transport. Although theoretically these prescriptive strategies may maximize the efficiency of peritoneal transport, it is not a practical approach used in everyday practice. PD prescriptions should be individualized according to patient priorities and lifestyle rather than relying on transport kinetics. For instance, patients who have undergone recent abdominal surgery or have a history of hernias may be better suited for cycler-based APD therapy. This technique provides rapid exchanges for patients while maintaining adequate dialysis without significantly increasing IPP, in turn reducing the risk of leaks and other complications. Additionally, patients with daytime employment may find it challenging to perform exchanges during the day. Nightly APD followed by a long day-dwell allows flexibility in the daytime schedule for patients. Automated cyclers have evolved with newer technological features that allow for remote monitoring of inflow time, dwell time, and drain time along with drain volumes. Most APD machines are equipped with warmers that can warm fluid before inflow into the peritoneal cavity, reducing the episodes of discomfort and shivering that may occur with room temperature fluid. In certain patients, low drain alarms may occur on the cycler, which affects the efficiency of an exchange. This can be overcome by increasing the residual intraperitoneal volume and proportionally decreasing subsequent fill volumes in a process called tidal peritoneal dialysis (TPD). For example, 70% TPD implies that, for a 2-L inflow volume, 1.4 L would be drained out, and the next inflow volume would also be 1.4 L, leaving a residual intraperitoneal volume of about 0.6 L repeated over the cycles until the final drain. TPD was initially developed to enhance the diffusive clearance of solutes, but results have been disappointing; TPD is now used primarily for the management of low drain alarms on the cycler and for those experiencing pain during the inflow and/or drain phase of the exchange.

Alternatively, patients can be managed with CAPD using a volume of 1.5 to 2.5 L of fluid with up to five exchanges daily depending on RKF. CAPD day-dwell times can range from 4 to 6 hours before dissipation of the glucose osmotic gradient. The overnight dwell for CAPD can last for a period of 10 to 12 hours, where icodextrin or a high-concentration glucose-containing solution can be used to sustain an osmotic gradient.

PD is also dependent on a functioning connection system that is safe and simple to use. There are three major types of connection systems used in PD. They include the "standard" or straight connecting system, the Y connecting system, and the double bag system. The standard connecting system has fallen out a favor due to higher rates of peritonitis and is now rarely used. The Y connecting system uses a Y-shaped tube that attaches to an extension tube from the patient's catheter; the two other limbs of the system are connected to unused PD

fluid and a sterile empty drain bag. This system uses a principle called "flush before fill," which is likely the underlying reason that peritonitis rates are lower with this system. Intraluminal microorganisms are flushed into the drain bag, avoiding intraperitoneal contamination.[39] The original Y system developed in the 1980s has since evolved to the double-bag system, which is the most widely used connection system.[40] In this system the solution bag and drain bags are already attached to the two limbs of the Y connector; patients now have to make one simple connection to extension tubing rather than three with the original system.[40] The double-bag system is flushed for about 5 seconds and then a "frangible" (breakable) pin within the tubing is broken, allowing the spent dialysate from the peritoneal cavity to fill in the drain bag for up to 20 minutes. The limb to the drain bag is then clamped and the limb from the PD solution is opened to fill the peritoneal cavity. The time for exchange, accounting for the instillation and drainage, should not exceed 30 minutes provided that the PD catheter is functional. The initial volume (the first 1.6–1.8 L) from the peritoneal cavity usually drains rapidly, but this rate decreases as the residual intraperitoneal volume (sump volume) falls to less than 300 mL.

PERITONEAL SOLUTE TRANSPORT AND ULTRAFILTRATION

Small-Solute Removal

Most solutes typically removed by normal functioning kidneys are primarily removed by diffusive clearance in PD. The two methods commonly used in PD to assess solute clearance are the urea clearance normalized to total body water, expressed as Kt/V_{urea} (where *Kt* is the weekly clearance and V_{urea} is the volume of distribution of urea), and the peritoneal creatinine clearance standardized to body surface area (1.73 m^2).

In determining Kt, daily clearance must first be established by the measurement of urea and creatinine with PD in using the dialysate-plasma concentration ratios (D/P). The D/P_{urea} and $D/P_{creatinine}$ for either solute is done by measuring the concentration of the solute in the "used" dialysate and that in the plasma multiplied by the daily drain volume to provide the 24-hour clearance, providing the daily clearance. The weekly clearances can then be calculated by multiplying these values by 7.

Despite more contemporary studies showing little association between small-solute kinetics and patient outcomes, Kt/V_{urea} is still used as a marker of adequacy.[41,42] However, some centers use peritoneal creatinine clearance as a marker of solute removal given the data for Kt/V_{urea} and the imprecision in determining V.

Large-Solute Removal

Large solutes are removed more slowly compared with small solutes with PD via convective clearance. Although surrogate markers for large-solute clearance can be measured using albumin, immunoglobulins, and α_2-macroglobulin, this is not common practice. These solutes move across the large pores very slowly, such that equilibration in the dialysate with the plasma does not occur with the typical dwell time that is used for PD. Nevertheless, removal of large solutes is time dependent, and so the long dwell is important for this process.

Ultrafiltration

The volume of UF achieved with PD can vary significantly from day to day. This variability stems from changes in the tonicity of the solution used and patient positioning along with common factors affecting drainage such as constipation, which may lead to elevations in residual intraperitoneal volume. Collecting fluid volumes over several days and using the average value improves the accuracy of estimated daily UF volume. If UF volumes remain low, then patients should be evaluated for ultrafiltration failure (UFF) by using a high-concentration solution (3.86%/4.25%). A UF volume of less than 400 mL after a 4-hour dwell with high-concentration solution is consistent with UFF. Additionally, UF volumes can also be evaluated using the PET (see later). In determining intraperitoneal volume as a function of time, iodine-125 (^{125}I)–human serum albumin (HSA) can be used as a more accurate measurement of fluid kinetics in PD,[43] although this is rarely done in clinical practice.

BOX 101.1 Peritoneal Equilibration Test

1. Two liters (warm) 2.27% fluid are instilled for 10 min with the patient supine and rolling from side to side every 2 min.
2. Exactly 10 min after start of the infusion, 200 mL is drained into the bag. Draw 5 mL (discard); the next 5 mL is taken for creatinine and glucose determination.
3. After 2 h, new samples are collected as in step 2.
4. After 4 h exactly, collect drainage over 20 min. Note total bag weight. Subtract empty bag weight. Take samples (after mixing) for creatinine and glucose.
5. Glucose D/D_0 (ratio of dialysate glucose at 4 h and at time zero) and creatinine D/P (ratio of dialysate and serum creatinine at 4 h) are plotted versus time (see Fig. 101.8). Record the total drain volume.

The night bag (8–12 h) must be 1.36% or 2.27% glucose, drained for 20 min with patient sitting upright.

ASSESSING PERITONEAL MEMBRANE FUNCTION

Peritoneal Equilibration Test

The peritoneal equilibration test (PET) provides an estimation of small-solute transport and UF capacity[44] by using equilibration ratios between the dialysate and plasma (D/P) for various solutes across the peritoneal membrane. These include urea (D/P_{urea}), creatinine ($D/P_{creatinine}$), and sodium (D/P_{sodium}). The procedure is summarized in Box 101.1 and traditionally involves the instillation of 2 L of an intermediate (2.27% or 2.5%) glucose-based solution; more recently, some centers have used 4.25% solutions. As the fluid is instilled over a period of about 10 minutes, the patient is encouraged to roll from side to side while in a supine position. This allows the infused fluid to be well distributed in the peritoneal cavity, particularly in the paracolic gutters. After the fill is completed, dialysate samples are taken three times: at time zero, 2 hours postfill, and 4 hours postfill. At the end of the 4-hour dwell, the dialysate drained is measured to calculate the total UF. During the test, the concentrations of glucose, creatinine, urea, and sodium are noted in three dialysate samples and the plasma. These values are used to determine D/P ratios; glucose is expressed differently as the glucose concentration in the 4-hour dialysate relative to that at time zero ($D/D_{0\ glucose}$). The $D/P_{creatinine}$ and $D/D_{0\ glucose}$ values are used to categorize patients into one of four different transporter categories: slow, slow average, fast average, or fast (Fig. 101.8). Although transport characteristics may change with time due to alterations in peritoneal membrane, nearly 70% of patients have stable transport status 1 year post-PET and about 50% of patients at 2 years post-PET.

Alternatives to the traditional PET include the mini-PET and the double-mini PET. The mini-PET provides a quicker method to assess small-solute and free water transport. It uses a high-concentration (3.86% or 4.25%) glucose-based solution that is infused intraperitoneally and dwells for 1 hour.[45] The concentration of sodium is measured in the drained dialysate sample; free water transport across the

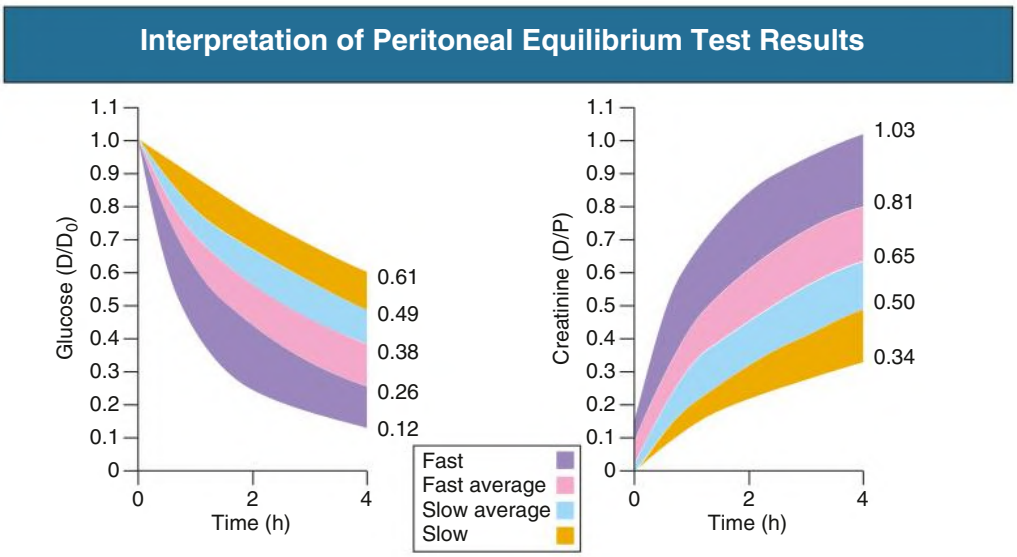

Fig. 101.8 Interpretation of Peritoneal Equilibration Test Results. Changes in solute concentration during a peritoneal equilibration test allow classification into different transport types. D/D_0, Ratio of dialysate glucose at 4 hours and at time zero) *D/P,* ratio of dialysate and serum creatinine at 4 hours. (Modified from Twardowski ZJ, Nolph KD, Khanna R. Limitations of the peritoneal equilibration test. *Nephrol Dial Transplant.* 1995;10[11]:2160–2161.)

membrane is determined indirectly. The double-mini PET test is used to evaluate the free transport of water and osmotic conductance of glucose (OC_G) across differing concentrations of solutions. The test is conducted by performing two consecutive mini-PETs[46]: the first uses a low-concentration (1.36% or 1.5%) glucose, and the second uses a high-concentration (3.86% or 4.25%) glucose solution. The double-mini PET can be used to calculate the OC_G without computer modeling by using the differences in drain volume between the low- and high-concentration solutions. In theory, it could be used to identify early signs of UFF in PD patients, but further data are needed.

It isn't clear that the PET has to be routinely performed in all PD patients. As discussed earlier, the transport status has historically been used to dictate the PD prescription, but more recently the choice of CAPD versus cycler is primarily driven by patient preference and finances. We no longer routinely perform the PET in our PD patients.

If a PET is done, this should occur no sooner than a month after catheter insertion, as the inflammation from the procedure can affect transport status. Similarly, a PET should not be done in a patient with current or recent peritonitis.

DOSE AND ADEQUACY OF PERITONEAL DIALYSIS

The use of absolute targets for Kt/V_{urea} to determine the adequacy of PD remains controversial. Historically, clinical practice guidelines recommended weekly Kt/V_{urea} of 2.0, but recent studies have failed to demonstrate a clinical benefit of Kt/V_{urea} values of greater than 1.7. Rather, a better survival advantage is associated with high RKF compared with a higher peritoneal solute clearance with higher Kt/V_{urea}.[41] Based on this emerging data, current clinical practice guidelines have evolved and now recommend that patients with a RKF of more than 100 mL/day have a minimal delivered total (peritoneal and renal) dose of small-solute clearance with a weekly Kt/V_{urea} of 1.7.[47]

Residual Kidney Function

RKF and its preservation has been associated with numerous benefits, including lower relative risk of death in dialysis patients.[41,48] Observational data has demonstrated that RKF is better preserved in patients on PD compared with HD.[49] RKF can easily be assessed by performing a 24-hour urine collection with assessment of the urea and creatinine concentrations along with the total urine volume. Because renal creatinine clearance may result in an overestimation of glomerular filtration rate (GFR) due to its tubular secretion, GFR can be more accurately estimated by averaging the renal creatinine and urea clearances respectively. However, if a 24-hour urine collection is impractical, the serum creatinine can be used as a surrogate marker of RKF. If serum creatinine is stable in the absence of changes in muscle mass or recent changes to the PD prescription, it can be assumed that RKF is preserved.[4]

PRINCIPLES AND PRACTICE OF INCREMENTAL DIALYSIS

The adoption of incremental PD has numerous benefits to patients and the health care system. It allows patients time to become comfortable with the therapy, and the prescription is enhanced to promote appropriate small-solute clearance if there is a decline in RKF. Simply put, as RKF declines, the dose of PD will need to increase. Longitudinal observational data has demonstrated that in comparison to standard PD prescriptions, survival rates in PD patients were similar, but the rates of hospitalizations and cost to the health system were much less in the incremental group. Incremental PD also reduces the reliance on Kt/V_{urea} and redirects more attention to clinical assessments and other biochemical data to determine adequacy. Incremental PD has some disadvantages that include a reluctance of patients to increase the dialysis dose when a decrease in RKF suggests that this is necessary. Delays in adjusting the PD prescription to achieve effective solute clearance can result in uremia in patients. Therefore, patients and caregivers should be informed about the principles of incremental PD before starting this type of treatment so that prescription changes are better accepted when they are warranted.

However, in our experience, the RKF does not usually suddenly decline in a stable outpatient unless there has been some notable intercurrent event. Therefore, the concern that a patient on an incremental prescription may suddenly become underdialyzed due to a sudden drop in RKF is unwarranted.

Prescribing Incremental Peritoneal Dialysis

In adopting the principles of incremental PD, clinicians should individualize prescriptions to patient needs while focusing on clinical symptoms in conjunction with laboratory investigations. For example,

a patient who prefers to do manual exchange therapy can be started on CAPD with 1 to 2 exchanges per day at 1.5-L fill volumes with each exchange. Depending on patient comfort, fill volumes can be increased incrementally up to maximum of 2.5 L with each exchange. If a patient needs more solute clearance, then additional daytime exchanges can be incorporated if a maximal tolerated fill volume has been achieved. On the other hand, for patients receiving cycler-based therapy, nocturnal intermittent peritoneal dialysis (NIPD) is an initial preferred option. NIPD may be more attractive to patients with reduced flexibility in daytime schedules and can be provided initially with two to three exchanges overnight with volumes of 1.5 L with each exchange. If there is a gradual decline in RKF, then the fill volumes could be increased in 20% to 30% increments up to a maximum patient tolerance, or a value not exceeding 2.5 L, in order to improve solute clearance. If more solute clearance is still needed, then the number of exchanges on the cycler can gradually be increased followed by the addition of a daytime dwell.

Fluid Balance

Patients on PD have significant day-to-day variation in their fluid balance, which requires changes in the PD prescription and diuretic dosing in those with significant RKF. Maintaining euvolemia is an important predictor of outcomes in PD patients, but hypervolemia is quite common in this population.[50] Observational data have revealed that among 639 prevalent patients who had been on PD for at least 2 years, more than 70% had hypervolemia.[51] The reasons for hypervolemia are multifactorial and include loss of RKF, increased dietary intake of salt and fluid, nonadherence to dialysis, and inadequate prescription (low-concentration solution leading to rapid dissipation of osmotic gradient in a fast transporter). Hypervolemia can exacerbate hypertension in PD patients and may lead to left ventricular hypertrophy. As patients remain on PD for longer periods, their antihypertensive regimen (number of agents and their doses) often increases over time. In patients with hypervolemia, clinical assessment (in conjunction with a mini-PET or double mini-PET test if required; see earlier) is used to determine whether UFF is the underlying cause for volume overload.

Management of Fluid Overload

In treating fluid overload, a stepwise approach should be considered for all PD patients. First, patients must be encouraged to reduce dietary intake of sodium to less than 2 g/day. Second, if RKF is more than 100 mL/day and volume overload persists, then a loop diuretic such as furosemide can be increased to 320 to 400 mg/day in divided doses[52]; a thiazide-like diuretic such as metolazone can be added to enhance urinary volumes. Increased doses of diuretics serve to promote natriuresis and do not augment renal clearance of solutes. Last, if volume overload remains despite dietary modifications and increased diuretic dosing, then volume removal can be enhanced with peritoneal UF by increased glucose concentration of PD solutions. Icodextrin can be used for longer dwells, particularly for daytime dwells with APD, as this increases UF and reduces extracellular volume.[53] The rate of UF with icodextrin is much slower compared with glucose solutions with maximal UF occurring about 10 hours into the dwell. Therefore, icodextrin should not be used for the management of acute volume overload, where hypertonic solutions with faster UF profile rates are preferred.

Nutrition

The importance of good nutrition while on PD may be neglected, leading to poor patient outcomes. PD initially leads to weight gain in patients in the absence of volume overload. This weight gain is due to increase in caloric intake from peritoneal glucose reabsorption. Peritoneal glucose reabsorption leads to daily average of 400 to 600 kcal/day, which may lead to metabolic syndrome in nearly half of all prevalent PD patients.[54] However, despite glucose reabsorption, patients may still have energy malnutrition as a result of uremic wasting syndrome. Furthermore, as RKF declines, protein-energy malnutrition and wasting increases due to impairment in protein metabolism in the presence of uremia.[55] The suggested daily energy target for PD patients is at least 35 kcal/kg/day, with about 10% to 30% of this target being derived from the glucose-based PD solutions. Considering protein losses with PD (5–7 g/day, 80% of which is albumin), the recommended dietary daily protein target should be more than 1.2 g protein/kg/day.

Acknowledgment

We thank Dr. Bengt Rippe (1950–2016) for his contributions to the previous edition. Dr. Rippe was a trailblazer in the field of physiology, with his research findings being the bedrock of many applied principles of PD in today's practice.

SELF-ASSESSMENT QUESTIONS

1. In PD, the fraction of AQP-mediated water flow is much higher for glucose than for ICO as osmotic agent. Why?
   - **A.** Glucose will induce more initial vasodilation and recruitment of exchange vessel surface area than ICO.
   - **B.** The glucose molecules are smaller than the ICO molecules and therefore are relatively "inefficient" as osmotic agents in small pores but relatively more efficient across AQP.
   - **C.** Glucose, but not ICO, will regularly induce an increase in the number of AQPs.
   - **D.** Glucose, but not ICO, can increase the peritoneal capillary filtration coefficient.
   - **E.** Oncotic agents such as ICO cannot pull fluid across AQP at all.
2. Which PD catheter has a superior clinical outcome?
   - **A.** The Toronto Western catheter
   - **B.** The Swan neck catheter
   - **C.** The straight one-cuff (original) Tenckhoff catheter
   - **D.** The straight two-cuff (original) Tenckhoff catheter
   - **E.** None of these catheters shows significant clinical superiority
3. Long-term changes in peritoneal transport parameters usually involve:
   - **A.** increases in PET_{creat} and marked increases in the peritoneal UF coefficient.
   - **B.** reductions in PET_{creat} and increases in the peritoneal UF coefficient.
   - **C.** increases in PET_{creat} combined with no or only moderate increases in the UF coefficient.
   - **D.** increases in large-solute transport together with increases in UF coefficient.
   - **E.** increases in large-solute transport combined with reductions in the UF coefficient.
4. Glucose-based dialysis fluids for PD that are low in GDPs have which of the following advantages?
   - **A.** They prevent peritoneal fibrosis and encapsulating peritoneal sclerosis.
   - **B.** They preserve residual renal function.
   - **C.** They prevent increases in small-solute transport over treatment time.

D. They produce higher concentrations of the dialysate effluent marker CA-125.
E. They increase peritoneal UF capacity.

5. Which of the following is true about icodextrin as a high molecular weight osmotic agent?
A. ICO is monodispersed.
B. ICO is polydispersed, but with 100% of the molecules being larger than 3 kDa.
C. ICO is polydispersed, but with 80% of the molecules being larger than 3 kDa.
D. ICO is polydispersed, but with 50% of the molecules being larger than 3 kDa.
E. ICO is polydispersed, but with 30% of the molecules being larger than 3 kDa.

6. Net fluid reabsorption from the peritoneal cavity occurs via lymphatic reabsorption plus backfiltration through:
A. small pores.
B. AQP-1.
C. large pores.
D. larges pores + AQP-1.
E. small pores + large pores.

Complications of Peritoneal Dialysis

Simon J. Davies, Martin E. Wilkie

CATHETER MALFUNCTION

Optimal Timing and Placement of the Peritoneal Dialysis Catheter

Catheter dysfunction adversely affects patient outcome by preventing commencement of the chosen dialysis modality, as well as by disrupting training schedules and increasing health care costs. Published literature does not demonstrate that one insertion technique is better than another, although a recent meta-analysis suggested an advantage of the laparoscopic compared with the open surgical insertion technique.[1] It is clear that the enthusiasm and experience of the operator are key determinants of catheter outcome,[2] and international guidelines describe the optimal conditions for catheter insertion.[3] Timing is also important; patients randomized to the late start arm of the Initiating Dialysis Early and Late (IDEAL) study (estimated glomerular filtration rate [eGFR] 5–7 mL/min/1.73 m^2) were less likely to start kidney replacement on peritoneal dialysis (PD) than those starting early (eGFR 10–14 mL/min/1.73 m^2), despite PD being their preferred treatment.[4] Early catheter problems are more difficult to manage in the absence of residual kidney function. Our practice is to place catheters once the GFR falls below 10 mL/min/1.73 m^2, aiming to start dialysis when the GFR is 7 to 8 mL/min/1.73 m^2. However, this is individualized according to patient symptoms and whether fluid retention is a particular problem. Some centers use an approach where the external part of the catheter is buried in the subcutaneous tissue at the time of implantation (known as the Moncrief technique) so that it can be exteriorized at the time it is required. This approach means that the catheter can be placed several months prior to be needed. For optimized catheter function, it is necessary that each center audit its success with catheter placement against internationally agreed-upon standards as part of local quality improvement.[2,3]

Catheter Function: Inflow

A 2-L bag of dialysate should normally take 15 minutes or less to run into the peritoneal cavity. If inflow has stopped or significantly slowed, mechanical causes should be suspected. After checking to ensure that the tubing and catheter are not kinked, that all clamps or rollers are open to the inflow position, and that any frangible seal is fully broken, the catheter should be flushed vigorously with 20 mL of heparinized saline. If the catheter is cleared, heparin should be added (500 U/L) to the next few cycles because the cause of the blockage is often a fibrin plug. Should the catheter remain blocked, a plain abdominal radiograph is required. If this shows that the catheter is in a satisfactory position in the deep pelvis, an attempt to restore patency should be made with a thrombolytic agent (urokinase 5000 U or tissue plasminogen activator [tPA] 2 mg in 40 mL of normal saline),[5] which can be instilled into the PD catheter for approximately 1 hour before being withdrawn. If inflow is restored, heparin should be added to the dialysate for the next few cycles. We no longer recommend the use of an endoscopic brush because of safety concerns.

If the radiograph shows the catheter to be malpositioned, an attempt should be made to reposition the catheter tip into the pelvis (Fig. 102.1). This can be done under radiologic guidance with a sterile guidewire inserted into the catheter; alternatively, the catheter can be repositioned at laparotomy or with the laparoscope. Sometimes the catheter becomes wrapped in omentum, suggested usually by complete inflow and outflow failure. This requires a partial omentectomy or an omental hitch, a surgical procedure in which the omentum is temporarily held away from the catheter by a dissolvable suture (omentopexy). The value of laparoscopy in this context is that it can provide a diagnosis as to the cause of catheter flow failure and provide a solution (e.g., by repositioning the catheter, removing an omental wrap, or performing a limited omentectomy).

Catheter Function: Outflow

The most common reason for outflow failure is constipation, although causes of inflow failure discussed previously should also be considered. Loading of the bowel with fecal material is often obvious on a plain radiograph, but treatment for constipation should be initiated without recourse to this investigation because it is so common. Constipation should be treated with oral laxatives or an enema. Subsequently, bowel action should be kept regular by increasing the fiber in the diet and, if necessary, adding a mild laxative. Slow outflow can be a problem in patients using automated peritoneal dialysis (APD), resulting in excessive machine alarms. This can be managed by switching to tidal APD and using a relatively large residual volume (e.g., 25% to 50% of the fill volume). Recently, concerns have been raised about the risk for excessive intraperitoneal dialysate volume that might occur during tidal PD; as a precaution, cycler algorithms have been altered to incorporate a complete drain into the treatment schedule.

Fibrin in the Dialysate

The mesothelial cells of the peritoneal membrane have a range of physiologic functions, including the production of fibrinolytic agents such as tPA. This process is disrupted during peritonitis when the appearance of fibrin in the dialysate is common. If fibrin causes restriction of dialysate flow, heparin (500 U/L) should be added to each bag. A small number of patients have fibrin formation in the absence of peritonitis. Immediately on drainage the bag may appear cloudy, but on standing the fibrin will aggregate and the fluid becomes clear. The first time this happens, a sample must be sent to the microbiology laboratory to exclude infection. If the results of this testing prove negative, the patient can be reassured.

FLUID LEAKS

Fluid leaks occur in which dialysate leaks out of the peritoneal cavity, which can be either visible externally or not. It is

recommended that after PD catheter surgery, patients be allowed to heal sufficiently before use (1–2 weeks) to minimize this risk. If the catheter must be used early, low volumes should be used (start with 1 L) in the supine position (e.g., APD with a dry day), with the patient instructed not to mobilize while dialysate is in the peritoneal cavity during the first 2 weeks after catheter insertion. Although PD catheters can be used successfully as the primary approach to manage late-presenting patients or for acute kidney injury, the incidence of leaks is higher under these conditions unless precautions are taken.[6,7]

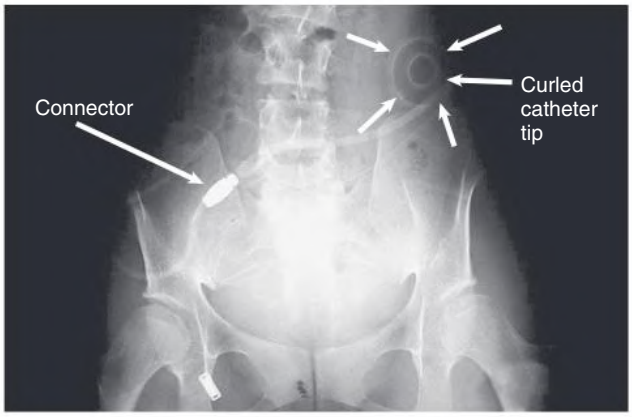

Fig. 102.1 Catheter Malposition. Plain radiograph of the abdomen with curled catheter *(arrows)* misplaced in the upper left abdomen.

External Leaks

On occasion, fluid may leak from the exit site or even the incision used to insert the catheter into the peritoneal cavity. A leak of dialysate, which is confirmed by measuring glucose concentration in the leaking fluid, is a risk factor for infection. It is important that PD catheters be adequately immobilized if used for early-start PD to reduce the risk for tugging and leak.

Internal Leaks

Isolated edema of the abdominal wall suggests an internal leak from the peritoneal cavity, either spontaneously or in association with a surgical hernia. In contrast, genital edema suggests an inguinal hernia or patent processus vaginalis. On occasion, both can be present. The site of the leak can be visualized on computed tomography (CT) scanning after intraperitoneal instillation of contrast material or on magnetic resonance imaging without the use of contrast. It may be necessary for the patient to stand or perform other maneuvers to increase intraabdominal pressure before the leak is demonstrated (Fig. 102.2A). An alternative diagnostic test is to perform scintigraphy after injection of a compound such as technetium 99m–labeled diethylenetriaminepentaacetic acid (^{99m}Tc-DTPA; see Fig. 102.2B). A surgical repair will be required if a major leak is visualized and should always be considered when there is a hernia. Most leaks, however, will heal after resting or with APD, using dry days, or temporary HD.

Hydrothorax

A pleural effusion can occur with generalized fluid overload or local lung disease, but it is occasionally caused by a leakage of dialysate

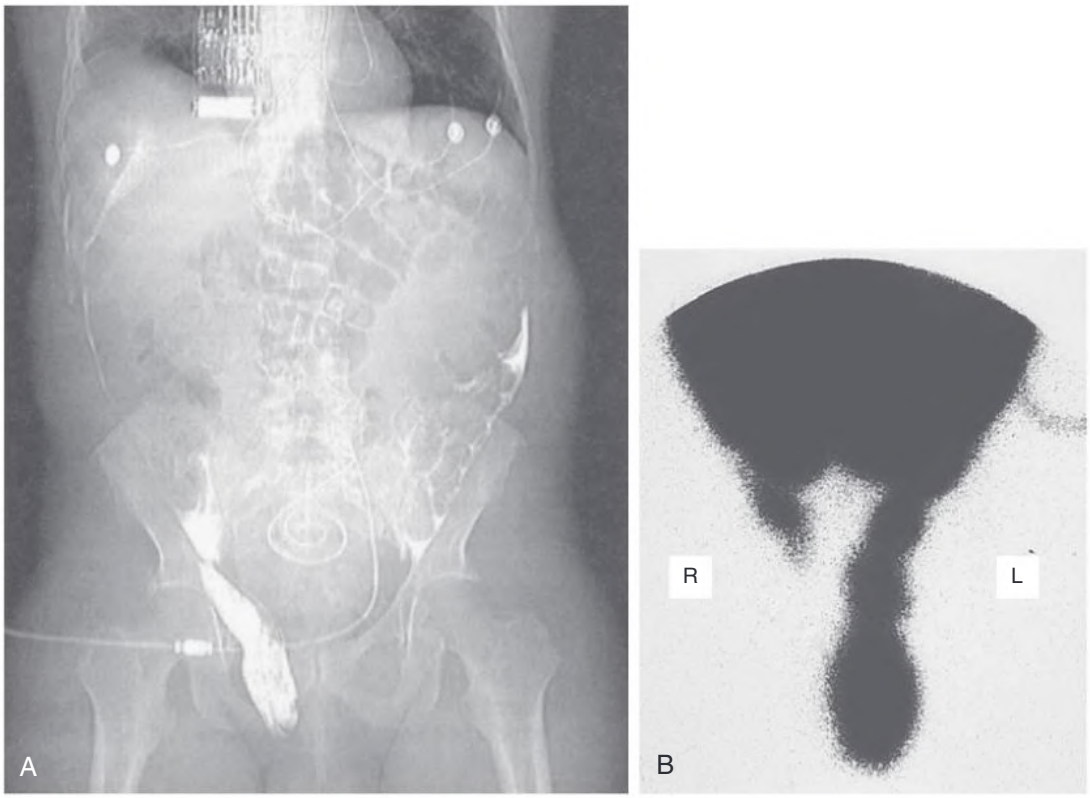

Fig. 102.2 Inguinal Hernia During Peritoneal Dialysis. (A) Computed tomography scan after intraperitoneal injection of contrast material in a male patient showing dialysate flowing into a right inguinal hernia. (B) Peritoneal scintigram of a male patient on peritoneal dialysis showing bilateral inguinal hernias. The left hernia extends into the scrotum; the right hernia is less extensive. (From Tintillier M, Coche E, Malaise J, et al. Peritoneal dialysis and an inguinal hernia. *Lancet.* 2003;362:1893.)

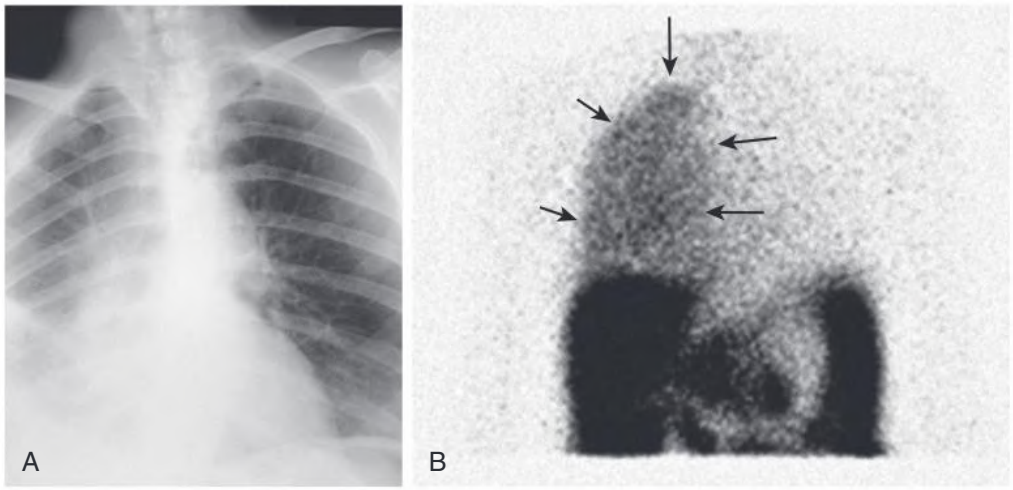

Fig. 102.3 Hydrothorax in Peritoneal Dialysis. (A) Chest radiograph showing a right-sided pleural effusion with partial collapse of the right lung caused by a diaphragmatic leak. (B) Scintigram in a peritoneal dialysis patient showing isotope in the right hemithorax *(arrows)* confirming a right pleural effusion.

through the diaphragm (Fig. 102.3A). This occurs more commonly on the right side. A leak is most simply indicated by aspirating a sample of the effusion and demonstrating that its glucose concentration is higher than the patient's blood glucose concentration, which can be confirmed by scintigraphy after intraperitoneal instillation of isotope, usually ^{99m}Tc-DTPA (see Fig. 102.3B). If one can be confident that the pleural effusion is not caused by the PD, then PD can be continued while the effusion is investigated and managed. Although there are reports that repairing pleural leaks allows subsequent PD, the best advice is to transfer the patient to HD unless there are very strong reasons not to do so.

PAIN RELATED TO PERITONEAL DIALYSIS

Inflow Pain

Soon after starting PD, patients may experience pain during fluid inflow, and occasionally pleuritic pain affects the shoulders, possibly because of diaphragmatic irritation, which usually resolves over the following days. Slowing the rate of fluid inflow will often reduce the symptoms, and peritonitis should be excluded and treated. A small number of individuals have persistent inflow pain, and the use of bicarbonate-lactate–buffered dialysate at physiologic pH improves symptoms in such patients.[8]

Outflow Pain

Some patients have discomfort or pain when the fluid is drained out, which can be experienced in the genital area or rectum and is commonly a result of pelvic irritation related to the catheter tip. This emptying sensation is abolished when the next cycle runs in and is best treated by leaving a small residual volume of fluid in the peritoneal cavity at the end of the drain (e.g., by using tidal APD). In tidal APD, a residual volume is left in the peritoneal cavity at the end of each dialysis cycle (e.g., 20% of the drain volume). To reduce the risk for intraperitoneal volume overload, the treatment algorithm includes at least one complete drain during and at the end of treatment.

Blood-Stained Dialysate

Blood-stained dialysate is uncommon. It is rarely serious but causes considerable alarm to the patient. There is sometimes a clear history of trauma to the abdomen or of unexpected strain. A range of rare conditions are associated with this complication[9]; a few female patients relate the episode to their time of ovulation or menstruation. The treatment is to flush the abdomen with a few cycles of dialysate containing heparin (500 U/L) to minimize the chances of clotting in the catheter. The problem usually resolves spontaneously and often is visible only in one outflow. It is unusual for the blood-stained dialysate to be associated with infection, although it is wise to have the fluid cultured. Routine use of antibiotics is not necessary.

INFECTIOUS COMPLICATIONS

Peritonitis

There are wide variations in peritonitis rates both between and within countries. Reducing peritonitis rates requires a multifaceted, multidisciplinary approach based on the use of preventive measures around the time of catheter insertion, the use of modern disconnect systems, exit site management, and education of patients and health care professionals.[10] This should be supported by regular local audit of peritonitis rates including causative organisms and local sensitivities, which is increasingly important because of the emergence of resistant organisms and the requirement to use antibiotics effectively. Root cause analysis (e.g., inquiring about breaches in sterile technique) should be performed after each episode of PD peritonitis, with retraining as appropriate. Guidelines for the diagnosis and management of PD peritonitis are published by the International Society for Peritoneal Dialysis in adults and children (ISPD; https://www.ispd.org) (Box 102.1).[10,11] The Peritoneal Dialysis Practice and Outcomes Study has provided information on the variation in peritonitis rates between countries and center practices that are associated with lower rates. The findings included advantages for APD use and longer training periods and corroborated the use of antibiotic prophylaxis for catheter insertion and topical application to prevent exit site infection.[12]

Diagnosis of Peritonitis

Peritonitis should be suspected in any patient who develops abdominal pain or a cloudy bag when PD fluid is drained; patients with these symptoms should be advised to contact their dialysis center immediately. Fever may be present but is not a universal feature. Samples of the dialysate should be taken for cell count and microbiologic examination. The diagnosis is confirmed by finding more than 100 white blood cells (WBCs) per microliter (1×10^7/L), which should be more

All guidelines available at ISPD.org.

than 50% neutrophils. A Gram stain of the spun deposit should be performed to help identify the type of causative organism, although initial treatment will usually be empiric pending culture and sensitivity results. Various culture techniques have been proposed, but WBC lysis and inoculation into blood culture media is often helpful in increasing the yield of a positive growth.

The dialysate leukocyte count will be affected by dwell length, and this needs to be considered in APD patients. In short dwells, the count will be lower, and under these circumstances, if the proportion of cells that are neutrophils exceeds 50%, empiric treatment of peritonitis should be commenced. Conversely, if the patient has had a dry abdomen during the day, the initial drain on connection may be cloudy. This will clear within one or two cycles, and most of the cells found will be mononuclear leukocytes.

Treatment of Peritonitis

The empiric treatment of peritonitis will vary according to center and should be developed in close collaboration with the local microbiology service, taking into account sensitivity patterns and infection control policy. Initial regimens must cover both gram-positive and gram-negative organisms; the latest ISPD guidelines give examples of appropriate antibiotics and their doses, including vancomycin, cephalosporins, and aminoglycosides. Antibiotic regimens are adjusted as soon as culture results are available, usually after about 48 hours.[10] The preferred route of administration is intraperitoneal (IP) unless the patient has features of systemic sepsis. IP gentamicin can be administered as daily intermittent dosing at a dose of 0.6 mg/kg/day (aiming to maintain the trough serum concentration of <2 mg/L); IP vancomycin also can be administered intermittently every 5 to 7 days, at a dose of 15 to 30 mg/kg, aiming to maintain the serum vancomycin level above 15 µg/mL. IP cephalosporin can be administered either continuously (in each exchange) or on a daily intermittent basis.[10]

Dosage regimens will depend on whether the patient is on continuous APD (CAPD) or APD. For CAPD, the antibiotic is administered as a loading dose in the first bag and then as a maintenance dose in subsequent bags. The intermittent IP dose can be given in the day dwell of APD patients; however, APD results in a higher peritoneal clearance of antibiotics than CAPD, and therefore extrapolation of data from CAPD to APD may result in underdosing.

Once the culture result is available, the regimen should be modified accordingly (Table 102.1). If the organism is methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin will be continued as part of the regimen. If the culture is negative, empiric therapy should be continued for 2 weeks, assuming there is a clinical response. If a gram-negative organism is identified, the subsequent management will depend on the sensitivity (Fig. 102.4). The isolation of multiple organisms with or without anaerobes strongly suggests perforation of the small or large intestine or biliary system. Metronidazole should be added to the regimen to cover anaerobic organisms, antibiotic therapy augmented to intravenous administration, and prompt surgical review obtained with necessary imaging (CT scan if appropriate).

A wide variety of antibiotics other than those cited have been used with success, and these are documented in the ISPD 2016 guideline.[10] A commonly used strategy is to include an oral quinolone, such as ciprofloxacin. There is debate surrounding the role of aminoglycosides, the advantages being simplicity of use and good coverage for gram-negative organisms; however, there are concerns regarding ototoxicity and nephrotoxicity, the former of which is irreversible. Reports regarding the impact of these agents on residual kidney function are inconsistent, but serious episodes of peritonitis tend to adversely affect residual kidney function. It is advisable to avoid recurrent or protracted courses of aminoglycosides, with an early switch to alternative agents (e.g., third-generation cephalosporins) if they are used as empiric first-line treatment. There is evidence for the use of concomitant *N*-acetylcysteine, which should be considered to prevent the ototoxicity.[13] Current recommendations are that for gram-positive organisms, therapy should be for 14 days except in the case of *S. aureus,* for which 21 days is suggested. For culture-negative episodes, 14 days of therapy should suffice. The same is true in the case of single-organism gram-negative peritonitis.

TABLE 102.1 Antibiotic Regimens for Bacterial Peritoneal Dialysis Peritonitis

Culture	Antibiotic
Gram positive: based on sensitivities	Vancomycin or other appropriate antibiotic
Coagulase-negative staphylococci	Treat for 14 days
Staphylococcus aureus[a]	Treat for 21 days: screen for carriage
Enterococci	Treat for 21 days
Other streptococci	Treat for 14 days
Gram-negative bacilli or mixed bacterial growth	Continue gram-negative coverage based on sensitivities Consider switching to third- or fourth-generation cephalosporins
Pseudomonas[a] or *Stenotrophomonas* spp.	Two antibiotics based on sensitivity Treat for 21–28 days
Other gram-negative bacilli	Treat for 21 days For mixed gram-negative or gram-negative + gram-positive, consider metronidazole and ampicillin/vancomycin

Suggested antibiotic regimens when dialysate fluid culture is available. Except for culture-negative episodes, empiric treatment is stopped once the sensitivities are known. All antibiotic regimens should be adjusted for local microbiologic practices.
[a]Examine for exit site or catheter tunnel infection.

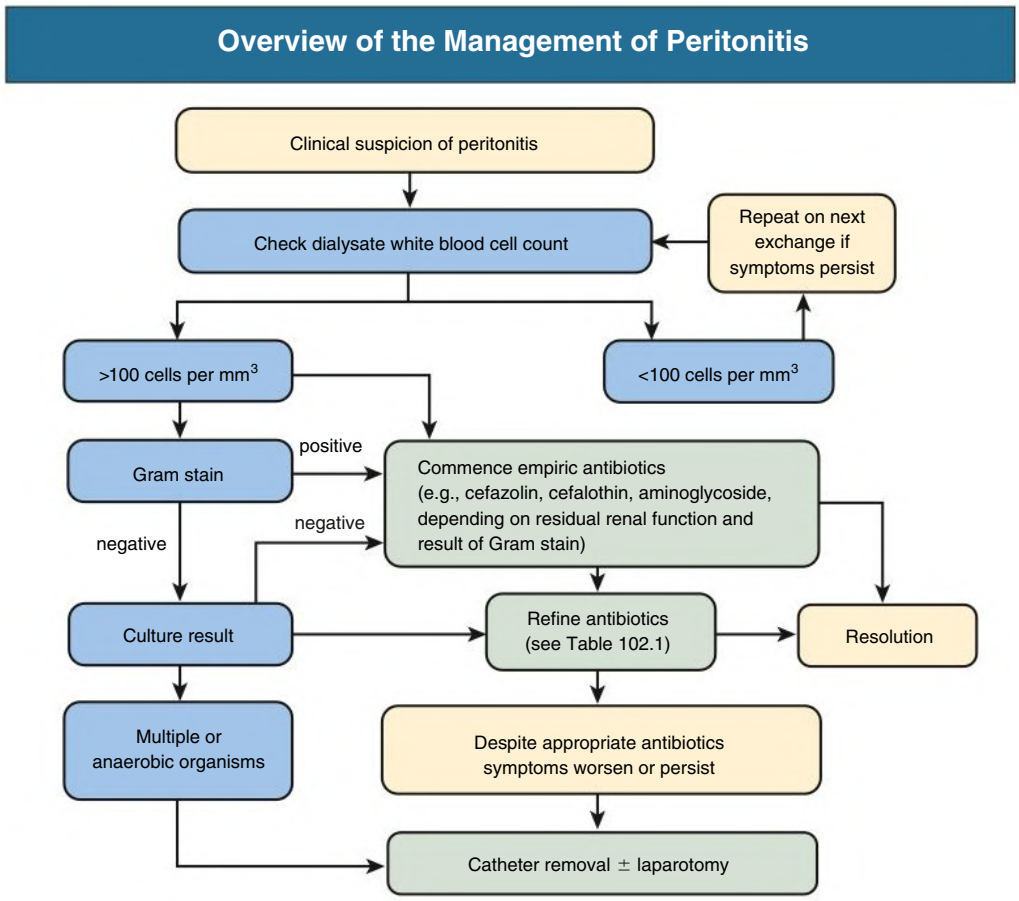

Fig. 102.4 Management of peritonitis.

Many patients can be treated successfully as outpatients. It is extremely important, however, that they be followed either in the clinic or by telephone. In most patients, clinical resolution (as judged by the clearing of the bags) starts within 48 hours. If there is no improvement within 96 hours despite use of the correct antibiotic, as judged by sensitivity tests, the fluid must be retested by cell count, Gram stain, and culture. The ISPD recommends that the catheter be removed if there is no improvement in 5 days; however, in a severe infection this should be done earlier, and in a more indolent case, the period of observation can be longer. A specific recommendation is that the catheter should be removed where a *Pseudomonas* or *S. aureus* peritonitis occurs in conjunction with an exit site or tunnel infection.[10] In addition, the possibility of intraabdominal or gynecologic disease or the presence of unusual organisms such as mycobacteria should be considered. Under these circumstances, a minilaparotomy should be performed to exclude intraabdominal disease, and if mycobacterial infection is suspected, a peritoneal biopsy specimen should be obtained for culture.

Fungal Peritonitis

If peritonitis is caused by yeasts or fungi, the peritoneal catheter should be removed promptly. This should be combined with treatment with an appropriate antifungal for at least 2 weeks after catheter removal. Fungal peritonitis is a serious complication of PD, commonly requiring hospitalization and transfer to hemodialysis (HD), with a high associated mortality. It is essential to review the appropriate antifungal agent with the local microbiologic team; options are described in some detail in the 2016 peritonitis update from the ISPD.[10] Amphotericin B should not be given intraperitoneally because it causes chemical peritonitis and pain. Appropriate antifungal therapy should be continued for at least 2 weeks after catheter removal.

Relapsing Peritonitis

Relapsing peritonitis is defined as infection caused by the same organism as the original infection occurring within 4 weeks, whereas *recurrent peritonitis* is defined as a different organism within 4 weeks of completion of an appropriate course of antibiotics. In general, the advice is to treat as for a primary infection but to try to establish an underlying cause. For example, recurrence of *S. aureus* infection should trigger a search for pericatheter infection. If enterococci or gram-negative organisms are the cause of a relapse, the possibility of intraabdominal disease or an abscess should be considered (although these organisms are frequently waterborne). If a patient has other gastrointestinal symptoms, such as change in bowel habit, appropriate investigation should be conducted. Some organisms (including coagulase-negative staphylococci) produce biofilm that can lead to a relapse of the infection. Consideration should be given to changing the PD catheter once the infection has been treated; of course, the catheter will need to be removed if the infection does not respond to treatment. Current practice in most units is to allow up to 3 weeks of treatment before a new catheter is inserted and to bridge with hemodialysis if required.

Culture-Negative Peritonitis

Culture-negative peritonitis is associated with increased risk for treatment failure. Commonly, the cause relates to the sampling technique or the microbiologic approach; alternatively, concurrent antibiotic use may be responsible. It is important to be aware of the possibility of

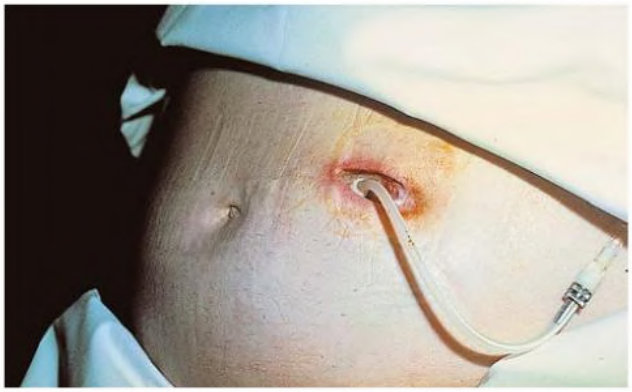

Fig. 102.5 Exit Site Infection. Severe exit site infection that has exposed the outer cuff of the catheter.

fastidious organisms (e.g., atypical mycobacteria, suspicious of contaminated water sources, or yeasts). In addition, other causes of peritoneal inflammation may be responsible; these include the presence of an intraabdominal malignancy or surgical pathology or eosinophilic reactions (e.g., in the case of vancomycin allergy or some fungal infections). An eosinophilic or allergic peritonitis can be diagnosed from the nature of the effluent cell type and requires specific action such as avoiding the causative agent if identifiable, although this usually resolves with time. Chylous effluent is a rare finding in PD; the cause is often unclear, but if recurrent, conditions affecting lymphatic drainage should be considered.

Exit Site Infection

Exit site infection (ESI) is an important complication of long-term PD. The diagnosis is suspected on clinical grounds, usually by the presence of marked erythema or discharge from the exit site (Fig. 102.5). A scoring system for exit sites has been developed to determine the likelihood of infection and grade its severity, with points assigned for crusting, swelling, pain, and discharge according to severity; if the discharge is purulent, this mandates treatment.[14] Extension of the infection into the tunnel may be assessed either clinically or by ultrasound. The most common infecting organism is *S. aureus.* There is now substantial evidence for the use of prophylactic topical antibiotics at the exit site, the strongest being for mupirocin for the prevention of ESI caused by *S. aureus,*[12,14] which we recommend in our practice. There is also evidence for the use of topical gentamicin, although there were some reports of an increase in ESI caused by Enterobacteriaceae, *Pseudomonas* spp., and probably nontuberculous mycobacteria after a change of prophylactic protocol from topical mupirocin to gentamicin.[10]

All suspected infected exit sites should be swabbed; routine swabbing of healthy exit sites should be avoided, and incidental bacterial growth does not require treatment. Unless there is prior evidence that the patient carries MRSA or *Pseudomonas,* initial treatment should be with an antibiotic effective against *S. aureus*—such as a penicillinase-resistant penicillin (e.g., cloxacillin, dicloxacillin, or flucloxacillin; it is important to be aware of the risk for associated hepatotoxicity with the latter) or a first-generation cephalosporin if the patient is allergic to penicillin. In most patients, the drug can be given orally, but if the individual is systemically ill, the antibiotics should be administered intravenously until clinical improvement occurs. Hospitalization, parenteral antibiotics, and often urgent catheter removal are required if there is evidence of spread into the tunnel. If the infection is with MRSA, eradication should be attempted with systemic vancomycin, as for peritonitis. Should the culture grow a gram-negative organism, ciprofloxacin (500–750 mg once daily orally) will be effective empiric treatment in most patients. ESIs caused by *Pseudomonas* spp. are particularly difficult to treat and often require prolonged therapy with two antibiotics.

Treatment is recommended for a minimum of 2 weeks, extended to 3 weeks in *Pseudomonas* infections. In gram-positive infections, if there is no improvement within 7 days, ultrasound of the catheter tunnel should be performed because a collection of fluid around the catheter signifies a tunnel infection. If complete healing does not take place after 4 weeks of therapy, further measures should be considered, such as exteriorizing and shaving the outer cuff, because it may be involved in the infection. If the infection persists or relapses, catheter removal must be considered because there is a high risk that the ESI will lead to peritonitis. It is important that the new exit site be formed in a different part of the anterior abdominal wall.

MEMBRANE DYSFUNCTION AND INSUFFICIENT ULTRAFILTRATION

Recognition and Significance of Membrane Dysfunction

There are two complementary approaches to recognizing membrane dysfunction as the cause of insufficient ultrafiltration (UF). The first is based solely on the net fluid removal (termed *ultrafiltration capacity*) from a standard 4-hour peritoneal equilibration test (PET). The conduct and interpretation of the PET are further discussed in Chapter 101. Account should be taken of the overfill of dialysis bags by the manufacturers, which can be as much as 200 mL. A net UF capacity below 400 mL with a hypertonic exchange (3.86% glucose/4.25% dextrose) is indicative of an inadequate membrane,[15] bearing in mind that this may not be clinically relevant in a patient with well-preserved residual kidney function. If a middle-strength glucose solution is used (2.27%), the equivalent value is 100 mL (again excluding overfill). The main limitation of this approach is that it relies on a single measurement of UF capacity, which is subject to significant error (coefficient of variation is up to 25%) and does not identify the cause. The second approach to recognizing UF failure is more holistic in that it considers patient factors that affect fluid status (e.g., comorbid conditions) and an acceptable glucose exposure required to maintain adequate hydration. Many clinicians now take the view that regular use of hypertonic solutions is not acceptable unless the life expectancy is shorter than the likely time to development of severe injury and its complications, unusual before 5 years.

Insufficient UF is a significant cause of technique failure[16]; it results in low UF, which in turn increases the risk for mortality in anuric patients[17,18] and is also a risk factor for encapsulating peritoneal sclerosis (EPS).[19] Although it is impossible to set a fluid removal goal that applies to all patients, the European Automated Peritoneal Dialysis Outcomes Study (EAPOS) found that anuric patients who did not reach an UF target of more than 750 mL/day had less efficient membranes (specifically lower osmotic conductance; see later) and higher mortality.[18] Patients whose total fluid removal is less than 1 L/day because of poor UF should have their membrane function assessed.

Establishing the Causes of Membrane Dysfunction

Failure of the membrane to ultrafiltrate sufficiently needs to be distinguished from other causes of inadequate peritoneal fluid removal, such as catheter dysfunction, leak, or excessive fluid reabsorption.[14] The latter can occur if the intraperitoneal cavity pressure is too high, suspected if the UF falls after an increase in dialysate volume. If there is doubt, a fall in the dialysate sodium concentration by more than 5 mmol/L at 1 hour into a PET using 3.86% glucose is an indicator of preserved sodium sieving (see later), suggesting that UF is preserved.

There are two main causes of UF failure: a *fast peritoneal solute transfer rate* (PSTR) or a low intrinsic membrane UF efficiency, despite

a preserved osmotic gradient, termed *reduced osmotic conductance.* Both can exist at the start of PD or can be acquired with time on therapy, although it is rare for a patient to develop reduced osmotic conductance without also developing a fast PSTR.

Fast PSTR–Related Membrane Dysfunction: Diagnosis and Management

With the 4-hour PET, a dialysate–plasma creatinine ratio greater than average (typically 0.64) could contribute to poor UF. This is because more rapid diffusion of small solute across the membrane leads to earlier dissipation of the osmotic gradient driving UF. Furthermore, once the gradient is lost, membranes with a larger diffusive area will reabsorb fluid more rapidly. A higher than average PSTR is associated with increased mortality, technique failure, and hospitalization,[20,21] whereas this association is ameliorated when APD is used.[20,22] Thus, both theoretically and empirically, the short exchanges used in APD prescription are associated with better outcomes in fast PSTR–associated insufficient UF. Prevention of fluid reabsorption during the long day or night exchange is also required in these patients, and this can be achieved by use of icodextrin (polyglucose solution), which also improves the fluid status[23] and ultrafiltration, reduces episodes of fluid overload and possibly survival.[24,25] The main determinant of fast PSTR is increased intraperitoneal inflammation, which is independent of systemic inflammation.[26] Only the latter is an independent predictor of mortality.

Low Osmotic Conductance–Related Membrane Dysfunction: Diagnosis and Management

This problem should be suspected if UF insufficiency is suspected or there is reduced UF capacity as described earlier. Osmotic conductance is a measure of the efficiency of the peritoneal membrane to ultrafiltrate for a given osmotic agent, typically glucose. Reduced osmotic conductance can be demonstrated quite easily in the clinic. Sodium sieving is the consequence of free water entering the peritoneal cavity via the transcellular endothelial aquaporin pathway, resulting in a drop resulting from dilution in the dialysate sodium concentration; it is independent of the sodium-coupled UF that occurs across endothelial tight junctions. Thus, the absence of a fall in the dialysate sodium concentration 1 hour after using a high glucose exchange indicates the lack of sodium sieving, which implies reduced free water UF. A sodium dip of less than 5 mmol/L is indicative of this type of membrane dysfunction and is associated with worse outcome on PD, including the risk of EPS.[15] The two causes so far identified are reduced aquaporin function, possibly constitutive and thus present at the start of treatment, and progressive fibrosis of the membrane as a result of acquired membrane injury. There is no specific treatment, so clinical effort should focus on prevention (see next section) and timely switch to HD or transplantation.

CHANGES IN PERITONEAL STRUCTURE AND FUNCTION

It is widely assumed that acquired changes in membrane function, a combination of a fast PSTR, and loss of osmotic conductance are related to structural changes in the peritoneal membrane.[27] There is accumulating evidence that continuous exposure to dialysis solution components and repeated episodes of bacterial peritonitis are the main drivers of this process (Fig. 102.6). The relationship between structure and function is becoming clearer: increased PSTR is likely to reflect a greater vascular surface area, whereas loss of osmotic conductance requires an additional mechanism that is associated with progressive membrane fibrosis and an increased risk for EPS. The submesothelial collagenous zone shows progressive increase in thickness with time on PD (Figs. 102.7 and 102.8), and this is associated with progressive changes to the structure of small venules ranging from subtle thickening of the subendothelial matrix to complete obliteration of vessels (Fig. 102.9).[28,29] This process is accompanied by a reduction in sodium sieving, implying reduced free water transport, but no change in aquaporin expression, suggesting that the fibrosis is the main cause of UF failure.[30]

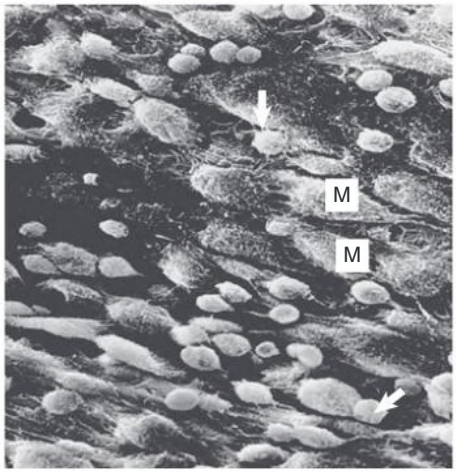

Fig. 102.6 Peritonitis. Scanning electron micrograph of the peritoneum from a patient receiving peritoneal dialysis who has peritonitis. The small round cells *(arrows)* are phagocytes, which are widely distributed among the mesothelial cells *(M).* (Magnification, ×1800.)

Preventing Membrane Injury

The main clinical factors associated with more rapid and severe membrane injury are early loss of residual kidney function, recurrent or severe peritonitis, and the earlier use of higher glucose–containing solutions (often associated with loss of diuresis but an independent risk factor).[31] Hypertonic solutions may induce injury because of direct glucose toxicity; glucose degradation products (GDPs) manifest as a result of the sterilization process; or both. The prevention of membrane injury should focus on all of these drivers and include (1) preservation of residual kidney function by avoiding both volume depletion and the use of angiotensin-converting enzyme inhibitors and angiotensin receptor blockers; (2) use of loop diuretics to maintain urine volume and delay use of hypertonic exchanges; (3) use of icodextrin in the long exchange; (4) avoidance of peritonitis; and (5) use of low-GDP neutral pH solutions.[32] The balANZ study shows that the increase in PSTR over the first 2 years of PD is prevented by use of ultralow-GDP dialysis fluid. More importantly, this study showed that achievement of less UF, lower use of hypertonic glucose, and in particular low-GDP solutions early in the course of PD, now confirmed in meta-analyses of several trials is associated with preservation of residual kidney function.[24,33] This, combined with trial evidence that fluid status is stable in patients with residual kidney function,[34] supports the main strategy clinicians should adopt in preserving the membrane: prescribing to maintain adequate but not excessive UF, which will only drive thirst and increase the risk for volume depletion.

Encapsulating Peritoneal Sclerosis

A minority of patients on PD develop EPS, in which the bowel is enveloped in a thick cocoon of fibrous tissue, causing intestinal obstruction (Fig. 102.10).[19] It is variable in severity but may be life-threatening, causing death from malnutrition or intraabdominal catastrophe; but with experienced management by a multidisciplinary team, overall

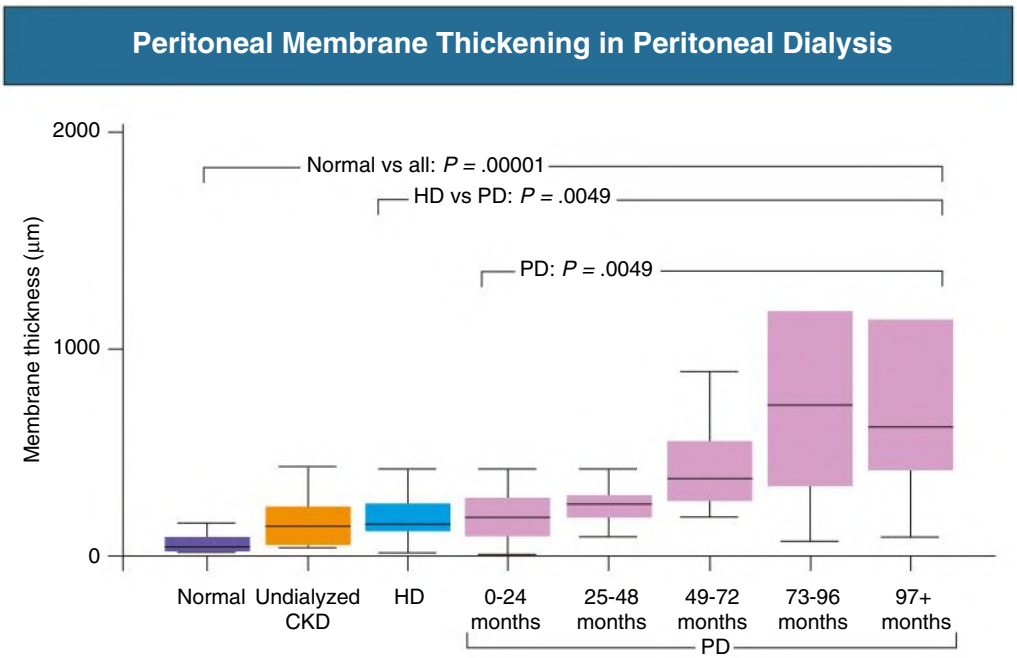

Fig. 102.7 Peritoneal Membrane Thickening in Peritoneal Dialysis (PD). The thickness of the submesothelial collagenous zone of the peritoneal membrane in normal individuals, in undialyzed patients with advanced chronic kidney disease (CKD), patients with uremia, in patients receiving hemodialysis (HD), and in those who have received PD for different periods. Membrane thickness is significantly increased in all uremic and dialysis patients compared with normal individuals. Membrane thickness increases significantly with duration of PD and is increased in PD patients as a group compared with HD patients.

survival compares well with that of matched controls. Diagnosis of this syndrome requires both clinical signs and symptoms of bowel obstruction leading to weight loss and malnutrition (with or without features of systemic inflammation) combined with either typical features on imaging (CT scanning) or confirmation of fibrous cocooning at laparotomy. Although UF failure is a risk factor for EPS (especially when there is also loss of osmotic conductance), EPS appears to be a different pathologic process that predominantly affects the visceral membrane, is usually associated with another trigger (e.g., severe peritonitis or interruption of PD), and frequently has a systemic inflammatory phase (biopsy material more often shows inflammation and fibrinous exudates).

The single most important risk factor for EPS is time on PD; at 5 years the incidence is 2% to 3%, whereas by 10 years, this rises to 6% to 20%.[19] Recent reports from Japan[35] and the Netherlands suggest that the incidence of EPS is decreasing, possibly because of a better understanding of the management of risk factors. There is increasing evidence that surgical treatment (extensive adhesion lysis and excision of the peritoneum while avoiding enterotomy) is most effective, especially when there are obstructive symptoms. This should be undertaken by an experienced surgical team, which can achieve cure rates of 70% to 80%. Parenteral nutrition can be used as a preparation for surgery and occasionally as a long-term solution. In about 50% of patients, symptoms are less severe and gradually resolve. There is no

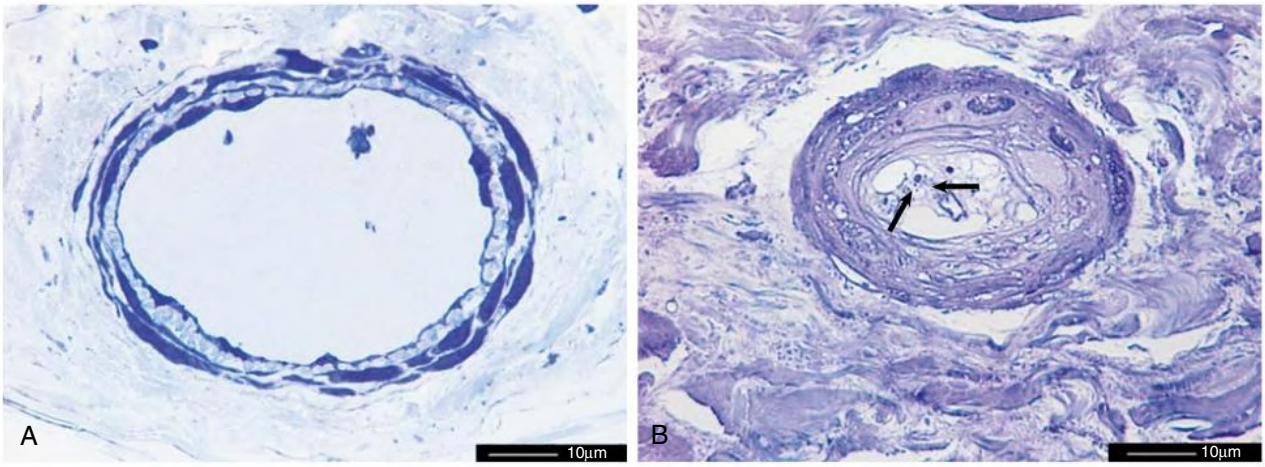

Fig. 102.9 Blood Vessels in the Parietal Peritoneum: Transverse Sections of Peritoneal Arterioles. (A) Normal. (B) Vasculopathy in a patient on peritoneal dialysis; the vascular lumen *(arrows)* is occluded by connective tissue containing fine calcific stippling *(arrows)*.

role for screening with CT scanning, but this is helpful in diagnosis. Most commonly, EPS develops after transfer from PD to either HD or transplantation; but if it develops in a patient on PD, the consensus is that PD should be stopped to avoid continued exposure to nonphysiologic dialysis solutions. Other strategies, such as continued irrigation, dual-modality treatment with PD and HD, and use of antifibrotic drugs such as tamoxifen, are practiced, but an evidence base for such management is lacking.

NUTRITIONAL AND METABOLIC COMPLICATIONS

Undernutrition

Cross-sectional surveys of patients receiving PD show that about 40% have evidence of mild and 8% severe protein-calorie depletion as judged by the subjective global assessment of nutritional state. Malnutrition is a risk factor for morbidity and mortality of patients on PD and often associated with systemic inflammation. The assessment and management of malnutrition are discussed further in Chapter 90. One obvious contributing factor is protein loss through the peritoneum, which averages 8 g/day. Protein loss is proportional to effective membrane area and so is most marked during peritonitis and in patients with fast peritoneal transport. The ensuing hypoalbuminemia exacerbates the extravascular extracellular fluid expansion in these patients.[36] Therefore, it has been recommended that PD patients should consume daily at least 1.2 to 1.3 g of protein per kilogram of body weight. In practice, many patients take only about 0.8 g/kg/day, and nitrogen balance is maintained partly as a result of calories from dialysate. However, especially once patients are anuric, there is a progressive loss in lean body mass.[34] Despite concerns about the increased prevalence of hypoalbuminemia among peritoneal dialysis patients, the association with mortality is not worse than for HD patients.[37]

PD patients have abnormal eating behavior with smaller meals, slow eating, and impaired gastric emptying, which causes nausea, especially in patients with diabetes. This is worst when using more hypertonic glucose and least severe with icodextrin. Amino acid–based dialysate improves nitrogen balance in malnourished patients, but the long-term nutritional benefit is marginal.[38]

Acid-Base Status

Correction of acidosis is best achieved by use of dialysate with higher levels of potential buffer,[39] but if necessary, oral bicarbonate may be added. There is evidence that correction of acidosis, by whatever means, to within the upper half of the normal range for serum bicarbonate reduces protein catabolism, resulting in weight gain and increased midarm muscle circumference.[38] The use of amino acid–containing dialysate fluid can worsen acid-base status, requiring close monitoring.

Lipids and Obesity

PD results in significant daily glucose absorption, which may range from 80 to 200 g/day (300–800 kcal). Therefore, PD patients tend to develop features of metabolic syndrome, including central obesity, hyperglycemia, dyslipidemia, and hyperinsulinemia; they may even develop frank diabetes, although there is no evidence that this or worsening obesity is more common than in HD patients.[40] These problems can be reduced by use of icodextrin and amino acid solutions in place of glucose with better glycemic control in diabetics.[41] Blood glucose monitoring in diabetic patients using icodextrin must

not use glucose dehydrogenase pyrroloquinoline quinone test strips because this will lead to falsely high estimates and risk for severe hypoglycemia.

Despite these concerns, there is no evidence to suggest that PD should be avoided in obese patients even though the survival advantage seen in HD associated with a higher body mass index is not seen with PD.[42]

SELF-ASSESSMENT QUESTIONS

1. Regarding catheter function, which of the following statements are *false?*
   - **A.** Introducing the routine use of laparoscopic technique for catheter insertion will improve early catheter survival more than carefully audited standard methods used by an experienced surgeon.
   - **B.** Slow catheter drainage is most commonly a result of constipation.
   - **C.** Pain on draining in ("inflow pain") is best solved by use of tidal PD.
   - **D.** Pain on draining out is best solved in APD patients by use of tidal PD.
   - **E.** Poor drainage associated with edema in the genital area indicates an inguinal hernia or patent processus vaginalis.
2. Regarding peritonitis and infection, which of the following statements are *false?*
   - **A.** Treatment of suspected peritonitis should always commence with antibiotics covering both gram-positive and gram-negative organisms and antifungal prophylaxis.
   - **B.** Fungal peritonitis usually can be successfully treated with intraperitoneal agents without requiring catheter removal.
   - **C.** Redness and pain at the exit site always should be treated immediately with oral antibiotics.
   - **D.** Prophylactic use of mupirocin or gentamicin at the exit site has been shown to reduce the chances of peritonitis.
   - **E.** Culture of more than one organism in a patient with peritonitis should raise serious concerns of a perforated viscus and lead to minilaparotomy and catheter removal.
3. Regarding ultrafiltration insufficiency, which of the following statements are *false?*
   - **A.** Membrane function should be fully assessed if the ultrafiltration capacity is less than 100 mL on a 4-hour middle-strength glucose 2.27% (dextrose 2.5%) exchange.
   - **B.** There should be a minimum target of 1 L UF per day regardless of residual kidney function.
   - **C.** Fast peritoneal solute transfer rate contributes to poor UF, but this can be addressed by use of APD and icodextrin.
   - **D.** Routine computed tomography scanning to look for progressive membrane thickening and calcification is the best way to screen for EPS.
   - **E.** Progressive loss of osmotic conductance (a 1-hour sodium dip <5 mmol/L using a glucose 3.86% exchange) is thought to represent increasing fibrotic damage, may predispose to EPS, and is a reason for switching to hemodialysis.

Extracorporeal Therapies for Drug Overdose and Poisoning

Nigel Suren Kanagasundaram, Andrew Lewington, Etienne Macedo

p0010 Whether intentional or accidental, poisoning and drug overdose are common medical emergencies that account for around 160,000 presentations annually in the United Kingdom and many more consultations with primary care and National Health Service (NHS) advice services.[1] Most exposures do not require hospitalization, with around 66% of US cases in 2019 being managed in a non–health care facility, usually at the site of the incident.[2] Overall exposure-related mortality remains relatively low, with 1411 exposure-related fatalities recorded in around 2.15 million exposures in this same US report.[2] However, poisoning is a significant cause of death in young people.[3]

p0015 The spectrum of agents ingested is wide, ranging from overdose of prescribed and nonprescribed medicinal drugs to poisoning with nonpharmacologic substances and recreational drugs. The pattern of toxin ingestion has changed over the years and varies according to geographic location. Frequently implicated agents in industrialized societies include analgesics (acetaminophen, opioids, and salicylates), antidepressants, sedatives, and antipsychotics. Pesticides are a frequent cause of poisoning in low- and middle-resource countries.[3] Legislation has been used to reduce the availability of potential toxins; for instance, paraquat has not been sold in the United Kingdom since July 2008. Similarly, UK legislation limiting pack size of paracetamol (acetaminophen) in 1998 was followed by a significant reduction in the number of deaths from paracetamol overdose.[4]

p0020 Effective management of poisoning depends on hemodynamic, respiratory, and other supportive care, prevention of further poison absorption (through oral activated charcoal in specific patients), neutralization of toxicity (e.g., with intravenous *N*-acetylcysteine after significant acetaminophen overdose or digoxin immune Fab [Digibind]), and enhancement of endogenous toxin elimination (e.g., through urinary alkalinization). These aspects of management are well described by resources such as Toxbase in the United Kingdom (https://www.toxbase.org) and via the American Association of Poison Control Centers (https://www.aapcc.org). Other local and regional poison information services are linked through the website of the European Association of Poisons Centres and Clinical Toxicologists (https://www.eapcct.org).

p0025 Extracorporeal treatment (ERCT) for poison elimination includes kidney replacement therapy (KRT) and other modalities such as hemoperfusion and therapeutic plasma exchange. However, ERCT is only occasionally needed to manage poisoning and overdose; in the United States in 2019, only around 3400 patients were treated, mostly with hemodialysis (HD) or continuous KRT (CKRT).[2] Only 21 patients were recorded as receiving hemoperfusion, reflecting a long-term decline explained partly by the increasing rarity of theophylline and barbiturate overdose (historically, the main indications for this technique) but also by the increased use of high-efficiency, high-flux HD, allowing removal of toxins previously regarded as being nondialyzable.[5,6]

p0030 ERCT has long been used to manage poisoning,[5] but common practices are often not supported by high-quality evidence, at least partly because of the practical and ethical barriers to randomized controlled trials.[5] Despite these barriers the EXTRIP (Extracorporeal Treatments in Poisoning) consensus group (https://www.extrip-workgroup.org)[6] has created several useful resources for clinicians endorsed by various national and international stakeholder societies.

WHEN SHOULD EXTRACORPOREAL REMOVAL BE CONSIDERED?

s0010

p0035 ERCT is most commonly used for lithium, toxic alcohol, and salicylate ingestions[7]; other potential indications are shown in Table 103.1. Extracorporeal elimination should be considered when it is evident that other treatments (e.g., activated charcoal, specific antidotes) will not reduce poison levels below toxic thresholds. It is therefore important to understand the general principles underpinning the use of ERCT to make decisions about management of poisonings, particularly for those for which no consensus or evidence base exists.

p0040 Extracorporeal removal is appropriate for only a small proportion of poisonings. The potential advantages of therapy must be balanced with the risks that are generic to all forms of ERCT (e.g., acute transfer to a specialist center, vascular access, anticoagulation[8,9]) and those specific to its use in poisoning (discussed later under individual treatment modalities). Factors that help determine the potential value of extracorporeal removal are summarized in Box 103.1. It should be noted that effective clearance by ERCT does not necessarily prevent ongoing end organ toxicity[5] or death, as may occur in cases of paraquat poisoning.[10]

Molecular Weight

s0015

p0045 Most ingested poisons have a molecular weight (MW) in the 100 to 1000 Da range and so are amenable to removal by HD,[11] which is the modality of choice for clearance of small solutes. Higher flux membranes extend the range of dialyzable solutes up to approximately 10,000 Da, particularly if performed for long hours, and allow removal of toxins such as theophylline and carbamazepine, for which hemoperfusion might historically have been indicated.[11] Molecules toward the upper end of this range and up to about 40 kDa are more effectively removed using modalities with a significant convective component such as hemofiltration (HF) or hemodiafiltration (HDF). Even larger solutes may be removed by non-KRT, such as plasma exchange or one of the albumin dialysis techniques used for liver support.

Protein Binding

s0020

p0050 Diffusive and convective modalities (HD, HF, HDF; either intermittent or continuous) are generally unsuitable for removing poisons with protein binding greater than 80%.[11] However, certain toxins (e.g.,

t0010

TABLE 103.1 Poisonings for Which Extracorporeal Removal May Be Indicated[a]

Agent	Preferred Modality	Other, Acceptable Modalities
Acetaminophen	IHD	IHP, CKRT, Ex
Long-acting barbiturates	IHD	HP, CKRT
Carbamazepine	IHD	IHP, CKRT
Ethylene glycol	IHD	CKRT
Lithium	IHD	CKRT[a]

BOX 103.1 Factors Affecting Toxin Removal by Extracorporeal Therapy

b0010

- Molecular weight
- Protein binding
- Volume of distribution
- Solute compartmentalization
- Contribution of extracorporeal toxin removal relative to endogenous clearance

salicylate, valproate) are highly protein bound under normal circumstances but saturate protein-binding sites during poisoning, leading to high (and therefore dialyzable) serum concentrations of free agent.[5] In addition, easy dissociation of protein-toxin complexes may allow significant diffusive removal, as with phenytoin.[5] Agents with very high (>90%) protein binding and that are not amenable to diffusive or convective elimination may be removed by plasma exchange (e.g., L-thyroxine and cisplatin).[11]

p0055 The interplay between MW and protein binding and their impact on modality choice are shown in Fig. 103.1.

s0025

Volume of Distribution

p0060 The efficacy of toxin removal is also influenced by the theoretical volume of distribution (V_D). Substances confined to the bloodstream will have a low V_D (~0.07 L/kg body weight); those distributed in the extracellular space, a V_D of approximately 0.2 L/kg; and those confined to total body water, approximately 0.6 L/kg. Higher distribution volumes are often found in substances with avid tissue binding, lipophilicity, or sequestration. As V_D increases, more solute must be removed for achievement of a particular blood level. The ideal solute for extracorporeal removal would therefore have a low distribution volume and would be located within a single, well-mixed compartment that is directly accessible by ERCT. There are exceptions: carbamazepine, metformin, and thallium all have high distribution volumes but are amenable to extracorporeal removal.[11]

s0030

Solute Compartmentalization

p0065 Solutes are often distributed across one or more body compartments that may not be directly accessible by ERCT (Fig. 103.2). If there is any resistance to solute movement between the accessible proximal and the remote compartments, disequilibrium will develop during ERCT, reducing the overall efficiency of toxin removal, and potentially leading to a large postsession rebound in toxin blood levels. Potentially toxic posttreatment levels may be missed if the immediate postdialysis blood level is used to estimate elimination (Fig. 103.3). After ERCT for lithium poisoning, for example, it is recommended that levels be rechecked after 6 to 12 hours to detect clinically significant rebound.[12] Vigilance for rapidly rising levels is also important if ongoing toxin absorption is suspected and may require earlier and more frequent monitoring.

p0070 High clearance techniques (i.e., intermittent HD or HDF) rapidly reduce blood solute levels but are more likely to result in intercompartmental disequilibrium. Extending sessions beyond 4 hours can ameliorate rebound, but intermittent HD and the diffusive component of intermittent HDF are inherently inefficient processes that depend on the solute concentration presented to the dialyzer. Most solute removal will therefore occur at the start of dialysis, so any gains in solute removal will be disproportionately lower as dialysis time extends. Increasing treatment frequency can mitigate the risk for significant rebound to toxic blood levels.

p0075 Compartmentalization need not preclude HD-/HDF-mediated toxin removal, but the total body burden of highly compartmentalized toxins (e.g., digoxin; tricyclic antidepressants [TCAs]) cannot be effectively reduced by HD even though blood levels are rapidly reduced. Therefore, ERCT is not recommended in digoxin or TCA poisonings[6] despite occasional reports of successful clearance of TCAs with dialysis.[5]

s0035

Contribution of Extracorporeal Toxin Relative to Endogenous Clearance

p0080 Even toxins that may be readily cleared by ERCT may not require such treatment if endogenous clearance rates are high. It is proposed that ERCT is justified if it increases total body clearance by at least 30%[13] or if endogenous clearance is less than 4 mL/min/kg body weight.[14] Unfortunately, these thresholds can be difficult to estimate at the bedside, although an indication of endogenous clearance rates is available for some drugs (see https://www.medicines.org.uk/emc/), and estimates of dialyzer clearances can be obtained from product inserts. For HF, an estimate of clearance can be provided by the ultrafiltration rate. Maximal clearances for ERCT are approximately 240 mL/min (for intermittent HD/HF/hemoperfusion), 50 mL/min (for CKRTs and plasma exchange), and 10 mL/min (for exchange transfusion).[11]

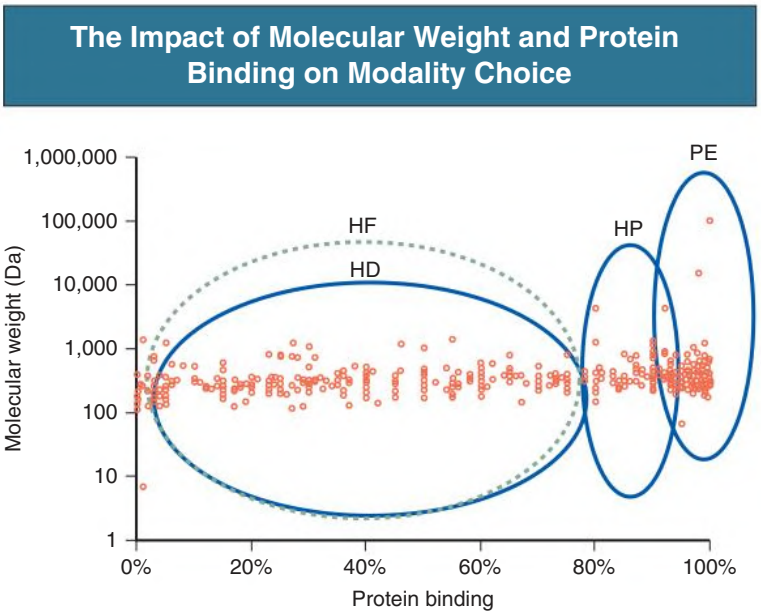
p0085 However, endogenous elimination in the setting of poisoning may be markedly lower than in health. High endogenous clearances of approximately 2000 mL/min (e.g., for cocaine, labetalol, toluene, and verapamil)[11] would appear to obviate the need for ERCT. However, if these elimination routes are limited by end organ dysfunction (e.g., by kidney or liver failure), ERCT may be life-saving.

p0090 These considerations are summarized in Fig. 103.4.

s0040

TREATMENT MODALITIES

p0095 The range of ERCT used for toxin elimination with parameters that might be manipulated to enhance toxin clearances is shown



f0010

Fig. 103.1 Impact of Molecular Weight and Protein Binding on Modality Choice. *Circles* indicate for which poisons a specific modality might be most useful. The decline in use of hemoperfusion in many parts of the world means that it may be unavailable as a treatment option. In these circumstances, plasma exchange, which is widely available, may be used. *HD,* Hemodialysis; *HF,* hemofiltration; *HP,* hemoperfusion; *PE,* plasma exchange. in Box 103.2. Generic considerations, including the basics of physical process, nomenclature, and vascular access (and its care) are detailed elsewhere.[8,9]

s0045

Intermittent Hemodialysis, Hemofiltration, and Hemodiafiltration

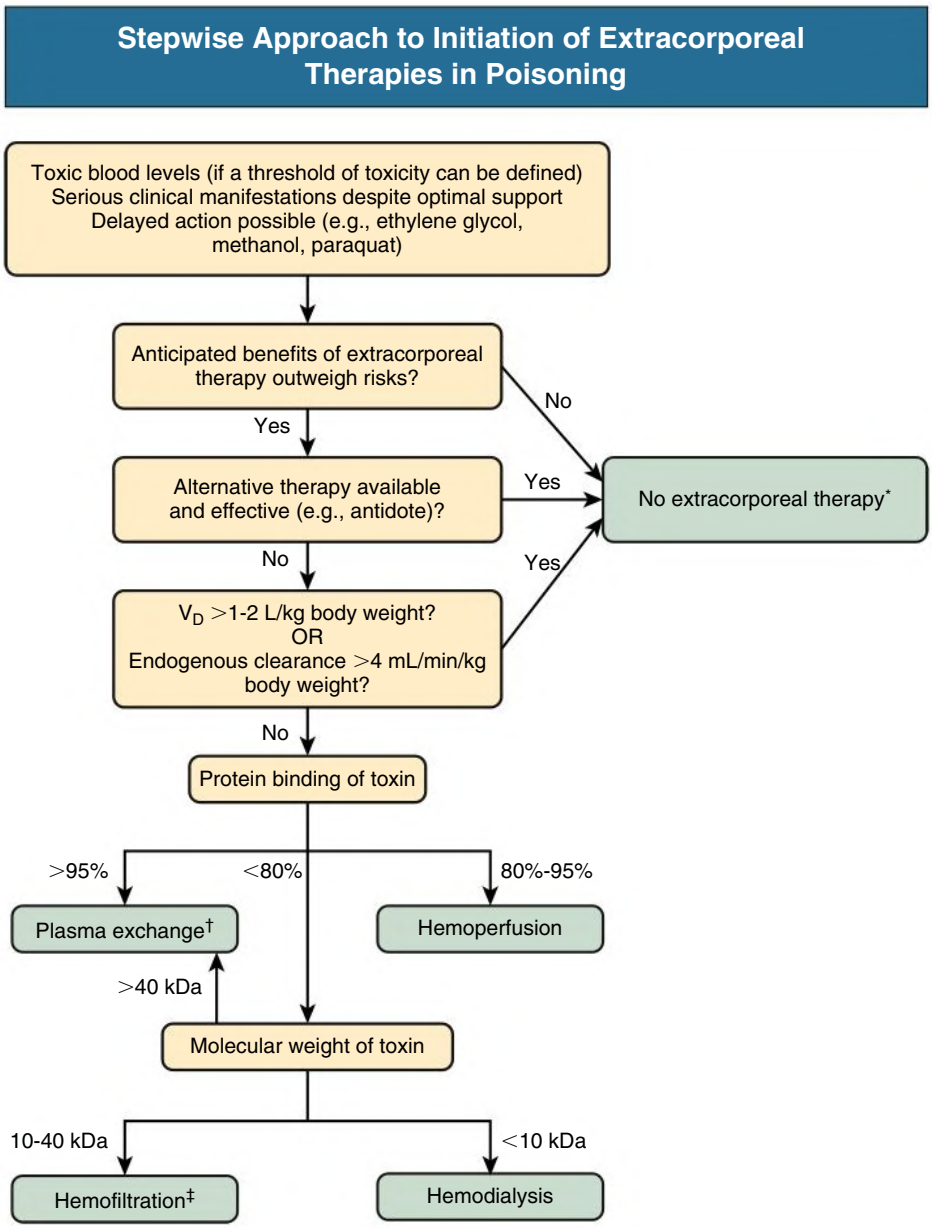
p0100 Diffusion against a steep concentration gradient (as in intermittent HD) encourages the rapid removal of smaller solutes, including most poisons, unless there is significant protein binding. Clearances can be enhanced by increasing dialyzer efficiency (indicated by the KoA, the urea mass transfer area coefficient) or membrane surface area. Larger solute removal can be enhanced by increasing dialyzer flux (Kuf) when intermittent HD is used (for toxins with MW between 500 Da and 10,000 Da, such as deferoxamine and aminoglycosides) or by introducing convective removal (with HF or HDF), which can allow removal of toxins up to approximately 40,000 Da.

p0105 Intermittent HD is usually the first-choice extracorporeal modality because of its common availability, the rapidity of toxin removal, and the low MW of common poisons. The role of other kidney replacement modalities is less clear because of a lack of published data.

Peritoneal Dialysis

s0050

p0110 Peritoneal dialysis (PD) is not an "extracorporeal" technique per se and is rarely used to treat poisoning because of the comparatively slow rate of clearance, the risks associated with acute PD catheter insertion, and the widespread availability of other modalities, at least in the



f0025

Fig. 103.4 Stepwise Approach to the Initiation of ERCT for Enhanced Elimination in Poisoned Patients. *Unless other indication (e.g., acute kidney injury [AKI], such as from acetaminophen overdose; severe metabolic acidosis; severe liver failure; hypothermia; hyperthermia). Choice of technique will depend on the indication (e.g., one of the kidney replacement therapies for AKI). †Or albumin dialysis if available. ‡Or hemodialysis with high cut-off membrane, if available (pore size cut-off ~65 kDa). V_D, Solute volume of distribution. (Modified from Ghannoum M, Roberts DM, Hoffman RS, et al. A stepwise approach for the management of poisoning with extracorporeal treatments. *Semin Dial.* 2014;27[4]:362–370.)

industrialized world. It may have a role in the treatment of poisoning in childhood because its lower clearance may be sufficient for the smaller solute distribution volumes in children and because of technical challenges associated with HD in very young children.

s0055 ## Continuous Kidney Replacement Therapy

p0115 CKRT may be used when intermittent HD is not immediately available or when more rapid solute removal would be compromised by significant intercompartmental disequilibrium. For small-solute clearances, continuous HF and continuous HD have near kinetic equivalence. Full saturation of dialysate effluent in continuous HD, because of its slow flow rates, gives a small-solute concentration similar to both the ultrafiltrate from HF and plasma water as it leaves the hollow-fiber device. CKRT gives better solute clearances when applied over the course of several days, but elimination is not as rapid as with intermittent HD. Delivered small-solute clearances of CKRT can be maximized by combining diffusion and convection in continuous HDF. If it is logistically possible, an ideal combination may be initial use of intermittent HD for rapid reduction of toxin levels, with continuous therapy then used to ameliorate any postdialysis rebound when this is anticipated.

p0120 Although small-solute clearances are similar in continuous HF and continuous HD, the former should be used in preference to remove larger toxins.

p0125 Because HF and HD modalities are often applied for drug elimination in the absence of kidney dysfunction or serious electrolyte disturbance, careful monitoring for evolving biochemical abnormalities is required.

BOX 103.2 Practical Considerations in Prescribing Extracorporeal Therapy for Poisonings

b0015

Intermittent Hemodialysis

- Maximize Qb and dialyzer membrane surface area
- Aim for Qb/Qd ratio of 2.5:1 or greater (although diminishing benefits gained from increasing Qd beyond ~600 mL/min)[33]
- Maximize treatment times to at least 4 hours
- Use high-flux (Kuf), high-efficiency (KoA) dialyzer, particularly if middle molecular weight solutes (>1000 Da) are to be cleared

Intermittent Hemofiltration/Filtrative Component of Intermittent Hemodiafiltration

- Aim for postdilution fluid replacement to maximize efficiency with high-flux membrane
- Maximize Quf according to filtration fraction

Continuous Kidney Replacement Therapies[a]

- Aim for high convective clearances (i.e., postdilutional CVVH with high-flux membrane) for larger solutes (>1000 Da)
- Aim for high diffusive clearances (i.e., CVVHD) for small solutes (≤1000 Da)
- For CVVH, maximize Quf according to filtration fraction[b]
- For CVVHD, CVVHDF, maximize Qd up to at least 2.5 L/h[c] for small solutes
  - For larger solutes (e.g., of an equivalent size to β_2-microglobulin; MW 11,800), there may be little gain from a Qd >1.5 L/h[34]

Hemoperfusion

- Limit Qb to ~100 to 250 mL/min (see section on hemoperfusion)
- Change cartridge every 3 to 4 hours
- Consider benefits of charcoal vs. resin cartridges depending on poison[15]

Plasma Exchange

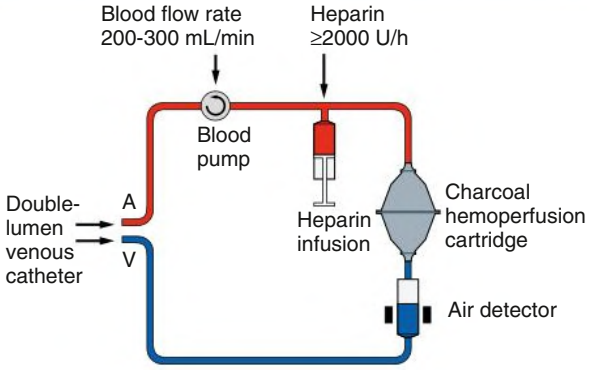
- Aim for two plasma volume exchanges per day
- Modify replacement fluid according to poison (see text for details)

[a]Aiming for conventional effluent flow rates (i.e., 25 mL/kg/h)[36] for support of the patient with acute kidney injury may fail to maximize potential poison clearances.
[b]The chief risk with postdilutional fluid replacement is hemoconcentration. This can be minimized by keeping the filtration fraction (FF) at 50% or less. The minimum Qb to achieve this can be calculated from the formula[35]: Minimum Qb = Quf/(0.5 × [1 – Hematocrit]). Alternatively, the maximum Quf would solve as: Quf = Qb × 05 × (1 – Hematocrit). In addition, transmembrane pressures should be kept <400 mm Hg to help prevent membrane fiber rupture.
[c]For small solutes at Qb 150 mL/min, there appears to be a direct linear relationship between increasing clearances and Qd to flow rates of at least 2.5 L/h.[34] It would therefore seem reasonable to maximize Qd as machine hardware, dialyzer specifications, and practicalities (fluid availability, nursing workload) allow.
CVVH, Continuous venovenous hemofiltration; *CVVHD,* continuous venovenous hemodialysis; *CVVHDF,* continuous venovenous hemodiafiltration; *MW,* molecular weight; *Qb,* extracorporeal blood flow; *Qd,* dialysate flow; *Quf,* ultrafiltration rate.
From Bouchard J, Roberts DM, Roy L, et al. Principles and operational parameters to optimize poison removal with extracorporeal treatments. *Semin Dial*. 2014;27(4):371–380.

Hypokalemia can be corrected by adjusting the dialysate or replacement fluid composition and by supplementation. Hypophosphatemia can be addressed with standard supplements. At least for intermittent HD, the risk of developing metabolic alkalosis can be attenuated in patients with normal kidney function and baseline serum bicarbonate by using a dialysate bicarbonate concentration at the lower end of the deliverable range. Because the bicarbonate concentration of premanufactured replacement or dialysate fluid in CKRT cannot be manipulated, intermittent HD against a low bicarbonate dialysate may be preferable if severe metabolic alkalosis is present.

f0030
Fig. 103.5 Charcoal hemoperfusion cartridge.

Extracorporeal Circuit for Hemoperfusion



f0035
Fig. 103.6 Extracorporeal circuit for hemoperfusion.

Hemoperfusion

s0060

The technique involves the extracorporeal circulation of blood through a hemoperfusion cartridge (Fig. 103.5) containing an adsorbent material such as activated charcoal or a resin. Hemoperfusion removes substances that bind to the adsorbent material. It is effective at removing uncharged molecules through competitive binding, especially those that are significantly plasma protein bound and lipophilic, although those toxins exceeding about 5000 to 10,000 Da are less well removed.[15] As with other modalities, the decision to start hemoperfusion should be based on its likely proportional contribution to total toxin elimination, as well as the availability of potentially safer techniques such as long-hour, high-flux dialysis (see later).

p0130

Other than the cartridge and the lack of dialysate and other replacement fluid circuits, the disposables and hardware for hemoperfusion are the same as those used for intermittent HD (Fig. 103.6). Blood flow should be limited to approximately 100 to 250 mL/min to minimize the risk of hemolysis during passage through the cartridge.[16]

p0135

Standard anticoagulation protocols may be insufficient for hemoperfusion because heparin is also adsorbed. A larger initial bolus and maintenance dose of unfractionated heparin is usually required (e.g., ≥2000 U/h), with adjustments guided by regular monitoring of clotting times during the procedure. The manufacturer's instructions should be reviewed carefully because some cartridges require priming with dextrose solution to prevent hypoglycemia. Other complications

p0140

include hypocalcemia, hypophosphatemia, charcoal embolization, leukopenia, thrombocytopenia (usually uncomplicated and self-limiting), pyrogenic reactions, and adsorption of coagulation factors.[15]

p0145 The charcoal sorbent particles may be coated with a polymer or other substance to increase biocompatibility and reduce the risk of embolization. Pretreatment of cartridges with albumin, plasma, or heparin to improve biocompatibility and reduce removal of endogenous molecules is of uncertain benefit.[15]

p0150 Saturation of the adsorbent material limits the duration of treatment with any individual hemoperfusion cartridge. It is usually recommended that cartridges are changed approximately every 3 to 4 hours, but treatments of this length are usually adequate for a significant lowering of toxin blood levels.[15]

p0155 If a toxin is equally removed by intermittent HD and hemoperfusion, intermittent HD should be used preferentially because it is less risky and also allows correction of fluid balance, electrolyte status, and other metabolic abnormalities.

p0160 Decreasing familiarity with hemoperfusion and increasing scarcity of the requisite cartridges, coupled with the ready availability of alternative treatment (long-hour, high-flux kidney support), will likely continue to reduce its application, although the modality remains a more used option in China, India, and elsewhere.[15]

s0065 Other Modalities

p0165 Hybrid modalities, such as sustained low-efficiency dialysis, have theoretical appeal for management of poisoning and overdose but require further evaluation.

p0170 There are a few reports of the use of plasma exchange and the molecular adsorbent recirculating system in poisoning. In principle, both should be useful for toxins that are strongly protein bound but not lipid soluble, are tissue bound, or have a large V_D outside the blood compartment.[17] Plasma exchange is most commonly used in *Amanita phalloides* poisoning but may also prevent limb loss in snake envenomation and reduce toxic levels of biologic therapeutic agents (e.g., monoclonal antibodies).[17] Plasma exchange can clear the red cell fragments and free hemoglobin that result from poisoning with sodium chlorate or other agents that can cause hemolysis. The replacement fluid used in plasma exchange warrants some consideration because the plasma free fraction of toxins that are highly albumin bound may rebound after treatment if insufficient albumin is administered.[17] Some toxins have a greater affinity for other plasma proteins such as α1-acid glycoprotein than for albumin (e.g., dipyridamole, quinidine, imipramine, propranolol, and chlorpromazine), arguing for the use of plasma-based rather than albumin-based replacement in these situations.[17] Plasma replacement may be preferable where there is a significant coagulopathy, such as in certain instances of snake envenomation.[17] One to two plasma volume exchanges per day is likely to be sufficient until toxic manifestations and tissue release have subsided.[17]

p0175 Exchange transfusion may be useful in neonates and small children who have been poisoned with toxins that have a low volume of distribution (e.g., theophylline, salicylates).[11]

s0070 EXTRACORPOREAL THERAPY FOR SPECIFIC DRUGS AND POISONS

s0075 Alcohols

p0180 Ethylene glycol (MW 62 Da) and methanol (MW 32 Da) can be found in antifreeze, deicing solutions, and windshield cleaning fluid. The ingestion of as little as 1 g/kg body weight of either methanol or ethylene glycol is potentially lethal. Toxicity results from the metabolism of ethylene glycol and methanol by alcohol dehydrogenase to glycolic acid and formic acid, respectively, and may result in optic nerve damage, seizures, coma, and ultimately death. Poisoning should be suspected in any patient presenting with nausea, vomiting, abdominal pain, impaired consciousness, severe metabolic acidosis, and acute kidney injury (AKI).

p0185 Early recognition of ethylene glycol or methanol poisoning may allow treatment with ethanol or fomepizole to inhibit hepatic alcohol dehydrogenase. Fomepizole has now replaced ethanol as first-line therapy because the former has more predictable pharmacokinetics than ethanol, has a safer side effect profile, shortens ICU and hospital stays, and decreases need for HD, at least in patients poisoned with ethylene glycol.[18,19]

p0190 Clinicians often have to make treatment decisions based on clinical suspicion and without serum drug levels. Fomepizole should be prescribed if there is a clear history of ethylene glycol and/or methanol ingestion, if the osmol gap is greater than 10 mOsm/kg, or the ethylene glycol/methanol blood level is greater than 20 mg/dL (3.2 mmol/L for ethylene glycol and 6.2 mmol/L for methanol). Fomepizole is administered as a loading dose of 15 mg/kg intravenously (IV). This is followed by 10 mg/kg every 12 hours for 4 doses and then 15 mg/kg every 12 hours until the pH is normal and the serum concentration of ethylene glycol and methanol is less than 20 mg/dL (or <10 mg/dL in the presence of end organ damage). Patients who have ingested methanol also should receive folinic acid 50 mg IV every 6 hours to enhance the metabolism of formic acid. Administration of thiamine 100 mg IV or pyridoxine 50 mg IV should be considered in patients with poor nutritional status after ethylene glycol ingestion.

p0195 If fomepizole is not available, ethanol can be used. It is a competitive inhibitor of antidiuretic hormone (ADH), as ADH has greater affinity for ethanol than for methanol or ethylene glycol. Ethanol 10% can be administered as a loading dose of 10 mL/kg over 60 minutes to avoid side effects, such as hypotension, respiratory depression, and excessive somnolence. A maintenance infusion should be started at 1 mL/kg/h, aiming to maintain an ethanol concentration of around 100 mg/dL, but an ethanol concentration as low as 20 mg/dL can effectively inhibit the metabolism of methanol or ethylene glycol. Ethanol should be administered until no ethylene glycol or methanol is detectable in the blood. Intravenous sodium bicarbonate should be considered to help correct any associated metabolic acidosis.

p0200 HD is considered for treatment of alcohol poisonings to expedite removal of the alcohol and its metabolites. Ethylene glycol and methanol have low MWs, limited protein binding, single-compartment kinetics, and a limited volume of distribution and thus are efficiently cleared by dialysis. Immediate HD is recommended in the presence of severe metabolic acidosis (pH 7.15) regardless of drug level, or if serum concentration is greater than 50 mg/dL (8.1 mmol/L for ethylene glycol and 15.6 mmol/L for methanol) with pH less than 7.3. If no levels are available, HD can also be indicated in the setting of coma seizures or the presence of end organ damage such as AKI or visual disturbance. Because fomepizole is removed by HD, a maintenance infusion of 1 to 1.5 mg/kg/h should be prescribed for the duration of the HD session after administration of the loading dose. Similarly, ethanol doses should be doubled during the dialysis session.

p0205 To achieve optimal clearance, the dialyzer should have a large surface area (>1.5 m^2) and the blood flow rate should be greater than 300 mL/min. Bicarbonate buffer should be used, and serum concentrations of ethylene glycol and methanol should be measured 2 hours after the treatment to take account of rebound. HD should continue until the pH has normalized and the concentration of ethylene glycol or methanol is less than 25 mg/dL (<4.0 mmol/L for ethylene glycol and <7.8 mmol/L for methanol). Based on their half-life, it is recommended to start with 8 hours for intermittent HD or 18 hours for continuous modalities if there is no knowledge of the starting concentration or

rate of removal of methanol or ethylene glycol. Regardless, acid-base status should be monitored after HD to detect recurrence of poisoning, which may prompt the reinitiation of HD. Patients who have ingested large quantities of ethylene glycol and methanol may require further HD treatment.

p0210 The EXTRIP workgroup recommends intermittent HD as the modality of choice; continuous modalities are acceptable if intermittent HD is not available, although they are not as effective at removing methanol.[20]

s0080

β-Blockers

p0215 β-Blocker overdose will manifest with bradycardia and hypotension and may also include altered mental state, seizures, bronchospasm, hypoglycemia, and cardiogenic shock. Extracorporeal removal is rarely required unless patients have not improved despite maximal medical therapy. β-Blockers have different physicochemical properties and pharmacokinetics that will affect their removal by ERCT. Specifically, ERCT is only effective for hydrophilic, minimally protein-bound drugs such as atenolol, sotalol, nadolol, and acebutolol. Propranolol, carvedilol, labetalol, timolol, and metoprolol are not or minimally removed. Recently, the EXTRIP workgroup recommended against using ERCT for patients severely poisoned with propranolol and offered no recommendation for ERCT in patients severely poisoned with atenolol or sotalol because of apparent balance of risks and benefits, except for impaired kidney function in which ERCT was suggested. Indications for ERCT in patients with impaired kidney function include refractory bradycardia and hypotension for atenolol or sotalol poisoning, and recurrent torsades de pointes for sotalol.[20] Intermittent HD is recommended in hemodynamically stable patients. CKRT may be considered in patients who are hemodynamically unstable.

s0085

Lithium

p0220 Severe lithium poisoning may manifest with arrhythmias, hypotension, confusion, coma, or seizures. Lithium is a small (MW 7 Da) monovalent cation with properties similar to those of sodium. It is administered as either lithium citrate (liquid formulation) or lithium carbonate (solid formulation) and almost completely absorbed, with peak concentrations occurring in 30 minutes to 2 hours with immediate release capsules or 4 to 5 hours with modified-release preparations.

p0225 Mild lithium toxicity can be present with levels between 1.5 and 2.5 mEq/L and moderate toxicity when greater than 2.5 mEq/L and severe toxicity when greater than 3.5 mEq/L.[21] However, clinical manifestations are both variable and dependent on the specific pattern of poisoning.[22] The delayed symptoms in patients with acute lithium poisoning are due to the slow diffusion of lithium to the brain; thus lithium concentrations are only rough correlates of the potential risk of toxicity and should be interpreted based on history, clinical findings, and kidney function.

p0230 In patient with preserved kidney function, intravenous hydration should be provided with isotonic saline at a rate depending on the patient's fluid status and cardiac function. In patients with lithium-induced nephrogenic diabetes insipidus, sodium levels need to be closely monitored during intravenous hydration to prevent hypernatremia and potentially deteriorating neurologic symptoms. Hemodialysis is recommended if the serum lithium concentration is greater than 4 mmol/L, or greater than 2.5 mmol/L in a patient with central nervous system (CNS) manifestations of toxicity, such as altered mental status and seizures.[12] The protein binding of lithium is negligible, and it is easily removed by HD. High-efficiency HD can achieve a lithium clearance of 180 mL/min—superior to that achieved by native kidney function, which is limited by significant proximal tubular reabsorption. However, impairment of kidney function is often present in lithium toxicity due to lithium's chronic nephrotoxic effects. Lithium equilibrates relatively slowly between the extracellular and intracellular compartments; thus postdialysis rebound may be significant,[21] and extended or frequent HD treatment may be needed to minimize its effect. Postdialysis lithium rebound occurs can be pronounced after high-efficiency techniques, reaching 0.5 to 1.0 mEq/L after 6 to 12 hours. Rebound from ongoing absorption can occur in poisonings from extended-release formulations or patients with decreased gastrointestinal motility and may be associated with recurrence of symptoms or clinical deterioration. Serum lithium levels should be checked at 6 hours after dialysis to guide further therapy, and, if the level remains below 1 mEq/L, a second treatment may not be necessary. CKRT may complement intermittent HD by helping mitigate the effect of the postdialysis rebound.

s0090

Metformin

p0235 Metformin (MW 166 Da) is the most commonly prescribed oral antidiabetic drug. It inhibits gluconeogenesis, facilitates cellular glucose uptake by muscle and adipose cells, and decreases insulin resistance in patients with type 2 diabetes. Metformin toxicity is associated with mortality of 30%, and its management can be challenging. A recent literature review noted that metformin poisoning was the most common toxicologic indication for ERCT.[23] Symptoms include tachypnea, nausea, abdominal pain, tachycardia, hypotension, and, in the setting of AKI, severe lactic acidosis. Metformin has negligible plasma protein binding and a volume of distribution ranging from 63 to 276 L (1–5 L/kg), but the limiting factor for its extracorporeal elimination is the relatively large volume of distribution. Metformin is excreted, unmetabolized, via transporters in the proximal tubules of the kidneys and may accumulate in acute and chronic kidney disease.[24] Metformin-associated lactic acidosis (MALA) occurs due to inhibition of hepatic gluconeogenesis from lactate and enhanced conversion of glucose to lactate in the small intestine. The mortality from MALA is high, and treatment options are limited. Medical management involves supportive measures and the intravenous administration of sodium bicarbonate. ERCT is recommended in patients who are unresponsive to medical management.[22] As metformin is almost exclusively eliminated by the kidneys, the presence of impaired kidney function will increase the likelihood of severe and more prolonged toxicity. Liver failure can impair lactate clearance, and its presence should also lower the threshold for dialysis support. Extracorporeal removal can be beneficial in metformin toxicity by not only removing the drug but also by delivering a more rapid, predictable, and safe correction of acidemia than can be achieved with bicarbonate therapy, and correction of electrolyte abnormalities and supportive therapy if kidney function is impaired. Both intermittent HD and CKRT can provide effective extracorporeal removal, but a rebound after extracorporeal removal can result in a marked resurgence of lactic acidosis after therapy is discontinued. Close monitoring of the acid-base status is recommended, and extended duration or repeat session may be needed if severe metabolic acidosis (pH ≤7.0) is persistent or serum lactate concentration is greater than 20 mmol/L.

s0095

Salicylates

p0240 Aspirin remains a commonly used analgesic and widely prescribed antiplatelet therapy; despite improvements in supportive care, poisoning by salicylates (MW 180 Da) remains an important cause of poisoning-related mortality.

p0245 Aspirin is rapidly absorbed in the stomach, with peak blood concentrations usually reached within 1 hour. At therapeutic levels, 90% of salicylate is protein bound and therefore limited to the vascular space, being metabolized in the liver to salicyluric acid, which is less

toxic and more rapidly excreted by the kidney. The clinical manifestations of salicylate overdose include fever, sweating, tinnitus, epigastric pain, nausea, vomiting, diarrhea, vertigo, and blurring of vision. Severe overdoses may progress to depression of mental state, noncardiogenic pulmonary edema, and death. Salicylate intoxication initially results in hyperventilation and respiratory alkalosis. This is followed by metabolic acidosis secondary to the accumulation of lactic acid and ketoacids. Therefore, patients may present with either respiratory alkalosis or mixed respiratory alkalosis–metabolic acidosis. Diagnosis is based on the presenting history and clinical examination and confirmed with plasma salicylate levels.

p0250 Increased salicylate tissue penetration and toxicity can occur with only small decreases in pH because of increased concentration of nonionized salicylate. Intravenous sodium bicarbonate should be given to decrease tissue penetration and facilitate the excretion of salicylate through the kidneys unless the patient has oliguric AKI, pulmonary edema, or cerebral edema.

p0255 Despite being highly protein bound, saturation of protein binding in significant poisoning and its limited volume of distribution makes it amenable to removal by dialysis. ERCT is recommended in patients with severe salicylate poisoning reflected by altered mental state, acute respiratory distress syndrome, and failure to respond to medical management irrespective of salicylate levels. ERCT is also indicated, regardless of signs and symptoms, at levels greater than 100 mg/dL (>7.2 mmol/L). Lower thresholds are applied for patients with AKI. Intermittent HD has advantages compared with hemoperfusion because the former allows rapid correction of associated electrolyte abnormalities and acidemia. CKRT provides lower salicylate clearance than HD and should be implemented only if intermittent modalities are not available.[23]

s0100 Theophylline

p0260 β_2 agonists have gradually replaced theophylline in the treatment of lung disease over the past 20 years. Still, new therapeutic uses are emerging, and it remains a potential toxin. Methylxanthine (MW 180 Da) overdose manifests with nausea, vomiting, diarrhea, gastrointestinal hemorrhage, hypokalemia, seizures, arrhythmias, and hypotension. Overdose may be acute or chronic. Theophylline is readily cleared by either HD or hemoperfusion because of its low volume of distribution and minimal protein binding. ERCT is recommended for severe acute theophylline poisoning (theophylline level > 100 mg/L [>555 μmol/L], or the presence of seizures, life-threatening arrhythmias, shock, or failure of standard therapy). In chronic poisoning, extracorporeal removal is suggested if theophylline levels are greater than 60 mg/L (>333 μmol/L) or greater than 50 mg/L (>278 μmol/L) in a patient older than 60 years. Maximal theophylline clearance can be achieved with charcoal hemoperfusion. However, with the advent of new high-efficiency filters and higher achievable blood flow rates, the clearances achievable with HD now rival those with hemoperfusion and are associated with fewer side effects. Continuous venovenous HF can be used but requires a longer treatment duration than with hemoperfusion.[24]

s0105 Valproate Acid

p0265 Valproate acid (VPA) is commonly used to treat epilepsy and bipolar disorder and to prevent migraine. VPA has a low molecular weight (144 Da), has a small volume of distribution (0.1–0.5 L/kg) and saturable plasma protein binding. At therapeutic concentrations, VPA is 94% protein bound, but it decreases to as low as 15% as concentrations rise to more than 1000 mg/dL, leading to greater clinical toxicity. Overdose may manifest with mild confusion, lethargy, nausea, vomiting, tachycardia, hypotension, metabolic acidosis, and electrolyte disturbances (hyponatremia and hypocalcemia). VPA concentrations can be helpful in determining the severity of intoxication; mild if less than 400 mg/L, moderate if between 450 and 850 mg/L, and severe if more than 850 mg/L. In addition to electrolyte abnormalities (hypernatremia, hypocalcemia), evidence of impaired mitochondrial function can be present, including metabolic acidosis, hyperlactatemia, and hyperammonemia.

p0270 ERCT is recommended for severe overdose (VPA level >1300 mg/L [>9000 μmol/L], cerebral edema, or shock). ERCT can be considered for VPA concentrations greater than 900 mg/L (>6250 μmol/L), coma or respiratory depression requiring ventilation, acute hyperammonemia, or pH less than 7.1. HD is preferred to hemoperfusion because it clears the unbound drug and also reverses associated metabolic abnormalities.[25]

Tricyclic Antidepressant Drugs

s0110

p0275 ERCT is not likely to have any clinical benefit for patients who have experienced an overdose with TCA drugs.[26]

Thallium

s0115

p0280 Thallium salts were once used in the treatment of ringworm. Poisoning continues to be reported where it is used as a rodenticide and a contaminant of herbal and illicit drug products.[27] It is absorbed extensively through almost all routes of exposure and is widely distributed across multiple body compartments. Thallium is a small molecule (MW 204 Da) and does not bind to protein, but the efficacy of extracorporeal removal is limited by its large volume of distribution.

p0285 Toxicity is caused by thallium replacing potassium as a stimulator or inhibitor of a variety of intracellular electrochemical and enzymatic processes. ECTR removes around 3% of total body stores over 6 hours, with hemoperfusion seeming to be the most efficient modality. PD and plasmapheresis do not appear to deliver significance clearances. Based on a recent literature review, the EXTRIP workgroup strongly recommended extracorporeal removal for treatment of thallium poisoning, given the absence of alternative treatments.[27] Intermittent HD is preferable, but hemoperfusion and CKRT are valid alternatives.

Barbiturates

s0120

p0290 The use of barbiturates in clinical practice has largely been replaced by benzodiazepines because of the lower risk from overdose and an available antidote to reverse toxicity. Nonetheless, barbiturate overdose is still a significant cause of fatal poisoning, especially phenobarbital, which is still used clinically and in veterinary practice.

p0295 Barbiturates mainly act on the CNS, and symptoms of a moderate overdose typically include sluggishness, lack of coordination, slow speech, faulty judgment, and drowsiness. Shallow respiration and coma occur in severe poisoning. It is recommended that ERCT be restricted to cases of severe, long-acting barbiturate poisoning with clinical features including prolonged coma, respiratory depression requiring ventilation, shock, and a failure to treat effectively with multiple-dose activated charcoal. ERCT improves barbiturate elimination and will be most beneficial if it is initiated early, ideally within 24 hours of exposure. Intermittent HD is the preferred modality: it is equivalent to hemoperfusion and superior to CVVH, which is in turn superior to PD.[28]

Acetaminophen/Paracetamol

s0125

p0300 Acute ingestions of acetaminophen (MW 46 Da) can still be lethal even when patients are treated early, within 8 hours of ingestion, and despite the availability of the antidote, *N*-acetylcysteine (NAC). In massive ingestions (>500 mg/kg), patients can present with an altered level of consciousness and metabolic acidosis with elevated lactate concentrations. Acetaminophen concentrations should be checked after 4 hours after ingestion or earlier in the case of massive ingestions.

p0305 There is a paucity of high-quality evidence for extracorporeal removal of acetaminophen, although it may have a role in the rare cases when *N*-acetylcysteine has not been effective. Patients with severe poisoning can also develop AKI even without liver dysfunction as a result of local production of the toxic by-product, *N*-acetyl-*p*-benzoquinone imine, by kidney prostaglandin synthetases. Thus, patients with acetaminophen-associated AKI may develop indications for ERCT other than acute toxin removal. Intermittent HD is the preferred modality.[29]

s0130

Carbamazepine

p0310 Carbamazepine is currently used to treat bipolar disorder, neuropathic pain, hyperactivity, and seizure disorder. It has a low molecular weight (236 Da), a structure similar to that of TCAs, and is highly bound to both albumin and α1-acid glycoprotein (70%–80%). It is metabolized in the liver, and only 1% to 3% of the drug is excreted unchanged in the urine. The therapeutic range is 4 to 12 mg/L, with toxicity usually occurring at more than 40 mg/L. Symptoms are mainly neurologic and include movement disorders, altered mental status, and seizures. Respiratory depression and cardiovascular symptoms can occur in severe overdose.

p0315 As the drug is moderately well dialyzed, extracorporeal removal is suggested in severe carbamazepine poisoning (as evidenced by coma, respiratory depression requiring ventilation, or carbamazepine levels that do not respond to standard therapy with activated charcoal). Intermittent HD is the favored modality. If HD is not available, hemoperfusion or CKRT can be considered.[30]

s0135

Phenytoin

p0320 Phenytoin (MW 252 Da) has a large volume of distribution and is extensively protein bound (90%) but dissociates easily and is amenable to extracorporeal removal. However, phenytoin poisoning rarely causes permanent organ damage or death, so extracorporeal removal is recommended only in very severe poisoning that has been resistant to standard therapy.[31] Enteral absorption of phenytoin is slow and unpredictable, so vigilance should be maintained for the delayed effects of poisoning. Extracorporeal removal should be reserved for patients with severe poisoning or prolonged coma, aiming to reduce morbidity and resource use rather than decrease mortality.

s0140

Digoxin

p0325 Digoxin (MW 781 Da) has variable absorption from the gut depending on the size of the ingestion. Although it is 20% to 30% protein bound, it also has a large volume of distribution and an effective antidote (digoxin immune Fab), so extracorporeal removal is not useful for managing overdose.[32]

SELF-ASSESSMENT QUESTIONS

o0010 **1.** Which one of the following statements is *true* regarding ethylene glycol toxicity?

o0015 **A.** Ethylene glycol is metabolized to glycolic acid.

o0020 **B.** Ethylene glycol is metabolized to formic acid.

o0025 **C.** Ethylene glycol is metabolized by alcohol hydrogenase.

o0030 **D.** Urinalysis demonstrates uric acid crystals.

o0035 **E.** Ethylene glycol toxicity is associated with a normal anion gap.

o0040 **2.** Which one of the following is *not* associated with a raised osmolar gap?

o0045 **A.** Ethylene glycol intoxication

o0050 **B.** Methanol intoxication

o0055 **C.** Isopropanol intoxication

o0060 **D.** Diabetic ketoacidosis

o0065 **E.** Acute kidney injury

o0070 **3.** Intermittent HD is *not* effective for removal of which of the following in overdose?

o0075 **A.** Lithium

o0080 **B.** Ethylene glycol

o0085 **C.** Metoprolol

o0090 **D.** Carvedilol

o0095 **E.** Methanol

o0100 **4.** Which one of the following statements is *true?*

o0105 **A.** Hemoperfusion remains the first-choice treatment for removal of theophyllines.

o0110 **B.** If endogenous clearance rates of toxins are less than 10 mL/min/kg body weight, ERCT should be considered.

o0115 **C.** Highly protein-bound toxins are not suitable for ERCT.

o0120 **D.** When continuous venovenous hemofiltration is used solely for poison removal, conventional doses for patients with AKI should be used.

o0125 **E.** Toxin rebound after intermittent HD may be mitigated by frequent scheduling of treatment or adjunctive therapy with one of the continuous renal replacement therapies.

Plasma Exchange

c0104

Jeremy Levy

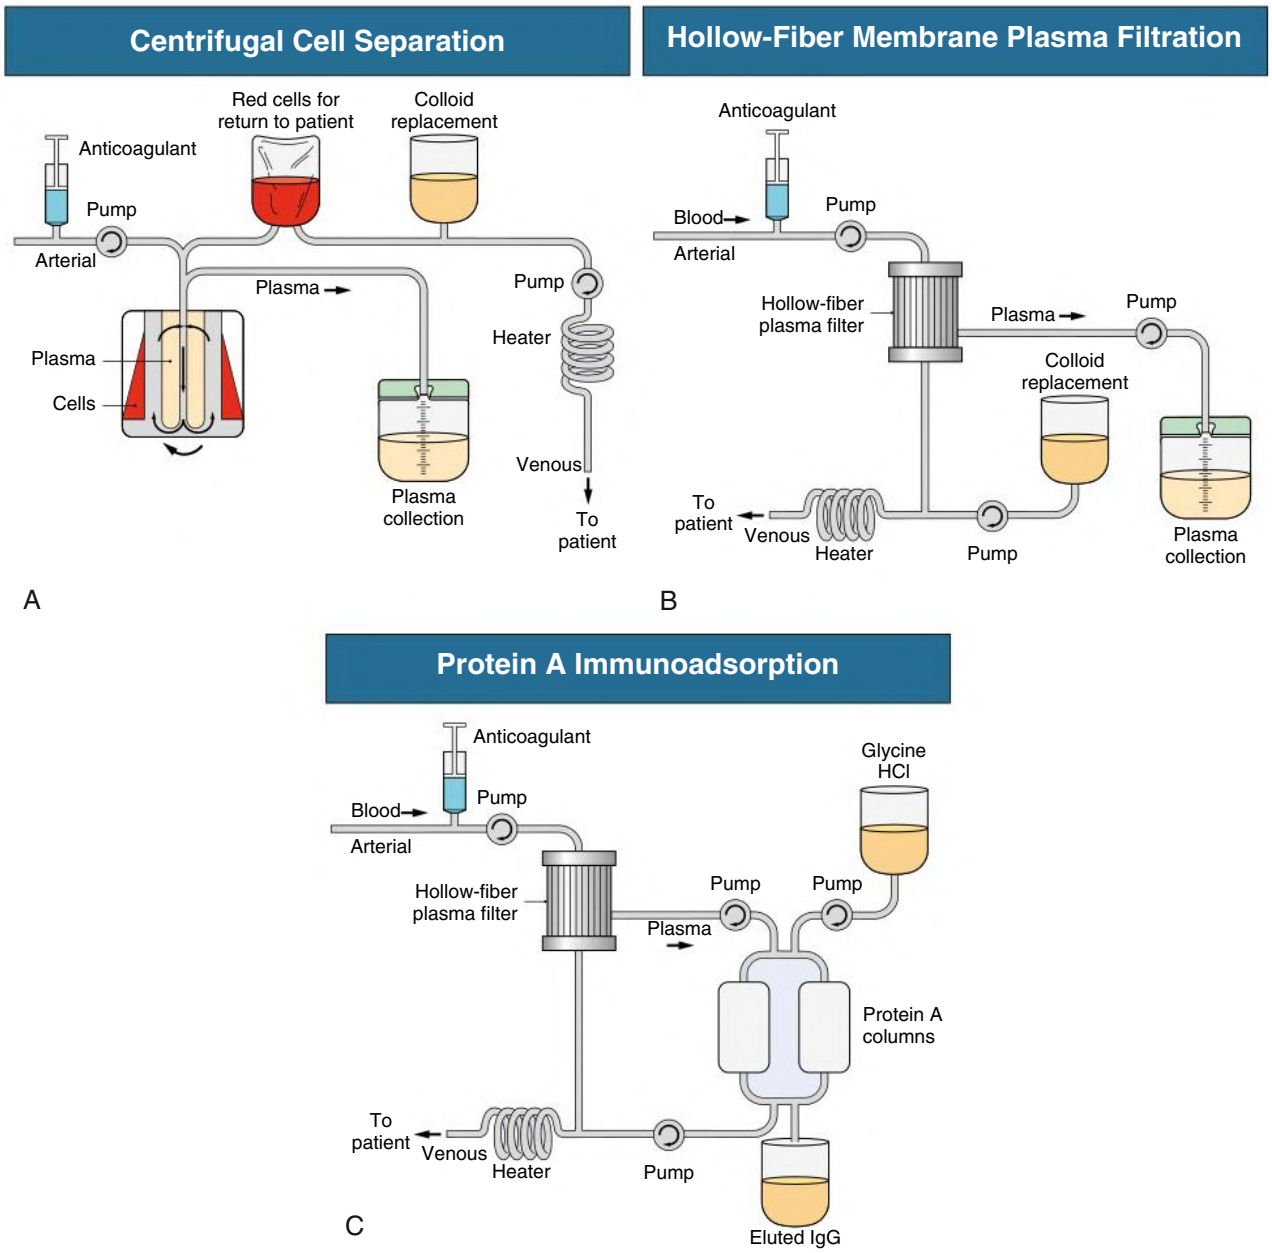
p0010 Over the past 10 years, it has become clearer how best to use plasma exchange (plasmapheresis) in the management of kidney disease, but the quality of published data remains relatively poor, with less than 1% of relevant literature in the form of randomized controlled trials (RCTs). Plasma exchange came into widespread clinical use after early reports of beneficial effects in Goodpasture disease in the mid-1970s. It is used to remove many large-molecular-weight substances from plasma, including pathogenic antibodies, cryoglobulins, and lipoproteins. Newer techniques allow more selective removal of plasma components, such as double-filtration plasma exchange, cryofiltration, and immunoadsorption with or without immobilized ligands. The most common kidney indications are thrombotic thrombocytopenic purpura/hemolytic-uremic syndrome (TTP/HUS), kidney transplantation (antibody-mediated rejection and for desensitization either for anti-ABO blood group antibodies or anti–human leukocyte antigen [HLA] antibodies), antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis, cryoglobulinemia, recurrent focal segmental glomerulosclerosis (FSGS), and anti–glomerular basement membrane (anti-GBM) antibody disease.

s0010 TECHNIQUES

p0015 Plasma exchange can be carried out either by centrifugal cell separators or (more commonly in dialysis units) with hollow-fiber plasma filters (membrane filtration) and standard hemodialysis (HD) equipment (Figs. 104.1 and 104.2). Centrifugal devices allow withdrawal of plasma from a bowl with either synchronous or intermittent return of blood cells to the patient.[1] There is no upper limit to the molecular weight of proteins removed by this method. The bowls and circuits are single use and disposable and require relatively low blood flow rates (50–150 mL/min and can be as low as 5 mL/min for children) that can be delivered through large-bore peripheral cannulae. Platelets can be inadvertently removed by centrifugal devices, although this risk has reduced significantly with newer technologic approaches. Membrane plasma filtration uses highly permeable hollow fibers with membrane pores of 0.2 to 0.5 μm. Plasma readily passes through the membrane and the cells are simultaneously returned to the patient. All immunoglobulins will cross the membrane (immunoglobulin G [IgG] slightly more efficiently than immunoglobulin M [IgM]), and molecules up to 3 million Da are cleared. Hemolysis can occur if transmembrane pressures are too high (a rare complication). The blood flow rates required for membrane plasma filtration are higher than for centrifugal cell separators (100–300 mL/min) and require central venous access or a fistula. Membrane exchange takes slightly longer than centrifugal techniques for the same plasma volume removal. It has been suggested that the adsorptive properties of the membrane for cytokines and other biomolecules may account for some of the beneficial effects of plasma filtration. There have been occasional reports of mild adverse reactions in patients taking angiotensin-converting enzyme inhibitors when plasma is filtered with ethylene vinyl alcohol or acrylic copolymer membranes. Reuse of plasma filters is not advised because of potential risks resulting from loss of filtration capacity and to staff from cleaning procedures, but performance data do not indicate a major loss of function during routine plasma exchange. For patients with severe kidney failure, sequential HD and plasma exchange can easily be performed with plasma filtration.

p0020 Vascular access is usually achieved using standard central venous catheters, but existing arteriovenous fistulas (AVFs) can be used if available. Sometimes plasma exchange can be done using large-bore, short intravenous (IV) cannulas placed in the antecubital fossa, especially with centrifugal devices. Single-needle access using an AVF is also relatively easy to accommodate, especially for centrifugal plasma exchange, in which the blood removal and return can be asynchronous, but also for membrane filtration. Anticoagulation must be carefully managed in patients at higher bleeding risk (e.g., thrombotic microangiopathy [TMA], recent or ongoing pulmonary hemorrhage, or a recent kidney biopsy). Citrate is used for anticoagulation with centrifugal plasma exchange and heparin for membrane plasma filtration; however, citrate is superior for patients at higher bleeding risk in view of its lack of systemic anticoagulation.[1] When heparin is used, higher doses may be needed than in HD because of increased losses during the procedure (heparin is protein bound). Bolus doses of unfractionated heparin of 2000 to 5000 U are given initially and then 500 to 2000 U/h. Anticoagulant is administered prefilter. Increasingly low-molecular-weight heparin (LMWH) is also used with a single bolus dose at initiation of exchange.

p0025 Both methods of plasma exchange require large volumes of colloid replacement. A single plasma volume exchange will lower plasma macromolecule levels by approximately 60%, and five exchanges over 5 to 10 days will clear 90% of the total body immunoglobulin (Fig. 104.3).[1,2] For most patients, this is achieved by removing 50 mL of plasma per kilogram body weight at each procedure (~4 L for a 75-kg person). Daily plasma exchange more rapidly depletes total body load of immunoglobulins, but there is no good evidence that intensity of exchanges has a major effect on outcomes except in patients with HUS with poor prognostic markers (see later discussion). Indeed, alternate-day exchanges are of proven efficacy in ANCA-associated diseases. Replacement solely with crystalloid is contraindicated because of the need to maintain colloid oncotic pressure. Synthetic gelatin–based plasma expanders or hydroxyethyl starch (Hespan) can be used as part of a replacement regimen but have been reported to cause a coagulopathy in patients with sepsis and have a shorter half-life than human albumin, which is the main replacement fluid. The major disadvantage of albumin solutions is the lack of clotting factors, with the potential development of depletion coagulopathy after plasma exchange. Fresh-frozen plasma (FFP)



f0010

Fig. 104.1 Plasma Exchange and Immunoadsorption Techniques. Techniques include centrifugal cell separation (A), hollow-fiber membrane plasma filtration (B), and protein A immunoadsorption (C). *IgG,* Immunoglobulin G.

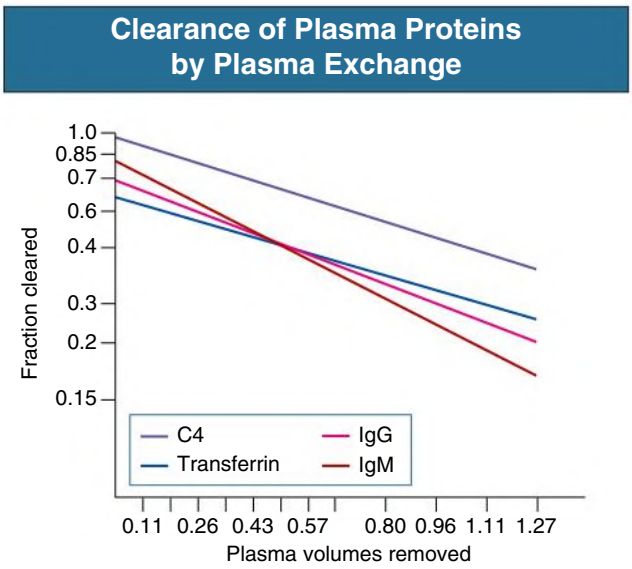
should be given, usually in addition to human albumin solution, in patients at particular risk for bleeding. If partial replacement is with FFP, this should be given late during the exchange so the constituents are not removed by the ongoing plasma exchange. However, almost all the serious complications of plasma exchange (hypotension, anaphylaxis, citrate-induced paresthesia, urticaria) have been reported in patients receiving FFP rather than albumin (see later discussion).[1,3] Both human products carry a tiny risk for transmission of infectious diseases, especially viral. Standard regimens for plasma exchange are summarized in Table 104.1. Human albumin solution (4%–5%) should be used for all exchanges except in TMAs (in which plasma should provide the total exchange), and FFP should form part of the exchange when bleeding risk is high (ongoing pulmonary hemorrhage or within 48 hours of biopsy or surgery). If fibrinogen levels decrease to less than 1.25 to 1.5 g/L or prothrombin time (PT) is increased 2 to 3 seconds above normal, FFP should be administered (Table 104.2).

p0030 Double-filtration plasma exchange (or cascade filtration) uses membrane filtration to separate cells from plasma and then a secondary plasma filtration (pore size 0.01–0.03 μm) to remove plasma solutes based on molecular size. Most albumin is therefore returned to the patient, together with lower molecular weight proteins, reducing the need for replacement fluids. Cryofiltration uses a similar principle but exposes the filtrate to 4°C during the procedure, with the aim of precipitating cryoproteins. These techniques are not widely available.

p0035 Selective and specific immunoadsorption techniques are available but rarely used. Protein A immunoadsorption has been used to remove immunoglobulin alone from plasma, without the need for replacement fluids and without depletion of clotting factors and complement (see Fig. 104.1C). Protein A selectively binds the Fc domains of

f0015

Fig. 104.2 A centrifugal cell separator in use for plasma exchange.



f0020

Fig. 104.3 Clearance of Plasma Proteins by Plasma Exchange. Clearance from the intravascular compartment varies with the plasma volume exchanged and among individual proteins. *IgG,* Immunoglobulin G; *IgM,* immunoglobulin M. (Modified from Derksen RH, Schuurman HJ, Meyling FH, et al. The efficacy of plasma exchange in the removal of plasma components. *J Lab Clin Med.* 1984;104:346–354.)

immunoglobulin molecules, and the immunoadsorption columns can be repeatedly regenerated. Columns have been used for 1 year for a single patient on up to 30 occasions; however, the repeated acid stripping during regeneration reduces the efficacy of antibody binding. Selective immunoadsorption has been used to treat conditions in which autoantibodies are thought to be important and usually in place of plasma exchange (e.g., Goodpasture disease, rheumatoid arthritis, lupus, or systemic vasculitis) and to remove anti-ABO or anti–HLA antibodies in highly sensitized transplant recipients. In general, the reported efficacy has been equal to that of plasma exchange, although if used over the long term, immunoadsorption is much more cost-effective in single patients because replacement of albumin or plasma is not required. Specific ligands also have been immobilized onto columns for more specific removal of potentially pathogenic serum factors; ligands used include anti–human IgG, C1q, phenylalanine, hydrophobic amino acids, acetylcholine receptor, β-adrenoreceptor peptides, and blood group–related oligosaccharides. Immunoadsorption is not widely available because the initial column costs are high and few centers have much clinical experience. Costs of all other plasma exchange modalities are dominated by the costs of replacement albumin and plasma; equipment costs do not vary much among modalities, and all require skilled and trained nursing staff.

COMPLICATIONS

s0015

The complication rate of plasma exchange is not high.[3] The Swedish registry reported no fatalities during 20,485 procedures and an overall adverse incidence rate of only 4.3% of all exchanges (0.9% for severe adverse events) of which 27% were paresthesias, 19% transient hypotension, 13% urticaria, and 8% nausea.[4] The Canadian Apheresis Registry collected data on 144,432 apheresis procedures since 1981 and reported adverse events occurring in 12% of procedures (mostly minor) and overall in 40% of patients. Severe events occurred in only 0.4% of procedures. Three deaths were probably related directly to the procedure: one from a transfusion-related acute lung injury and two from complications from central venous catheters.[5] An overall complication rate of 1.4% has been reported in more than 15,000 treatments in patients receiving albumin and 20% in patients receiving FFP.[1,3,5,6] Plasma exchange by centrifugation had a lower risk for adverse events than by filtration.

p0040

Other complications directly attributable to plasma exchange include citrate-induced hypocalcemia (presenting with perioral tingling and paresthesias) and citrate-induced metabolic alkalosis. Citrate is usually present in FFP (up to 14% by volume) or is administered in the extracorporeal circuit as an anticoagulant; it binds free calcium in plasma. Symptomatic hypocalcemia can be averted by infusing 10 to 20 mL of 10% calcium gluconate during each plasma exchange. Alkalosis is rare and is caused by metabolism of citrate to bicarbonate and failure to excrete the latter in patients with kidney impairment.

p0045

Plasma exchange predictably increases the risk for bleeding by depleting coagulation factors in patients receiving albumin as sole replacement colloid. PT is increased by 30%, and partial thromboplastin time by 100% after a single plasma volume exchange. Patients at risk for bleeding (pulmonary hemorrhage, postbiopsy, postoperative) should receive FFP (300–600 mL) with replacement fluids. Dilutional hypokalemia is avoided by replacing potassium according to daily blood testing. An increased incidence of infection secondary to hypogammaglobulinemia has not been confirmed in recent series.[3–6] Sepsis related to IV access is the most common infectious complication of plasma exchange. Hypotension can occur for a variety of reasons related to extracorporeal circuits, sepsis, and allergic reactions. Cascade filtration can lead to hemolysis (in up to 20% patients) but rarely necessitates transfusion.

p0050

MECHANISMS OF ACTION

s0020

The pathogenicity of autoantibodies in anti-GBM disease (Goodpasture disease) provided the impetus for development of plasma exchange therapy, but it is now clear that antibodies, although necessary, are not alone sufficient to cause the necrotizing glomerulonephritis (GN) in that disease. Plasma exchange, however, removes

p0055

t0010

TABLE 104.1 Practical Regimens for Plasma Exchange in Kidney Disease

Indication	Anti-GBM Disease	Small-Vessel Vasculitis	Cryoglobulinemia	Recurrent FSGS After Transplantation	HUS/TTP
Duration of treatment	Daily, at least 14 days until anti-GBM antibodies 20% of baseline	Daily or alternate daily, 7–10 days depending on clinical response	At least 7–10 days or until clinical response	Daily for at least 10 days initially, then continuing less frequently, often for months	Daily for 7–10 days or until platelet count 80–100 $\times 10^9$/L (sometimes needed twice daily)
Exchange volume	50 mL/kg each treatment	As for anti-GBM disease	As for anti-GBM disease	As for anti-GBM disease	As for anti-GBM disease
Replacement fluid	Human albumin 5% (unless bleeding risk)	As for anti-GBM disease	As for anti-GBM disease	As for anti-GBM disease	FFP or cryo-poor FFP
Additions to replacement fluid	20 mL 10% calcium gluconate (occasionally more), 3 mL 15% KCl if not dialysis dependent, heparin 2000–5000 U bolus, then 500–2000/h (LMWH an alternative with bolus only) *or* citrate anticoagulation	As for anti-GBM disease	As for anti-GBM disease	As for anti-GBM disease	As for anti-GBM disease (may need more calcium because of increased volume of FFP-containing citrate)
Immunosuppression	See Chapter 25	See Chapter 26	See Chapter 22	See Chapter 30	See Chapter 30
Variations	FFP 5–8mL/kg at end of exchange volume if hemorrhage risk (kidney biopsy in last 48h, lung hemorrhage, platelets <40 $\times 10^9$/L, fibrinogen < 1.5g/L) Immunoadsorption may be as effective	As for anti-GBM disease Immunoadsorption may be as effective	As for anti-GBM disease	As for anti-GBM disease; may need to include replacement immunoglobulins if continuing long term Immunoadsorption may be as effective	

FFP, Fresh-frozen plasma; *FSGS,* focal segmental glomerulosclerosis; *GBM,* glomerular basement membrane; *HUS,* hemolytic-uremic syndrome; *LMWH,* low-molecular-weight heparin; *TTP,* thrombotic thrombocytopenic purpura.

t0015

TABLE 104.2 Investigations to Undertake Before Every Plasma Exchange Session

Investigation	Action to Take
Platelet count	Use plasma exchange with caution if platelet count < 40 × 10^9/L unless disease itself associated with thrombocytopenia (e.g., aHUS/TTP), and use FFP as part of replacement fluid.
Plasma fibrinogen	If <150 mg/dL, should use FFP as part of exchange fluid.
Prothrombin time	If prolonged more than 2–3 seconds, use FFP as part of exchange fluids.
Serum calcium	If <2.1 mmol/L (<8.4 mg/dL), increase amount being provided with replacement albumin/FFP.
Serum potassium	Can be highly variable depending on changing kidney function in addition to plasma exchange treatment; adjust potassium replacement according to serum potassium.

aHUS, Atypical hemolytic-uremic syndrome; *FFP,* fresh-frozen plasma; *TTP,* thrombotic thrombocytopenic purpura.

all large-molecular-weight substances from the plasma in addition to antibodies, including complement components, immune complexes, endotoxin, lipoproteins, and von Willebrand factor (vWF) multimers. In animal studies, for example, complement depletion abrogates anti-GBM GN very effectively. Therefore, plasma exchange may have benefits in addition to clearance of autoantibodies.

p0060 The clearance of antibodies from patients is variable and depends on several factors, including the rate of equilibration of macromolecules between the intravascular and extravascular compartments. IgM antibodies are cleared more effectively than other classes of immunoglobulin because they are retained in the vascular compartment almost wholly. A rebound increase in antibody production will occur unless there is concomitant immunosuppression to prevent resynthesis.

p0065 Plasma exchange has been shown to remove immune complexes, which may have clinical significance in cryoglobulinemia and systemic lupus, and fibrinogen and complement components. There is no good evidence that removal of cytokines has any clinical significance. Plasma exchange reduces plasma viscosity, with consequent improved blood flow in the microvasculature. There is also some evidence for improvement in monocyte/macrophage function, alteration in lymphocyte function, and sensitization of antibody-producing cells to immunosuppressive drugs after plasma exchange.

INDICATIONS FOR PLASMA EXCHANGE

s0025

p0070 Evidence to support specific indications for plasma exchange is variable in quality. Direct comparison among RCTs can be unsatisfactory because of variations in dose and frequency of plasma exchange and in immunosuppressive and other adjunctive therapy. The American Society for Apheresis (ASFA) reviewed all indications for plasma

exchange most recently updated in 2016 and summarized available trial data.[7,8] In this chapter, evidence from available RCTs is discussed alongside observational data. The indications are summarized in Tables 104.3 and 104.4.

s0030

Anti–Glomerular Basement Membrane Antibody Disease (Goodpasture Disease)

p0075 Most patients can be depleted of pathogenic anti-GBM antibodies after 7 to 10 plasma volume exchanges if further antibody synthesis is inhibited by the concurrent use of cyclophosphamide and corticosteroids. Before plasmapheresis, the mortality from Goodpasture disease was higher than 90%, and only 11% of patients who were not dialysis-dependent at presentation survived with preserved kidney function. The use of plasma exchange improved the outcome considerably: 70% to 90% of patients now survive. However, only 50% of survivors retain independent kidney function and 10% or less of those who are dialysis dependent at presentation. There has been only one small controlled trial of plasma exchange in the treatment of Goodpasture disease, which used a low intensity of plasma exchange.[7,9] A total of 17 patients were randomized to receive corticosteroids and cyclophosphamide, with or without plasma exchange. Only 2 of the 8 who received plasma exchange developed end-stage kidney disease (ESKD) compared with 6 of the 9 who received drugs alone.

p0080 Long-term data from 71 patients with Goodpasture disease confirmed the benefit of a treatment regimen including plasma exchange because most patients with mild to moderate kidney failure retained independent kidney function over 10 to 25 years,[10] and kidney recovery was possible even in some of those with the most severe kidney disease. Very similar results were identified in the largest reported series from China. Combining all the available published data for patients with Goodpasture disease, 76% of patients presenting with serum creatinine less than 5.5 to 6.8 mg/dL (500–600 μmol/L) will remain independent of dialysis if treated with plasma exchange, in contrast to only 8% of those who are dialysis dependent at presentation. Diffuse alveolar hemorrhage, which occurs in up to 50% of patients and can be life threatening, is an independent indication for plasma exchange regardless of kidney function.

Recommendation

s0035

p0085 All patients who are not dialysis dependent at presentation should receive intensive plasma exchange with daily 4-L exchanges initially for 14 days (regimen shown in Table 104.2). For dialysis-dependent patients, we recommend plasma exchange with immunosuppression only for those who have biopsy or clinical evidence of recent-onset disease. Pulmonary hemorrhage is an independent indication for plasma exchange. Treatment of Goodpasture disease is discussed further in Chapter 25.

t0020

TABLE 104.3 Conditions for Which There Is Strong Evidence for the Benefit of Plasma Exchange

Indication	RCTs (No. Patients)	Controlled Trials (No. Patients)	Case Series (No. Patients)	Replacement Fluid	Comments
ANCA-associated systemic vasculitis	9 (652)	1 (26)	>22 (>347)	Albumin unless pulmonary hemorrhage or need to prevent coagulopathy	Possible benefit only in dialysis-dependent patients or those with most severe kidney impairment. Should consider daily exchanges in fulminant cases or with pulmonary hemorrhage.
Anti-GBM antibody disease	1 (17)	0	>10 (>587)	Albumin unless pulmonary hemorrhage or need to prevent coagulopathy	Minimum course 14 days to remove antibodies effectively. Especially beneficial in nonoliguric patients predialysis. Patients with creatinine >5.5 mg/dL (500 μmol/L) unlikely to benefit.
Cryoglobulinemia	1 (57) 1 (17) using immunoadsorption	0	24 (302)	Albumin	Long-term maintenance treatment needed in some patients. Ensure blood warmer on return lines or warm replacement fluids.
TTP	7 (301)	2 (133)	>38 (>1541)	Plasma or cryo-poor plasma	Daily, often with corticosteroids; the only treatment that has improved mortality.
ABO-incompatible kidney transplantation	0	0	>21 (>750)	Albumin ± plasma (compatible with donor and recipient or AB)	Used pretransplant to reduce titers of antibodies and often continued for a few days after surgery to allow successful transplantation.
Antibody-mediated kidney transplant rejection	3 (61)	8 (342)	>37 (>727)	Albumin	Daily or alternate day. Usually with IVIG and sometimes enhanced immunosuppression.
HLA desensitization for transplantation (in highly sensitized patients)	0	5 (441)	29 (466)	Albumin	Always in combination with immunosuppression and usually IVIG, and continued until cross-match negative. Usually five plasma exchanges are needed to reduce Ab levels sufficiently.

ANCA, Antineutrophil cytoplasmic antibody; *GBM,* glomerular basement membrane; *HLA,* human leukocyte antigen; *IVIG,* intravenous immunoglobulin; *RCTs,* randomized controlled trials; *TTP,* thrombotic thrombocytopenic purpura.

t0025 **TABLE 104.4 Conditions for Which There Is Some Evidence for Plasma Exchange**

Indication	RCTs (No. of Patients)	Controlled Trials (No. of Patients)	Case Series (No. of Patients)	Replacement Fluid	Comments
Catastrophic antiphospholipid antibody syndrome	0	0	6 (109)	Plasma	Should be done daily. Combination of plasma exchange or IVIG, heparin, and corticosteroids (from registry data) gives best outcomes.
Recurrent FSGS after transplantation	0	3 (48)	77 (378)	Albumin	Sometimes in combination with rituximab. May need long-term maintenance treatment.
Atypical hemolytic-uremic syndrome	0	0	>10 (>200)	Plasma or cryo-poor plasma	Daily plasma exchange initially. Eculizumab is the preferred treatment if available.
Myeloma	5 (182)	0	8 (102)	Albumin	Daily or alternate day for 7–10 exchanges. Despite negative randomized trial in 2005, plasma exchange might be considered if high light-chain load, severe kidney failure, and oliguria and light chains not depleted with urgent chemotherapy.
Rapidly progressive glomerulonephritis (may include patients with ANCA-associated disease in older literature)	7 (196)	0	21 (295)	Albumin	No good evidence for benefit in immune complex disease of any cause. Small case series of benefit in crescentic IgA vasculitis (Henoch-Schonlein purpura) with RPGN.
Scleroderma	0	3 (75)	7 (70)	Albumin	No good evidence for benefit, but some patients have reported improvement.
Systemic lupus (not nephritis)	1 (20)	1 (4)	14 (128)	Albumin	For cerebritis, lupus-associated TTP, severe hemolysis, or pulmonary hemorrhage.

ANCA, Antineutrophil cytoplasmic antibody; *FSGS,* focal segmental glomerulosclerosis; *IgA,* immunoglobulin A; *IVIG,* intravenous immunoglobulin; *RCTs,* randomized controlled trials; *RPGN,* rapidly progressive glomerulonephritis; *TTP,* thrombotic thrombocytopenic purpura.

s0040 ## Small-Vessel Vasculitis

p0090 The majority of patients with rapidly progressive glomerulonephritis (RPGN), other than anti-GBM disease, have small-vessel vasculitis with ANCA detectable in their serum, and there is increasing evidence that these autoantibodies are pathogenic. Several trials of plasma exchange in non–anti-GBM RPGN have been reported.[7,11] Most of the early trials included patients with a variety of diseases, used a low intensity of plasma exchange, and often excluded those with oligoanuria. These trials showed no overall benefit of plasma exchange in addition to conventional immunosuppression; however, those patients with the most severe disease did seem to benefit. Two recent large RCTs have, however, added to the controversy. MEPEX (Methylprednisolone or Plasma Exchange in Severe ANCA-Associated Vasculitis) randomized 137 patients with ANCA-associated systemic vasculitis and serum creatinine greater than 5.5 mg/dL (500 μmol/L) to plasma exchange or IV methylprednisolone in addition to oral corticosteroids and cyclophosphamide.[11] Sixty-nine percent of patients recovered kidney function when treated with plasma exchange compared with 49% of those receiving IV methylprednisolone, and significantly more patients were dialysis independent at the trial endpoint, although this difference was not maintained at 3 years. MEPEX was the largest study in a meta-analysis of 387 patients, with creatinine levels ranging from 3.2 to 13.5 mg/dL. The addition of plasma exchange to standard immunosuppression in MEPEX was associated with reduced risk for ESKD or death. The PEXIVAS trial randomized 352 patients with ANCA-associated vasculitis and estimated glomerular filtration rate (eGFR) less than 50 mL/min to plasma exchange (7 exchanges in 14 days) or no plasma exchange, and also low- or high-dose oral steroids.[12] Overall, there was no difference in deaths or ESKD with or without plasma exchange (28.5% vs. 31%; hazard ratio [HR] 0.86, 95% confidence interval [CI] 0.65–1.13) but a suggestion that plasma exchange might increase the chance of kidney recovery in those with the most severe kidney impairment at presentation, and a new meta-analysis including PEXIVAS is awaited.

p0095 Patients with both ANCA and anti-GBM antibodies (so-called double-positive patients) and RPGN do not respond well to plasma exchange and rarely, if ever, recover kidney function.[13]

Recommendation

s0045

p0100 We perform plasma exchange in patients with small-vessel vasculitis who present with severe kidney failure (serum creatinine > 5.5 mg/dL [~500 μmol/L] or dialysis dependent) or pulmonary hemorrhage. The regimen is shown in Table 104.2.

Other Crescentic Glomerulonephritis

s0050

p0105 Crescent formation is a common histologic finding in several other patterns of GN, including postinfectious GN, GN associated with infective endocarditis, IgA nephropathy (IgAN), membranoproliferative glomerulonephritis (MPGN), and membranous nephropathy. Such patients were often included in studies of treatment of RPGN, and plasma exchange has been used in the treatment of a number of these conditions. More than 400 patients with such diseases have been treated with plasma exchange with no good evidence for any benefit in crescentic GN not caused by anti-GBM disease or vasculitis.[7,8] In crescentic IgAN, there are anecdotal reports of short-term benefit in patients with severe kidney impairment, but longer-term follow-up has proved disappointing. A single report showed some benefit of 5 to 10 plasma exchanges in preventing or reversing dialysis dependency in 12 patients with crescentic IgAN manifesting with RPGN, with measured decreases in circulating plasma IgA-IgG complexes.[14]

s0055 **Recommendation**

p0110 We offer plasma exchange in patients with IgAN and other GNs who have rapidly deteriorating kidney function and extensive fresh crescents in the biopsy specimen.

s0060 ## Focal Segmental Glomerulosclerosis

p0115 Plasma exchange, protein A immunoadsorption, and lipoprotein apheresis have been used to treat patients with primary FSGS or recurrent disease after transplantation. The results have been worse in primary disease with less than 40% of patients achieving either partial or complete remission,[7,8,13] and we do not recommend plasma exchange in this setting. Plasma exchange for recurrent disease is discussed later and in Chapter 113.

s0065 ## Thrombotic Microangiopathies

p0120 In both HUS and TTP, endothelial activation leads to TMA but through distinct mechanisms.

s0070 **Infection-Associated Hemolytic-Uremic Syndrome**

p0125 Infections leading to HUS are most recognized after enteropathogenic *Escherichia coli* from Shiga toxin production (Stx-associated HUS) and after *Streptococcus pneumoniae* (pHUS). The prognosis is generally good, especially in childhood. Most children will recover extremely well with supportive care and management of fluid and electrolyte imbalance and hypertension. Two controlled trials of plasma infusion (at least 10 mL/kg/day) in childhood HUS complicated by dialysis-dependent kidney failure showed no clinical benefit (as determined by hypertension, kidney dysfunction, and proteinuria) in either short- or medium-term follow-up.[15] There has been no study of plasma exchange in childhood Stx-associated HUS. Plasma exchange and infusion have not been subjected to any controlled trials in adult Stx-associated HUS, but uncontrolled observations suggest possible benefit.[7,16] The 2011 outbreak of enterohemorrhagic and Stx-producing *E. coli* O104:H4 in Europe led to 855 confirmed cases of HUS, but despite severe illness in many patients, a retrospective analysis of 491 treated patients did not support any major benefit of plasma exchange in addition to intensive supportive care.[17]

s0075 **Thrombotic Thrombocytopenic Purpura**

p0130 Patients with TTP usually have a defective vWF cleaving protease (ADAMTS13), an enzyme that normally degrades large vWF multimers. The defect is typically because of an inherited deficiency or autoantibodies directed against the protease. Accumulation of vWF multimers leads to systemic platelet activation under conditions of high shear stress (the microcirculation) and thrombosis. The rationale for plasma infusion and plasma exchange in TTP is therefore to replenish vWF cleaving protease, to remove antibodies against the protease, and to remove the large vWF multimers from circulation. There are well-designed RCTs in the treatment of TTP.

p0135 The first prospective controlled trial compared plasma infusion with plasma exchange (1–1.5 plasma volumes at least seven times in the first 9 days).[18] Of patients receiving plasma exchange, 47% had a platelet count exceeding 150×10^9 cells/L and no new neurologic features, compared with only 25% of those receiving plasma infusion over the first 2 weeks. At 6 months, survival was substantially better in those given plasma exchange (50% vs. 78%). More recent series using plasma exchange have reported mortality rates as low as 15%,[7] and there may be an association of reduced early mortality with more intensive plasma exchange. Kidney impairment is not an independent predictor of poor outcome in TTP and does not in itself warrant more intensive therapy.

p0140 TTP may also be induced by drugs, including ticlopidine, clopidogrel, mitomycin C, cyclosporine, tacrolimus, gemcitabine, and quinine, and the evidence for benefit of plasma exchange in this context is poor, except for ticlopidine-induced TTP in which ADAMTS13 activity is severely depressed.[7]

Atypical Hemolytic Uremic Syndrome s0080

p0145 The less common forms of HUS in which there is no clear diarrheal prodrome (atypical HUS [aHUS]) are commonly caused by mutations, polymorphisms, or acquired dysregulation of the complement pathway (including the development of autoantibodies), especially of factor H, factor I, and membrane cofactor protein, leading to uninhibited activation of complement. Other causes include infections or drugs that cause platelet or leukocyte activation and complement activation and consumption. Direct activation of endothelial cells also may be a cause. Plasma exchange and infusion have not been evaluated in controlled trials in aHUS, but uncontrolled series suggest benefit and current guidelines recommend early initiation of plasma exchange with FFP (see Chapter 30), both to remove potential complement inhibitors or autoantibody and to replace absent or defective complement regulators.[7] The introduction of the complement inhibitor eculizumab, a humanized anti-C5 monoclonal antibody, has revolutionized the treatment of aHUS and should now be the mainstay of management after urgently excluding other diagnoses and can replace plasma exchange. If eculizumab is not available, plasma exchange should be continued. TMA after kidney transplantation has also responded to plasma exchange.

Recommendation s0085

p0150 We use plasma exchange in all adults with TTP and perform all exchanges using FFP or cryo-poor FFP as the exchange fluid. In aHUS, we use plasma exchange until we can initiate eculizumab, which is the preferred treatment.

Systemic Lupus s0090

p0155 Plasma exchange has been used extensively in patients with lupus. Most studies have included patients with diverse patterns of disease, often with only mild kidney involvement. A prospective RCT could show no benefit of plasma exchange over conventional immunosuppression for kidney, serologic, or clinical outcomes, both in the short and long term.[19] However, patients with crescentic lupus nephritis and those with the most severe kidney dysfunction (dialysis dependency) were excluded. Anecdotal evidence suggests that plasma exchange may benefit patients with systemic lupus and crescentic GN, pulmonary hemorrhage, cerebral lupus, catastrophic antiphospholipid syndrome, severe antibody-induced hemolysis, lupus-associated TTP, or severe lupus unresponsive to conventional drugs or in patients for whom cytotoxic therapy has been withdrawn because of bone marrow suppression or other toxicity. Immunoadsorption may be more successful in the severe forms of lupus nephritis. A variety of techniques have been used, including standard protein A and anti-immunoglobulin absorption, and also phenylalanine, tryptophan, and dextran sulfate ligands, all of which bind immunoglobulin, rheumatoid factors, and immune complexes to varying degrees and all of which have been reported to induce remission in patients with severe disease after failure of conventional therapy.

Recommendation s0095

p0160 We offer plasma exchange to lupus patients with rapidly progressive kidney failure and class IV lupus nephritis with crescents, to patients with severe neurologic involvement or severe hemolysis, to patients with myelosuppression who are thought unable to tolerate

cyclophosphamide, and to those with catastrophic antiphospholipid syndrome or severe macrophage activation syndrome. The treatment of lupus is further discussed in Chapter 27.

s0100 ## Cryoglobulinemia

p0165 In type I cryoglobulinemia, usually associated with myeloma or lymphoma, a monoclonal immunoglobulin causes hyperviscosity and cryoprecipitation. Such antibodies are easily removed by plasma exchange, often with immediate clinical benefit. Cytotoxic agents are used simultaneously to inhibit further paraprotein production. There are no controlled trials of plasma exchange, but symptoms are closely related to the presence of the cryoimmunoglobulin, and hence treatment with plasma exchange appears effective.[7]

p0170 Patients with type II (mixed essential) cryoglobulinemia develop a monoclonal antibody (usually IgM) with specificity for a second, usually polyclonal, immunoglobulin. Type II cryoglobulins occur most commonly in association with hepatitis C virus (HCV) infection and lymphoma. The resulting immune complexes can be deposited in the microcirculation and are particularly associated with an MPGN pattern of injury (see Chapter 22). Plasma exchange is effective at clearing the immune complexes, although the cryoglobulins often recur, and sustained benefit has not been clearly demonstrated. However, many of the acute features of cryoglobulinemia resolve with plasma exchange, particularly arthralgia, skin lesions, and digital necrosis, and patients with RPGN can recover kidney function. Concomitant treatment with rituximab may prevent resynthesis of the cryoproteins, although some patients require long-term intermittent plasma exchange to control symptoms. Patients with HCV-associated cryoglobulinemia should be treated with the newer antiviral agents, which are extremely effective in curing the viral infection, after which cryoglobulins usually disappear. A single RCT in 17 patients with HCV-associated cryoglobulinemia added immunoadsorption apheresis (with dextran sulfate) to antivirals and immunosuppression and showed significant clinical improvements, but this was from an era before the current antiviral agents.[20]

p0175 Cryofiltration apheresis (in which a normal plasma filter is used to separate plasma, which is then cooled to precipitate the cryoglobulin before return to the patient) selectively removes cryoglobulins, avoids large volumes of replacement fluids, and avoids deficiency of clotting factors, but needs to be combined with immunosuppression to prevent synthesis of further cryoglobulin. Few centers currently perform this technique, especially because of the widespread introduction of rituximab for cryoglobulinemia.

s0105 ### Recommendation

p0180 We offer plasma exchange (in addition to rituximab or antiviral treatments) to patients with cryoglobulinemia and rapidly progressive kidney failure, necrotic ulceration, and digital infarction and to patients with type 1 cryoglobulins and complications from hyperviscosity.

s0110 ## Myeloma

p0185 Plasma exchange almost certainly does not provide benefit in myeloma with either cast nephropathy or light-chain kidney toxicity, and the most important therapy seems to be urgent initiation of chemotherapy, especially thalidomide, lenalidomide, bortezomib, or newer agents. A large prospective RCT randomized 97 patients with myeloma and progressive acute kidney injury (creatinine > 200 μmol/L [2.3 mg/dL] with an increase of over 50 μmol/L over the previous 2 weeks despite conventional management) to receive plasma exchange (five to seven sessions of 50 mL/kg over 10 days) in addition to chemotherapy (vincristine, adriamycin, and dexamethasone [VAD] or melphalan and prednisolone).[21] This study showed no benefit of plasma exchange on mortality or recovery of kidney function. However, patients had a wide degree of kidney dysfunction, and relatively few had a kidney biopsy performed to confirm cast nephropathy. A retrospective review suggested that those with myeloma and high light-chain loads or severe kidney failure may benefit if plasma exchange reduces light chains rapidly.[22] More recently a variety of studies in patients with kidney disease and myeloma, especially using bortezomib-based regimens, have shown significant improvements even in patients with dialysis-requiring kidney failure but without plasma exchange. An RCT of HD using novel membranes allowing the removal of large-molecular-weight substances and lengthy dialysis sessions (6–8 hours) failed to show any benefit (for survival or recovery of kidney function) when added to modern chemotherapy, which depleted light chains rapidly in the absence of plasma removal.

Recommendation

s0115

p0190 We no longer use plasma exchange in patients with myeloma but ensure that effective chemotherapy is urgently initiated.

TRANSPLANTATION

s0120

Antibody-Mediated Rejection

s0125

p0195 A review of 157 patients included in five trials did not show any benefit of plasma exchange for the treatment of acute vascular rejection.[7,8] At least 11 trials including more than 400 patients with more clearly defined antibody-mediated rejection and case series of more than 700 patients have suggested that plasma exchange, combined with IV immunoglobulin (IVIG) and/or rituximab, but sometimes antithymocyte globulin, may reverse 55% to 100% of such rejection episodes.[7]

p0200 There is no convincing evidence that plasma exchange has any role in the treatment of chronic rejection.

Anti–Human Leukocyte Antigen Antibodies

s0130

p0205 Highly sensitized patients with preformed anti-HLA antibodies have been treated before and after transplantation with plasma exchange or immunoadsorption to reduce cytotoxic antibody levels, often with high-dose IVIG.[7] Patients usually received intensive immunoadsorption or plasma exchange before transplantation to ensure a current negative crossmatch immediately before transplantation; some received longer-term immunoadsorption or plasma exchange in combination with immunosuppressive therapies in the months before transplantation. Most recent studies have shown that donor-specific antibody titers of less than 1 to 32 are often depleted completely with preoperative plasma exchange, allowing successful kidney transplantation. Such patients have an increased risk for antibody-mediated rejection—approximately 40%—but despite this, 90% have 1-year graft survival.

ABO-Incompatible Kidney Transplantation

s0135

p0210 Plasma exchange is widely used to remove natural anti-A or anti-B blood group antibodies from the recipient before living donor transplantation from an ABO-incompatible donor. Various protocols are in use, but all rely on depletion of specific antibody over 2 to 5 days before transplantation by exchanging a single plasma volume for human albumin solution (in addition to routine immunosuppression, sometimes including rituximab and IVIG). Plasma exchange is sometimes continued for one or two sessions after transplantation or if antibody-mediated rejection occurs.[23] One-year graft survival rates of over 90% have been reported with such protocols, and although rejection episodes are more common than in ABO-compatible transplants, overall graft survival is similar. Subsequent return of ABO antibodies in the weeks after the kidney transplant does not usually cause rejection (a process termed accommodation and which is not fully explained).

Patients with increasingly high antibody titers are being treated in this way. Immunoadsorption using synthetic A- or B-oligosaccharide epitopes linked to Sepharose has been developed, which specifically remove anti-A or anti-B antibodies, but any clinical benefit remains uncertain and the costs are high.

s0140 ## Recurrent Focal Segmental Glomerulosclerosis

p0215 Plasma exchange, double-filtration plasma exchange, and protein A immunoadsorption have been used to treat nephrotic syndrome after transplantation in patients with recurrent FSGS.[7,24,25] An incompletely defined circulating factor causing increased permeability of glomerular capillaries can be found in most patients with recurrent FSGS. There are no controlled trials of plasma treatments in recurrent FSGS, and most series are small. A meta-analysis and systematic review of 77 case reports including 378 patients demonstrated an overall remission rate of 71%, with 46.8% achieving a complete remission after plasma exchange.[25] The study suggested that those with a more rapid relapse after transplantation and lower proteinuria were more likely to respond, with no difference between deceased and living donors. Patients received a median of 12 plasma exchange sessions. All three apheresis modalities have been used prophylactically in patients deemed to be at high risk for recurrence, with variable success. Intriguingly, lipoprotein apheresis (LDL-A) has been shown in small case series to induce remission of proteinuria in both primary and recurrent FSGS, via unknown mechanisms. LDL absorption occurs using dextran sulfate cellulose columns which absorb and remove LDL, VLDL, and lipoprotein (a) from plasma. Treatments are undertaken weekly for 6 to 12 weeks, and in very small and selected series achieve remission rates of approximately 50%.[26]

Recommendations s0145

We recommend plasma exchange for patients with recurrent FSGS, started early, initially daily for 7 to 10 days. If proteinuria is successfully reversed, this may need to be continued less frequently for several months. Management of recurrent FSGS is discussed further in Chapter 113 We recommend plasma exchange for acute antibody-mediated rejection together with enhanced immunosuppression. p0220

SELF-ASSESSMENT QUESTIONS

o0010 1. A patient with anti–GBM disease, serum creatinine 250 μmol/L, and pulmonary hemorrhage is being treated with plasma exchange and immunosuppression. Which complication can occur as a direct result of the plasma exchange?

o0015 **A.** Hypernatremia
o0020 **B.** Hyperviscosity
o0025 **C.** Hypocalcemia
o0030 **D.** Pulmonary embolism
o0035 **E.** Thrombocytosis

o0040 2. A 52-year-old woman presented with acute kidney injury and evidence of hemolysis and thrombocytopenia. The results of investigations showed:

u0010 • Hemoglobin: 86 g/L (115–165)
u0015 • White blood cell count: 4.2×10^9/L (4.0–11.0)
u0020 • Platelet count: 35×10^9/L (150–400)
u0025 • Serum creatinine: 238 μmol/L (60–110)

The results of remaining investigations are awaited. Which one of these diagnoses should lead to urgent initiation of plasma exchange? u0030

A. Atypical HUS o0045
B. Infection-associated HUS o0050
C. Myeloma o0055
D. Scleroderma renal crisis o0060
E. Systemic lupus o0065

3. A 42-year-old man received a cadaveric kidney transplant under standard immunosuppression. Six weeks later, his kidney function deteriorated, an ultrasound scan was normal, and a kidney biopsy was performed. Which finding might lead to initiation of plasma exchange? o0070

A. Antibody-mediated rejection o0075
B. $CD4^+$ staining on the biopsy o0080
C. Cyclosporine-induced microangiopathy o0085
D. Recurrent membranous nephropathy o0090
E. T-cell–mediated cellular rejection o0095

Immunologic Principles in Kidney Transplantation

Orhan Efe, Karl L. Womer, Leonardo V. Riella

s0010 ## INTRODUCTION

p0010 In 1954, Joseph Murray performed the first successful human kidney transplant between two identical twins. For decades now, kidney transplantation has been the standard of care for kidney failure patients. Maintenance of intact allograft function requires immunosuppression or immune tolerance in genetically nonidentical individuals. Thus, understanding of the immunologic principles remains cardinal in the management of kidney transplant patients (see Box 105.1 for graft terminology).

p0015 Protection against nonself antigens constitutes a paramount function of the immune system. After encountering a foreign antigen, the innate immune system responds by inducing antigen-nonspecific mechanisms such as phagocytosis and cytokine release. Afterwards, antigen-presenting cells (APC) of the innate immune system carry nonself peptides to T lymphocytes in the peripheral lymphoid organs to activate the adaptive immunity. B lymphocytes capture circulating foreign antigens through their B-cell receptors. Consequently, activation of T and B lymphocytes initiate antigen-specific responses that ultimately lead to direct cellular killing and antibody secretion, respectively.

p0020 Similar cascades of events provoke allorecognition and allograft rejection in transplant patients. Recipient's naive T and B cells constitute a diverse repertoire of receptors for an enormous number of potential foreign antigens, including mismatched donor human leukocyte antigens (HLAs). Recognition of mismatched antigens instigates an immune response against the graft parenchyma and the vasculature, leading to allograft rejection (Fig. 105.1).

p0025 This chapter reviews the immunologic principles in kidney transplantation by dissecting the elements of the innate and the adaptive immune systems, the role of HLA in transplantation, and the pathophysiology of allorecognition and transplant rejection.

s0015 ## INNATE IMMUNE SYSTEM

p0030 Innate immunity is the frontline defense of the immune system that is activated by the entrance of foreign antigens such as microorganisms and tissue injury. Innate immunity occurs rapidly, with limited specificity and without memory. Innate responses are driven by cellular elements such as neutrophils, macrophages, dendritic cells (DCs), and natural killer (NK) cells, and by molecular components, such as pathogen-associated pattern recognition receptors (PRRs), complement proteins, and cytokines.

p0035 The innate response to an insult starts with local chemical signals. Invasion of a microorganism leads to leaking of certain microbial structures called pathogen-associated molecular patterns (PAMRP), such as lipoproteins and lipopolysaccharides. Alternatively, sterile tissue damage, such as because of ischemia, leads to release of endogenous molecules termed damage-associated molecular patterns (DAMP), such as adenosine triphosphate (ATP), calcium, uric acid, and DNA. PRRs of the innate system cells then recognize these molecular signals and their activation induces a cascade of events: (1) cytokine release for chemotaxis, (2) labeling of infected or damaged cells (opsonization), and (3) direct cellular killing. Toll-like receptors (TLRs) are the most well-known PRRs, which involve a family of receptors against microbial epitopes including bacteria, virus, and fungi. Similar insults could also activate the complement system through binding of complement factors to microbial proteins (lectin pathway) or antigen-antibody complexes (classical and alternative pathways) that ultimately provoke chemotaxis (by releasing C3a and C5a) and cell death (by terminal complex formation; C5b-9). Overall, these signals alert the immune system to recruit and activate its defense mechanisms.

p0040 During donor organ procurement and transplantation, acute ischemia and reperfusion of allograft induce tissue damage and endothelial cell activation by sparking free radicals and inducing apoptosis, which is known as *ischemia/reperfusion injury* (IRI). DAMPs released from damaged graft cells activate PRRs on innate immune cells, resulting in the secretion of cytokines, such as tumor necrosis factor (TNF), type I interferons, chemokines, interleukin (IL)-1, and IL-6.[1] Neutrophils are the prime cells that mediate microvascular plugging and local tissue destruction in IRI. In the next phase, monocyte/macrophage infiltration contributes to the extension of early injury and to repair.[2] The complement system fixation could occur through activation of classical, alternative, and/or lectin pathway during IRI. Donor-derived APCs migrate to recipient lymphoid tissue to activate lymphocytes. Ultimate parenchymal and vascular injury along with tissue edema contributes to *delayed graft function.* These events may also trigger adaptive, or antigen-specific, immune responses that can induce allograft rejection and negatively affect long-term graft survival.

Adaptive Immune System

s0020 p0045 B and T lymphocytes and their products, including immunoglobulins and cytokines, make up the adaptive immunity. The adaptive immune response usually follows the innate system activation. After an immune insult, APCs deliver foreign antigens to *secondary lymph organs* (SLOs), such as lymph nodes and spleen, to present them to naive T cells. B cells

b0010

BOX 105.1 Graft Terminology

Autograft (autologous graft): A graft from one part of the body to another. Examples include skin and vascular grafts, such as in extensive burn or coronary bypass surgery. No rejection occurs.

Isograft (isogenic or syngeneic graft): A graft from one member of a species to a genetically identical member of the same species. Examples include grafts between identical twins and between members of the same inbred rodent strain. No rejection typically occurs.

c0105

Allograft (allogeneic graft): A graft between nonidentical members of the same species. Examples include grafts between unrelated or related nonidentical humans and between members of different inbred rodent strains. Rejection occurs primarily by lymphocytes reactive to alloantigens on the graft (i.e., alloresponse).

Xenografts (xenogeneic grafts): A graft between members of different species. Examples include pig or baboon to human and rat to mouse. Rejection occurs by lymphocytes reactive to xenoantigen on the graft (i.e., xenoresponse).

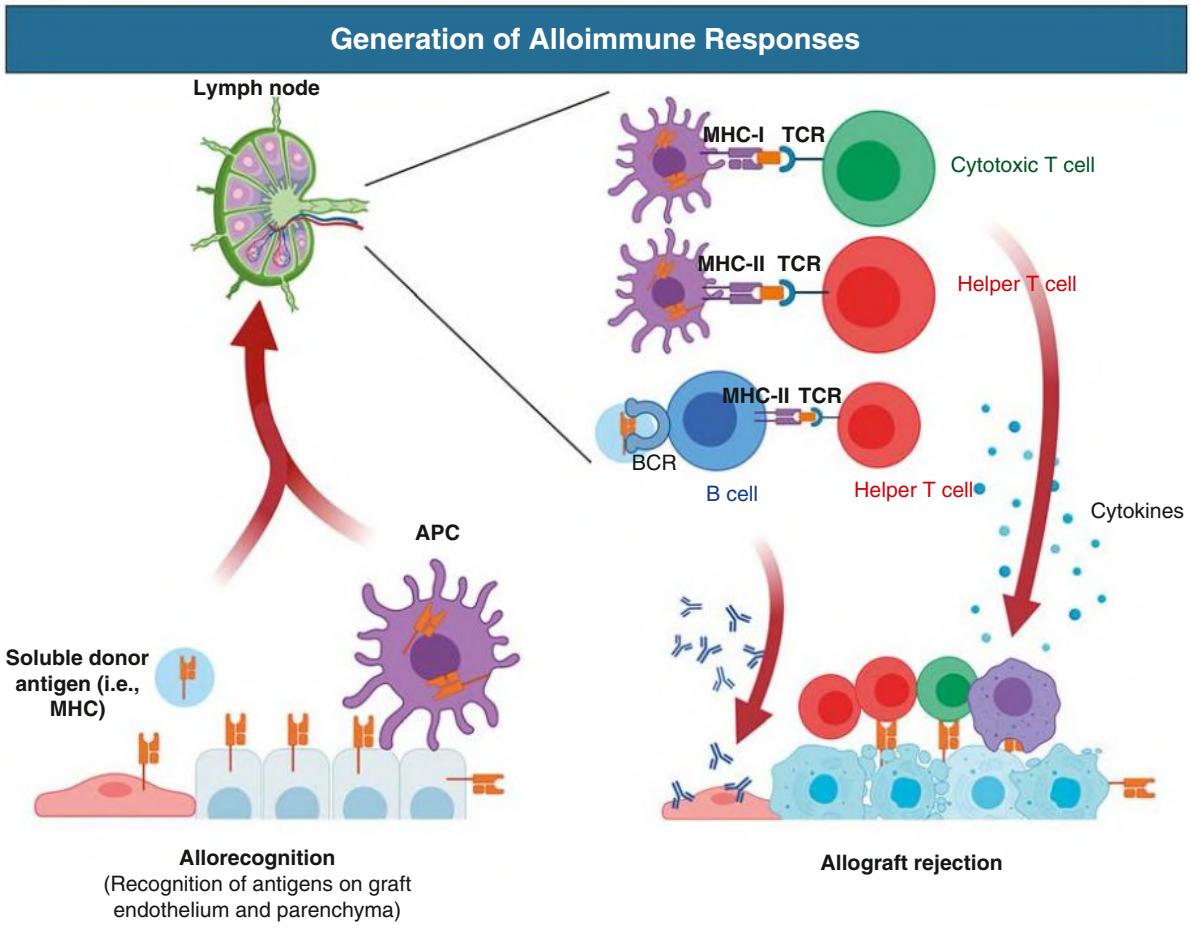
bind circulating soluble antigens through their B-cell receptor (BCR). Each one of the B and T lymphocyte clones is responsive to only a specific foreign antigen because of the selectivity of their receptors. Activation of B and T cells leads to the development of antigen-specific *memory clones* in the SLOs, which enables a more rapid and robust response during repetitive exposure to the same antigen. Activated *effector T cells* emigrate into the inflamed tissue and respond by direct cellular killing ($CD8^+$ cells) and cytokine release ($CD4^+$ cells). B cells respond by producing immunoglobulins against foreign antigens and releasing cytokines in the SLOs and rarely occupy the tissue parenchyma. These antigen-specific responses play a cardinal role during allograft rejection by recognition of donor's mismatched antigens.

Resolution of Inflammation

s0025

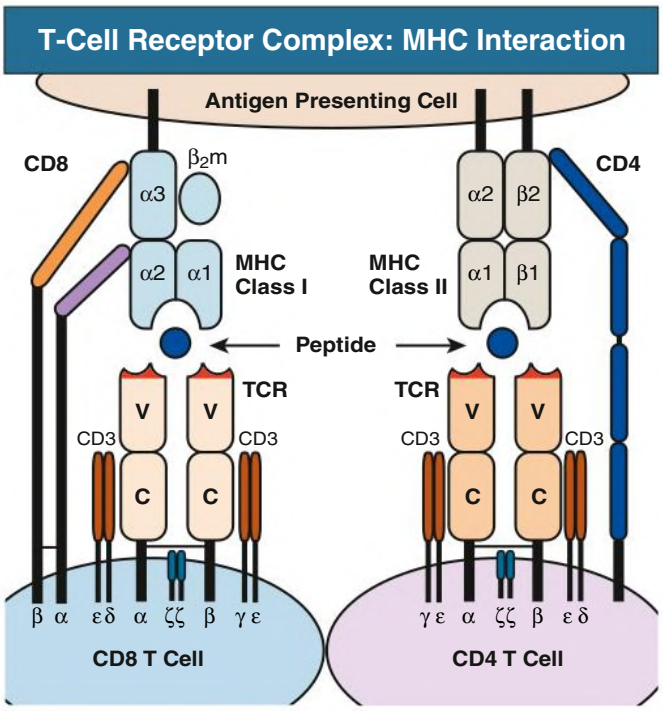
p0050

After the source of antigen is destroyed, both innate and adaptive immune cells help abrogate the inflammation. When activated, certain TLRs concurrently silence certain genes to create a negative feedback loop. Neutrophils and eosinophils catabolize the inflammatory



f0010

Fig. 105.1 Generation of Alloimmune Responses. Immunologic responses after kidney transplantation represent a series of well-defined stages that result in rejection of the allograft in the absence of exogenous immunosuppression. Injury to allograft tissue such as because of ischemia/reperfusion injury induces innate (antigen-nonspecific) immune responses, which recruit inflammatory cells and initiate adaptive (antigen-specific) immune responses. Donor major histocompatibility complex (MHC) and/or minor proteins that are revealed during tissue injury are taken up by antigen-presenting cells (APCs) of donor (direct pathway) or recipient (indirect pathway) origin. Then, APCs migrate to secondary lymphoid organs (SLO), where they present alloantigen to T cells through MHC structures on their cell surface. After T-cell receptor (TCR) signaling and appropriate costimulation, T cells become activated to produce large amounts of cytokine and undergo clonal expansion. CD4 T cells provide help to B cells, CD8 T cells, and macrophages for the production of alloantibody, cellular cytotoxicity, and delayed-type hypersensitivity responses, respectively. These effector functions result in destruction of the graft by acute rejection, which may be T-cell and/or antibody mediated. *BCR,* B-cell receptor; *TCR,* T-cell receptor.



f0015 **Fig. 105.2 T-Cell Receptor (TCR) Complex: Major Histocompatibility Complex (MHC) Interaction.** The formation of a stable immunologic synapse between T cells and antigen-presenting cells is crucial for an effective T-cell activation. Each TCR consists of an α and β chain linked by a disulfide bond. The α:β heterodimers are similar in structure to the Fab fragment of immunoglobulin molecules (see Fig. 105.4), including variable *(V)* and constant *(C)* regions. Diversity in the T-cell repertoire is encoded in the V domains of the α and β chains in three complementarity-determining regions that form the antigen-binding site at the end of the TCR *(highlighted in red)*. CD8 binds to class I MHC molecule on antigen-presenting cells (APCs), whereas CD4 binds to class II MHC molecule on APCs. Triggering of the TCR by antigen initiates a signaling cascade started by the signaling complex made up of CD3 γ, ε, and δ chains and the ζ chain homodimer.

mediators such as eicosanoids and cytokines. DCs switch cytokine production from IL-12 to IL-10, favoring the generation of regulatory mechanisms that suppress the function of effector T cells. In the absence of continued cytokine production, T cells lack the necessary growth factors and undergo passive cell death. Activated T cells also undergo activation-induced cell death by the expression of Fas and FasL on their surface, leading to apoptosis.[3] Certain regulatory T and B cells also produce antiinflammatory cytokines, such as IL-10 and TGF-β, that suppress immunity.[4] These mechanisms of immune regulation are crucial for avoiding overactivation and persistence of the immune response once the threat is gone.

s0030 ## CELLS OF THE IMMUNE SYSTEM

s0035 ### T Lymphocytes

p0055 As a cellular component of adaptive immunity, T cells have a pivotal role in orchestrating the antigen-specific responses by exerting regulatory and effector functions. During T-cell ontogeny in embryogenesis, multilineage bone marrow precursors migrate to the thymus. In the thymus, T-cell receptor (TCR) genes undergo rearrangement to ensure that a diverse repertoire of T cells exists to respond to the enormous number of potential foreign antigens, including foreign HLAs, which play a crucial role in alloresponses.[5] The mature T-cell repertoire is determined in the thymus by two processes, positive and negative selection. *Positive selection* depends on a certain degree of antigen-specific T-cell affinity to self–major histocompatibility complex (MHC) molecules expressed on thymic cortical epithelial cells. This process ensures that mature T cells will interact effectively with self-MHC molecules. *Negative selection* occurs by deletion of T cells with excessively high affinity for self-peptide and MHC, thereby preventing release of high-affinity T cells with autoimmune potential.

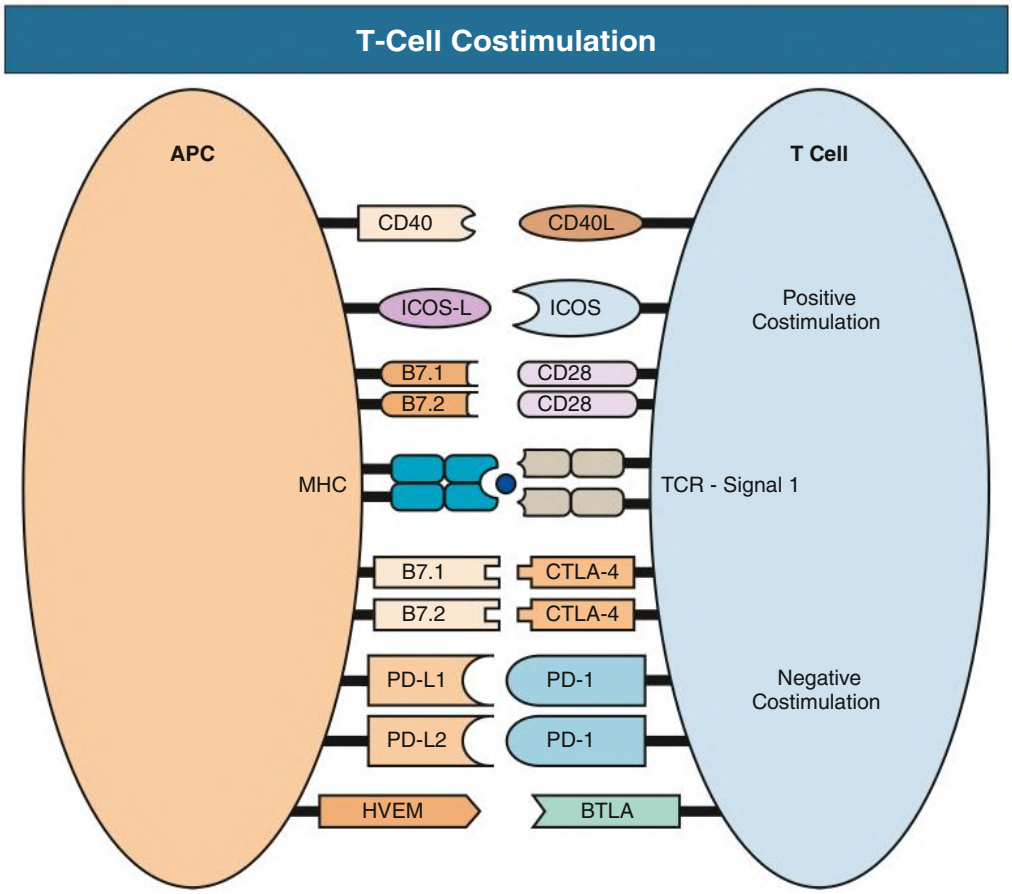
p0060 Mature T cells expressing their clone-specific TCRs exit the thymus as either CD4 or CD8 T cells. The TCRs of CD4 T cells (also called *T helper cells*) are selected to interact with class II MHC molecules, whereas the TCRs of CD8 T cells interact with class I MHC molecules. Each TCR consists of two different polypeptide chains, termed the TCR α and β chains. In the functional receptor complex, TCR α:β heterodimers are associated with a complex of four other signaling chains (two ε, one δ, one γ) collectively called CD3 (Fig. 105.2). Downstream to TCR, calcineurin acts as an effector through its phosphatase activity by activating NFAT, a transcription factor, leading to IL-2 secretion. This critical molecule for the T-cell activation serves as a target for calcineurin inhibitors in transplantation.

s0040 ### T-Cell Stimulation

p0065 Stimulation of T cells are mediated by APCs, which require receptor-ligand interactions and cytokine signaling. In contrast to the BCRs, TCRs do not recognize antigen in its native state but instead recognize a composite ligand of a peptide bound to an MHC molecule. Engagement of the TCR with peptide-bound MHC of an APC is called signal 1. Signal 1, the antigen-specific signal, is effective only in the presence of costimulatory signals, which is termed as signal 2. Costimulation serves as a checkpoint to prevent the activation of self-reactive T cells that escaped negative selection in the thymus. Antigen binding to the TCR in the absence of costimulation fails to activate the T cell and also leads to anergy, in which T cells become refractory to subsequent activation or even undergo apoptosis (programmed cell death). Thus, costimulation removes this inhibition and determines whether a T-cell will proceed with clonal expansion and the development of effector functions. Costimulatory molecules can provide both positive and negative signals to T cells (Fig. 105.3). It is the integration of both positive and negative costimulatory signals during and after initial T-cell activation, dictated by their temporal and spatial expression patterns, that ultimately determines the fate and functional status of the T-cell response.[6] For an effective and strong T-cell stimulation, cytokine secretion is also required, serving as the signal 3. IL-2 is a cardinal cytokine for T-cell activation and proliferation, by acting in an autocrine or paracrine fashion. IL-2 activation, in turn, triggers another pathway mediated in part through the protein mammalian target of rapamycin (mTOR). New proteins are then translated, allowing the cell to progress from the G1 phase to the S phase of the cell cycle, resulting in proliferation. Table 105.1 lists selected cytokines involved in allograft rejection, their sources, and their effects.

s0045 ### Memory T Cell Formation

p0070 Encountering a new foreign antigen transforms part of the naive T cells into memory T cells in SLOs. The principle of immunologic memory is that the immune response to a previously encountered antigen is swifter and more effective than the initial response. Furthermore, there is an increase in antigen-specific T-cell frequency after exposure to a given antigen. *Effector memory T cells* are specialized for quickly entering the inflamed tissues because they can rapidly mature into effector T cells and secrete larger amounts of cytokines independent of costimulatory signals. *Central memory T cells* likely remain in the SLOs and do not produce as much cytokine release.[7] Memory cells are believed to persist after an initial immune



f0020

Fig. 105.3 T-Cell Costimulation. Binding of the TCR:CD3 complex to peptide:MHC on antigen-presenting cells (APCs) delivers a signal that can induce the clonal expansion of naive T cells only when the appropriate costimulatory signal is delivered (Signal 2). CD28 and its ligands, B7.1 (CD80) and B7.2 (CD86), are the best-characterized costimulatory molecules that induce clonal expansion of naive CD4 T helper cells. Once activated, T cells express increased levels of CTLA-4 (CD152). CTLA-4 has an affinity 10 to 20 times greater than that of CD28 for B7 molecules and thus binds most or all of the B7 molecules, effectively shutting down the proliferative phase of the response. B- and T-lymphocyte attenuator (BTLA) and programmed death-1 (PD-1) are two other coinhibitory molecules on T cells. Activated T cells express proteins that contribute to sustaining or modifying the costimulatory signal to drive clonal expansion and differentiation. The inducible costimulatory molecule (ICOS) is a CD28 homologue, but unlike CD28 is not constitutively expressed on naive T cells. Rather, ICOS is induced only after T-cell activation. Engagement of ICOS by B7H enhances T-cell proliferation, cytokine production, and survival. Binding of CD40 by CD40L, which is upregulated by CD28 signaling, transmits activating signals to the T cell but also activates the APCs to secrete proinflammatory molecules and to express B7 molecules, thus stimulating further T-cell proliferation. *HVEM,* Member of the tumor necrosis factor receptor superfamily; *MHC,* Major histocompatibility complex; *TCR,* T-cell receptor.

response through expression of the antiapoptotic genes *Bcl-2* and *Bcl-xL,* which are induced primarily by IL-2 and CD28 stimulation. Long-term memory cell survival is likely a function of periodic interactions with self-MHC:peptide complexes on APCs. Memory T cells constitute an important risk factor for allograft rejection in patients with history of HLA sensitization through pregnancy, blood transfusion, or prior transplant.

s0050

CD4 T Cells

p0075 CD4 T cells have both effector and regulatory functions, mostly through secreting specific cytokines. After prolonged stimulation, CD4 T cells express their signature cytokines, probably depending on the local environment, nature of the antigen, and type and activation status of the APC. These different T helper (Th) subsets, each with unique transcription factor and cytokine signatures, are referred to as Th1, Th2, Th17, and Tfh (follicular help) populations.

p0080 The Th1 clones produce IL-2, IFN-γ, and lymphotoxin, which are growth and maturation factors for cytotoxic T lymphocytes (especially IL-2) and macrophages (particularly IFN-γ). T helper 17 (Th17) cells produce proinflammatory cytokines, including IL-17, IL-21, and IL-22.[8] Th1, in particular, plays a dominant role in acute cellular rejection. Th2 clones secrete TGF-β, IL-4, IL-5, and IL-10, which facilitate B cell activation and class switching. Th cells are found in lymph nodes and are also important for B cell maturation. Thus, these two cell types contribute to antibody-mediated rejection by facilitating antibody production.

p0085 In addition to T cells that promote immune responses, there are CD4 T-cell subpopulations that control immune responses termed *regulatory T cells* (Tregs). Tregs are responsible from peripheral tolerance by suppressing autoimmunity and contribute to the resolution of inflammation by secreting inhibitory cytokines such as TGF-B, IL-10, and IL-35. The most well-characterized Treg is known for its

t0010 **TABLE 105.1 Cytokines Involved in Allograft Rejection**

Cytokine	Source	Biologic Activity
IL-1	Macrophages, DCs, ECs, NK cells	Proinflammatory, adhesion molecule expression on ECs, NK cell function
IL-2	Activated T cells	T-cell proliferation, CTL and NK cell function, Treg maintenance, immunoglobulin production by B cells, AICD of activated T cells
IL-4	Activated T cells	Activated T and B cell proliferation, Th2 differentiation, allergic responses, MHC II upregulation on B cells
IL-6	T cells, macrophages, ECs	Proinflammatory and anti-inflammatory, acute-phase responses
IL-10	T cells, Tregs, Bregs, macrophages, DCs	Anti-inflammatory, suppression of APC function, NK cell inhibition
IL-12	Macrophages, DCs	Proinflammatory, Th1 differentiation, NK cell and CTL activity, IFN-γ and TNF-α production by NK and T cells
IL-15	Epithelial cells, stromal cells, macrophages	NK cell proliferation, T-cell proliferation, memory T-cell survival
IL-17	T cells	Proinflammatory and allergic responses, Th17 function, cytokine production from many cell types
IFN-γ	Activated Th1 cells, CTLs, DCs, NK cells	MHC expression by EC, macrophage function, Th1 differentiation, Th2 suppression, adhesion and binding of T cells to ECs, NK cell activity
TGF-β	T and B cells, Tregs, Bregs, macrophages, platelets	Anti-inflammatory, wound healing, fibrosis
TNF-α	Macrophages, T and B cells, ECs, NK cells	Proinflammatory, acute phase responses, cytotoxicity

AICD, Activation-induced cell death; *Breg,* regulatory B cells; *CTL,* cytotoxic T lymphocytes; *DC,* dendritic cells; *EC,* endothelial cells; *IFN-γ,* interferon-γ; *IL,* interleukin; *NK,* natural killer; *TGF-β,* transforming growth factor-β; *Th,* T helper (cell); *TNF-α,* tumor necrosis factor-α; *Treg,* regulatory T cells.

high expression of Foxp3 and IL-2 receptor alpha chain, CD25. Treg-expanding strategies, such as low-dose IL-2 or infusion of ex vivo expanded Tregs, have shown promising results in patients with autoimmune disorders and in transplantation.[9–11]

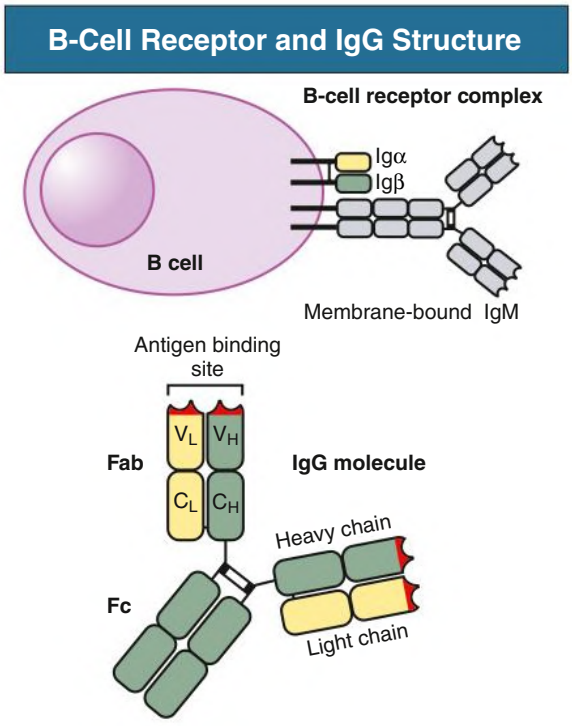
s0055 ## CD8 T Cells

p0090 CD8 T cells are effector cells with functions of direct cellular killing and they are called *cytotoxic T lymphocytes* (CTLs) in their activated form. CTLs possess two mechanisms to kill target cells that require cell-to-cell contact.[12] First, they release perforin and granzyme B from specialized lytic granules. The granzyme B–perforin complex enters the cell through the mannose 6-phosphate receptor, and, after internalization, perforin allows granzyme B to enter the cell by pore formation on the vesicle surface to induce programmed cell death through apoptosis.[13] The second mechanism is mediated by Fas/Fas ligand (FasL) interactions. Fas (CD95) on the target cell surface is activated by FasL on CTLs to induce apoptosis. Both pathways induce apoptosis through activation of the caspase cascade in target cells.[14] CD8 CTLs also release several cytokines that exert direct cytotoxic effects, including IFN-γ, TNF-α, and TNF-β.[15] Current studies delineated the presence of CD4 CTLs that own similar cytolytic features to CD8 CTLs.[16]

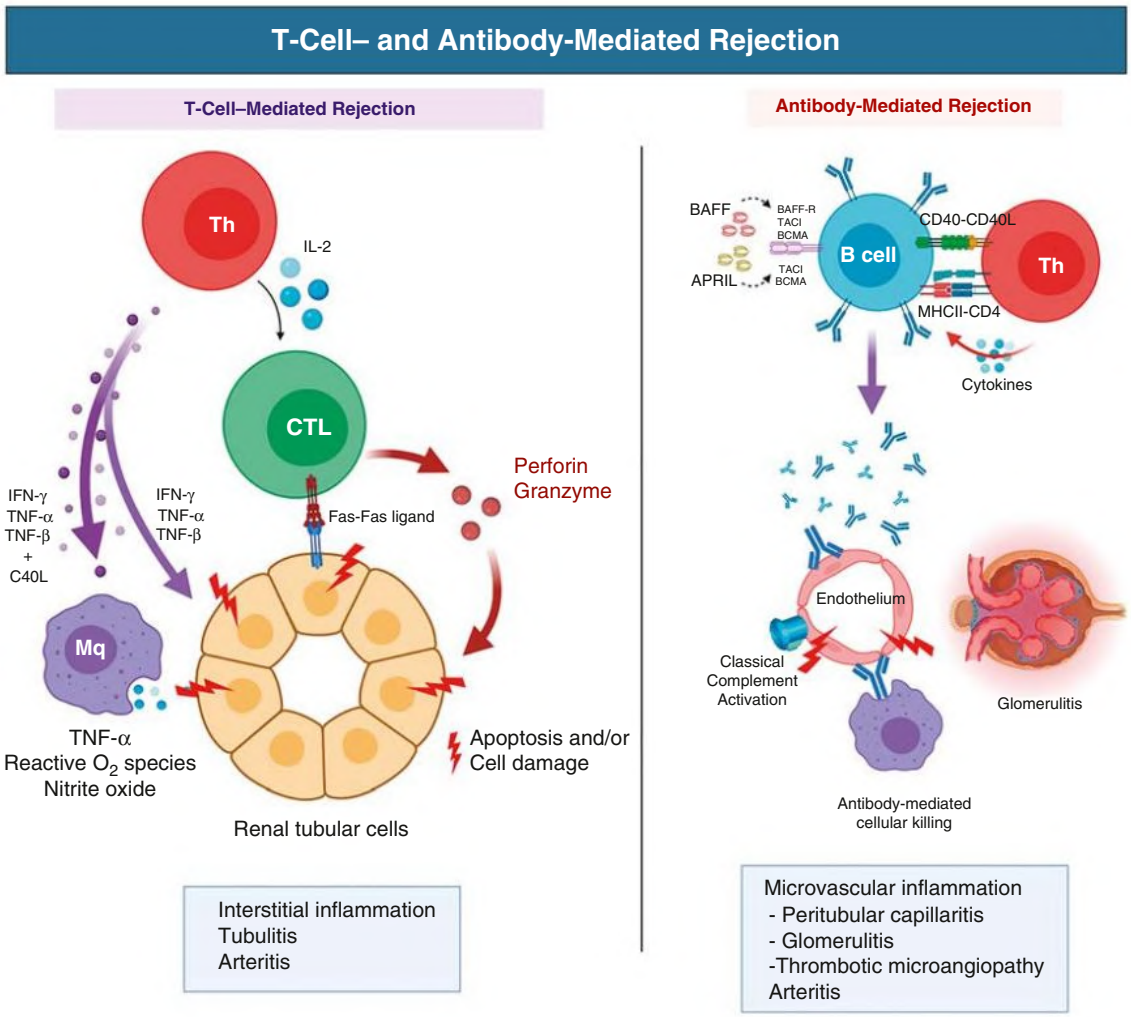
s0060 ## B Lymphocytes

p0095 B cells protect extracellular spaces of the body by producing antibodies and contribute to antibody-mediated allograft rejection. B-cell development starts in the primary lymphoid organs including fetal liver (until birth) and bone marrow from common lymphoid progenitor cells. From the very early stages of development, B cells constitute a BCR, which contains an antigen specific immunoglobulin (Ig)M and/or IgD component and associated antigen nonspecific Ig-α and -β proteins (Fig. 105.4). In primary lymphoid organs, autoreactive B cells undergo either *receptor editing* to eliminate self-reactivity or *negative selection* by apoptosis.

p0100 Survivor naive B cells emigrate into SLOs where the majority die and the rest will switch into mature B cells to become either memory cells or plasma cells. In the SLOs, B cells continue to mature by *class switching* to produce IgA, IgE, or IgG apart from IgM and IgD and *somatic hypermutation* of variable domains of BCR to further increase their affinity to a given antigen. The first could occur either in a T-cell–dependent or independent manner that leads to differentiation into the short-lived plasma cells that remain in the SLOs. The latter only ensue in the presence of T helper cells in the germinal centers, which evolve higher affinity B cells into memory cells and plasma cells generating a long-lived humoral immunity. BAFF and APRIL, which are survival



f0025 **Fig. 105.4 B-Cell Receptor and Immunoglobulin G (IgG) Structure.** B-cell surface membrane–bound immunoglobulin M (IgM) associated with antigen-nonspecific signaling molecules, Igα and Igβ, forms the B-cell receptor complex. The IgG molecule is made up of four polypeptide chains, involving two identical light (L) chains *(yellow)* and two identical heavy (H) chains *(green)*. Each of the four chains has a variable *(V)* region at its amino terminus (Fab portion), which contributes to the antigen-binding site, and a constant *(C)* region (Fc portion), which determines the isotype. The V domains contain hypervariable regions that determine antigen specificity called complementarity-determining regions (highlighted in *red*).



f0030

Fig. 105.5 T-Cell–Mediated and Antibody-Mediated Rejection. CD4 T cells induce epithelial and endothelial cell damage directly by secretion of cytokines but also indirectly by activation of cytotoxic T lymphocytes (CTLs) and macrophages. CTLs may cause apoptosis by releasing cytolytic granules containing granzymes and perforin or by exposure of Fas ligand (FasL) on the T-cell surface. Macrophages induce local tissue damage through secretion of cytokines, oxygen species, and nitric oxide (delayed-type hypersensitivity response). CD4 T cells secrete cytokines, which induce upregulation of major histocompatibility complex (MHC) molecules on epithelial and endothelial cells. CD4 T cells also provide help to B cells for production of alloantibody by engagement of CD40L and production of cytokines. BAFF and APRIL induce B-cell development and survival. Antigraft antibody is usually directed at MHC molecules, and it leads to injury either through the activation of the complement pathway or by recruiting innate cytotoxic cells through the Fc receptor binding to the antibody. Damaged endothelial cells secrete factors that activate coagulation systems and result in formation of microthrombi. Exposure of tubular cells and glomerular capillary loops to alloimmunity over time results in interstitial fibrosis, tubular atrophy, and glomerulosclerosis. *BAFF-R,* BAFF receptor; *BCMA,* B-cell maturating antigen; *CTL,* cytotoxic T lymphocytes; *IFN,* interferon; *Mq,* macrophages; *TACI,* T cell activator and calcium modulating ligand interactor; *TNF,* tumor necrosis factor; *Th,* T helper cell.

stimulating proteins for B cells, contribute to optimal development of B cells (Fig. 105.5). After their generation, plasma cells locate into bone marrow where a niche for longevity exists.

p0105 B cells express CD-19 and CD-20 starting from pro-B cell and pre-B cell phase, respectively, up to memory B cells. These markers are lost during differentiation into plasma cells and replaced by high expression of CD-38. Given differential expression of these surface markers, rituximab (a monoclonal antibody against CD-20 used to treat antibody-mediated rejection) targets a broad range of B cell stages but excludes primitive B cells and plasma cells.

p0110 There are three effector functions of B-lymphocytes: (1) antibody production, (2) antigen presentation to T cells, and (3) cytokine production. Immunoglobulins function in several different ways once bound to their target antigen: fixation of complement, opsonization for phagocytosis by Fc receptor (FcR)-positive cells (including B cells, NK cells, macrophages, and neutrophils), opsonization for cell lysis by the cells capable of antibody-dependent cellular cytotoxicity (NK cells, macrophages, neutrophils, and eosinophils), and induction of eosinophil degranulation. The five major classes of antibodies are IgM, IgD, IgG, IgA, and IgE. IgG is by far the most abundant immunoglobulin. The IgG molecule is made up of two identical light (L) and two identical heavy (H) chains that form a flexible Y-shaped structure (see Fig. 105.4). Variable (V) regions of each of the four chains contain the antigen specific part (Fab portion), and constant (C) regions determine

f0035

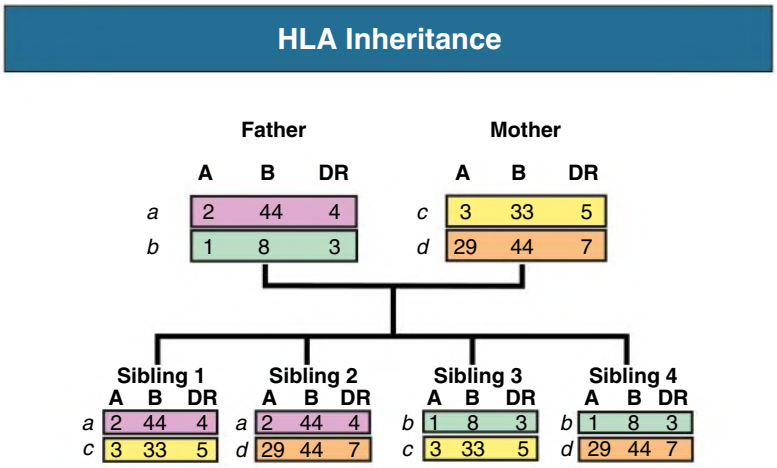


Fig. 105.6 Example of Human Leukocyte Antigen (HLA) Inheritance. HLA antigens are inherited and expressed in a mendelian codominant fashion, whereby one copy of each HLA gene called a haplotype (e.g., *a, b, c, d*) is inherited from each parent. Efforts are made to match both class I (HLA-A and -B) and class II (HLA-DR) antigens.

the isotype (Fc portion). The V regions of a given antibody contain hypervariable segments that determine antigen specificity by forming a surface complementary to the antigen referred to as *complementarity-determining regions* (CDRs).

s0065

ANTIGEN-PRESENTING CELLS

p0115 APCs are specialized cells with capability of activating T cells. DCs, macrophages, and B lymphocytes are considered "professional APCs," although DCs are the most potent. Professional APCs engulf target antigens by phagocytosis, migrate into T cell areas of lymphoid organs, and present processed antigen on MHC I molecule to CD8 T cells or on MHC II molecule to CD4 T cells (signal 1). As previously explained, costimulation and cytokine signals (signal 2 and 3) are also essential for a successful T-cell stimulation. In the allograft after transplantation, APCs (mostly DCs) of either donor or host origin take up the donor MHC proteins and present to recipient T cells.

p0120 Two most important APCs during transplant rejection are macrophages and DCs. *Macrophages* are recruited to the graft in response to proinflammatory cytokines, such as IL-1 and IL-6. Th1 and CD8 T cells activate macrophages by producing IFN-γ or binding of CD40L-CD40. As an effector function, macrophages mediate cytolysis by producing TNF-α, oxygen radicals, and nitric oxide. Activated macrophages also can produce IL-12, which directs the differentiation of activated naive CD4 T cells into Th1 effector cells. On the other hand, macrophage activation is inhibited by cytokines such as transforming growth factor-β (TGF-β) and IL-10, many of which are produced by Th2 and regulatory T and B cells. DCs are also part of the mononuclear phagocyte system. As an effector function, DCs release IL-12 and type I and III interferons to induce Th1 differentiation and CD8 T-cell activation.[17,18] Lastly, *local endothelium* and *parenchyma* could also serve as in situ APCs when they are activated.[19]

s0070

Natural Killer Cells

p0125 NK cells are a subset of peripheral lymphocytes that share developmental and functional features with CD8 T lymphocytes.[20] Unlike T or B cells, NK cells do not possess an antigen-specific cell surface receptor that is generated by gene recombination. Instead, NK cells use receptors that recognize the loss of HLA class I molecules on susceptible targets. Thus, NK cells can recognize when self-MHC class I is absent, the so-called "missing self," which triggers their activation. Peripheral NK cells are mature, do not require costimulation or differentiation as with T cells, and immediately release cytotoxic granules and inflammatory cytokines such as TNF-α and IFN-γ on detection of relevant targets. Given the strong cytolytic function and potential for autoreactivity, NK cell activity is tightly regulated. Mechanisms of activation include cytokines, binding of antibody to FcRs, and binding of ligands to activating receptors. In kidney transplantation, NK cells contribute to allograft rejection through antibody-mediated cytotoxicity in the presence of donor-specific antibodies (DSAs) and missing self-mechanism on the allograft cells with HLA class I mismatch.[21]

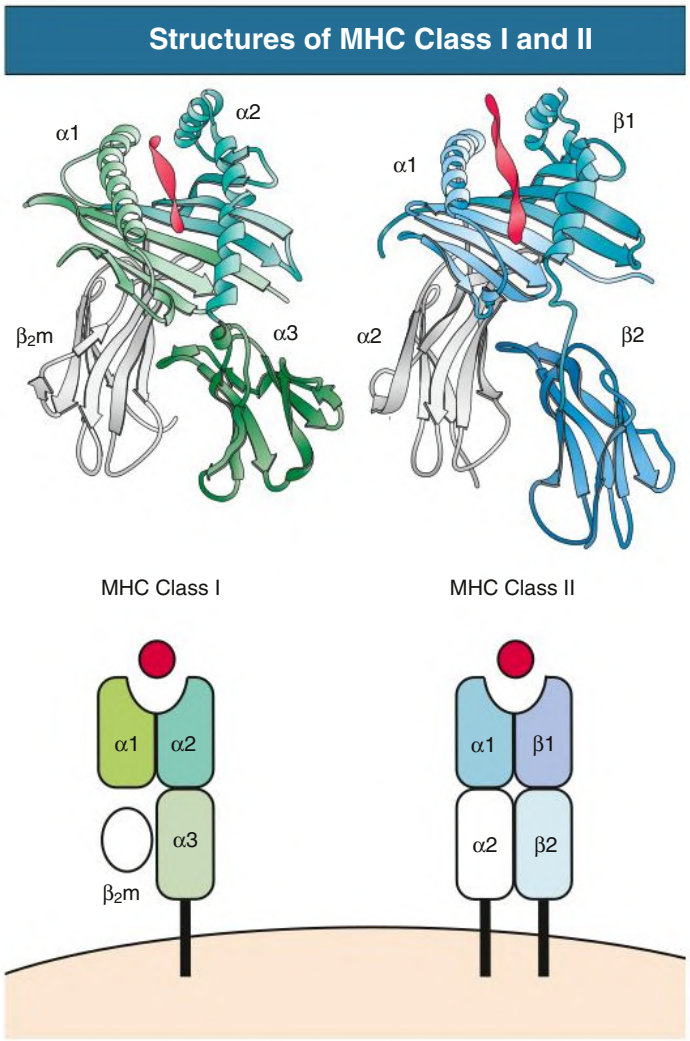
MAJOR HISTOCOMPATIBILITY COMPLEX AND ALLORECOGNITION

s0075

p0130 The MHC, which encodes HLAs, are the most polymorphic molecules in humans and are made up of closely linked series of genes at the short arm of chromosome 6. MHC genes are inherited in a mendelian codominant fashion (Fig. 105.6) and divided into three regions: class I, II, and III. Class I and II HLAs play a key role in antigen presentation and self-recognition. The key antigens encoded by class I MHC genes include HLA-A, -B, and -C, and the class II gene products include HLA-DP, -DQ, and -DR.

p0135 The class I and II proteins share structural homology but are functionally different[22] (Fig. 105.7). MHC I is designed to sample intracellular proteins to detect tumors or intracellular pathogens, such as virus and intracellular bacteria. It is expressed on all nucleated cells. MHC I–peptide complex is recognized by CD8 T cells, which leads to destruction of target cells. The class II MHC system is designed to sample extracellular proteins that have been taken up by APCs to present to CD4 T helper cells. Class II proteins are expressed by only limited cell types including "professional" APCs (DCs, B cells, macrophages, and Langerhans cells) and by activated parenchymal and endothelial cells. Importantly, both class I and II MHC expression are prompted on allograft cells by IFN-γ in synergy with other cytokines during transplant rejection, which leads to a sustained inflammation. Lastly, certain APCs employ *cross-presentation* by taking up, processing, and presenting extracellular antigen on their class I MHC molecules to CD8 T cells.[23] This mechanism is used for generation of immunity against tumors and viruses that do not infect APCs.

p0140 In transplantation, recipient T cells encounter alloantigen by either direct, semidirect, or indirect pathways of *allorecognition* depending on



f0040

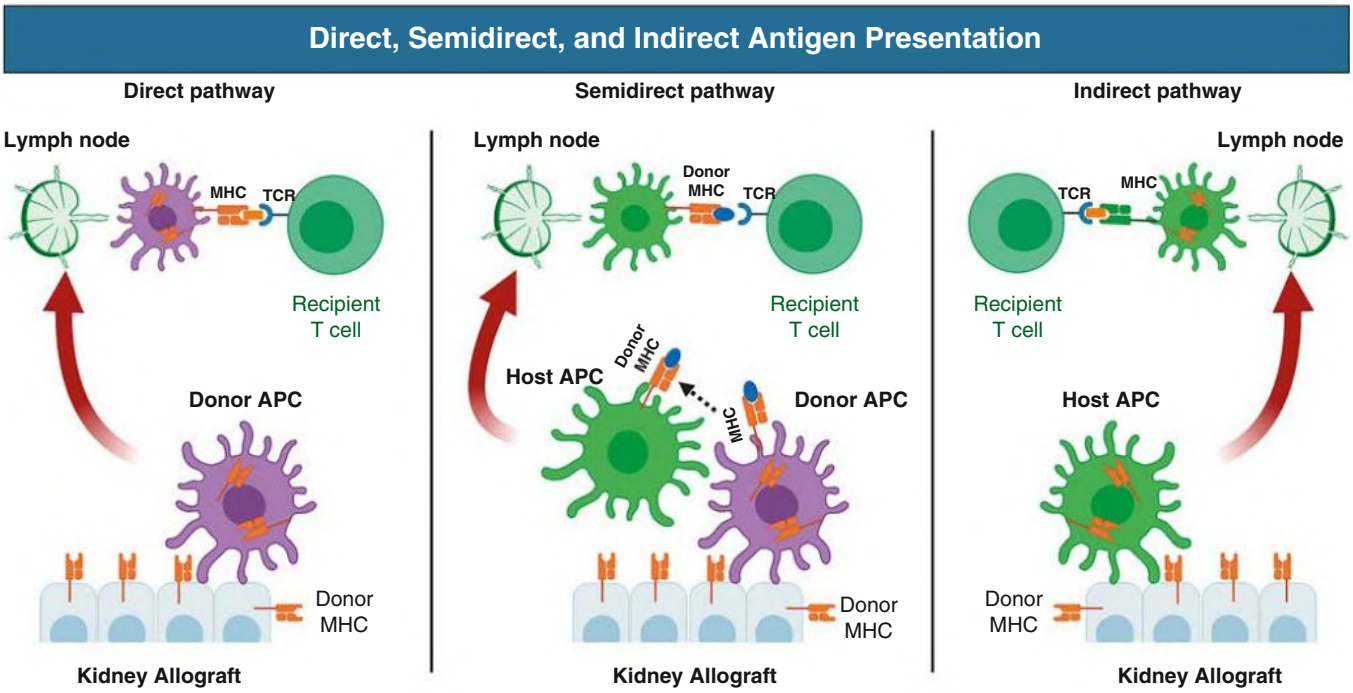
Fig. 105.7 Structures of Major Histocompatibility Complex (MHC) **Classes I and II.** MHC class I is composed of a heavy chain divided into α1, α2, and α3 domains noncovalently associated with β_2-microglobulin (β_2m). The α1 and α2 domains each form a long α helix and β sheet to make up the floor and walls of the peptide-binding groove (peptide indicated by *red ribbon*). MHC class II is a dimer composed of α and β chains. Each chain is divided into two domains, with α1 and β_1 domains forming the two α helices and β-pleated sheet that surround the peptide-binding groove.

recipient's or donor's APC involvement (Fig. 105.8). In the *direct pathway*, donor APCs present their own peptides, most importantly MHC proteins, on their intact MHCs to recipient T cells. The direct pathway may be more active early after transplantation, when a large number of donor APCs are present in the allograft. The direct pathway also occurs later when recipient T cells directly interact with intact donor MHC molecules on the surface of endothelium or parenchymal cells. The *indirect pathway* is the physiologic mechanism of foreign antigen recognition in which recipient APCs present donor antigens to recipient T cells.[24] Lastly, the *semidirect pathway* involves the transfer of intact donor MHC:peptide complexes from donor APCs or from the graft cells to the surface of recipient APCs to be delivered to recipient T cells, a process called *cross-dressing* or *cell nibbling*.[25]

s0080 ## Human Leukocyte Antigen Typing and Transplantation

p0145 MHC class I and II genes are highly polymorphic in the regions that encode the peptide-binding groove, leading to thousands of different HLA types (see www.ebi.ac.uk/imgt/hla).[26] Mismatched donor HLAs are regarded as foreign antigens by the recipient's immune system, which predisposes to allograft rejection. Originally, HLA typing was performed by mixing donor or recipient's lymphocytes with sera from multiparous women or persons who had received blood transfusions. Currently, HLA typing is performed by molecular biology techniques including polymerase chain reaction (PCR) sequencing or next-generation sequencing, which allows more precise analysis. Although complete allele matching between donor and recipient would minimize the risk of sensitization against donor kidney, this also reduces likelihood of receiving a transplant offer. Hence, studies compared impact of matching different HLA types on graft survival. Currently, HLA-A, -B, and -DR alleles are used in HLA-matching algorithms, but this could show variation between centers.[27,28]

p0150 In addition to HLA matching, the patient should be screened for preexisting anti-HLA antibodies (DSA), which are associated with antibody-mediated rejection and poor graft survival. Currently, single antigen bead assay is the preferred method for DSA testing. In this method, patient serum is added to multiple different HLA-coated beads. Binding of antibodies from patient's serum is detected with a secondary antibody. Potential recipient's antibody profile is used to



f0045

Fig. 105.8 Direct, Semidirect, and Indirect Antigen Presentation. In direct allorecognition, donor antigen (shown in *red*) is presented to recipient T cells as a peptide in the context of intact donor major histocompatibility complex (MHC) molecules on the surface of donor antigen-presenting cells (APCs). In semidirect allorecognition, donor APCs transfer their own peptide-MHC complexes to the surface of recipient APCs (without intracellular processing) that deliver them to recipient T cells. In indirect allorecognition, the donor antigen is processed by recipient APCs and presented as a peptide in the context of recipient MHC molecules.

determine *calculated panel-reactive antibody*, which gives the percentage of potentially positive-cross matches among the HLA types in a donor pool.[29] Defining the presence of specific anti-HLA antibodies may also allow us to perform a virtual crossmatch, which entails verifying the presence of any anti-HLA antibodies that may react against a specific donor HLA antigen. This approach could help exclude potential recipients who may have a positive cross-match test against a specific donor without actually performing the cross-match assay.

s0085

Non–Major Histocompatibility Antigens

p0155 Minor histocompatibility antigens are normal proteins that are polymorphic within a given species. Even when a transplant donor and recipient are identical with regard to MHC genes, amino acid differences in these minor proteins can lead to rejection. Minor antigens are encoded by a large number of chromosomes and are presented only as peptides in the context of recipient MHC (indirect allorecognition). Minor antigens are responsible for the need for immunosuppression after donation between HLA matched but nonidentical twin siblings. The prototypic minor histocompatibility antigen, the male or H-Y antigen, is derived from a group of proteins encoded on the Y chromosome. Alloresponses to this antigen are responsible for the rejection of male mouse skin grafts by otherwise identical female recipients and may explain observations of reduced long-term graft survival in human male-to-female donations. MHC I–related chain A (MICA) antigens are endothelial surface glycoproteins with functions related to innate immunity. Exposure to allogeneic MICA during transplantation was shown to elicit antibody formation.[30] ABO blood group glycolipids expressed on endothelial and red blood cells and angiotension-1 receptors are other notable non-MHC antigens.[31]

s0090

Allograft Rejection

p0160 Allograft rejection is defined as tissue injury produced by the effector mechanisms of the alloimmune response, leading to deterioration of graft function.[32] There are two main types of rejection: T-cell–mediated or cellular rejection (TCMR) and antibody-mediated rejection (AMR). Both types of rejection can be early or late, fulminant or indolent, and isolated or concomitant and can share pathologic features on biopsy.[1] Kidney allograft biopsies have been evaluated according to the Banff classification, which guides clinicians in treating the different allograft pathologies.[33]

p0165 Allograft rejection is caused by several cellular elements of the immune system, including T cells, B cells, plasma cells, macrophages, NK cells, and neutrophils. Although there are a variety of target cells in the graft, endothelial and tubular cells are particularly affected by these mediators. T cells serve as the main effectors and regulators of the alloimmune response, and macrophages serve as effectors but also aid in the removal of apoptotic cells. B cells and plasma cells serve in the production of alloantibodies, and neutrophils and NK cells may cause significant damage, particularly during AMR through antibody-mediated cell toxicity.[21,34]

s0095

Acute T-Cell–Mediated Rejection

p0170 Acute TCMR starts with the phagocytosis of donor antigens by either the donor or recipient's APCs, such as macrophages and DCs (see Fig. 105.8). Afterwards, APCs migrate into SLOs and activate naive or memory T cell clones, which then migrate into the allograft. Inflammation in the allograft microenvironment grow in time by chemotaxis of further macrophages and T cells. Although a small number of B cells may also be present in the TCMR infiltrate, these are likely recruited nonspecifically.[35] The first pathologic event in TCMR

is *interstitial inflammation,* and this is followed by T cell infiltration of the tubules, causing *tubulitis*. Thus, interstitial nephritis and tubulitis constitute two core features of TCMR (see Fig. 105.5). Similar inflammation can take place in the arteries causing *endarteritis* in a minority of cases.

p0175 Deterioration of kidney function during TCMR correlates with tubulitis and arterial inflammation (endothelialitis), which is less common. CTLs can kill target cells by release of cytotoxic molecules (perforin, granzyme B, and granulysin) or engagement of Fas on target cells by FasL. CD4 T-helper cells, especially Th1, release numerous cytokines that affect the alloimmune response. They stimulate macrophages to produce nitric oxide, reactive oxygen species, and TNF-α.[36] T-cell cytokines also act directly on parenchymal cells or endothelium. TNF-α and TNF-β exert local cytotoxic effects on graft endothelial cells and tubular cells through TNF receptors. IFN-γ, the prototypical Th1 cytokine, induces MHC class II expression on endothelium and MHC class I expression on vascular endothelial cells, epithelial cells, and parenchymal cells in the graft promoting the allorecognition. Production of cytokines such as IL-2 by CD4 T cells provides help for the generation of CTLs from their CD8 T-cell precursors. CD4 T cells may themselves become cytolytic T cells, by mechanisms similar to those used by CD8 CTLs. CD4 T cells also provide help to B cells to enhance their production of alloantibodies. Finally, Foxp3 + CD4 Tregs that are responsible for peripheral immune regulation are concentrated in the tubules during TCMR as a counterregulatory mechanism.

s0100 ## Acute Antibody-Mediated Rejection

p0180 Acute AMR may develop because of either preexisting antibodies in presensitized patients or de novo antibody formation against donor HLA antigens, which together are called DSAs. In de novo antibody formation, donor antigens are shed into the bloodstream and interact with B cells in SLOs, which induce differentiation of naive B cells into memory B cells and plasma cells (see Fig. 105.5). Although AMR typically occurs with antibody response against the donor HLA antigens, it can also occur to non-HLA antigens (minor antigens). *Hyperacute rejection*, which is most commonly because of the presence of preformed antidonor HLA antibody in sensitized recipients, is a form of AMR that can result in immediate graft failure. This type of AMR is rare now given current anti-HLA testing and crossmatching practices employed by transplant centers.

p0185 Alloantibody-antigen binding mediates graft damage through different mechanisms including opsonization for phagocytosis, opsonization for antibody-dependent cellular cytotoxicity, and fixation of complement.[37] The kidney typically shows an accumulation of NK cells, neutrophils, and monocytes in peritubular capillaries (PTCs) and glomeruli *(microvascular inflammation),* although the infiltrate can be quite sparse.[38] As a result of antibody-mediated damage, endothelium release von Willebrand factor and proinflammatory cytokines, leading to platelet aggregation and microthrombi and the aggravation of inflammation.[39,40] *Endarteritis* is another pathologic finding observed in AMR, which could also be seen in TCMR in a lesser degree.[41] Tubulitis is generally minimal, unless a component of TCMR is present.

p0190 Only the *classical pathway* has been shown to participate in acute or chronic AMR. Binding of C1 to alloantibody-antigen complex initiates classical complement cascade. C4b and its inactive fragment C4d are products of the classical pathway. Both contain an occult sulfhydryl group that forms a covalent thioester bond with nearby proteins in the tissue. No functional role for C4d is known, but it remains in the tissue for several days after immunoglobulin and C1 have been released. C4d deposition is strongly associated with circulating antibody to donor HLA class I or II antigens and is currently the best single marker of complement-fixing circulating antibodies to the endothelium. C3a and C5a drive chemoattraction of neutrophils and macrophages.[42] The membrane attack complex, C5b-9, causes lysis of endothelial cells.

p0195 The current diagnostic criteria for acute AMR include the histologic evidence of acute tissue injury (in the absence of other possible causes), immunopathologic evidence of current/recent antibody interaction with vascular endothelium (e.g., C4d staining or microvascular inflammation), and the evidence of circulating antibody reactive to the donor HLA or minor antigens.

s0105 ## Chronic Rejection

p0200 Late allograft dysfunction is because of both alloimmune mechanisms (i.e., chronic rejection) and alloimmune-independent mechanisms, including hypertension, calcineurin inhibitor toxicity, and recurrent disease.[43] Chronic rejection may occur by either cellular or humoral mechanisms, or both.

p0205 *Chronic active AMR* is diagnosed in the presence of histologic evidence for chronic injury including transplant glomerulopathy, peritubular capillaropathy, or arteriopathy; immunopathologic evidence of antibody action (e.g., C4d staining), and evidence of circulating antibody reactive to the donor (HLA or minor antigens).[38] *Transplant glomerulopathy* is defined by the widespread duplication or multilamination of the glomerular basement membrane (GBM), sometimes accompanied by mesangial expansion and accumulation of mononuclear cells in glomerular capillaries. Majority of cases of transplant glomerulopathy are associated with circulating DSAs, and approximately 30% of these cases have C4d deposition in the PTCs.[44] Absence of C4d deposition in the remainder of cases may represent intermittent antibody involvement or complement-independent antibody-mediated injury. In *peritubular capillaropathy*, PTCs display multilamination under electron microscopy. Repeated episodes of antibody-mediated injury to the endothelium may result in repair mechanisms characterized by duplication of the basement membrane. What leads to episodic antibody injury is unknown, but fluctuating DSA levels are observed in some patients. Lastly, *transplant arteriopathy* is characterized by arterial intimal fibrosis without cellular elements, which ultimately narrows vascular lumen, reducing blood flow to the glomeruli and tubules.

p0210 *Chronic active TCMR* is diagnosed when the histology shows interstitial fibrosis along with at least moderate interstitial inflammation, concurrent tubulitis, and the presence of inflammation in at least 25% of the cortex. An alternative diagnostic criterion is the presence of allograft arteriopathy with arterial intimal fibrosis, mononuclear cell infiltration in the fibrosis, and formation of neointima.[45]

s0110 # TRANSPLANTATION TOLERANCE

p0215 Transplantation tolerance is a state characterized by the absence of a destructive immune response in the recipient toward a well-functioning donor allograft, with a fully intact immune system and no exogenous immunosuppression.[46,47] As with self-tolerance, transplantation tolerance is achieved through control of T-cell reactivity by both central and peripheral mechanisms. *Central tolerance* involves thymic deletional mechanisms that eliminate T cells with reactivity against self-antigens (or donor antigens in the case of transplantation tolerance). In experimental transplant models, central tolerance is achieved by elimination of the preexisting mature T-cell population by irradiation and/or cytotoxic agents, followed by infusion of donor hematopoietic progenitor cells. Reconstituted donor antigen "reeducates" the thymus to delete developing T cells with antidonor reactivity, leading to a state of *chimerism*, in which both donor and recipient cells coexist. Although adult humans lack a thymus, this was translated into the clinical setting with concurrent bone marrow and kidney transplantation

along with transient immunosuppression, which led to promising outcomes in case series.[48]

p0220 *Peripheral tolerance* mechanisms include deletion, anergy, and regulation. With self-tolerance, these mechanisms prevent deleterious autoimmune responses from T cells that escape central deletion. Tregs play a pivotal role in peripheral tolerance. Various approaches to induce peripheral transplant tolerance with the goal of inhibiting deleterious alloimmune responses are currently under investigation, including costimulatory blockade, pharmacologic manipulation of DCs, and the induction of Tregs. Clinical studies indicated that the selective stimulation of Tregs through IL-2 receptors could induce peripheral tolerance and allow the reduction of the immunosuppression in autoimmunity and potentially transplant recipients.[9,11] Most recently, the infusion of ex vivo expanded Tregs in the kidney transplant patients enabled reduction of immunosuppression safely and effectively.[10] A hurdle to the development of clinical tolerance strategies is the lack of reproducible immune monitoring assays for tolerance, which would determine when immunosuppressive medications could be safely withdrawn. Although transplantation tolerance is not yet a clinical reality, progress is being made.[49,50]

SELF-ASSESSMENT QUESTIONS

o0010 **1.** Which one of the following costimulation molecules on APCs has an inhibitory function on T cells?

o0015 **A.** B7.1
o0020 **B.** B7.2
o0025 **C.** CD40
o0030 **D.** ICOS-L
o0035 **E.** PD-L1

o0040 **2.** Which B-cell development stages are not targeted by rituximab (anti-CD20 antibody)?

o0045 **A.** Pro-B cell
o0050 **B.** Pre-B cell
o0055 **C.** Memory B cell
o0060 **D.** Plasma cells
o0065 **E.** A and D

o0070 **3.** Which of the below options includes the pathologic findings of acute T-cell–mediated rejection?

o0075 **A.** Peritubular capillaritis, tubulitis, interstitial inflammation
o0080 **B.** Glomerulitis, peritubular capillaritis, arteritis
o0085 **C.** Tubulitis, interstitial inflammation, arteritis
o0090 **D.** Glomerulitis, tubulitis, interstitial inflammation
E. Interstitial inflammation, tubulitis, thrombotic microangiopathy o0095

4. Which one of the following statements is *not* true regarding HLA genes? o0100

A. HLA genes are inherited in a mendelian codominant fashion. o0105
B. Siblings from the same parents are predicted to have a 50% chance of having zero HLA mismatches. o0110
C. In kidney transplantation, efforts are made to avoid the presence of preformed antibodies against donor HLA antigens. o0115
D. One haplotype of HLA genes is inherited from each parent. o0120

5. Which one of the following statements is *not* true regarding alloantigen presentation to T cells? o0125

A. T cells recognize alloantigen via direct, indirect, and semidirect pathways. o0130
B. Class II MHC molecules are recognized by CD4 T cells. o0135
C. The MHC class I system is designed to present extracellular proteins taken up and processed by antigen-presenting cells. o0140
D. T cells recognize alloantigen as peptides presented by MHC molecules. o0145

Immunosuppressive Medications in Kidney Transplantation

Pitchaphon Nissaisorakarn, Karl L. Womer, Leonardo V. Riella

s0010 ## INTRODUCTION

p0010 Much of the success of kidney transplantation is due to advances in immunosuppressive medications used during the induction and maintenance phases and for treatment of acute rejection.[1] The term *maintenance immunosuppression* is usually used to describe drug regimens consisting of small-molecule agents administered to stable kidney transplant recipients to prevent transplant rejection. Increasingly, physicians outside specialist transplant centers are involved in the care of kidney transplant recipients. In contrast, biologic agents that are used as induction immunosuppression before the maintenance stage or for the treatment of acute rejection episodes are usually managed by specialist transplant physicians.

s0015 ## SMALL-MOLECULE DRUGS

s0020 ### Corticosteroids

p0015 Corticosteroids have been a cornerstone of transplant immunosuppression for the past 50 years, both as maintenance immunosuppression and for treatment of acute rejection.

s0025 #### Mechanism of Action

p0020 Corticosteroids suppress the production of numerous cytokines and vasoactive substances, including interleukin (IL)-1, IL-2, tumor necrosis factor (TNF)-α, major histocompatibility complex class II, chemokines, and proteases. Corticosteroids also cause neutrophilia (often with a left shift), but neutrophil chemotaxis and adhesion are inhibited. Corticosteroids act as agonists of glucocorticoid receptors but at higher doses have receptor-independent effects. Corticosteroid receptors (CRs) belong to a family of ligand-regulated transcription factors called *nuclear receptors* and are generally present in the cytoplasm in an inactive complex with heat shock proteins. The binding of corticosteroids to the CRs dissociates heat shock protein and forms the active corticosteroid-CR complex, which migrates to the nucleus and dimerizes on palindromic DNA sequences in many genes; this action is called the *corticosteroid response element.* The binding of CR in the target genes' promoter region can lead to either induction or suppression of gene transcripts (e.g., of cytokines). CRs also exert effects by interacting directly with other transcription factors independent of DNA binding. Corticosteroids influence immune responses by regulating the transcription factors activator protein 1 (AP-1) and nuclear factor-κB (NF-κB). Typically, NF-κB is present as an inactive complex with an inhibitor of NF-κB (IκB), but it can be released by IκB kinase. Corticosteroids limit inflammation by stimulating IκB, which then competes with the IκB–NF-κB complex for degradation by IκB kinase. Corticosteroids also stimulate lipocortin, which inhibits phospholipase A_2, thereby inhibiting the production of leukotrienes and prostaglandins. Also, animal data suggest that there may be direct corticosteroid effects on kidney glomerular cells separate from its immunosuppressive effects.[2] The net effect of corticosteroids involves immunosuppressive effects on cytokines, adhesion molecules, apoptosis, and inflammatory cells, as well as possible direct effects on glomerular cells.

Pharmacokinetics

s0030 p0025 The major corticosteroids used are oral prednisone (or prednisolone) and oral or intravenous (IV) methylprednisolone. The oral agents have good bioavailability and short pharmacokinetic half-lives (60–180 minutes) but long biologic half-lives (18–36 hours). Corticosteroids are eliminated by hepatic conjugation and are excreted by the kidneys as inactive metabolites. Coadministration of inducers of cytochrome P-450 enzymes that metabolize corticosteroids (e.g., phenytoin, rifampin) decreases corticosteroid half-life, whereas concomitant use of P-450 3A4 inhibitors (e.g., ketoconazole) has the opposite effect. Because corticosteroid levels are not routinely monitored, dosage adjustment during concurrent therapy with these medications is problematic. For treatment of acute rejection, pulse doses of 250 to 500 mg of methylprednisolone are typically used.

Side Effects

s0035 p0030 Side effects of corticosteroid therapy are common and associated with significant morbidity, particularly cataracts, osteoporosis, and avascular necrosis, especially of the femoral head (Table 106.1). Other side effects include hypertension, increased appetite with weight gain, hyperglycemia, hyperlipidemia, cushingoid features, acne, skin striae, psychiatric disturbances, sleep disorders, peptic ulcer disease, pancreatitis, colonic perforation, growth retardation, and myopathy. Infection risk is also increased and is excessive if high-dose therapy is prolonged. Interestingly, corticosteroids are not associated with an increased incidence of malignancy. Although corticosteroids are generally considered safe in pregnancy, fetal adrenal suppression has been reported. Rapid corticosteroid reduction protocols with low maintenance doses (5–10 mg/day of prednisone) can improve corticosteroid tolerability by ameliorating many of these side effects. Withdrawing corticosteroids altogether is another strategy that has been implemented to minimize these side effects, especially in selected low-immunologic risk patients.[3] This was demonstrated by a recent trial comparing rabbit antithymocyte globulin (ATG) to basiliximab induction therapy with rapid steroid withdrawal. Not only was rabbit ATG nonsuperior to basiliximab for the prevention of biopsy-proven acute rejection after steroid withdrawal within 1 year after kidney transplantation, for patients with low immunologic risk, rapid steroid withdrawal was achieved without loss of efficacy and with lower risk of post-transplant diabetes.[4] However, most transplant centers advocate for low-dose maintenance steroids, especially in those at high risk for adverse outcomes, such as those highly sensitized and those who may experience delayed graft function, in

t0010

TABLE 106.1 Side Effects of Small-Molecule Immunosuppressive Medications

	Cyclosporine	Tacrolimus	Mycophenolate	Azathioprine	Corticosteroids	mTOR Inhibitors	Leflunomide
Kidney	Nephrotoxicity, type 4 RTA, HTN, diuretic resistance, hyperkalemia, hypomagnesemia, hypophosphatemia	Nephrotoxicity, type 4 RTA, HTN, diuretic resistance, hyperkalemia, hypomagnesemia, hypophosphatemia			HTN, hypokalemia, diuretic resistance	Synergistic nephrotoxicity with CNIs, delayed recovery from ATN, proteinuria, hypokalemia, HTN	
Gastrointestinal		Diarrhea, abdominal pain	Diarrhea, nausea and vomiting, gastritis, esophagitis, oral and colonic ulcers	Nausea and vomiting, hepatotoxicity, pancreatitis	Peptic ulcers, gastritis, esophagitis, diarrhea, colonic perforation	Diarrhea	Nausea, diarrhea, hepatitis
Hematologic	Thrombotic microangiopathy	Thrombotic microangiopathy	Anemia, leukopenia, thrombocytopenia	Anemia, leukopenia, thrombocytopenia	Leukocytosis, polycythemia	Thrombotic microangiopathy, anemia, thrombocytopenia	Anemia, leukopenia
Metabolic	Hyperlipidemia, hyperuricemia, gout, glucose intolerance	New-onset diabetes			Hyperlipidemia, hyperuricemia, hyperglycemia, osteoporosis, avascular necrosis, increased appetite and weight gain	Hyperlipidemia	
Dermatologic	Gingival hyperplasia, coarsened facial features	Alopecia			Hirsutism, acne, cushingoid facies, buffalo hump	Impaired wound healing, oral ulcers	Alopecia, rash
Neurologic	Encephalopathy, insomnia, myopathy, tremors	Encephalopathy, insomnia, myopathy, tremors	Progressive multifocal leukoencephalopathy		Psychosis, insomnia, myopathy	Reflex sympathetic dystrophy	
Other	Edema	Myocardial hypertrophy	Viral infections, pulmonary edema in elderly		Cataracts	Lymphocele, interstitial pneumonitis, rash, edema	

ATN, Acute tubular necrosis; *CNIs,* calcineurin inhibitors; *HTN,* hypertension; *mTOR,* mammalian target of rapamycin; *RTA,* renal tubular acidosis.

f0010

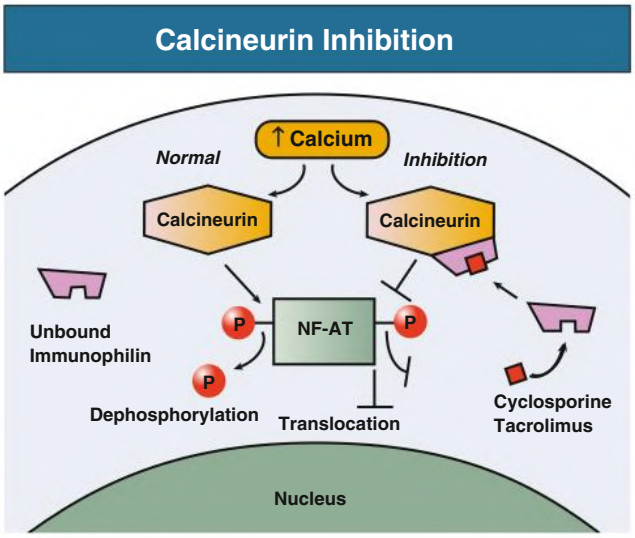

Fig. 106.1 Calcineurin Inhibition. During normal T-cell activation, calcium release activates calcineurin's phosphatase activity, causing dephosphorylation of the transcription factor, nuclear factor of activated T cells (NF-AT), and subsequent translocation to the nucleus. Cyclosporine and tacrolimus form a complex with immunophilins (cyclophilin or FK-binding protein 12, respectively), which bind calcineurin and sterically inhibit the phosphatase activity, preventing dephosphorylation and nuclear translocation of NF-AT.

f0015

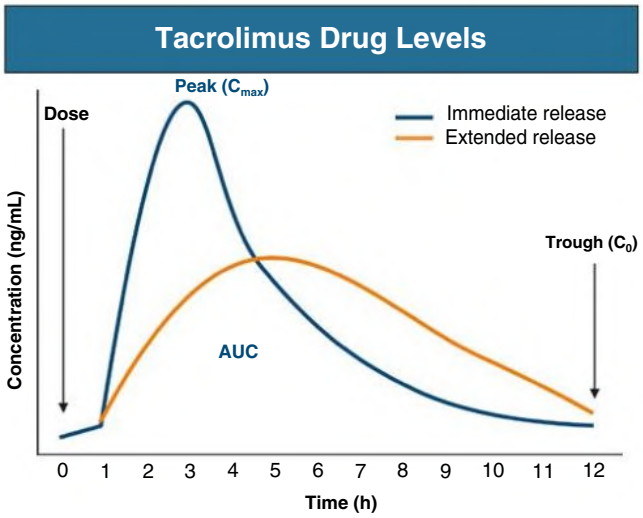

Fig. 106.2 Drug Levels During a Dosing Interval Using Either Immediate- or Extended-Release Tacrolimus. The drug concentration is lowest just before the dose is taken (C_0), then rises to a peak concentration at a certain time after the dose (C_{max}). The area under the concentration-time curve (AUC) describes total drug exposure during the entire administration interval.

which early glucocorticoid withdrawal has been associated with an increased risk of allograft loss.[5]

s0040

Calcineurin Inhibitors

p0035 Calcineurin inhibitors (CNIs), including cyclosporine and tacrolimus, are fungus-derived lipid-soluble small molecules that are the mainstay of current maintenance immunosuppression. Considerable variability exists in their pharmacokinetics, interactions, and side effect profiles, which raises the question of which agent to use in the individual patient. Cyclosporine is a cyclic, lipophilic undecapeptide with several *N*-methylated amino acids, which may explain its resistance to inactivation in the gastrointestinal (GI) tract. Tacrolimus is a macrolide lactone antibiotic.

s0045

Mechanism of Action

p0040 CNIs exert their effect by binding to cytoplasmic proteins called *immunophilins* (Fig. 106.1). Cyclosporine binds to cyclophilin, and tacrolimus binds to FK-binding protein 12 (FKBP12).[6] Such binding enhances immunophilin affinity for and subsequent inhibition of calcineurin, which is a calmodulin-activated serine phosphatase important for dephosphorylation of inactive nuclear factor of activated T cells (NF-AT). Nuclear translocation of dephosphorylated (active) NF-AT, in association with other transcription factors, initiates downstream events, leading to T-cell activation. The tacrolimus-FKBP12 complex inhibits calcineurin with greater molar potency than the corresponding cyclosporine complex. Cyclosporine and tacrolimus can interfere with calcineurin's activation on substrates other than NF-AT, which likely explains many of their side effects. Treatment with CNIs also causes upregulation of the cytokine transforming growth factor-β (TGF-β), which has significant immunosuppressive properties but also promotes the production of matrix proteins and tissue fibrosis. CNIs can suppress the immune response by calcineurin-independent pathways, likely by blocking intracellular signaling pathways specific to T cells. These agents' ability to interfere with two distinct mechanisms of T-cell activation contributes to their highly specific immunosuppressive properties.

s0050

Pharmacokinetics, Monitoring, and Drug Interactions

p0045 After a dose of CNI, there is an initial absorptive phase, during which blood concentrations reach a peak level (C_{max}).[7] Typically, C_{max} occurs during the first 2 to 3 hours after the dose and corresponds to the time of maximum calcineurin inhibition. Drug levels then fall because of metabolism (also known as the *elimination phase*) until they are at the trough level (C_0) immediately before the next dose. The total drug exposure throughout the period from one dose until the next is the area under the concentration-time curve (AUC; Fig. 106.2).

p0050 For both CNIs, most of the interpatient and intrapatient variability occurs in the absorption rather than in the elimination phase. The oil-based formulation of cyclosporine requires solubilization in bile and is plagued by highly variable and unpredictable bioavailability. The microemulsion preparation of cyclosporine (modified) has enhanced bioavailability and less dependence on bile secretion. In blood, cyclosporine resides primarily in erythrocytes (60%–70%) and leukocytes, with some binding to lipoproteins and, to a lesser extent, other plasma proteins. Cyclosporine is metabolized primarily by CYP3A4, a member of the cytochrome P450 superfamily. Metabolism occurs mostly in the liver. Interindividual differences in CYP3A4 activity and the large number of exogenous and endogenous substances capable of altering its function and expression explain the wide variation in clearance rates. One factor is the multidrug resistance 1 gene product, P-glycoprotein, which is variably expressed in the intestine and reduces the absorption of several xenobiotics, including CNIs, by transport out of intestinal epithelial cells. The average half-life of cyclosporine is about 19 hours, with excretion primarily in bile. Generic formulations of modified cyclosporine exist, although they may not have identical pharmacokinetics and therefore may not be readily interchangeable.

p0055 The absorption of tacrolimus, like that of cyclosporine, is highly variable, with bioavailability ranging from 5% to 67%. Absorption is not bile dependent but does depend on GI transit time and is affected by the presence or absence of food and the lipid content of food. Clearance appears to be faster in children, necessitating higher or more frequent dosing. In the United States, Black and Hispanic patients also require higher doses than White patients to achieve equivalent therapeutic

levels, likely because of genetic differences in subtypes of CYP3A, such as CYP3A5 (faster metabolism of CNIs).[8] Similarly, higher tacrolimus dose requirements were reported for non-White Brazilian transplant recipients and for Black transplant recipients in the United Kingdom.[9,10]

p0060 In blood, tacrolimus distributes primarily to erythrocytes, with whole-blood concentrations 10 to 30 times higher than in plasma. In contrast to cyclosporine, no lipoprotein binding occurs. Tacrolimus has 20- to 30-fold higher potency than cyclosporine on a molecular weight basis. Like cyclosporine, metabolism occurs through the CYP3A4 system, with pharmacokinetics also affected by intestinal P-glycoprotein. Both CNIs are generally administered twice daily, but newer slow-release formulations for tacrolimus are now available with once-a-day dosing and reduced peak levels, with potential benefits in lowering side effects such as tremor (reduced peak) and improvement in compliance (see Fig. 106.2). Because of the narrow therapeutic index for CNIs, the variability of concentrations among patients after a dose, and the potential for drug interactions, monitoring of drug levels is required to ensure both safety and adequacy.

p0065 Given the complementary influence of both CYP3A4 and P-glycoprotein on the pharmacokinetic profiles of CNIs, it is assumed that CNI-drug interactions on both CYP3A4 and P-glycoprotein have similar complementary effects on CNI pharmacokinetics. Drugs that competitively inhibit CYP3A4 activity, such as ketoconazole, usually also inhibit P-glycoprotein, thereby increasing the bioavailability of CNIs, with potential for toxicity. Likewise, drugs such as phenytoin that increase CYP3A4 levels tend to upregulate P-glycoprotein, decreasing overall bioavailability. In this case the likelihood of rejection increases. Diarrhea may increase the absorption of CNIs by affecting P-glycoprotein transport in the gut, and monitoring of CNI levels is recommended in the setting of persistent diarrhea for more than 3 days. Despite similar drug interactions, the age-related and ethnic differences in pharmacokinetics between the two CNIs are likely to influence the degree and importance of such interactions. Common interactions are presented in Box 106.1.

BOX 106.1 Drugs and Other Substances That Interact With Calcineurin Inhibitors

b0010

Increase Blood Levels (P450-3A4 and/or P-Glycoprotein Inhibitors)

- Ketoconazole
- Fluconazole
- Itraconazole
- Voriconazole
- Erythromycin
- Clarithromycin
- Diltiazem
- Verapamil
- Nicardipine
- Cimetidine
- Methylprednisolone
- Metronidazole
- Ezetimibe
- Metoclopramide
- Fluvoxamine
- Human immunodeficiency virus (HIV) protease inhibitors
- Lovastatin
- Atorvastatin
- Simvastatin
- Grapefruit juice
- Chamomile
- Wild cherry

Decrease Blood Levels (P450-3A4 and/or P-Glycoprotein Inducers)

- Rifampin
- Rifabutin
- Phenytoin
- Carbamazepine
- Phenobarbital
- Caspofungin
- St. John's wort

s0055 ## Side Effects

p0070 Cyclosporine and tacrolimus have similarities and differences in their toxicity profiles (see Table 106.1). Both can cause nephrotoxicity, hyperkalemia, hyperuricemia, hypomagnesemia and hypophosphatemia (secondary to urinary loss), type 4 renal tubular acidosis, hypertension, diabetes, and neurotoxicity. Gingival hyperplasia, hirsutism, hypertension, hyperuricemia, and hyperlipidemia are more common with cyclosporine, whereas tremor and glucose intolerance are more common with tacrolimus. The most common and vexing problem with CNIs is nephrotoxicity, with its importance evident from heart and liver transplant recipients, in whom CNIs were associated with progression to end-stage kidney disease. Both reversible hemodynamic and irreversible structural components underlie the nephrotoxicity of CNIs. Reversible vasoconstriction is caused by direct vascular effects but is also because of activation of the renin-angiotensin system (RAS), endothelin, thromboxane, and the sympathetic nervous system. Over time, chronic kidney injury occurs, characterized by afferent arterial hyalinosis and tubulointerstitial fibrosis, presumably as the result of prolonged kidney vasoconstriction with ischemia and direct tubular toxicity. Finally, CNIs can cause thrombotic microangiopathy (TMA) in a minority of cases, probably by direct endothelial cell injury and dysfunction.

s0060 ## Mycophenolate

p0075 Mycophenolate mofetil (MMF) and enteric-coated mycophenolate sodium (EC-MPS) are important components of immunosuppressive regimens that are associated with some of the most successful outcomes in kidney transplantation.[11] Because of its well-documented efficacy and acceptable side effect profile, MMF is by far the most frequently used antiproliferative agent and is commonly used in combination with CNIs.

Mechanism of Action

s0065

p0080 The immunosuppressive effects of mycophenolate are likely mediated through the active metabolite mycophenolic acid (MPA). MMF is a morpholinoethyl ester of MPA, a potent reversible inhibitor of inosine monophosphate dehydrogenase (IMPDH), isoform 2. EC-MPS is a salt that combines an acid (MPA) with a base (sodium). The enteric coating delays MPS release so that the MPA is absorbed in the small intestine rather than in the stomach. MPA noncompetitively inhibits IMPDH, which is the rate-limiting enzyme in the de novo synthesis of guanosine monophosphate (GMP). Inhibition of IMPDH creates a relative deficiency of GMP and a relative excess of adenosine monophosphate (AMP). GMP and AMP levels act as a control on de novo purine biosynthesis; therefore MPA, by inhibiting IMPDH, blocks de novo purine synthesis, which selectively interferes with proliferative responses of T and B cells. Some other cell types, such as GI epithelial cells, use the de novo pathway. Thus, MPA may inhibit replication of GI epithelial cells, leading to the disruption of fluid absorption and diarrhea. However, most other cell types depend primarily on the alternative pathway for DNA synthesis and cell division and thus are relatively spared from toxicity.

s0070 ## Pharmacokinetics

p0085 MMF is absorbed rapidly and completely from the GI tract and undergoes extensive presystemic deesterification to become MPA, the active form. Food intake can delay the rate of MMF absorption but does not affect the extent. However, coadministration of antacids (proton pump inhibitors), calcium, or cholestyramine decreases absorption by 20% to 40%. EC-MPS has shown bioavailability equivalence and similar efficacy to that of MMF. MPA undergoes enterohepatic circulation, and its plasma concentration shows a secondary peak at 6 to 12 hours after oral administration. The mean contribution of enterohepatic circulation to the overall AUC of MPA is 37% (range, 10%–61%). Most MPA is metabolized in the liver through a phase II glucuronidation process.

p0090 The major metabolite of MPA is the pharmacologically inactive 7-*O*-glucuronide metabolite (MPAG), although two other metabolites, MPA-acylglucuronide (AcMPAG) and MPA-phenyl-glucoside (glucoside-MPA), are isolated from the plasma of kidney transplant patients. AcMPAG has shown in vitro pharmacologic activity (inhibition of IMPDH) and proinflammatory effects and potentially is responsible for the GI toxicity of MPA. The glucuronide metabolites are excreted into the bile, a process mediated by the multidrug resistance–related protein 2 (MRPR2), then undergo deglucuronidation back to MPA by enzymes that are produced by colonic bacteria. Blockade of MRPR2 by an inhibitor, such as cyclosporine but not tacrolimus, decreases the biliary excretion of MPAG and increases plasma MPAG levels. This eventually leads to lower plasma levels of MPA because the glucuronide metabolites no longer can be reabsorbed as MPA by enterohepatic cycling. Thus, tacrolimus-treated patients have higher exposure to MPA than cyclosporine-treated patients. The ultimate elimination pathway for the glucuronide metabolites is through the kidney, and more than 95% of an administered dose eventually is found in the urine as glucuronide metabolites. For the most part, MMF and EC-MPS are used in fixed-dose regimens. No studies in transplantation have shown that monitoring MPA drug AUC or trough levels reduces the rejection rate or minimizes toxicity.

s0075 ## Side Effects

p0095 MMF and EC-MPS have similar side effect profiles, including GI toxicity, bone marrow suppression, and increased infections, especially those of viral cause (see Table 106.1). GI disturbances include oral ulcerations, esophagitis, gastritis, nausea, vomiting, diarrhea, and colonic ulcers. Diarrhea and leukopenia frequently necessitate a dose reduction that could precipitate allograft rejection. Because the metabolites of MPA appear to play a major role in the GI disturbances associated with MMF, there is little rationale for enteric coating of the prodrug to reduce these symptoms. In fact, randomized controlled trials (RCTs) have found no significant difference in GI adverse events between MMF and EC-MPS.[12–14] MMF is generally avoided during pregnancy because of its teratogenicity in experimental animal models and clinical reports of major fetal malformations.

s0080 ## Azathioprine

p0100 The use of azathioprine has decreased dramatically in kidney transplantation since the introduction of MMF. Azathioprine is metabolized in the liver to 6-mercaptopurine and further converted to the active metabolite thioinosinic acid by hypoxanthine-guanine phosphoribosyltransferase. Because allopurinol (a xanthine oxidase inhibitor) increases levels of thioinosinic acid and can lead to life-threatening bone marrow suppression, the dose of azathioprine must be substantially reduced or azathioprine substituted with another agent—commonly MMF—in patients taking allopurinol. Azathioprine suppresses the proliferation of activated T and B cells and reduces the number of circulating monocytes by arresting the cell cycle of promyelocytes in the bone marrow. The antiproliferative effect is mediated by the metabolites of azathioprine, including 6-mercaptopurine, 6-thiouric acid, 6-methylmercaptopurine, and 6-thioguanine. These compounds are incorporated into replicating DNA and halt replication. They also block the de novo pathway of purine synthesis by formation of thioinosinic acid; this effect confers specificity of action on lymphocytes that lack a salvage pathway for purine synthesis. The major side effect of azathioprine is bone marrow suppression, leading to leukopenia, thrombocytopenia, and anemia (see Table 106.1), with potentially life-threatening complications arising from the concurrent use of azathioprine and xanthine oxidase inhibitors such as allopurinol. The mean cell volume is commonly increased in patients taking azathioprine, and red cell aplasia occasionally can occur. The hematologic side effects are dose-related and usually reversible on dose reduction or temporary discontinuation of the drug. Other common side effects are increased risk for malignancy (especially skin cancers), hepatotoxicity, pancreatitis, and hair loss.

s0085 ## Mammalian Target of Rapamycin Inhibitors

p0105 Mammalian target of rapamycin (mTOR) inhibitors are proliferation signal inhibitors with immunosuppressive activity. Sirolimus, also known as *rapamycin,* was the first mTOR inhibitor used in transplantation and is a macrolide product of a soil fungus discovered on Easter Island.[15] Everolimus is a rapamycin analog with a similar mechanism of action, immunosuppressive properties, and side effect profile. Although initially used in drug regimens with the intent of minimizing exposure to CNIs with its known side effects, the mTOR inhibitors have been associated with their own set of toxicities that have prevented their widespread use. A recent study failed to demonstrate noninferiority of everolimus compared with MPA in groups with similar tacrolimus or cyclosporine exposure in terms of mean estimated glomerular filtration rate (eGFR) 12 months after transplant.[16] Many trials using mTOR inhibitors in place of CNIs revealed a higher risk of kidney transplant rejection and variable improvement in kidney function.[17–21] Lastly, trials using mTOR inhibitor in place of MMF have suggested a lower risk of opportunistic viral infections, such as cytomegalovirus.[22]

s0090 ## Mechanism of Action

p0110 Sirolimus has a structural similarity to tacrolimus and binds to FKBP12. The affinity of sirolimus for FKBP12 is higher than that of everolimus. mTOR inhibitors do not inhibit calcineurin or the calcium-dependent activation of cytokine genes but instead inhibit cytokine receptor–mediated signal transduction and cell proliferation that block lymphocyte responses to cytokines and growth factors. The sirolimus-FKBP12 or everolimus-FKBP12 complex binds with high affinity to the kinase enzyme mTOR, which is a serine-threonine kinase of the phosphatidylinositol 3–kinase pathway that acts during costimulatory and cytokine-driven pathways. mTOR inhibits a translation repressor protein (4E-BP1) and activates a ribosomal enzyme (p70-S6 kinase), both of which are important for translation of the mRNAs for certain proteins needed for progression from the G1 phase to the S phase of DNA synthesis. mTOR has been identified as the principal controller of cell growth and proliferation. The sirolimus-FKBP12 complex inhibits mTOR-mediated signal transduction pathways by blocking postreceptor immune responses to costimulatory signal 2 during G0 to G1 transition and to cytokine signaling during G1 progression. It also inhibits IL-2– and IL-4–dependent proliferation of T and B cells, leading to suppression of new ribosomal protein synthesis and arrest of the G1-S phase of the cell cycle. Proliferation of nonimmune cells, such as fibroblasts, endothelial cells, hepatocytes, and smooth muscle cells, is also impaired by inhibition of the growth factor–mediated responses (e.g., basic fibroblast growth factor, platelet-derived growth factor, vascular

endothelial cell growth factor, and TGF-β). In addition, mTOR contributes to several protein synthesis pathways that could be involved in oncogenesis.

s0095 ### Pharmacokinetics

p0115 The oral bioavailability of sirolimus is poor (10%–16%), with significant interindividual and intraindividual variability. Peak concentrations occur approximately 1 to 2 hours after an oral dose, and sirolimus distributes extensively into tissues, including blood cells. The oral bioavailability of everolimus is higher than that of sirolimus. High-fat meals increase sirolimus levels while decreasing everolimus levels. Because sirolimus has a relatively long half-life (~62 hours), it is reasonable to wait 1 week (approximately three half-lives to achieve steady state) before monitoring sirolimus blood levels after initiation or dose adjustment. Sirolimus is metabolized by the P-450 3A4 isoenzyme and P-glycoprotein system and thus has interactions similar to those described for CNIs (see Box 106.1).

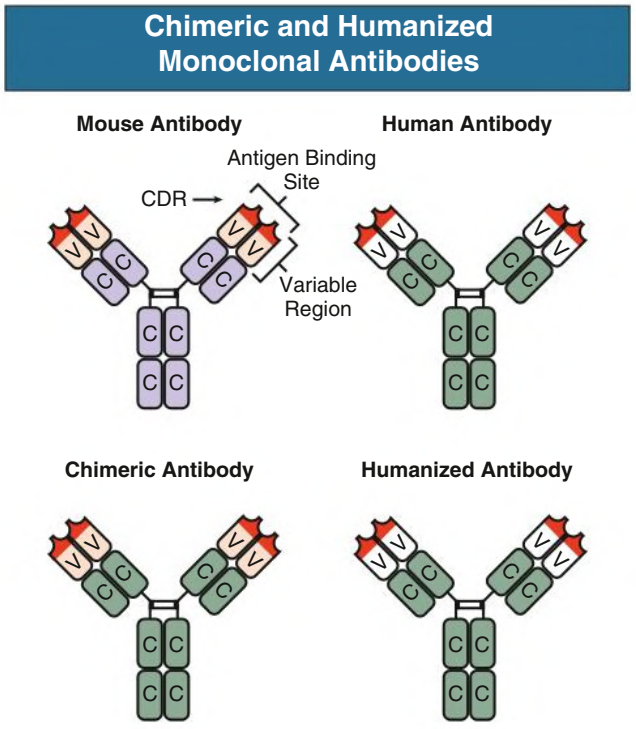
p0120 When an mTOR inhibitor is administered simultaneously with cyclosporine, the C_{max} and AUC for both compounds are increased. Also, cyclosporine clearance may be reduced during concurrent therapy.

s0100 ### Side Effects

p0125 The mTOR inhibitors have a wide variety of toxicities (see Table 106.1). The most common adverse effects associated with sirolimus are dose-dependent hypertriglyceridemia, anemia, thrombocytopenia, and leukopenia. Other adverse effects include impaired wound healing and dehiscence, formation of lymphoceles, oral ulcers, reduced testosterone levels, proteinuria, diarrhea, and pneumonitis. Although not inherently nephrotoxic, the mTOR inhibitors result in kidney graft damage through several mechanisms. When used in combination with full-dose cyclosporine (and probably tacrolimus), sirolimus potentiates CNI-induced nephrotoxicity. In patients with kidney impairment, sirolimus is associated with marked yet potentially reversible proteinuria and worsening of established proteinuria. Sirolimus also can cause delayed recovery from acute tubular necrosis and may be linked to podocyte injury and focal segmental glomerulosclerosis. Finally, cases of TMA have been reported, and there is concern that higher doses of sirolimus may inhibit endothelial cell growth. Interestingly, sirolimus-based regimens have been associated with a reduced incidence of post-transplantation malignancy. Some physicians regard sirolimus as the preferred immunosuppressive agent in transplant patients who develop malignancy because of data suggesting that mTOR inhibitors may reduce the risk of malignancies[23,24]; however, most data are limited to kidney transplant recipients with squamous cell skin cancer.[25,26] Sirolimus is not routinely used during pregnancy because of its teratogenicity in animal models, although successful pregnancies have been reported.

s0105 ## BIOLOGIC AGENTS

p0130 Biologic agents in the form of polyclonal antibodies and monoclonal antibodies (mAbs) are frequently used in kidney transplantation either as induction therapy or for the treatment of rejection. Polyclonal antibodies are derived from horses or rabbits; historically, mAbs have been murine in origin. However, because foreign proteins can elicit an immune response, there has been an attempt to replace murine monoclonal products with humanized or chimeric mAbs (Fig. 106.3). Humanized antibodies are produced by merging the DNA that encodes the antigen-binding portion of a monoclonal mouse antibody with human antibody–producing DNA. Mouse hybridomas are then used to express this DNA to produce hybrid antibodies that are not as immunogenic as the murine variety. Chimeric antibodies use the same strategy but for the entire variable region and thus are more immunogenic than humanized antibodies. Polyclonal antibodies and mAbs can be depleting agents or immune modulators.



f0020 **Fig. 106.3 Chimeric and Humanized Antibodies.** Chimeric antibodies consist of human constant *(C)* regions and mouse variable *(V)* regions. A chimeric antibody therefore retains the antigen binding site of the mouse antibody but with fewer amino acid sequences foreign to the human immune system than a standard mouse antibody. Humanized monoclonal antibodies retain only the minimum necessary parts of the mouse antibody for antigen binding, the complementarity-determining region (CDR, highlighted in *red*), and therefore are even less immunogenic in the human host.

Polyclonal Antilymphocyte Sera

s0110 p0135 Polyclonal antilymphocyte agents are produced by immunizing animals with human thymus–derived lymphoid cells. Although rabbit ATG is currently the preferred preparation, equine preparations historically have been used. Most regimens involve daily IV administration of ATG for 3 to 4 days either as induction therapy or for treatment of corticosteroid-resistant rejection. ATG contains antibodies that react against a variety of targets, including red blood cells, neutrophils, dendritic cells, and platelets. ATG binds to multiple epitopes on the surface of T cells and induces a rapid lymphocytopenia by several mechanisms, including complement-dependent cytolysis, cell-dependent phagocytosis, and apoptosis. ATG is a potent immunosuppressive, and T- and B-lymphocyte counts can remain depressed up to 24 hours after administration. The lack of specificity coupled with marked immunosuppression increases the risk for infection and cancer. Because polyclonal agents are xenogeneic proteins, they may elicit a number of side effects, including fever and chills. The initial lysis and activation of T cells that follow ATG administration may generate significant side effects after the first dose with the release of TNF-α, interferon-γ (IFN-γ), and other cytokines. Therefore, steroids are frequently used before ATG infusion. Less commonly, ATG can induce a serum sickness–like syndrome and, rarely, acute respiratory distress syndrome.

s0115 ## Humanized Monoclonal Anti-CD52 Antibody

p0140 Alemtuzumab is a humanized IgG1 mAb directed against CD52, a glycoprotein found on circulating T and B cells, monocytes, macrophages, natural killer cells, and granulocytes. Alemtuzumab was originally approved for the treatment of B-cell chronic lymphocytic leukemia, but it has been used off label as an induction agent in kidney transplantation. Treatment results in a rapid and effective depletion of peripheral and central lymphoid cells, which may take months to return to pretransplantation levels. Side effects of alemtuzumab include first-dose reactions, neutropenia, anemia, and rarely, pancytopenia and autoimmunity (e.g., hemolytic anemia, thrombocytopenia, and hyperthyroidism). The risks for immunodeficiency complications such as infection and malignant neoplasia with alemtuzumab appear to be similar to ATG.

s0120 ## Monoclonal Anti-CD25 Antibody

p0145 The alpha subunit of the IL-2 receptor (CD25) is upregulated on activated T cells and leads to the expression of high-affinity IL-2 receptors. The engagement of IL-2 receptors by IL-2 triggers the activated T cell to undergo proliferation. Basiliximab is a chimeric mAb with a specificity for CD25; it induces relatively mild immunosuppression and is used as an induction agent to prevent rejection but not to treat established rejection.[27,28] Although the exact mechanism of action is not fully understood, it is clear that significant depletion of T cells does not play a major role. Saturation of the IL-2 receptor alpha subunit persists for up to 25 to 35 days after treatment with basiliximab. Although saturation is important as a determinant of minimal blood concentrations, it is not predictive of rejection. No major side effects have been associated with anti-CD25 induction compared with transplant recipients receiving no anti-CD25 induction.

s0125 ## B-Cell–Depleting Monoclonal Anti-CD20 Antibody

p0150 Rituximab is an engineered chimeric mAb that contains murine heavy- and light-chain variable regions directed against CD20 plus a human IgG1 constant region.[29] The CD20 antigen, a transmembrane protein, is found on immature and mature B cells and on malignant B cells. CD20 mediates proliferation and differentiation of B cells. Rituximab directly inhibits B-cell proliferation and induces apoptosis and lysis by complement-dependent cytotoxicity, antibody-dependent cell cytotoxicity, and activation of tyrosine kinases as a direct effect of the antibody binding to its CD20 ligand. Rapid and sustained depletion of circulating and tissue-based B cells occurs after IV administration, and recovery does not begin until approximately 6 months after treatment. Although plasma cells are usually CD20 negative, many are short lived and require replacement from CD20-positive precursor cells. In addition, CD20-positive B cells can act as secondary antigen-presenting cells (APCs), thereby enhancing T-cell responses. Thus, by targeting CD20 on precursor B cells, rituximab decreases the production of activated B cells and limits their antibody production and antigen presentation capability. Most adverse events are first-infusion effects, such as fevers and chills, and are generally of mild severity, becoming less frequent with subsequent infusions. Viral infections, including reactivation of hepatitis B virus and JC virus, have been reported, although it is not known whether these events are specific to the agent or instead reflect the overall state of immunosuppression. Antichimeric antibodies develop in some patients, but their true incidence and therapeutic significance are uncertain. Rituximab has been used in kidney transplantation to treat antibody-mediated rejection and in combination with IV immunoglobulin (IVIG) to reduce high-titer anti–human leukocyte antigen (anti-HLA) antibodies in highly sensitized patients awaiting kidney transplantation.[30] Rituximab is also used as induction therapy after desensitization therapy for ABO blood group–incompatible and high-risk positive crossmatch kidney transplantation. Finally, rituximab is often used to treat post-transplantation lymphoproliferative disease. A phase 1b study assessing the safety, pharmokinetics, and pharmacodynamics of obinutuzumab, a novel type 2 anti-CD20 monoclonal antibody in highly sensitized patients with kidney failure, demonstrated good tolerability and effective depletion of B lymphocytes. However, its effect on reductions in anti-HLA alloantibodies were inconsistent and not clinically meaningful.[31]

Intravenous Immunoglobulin

s0130

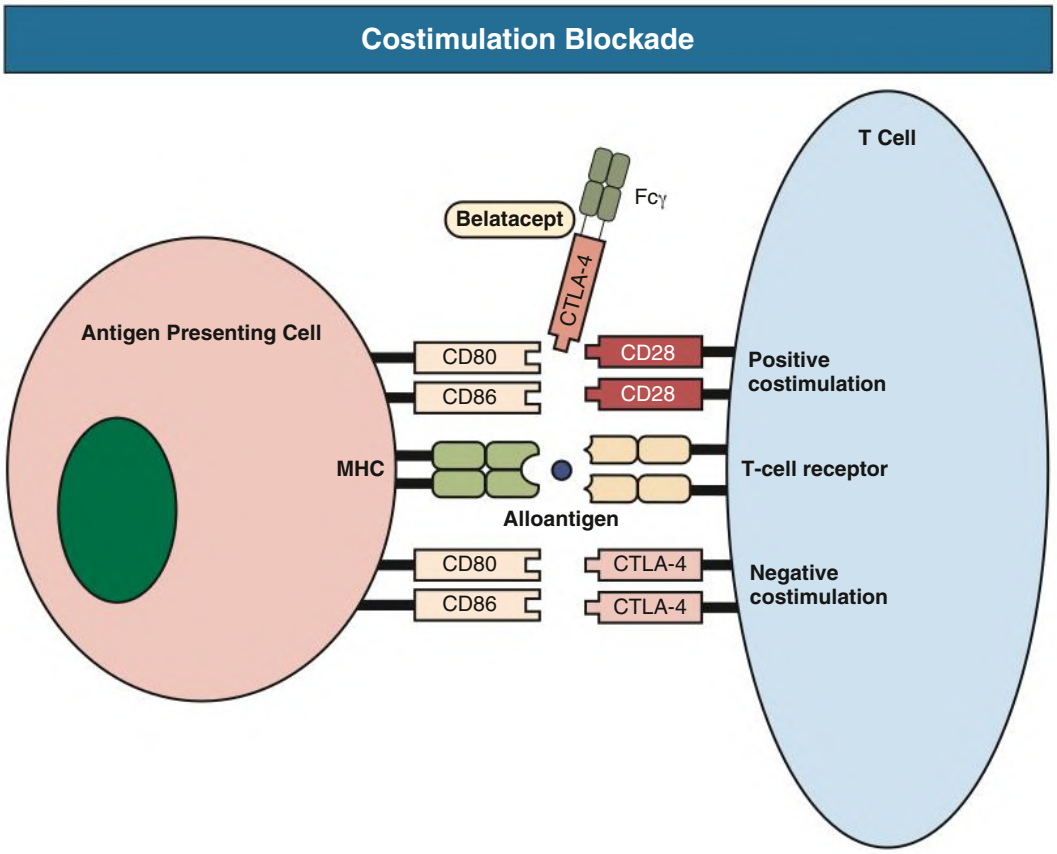
IVIG products are known to have powerful immunomodulatory p0155 effects in inflammatory and autoimmune conditions. The mode of action of IVIG is not well understood. In kidney transplantation, the most important effect appears to be a reduction of alloantibodies through inhibition of antibody production and increased catabolism of circulating antibodies. Additional potential mechanisms include inhibition of complement-mediated injury, inhibition of inflammatory cytokine generation, and neutralization of circulating antibodies by anti-idiotypes. Side effects related to IVIG administration include minor self-limited reactions, such as flushing, chills, headache, myalgia, and arthralgia. Rarely, anaphylactic reactions may occur. Delayed reactions include severe headache and aseptic meningitis, which respond to analgesics. More recently, severe thrombotic events have been linked to the administration of IVIG products. Osmotic injury of the proximal tubular epithelium can occur after administration of sucrose-containing IVIG preparations. This tubular injury is self-limited and can be minimized or avoided by use of sucrose-free preparations and by slowing rate of infusion. In combination with plasma exchange, IVIG appears to offer significant benefits in the desensitization of positive-crossmatch and ABO-incompatible patients to allow successful transplantation as well as in the treatment of antibody-mediated rejection. Alone or in combination with rituximab, IVIG has been successful in the desensitization of highly sensitized waitlisted patients to increase the chances of finding a compatible donor.

Belatacept

s0135

Costimulation blockade is an immunosuppression alternative for p0160 kidney transplant recipients. Belatacept, a first-in-class costimulation blocker, is a fusion protein that binds to CD80 and CD86 on APCs to prevent T cell activation and proliferation (Fig. 106.4). The drug primarily affects the costimulatory CD28 pathway, preventing full T-cell activation. Belatacept was initially approved by the U.S. Food and Drug Administration (FDA) for de novo kidney transplantation only in Epstein-Barr virus (EBV)-seropositive adult patients because of concerns that administering belatacept might increase the risk for early post-transplant lymphoproliferative disorder (PTLD) in EBV-seronegative patients. Also, it has been used off label for conversion from CNIs after kidney transplantation, in particular in patients intolerant to CNIs. Converting from CNIs to belatacept has been associated with a higher risk of rejection when done in the first year after transplant in sensitized patients; however, there was no difference in rejection-free, patient, or graft survival over 5 years.[32] Other potential benefits of conversion include improved glycemic parameters in those with diabetes[33] and improved kidney function in those with chronic vascular lesions[34] on kidney biopsy. Side effects of belatacept include anemia and leukopenia. Rare but serious side effects include progressive multifocal leukodystrophy and PTLD.

In the phase III BENEFIT trial, belatacept showed a significantly p0165 better GFR despite higher rates of early acute rejection compared with cyclosporine.[35] Belatacept-treated patients also had better blood pressure and lipid control compared with cyclosporine controls. The



f0025

Fig. 106.4 Costimulation Blockade. Lymphocyte T-cell activation requires two signals with the first signal mediated by the major histocompatibility complex (MHC) and the T-cell receptor, and the second signal (positive costimulation) mediated by CD80/CD86 on the antigen-presenting cell (APC) and *CD28* on the T cell. Negative costimulation is mediated by the cytotoxic T lymphocyte–associated protein 4 (CTLA-4) on activated T cells that binds to CD80/CD86 on the APC and suppresses T-cell responses (negative costimulation). Belatacept is a CTLA-4 fusion protein that binds CD80/CD86 and blocks positive costimulation via the CD28 pathway, thus preventing T-cell activation.

s0140 s0145 p0175 7-year follow-up data showed that the composite endpoint of graft and patient survival was better with belatacept, but the individual graft survival and patient survival were separately not statistically different compared with cyclosporine.[36] Belatacept continued to show better 7-year kidney function with no increased risk for late PTLD in EBV seropositive patients.

p0170 Other studies looked at patients who were not included in the BENEFIT trial. The BENEFIT-EXT trial included patients who received a kidney transplant from an expanded criteria donor, donation after cardiac death donor, or a donor with long cold ischemia time.[37] This trial also found that patient and graft survival with belatacept were not inferior, but unlike in the BENEFIT trial, the acute rejection rate and GFR were similar between belatacept and cyclosporine. More recently a retrospective study of the Scientific Registry of Transplant Recipients database compared the 1-year outcomes between belatacept and tacrolimus.[38] Similar to the BENEFIT trial, this study showed no difference in graft survival, but better kidney function despite a greater risk for acute rejection was seen with belatacept compared with tacrolimus. Also, a lower risk for new-onset diabetes after transplantation was observed with belatacept. In summary, belatacept seems to better preserve GFR and have a better metabolic profile compared with CNIs, but the high acute rejection rate has affected its broader use because of concerns of long-term impact on graft survival.

Other Agents Used in Transplantation

Bortezomib

Bortezomib is an antineoplastic agent originally approved for the treatment of plasma cell dyscrasias such as multiple myeloma and several types of lymphomas. It inhibits proteasomes, which are enzyme complexes that regulate protein homeostasis. Specifically, bortezomib reversibly inhibits chymotrypsin-like activity at the 26S proteasome, leading to activation of signaling cascades, cell-cycle arrest, and apoptosis. It targets mature rapidly proliferating antibody-producing plasma cells but also interferes with T-cell function and IL and TNF production. Bortezomib has been used off label for both primary and refractory antibody-mediated rejection, experimental desensitization protocols, and induction immunosuppression in patients who are highly sensitized with HLA antibodies.[39–41] Also, the BORTEJECT study is an ongoing phase 2 RCT investigating the impact bortezomib might have on treating late antibody-mediated rejection.[42] Bortezomib is administered via IV and is metabolized by the liver. GI symptoms are common, but thrombocytopenia and peripheral neuropathy are significant side effects. Herpes zoster prophylaxis is required.

Eculizumab

s0150 p0180 Eculizumab is a humanized monoclonal antibody directed against complement protein C5 that prevents cleavage into C5a and C5b, thus

BOX 106.2 Prescribing Considerations for Immunosuppressive Medications

b0015

Tacrolimus

- Close monitoring of tacrolimus level is recommended in patients with diarrhea. Diarrhea elevates tacrolimus levels because of downregulation of (1) intestinal CYP450 and (2) p-glycoprotein, which normally transports drugs back into the intestinal lumen from enterocytes, thus increasing bioavailability.
- Hair loss associated with tacrolimus has been suggested to be dose-related and at times may respond to biotin supplementation; however, if persistent and severe, it may lead to poor compliance and a need for alternate therapy.
- Neurologic effects include night tremors, headaches, and tremors that can sometimes be alleviated with extended-release formulation.
- Urge cautious tacrolimus use with drugs that affect CYP450.
- Hypomagnesemia is common because tacrolimus downregulates TRPM6 and may also increase claudin-14 expression, which inhibits paracellular magnesium transport.
- Monitor for QT prolongation.
- It is associated with thrombotic microangiopathy and posttransplant diabetes.
- There is high interindividual variability on pharmacokinetics dependent on ethnicity; CYP3A5*1 polymorphism is high in African Americans and may lead to a higher tacrolimus dosage requirement.

Cyclosporine

- It is associated with hirsutism and gingival hyperplasia.

Mycophenolate

- Myelosuppression is a common side effect, and close complete blood count (CBC) monitoring is required.
- Gastrointestinal (GI) side effects are common. In cases of significant GI side effects, patients could be tried on enteric-coated mycophenolate mofetil (mycophenolic acid). Spacing out mycophenolic acid from twice daily to four times daily also sometimes helps.
- It is associated with teratogenicity; women of child-bearing age should be on dual contraception while on mycophenolate and should stop mycophenolate at least 6 weeks before conception.

Mammalian target of rapamycin inhibitors (mTORi)

- Routine monitoring of lipid panel and proteinuria is recommended.
- These are associated with pneumonitis.
- There is poor wound healing; these should not be used perioperatively.

Azathioprine

- Azathioprine has been associated with skin cancer with long-term use.
- Avoid use with allopurinol or febuxostat because it may increase serum concentrations of the active metabolite of azathioprine.
- Myelosuppression is a common side effect and close CBC monitoring is required, especially in those with low or absent thiopurine methyltransferase activity, often manifesting as macrocytic anemia.
- It is acceptable for use during pregnancy.

Belatacept

- There is a Black Box warning in Epstein-Barr virus–naive recipients, and it may increase post-transplant lymphoproliferative disorder risk.

blocking the subsequent formation of the terminal complex C5b-9 or membrane attack complex. Eculizumab prevents antibody-dependent complement-mediated cytotoxicity; therefore it has been used as an off-label treatment for antibody-mediated rejection. However, because of its experimental use and extreme cost, eculizumab is usually reserved as a rescue therapy for allografts resistant to other antirejection therapies. Eculizumab use in severe acute antibody-mediated rejection appears to be effective, but long-term follow-up of eculizumab-treated patients did not show prevention of chronic glomerular changes such as transplant glomerulopathy.[43–46] A phase II RCT in living-donor kidney transplant recipients who required desensitization therapy showed that eculizimab did not reduce the risk of biopsy-proven acute antibody mediated rejection, graft loss, or death.[47] As a result of increased incidence of meningococcal infections associated with eculizumab, meningococcal vaccine and antibiotic prophylaxis are required before starting therapy. Finally, eculizimab has been used successfully in the prevention of recurrence of certain complement-mediated glomerular diseases, such as atypical hemolytic syndrome.[48]

See Box 106.2 for a list of considerations when prescribing immunosuppressive medications. p0185

SELF-ASSESSMENT QUESTIONS

o0010 **1.** What is the *most* common and vexing problem with cyclosporine and tacrolimus in kidney transplantation?

o0015 **A.** Nephrotoxicity
o0020 **B.** Hypertension
o0025 **C.** TMA
o0030 **D.** Alopecia

o0035 **2.** Belatacept offers patients a CNI alternative to maintenance immunosuppression and works by which mechanism of action?

o0040 **A.** Blocks complement C5 cleavage
o0045 **B.** Blocks CD25 on the IL-2 receptor
o0050 **C.** Blocks CD28-mediated costimulation of T cells
o0055 **D.** Inhibits B-cell proliferation by targeting CD20

o0060 **3.** Which immunosuppressive agent has been associated with teratogenicity in experimental animals and major fetal malformations?

o0065 **A.** Tacrolimus
o0070 **B.** Azathioprine
o0075 **C.** Corticosteroids
o0080 **D.** Mycophenolate

o0085 **4.** All of the following agents have been commonly used in the treatment of acute rejection *except:*

o0090 **A.** Antithymocyte globulin
o0095 **B.** Basiliximab
o0100 **C.** Rituximab
o0105 **D.** Intravenous immunoglobulins

Evaluation and Preoperative Management of Kidney Transplant Recipient and Donor

William R. Mulley, John Kanellis

p0010 Kidney transplantation provides superior long-term outcomes compared with dialysis, in both quantity and quality of life, although the benefit gained varies among individuals.[1] The better outcomes associated with transplantation coupled with the shortage of available organs has led to an expansion of donor criteria and an increasing tendency for centers to accept marginal donor kidneys. This chapter reviews the evaluation and preoperative management of both the kidney transplant recipient and the donor.

s0010 RECIPIENT EVALUATION

p0015 Many transplant centers now accept patients who were previously excluded from transplantation, such as those with human immunodeficiency virus (HIV) infection, obesity, and diabetes. This is because of the availability of newer treatment options for some conditions, a greater understanding of the impact of these conditions on patients and graft survival, and changing societal attitudes regarding equality of access to transplantation. Some absolute contraindications to transplantation remain (Box 107.1), including current infection or malignancy, noncompliance or substance abuse, and any condition likely to severely limit life expectancy (<1–2 years).[2–4]

p0020 Although the application of guidelines for transplant suitability may be relatively straightforward for patients with a single comorbidity, it is not as simple for those with multiple medical conditions, who represent a growing group of potential transplant recipients. Determination of suitability in such patients often requires input from specialists in a variety of medical and surgical disciplines along with allied health professionals. The final decision needs to be made by clinician and patient together after full discussion of the likely risks and benefits followed by regular reassessment of suitability while the patient awaits transplantation.

p0025 A summary of national and international guidelines[2–5] is presented in Box 107.2, and selected aspects are discussed.

s0015 Cardiovascular Disease

p0030 Cardiovascular (CV) disease is common in patients with end-stage kidney disease (ESKD) and is a major cause of death in transplant recipients. Hence, CV evaluation is critical in the evaluation of the potential transplant recipient.

s0020 Coronary Heart Disease and Left Ventricular Dysfunction

p0035 The role of pretransplantation investigation and intervention for coronary artery disease (CAD) is controversial. However, given the high incidence of cardiac events in the peri-transplantation period and its major contribution to posttransplantation mortality, we favor aggressive evaluation and intervention in at-risk patients while avoiding unnecessary tests and procedures in low-risk candidates. Patients may be risk-stratified using history and examination, resting electrocardiography, and chest radiography. Further evaluation is unnecessary in asymptomatic patients without risk factors because of a very low incidence of coronary events.[6] Further investigation is recommended in patients with abnormal test results or significant risk factors, such as previous cardiac ischemic events, diabetes, smoking, age older than 50 years, hypertension, dialysis duration greater than 2 years, or a family history of CAD.[2–4]

p0040 Symptomatic patients should proceed directly to coronary angiography; noninvasive functional testing should be used to evaluate the need for angiography in asymptomatic patients.[6,7] Exercise echocardiography or myocardial perfusion scintigraphy are preferred; both testing modalities have negative predictive values for myocardial infarction or cardiac death in excess of 90% in patients with kidney failure.[8] If significant CAD is identified, treatment before transplantation is required. Treatment consists of aggressive risk factor modification, angioplasty, and stenting or coronary artery bypass grafting in patients with significant stenoses[6,7] (Fig. 107.1).

p0045 In patients with evidence of left ventricular (LV) dysfunction, transthoracic echocardiography should be arranged; a cause should be sought and treated when possible. Severe LV dysfunction may improve significantly after transplantation, so is not an absolute contraindication to transplantation. However, because it is associated with reduced posttransplantation survival, it represents a contraindication in patients with significant comorbidities, unless combined heart and kidney transplantation is appropriate.[2–4]

Cerebrovascular Disease

s0025

p0050 Patients with recent transient ischemic attack or stroke are at greatest risk for recurrence early after the primary event; and because stroke after transplantation is associated with a high rate of mortality,[9] a waiting time of 6 months is recommended. Meanwhile, aggressive risk factor modification is required to limit the likelihood of further stroke. Risk factors for de novo stroke posttransplantation include older age, diabetes, and atrial fibrillation, although transplantation is associated with a reduced risk for stroke relative to remaining on the waiting list or maintenance dialysis. Routine testing for cerebrovascular disease is not advocated in asymptomatic patients. Patients with polycystic kidney disease (PCKD) should be offered investigation for cerebral aneurysm before transplantation, particularly those with additional risks for cerebral aneurysm rupture (e.g., personal or family history of cerebral hemorrhage). Risk for cerebral aneurysm in PCKD is discussed further in Chapter 46.

Peripheral Vascular Disease

s0030

p0055 Asymptomatic patients with strong femoral and peripheral pulses generally require no further investigation. Patients with diabetes, history of claudication, or reduced pulses require vascular imaging beginning with Doppler ultrasound. Significant disease involving the iliac vessels may make

BOX 107.1 Contraindications to Kidney Transplantation

b0010

Current Absolute Contraindications to Transplantation

- Active sepsis
- Current uncontrolled malignancy
- Uncontrolled psychosis
- Active drug dependence
- Any medical condition with a severely shortened life expectancy (<1–2 years)
- Positive T-cell CDC crossmatch

Historical Contraindications to Transplantation[a]

- HIV infection
- Hepatitis B and C infection
- Obesity
- Mood disorders
- Age > 60 years
- Previous malignancy
- Blood group incompatibility

[a]These conditions are now acceptable under certain circumstances (see text).

CDC, Complement-dependent cytotoxicity; *HIV,* human immunodeficiency virus.

BOX 107.2 Recipient Evaluation Checklist

b0015

History and Examination

- Cause of kidney failure and risk for recurrence
- Sensitization (transfusion, pregnancy, previous transplant)
- Past and current infections (TB, hepatitis, HIV)
- Immunization (especially hepatitis B)
- Malignancy
- Cardiovascular risks (smoking, hypertension, diabetes)
- Pulmonary, gastrointestinal disease
- Genitourinary tract
- Psychiatric, psychological history
- Surgical issues (weight, iliac vessels, abdomen, previous surgery)

Laboratory and Radiologic Investigations

- Viral serology (HIV, CMV, EBV, hepatitis B and C)
- Liver function tests
- Bone-related issues (PTH, calcium, phosphate)
- Chest radiograph
- Electrocardiogram
- Prostate-specific antigen (for men >50–60 years)
- Mammogram or breast ultrasound (women >50 years or with family history of breast cancer)
- Pap smear (sexually active women)

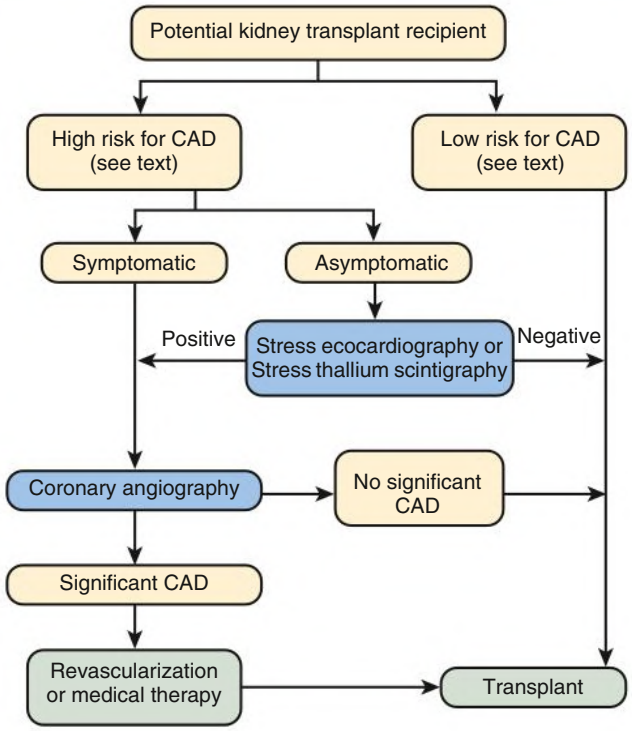
Immunologic Investigations

- ABO blood group and HLA typing
- Screening for HLA antibodies and autoreactive antibodies
- Crossmatching

CMV, Cytomegalovirus; *EBV,* Epstein-Barr virus; *HIV,* human immunodeficiency virus; *HLA,* human leukocyte antigen; *PTH,* parathyroid hormone; *TB,* tuberculosis.

transplantation difficult or impossible and may worsen ischemia in the distal leg. Although it is not an absolute contraindication to transplantation, peripheral vascular disease is associated with increased mortality and should be considered in conjunction with the patient's other comorbidities.

Assessment and Management of Cardiac Status in Potential Transplant Recipients



f0010

Fig. 107.1 Assessment and management of coronary artery disease (CAD) in potential transplant recipients.

Cancer

s0035

Cancer is a major cause of death in kidney transplant recipients. Further increases in the incidence of malignancy are likely with increased graft survival and acceptance of older recipients. The incidence of malignancy is also increased in transplant recipients compared with the general population.[10] However, the effect of transplantation on different types of cancer is not uniform, nor is the effect of different immunosuppressive agents.[11] Some cancers, such as nonmelanoma skin cancers (61%–82% at 20 years) and lymphoma, have a markedly increased incidence in transplant recipients compared with the general population, in contrast to breast and prostate adenocarcinoma, which are not as substantially increased.

p0060

In patients with previous malignancy, guidelines for recommended waiting time are based on the likelihood of recurrence after transplantation (Box 107.3). In general, the longer the cancer-free interval before transplantation, the smaller the recurrence risk. For most malignancies, a period of 2 to 5 years is recommended.[2–4] There are several exceptions: longer waiting time (≥5 years) is recommended for breast cancer with nodal involvement, melanoma, and colorectal cancer worse than Duke's stage B1; no waiting time is thought necessary for nonmelanocytic skin cancers confined to the skin, in situ cancers of bladder and cervix, focal microscopic low-grade prostate cancer, monoclonal gammopathy of uncertain significance (without evidence of multiple myeloma), and small (<7 cm) incidentally discovered and surgically removed kidney cell carcinomas. Waiting periods before transplantation should be individualized, taking into account the patient's other comorbidities.

p0065

BOX 107.3 Guidelines for Transplantation in Patients With Previous Malignancy

b0020

Usual Wait Time of 2 Years
- Most cancers

No Wait Time Necessary
- Asymptomatic T1a (<4 cm) renal cell carcinoma without metastases or suspicious histologic features
- In situ carcinoma
- Focal neoplasm (defined as a localized tumor without metastases)
- Low-grade bladder cancer
- Basal cell skin cancer

Wait Time of >2 Years May Be Necessary
- Melanoma
- Breast cancer
- Colorectal cancer
- Uterine cancer

p0070 Chest radiography is performed as part of the routine assessment. Although extensive screening of all potential recipients is not warranted, potential recipients should be evaluated for breast, cervical, prostate, and colorectal cancer. More comprehensive and targeted evaluation is recommended in patients with a strong family history or suggestive clinical features of malignancy or conditions associated with an increased risk for malignant disease, such as kidney imaging in patients with acquired cystic disease of the kidney for possible kidney cell carcinoma.[2,3]

s0040

Infectious Complications

p0075 All patients are tested for previous exposure to Epstein-Barr virus (EBV) and cytomegalovirus (CMV) to assess the risk for infection, either primary or reactivation. This guides the appropriate use of prophylactic antiviral agents. For example, patients who are negative for CMV immunoglobulin G (IgG) who receive a kidney from a CMV-positive donor are at the highest risk for infection and may benefit from prolonged prophylaxis compared with the lower risk CMV-negative donor to a CMV-negative recipient (see Chapter 110). Testing for other infections should be tailored to geographic location; a guide is presented in Box 107.4. All potential recipients should be immunized against hepatitis B virus (HBV). Immunization against encapsulated organisms (pneumococci, *Haemophilus influenzae,* and meningococci) should be considered in patients at high risk for antibody-mediated rejection in case-rescue therapy (e.g., splenectomy) or when complement inhibition with eculizumab is required.

p0080 Centers experienced in managing HIV infection and transplantation report excellent patient and graft survival in carefully selected recipients.[12] In the absence of an acquired immunodeficiency syndrome (AIDS)-defining illness, patients with sustained CD4 counts greater than 200/mL and undetectable HIV viral loads can be considered for transplantation.[2] Patients with HBV infection may be considered for kidney transplantation if there is no evidence of active viral replication (HBV DNA or HBV early antigen [HBeAg] negative), advanced liver disease or cirrhosis (as determined by liver biopsy), or hepatocellular carcinoma (HCC).[2–4] Immunosuppression can increase HBV replication; hence, treatment before transplantation is indicated in patients with active disease, and although data to support prophylactic antiviral therapy after transplantation are scarce, treatments such as entecavir are commonly used while immunosuppression is at its highest (first 12–24 months). Early reports suggested that mortality may be increased

BOX 107.4 Screening Tests for Occult Infection

b0025

Routine Serology
- Cytomegalovirus
- Epstein-Barr virus
- Hepatitis B virus
- Hepatitis C virus
- HIV

Where Indicated, Tests for the Following Conditions and Infections
- HTLV
- Human herpesvirus 8
- Malaria
- Schistosomiasis

- *Trypanosoma cruzi*
- Tuberculosis

Other Routine Investigations
- Chest radiograph
- Urine culture

HIV, Human immunodeficiency virus; *HTLV,* human T-lymphotropic virus.

in HBV-positive patients after transplantation compared with HBV-negative recipients,[13] but it is unclear whether this is true in the current era. We recommend frank disclosure of potential risks.[2–4]

p0085 Patients with hepatitis C should be assessed by measurement of hepatitis C virus (HCV) viral load and a liver biopsy. In patients without cirrhosis, transplantation should not be delayed by treatment because direct-acting antivirals can be safely used to treat HCV after transplantation,[14] and mortality in HCV-positive patients is reduced by transplantation compared with remaining on dialysis.[15] With informed consent, HCV-positive patients may receive a kidney from an HCV-positive donor because any possible increased risk for the latter is offset by a significantly reduced waiting time. Patients with HBV and HCV infection should be screened every 12 months for HCC by liver ultrasound and serum α-fetoprotein. Those with cirrhosis may be considered for combined kidney-liver transplantation.

p0090 Patients at high risk for tuberculosis (TB) reactivation after transplantation (previous TB, abnormal chest radiograph, or positive tuberculin skin test result; residence in an endemic area) who have not been previously treated should receive prophylactic isoniazid after transplantation (see Chapter 110). Interferon-γ (IFN-γ) release assays may replace or supplement the tuberculin skin test because they appear more sensitive for detecting latent TB infection.[16] The need to evaluate patients for TB is determined by the likelihood of previous exposure.

p0095 Previous graft loss caused by polyoma (BK) viral nephropathy is not a contraindication to repeated transplantation. Waiting for serum and urine BK polymerase chain reaction test results to become negative appears to be preferable,[17] whereas the value of graft nephrectomy before repeated transplantation is unclear. Vigilant evaluation for recurrence is recommended.[4]

s0045

Obesity

p0100 Transplantation in obese patients (body mass index [BMI] > 30 kg/m^2) generally improves survival compared with matched waiting list controls,[18] but inferior outcomes for patient and graft survival, delayed graft function, wound healing, and infectious complications have been reported compared with nonobese patients, particularly those with BMI

greater than 35 kg/m^2.[19,20] Additionally, overweight and obese patients are more likely to develop diabetes after transplantation, which can adversely affect graft and patient survival. Although not an absolute contraindication to transplantation, patients with obesity should be offered weight loss strategies (including bariatric surgery where appropriate) before transplantation to reduce their risk of mortality and morbidity.

Recurrent Disease

The risk for disease recurrence should be discussed as part of the informed consent process, particularly in primary kidney diseases with a high risk for recurrence (e.g., focal segmental glomerulosclerosis).[21] Recurrent disease accounts for more than 5% of graft loss[21] and is an increasingly important cause of graft dysfunction with increasing time posttransplantation. The risks and management of recurrent disease are discussed in Chapter 113.

Gastrointestinal Disease

Investigations searching for gastrointestinal disease are not warranted in the asymptomatic patient.[3,4] Patients with active acute or chronic pancreatitis should not undergo transplantation until they have been clear of symptoms for at least 3 months. Patients with active peptic ulcer disease should be treated before transplantation with proton pump inhibitors, and this should be continued to prevent ulceration after transplantation. Patients with symptomatic diverticular disease require colonoscopy and potential colonic resection in severe cases before transplantation because they are at increased risk for perforation on immunosuppressive medications.[3] Although symptomatic cholecystitis should be treated surgically before transplantation, asymptomatic cholelithiasis does not require surgery before transplantation because cholecystectomy after transplantation is required in less than 10%, and results in no increased mortality or morbidity compared with pretransplantation cholecystectomy.[22]

Genitourinary Disorders

Testing for genitourinary tract disorders before transplantation is indicated in those with features suggestive of urinary obstruction, especially in children, in whom urologic problems are a major cause of ESKD. If obstruction is found, urologic assessment and/or voiding cystourethrography and urodynamic studies are indicated. Depending on the findings, intervention may be warranted to ensure bladder emptying and limit bladder pressures after transplantation; this may involve bladder augmentation, urinary diversion, or self-catheterization.

Native nephrectomy before transplantation should be considered in patients with recurrent or persistent kidney sepsis, particularly in the setting of nephrolithiasis. Very large polycystic kidneys may need to be removed to accommodate the transplant kidney. Whether previous grafts should be removed before repeated transplantation is controversial. Nephrectomy of a failed graft is commonly performed on withdrawal of immunosuppression in patients with early graft failure (<12 months) to alleviate symptoms such as pain, fever, and weight loss.[23] Other indications include graft sepsis and allowance of room for the new graft. However, unless there is a convincing reason to remove the graft, it is generally left in situ. In these circumstances the patient may need to stay on minimal immunosuppression, such as prednisolone for 3 to 6 months, to minimize graft tenderness and inflammation. Graft nephrectomy may be associated with an increased risk for human leukocyte antigen (HLA) sensitization,[23] but this is not a universal finding. Another advantage of leaving the previous transplant in situ is preservation of any residual kidney function and urine output.

Pulmonary Disease

Physical examination and chest radiography are indicated for all potential recipients; pulmonary function tests or computed tomographic (CT) scanning are done if clinically indicated. Guidelines suggest that patients with a short life expectancy associated with pulmonary disease, such as cor pulmonale, uncontrolled asthma, and severe obstructive lung disease (FEV_1 < 25% of predicted or Po_2 < 60 mm Hg [8 kPa] on room air), or those needing home oxygen should be excluded from transplantation.[4] Many centers require patients to cease smoking before acceptance because smokers have an increased risk for death and graft loss. Cessation of smoking demonstrates positive lifestyle behavior and good adherence, suggesting these factors will remain optimal after transplantation.

Psychosocial Issues

Psychosocial issues can have a major impact on transplant outcomes. Patients should be evaluated to judge capacity to consent and assess likely adherence to the transplant medication regimen. Predicting adherence can be challenging and may be based on pretransplantation adherence, such as to dialysis management regimens; transplantation should not proceed if the multidisciplinary assessment suggests that adherence is unlikely.[2-4]

Cognitive impairment is not an absolute contraindication to transplantation if appropriate supports and proxy arrangements are in place. Patients with serious psychiatric illnesses require assessment by a psychiatrist to determine transplant suitability and devise a management plan to cope with possible consequences of immunosuppressive medications such as corticosteroids.[2-4] Drug and alcohol addiction should be addressed with rehabilitation and demonstrated abstinence before the patient is listed for transplantation.

Presence of Multiple Comorbidities

Increasingly, patients with multiple comorbidities are referred for consideration of transplantation. Each morbidity in itself often is not an absolute contraindication but taken together they may significantly affect prognosis. Controversially, some have suggested that patients must have specified long-term survival prospects—for example, an 80% chance of surviving 5 years—to be accepted for transplantation from a deceased donor. In addition, risk calculators have been devised based on registry data to allow such predictions (e.g., https://optn.transplant.hrsa.gov/resources/allocation-calculators/epts-calculator/).[24]

Reevaluation of Patients on the Waiting List

Patients may wait several years on the waiting list before an opportunity arises to undergo transplantation. It is vital that when their opportunity comes, they are still suitable candidates. Waiting list patients therefore should be reassessed at regular intervals (Box 107.5). General measures, such as cancer screening (e.g., skin, prostate, breast, and cervical), should be continued as indicated. Reassessment of cardiac status is advocated based on risk. Diabetic and other high-risk patients should be reassessed every 1 to 2 years.[6] The value of reassessing low-risk patients is more questionable, but given that CKD is a strong risk factor for cardiac disease, repeated stress testing by exercise or pharmacologically driven echocardiography or myocardial perfusion scintigraphy at least every 3 years seems appropriate. Patients with preexisting medical conditions (e.g., HIV infection or viral hepatitis) require regular specialist reviews, with any issues arising brought to the attention of the transplant team. Surgical reassessment may be needed in patients with peripheral vascular disease, if patients gain weight, or if a complication such as peritonitis occurs while the patient awaits transplantation. Patients should be temporarily removed from the waiting list if they develop a serious infection or other illness until it is resolved.

DONOR EVALUATION

Classification of the Deceased Donor

Deceased donors can be classified as either heart-beating donors with loss of brainstem function (donation after brain death [DBD]) or non–heart beating donors (donation after cardiac death [DCD]). In the last

BOX 107.5 Potential Recipient Reevaluation While Awaiting Transplantation

b0030

- Stress echocardiogram or thallium scan
- Angiography if indicated (see Fig. 107.1)

Cancer Surveillance Relevant to Age, Sex, and Risk Factors

- Prostate-specific antigen
- Mammography
- Pap smear
- Colonoscopy if indicated
- Skin cancer check

Comorbidity Reassessment

- Viral hepatitis
- Liver function tests
- α-Fetoprotein
- Liver ultrasound
- HIV infection
- CD4 count
- AIDS-defining illness
- Other (see discussion of individual organ systems)
- Cardiac reevaluation every 1 to 2 years depending on risk factors (e.g., diabetes)

BOX 107.6 Classification of Donation After Cardiac Death Donors[a]

b0035

Uncontrolled

Category I: Dead on Arrival to Hospital

Cause of death is usually obvious (e.g., severe head injury), and no resuscitation is given.

Category II: Unsuccessful Resuscitation

The patient is brought to the emergency department while being resuscitated, but this is not effective. Alternatively, cardiac arrest occurs in hospital and the patient cannot be resuscitated.

Controlled

Category III: Awaiting Cardiac Arrest

Severe brain injury without brain death. Patients are usually ventilator dependent. Cardiac arrest occurs once support is withdrawn.

Category IV: Cardiac Arrest While Brain Dead

Patient has a cardiac arrest after being declared brain dead. Alternatively, this occurs during brain death testing and the patient is not successfully resuscitated.

Category V: Unexpected Cardiac Arrest in a Critically Ill Patient

Example: unsuccessful resuscitation after unexpected cardiac arrest in intensive care.

[a] As per Maastricht classification[24] (also known as non–heart-beating donors).

From Indudhara R, Kenney PJ, Bueschen AJ, Burns JR. Live donor nephrectomy in patients with fibromuscular dysplasia of the renal arteries. *J Urol.* 1999;162:678–681.

two decades the proportion of DCD donors has been increasing in many countries as a result of policies aiming to maximize the opportunities for donation.[25]

p0155 In the United States, DBD donors were previously divided into standard criteria donors (SCDs) and expanded-criteria donors (ECDs) for allocation purposes. ECD referred to heart-beating donors aged older than 60 years or 50 to 59 years with two or three of the following criteria: a history of hypertension, elevated serum creatinine at donation (>1.5 mg/dL or 130 μmol/L), or death from a cerebrovascular accident. In some jurisdictions, the term *marginal donor* is used to describe donors with significant underlying disease (hypertension, diabetes, vascular disease, kidney impairment) or advanced age (>65 years). In the last decade the United Network for Organ Sharing (UNOS) in the United States adopted a new system for classifying and allocating kidneys using a quality index.[26] Other countries have also begun to use a similar system.[27] The Kidney Donor Risk Index (KDRI) is a score that combines various donor factors to summarize the perceived quality of deceased donor kidneys. Factors in the calculation include age, creatinine, mode of death, donor pathway (brain death vs. circulatory death), history of hypertension or diabetes, race, and risk for HCV infection. A raw index score is converted to a percentile producing the Kidney Donor Profile Index (KDPI), rating from 0 (best) to 100 (worst).

p0160 The Maastricht classification defines DCD donors as controlled or uncontrolled (Box 107.6).[28] Controlled donors are those who experience cardiac arrest after withdrawal of support or after brain death. Uncontrolled donors are those who are deceased on arrival to the hospital or who had unsuccessful cardiopulmonary resuscitation. From a practical point of view, a system that uses controlled donors is easier to implement than one using uncontrolled donors. This is largely related to factors surrounding ethical considerations and the consent process involving relatives of the donor.

p0165 The survival of kidneys from ECD donors (loosely correlating with a KDPI > 85%) and from some categories of DCD donors is generally inferior to that of kidneys retrieved from SCD donors.[28] Many matching schemes attempt to allocate these less ideal grafts to recipients who are predicted to have a lower than average overall survival, but practice varies considerably across countries.[29] Simple age matching can be a part of this allocation process, or, alternatively, a more complex longevity-matching process can be performed using a recipient index.[30] The Expected Post Transplant Survival (EPTS) score is the best known example, which incorporates factors such as age, diabetes, years on dialysis, and previous transplantation into the score.[31]

p0170 An attempt to better use kidneys from donors perceived to have an increased risk of viral infection (HBV, HCV, and HIV) despite negative nucleic acid testing (NAT) has been made in some countries in recent years.[32] The issue here consists of a residual risk of viral transmission, related to a window period of possible infection in the donor, leaving the viral tests negative despite the presence of infection. In reality, the risk is low provided that results of NAT testing are negative. Additionally, HCV can now be effectively treated, leading to some units actually transplanting organs known to be infected and then treating the recipient for HCV.[33]

Evaluation of the Deceased Donor

s0095

p0175 In most circumstances, organ donor coordinators screen potential deceased donors after referral from intensive care units (ICUs) or emergency departments (EDs). Patient records are assessed and relatives are interviewed about important aspects of the clinical history. The assessment focuses on general health (including history of infections and cancer), social history (especially drug use and sexual history), and laboratory evidence of kidney impairment or other diseases (Box 107.7). Patients with sepsis, acute hepatitis, or HIV infection are excluded from donation, as are those with a history of malignancy. Nonmelanoma skin cancers do not lead to exclusion, nor do primary brain tumors unless they are of a high grade or the donor has received

chemotherapy or had a craniotomy or cerebral shunt inserted.[34] In some centers, donors potentially carrying HBV or HCV are accepted only for recipients who are seropositive for these viruses. The risk for an unknown donor malignant neoplasm is approximately 1.3%; however, the risk for transmitting a donor malignant neoplasm is lower at approximately 0.2%.[35]

p0180 Evaluation of kidney function is determined by history, urinalysis, and serum creatinine concentration. In some patients a biopsy (often performed at retrieval) may provide useful information, particularly with ECDs or donors with a high KDPI. Estimated glomerular filtration rate (eGFR) at admission should not be overtly reduced (>60 mL/min/1.73 m^2), but a temporary decline in kidney function is acceptable if function is expected to recover. Proteinuria (>0.5 g/day) may indicate structural kidney damage and is a valid reason for nonacceptance.

p0185 The use of kidneys from very young donors varies among centers. Donors aged younger than 5 or 6 years are associated with high risk for graft failure, especially from vascular thrombosis.[36] For this reason, some centers occasionally transplant two kidneys in the one recipient en bloc, using the aorta and inferior vena cava as conduits.[37]

Deceased Donor Management Before Transplantation

s0100

p0190 In the DBD donor, maintenance of adequate blood pressure (BP) and oxygenation are important to prevent warm ischemic kidney injury. The use of pressor agents, volume resuscitation, and other conditioning strategies is complex and has been the subject of several guideline documents (see the Intensive Care Society website, www.ics.ac.uk). In this category of donor, the kidneys are generally not subject to significant warm ischemia at the time of organ retrieval unless the donor experiences prolonged hemodynamic compromise.

p0195 In DCD, once death is certified and deemed irreversible, either rapid surgical exposure of the great vessels with cooling of the organs followed by prompt retrieval is required, or, alternatively, the kidneys are cooled in situ by insertion of perfusion catheters through the femoral vessels (see also Chapter 108). Surgical retrieval can then take place after the following occur, as required: family counseling, donor assessment, or relocation from one hospital area to another (e.g., from the ICU or ED to the operating room). DCD is inevitably associated with warm ischemic kidney injury. This is responsible for the higher rate of delayed graft function that is seen in this group. The need for dialysis after transplantation is approximately 50% but varies from 30% to 90%, depending on the Maastricht category of donor.[28]

Living Donors

s0105

p0200 Live kidney donation is currently accepted in most countries based on the demand for deceased donor organs—which far outweighs the supply—and the apparent very low level of risk to the majority of healthy donors.[38] Added to this are the detrimental effects for the recipient of waiting on dialysis and the generally superior results obtained through use of living donors.

p0205 Living donors may be related, unrelated, altruistic, or part of a donor exchange or list-exchange program. In many countries with well-established transplant programs, half or more of all transplants are now performed with living donors. In Japan, Brazil, and the Middle East, more than 80% of transplants use living donors. The superior outcomes of transplantation from living donors compared with that from deceased donors has supported the development of living donor paired exchange, in which living donors who are incompatible with their intended recipients are exchanged between recipients. Another approach is living donor–deceased donor exchange, in which the donor donates to the wait list in exchange for the intended recipient receiving priority on the list.[39]

p0210 In some countries, either a state-organized or a free-market system results in the purchase of living donor kidneys.[39] The Declaration of Istanbul and the World Health Organization both condemn the exploitation of living donors who are vulnerable (illiterate, impoverished, undocumented immigrants, prisoners, and political or economic refugees).[40]

p0215 Many centers have extended their selection of donors to include patients who are mildly hypertensive, overweight, or hyperlipidemic or who have other abnormalities (such as isolated microhematuria or

f0015

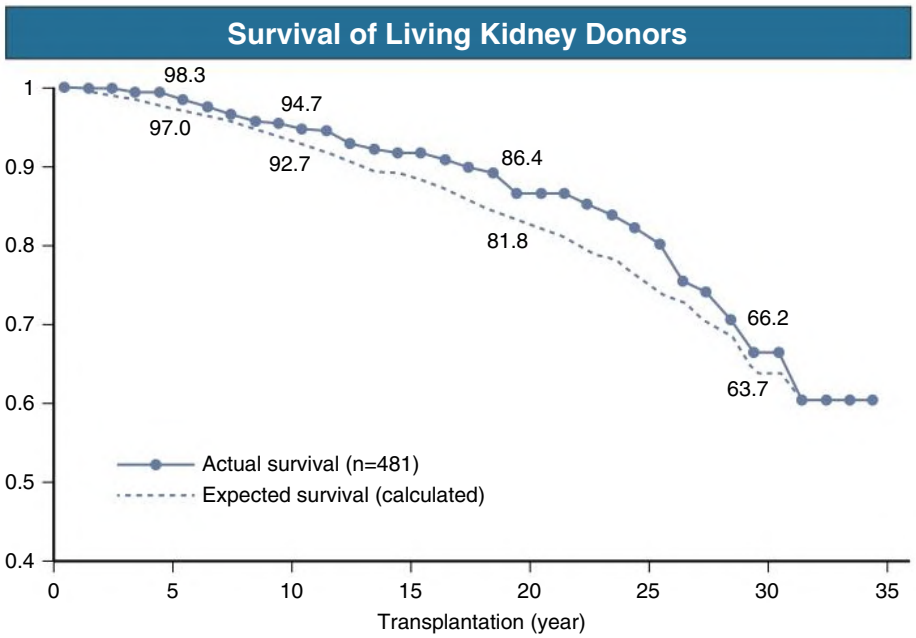

Fig. 107.2 Survival of Living Kidney Donors. Donor survival rates after living-donor kidney donation. Retrieval rate was 80.0% (481/601). Expected survival was calculated using data for an age- and sex-matched normal population in Japan provided by the National Cancer Center. (From Okamoto M, Akioka K, Nobori S, et al. Short- and long-term donor outcomes after kidney donation: analysis of 601 cases over a 35-year period at Japanese single center. *Transplantation.* 2009;87[3]:419-423.)

previous nephrolithiasis).[41] Although donation appears to be safe in the short- to medium-term for most of these patients, long-term risks have not been adequately assessed.

s0110

Mortality and Morbidity

p0220 Mortality related to living donation is a catastrophic and unexpected event; the perioperative risk for donor death is approximately 3 in 10,000.[4,42] In the longer term, survival of donors appears to be similar to that of the general population (Fig. 107.2).

p0225 Physical and psychological function in living donors is higher than the community norm. Physical issues reported by donors after donation frequently include a temporary decrease from baseline in energy; some note a longer time to full recovery than anticipated and incision pain (after open nephrectomy) that lasts longer than expected. Psychological factors usually include an improved relationship with the recipient, an improved self-image, and frequently a positive effect on the donor's life. Longer-term psychological morbidity appears minimal; however, some series have reported an association with anxiety, depression, or other psychological issues in a small proportion of the patients.[43] Although most donors have a positive experience, a small number for a variety of reasons regret the decision to donate (0%–5%).[44] Psychological evaluation before donation is therefore extremely important, as is support and counseling after donation, especially when the transplant does not go as well as anticipated.

s0115

Donor Evaluation: Living Donors

p0230 Several groups have developed guidelines for the evaluation and aftercare of living donors.[45–47] An outline of the usual donor evaluation is shown in Boxes 107.8 and 107.9. An assessment of relevant anatomy may be achieved by CT angiography or magnetic resonance angiography, depending on the center. Kidney arteriography is not usually necessary, given the anatomic detail available from noninvasive techniques.

b0045

BOX 107.8 Living Donor Evaluation Checklist: History and Examination

History

- Hypertension
- Diabetes (including gestational)
- Infections
- Cancer (including skin lesions)
- Vascular disease
- Kidney calculi
- Gout
- Urinary tract
- Family history
- Medication use (including NSAIDs, herbs)
- Smoking

BOX 107.9 Living Donor Evaluation Checklist: Investigations

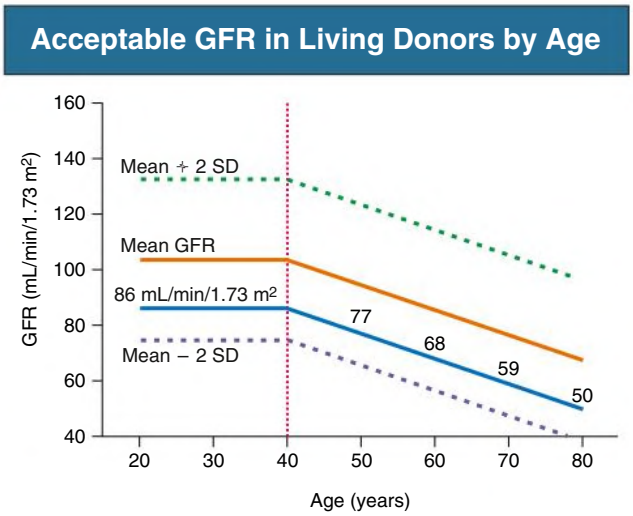
Laboratory and Radiologic Investigations

- Urinalysis (blood, protein)
- Urine microscopy and culture (blood, organisms)
- Serum electrolytes, urea, and creatinine
- Liver function tests
- Full blood examination
- Fasting blood glucose and/or oral glucose tolerance test
- Fasting lipids
- 24-Hour urine, creatinine clearance, or GFR measurement by iothalamate, Cr-EDTA, DTPA clearance, 24-hour urine protein, or protein excretion by other methods (e.g., protein-creatinine ratio)
- Serum uric acid, calcium, phosphate
- Viral screening: HBV, HCV, HIV, CMV, EBV serology
- Syphilis screening (RPR)
- TB screening (PPD)
- Electrocardiogram
- Chest radiograph
- Females: Pap smear, mammography (according to age and family history)
- Males: Prostate-specific antigen (according to age and family history)
- Additional cardiac investigations (where indicated by age, history, risk factors)
  - Stress test
  - Echocardiography
  - Ambulatory blood pressure

Kidney Imaging (According to Local Expertise)

- Computed tomographic angiography
- Magnetic resonance imaging angiography
- Catheter angiography

CMV, Cytomegalovirus; *Cr-EDTA,* chromium-labeled ethylenediaminetetraacetic acid; *DTPA,* diethylenetriaminepentaacetic acid; *EBV,* Epstein-Barr virus; *GFR,* glomerular filtration rate; *HBV,* hepatitis B virus; *HCV,* hepatitis C virus; *HIV,* human immunodeficiency virus; *PPD,* purified protein derivative test; *RPR,* rapid plasmin reagent; *TB,* tuberculosis.



f0020

Fig. 107.3 Acceptable glomerular filtration rate *(GFR)* in living donors by age. Diagram explaining the minimum acceptable age–associated GFR in living donor candidates. The *solid orange line* shows the variation with age of mean GFR. The *outer dashed lines* show the +2 and −2 population standard deviation (*SD*) limits. GFR is constant up to the age of 40 years and then declines at the rate of 9 mL/min/1.73 m^2 per decade. The reference plot is based on an analysis of data for 428 living kidney transplant donors who had chromium-51–labeled ethylenediaminetetraacetic acid (^{51}Cr-EDTA) GFR measurements. The *solid blue line* shows the acceptable lowest GFR for young adults, declining to 50 mL/min/1.73 m^2 at age 80 years. For transplant donors with preoperative GFR values above the solid blue line, the GFR of the remaining kidney will still be above 37.5 mL/min/1.73 m^2 at age 80 years. (Modified from the revised British Transplantation Society/Kidney Association U.K. guidelines for living donor kidney transplantation. www.bts.org.uk/.)

s0120

Assessment of Kidney Function

p0235 Most centers use GFR of 80 mL/min/1.73 m^2 as the lower limit for donors. It is accepted that this threshold may be too low for donors younger than 40 years and too high for donors older than 60 to 65 years. An alternative approach is to consider the age-specific GFR and accept donors only if they fall within the average for this age range. This method has been recommended by the British Transplantation Society (guidelines available at www.bts.org.uk) and is presented in Fig. 107.3. An alternative approach uses the life expectancy of the donor.[48] Based on these calculations, a 30-year-old donor would require a GFR of 123 mL/min/1.73 m^2; the required GFR for a 70-year-old person would be 68 mL/min/1.73 m^2.

s0125

Hypertension and Proteinuria in the Living Donor

p0240 Donation may be acceptable for some hypertensive individuals if BP is well controlled, GFR is as expected for donation and age, and there are no features of end-organ involvement from hypertension.[45–47] The evaluation for hypertension should include BP measurements on three separate occasions. Borderline elevated levels should be further evaluated with ambulatory BP monitoring. If elevated BP is detected and the prospective donor is still under consideration, echocardiography (looking for LV hypertrophy), ophthalmologic evaluation (looking for hypertensive retinal changes), and assessment for albuminuria (suggesting hypertensive kidney damage) should be undertaken. The prospective donor should be excluded if any of these features are present.

p0245 KDIGO (Kidney Disease: Improving Global Outcomes) recommends using the ratio of albumin to creatinine from a random urine sample with confirmation using an albumin excretion rate (AER) to assess donors for significant albuminuria (www.kdigo.org/guidelines/).[47,49] An acceptable AER is less than 30 mg/day, with 30 to 100 mg/day requiring an individualized approach. An AER greater than 100 mg/day should exclude potential donors.

s0130

Obesity and Abnormal Glucose Tolerance in the Living Donor

p0250 Although many centers accept obese living donors, several issues must be addressed. These include the impact of obesity on perioperative complications, future kidney function, and CV health. In one study, obese (BMI > 30) patients had an increased rate of proteinuria and kidney impairment 10 to 20 years after nephrectomy.[50] Obese individuals may therefore be more prone to development of kidney disease after donation, but this issue has not been carefully studied.

p0255 Future risk for diabetes is another important consideration. In addition to close assessment of those who are overweight, prospective donors with an abnormal fasting glucose concentration, a history of gestational diabetes, or a first-degree relative with diabetes should be evaluated with an oral glucose tolerance test. An abnormal glucose tolerance test result is a contraindication to donation. Patients often lose weight and otherwise change their lifestyle (exercise, diet), leading to an improvement in their results and eventual acceptance as donors. It is important that these lifestyle and risk modifications be sustained after donation occurs.

s0135 ### Kidney Abnormalities in the Living Donor

p0260 As well as factors identified in the history (e.g., previous calculi, urinary tract infections, prostatic disease), a variety of previously unidentified kidney abnormalities can be encountered in prospective donors during their assessment. These include microhematuria, kidney scarring (e.g., polar distortion suggesting reflux nephropathy), renovascular abnormalities, and kidney masses and cysts.

p0265 Isolated microhematuria in a prospective donor necessitates consideration of thin basement membrane nephropathy, Alport syndrome (carrier status in women may cause minor or moderate abnormalities), and IgA nephropathy, as well as urinary tract infection, malignancy, and nephrolithiasis. Persistent microhematuria is relatively common and is evident in approximately 3% of the general population.[47] Among the possible disorders, IgA nephropathy is generally a contraindication to live donation, whereas thin basement membrane nephropathy may not necessarily be so.[47] The implications of isolated mesangial IgA without other manifestations of glomerulonephritis requires further research, and donation should be decided in the context of family history, absolute kidney function, presence of interstitial disease, and age. If persistent isolated asymptomatic microhematuria is detected during living donor evaluation, a workup should include cystoscopy and urinary cytology. A kidney biopsy also should be considered because glomerular hematuria cannot otherwise be excluded. If there is a possibility of familial disease (e.g., Alport syndrome, IgA nephropathy), this also helps clarify the prospective donor's future risk for progressive kidney disease.[5,47]

p0270 Those with a history of bilateral or recurrent stones and those with systemic conditions associated with recurrent stone disease should not donate. An asymptomatic potential donor with a current single stone is suitable if the donor does not have a high risk for recurrence, if the stone is less than 1.5 mm, and especially if the stone is potentially removable during transplantation.[47] The evaluation of an asymptomatic donor with a single prior episode of nephrolithiasis should include evaluation of serum calcium, creatinine, albumin, and parathyroid hormone levels; spot urine for cystine; urinalysis and urine culture; spiral CT scan; chemical analysis of the stone, if available; and 24-hour urine measurement of oxalate, uric acid, and creatinine.

p0275 Atherosclerotic kidney vascular disease is a relative contraindication to living donation. If it is discovered, the donor should be normotensive, have normal kidney function, and have only unilateral disease. Careful evaluation for CAD and peripheral vascular disease should be undertaken, given the significant association of renovascular disease with atherosclerosis elsewhere. Fibromuscular dysplasia is found in 2% to 4% of prospective donors. Donors with severe and diffuse disease should not be accepted for donation. The age of the prospective donor should be considered, with the outcome in donors aged older than 50 years more benign than in younger donors.[51]

s0140 ### Malignancy

p0280 A history of certain malignancies is a contraindication to live kidney donation. These include melanoma, testicular cancer, kidney cell cancer, bronchial and breast cancer, choriocarcinoma, hematologic malignant neoplasm, and multiple myeloma.[45–47] A history of malignancy may be acceptable for donation if prior treatment does not decrease kidney reserve, place the donor at increased risk for kidney disease, or increase the operative risk for nephrectomy. A history of malignancy may be acceptable if the specific cancer is curable and transmission of the cancer can be reasonably excluded; consultation with an oncologist may be required. Examples of cancers with low risk for transmission include certain mild forms of prostate, bladder, and cervical cancer. Consent to receive a kidney transplant must include a discussion with the donor and the recipient indicating that risk for transmission of malignancy cannot be completely excluded.

s0145 ### Cardiovascular and Pulmonary Disease

p0285 In prospective donors, the cardiac assessment should be based on the history, risk factors, examination, and electrocardiographic findings.[47] An exercise or pharmacologic stress test and echocardiography may be warranted in certain circumstances. Individuals with myocardial dysfunction or coronary ischemia are at increased perioperative risk and should generally not donate. Pulmonary contraindications to donation include chronic lung diseases that significantly increase the anesthetic risk. If indicated by history and examination, pulmonary function testing, echocardiography, or sleep studies should be performed.[47] All donors should cease smoking for at least 8 to 12 weeks before surgery to minimize the risk for postoperative pneumonia.

s0150 ## COMPATIBILITY AND IMMUNOLOGIC CONSIDERATIONS

s0155 ### Blood Group Compatibility

p0290 Historically, transplantation across incompatible blood groups had been avoided because of the risk for hyperacute rejection mediated by preformed anti-A or anti-B antibodies to the carbohydrate blood group antigens, expressed by endothelial cells and by red blood cells. In the last two decades, ABO-incompatible transplantation has become more widespread, initially based on excellent outcomes described by Japanese centers.[52] "Desensitizing" the recipient can avert hyperacute rejection. This involves removal of blood group antibodies by plasma exchange or immunoadsorption to achieve target titers. Preemptive splenectomy or rituximab administration (anti-CD20 monoclonal antibody) also is often used; however, the need for these measures is not clear. Rejection is predicted by high initial antibody titers and high rebound titers early after transplantation.[53] A further period of plasma exchange or immunoadsorption after transplantation is commonly instituted, whereas other centers determine the need for these therapies preemptively based on posttransplantation antibody titers. With use of this protocol, patient and graft survival was initially reported as similar to that of blood group–compatible transplantation for the short to medium term (up to 9 years).[52] A recent systematic review, including data on 7098 patients who underwent ABO-incompatible transplant, reports an increase in mortality, graft loss, and infection at 5-years posttransplantation relative to recipients of ABO-compatible transplants.[54] Although the increase in absolute risk is small, these findings have prompted some to refer ABO-incompatible pairs to paired exchange programs (see www.bts.org.uk).

s0160 ### Human Leukocyte Antigen Compatibility

p0295 Tissue typing of recipient and donor determines their HLA match. HLA antigens are coded on chromosome 6, with half (one haplotype) inherited from each parent. The major histocompatibility class I HLA-A and HLA-B and class II HLA-DR antigens have routinely been determined because rejection responses are thought to most commonly stem from mismatches at these alleles. However, an increasing awareness of the importance of immune responses to other HLA antigens has resulted in centers routinely looking for the presence of antibodies to HLA-C, HLA-DQ, and HLA-DP. A six-antigen (HLA-A, HLA-B, and HLA-DR) match confers a graft survival advantage compared with zero antigen matches for both deceased and living donor transplantation of 10% at 10 years.[55] A further advance has been the description of the immunologically important antigenic subunits of HLA (epitopes) that rejection responses are directed against.[56] Each HLA antigen has multiple epitopes that can be compared between donor and recipient

to determine the degree of epitope matching, which also has implications for transplant outcomes.[57] In addition to determination of HLA compatibility, crossmatching and screening for anti-HLA antibodies are performed to assess the risk for rejection.

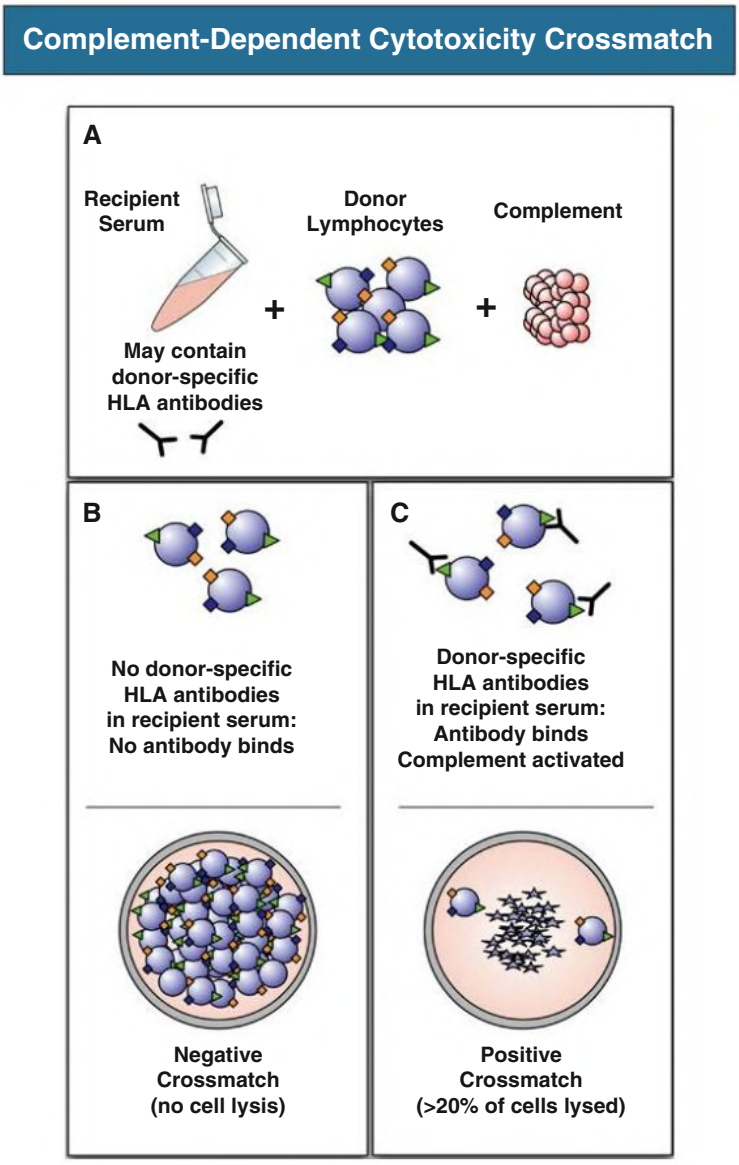
s0165 ## Assessing Human Leukocyte Antigen Sensitization

p0300 Sensitization to HLA antigens generally occurs through blood transfusion, pregnancy, or prior transplantation. The extent of HLA sensitization in an individual can be measured using complement-dependent cytotoxicity (CDC), enzyme-linked immunosorbent assays (ELISA), and antigen-coated bead technology; the latter is most common. These assays determine the number and specificity of antibodies against HLA antigens present in sera from the potential recipient and compare them to the HLA of a panel of individuals from the recipient's prospective donor population. A panel reactive antibody (PRA) of 75% means that the recipient has anti-HLA antibodies that react with 75% of people from that population. To avoid donors against whom they have donor-specific antibodies, patients with higher PRAs typically wait longer for deceased donor transplantation.

p0305 Presence in the recipient of antibodies to donor-specific HLA antigens can result in hyperacute rejection. Crossmatching of donor lymphocytes with recipient serum allows screening for this possibility. Terasaki and coworkers pioneered the CDC crossmatch,[58] which determines the presence of clinically significant antibodies by mixing donor T or B lymphocytes with recipient serum in the presence of complement. The sensitivity of the assay can be augmented by the addition of antihuman globulin. Presence of a positive T-cell CDC crossmatch to the donor is highly predictive of hyperacute rejection,[58] whereas a B-cell CDC crossmatch is more subject to false-positive results but should prompt a search for donor-specific antibodies (Fig. 107.4).[59,60] A positive T-cell CDC crossmatch is an absolute contraindication to transplantation. The CDC crossmatch has limitations in detecting low level and non–complement-fixing antibodies, high false-positive rates, and logistical issues with obtaining reagents and running the assays in a timely fashion.

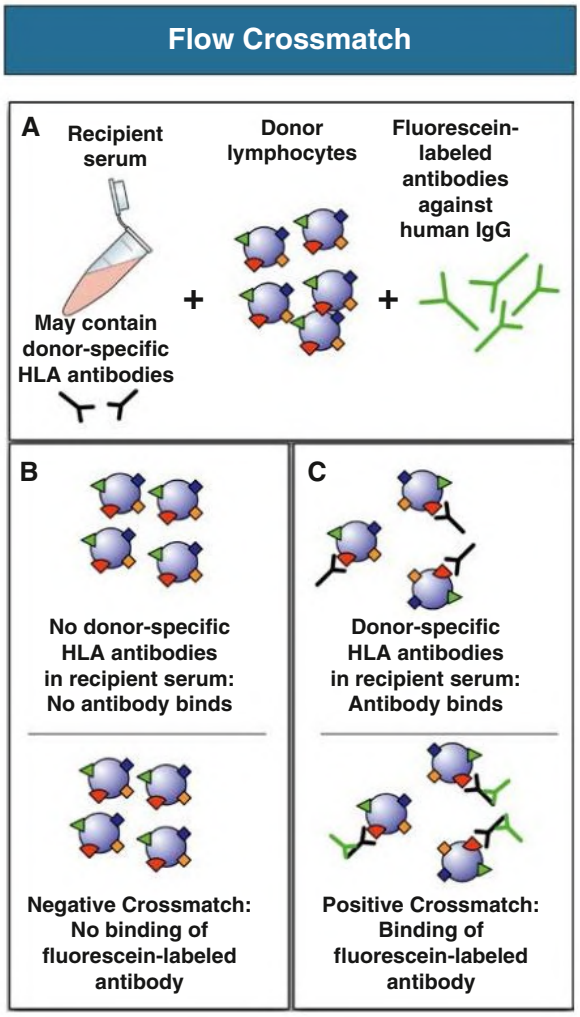
p0310 The flow crossmatch is more sensitive than the CDC in detecting antibody capable of binding to donor T or B lymphocytes. Binding of antibody from donor serum is detected by flow cytometry after probing with a fluorescein-labeled anti-immunoglobulin antibody (Fig. 107.5).[60] The strength of a positive flow crossmatch can be estimated by the degree of lymphocyte fluorescence that is measured in channel shifts. An increasing number of channel shifts is associated with an increasing risk of rejection. The predictive value of a positive flow crossmatch for rejection is less than that of a CDC crossmatch because of its increased sensitivity, and it does not assess the ability of the antibody to fix complement. Some deceased donor allocation systems now employ flow crossmatching, in conjunction with virtual crossmatching, in place of CDC crossmatching. Flow crossmatching is commonly performed in a living donor transplant workup. A positive-flow crossmatch (with a negative CDC crossmatch) is not an absolute contraindication to proceeding; however, it may lead to alteration of the immunosuppressive regimen (e.g., use of a desensitization protocol) to decrease the risk or severity of antibody-mediated rejection.

p0315 Testing for anti-HLA antibodies in the recipient's serum is increasingly used as a means of predicting rejection. This virtual crossmatch compares the specificity of the antibodies identified with the prospective donor's HLA typing. Donor-specific anti-HLA antibodies correlate with worse graft survival even in the setting of a negative crossmatch.[61] Although antibodies can be detected through a variety of techniques, including CDC panel reactive antibody testing and ELISA, the more sensitive antigen-coated bead technique is now almost exclusively employed. Multiple microscopic beads, each with a unique color that corresponds to a single HLA antigen that coats its surface, are mixed with recipient serum and probed with a fluorescein-labeled anti-immunoglobulin antibody (Fig. 107.6). Beads that bind antibody are identified as positive by fluorescence, and their HLA antigen specificity is detected by the unique coloring of the bead.[60] A positive virtual crossmatch is one in which a donor-specific antibody is detected. The strength of positivity of the virtual crossmatch can be estimated by the degree of fluorescence of the positive bead; however, this is not always accurate. The decision on whether to proceed with transplantation in the context of this information is complex. Recommendations for detection and characterization of clinically relevant antibodies in solid organ transplantation are summarized at www.bts.org.uk.



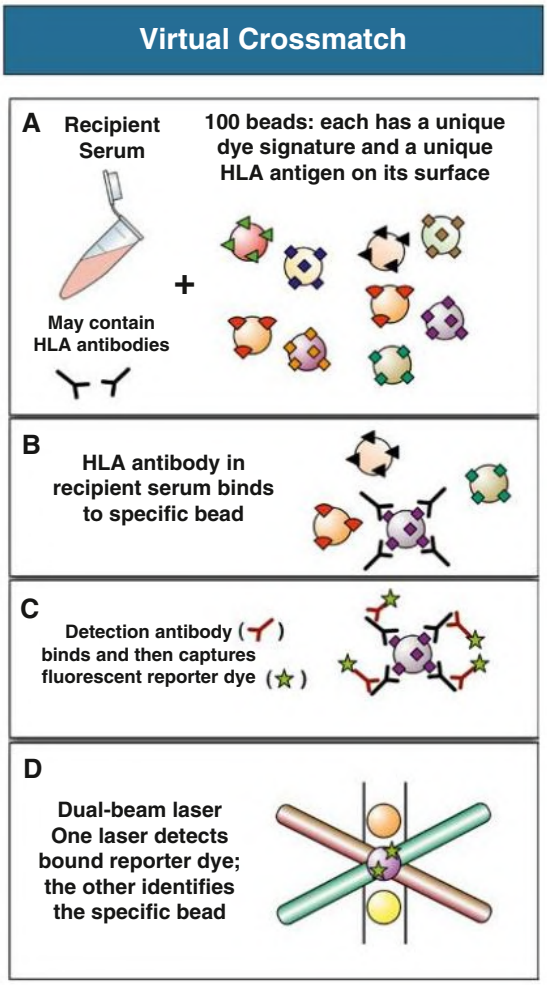
f0025

Fig. 107.4 Complement-Dependent Cytotoxicity (CDC) Crossmatch. (A) Recipient serum potentially containing donor-specific anti–human leukocyte antigen (HLA) antibodies is added to donor T or B lymphocytes, along with complement. (B) If donor-specific antibodies are not present, no lysis occurs and the result is deemed negative. (C) If donor-specific anti-HLA antibodies bind to the lymphocytes and then activate complement, cell lysis will occur and the crossmatch result will be deemed positive. The proportion of lysed cells is assessed, and the crossmatch is graded as being weakly, moderately, or strongly positive. (From Mulley WR, Kanellis J. Understanding crossmatch testing in organ transplantation: a case-based guide for the general nephrologist. *Nephrology*. 2011;16[2]:125–133.)



f0030

Fig. 107.5 Flow Crossmatch. (A) Recipient serum potentially containing donor-specific anti–human leukocyte antigen (HLA) antibodies is added to donor T or B lymphocytes, along with fluorescein-labeled antibodies against human immunoglobulin G (IgG). (B) If donor-specific antibodies are not present, no binding occurs and the result is deemed negative. (C) If donor-specific anti-HLA antibodies bind to the lymphocytes, these can then bind the fluorescein-labeled antihuman IgG antibody, and this will be detectable by flow cytometry. The strength of the fluorescence can be measured and expressed as "channel shifts" above the control sample. (From Mulley WR, Kanellis J. Understanding crossmatch testing in organ transplantation: a case-based guide for the general nephrologist. *Nephrology*. 2011;16(2):125–133.)



f0035

Fig. 107.6 Virtual Crossmatch. (A) Recipient serum potentially containing anti–human leukocyte antigen (HLA) antibodies is added to a mixture of synthetic beads. Each bead is coated with a set of antigens (screening beads) or, for more precise detail, with a single antigen (single antigen beads). A unique dye signature (up to 100) specifies the identity of each bead. (B) If anti-HLA antibodies are present, they will bind to the appropriate bead. (C) A detection antibody can subsequently bind and capture a reporter dye. (D) Each unique bead can then be interrogated for the presence of the reporter dye on its surface using a dual-beam laser. A profile of antibodies can thus be identified in the recipient and compared with the known HLA identity of any potential donor, allowing a prediction of the crossmatch result. (From Mulley WR, Kanellis J. Understanding crossmatch testing in organ transplantation: a case-based guide for the general nephrologist. *Nephrology*. 2011;16[2];125–133.)

SELF-ASSESSMENT QUESTIONS

o0010 **1.** Which one of the following recipient factors is an absolute contraindication to transplantation?

o0015 **A.** Active sepsis
o0020 **B.** HIV infection
o0025 **C.** Obesity
o0030 **D.** Age older than 70 years
o0035 **E.** Previous malignancy

o0040 **2.** In predicting the risk for cardiac death in potential kidney transplant recipients, stress echocardiography performs best in terms of which of the following parameters?

o0045 **A.** Sensitivity
o0050 **B.** Specificity
o0055 **C.** Positive predictive value
o0060 **D.** Negative predictive value
o0065 **E.** A and B equally

o0070 **3.** Which one of the following brain-dead donors meets the definition for an expanded criteria deceased donor (as previously used in the United States)?

o0075 **A.** A previously well 53-year-old person with a serum creatinine at donation of 1.7 mg/dL (150 μmol/L)

o0080 **B.** A 48-year-old person with diabetes, hypertension, vascular disease, and smoking history

o0085 **C.** A 48-year-old person with hypertension and death from a cerebrovascular accident

o0090 **D.** A 62-year-old person with no significant medical history

o0095 **E.** A 58-year-old person with hepatitis

o0100 **4.** Which one of the following investigations would you *not* routinely perform on a 67-year-old man to assess his suitability to donate a kidney to his wife?

o0105 **A.** Urine microscopy

o0110 **B.** Colonoscopy

C. Hepatitis serology o0115

D. Electrocardiogram o0120

E. Kidney imaging o0125

5. Which one of the following will *best* identify a high risk for hyperacute rejection? o0130

A. Recipient tissue typing o0135

B. Positive flow crossmatch o0140

C. Positive T-cell cytotoxicity–dependent crossmatch o0145

D. Positive virtual crossmatch o0150

E. Donor O blood group o0155

Kidney Transplantation Surgery

Adam D. Barlow, Michael L. Nicholson

SOURCES OF KIDNEYS FOR TRANSPLANTATION

The usual and most frequent source of kidneys for transplantation has been donation after brain death (DBD), formerly known as donation from a heart-beating cadaveric donor. The increasing worldwide discrepancy between the availability of and the need for kidney allografts[1] has led to the increasing use of alternative sources of organs, including donation after cardiac death (DCD) donors (previously known as non–heart-beating donors) and living donors. The evaluation and selection of donors are discussed in Chapter 107. This chapter discusses surgical aspects of retrieval and transplantation of kidneys.

DONATION AFTER BRAIN DEATH DONORS

The potential DBD donor is maintained by artificial ventilation in a critical care setting until death has been diagnosed by brainstem death criteria,[2] the consent of the next of kin for donation has been given, and the necessary legal and institutional approvals have been obtained.

In the operating room some dissection is undertaken initially to define any aberrant anatomy and increase the speed and safety of organ retrieval after perfusion (warm dissection). Cannulation of the aorta and inferior vena cava is performed while the heart is still beating. This allows perfusion of the organs with cold preservative solution immediately before cardiac arrest, minimizing warm ischemia. The priorities of the organ retrieval team are influenced by the range of organs being donated. Heart, lung, liver, and pancreas retrieval take priority over kidney retrieval, which may significantly lengthen the ischemic time. The kidneys are removed with a cuff of aorta (Carrel patch) attached to the renal artery, with the maximum achievable length of renal vein, and 10 to 15 cm of ureter. The length of the right renal vein should be maximized by including a portion of inferior vena cava in continuity. Care is taken to avoid damage to polar and other accessory arteries, especially the lower pole artery, which may supply the ureter. Stripping of adventitial tissue from the ureter must also be avoided, because this also may compromise its blood supply.

The kidneys are flushed with ice-cold preservation fluid until the effluent is clear and then are stored for transport in crushed ice or on a perfusion machine (see the discussion of kidney preservation).

DONATION AFTER CARDIAC DEATH DONORS

Before consensus was reached regarding the definition of brainstem death, DCD donors were the main source of transplant organs. These donors were intensive care unit based and had sustained head injuries or cerebrovascular accidents deemed irrecoverable, but organ retrieval could proceed only after cardiorespiratory death. This changed with the introduction of brainstem death legislation, but the use of DCD kidneys has recently increased again in response to the shortage of suitable organs for transplantation. An international consensus has defined categories of DCD donors[3] to facilitate legal and ethical discussion and to highlight possible differences in organ viability (see Chapter 107, Box 107.6). DCD kidneys sustain a period of warm ischemia, the period between cardiac arrest and the time that in situ cold perfusion is started. The duration of ischemia correlates with rates of primary nonfunction, delayed graft function, acute rejection, allograft, and patient survival. The main requirement of organ procurement from DCD donors is therefore to achieve rapid in situ perfusion of the kidneys to limit warm ischemia. This requires an emergency response team of surgeons and transplant coordinators, with considerable on-call and logistic commitments.

DCD donors may be either uncontrolled (Maastricht categories I and II) or controlled (Maastricht categories III through V). In controlled donors, cardiac arrest is expected, and it is therefore possible to reduce the warm ischemia time to only a few minutes because the surgical retrieval team will be on standby. Unexpected donor cardiac arrest may result in prolonged warm ischemia times. The duration of reversible warm ischemia time that the human kidney can sustain is unknown, but DCD kidneys with warm ischemia exceeding 60 minutes are considered by many to be of marginal suitability.

Donation After Cardiac Death Protocol

Centers involved with DCD donation should adhere to the Maastricht protocol,[4] which includes the following principles:

- Approval by the local medical ethics committee
- Diagnosis of death by doctors who are independent of the transplantation team
- Five-minute rule (after declaration of cardiac death, the body is left untouched for a period of at least 5 minutes before intervention)
- Rapid in situ cooling with use of a catheter inserted into the aorta
- Organ retrieval by standard surgical techniques

Uncontrolled Donation After Cardiac Death Donors

After a period of unsuccessful resuscitation, confirmation of cardiac death, and observation of the 5-minute rule, cardiac massage and ventilation with 100% oxygen are recommenced in an attempt to deliver oxygenated blood to the kidneys. A mechanical resuscitation device may be used. In situ renal cooling is achieved by placing a double-balloon, triple-lumen perfusion catheter into the aorta via a femoral artery cut-down (Fig. 108.1) with instillation of preservation solution. Alternatively, the donor can be moved to an operating room as soon as death has occurred, and the aortic perfusion catheter placed directly at laparotomy rather than via a femoral artery cutdown.

Controlled Donation After Cardiac Death Donors

For controlled DCD donors, the transplantation team awaits cardiac arrest following withdrawal of life sustaining treatment. This usually

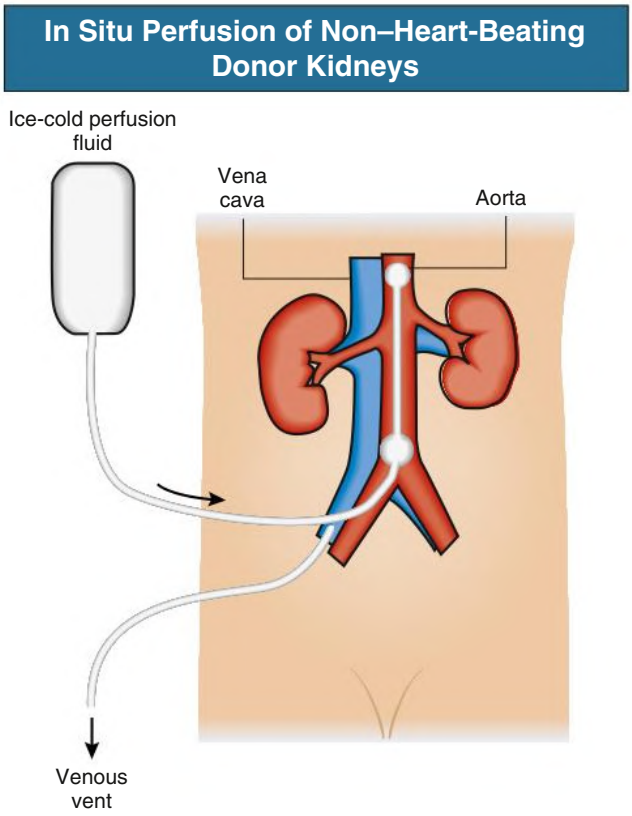

Fig. 108.1 Technique for in Situ Perfusion of Donation After Cardiac Death Kidneys. A double-lumen, double-balloon arterial catheter is introduced through the femoral artery and the lower balloon inflated at the aortic bifurcation and the upper balloon above the renal arteries. Ice-cold perfusion fluid is introduced and vented through the femoral vein until the effluent becomes clear.

takes place in the theatre anesthetic room or intensive care unit if it is close to the operating theatre. Withdrawal involves cessation of mechanical ventilation, extubation, and cessation of inotropic medications. Following asystole and confirmation of death, the 5-minute rule is observed and the patient is transferred to the operating theatre. A rapid laparotomy is performed and the perfusion catheter is inserted via the aorta or iliac artery.

LIVING KIDNEY DONORS

In the United States in 2018, 29% of kidney transplants were from living donors[5] compared with 28% in the United Kingdom in 2018–19.[6] After a rapid increase in living donor transplantation at the beginning of this decade, rates have become more static. Superior recipient post-transplantation outcome compared with use of kidneys from deceased donors,[7] the potential for preemptive transplantation before dialysis, and the ability to plan the procedure (allowing optimization of recipient condition) are major advantages and justify continued efforts to expand use of living donors. The medical evaluation of the living donor is discussed in Chapter 107.

Preoperative Imaging

Preoperative imaging of living donors confirms the presence of two functioning kidneys, indicates pathology that would preclude donation, and provides anatomic information necessary for planning the procedure. Imaging assumes paramount importance before minimal access donor nephrectomy because of the reduced operative exposure

Fig. 108.2 Living Donor Preoperative Computed Tomographic Angiogram. (A) Three-dimensional reconstruction of arterial supply. Note the lower pole artery to the right kidney *(arrow),* which may supply the ureter as well as the lower pole parenchyma. (B) Conventional image showing single artery and vein to the left kidney.

and particular difficulties in the identification of complex vascular anatomy. The location, size, and number of renal arteries and veins needs to be accurately described preoperatively. Angiography combined with excretion urography is now obsolete. For preoperative description of the main renal artery and vein anatomy, magnetic resonance angiography and computed tomographic angiography are comparable,[8] but computed tomographic angiography is more sensitive and specific for complex vascular anatomy and provides excellent correlation between imaging and surgical findings[9] (Fig. 108.2).

Minimal Access (Laparoscopic) Donor Nephrectomy

Living donor nephrectomy was traditionally performed through an open incision, necessitating a prolonged period of recovery. This and the cosmetic implications of a large flank wound may discourage potential donors (Fig. 108.3). To reduce such disincentives, there was

Fig. 108.3 Flank wound from open nephrectomy.

BOX 108.1 Donor Benefits of Minimally Invasive Donor Nephrectomy

- Shorter incisions
- Less pain
- Shorter hospital stay
- Shorter recovery
- Better cosmetic appearance

a move in the late 1990s and early 2000s toward minimally invasive donor nephrectomy, first performed as a transperitoneal laparoscopic procedure (laparoscopic donor nephrectomy [LapDN]).[10] LapDN is associated with decreased severity and duration of postoperative pain, shorter inpatient stay, quicker return to work and normal activities, and improved cosmetic result compared with open donor nephrectomy[11] (Box 108.1). Furthermore, the overall societal cost of LapDN is lower,[12] and recipient quality-of-life scores are higher.[13] The procedure is, however, technically demanding, and there is potential for damage to the kidney parenchyma, vessels, and ureter during dissection. It takes longer than open nephrectomy and exposes the allograft to a longer period of warm ischemia, albeit only of a few minutes.[11,14]

Nevertheless, retrospective data suggest that minimal access donor nephrectomy not only offers postoperative advantages to the donor but also increases the number of transplants performed by reducing donor disincentives; estimates range from a 25% to a 100%[15] increase in transplantation activity. The widespread introduction of LapDN at the beginning of the 2000s saw an initial dramatic increase in the number of live kidney donors. However, rates have been static in both the United States and the United Kingdom over the last 5 years, suggesting that we may have seen the maximum benefits of this effect. Three minimal-access approaches have been described: transperitoneal, extraperitoneal, and hand-assisted living donor nephrectomy.

Transperitoneal LapDN

Pneumoperitoneum is established, and four laparoscopic ports are usually required (Fig. 108.4). After laparoscopic dissection a Pfannenstiel or iliac fossa incision is made through which the kidney is brought out within an endoscopy retrieval bag after control and division of the artery vein and ureter.

Hand-Assisted LapDN

The hand-assisted technique allows tactile sense to facilitate dissection, retraction, and exposure. It is said to be easier to learn and can be safely and efficiently performed by surgeons with less laparoscopic experience. The hand-assist device allows the operator's nondominant hand to enter the abdomen through an airtight system.

Retroperitoneoscopic Operative Technique

The retroperitoneal approach avoids breaching the peritoneum, displays the kidney anatomy in a very different manner, and may be easier for retrieving the full length of the vessels, especially on the right side. The disadvantage is that a more limited operating space is available than with the transperitoneal or hand-assisted laparoscopic techniques.

Robotic Live Donor Nephrectomy

All of the earlier minimally invasive techniques can be undertaken using robotic assistance, and this has been adopted by a number of centers worldwide. However, there is no high-level evidence of clinical benefit over laparoscopic-assisted approaches, and it is difficult to justify the additional costs and infrastructure required, given the excellent outcomes of the current minimally invasive techniques.

Contraindications to Minimal Access Donor Nephrectomy

There are no absolute contraindications other than those applying to the open operation. The relative contraindications are dictated by donor factors and the experience of the surgeon. The donor must be fit for anesthesia, including the physiologic stress of pneumoperitoneum. Obesity is a relative contraindication for both open and laparoscopic surgery, and the hand-assisted approach may be better suited in such patients. Previous abdominal surgery is a further relative contraindication because of the potential for adhesions. Multiplicity of renal vessels should not hinder LapDN.

Effect of Pneumoperitoneum

Transient intraoperative oliguria secondary to decreased renal blood flow is a frequent occurrence during laparoscopic procedures. Proposed mechanisms include decreased cardiac output, renal vein compression, ureteral obstruction, renal parenchymal compression, and systemic hormonal effects. Intracranial pressure increases during pneumoperitoneum, with release of vasoconstrictor agents that decrease renal blood flow. Use of a lower pressure reduces the adverse effects of pneumoperitoneum on kidney perfusion. In donor nephrectomy, impaired renal blood flow may compromise early allograft function and compound the damaging effects of warm and cold ischemia and operative manipulation of the kidney. The pioneers of LapDN used high volumes of crystalloid preoperatively and intraoperatively to maintain kidney perfusion in the presence of pneumoperitoneum. However, this was associated with episodes of unilateral pulmonary edema in the dependent lung, and we now recommend no additional volume loading in the donor beyond standard perioperative fluid replacement. The revised protocol has not apparently reduced the likelihood of good graft function.

Graft Function and Acute Rejection

There is no consistent evidence that graft function differs among kidneys retrieved by open, laparoscopic, or hand-assisted donor nephrectomy. The exception is that rates of delayed graft function and acute rejection may be higher in pediatric recipients, especially the 0- to 5-year age group.

Pretransplantation ischemia could, in theory, render the donor kidney more immunogenic by inducing major histocompatibility complex (MHC) class II expression. However, despite the longer warm ischemia time, acute rejection rates and severity of rejection are not higher in laparoscopic than in openly retrieved living donor kidneys.

Technical Issues

Ureteral ischemia was more common in early experience of LapDN but can be avoided if care is taken to ensure that sufficient periureteral tissue is taken and that the dissection does not occur too close to the renal pelvis.

Multiple arteries need not be a barrier to successful use of grafts from laparoscopic donors. In open donor nephrectomy, the right kidney is retrieved in 20% to 30% of procedures, whereas LapDN uses the right kidney in fewer than 10%,[16] reflecting concern over the operative safety of the right-sided laparoscopic operation, principally the difficulties involved in obtaining an adequate length of renal vein. It has been argued that this practice has led to compromise of the principle that the better kidney should remain with the donor.

Postoperative Recovery

After uneventful open nephrectomy, the donor can expect to be discharged from the hospital in 5 or 6 days and is able to return to work after 3 to 6 weeks, although return to work has been shown to be 2 to 3 weeks later in open nephrectomy compared with LapDN.[11] After LapDN the donor usually leaves the hospital in 1 to 2 days and can return to work in 3 to 6 weeks.

Choice of Donor Operative Technique

The choice of operative procedure depends on the local expertise of the surgeons. There is accumulating evidence that the laparoscopic operation removes some of the disincentives to donation, and this approach has now been widely adopted around the world.

KIDNEY PRESERVATION

Preservation of deceased donor organs is crucial to allow time for matching, sharing of organs, and preparation of the recipient. Damage from hypothermia and reperfusion must be minimized. There is little standardization of the type of preservation solution used. Marshall's hyperosmolar citrate solution and histidine-tryptophan-ketoglutarate are popular choices in Europe, but University of Wisconsin solution is more commonly used in the United States, where extended preservation times are more often required.

Organs can be preserved by cold storage (kept in crushed ice after flushing with preservation solution) or by machine-driven pulsatile perfusion. The proposed benefits of machine perfusion come from allowing aerobic function through provision of oxygen and substrate and removal of metabolic end-products. Although hypothermic machine perfusion has been used for many years, there is still no consensus about its superiority to cold storage nor about the best perfusion parameters. However, recent meta-analyses have suggested benefits of machine perfusion in improved delayed graft function rates and graft survival.[17,18] This effect seems to be similar for kidneys from both DCD and DBD donors and to have cost benefits over static cold storage.[18]

Further developments in hypothermic machine perfusion have led to the addition of oxygen to the perfusion fluid. Clinical trials are ongoing to assess the benefits of hypothermic oxygenated perfusion over both static cold storage and standard hypothermic machine perfusion, with one recent RCT suggesting a reduction in severe complications and graft failure with the addition of oxygen to hypothermic machine perfusion.[19]

A novel approach to kidney preservation, only recently introduced into clinical practice, is *ex vivo* normothermic perfusion. Early results

are promising,[20] but the technique needs to be studied in larger clinical trials, one of which is ongoing in the United Kingdom.[21]

Decisions on the use of a kidney from a marginal donor can be supported by data from machine or normothermic perfusion; high perfusion pressures are associated with primary nonfunction and delayed graft function.

KIDNEY TRANSPLANTATION PROCEDURE

The transplanted kidney is placed heterotopically in one or another iliac fossa. The right side is usually preferred for first-time kidney transplant as the external iliac vessels, particularly the vein, lie more superficially than on the left. The inferior epigastric vessels are ligated, as is the round ligament of the uterus in female patients. Occasionally the inferior epigastric artery may be preserved and used for revascularization of small polar arteries. In male patients the spermatic cord is mobilized and preserved. The peritoneum should not be breached but instead swept superiorly to reveal the extraperitoneal bed into which the transplanted kidney will be placed. The external iliac blood vessels are then mobilized, with care taken to meticulously ligate all the associated lymphatic channels to reduce the risk for posttransplantation lymphatic leak.

Vascular Anastomosis

The renal vein is anastomosed end to side to the external iliac vein. The arterial anastomosis can be performed either end to side to the external iliac artery or end to end to the divided internal iliac artery (Fig. 108.5). The end-to-side anastomosis is technically easier and is the usual method used in cadaveric transplantation, where it is possible to include a Carrel aortic patch with the renal artery.

With living donor kidneys it is not possible to include a Carrel patch, and occasionally a cadaveric kidney may be provided without a useable patch. In these circumstances the options are to anastomose the renal artery end to end to the divided internal iliac artery or end to side to the external iliac artery. Use of an aortic punch to create a circular arteriotomy may facilitate the latter technique. For living donor kidneys, most surgeons use the external iliac artery. It is our experience that positioning the kidney is often easier if the internal iliac artery has been used for the anastomosis, but this does risk buttock claudication and potentially increases the risk for erectile dysfunction in male recipients.

After completion of the vascular anastomoses, the kidney must sit in such a position that the renal vessels are not kinked. The transplanted kidney can be placed laterally in the iliac fossa or may be placed in a subrectus pouch fashioned specifically for the purpose.[22] In the latter case the renal vessels run laterally from the kidney, and this should be noted when a posttransplantation biopsy is performed. An operative diagram of the position of the kidney and vessels is therefore an important component of the clinical notes.

If there are multiple renal vessels, the number of anastomoses should be minimized. This usually can be achieved by careful bench surgery before implantation. If there are two or more renal arteries, their aortic patches are joined in such a way that a single arterial anastomosis is required. If necessary, recipient iliac artery or saphenous vein is used to facilitate reconstruction. Occasionally, small polar arteries will be recognized only after a kidney has been retrieved, and it is particularly important to reanastomose lower polar arteries accurately because these may provide all the ureteral blood supply. In the case of double renal veins, the most common course of action is simply to ligate the smaller vein; the larger one is usually sufficient to drain the whole kidney. If there are two equally sized veins, both may need to be anastomosed, either separately to the external iliac vein or joined and anastomosed together.

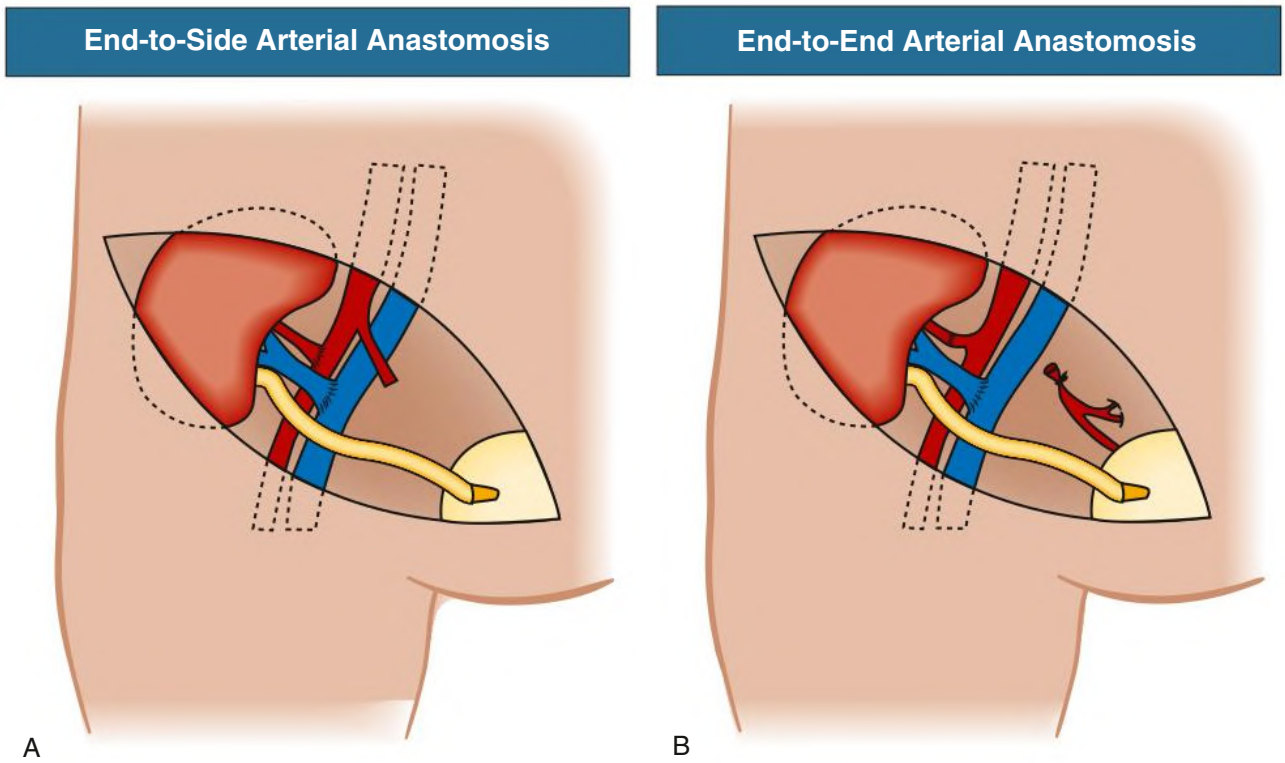

Fig. 108.5 Vascular Anastomosis Techniques for kidney Transplantation. (A) End-to-side anastomosis to the external iliac artery. (B) End-to-end anastomosis to the divided internal iliac artery, suitable for living donor transplantation in which no aortic patch is available.

Urinary Drainage

The traditional method of ureteral anastomosis is the Politano-Leadbetter technique, involving a transvesical ureteroneocystostomy with creation of a submucosal antireflux tunnel. The end of the transplanted ureter is drawn through a submucosal tunnel from outside to inside and sutured to the bladder mucosa. The majority of surgeons now prefer the technically simpler extravesical ureteroneocystostomy onlay, in which the spatulated end of the ureter is anastomosed to the cystostomy and the divided muscle layer is then resutured over the ureter to create a short antireflux muscle tunnel. The onlay method has the advantage of being possible with only a short length of ureter. The shorter the ureter, the less likely it is that there will be an inadequate blood supply to the distal end, thereby reducing the risks for ischemic ureteral leaks or stenosis. A temporary double-J ureteral stent is usually placed. Stents reduce the impact of small technical errors while the ureter is healing and reduce major urologic complications to an incidence of 1.5%.[23] However, they are a potential source of urinary tract infection, can become encrusted or blocked by debris, and can migrate or fragment. Nevertheless, antibiotic prophylaxis is not justified because it increases the risk for infection with multiresistant organisms. A further danger is the forgotten stent that has not been removed, which should always be considered in patients with unexplained and persistent lower urinary tract symptoms after transplantation. Stents are usually removed 4 to 6 weeks posttransplantation, and this can be performed without general anesthesia with use of a flexible cystoscope.

Alternative Techniques of Urinary Reconstruction

Kidney transplantation is quite commonly performed in patients who have abnormal bladders. In many patients it is possible to anastomose the transplanted ureter to the bladder in the hope that the bladder can be rehabilitated, if necessary, with use of posttransplantation intermittent self-catheterization. Nonetheless, some patients require urinary diversion with an ileal conduit. The conduit should be fashioned at least 6 weeks before transplantation, but it may have been present for many years. If so, a contrast study (a conduitogram) should be performed before transplantation to exclude the development of conduit stenosis, although this is rare. The transplanted kidney is best placed in the ipsilateral iliac fossa to avoid tension in the ureter, and it may be preferable to deliberately place the transplanted kidney upside down so that the ureter runs cranially and has a more direct route to the conduit. After revascularization, the peritoneum is opened, and the ureter is anastomosed to the conduit over a double-J stent. Excellent long-term results have been achieved with this technique.[24]

Drainage and Wound Closure

Both the transplant bed and the subcutaneous tissues may be drained to prevent the accumulation of serosanguineous fluid or lymph around the transplanted kidney, although many surgeons no longer routinely place drains. The skin is best closed with a subcuticular absorbable suture and then dressed with a clear adhesive dressing so ultrasound scanning can be performed early without disturbing the wound. For this reason, metal clips are rarely used for the skin.

Postoperative Course

The recipient is nursed in a general ward with standard precautions and no need for reverse barrier nursing. There is no benefit to continuing prophylactic antibiotics beyond a single dose given at induction of anesthesia. Prophylaxis against thromboembolic disease is in the form of thromboembolic deterrent stockings, and low-molecular-weight heparin (LMWH) is continued until discharge. Oral fluids and diet are commenced as tolerated immediately after surgery. Maintenance immunosuppressive agents are given orally, except in the presence of a prolonged postoperative ileus with high volumes of nasogastric drainage, when they should be administered intravenously. If recovery is straightforward, the bladder catheter and wound drains are usually removed by day 5, and the recipient is fit for discharge after 7 to 10 days to be kept under close outpatient monitoring.

SURGICAL COMPLICATIONS OF KIDNEY TRANSPLANTATION

There is a small but significant incidence of technical complications, which can be minimized by avoiding damage to the kidneys at the time of the retrieval. Nonetheless, the presence of multiple renal vessels and donor atherosclerotic disease does increase the likelihood of technical problems in the recipient, as do recipient obesity, atherosclerosis, and previous transplantation. Algorithms to aid in the management of complications in the early posttransplant period can be found in Figs. 108.6 and 108.7.

Wound Infection

The use of preoperative prophylactic antibiotics, commonly amoxicillin–clavulanic acid, has reduced the incidence of wound infection

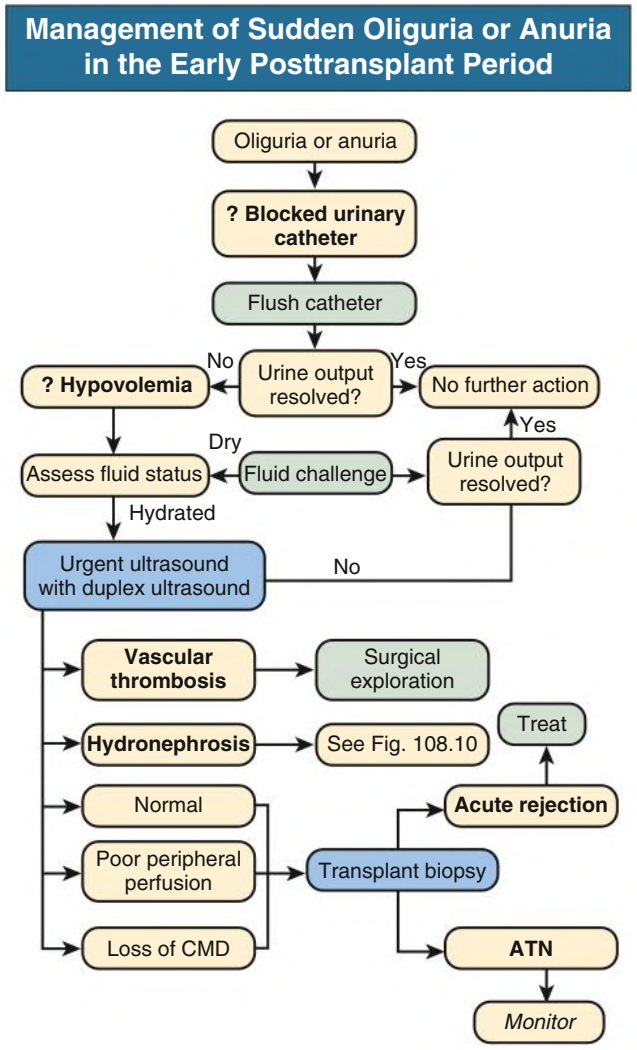

Fig. 108.6 Management of sudden oliguria or anuria in the early posttransplant period. *ATN,* Acute tubular necrosis; *CMD,* corticomedullary differentiation.

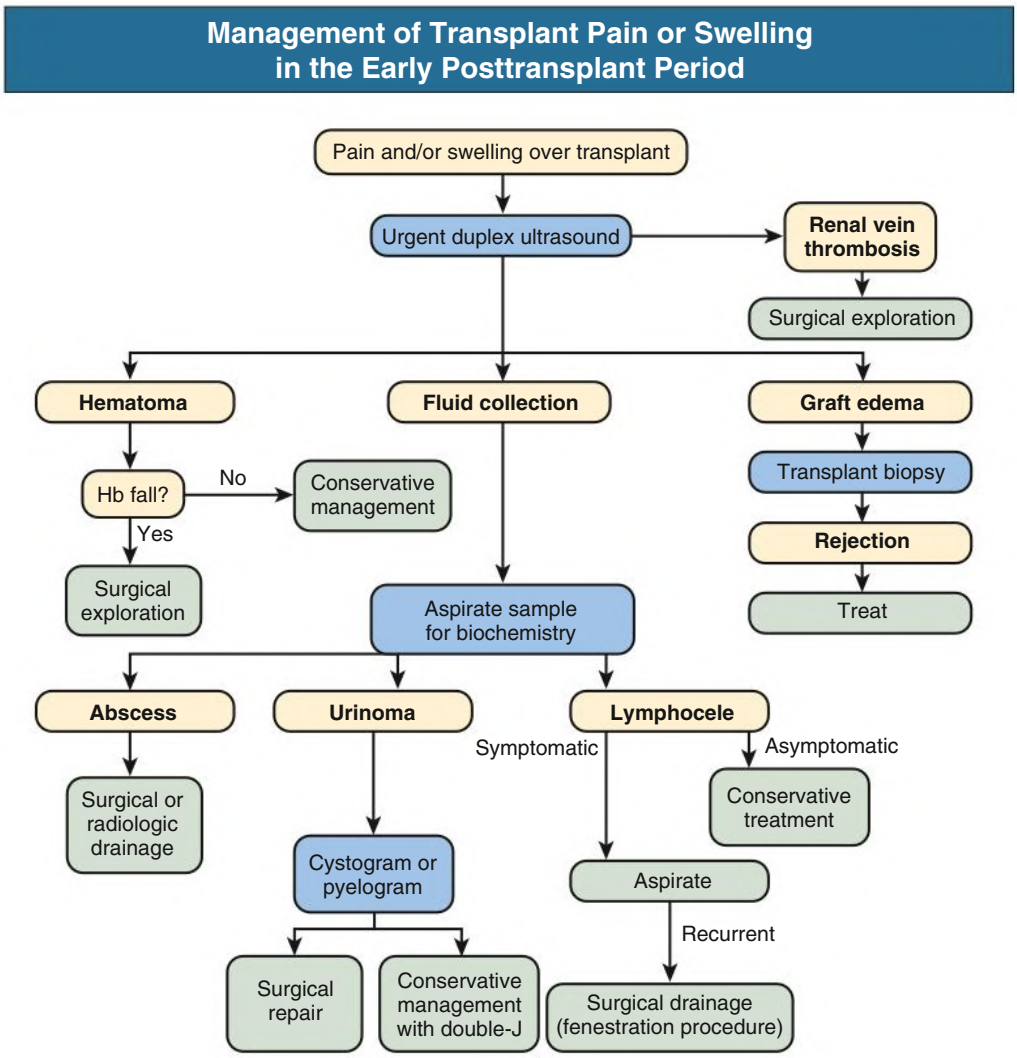

Fig. 108.7 Management of transplant pain or swelling in the early posttransplant period. *Hb,* Hemoglobin.

to less than 1%. If a wound infection does occur, treatment is with antibiotics, guided by microbiologic wound swabs, and drainage of collections as necessary.

Wound Dehiscence

The risk for wound dehiscence is increased in obese and diabetic patients and those receiving sirolimus. Identification and treatment of any infection are mandatory. Resuturing of the wound is rarely justified. Large areas of dehiscence often benefit from vacuum-assisted closure, but the majority require only frequent dressing.

Vascular Complications

Transplant vascular thrombosis is a feared complication that may cause early and irreversible graft failure. Although there are also significant hemorrhagic risks, routine perioperative prophylaxis should be given with subcutaneous LMWH, and some units prescribe aspirin for the first few postoperative months.

Bleeding From Vessels in the Renal Hilum

Careful postoperative observation and regular hemoglobin and hematocrit measurements are crucial for the early detection of bleeding. Output from the transplant drains may give an early indication of heavy blood loss. Unsecured small vessels in the renal hilum may not be obvious during surgery, but they may start bleeding postoperatively. This form of blood loss can be slow, persistent, and serious. If the patient's condition allows, urgent imaging may be performed to secure a diagnosis, but the best course of action is usually emergency exploration of the transplant under general anesthesia.

Anastomotic Hemorrhage

Anastomotic hemorrhage is a rare occurrence, usually caused by a technical surgical error, and is more common with multiple arteries and the use of antiplatelet agents.[25,26] Early after transplantation, the patient may report pain over the graft. This symptom always should be taken seriously. There also may be pain in the back or the rectum caused by a tension hematoma in the retroperitoneum or pelvis. Significant hemorrhage will be attended by circulatory collapse, with tachycardia and hypotension. There will be a decrease in the hemoglobin and hematocrit, sometimes to alarmingly low levels. The patient must be returned to the operating room immediately and the transplant reexplored.

Hemorrhage also can occur some weeks after transplantation because of the development of a mycotic aneurysm of the renal artery. In the rare case of a ruptured mycotic aneurysm, an immediate graft nephrectomy is required, but the mortality is high.

Renal Artery Thrombosis

Renal artery thrombosis is a rare event, occurring in less than 1% of transplants. The usual outcome is loss of the kidney. Acute arterial

thrombosis may occur intraoperatively or during the first days or weeks after transplantation. Potential causes include hyperacute rejection or a procoagulant state, but most cases are caused by a technical error during the anastomosis of small or atheromatous vessels.[26] Successful vascular anastomosis requires that the vessels are not under tension and that there is a smooth transition between the two endothelial surfaces; sutures must be placed through all layers of the vessel walls, so an intimal flap is avoided. Vascular adventitia is thrombogenic and must be excluded from the lumen of the anastomosis. The risk for renal artery thrombosis is increased in the presence of atherosclerosis, persistent hypotension, volume depletion (e.g., diarrhea, excessive preoperative dialysis), and prothrombotic states, including diabetes.

Renal arterial thrombosis manifests with sudden anuria, the differential diagnoses being a blocked urinary catheter, dehydration, acute tubular necrosis, or a urologic complication. A high index of suspicion is required to make this diagnosis, particularly in the immediate postoperative period. The only worthwhile investigation is an urgent duplex ultrasound scan, but if the diagnosis is seriously entertained, the only hope of saving the transplant is to reexplore it immediately in the hope that a correctable cause can be found. The reality is that unless the acute arterial thrombosis occurs during surgery, there is little chance of saving the transplanted kidney. Acutely thrombosed grafts must nevertheless be explored and removed to avoid the development of sepsis in a necrotic graft, a potentially fatal complication.

Renal Vein Thrombosis

Renal vein thrombosis is more common than arterial thrombosis and occurs in 1% to 6% of renal transplants.[26,27] Although it may result from a technical error at the time of surgery, its cause is usually less certain. The renal vein can certainly be twisted or kinked if it is not correctly placed after completion of the vascular and ureteral anastomoses. The peak incidence of renal vein thrombosis is 3 to 9 days after transplantation;[28] transplant patients with good initial graft function will have a sudden loss of urine output, which is often markedly bloodstained, associated with severe pain arising from swelling and (very rarely) rupture of the allograft. The ipsilateral leg may swell if there is involvement of the iliac venous system. Renal vein thrombosis also may be occult and is one differential diagnosis of delayed graft function. Duplex ultrasound scanning is the best investigation. In an established renal vein thrombosis this may show an obviously swollen allograft with surrounding hematoma and an absence of renal perfusion. Lesser degrees of thrombosis, or indeed incipient thrombosis, may be highlighted by an absence of arterial flow in diastole. An even later development is a reversal of flow in diastole.

As with arterial thrombosis, if this diagnosis is entertained, the best course of action is to reexplore the transplant as an emergency. The renal vein anastomosis can be opened to allow the clot to be extracted, and the venotomy is then closed and the kidney observed for improvement. A more radical alternative is to immediately explant the kidney by taking down the arterial, venous, and ureteral anastomoses. The kidney can then be reflushed with cold perfusion fluid on the back table and held in preservation fluid at 4°C. This allows much more time to assess the cause of the venous thrombosis, and if the kidney remains viable, the transplant operation can be repeated. If the transplant is already infarcted or cannot be adequately flushed with preservation fluid, the organ will need to be discarded anyway and nothing is lost by immediate explantation. Successful emergency surgical exploration with subsequent long-term function is rare. Interventional radiographic techniques offer an alternative to surgery. The renal vein can be selectively catheterized via the ipsilateral femoral vein, and graft thrombolysis then may be attempted. This technique is particularly useful when renal vein thrombosis occurs late after transplant and the risk for systemic anticoagulation is low. The use of various thrombolytic agents has been reported, including heparin, urokinase, streptokinase, and tissue plasminogen activator, with no consensus as to which is the most appropriate.

Transplant Renal Artery Stenosis

Transplant renal artery stenosis is a later complication occurring 3 to 48 months after transplantation. Not all stenoses are of functional or clinical significance, as shown by studies in which all functioning transplants have undergone angiography.[29] Causal factors include donor and recipient atherosclerosis, factors associated with surgical technique, and severe acute rejection.[30] The presentation and management of transplant renal artery stenosis are discussed in Chapter 43.

Lymphocele

Small, clinically insignificant lymphatic collections can be demonstrated by ultrasound scan in up to 50% of kidney transplants.[31] Larger lymphoceles that cause complications or require treatment occur in 2% to 10% of patients.[32] The source of peritransplant lymph leaks is the lymphatic channels around the iliac arterial system rather than the lymphatics of the transplanted kidney itself.[33] Therefore, during the dissection of the iliac arterial system, all the surrounding lymphatic channels must be meticulously secured with nonabsorbable ligatures or metal clips. Wound suction drains should not be removed postoperatively until less than 30 mL of fluid is produced on 2 consecutive days. It is safe to leave drains in place for several weeks posttransplantation to allow a low-volume lymphatic leak to seal by gradual fibrosis. Despite the theoretical risk for infection, this does not seem to be a problem in practice. If necessary, the patient can be discharged from the hospital with the drain in situ.

Compression of the transplanted ureter leading to kidney dysfunction is produced only by very large lymphoceles (volume > 300 mL). The peak incidence is at 6 weeks, but a lymphatic collection may manifest 2 weeks to 6 months after transplantation.[31] Most lymphatic collections are found anterior to the iliac vessels and lying between the transplant and the bladder (Fig. 108.8). Presenting features may include wound or ipsilateral thigh swelling in association with suprapubic discomfort and urinary frequency caused by bladder compression. Other presentations include pain over the transplanted kidney, sometimes associated with fever, ureteral obstruction with graft dysfunction, and ipsilateral thrombophlebitis. However, the vast majority are asymptomatic and manifest as an incidental finding during an ultrasound scan being performed for another reason. It is important to aspirate all peritransplant fluid collections under ultrasound control to aid diagnosis. Macroscopic findings are usually sufficient to differentiate infected from noninfected lymph, and biochemical analysis of the fluid allows a urine leak to be excluded. Computed tomography or magnetic resonance imaging is an essential investigation if surgery is being contemplated, particularly if a laparoscopic procedure is planned. This allows accurate definition of the relationship between the lymphocele and the transplanted ureter. If the ureter is bow-strung across the superior surface of the lymphocele, it could be damaged during a laparoscopic fenestration procedure.

Many small lymphoceles are asymptomatic and will resolve spontaneously given enough time. If action is deemed necessary, first-line treatment is aspiration under ultrasound control. If there is a recurrence, further aspirations can be performed or an external drain can be placed with ultrasound guidance. If these simple measures fail, open or laparoscopic surgical drainage may be required. A 5-cm-diameter disk of the lymphocele wall is removed to create a large opening into the peritoneal cavity, allowing reabsorption of the lymph through the abdominal lymphatic drainage system. These peritoneal fenestrations

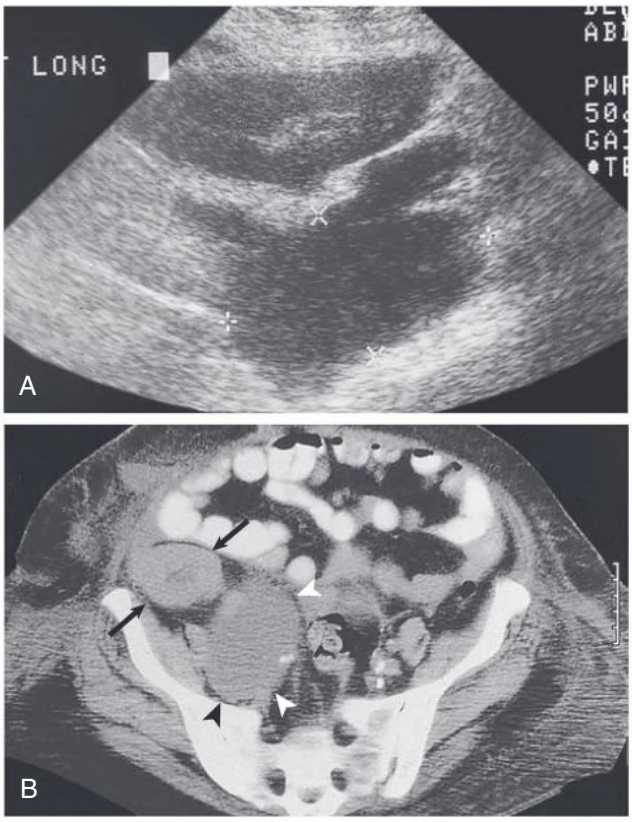

Fig. 108.8 Posttransplantation Lymphocele. (A) Ultrasound appearance. A large, echolucent lymphocele can be seen inferior to the transplanted (marked by *crosses*). (B) Computed tomography appearance. A 5 × 5 cm lymphocele *(arrowheads)* is present under the transplanted kidney *(arrows)*.

tend to heal before the lymphocele is completely reabsorbed, leading to early recurrence; a metal or omental plug may prevent this.

Urologic Complications

Urinary tract complications are relatively common after kidney transplantation, with an incidence of 5% to 14%.[34] Although they can be difficult to manage, they only rarely cause graft loss or mortality. The relatively high incidence of urologic problems is a consequence of the tenuous blood supply of the transplanted ureter. After kidney retrieval, the only ureteral blood supply that is preserved is derived from the renal artery near the hilum of the kidney, and this can be easily damaged during retrieval.

Urinary Leaks

Urinary leaks most commonly occur because of ischemic necrosis in any part of the transplanted urinary collecting system. The distal ureter has the poorest blood supply and is therefore the most common site. Less commonly, leaks occur from the renal pelvis or the midportion of the ureter, which may be a result of unrecognized direct damage to the ureter during organ retrieval. Urinary leaks tend to occur in the first few days after transplantation but can manifest much later. The usual presentation is with straw-colored fluid leaking directly from the transplant wound or accumulating in the drains in association with oliguria. Alternatively, extravasating urine may accumulate as a peritransplant fluid collection. This manifests as a painful swelling of the wound, and the patient may have a fever. In either case, the extravasated fluid must be differentiated from lymph by biochemical analysis of the fluid and a simultaneous serum sample. Urine will have markedly elevated urea and creatinine levels compared with the patient's serum, whereas lymph will have a similar biochemical profile.

The presence of a urinary fistula should be confirmed by antegrade or retrograde pyelography. Both techniques present challenges. Antegrade puncture of a nondilated pelvicaliceal system is technically difficult but usually possible. Retrograde cannulation of the transplanted ureteral orifice can be attempted with a flexible cystoscope. This is also a difficult maneuver because the transplanted ureter is implanted into the dome of the bladder rather than at its base. If the urine leak is contained as a urinoma, ultrasound will demonstrate a fluid collection between the transplanted kidney and the bladder, which can be sampled by needling or drained by the placement of a suitable percutaneous catheter.

The management of urinary leaks has changed significantly in recent years. The former practice of early reexploration and surgical reconstruction[35] is no longer always necessary. Interventional radiographic techniques offer an alternative, at least for initial treatment. The aim is to place a double-J (pigtail) ureteral stent across the region of damage via an antegrade nephrostomy; this may allow time for the urinary fistula to heal.[36] This technique, however, is unlikely to be successful if there is significant ischemic necrosis of the ureter, in which case surgery still has a role. Reexploration of kidney transplants is straightforward in the early postoperative period but may be a considerable challenge later because of the development of an intense peritransplant fibrotic reaction. The choice of operative procedure for a necrotic distal ureter depends on the length of remaining viable ureter. If there is sufficient length after excision of the necrotic distal portion, the transplanted ureter may simply be reimplanted into the bladder. If this is not possible, the urinary tract should be reconstructed with use of the patient's native ureter. Depending on length of viable transplanted ureter, there is a choice between anastomosing the native ureter to the transplanted ureter proximal to the ischemic segment (ureteroureterostomy) or to the transplanted renal pelvis (ureteropyelostomy; Fig. 108.9). Whichever technique is chosen, the anastomosis should be protected with a double-J stent. Although these techniques require the native ureter to be ligated proximally, there is usually no need to perform an ipsilateral nephrectomy.[37] Postoperatively, the antegrade nephrostomy can be left in situ so a contrast study can be performed after 7 to 10 days to confirm healing of the new anastomosis. If the transplant recipient has undergone an ipsilateral nephrectomy in the past or the native ureter is too diseased to be used for reconstruction, a Boari bladder flap can be used to reconstruct the urinary tract.

Ureteral Obstruction

Obstruction of the transplanted ureter may occur at any time after transplantation. It should always be considered in the differential diagnosis of acute transplant dysfunction and excluded by ultrasound examination. The management of transplant ureteral obstruction is summarized in Fig. 108.10. Early obstruction is uncommon and suggestive of a technical error, such as creating a submucosal bladder tunnel that is too tight, kinking of a redundant length of ureter, and incorrect suture placement during anastomosis. Early obstruction may be caused by a blood clot in the ureter, bladder, or catheter. Bleeding may occur from the ureterovesical anastomosis or cystostomy or after a transplant biopsy. It is common practice to drain the urinary bladder using a three-way irrigating catheter because small-diameter two-way Foley catheters are easily blocked by blood clot.

Late ureteral obstruction may occur at the vesicoureteral or pelviureteral junctions. Ischemia that is not severe enough to cause necrosis is presumed to be the cause of most vesicoureteral obstructions.[38] Kidney transplants invariably excite a pronounced perigraft fibrotic response, and this is more likely to be the cause of an obstruction at the

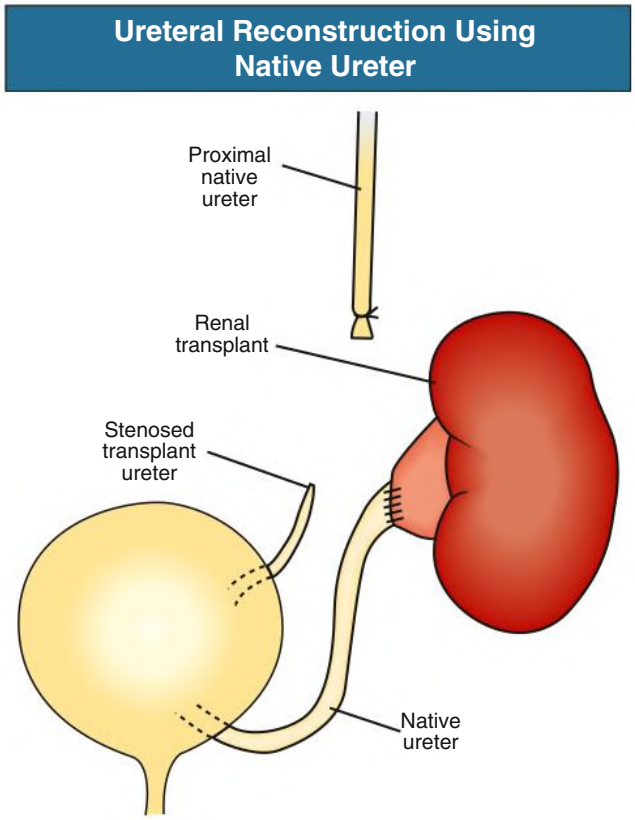

Fig. 108.9 Ureteral reconstruction using native ureter.

level of the pelviureteral junction. It is also possible that acute rejection episodes contribute to subsequent fibrosis.[36] BK polyoma virus also can cause late ureteric obstruction because of hypertrophy of ureteric epithelial cells in combination with infiltration of inflammatory cells.

An ultrasound scan will demonstrate a dilated pelvicaliceal system. However, long-standing kidney transplants may have quite marked pelvicaliceal dilation without being obstructed. This most commonly causes uncertainty in assessment of whether obstruction may be contributing to chronic allograft dysfunction in a patient with biopsy-proven chronic allograft nephropathy. Further investigation is needed to confirm or refute the presence of obstruction and define its anatomy. Retrograde pyelography has a low success rate because of the difficulty of catheterizing the transplanted ureteral orifice at cystoscopy. Therefore, percutaneous nephrostomy followed by antegrade pyelography is the investigation of choice in suspected transplant ureteral obstruction. The nephrostomy is performed under antibiotic cover using ultrasound control, and the nephrostomy tube should be left in place for a few days. If serum creatinine decreases during this period, obstruction is confirmed. If there is no improvement in kidney function, significant obstruction can be confidently excluded. This simple observation avoids the need for an antegrade pressure study (Whitaker test), which may be difficult to interpret in transplanted kidneys. After external decompression of the transplanted kidney for a few days, an antegrade pyelogram is obtained to accurately define the anatomy of the obstructing lesion.

Nonoperative approaches for the treatment of transplant ureteral stricture are often preferred.[39] The simplest approach is to place a double-J stent across the stricture via a percutaneous nephrostomy. This may require initial balloon dilation.[40] The stent can be removed after 6 weeks, but the restenosis rate is high. An alternative is long-term

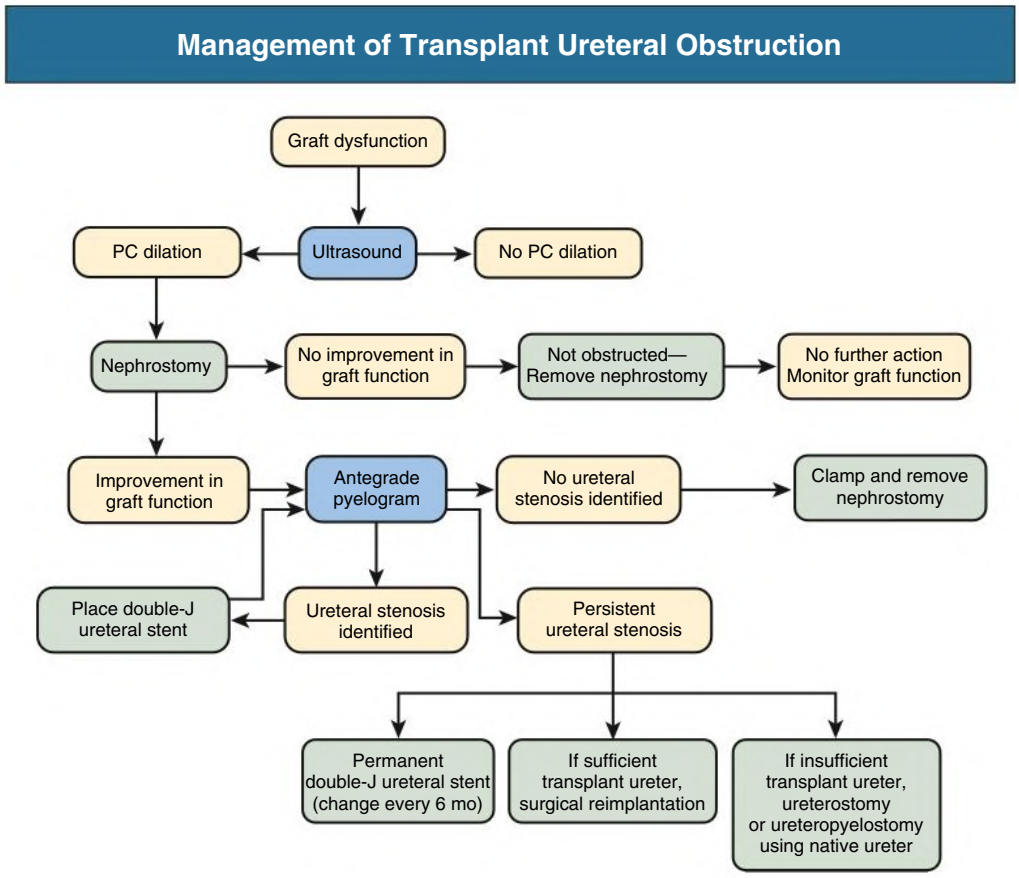

Fig. 108.10 Management of transplant ureteral obstruction. *PC,* Pelvicaliceal.

stenting, changing the stent every 6 months. The disadvantage of this method is a high incidence of urinary tract infection, with potential severe consequences for immunosuppressed patients, and long-term antibiotic prophylaxis is a sensible precaution. Open surgical management still has a place in the management of ureteral obstruction. The operation performed depends on the site of obstruction and remaining length of healthy transplanted ureter proximal to the obstruction (see discussion of urinary leaks). Not all cases of obstruction require intervention. When there is a mild degree of obstruction not associated with urinary tract infection and in a long-standing kidney that is affected by chronic allograft nephropathy, it may be better to simply monitor transplant function, reserving intervention for a later date should it become necessary.

Complications in the Transplant Bed

A number of nerves may be encountered in the retroperitoneal dissection required for kidney transplantation. These include the lateral femoral cutaneous nerve and the femoral, obturator, and sacral nerves. Each of these may be damaged by a traction injury, particularly when modern fixed wound retraction systems are used, because these can exert a great deal of pressure on the surrounding tissues. Patients with such neurapraxias should recover completely, but this may take some months, and the condition can be very disabling.

In male transplant recipients, the spermatic cord must be mobilized during the dissection to gain access to the retroperitoneal space. Damage to the testicular artery in the cord can result in testicular atrophy.

TRANSPLANT NEPHRECTOMY

The optimal management strategy for patients with a failed kidney transplant remains unclear, with a lack of good-quality evidence. Transplant nephrectomy is mandatory for early graft failure caused by vascular thrombosis, capsular rupture, and irreversible rejection. However, the management of a kidney transplant that has chronically failed is more challenging. The options are transplant nephrectomy or leaving the graft in situ, with or without continuation of immunosuppression. Mortality from both infection and cardiovascular disease has been shown to be higher in patients with failed grafts continuing immunosuppression.[41] However, weaning and discontinuation of immunosuppression also have been shown to increase the risk for transplant nephrectomy and allosensitization.[42]

If the graft remains in situ without immunosuppression, signs and symptoms such as pain, fever, hematuria, and thrombocytopenia may prompt transplant nephrectomy, although the patient also can be treated initially with corticosteroids.

Historically, transplant nephrectomy was advocated to remove antigenic stimulation for anti–human leukocyte antigen (anti-HLA) antibody production, which might adversely affect the possibility of retransplantation. However, there is some evidence that transplant nephrectomy, particularly late after transplantation, may actually increase allosensitization.[43] The suggestion is that the graft may act as an "immunologic sponge" to absorb antibody or may regulate the production of antidonor antibody by the recipient's immune system.

Early graft nephrectomy is straightforward, but after the first few weeks kidney transplants usually develop quite intense perigraft fibrosis, and this can make late allograft nephrectomy a difficult technical challenge. A subcapsular dissection is preferred, and after removal of the kidney, the hilum is sutured, leaving a cuff of donor vessels in place. Careful hemostasis is required, and the whole raw capsular bed should be cauterized. The wound is usually closed without drains.

SELF-ASSESSMENT QUESTIONS

1. Which of the following statements are *false* regarding organ donation and retrieval?
   - **A.** For donation after brain death, the aorta is cannulated after cardiac arrest.
   - **B.** Kidneys to be obtained by donation after cardiac death sustain a period of warm ischemia during retrieval.
   - **C.** Approximately 30% of kidney transplants in the United Kingdom are currently from living donors.
   - **D.** Laparoscopic donor nephrectomy is contraindicated with multiple renal arteries.
   - **E.** The usual hospital stay after laparoscopic donor nephrectomy is 1 to 2 days.
2. Which of the following statements are *true* regarding the kidney transplant surgical procedure?
   - **A.** The kidney is placed in an extraperitoneal position in one or the other iliac fossa.
   - **B.** For cadaveric kidney transplants, the renal artery is usually anastomosed to the internal iliac artery.
   - **C.** Lower-pole renal arteries can be sacrificed without increasing the risk for ureteral complications.
   - **D.** The transplant ureter is anastomosed directly to the bladder.
   - **E.** Transplant ureteral stents should remain in place for 3 months.
3. Which of the following are *not* risk factors for transplant renal artery thrombosis?
   - **A.** Atherosclerosis
   - **B.** Dehydration
   - **C.** von Willebrand disease
   - **D.** Diabetes
   - **E.** Protein C deficiency
4. Which of the following statements are *true* regarding urologic complications after kidney transplantation?
   - **A.** Urologic complications are less common than vascular complications.
   - **B.** Urologic complications invariably manifest early.
   - **C.** Urine leaks are diagnosed by markedly raised urea and creatinine levels in the fluid compared with serum.
   - **D.** Reexploration and surgical reconstruction are always required for urine leaks.
   - **E.** Transplant ureteral stenosis is associated with BK polyoma virus infection.
5. Which of the following statements are *true* regarding transplant nephrectomy?
   - **A.** Transplant nephrectomy is mandatory for early graft failure caused by thrombosis.
   - **B.** Transplant nephrectomy reduces allosensitization.
   - **C.** Mortality is higher in patients with failed grafts weaned from immunosuppression.
   - **D.** Graft nephrectomy, particularly late after transplantation, is straightforward.
   - **E.** All failed kidney transplants should be removed.

Prophylaxis and Treatment of Kidney Transplant Rejection

James E. Cooper, Erik Stites, Scott Davis, Alexander C. Wiseman

The clinical presentation of the immune response to transplanted tissue (referred to as *rejection*) became apparent in 1960 when, after successful proof-of-principle kidney transplants were performed in identical twins, kidney transplantation was attempted between immunologically dissimilar individuals.[1] Eleven patients underwent lymphoid irradiation to prevent rejection after kidney transplant from nonidentical donors. Although 10 of 11 died of overwhelming infection, illustrating the potential consequences of immunosuppression, the lone surviving patient from this series subsequently experienced two episodes of acute rejection, both of which were treated with corticosteroids, and recovered good graft function. Thus, began the development of immunosuppressive agents that could prevent and treat rejection while not inducing severe life-threatening side effects. As a result of the development of newer immunosuppression medications, the incidence of acute rejection in the first year after transplant has significantly decreased over time and is now approximately 10% to 15%[2] (Fig. 109.1). However, the management of chronic rejection has remained a challenge, with continued attempts to better define the nature of injury and methods to prevent or reverse this process. As attention shifts to limiting the toxicity of immunosuppression medications (e.g., withdrawal of corticosteroids or calcineurin inhibitors [CNIs]) and attempts to increase access to transplant (e.g., performing transplants across human leukocyte antigen [HLA] and blood type barriers), management of acute rejection continues to be an important clinical issue.

DEFINITION

Rejection (both acute and chronic) is defined by histologic findings after kidney transplant biopsy. An adequate biopsy specimen contains at least 10 glomeruli and 2 small arteries, stained for hematoxylin-eosin (HE), periodic acid–Schiff (PAS) or methenamine silver, and Masson trichrome, and a specimen with seven to nine glomeruli and one artery is considered of marginal adequacy. When performed for clinical indications (kidney dysfunction), two separate cores should be obtained because the findings of rejection are often patchy in distribution (Fig. 109.2).[3]

The Banff Working Classification of Renal Allograft Pathology forms the basis of the histologic definition of rejection and is updated biannually (Boxes 109.1 and 109.2). First developed in 1993 with a primary focus on T-cell–mediated acute inflammatory infiltrates to classify the degree of rejection, updates in the classification differentiated humoral (antibody-mediated) and T-cell responses and further distinguished a chronic humoral form of injury previously classified as chronic allograft nephropathy (see Chapter 112).[4] This was based on the indirect identification of antibody-mediated injury by evidence of complement (C4d) deposition. C4d is a fragment of C4b that is generated after immunoglobulin G (IgG) and IgM binding to host antigens with activation of the classical complement pathway. C4b/C4d forms a covalent bond with proteins on tissue such as capillary endothelial cells via a sulfhydryl group and remains bound to tissue after immunoglobulin and other complement products have been released.[5] Staining for C4d, either by immunohistochemistry or immunofluorescence, indicates that an antibody-mediated process may be involved.

Although C4d remains a specific marker for antibody-mediated graft pathology, it has limited sensitivity.[6] Studies of endothelial-associated transcript (ENDAT) expression[7,8] and C4d-negative histologic findings from protocol biopsy studies in patients with microvascular inflammation[9] helped identify the clinical importance of C4d-negative antibody–mediated rejection, which led to these updated Banff criteria.

Antibody-Mediated Rejection

Acute antibody-mediated (humoral) rejection occurs in 5% to 7% of all transplants and is present in 20% to 30% of episodes of acute rejection[10] in patients with ABO- and HLA-compatible transplants, occurring typically within the first few weeks of transplantation or in association with a change or poor adherence to immunosuppression. Although patients who have preexisting donor-specific HLA alloantibodies (donor-specific antibodies) are at higher risk for acute humoral rejection, the identification of de novo donor-specific antibodies at the time of graft dysfunction is common. There is also increasing recognition of the pathologic role of non-HLA antibodies directed against autoantigens on the vascular endothelium. The diagnosis of acute humoral rejection requires (1) identification of circulating donor-specific antibodies, (2) evidence that those antibodies are interacting with the vascular endothelium, and (3) evidence that this interaction is causing tissue injury (Box 109.1 and Fig. 109.3).[6] Patterns of injury associated with acute humoral rejection range from acute tubular cell injury to thrombotic microangiopathy, but neutrophils and/or macrophages are typically present in peritubular capillaries. The requirement for evidence of antibody/endothelial interaction has been expanded beyond C4d staining and now includes at least moderate microvascular inflammation or evidence of increased ENDAT expression if using a validated assay.

Chronic active antibody-mediated rejection has been identified as a leading cause of late allograft loss[7,11] and is likely the result of an indolent alloimmune response that can result in transplant glomerulopathy and microcirculatory inflammation. Although transplant glomerulopathy is often associated with circulating donor-specific antibodies and C4d deposition, these diagnostic markers are not detected in 30% to 50% of cases.[12] One possibility is that transplant glomerulopathy is not solely due to a humoral response. Alternatively, the failure to detect donor-specific antibodies and C4d deposition could be due to non–complement-fixing antibodies and/or the waxing/waning nature of the humoral response.

The current Banff diagnostic criteria for chronic humoral rejection require (1) evidence of donor-specific antibodies, (2) evidence of current/recent antibody interaction with vascular endothelium, and (3)

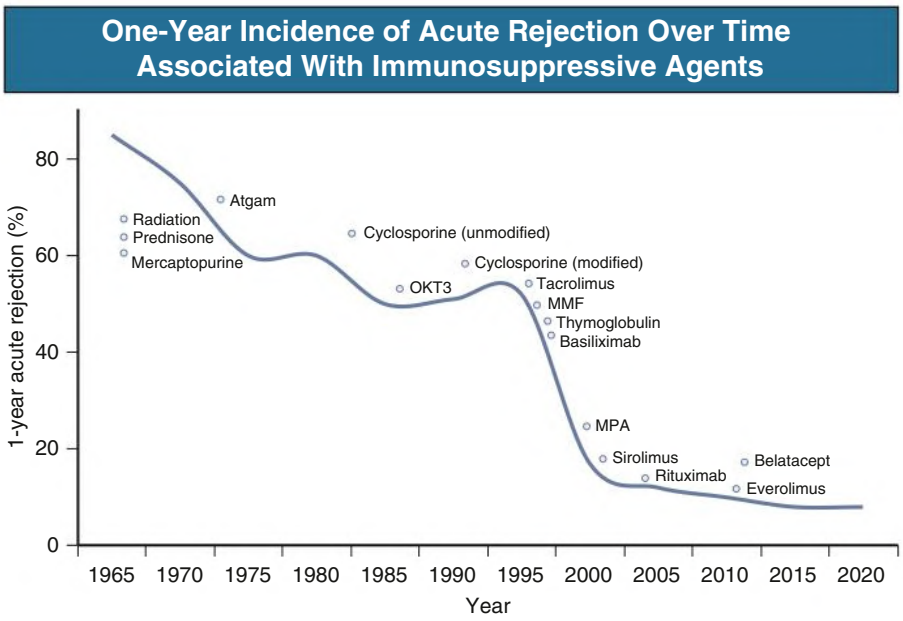

Fig. 109.1 One-year incidence of acute rejection over time as associated with the introduction of new immunosuppressive agents. *MMF,* Mycophenolate mofetil; *MPA,* mycophenolate sodium. (From Cooper JE. Evaluation and treatment of acute rejection in kidney allografts. *Clin J Am Soc Nephrol.* 2020;15[3]:430–438.)

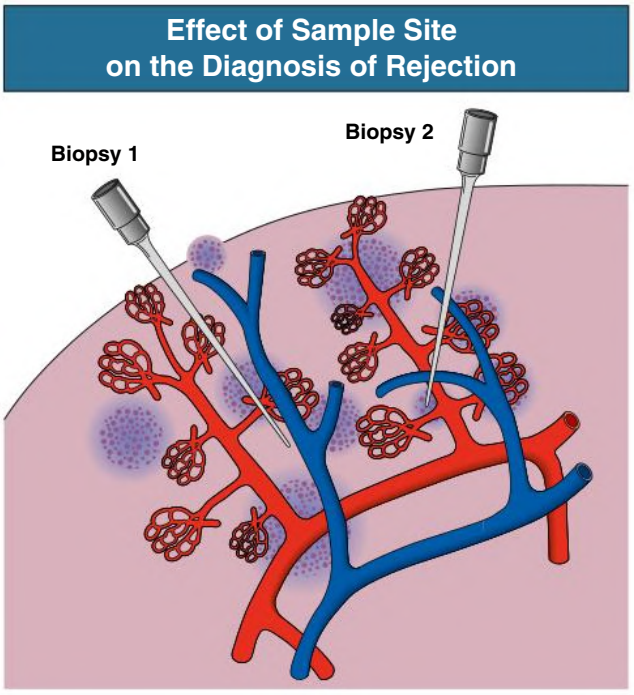

Fig. 109.2 Biopsy Technique. Acute rejection begins as patchy, focal infiltrates and becomes homogeneous only in advanced stages. The intensity of mononuclear infiltrate seen on the biopsy sample would differ between core 1 and core 2. Routinely taking two core biopsy samples can help decrease the sampling errors, which can affect the histologic interpretation of rejection.

evidence of chronic tissue injury such as transplant glomerulopathy, multilamination of the peritubular capillary basement membrane, and/or arterial intimal fibrosis (Fig. 109.4).

T-Cell–Mediated Rejection

The original pathologic description of rejection is now referred to as *T-cell–mediated rejection.* The classification of acute T-cell–mediated rejection (acute cellular rejection [ACR]) is based on the degree and location of mononuclear cell inflammation. Because interstitial inflammation and tubulitis are frequently present immediately beneath the kidney capsule (subcapsular inflammation) in stable allografts, this finding is not considered when interpreting an allograft biopsy result for the presence of rejection. When severe, interstitial inflammation may extend into tubules via injury to the tubular basement membrane (tubulitis). The predominant phenotype of these infiltrates is a mixture of $CD4^+$ and $CD8^+$ T-cells; however, B-cells, eosinophils, and macrophages also may be present. Less commonly, endarteritis (endothelialitis) may be present in which T-cells and macrophages extend under the arterial endothelium, a phenomenon that may or may not be accompanied by interstitial inflammation or tubulitis. The finding of interstitial infiltrates and tubulitis in a kidney transplant biopsy is not specific to ACR, and other causes such as viral nephropathy (BK virus, less commonly cytomegalovirus), pyelonephritis, or posttransplant lymphoproliferative disease should be considered. In contrast, histologic evidence of endothelialitis is pathognomonic of rejection and may overlap with antibody-mediated injury.

Acute T-cell–mediated rejection is histologically classified in the Banff criteria by the degree of interstitial inflammation, the quantity of cells infiltrating into tubules, or by endothelialitis of the small arterioles. Type I ACR is characterized by the absence of endothelialitis, with interstitial inflammation of at least 25% of the parenchyma, and tubulitis (Box 109.2 and Fig. 109.5). Type II ACR is characterized by vascular involvement/endothelialitis (Fig. 109.6). Type III ACR is characterized by vascular inflammation that extends to the media (transmural) and may be accompanied by fibrinoid change and necrosis of the smooth muscle cells (Fig. 109.7). Types II and III ACR may or may not be associated with elements of type I ACR; thus the pathologic description of rejection should not be viewed as a pathogenic continuum. However, types II and III ACR often require different therapeutic interventions and carry different prognostic implications than type I ACR (see later sections).

Chronic active T-cell–mediated rejection is a histologic diagnosis that refers to arterial intimal fibrosis specifically with evidence of mononuclear cell infiltration and formation of neointima (Fig. 109.8). This is distinguished from chronic humoral rejection by the location of vascular injury and lack of evidence of pathogenic antibody; it is

BOX 109.1 Banff Classification of Antibody-Mediated Rejection

Active (All Three Criteria Must Be Met for Diagnosis)

1. Acute tissue injury with 1 or more of the following:
   - Microvascular inflammation (g > 0, ptc > 0)
   - Intimal or transmural arteritis (v > 0)
   - Acute thrombotic microangiopathy
   - Acute tubular injury
2. Evidence of current/recent antibody interaction with vascular endothelium with one or more of the following:
   - Linear peritubular capillary C4d staining
   - Moderate microvascular inflammation (g + ptc ≥ 2)
   - Increased expression of validated gene transcripts/classifiers in the biopsy tissue strongly associated with antibody-mediated rejection
3. Serologic evidence of donor-specific antibodies, including antibodies to human leukocyte antigens and nonhuman leukocyte antigens. C4d staining or expression of validated transcripts/classifiers (criterion 2 earlier) may substitute for donor-specific antibodies.

Chronic Active (All Three Criteria Must Be Met for Diagnosis)

1. Morphologic evidence of chronic tissue injury, including 1 or more of the following:
   - Transplant glomerulopathy (cg > 0)
   - Severe peritubular capillary basement membrane multilayering on electron microscopy
   - Arterial intimal fibrosis
2. Identical to criterion 2 for active antibody-mediated rejection, above
3. Identical to criterion 3 for active antibody-mediated rejection, above

Chronic Inactive (All Three Criteria Must Be Met for Diagnosis)

1. Transplant glomerulopathy (cg > 0) or severe ptc basement membrane multilayering
2. Absence of criterion 2 of current/recent antibody interaction with the endothelium
3. Prior documented diagnosis of active or chronic active antibody-mediated rejection and/or documented prior donor-specific antibodies

cg, Chronic glomerulopathy; *g,* glomerulitis; *ptc,* peritubular capillaritis; *v,* vasculitis.

Modified from Loupy A, Haas M, Roufosse C, et al. The Banff 2019 Kidney Meeting Report (I): updates on and clarification of criteria for T-cell- and antibody-mediated rejection. *Am J Transplant.* 2020;20:2318–2331.

BOX 109.2 Banff Classification of T-Cell–Mediated Rejection

Borderline or Suspicious

Foci of tubulitis (t1–3) with mild interstitial inflammation (i1) or mild tubulitis (t1) with moderate to severe interstitial inflammation (i1 or i2)

Acute

Grade IA: Interstitial inflammation involving >25% of nonsclerotic cortical parenchyma (i > 2) and moderate tubulitis (t2, 4–10 mononuclear cells/tubular cross section)

Grade IB: Interstitial inflammation involving >25% of nonsclerotic cortical parenchyma (i > 2) and severe tubulitis (t3, >10 mononuclear cells/tubular cross section)

Grade IIA: Mild to moderate intimal arteritis (v1, 0%–25% of luminal area), with or without interstitial inflammation and/or tubulitis

Grade IIB: Severe intimal arteritis (v2, >25% of luminal area), with or without interstitial inflammation and/or tubulitis

Grade III: Transmural arteritis and/or fibrinoid change and necrosis of medial smooth muscle cells with accompanying lymphocyte inflammation (v3)

Chronic Active

Grade IA: Interstitial inflammation involving >25% of sclerotic cortical parenchyma (i-IFTA2 or i-IFTA3) *and* >25% of total cortical parenchyma (ti2 or ti3) with moderate tubulitis (t2 or t-IFTA2) involving one or more tubules

Grade IB: Interstitial inflammation involving >25% of sclerotic cortical parenchyma (i-IFTA2 or i-IFTA3) *and* >25% of total cortical parenchyma (ti2 or ti3) with severe tubulitis (t3 or t-IFTA3) involving one or more tubules

Grade II: Chronic allograft arteriopathy (arterial intimal fibrosis with mononuclear cell inflammation in fibrosis and formation of neointima)

i, Interstitial inflammation; *i-IFTA,* inflammatory interstitial fibrosis and tubular atrophy; *t,* tubulitis; *t-IFTA,* tubulitis in areas of tubular atrophy; *v,* vasculitis.

Modified from Loupy A, Haas M, Roufosse C, et al. The Banff 2019 Kidney Meeting Report (I): updates on and clarification of criteria for T-cell- and antibody-mediated rejection. *Am J Transplant.* 2020;20:2318–2331.

distinguished from other nonimmunologic processes that may lead to vascular and interstitial fibrosis by the presence of persistent infiltrating cells within vessels. This is covered in greater detail in Chapter 107.

Borderline Rejection

The finding of inflammation in 10% to 25% of the interstitium with tubulitis of less than four mononuclear cells per tubular cross-section is classified as borderline rejection, which remains a pathologic definition without clear clinical significance. When identified in the setting of graft dysfunction or with other findings such as glomerulitis, the risk for progression to clinical rejection on subsequent biopsies is increased and thus treatment may be considered.[13]

CLINICAL MANIFESTATIONS

The clinical presentation of acute rejection is common to both T-cell–mediated and antibody-mediated rejection. Patients typically present with a rapid rise in serum creatinine and in severe cases may have decreasing urine output, weight gain, fever, or graft tenderness. The clinical findings are commonly nonspecific, and other etiologies of graft dysfunction should be considered at the time of presentation (Box 109.3) together with the patient's risk for acute rejection (Box 109.4). As a result of the increase in the number of patients who undergo transplantation despite a risk factor for humoral rejection (e.g., presensitization, known donor-specific antibody in desensitization protocols, and ABO-incompatible transplants), approximately 25% of acute rejection episodes now have a humoral component. In acute humoral rejection there may be features of thrombotic microangiopathy with anemia, evidence of hemolysis, and thrombocytopenia. If there is immediate cyanosis of the graft on revascularization (hyperacute rejection) or an abrupt decline in urine output and graft tenderness 3 to 14 days after transplant (delayed hyperacute or accelerated rejection), donor-specific antibody is implicated. Typically, there is type III ACR and interstitial hemorrhage on biopsy.

PROPHYLAXIS AND PREVENTION

Prophylaxis

The primary goal of transplant management is prevention of immunologic graft loss in the early period after transplant. Over time, the risk for acute rejection diminishes and the approach to immunosuppressive therapy shifts toward considerations of adverse effects of the

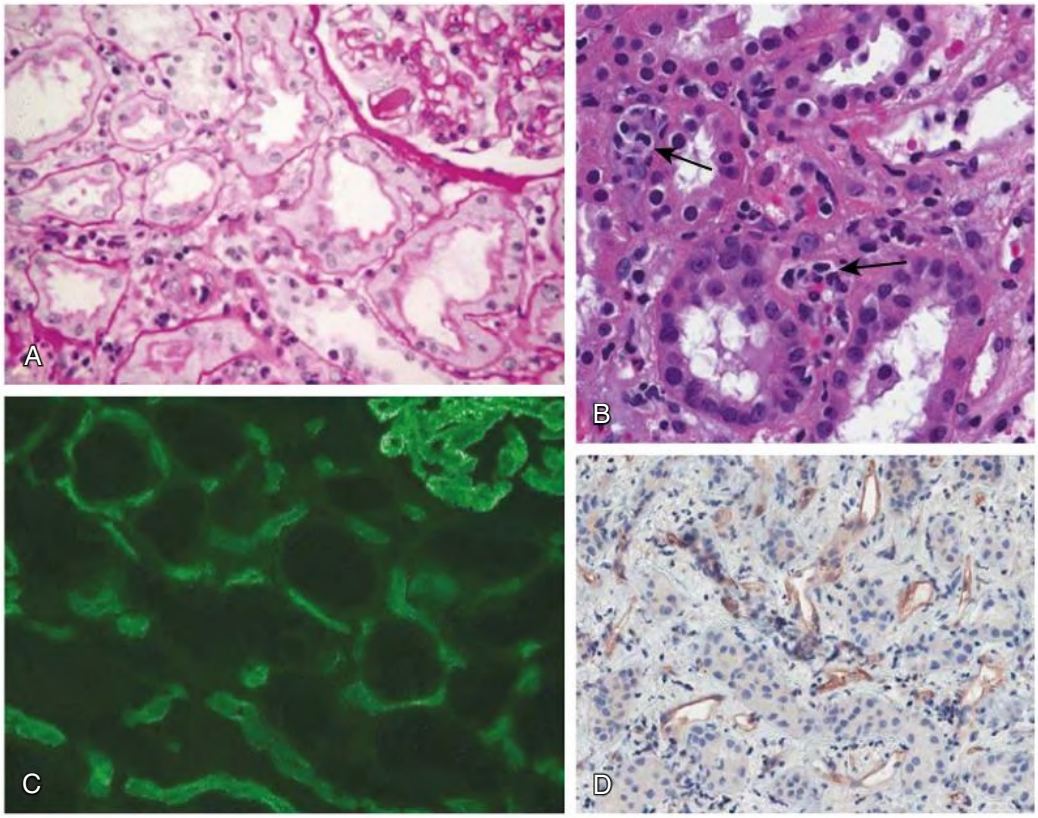

Fig. 109.3 Acute Antibody-Mediated Rejection. (A) Peritubular and glomerular capillaries contain numerous polymorphonuclear leukocytes and mononuclear cells. BOX 109.3 Differential Diagnosis of Kidney Allograft Dysfunction

Week 1 Posttransplantation

- Acute tubular necrosis
- Hyperacute or accelerated rejection
- Urologic
  - Obstruction
  - Urine leak
- Vascular thrombosis
  - Renal artery
  - Renal vein
- Volume contraction

Less Than 12 Weeks Posttransplantation

- Acute rejection
- Calcineurin inhibitor toxicity
- Volume contraction
- Urologic
  - Obstruction
- Infection
  - Bacterial pyelonephritis
  - Viral infections
- Interstitial nephritis
- Recurrent disease

Longer Than 12 Weeks Posttransplantation

- Acute rejection
- Volume contraction
- Calcineurin inhibitor toxicity
- Urologic
  - Obstruction
- Infection
  - Bacterial pyelonephritis
  - Viral infections
- Chronic allograft nephropathy
- Recurrent disease
- Renal artery stenosis
- Posttransplantation lymphoproliferative disorder

BOX 109.4 Risk Factors for Acute Rejection

High Risk

- Donor-specific HLA sensitization
  - Positive cell-based crossmatch (flow cytometry or CDC)
  - Donor-specific antibody on single-antigen bead analysis
- Delayed graft function
  - Deceased donor source
  - Increased donor age
  - Prolonged ischemic time
  - Donor brain death
  - Donor acute kidney dysfunction
- HLA mismatching
- ABO incompatibility
- Corticosteroid minimization
- Infection
  - Bacterial pyelonephritis
  - Cytomegalovirus
- Adolescent recipient
- Previous rejection episode

Low Risk

- Zero HLA mismatch
- Elderly recipient of young donor kidney
- Preemptive transplantation
- Living donor source
- First transplant

CDC, Complement dependent cytotoxicity; *HLA,* human leukocyte antigen.

therapy and risks for other events such as cardiovascular (CV) disease and malignancy. Therefore, management includes intensive immunosuppression and monitoring in the first months after transplant with a reduction in the intensity of treatment thereafter.

Prevention of Acute T-Cell–Mediated Rejection: Induction Therapy

A brief course of potent immunosuppression at the time of transplant (referred to as *induction therapy*) is commonly used to prevent acute rejection in transplant recipients, regardless of immunologic risk. According to the Scientific Registry of Transplant Recipients (SRTR), over 90% of US kidney transplant recipients received induction therapy in 2018. The assessment of immunologic risk at the time of transplant has historically considered factors such as overall level of anti-HLA sensitization (panel reactive antibody, or PRA), repeat transplant, African-American race, and recipient age. More recent data suggest pretransplant donor-specific antibodies (DSA) and HLA A/B/DR mismatch to be the main predictors of antibody-mediated rejection and T-cell–mediated rejection, respectively, while PRA and repeat transplantation had no predictive effect[14] (Box 109.4). There continues to be significant variability among transplant centers in the assessment of immunologic risk and its influence on induction immunosuppression prescribing practice. Nevertheless, for higher immunologic risk patients, induction therapy is usually combined with standard doses of immunosuppression to prevent rejection. For those at lower immunologic risk, induction therapy is often employed to minimize exposure to maintenance immunosuppression.

Induction agents can be classified as T-cell depleting or nondepleting. Nondepleting agents include the monoclonal humanized interleukin-2 (IL-2) receptor antibody (IL-2ra) basiliximab. The IL-2 receptor was identified as a potential immunosuppressive target because it is present on T-cells and inhibition of IL-2/IL-2r signaling inhibits T-cell proliferation (see Chapter 106). Use of IL-2ra has led to lower rates of acute rejection with minimal side effects when combined with cyclosporine-based immunosuppression in the absence of mycophenolate.[15] Importantly, these agents have not been studied in a prospective randomized fashion in combination with a tacrolimus/mycophenolate-based maintenance regimen; thus questions remain regarding the relative benefits of the addition of IL-2ra with more potent, commonly used maintenance agents.[16]

Depleting agents include antithymocyte globulin and anti-CD52 monoclonal antibody (alemtuzumab). Unlike the IL-2ra agents, none of these agents have been compared with placebo for the prevention of rejection, and thus their use as induction agents is considered off-label in the United States. Antithymocyte globulin is a polyclonal preparation of antibodies directed at T-cells prepared by immunizing animals with human lymphoid cells derived from the thymus. Currently, the most common antilymphocyte preparation in use is rabbit antithymocyte globulin (rATG). Alemtuzumab binds to CD52, an antigen of unclear physiologic significance that is present on both B and T-cells, and results in depletion of both lymphoid cell lines. Its ability to induce prolonged, significant lymphopenia for up to 6 to 12 months after dosing led to its use in refractory chronic lymphocytic leukemia. Unlike other depleting agents, alemtuzumab is a humanized antibody, and therefore has fewer infusion-related side effects than rATG. Initial trials suggest equivalence to other depleting agents for preventing rejection, but the long-term impact of prolonged lymphopenia on the risk for infection or posttransplant lymphoproliferative disorder has yet to be determined, and comparative trials of induction agents are lacking (see later discussion). Alemtuzumab has been rebranded for use in multiple sclerosis in the United States and is often cost-prohibitive as transplant induction therapy; however, it is still in use in some US and European centers.

Although depleting agents are effective in inhibiting the T-cell response, there is concern about long-term safety. Registry analyses suggest there is an increased risk for future development of lymphoma with depleting agents compared with nondepleting agents or no induction therapy,[17,18] an association that appears to be dose dependent. Therefore, the potential for recovery or improvement of graft function as a result of repeated or prolonged courses of depleting antibody therapy must be balanced against the potential long-term risk for malignancy.

Three multicenter randomized trials have compared the efficacy of induction agents in the prevention of acute rejection. A multicenter trial in patients at high risk for acute rejection (defined as recipients with an elevated risk for delayed graft function, elevated PRAs, repeat transplants, or HLA mismatches) compared the IL-2ra basiliximab to rATG with maintenance immunosuppression of cyclosporine, mycophenolate mofetil (MMF), and prednisone.[19] At 12 months, the rate of acute rejection in the basiliximab cohort was 26% versus 16% in the rATG arm. A second trial in patients at high risk for acute rejection (defined by elevated PRAs, repeat transplants, or loss of a previous kidney transplant to acute rejection) compared the IL-2ra daclizumab to rATG, with a remarkable increase in the risk for rejection for patients randomized to daclizumab (27%) compared with rATG (15%) at 1 year.[20] Thus, for patients at increased risk for rejection, rATG provided greater prevention of acute rejection, supporting its use in higher risk populations. In contrast, the European multicenter randomized controlled HARMONY trial showed no difference in the proportion of low immunologic risk patients with acute rejection receiving either rATG followed by rapid steroid withdrawal or basiliximab with or without

rapid steroid withdrawal.[21] Finally, a clinical trial compared anti-CD52 to either rATG in high-risk patients (repeat transplant, elevated PRAs, or Black ethnicity) or to an IL-2ra in low-risk patients, followed by early corticosteroid withdrawal and maintenance tacrolimus and mycophenolate immunosuppression.[22] Acute rejection rates over the first 12 months in the high-risk arms were 10% for anti-CD52 and 13% for rATG and in the low-risk arms were 20% for IL-2ra and 3% for anti-CD52. However, acute rejection rates in anti-CD52–treated patients were higher in both low- and high-risk arms, suggesting a delayed (>12 months) immunologic risk for immune reconstitution with anti-CD52 therapy. This may be problematic for transplant care providers who generally adhere to less rigorous late (>12 months) clinical monitoring protocols for otherwise stable transplant recipients. Therefore, we recommend adhering to a more frequent late (>1 year) clinical monitoring protocol for patients receiving induction with alemtuzumab.

In summary, it remains unclear whether induction therapy is required in low-risk patients pending further prospective head-to-head trials, whereas patients at higher immunologic risk appear to benefit from lymphocyte-depleting treatment. Based on SRTR data in 2018, approximately 75% of US transplant recipients received rATG induction and 20% received IL-2ra induction, with the remaining cohort receiving either no induction or other agents. Induction regimens are commonly protocolized at individual transplant centers by balancing immunologic protection against cost and the risk of adverse effects. Common dosing regimens of induction agents are listed in Table 109.1.

Prevention of Acute Antibody-Mediated Rejection: Desensitization and Paired Exchange

Nearly all patients with high levels of donor-specific antibodies before transplant or who are blood type–incompatible to the donor before transplant will develop acute antibody-mediated rejection after transplant without pretransplant intervention such as desensitization protocols. Desensitization protocols typically involve removal of preformed antibody with plasma exchange and/or suppression of antibody production and action with intravenous immunoglobulin (IVIG) or B-cell inhibition with rituximab. Choice of desensitization strategy is influenced by factors such as type of transplant (living vs. deceased donor) and the degree of HLA-antibody reactivity one is attempting to overcome. In the case of living donation the crossmatch barriers are known in advance, so plasma exchange followed by low-dose (100–200 mg/kg) IVIG can be arranged followed by transplantation when the desired crossmatch results are obtained. Protocols consisting of monthly high-dose IVIG (1–2 g/kg) infusions with or without rituximab[23] have been used when pretransplant plasma exchange is not feasible, such as in sensitized patients without living donor options awaiting a deceased donor kidney, but the effectiveness of this strategy has been questioned.[24] Published desensitization agents and protocols are listed in Table 109.2.

Desensitization strategies allow transplantation to proceed in many sensitized patients, but are associated with high rates of acute rejection, ranging from 20% to 70% (depending factors including specific protocol, induction immunosuppression, and immunologic risk), which are often humoral and frequently progress to chronic antibody-mediated injury.[25,26]

Kidney paired exchange programs increasingly have been used over the past 10 years in Europe and the United States and allow patients with existing HLA- or ABO-incompatible living donors to receive a compatible transplant while avoiding toxicities and long-term immunologic damage associated with desensitization protocols. Donor-recipient "chains" are usually initiated by a single nondirected live donor and can result in multiple patients with incompatible live donors receiving HLA- and ABO-compatible organs. According to the US

TABLE 109.1 Agents Used for Induction and Treatment of T-Cell–Mediated Rejection

Agent	Target	Dose (Induction)	Dose (Rejection)
Methylprednisolone	B cells, T-cells, macrophages	250–500 mg IV with induction therapy, followed by taper over 1–5 days	3–5 mg/kg (250–500 mg) IV × 3–5 days
Basiliximab	IL-2 receptors on cells	20 mg IV × 2 on days 0 and 4	N/A
rATG	T-cell surface antigens	1–1.5 mg/kg IV × 4–14 days	1–1.5 mg/kg IV × 7–14 days
Alemtuzumab	CD52 on T and B cells	30–60 mg × 1 or 2 on days 0 and 2	Same as induction

IL-2, Interleukin-2; *IV,* intravenous; *N/A,* not applicable; *rATG,* rabbit antithymocyte globulin.

TABLE 109.2 Agents Used for Desensitization and Treatment of Antibody-Mediated Rejection

Treatment	Mechanism	Protocol (Desensitization)	Dose (Antibody-Mediated Rejection)
Plasma exchange[a]	Antibody removal	2–4 sessions or until XM acceptable, combined with IVIG	2–5 treatments, daily or every other day, combined with IVIG
IVIG[a]	Multiple, antibody inhibition(?)	100–200 mg/kg after plasma exchange until acceptable XM *or* 1–2 g/kg/mo until transplant	100–200 mg/kg after plasma exchange
Rituximab[a]	Anti-CD20 B-cell inhibition	375 mg/m^2 (day 15) combined with IVIG 1–2 g/kg (days 1 and 30)	375 mg/m^2 with plasma exchange and IVIG
Bortezomib	Plasma cell inhibition	Not established	1.3 mg/m^2 × four doses over 1–2 wk, usually combined with plasma exchange and IVIG
Eculizumab	Terminal complement C5 inhibition	Not established	For prevention in + XM transplant: 600–1200 mg/wk × 4 then biweekly until successful antibody reduction
Splenectomy	B-cell removal	No longer used	N/A, for severe refractory cases only

[a]Commonly used.
IVIG, Intravenous immunoglobulin; *N/A,* not applicable; *XM,* crossmatch.

Renal Data System, paired exchange accounted for 14% of living donor transplants in 2018, up from 5% in 2009. Recent data show no difference in graft or patient survival at 3, 5, and 7 years between patients receiving paired exchange transplants through the US National Kidney Registry versus those receiving direct living donor transplants in the United States, despite a higher burden of risk factors in the patients transplanted through paired exchange.[27]

Maintenance Therapy for Prevention of Acute Rejection

Current maintenance immunosuppression most commonly includes a CNI, an antiproliferative agent, and corticosteroids. This combination of agents forms the standard against which novel strategies are compared, such as corticosteroid withdrawal/avoidance and CNI withdrawal/avoidance. Cyclosporine has been replaced by tacrolimus as the preferred CNI in the United States and, together with the antiproliferative agent MMF, it forms the most common immunosuppressive regimen in current practice in most high-income countries (Table 109.3). More affordable regimens that include cyclosporin A (CsA) and azathioprine (AZA) are commonly used in areas where resources are more limited, but appear to lead to higher rates of rejection.[28]

Calcineurin Inhibitors in the Prevention of Acute Rejection

Since the early 1980s, when the introduction of CsA led to reduced risk of acute rejection and to better graft survival,[29] calcineurin inhibition has been a cornerstone of maintenance immunosuppression. Tacrolimus, first introduced in 1990s and compared head-to-head with CsA in multiple trials, provides greater protection from acute rejection but with a different side effect profile. A recent meta-analysis of trials demonstrated that compared with CsA, tacrolimus reduced the risk of acute rejection by 31% but increased the risk of new diabetes by 86%. Tacrolimus was also associated with better death-censored graft survival (hazard ratio, 0.56), particularly at target trough doses less than 10 ng/mL, a finding that was not shown in individual studies.[30]

Antiproliferative Agents in the Prevention of Acute Rejection

AZA was the first antiproliferative agent used in kidney transplantation and was used initially in conjunction with corticosteroids and later with CsA. Although its development was critical in the advancement of allotransplantation, acute rejection was quite common, with acute rejection rates of 35% to 40% in a number of clinical trials using CsA/AZA/prednisone. Newer antiproliferative agents emerged in the 1990s with MMF and later with the mammalian target of rapamycin (mTOR) inhibitors sirolimus and everolimus, which significantly reduced the incidence of acute rejection.

TABLE 109.3 Immunosuppression Regimens in the United States, 2018

Regimen	Percent (Approximated)
Induction Regimens at Time of Transplant	
IL-2 receptor antibody	20
T-cell depleting	72
Maintenance Regimens at Time of Hospital Discharge	
TAC/MMF-MPA/Pred	65
TAC/MMF-MPA	30
Other	5

MMF, Mycophenolate mofetil; *MPA,* mycophenolate acid; *Pred,* prednisone; *TAC,* tacrolimus.
Modified from OPTN/SRTR Annual Report, 2020.

MMF is a purine antagonist that interferes with DNA synthesis in rapidly dividing cells such as activated lymphocytes, and it gained popularity after a number of multicenter prospective clinical trials demonstrated that it reduced the risk of acute rejection by approximately 50% compared with AZA.[31,32] A recent meta-analysis of 23 studies showed MMF to be associated with significantly fewer cases of acute rejection and graft loss compared with AZA.[28] Most studies in this analysis reported outcomes of MMF and AZA in combination with CsA and thus may not translate to regimens using tacrolimus. One drawback of MMF has been its poor gastrointestinal (GI) tolerability, which often results in reduction of therapy with attendant risks for acute rejection[33] and graft loss.[34] An MMF analog, enteric-coated mycophenolate acid (MPA), has been developed and appears to be "noninferior" in efficacy to MMF,[35] with fewer GI side effects reported in one open-label study.[36]

Similar to MMF, the mTOR inhibitors sirolimus and everolimus were initially tested in clinical trials as a substitute for AZA and reduced the risk of acute rejection to a similar extent as MMF.[37] mTOR inhibitors inhibit the progression from G1 to S phase of the cell cycle and appear to have additional antiproliferative effects on nonimmune cells that may increase the risk of side effects (impaired wound healing, lymphocele formation, proteinuria, and slower recovery from delayed graft function) but may reduce the incidence of viral infection and malignancy.[38,39] mTOR inhibitors also augment the nephrotoxic effects of CNI, and therefore a reduced dose of CNI is advisable when used together with mTOR inhibitors. A recent large trial (TRANSFORM) randomized 2037 subjects to reduced-dose CNI, most commonly tacrolimus (tacrolimus C_0 2–4 ng/mL) in combination with everolimus (everolimus C_0 3–8 ng/mL), or standard CNI (e.g., tacrolimus C_0 6–10 ng/mL) with mycophenolate.[40] At 12 months posttransplant, noninferiority was demonstrated between treatment arms for the combined endpoint of treated biopsy-proven acute rejection or estimated glomerular filtration rate (eGFR) less than 50 mL/min/1.73 m^2 (48.2% in everolimus arm vs. 45.1% in mycophenolate arm) with no difference in graft loss or death but less cytomegalovirus and BK virus infections in the everolimus arm.

Acute Rejection Rates in Calcineurin-Sparing and Corticosteroid-Sparing Immunosuppression Regimens

There has been increasing interest in how best to minimize side effects of immunosuppression. Avoidance of CNIs offers the hope of prolonged graft survival given the inherent nephrotoxicity of these medications, and avoidance of corticosteroids offers the hope of reducing a number of cosmetic, metabolic, and CV side effects attributable to prednisone.

In the United States approximately one-third of patients undergo early corticosteroid cessation (within 7 days after transplant).[41] Generally, patients at lower immunologic risk (low PRAs, first transplants) are selected,[42,43] and immunosuppression includes induction therapy, a CNI, and an antiproliferative agent. The proportion of patients with acute rejection in single-center studies ranges from 10% to 15%. In the largest prospective, double-blind multicenter study to date of corticosteroid cessation versus standard corticosteroid maintenance,[44] a standard steroid taper or a rapid elimination of steroids at 7 days posttransplant was compared on the background of induction therapy plus a tacrolimus/MMF-based immunosuppression. Patient survival, graft survival, and creatinine clearance were comparable at 5 years. CV risk factors and weight gain were not significantly different between groups, but corticosteroid withdrawal was associated with less bone disease, less insulin-requiring new-onset diabetes, and lower triglyceride levels. One cause for concern with corticosteroid withdrawal was that rejection rates were higher (18% vs. 11%,

$P = .04$), and a post hoc analysis suggested a higher proportion of chronic allograft nephropathy in the corticosteroid withdrawal arm. In contrast, the aforementioned HARMONY study reported similar rejection rates and significant reductions in posttransplant diabetes in two rapid (8-day) steroid withdrawal arms (one using basiliximab and the other using rATG induction) compared with the control arm of basiliximab induction and maintenance steroids, with all patients receiving tacrolimus and MMF.[21]

Clinicians must weigh the possibility of higher rejection risk versus the potential benefits when counseling patients regarding corticosteroid withdrawal. Consideration of corticosteroid withdrawal is best supported for the patient with a lower risk of rejection (low immunologic risk, expected immediate graft function) or increased risk of corticosteroid-related complications such as bone disease and diabetes.

CNI avoidance has been studied with both dual therapy (MMF/prednisone) and triple therapy with two antiproliferative agents (sirolimus/MMF/prednisone) in combination with induction therapy. In general, MMF/prednisone maintenance immunosuppression does not appear to effectively prevent rejection (70% incidence in one pilot study[45]), and although single-center studies report acute rejection rates of 6% to 13% with sirolimus/MMF/prednisone therapy,[46,47] a large multicenter trial using this combination and target trough concentrations of sirolimus 4 to 8 ng/mL also revealed an excessively high acute rejection rate (38%).[48] CNI avoidance with the costimulation blocker belatacept also is associated with a higher proportion of early acute rejection than CNI-based regimens but still may better protect glomerular filtration rate (GFR) over the longer term. In the BENEFIT trial, which compared 2 dosing regimens of belatacept (low and moderate intensity) to CsA with IL-2ra induction and MPA/prednisone maintenance,[49] higher 1-year acute rejection rates were noted in the belatacept arms (22% and 17% for higher and lower intensity, respectively, vs. 7% for CsA) but graft survival was comparable and measured GFR was significantly higher for those receiving belatacept (65 and 63 mL/min for high- and low-intensity belatacept vs. 50 mL/min for CsA). With follow-up to 7 years, the belatacept arms demonstrated a 43% reduced risk for a composite endpoint of death or graft loss compared with CsA.[50] Importantly, patients with low immunologic risk were selected for study, and excluded those who were Epstein-Barr virus (EBV)-seronegative given higher rates of posttransplant lymphoproliferative disorder associated with belatacept use in previous reports.[51] A post hoc analysis of patients included in both the BENEFIT and BENEFIT-EXT studies (the latter including patients receiving extended-criteria donor kidneys) showed significantly lower blood pressure, serum lipids, and incidence of new-onset diabetes in those randomized to belatacept regimens compared with CsA.[52] We suggest that EBV-seronegative patients at low immunologic risk, in particular those with pretransplant metabolic profiles at risk for posttransplant metabolic complications, may benefit from belatacept-based CNI-free immunosuppression.

In contrast to their use in strategies, that avoid CNI, mTOR inhibitors have achieved relative success when used in CNI withdrawal[53,54] and conversion protocols. In one study, patients receiving a CNI, MMF, and prednisone were randomized to continue this regimen or undergo CNI conversion to sirolimus at 1 to 6 months after transplant with statistically similar rates of acute rejection and comparable kidney function at 2 years.[55] Another study, employing a similar approach of CNI conversion to everolimus at 4 to 5 months posttransplant, demonstrated equivalent rates of acute rejection (15% in both groups) and significantly better eGFR at 12 months in the conversion group (72 mL/min vs. 62 mL/min in the CNI continuation arm).[56] A recent meta-analysis that included 23 studies comparing CNI conversion to mTOR inhibitors found a modest improvement in GFR with no difference in rates of rejection or graft loss.[57] Widespread acceptance of CNI to mTOR inhibitor conversion strategies has been hindered because of mTOR inhibitor–related side effects and reluctance to alter immunosuppression in stable transplant recipients.

Ideally, a strategy of combined CNI and steroid avoidance would eliminate the chronic accumulation of side effects and toxicities caused by these agents. A recent trial using depleting antibody induction (alemtuzumab or rATG) and belatacept/MMF-based immunosuppression combined with early corticosteroid withdrawal demonstrated comparable kidney function and patient and graft survival compared with rATG, tacrolimus/MMF-based immunosuppression with early corticosteroid withdrawal.[58] However, 1-year acute rejection rates were still higher in the belatacept cohorts (15.9% with alemtuzumab, 22.1% with rATG) compared with the tacrolimus cohort (4.8%, $P = .024$ and $< .001$, respectively). Thus, there is still room for improvement and additional immunosuppression strategies are needed to minimize side effects while preventing alloimmunity. Acute rejection rates by treatment regimen reported in recent multicenter clinical trials are shown in Table 109.4.

TREATMENT

Acute T-Cell–Mediated Rejection

Treatment of T-cell–mediated acute rejection is often directed by the findings on biopsy and the clinical response to pulse corticosteroids. For the patient with graft dysfunction and biopsy-proven rejection, treatment with intravenous methylprednisolone 3 to 5 mg/kg (250–500 mg/day) for 3 to 5 days is often effective if the histologic injury is tubulointerstitial (Banff class IA or IB). Remarkably few studies of the clinical response to corticosteroids in the treatment of acute rejection have been performed under modern immunosuppression, but prior data suggest that 60% to 70% of patients will respond with improved urine output and decreasing serum creatinine within 5 days. If there is inadequate response after corticosteroid pulse therapy or if there is vascular involvement (Banff class IIA, IIB), corticosteroids often must be supplemented with T-cell–depleting antibody therapies in a similar dosing strategy but longer treatment course compared with their use for induction (see Table 109.1). The duration of treatment has typically been 7 to 14 days, with no clinical trials investigating the efficacy of shorter courses versus longer courses. For patients who are on a maintenance regimen that is not tacrolimus based, tacrolimus conversion may be considered in the setting of rejection with an inadequate response to corticosteroids,[59] whereas for patients on a corticosteroid-free regimen, reinstitution of maintenance prednisone may be warranted.[60] For patients who do not respond adequately to corticosteroids, T-cell–depleting agents are required. A typical course of rATG for T-cell–mediated rejection is 1.5 mg/kg for 4 to 14 days dictated by clinical response and absolute lymphocyte counts, again with no controlled study comparing one treatment regimen versus another.

Acute Antibody-Mediated Rejection

Treatment of acute humoral rejection is indicated when the triad of graft injury, evidence of antibody/endothelium interaction, and circulating donor-specific antibody is present, but should also be considered in high-risk circumstances (prior desensitization or known donor-specific antibody) even if all three criteria are not met. High-quality randomized trials investigating treatment options for acute humoral rejection are lacking,[61] and strategies are generally dictated by center experience. Traditionally, treatment has entailed plasma exchange (to remove the pathogenic immunoglobulin[s]) and IVIG (to inhibit/suppress antibody production). In general, at least 5 plasma exchange treatments should be administered with 1 to 2 g/kg total dose

TABLE 109.4 Maintenance Immunosuppression and Reported Rejection Rates in Randomized Multicenter Trials

Regimen	Induction	CNI Dose or Trough Level Goal (ng/mL)	Antiproliferative Dose or Trough Level Goal	Acute Rejection at 6 Months (%)
Low Immunologic Risk				
CsA/AZA/Pred		4 mg/kg/d	1.5–2 mg/kg/day	36
CsA/AZA/Pred	IL-2ra	Not stated	Not stated	22
CsA/MMF/Pred		150–300 × 3 mo, 100–200	1 g bid	24
CsA/MMF/Pred	IL-2ra	125–400 × 3 mo, 100–300	1 g bid	12
TAC/AZA/Pred	OKT3 or Atgam	5–14	1.5 mg/kg/day	32
TAC/MMF/Pred	OKT3 or Atgam	5–14	1 g bid	7
TAC/MMF/Pred	IL-2ra	7–16 × 3 mo, 5–15	1 g bid	4
CsA/SRL/Pred		200–350 × 1 mo, 200–300 × 1 mo, 150–250	2 mg/day	17
TAC/SRL/Pred		8–16 × 3 mo, 5–15	4–12 ng/mL	13
High Immunologic Risk				
CsA/SRL/Pred	IL-2ra or rATG	200–300 0–14 days 150–200	10–15 ng/mL	14[a]
TAC/SRL/Pred	IL-2ra or rATG	10–15 0–14 days 5–10	10–15 ng/mL	17
Drug Minimization or Avoidance				
CsA (low)/MMF/Pred	IL-2ra	50–100	1 g bid	23
TAC (low)/MMF/Pred	**IL-2ra**	**3–7**	**1 g bid**	**12**[18]
TAC/MMF	**IL-2ra or rATG**	**10–20 × 3 mo, 5–15**	**1.5 g bid × 14 days 1 g bid**	**9**[44]

AZA, azathioprine; *Bela,* belatacept; *bid,* twice daily; *CNI,* calcineurin inhibitor; *CsA,* cyclosporine A; *EVL,* everolimus; *IL-2ra,* interleukin-2 receptor antibody; *LI,* less intensive; *MI,* more intensive; *MMF,* mycophenolate mofetil; *N/A,* not applicable; *Pred,* prednisone; *rATG,* rabbit antithymocyte globulin; *SRL,* sirolimus; *TAC,* tacrolimus.

IVIG. IVIG is removed by plasma exchange, so a common strategy is to administer IVIG 100 to 200 mg/kg after each exchange. For refractory acute humoral rejection, rituximab may be considered despite targeting B-cells at an earlier phase of maturation than the antibody-producing plasma cell line.[62] The largest randomized clinical trial of rituximab treatment for antibody-mediated rejection to date found no difference between the treatment group and placebo when added to plasma exchange and IVIG for a composite endpoint of early improvement in kidney function at 12 days after treatment and graft loss at 1 year. However, the study was limited by a small sample size ($n = 38$) and significant crossover between groups with 42% of subjects in the placebo arm receiving rescue doses of rituximab.[63] In contrast, the proteosome inhibitor bortezomib directly inhibits antibody-producing plasma cells and has been reported in single-center case series as a potential treatment for refractory antibody-mediated rejection, usually in combination with other modalities such as plasma exchange and IVIG.[64] Eculizumab is a humanized monoclonal antibody that blocks terminal complement activation and has been shown to significantly reduce the risk for acute humoral rejection, as well as subsequent transplant glomerulopathy in patients who have undergone positive crossmatch kidney transplant[65]; however, feasibility of this approach is limited by high cost. Targeting the initiation of the classical complement cascade with C1 inhibition has also gained recent interest; pilot studies suggest that C1 inhibition may be associated with improved eGFR and a reduced risk of development of transplant glomerulopathy.[66,67] Finally, there are case reports of splenectomy for refractory acute humoral rejection.[68] These therapies are typically coupled with targeted T-cell therapy such as high-dose steroids and/or depleting antibody therapy, because histologic evidence of mixed T-cell rejection is often present and helper T-cell function may contribute to an enhanced B-cell response. Agents used for treatment of acute humoral rejection are summarized in Table 109.2.

Chronic Rejection (T-Cell–Mediated and/or Antibody Mediated)

T-cell–mediated or antibody-mediated injury in a graft without features of acute tissue injury remains a therapeutic dilemma. No intervention has been proven effective in reversing the chronic tissue injury; transitioning to tacrolimus/MMF therapy or increasing the dose of these agents should be considered if CNI nephrotoxicity is not

identified.[69] Any intervention should be weighed against the potential for risk for enhanced immunosuppression and the lack of long-term data. This topic is discussed in greater detail in Chapter 112.

PROGNOSIS

Acute rejection may predispose to chronic graft dysfunction, with increased histologic findings of chronic rejection and/or interstitial fibrosis and tubular atrophy and clinical findings of reduced graft survival. The clinical response to antirejection therapy appears to be critical in this regard because the change in kidney function from 6 and 12 months posttransplant is more predictive of long-term graft survival than the occurrence of prior episodes of acute rejection.[70] Two analyses (one examining the US experience[71] and another examining the Australia/New Zealand experience[72]) have shed light on risk factors for graft loss after episodes of acute rejection. In general, acute T-cell–mediated rejection that responds to therapy with return to near baseline kidney function does not portend worse graft survival. However, vascular rejection, late rejection (after 3 months), and rejection that does not respond to within 75% of baseline serum creatinine is associated with worse graft outcomes. Although the risk for acute rejection has fallen significantly over the past decade, the likelihood of graft survival has not improved in parallel, possibly because contemporary rejection is less responsive to therapy, with fewer cases achieving near-baseline serum creatinine levels. The long-term prognosis after episodes of acute antibody-mediated rejection has not been fully defined in prospective analyses. However, it appears that episodes of acute humoral rejection likely affect long-term graft survival. For example, a retrospective analysis of 302 patients with biopsy-proven acute rejection (192 with T-cell–mediated rejection and 110 with antibody-mediated rejection) found a threefold to ninefold increased risk for graft loss at 5 years associated with antibody-mediated rejection compared with T-cell–mediated rejection.[10] Similarly, the emergence of de novo HLA antibodies at any time after transplant is associated with a 5% worse graft survival per year compared with those who do not form anti-HLA antibodies.[73] For this reason, patients who have had episodes of acute rejection must be rigorously monitored with optimization of baseline maintenance immunosuppression. Remaining questions include the value of escalated immunosuppression, such as longer-term scheduled antibody therapy and additional IVIG treatment for those without adequate clinical response or with persistently elevated titers of HLA antibodies.

SUMMARY AND RECOMMENDATIONS

The incidence of acute rejection has decreased over time, but it remains an important cause of graft dysfunction and progressive graft loss, particularly when antibody-mediated forms of injury are identified. Higher-risk patients benefit from induction therapy with lymphocyte-depleting agents for the prevention of rejection. Although many maintenance immunosuppressive regimens have been used to minimize the incidence of rejection and side effects, the most effective maintenance immunosuppressive regimen for the prevention of rejection is a three-drug regimen consisting of tacrolimus, mycophenolate, and prednisone. Alternative immunosuppressive strategies may be considered for side effects or toxicities related to immunosuppressive agents, which in clinical practice has led to a myriad of treatment combinations (see Table 109.4). Steroid minimization and belatacept-based CNI-free immunosuppression have been associated with adequate short- and intermediate-term outcomes but should be limited to those patients at lower immunologic risk for acute rejection. Until it is possible to determine an individual patient's degree of immune function, suppression, or graft-specific immunity, the clinician must determine the best treatment regimen based on potency (potential to minimize rejection) and tolerability.

SELF-ASSESSMENT QUESTIONS

1. According to the Banff Working Classification of Renal Allograft Pathology, which one of the following patterns would be recognized as acute antibody-mediated rejection?
   - **A.** Circulating donor-specific antibodies, severe tubulitis, interstitial inflammation
   - **B.** Peritubular capillaritis (ptc1), interstitial inflammation, moderate transplant glomerulopathy (cg2)
   - **C.** Circulating donor-specific antibodies, mild to moderate large-vessel intimal arteritis, moderate interstitial fibrosis
   - **D.** Peritubular capillary C4d deposition, circulating donor-specific antibodies, peritubular capillaritis (ptc2)
2. Which one of the following statements is *true* regarding induction immunosuppression for the prevention of acute rejection?
   - **A.** rATG is a monoclonal antibody directed against the CD3 subunit of the T-cell receptor associated with a significant innate immune response resulting in a cytokine release syndrome.
   - **B.** Lymphocyte-depleting agents are more effective in preventing acute rejection compared with IL-2 receptor antibodies in patients at high immunologic risk.
   - **C.** The risk for posttransplant lymphoproliferative disorders is higher in patients treated with IL-2 receptor antibodies than in those treated with lymphocyte-depleting agents.
   - **D.** Patients at low immunologic risk experience higher early (<12 months) rates of acute rejection when treated with anti-CD52 therapy (Campath) compared with IL-2 receptor antibody therapy.
3. Which one of the following is the *most* effective maintenance immunosuppressive regimen for the prevention of rejection?
   - **A.** Sirolimus, MMF, prednisone
   - **B.** Tacrolimus, MMF, prednisone
   - **C.** Belatacept, MMF, prednisone
   - **D.** Tacrolimus, MMF, prednisone withdrawal at 7 days posttransplant
4. A 47-year-old man treated with tacrolimus, MMF, and 5 mg of prednisone after undergoing deceased-donor kidney transplant 5 months prior presents with an elevated serum creatinine of 5.2 mg/dL (recent baseline 1.3 mg/dL) and mild graft tenderness. Kidney ultrasound is nondiagnostic, a workup for infectious causes is negative, and an assay for donor-specific antibody is negative. Allograft biopsy is performed and reveals severe tubulitis with vascular intimal arteritis without evidence of peritubular capillary C4d deposition. Which of the following is the *most* appropriate initial therapy?
   - **A.** Increasing the dose of maintenance prednisone to 60 mg/day for 7 days followed by a dose taper back to 5 mg
   - **B.** 3 to 5 days of intravenous methylprednisolone at 500 mg/day
   - **C.** rATG 1.5 mg/kg IV for 7 to 14 days
   - **D.** Plasmapheresis followed by 100 to 200 mg/kg immune immunoglobulin for a total of 5 sessions

Infections and Malignancies in the Kidney Transplant Recipient

Phuong-Thu T. Pham, Joanna Schaenman, Phuong-Chi T. Pham

INFECTIOUS DISEASES

Infection follows cardiovascular (CV) disease as the second most common cause of death with a functioning graft in kidney transplant recipients. Infection and malignancy are more commonly the cause of death among those without diabetes. Predisposing risk factors for infectious complications include immunosuppression, increased recipient age, indwelling Foley or vascular catheters, surgical drains, drug-induced leukopenia, and metabolic derangement. Epidemiologic exposures, shifts in nosocomial flora associated with repeated antimicrobial exposures (antimicrobial resistance), and improvement in molecular diagnostic assays also contribute to the emergence of novel infections and changes in the epidemiology of infections.[1]

Immunizations Before and After Transplantation

All kidney transplant candidates should receive immunization for hepatitis B, pneumococcus, and other standard immunizations appropriate for age and the presence of end-stage kidney disease. Inactivated vaccine should be completed by 2 weeks prior to transplantation to optimize immune response to vaccination, and a minimum of 4 weeks should elapse between live attenuated virus vaccine administration and transplantation to minimize the possibility of live vaccine–derived infection in the posttransplantation period.[2] Live virus or live organism vaccines should be avoided after transplantation. Immunizations using inactivated or killed microorganisms, components, and recombinant moieties are safe for transplant recipients. Most centers restart vaccinations 3 to 6 months after transplantation. Vaccination during the first 3 months after transplantation may result in suboptimal response and protection because of increased levels of immunosuppression early posttransplant, especially in patients who receive lymphocyte-depleting agents as part of induction. Ensuring adequate response to hepatitis B vaccination is important to prevent transmission of donor-derived infection. Seasonal influenza vaccine is safe and effective, and no conclusive evidence exists for a link between vaccination and allograft dysfunction. Household members, close contacts, and health care workers should also be fully immunized. In addition, they should receive annual influenza vaccine, preferably with inactivated influenza vaccine. If live attenuated vaccine is used, frequent handwashing for a 2-week period after vaccination is recommended. With the exception of smallpox and oral polio vaccines, there is little to no risk to the transplant recipient if family members or close contacts receive live vaccines. Pets should also be fully immunized. Immunization of pets with live vaccines (e.g., canine *Bordetella bronchiseptica* intranasal vaccine) poses little to no risk of transmission.[2] Recommended immunizations before and after transplantation are listed in Table 110.1. For vaccination of transplant recipients who travel to countries where endemic infections such as malaria are present, see Buchan et al.[3] All solid organ transplant recipients should be seen by a travel medicine specialist prior to traveling to destinations with higher rates of infection.[3]

Infectious Causes

The type and occurrence of infections in the immunocompromised transplant recipient follow a predictable pattern based on time since transplantation (Table 110.2). Timing of infections may be altered by the intensity of immune suppression, use of target antibiotic prophylaxis, and patient exposures.

Risk Factors for Posttransplant Infectious Complications

Risk factors for posttransplant infectious complications include active or latent infections in the donors, net state of immunosuppression, surgical instrumentation, wound-healing issues, abdominal fluid collections, reactivation of latent infections, epidemiologic exposure, metabolic conditions (e.g., diabetes, uremia), infections with immunomodulating viruses, and hypogammaglobulinemia, among others. Severe hypogammaglobulinemia (immunoglobulin [Ig] G < 400 mg/dL) during the first year posttransplantation is associated with a significant increase in the risk for cytomegalovirus (CMV) infection, fungal and respiratory infections, and 1-year all-cause mortality among recipients of solid organ transplantation.[4] Although controlled trials are lacking, posttransplant monitoring of IgG levels and Ig replacement therapy to keep IgG level above 700 to 800 mg/dL may reduce infection rates in patients with hypogammaglobulinemia.

Donor-Derived Infections

Donor-derived infections include bacterial, fungal (*Candida* spp.), viral (human immunodeficiency virus [HIV], hepatitis B and C [HBV and HCV], cytomegalovirus [CMV]), and parasitic infections (malaria, *Babesia* and *Balamuthia* infections, amebic meningitis). Allograft-transmitted infections with unusual viruses include lymphocytic choriomeningitis virus, West Nile virus, and rabies. Despite routine surgical prophylaxis, transmission of resistant organisms, including methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant enterococci (VRE), and azole-resistant *Candida* spp. may still occur. Donor-derived carbapenem-resistant Enterobacteriaceae (CRE) infections are associated with high morbidity and mortality. Donation of organs that are directly involved in CRE infection should be evaluated on a case-by-case basis with input from an infectious disease consultation given the high risk of donor-derived infection (e.g., kidneys from donors with CRE urinary tract infection [UTI], donors with CRE bacteremia). Systematic review and meta-analyses revealed that donor–derived viral infections were most prevalent (56.0%), followed by bacterial (15.5%), fungal (15.5%), and parasitic (13.0%) infections. Among viral donor–derived transmissions, HIV and human T–cell lymphotrophic virus (HTLV) were the most frequently observed infections (9.7%), followed by West Nile virus (6.3%). Most commonly reported donor-transmitted bacterial infections were *Mycobacterium tuberculosis* (4.8%) and *Pseudomonas aeruginosa* (4.3%); *Candida* spp.

TABLE 110.1 Recommended Immunizations Before and After Transplantation

Vaccine	Inactivated (I) Virus or Live Attenuated (LA) Virus	Before Transplant	After Transplant (>3–6 Mo Posttransplant)	Comments
MMR	LA	Yes	Contraindicated	Presence of measles antibody can be assessed to determine need for vaccination or revaccination prior to transplantation
DPT	I	Yes	See comments	Diphtheria and tetanus: booster every 10 yr
Herpes zoster (Shingrix)	I	Yes	Yes	Indicated for age≥ 50 yr
Poliovirus	I	Yes	Yes	For travelers to endemic areas (e.g., some parts of Asia, Africa)
Haemophilus influenza type b	I	Yes	Yes	Indicated for patients with sickle cell disease, complement deficiency, or those who had a splenectomy
Influenza A and B[a]	I	Yes	Yes	Annually[b] All patients who are >3 mo posttransplant should receive influenza vaccine May be administered in the immediate posttransplant period during an outbreak
Hepatitis A	I	Yes	Yes	Recommended posttransplant if not administered pretransplant For travelers to endemic areas
Hepatitis B (Heplisav, Engerix)	I	Yes	Yes	Recommended posttransplant if not administered pretransplant Monitor titers for response Repeat series if needed
PCV20 (Prevnar)	I	Yes	Yes	If possible, PCV13 should be administered before PPSV23For adults who have not previously received PPSV23, administer PCV13, followed by PPSV23 at least 8 wk later For adults who just received PPSV23 but have not received PCVI3, wait 12 mo before administering PCV13 Adults <65 years who are high risk should receive 2 doses of PPSV23 5 yr apart (but no sooner than 8 wk after PCV13), with a third dose after they turn age 65 yr
PPSV23 (Pneumovax)	I	Yes	Yes	
HPV	I	Yes	Yes	Nonpregnant female candidates ages 11–26 yr, males ages 11–21 yr
Neisseria meningitidis (both quadrivalent and group B vaccines)	I	Yes	Yes	Recommended for patients with properdin terminal component deficiencies or receiving eculizumab therapy, or those with functional or anatomic asplenia Others: military members travelers to high-risk areas, college freshmen living on campus
COVID-19	Vaccine type[c]: mRNA Replication defective adenovirus vector[d]	Yes	Yes	Preexposure prophylaxis with tixagevimab plus cilgavimab is recommended for all immunosuppressed kidney transplant recipients unless contraindicated (must complete primary vaccine series) Monovalent vaccines protect against the original SARS-CoV-2 whereas bivalent vaccines protect against both the original and the Omicron variants BA.4 and BA.5 (should be administered at least 2 months after completion of the primary series)

[a]Live attenuated nasal influenza vaccine has been removed from the US market.
[b]If possible, patients being treated for or recently treated for allograft rejection should avoid vaccinations until 3 months after treatment to ensure optimal immune response. However, vaccination should not be delayed if such delay represents more of a risk than the risk of impaired response. All transplant recipients over age 65 years should receive the high-dose vaccine where available.
[c]Vaccines available in the United States: mRNA (Pfizer-BioNTech, Moderna), protein-based (Novavax), replication defective adenovirus vector (Johnson & Johnson's Janssen).
[d]The US Centers for Disease Control and Prevention recommend that the Janssen vaccine only be considered in certain situations due to safety concerns (last updated August 2022).
AST, American Society of Transplantation; *DPT,* diphtheria, pertussis, tetanus; HPV, human papillomavirus; *MMR,* measles, mumps, rubella; *PCV,* pneumococcal conjugate vaccine; *PPSV,* pneumococcal polysaccharide vaccine, *SARS-CoV-2,* severe acute respiratory syndrome coronavirus 2.

(3.9%) and *Toxoplasma gondii* (3.4%) were the most common donor-derived fungal and parasitic infections, respectively.[5] Nucleic acid testing (NAT) for HIV and hepatitis infections should be performed on all donors, and all recipients should undergo posttransplant infection surveillance. If a donor is at increased risk for HIV, HBV, or HCV transmission, potential recipients of such kidneys should undergo additional counseling prior to organ acceptance (Box 110.1). Currently all deceased and living organ donors and potential recipients are tested for the novel COVID-19 by polymerase chain reaction (PCR) prior to organ procurement or transplantation. One fatal case of transmission

TABLE 110.2 Timetable of Infections

Timetable of Infections	Comments
First Month After Transplant ***Bacterial (Sites and Sources)*** • Urinary tract • Respiratory system • Bacteremia • Surgical wound or intraabdominal sources (lymphoceles, hematoma, urine leak) • Vascular access or instrumentations (catheters, drains, urinary stents) • Anatomic or functional genitourinary tract abnormalities (ureteral stricture, vesicoureteric reflux, neurogenic bladder) • *Clostridioides difficile* or center-specific multidrug-resistant species ***Viral*** • Uncommon except HSV ***Fungal*** • *Candida* spp. predominate (recipient pretransplant colonization or donor derived)	• Common nosocomial bacterial pathogens and *Candida* spp. predominate • Risk can be mitigated by appropriate prophylaxis • Minimize or avoid environmental exposure at all times after transplant (primarily avoiding pigeons and areas of active building construction)

Organisms Transmitted With Donor Organs
Months 1–6
Viral
• CMV, HSV, VZV, EBV, HBV, HCV, BK virus (exogenous infection or reactivation of latent disease as a result of immunosuppression)
• Others: HHV-6, HHV-7, influenza, parainfluenza, RSV, adenovirus
Fungal
• *Aspergillus* spp., *Cryptococcus,* agents of mucormycosis
Bacterial
• Recurrent urinary tract infections or pyelonephritis, *Nocardia, Listeria, Mycobacterium* spp. (tuberculous and nontuberculous), *Legionella*
Parasitic
• *Pneumocystis jirovecii, Toxoplasma* and *Strongyloides* spp., leishmaniasis, *Trypanosoma cruzi*
	• Unconventional or opportunistic infections secondary to immunosuppression
	• Measures to reduce HBV and HCV infection and/or reactivation
	  • Universal immunization for HBV
	  • All patients with HBV infection (HBsAg or HBeAg positive) should receive lifelong antiviral prophylaxis[a]
	  • HCV patients should be referred to a hepatologist for consideration of DAA therapy[b]
	• Minimize or avoid environmental exposure at all times after transplant

After 6 Months *Stable Patients on Low-Dose Immunosuppressants* • Community-acquired respiratory and GI viral pathogens *History of Multiple Rejection Episodes Requiring Intensification of Immunosuppression* • Viral infections (invasive CMV such as CMV colitis or pneumonitis, VZV, parvovirus B19), late opportunistic infections *(Pneumocystis, Cryptococcus, Listeria, nocardiosis),* tuberculosis *Persistent Infections* • HBV, HCV, papillomavirus, BK virus *Geographically Restricted Infections* • Examples: coccidioidomycosis, histoplasmosis, blastomycosis, paracoccidioidomycosis *Deep-Seated Infections* • Examples: osteomyelitis, paravertebral abscess • Predisposing risk factors: chronic skin infections, long-standing poorly controlled diabetes, peripheral vascular disease *Associated With Malignancies* • EBV (PTLD), papilloma virus (squamous cell carcinoma), HSV (cervical cancer), HHV-8 (Kaposi sarcoma)	• Infection risks associated with duration and intensity of immunosuppression and epidemiologic exposures • Excellent sustained virologic response achieved with direct-acting antiviral agents may lower the long-term incidence of chronic liver disease and cirrhosis in HCV patients • Minimize or avoid environmental exposure at all times after transplant

[a]All patients should receive antiviral therapy after transplantation. Transplant candidates with active HBV replication (i.e., detectable HBV DNA) should start therapy pretransplant.

[b]In patients with HBV and HCV coinfection, HBV antiviral prophylaxis should be considered prior to DAA therapy because HBV reactivation can occur as a consequence of DAA therapy. Patients with evidence of resolved infection (hepatitis B core antibody positive) should be monitored for HBV reactivation with serial HBV DNA and liver function tests during DAA therapy.

CMV, Cytomegalovirus; *DAA,* direct-acting antiviral agent; *EBV,* Epstein-Barr virus; *GI,* gastrointestinal; *HBeAG,* hepatitis B e-antigen; *HBsAG,* hepatitis B surface antigen; *HBV,* hepatitis B virus; *HCV,* hepatitis C virus; *HHV,* human herpesvirus; *HSV,* herpes simplex virus; *PTLD,* posttransplant lymphoproliferative disease; *RSV,* respiratory syncytial virus; *VZV,* varicella zoster virus.

BOX 110.1 United Network for Organ Sharing Protocol Surveillance for All Transplant Recipients

Pretransplant

At baseline:

- Any CDC-approved HIV testing modality
- HBsAg
- HCV quantitative PCR

Posttransplant

At 4–8 wk posttransplant:

- HIV RNA quantitative PCR
- HBV DNA quantitative PCR
- HCV RNA quantitative PCR

At 12 mo posttransplant (for liver transplant recipients only)

- HBsAg or HBV NAT, anti-HBsAb, and anti-HBcAb

CDC, Centers for Disease Control and Prevention; *HBV,* hepatitis B virus; *HBcAb,* hepatitis B core antibody; *HBsAb,* hepatitis B surface; *HBsAg,* hepatitis B surface antigen; *HCV,* hepatitis C virus; *NAT,* nucleic acid testing; *PCR,* polymerase chain reaction.

of COVID-19 from lung donor to recipient has been reported despite a negative nasopharyngeal swab.[6] Hence, for thoracic organ transplantation, COVID-19 testing of the donor lower respiratory tract is recommended (if safe and feasible). Limited data suggest that transplantation of nonlung organs from COVID-19 infected donors can be safely performed. Assessing viral load using cycle threshold might be helpful in clinical decision-making (opinion based).

Month 1 After Transplantation

In the first month after transplantation, donor- and recipient-derived infections with common nosocomial bacterial microorganisms and *Candida* spp. predominate. Infections caused by multidrug-resistant bacteria are center specific. Despite the advent of potent broad-spectrum antimicrobial agents, infections caused by multidrug-resistant bacteria, including gram-positive bacteria (MRSA, VRE), extended-spectrum β-lactamases, and gram-negative bacilli and multidrug-resistant nonfermenting gram-negative bacilli, including CRE, continue to be important causes of morbidity and mortality.

Most bacterial infections during this period involve wounds, catheters, and drainage sites. Aspiration pneumonia and UTIs are common. Most UTIs are caused by gram-negative bacteria with *Escherichia coli* being the predominant causative organism. *Enterococcus* species account for the majority of gram-positive pathogens. Preventive measures for UTIs include early urethral catheter removal and antibiotic prophylaxis. Trimethoprim-sulfamethoxazole (TMP-SMX) prophylaxis during the first 3 to 6 months after transplantation may reduce the risk for UTIs and eliminate urosepsis unless anatomic or functional derangement of the urinary tract is present. Strict aseptic surgical techniques and perioperative use of first-generation cephalosporins reduce the incidence of wound infections. Except for herpes simplex virus (HSV), viral infections are uncommon during this period.

Months 1 to 6

During months 1 to 6, unconventional or opportunistic infections secondary to immunosuppression are most common. Viral infections such as CMV, HSV, varicella-zoster virus (VZV), Epstein-Barr virus (EBV), HBV, and HCV may occur from exogenous infection or reactivation of latent disease. Historically, reactivation of de novo HCV infection was an important cause of morbidity and mortality after transplantation. The advent of fixed-dose direct-acting antiviral agent (DAA) combination therapy has improved outcomes in hepatitis C–positive transplant recipients. Repeated courses of antibiotics and corticosteroids increase the risk for fungal infections, whereas viral infections not only may result from immunosuppression but may further impair immunity and increase the risk for additional opportunistic infections. TMP-SMX prophylaxis eliminates or reduces the incidence of *Pneumocystis*, *Listeria monocytogenes*, *Nocardia* spp., and *Toxoplasma gondii* infection. Reactivation of latent infection such as from *Mycobacterium tuberculosis, Trypanosoma cruzi, Leishmania* spp., *Strongyloides stercoralis, Cryptococcus neoformans, Histoplasma capsulatum,* and *Coccidioides* and *Paracoccidioides* spp. may be observed. Community-acquired respiratory viruses are a common hazard in these vulnerable immunocompromised patients during this period, whereas BK polyomavirus infection is an important cause of allograft loss (discussed later).

After 6 Months

After 6 months, the infection risk is largely a function of chronic maintenance immunosuppression, exposure to T-cell–depleting agents, graft function, and epidemiologic exposures. Patients can be divided into three categories of infection risk.

The first category consists of most transplant recipients (70%–80%), who have satisfactory or good allograft function, relatively low doses of immunosuppressants, and no history of chronic viral infection. The risk for infection approaches that of the general population, with community-acquired respiratory viruses constituting the major infective agents. Opportunistic infections are unusual unless environmental exposure has occurred.

The second group (~10% of patients) consists of those with chronic viral infection that may include HBV, HCV, CMV, EBV, BK polyomavirus (BKPyV), or papillomavirus. In the setting of immunosuppression, such viral infections may lead to the development of BKPyV-associated nephropathy (BKVAN), posttransplantation lymphoproliferative disorder (PTLD), squamous cell carcinoma (papillomavirus), or progressive liver disease or cirrhosis (HBV, HCV). The sustained virologic response achieved with DAAs in both the dialysis and kidney transplant populations with chronic hepatitis C may lower the long-term incidence of chronic liver disease and cirrhosis in these populations. The advent of pangenotypic (genotypes 1–6) DAAs along with universal immunization for HBV can potentially eradicate HBV and HCV infection after transplant.[7,8] New infections occurring after the first 6 months posttransplantation often reflect new exposures (e.g., *L. monocytogenes* [dietary ingestion], Lyme disease [tick exposure], and malaria [travelers to endemic areas]).[1] Alemtuzumab (a humanized monoclonal antibody directed against CD52 found on T and B cells) is associated with increased risk for late invasive viral and fungal infections because of its profound and prolonged effect on pan–T-cell depletion.

The third group (~10% of patients) consists of those who experience multiple rejection episodes requiring repeated exposure to heavy immunosuppression. These patients are the most likely to develop chronic viral infections and superinfection with opportunistic infections. Causative opportunistic pathogens include *Pneumocystis, Listeria, Nocardia, Cryptococcus,* and geographically restricted mycoses (coccidioidomycosis, histoplasmosis, blastomycosis, paracoccidioidomycosis). Risk factors include intensive immunosuppression for graft rejection, CMV infection, higher-dose corticosteroid therapy (defined as >20 mg of prednisone daily for at least 2 weeks), prolonged neutropenia, or flare of autoimmune disease. The widespread use of prophylactic therapy has resulted in a decrease in the incidence of *Pneumocystis* infection in solid organ transplant recipients with an estimated incidence of 0.3% to 1.5% compared with 3% to 5% historically.[9]

TABLE 110.3 Posttransplantation Antimicrobial Prophylaxis

Prophylaxis	Regimen	Comments
Pneumocystis jirovecii	First line: TMP-SMX × 6–12 mo[a] (lifelong in some, especially thoracic organs) Second line (sulfa allergies)[b]: dapsone, atovaquone, or aerosolized pentamidine[c]	TMP-SMX also reduces the incidence of *Toxoplasma gondii, Listeria monocytogenes,* and *Nocardia asteroides* and reduces the incidence of UTI in kidney transplant recipients Check G6PD before initiation of dapsone
Fungal	Nystatin S&S or fluconazole[c]	Fluconazole recommended in high-risk recipients (e.g., simultaneous pancreas-kidney or liver-kidney transplant recipients, history of coccidioidomycosis, or patients who live in endemic areas)
CMV	Acyclovir, valganciclovir, ganciclovir (for CMV prophylaxis protocol, see Box 110.2)	Acyclovir (or famciclovir or valacyclovir) for HSV and VZV prophylaxis for patients not on CMV prophylaxis

[a]Duration of therapy may vary among centers. Restart TMP-SMX prophylaxis for 3–6 months after any corticosteroid pulse or antibody treatment.
[b]Listed in order of preference. Dapsone is preferred over atovaquone for patients without anemia or G6PD deficiency. Consider adding fluoroquinolones or cephalexin (or other agents) for antibacterial activity for higher risk patients.
[c]We advocate lifelong therapy in patients with history of coccidioidomycosis or in those who live in endemic areas.
CMV, Cytomegalovirus; *G6PD,* glucose-6-phosphate dehydrogenase; *HSV,* herpes simplex virus; *TMP-SMX,* trimethoprim-sulfamethoxazole; *UTI,* urinary tract infection; *VZV,* varicella zoster virus.

MANAGEMENT AND PROPHYLACTIC THERAPY FOR SELECTED INFECTIONS

Suggested prophylactic therapy in kidney transplant recipients is shown in Table 110.3.

Cytomegalovirus Infection

CMV infection may cause primary infection in a seronegative recipient (donor seropositive, recipient seronegative), reactivation of endogenous latent virus (donor seropositive or seronegative, recipient seropositive) or superinfection with a new virus in a seropositive recipient (donor seropositive, recipient seropositive). Primary CMV infection is usually more severe than reactivated infection or superinfection.

Clinical Manifestations

CMV infection may be asymptomatic, manifesting as a mononucleosis-like syndrome, an influenza-like illness with fever and leukopenia or thrombocytopenia, or a severe systemic or tissue-invasive CMV disease. Gastroenteritis is the most common tissue-invasive CMV disease observed in solid organ transplantation but any organ system may be affected. Patients may present with esophagitis, gastroenteritis, hepatitis, pneumonitis, carditis, encephalitis, chorioretinitis, and even otitis. The spectrum of CMV-induced kidney injury includes tubulointerstitial nephritis, CMV glomerulopathy, and rarely CMV-induced thrombotic microangiopathy. CMV often invades the transplanted allograft due to aberrant immune response within the allograft. Without prevention strategies (discussed in a later section), CMV infection typically occurs during the first 3 months after transplant. Delayed-onset CMV infection refers to the occurrence of CMV infection 3 to 6 months after completion of antiviral prophylaxis, whereas late-onset CMV infection refers to the development of CMV infection 1 year after transplantation. Suggested risk factors for delayed-onset CMV infection include D+/R− serostatus, allograft rejection, overimmunosuppression, severe lymphopenia, and lack of CMV-specific immunity.

Immunomodulating Effects of Cytomegalovirus Infection

CMV infection is associated with immune modulation and dysregulation of helper and suppressor T cells. It may be a risk factor for acute and chronic allograft rejection, secondary infection with opportunistic agents (e.g., *Pneumocystis, Candida, Aspergillus*), and reactivation of human herpesvirus 6 (HHV-6) and HHV-7 and may favor development of PTLD. CMV infection may also accelerate HCV infection and the development of posttransplantation diabetes mellitus (also known as *new-onset diabetes after transplantation;* see Chapter 111).

A Swiss transplant cohort study involving heart, kidney, liver, and lung transplant recipients demonstrated significantly increased risk of graft rejection within 4 weeks after detection of CMV replication with the highest risk seen in lung transplants and the lowest risk in kidney grafts. There was no significant difference in rejection risk among patients with asymptomatic untreated, asymptomatic treated, and symptomatic CMV replication.[10] In recipients of liver and lung transplants, donor or recipient CMV seropositivity was associated with increased incidence of rejection even in the absence of detectable CMV DNA or disease. Although the cause-and-effect relationship of CMV infection and allograft rejection remains hypothetical, the common mediator may be the release of inflammatory cytokines. It also remains possible that immunosuppression reduction in the context of CMV DNAemia may increase the risk of acute rejection, whereas intensification of immunosuppression to treat rejection may trigger CMV reactivation.

Risk Factors for Cytomegalovirus Infection

High-risk donor and recipient serostatus (donor CMV seropositive, recipient CMV seronegative) and the use of blood products from CMV-seropositive donors are well-established risk factors for CMV infection. Other risk factors include antilymphocyte antibodies, prolonged or repeated courses of antilymphocyte preparations, high doses of maintenance immunosuppression, acute rejection episodes, comorbid illnesses, concomitant HHV-6 and HHV-7 viral infections, neutropenia, hypogammaglobulinemia, and lack of CMV-specific $CD4^+$ and $CD8^+$ T cells. Belatacept-based maintenance immunosuppression is associated with an increased risk of CMV primary infection and a prolonged course of viral replication in CMV high-risk patients.[11] CMV infection is lower among kidney transplant recipients receiving mTOR inhibitor-based compared with calcineurin inhibitor (CNI)-based regimens.[12]

CMV Screening and Prevention

Surveillance for CMV is best performed using PCR-based methods for CMV DNA. Whole blood may result in higher CMV DNA results than plasma, hence it is best to use one specimen type for comparison. CMV DNA assay is highly specific and sensitive for the detection of CMV DNAemia. Antigen-based methods (e.g., testing for pp65) have largely been replaced by CMV DNA testing, and the former may also

be falsely negative in the setting of leukopenia. Quantitative CMV assays in patients with invasive colitis and gastritis or neurologic disease, including chorioretinitis, are often negative and diagnosis may require invasive testing and biopsies. CMV DNAemia is rarely useful as a predictor of CMV retinitis and diagnosis is generally based on ophthalmologic examination. The detection of CMV DNA in vitreous fluid may be helpful in guiding the diagnosis of CMV retinitis.[13]

CMV prevention can be achieved by prophylaxis or preemptive therapy. Prophylaxis involves antiviral therapy beginning in the immediate postoperative period and continuing for 3 to 6 months. Preemptive therapy entails close CMV surveillance after transplant and initiation of treatment in patients who are found to reach a certain threshold of positive CMV DNA by PCR (threshold to treat may differ among centers). Oral acyclovir (or famciclovir or valacyclovir) is necessary for HSV and VZV prophylaxis in patients not receiving anti-CMV prophylaxis. A preemptive approach (with once weekly surveillance for 3–4 months) and universal prophylaxis appear to be comparably effective for preventing CMV disease among D+/R− and/or R+ kidney transplant recipients, and both are recommended in the 2018 International Consensus Guidelines. However, prophylaxis may be preferred in donor and/or recipient seropositive patients whose risk for CMV may be increased, and a longer duration of prophylaxis (i.e., 6 months) may also be more effective.[13] CMV surveillance weekly for 8 to 12 weeks after the end of prophylaxis may be considered in patients at increased risk for postprophylaxis CMV disease. Retrospective studies demonstrated that secondary prophylaxis after successful treatment completion is not protective against CMV relapse.[13,14] Suggested CMV prophylaxis protocol is shown in Box 110.2.

Treatment

The Third International Consensus Guidelines and the AST Infectious Diseases Community of Practice Guidelines on the Management of CMV in Solid-Organ Transplantation are summarized in Box 110.3. Mutation in the viral kinase *UL97* gene that prevents phosphorylation of ganciclovir to its active form confers ganciclovir resistance. Cidofovir and foscarnet should be reserved for those with ganciclovir-resistant strains because of their associated nephrotoxicity and potential synergistic nephrotoxicity with CNIs. Mutation in the *UL54* gene, which encodes for CMV DNA polymerase (a target for all currently available systemic anti-CMV drugs) could lead to cidofovir or foscarnet resistance or cross-resistance among ganciclovir, foscarnet, and cidofovir. Concomitant *UL97* and *UL54* mutations often confer high-level ganciclovir resistance. Letermovir is a novel anti-CMV agent with a mechanism of action distinct from that of the CMV DNA polymerase inhibitors. Letermovir inhibits CMV viral terminase complex (encoded by *UL56, UL51,* and *UL89* genes) and is used in CMV prophylaxis in allogeneic hematopoietic stem cell transplant recipients.[15] However, letermovir has no activity against other herpesviruses, and its use for CMV prophylaxis should be complemented by acyclovir (or famciclovir or valacyclovir) for the prevention of HSV and VZV. Unlike cidofovir and foscarnet, it does not share cross-resistance with ganciclovir. Whether letermovir is effective in treating refractory or resistant CMV infection remains to be determined,[16] and whether it is superior to valganciclovir in preventing CMV disease in high-risk (CMV D+/R−) adult kidney transplant recipients is being evaluated in a phase III clinical trial (study results not yet available). Maribavir is another new antiviral medication with a novel mechanism of action that has proven activity against resistant and refractory disease.[17]

Candida Infections

Candida infections are common in transplant recipients; *Candida albicans* and *Candida tropicalis* account for 90% of the infections. Risk factors include diabetes, high-dose corticosteroids, broad-spectrum antibacterial therapy, indwelling urinary tract device, and, rarely, donor-derived candidiasis. Fluconazole is commonly considered the drug of choice for the prevention or treatment of donor-derived candidiasis. Other azoles (such as voriconazole or itraconazole) and the echinocandins do not effectively enter the urine as active drugs and should not be used.

Superficial candidal infections involving the mouth or intertriginous areas can be treated with nystatin and topical clotrimazole, whereas candidal UTIs require systemic antifungal therapy (see Chapter 55). Whenever possible, bladder catheters, surgical drains, and urinary stents should be removed. Systemic antifungal therapy is

BOX 110.2 Suggested CMV Prophylaxis and Preemptive Protocol[a]

2018 International Consensus Guidelines

D+/R–

- Antibody induction with lymphocyte depleting agents: valganciclovir 900 mg PO once a day × 6 mo
- If no antibody induction: valganciclovir 900 mg PO once a day × 3 mo[b]
- After the end of prophylaxis, consider CMV DNA weekly × 3 mo[c]

R+ (D– or D+)

- Valganciclovir 900 mg PO once a day × 3–6 mo
- Lung transplantation, composite tissue: valganciclovir 900 mg PO once a day × 6 mo

D–/R–

- Acyclovir[d] 400 mg twice a day (for herpes prophylaxis) × 3 mo
- CMV DNA screening when clinically indicated (or if exposure to high volume of blood products)

2019 AST Infectious Diseases Community of Practice Guidelines

D+/R–

- Prophylaxis: valganciclovir (preferred), IV ganciclovir,[a] or valacyclovir[a] × 6 mo
- Preemptive therapy[e]: weekly CMV DNA (or pp65 antigenemia) for 12 weeks after transplant. If a positive CMV threshold is reached, treat with (a) valganciclovir 900 mg orally twice a day (preferred) or (b) ganciclovir 5 mg/kg IV q12h until negative test

R+ (D– or D+)

- Prophylaxis: valganciclovir (preferred), IV ganciclovir, or valacyclovir × 3 mo
- Preemptive therapy[e]: weekly CMV DNA (or pp65 antigenemia) for 12 weeks after transplant. If a positive CMV threshold is reached, treat with (a) valganciclovir 900 mg PO twice a day (preferred) or (b) ganciclovir 5 mg/kg IV q12h until negative test

[a]Valganciclovir, ganciclovir, acyclovir, valacyclovir, famciclovir: dose adjustment for renal function necessary.
[b]At the authors' institution, 6 months of valganciclovir prophylaxis is recommended for high risk (D+/R⁻) transplant recipients regardless of induction therapy.
[c]At the authors' institution, because of the increased incidence of delayed CMV DNAemia in high-risk (D+/R–) transplant recipients, preemptive CMV surveillance is routinely performed after completion of prophylaxis therapy as follows: following discontinuation of CMV prophylaxis, CMV DNA is monitored biweekly for 2 months. If after 2 months postmedication discontinuation, the patient is found to be CMV negative, CMV DNA testing is performed monthly until 1 year posttransplant.
[d]May use acyclovir, famciclovir, or valacyclovir (center dependent).
[e]If logistic support is available.
CMV, Cytomegalovirus; *D+,* donor CMV seropositive; *D–,* donor CMV seronegative; *IV,* intravenous; *PO,* orally; *R+,* recipient CMV seropositive; *R–,* recipient CMV seronegative.

BOX 110.3 CMV Treatment Protocol

CMV Treatment

First-Line Treatment

- Mild to moderate disease: valganciclovir 900 mg PO twice daily (adjusted for GFR)
- Severe or life-threatening disease *or* GI malabsorption: ganciclovir 5 mg/kg IV q12h (adjusted for GFR)

Second-Line Treatment (for Patients Resistant to Valganciclovir or Ganciclovir)

- Foscarnet

Comments

Monitoring During Treatment

- Weekly plasma CMV DNA.
- Due to individual variation in virologic response, change in antiviral agent is not recommended in clinically improving patients with unchanged or rising DNAemia during the first few weeks of therapy (strong, moderate).
- Antiviral drug doses should be reduced only for worsening estimated GFR because suboptimal dosing may increase risk of clinical failure and/or resistance.
- In the setting of leukopenia, treatment with GCSF and/or withholding of myelosuppressive agents should be considered before changing valganciclovir or ganciclovir to another agent (strong, low).

Treatment Duration

- Treatment should be continued for a minimum of 2 weeks, until clinical resolution of disease and eradication of CMV DNAemia below a specific threshold (e.g., LLOQ < 200 U/mL) on 1 or 2 consecutive weekly samples.

Other

- In patients without concomitant rejection immunosuppression, reduction may be considered in the settings of severe CMV disease, inadequate clinical response, high viral loads, and cytopenia.
- Adjunctive immunoglobulin therapy is not routinely recommended.
- Secondary prophylaxis is not routinely recommended.
- In patients with prior cumulative exposure to valganciclovir or ganciclovir that exceeds 6 weeks, drug resistance should be suspected in the setting of clinical treatment failure despite 2 weeks of antiviral treatment or development of DNAemia during prophylaxis.

CMV, Cytomegalovirus; *GCSF,* granulocyte colony-stimulating factor; *GFR,* glomerular filtration rate; *GI,* gastrointestinal; *IV,* intravenously; *LLOQ,* lower limits of quantification; *PO,* orally.

indicated in the presence of any blood culture positive for *Candida* spp. (see Chapter 55).

BK Polyomavirus Infection

The clinical spectrum of BKPyV infections includes BK viruria, BK DNAemia (formerly known as *BK viremia*), BKVAN, and, less commonly, ureteral stenosis. The highest prevalence of BK viruria and BK DNAemia occurs at 2 to 3 months, and 3 to 6 months, respectively. BKPyV is an important cause of allograft dysfunction and graft loss and commonly manifests with an asymptomatic rise in serum creatinine during the first posttransplantation year. However, BKVAN may occur as early as the first week and as late as 6 years after transplantation. Urinalysis is usually unremarkable but may reveal pyuria, hematuria, and/or cellular casts consisting of kidney tubular cells and inflammatory cells. The American Society of Transplantation Infectious Diseases Community of Practice expert panel defines sustained BK DNAemia as more than 1000 copies/mL in two measurements within 3 weeks, or increasing to more than 10,000 copies/mL in at least 1 of 2 measurements as probable and presumptive BK nephropathy (BKN), respectively. Since PCR assays are not standardized, the sensitivity and specificity of the assays vary. A definitive diagnosis of BKVAN requires an allograft biopsy demonstrating BK viral inclusions in kidney tubular cell nuclei and occasionally in glomerular parietal epithelium (Fig. 110.1). However, a false negative BKVAN biopsy rate of 10% to 30% can occur if the biopsy sample lacks tissue from the kidney medulla where a significant reservoir of BKPyV can be found. Interstitial mononuclear inflammation, often with many plasma cells, degenerative changes in tubules, and focal tubulitis, may mimic acute rejection. BKPyV infection and acute rejection may occur simultaneously, and distinguishing between BKVAN and acute rejection or the presence of both can be a diagnostic challenge. The 2017 Banff Working Group on BKN proposed using interstitial fibrosis and intrarenal BK load levels to diagnose "definitive BKN." BKVAN can be further categorized into 3 classes based on the percentage of tubules/ducts with evidence of viral replication, as well as Banff scores of interstitial inflammation and tubulitis. Class 1 denotes early stage BKN with favorable outcome. Class 2 and class 3 have a more pronounced negative effect on graft function, with graft failure rate reaching 50% in class 3.

Treatment strategies for BK DNAemia with or without BKVAN vary, but immunologic containment of BKV replication is universally accepted as the mainstay of therapy.[18] Optimal reduction of immunosuppressive therapy may allow sufficient reconstitution of BKPyV-specific T cells to control BKPyV replication while maintaining adequate immunosuppression to prevent allograft rejection. The 2019 AST-IDCOP guidelines recommend testing all kidney transplant recipients for BK-DNAemia monthly until month 9, and then every 3 months until 2 years posttransplant. Extended surveillance after 2 years may be considered in pediatric kidney transplant recipients. Stepwise immunosuppression reduction is recommended for patients with plasma BK DNAemia more than 1000 copies/mL sustained for 3 weeks or increasing to more than 10,000 copies/mL, or in those with biopsy-proven BK-associated nephropathy. Allograft biopsy is not required for treating BK DNAemic patients whose GFR is at or close to their baseline.[19]

Experimental studies demonstrated that sirolimus impairs BKPyV replication in kidney tubular epithelial cells during viral early gene expression but not during viral late gene expression by interfering with mammalian target of rapamycin (mTOR)-SP6-kinase activation. Cyclosporine was similarly shown to inhibit BKPyV replication, whereas tacrolimus activates BKPyV replication and reverses sirolimus inhibition, leading to increased BKPyV replication.[20] In a small trial of 40 kidney transplant recipients, mycophenolate mofetil (MMF) to everolimus conversion versus 50% MMF dose reduction showed a nonsignificant trend toward improved viral clearance with everolimus conversion at 3 months follow-up.[21] There have been no trials evaluating the safety and efficacy of leflunomide or cidofovir in BK DNAemia or BKVAN. A systematic review of 40 studies showed no graft survival benefit of adding cidofovir or leflunomide to immunosuppressive reduction for the management of BKN.[22] Despite virological rationales, no trial data support switching from tacrolimus to cyclosporine-A, from mycophenolate to mTOR inhibitors or leflunomide or adding adjuncts such as intravenous immunoglobulins, cidofovir, or leflunomide (AST-IDOCP guidelines).[19] Although quinolones have been shown to inhibit DNA topoisomerase and SV40 larger tumor antigen helicase, a prospective, double-blind, randomized, placebo-controlled trial of ciprofloxacin versus placebo for the prevention of BK viremia in kidney transplant recipients demonstrated no benefit of ciprofloxacin at preventing BK viremia.[23] Fluoroquinolones are not recommended for prophylaxis or therapy. BK virus–specific T-cell adoptive transfer therapy is a subject of ongoing clinical research.

Reduction in immunosuppression is not universally effective. Nonetheless, routine BK screening and early reduction in

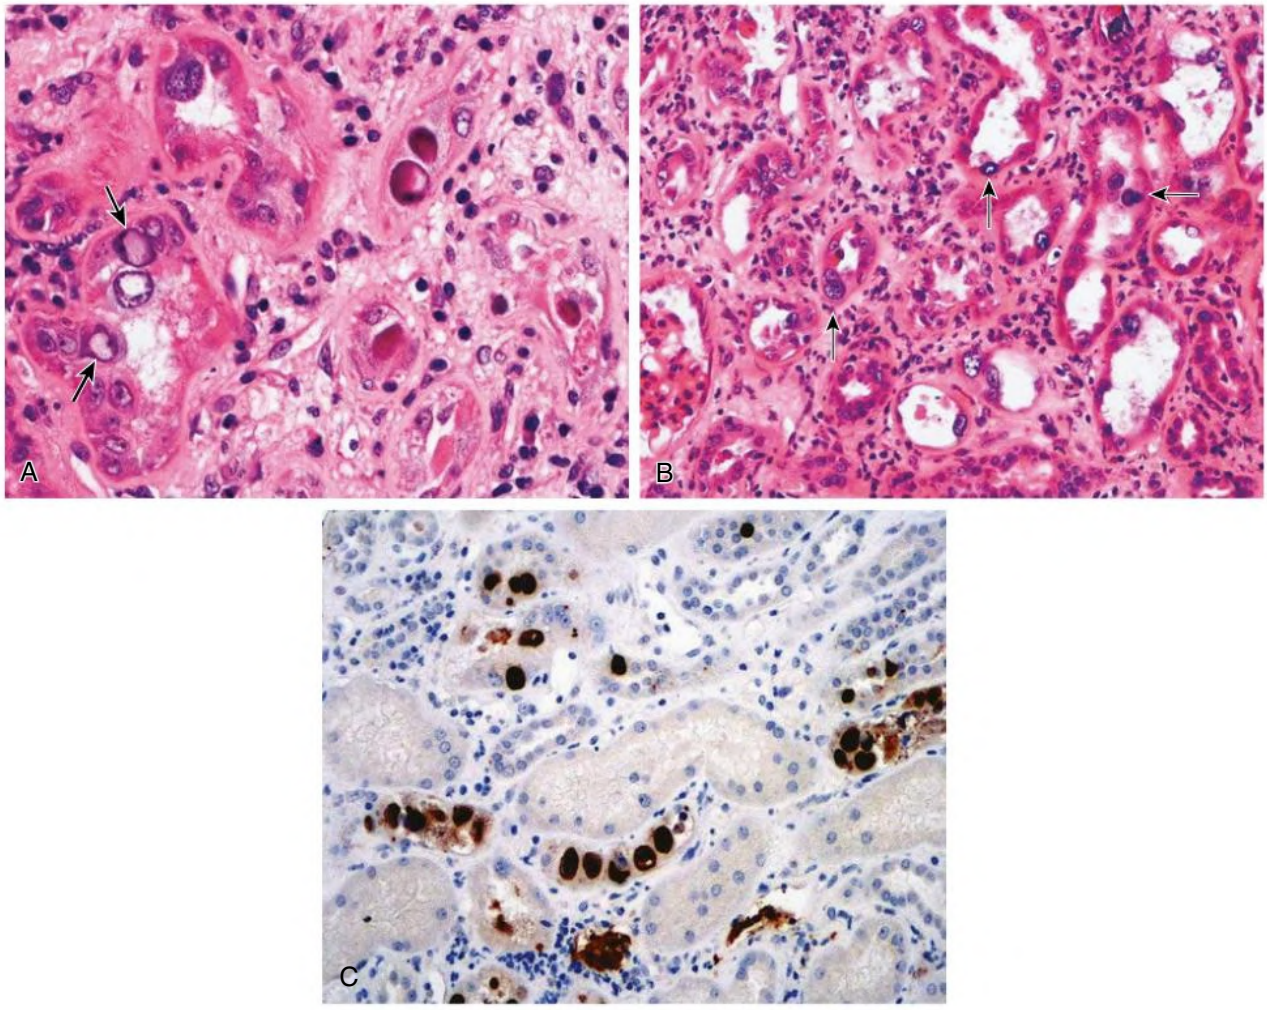

Fig. 110.1 BK Virus Nephropathy. (A) Prominent intranuclear viral inclusions are present within tubular epithelial cells *(arrows).* (H&E stain; original magnification ×400.) (B) Tubulointerstitial nephritis with diffuse intranuclear polyomavirus inclusions *(arrows).* (H&E stain, original magnification ×200.) (Courtesy Charles Lassman and William Dean Wallace, David Geffen School of Medicine at UCLA.)

immunosuppression if positive may prevent the development of BKVAN. Monitoring plasma BK alone (vs. urine BK alone or simultaneous urine and plasma BK) appears to be cost-effective because BKVAN is unusual in the absence of BK viremia. Suggested guidelines for posttransplant screening and monitoring for BKPyV replication are shown in Fig. 110.2. Although immunosuppression reduction may improve BK DNAemia and subsequent development of BKN, it may increase the risk of de novo donor specific antibody (DSA) development, underscoring the need for routine DSA surveillance. Treatment should be individualized based on each patient's immunologic risk. Although evidence is lacking, mycophenolic acid (MPA) to mTOR inhibitor switch may be considered in patients with steadily rising BK DNAemia despite MPA dose reduction or withdrawal or in those with impaired graft function to avoid the long-term nephrotoxic effect of CNI toxicity. One large international multicenter, open-label clinical trial of kidney transplant recipients randomized to receive everolimus with reduced-exposure CNI (everolimus arm) or MPA with standard-exposure CNI (MPA arm), reported less BKPyV infection (in the everolimus compared with the MPA-treated arm. Histologic evidence of organ involvement occurred in 1.2% and 2.1% of patients, respectively.[24]

There is no consensus on the management of biopsy-proven acute rejection and concomitant BKVAN. We treat acute rejection with antirejection therapy with subsequent reduction in maintenance immunosuppression. Intravenous immunoglobulin (IVIG) therapy may be considered in patients with persistent BK DNAemia and DSAs (which may be seen arising in association with BK viremia), in those with BKVAN and histopathologic changes that are indistinguishable from those of rejection, and in those with hypogammaglobulinemia. IVIG may be beneficial due to its direct BKPyV neutralizing activity and immunomodulatory effects. Retransplantation after allograft loss due to BKPy nephropathy can be successful if BK DNAemia is definitively cleared, independent of failed allograft nephrectomy.[19]

Tuberculosis

Tuberculosis (TB) is an important cause of morbidity and mortality in solid organ transplantation, with an estimated mortality rate of 20% to 30%. Over two-thirds of reported cases of active TB in solid organ transplant recipients occur in the first posttransplant year (median, 6–11 months). Although TB commonly results from inhalation of airborne bacilli, it more commonly emerges from the reactivation of dormant lesions due to immunosuppressive therapy. Hence, all potential kidney transplant candidates should undergo a purified protein derivative (PPD) skin test or preferably the interferon-γ (IFN-γ) release assays before transplantation to diagnose latent

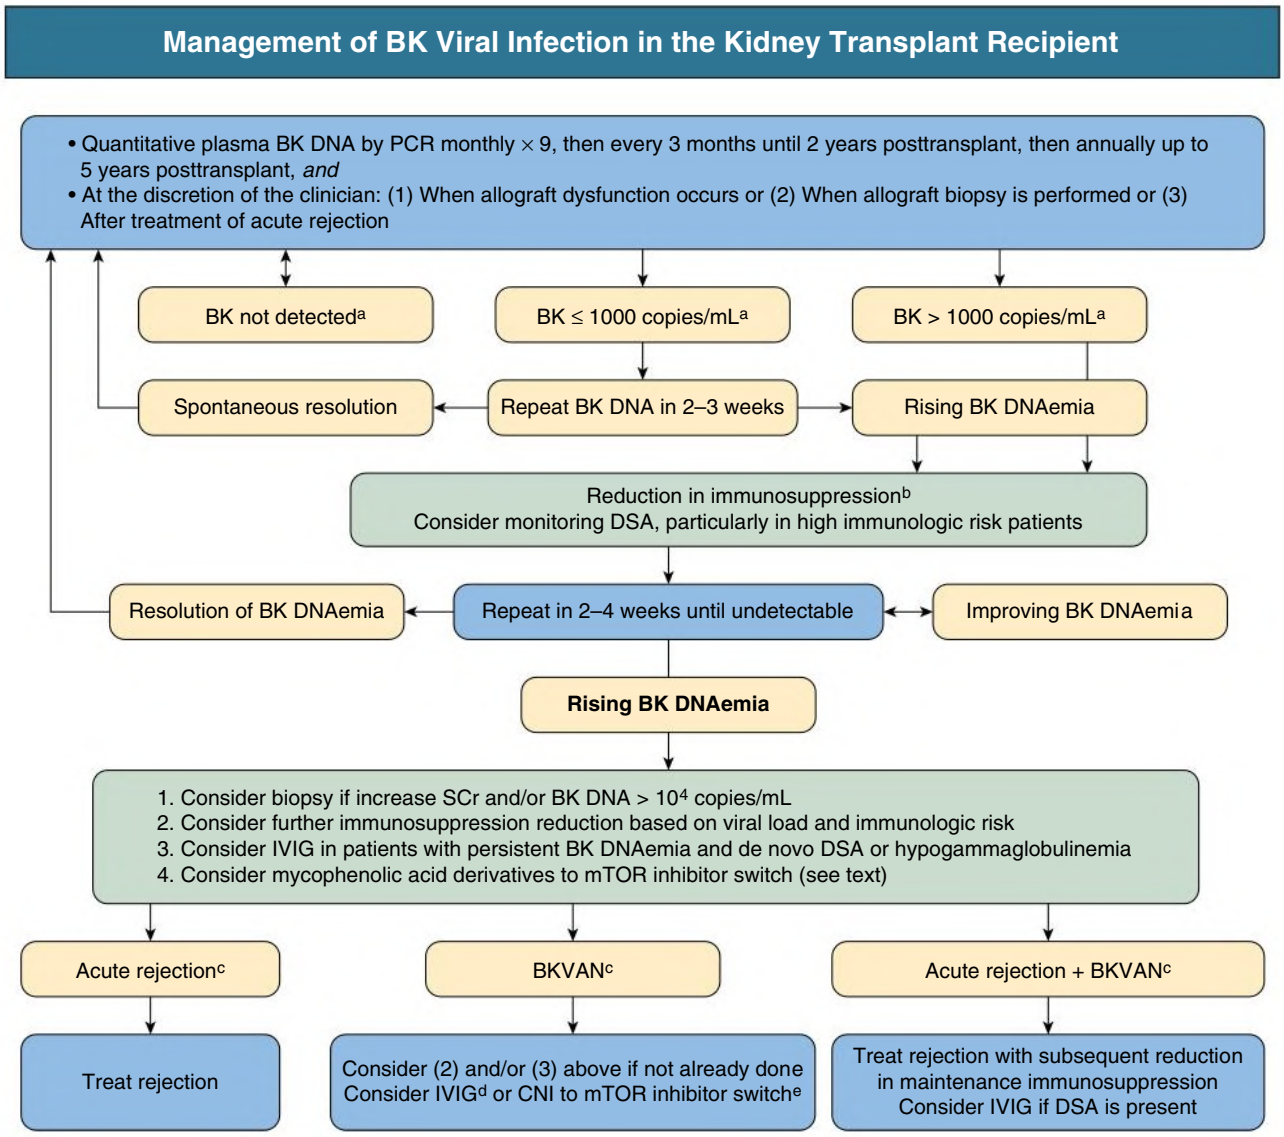

Fig. 110.2 Management of BK Viral Infection in the Kidney Transplant Recipient. [a]No standardized PCR assays for BK virus are currently available. Cutoff levels for viral detection should be based on PCR assays used at individual institutions. Viral load of 500 copies/mL is the lowest detection level at the author's institution. [b]Common practice: (1) Decrease or hold MFA derivatives (or antimetabolite). (2) Decrease (MFA + CNI by 25% to 50%. (3) Decrease CNI. Less common practice: (1) Decrease prednisone with or without a decrease in CNI. (2) CNI to mTOR inhibitor switch with or without a decrease in MFA. (3) Tacrolimus to cyclosporine switch. [c]Biopsy proven. [d]If DSA is present or histopathologic findings are indistinguishable from those of rejection. [e]May avoid long-term nephrotoxic effect of CNI therapy. Not recommended in patients with baseline significant proteinuria (arbitrarily defined as >500 mg/24 h or at the discretion of the clinician). *BKVAN,* BKPyV-associated nephropathy; *DSA,* donor specific antibody; *IVIG,* intravenous immunoglobulin; *MFA,* mycophenolic acid; *mTOR,* mammalian target of rapamycin; *PCR,* polymerase chain reaction; *SCr,* serum creatinine.

TB. A positive skin test or IFN-γ release assay result or a history of TB mandates ruling out active disease. Clinical, radiologic, or culture evidence of active TB infection is a contraindication to transplantation. Isoniazid (INH) prophylactic therapy should be considered in the following situations:

- Transplant candidates with a history of positive tuberculin skin test or IFN-γ release assay result
- Patients with evidence of old granulomatous disease on chest radiograph or computed tomographic imaging and epidemiologic risk factors for TB
- Those with known prolonged exposure to a person with active TB
- Kidney transplant recipients in endemic areas
- Donor with positive tuberculin skin test or IFN-γ release assay result, or history of untreated TB
- In highly endemic areas where TB transmission is common, universal INH prophylaxis for the first year posttransplant during the period of maximum immunosuppression is recommended. In countries where there is an increased prevalence of INH-resistance strain, such as India, close monitoring and treatment of active infection is recommended over initiation of INH prophylaxis.
- In patients with a known history of adequately treated TB infection, we suggest secondary INH prophylaxis for the first 9 months after transplantation in patients with a history of extensive disease such as positive blood cultures, visceral involvement, or recent treatment

history (arbitrarily defined as <10 years before transplant). Others, however, have suggested that INH prophylaxis is not indicated for patients whose TB had been properly treated.

Strongyloides

Strongyloides is a rare but important cause of infection in transplant patients, particularly those from endemic areas such as Southeast Asia. In the presence of immunosuppression, a hyperinfection syndrome may be observed with parasitic pneumonia and gastrointestinal (GI) involvement.

EMERGING INFECTIOUS DISEASE

COVID-19

The coronavirus disease 2019 (COVID-19) pandemic caused by SARS-CoV-2 has severely impacted both immunocompetent and immunocompromised populations worldwide. Solid organ transplant (SOT) recipients, including kidney transplant recipients, are at increased risk because of their immunocompromised state.[25] Similar to the general population, the clinical spectrum of COVID-19 in SOT recipients spans from asymptomatic/pauci-symptomatic to acute respiratory distress syndrome with multiorgan failure and death. Common presenting symptoms include fever, dry cough, dyspnea, and fatigue. Others include diarrhea, anorexia, nausea, headache, myalgias, and anosmia. Limited retrospective studies suggest that the Omicron variant causes less severe illness compared with ancestral SARS-CoV-2 in both the general population and in SOT recipients. In addition, although vaccination response as measured by humoral or T-cell response is impaired in SOT recipients compared with those on dialysis or healthy controls,[26] one large single-center registry study ($n = 2151$ SOT recipients) demonstrated decreased hospitalization and mortality rates among vaccinated compared with unvaccinated SOT recipients with COVID-19 infection.[27]

Management of Immunosuppression During COVID-19 Infection

The optimal approach to the management of immunosuppression in kidney transplant recipients infected by COVID-19 has not been well defined. Nonetheless, many transplant centers favor reduction or discontinuation of antimetabolites in symptomatic patients, particularly those with lymphopenia. Additionally, the use of lymphocyte-depleting agents such as antithymocyte globulin is generally avoided. Lymphopenia at the time of admission correlates with worse outcomes, including increased mortality and intensive care unit admission.[28] Rituximab causes B-cell depletion and has been shown to compromise antiviral immunity and impair COVID-19 vaccine efficacy.

A meta-analysis of randomized controlled trials conducted in the general population demonstrated that in critically ill COVID-19 patients, administration of systemic corticosteroids (dexamethasone, hydrocortisone, or methylprednisolone) was associated with lower 28-day all-cause mortality, compared with standard care or placebo.[29] The beneficial effect of high-dose corticosteroids may be due to their immunomodulatory and antiinflammatory effects. The Centers for Disease Control and Prevention guidelines recommend that hospitalized patients, including kidney transplant recipients requiring supplemental oxygen, receive a short course of dexamethasone (6 mg daily for 5 to 10 days) (https://www.covid19treatmentguidelines.nih.gov/tables/therapeutic-management-of-hospitalized-adults/). Low-dose chronic maintenance prednisone therapy is withheld until after completion of dexamethasone.

Interleukin-6 (IL-6), which stimulates the inflammatory pathways in response to infection, is commonly found to be elevated in subjects with severe COVID-19 infection,[30] suggesting that IL-6 could be a potential therapeutic target for patients presenting with severe cytokine storm syndrome. Calcineurin inhibitors (CNIs) inhibit IL-6 and IL-1 pathways, and their use may confer theoretical benefits in the settings of COVID-19 infection. Hence CNIs can generally be continued without dose reduction.

Large randomized controlled trials demonstrated that adding an immunomodulator such as an IL-6 inhibitor (e.g., tocilizumab or sarilumab) or Janus kinase inhibitor (e.g. baricitinib, tofacitinib) to dexamethasone improved survival in symptomatic hospitalized patients with evidence of systemic inflammation. A phase III randomized, double-blind, parallel-group, placebo-controlled trial demonstrated that baricitinib reduced 28-day and 60-day all-cause mortality when used in conjunction with standard care, including systemic corticosteroid (e.g., dexamethasone), antiviral (remdesivir), or both (hazard ratio [HR], 0.57; 95% CI, 0.410.78; nominal $P = .0018$; and HR, 0.62; 95% CI, 0.470.83; $P = .0050$, respectively). There was a nonsignificant reduction in the frequency of disease progression (defined as progression to high-flow oxygen, noninvasive ventilation, mechanical ventilation, or death by day 28).[31] Safety profile was similar among baricitinib-treated and standard of care alonetreated patients. Nonetheless, immunosuppressed organ transplant recipients must be closely monitored for secondary infections.

The beneficial effect of tocilizumab has not been consistently demonstrated in randomized controlled trials conducted earlier in the pandemic. However, a subsequent international, multifactorial, adaptive platform trial consisting of critically ill patients (defined as those requiring intensive care unit admission and receiving respiratory or cardiovascular organ support) demonstrated that both IL-6 receptor antagonists tocilizumab ($n = 353$) and sarilumab ($n = 48$) confer a survival benefit compared with controls ($n = 402$). The in-hospital mortality in the pooled IL-6 receptor antagonist groups was 27% vs. 36% in the control group.[32]

Antiviral Therapy

Remdesivir is the first FDA-approved COVID-19 specific antiviral agent. It binds to the SARS-CoV-2 RNA-dependent RNA polymerase and inhibits viral replication via premature termination of RNA transcription. In vitro studies showed that remdesivir retains antiviral activity against the Omicron variant and subvariants. Potential adverse effects include increased serum transaminase levels and accumulation of the potentially nephrotoxic drug vehicle cyclodextrin in patients with kidney dysfunction. Remdesivir is indicated for both nonhospitalized and hospitalized patients who require no to minimal supplemental oxygen therapy (https://www.covid19treatmentguidelines.nih.gov/tables/therapeutic-management-of-nonhospitalized-adults/). Dexamethasone and remdesivir combination therapy should be considered in those requiring supplemental oxygen. Other FDA-approved antiviral agents include molnupiravir and ritonavir-boosted nirmatrelvir (Paxlovid). The latter should be avoided in tacrolimus or cyclosporine-treated patients due to significant drug-drug interactions. Ritonavir is a strong CYP3A4 inhibitor that is used as a druglevel boosting agent for nirmatrelvir to achieve its target therapeutic range. Similarly, concomitant use of ritonavir and drugs that are metabolized primarily by the CYP3A4 system, such as cyclosporine and tacrolimus, can result in significantly elevated CNI drug level and CNI toxicity. At the time of this writing, there is insufficient data to recommend or refute the use of molnupiravir in kidney transplant recipients. In one single-center prospective cohort study ($n = 16$ with SARS-CoV-2 [Omicron variant] and mild symptoms), one of nine patients treated with molnupiravir developed pneumonia requiring hospital admission, whereas none of seven patients treated with remdesivir progressed in disease severity. No drug-drug interaction with tacrolimus or adverse effect related to molnupiravir were observed.[33 3031]

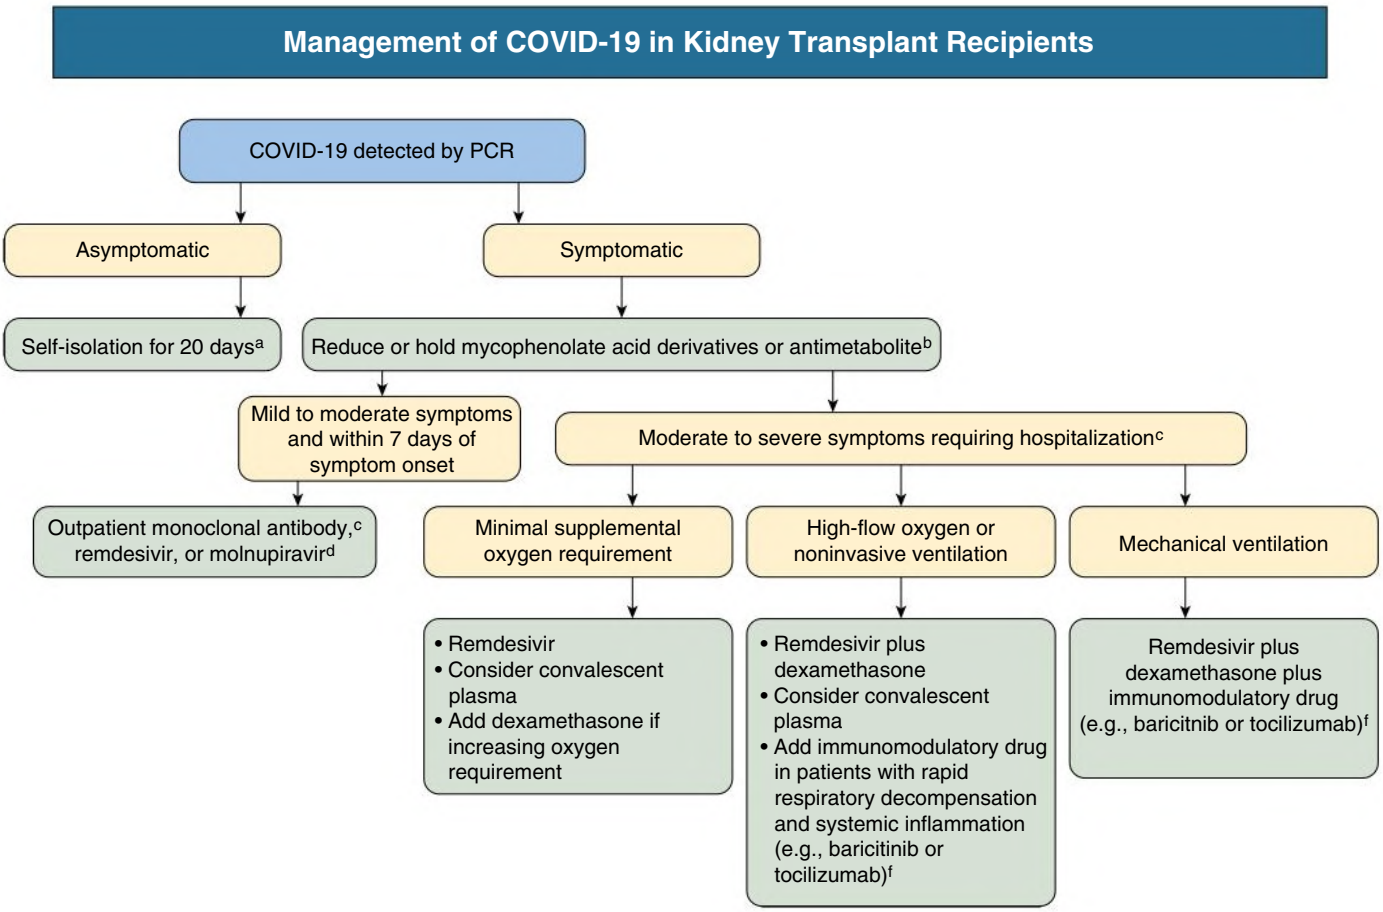

Fig. 110.3 Management of COVID-19 in Kidney Transplant Recipients. [a]Self-isolation period may vary among geographical locations and countries. [b]Consider resuming mycophenolic acid derivatives or antimetabolites when patients are asymptomatic for 5 to 7 days (opinion based). [c]Bebtelovimab retains its activity against the Omicron variant and its subvariants. [d]Consider molnupiravir for those unable to receive monoclonal antibody or remdesivir. [e]Monitor inflammatory markers at the discretion of the clinician: CBC with differentials, ferritin, D-dimer, CRP, LDH. [f]Monitor closely for secondary infections. Obtain baseline *Strongyloides* antibody, and interferon release assay (quantiferon test). Recommended prophylactic therapy: TMP-SMX daily for 3 months and valacyclovir 500 mg twice daily for 3 months. Monitor cytomegalovirus DNA at the discretion of the clinician. Low threshold for initiation of antifungal prophylaxis or treatment with prolonged steroid use. *CBC,* Complete blood cell count; *CRP,* C-reactive protein; *LDH,* lactate dehydrogenase; *MPA,* mycophenolic acid; *PCR,* polymerase chain reaction.

Monoclonal Antibody Therapy

Anti-SARS-CoV-2 monoclonal antibodies target against the SARS-CoV-2 spike protein, thereby blocking the attachment and entry of the virus into host cells. Bebtelovimab is recommended for nonhospitalized patients with mild to moderate symptoms who are at high risk of progressing to severe disease (https://www.covid19treatmentguidelines.nih.gov/tables/therapeutic-management-of-nonhospitalized-adults/). The United States CDC expert panel recommends against the use of bamlanivimab/etesevimab, casirivimab/imdevimab, and sotrovimab because of their markedly reduced in vitro susceptibility to the Omicron variant and its subvariants. Such variants have become the dominant SARS-CoV-2 variant in the United States. Monoclonal antibody therapy is still considered first-line therapy for high-risk outpatients with contraindication to ritonavir-boosted nirmatrelvir (Paxlovid) use due to drug-drug interactions such as the typical SOT recipient.

Anti-SARS-CoV-2 Convalescent Plasma

Plasma from donors who have recovered from COVID-19 may contain antibodies against the SARS-CoV-2 that could potentially suppress viral replication. There is currently insufficient evidence to recommend for or against the use of convalescent plasma in kidney transplant recipients. However, given the low side effect profile of this treatment and immunologic rationale for antibody administration in immunocompromised patients, it is reasonable to consider convalescent plasma therapy in kidney transplant recipients requiring hospitalization (https://www.covid19treatmentguidelines.nih.gov/therapies/anti-sars-cov-2-antibody-products/covid-19-convalescent-plasma/). With the emergence of the Omicron variant, only high-titer products collected after the surge of the Omicron variant should be used. Furthermore, studies suggest that they should be given early in the course of illness for best efficacy.[34] A suggested algorithm for the management of COVID-19 in kidney transplant recipients is shown in Fig. 110.3 (authors' institution protocol).

GASTROINTESTINAL DISEASE

Posttransplantation GI complications are common. Selected complications are discussed.

Drug-Related Gastrointestinal Complications

MMF and to a lesser extent, enteric-coated mycophenolate sodium (EC-MPS) cause GI side effects, including nausea, vomiting, dyspepsia, anorexia, flatulence, and diarrhea. Dose reduction, temporary drug discontinuation, or administration of the drug in 3 or 4 divided doses often ameliorate the symptoms. Switching from MMF to EC-MPS can increase the maximum tolerated dose of MFA and reduce GI symptoms. MMF- and MPA-induced diarrhea may be due to direct enterocyte damage[35]; although uncommon, Crohn's disease-like changes in the colon, erosive enterocolitis, and graft-versus-host disease–like colonic changes associated with the use of MMF have also been reported.[36] Proton pump inhibitor (PPI) use can reduce the dissolution of MMF by increasing gastric pH. In contrast to MMF, EC-MPS is not absorbed in the stomach, and its bioavailability is not affected by PPIs. Sirolimus, everolimus, tacrolimus, and cyclosporine may cause diarrhea in some patients. Diarrhea associated with tacrolimus use is thought to be due to increased GI motility. Sirolimus may cause oral mucocutaneous lesions that may resemble HSV or CMV infection but are culture negative. Drug-related oral ulcers usually resolve after discontinuation of the offending agent.

Infections

Posttransplantation infections of the GI tract may have a viral, fungal, or bacterial cause. Viral infections are most commonly caused by CMV and HSV; *C. albicans* and *C. tropicalis* are common opportunistic fungal infections. Leukoplakia and posttransplant lymphoproliferative disorders (PTLDs) may develop in patients with EBV infection (PTLD is discussed in a later section). Commonly encountered bacterial pathogens include *Clostridium difficile* and *Helicobacter pylori.*

Cytomegalovirus Infection

CMV can affect any segment of the GI tract. Patients may present with dysphagia, odynophagia, nausea, vomiting, gastroparesis, abdominal pain, diarrhea, or GI bleeding. Leukopenia and elevated transaminases are common. Persistent or unexplained symptoms of nausea, vomiting, or diarrhea, particularly in the early posttransplantation period or during intensification of immunosuppression, warrant further investigation with upper and lower endoscopies and biopsies. At our institution, severe CMV and candidial gastritis/esophagitis were found in a patient who was heavily immunosuppressed with antithymocyte globulin and presented with intractable vomiting 4 months after transplantation. Histologic examination of the tissue obtained from the vomitus was compatible with foveolar gastric lining detachment (Fig. 110.4).

Fig. 110.4 Tissue Obtained From Patient's Vomitus. Histologic examination of the necrotic tissue showed numerous fungal organisms (consistent with *Candida* spp.), and degenerated squamous epithelium with detached columnar (gastric foveolar type) epithelium. Occasional cells demonstrated enlarged nuclei and intracytoplasmic granular eosinophilic inclusions, consistent with cytomegalovirus viral inclusions.

Herpes Simplex Virus Infection

HSV infection results primarily from reactivation of endogenous latent virus, causing clinical infection within the first 1 to 2 months after transplantation. Patients commonly present with oral mucocutaneous lesions or gingivostomatitis with or without odynophagia and dysphagia. HSV esophagitis has been noted to occur in patients receiving high-dose corticosteroids and antilymphocyte preparations for acute rejection. Limited oral mucocutaneous lesions are treated with oral acyclovir; extensive infections require intravenous acyclovir or ganciclovir. For patients not receiving anti-CMV prophylaxis, acyclovir prophylaxis in the early posttransplantation period is recommended (see Box 110.2).

Fungal Infections

Candida stomatitis and esophagitis are common during the first 6 months after transplantation and are increased in patients with leukopenia, severe immunosuppression, diabetes, or concomitant infections. The use of prophylactic oral nystatin "swish and swallow" during the first month after transplantation is recommended. Fluconazole prophylaxis is warranted in high-risk candidates, including liver or pancreas transplant recipients.

Helicobacter Infection

H. pylori infection is associated with a wide range of GI complications including chronic gastritis, duodenal and gastric ulcers, mucosa-associated lymphatic tissue (MALT) lymphoma, and gastric carcinoma, both in the general population and in solid organ transplant recipients. Unexplained dyspeptic or reflux symptoms should be investigated further with endoscopy and biopsy to exclude malignancy. *H. pylori*–associated MALT lymphoma in kidney transplant recipients may be less aggressive than other lymphomas, and the disorder may be cured by eradication of *H. pylori.*

Diarrhea and Colon Disorders

Diarrhea is common after solid organ transplantation because of adverse drug effects (discussed in an earlier section) and infectious pathogens. *Clostridiodes difficile* (formerly known as *Clostridium difficile*) is the most commonly encountered bacterial pathogen, and CMV and norovirus are the most commonly encountered viral pathogens. Suggested treatment regimen for *C. difficile* diarrhea is shown in Table 110.4. Although norovirus often causes acute self-limited illness in immunocompetent individuals, solid organ transplant recipients can experience prolonged or intermittent diarrhea associated with chronic viral shedding. A median viral shedding period of 289 days (97–898 days) has been reported. Molecular analysis of viral strains in kidney transplant recipients with chronic intermittent diarrhea suggests that continuous genetic mutation and viral evolution may promote viral persistence.[37] Other less common infectious causes of posttransplantation diarrhea are shown in Table 110.4.[35,36,38]

Diverticulitis and colonic perforations may be life-threatening and difficult to diagnose after transplantation because symptoms may be masked by immunosuppressive therapy, particularly in the early postoperative period. Diverticulitis complicated by perforation, abscess formation, phlegmon, or fistula has been reported in 1% of kidney

TABLE 110.4 Causes of Diarrhea After Solid Organ Transplantation

Pathogens	Suggested Therapies/Comments
Bacterial	
Clostridioides difficile *Campylobacter* spp. *Salmonella* spp. *Shigella* spp. *Aeromonas* spp. *Escherichia coli* Others: *Vibrio* cholera, *Yersinia enterocolitica*, bacterial overgrowth, chlamydia, *Helicobacter pylori*	*C. difficile*[a] • *First episode:* Oral vancomycin 125 mg 4 times daily for 10–14 days or fidaxomicin 200 mg twice daily for 10 days • *First relapse:* treatment same as first episode • *Second relapse:* oral vancomycin or fidaxomicin • *Third or more relapses:* prolonged oral vancomycin taper (125 mg 4 times a day for 10–14 days, twice times a day for a week, once a day for a week, and then every 2 or 3 days for 2–8 weeks). May consider fecal microbiota transplantation or bezlotoxumab (monoclonal antibody). *E. coli* • Enteropathogenic: fluoroquinolone, cephalosporin • Enterohemorrhagic: avoid antimotility agents, role of antibacterials unclear and should be avoided
Viral	
CMV Norovirus Sapovirus Others: rotavirus, adenovirus, enterovirus, herpes simplex virus, SARS-CoV-2	CMV (see text) Norovirus • Diagnostic testing: norovirus PCR • Treatment: supportive (volume repletion, antimotility agents), reduction of immunosuppression (inconclusive evidence), nitazoxanide (anecdotal case reports)
Parasitic	
Giardia, Cryptosporidium, Cyclospora, Microsporidia, Strongyloides, Entamoeba, Isospora	

[a]Metronidazole is no longer considered first-line treatment because of the risk of recurrence after treatment.
CMV, Cytomegalovirus; *PCR,* polymerase chain reaction.

transplant recipients, and its incidence may be increased in patients with autosomal dominant polycystic kidney disease (ADPKD).[39]

Early posttransplantation colonic perforations are largely caused by high-dose corticosteroids, diverticulitis, CMV colitis, and intestinal ischemia; perforations occurring late or years after transplantation are commonly caused by diverticulosis or malignant disease.

TRANSPLANT-ASSOCIATED MALIGNANCY

The incidence of de novo malignancies is twofold to fourfold greater in solid organ transplant recipients compared with the general population.[40] Among long-term survivors after kidney transplantation (>20 years), cancer was the most common cause of death with a functioning graft followed by CV disease.[41] The intensity and duration of immunosuppression, as well as the ability of these agents to promote replication of various oncogenic viruses, are important risk factors. Table 110.5 provides a summary of the incidence of cancers related to infections in solid organ transplant recipients.[42] The Transplant Center March Study database demonstrated a strong association of lip cancer with

TABLE 110.5 Meta-Analysis Standardized Incidence Ratios (SIRs) for Cancers Related to Infections in Transplant Recipients

Cancers	Meta-Analysis SIRs
EBV-Related Cancers	
Hodgkin lymphoma	3.89 (2.42–6.26)
Non-Hodgkin lymphoma	8.07 (6.40–10.2)
HHV-8–Related Cancer	
Kaposi sarcoma	208.0 (114–369)
HBV- and HCV-Related Cancer	
Liver	2.13 (1.16–3.91)
HPV-Related Cancers	
Cervix uteri	2.13 (1.37–3.30)
Vulva and vagina	22.8 (15.8–32.7)
Penis	5.8 (5.79–34.4)
Anus	4.85 (1.36–173)
Oral cavity and pharynx	3.23 (2.40–4.35)
Nonmelanocytic-related skin	28.6 (9.39–87.2)

EBV, Epstein-Barr virus; *HBV,* hepatitis B virus; *HCV,* hepatitis C virus; *HHV,* human herpes virus; *HPV,* human papilloma virus; *SIR,* standardized incidence ratio.
Modified from McCaughan JA, Courtney AE. The clinical course of kidney transplant recipients after 20 years of graft function. *Am J Transplant*. 2015;15(3):734–740.

White ethnicity and prior history of skin cancer, suggesting that ultraviolet (UV) radiation exposure is an important risk factor. A higher incidence of lip cancer was also found among transplant recipients receiving cyclosporine and azathioprine (AZA) compared with tacrolimus/MMF maintenance immunosuppression. The contributory role of cyclosporine and AZA was thought to be due to their photosensitizing or DNA damaging effects.[43] Other suggested risk factors for posttransplantation malignancies include older age, male sex, White ethnicity, pretransplant dialysis duration, smoking history, deceased donor organ, cumulative exposure to radiation from repeated medical imaging studies, and prior use of immunosuppressive agents.

Skin cancers are the most common de novo posttransplant tumors in the adult transplant population and occur with increasing frequency with time. Among nonskin malignant neoplasms, PTLDs are the most common type of posttransplantation malignancy. The mean time to diagnosis of different neoplasms varies with the type of organ involved. Kaposi sarcoma, PTLD, testicular cancer, cancer of the small intestine, and thyroid cancer occur early (<800 days) after transplantation. In the AZA era, nearly 50% of adult transplant recipients have one or more skin cancers by 20 years after kidney transplant. The use of MPA-containing regimen has been reported to be associated with a lower incidence of posttransplantation nonmelanoma skin cancers compared with AZA. (The effects of various immunosuppressive agents on cancer risk are discussed later.[40]) Renal cell carcinoma (RCC) occurs mainly in native kidneys and is associated with acquired cystic kidney disease and dialysis duration. A bimodal distribution is observed with the highest incidence occurring in the first year and a second peak 4 to 15 years after transplant.[44] RCC occurring early after transplant is thought to reflect undetected or malignant transformation of preexisting cysts that developed during the course of end-stage kidney disease. Common cancers in the general population, including cancers of the breast, colon, prostate, lung, bladder, stomach, and pancreas, were found to occur more frequently in kidney transplant recipients in some but not all studies. The Kidney Disease Outcomes Quality Initiative guidelines suggest an individualized plan for each kidney

transplant recipient, considering the patient's medical and family history, tobacco use, and competing risk for death. We evaluate hepatitis B–positive transplant candidates and recipients for hepatocellular carcinoma with abdominal ultrasound and α-fetoprotein level every 6 months. Although practice differs among centers, screening should be considered in high-risk patients, such as those with high HBV viral load, hepatitis B e antigen–positive, hepatitis B surface antigen–positive, and Asian or African ethnicity. Screening for cervical, breast, prostate, and colon cancer should follow local guidelines for the general population. In recipients with a history of preexisting malignant neoplasms, close monitoring for recurrences is mandatory. Suggested guidelines for tumor-free waiting periods for common pretransplant malignant neoplasms are shown in Table 110.6.[45]

Posttransplantation Lymphoproliferative Disorder

PTLD encompasses a wide spectrum of lymphoid proliferations ranging from reactive polyclonal lesions to frank malignant monoclonal lymphomas and can be divided into four subtypes based on morphology, clonality, and molecular criteria (Table 110.7).[45,46] Most PTLDs are non-Hodgkin lymphoma of B-cell origin, 80% to 90% of which are linked to EBV infection. However, the incidence of EBV-negative PTLD has increasingly been reported. PTLD commonly occurs in the first year after transplant, although the cumulative incidence increases with time after transplantation. Registry studies demonstrate that PTLD occurs at a median of 18 to 18.5 months after transplantation. Notably, EBV-negative PTLD generally manifests later after transplant (>5 years) and has been suggested to account for the bimodal distribution pattern of PTLD occurrence, with early cases being predominantly EBV positive and late cases being EBV negative.[40] Another registry study suggests that late-occurring PTLD (8–10 years) is less likely to be due to EBV lymphoproliferation and more likely to be a consequence of aging and duration of immunosuppression exposure.[47] The incidence of EBV-associated PTLD by PTLD subtypes and time of onset after transplant is shown in Table 110.8.[45] Mortality is greater with PTLD than with lymphomas in the general population.

EBV-Positive Versus EBV-Negative PTLD

Immunosuppression-related decrease in T-cell immune surveillance may play a major contributory role in EBV-positive PTLD. In immunocompetent hosts, EBV-specific $CD8^+$ effector and memory T cells are responsible for controlling EBV-infected B cells from uncontrolled proliferation and transformation. The pathogenesis of EBV-negative PTLD remains speculative. Proposed hypotheses include hit-and-run EBV infection (disappearance of EBV following an initial infection that leads to PTLD), viral infection other than EBV (e.g., cytomegalovirus), persistent antigen stimulation by the graft, and long-term immunosuppression. Molecular-genomic studies revealed that EBV-negative PTLD shares many genomic and transcriptomic features with diffuse large B-cell lymphoma in immunocompetent patients, whereas EBV-positive PTLD has fewer genomic abnormalities. Although the molecular genetic separation between EBV-positive and EBV-negative PTLD is well-defined, EBV status is not prognostic or predictive with respect to treatment response. In a subset of patients, reduction in immunosuppression alone is effective regardless of EBV status.

Risk Factors

Risk factors for PTLD can be classified into those associated with EBV or other infectious agents, the type of organ transplant, recipient age, the type and intensity of immunosuppression, and human leukocyte antigen (HLA) mismatch among others (Table 110.9). Selected risk factors are discussed.

Epstein-Barr virus infection. During primary infection, EBV is incorporated into B lymphocytes and establishes lifelong latency. Immunocompetent hosts mount an antibody response and, more importantly, an EBV-specific cytotoxic T-cell immune response. EBV-naive transplant recipients lack both virus-specific antibodies and EBV-specific T cells; therefore an EBV-negative recipient of an EBV-positive donor is at greatest risk for developing PTLD.

Type of immunosuppression

Calcineurin inhibitors. Cyclosporine and tacrolimus may enhance the development of EBV-associated PTLD by directly promoting survival of EBV-infected B cells, presumably via the inhibition of EBV-transformed cells from apoptosis. Although single-center retrospective studies demonstrated that tacrolimus increased the risk for PTLD twofold to fivefold compared with cyclosporine, tacrolimus use has not been consistently shown to be associated with increased PTLD risk compared with cyclosporine.[48]

mTOR inhibitors. Sirolimus has a strong antiproliferative effect on PTLD-derived B-cell lines. Although there are theoretical reasons to suspect that mTOR inhibitors might decrease the risk of PTLD, one retrospective study demonstrated that sirolimus-containing regimens are associated with a 1.2-fold higher incidence of PTLD compared with no sirolimus.[49] The UNOS/OPTN database similarly demonstrated that in EBV-negative kidney transplant recipients, mTOR inhibitor + tacrolimus (Tac) combination therapy was associated with a nearly twofold increased PTLD risk compared with MMF/MPS + Tac combination therapy, whereas MMF/MPS + cyclosporine A (CsA) immunosuppression was associated with lower PTLD risk.[50] In contrast, a favorable effect of mTOR inhibitor on PTLD has also been reported. In a case series of 13 kidney transplant recipients with PTLD, immunosuppression reduction (MMF or AZA dose reduction along with discontinuation of Tac or CsA) in conjunction with initiation of sirolimus alone was effective in induction of remission in 4 patients with diffuse large B-cell PTLD after a median time of 12 weeks.[51] The potential beneficial effect of sirolimus on PTLD risk reduction was also shown in a retrospective study of 523 heart transplant recipients. Of these, 307 underwent CNI to sirolimus conversion therapy with complete withdrawal of CNI at a median of 1.1 years after heart transplant. Over median follow-up of 10 years posttransplantation, 0.65% of patients (2/307) in the sirolimus conversion group developed PTLD compared with 10.18% of patients (22/216) in the CNI group (adjusted HR, 0.13; $P = .009$). Of note, however, 7.9% of patients in the CNI maintenance group were recipients of combined heart-lung transplantation, whereas only 0.65% of patients in the sirolimus group received combined heart-lung transplant. Whether the overall degree of immunosuppression accounted for the higher incidence of PTLD in the CNI-maintenance group could not be determined from the study.[52]

Antimetabolites. The use of antimetabolites such as AZA and MMF has not been consistently shown to be associated with an increased risk for PTLD.

Induction agents. Whereas induction therapy with muromonab CD3/OKT3 (removed from the US market in 2010) or antithymocyte globulin may increase PTLD risk, the use of IL-2 receptor inhibitors (basiliximab and daclizumab [removed from the market in 2018]) or anti-CD52 antibody (alemtuzumab) induction has not been reported to increase PTLD risk. Analysis of the UNOS/OPTN database demonstrated that thymoglobulin was associated with significantly increased PTLD risk, whereas alemtuzumab, basiliximab, and daclizumab were associated with a borderline protective effect ($P = .06$). In this study maintenance therapy with an mTOR inhibitor was strongly associated with PTLD, in contrast to earlier reports suggesting its beneficial effect on PTLD because of its antiproliferative and antiangiogenic effects. Although both alemtuzumab and thymoglobulin are T-cell–depletional agents, the former has been shown to have a more

TABLE 110.6 Tumor-Free Waiting Period for Common Pretransplantation Malignancies[a,b]

No Waiting Time	
Long-standing history of MGUS; hematology-oncology consult is advisable in patients with newly diagnosed monoclonal gammopathy	
No Waiting Time if Cure at the Time of Transplantation	
Incidental renal cell carcinoma, in situ carcinoma of bladder, in situ carcinoma of cervix, basal cell carcinoma	
Waiting Time Varies With Staging, Tumor Size	
Breast cancer	2–5 years 2-year waiting time for ductal carcinoma in situ Patients with stage III or IV breast cancer should be advised against transplantation
Prostate cancer	Old paradigm: 2-year tumor-free waiting time Current trend[b]: shorter waiting time is acceptable for patients with grade group 1 or 2 prostate cancer (Gleason score≤ 6 or Gleason 3 + 4, respectively)
Renal cell carcinoma	2 years if <5 cm 5 years if >5 cm or <5 cm with invasion
Skin SCC[b,c]	Old paradigm: 0- to 2-year waiting time New paradigm[d]: low-risk SCC: surgical excision with clear margins or Mohs surgery and no waiting time High-risk SCC with no perineural invasion: surgical excision with clear margins or Mohs surgery and 2-year waiting time High-risk SCC with perineural invasion: surgical excision with clear margins or Mohs surgery ± adjuvant radiation therapy and waiting time of 5 years High-risk SCC with local nodal disease: surgical excision, lymph node dissection, adjuvant radiation therapy, and 5-year waiting time
Melanoma[b,c]	Old paradigm: 5-year waiting time New paradigm[d]: in situ: wide excision and no waiting time Stage Ia: wide local excision and 2-year waiting time Stage Ib/IIa: wide local excision and ± sentinel lymph node biopsy and 2- to 5-year waiting time Stage IIb/IIc: wide local excision and ± sentinel lymph node biopsy and 5-year waiting time Stage III or IV: not a transplant candidate
PTLD (retransplantation)	At least 1–2 years[b]
Waiting Time 2–5 Years[b]	
2-year waiting time: invasive bladder, uterine body, Wilms tumor 2- to 5-year waiting time: lymphoma, invasive cervical carcinoma, colorectal carcinoma (at least 5 years for Dukes BI or higher)	

[a]Certain cancers may recur despite a tumor-free waiting period.
[b]Oncology evaluation or consultation with the Israel Penn International Transplant Tumor Registry at https://ipittr.uc.edu may be invaluable.
[c]Dermatology consultation is recommended.

TABLE 110.7 WHO Classification of Posttransplant Lymphoproliferative Disorder

Categories	Histopathology	EBV Association/Comments
Early lesions	• Plasmacytic hyperplasia: many polyclonal plasma cells with occasional immunoblasts and lymphocytes • Infectious mononucleosis–like: many immunoblasts, with T lymphocytes and plasma cells • Florid follicular hyperplasia (included in the 2016 WHO classification of lymphoid neoplasms)	• Usually EBV positive • No or very focal clonality, no atypical morphology
Polymorphic PTLD	• Lymphocytes, plasma cells, immunoblasts, may be Reed-Sternberg–like cells • Often monoclonal, may have necrosis	• Often EBV positive • Cellular atypia, gene rearrangements may occur

Monomorphic PTLD	• Fulfills WHO criteria for non-Hodgkin lymphoma or plasma cell neoplasm
	  • B cell (most common)
	  • Diffuse large B-cell lymphoma, not otherwise specified
	  • Burkitt lymphoma
	  • Plasmacytoma-like lesions and plasmacytoma
	  • Other
	• T cell/NK cell: EBV negative
	  • Peripheral T-cell lymphoma, not otherwise specified
	  • Hepatosplenic lymphoma
	  • T-cell/NK-cell lymphoma
	  • Other
		• EBV less often positive
		• Uniform population of neoplastic cells with clonality and gene rearrangements

Hodgkin lymphoma–like PTLD	• Rare, usually mixed cellularity type	• EBV positive

EBV, Epstein-Barr virus; *NK,* natural killer; *PTLD,* posttransplantation lymphoproliferative disorder; *WHO,* World Health Organization.

pronounced B-cell–depleting effect. We speculate that depletional induction is not an independent risk factor for PTLD, but rather that maintenance drug selection and the balance between B-cell and T-cell depletion may determine the risk of PTLD. Nonetheless, aggressive PTLD attributed to alemtuzumab induction has been reported. It is speculated that the overall intensity of immunosuppression increases PTLD risk by decreasing host cytotoxic T cells directed against grafted EBV-infected B lymphocytes.

Belatacept. Belatacept is a nonantigen-specific biologic agent that blocks T-cell costimulatory signals, hence preventing T-cell activation. Phase III clinical trials suggest that its use in transplant recipients with pretransplant EBV seronegativity is associated with an increased risk for PTLD. However, a systematic review suggested that belatacept use at different dosages and in patients who were EBV seronegative or seropositive before transplant confers no additional risk compared with CNI immunosuppression.[53] Nonetheless, the black box warning for belatacept use in EBV-seronegative transplant candidates remains, and its use should be avoided in transplant recipients with pretransplant EBV-seronegative or unknown EBV status.

Donor-recipient HLA mismatch and HLA type. Retrospective analysis of more than 172,000 kidney, heart, pancreas, and lung recipients transplanted in the United States demonstrated that compared with recipients who had 2 HLA-donor-recipient (DR) mismatches, those with zero or 1 mismatch had reduced diffuse large B-cell lymphoma (DLBCL) risk (*0 DR mismatch:* incidence rate ratio [IRR], 0.76; 95% confidence interval [CI], 0.61–0.95; $P = .0149$; *1 DR mismatch:* IRR, 0.83; 95% CI, 0.69–1.00). Analysis of individual HLA type showed that recipient HLA-B38 was associated with a 1.48-fold increased DLBCL risk, whereas recipient HLA-B58 and HLA-DR13 were associated with reduced DLBCL risk.[54]

TABLE 110.8 Incidence of EBV-Associated PTLD by Subtypes and Time of Onset After Transplant

PTLD Subtypes	EBV Association	Onset After Transplant
Early lesions	Almost 100% EBV positive	Most early PTLD
Polymorphic PTLD	>90% EBV positive	Variable
Monomorphic PTLD	Both EBV positive and EBV negative	• EBV positive: most occur within the first 3 years after transplant • EBV negative: late occurring PTLD (>5 years after transplant)
Hodgkin lymphoma–like PTLD	>90%	

EBV, Epstein-Barr virus; *PTLD,* posttransplantation lymphoproliferative disorder.

Clinical Manifestations

PTLD may manifest with constitutional symptoms such as fevers, night sweats, malaise, and weight loss or with localized symptoms of the respiratory tract (infection or mass, including tonsillar or even gingival involvement), GI tract (diarrhea, pain, perforation, bleeding, mass), or central nervous system (CNS; headache, seizure, confusion). Other clinical manifestations may include lymphadenopathy or symptoms related to allograft dysfunction or compression of surrounding structures. Extranodal involvement occurs in more than two-thirds of patients. GI tract involvement occurs in 20% to 30% of cases, and solid graft organs in 10% to 15%. In contrast to lymphomas in the general population, the CNS is frequently involved in PTLD, occurring in up to 25% to 30% of patients, and can be the only site of disease. Early diagnosis requires a high index of suspicion and radiologic findings. Although computed tomography and magnetic resonance imaging are the most commonly used imaging modalities in PTLD, positron emission tomography-computerized tomography (PET-CT) has emerged as a potentially useful adjunct test for the diagnosis, staging, and

TABLE 110.9 Risk Factors for PTLD

Risk Factors	Comments
• Pretransplant EBV seronegative and primary EBV infection • Young recipient age (children compared with adults)	• Well-established risk factor • Higher incidence of PTLD in children compared with adults has been attributed to pretransplant EBV-naive status in pediatric population
PTLD incidence by type of organ transplant: • Small bowel and multiviscera (up to 33%) • Lung, heart, and heart-lung (2%–10%) • Pancreas or simultaneous kidney-pancreas (2%–3%) • Liver (1%–4%) • Kidney (1%–2%)	• More intensive immunosuppression and the amount of donor-derived lymphoid tissue transferred at organ transplantation may account for a high incidence of PTLD in multiorgan and bowel transplantation
Type of immunosuppression: • Belatacept (increased risk in pretransplant EBV seronegative recipients) • Lymphocyte-depleting agents (antithymocyte globulin > alemtuzumab) • CNIs • mTOR inhibitors (inconclusive or contradictory data) • Antimetabolites (inconsistent data) • Others (less well-established or controversial): HLA matching/HLA type, Black ethnicity, male sex, CMV infection/disease, HCV, pretransplant malignancy, HHV-8 and simian virus 40 infections, preexisting chronic immune stimulation, recipient MGUS	• Belatacept use is contraindicated in patients with pretransplant EBV-seronegative or unknown EBV status • Overall intensity of induction and maintenance therapy may play a more important role than any single agent • Duration of immunosuppression • 2 DR mismatches compared with 0–1 DR mismatch

CMV, Cytomegalovirus; *CNI,* calcineurin inhibitor; *EBV,* Epstein-Barr virus; *DR,* donor-recipient; *HCV,* hepatitis C virus; *HHV,* human herpesvirus; *HLA,* human leukocyte antigen; *MGUS,* monoclonal gammopathy of undetermined significance; *mTOR,* mammalian target of rapamycin; *PTLD,* posttransplantation lymphoproliferative disorder.

assessment of PTLD treatment response.[55] Tissue sampling is necessary for a definitive diagnosis and subcategorization of PTLD.

Treatment

Immunosuppression reduction is the first-line of treatment. Although their use has not been consistently demonstrated to increase PTLD risk, azathioprine and MPA derivatives are generally discontinued because of the theoretical net protumor effect of overimmunosuppression. CNI dose (or target level) can be reduced by 50% to 75% at the discretion of the clinician. Low-dose prednisone 5 mg daily can be continued to prevent allograft rejection. The 2019 AST-IDCOP do not recommend for or against switching to an mTOR inhibitor because of insufficient data.[55] Although a direct antitumor effect of sirolimus cannot be excluded, it is speculated that the beneficial effect of conversion to sirolimus monotherapy (or sirolimus and prednisone dual therapy) may be due to a reduction in overall immunosuppression. Restaging should be performed 2 to 4 weeks after immunosuppression reduction. For critically ill patients and those with monoclonal tumors or extensive disease, immunosuppression should be drastically reduced or discontinued. Currently reducing immunosuppression and risk-stratified sequential treatment with rituximab followed by cyclophosphamide, hydroxydaunorubicin or doxorubicin, oncovin or vincristine, prednisone (R-CHOP) is considered standard of care for polymorphic and monomorphic diffuse large B-cell lymphoma-like PTLD irrespective of EBV status (rituximab at 375 mg/m^2 weekly for 4 weeks, followed by CHOP every 3 weeks with granulocyte-stimulating factor support). Surgical resection with or without adjunctive local radiation can be used for localized disease. Local radiation has been advocated to treat PTLD involving the CNS, but chemotherapy is still recommended by some experts in the field. Poor prognostic factors include multiple-site versus single-site involvement, tumor monoclonality, graft organ involvement, advanced age, CD20-negative large cell lymphomas, and recipient EBV-negative serostatus. Other poor prognostic factors include World Health Organization performance status score of 3 or 4 (a score of 3 is defined as confined to bed or a chair for more than 50% of waking hours, and a score of 4 as completely disabled), late onset of disease (>1 year after transplant), elevated lactate dehydrogenase (LDH), CNS disease, severe organ dysfunction, acute kidney injury at diagnosis, impaired kidney function, and T-cell disease.[45] Suggested treatment modalities for PTLD are shown in Table 110.10. Acyclovir and ganciclovir are of unproven benefit. A systematic review of 31 studies showed no beneficial effect of antiviral prophylaxis on the incidence of PTLD in high-risk EBV-naive transplant recipients. The findings were consistent across all types of solid organ transplants, age groups, prophylactic or preemptive therapy, duration of antiviral prophylaxis, or different antiviral agents (acyclovir, valacyclovir, ganciclovir, valganciclovir).[56] Although arginine butyrate (a thymidine kinase–inducing agent) and ganciclovir combination therapy appears to have a promising role in EBV-associated PTLD, clinical trials evaluating its safety and efficacy have not been done.

EBV Monitoring and Preemptive Treatment Strategies

Most patients with EBV+ PTLD were shown to have a significantly higher viral load than those without PTLD. Posttransplantation EBV surveillance and preemptive treatment strategies including

TABLE 110.10 PTLD Treatment Modalities

Treatment	Indications	Comments
IS reduction	• Mainstay of therapy in all PTLD subtypes	• Factors predictive of a poor response to IS reduction alone: elevated LDH, organ dysfunction at diagnosis, multiple organ involvement, bulky disease (tumor deposit > 7 cm), advanced stage (Ann Arbor stage III or IV), age > 50 years
Rituximab	• First-line treatment for CD20+ PTLD not responsive to IS reduction alone	
Chemotherapy	• For those who do not achieve complete remission despite IS reduction and rituximab therapy Currently, IS reduction and risk-stratified sequential treatment with rituximab followed by CHOP (aka R-CHOP) are considered standard of care for polymorphic and monomorphic diffuse large B-cell lymphoma • Other indications: aggressive disease at presentation, lesions not amenable to surgery among others	• CHOP-based therapy is the most widely used regimen • Increased infectious risk • G-CSF use may decrease morbidity and mortality
Surgery	• For localized disease in conjunction with IS reduction • Palliative care (symptomatic relief)	
Radiation therapy	• For localized disease in conjunction with surgery and IS reduction • Palliative care (symptomatic relief)	
Antiviral therapy	• Acyclovir and ganciclovir are of unproven benefit because their activity is dependent on intracellular phosphorylation by virally coded thymidine kinase • EBV-driven lymphomas do not express thymidine kinase	• Some centers continue to use antiviral therapy based on limited studies suggesting that lytic viral DNA (not just latent viral DNA) is also present in established PTLD
mTOR inhibitors	• Insufficient data to recommend or refute its use in the treatment of PTLD	
Adoptive immunotherapy (adoptive transfer of EBV-specific cytotoxic T cells)	• Relapsed or refractory PTLD	• EBV-positive PTLD only • Expensive, not readily available, time consuming
Retransplantation	• Should be disease-free for at least 1–2 years prior to retransplantation • Consultation with hematology-oncology recommended	

CHOP, Cyclophosphamide, hydroxydaunorubicin or doxorubicin, oncovin or vincristine, prednisone; *EBV,* Epstein-Barr virus; *G-CSF,* granulocyte-colony stimulating factor; *IS,* immunosuppression; *LDH,* lactate dehydrogenase; *PTLD,* posttransplantation lymphoproliferative disorder.

immunosuppression reduction, rituximab therapy, and/or adoptive transfer of EBV-specific T cells may have a beneficial effect on the incidence of PTLD. Rituximab-mediated elimination of B cells may prevent transmission of EBV to the recipient, because EBV persistence requires a latent infection in recipient B cells. Single-center retrospective study in pediatric kidney transplant recipients demonstrated that a high-PCR EBV viral load (maximum peak EBV viral load above 59,909.5 copies/mL) was a significant and independent predictor of PTLD. Ten of 103 patients developed nonearly lesions PTLD, and 5 of 103 patients developed early lesions PTLD. In all cases EBV viral load was detected prior to the clinical diagnosis of PTLD.[57] Of 5 patients who received rituximab, none developed PTLD in follow-up (range, 3–60 months). However, given the small number of patients in this group, no conclusions on the effect of rituximab could be drawn. In a multicenter observational study of 4765 solid organ transplant recipients, antiviral prophylaxis was found to have no beneficial effect on early or late EBV+ PTLD occurrence. However, of the 191 patients who received rituximab-containing induction regimen, none developed PTLD. In contrast, 1.2% of patients (57/4574) who did not receive rituximab induction developed PTLD.[58] The 2019 AST-IDCOP guidelines recommend monitoring EBV viral load and preemptive interventions in patients who are EBV-seronegative pretransplant (weak/low).[55] Currently, EBV surveillance and preemptive therapy cannot be routinely recommended because of the lack of standardized time points for monitoring, cutoff values, and sources of samples (e.g., whole blood, plasma, serum, peripheral blood mononuclear cells, or isolated B cells) and the unclear risks and benefits of immunosuppression reduction. Nonetheless, this approach warrants further exploration.

Skin Cancer

Skin cancers are the most common de novo posttransplant tumors in the adult transplant population. Risk factors include light skin color, total sun burden and recreational sun exposure, genetic factors, history or present use of AZA, increasing number of immunosuppressants used, pretransplant history of squamous cell carcinoma (SCC), older age at transplant (>50 years), male sex, and duration of follow-up after transplantation. Cumulative UV radiation exposure has been suggested to be the primary carcinogen. Daily high-SPF sunscreen use is associated with a decrease in the incidence of actinic keratosis, SCC, and basal cell carcinoma (BCC) in solid organ transplant recipients. Potential pathogenic mechanisms of photocarcinogenesis include direct DNA damage, UV effects on host immunity, and synergistic effect with immunosuppressive drugs (particularly CNIs and AZA).[59] Limited studies suggest that AZA can also directly cause UVA-mediated DNA mutagenesis. Nonmelanoma skin cancer risk appears to be lower with MMF than with AZA use. In contrast, sirolimus or mTOR inhibitors may delay the onset or reduce the incidence of posttransplant skin and nonskin malignant neoplasms (discussed further later). Voriconazole (a previously commonly used antifungal agent to treat invasive fungal infection in organ transplantation) has been reported to be associated with a 73% increased risk of developing SCC. The newer antifungal agents posaconazole and isavuconazole have not been shown to increase skin cancer risk to date. Whereas BCC is the most common type of skin cancer in the general population, SCC has been reported to be 2 to 5 times more common than BCC in recipients of solid organ transplantation. In addition, immunosuppression in combination with enhanced sunlight exposure may induce malignant changes in papilloma-induced warts.

Immunosuppressive Therapy in Posttransplantation Malignancy

In principle, immunosuppression dose reduction improves immune surveillance against malignant cells. However, no systematic studies have been performed to determine whether immunosuppression reduction or withdrawal benefits the natural history of established posttransplantation malignancy. In our opinion, a switch from CNI to sirolimus or CNI minimization in conjunction with sirolimus may be a viable therapeutic option in selected posttransplant malignancies (the antitumoral effect of sirolimus is discussed later). In patients with metastatic cancer, manipulation of immunosuppression is probably futile, and the risk for rejection and graft loss likely outweighs the benefit.

Immunosuppressive agents appear to have different effects on cancer risk after transplantation. The carcinogenic effects of antithymocyte globulin, cyclosporine, tacrolimus, and AZA have been well documented. In contrast to AZA, MFA derivatives have been shown to have an antiproliferative effect and have been suggested to be protective of posttransplantation malignancy. Analysis of more than 17,000 adult patients with preexisting diabetes indicated a significantly higher incidence of malignancy in AZA-treated than in MMF-treated patients (3.7% vs. 2.2%). In a nested case-control study to evaluate the association between immunosuppressive medications and squamous cell skin cancer risk among cardiac ($n = 35$) and kidney transplant recipients (kidney alone, $n = 124$; simultaneous kidney-pancreas, $n = 11$), an inverse association between MFA derivatives and squamous cell skin cancer was observed independent of tacrolimus use. MFA use was associated with a 57% squamous cell skin cancer risk reduction compared with no MFA derivative use. In contrast, AZA use was associated with a greater than twofold increase in squamous cell skin cancer risk compared with no AZA use.[60] In a study of 544 lung transplant recipients with a median survival of 11 years, the sequential use of AZA and MMF, each for at least 1 year, was similarly found to be associated with a lower risk of developing a cutaneous SCC compared with AZA use only (hazard ratio [HR], 0.24; 95% CI, 0.10–0.56).[61] Limited studies suggest that AZA to MMF conversion therapy reduces skin photosensitivity to UVA and attenuates UVA-induced skin DNA damage. Nonetheless, one single-center study consisting of 930 heart transplant recipients demonstrated a lower incidence of skin cancer among patients receiving CsA/AZA combination therapy compared with those receiving CsA/MMF or Tac/MMF combination therapy.[62] Whether MMF is protective of posttransplant malignancies remains unclear. Nonetheless, it is common practice to reduce or discontinue MMF in the presence of malignancies because of the theoretical risk for net protumor effect of overimmunosuppression.

Both sirolimus and everolimus have antiproliferative and antitumoral effects. mTOR inhibitor-containing regimens are associated with decreased nonmelanoma skin cancer risks, and their use is effective in both primary and secondary skin cancer prevention. The earlier the conversion after an initial diagnosis of cutaneous SCC, the greater the efficacy. The protective effect of mTOR inhibitors against skin cancer may be a result of its inhibition of several UV-induced mechanisms involved in skin carcinogenesis. The mTOR inhibitors are also effective in inducing remission of Kaposi sarcoma in organ transplant recipients.[44]

Although sirolimus appears to have a beneficial effect for preventing primary and secondary skin cancer, its use in the management of other malignancies after solid organ transplantation remains to be defined. A systematic review of 20 RCTs and two observational studies demonstrated that sirolimus use was associated with lower overall cancer incidence, driven by a reduction in nonmelanoma skin cancer incidence. The protective effect of sirolimus on nonmelanoma skin cancer (NMSC) risk was most notable in studies comparing sirolimus against cyclosporine. After excluding NMSCs, there was no overall association between sirolimus and incidence of other cancers. Further analysis demonstrated that sirolimus use was associated with lower

kidney cancer incidence (IRR = 0.40; 95% CI, 0.20–0.81), and higher prostate incidence (IRR = 1.85; 95% CI, 1.17–2.91). The lower incidence of NMSC among sirolimus users was thought to be due in part to cyclosporine withdrawal. Overall, these findings suggested that sirolimus may reduce kidney cancer risk but is not protective for other cancers (including non-Hodgkin lymphoma, Kaposi sarcoma, and lung cancers) and may increase prostate cancer risk.[63] Notably, controlled trials demonstrated that although sirolimus was associated with a reduction in the risk of malignancy and nonmelanoma skin cancer in kidney transplant recipients, its use was associated with increased mortality risk compared with controls. This led some investigators to argue against mTOR inhibitor use in all patients with posttransplant malignancies.[48]

We start patients with newly diagnosed skin cancer, renal cell carcinoma, or Kaposi sarcoma on an mTOR inhibitor in conjunction with discontinuation of antimetabolites and reduction of CNI therapy tailored to each individual patient. In those with a history of these malignancies prior to transplant, mTOR inhibitor therapy is generally not introduced until after the first 3 posttransplant months. There are insufficient data to recommend or refute its use in PTLD. Available data do not support the routine use of mTOR inhibitors in the management of other cancer types. Of interest, however, experimental mouse models demonstrated that everolimus significantly inhibits breast cancer cell growth, migration, and invasion.[64] The use of mTOR inhibitor in human breast cancer in the settings of transplantation warrants further studies.

SELF-ASSESSMENT QUESTIONS

1. Which one of the following statements regarding immunization before and after transplantation is *correct?*
   - **A.** Seasonal influenza vaccine is contraindicated in the early posttransplant period because it is associated with allograft dysfunction and acute rejection.
   - **B.** COVID-19 vaccine is contraindicated in kidney transplant recipients with prior COVID-19 infection.
   - **C.** Live virus vaccination should be administered at least 2 weeks before transplantation to minimize the possibility of live vaccine-derived infection in the posttransplantation period.
   - **D.** Immunization of pets with live vaccines (such as canine *Bordetella bronchiseptica* intranasal vaccine) poses little to no risk of transmission.
2. Clinical manifestations and management of CMV infections include all of the following *except:*
   - **A.** The absence of CMV DNAemia rules out invasive CMV disease.
   - **B.** Primary CMV infection is usually more severe than reactivated infection or superinfection.
   - **C.** Plasma CMV DNA should be monitored weekly during treatment.
   - **D.** The Third International Consensus guidelines on the management of CMV advocate foscarnet as the second-line agent for the treatment of ganciclovir-resistant CMV infection.
3. Which of the following statements regarding posttransplantation lymphoproliferative disorder (PTLD) is *correct?*
   - **A.** Antiviral therapy with acyclovir or ganciclovir should be considered in Epstein-Barr virus–positive PTLD refractory to immunosuppression reduction alone.
   - **B.** Substitution of calcineurin inhibitor (cyclosporine or tacrolimus) for an mTOR inhibitor (sirolimus or everolimus) is considered standard of care.
   - **C.** Rituximab is considered as first-line treatment for CD20-positive PTLD that fails to respond to manipulation of immunosuppression alone.
   - **D.** PTLD is the most common type of posttransplantation malignancy in adult kidney transplant recipients.
   - **E.** A and C.

Cardiovascular Disease and Metabolic Abnormalities in the Kidney Transplant Recipient

Phuong-Thu T. Pham, Son V. Pham, Phuong-Anh Pham

CARDIOVASCULAR DISEASE

Cardiovascular disease (CVD) is the most frequent cause of death with a functioning kidney allograft. The US Renal Data System (USRDS) 2014 annual data report revealed that mortality from CVD among kidney transplant recipients (kidney alone or combined organ transplant) is nearly twice that observed for infection or malignancy. Cardiovascular (CV) risk factors in kidney transplant recipients encompass both conventional and unconventional risk factors. Although transplantation ameliorates some CV risks by restoring kidney function, it introduces new CV risks, including impaired glucose tolerance or diabetes mellitus (DM), hypertension, and dyslipidemia, which are derived in part from immunosuppressive medications. Box 111.1 summarizes suggested CV risk factors in transplant recipients. Selected risk factors are also discussed.

CONVENTIONAL CARDIOVASCULAR DISEASE RISK FACTORS

Postttransplantation Hypertension

Hypertension is present in more than 50% of kidney transplant recipients, and the true proportion may be much higher. In one single-center study, ambulatory blood pressure (BP) measurements demonstrated that only 5% of kidney transplant recipients were normotensive (defined as BP < 130/80 mm Hg).[1] Another study suggests that clinic BP measurements (vs. ambulatory BP monitoring) may underestimate the prevalence of hypertension in kidney transplant recipients; of 76 patients studied, 22.4% had masked hypertension (defined as BP > 130/80 mm Hg).[2]

Hypertension is a risk factor for both CVD and kidney graft failure. A retrospective cohort study revealed a graded risk for graft failure and death with increasing levels of systolic BP (each 10 mm Hg of systolic BP increase was associated with an increased relative risk for graft failure [risk ratio (RR), 1.12; $P < .000$], death-censored graft failure [RR, 1.17; $P < .0001$], and death [RR, 1.18; $P < .0001$]).[3] Post hoc analysis of the Folic Acid for Vascular Outcome Reduction in Transplantation (FAVORIT) study showed that each 20 mm Hg increase in baseline systolic BP was associated with a 32% increase in CVD risk and a 13% increase in mortality risk. However, for every 10 mm Hg decrease in diastolic BP below 70 mm Hg, a 31% increase in CVD and mortality risk was observed. For diastolic BP levels greater than 70 mm Hg, no significant association between diastolic BP and outcomes was observed.[4]

Risk factors for posttransplantation hypertension include preexisting hypertension, cyclosporine (and, to a lesser degree, tacrolimus), corticosteroids, various donor-related factors (e.g., donor age, donor hypertension, donor family history of hypertension), delayed graft function, chronic allograft injury, high body mass index or excess weight gain, acute rejection episodes, recurrent or de novo glomerulonephritis, and transplant renal artery stenosis. Sodium intake after transplantation and excess renin output from the native kidneys also may contribute in some patients. In kidney transplant recipients with severe hypertension refractory to medical therapy, bilateral native nephrectomy may ameliorate BP control. In a retrospective study of kidney transplant recipients with autosomal dominant polycystic kidney disease, ipsilateral native nephrectomy at the time of allograft transplant was associated with a significant decrease in the use of antihypertensive drugs needed for hypertension control compared with kidney transplantation alone at 12-, 24-, and 36-month follow-up. Subsequent contralateral native nephrectomy further improved BP control.[5]

The American College of Cardiology (ACC)/American Heart Association (AHA) guidelines on BP management advocate liberalizing the BP target to less than 160/90 mm Hg in the early posttransplantation period to maintain organ perfusion and avoid hypotension to reduce the risk of graft thrombosis. Beyond the first posttransplantation month, more stringent BP control to less than 130/80 is recommended to prevent end-organ damage.[6] The Kidney Disease: Improving Global Outcome (KDIGO) guidelines suggest a BP goal of less than 130/80 mm Hg for kidney transplant recipients irrespective of the level of albuminuria. However, such recommendations are based solely on epidemiologic data because no randomized trials demonstrate the optimal BP target in kidney transplant recipients. A BP goal of less than 125/75 mm Hg for patients with proteinuria is of uncertain benefit. Management of posttransplantation hypertension should include identification and treatment of the underlying cause, lifestyle modifications (see Chapter 36), and treatment of associated CV risk factors.

We recommend perioperative β-blockers in transplant candidates with a history of coronary artery disease because they reduce coronary artery disease (CAD) events. Diuretics are frequently used in the early posttransplantation period in patients who are volume expanded. Most transplant centers use calcium channel blockers for initial therapy because of their added benefit of antagonizing calcineurin inhibitor (CNI)-induced afferent arteriolar vasoconstriction, and their demonstrated efficacy in the general population irrespective of age, sex, and salt intake.[7] The nondihydropyridine calcium channel blockers diltiazem and verapamil are cytochrome CYP3A4 inhibitors, and their use also permits CNI or mammalian target of rapamycin (mTOR) inhibitor dose reductions. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) can cause acute changes in renal function and hyperkalemia and hence are usually not started until allograft function is stable. Transplant renal artery

BOX 111.1 Cardiovascular Risk Factors in Kidney Transplant Recipients

Conventional

Modifiable

Hypertension
Dyslipidemia
Obesity or metabolic syndrome
Smoking

Nonmodifiable

Age
Family history
Male sex
History of pretransplant and posttransplant cardiovascular disease
Race/ethnicity (White ethnicity)

Unconventional

Modifiable or Potentially Modifiable

Proteinuria
Posttransplantation diabetes mellitus
Left ventricular hypertrophy
Inflammatory markers (e.g., inflammatory cytokines, C-reactive protein)
Anemia
Hyperuricemia
Cytomegalovirus infection
Delayed graft function
Hyperhomocysteinemia
Time on dialysis
Chronic kidney disease (posttransplant)
Low albumin
Obstructive sleep apnea
Prothrombotic state
Low physical activity

Nonmodifiable

Recipient Factors

Prior acute rejection episodes
Preexisting coronary calcification
Cardiac troponin T

Donor Factors (Donor Quality)

Donor age
Donor hypertension
Donor recipient size mismatch
Donor *APOL1* gene polymorphism (may be associated with early graft dysfunction)

stenosis should be considered when serum creatinine rises to over 30% above baseline (see Chapter 43). Limited studies in kidney transplant recipients suggest that renin-angiotensin-aldosterone system (RAAS) blockade reduces CV events and ameliorates CNI-induced interstitial fibrosis and tubular atrophy. However, the beneficial effect of ACE inhibitors or ARBs on patient or graft survival has not been consistently demonstrated.[8] A meta-analysis of eight randomized trials demonstrated that RAAS inhibitors did not significantly alter all-cause mortality (RR, 0.96; 95% confidence interval [CI], 0.62–1.51), graft failure (RR, 0.76; 95% CI, 0.49–1.18), or doubling of serum creatinine (RR, 0.84; 95% CI, 0.51–1.39) compared with placebo (with similar BP control) or standard of care.[9] Because of the lack of conclusive evidence that one class of antihypertensive agent is superior to another in transplant recipients, treatment should be individualized based on efficacy, tolerability, concomitant comorbidity, and drug-drug interactions with immunosuppressive agents. Potential advantages and disadvantages of different classes of antihypertensive agents in kidney transplant recipients are shown in Table 111.1.

Posttransplantation Dyslipidemia

Dyslipidemia is common after transplantation, in part because of the hyperlipemic effect of corticosteroids, cyclosporine, tacrolimus, and the mTOR inhibitors sirolimus and everolimus. Sirolimus and everolimus are associated with the worst lipid profiles, followed by cyclosporine, and to a lesser extent tacrolimus. One single-center study demonstrated that the mean values of total cholesterol, low-density lipoprotein (LDL) cholesterol, and triglycerides (TGs) and the incidence of CAD were higher among patients receiving mTOR inhibitors compared with those receiving CNI-based immunosuppression (controls). However, the risk for CV events is not significantly higher among patients receiving mTOR inhibitors compared with controls.[10,11] A substudy of the MECANO trial also found no difference in CV outcomes among kidney transplant recipients randomized to early cyclosporine (CSA) to everolimus conversion therapy (n = 96) compared with those remaining on CSA-based immunosuppression (n = 89) over a 7-year follow-up period.[12] Studies in heart transplant recipients suggest that CNI to sirolimus conversion therapy may attenuate cardiac allograft vasculopathy (CAV) progression and CAV-related events compared with CNI continuation independent of LDL levels.[13] The antiproliferative and cardioprotective effects of mTOR inhibitors and the reduction in CNI-related risk factors may offset the adverse effects of mTOR inhibitor–associated hyperlipidemia.

Other etiologic factors for posttransplant dyslipidemia include age, diet, rapid weight gain, hyperinsulinemia, preexisting hypercholesterolemia, allograft dysfunction, proteinuria, genetic predisposition, and the use of diuretics and β-blockers (nonselective > selective β_1-blockers).

Management of Hyperlipidemia

Lifestyle changes (diet and exercise) and statins remain the cornerstone of therapy. In addition to their lipid-lowering effect, statins may protect against CVD via their antiproliferative and anti-inflammatory properties and ability to reduce circulating endothelin-1, C-reactive protein levels, systolic and diastolic BP, and pulse pressure. The benefits of statins in the general population have been demonstrated in several large randomized controlled trials (RCTs). The ALERT trial, the only prospective RCT in transplant recipients comparing statins (fluvastatin) with placebo, found a beneficial effect of early initiation of fluvastatin on posttransplant CV outcome. Patients who received statin therapy within the first 4 years after transplantation had a risk reduction of 64% compared with 19% for those who received therapy after 10 years.[14]

Box 111.2 summarizes different guidelines for the management of posttransplantation dyslipidemia.[15,16] The different classes of lipid lowering-agents are discussed in the following sections.

Statin Therapy

Kidney transplantation is considered a risk factor for CAD similar to other conventional cardiac risk factors. Despite the lack of evidence-based recommendations, most transplant centers treat dyslipidemias aggressively with statin therapy along with lifestyle modification. The concomitant use of statins and cyclosporine often results in a several-fold increase in statin blood level because CSA inhibits CYP450 3A4 enzyme, of which statins are major substrates. In addition, CSA inhibits OATP1B1/SLCO1B1-mediated hepatic uptake of statins, resulting in significant medication interaction. Therefore, in CSA-treated patients, all statins should be introduced at low doses and uptitrated

TABLE 111.1 Potential Advantages and Disadvantages of Different Classes of Antihypertensive Agents

Classes of Drugs	Advantages/Beneficial Effects	Disadvantages/Adverse Effects
ACE inhibitors, ARBs	• Beneficial in patients with proteinuria,[a] DM, LVH • Potential renoprotective and cardioprotective effects • Beneficial in posttransplantation erythrocytosis • Losartan may lower serum uric acid levels[b]	• Potential worsening anemia • GFR decline, hyperkalemia
Mineralocorticoid receptor antagonists (e.g., spironolactone, eplerenone)	• Improve outcome in patients with HFrEF • May improve blood pressure control in difficult-to-treat hypertension	• Severe hyperkalemia when used in combination with ACE inhibitor or ARB, particularly in patients with poor kidney function
α-Blockers (e.g., prazosin)	• Beneficial in patients with benign prostatic hypertrophy or neurogenic bladder	• Orthostatic hypotension
β-Blockers (e.g., carvedilol, metoprolol, bisoprolol)	• Beneficial in patients with CAD or ischemic heart disease	• Blunting of hyperglycemic unawareness, erectile dysfunction, hyperlipidemia, hyperkalemia (nonselective > selective β1- blockers), bronchospasm
Calcium channel blockers: nondihydroperidine (diltiazem, verapamil) and dihydroperidine (amlodipine, nifedipine)	• Ameliorate CNI-induced vasoconstriction • Diltiazem may permit CNI dose reduction by up to 40% • Verapamil by 30%–50%	
Central α-agonists (e.g., clonidine, methyldopa)	• Beneficial in patients with diabetic autonomic dysfunction	
Diuretics (loop and thiazide)	• Beneficial in patients who are volume expanded • Thiazide may improve hyperkalemia commonly seen in CNI-treated patients. Its use may also increase BMD decrease fracture risk (beneficial in osteoporosis).	
Direct vasodilators (e.g., hydralazine, minoxidil)	• Minoxidil: may be beneficial in difficult-to-treat hypertension • Hydralazine/nitrate combination therapy is recommended as add-on therapy in African Americans with refractory HFrEF and NYHA class III-IV heart failure despite standard of care therapy	

[a]The 2009 KDIGO clinical practice guidelines recommend an ACE inhibitor or ARB as first-line therapy for patients with hypertension and proteinuria of 1 g/day or greater.
[b]May be beneficial in patients with gout.
ACE, Angiotensin-converting enzyme; *ARBs,* angiotensin receptor blockers; *CAD,* Coronary artery disease; *CNI,* calcineurin inhibitor; *DM,* diabetes mellitus; *GFR,* glomerular filtration rate; *HFrEF,* heart failure with reduced ejection fraction; *LVH,* left ventricular hypertrophy; *NYHA,* New York Heart Association.

at the discretion of the clinicians. Maximal doses should be avoided because CSA-induced increase in statin bioavailability can result in an increased risk for myopathy and rhabdomyolysis. In contrast, tacrolimus does not inhibit CYP3A4 to a significant extent and has no effect on OATP1B1/SLCO1B1 and thus drug-drug interaction with statins is not observed. However, rhabdomyolysis associated with tacrolimus and statin use may be seen in patients on concomitant diltiazem therapy because the latter is a moderate CYPA3A4 inhibitor.

Non-Statin Drug Therapy

Ezetimibe. Ezetimibe and statin combination therapy may improve cholesterol control because of their complementary mechanisms of action. Ezetimibe blocks intestinal absorption of dietary cholesterol, whereas statin inhibits hepatic cholesterol synthesis. Results of the SHARP trial in which CKD patients were randomized to receive simvastatin 20 mg plus ezetimibe 10 mg (n = 4650) or placebo (n = 4620) demonstrated that simvastatin and ezetimibe combination therapy conferred a 17% risk reduction compared with placebo at a median follow-up of 4.9 years.[17] Limited studies suggest that statin and ezetimibe combination therapy is safe and effective in the treatment of dyslipidemia in kidney transplant patients who are refractory to statin therapy. In a study of 67 patients with posttransplantation hyperlipidemia resistant to statins, treatment with ezetimibe alone or with ezetimibe and statin significantly reduced total cholesterol and LDL cholesterol by 25% and 34%, respectively, during the first month of treatment.[18] The 2019 European Society of Cardiology (ESC)/European Atherosclerosis Society (EAS) guidelines advocate adding ezetimibe to statin therapy for solid organ transplant recipients who are refractory to the highest tolerated statin dose or as a second-line agent in those who are intolerant to statin. The AHA/ACC guidelines recommend adding ezetimibe to statin therapy in very high CVD risk patients if LDL-C level remains at least 70 mg/dL despite maximally tolerated statin therapy.

Protein convertase subtilisin/kexin type 9 inhibitors (PCSK9). PCSK9 is a proprotein convertase involved in the degradation of LDL receptors in the liver. PCSK9 inhibitors are human monoclonal antibodies that inhibit the binding of PCSK9 to the LDL receptors. Two large randomized, placebo-controlled trials involving high CV risk patients demonstrated that the PCSK9 inhibitors evolocumab (FOURIER trial, n = 27,564) and alirocumab (ODYSSEY trial, n = 18,924) reduced LDL-C levels significantly more than statins and significantly decreased CV morbidity and mortality (CV death, nonfatal myocardial infarction [MI], or stroke) independent of baseline LDL-C levels. Post hoc analysis of the ODYSSEY and FOURIER trials demonstrated that the efficacy and safety of alirocumab and evolocumab were comparable among subjects with and those without estimated glomerular filtration rate (eGFR) less than 60 mL/min/1.73 m^2.[19] The role of PCSK9 inhibitors in the treatment of dyslipidemia or CV risk reduction in chronic kidney disease (CKD) patients and in kidney transplant patients remains to be studied.

Management of Hypertriglyceridemia

Initial management should include lifestyle changes, increased physical activity, weight reduction, dietary counseling (carbohydrate restriction),

BOX 111.2 Pharmacologic Therapy for Dyslipidemia in Kidney Transplant Recipients

KDIGO Guidelines

- Statins in all adult transplant recipients.
- In the absence of traditional risk factors, transplant recipients <30 years old could choose not to receive statins if priority is placed on minimizing polypharmacy and drug toxicity over the small absolute risk reduction.[a]
- Elevated TGs:
  - Therapeutic lifestyle changes: low-fat diet (<15% total calories), reduction of mono- and disaccharide intake, reduction in total amount of dietary carbohydrates, use of fish oil to replace some long-chain TGs
  - Fibrate use to prevent pancreatitis or reduce CV risk not recommended

ACC/AHA Guidelines

- Statin therapy should be based on clinical judgment (weigh risk and benefits) and patient preference
- Follow-up lipid profile at 4 and 12 weeks after treatment assess medical adherence, then every 3–12 months as clinically indicated
- Benefits outweigh risk in patients with:
  - Clinical ASCVD
  - LDL-C > 190 mg/dL
  - DM, age 40–75 years, LDL-C 70–189 mg/dL, no clinical ASCVD
  - Clinical ASCVD or diabetes, LDL-C 70–189 mg/dL, and estimated 10-year ASCVD risk > 7.5%
- Elevated TGs not addressed; however, in nontransplant setting, ACC/AHA guidelines suggest adding n-3 polyunsaturated fatty acid (icosapent ethyl) to statin therapy in high-risk patients with TG ≥ 150 mg/dL[b]

2019 ESC/EAS Guidelines

- Treatment of dyslipidemias in transplant recipients similar to that for patients at high or very high CV risk
- Statins should be considered first-line agents
- Consider ezetimibe or ezetimibe-statin dual therapy in patients who are intolerant of statins or those with significant dyslipidemia despite maximally tolerated statin treatment, respectively[c]
- Elevated TGs[d]: consider adding omega-3 fatty acid to statin therapy in high-risk patients with TG 135–499 mg/dL (currently insufficient evidence to recommend routine use of fish oil in the transplant population)

[a]Rationale for recommendations: risk of coronary events is age dependent, and the ALERT trial did not enroll subjects <30 years.
[b]Approved by the US Food and Drug Administration for use as an adjunctive therapy to maximally tolerated statins to reduce the risk of CV events in adults with TG > 150 mg/dL. Patients must also have established CV disease or DM, and two more risk factors for CV disease.
[c]Cyclosporine can induce a 2- to 12-fold increase in the ezetimibe level. Concomitant ezetimibe and cyclosporine therapy can also raise cyclosporine concentration by 15%.
[d]Suggested lifestyle changes: reduce excessive body weight; increase physical activity; reduce alcohol, carbohydrate, and mono- and disaccharide intake; replace saturated fats with mono- or polyunsaturated fats.
ACC, American College of Cardiology; *AHA,* American Heart Association; *ASCVD,* atherosclerotic cardiovascular disease; *CV,* cardiovascular; *DM,* diabetes mellitus; *EAS,* European Atherosclerosis Society; *ESC,* European Society of Cardiology; *KDIGO,* Kidney Disease Global Outcomes; *LDL,* low-density lipoprotein; *TGs,* triglycerides.

smoking cessation, and correction of secondary causes. The latter may include untreated DM, excess alcohol intake, or drug-induced causes. Severe hypertriglyceridemia (TG level > 500 mg/dL or 5.65 mmol/L) may occur with the use of sirolimus and everolimus. Management includes dose reduction, pharmacologic therapy, and, in refractory cases, switching of mTOR inhibitors to mycophenolic acid derivatives or tacrolimus.

Drug Therapy for Hypertriglyceridemia

Fibrates. Fibrates have the most pronounced effect on lowering plasma TG levels of available lipid-lowering agents. Of available options (bezafibrate, ciprofibrate, fenofibrate, and gemfibrozil), the first three can increase serum creatinine in cyclosporine-treated patients. Although all fibrates have been associated with creatinine kinase elevations (with or without overt rhabdomyolysis and myopathy) when used in combination with statins, gemfibrozil may have a greater risk for myopathy compared with fenofibrate or bezafibrate. In kidney transplant recipients, a daily dose exceeding 900 mg for gemfibrozil, 400 mg for bezafibrate, and 200 mg for fenofibrate is not recommended.[16] Fenofibrate is contraindicated in patients with eGFR less than 30 mL/min/1.73 m^2. Data on the safety of gemfibrozil in patients with advanced CKD are lacking.

Ezetimibe. Limited studies demonstrated that ezetimibe has TG-lowering effects and is safe and effective in the transplant settings.

Bile acid sequestrants. Bile sequestrants are currently seldomly used given the available wide selection of highly effective lipid-lowering agents with more favorable side effect profiles.[16] Notably, studies in the general population suggest that bile acid sequestrants may increase TG levels. Their use is contraindicated in individuals with TGs greater than 400 to 500 mg/dL.

Niacin. Two large RCTs showed that nicotinic acid use is of no benefit but is associated with serious adverse effects. Currently, no medication containing nicotinic acid is approved for use in Europe.[20]

Fish oil. The ESC/EAS guidelines recommend adding omega-3 polyunsaturated fatty acids (2 g icosapent ethyl twice daily) to statin therapy in high-risk patients with TG levels between 135 to 499 mg/dL. There is insufficient evidence to recommend routine use of fish oil in the kidney transplant population.[16]

Summary

Statins should be the first-line therapy for the treatment of nonhigh-density lipoprotein (non-HDL) cholesterol because of their well-established safety and efficacy in preventing CVD in the general population. Ezetimibe should be used as a second-line agent in patients intolerant of statins or in combination therapy with statin when the LDL-C level remains at least 70 mg/dL despite maximally tolerated statin therapy. Adherence to lifestyle changes and to statin therapy should be reemphasized before adding a nonstatin lipid-lowering agent to statin therapy. In patients with severe hypertriglyceridemia, adding omega-3 polyunsaturated fatty acids or fibrate to statin therapy may be considered. However, caution should be exercised because of potential fibrate and statin drug-drug interactions. The choice of one lipid-lowering agent over the other should be based on adverse effects and potential drug-drug interactions. Simvastatin and gemfibrozil combination therapy is associated with an increased risk for rhabdomyolysis and should be avoided. Whether PCSK9 inhibitors are safe and effective in the transplant setting remains to be studied.

POSTTRANSPLANTATION DIABETES MELLITUS (NEW-ONSET DIABETES AFTER TRANSPLANTATION)

Posttransplantation DM (PTDM) occurs in 4% to 25% of kidney transplant recipients. Variations in incidence may arise from differences in definition, duration of follow-up, and the presence of both modifiable and nonmodifiable risk factors. Over the years, PTDM has undergone changes in nomenclatures including steroid diabetes, PTDM, new-onset DM, transplant-associated hyperglycemia, and new-onset diabetes after transplantation (NODAT).[21] In 2014 the International Expert Panel recommended changing the terminology

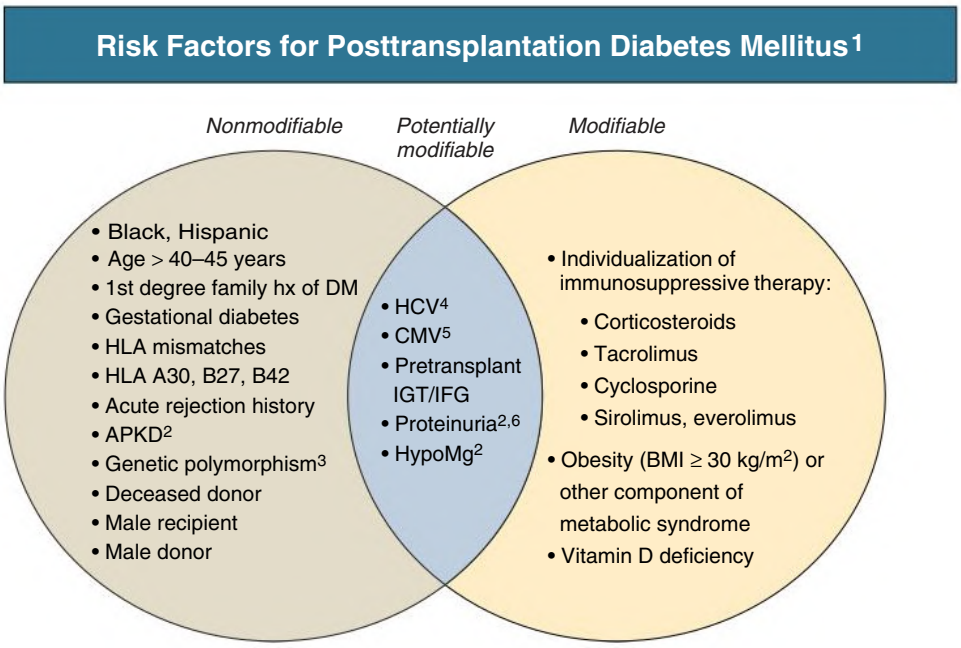

Fig. 111.1 Risk Factors for Posttransplantation Diabetes Mellitus. [1]Restoration of insulin metabolism by a functioning graft may unmask pretransplant impaired glucose tolerance or DM. [2]The associations between APKD, proteinuria, and hypomagnesia and PTDM have not been consistently observed. [3]Three genetic variants significantly associated with PTDM in random effects meta-analysis include CDKAL1 rs10946398, KCNQ1 rs2237892, and TCF7L2 rs7903146. [4]Antiviral therapy with direct-acting antiviral agents is discussed in Chapter 110. [5]Posttransplant CMV prophylactic and preemptive therapy is discussed in Chapter 110. [6]One study showed that moderately elevated early posttransplantation albuminuria is a risk factor for PTDM in a dose-dependent manner (increasing risk from normoalbuminuria to severely increased albuminuria). *APKD,* Autosomal dominant polycystic kidney disease; *BMI,* body mass index; *CMV,* cytomegalovirus; *DM,* diabetes mellitus; *HCV,* hepatitis C; *HLA,* human leukocyte antigen; *Hx,* history; *HypoMg,* hypomagnesemia; *IGT/IFG,* impaired glucose tolerance/impaired fasting glucose; *PTDM,* posttransplantation diabetes mellitus.

NODAT back to PTDM, excluding transient posttransplantation hyperglycemia.[22] Using the term NODAT is thought to be misleading because it seemingly excludes patients with pretransplant diabetes. Preexisting diabetes is often undiagnosed because of the effect of CKD on insulin metabolism and clearance and the lack of effective pretransplant screening.

Risk Factors

PTDM may arise from both transplant-related and traditional risk factors. The diabetogenic effect of corticosteroids, CNIs (tacrolimus > cyclosporine), and mTOR inhibitors have been well-described. Azathioprine, mycophenolic acid derivatives, and belatacept have not been shown to increase PTDM risk. Risk factors for PTDM are summarized in Fig. 111.1. They can be loosely categorized into those that are nonmodifiable, potentially modifiable, and modifiable.

Management

Management of PTDM follows the conventional approach and clinical guidelines for diabetes in the general population. Medical management usually involves a multidisciplinary team approach involving patients (and frequently family members), transplant coordinators, transplant physicians, and diabetic educators. A shared decision-making approach by which clinicians and patients exchange information and reach a consensus on treatment decisions can be helpful.

The American Diabetes Association and European Association for the Study of Diabetes recommend a hemoglobin A1c (A1c) target of less than 7% in most patients to reduce the incidence of microvascular disease. More stringent control (A1c 6.0%–6.5%) might be considered in a subset of patients with short disease duration, long life expectancy, and no significant CV disease, if this can be achieved without significant treatment-related adverse effects. For PTDM, the 2009 KDIGO clinical practice guidelines suggest a target A1c level from 7.0% to 7.5% but not less than 6.0%, particularly if hypoglycemic reactions are common.

Therapeutic Interventions

Nonpharmacologic Management

Obesity management is indicated because higher pretransplant BMI correlates with insulin resistance after transplantation. Lifestyle modifications in kidney transplant recipients include moderation of dietary sodium (<2400 mg sodium per day) and saturated fat intake (<7% calories from saturated fats, 2%–3% calories from trans-fatty acids), regular aerobic exercise, and weight reduction. Carbohydrate intake should be limited to 50% to 60% of caloric intake. The AHA guidelines for the general population recommend an intake of more than 25 g of dietary fiber per day and two servings of fish per week. Dietary guidelines for vegetarians are lacking. Flax seeds (or flaxseed oil) and chia seeds are alternative sources of omega-3 fatty acid. Dietitian referral is recommended. Defining realistic goals such as a target weight loss of 5% to 10% of total body weight and a patient-centered approach to education may be helpful.

Modification of Immunosuppression

Tacrolimus (TAC) has more consistently been shown to have a greater diabetogenic effect than CSA. A multicenter, prospective, randomized trial demonstrated that conversion from TAC to CSA resulted in reversal of diabetes, improved metabolic control, and reduced need for glucose–lowering therapy. At 12-month follow-up, 34% of patients

(14/41) in the CSA arm were free of diabetes compared with 10% (4/39) in the tacrolimus arm ($P = .01$). During the follow-up period, 39% of patients in the CSA arm discontinued glucose–lowering medication compared with 13% in the tacrolimus arm ($P = .01$). CSA conversion was associated with a mild increase in total and LDL-cholesterol and a greater reduction in eGFR (using the Modification of Diet in Renal Disease [MDRD] formula) compared with TAC maintenance immunosuppression at 12-month follow-up.[23] A meta-analysis of controlled clinical trials to assess the safety and efficacy of early steroid withdrawal or avoidance, steroid avoidance, or steroid withdrawal was associated with a decrease in PTDM incidence among CSA- but not TAC-treated kidney transplant recipients.[24] However, among CSA-treated patients, acute rejection episodes were more frequently observed in steroid avoidance compared with conventional steroid-treated groups.

A randomized trial of corticosteroid withdrawal (CSWD) demonstrated that CSWD has a limited impact in reducing PTDM compared with low-dose prednisone (5 mg/day from month 6–5 years). The proportion of PTDM patients requiring treatment was similar between CSWD and chronic corticosteroid (CCS) groups (CSWD 22.5% vs. CCS 21.5%). However, insulin use at 5 years was lower in the CSWD group (3.7% vs. 11.6%; $P = .049$).[25] In the current era of transplantation, most transplant centers advocate rapid steroid taper and lower target CSA and TAC levels, which may improve PTDM risk. However, modification of immunosuppression to alleviate the incidence of PTDM should be tailored to each patient, with the benefits of better glycemic control weighed against the risk for acute rejection. Furthermore, CSA use is associated with worse lipid profile compared with TAC therapy.

Pharmacologic Treatment

When lifestyle modification fails to achieve glycemic control, medical intervention is necessary. Metformin is not widely used in transplant recipients because of the concern for lactic acidosis in the presence of dynamic kidney allograft function, particularly in the early posttransplant period. However, the potential beneficial effects of metformin, including weight neutral or weight loss, cardioprotection, and lack of significant drug-drug interactions renders metformin an attractive treatment option for selected patients.[22] Experimental studies suggest that sulfonylureas are associated with beta cell apoptosis and beta cell exhaustion, raising theoretical concern about their use in PTDM, particularly in the early posttransplantation period. In contrast, the dipeptidyl peptidase-4 (DPP-4) inhibitors preserve pancreatic beta cell function in diabetic animal models. DPP-4 inhibitors are also safe and effective in the treatment of PTDM. Studies in patients with type 2 DM (T2DM) demonstrated that GLP-1 receptor agonists have a beneficial effect on CVD and weight loss. However, delayed gastric emptying associated with their use raises the concern for erratic immunosuppressant drug absorption in the transplant setting. Studies evaluating the safety and efficacy of GLP-1 inhibitors in kidney transplant recipients are lacking. One small single-center retrospective study showed that GLP-1 receptor agonist use allowed insulin dose reduction and ameliorated hypoglycemia risk. Allograft function was stable and no impact on TAC dosing was observed during the 12-month study period ($n = 14$).[26] Further studies are needed. The sodium-glucose cotransporter type 2 (SGLT2) inhibitors are a new class of drugs that appear to reduce CV events and slow renal progression in the nontransplant population with diabetic CKD.[27] In a single-center, prospective, randomized, placebo-controlled trial involving 44 kidney transplant recipients with PTDM randomized to receive either empagliflozin ($n = 22$) or placebo ($n = 22$) for 24 weeks, both A1C and weight loss were found to be significantly reduced in empagliflozin-treated patients compared with their placebo-treated counterparts (–0.2% vs. 0.1%, $P = .025$ and –2.5 kg vs. an increase of 1.0 kg, $P = .014$, respectively).[28] No significant differences in adverse events, immunosuppressive drug levels, or eGFR were observed between the two treatment groups except for one genital mycotic infection in the SGLT2 inhibitor treated group. Although the risk of genitourinary infectious complications associated with SGLT2 inhibitor use has not been consistently demonstrated, the US Food and Drug Administration warning labels regarding serious UTIs, including urosepsis and pyelonephritis, associated with its use remain in effect (updated March 2022). It is prudent to avoid SGLT2 inhibitor use in kidney transplant recipients with a history of recurrent UTIs, neurogenic bladder, or urologic abnormalities requiring chronic intermittent self-catheterization.

Evidence-based studies recommending one antidiabetic agent over the other in the context of transplantation are lacking. Hence, the choice should be based on the potential advantages and disadvantages of different classes of agents. Failure to achieve glycemic control despite glucose-lowering drug combination therapy requires initiation of basal-prandial insulin therapy. The 2014 international consensus guidelines on the screening, diagnosis, and management of early posttransplant hyperglycemia and PTDM is shown in Fig. 111.2.

Cigarette Smoking

Cigarette smoking in kidney transplant recipients is associated with perioperative complications, wound infections, increased risk of CVD, opportunistic infections, malignancies, and decreased patient and graft survival.[29] A multifaceted approach including behavioral and pharmacologic strategies appears to be most effective at getting patients to stop smoking.

Obesity

Single-center and large registry studies in kidney transplant recipients demonstrated that obesity (generally defined as body mass index [BMI] > 30 kg/m^2) at transplant is associated with increased risk of wound and surgical site infections, delayed graft function (DGF), acute rejection episodes, and graft loss. Posttransplant obesity also increases the risk of heart failure, atrial fibrillation, CVD, and cardiac death after transplant. Management of posttransplantation obesity can be a challenge because weight gain is common after transplant because of improved appetite related to resolving uremia, use of corticosteroid, liberation of dietary restrictions, and an overall improved sense of well-being. Early initiation of healthy lifestyle changes and counseling by a dietitian are important for successful weight management. Corticosteroid reduction or withdrawal must be balanced against the risk of acute rejection and graft loss. The use of pharmacologic agents for weight reduction in the posttransplantation period is not recommended because of unknown potential drug-drug interactions. Data are inadequate regarding the safety and efficacy of posttransplantation gastric bypass surgery or adjustable gastric banding in ameliorating comorbid conditions such as hypertension, DM, and dyslipidemia. All studies reported to date were limited by lack of suitable comparison group, short follow-up, and heterogeneity in type of bariatric procedure and approach.[30] However, with refinement in surgical techniques and advancement in postoperative care, posttransplantation bariatric surgery for morbid obesity should be considered on a case-by-case basis. Laparoscopic procedures are generally associated with fewer complications compared with open procedures.

UNCONVENTIONAL CARDIOVASCULAR DISEASE RISK FACTORS

Proteinuria

Proteinuria occurs in 9% to 40% of kidney transplant recipients with a functioning graft. Proteinuria from native kidneys typically decreases

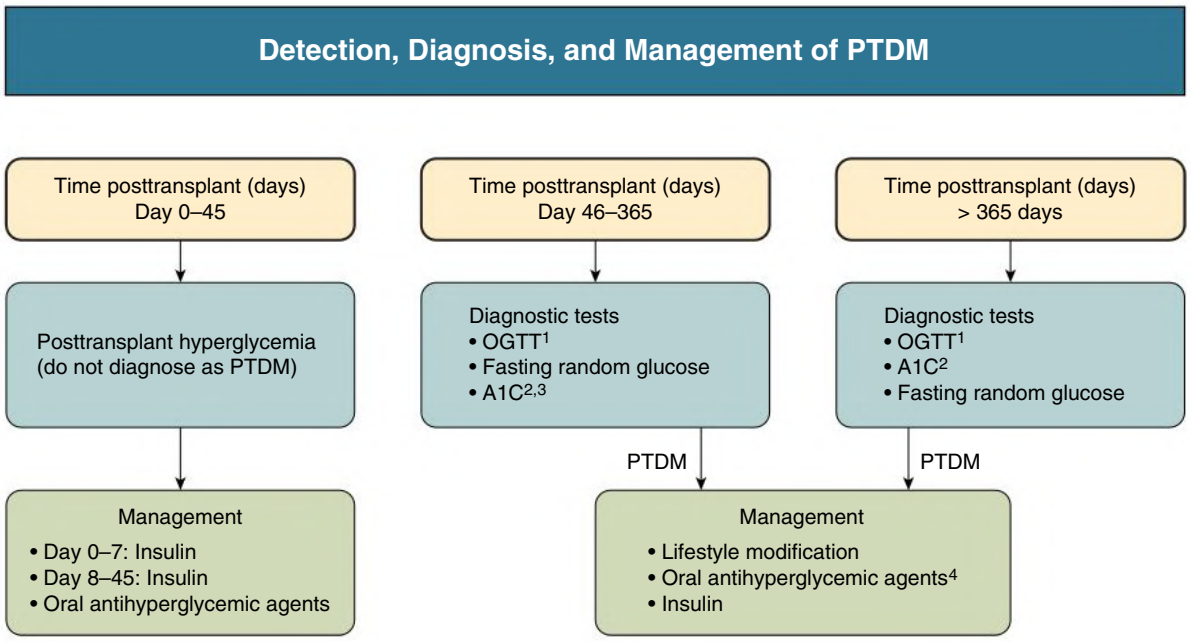

Fig. 111. 2 2014 International Consensus Guidelines on the Detection, Diagnosis, and Management of Posttransplantation Diabetes Mellitus (PTDM). [1]Seldom performed in clinical practice (time-consuming/cost). [2]A1C cannot be accurately interpreted within the first 3 months after transplantation because anemia and impaired graft function can directly interfere with the A1C assay. Recent blood transfusion and dapsone may alter A1C level. [3]A1C alone <365 days may underestimate PTDM and require confirmatory testing. [4]Over the past several years, newer injectable antidiabetic agents have increasingly been used (however, it should also be noted that evidence-based recommendations are lacking). *A1C,* Hemoglobin A1C; *OGTT,* oral glucose tolerance test; *PTDM,* posttransplantation diabetes mellitus.

rapidly after transplantation and resolves within the first month after transplantation. Persistent or worsening proteinuria is usually indicative of allograft pathology. Hence, monitoring the urine protein-to-creatinine ratio at each clinic visit and allograft biopsy should be performed in kidney transplant recipients with persistent or worsening proteinuria and in those whose primary renal disease is focal segmental glomerulosclerosis, to monitor for disease recurrence. As in the nontransplant setting, posttransplantation proteinuria increases the risk for CV events, graft loss, and mortality. In a single-center cohort analysis of 137 heart transplant recipients, the development of proteinuria after CNI to sirolimus conversion therapy was found to be associated with diminished benefit on cardiac allograft vasculopathy progression and higher all-cause mortality risk compared with those without proteinuria (hazard ratio [HR], 3.8; $P = .01$).[31] Whether mTOR inhibitor-induced proteinuria similarly increases mortality in kidney transplant recipients is unknown and warrants further studies. Although controlled trials evaluating the beneficial effect of treating proteinuria in reducing CV risk in kidney transplant recipients are lacking, ACE inhibitors or ARBs should be considered in transplant recipients with proteinuria because of their well-established antiproteinuric and cardioprotective effects.

Hyperhomocysteinemia

Although hyperhomocysteinemia has long been recognized as a risk factor for CAD, systematic review and meta-analysis showed no beneficial effect of homocysteine-lowering therapy on CVD risk reduction in patients with ESKD or in kidney transplant recipients.[32] The use of homocysteine-lowering agents for the primary prevention of CVD is not recommended.[8]

Belatacept Use

Phase III RCTs comparing the safety and efficacy of belatacept-based versus cyclosporine-based immunosuppression in recipients of standard donor kidneys (BENEFIT study) and in those of extended-criteria donor kidneys (BENEFIT-EXT study) demonstrated that, compared with cyclosporine, belatacept-based regimens resulted in (1) lower BP, cholesterol levels, and incidence of PTDM, (2) significantly reduced death and graft loss, and (3) improved long-term renal function. However, whether improvement in CV risk factor profile translates into reduction in CVD remains to be studied. In one single-center retrospective cohort study involving kidney transplant recipients at high CV risk, belatacept-based immunosuppression ($n = 35$) was not found to be associated with CV risk reduction compared with CNI-based therapy (control, $n = 150$). However, the study had several limitations, including retrospective nature, small sample size, different baseline characteristics, and duration of follow-up between the two treatment groups.[33]

COMMON LABORATORY ABNORMALITIES

Anemia

In the immediate posttransplantation period, aggressive perioperative volume expansion may result in dilutional anemia. Refractory or severe anemia mandates aggressive evaluation to exclude the possibility of surgical postoperative bleeding, particularly in those with a rapid fall in hemoglobin (Hb) and hematocrit (Hct) levels.

Mild anemia is common in the early posttransplantation period when erythropoietin (EPO) therapy is typically discontinued but usually improves within several weeks to months. Suggested etiologic factors for posttransplantation anemia include iron deficiency, impaired graft function, acute rejection episodes, recent infection, and medications (e.g., azathioprine, mycophenolic acid derivatives, sirolimus, everolimus, dapsone, ACE inhibitors, and ARBs).

Assessment of baseline iron stores at the time of transplantation may be invaluable because iron deficiency is common in the dialysis population. Profound iron deficiency should be treated with intravenous (IV) iron as tolerated. The 2012 KDIGO anemia guidelines recommend initiating an erythropoiesis-stimulating agent in CKD patients

when Hb values are less than 9 to 10 g/dL, provided iron stores are adequate. A target Hb level of 10 to 11 g/dL is recommended. Large CKD anemia trials demonstrated a possible harmful effect of higher Hb levels and high epoetin doses. Observational studies in kidney transplant recipients similarly suggested that mortality may be increased with Hb levels greater than 12.5 g/dL. Although evidence-based recommendations are lacking, management of posttransplantation anemia to keep Hb level in the range of 10 to 11 g/dL seems reasonable.

Refractory anemia or anemia that fails to rise gradually to a normal or near-normal level after the first few posttransplantation weeks can be a result of occult gastrointestinal (GI) bleeding, tertiary hyperparathyroidism, underlying inflammatory conditions, or parvovirus B19 infection. EPO-resistant anemia has been described in patients receiving sirolimus immunosuppression. In stable kidney transplant recipients, conversion from sirolimus to mycophenolic acid derivatives may help resolve anemia. Although uncommon, drug-induced hemolysis from agents such as dapsone should also be considered.

Leukopenia and Thrombocytopenia

Leukopenia and thrombocytopenia are most commonly due to medications, including lymphocyte-depleting agents (e.g., thymoglobulin or alemtuzumab), azathioprine, mycophenolic acid derivatives, sirolimus, everolimus, and trimethoprim-sulfamethoxazole, among others. Withholding or reducing the dose of the offending agent generally corrects these abnormalities. Severe leukopenia may be safely treated with granulocyte-stimulating factor (GSF). Thrombotic microangiopathy (TMA) or cytomegalovirus (CMV) infection should be excluded. Parvovirus B19 infection may manifest with refractory anemia, pancytopenia, and TMA. Alemtuzumab can cause potentially fatal immune thrombocytopenia. Bortezomib has been reported to cause leukopenia and thrombocytopenia.

Posttransplantation Erythrocytosis

Posttransplantation erythrocytosis (PTE) may develop within the first 2 years and generally affects those with good allograft function. Its incidence appears to have decreased to less than 10% concomitant with the more frequent use of ACE inhibitors and ARBs. Spontaneous remission is observed in one-fourth of patients within 2 years from onset, whereas in the remaining three-fourths, erythrocytosis may persist for several years. Risk factors for PTE include the presence of native kidneys, male sex, absence of rejection episodes, high pretransplantation Hb, and hypertension. Smoking and diabetes have been shown to be risk factors for PTE in some but not all studies. Other suggested risk factors include polycystic kidney disease and glomerulonephritis as the cause of end-stage kidney disease (ESKD). Although transplant renal artery stenosis has not consistently been shown to be a risk factor for PTE, imaging studies to evaluate the iliac and renal arteries should be considered in patients with refractory PTE (see Chapter 43). In addition, the possibilities of renal cell carcinoma in the native or transplanted kidneys should be excluded.

Treatment is generally recommended for an Hb level greater than 17 to 18 g/dL or an Hct level greater than 51% to 54% because of the associated risk for thromboembolic complications, hypertension, and headaches. Hb and Hct treatment range may vary depending on sex and institutional reference range. Treatment with ACE inhibitors or ARBs is often sufficient, although phlebotomy may occasionally be necessary. Relapse is common and often necessitates long-term ACE inhibitor or ARB treatment. We often prescribe low-dose aspirin 81 mg daily unless contraindicated.

Hyperkalemia

Mild hyperkalemia is commonly encountered in kidney transplant recipients, particularly in the early posttransplantation period when higher doses of CNI are used (TAC > CSA). It is often associated with mild hyperchloremic acidosis, a clinical presentation reminiscent of that of type 4 renal tubular acidosis. Other suggested mechanisms of CNI-induced hyperkalemia include activation of the sodium chloride cotransporter (NCC) in the distal convoluted tubule (leading to a decrease in the electrical gradient for potassium secretion via ROMK channels), inhibition of the ROMK channels and Na^+/K^+-ATPase in the distal tubule, and/or downregulation of mineralocorticoid receptor expression.[34] In patients receiving CSA or TAC immunosuppression, a potassium level of 5.2 to 5.5 mmol/L is typical. Higher potassium levels, especially in the presence of concomitant use of drugs that may exacerbate hyperkalemia such ACE inhibitors, ARBs, and β-blockers, may require their discontinuation. Caution is needed when potassium-containing phosphorus supplements are prescribed. Although both high-dose and standard-dose trimethoprim can cause hyperkalemia via an amiloride-like effect, the routine use of low-dose trimethoprim-sulfamethoxazole (TMP-SMX) prophylactic therapy is rarely the cause of severe or refractory hyperkalemia in kidney allograft recipients. Nonetheless, withholding of TMP-SMX should be considered in patients with severe or refractory hyperkalemia. In patients with recurrent hyperkalemia, consideration should be given to TMP-SMX dose reduction or TMP-SMX to dapsone or atovaquone conversion therapy (see Chapter 110 for *Pneumocystis jirovecii* prophylaxis treatment options). Treatment of hyperkalemia is discussed in Chapter 10. Sodium polystyrene sulfonate (Kayexalate) or calcium resonium enemas should be avoided in the early posttransplantation period to avoid colonic dilation and perforation. Although large-scale clinical trials in kidney transplant recipients are lacking, the newer cation exchangers patiromer and sodium zirconium cyclosilicate appear safe and effective in the treatment of hyperkalemia in kidney transplant recipients.[34] However, patiromer use in kidney transplant recipients may be hindered by potential drug-induced hypomagnesemia. This adverse drug effect may exacerbate the electrolyte abnormalities commonly seen in the posttransplantation period (discussed later). Limited studies suggest that patiromer may increase serum concentrations of TAC, whereas sodium zirconium cyclosilicate appears to have no impact on TAC pharmacokinetics.[34]

Hypophosphatemia

Hypophosphatemia is frequently encountered in the first months after transplantation. Concomitant hypercalcemia suggests posttransplantation hyperparathyroidism. In the absence of hypercalcemia, renal phosphate-wasting syndrome or malnutrition should be considered. Early after transplantation, hypophosphatemia has been attributed to a massive initial diuresis, particularly after a living-donor kidney transplant, defective renal phosphate reabsorption caused by ischemic injury, glucosuria (caused by hyperglycemia-induced osmotic diuresis), and corticosteroid use, the latter by inhibiting proximal tubular reabsorption of phosphate. Fibroblast growth factor-23 (FGF-23) may contribute to early posttransplantation hypophosphatemia independent of parathyroid hormone (PTH) level, and pretransplant FGF-23 is the main predictor of posttransplant phosphate levels. In contrast to hypophosphatemia occurring in the early posttransplant period, persistent hypophosphatemia beyond 1 year after transplant is mainly because of persistent hyperparathyroidism rather than increased FGF-23 levels.

Hypercalcemia

Hypercalcemia is common after transplantation and is generally due to persistent secondary hyperparathyroidism. The concomitant presence of severe hypophosphatemia, particularly in patients

with excellent graft function, may exacerbate hypercalcemia through stimulation of renal proximal tubular 1 α-hydroxylase. Resolution of soft tissue calcifications and immobilization are potential contributing factors. Hypercalcemia may be masked by high-dose corticosteroid therapy but may manifest during tapering. In about two-thirds of patients, hypercalcemia resolves spontaneously within 6 to 12 months. However, spontaneous resolution occurs in less than half of those whose hypercalcemia existed before transplantation. Persistent hyperparathyroidism has generally been attributed to continued autonomous production of PTH from nodular hyperplastic glands, reduced density of calcitriol receptors, and decreased expression of the membrane calcium sensor receptors that render cells more resistant to physiologic concentrations of calcitriol and calcium. Persistently elevated FGF-23 levels after transplant may contribute to persistent hyperparathyroidism through inhibition of α1-hydroxylase activity leading to low calcitriol levels. The risk for persistent hyperparathyroidism is increased with the duration of dialysis and the severity of pretransplant hyperparathyroidism. Severe and persistent hypercalcemia (>11.5–12 mg/dL [2.87–3.0 mmol/L]) for longer than 6 months in the first posttransplant year requires further evaluation. Initial assessment should include an intact PTH level. Parathyroid technetium-99m (99mTc)-sestamibi scan is generally required to determine whether the hyperparathyroidism arises from parathyroid adenoma, parathyroid gland hyperplasia, or hyperplastic nodular formation. Treatment with cinacalcet can be considered in kidney transplant recipients with hyperparathyroidism-associated hypercalcemia in the early posttransplant period. Serum calcium, phosphorus, and alkaline phosphatase should be monitored at each clinic visit. Because spontaneous resolution of hyperparathyroidism may take time, it is generally advisable to delay parathyroidectomy to 1 year after transplant. However, severe hypercalcemia associated with parathyroid adenoma often necessitates surgical parathyroidectomy. A multicenter, randomized, placebo-controlled trial demonstrated that cinacalcet use is safe and effective in the treatment of posttransplant hyperparathyroidism-associated hypercalcemia. Approximately 79% of cinacalcet, versus 3.5% of placebo-treated patients, achieved control of hypercalcemia (defined as calcium < 10.2 mg/dL; $P < .001$). Markers of bone density (alkaline phosphatase, osteocalcin, urine N-telopeptide) and measured bone mineral density (BMD) at the femoral neck at 1 year were comparable between the two treatment groups.[35] Subtotal parathyroidectomy (or total parathyroidectomy with autotransplantation) is warranted in patients with tertiary hyperparathyroidism or persistent severe hypercalcemia refractory to medical management (>11.5–12 mg/dL [2.87–3.0 mmol/L]) for longer than 6 to 12 months, symptomatic or progressive hypercalcemia, nephrolithiasis, persistent osteitis fibrosa, calcium-related renal allograft dysfunction, or progressive vascular calcification and calciphylaxis.[36] Clinicians should remain vigilant for the potential development of nephrocalcinosis associated with the use of cinacalcet.

Hypomagnesemia

CSA, TAC, and sirolimus can cause hypomagnesemia by inducing urinary magnesium wasting. Other factors that may contribute to posttransplantation hypomagnesemia include loop diuretics, recovery from acute tubular necrosis, postobstructive polyuria, renal tubular acidosis, and proton pump inhibitors. Hypomagnesemia may be more common in diabetics. In the first 3 months after transplantation, a magnesium level of less than 1.5 mg/dL (0.62 mmol/L) is common. Dietary magnesium intake is usually insufficient, and high-dose oral magnesium supplementation may be required. IV magnesium should be considered in patients with severe hypomagnesemia (<1.0 mg/dL or 0.41 mmol/L), particularly patients with a history of CAD or cardiac arrhythmias and those taking digoxin.

Abnormal Liver Function Tests

Elevation of liver enzymes is common in the early posttransplantation period and is generally caused by drug-related toxicity (Fig. 111.3). CSA and, less commonly, TAC may cause transient, self-limited, dose-dependent elevations of transaminase levels and mild hyperbilirubinemia secondary to defective bile secretion. Elevated liver enzymes caused by drug-related adverse effects (such as from statin use) generally improve or resolve after drug discontinuation or dose reduction.

Persistent or profound elevation in liver enzymes should prompt further evaluation to exclude infectious causes, including CMV, hepatitis B, and hepatitis C infections. Preemptive therapy to prevent posttransplantation reactivation of HBV and treatment of hepatitis B and C are discussed in Chapter 110. A suggested algorithm for the management of kidney transplant recipients with elevated liver enzymes is shown in Fig. 111.3.

BONE AND MINERAL METABOLISM AFTER KIDNEY TRANSPLANTATION

Posttransplantation bone disease is common after kidney transplantation because of corticosteroid use, hypophosphatemia, and disturbances in the FGF-23-PTH-vitamin D axis. Corticosteroids directly inhibit osteoblastogenesis, induce apoptosis of osteoblasts and osteocytes, and increase bone resorption through osteoclast activation. Other adverse effects of corticosteroids include inhibition of intestinal calcium absorption, enhancement of renal calcium excretion, and direct suppression of gonadal hormone secretion. Low plasma calcidiol (25(OH) vitamin D) level also may contribute to bone disease and is very common in kidney transplant recipients, with a reported prevalence of calcidiol deficiency of 30% (levels < 20 ng/mL) and insufficiency of 81% (levels < 30 ng/mL). Suggested causative factors include nutritional deficiency, malabsorption, decreased sun exposure, increased metabolism of calcidiol to calcitriol after a successful kidney transplant, and proteinuria (which may decrease levels of binding protein and total calcidiol levels). Other potentially causal factors include "normal" age-dependent osteoporosis, persistent metabolic acidosis, phosphate depletion, DM, hypogonadism, smoking, and CNI therapy. Experimental murine models demonstrated that CSA increases both bone formation and bone resorption, leading to a high-turnover bone loss, whereas TAC increases bone resorption without affecting bone formation.[37] In contrast, mTOR inhibitors may have a bone-sparing effect. Sirolimus was shown to inhibit osteoclast formation both in vitro and in vivo. One small European study showed that sirolimus decreased serum level of bone resorption markers in patients treated with sirolimus compared with those receiving a CNI-based regimen.[38]

Osteoporosis

Posttransplantation decline in BMD is most pronounced in the first 6 months and correlates with higher corticosteroid exposure. This early rapid decrease in BMD is usually followed by a slower rate of bone loss, which reflects cumulative corticosteroid dose. Bone loss in the first posttransplantation year ranging from 4% to 10% at the lumbar spine

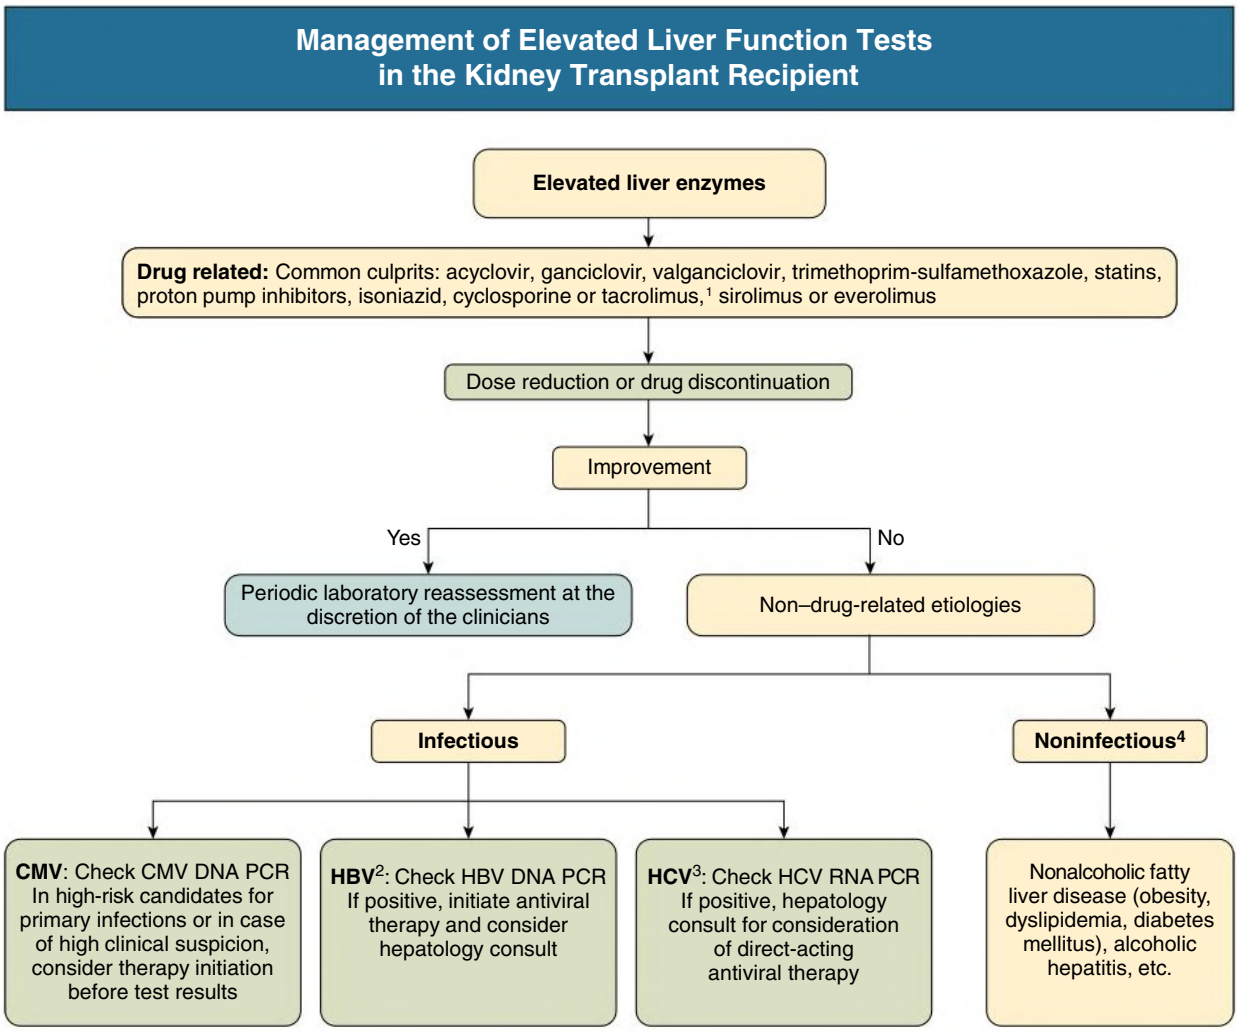

Fig. 111.3 Algorithm for the Management of Elevated Liver Enzymes in Kidney Transplant Recipients. [1]Cyclosporine and, less commonly, tacrolimus may cause transient, self-limited, dose-dependent elevation of aminotransferase levels and mild hyperbilirubinemia secondary to defective bile secretion. [2]We advocate antiviral prophylactic therapy in all HBsAg-positive candidates at the time of transplantation. [3]Treatment of HCV is discussed in Chapter 110. [4]Appropriate evaluation and management similar to those in the nontransplant settings. *CMV,* Cytomegalovirus; *HBV,* hepatitis B; *HCV,* hepatitis C; *PCR,* polymerase chain reaction.

and 5% to 8% at the hip have been reported. However, in more recent years, more modest bone loss or even no loss have been noted, perhaps due to lower corticosteroid doses and increased use of calcium and vitamin D.[39] Evaluation of patients for bone loss or osteoporosis relies on dual-energy x-ray absorptiometry (DEXA) scan. One retrospective cohort study of 238 kidney transplant recipients with CKD stage 1 to 5 demonstrated that osteopenia (HR, 2.7; 95% CI, 1.6–4.6) and osteoporosis (HR, 3.5; 95% CI, 1.8–6.4) were associated with significantly increased hip fracture risk compared with normal BMD, independent of age, sex, and diabetes.[40] The mean eGFR at the time of DEXA testing was 48 mL/min/1.73 m^2 (range, 12–98 mL/min). In patients in the first 12 months after kidney transplant with eGFR greater than 30 mL/min/1.73 m^2 and low BMD, the 2017 KDOQI guideline suggests initiating treatment with vitamin D, calcitriol/alfacalcidol, and/or antiresorptive agents. The choice of treatment can be influenced by abnormal levels of calcium, phosphate, PTH, alkaline phosphatase, and 25-OH Vitamin D as well as bone biopsy if required. Data are insufficient to guide treatment after the first 12 months.

Avascular Necrosis

Historically, posttransplantation avascular necrosis (AVN) occurs in up to 15% to 20% and most commonly affects the femoral head and neck. More recently its prevalence has decreased to approximately 3% to 5% concomitant with the use of lower corticosteroid dose and rapid steroid tapering. AVN usually occurs within the first few years after transplantation and may affect other joints, including the knees, the shoulders, and, less commonly, the ankles, elbows, and wrists. Predisposing factors for AVN include greater exposure to IV corticosteroid pulse therapy, cumulative doses of more than 2 g for longer than 3 months, low bone mass, hyperparathyroidism, increasing dialysis duration, excessive weight gain, hyperlipidemia, microvascular thrombosis, and a history of local trauma. Early AVN of the femoral head commonly presents with hip or groin pain or referred knee pain. Magnetic resonance imaging (MRI) is the most sensitive technique for early detection, and plain radiographs are of limited value. Corticosteroid dose reduction or discontinuation has little if any effect on altering the course of established AVN and may jeopardize graft function.

Prevention and Management of Posttransplantation Bone Diseases

Management of posttransplantation bone disease has largely been based on studies involving postmenopausal osteoporosis and corticosteroid-induced osteopenia in nontransplant settings. Studies in solid organ transplantation have yielded variable and conflicting results. Nonetheless, preventive measures to minimize posttransplantation bone loss should be initiated early after transplantation. Early ambulation and regular weight-bearing exercise should be encouraged. Adequate calcium supplementation (1000 mg/day) in nonhypercalcemic patients is recommended in the first posttransplantation year to prevent rapid bone loss resulting from corticosteroid-induced decreased intestinal calcium absorption. The 2017 KDIGO guideline recommends measuring calcidiol levels and correcting vitamin D deficiency and insufficiency using treatment strategies recommended for the general population. In patients at increased risk for fracture, consideration should be given to rapid corticosteroid taper or corticosteroid-free immunosuppressive protocols after weighing the risks and benefits of acute rejection. High pretransplantation PTH levels predict persistent hyperparathyroidism after transplantation, which may contribute to bone loss after transplantation. Hence, preexisting hyperparathyroidism associated with CKD should be treated according to the KDIGO guideline.

In patients with preexisting secondary hyperparathyroidism, hypercalcemia and hypophosphatemia may develop after transplantation because of persistent hyperparathyroidism and the newly elevated calcitriol level. Conservative management with phosphate replacement and suppression of hyperparathyroidism with cinacalcet has generally been recommended. Although no guidelines exist, phosphate supplementation should be considered in patients with a phosphate level of up to 1.5 to 1.7 mg/dL (0.5 mmol/L) to avoid complications associated with severe hypophosphatemia (e.g., rhabdomyolysis, left ventricular dysfunction, respiratory muscle weakness, and hemolysis). The indication for treatment may depend on the institutional reference range for serum phosphate. Patients should be encouraged to increase phosphate-rich food intake, and phosphate replacement should be discontinued when serum phosphate stabilizes at around 2.0 mg/dL (0.64 mmol/L). Overaggressive phosphate replacement is not recommended because it can result in worsening existing hyperparathyroidism and persistently elevated FGF-23 levels. Phosphate supplementation may also increase the risk of vascular and kidney allograft calcifications.

Bisphosphonates increase BMD in postmenopausal females and patients with corticosteroid-induced osteoporosis, particularly at the lumbar spine and trochanter. Studies evaluating the safety and efficacy of bisphosphonates in the treatment and prevention of bone disease after kidney transplantation have yielded mixed and even contradictory results, in part because of differences in study design, concomitant use of calcium or vitamin D, timing of treatment, duration of follow-up, and preexisting renal osteodystrophy, among others. The benefit of bisphosphonates for BMD may be skeletal site-specific. Several meta-analyses of RCTs showed a significant improvement in BMD with bisphosphonates compared with controls in the lumbar spine and femoral neck. No effect on fracture risk was observed. However, the low incidence of fracture events, small sample sizes, and short follow-up duration in all these studies might limit the ability to draw conclusions on fracture risk.[39] The 2019 "Cochrane Kidney and Transplant Register of Studies" database involving RCTs and quasi-RCTs suggested that bisphosphonate therapy may reduce fracture and bone pain after kidney transplantation among all age groups based on evidence of low certainty.[41] Bisphosphonates should be used with caution in patients with impaired kidney function and avoided in CKD stages 4 to 5.

Denosumab is a humanized monoclonal antibody that binds to and prevents RANKL (receptor activator of nuclear factor kappa-β ligand) from activating its receptor (RANK) on the surface of osteoclasts and their precursors. Denosumab has been shown to increase BMD and decrease fracture risk in postmenopausal females. Limited studies in kidney transplant recipients suggest that denosumab in combination with calcium and vitamin D may improve BMD compared with calcium and vitamin D alone.

Estrogen or androgen deficiencies also have been suggested to contribute to posttransplantation bone loss. However, no data support or refute the use of hormonal therapy to prevent posttransplantation-related bone loss in postmenopausal females or in males with hypogonadism; hence, treatment should be individualized.

Teriparatide, a recombinant human parathyroid hormone 1 to 34, is the only osteoanabolic agent approved by the FDA for use in corticosteroid-induced osteoporosis in the general population. Little evidence exists to support its use after kidney transplantation.[42]

In summary, calcium supplementation, vitamin D, and bisphosphonates remain the backbone of treatment of abnormal bone and mineral metabolism after kidney transplantation. Persistent hyperparathyroidism or hypophosphatemia should be treated before considering additional therapies for osteoporosis. In the absence of evidenced-based recommendations, the use of bisphosphonates in the posttransplantation setting should be individualized. In our opinion, bisphosphonate therapy may be justifiable in high-risk individuals, including those with preexisting osteoporosis or documented overall low bone mass, those who are receiving high-dose corticosteroids or those with history of fractures, and those who are postmenopausal. Biochemical markers of low bone turnover (serum PTH and bone-specific alkaline phosphatase levels below or at the lower limits of normal) may be used to guide therapy. In high-risk individuals who are intolerant of bisphosphonates, denosumab can be used as an alternative treatment option. Profound hypocalcemia associated with the use of denosumab, particularly in patients with low GFR, has been reported and should not be overlooked.

GOUT

Potential risk factors for the development of posttransplantation hyperuricemia and gouty arthritis include pretransplantation hyperuricemia, graft impairment, obesity, diuretic use, and CSA compared with TAC. CSA may impair renal excretion of uric acid secondary to decreased GFR and increase net uric acid reabsorption by the proximal tubule.

Management of the acute gouty attack includes topical ice and rest of the inflamed joint. Pharmacologic treatments include colchicine, increased corticosteroid dose, or nonsteroidal anti-inflammatory drugs (NSAIDs). However, NSAIDs should be avoided unless absolutely necessary. Progressive steroid tapering to low-dose maintenance antirejection therapy (usually over 2 to 3 weeks) is recommended to prevent rebound gout flare.

Management of chronic gout is directed at lowering uric acid levels. Allopurinol, a xanthine oxidase inhibitor, should be started at 100 to 200 mg/day, particularly in the presence of impaired

allograft function, because lower eGFR predisposes to severe allopurinol toxicity from retention of the metabolite oxypurinol. The dose can be increased by 50-mg increment (adjusted for renal function) every 4 weeks to maintain uric acid level less than 6 mg/dL in symptomatic patients. We do not recommend allopurinol in asymptomatic patients based on uric acid level alone. Febuxostat, a nonpurine analog xanthine oxidase inhibitor, can be considered in allopurinol-allergic patients. It is administered as 40 or 80 mg/day with no dose adjustment required for patients with renal impairment. However, one large randomized trial involving high CV risk patients (defined as patients with a history of major cardiovascular disease before randomization) demonstrated higher all-cause and CV mortality among febuxostat-treated compared with allopurinol-treated patients.[43] Both allopurinol and febuxostat should be used cautiously in patients taking azathioprine because of the inhibition of azathioprine metabolism by xanthine oxidase inhibitors (e.g., when used in combination therapy with allopurinol or febuxostat, consider azathioprine dose reduction by 25% and close monitoring of complete blood counts). Alternatively, azathioprine to mycophenolic acid derivative conversion therapy may be considered. The latter does not interact with allopurinol or febuxostat. Recombinant pegylated uricase (pegloticase), which converts uric acid to the more soluble and readily excreted purine end-product allantoin, rapidly reduces uric acid levels in patients refractory to conventional therapy. Pegloticase was approved by the FDA in 2010 for treatment of refractory gout, but high titers of antibodies against the drug is associated with loss of efficacy and infusion reactions. Recent studies suggest that posttransplantation immunosuppressive therapy may reduce immunologic response to pegloticase therapy by inhibiting the development of antipegloticase antibodies. Successful treatment of a heart transplant recipient with polyarticular tophaceous gout and hyperuricemia with a 38-week course of pegloticase has been reported.[44] Whether immunosuppressive therapy in the transplant setting may prevent antipegloticase antibody development and retain the urate-lowering efficacy among organ transplant recipients warrants further studies.

OUTPATIENT CARE

We recommend that patients be seen two times a week for the first 4 weeks after transplantation and weekly for the next month. After the first 2 months, the frequency of outpatient visits depends on the complexity of the patients' early postoperative course. Patients with stable graft function and an uneventful postoperative course can return to work or their regular daily activities 2 to 3 months after transplantation. Laboratory assessment during the first month after transplantation should include serum creatinine and electrolyte values, fasting glucose level, liver enzymes, immunosuppressive drug levels, and complete blood count with platelets. Urinalysis and, if clinically indicated, urine culture, and urine protein-to-creatinine ratio (see proteinuria section) also should be performed. At our institution, the patient's care will generally be returned to the referring nephrologist after 3 months. However, continued annual follow-up at the transplantation center is recommended.

SELF-ASSESSMENT QUESTIONS

1. Management of posttransplantation hypertension should include lifestyle modifications and which one of the following?
   - **A.** Stringent blood pressure control to a goal of less than 130/80 mm HG should begin in the early posttransplantation period.
   - **B.** An ACE inhibitor is the antihypertensive agent of choice after kidney transplantation because it improves patient and graft survival.
   - **C.** The KDIGO guidelines suggest a blood pressure goal of less than 130/80 mm Hg if albuminuria is present.
   - **D.** None of the above.
2. Which of the following drug combination therapies is more likely to cause myopathy and rhabdomyolysis?
   - **A.** High-dose statin and ezetimibe
   - **B.** High-dose statin and tacrolimus
   - **C.** High-dose statin and cyclosporine
   - **D.** Both B and C
3. Which one of the following statements is *correct?*
   - **A.** Cyclosporine (CSA) is more diabetogenic than tacrolimus (TAC).
   - **B.** Belatacept is less diabetogenic than both TAC and CSA.
   - **C.** Unlike the calcineurin inhibitors (CSA and TAC), mTOR inhibitors (sirolimus and everolimus) are nondiabetogenic.
   - **D.** Among currently available immunosuppressive agents, mTOR inhibitor use is associated with the worst lipid profile followed by CSA and TAC.
   - **E.** The mycophenolic acid derivatives mycophenolate mofetil and mycophenolate sodium are less diabetogenic than azathioprine.

Chronic Allograft Injury

Christian Morath, Claudius Speer, Martin Zeier

DEFINITIONS AND EPIDEMIOLOGY

The results after kidney transplantation have steadily improved over the past 30 years with a 1-year overall graft survival rate of about 94% and acute rejection rates within the first year after transplantation of 12%.[1] Loss of an allograft from acute rejection is now rare and is predominantly found in patients who are presensitized against human leukocyte antigens (HLAs).[2] Today, most allografts are lost by chronic antibody-mediated rejection that is a consequence of (de novo) development of donor-specific HLA antibodies (DSAs) but also non-HLA antibodies.[3,4,5] Every year, about 4% of kidney grafts are lost (Fig. 112.1). Only 2 decades ago, it was believed that nonimmunologic causes were the main factors leading to chronic allograft injury and graft loss.[6] Today, HLA alloantibodies are believed to be the main culprit, accounting for more than half of graft losses in the long term.[7] With the acknowledgment of alloantibodies as main factors that contribute to graft failure, the term *chronic allograft nephropathy* has been replaced by more specific terminology in the Banff classification of kidney allograft pathology (Table 112.1).[8,9]

Although immunologic causes are mainly responsible for late allograft injury and graft failure, nonimmunologic causes still represent significant risk factors for (late) graft injury and graft loss. The donor graft may present with significant preexisting disease limiting long-term graft survival.[10] In addition, chronic interstitial fibrosis and tubular atrophy (IFTA) may result from early damage to the allograft such as ischemia/reperfusion injury or early acute rejection. Calcineurin-inhibitor (CNI) nephrotoxicity, recurrent or de novo glomerular disease, BK virus infection, and IFTA originating from other causes further contribute to graft damage and graft loss over the long term.

Although some allografts are lost because of one specific cause, others accumulate damage from several different causes with gradual loss of functioning nephrons. Main contributors to late graft injury and late graft loss are summarized in Box 112.1.

PATHOGENESIS: NONIMMUNOLOGIC FACTORS

Donor Age, Donor Sex, and Donor-Recipient Size Mismatching

Long-term graft survival is reduced in kidneys from older donors, an effect that is more pronounced in deceased compared with living kidney transplant recipients.[11] Impaired graft survival is attributed to a differential response of the older organ to injury, an impaired capacity to withstand stress, a limited ability to repair structural damage, or amplification of external injury because of preexisting structural abnormalities.[12]

Reduced nephron mass resulting in glomerular hyperfiltration and hypertension with accelerated senescence is also a postulated mechanism for a progressive decline in kidney graft function.[13] The effect of kidney size mismatching is thought to be related to insufficient numbers of nephrons within the donor kidney, which, in turn, leads to compensatory hyperfiltration.[14] Although some experimental data support this hypothesis, the extent to which an inadequate number of nephrons contributes to chronic injury in clinical transplantation is unknown.

Female donor sex has a negative impact on kidney graft survival, with reduced survival when female grafts are transplanted into male recipients (risk ratio [RR], 1.22). This may be the result of reduced nephron mass of female donor kidneys (nephron underdosing). Other mechanisms may include possible differences in the immunogenicity of male and female grafts.[15,16]

Ischemia/Reperfusion Injury and Delayed Graft Function

Graft survival is lower in recipients with longer ischemia times, and longer cold ischemia time represents a risk factor for the development of IFTA at 6 months after transplantation.[17] Ischemia-reperfusion injury also may trigger immune-mediated injury because ischemia and oxidative injury resulting from reperfusion are associated with activation of the adaptive immune response, antigen-presenting cells and Toll-like receptors, and release of proinflammatory cytokines—all of which can lead to acute rejection and subsequent IFTA.[18] Pretreatment of the deceased organ donor with low-dose dopamine (aiming to reduce ischemia/reperfusion injury) reduced the need for dialysis early after kidney transplantation but failed to improve long-term kidney graft survival.[19,20] Similarly, therapeutic hypothermia compared with normothermia of the deceased organ donor was associated with a lower incidence of delayed graft function in the kidney transplant recipient (28% vs. 39%).[21] Another promising approach to reduce ischemia/reperfusion injury and improve early kidney graft function is the replacement of cold storage of kidneys by pulsatile machine perfusion during transportation. This strategy has been tested in clinical trials and is now routine practice in some centers.[22]

Delayed graft function, commonly defined by the need for dialysis in the first week after transplantation, is a risk factor for IFTA.[23] There are also independent associations between delayed graft function and late graft failure and between delayed graft function and graft failure that is mediated by acute rejection. Major risk factors for delayed graft function are prolonged cold ischemia time, donor age older than 50 years, diabetes mellitus as a cause of end-stage kidney disease (ESKD), time on dialysis of more than 5 years, and the presence of HLA alloantibodies.[24] The risk for delayed graft function is reduced when the donor or recipient is of female sex or when trauma is the cause of donor death. Ischemia and oxidative injury resulting from reperfusion of an ischemic kidney may cause an upregulation of major histocompatibility complex (MHC) antigens or proinflammatory cytokines, predisposing to acute rejection.

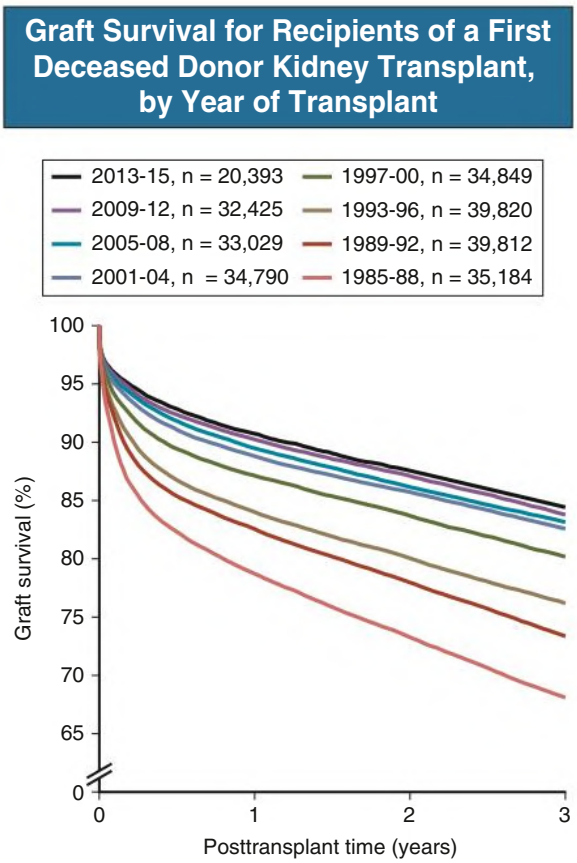

Fig. 112.1 Graft Survival for Recipients of a First Deceased Donor Kidney Transplant According to Year of Transplantation. Graft survival has steadily improved over the past years but mainly as a result of reduction of early graft loss. (Courtesy Prof. Gerhard Opelz, CTS Study.)

BK Virus Nephropathy

BK virus is an endemic polyomavirus that is usually acquired during childhood and persists in the urinary tract. Although it is asymptomatic in the immunocompetent host, it becomes activated in the immunocompromised patient. Viremia may be found in 10% to 30% of patients within the first 6 months after transplantation with biopsy-proven BK virus–associated nephropathy in 1% to 10% of patients. BK virus–associated nephropathy mimics the pattern of interstitial cellular rejection but may be distinguished in immunohistochemistry by positive staining for the SV40 antigen. The Banff working group identified two histologic markers predictive for graft function and graft survival. The Banff interstitial fibrosis (ci) score and a new score termed "the intrarenal polyomavirus load level (pvl)." The pvl score is based on the fraction of tubules with evidence of BK replication by light microscopy or immunohistochemical staining of epithelial cell nuclei for SV40 antigen. The pvl and ci scores were used to define the following three BK virus–associated nephropathy classes: pvl1 up to 1%, pvl2 greater than 1%, and less than 10%, and pvl3 of 10% or greater.[25] BK virus–associated nephropathy, if untreated, may lead to severe IFTA and graft loss in most patients. The mainstay of therapy is the reduction of immunosuppression.[26] The diagnosis and management of BK virus nephropathy are discussed further in Chapter 110.

Calcineurin Inhibitor Toxicity

CNI nephrotoxicity affects all histologic compartments of the transplanted kidney. Although not specific for CNI toxicity, CNI lesions include medial arteriolar hyalinosis, striped interstitial fibrosis, global glomerulosclerosis, and tubular microcalcification unrelated to other causes, such as tubular necrosis and hyperparathyroidism.[27,28] CNI-induced arteriolopathy is characterized by nodular hyaline deposits in the media of afferent arterioles sufficient to cause narrowing of the vascular lumen.[29,30] It is attributed to eosinophilic transformation and vacuolization of smooth muscle cells with subsequent necrosis. Arteriolar hyalinosis is the most reliable diagnostic marker of CNI nephrotoxicity. Confirmation of the diagnosis is made by exclusion of other causes, such as donor hyalinosis (which can be detected on the implantation biopsy specimen), diabetes, and hypertensive nephrosclerosis. Striped fibrosis is subjectively defined by a dense stripe of cortical fibrosis and atrophic tubules adjacent to normal cortex and is traditionally regarded as pathognomonic of CNI nephrotoxicity but can be seen in any cause of fibrosis, especially those associated with microvascular injury. It is likely that the associated arteriolopathy and narrowing of the lumen contribute to development of fibrosis and atrophy after watershed infarcts within areas of ischemia. Local hypoxia leads to formation of free oxygen radicals, which promote cellular death by apoptosis. In addition, upregulation of transforming growth factor-β is considered an important etiologic factor in CNI toxicity.[28]

Today, CNI nephrotoxicity is believed to be responsible for only a small proportion of graft failures. The Study of Long-term Deterioration of Kidney Allograft Function (DeKAF) demonstrated that 70% of patients with a primary or secondary histologic diagnosis of CNI nephrotoxicity had evidence of deposition of the complement split-product C4d and had DSA linking chronic graft failure to alloimmunity rather than CNI nephrotoxicity.[31,32]

Recurrent and De Novo Glomerular Diseases

Recurrent glomerulonephritis (GN) is diagnosed by exclusion of donor-transmitted disease and de novo GN. Its relative importance for graft loss increases as graft survival lengthens.[33] Given that it is a relatively common occurrence and has implications for treatment and retransplantation, clinicians should carefully search for recurrence in patients with prior GN. Diagnosis and management of recurrent disease are discussed further in Chapter 113.

Cardiovascular Risk Factors

The vasculopathy in chronic allograft injury resembles systemic vascular disease, raising the possibility that conventional cardiovascular (CV) disease risk factors may be implicated. Hypertension occurs in about 70% to 90% of transplant recipients and predisposes to graft failure.[34] Dyslipidemias, including raised total cholesterol, low-density lipoprotein cholesterol, and triglycerides and cigarette smoking, have also been associated with late graft failure. The management of CV risk factors in the transplant recipient is discussed in Chapter 111.

PATHOGENESIS: IMMUNOLOGIC FACTORS

T-Cell–Mediated Rejection

Acute T-cell–mediated rejection, vascular or corticosteroid-resistant rejection, subclinical rejection, and late (chronic-active) T-cell–mediated rejection all contribute to the burden of chronic allograft injury. Early acute T-cell–mediated rejection (within 3 months of transplantation) that is adequately diagnosed and treated usually has no impact on long-term graft survival, but late chronic-active T-cell–mediated rejection in which serum creatinine does not return to baseline usually translates into IFTA and/or vascular damage, contributing to graft injury. Multiple and severe late acute T-cell–mediated rejection episodes are predictive of chronic graft dysfunction more than early cellular rejection and acute vascular rejection, which have stronger associations with acute graft loss.[35] There is some evidence from

TABLE 112.1 Updated 2019 Banff Classification Categories

Category 1: Normal Biopsy or Nonspecific Changes	
Category 2: Antibody-Mediated Changes 1. Active ABMR 2. Chronic active ABMR[b] 3. Chronic ABMR 4. C4d staining without evidence of rejection	**Active ABMR** All three features must be present for diagnosis. 1. Histologic evidence of acute tissue injury, including one or more of the following: • Microvascular inflammation (g > 0 and/or ptc > 0), in the absence of recurrent or de novo glomerulonephritis, although in the presence of acute TCMR, borderline infiltrate, or infection, ptc ≥ 1 alone is not sufficient and g must be ≥ 1 • Intimal or transmural arteritis (v >0)[a] • Acute TMA in the absence of any other cause • Acute tubular injury in the absence of any other apparent cause 2. Evidence of current/recent antibody interaction with vascular endothelium, including at least one of the following: • Linear C4d staining in peritubular capillaries (C4d2 or C4d3 by IF on frozen sections or C4d > 0 by IHC on paraffin sections) • At least moderate microvascular inflammation ([g + ptc] ≥ 2), although in the presence of acute TCMR, borderline infiltrate, or infection; ptc ≥ 2 alone is not sufficient, and g must be ≥ 1 • Increased expression of gene transcripts in the biopsy tissue indicative of endothelial injury, if thoroughly validated 3. Serologic evidence of circulating donor-specific antibodies (DSA to HLA or other antigens). C4d staining or expression of validated transcripts/classifiers as noted previously in criterion 2 may substitute for DSA; however, thorough DSA testing, including testing for non-HLA antibodies if HLA antibody testing is negative, is strongly advised whenever criteria 1 and 2 are met.
	Chronic Active ABMR All three features must be present for diagnosis. As with active ABMR, biopsy samples showing histologic features plus evidence of current/recent antibody interaction with vascular endothelium or DSA, but not both, may be designated as suspicious, and it should be noted if the lesion is C4d positive or C4d negative, based on the criteria listed: 1. Histologic evidence of chronic tissue injury, including one or more of the following: • TG (cg > 0), if no evidence of chronic TMA; includes changes evident by EM only (cg1a; see Table 112.4) • Severe peritubular capillary basement membrane multilayering (requires EM)[c] • Arterial intimal fibrosis of new onset, excluding other causes; leukocytes within the sclerotic intima favor chronic ABMR if there is no history of biopsy-proven TCMR with arterial involvement but are not required 2. Identical to criteria for active ABMR 3. Serologic evidence of DSAs (HLA or other antigens): • Biopsy results suspicious for ABMR on the basis of meeting criteria 1 and 2 should prompt expedited DSA testing
	Chronic ABMR All three features must be present for diagnosis: 1. cg > 0 and/or severe ptcml (ptcml1) 2. Absence of criterion 2 of recurrent/recent antibody interaction with the endothelium 3. Prior documented diagnosis of active or chronic active ABMR and/or documented prior evidence of DSA **C4d Staining Without Evidence of Rejection** All four features must be present for diagnosis[d]: 1. Linear C4d staining in peritubular capillaries (C4d2 or C4d3 by IF on frozen sections, or C4d > 0 by IHC on paraffin sections) 2. Criterion 1 for active or chronic active ABMR not met 3. No molecular evidence for ABMR as in criterion 2 for active and chronic active ABMR 4. No acute or chronic active TCMR, or borderline changes
Category 3: Borderline Changes Suspicious for Acute TCMR	• Foci of tubulitis (t1, t2, or t3) with mild interstitial inflammation (i1), or mild tubulitis (t1) with interstitial inflammation (i2, i3) • No intimal arteritis (v = 0)

TABLE 112.1 Updated 2019 Banff Classification Categories—cont'd

Category 4: TCMR 1. Acute TCMR 2. Chronic active TCMR	**Acute TCMR** IA. Significant interstitial inflammation (>25% of nonsclerotic cortical parenchyma, i2 or i3) and foci of moderate tubulitis (t2) IB. Significant interstitial inflammation (>25% of nonsclerotic cortical parenchyma, i2 or i3) and foci of severe tubulitis (t3) IIA. Mild to moderate intimal arteritis (v1) with or without interstitial inflammation and tubulitis IIB. Severe intimal arteritis comprising > 25% of the luminal area (v2) with or without interstitial inflammation and tubulitis III. Transmural arteritis and/or arterial fibrinoid change and necrosis of medial smooth muscle cells with accompanying lymphocytic inflammation (v3)
	Chronic active TCMR IA. Interstitial inflammation involving >25% of the total cortex (ti score 2 or 3) and >25% of the sclerotic cortical parenchyma (i-IFTA score 2 or 3) with moderate tubulitis (t2) involving 1 or more tubules, not including severely atrophic tubules; other known causes of i-IFTA should be ruled out IB. Interstitial inflammation involving >25% of the total cortex (ti score 2 or 3) and >25% of the sclerotic cortical parenchyma (i-IFTA score 2 or 3) with severe tubulitis (t3) involving 1 or more tubules, not including severely atrophic tubules; other known causes of i-IFTA should be ruled out II. Chronic allograft arteriopathy (arterial intimal fibrosis with mononuclear cell inflammation in fibrosis and formation of neointima)
Category 5: Interstitial Fibrosis and Tubular Atrophy (IFTA)	Chronic allograft arteriopathy (arterial intimal fibrosis with mononuclear cell infiltration in fibrosis, formation of neointima); note that such lesions may represent chronic active ABMR and TCMR; the latter also may be manifest in the tubulointerstitial compartment I. Mild interstitial fibrosis and tubular atrophy (≤25% of cortical area) II. Moderate interstitial fibrosis and tubular atrophy (26%–50% of cortical area) III. Severe interstitial fibrosis and tubular atrophy (>50% of cortical area)
Category 6: Other Changes Not Considered Caused by Acute or Chronic Rejection	• BK virus nephropathy • Posttransplant lymphoproliferative disorders • Calcineurin inhibitor nephrotoxicity • Acute tubular injury • Recurrent disease • De novo glomerulopathy (other than transplant glomerulopathy) • Pyelonephritis • Drug-induced interstitial nephritis

[a]These arterial lesions may be indicative of ABMR, TCMR, or mixed ABMR/TCMR. The v lesions are scored in arteries only having a continuous media with two or more smooth muscle layers.

[b]Lesions of chronic, active ABMR can range from primarily active lesions with early TG evident only by EM to those with advanced TG and other chronic changes in addition to active microvascular inflammation. In the absence of evidence of current/recent antibody interaction with the endothelium (those features in the second section of Table 112.3), the term "active" should be omitted; in such cases, DSAs may be present at the time of biopsy or at any previous time after transplantation.

[c]Seven or more layers in one cortical peritubular capillary and five or more in two additional capillaries, avoiding portions cut tangentially.

[d]The clinical significance of these findings may be quite different in grafts exposed to anti–blood group antibodies (ABO-incompatible allografts), in which they do not appear to be injurious to the graft and may represent accommodation; however, with anti-HLA antibodies, such lesions may progress to chronic ABMR and more outcome data are needed.

protocol biopsy studies that subclinical T-cell–mediated rejection may be an important factor contributing to chronic graft injury.[36,37]

Besides the direct effects of T-cell–mediated rejection on graft function, acute T-cell–mediated rejection may be linked to the development of DSA and subsequent antibody-mediated rejection.[38]

Antibody-Mediated Rejection

Chronic active antibody-mediated rejection is the leading cause of graft loss, together with death with a functioning graft, recurrent kidney disease, and IFTA of unknown origin.[39]

For the diagnosis of antibody-mediated kidney graft rejection, histologic features of antibody-mediated rejection in the biopsy sample (Figs. 112.2–112.4), together with evidence of current or recent antibody interaction with the vascular endothelium (see Fig. 112.3) and the detection of circulating DSA (either HLA or non-HLA), are required. Because C4d in peritubular capillaries is not detectable in more than 50% of patients with chronic antibody-mediated rejection, C4d-positivity is no longer a prerequisite for the diagnosis of antibody-mediated rejection.[9] This finding, together with the observation that chronic antibody-mediated rejection may occur in the absence of complement activation (e.g., the occurrence of transplant glomerulopathy in patients during effective therapeutic complement inhibition by eculizumab), led to the hypothesis that complement-independent mechanisms such as direct endothelial cell activation and infiltration of natural

BOX 112.1 Main Factors Contributing to Late Graft Injury and Late Graft Loss

Donor Factors
- Deceased donor kidney (DBD or DCD)
- Older donor age, female donor
- Donor vascular disease
- Ischemia/reperfusion injury and long ischemia time
- Delayed graft function

Recipient Risks (Nonimmune)
- Obesity
- Urinary tract infection
- Transplant ureteral obstruction
- BK virus nephropathy
- Calcineurin inhibitor toxicity
- Recurrent kidney disease or de novo glomerulonephritis
- Hypertension, dyslipidemia, smoking
- Diabetes (preexisting or posttransplantation)

Recipient Risks (Alloimmune)
- Child or adolescent recipient
- Variable immunosuppressive medication trough concentrations from malabsorption or nonadherence
- HLA mismatches, presensitization status (donor-specific HLA alloantibodies)
- Acute rejection that is severe, corticosteroid resistant, vascular, antibody mediated, or late occurring
- Late de novo donor-specific antibodies and chronic (antibody-mediated) rejection

DBD, Donation after brain death; *DCD,* donation after cardiac death; *HLA,* human leukocyte antigen. Modified from Nankivell BJ, Kuypers DRJ. Diagnosis and prevention of chronic kidney allograft loss. *Lancet.* 2011;378:1428–1437.

killer (NK) cells or monocytes may contribute to chronic antibody-mediated allograft injury. C4d-negative antibody-mediated rejection shares the same histologic and ultrastructural features as C4d-positive rejection. To improve the diagnosis of antibody-mediated rejection, a molecular microscope strategy was adopted in the 2013 update of the Banff classification.[40] This means that in the absence of C4d positivity or microvascular inflammation, antibody interaction with the vascular endothelium is also suggested by detection of an increased expression of specific gene transcripts in the biopsy tissue indicative of endothelial injury (the "molecular microscope"), although this approach still needs further validation.

Unrecognized DSAs, if strongly reactive and complement-activating, can cause hyperacute rejection or accelerated antibody-mediated rejections in the early phase after kidney transplantation. Acute antibody-mediated rejection in the early phase occurs in about 1% to 6% of patients overall, but in as many as 21% to 55% of patients who had detectable DSAs already before transplantation and who received desensitization therapy.[41–43] Weakly positive DSAs have been associated with rather subtle types of graft damage, often leading to delayed graft function.[2] Early damage can lead to chronic rejection, most probably because the structure of the endothelium is no longer intact and new antigenic epitopes are expressed on the surface of transplanted tissue. During later phases after transplantation, insufficient immunosuppression can facilitate the development of de novo DSAs against these new epitopes and result in chronic antibody-mediated rejection and failure of the transplanted organ. De novo DSAs, but to a lesser extent also persistence or reemergence of DSAs that were detectable before transplantation, are associated with poor allograft outcome.

Chronic active antibody-mediated rejection is found more frequently in patients who are nonadherent to immunosuppressive medication or in whom immunosuppression was reduced for other reasons, such as conversion to CNI-free or steroid-free immunosuppressive protocols, recurrent infection, or malignancy.[44–46] In these patients, antibody-mediated lesions and T-cell–mediated lesions are often found in kidney graft biopsy samples at the same time. Additional risk factors for the development of de novo DSAs and antibody-mediated rejection are HLA class II DR mismatches between donor and recipient, prior cellular rejection episodes, and younger recipient age. In many patients with late antibody-mediated graft loss, even when HLA class I alloantibodies are detectable, HLA class II de novo DSAs are considered to be mainly responsible for rejection. In a recent study on the evolution of HLA alloantibodies after transplantation, de novo DSAs appeared at a mean of 4.6 years after transplantation, and the prevalence of de novo DSAs after 10 years was 20% in those adherent to the immunosuppressive regimen, compared with 60% in nonadherent graft recipients.[46] In another study, DSAs were found in 37% of patients who had an indication biopsy 7 days to 31 years after transplant.[7] De novo DSAs that were directed against HLA class II antigens had an especially strong association with strongly impaired graft survival. A recent development for the detection of harmful DSAs is the introduction of solid-phase assays into a clinical routine, which

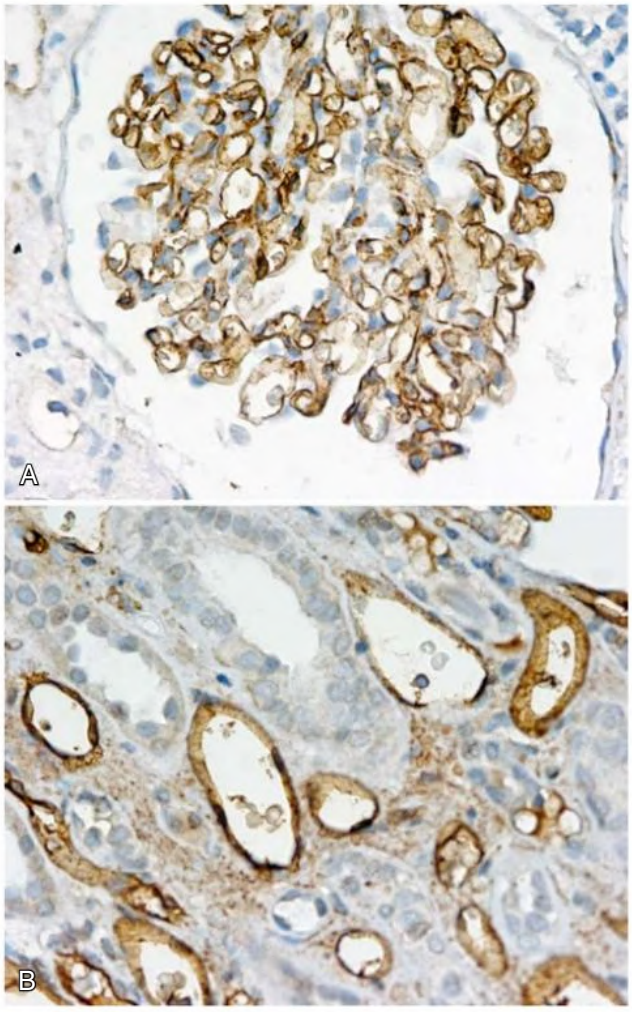

Fig. 112.3 C4d Immunoperoxidase Staining in Association With Chronic Antibody-Mediated Rejection. Staining of glomerular capillaries (A) and circumferential staining of peritubular capillaries (B) are typical.

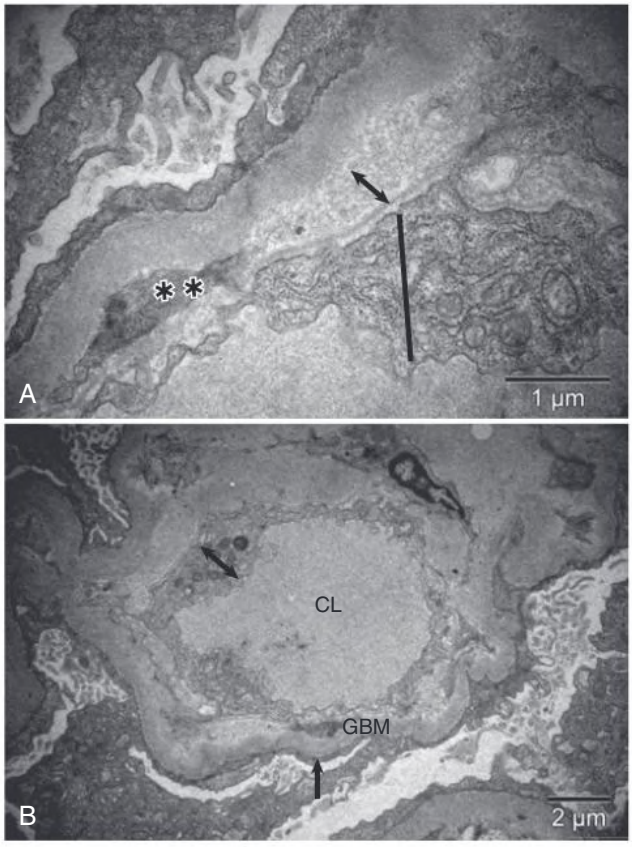

Fig. 112.4 Transplant Glomerulopathy: Electron Microscopy. enables the distinction of complement-binding (C1q assay) HLA antibodies from antibodies that do not bind complement. In a cohort of more than 1000 patients, it was recently demonstrated that the posttransplant occurrence of complement-binding DSA is associated with adverse events. The 5-year graft survival in patients with complement-binding antibodies was 54% compared with 93% in patients with DSAs that were not able to bind complement. The higher risk for graft loss in patients with complement-binding DSAs was attributable to a higher risk for chronic antibody-mediated rejection.[47] Recent preliminary data also suggest that DSAs of different immunoglobulin G subclasses may be associated with different distinct injury phenotypes in kidney allograft biopsies.

Other antibodies that may contribute to chronic antibody-mediated rejection are MHC class I–related chain A antibodies, angiotensin II type 1 receptor–activating antibodies, and other antiendothelial cell antibodies.[48,49]

Insufficient Immunosuppression and Nonadherence to Medication

The recognition that HLA alloantibodies are responsible for a great proportion of late graft losses[37,50] has focused attention on insufficient immunosuppression and nonadherence to immunosuppressive medication (Fig. 112.5).[44,51]

A retrospective analysis of more than 25,000 kidney transplant recipients showed that reduction or discontinuation of cyclosporine, tacrolimus, or mycophenolate mofetil after the first posttransplant year in patients with good graft function was associated with significantly reduced subsequent kidney graft survival.[44] In a recent study in which 64% of graft losses in a cohort with indication biopsies were attributable to (antibody-mediated) rejection, about half of the patients with rejection-associated allograft loss were identified as nonadherent.[51]

Young adults who are in transition from pediatric to adult nephrology care are at high risk for nonadherence. Other risk factors are previous nonadherence, psychiatric disorders, substance abuse, insufficient socioeconomic support, and adverse effects from immunosuppressive medication. Insufficient immunosuppression may also occur during immunosuppressive minimization (tapering) or CNI-avoidance trials. In a recent study, 14 of 61 patients (23%) who were converted from cyclosporine to everolimus at 3 to 4.5 months after transplantation developed DSA, compared with only 7 of 65 patients (11%) who continued on cyclosporine.[41] Eight patients on everolimus but only two patients on cyclosporine developed antibody-mediated rejection. Therefore, such patients should be rigorously evaluated for alloantibodies and antibody-mediated allograft injury according to Transplantation Society Guidelines (see later).[52]

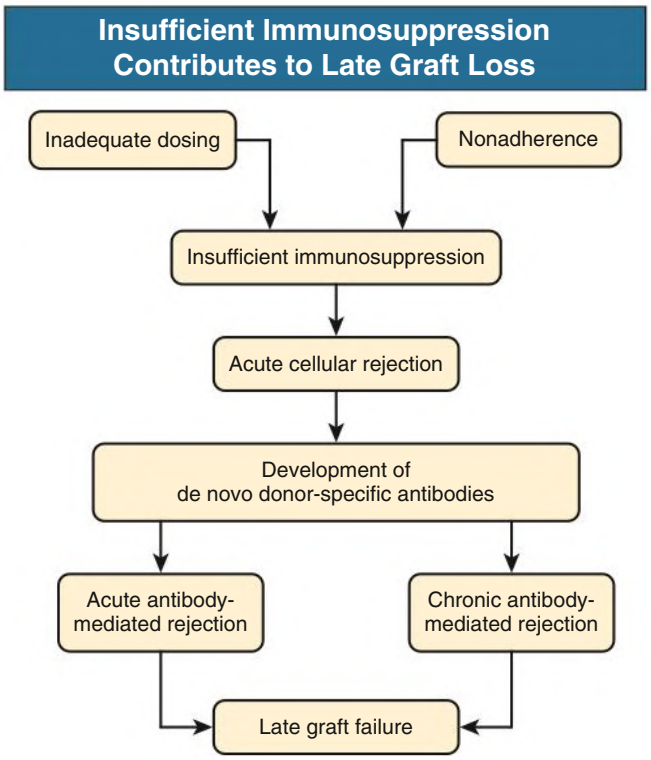

Fig. 112.5 Insufficient immunosuppression contributes to late graft loss.

CLINICAL MANIFESTATIONS

Routine laboratory evaluation of graft function does not facilitate the early diagnosis of chronic allograft injury. A rise in serum creatinine is a late marker of allograft dysfunction. Reduction in the glomerular filtration rate is usually estimated by equations such as the Modification of Diet in Renal Disease (MDRD) formula or the chronic kidney disease epidemiology collaboration (CKD-EPI) formula. However, substantial nephron loss may occur before a rise in serum creatinine becomes evident.

Persistent or worsening proteinuria is also a late sign of chronic allograft injury. Proteinuria greater than 1 g/day typically occurs with recurrent or de novo GN or with severe chronic antibody-mediated changes such as transplant glomerulopathy (see Figs. 112.2–112.4). A definite diagnosis of antibody-mediated rejection requires transplant kidney biopsy together with serologic testing for alloantibodies and viral disease such as BK virus or cytomegalovirus (CMV) infection. So far, no noninvasive tests can reliably diagnose antibody-mediated rejection. The evolution of antibody-mediated graft damage from the binding of DSAs to graft loss is given in Fig. 112.6.

Recently a risk prediction score for long-term kidney allograft failure has been developed and validated. The "iBox" combines functional, histologic, and immunologic allograft parameters together with HLA antibody profiling and showed good performance in predicting the risk of long-term kidney allograft failure.[53]

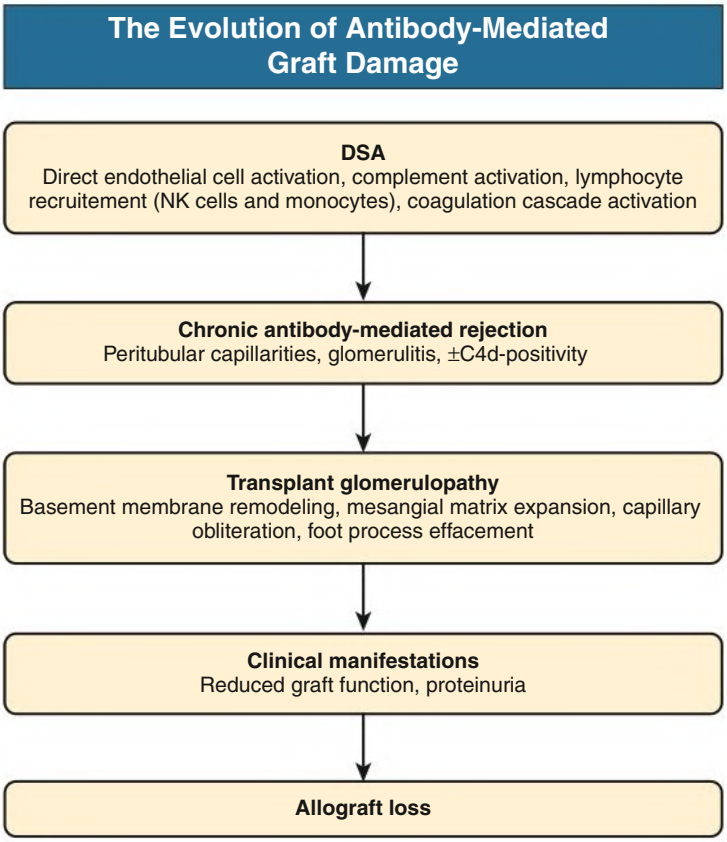

Fig. 112.6 Evolution of antibody-mediated graft damage from the binding of donor-specific antibodies (DSA) to graft loss. *NK,* Natural killer.

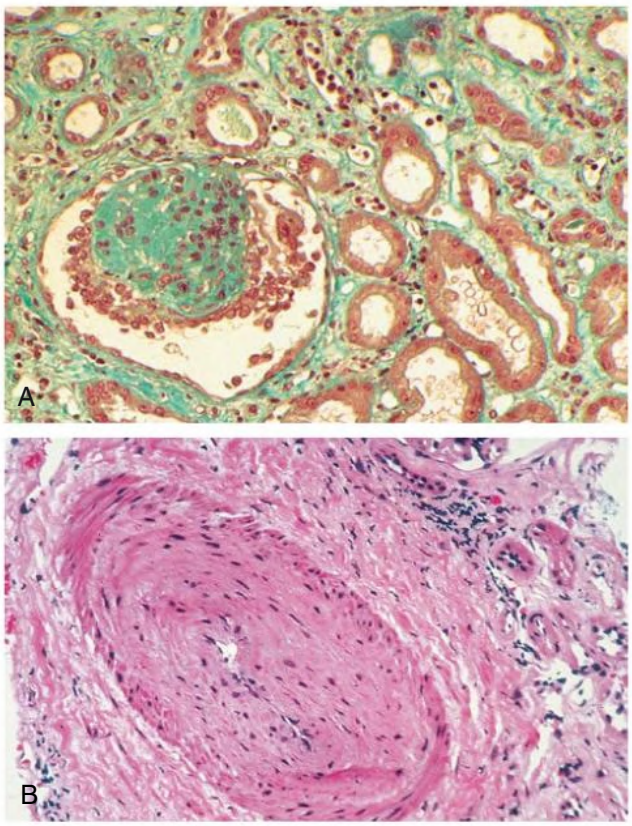

Fig. 112.7 Histologic Features of Chronic Allograft Injury and Interstitial Fibrosis–Tubular Atrophy With No Evidence of Specific Cause. (A) Interstitial fibrosis and glomerulosclerosis. (Trichrome stain.) (B) Fibrointimal proliferation in an intrarenal artery. (PAS stain.)

PATHOLOGY

Chronic IFTA (Fig. 112.7) represents the final pathway of nephron injury and is not specific for any graft disease. IFTA is found in most late graft biopsies, whether a result of early graft damage (e.g., tubular injury from ischemia reperfusion injury, overt or subclinical rejection, or even preexisting disease of the donor) or later graft damage (secondary to CNI toxicity, hypertension and hyperlipidemia, recurrent glomerular disease, or immune-mediated injury) or of unknown origin (IFTA).

Chronic antibody-mediated rejection is characterized by structural remodeling of glomerular basement membranes (GBMs; so-called transplant glomerulopathy) and similar changes in the peritubular capillaries together with IFTA and fibrous thickening of arteries (see Figs. 112.2–112.4). Transplant glomerulopathy is characterized by duplication of glomerular capillary basement membranes and mesangial matrix expansion, in the absence of immune deposits. In addition, deposition of C4d in peritubular and glomerular capillaries can sometimes occur (see Fig. 112.3). Clinicopathologic studies suggest that transplant glomerulopathy is a manifestation of capillary injury occurring in conjunction with interstitial, peritubular capillary, and glomerular inflammation, although it also may occur independently of IFTA or transplant arteriopathy.[54] On electron microscopy (EM), there is expansion of the subendothelial space with deposition of flocculent or fibrillary material, interposition of mesangial cell cytoplasm in the lamina densa, and mesangial matrix expansion (see Fig. 112.4). EM may be used to diagnose transplant glomerulopathy at its earliest stages. Ultrastructural abnormalities characteristic of endothelial activation occur long before GBM duplication and graft dysfunction are evident, implying that endothelial injury is the initial insult that resulted in GBM remodeling.[55] An association between transplant glomerulopathy and peritubular capillary basement membrane duplication has been well described, suggesting that the process resulting in transplant glomerulopathy involves the entire glomerular and peritubular capillary beds.[56,57] It is currently debated whether transplant glomerulopathy represents scarring that is refractory to treatment.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

When chronic allograft injury has been identified by a gradual rise in serum creatinine and/or by new or worsening proteinuria, ultrasound should be performed to exclude ureteral or vascular problems and assess the Doppler resistive index. The Doppler resistive index gives an estimate of intrarenal (but also systemic) compliance and is most useful in longitudinal studies in the same patient to assess progressive graft vascular injury.

In addition, testing for BK virus in plasma is also advised during deteriorating graft function and for all kidney transplant recipients at 3-month intervals during the first 2 years after transplantation. Circulating HLA alloantibodies also should be documented during graft dysfunction and may further guide diagnostics and therapy. Many centers now perform routine HLA alloantibody screening in stable graft recipients at different time points after transplantation to facilitate early diagnosis of antibody-mediated rejection. According to the 2013 The Transplantation Society Consensus Guidelines, nonsensitized first kidney transplant recipients should be tested for DSAs at least once 3 to 12 months after transplantation.[52] In presensitized patients, more frequent testing is recommended. Although there is consensus that HLA alloantibodies are responsible for a significant proportion of late graft losses and that HLA antibodies in the context of deteriorating graft function are harmful, the significance of HLA alloantibodies that are detected solely during routine testing is uncertain.[58,59]

Allograft biopsy is required to rule out a specific allograft pathology together with specific staining, such as C4d, for detection of antibody-mediated allograft injury in all patients and SV40 if there is suspicion for BK virus nephropathy. Other specific examinations of the biopsy specimen for immunoglobulins, complement components, or EM may in addition be useful to rule out recurrence of primary kidney disease or de novo GN. The role of protocol biopsies in the early detection of chronic allograft injury remains controversial.

Diagnosing allograft injury from blood samples represents a new area of research. For example, donor-derived cell-free DNA (dd-cfDNA) comes from the transplanted organ and is exogenous to the respective kidney transplant recipient. An increase of dd-cfDNA levels in the peripheral blood seems to occur even before the serum creatinine level starts rising, which may enable early diagnosis of transplant injury und ultimately avoid premature graft loss.[60] However, randomized controlled trials are still lacking and no firm recommendations can be made.[61]

Because the etiology of chronic allograft dysfunction is multifactorial, any specific diagnosis is made by combination of a biopsy with a review of the patient's history to identify important etiologic factors, such as preexisting donor disease, prior rejection, and high-titer anti-HLA antibodies, as well as issues not related to alloimmunity, such as CNI nephrotoxicity, de novo GN, or recurrent kidney disease. Chronic allograft dysfunction is common and can have many causes. If it is left untreated, it can ultimately result in kidney injury, which, in turn, will heal by scarring and interstitial fibrosis and progress to ESKD.

Prevention of Antibody-Mediated Allograft Injury

In the absence of established treatments of circulating DSAs and chronic antibody-mediated rejection, only prevention of antibody-mediated allograft injury is effective in preventing future graft loss. Once harmful HLA antibodies such as C1q-binding DSA are detectable, it becomes very difficult to avoid allograft injury and decline of kidney function. Preventive measures include avoidance of sensitization by limitation of blood transfusions and poor HLA matching during first transplantations.[62,63] The introduction of epoetin led to a dramatic decrease of recipient sensitization by a significant reduction in blood transfusions.[64] Sensitization should especially be avoided in young patients who may require retransplantation during their lifetime. New measures, such as matching for antibody epitopes in addition to whole HLA alleles, may further help preventing sensitization.

When the patient is already sensitized, antibody-mediated allograft injury can best be prevented by transplantation of the patient with an organ against which the recipient has not developed HLA alloantibodies. This may be achieved by inclusion of patients in special programs such as Eurotransplant Acceptable Mismatch Program or by kidney-paired donation.[64,65] However, successful transplantation in patients with preexisting HLA alloantibodies usually requires desensitization in combination with other measures.[66]

After transplantation, chronic antibody-mediated allograft rejection is best prevented by conventional triple-drug therapy including a CNI (preferably tacrolimus), an antiproliferative agent (preferably mycophenolic acid–based therapy), and corticosteroids. Induction therapy, with an interleukin-2 receptor antagonist or antithymocyte globulin, should be used to prevent early acute cellular rejection.

Insufficient immunosuppression and nonadherence may lead, unless a patient is prone to tolerance, to cellular rejection and then, via development of de novo DSA, to antibody-mediated rejection and graft loss. Precise knowledge of the patient's alloantibody status before and after transplantation is a prerequisite for early diagnosis of allograft injury and early and targeted treatment to prevent antibody-mediated rejection and ensure long-term graft survival. HLA alloantibodies should be tested at least once after transplantation in all patients. In immunologically high-risk patients, desensitized patients, patients with suspected rejection, and during therapy of antibody-mediated rejection, antibodies need to be monitored more frequently with the goal of recognizing allograft injury in its early stages and preventing its progression to chronic rejection.[52] Additional patient groups who may benefit from HLA alloantibody monitoring are patients who receive reduction, withdrawal, or change of immunosuppressive drugs, especially in the context of CNI- or steroid-free regimens. Protocol biopsies may further help in guiding posttransplant therapy at least in high-risk recipients, although definitive proof is lacking.

Strategies for the prevention of chronic allograft injury are summarized in Box 112.2.

Treatment of Chronic Allograft Injury

Although reduction of blood pressure to less than 130/80 mm Hg is believed to be beneficial, the preferred agent for blood pressure reduction remains controversial; in particular the use of angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) has not uniformly shown benefit.[67,68] Nor have there been specific studies confirming the benefits of reducing proteinuria in chronic allograft injury, although by extrapolation for other progressive proteinuric diseases, there is strong a priori evidence for the benefits of renin-angiotensin system blockade with dietary salt restriction.

A beneficial effect of treating dyslipidemia with statins in the transplant recipient also remains controversial,[69,70] and the adverse effects of statins such as rhabdomyolysis when used with CNIs must be considered. After a specific diagnosis had been established, targeted treatments can be initiated. These are summarized in Box 112.3.

BOX 112.2 Strategies for the Prevention of Chronic Allograft Injury

- Avoid sensitization in future organ recipients (e.g., avoid blood transfusions, avoid poor HLA matching during first transplantation).
- Obtain complete donor and recipient typing and precise knowledge on HLA alloantibodies at time of transplantation.
- Minimize ischemia/reperfusion injury (e.g., short cold ischemia time).
- Avoid insufficient immunosuppression.
- Perform prophylaxis for CMV (first 3–6 months).
- Test for BK virus after transplantation.
- Monitor donor-specific HLA alloantibodies after transplantation (at least in presensitized patients or during drug minimization).
- Perform protocol biopsies to detect subclinical rejection (at least in presensitized patients or during drug minimization).
- Review for nonadherence.

CMV, Cytomegalovirus; *HLA,* human leukocyte antigen.

BOX 112.3 Treatment of Chronic Allograft Injury

Treatment (Nonimmune)

- Treat hypertension (consider ACE inhibitors or AT_1 receptor antagonists)
- Lifestyle modification (stop smoking, control lipids)
- Control diabetes
- Prevention and treatment of urinary tract infection
- Target CNI toxicity by reduction or replacement of CNI (caveat: risk for insufficient immunosuppression)

Treatment (Alloimmune)

- Diagnose and treat early acute cellular rejection by steroids or antithymocyte globulin
- Diagnose and treat acute antibody-mediated rejection by means such as plasmapheresis or immunoadsorption ± anti-CD20 therapy
- Diagnose and treat chronic antibody-mediated rejection by means such as intravenous immunoglobulins ± anti-CD20 therapy
- Consider proteasome inhibitor, CD38 inhibitors, IL-6 receptor inhibitor, complement blockade, or the cysteine protease imlifidase (no clear evidence).

ACE, Angiotensin-converting enzyme; *AT_1,* angiotensin 1 receptor; *CNI,* calcineurin inhibitor.

SELF-ASSESSMENT QUESTIONS

1. Which one of the following is believed to be mainly responsible for late kidney graft loss?
   - **A.** Hypertension and hyperlipidemia
   - **B.** New-onset diabetes after transplantation
   - **C.** Recurrence of primary disease
   - **D.** HLA alloantibodies
   - **E.** Calcineurin inhibitors
2. Chronic antibody-mediated rejection:
   1. may be C4d negative in graft biopsy samples.
   2. has specific histopathologic features.
   3. is found more often in patients nonadherent to immunosuppressive medication.
   4. can be mediated only by HLA alloantibodies.
   5. is targeted by reduction of immunosuppression.

   - **A.** 1 and 2 are correct
   - **B.** 1, 2, 3, and 4 are correct
   - **C.** 1, 2, and 3 are correct
   - **D.** All are correct
   - **E.** No answer is correct
3. Clinical manifestations of chronic antibody-mediated rejection are:
   1. a rise in serum creatinine.
   2. a rise in protein excretion.
   3. specific for chronic antibody-mediated rejection.
   4. often late signs that occur after significant allograft damage has already occurred.

   - **A.** Only 1 is correct
   - **B.** 1 and 2 are correct
   - **C.** All are correct
   - **D.** 1, 2, and 3 are correct
   - **E.** 1, 2, and 4 are correct

Recurrent Disease in Kidney Transplantation

Steven J. Chadban, Melanie Wyld

Kidney transplantation is a treatment, not a cure. Although transplantation can restore kidney function, it rarely removes the cause of the original kidney disease and recurrence is dreaded by patients and clinicians alike. Globally, glomerulonephritis (GN) and diabetes are the two leading causes of kidney failure and are the most common primary diseases in patients undergoing kidney transplantation. That both GN and diabetes can recur after transplantation is a source of consternation for recipients and clinicians.

Recurrence is typically a time-dependent phenomenon. The likelihood of recurrence increases as the graft ages. With increased graft survival rates over the past 30 years, the apparent incidence of recurrence has grown.[1,2] An analysis of U.S. Renal Allograft Disease Registry data examining GN recurrence demonstrated a prevalence of 2.8% at 2 years, 9.8% at 5 years, and 18.5% at 8 years of follow-up after transplantation, and such patients were twice as likely to experience graft failure compared with those without recurrence.[3]

Recurrence has a powerful adverse impact on transplant survival, which is increasingly apparent as time since transplantation lengthens. In an analysis of data from the Australia and New Zealand Dialysis and Transplant Registry (ANZDATA) including more than 7968 patients with GN who received a kidney transplant, biopsy-proven recurrence was found in approximately 10% over the median follow-up time of 8.6 years, with 45% of those losing their graft within 5 years of the recurrence[2] (Fig. 113.1). For those with GN, recurrent disease is the third most common cause of graft loss after the first year after transplantation, behind death with a functioning graft and chronic rejection (CR) but substantially ahead of acute rejection (see Fig. 113.1).[4] However, for those with known recurrent disease, it is the most common cause of graft loss.[2]

De novo GN and new-onset diabetes after transplantation (NODAT) may affect the transplanted kidney, although both are relatively uncommon causes of graft failure and may be difficult to distinguish from recurrence or from CR. Like recurrent disease, the prevalence of both appears to increase with time after transplantation. Given the high incidence of NODAT and increasing graft survival in recent eras, de novo diabetic nephropathy may become a significant clinical problem in the future. However, the major impact of NODAT in the first 10 years after transplantation is an increase in cardiovascular (CV) mortality with little impact on death-censored graft failure.[5]

DEFINITIONS

Diagnosis of recurrence requires histologic demonstration of the same disease involving both the native and transplanted kidneys. Diagnosis of recurrence causing graft failure requires a clinical decision that recurrence was the dominant contributor to graft loss (other contributors, such as CR, may be present).

The incidence of recurrent disease is probably underestimated because a histologic diagnosis of the primary kidney disease is not always obtained, and many transplant biopsies are not done with recurrent disease in mind, so immunohistologic and electron microscopic (EM) examination (mandatory for optimal diagnosis of recurrent disease) may not be undertaken.[1] In addition, a clinical diagnosis of CR is often made in patients with declining graft function and proteinuria, so that recurrent disease is not properly excluded.

Additional factors confound the available evidence. Many reports of disease recurrence are retrospective, single-center studies. Recall bias and incomplete documentation, changes in practice over time, and peculiarities of local patient populations and local practices may limit relevance to other populations. The most definitive reports have come from analyses of the large registry databases of Europe, the United States, and Australasia (the latter registry being known as ANZDATA). Registries capture data on large numbers of patients but are still subject to bias because of factors including unit participation rates, quantity and type of data collected, accuracy, consistency of reporting, and reliability of data entry. How recurrence is defined and diagnosed and which outcomes are measured is crucial. For example, immunoglobulin A nephropathy (IgAN) recurred in 58% of patients in one series in which all recipients underwent biopsy,[6] but in approximately 25% of cases in which biopsy was performed only when clinically indicated.[7] When graft loss from IgAN recurrence is the outcome measure, the risk decreased to approximately 10% at 10 years of follow-up.[4] Thus, definition of recurrence, outcome measures, study design, era, and source of data all need to be considered in assessing the published literature.

RECURRENT GLOMERULONEPHRITIS

Many types of GN may recur after transplantation; however, the rate and consequences of recurrence vary enormously. For example, anti–glomerular basement membrane disease (anti-GBM; Goodpasture disease) recurs only rarely, but when it does, it is likely to cause rapid graft loss. In contrast, C3 glomerulopathy (formerly known as dense deposit disease and/or type II membranoproliferative glomerulonephritis [MPGN]) recurs in over 80% of patients; however, the disease tends to be very slowly progressive, and graft survival beyond 10 years is typical. Recurrence of focal segmental glomerulosclerosis (FSGS), IgAN, and membranous nephropathy (MN) are the most frequently encountered clinical problems (Fig. 113.2).

Several factors may influence the risk for recurrence in addition to the type of GN. Time since transplantation is clearly important and may be related to the duration of graft exposure to the nephritogenic factors responsible for GN.[1] Those grafts that survive long term are exposed to nephritogenic factors for longer and are more likely to develop recurrent GN. Consistent with this, recipients of human leukocyte antigen (HLA)-identical transplants rarely experience rejection

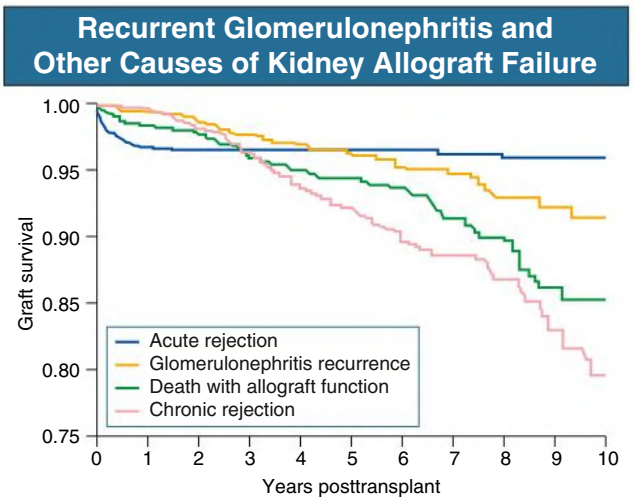

Fig. 113.1 Recurrent Glomerulonephritis (GN) and Other Causes of Kidney Allograft Failure. Kaplan-Meier analysis of the relative contributions of acute rejection, GN recurrence, death, and chronic rejection to graft loss during the first 10 years after transplantation among patients who underwent transplantation because of end-stage kidney disease caused by GN. (Modified from Briganti EM, Russ GR, McNeil JJ, Atkins RC, Chadban SJ. Risk of renal allograft loss from recurrent glomerulonephritis. *N Engl J Med.* 2002;347[2]:103–109.)

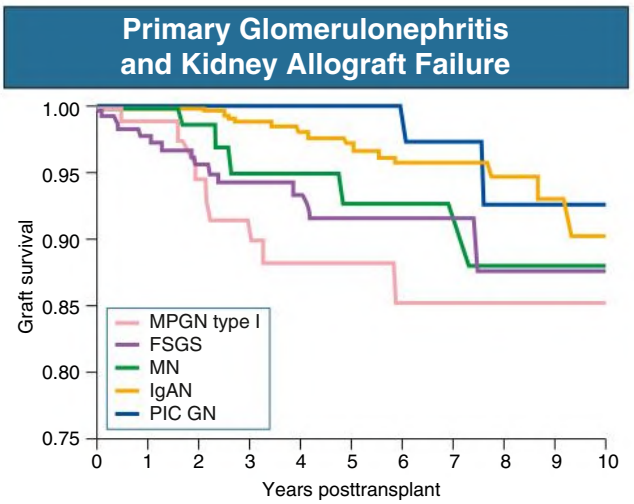

Fig. 113.2 Primary Glomerulonephritis (GN) and Kidney Allograft Failure. Kaplan-Meier analysis of freedom from graft loss caused by recurrent GN during the first 10 years after kidney transplantation among patients with a primary diagnosis of GN. *FSGS,* Focal segmental glomerulosclerosis; *IgAN,* IgA nephropathy; *MN,* membranous nephropathy; *MPGN,* membranoproliferative glomerulonephritis; *PIC GN,* pauci-immune crescentic glomerulonephritis. (Modified from Briganti EM, Russ GR, McNeil JJ, Atkins RC, Chadban SJ. Risk of renal allograft loss from recurrent glomerulonephritis. *N Engl J Med.* 2002;347[2]:103–109.)

and enjoy prolonged graft survival but have a high rate of recurrent GN.[8] In one report of HLA-identical recipients, recurrent GN was present in 36% to 42% of those in whom biopsy was performed and resulted in 24% of graft losses, being the second most frequent cause of graft loss after death in this group.[8] Patients sustaining first graft loss from recurrent GN are also at higher risk for recurrence in a subsequent graft.

Improvements in immunosuppression over the past 40 years have led to reduced rates of acute rejection. Such improvements also may have had an impact on rates of graft loss from IgAN recurrence, which has declined by nearly 50% over the past 10 years according to one ANZDATA registry analysis.[9]

U.S. Renal Data System (USRDS) registry data failed to demonstrate that any individual immunosuppressive agent is superior for preventing recurrence.[10] Nevertheless, the immunosuppressive regimen may be important. For example, one small retrospective study found that induction therapy with rabbit antithymocyte globulin was associated with a lower risk for IgAN recurrence compared with either anti-CD25 antibodies or no induction.[11] Corticosteroid withdrawal may lead to increased rates of recurrence,[12] especially in recipients with IgAN, in whom a twofold increase in the risk for graft failure from recurrence of IgAN has been reported.[9] Similarly, inclusion or addition of cyclophosphamide to immunosuppressive regimens may treat recurrent vasculitis affecting the graft.[13] Sirolimus or everolimus may result in proteinuria and kidney dysfunction, especially in patients with underlying GN, suggesting that mammalian target of rapamycin (mTOR) inhibition may accelerate preexisting glomerular injury in the graft.[14] Effects of individual agents are likely to be disease-specific, but the necessary data remain sparse.

Strategies to reduce the risk for recurrence have been reported. Bilateral native nephrectomy to eliminate persistent antigenic stimulation appears unhelpful; indeed, nephrectomized patients experienced a higher incidence of recurrence compared with those with native kidneys left in situ in one large single-center retrospective study.[15] Induction of disease remission before transplantation and prolonged time on dialysis pretransplantation (both aimed at permitting disease "burnout") do not appear to be effective except in the case of anti-GBM disease, in which a delay in transplantation until the patient has been serologically negative for at least 6 months virtually eliminates the risk for recurrence.[4] Avoiding living related donation to recipients with FSGS has been debated for years but overall appears not to have any impact on risk of recurrence.[16]

As with GN in native kidneys, proteinuria, deterioration in kidney function and, to a lesser extent, hematuria are the cardinal manifestations of recurrent GN.[17] The pattern of kidney and extrarenal manifestations is frequently similar to that of the native disease, except that the overall rate of progression may be slower. Extrarenal features of the primary condition may recur, such as thrombocytopenia and hemolysis in hemolytic uremic syndrome (HUS) and extrarenal vasculitis in recurrent antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis. Serology may be helpful in some patients, such as anti-GBM antibody detection in those with Goodpasture disease, but not necessarily in others, such as those with recurrent lupus nephritis (LN).

The differential diagnosis of recurrent GN is clinically important because it may influence management (Table 113.1). Chronic rejection and diabetic nephropathy, recurrent or de novo, may manifest with progressive graft dysfunction, proteinuria, and hypertension and may therefore be clinically indistinguishable from recurrence. De novo GN also should be considered. Viral diseases of the kidney should be considered (particularly BK nephropathy) because reducing immunosuppression, and in selected instances, antiviral drugs may provide benefit. Obstructive uropathy and tumors involving the graft should be excluded by an ultrasound scan. Finally, recurrence may coexist with chronic rejection or calcineurin inhibitor (CNI) toxicity. Indeed, every condition that can lead to chronic graft dysfunction should be considered in the differential diagnosis of recurrence (see Table 113.1 and Chapters 109 and 110).

Histologic evidence of recurrence is required in all patients. Biopsy can provide the diagnosis, exclude alternative diagnoses that may require different approaches to treatment, and provide important prognostic information pertinent to the affected graft and also relevant to any future consideration of retransplantation. Full evaluation of

TABLE 113.1 Differential Diagnosis of Recurrent Glomerulonephritis

Diagnosis	Frequency and Timing	Clinical Features	Laboratory Features	Biopsy Features	Management
Recurrent glomerulonephritis	Common; variable timing, days to years	Proteinuria, hematuria, kidney impairment, hypertension	Similar to primary glomerulonephritis; serology may be negative	Same as primary glomerulonephritis[5]	Disease specific
De novo glomerulonephritis	Uncommon; variable timing but typically later than recurrence	Proteinuria, hematuria, kidney impairment	Type specific	Type specific[5,8]	Antiprogression strategies (see Chapter 82)
Chronic rejection	Very common; increasing incidence with time	Hypertension, proteinuria, kidney impairment Calcineurin inhibitor exposure		Tubulointerstitial fibrosis, arteriolar hyalinosis, transplant glomerulopathy	Minimize calcineurin inhibitor and antiprogression strategies (see Chapter 82)
Graft pyelonephritis	Uncommon; typically early after transplantation	Fever, pyuria, kidney impairment	Positive blood or urine cultures	Neutrophil infiltration	Antibiotics
BK nephropathy	Uncommon; typically 1–5 y after transplantation	Kidney impairment, decoy cells in urine	Serum BK PCR positive	Tubulitis with tubular cell atypia and inclusions, normal glomeruli	Minimize immunosuppression and consider antiviral drugs
Acute rejection	Common; early	Kidney impairment, oliguria	Nonspecific	Tubulitis with or without vasculitis[15]	Increase immunosuppression
Kidney tumor/PTLD	Uncommon, rare; early or late	Kidney impairment, kidney mass	Anemia, EBV positive	Atypical cells, mitoses, monoclonality	Minimize immunosuppression, consider chemotherapy

EBV, Epstein-Barr virus; *PCR,* polymerase chain reaction; *PTLD,* posttransplantation lymphoproliferative disease.

the biopsy specimen by light microscopy, immunohistology, and EM is desirable and, in many patients, essential to confirm recurrence.[18] Light microscopy and immunohistology are necessary to differentiate recurrent from de novo GN, rejection, and CNI toxicity. The presence of tubulitis should suggest acute rejection. Chronic rejection may produce chronic interstitial inflammation and transplant glomerulopathy, which may be indistinguishable from MPGN on light microscopy (Fig. 113.3; see also Chapter 109). The use of immunohistology to define the immunoglobulin and complement component content of immune deposits and EM to establish the structure of basement membrane and location of deposits may clarify the diagnosis.[18] The risk of recurrence for common histologic types of kidney disease is summarized in Table 113.2.

RECURRENCE OF SPECIFIC GLOMERULAR DISEASES

Immunoglobulin A Nephropathy and IgA Vasculitis (Henoch-Schönlein Purpura)

IgAN is the most common form of GN leading to kidney failure, and affected patients frequently become transplant recipients. Histologic recurrence is frequent and increases with time since transplantation. Published recurrence rates vary greatly (from 8%–53%). Much of this variation appears to be because of study differences in biopsy indication (protocol or clinical) and length of posttransplant follow-up.[19] The highest published recurrence rates are from centers performing protocol biopsies in addition to those that are clinically indicated. This is likely because the early stages of IgAN recurrence are frequently not accompanied by clinical changes, such as proteinuria, hematuria, or graft dysfunction.[19]

Recurrence is difficult to predict. No large prospective multicenter cohort studies demonstrate risk factors for histologic and/or clinical recurrence. Single-center studies and registry analyses suggest that younger age at transplantation, rapid progression of the native IgAN, degree of proteinuria, and donor factors (including HLA matching) may be associated with higher risk.[17] The suspicion that living donor grafts have higher rates of recurrence than deceased donors has not been confirmed.[17] Thus, patients with IgAN should not be precluded from consideration for living donor transplantation. The number of HLA mismatches between donor and recipient also may have a role in recurrence rates. Two Australian registry studies have found that those with zero mismatch kidneys have higher rates of recurrence than those with one or more HLA mismatches.[9,20] Similarly, ABO-incompatible transplants have been found to have lower rates of recurrence, possibly because of differences in immunosuppression regimens.[21]

Choice of immunosuppression after transplantation is controversial. One large USRDS registry analysis suggested that individual drug choices did not affect the risk for graft loss attributed to recurrence.[10] In contrast, a retrospective analysis of ANZDATA found that continuation of corticosteroids was strongly associated with protection from graft loss caused by recurrence of IgAN, although not from other types of GN.[9] Observational data also suggest that induction with antithymocyte globulin may afford relative protection.[11]

The clinical expression of recurrent disease is variable and time dependent. Graft loss within the first 3 years after transplantation is uncommon (see Fig. 113.2), although it can occur, particularly when IgAN in the native kidney was rapidly progressive or after previous graft loss from recurrence.[7] An Italian cohort study of 190 patients followed for 15 years reported that of the 22% of patients who developed recurrence, almost a third ultimately lost their graft because of IgAN

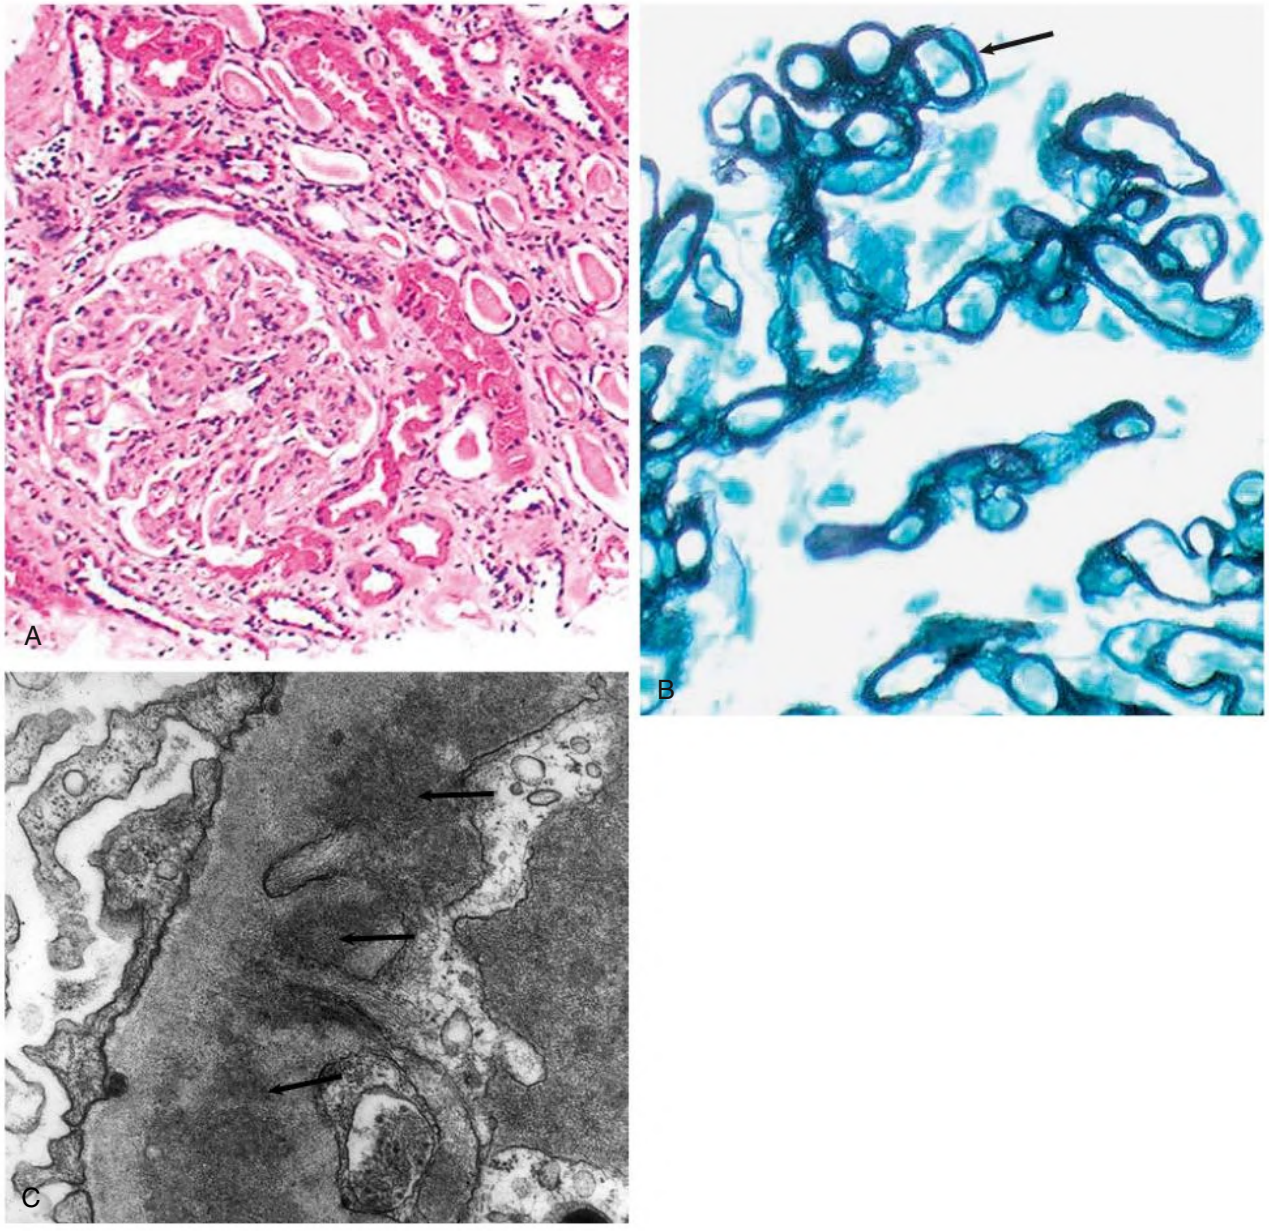

Fig. 113.3 Transplant Glomerulopathy and Membranoproliferative Glomerulonephritis (MPGN). Transplant biopsy specimen from a patient with end-stage kidney disease caused by biopsy-proven idiopathic MPGN type I, who received a kidney transplant and had a progressive reduction in glomerular filtration rate with proteinuria 1.5 g/day and hypertension. (A) Light microscopy. Glomerular hypercellularity and lobulation on a background of chronic interstitial inflammation and fibrosis, with protein casts within dilated tubules. (Hematoxylin-eosin stain; ×100.) (B) Subendothelial deposits and basement membrane reduplication *(arrow)*. (Methenamine silver stain; ×400.) (C) Electron microscopy showing subendothelial electron-dense deposits *(arrows)* (×7500). There were also prominent C3 deposits on immunofluorescence (not shown). Light microscopy was therefore suggestive of recurrent MPGN but was also consistent with chronic rejection (CR) with transplant glomerulopathy associated with CR. Immunofluorescence and electron microscopy (subendothelial deposits) confirmed recurrence of MPGN. Compare these images with Figs. 112.3 and 112.4. (A–B, Courtesy Dr. Paul McKenzie, Royal Prince Alfred Hospital, Sydney, Australia.)

recurrence during follow-up.[22] Death-censored graft survival at 15 years was approximately 10% lower in patients who had IgAN than in controls, largely attributable to IgAN recurrence.

Recurrence of IgA vasculitis (IgAV) is less well characterized but appears to be similar to IgAN. An analysis of the United Network for Organ Sharing (UNOS) database including 339 patients with kidney failure caused by IgAV who received a first kidney allograft reported a frequency of graft loss caused by recurrence of 13.6% and no difference in 10-year graft survival between recipients with IgAN (58.4%) or IgAV (59.3%) as their primary kidney disease.[23]

Treatment of recurrent IgAN and IgAV has not been systematically evaluated. The addition of corticosteroid maintenance in corticosteroid-free patients with recurrence is unproven but reasonable. A change to mycophenolate mofetil (MMF) or the use of fish oil, antiplatelet agents, and tonsillectomy cannot be recommended. The use of nonspecific measures to prolong kidney survival is appropriate,

TABLE 113.2 Recurrent Diseases in Kidney Transplants and Effects on Graft Survival

Disease	Clinical Recurrence Rate (%)	Graft Loss in Recurrent Disease (%)
Primary focal segmental glomerulosclerosis	20–50 (children), 10–15 (adults)	40–50
Membranoproliferative glomerulonephritis type 1	20–30	30–40
Dense deposit disease	80	20, often late
Hemolytic uremic syndrome (HUS)		
Classic D+ HUS	0–13	Uncommon
Atypical D– HUS	30–50	55–100
Familial HUS	57	Approaching 100
IgA nephropathy	30–40, increases with longer duration of follow-up (30%–60% histologic recurrence rate)	16–33
IgAV (Henoch-Schönlein purpura)	Rare (despite 50% histologic recurrence rate)	Rare
Membranous nephropathy	10–29 (histologic recurrence may be more common)	Up to 50
Systemic vasculitis, including granulomatosis and microscopic polyangiitis	10–20	20–50
Anti-GBM disease (Goodpasture disease)	<5	50
Systemic lupus erythematosus	1–30	Rare
Amyloidosis	25	10–20

including tight blood pressure control, renin-angiotensin system (RAS) blockade, and avoidance of nephrotoxins.

Membranous Nephropathy

Histologic recurrence of MN can be found in up to 40% of grafts,[24] and for those with documented recurrence, graft loss rates of over 50% at 3 years of follow-up have been reported.[25,26] Patients who have previously lost a graft to recurrence are at higher risk on retransplantation, but disease course, duration of dialysis, HLA genotype, graft source, and immunosuppression have not been found to predict recurrence risk.[26]

In 2009 M-type phospholipase A_2 receptor (PLA_2R) was identified as the antigen targeted in 70% to 80% of idiopathic MN.[27] This has spurred interest in the use of anti-PLA_2R antibody titers in monitoring disease activity and predicting recurrence. A number of small single-center and multicenter observational studies suggested a role for the adoption of PLA_2R measurement as a clinical tool in transplantation, with higher levels at transplantation associated with higher rates of recurrence.[28–31] The largest of these studies reported a recurrence rate of 57% among patients with primary MN, with a median time to recurrence of 4.1 months.[28] The positive predictive value of pretransplant anti-PLA_2R antibodies was 83% (10 of 12), and the negative predictive value was 42% (5 of 12).[28] Current data show that the presence of anti-PLA2R at the time of transplant increases the risk for recurrence; however, both sensitivity and specificity are imperfect and larger studies are required. At present, there is insufficient evidence to recommend delaying transplantation until anti-PLA_2R antibody status is negative; however, rising titers should warrant caution and consideration of a delay in transplantation.

Management of recurrent MN is based on anecdotal reports and extrapolation of data on the management of native kidney MN. There has been some success with rituximab reported in small case series, but the findings await confirmation in a randomized trial. Spontaneous remission appears to be less common than is seen in MN affecting native kidneys. The cumulative exposure to immunosuppressive therapy should be considered because these patients may be at increased risk for lymphoma. Living donor transplantation appears warranted for first grafts but in our opinion should probably be avoided for second grafts if the first was lost early because of recurrence.

To diagnose recurrence requires a native kidney biopsy showing MN and a graft biopsy showing MN. This is especially important in MN, in which de novo MN has been reported in 2% to 15% of transplant recipients and tends to manifest more insidiously and later than recurrent MN.[32]

Focal Segmental Glomerulosclerosis

FSGS recurs in 20% to 30% of first transplants.[33–35] FSGS is a heterogeneous group of conditions and those with familial or sporadic forms associated with mutation of slit-diaphragm proteins such as podocin do not recur, although rare cases of posttransplant nephrotic syndrome caused by the development of antibodies directed against the "neoantigen" within the donor kidney have been reported. FSGS secondary to obesity, vascular disease, or reflux nephropathy and those with a very slow rate of progression are at very low risk for recurrence. In contrast, patients with primary FSGS and in particular those with an aggressive initial course (heavy proteinuria and kidney failure within 3 years of onset), age younger than 15 years, mesangial hypercellularity on biopsy, or with recurrence in a previous graft are at greatest risk.[34,35] The rate of recurrence is higher than 75% in subsequent grafts when the first graft was lost because of recurrence.[36] Living related donor transplantation has previously been implicated as a risk factor for recurrence; however, a large USRDS analysis refutes this notion,[16] and ANZDATA data show improved graft survival from living donors.[37]

Recurrence may occur early (typically within the first month posttransplantation) and initially manifests with heavy proteinuria, followed by hypertension and graft dysfunction. Patients with recurrent disease appear more susceptible to acute rejection and acute kidney injury[38] and graft loss. Recurrence has been associated with early graft loss in up to 50% of patients[33,34,37]; however, treatment with plasma exchange appears to have delayed graft loss in many patients and decreased the incidence of overall graft failure[4,33] (see Fig. 113.2).

Primary FSGS appears to be caused by a circulating factor that targets podocytes, although the specific factor(s) involved remain unknown. Soluble urokinase plasminogen activator receptor (suPAR) and the costimulatory protein B7-1 (CD80) have been proposed to mediate recurrence; however, reports have been anecdotal and subsequent studies have failed to prove the role of either molecule or consistently demonstrate success with therapies targeting them.[39–43]

Plasma exchange or immunoadsorption with either a protein A or anti-IgG column is effective for some patients who develop recurrent FSGS, presumably because it removes the circulating permeability factor.[44,45] Although not studied in a randomized controlled trial (RCT), several series have reported disease remission in the majority of patients who receive treatment within 2 weeks of recurrence.[45,46] The potential for positive publication bias and the absence of RCT evidence make prognostic information speculative; however, response rates appear likely to exceed 50% when therapy is commenced within 2 weeks of clinical recurrence, with lower response rates anticipated when therapy is delayed.[46] Given that graft survival appears to be significantly prolonged in patients who respond to therapy, a course of plasma exchange is warranted in all patients without contraindications (see Chapter 104). Immunosuppression should include a CNI, and the addition of an angiotensin-converting enzyme (ACE) inhibitor should be considered. A minority of patients with an incomplete response or relapse after cessation of initial therapy will require repeated or long-term plasma exchange[47] or concurrent treatment with secondary agents such as rituximab or cyclophosphamide.[45,47–49] For such patients, we recommend a course of rituximab 500 mg weekly for 4 weeks, in addition to existing immunosuppression and weekly plasma exchange. Pretransplantation plasma exchange has not been shown to be beneficial for preventing recurrence. See Fig. 113.4 for an approach to the management of recurrent FSGS.

Minimal change disease is a far less frequent cause of kidney failure. Recurrence of disease after transplantation has been reported; however, it is difficult to be sure that the underlying disease was not FSGS.

Membranoproliferative Glomerulonephritis

Glomerular diseases with an MGPN pattern of injury are classified into immune complex (IC-MPGN) and complement-mediated forms (see Chapters 22 and 23).[50,51] Recurrent MPGN bears major clinical and histologic similarities with the subgroup of patients with CR who have transplant glomerulopathy, and comprehensive assessment of transplant biopsy specimens (see Fig. 113.3 and compare Figs. 112.3 and 112.4), as well as accurate diagnosis of the native kidney disease, is crucial in making this distinction (see Table 113.1). IC-MPGN, rather than transplant glomerulopathy, is suggested by the presence of crescents on light microscopy, stronger staining for C3 and weaker staining for IgM on immunohistologic examination, and subendothelial electron-dense deposits on EM.[18] This distinction has important clinical implications, particularly because recurrence carries a higher risk for subsequent recurrence should retransplantation be considered. A

Authors' recommendation based on Davenport.[47] *ACE,* Angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *CNI,* calcineurin inhibitor; *uPCR,* urine protein-to-creatinine ratio.

retrospective analysis of kidney biopsies that included 70 patients with MPGN suggested that the severity of histologic lesions is predictive of recurrence.[52]

Immune Complex Membranoproliferative Glomerulonephritis

IC-MPGN appears to be mediated by glomerular deposition of immune complexes, triggered by exposure to endogenous or exogenous (e.g., hepatitis C virus [HCV]) antigens or related to a monoclonal gammopathy. Because the antigens are not necessarily removed by transplantation, recurrence of disease is possible and is seen in 20% to 45% of kidney recipients.[50,53–56] Graft loss has been reported in up to 50% of those with recurrence, and the risk for recurrence in subsequent grafts approaches 80%.[50,57–59] Significant geographic diversity in the risk for recurrence is evident, with much higher rates of graft loss resulting from recurrence in areas where the majority of patients with IC-MPGN are HCV positive, such as Spain,[53] compared with low-HCV prevalence areas, such as Australia.[4]

No form of treatment for recurrent IC-MPGN has been proven effective, and the underlying cause of MPGN should be considered in each patient. In HCV-associated IC-MPGN, direct-acting antiviral therapy is effective for virus elimination and should provide substantial protection from HCV viremia and IC-MPGN recurrence after transplantation. Other forms of IC-MPGN have been successfully treated with immunosuppression or plasma exchange.

C3 Glomerulopathy

Complement-mediated MPGN, also referred to as C3 glomerulopathy, is a disease process secondary to dysregulated complement activation (see Chapter 23). There are two subtypes determined by EM appearance: C3 GN and dense deposit disease (DDD).[51] DDD has clinical and histologic similarities to transplant glomerulopathy. It is suggested by granular staining for C3 on capillary loops without immunoglobulin deposits, and the characteristic ribbon-like intramembranous dense deposits on EM (see Fig. 22.2).[18,60] DDD has been found to recur in 50% to 80% of grafts, typically manifesting with proteinuria, hematuria, and slowly progressive loss of kidney function.[61] The disease course tends to be slow, and whereas graft loss caused by recurrence is ultimately seen in the majority of patients, this generally occurs beyond the first 10 years after transplantation.[4,61] Graft loss has been associated with male sex, crescents on biopsy, and heavy proteinuria.[61] No effective therapy is known, and although plasma exchange and immunosuppression have been described, these are not supported by good evidence, and control of blood pressure and proteinuria with RAS blockade is the preferred therapy. Given the role of alternate complement pathway mutations in DDD (see Chapter 23), administration of complement antagonists such as eculizumab may be beneficial but remain unproven, with inconsistent results reported in published case series to date.[59,62–64]

Congenital Nephrotic Syndrome

Congenital nephrotic syndrome of the Finnish type has been reported to recur after transplantation and cause graft loss; however, the mechanism of kidney damage is likely different between primary and recurrent disease. The primary disorder in some cases is caused by a mutation of the *NPHS1* gene that results in the complete absence of nephrin, and therefore transplantation causes de novo exposure to nephrin in the transplanted kidney. Neoantigen exposure may cause antibody development and deposition that damages the slit diaphragm and produces a type of MN with podocyte fusion on EM and a clinical picture of heavy proteinuria and ultimately graft failure. Cyclophosphamide-based rescue therapy may be successful.[65]

Antineutrophil Cytoplasmic Antibody–Associated Pauci-Immune Vasculitis

Kidney transplantation for ANCA-associated vasculitis (AAV) is associated with a reduction in the frequency of disease relapse by approximately 50% compared with patients remaining on dialysis, and patient and graft survival posttransplantation is similar to that in other transplant recipients.[66]

Recurrence rates in AAV appear to be declining over time. A 1998 pooled analysis of reported case series examining recurrence of AAV detected recurrence in 17% of the 127 included patients, with kidney involvement demonstrated in approximately 60% and graft losses reported in 25% of these.[66] More recently, a review of transplant outcomes in AAV show a decline in recurrence rates to 1% to 2% per year in contemporary studies, possibly because of the improvement in immunosuppression regimens since the 1990s.[67,68]

Clinical parameters have not been found to be useful in predicting those patients most likely to relapse. Pretransplantation disease course, duration of dialysis, ANCA titers at time of transplantation and during follow-up, cytoplasmic ANCA (c-ANCA) or perinuclear ANCA (p-ANCA) pattern, antibody specificity to PR3 or MPO, disease subtype (granulomatous polyangiitis, microscopic polyangiitis, or kidney-limited vasculitis), and donor source have not been found to significantly impact recurrence rates.[66,67]

The prevention and management of relapse has not been prospectively examined. In most reports, patients did not receive a transplant until they were in clinical remission; however, successful transplantation in the face of persisting ANCA positivity is well recognized. In the absence of firm evidence, we recommend that clinical remission be maintained for 6 to 12 months before transplantation to reduce the risk for recurrence and also to avoid risks associated with performing transplantation in a debilitated patient, especially if kidney failure has occurred soon after presentation with systemic vasculitis.[69] Monitoring ANCA to indicate AAV recurrence is commonly performed; however, the test performance characteristics in this context have not been reported. Patients with kidney relapses have generally been managed with cyclophosphamide-based regimens, as used for kidney vasculitis in native kidneys, which have been reported to be successful in inducing remission in 11 of 16 (69%) cases.[66,67] No negative impact of the use of cyclophosphamide to treat relapse has been reported, but cumulative dose, if it had also been used pretransplant, would significantly increase the risk for bladder cancer and infertility. Significant interest exists in the use of rituximab for AAV recurrence posttransplant. Although current literature is limited to case reports, in our opinion, rituximab is a reasonable second-line alternative to cyclophosphamide in this context.[67,70]

Anti–Glomerular Basement Membrane Disease

Histologic recurrence of anti-GBM disease is seen in 50% of patients who receive a transplant while circulating anti-GBM antibodies persist but rarely when patients undergo transplantation 6 months or more after the disappearance of anti-GBM antibodies. With delayed transplantation, the rate of clinical recurrence is very low, and since the implementation of this practice in Australia, no grafts were lost after transplantation in 47 patients followed for up to 10 years.[4] Rare episodes of recurrence should be treated as for native kidney disease with corticosteroids, cyclophosphamide, and aggressive plasma exchange (see Chapter 25).

Recurrent anti-GBM disease is distinct from de novo anti-GBM disease, which is seen in up to 15% of transplant recipients with Alport syndrome who develop anti-GBM antibodies in response to neoantigen exposure (α chain of type IV collagen) via the transplant.[71] This is discussed further in Chapter 25.

Lupus Nephritis

The reported recurrence rate of LN has varied from 2% to 54% depending on the diagnostic criteria used.[72,73] Recurrence has been reported early (days) and late (years) after transplantation, with a median time to recurrence of approximately 4 years.[72,73] The clinical and histologic pattern of recurrence is variable but is typically more benign in histology and clinical expression than the patient's original disease. Although the majority of patients with kidney failure caused by lupus have had diffuse proliferative (class III or IV) LN, mesangial proliferative (class II) LN is the most commonly described lesion after transplantation, followed by class III and membranous LN (class V).[73] Duration of dialysis and serologic activity before transplantation do not predict recurrence, and antinuclear antibody titer and complement levels are unreliable markers of disease recurrence. There is no consistent relationship between recurrence of nephritis and activity of extrarenal lupus after transplantation.

The long-term outcome for lupus patients after transplantation is controversial but appears similar to that of the general posttransplantation population.[72,74] Although recurrence is an uncommon cause of graft loss within the first 10 years after transplantation, with no cases of graft loss reported from 86 recipients in one registry analysis,[4] late graft losses do occur. It is clear that lupus patients, particularly those with a lupus anticoagulant, are at increased risk for thrombotic events after transplantation, including graft thrombosis.[75]

Management of recurrent LN has not been systematically studied; corticosteroids, cyclophosphamide, MMF, and plasma exchange have been used, with variable results reported. Anticoagulation during the perioperative and early posttransplantation phases should be considered for those with a history of thrombosis or lupus anticoagulant positivity. Successful retransplantation has been reported after graft loss caused by recurrence.[75]

Thrombotic Microangiopathy and Hemolytic Uremic Syndrome

Recurrence risk is dependent on the underlying cause of thrombotic microangiopathy (TMA). Typical childhood Shiga toxin–associated HUS seldom recurs, whereas recurrence of atypical HUS (aHUS), which is associated with dysregulation of the alternative complement pathway, occurs in up to 80% of patients depending on the mutations involved.[76,77] The diagnosis of recurrent TMA, including HUS, is complicated by the fact that de novo TMA is seen in 1% to 5% of kidney transplant recipients, most commonly associated with the use of CNIs (both tacrolimus and cyclosporine carry a similar risk), sirolimus, or with acute vascular rejection. Drug-induced de novo TMA is generally observed within 14 days of drug commencement.

The risk for aHUS recurrence and its impact on graft survival is dependent on the complement pathway mutation responsible. Mutations in complement factor H are associated with a recurrence risk of approximately 75%, and more than 90% of those with recurrence incur graft failure, typically within the first year.[76,78] In contrast, mutations of membrane cofactor protein are associated with a recurrence rate of only 20% and substantially better survival rates than in patients with factor H or I mutations.[79] Given these variations in risk for recurrence, genotypic evaluation of the recipient and any potential living donors before transplantation is advisable for all patients with kidney failure caused by atypical HUS.[80] Combined liver-kidney transplantation may be considered in selected candidates with defined mutations.[81] Recurrence is generally within the first 6 months after transplantation, thought to be because of ischemia-reperfusion driven endothelial injury; however, late recurrences have been reported.[77] The clinical presentation may be gradual or abrupt, with thrombocytopenia, hemolysis, and progressive kidney dysfunction.

Historically, treatment for recurrent aHUS has relied on withdrawal of any potential causative agent such as CNIs (with a temporary increase in the dose of corticosteroids to reduce the risk of acute rejection), and plasma exchange. This strategy was only modestly effective, for both first episode and posttransplant aHUS.[76,82] The development of eculizumab, a humanized monoclonal antibody targeting C5 of the complement membrane attack complex, has revolutionized treatment for aHUS. In the last few years, a number of cohort studies and a large registry analysis have shown that the preemptive use of eculizumab in patients with aHUS leads to greatly reduced recurrence rates and improved graft survival.[83–85] A meta-analysis of 13 cohort studies and five case series that included a total of 380 patients confirmed protection against recurrence when eculizumab was used preemptively, with recurrence seen in under 6% of cases. Commencement of eculizumab after development of posttransplant aHUS recurrence was also relatively effective, with graft loss reported in approximately 20% of 192 cases.[86] Both outcomes were vastly superior to historical rates of recurrence and graft loss in those with recurrence. Although the responsible mutations were frequently not identified in this meta-analysis, where it was recorded, the most common mutations were complement factor H and I mutations, which have recurrence rates pre-eculizumab approaching 80%, with graft loss in those with recurrence of more than 90%, typically within the first year.[78] A subsequent retrospective analysis of the impact of eculizumab found prophylactic use to be superior to initiation after recurrence in terms of graft survival.[87]

We recommend that eculizumab be commenced pretransplant (day of surgery or prior) for high-risk mutations including complement factor H, complement factor B, and C3 and/or previous graft recurrence, and considered for moderate risk mutations such as complement factor I or anticomplement factor H antibody.[87] This position is supported by the 2016 KDIGO guidelines.[80]

There is less evidence to guide the decision on if and when to cease eculizumab. It is likely that this decision will differ for patients with different gene mutations. Recurrence rates decline after 12 to 24 months,[76] so we would recommend waiting 24 months posttransplant before attempting cessation. After cessation, intensive monitoring of graft function, hemoglobin and platelet count, blood film, and serum LDH appear warranted in our opinion; however, this strategy has not been scientifically examined. Prompt reintroduction of eculizumab should be considered in cases of recurrence after eculizumab cessation.

Scleroderma

Few patients with scleroderma undergo kidney transplantation. The largest analysis of transplanted scleroderma patients consisted of 86 patients reported to the UNOS registry and showed graft survival of 62% at 1 year, 47% at 5 years after transplantation, and 27% at 10 years; 24% of recipients died during the 10-year observation period.[88] The recurrence rate could not be accurately determined; however, recurrence was responsible for graft loss in 21% of patients in whom the cause was identified. A more recent analysis of 22 patients from the ANZDATA registry reported similar graft survival of 78% at 1 year, 53% at 5 years, and 28% at 10 years.[89] The management of scleroderma after transplantation is unstudied; however, the use of RAS blockade after transplantation to treat hypertension would seem appropriate. Overall, kidney transplantation appears to be an appropriate treatment for those with scleroderma and kidney failure, in the absence of contraindications to transplantation such as severe scleroderma gut or lung disease.[90]

AMYLOID, LIGHT-CHAIN DISEASE, AND FIBRILLARY AND IMMUNOTACTOID GLOMERULOPATHIES

Amyloidosis

The risk and impact of recurrence for patients who undergo transplantation because of systemic amyloidosis are dependent on its

cause. Management of AL amyloid is primarily directed at treating the underlying plasma cell dyscrasia, most commonly by high-dose chemotherapy and autologous stem cell or allogeneic bone marrow transplantation. Recurrence after transplantation is likely if the malignancy is not fully controlled but may be susceptible to further chemotherapy. The largest reported series by Heybeli et al. includes 60 patients who received a kidney transplant for AL amyloid-induced kidney failure, roughly half of whom (28 patients) had asymptomatic cardiac involvement.[91] Before kidney transplant, 51 of the 60 patients had received treatment for amyloidosis, which resulted in complete remission for 37 (62%) and partial remission in 11 (19%) patients.[91] Of 9 patients who were treatment naïve at the time of kidney transplant, 7 were treated with melphalan and autologous stem cell transplant after kidney transplant, all of whom had complete remission.[91] Death-censored graft survival was 98.3% at 1 year and 95.8% at 5 years. No grafts were lost through recurrence.[91] Protocol biopsies were performed out to 10 years and revealed amyloid recurrence in the graft in 13 (22%) patients, with an estimated median time to recurrence of 122 months.[91] Recurrence was predominantly observed in those with a poor response to initial chemotherapy. This paper built on previous work with small patient cohorts that revealed similar findings.[92,93] Thus transplantation appears to be a viable option for patients with kidney failure caused by AL amyloidosis, provided they have achieved a good hematologic response to treatment.[90]

Secondary (AA) amyloidosis is typically a more insidious disease; kidney failure is a relatively frequent complication, and kidney transplantation is frequently effective.[92] The risk for recurrence of AA amyloid depends on the ability to eradicate the underlying cause of chronic inflammation. In AA amyloid, recurrence as a result of chronic infection is unlikely if the infection can be eradicated pretransplantation, whereas conditions such as rheumatoid arthritis may persist after transplantation and lead to recurrent amyloid in the graft. Less than 5% of patients with AA amyloid associated with familial Mediterranean fever (which can be managed with colchicine after transplantation) have recurrence at 10 years after transplantation.[94] A Norwegian series of 62 transplants in patients with AA amyloid, mostly secondary to rheumatic diseases, demonstrated a recurrence rate of 10% at an average of 5 years of follow-up, with recurrence causing graft loss in two patients only. Overall, patient and graft survival rates were 65% and 62%, respectively, at 5 years, with most losses resulting from infection.[95]

Light-Chain Nephropathy

Patients with light-chain nephropathy have occasionally received transplants, and recurrence is common; one case series reported recurrence in five of seven patients at a range of 2 to 45 months after transplantation. Those with recurrence developed proteinuria, hypertension, and progressive graft dysfunction. One of seven has had long-term graft function, and one died soon after transplantation because of myeloma.[96] Kidney transplantation is therefore generally inadvisable for patients with this disease, unless performed in conjunction with bone marrow transplantation as a means of curing the underlying disease. Rituximab and bortezomib have been used with success in patients with light-chain nephropathy recurrence in the graft, but insufficient evidence exists to recommend either agent as a standard of care.

Fibrillary and Immunotactoid Glomerulopathies

Fibrillary glomerulopathy (DNAJB9 Deposition Disease) and immunotactoid glomerulopathies are known to recur in approximately 50% of those undergoing transplantation for these diseases, and although early graft loss as a result of recurrence has been reported, decline in graft function is most commonly slow and does not appear to have an impact on 5-year graft survival rates.[97]

RECURRENCE OF METABOLIC DISEASES AFFECTING THE KIDNEY TRANSPLANT

Diabetes Mellitus

Diabetes mellitus is the most common cause of kidney failure in most parts of the world. However, these patients undergo transplantation less commonly than those with GN because of a higher prevalence and severity of CV comorbidity and inferior survival in registry studies.[98,99] Recurrence of diabetic nephropathy affects at least 25% of recipients at an average follow-up of 6 years and with some patients diagnosed within 3 years of transplantation.[100] Histologic and clinical features are similar to those of native kidney diabetic nephropathy. The risk of graft loss from recurrence has not been well documented but appears to be significantly less than with GN, probably because of the competing risk of death from CV disease. NODAT is also common and has been reported to cause nephropathy in the graft, also manifesting within 5 years of transplantation in a small proportion of cases. The extent to which this contributes to graft loss also awaits clarification, although one registry analysis suggested that the impact on graft failure is insignificant compared with the impact on premature death with a functioning graft.[5]

Primary Hyperoxaluria

Primary hyperoxaluria (see Chapter 60) is a rare autosomal recessive disease caused by defective or absent hepatic production of alanine glyoxylate aminotransferase, resulting in systemic accumulation of calcium oxalate (oxalosis). Kidneys and blood vessels in particular are affected. Kidney transplantation alone is frequently complicated by hyperoxaluria and rapid deposition of oxalate crystals within the graft causing graft failure within weeks to months from transplantation (Fig. 113.5). By contrast, combined liver-kidney transplantation corrects the underlying metabolic deficit and permits long-term kidney graft survival, provided the total body burden of oxalate present at the time of transplantation can be managed. In an analysis of the USRDS that included 190 adults with oxalosis who went on to undergo kidney transplantation, 134 patients who received a kidney transplant alone experienced 48% 8-year death-censored graft survival. This was inferior to 56 patients who also received a liver (76%) and inferior to a control group with a primary diagnosis of GN (61%).[101] Aggressive removal of residual oxalate before transplantation by dialysis and after transplantation by maintenance of high urine volumes, urinary alkalinization,

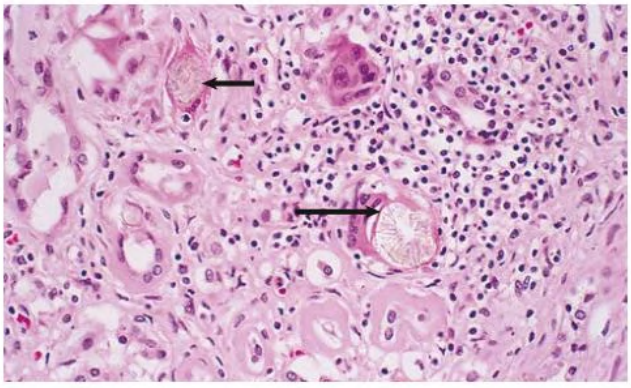

Fig. 113.5 Recurrent Primary Hyperoxaluria. Light microscopy demonstrates oxalate crystals within the tubular lumen *(arrows)* with a secondary interstitial inflammatory infiltrate.

and pyridoxine supplementation for pyridoxine-sensitive patients also may decrease the risk for graft damage.

Fabry Disease

Fabry disease results from a defect in the lysosomal α-galactosidase A enzyme, which results in tissue accumulation of trihexosylceramide, eventually causing kidney failure (see Chapter 48). Recurrent Fabry disease has been documented within the graft; however, graft survival does not appear to be affected. Treatment with recombinant α-galactosidase A, should this become widely available, is likely to reduce the risk for kidney failure and also for recurrence.

RECURRENCE OF VIRUS-ASSOCIATED NEPHROPATHIES AND TUMORS IN THE TRANSPLANTED KIDNEY

Virus-associated kidney diseases may recur after transplantation. Hepatitis B and C virus–associated IC-MPGN and MN are known to recur; however, the risk for this can be substantially decreased by successful antiviral therapy before transplantation (see Chapter 58).

Retransplantation has been reported in patients experiencing graft loss because of BK virus nephropathy. In the largest series with documented recurrence, BK viral replication was found in 11 of 31 (35%) recipients, and BK virus-associated nephritis (BKVAN) in 2 of the 31 (6%) at an median follow-up of 30 months after retransplantation.[102] Rates of BK recurrence were lower when viral clearance had been achieved before retransplantation, with recurrence seen in 15% of BK-negative recipients versus 100% who remained BK positive at the time of transplantation.[102] In a recently published study of the UNOS/OPTN database between 2005 and 2016, there were 46 (14%) regraft failures in 341 patients who had lost their first graft because of BKVAN. Of these, 7 (15%) lost their regraft because of BKVAN compared with 55 (2%) of the 2458 regrafts who had lost a previous graft for another reason.[103] There was no difference in overall regraft survival between those who lost their first graft to BKVAN compared with another cause over the median follow-up time of 4.7 years.[103] Thus, retransplantation, ideally delayed until BK virus is not detectable in serum by polymerase chain reaction, appears to be safe and effective.

Patients with posttransplantation lymphoproliferative disease (PTLD) who incur graft loss secondary to direct infiltration or rejection after the withdrawal of immunosuppression may safely and successfully undergo retransplantation after they recover. In an analysis of patients with second kidney transplants in the UNOS registry between 2000 and 2019, 254 patients were found to have had PTLD in their first transplant. These patients were found to have higher rates of PTLD in their second transplant (2.8% vs. 0.1% without previous PTLD, $P = .001$), but there was no difference in graft or patient survival at a median of 4.5 years of follow-up.[104]

SELF-ASSESSMENT QUESTIONS

1. Risk for graft loss because of recurrent disease is highest for kidney transplant recipients whose kidney failure was caused by:
   - **A.** IgAN.
   - **B.** FSGS.
   - **C.** Type 1 diabetes.
   - **D.** Lupus nephritis.
   - **E.** Reflux nephropathy.
2. A diagnosis of recurrent disease affecting the allograft requires which of the following pieces of information?
   - **A.** Allograft biopsy confirming the disease
   - **B.** Biopsy diagnosis of the native kidney disease
   - **C.** Clinical features of the original kidney disease recurring after transplant
   - **D.** Allograft failure caused by the disease
   - **E.** Both A and B
3. Which one of the following statements is *true* regarding management of recurrent FSGS?
   - **A.** First-line therapy includes a 3-day course of daily intravenous pulses of methylprednisolone.
   - **B.** Cyclophosphamide should be started once recurrence is confirmed.
   - **C.** In a patient who develops nephrotic-range proteinuria 2 weeks after transplant, a biopsy specimen that is normal on light microscopy excludes the diagnosis of recurrent FSGS.
   - **D.** Plasma exchange should be started once a diagnosis of recurrent FSGS is made, with a plan to complete approximately nine cycles of therapy.

Outcomes of Kidney Transplantation: Identification, Measures, and Evaluation

Jennifer S.Y. Li, Jeremy R. Chapman, Germaine Wong

INTRODUCTION

Chronic kidney disease (CKD) is a global public health problem that imposes a substantial burden on patients, families, and healthcare systems.[1] Kidney transplantation provides superior survival compared with dialysis but does not fully correct quality of life (QOL) and survival[2,3] compared with the general population. The overall risk of death in transplant recipients is at least three times higher than the general population, and transplant recipients have significantly reduced QOL, even compared with patients with other chronic disease. Strategies such as optimization of matching, crossmatching, and surgical techniques; improvement in perioperative care; effective antiviral, antifungal, and antibacterial prophylaxis; and contemporary immunosuppression have led to improvement in patient and allograft outcomes over the past two decades. Improvement in short-term outcomes is accompanied by evidence from the United Kingdom, Australia, and Europe on gains in long-term graft survival. Data from the Collaborative Transplant Study have shown that between 1985 and 1996, the 1- and 10 year-graft loss hazard rates have declined by 64% (95% confidence interval [CI], 61%–66%) and 45% (39%–50%), respectively. Between 2000 to 2015, the reduction in graft loss hazard rates at 1 and 10 years were 22% (12%–30%) and 64% (45%–76%), respectively.[4]

Despite these improvements, there are important challenges in improving the health and overall well-being of transplant recipients. Current immunosuppression regimens cannot completely prevent rejection and graft loss and can lead to undesirable complications such as cancer and infection. Importantly, the outcomes that researchers study and clinicians target often do not align with those that patients prioritize.[5] Patient engagement is a critical element of clinical research that can enhance the credibility of the findings and improve their translation into practice.

This chapter describes outcomes after transplantation including graft health, mortality, and long-term complications of immunosuppression and includes a brief description of the tools used to assess these outcomes. The chapter explicitly focuses on outcomes that are prioritized by patients and families, especially those that are not frequently considered by clinicians and health professionals, such as life participation.

GRAFT HEALTH AND PATIENT SURVIVAL

Graft health is a broad umbrella term for direct outcomes of the kidney transplant. Important aspects of graft health include patient survival, short- and long-term graft survival, graft rejection, and graft function.

Definitions that characterize patient and allograft survival include the following:

- *Patient survival* refers to the overall survival (OS) of the transplanted person measured from the time of transplantation to the time of death; censor at the end of follow-up time or the time the person was lost to follow.
- *Death with a functioning graft* is a major cause of graft loss after kidney transplantation. This occurs when a patient has sufficient graft function and does not need either retransplantation or dialysis at the time of death. The date of death is recorded as the last follow-up visit with function.
- *Graft survival* is the absence of irreversible graft failure, meaning the requirement for retransplantation or long-term dialysis therapy. This can be further divided:
  - *Death-censored graft survival* is time from date of transplantation to the occurrence of irreversible graft loss; censor on the date at which the patient was lost to follow-up, died, or at the end of follow-up time.
  - *Overall graft survival* is time from transplant to graft loss and/or death; censor on the date at which the patient was lost to follow-up or end of follow-up time for recipients with a functioning graft.

Measures of patient or graft survival can be reported with or without adjustment for potential confounders and typically at a specified time point (such as 30-day, 1-year, 5-year, or 10-year). Transplant data registries, such as the International Registry in Organ Donation (IRODaT), Organ Procurement and Transplantation Network (OPTN), United Network for Organ Sharing (UNOS), Scientific Registry of Transplant Recipients (SRTR), United States Renal Data System (USRDS), European Dialysis and Transplant Association Registry (ERA-EDTA), Collaborative Transplant Study (CTS), and the Australia and New Zealand Dialysis and Transplant Registry (ANZDATA), provide important data regarding the country-specific graft and patient survival (both short- and long-term) over the past 50 years.

Early Posttransplant Outcomes

There are high upfront risks associated with kidney transplantation, driven by surgical complications and adverse effects of intense immunosuppression early in the transplant course. A longitudinal, observational study of over 200,000 patients on long-term dialysis in the United States[6] showed that patients who were listed for transplantation (46,164) and received a first deceased-donor transplant (23,275) experienced a 2.8-fold higher risk of death in the first 2 weeks after the transplant compared with those who remained on the waitlist. The risk of death became similar between transplanted and waitlisted patients around 106 days, and a net survival benefit was seen after 244 days posttransplantation.[6] Importantly, the study showed a substantially lower annual death rate for those transplanted (3.8 deaths per 100 patient-years) compared with those who remained waitlisted on

dialysis (6.3 per 100 patient years) and on dialysis but not suitable for waitlisting (16.1 per 100 patient years), with benefits particularly favoring young patients (20–39 years old) and young diabetic patients.

Long-Term Posttransplant Outcomes

Interpretation of longer-term outcomes needs careful consideration of the case mix (such as recipient comorbidities, organ quality, immunologic risks, donor-recipient matching), transplant era (evolution of immunosuppression protocols and practices), and country-specific and resource-related factors (such as the impact of socioeconomic factors, access to care, and affordability of medications, which may vary between countries; Fig. 114.1). These factors may have accounted for the between-country differences in the adjusted graft loss rates in the United States, United Kingdom, and Australia and New Zealand, with the risk of graft loss at 1 year posttransplant being highest in the United Kingdom (Hazard ratio [HR] 1.22), followed by the United States from year 2 onward. The risk of allograft loss remains the lowest in Australia across all eras.[7] Other studies have reported a wide range of 10-year patient survival, ranging from 34% to 78% for transplants performed after the year 2000.[8–11] The impact of regional and ethnic differences was again highlighted in a study comparing European versus North American kidney transplant recipients from the UNOS and CTS for Europe databases. The 10-year graft survival rates between 2005 to 2008 were 56% in Europe, and 46%, 48%, and 34% for White, Hispanic, and Black Americans, respectively.[10]

Data from the Netherlands Organ Transplant Registry suggested that deceased-donor criteria (brain vs. circulatory death) were not a predictor for patient- or death-censored graft survival.[9] However, donor comorbid diseases, such as type 2 diabetes and hypertension, were risk factors for allograft survival.[12] For transplants performed in 2014 to 2015, the death-censored graft survival rates at 1 and 5 years were 98% and 83%, respectively, for deceased-donor grafts, and 99% and 91% for living-donor kidney grafts in Australia[13] (Fig. 114.2A). The rate of graft failure (censored for death) was approximately 3 per 100 graft-years, with chronic allograft injury being the dominant cause of graft loss[13] (Fig. 114.3).

Patient OS after transplantation differs by era and recipient age. The 5- and 15 year patient survivals after primary living-donor kidney transplant varied from 89% in the 1990–94 period to 94% in the 2000–04 period and 75% in the 1990–94 period to 80% in 2000–04. For primary deceased-donor kidney transplants, the 5- and 15- year survivals were 84% in 1990–94 and 89% in 2004–09 and 53% in 1990–94 and 64% in 2000–04, respectively (see Fig. 114.2B). The reported 5-year graft patient survival for older kidney transplant recipients (≥65 years old) transplanted between 2006 to 2016 was 79%.[14] Older transplant recipients also incur a survival advantage compared with age- and

sex-matched patients who remain on the waiting list,[15] but OS remains inferior compared with younger counterparts.[16] Donor age is also a major factor that influences transplant outcomes. Younger recipients of older donor grafts are at risk for poorer long-term graft survival.[16–18]

Acute Rejection Episodes After Transplantation

Acute rejection is an important outcome for patients and health professionals. Diagnosis of acute rejection is based on biopsy scoring using the Banff criteria for rejection.[19,20] Studies typically report on biopsy-proven acute rejection (BPAR)—whether cell-mediated or antibody-mediated rejection (ABMR)—to satisfy the predefined Banff criteria. The Banff classification was first developed in 1991 and has had several iterations over the past 30 years,[20,21] including updates as recently as 2019. Interpretation of studies require careful consideration given that the classification is typically-updated every 2 years, the addition of ABMR criteria after the 1997 meeting, and the acute versus chronic ABMR classification detailed in the 2005 update. Studies over the past 30 years have subtle variations in the definitions of BPAR, and definitions may be improved by incorporating diagnostic, predictive, and/or prognostic biomarkers (select examples listed in Table 114.1) and more precise definition of phenotypes of acute rejection defined by molecular and genomic markers.[22–26]

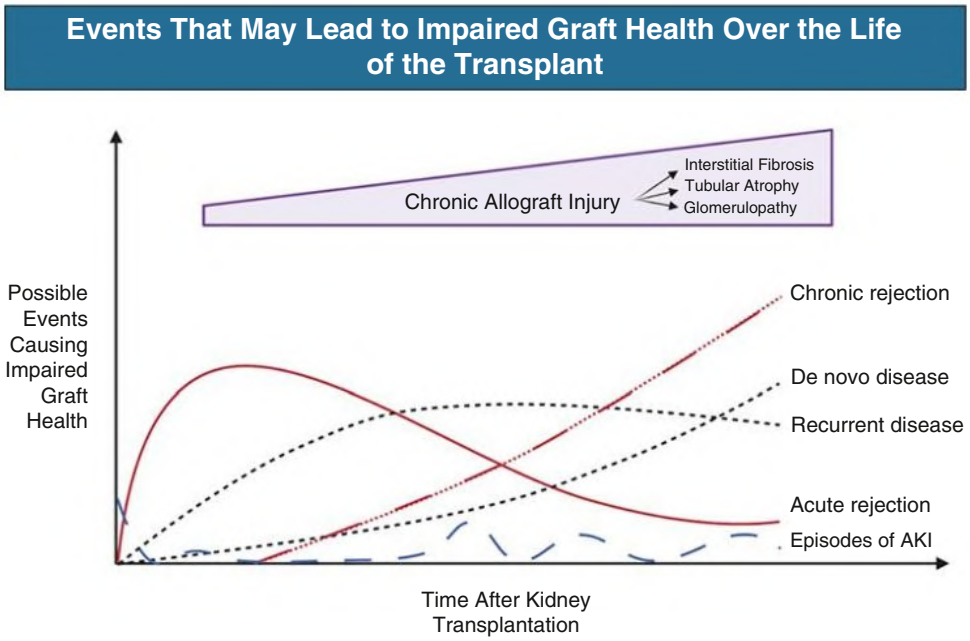

Fig. 114.3 Representative Events That May Lead to Impaired Graft Health Over the Lifetime of the Transplant. Early posttransplantation, acute rejection, and delayed graft function pose the highest risk to graft function, which reduce over time and are replaced by events such as chronic rejection and recurrent or de novo kidney disease superimposed by episodes of acute kidney injury (AKI) from any cause. (Created using Biorender.com.)

OX40, (CD134) OX40, ligand, programmed cell death protein 1 (PD-1), PD-2, FOXP3	Urine	86
MicroRNA species	Biopsy, blood, or urine	87–90

Acute rejection occurred in approximately 18% and 20% of patients with first and subsequent allografts within the first 6 months after deceased and living-donor kidney transplants. Early rejection (within the first 6 months posttransplantation) adversely affects longer-term patient and graft outcomes and is associated with an increased risk of death with a functioning graft, death because of cardiovascular disease (CVD), or cancer.[11]

Kidney Transplant Function

Kidney function is an important outcome that is usually reported using surrogate markers of serum creatinine (SCr) or estimated glomerular filtration rate (eGFR). These outcomes have known limitations, particularly with variations with sex, race, muscle mass, and age; aberrant results when drugs or conditions impair the tubular secretion component; and the relative insensitivity to small changes in function because of the reciprocal relationship between SCr and GFR. There are several methods for estimating eGFR, most commonly the Modification of Diet in Renal Disease (MDRD) and Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equations (see Chapter 3).[27,28] Despite their limitations, recording the eGFR and observing the magnitude of eGFR decline, slope, or drop of at least 30% in function is useful for predicting patient and graft survival.[29] The GFR slope and percentage decline in GFR are also used to detect the progression of kidney disease.[30,31] Proteinuria is an important biomarker in kidney transplantation, as it is in the CKD setting.[32] Proteinuria originating from the allograft (rather than native kidneys) can be from various etiologies (including transplant glomerulopathy, recurrent disease, and mammalian target of rapamycin [mTOR] inhibitor use), but even proteinuria of greater than 500 mg/day is associated with reduced graft survival[33] and development of de novo human leukocyte antigen (HLA) antibodies.[34]

Early Graft Outcomes

Delayed graft function (DGF) is typically defined as the need for dialysis within the first 7 days, but there are 18 definitions used in literature to define this entity.[35,36] The reported incidence of DGF varies from 5% to 50% depending on the definition and can be associated with increased risk of rejection[37,38] and reduced graft survival.[39] Recent evidence also suggested that the severity (based on the duration) of DGF has a "dose effect" on death-censored graft loss.[40] For patients with "slow graft

TABLE 114.2 Select Novel Biomarkers for Acute Kidney Injury

Marker	Source	Reference

Cell-free DNA	Blood	104

function" (poorer immediate function but not requiring dialysis within the first 72 hours), DGF was associated with worse outcomes in terms of overall graft loss and death-censored graft loss.[41] Similar to acute rejection, the definition of DGF can be precisely defined by incorporating noninvasive biomarkers to the clinical or laboratory definition(s) in the future. Some examples of biomarkers being investigated for acute kidney injury (AKI) in general are presented in Table 114.2.

Long-Term Graft Outcomes

Chronic allograft injury (CAI; previously known as chronic allograft nephropathy) is a histologic description of fibrosis, atrophy, and vascular damage in the kidney. The term interstitial fibrosis/tubular atrophy (IFTA) was introduced by the 2005 Banff Working Group[42] to capture this pathologic appearance, which represents the irreversible and common end pathway of many mechanisms of injury, including acute or chronic rejection, subclinical rejection, long-term calcineurin toxicity, polyoma virus infection, recurrent or de novo glomerulonephritis, or any cause of AKI seen in the general population.[43–45] IFTA is prone to sampling error from the biopsy procedure and ascertainment bias because of variation in the sampling rates of biopsies for indication only or indication plus surveillance biopsies. The quantification of IFTA alone is insufficient to predict long-term graft loss,[46] but inflammation in areas of IFTA (i-IFTA) may be associated with accelerated IFTA, chronic glomerulopathy, reduced kidney function, and long-term death-censored graft loss.[47,48] Thus, IFTA and i-IFTA are useful surrogate markers for kidney transplant outcomes.

The kidney donor risk index (KDRI) is a validated prediction tool for long-term graft survival and includes a numeric representation accounting for donor age, race, terminal creatinine, comorbid hypertension or diabetes, cause of death, donation after cardiac death, height, weight, and HCV status; and transplant factors including HLA-mismatch, cold ischemia time, and en-bloc double kidney transplant.[49,50] A higher KDRI denotes the higher risk of graft failure or a "poorer" quality organ but this is not absolute, with similar graft outcomes reported for KDRI between 35 to 85 and KDRI greater than 85.[51]

In recent years, the search has intensified for predictive or prognostic blood, biopsy, and/or urinary biomarkers that correlate with long-term outcomes in kidney transplantation, particularly those using proteinomics and genomic scoring sets.[24,52–54] Although there has been acceleration in molecular technologies and bioinformatics analysis, these newer research tools are yet to be translated into mainstream clinical practice and are not further discussed here.

COMPLICATIONS: MALIGNANCIES AND INFECTIONS

Cancer and infection are the two most feared complications of immunosuppression and are thus key research priorities for patients and clinicians.[5] Unlike CVD, for which outcomes have improved considerably over time, the risks of developing atypical infections and cancers remain high.[55]

MALIGNANCY

The overall risk of cancer is increased at least twofold to threefold compared with the age- and sex-matched general population, with the greatest increased risk from viral-related cancer. However, the risk of developing breast and prostate cancer is comparable to the general population.[56] The overall incidence of de novo cancer among kidney transplant recipients varies between 1000 and 1300 per 100,000 person years, and the overall risk increases with age. The cumulative incidence of de novo cancer (including nonmelanoma skin cancer) at 10 years after kidney transplantation is around 40%, increasing to 60% at 20 years. Once cancer has developed, the risk of death attributed to cancer is threefold higher than for patients with cancer in the general population.[57]

Measuring Cancer Outcomes in Kidney Transplant Recipients

Epidemiologic data such as incidence and mortality of cancer in transplant recipients are best obtained from national cancer-based registries. Linkage of data from different sources (e.g., linking data from a cancer registry to data from a kidney transplant registry) may allow more detailed analyses that cannot be done with either alone. Cancer incidence and mortality rates are presented by categories of cancer sites and types in kidney and general population cancer registries. Real-time data, including incidence rates (sex- and age-specific) and the cumulative cancer incidence (by cancer site), may be routinely provided by the registries to transplant units as a quality assurance measure. If historical incidence data are available, with sufficient and accurate number of cases and the denominator, recorded incidence rates can be projected to provide longer-term estimation within the population of interests using prediction modeling techniques.[58]

Although unadjusted incidence rates are useful to describe how many kidney transplant recipients develop cancer or die of cancer within a certain time period, they do not account for the age, sex distribution, and patient characteristics in the population of interest. Standardization gives a single figure to compare an incidence rate in two populations and accounts for the different population distributions.

Relative Mortality

Obtaining accurate information on the cause of death is notoriously difficult, especially using data from death certificates. To overcome some of these challenges, the risk of cancer-related death in kidney transplant populations can be assessed by assessing relative cancer survival. Relative survival can be defined as the ratio of kidney transplant recipients with cancers that have survived within a certain time period to the proportion of expected cancer survivors in a comparable cohort in the general population. Alternately, the comparator could be a similar cohort (age- and sex-matched) of patients without cancer in the general population. However, this method assumes that cancer deaths are independent of the other competing causes of death.

Competing Risk Analyses

Accounting for the competing risk of other causes of death is potentially important when assessing the risk of death from cancer in kidney transplant recipients. In survival analysis, censored observations (participants who complete follow-up without experiencing the outcome

of interest) contribute to the total number of participants at risk until the end of their follow-up. These analyses assume that factors that lead to censoring are independent of those that lead to the outcome of interest. However, if the outcome of interest is precluded by another event, the "independence" assumption is violated. For example, a transplant recipient who dies of infection cannot experience another death from cancer and is no longer "at-risk" for experiencing another type of death. Specific techniques such as the Fine and Gray method can be used to generate the subdistributional hazard ratios and estimate the risk of cancer-related death, assuming the recipient had not died of infection. Ignoring competing risk can lead to misleading results. For example, some analyses have suggested that patients with diabetes are protected from cancer compared with those without diabetes; the true explanation is that (compared with people without diabetes) these patients are at higher risk of early death from other causes and thus are less likely to live long enough to die of cancer.

Management of Cancer After Transplantation

Partnership between transplant professionals and oncologists is the key to cancer management in complex kidney transplant recipients. Judicious reduction in immunosuppression, particularly antiproliferative agents and those that affect T cells, may induce remission of certain cancer types, such as posttransplantation lymphoproliferative disorder (PTLD) and Kaposi sarcomas. However, this approach needs to be balanced carefully with the risk of allograft rejection. There are emerging studies to suggest that mTOR inhibitors (mTORIs) may reduce the risk of method can be used (particularly squamous cell carcinoma [SCC]) and Kaposi sarcomas.[59] However, the benefits of mTORIs in recipients with solid organ cancers are uncertain and mTORIs are poorly tolerated, with a discontinuation rate of more than 30% in trials.[60] There is also an increased risk of cancer and all-cause death among recipients who received mTORI as standard immunosuppression compared with those maintained on calcineurin inhibitors.

New targeted anticancer therapies, including checkpoint inhibitors and other immunotherapies, are now available to treat advanced-stage solid organ and hematologic malignancies, but most trials assessing these new agents have excluded transplant recipients. There are case reports and series suggesting that the use of anti-PD1, cytotoxic T-lymphocyte–associated antigen 4 (CTLA-4), and other immune modulators such as lenalidomide and pomalidomide in transplant recipients can lead to acute allograft rejection.[61] A recent observational multicenter study on the safety and efficacy of immune-checkpoint inhibitors (ICI) indicated approximately 40% of the cohort who received ICI developed acute rejection, and this compared with 5.9% in the non-ICI groups. Of those who experienced acute rejection, about 65% experienced graft loss. The median time from ICI initiation to acute rejection was 24 days. Key factors that may reduce the risk of acute rejection were mTORI use at the time of ICI initiation, and triple agent immunosuppression. The median survival in patients with metastatic SCC was 19.8 months in the ICI cohort, compared with 10.6 months in the non-ICI arm.[62]

INFECTIONS

Infections are major causes of early posttransplant death (within the first 12 months posttransplant), particularly in low- to middle-income countries where prophylactic treatments for viral and bacterial infections are not universally affordable. The timing, severity, and etiology of the infections are dependent on the recipients' epidemiologic infectious exposures and the individual's state of immunosuppression[63] (see Chapter 110). The types of infection also vary depending on the time since transplantation, with the risk of acquiring nosocomial infections being the highest during the first weeks after transplantation, followed by opportunistic and community acquired infections thereafter.[63] Unlike cancer, detailed data on the timing, frequency, and burden of infectious disease in transplant recipients are generally not available from national registries. Details about the incidence, prevalence, and exposure to certain types of infections and the responses to screening, preventive, and treatment strategies are often limited to single-center sources.

Prevention and Prophylaxis

Effective prophylactic and preventive strategies are available for a range of infections, including cytomegalovirus (CMV), human papillomaviruses (HPV), and pneumocystis pneumonia infections. Options for CMV prophylaxis include valganciclovir, oral ganciclovir, intravenous (IV) ganciclovir, or high-dose oral valacyclovir, corrected for kidney function.[64] For HPV, quadrivalent vaccines (against genotype 6, 11, 16, and 18), and, more recently, the HPV 9-valent vaccines (against 5 additional genotypes of 31, 33, 45, 52, and 58), are highly effective and have an overall efficacy of 99% to 100% for the prevention of cervical intraepithelial neoplasia.[65,66] HPV vaccination is indicated in both males and females aged 9 to 25 years in the general population for the prevention of HPV-related malignancies. Some recent data have shown that vaccination is also efficacious in women up to age 45 years. In the transplant population, HPV vaccines are generally safe, but evidence for decision making is limited to observational analyses. In a single cohort study, seropositivity was only detected in approximately 50% to 60% of patients, depending on genotypes, and higher tacrolimus levels were also detected in nonresponders.[67]

Early Detection

Although prevention is the key to preventing serious illnesses in the transplant populations, early detection of disease in patients at risk may provide the opportunity to initiate effective treatments and prevent advanced-stage disease. Polyomavirus is an important pathogen associated with interstitial nephritis and nephropathy in kidney transplant recipients. The risk of graft loss, once nephropathy has developed, ranges from 30% to 50% within 5 years.[68] In the absence of effective antiviral treatments, management of polyomavirus (BK) nephropathy relies on early detection and timely reduction of immunosuppression with urine real-time polymerase chain reaction (RT-PCR) or urine cytology. Additional studies of diagnostic test accuracy are required to determine which test or tests best distinguish a transplant recipient with BK nephropathy from those without the disease. The conduct and reporting of all diagnostic test accuracy studies should adhere to the Standards for the Reporting of Diagnostic Accuracy Studies (STARD) guidelines.[69]

Economic Evaluations

Economic evaluation can be used to assess the costs and benefits of interventions and help policy makers identify interventions that maximize health benefits and minimize resource use.[70,71]

A recent analysis reported that living-donor kidney transplant is cost-saving compared with dialysis because most recipients live longer and incur fewer costs. For those who received a lower kidney donor profile index (KDPI) deceased-donor kidney transplant, the incremental cost-effectiveness ratio (ICER) ranged between (USD) $36,000 to $40,000 per quality-adjusted life-year (QALY), and approximately $60,000 per QALY for higher KDPI deceased-donor kidney transplant and in patients who are immunologically complex. Despite the higher costs, the survival advantage of kidney transplantation over dialysis is so substantial that all options are highly cost-effective, based on a willingness-to-pay threshold of $100,000 (USD) per QALY.[72]

Although the cost-effectiveness and cost utility of kidney transplantation compared with dialysis are not in doubt, more uncertainty remains about which new treatments will lead to further gains, compared with current management. In some cases, clinical trial data are not available to guide such decisions, and in this circumstance an economic evaluation could be used to estimate the likely costs and effects of any interventions. A published example is the evaluation of cidofovir in kidney transplant recipients with BK nephropathy. Cidofovir is often used in patients with significant nephropathy resulting from BK infections. All efficacy and adverse effects data informing cidofovir use in transplant recipients are from observational studies. Decision analysis suggests that the addition of cidofovir may incur a small survival gains, approximately 2.2 days with savings of approximately $20,000 AUD over the lifetime of a recipient. However, uncertainties exist because of unclear clinical efficacy data, where the incremental health benefits could range from –1 (harm rather than benefit) to 1.3 life-years-gained, with incremental costs varying between an extra $30,000 to savings of $27,000. Other examples of how economic analysis has been used to assess the likely impact of treatment strategies on outcomes in kidney transplantation include immunosuppression use, induction therapy, cancer screening, and machine perfusion.

PATIENT-REPORTED OUTCOMES AFTER TRANSPLANTATION

Kidney transplantation is intended to improve both the survival and QOL of patients with kidney failure, but the adverse effects from immunosuppression and coexisting comorbidities such as infections, vascular disease, and mental health disorders may affect the recipients' capacity to return to normality, participate, and enjoy daily life activities such as work, education, and recreation. Other factors including age, sex, the types of transplant received, and the duration since transplantation also have a major impact on the overall QOL experienced. People adapt to their illnesses, but the extent and the time needed for the adaptation are associated with the types of transplants they receive and the complications that occur during the perioperative and postoperative periods. Compared with deceased-donor transplant recipients, patients who have received a living-donor transplant experienced better social functioning, vitality, and physical functioning in the first 5 years after transplantation but not thereafter.[73]

Inclusion of patient-centered outcome data in research and clinical care allows for explicit evaluation of the end-user engagement, satisfaction, and potentially real-world adherence. There are several reasons for incorporating patient-reported outcomes in the care of transplant recipients. First, patients are accurate in describing their own symptoms, pain, functions, and QOL. Second, patient-reported outcomes can be used to support shared decision making and patient-centered care. Finally, patient-reported outcomes can also generate valuable data on the treatment effectiveness of interventions, the side effects, and delivery of care in clinical practice. The Standardised Outcomes in Nephrology–Kidney Transplantation (SONG-Transplant) Initiative has identified a core set of clinical trial outcomes that reflect the priorities of key stakeholders,[74] based on a systematic review and an international Delphi survey that included key stakeholders such as patients, caregivers, and health professionals. The full range of outcomes are shown in Fig. 114.4. Although there was general agreement between healthcare professionals, patients, and caregivers that graft survival, function, cancer and infections, and QOL should be included in the core outcomes set, there was incongruency in their opinions regarding the best tools to measure these domains.

Outcome Measures

Life participation is an example of an outcome that is critically important for transplant recipients and their families but is not much considered by clinicians or researchers. Life participation can be defined as the ability to participate in activities that provide a sense of fulfillment, enjoyment, control, and hope. This encompasses a range of activities including, but not limited to, paid and volunteer work, family duties, social functions, recreational and leisure activities, and hobbies. Although life participation is a high priority for patients and

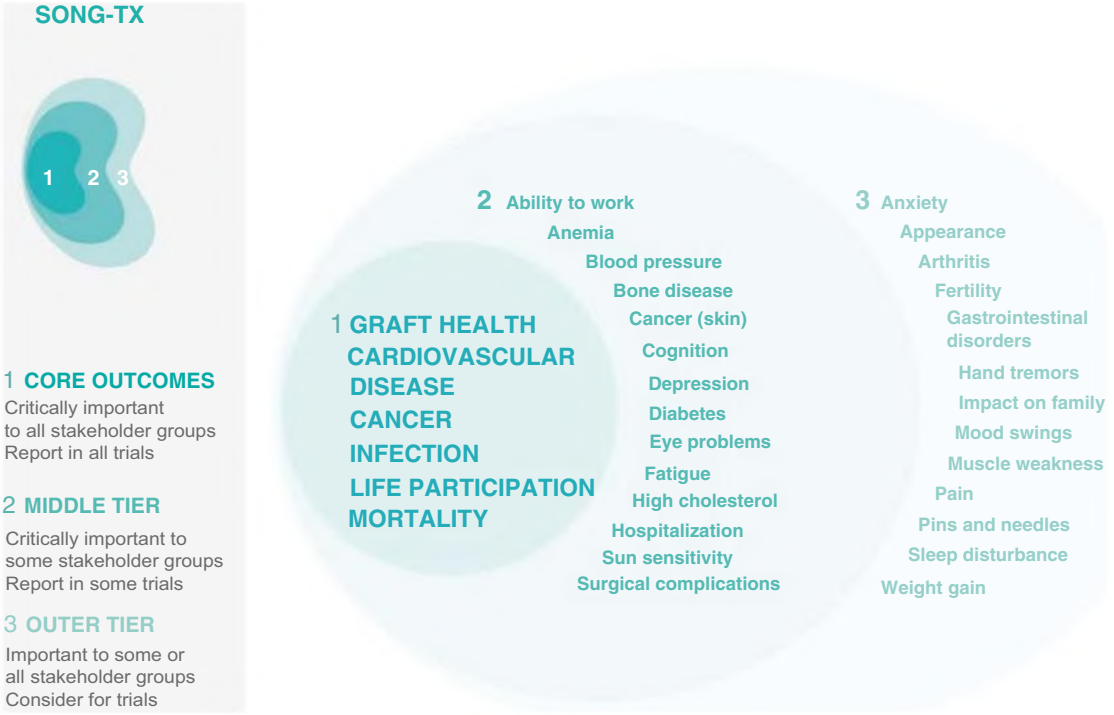

Fig. 114.4 Standardised Outcomes in Nephrology (SONG)-Transplant Core Outcomes. (Courtesy Outcome Measures in Rheumatology [OMERACT]).

their families, the domains, psychometric properties, and content of the outcome measures for life participation in transplant recipients have not been defined.[75] More importantly, this outcome is infrequently explored and inconsistently evaluated in intervention trials in transplant recipients. Life participation can be conceptualized into two dimensions: obligatory and nonobligatory. Obligatory activities are crucial for survival and independence such as work, education, and household chores, whereas nonobligatory events include mainly leisure activities but are important to maintain the well-being of the individual and return a sense of normalcy. There are many tools that measure life participation. Most of these evaluated constructs (such as QOL of the patients and caregivers) included life participation in the questionnaire. Few specifically evaluate the specific aspects of life participation such as daily activities of living and disability assessment. However, many of these measures have not yet been validated in kidney transplant populations, and further research is needed.

CONCLUSION

Kidney transplant recipients value optimal graft function and survival. Although most patients are willing to accept some adverse side effects as being necessary to avoid complications such as acute rejection, the high incidence of other undesirable outcomes such as infection and cancer indicate that further research is needed. Finally, the relative lack of data on how best to improve other patient-important outcomes such as life participation and other symptom burden should be a research priority for the transplant community.

SELF-ASSESSMENT QUESTIONS

1. Actuarial survival is a:
   - **A.** method of calculating how long a patient will live after kidney transplant failure.
   - **B.** statistical method of maximizing the information available for analysis of outcome from a group of patients and events.
   - **C.** way of making "actual results" seem more plausible.
   - **D.** statistical method to estimate the outcomes of patients who are lost to follow-up.
2. The composite endpoint accepted by the US Food and Drug Administration for immunosuppressive drug trials in transplantation includes:
   - **A.** graft failure and patient death.
   - **B.** graft failure, chronic rejection, and lost to follow-up.
   - **C.** acute rejection, graft failure, lost to follow-up, and patient death.
   - **D.** biopsy-proven acute cellular and acute antibody-mediated rejection.
3. Meta-analysis is a:
   - **A.** way of deciding which of several randomized trials is correct.
   - **B.** statistical software package.
   - **C.** method of combining the results from all similar trials to gain statistical power.
   - **D.** trial design used in large studies to decide which factor is most important in determining an outcome.

Self-Assessment Answers

CHAPTER 1

1. B. Myofibroblasts
2. B. Have contractile properties
3. C. The thin ascending limbs of long loops

CHAPTER 2

1. A and D

2.

A. **Correct. The proximal tubule normally reclaims almost all of the filtered glucose via SGLT2. Impairment of this pathway can explain glycosuria in Fanconi syndrome.**

B. Impaired fluid reabsorption in the proximal tubule can explain polyuria. However, the proximal tubule is "leaky" and cannot sustain a large osmotic gradient, so this statement is incorrect. It reabsorbs large amounts of water because of a high hydraulic permeability.

C. Approximately 65% of the filtered calcium is reabsorbed in the proximal tubule, and injury to this segment can cause hypercalciuria. This answer is incorrect because calcium reabsorption mostly occurs through the paracellular pathway and not via a calcium pump in the apical membrane.

D. The proximal tubule reabsorbs phosphate via a dedicated cotransport protein that uses the electrochemical gradient for sodium. Impairment of this process, as can occur in Fanconi syndrome, causes hyperphosphaturia.

E. This is incorrect. The proximal tubule is a leaky epithelium.

3.

A. Vasopressin-stimulated sodium and urea transport in the thick limb of Henle and will increase the gradient.

B. **Correct. Increased blood flow through the medullary vasa recta causes "washout" of osmolytes from the interstitial fluid, diminishing the gradient.**

C. Activation of this system increases the medullary gradient.

D. Activation of this system increases the medullary gradient.

E. Urea contributes significantly to the gradient.

CHAPTER 3

1. D. Larger than average body size based on height and weight is the most likely explanation.
2. F. Chronic kidney disease is defined as markers of kidney damage or decreased GFR for ≥3 months, so ascertainment of kidney damage and confirmation of decreased GFR could be used to confirm the diagnosis.
3. B. ACE inhibitors cause a reversible decline in GFR in patients with CKD.

CHAPTER 4

1. B. Detects Bence Jones proteinuria
2. B. All crystals are birefringent under polarized light.
3. D. Allow the examination of a high number of samples in a short period of time

CHAPTER 5

1. B. This is an M-mode tracing of the mitral valve obtained from parasternal long axis view, plotting the excursion of the anterior mitral leaflet over time. It is composed of two distinct diastolic waves, E and A, representing the early passive diastolic filling of the left ventricle and active filling from atrial contraction, respectively. E-point septal separation (EPSS) is measured from the peak of E-wave to the interventricular septum; an EPSS >7 mm is generally considered a marker of severe LV systolic dysfunction. The image does not demonstrate either color flow or a spectral Doppler tracing.
2. C. There is an anechoic branching area on the grayscale image mimicking hydronephrosis, but the color Doppler demonstrates blood flow indicating that these are just prominent vessels unrelated to the patient's AKI. Parapelvic cysts can mimic hydronephrosis, but they are usually well circumscribed (nonbranching) and do not demonstrate flow. This is not a typical location for hematoma except when there is bleeding into the collecting system following a kidney biopsy. A hematoma is a localized collection of blood and hence does not demonstrate flow on color Doppler.
3. A. This anechoic localized area with septations likely represents a hematoma, which is not an uncommon finding in the early post-transplant period. Fresh blood is completely anechoic, while fibrin strands/echogenic material start to appear during the clotting process. Urinoma typically does not contain internal echogenicities. It is not hydronephrosis because it is outside the kidney. Pelvic ascites is unlikely to be localized at one pole of the kidney or contain septations.
4. D. B-lines are due to thickened interlobular septae. They generally represent pulmonary congestion/edema but can be seen in other conditions such as fibrosis and pneumonia. Sonographic findings should always be interpreted in the appropriate clinical context.
5. A. Normal portal vein waveform is relatively continuous with little pulsatility (<30% during a given cardiac cycle). As the right atrial pressure increases, it becomes increasingly pulsatile. Part B demonstrates more than 50% pulsatility. Parts C and D demonstrate 100% pulsatility with flow reversal during systole (below the baseline component) indicating severe venous congestion.

CHAPTER 6

1. C. Hypoechoic
2. A. CO_2 angiography
3. D. Diffusion-weighted MRI
4. D. History of cerebral aneurysm clip
5. A. Noncontrast CT scan

CHAPTER 7

1.

A. **Correct. Half-life of naproxen is up to 16 hours; therefore after 24 hours platelet function would still be deranged.**

B. This BP level is not a contraindication.

C. This may indicate the presence of urinary infection, but in the absence of urinary symptoms it is not a contraindication to biopsy.

D. With appropriate ultrasound imaging it should be possible to perform a biopsy of the kidney away from the cysts.

E. Although this may make visualization of the kidneys difficult, high BMI is not a contraindication to kidney biopsy.

2.

A. This is likely related to preeclampsia, and a biopsy should not be required for diagnosis.

B. Investigation for this can be delayed until after the pregnancy is complete, assuming kidney function is stable.

C. This will require imaging of the renal tract, but a kidney biopsy is unlikely to be useful during pregnancy.

D. This is likely related to preeclampsia, and a biopsy should not be required for diagnosis.

E. **Correct. This may indicate the presence of a kidney disease that may require specific treatment during pregnancy; therefore knowledge of the underlying pathologic process is important.**

3.

A. This is possible, but B is a better answer because the bleeding diathesis is correctable.

B. **Correct. This will provide functioning platelets to circumvent the clopidogrel-mediated platelet dysfunction.**

C. This will not reverse clopidogrel-induced platelet dysfunction.

D. A delay of at least 7 days is required for correction of the effects of aspirin and clopidogrel on platelets.

E. This will not reverse clopidogrel-induced platelet dysfunction.

4.

A. This supports a diagnosis of diabetic nephropathy, and the diagnosis usually can be comfortably made with clinical criteria alone.

B. This supports a diagnosis of diabetic nephropathy, and the diagnosis can usually be comfortably made with clinical criteria alone.

C. This would be expected with diabetic nephropathy.

D. **Correct. The proteinuria of diabetic nephropathy is progressive over months to years. A negative urinalysis 4 months earlier suggests the presence of an alternative diagnosis to diabetic nephropathy.**

E. This provides no additional information in terms of clarifying the cause of proteinuria.

CHAPTER 8

1. B. This patient presents with extracellular fluid expansion secondary to chronic liver disease/cirrhosis, as suggested by consistent history of alcohol dependence and physical examination findings. In cirrhosis, nitric oxide and carbon monoxide overproduction leads to splanchnic and peripheral arteriolar vasodilation. In advanced stages of cirrhosis, this causes underfilling of the systemic arterial vascular space. Baroreceptor-mediated activation of RAAS, sympathetic nervous system stimulation, and nonosmotic release of ADH occur to restore the normal blood volume homeostasis. This results in renal sodium and water retention and constitutes the major mechanism for sustained ascites formation.
2. D. Therapy for extracellular fluid volume excess in patients with cirrhosis attempts to achieve negative sodium balance by dietary sodium restriction and diuretics. Other measures can be used when the patient has inadequate or no response to diuretics or when rapid decompression of the abdomen is desired. Large-volume paracentesis with albumin infusion can thus be used. Intravenous mannitol has augmented natriuresis in diuretic-resistant patients with cirrhosis but is not typically recommended.
3. C. The clinical scenario is consistent with presumptive SBP. Although the patient remains hypotensive, there is clear evidence that her venous volume is now replete; in this case a pressor might be a reasonable choice. Randomized trials have reported adverse outcomes of patients in the intensive care unit treated with HES compared with lactated Ringer's solution. The creatinine rise indicates acute kidney injury, and the urine sodium concentration suggests that she may have developed acute tubular necrosis. There is no clear indication for dialysis despite the rise in creatinine.

CHAPTER 9

1. D. A calculation would reveal that this patient is excreting electrolyte-free water despite the urine osmolality being much greater than serum osmolality. In such a patient setting, the failure to replace electrolyte-free water losses results in increased serum sodium concentration. The hyperosmolality of the urine is primarily caused by the extremely high excretion of urea in this patient receiving high-protein enteral feedings.
2. B. The data fulfil the criteria for SIADH. This patient not taking a thiazide diuretic does not protect her from developing SIADH, which can occur in elderly individuals occasionally without an obvious underlying cause. The high urinary osmolality speaks against poor solute intake. There is no known change in vasopressin metabolism in elderly patients.
3. B. This patient is excreting electrolyte-free water, most likely because of the loop diuretic. The regimen would match water losses, and the serum sodium would remain unchanged. Because the patient is also hypervolemic, a negative sodium balance is desirable and would be undermined by the other three regimens, all of which contain sodium.

CHAPTER 10

1. D. Hypomagnesemia often leads to renal K+ wasting and hypokalemia. Correction of the hypomagnesemia, whether by discontinuation of causative medications or by magnesium supplementation, corrects the renal K+ wasting and allows successful correction of the hypokalemia.

2.

A. **Correct. Blockade of α1-adrenoreceptor can stimulate cellular K+ uptake. This class of medication does not lead to hyperkalemia.**

B. Blockade of β2 receptors decreases β2-adrenoreceptor stimulated K+ uptake, and so leads to decreased K+ uptake and predisposes to hyperkalemia.

C. MR blockers decrease mineralocorticoid-induced cellular K+ uptake and inhibit principal cell-mediated renal K+ excretion, thereby increasing the risk of hyperkalemia.
D. Calcineurin inhibitors decrease collecting duct potassium secretion, thereby increasing the risk of hyperkalemia.

3. E

All are correct. Hypokalemia decreases both insulin release and insulin receptor sensitivity. Hypokalemia, when chronic, can lead to renal interstitial fibrosis and development of chronic kidney disease. Hypokalemia increases renal ammonia generation and addition to the renal vein and can contribute to generation of hyperammonemia and hepatic encephalopathy in patients with acute or chronic liver disease. Hypokalemia both has CNS effects to stimulate polydipsia and to impair expression of proteins such as AQP2, UT-A, and UT-B involved in renal concentrating mechanism.

CHAPTER 11

1. C. Malignant neoplasias
2. C. Impaired calcitriol synthesis
3. A. Proximal tubule
4. D. FGF-23
5. C. Urinary chloride

CHAPTER 12

1. B. K deficiency increases ammoniagenesis.
2. D. Nonthyroid glycoproteins Rhbg and Rhcg are involved in collecting duct ammonia secretion.
3. C. Animal foods are high in protein and organophosphates and provide a net acid diet.

CHAPTER 13

1. B. Serum HCO_3– concentration will increase after oral bicarbonate administration but then decrease to 18 mmol/L after therapy is discontinued.
2. C. Serum uric acid levels are likely to be low in this patient.
3. A. Propylene glycol toxicity

CHAPTER 14

1. A. Metabolic alkalosis can be divided into disorders with a low urine [Cl] (<20 mEq/L) and those with a high urine [Cl] (>20 mEq/L). When the urine [Cl] is low, the metabolic alkalosis is generally maintained, to a large degree, by a state of ECF volume depletion, which is the case with this patient. When the urine [Cl] is high, the alkalosis is generally maintained by the combination of generous distal tubule salt delivery and hyperaldosteronism (or a hyperaldosterone-like state). ECF volume is usually expanded. However, an exception to this general rule is increased renal salt excretion generated by diuretics or due to inherited tubule electrolyte transport disorders. Therefore, with vomiting or NG suction, the urine [Cl] is persistently low. In contrast, the urine [Na], [K], and pH may cycle up and down as bicarbonate salts are intermittently excreted.
2. C. This man has hypokalemia, potassium depletion, and metabolic alkalosis generated by NG suction. The alkalosis was primarily due to the loss of HCl in the aspirate. In addition, hypokalemia and K depletion, resulting from urinary K loss, causes K to move from the intracellular space to the extracellular space in exchange for protons. This further exacerbates his metabolic alkalosis. The alkalosis is maintained by the kidneys as a result volume depletion, avid kidney salt retention, and secondary hyperaldosteronism and hypokalemia (which also stimulates renal H secretion). Treatment of the metabolic alkalosis requires expansion of ECF volume and K repletion. A proton pump inhibitor will ameliorate (but not completely prevent) proton loss but will not correct the alkalosis. Although HCl infusion would correct the alkalosis, it is used only when all other means of correction have failed or are not available. Furthermore, HCl is difficult to administer, or unavailable, at many institutions. Kidney replacement therapy is reserved for treatment of metabolic alkalosis only in individuals with kidney failure.
3. C. This woman has a hypokalemic metabolic alkalosis and her urine chemistries show a low chloride concentration, indicating ECF volume depletion. Urine sodium and potassium are elevated due to intermittent renal excretion of bicarbonate. Individuals with primary hyperaldosteronism should have an elevated BP and an increase in urine [Cl]. Patients with Gitelman syndrome or active diuretic use will have an elevated urine chloride. However, if diuretics had been stopped prior to obtaining the lab tests, the urine [Cl] might be low. However, under those circumstances the urine sodium and potassium concentrations would usually also be low. Some of these patients induce vomiting and also take diuretics.

CHAPTER 15

1.

A. Respiratory acidosis
B. Yes
C. The patient has an acute and severe asthma exacerbation. Most of the time, an asthma exacerbation is accompanied by respiratory alkalosis secondary to the tachypnea. However, in this case, the respiratory acidosis is a sign that the patient has impaired air exchange and may be tiring as well. She has impending respiratory failure and may need to be intubated and mechanically ventilated.

2. Step 1: Look at the pH to classify if the person is acidotic or alkalemic; the patient is acidotic. Step 2: Is the primary disorder metabolic or respiratory? Metabolic because a low serum bicarbonate level is a feature of metabolic acidosis (which in this case is 8 mEq/L). In respiratory acidosis the pCO_2 should be elevated. Step 3: If the primary disorder is respiratory is it chronic or acute? If the primary disorder is metabolic, is the anion gap elevated? The anion gap is $[Na\text{-}(Cl+HCO_3] = 135 – (100 + 8) = 27$. Step 4: Is the compensation for the primary disorder appropriate? The expected pCO_2 in a metabolic disorder is calculated using Winter's formula ($1.5 \times [HCO_3] + 8 \pm 2 = 18$ to 22). Since the measured PCO_2 is higher than this expected value, concomitant respiratory acidosis is present.Thus, this patient has a combined high anion gap metabolic acidosis and respiratory acidosis. The delta anion gap (measured – normal) is 15 (assuming a normal anion gap of 12), and the delta bicarbonate is 16 (assuming a normal serum bicarbonate level of 24 mmol/L). Because the delta gap and the delta bicarbonate are similar, no addition metabolic disturbance is present.

CHAPTER 16

1.

A. Tubular proteinuria is low-molecular-weight proteinuria (including smaller proteins such as α1-microglobulin), whereas immunoglobulins are not usually present in significant amounts.
B. The metabolic response to heavy proteinuria is variable, and sometimes a normal serum albumin is maintained, probably as a result of both increased albumin synthesis and reduced catabolism.

C. In orthostatic proteinuria, there is less proteinuria when lying down; the early morning urine has no increase in protein.
D. **Correct. Light chain excretion should be suspected when the urine dipstick is negative for albumin when other tests show heavy proteinurea.**
E. Functional proteinuria occurs with fever, exercise, heart failure, and hyperadrenergic states.

2.
A. True (Kidney International. 2013;3[suppl 1]:1-150).
B. The major mechanism by which ACE inhibitors and ARBs reduce proteinuria is hemodynamic, reducing glomerular efferent arteriolar tone. However, they also may directly reduce glomerular capillary wall permeability.
C. The risk for hyperkalemia when using the combination of ACE inhibitor and ARB increases with falling GFR. Addition of a loop diuretic will usually reduce serum potassium.
D. **Correct. A statin or a statin-ezetimibe combination is recommended in adults <50 years with CKD only if there is established cardiovascular disease or diabetes.**
E. Dietary protein recommendations must account for urine protein loss to minimize the risk for malnutrition.

3.
A. Diuretic resistance is common in nephrotic syndrome with normal GFR; reduced protein binding limits drug access to the site of action in the tubule, increased protein binding once the drug has reached the urine reduces efficacy; and intestinal edema may reduce drug absorption.
B. Dietary protein recommendations should take account of urinary losses, but very high protein intakes (e.g., 2 to 3 g/kg/day), even if achievable, may worsen proteinuria.
C. **Correct. It also should be considered when the serum albumin is 2 to 2.5 g/dL if there are additional risk factors for thromboembolism, such as immobilization in the hospital or a prior history of thromboembolism.**
D. Microscopy and culture of ascetic fluid are required only when there is evidence of systemic infection, but routine screening for infection is not useful.
E. Nephrotic children are more prone than adults to hypovolemia. Care is needed to avoid too-rapid diuresis, which may provoke shock.

CHAPTER 17

1.
A. 70% of White and 50% of Asian patients with MN exhibit these autoantibodies.
B. 10% or less of patients with MN exhibit these autoantibodies.
C. Occur in neonatal MN.
D. **Correct. Has been related to atypical hemolytic uremic syndrome.**
E. May induce MN.

2. D. Despite autoantibody deposition in glomeruli and lung alveoli, there is usually no systemic complement consumption.
3. C. Podocyte injury, in particular slit diaphragm, typically leads to severe, often nephrotic proteinuria.

4.
A. FSGS mostly results from flocal podocyte damage.
B. FSGS is a nonspecific term to describe a glomerular scar and should not be confused with the clinical entity FSGS.
C. **Correct. Some clinical FSGS cases seem to originate from as-yet unknown circulating factors, which can give rise to rapid post-transplant recurrence of the disease.**
D. So far there is little evidence to implicate autoimmunity in the majority of FSGS cases.
E. Although some FSGS may relate to mutations of podocyte proteins, most cases originate from other types of podocyte injury.

CHAPTER 18

1. D. Children may present with abdominal pain, ascites, and diarrhea.
2. B. Most patients with MCD will undergo one or more relapses.
3. A. Tacrolimus.
4. E. Rituximab can contribute to hypogammaglobulinemia.

CHAPTER 19

1. D. Amlodipine
2. B. Glomerulomegaly and perihilar segmental sclerosis and hyalinosis
3. C. Remission of proteinuria is a strong predictor of a favorable outcome.

CHAPTER 20

1. E. Both C and D are possible
2. C. *INF2*
3. A. Glomerular epithelial
4. B. 30%
5. B. Coenzyme Q10

CHAPTER 21

1. B. THSD7A is a more common autoantigen in those of Japanese ancestry compared to Whites.
2. E. Microscopic hematuria is uncommon (5%–10%).
3. A. The predominant IgG subclass in many forms of primary MN is IgG3.
4. C. Immunosuppressive drug therapy should not be considered unless the patient has had persistent nephrotic-range proteinuria.

CHAPTER 22

1. A. MPGN secondary to a monoclonal gammopathy
2. D. Cryoglobulinemic glomerulonephritis
3. A. Mixed cryoglobulinemia
4. D. MPGN with IgG (++), IgM (+++), IgA (+), C3 (++), kappa (++), lambda (++)

CHAPTER 23

1. B. Full house of immunoglobulins and complement on immunofluorescence
2. E. An autoantibody against the alternative pathway C3 convertase
3. D. C3 glomerulopathy associated with heterozygous mutation of *CFHR5*
4. E. None of the above

CHAPTER 24

1. D
2. B. Cellular crescents were not associated with clinical outcome in the original Oxford Classification, although only a small number of cases had crescents in the original analysis.

3.
A. IgAN is more common in Asia than Europe.
B. The diagnosis of IgAN requires a kidney biopsy. Glycosylation of serumIgA is abnormal in the majority but not all cases of IgAN.
C. **Correct. The renal pathologic features can be identical to those IgA vasculiitis.**
D. More commonly, AKI with macrohematuria is due to acute tubular injury secondary to blockage by erythrocytes.
E. There is no evidence that different maintenance immunosuppressive regiments influence the recurrence rate of IgAN.
4.
A. Although most common in childhood, IgAV can occur at any age.
B. **Correct. The same alteration in IgA glycosylation is described in IgAV and IgAN.**
C. There is no evidence that delay reduces recurrence risk.
D. A French controlled trial of cyclophosphamide in adults with IgAV failed to detect benefit compared with steroids alone (Kidney International. 2010;78:495-502).
E. Randomized trials showed no benefit of corticosteroids in reducing nephritis risk.

CHAPTER 25

1. B
It is not uncommon for low levels of autoantibodies to persist some months after successful treatment of the acute illness, so we would not consider reinstituting plasma exchange or prolonging exposure to cyclophosphamide. In our experience, any persisting low-level autoantibodies disappear over subsequent months even when immunosuppression is withdrawn, so this is our preferred approach. However, one could justify continuing immunosuppression until autoantibodies become undetectable (or 1 year at most) to potentially bring forward the time when transplantation could be considered, in which case MMF would probably be preferred over continuing cyclophosphamide.
2. C
Recovery of kidney function is very unlikely if all glomeruli are severely affected with crescents. In such cases there is no renal benefit from immunosuppression, so potentially toxic treatment is only justified if there is lung hemorrhage. In this case we would recommend supportive treatment and close monitoring in anticipation of spontaneous reestablishment of self-tolerance and disappearance of autoantibodies, followed by preparation for renal transplantation.
3. B
Goodpasture syndrome generally has such an acute and dramatic manifestation, with kidney failure, hematuria, and oliguria with normal sized kidneys; it does not generally get labeled "unknown cause." In addition, recurrence of Goodpasture syndrome after transplantation is now practically unheard of. Alport syndrome, however, may progress without any particular symptoms and be labeled as unknown cause. New anti-GBM disease posttransplant is therefore more likely to be the very rare condition of Alport anti-GBM disease. In this case, subsequent analysis at a reference laboratory demonstrated there were abundant serum antibodies to alpha-5 collagen IV at the time the standard anti-GBM assay was negative.

CHAPTER 26

1. B. Small-vessel vasculitis.
2.
A. One-third to one-fourth of patients with anti-GBM also have ANCA.
B. ANCA disease may recur even if the anti-GBM disease enters remission.
C. **Correct. ANCA occurs with anti-GBM, and the ANCA disease may recur even if the anti-GBM disease enters remission.**

3.
A. GN does not occur in PAN. GN is a marker of small-vessel vasculitis, and PAN is a medium-vessel vasculitis.
B. Pulmonary hemorrhage does not occur in PAN. It is a marker of small-vessel vasculitis, and PAN is medium-vessel vasculitis.
C. Polymyalgia rheumatic is associated with giant cell arteritis and not PAN.
D. **Correct. There is an association between hepatitis B infection and PAN.**
4.
A. The gradual narrowing of arteries by chronic inflammation does not cause acute ischemia with infarction, unlike PAN, which can cause infarction because of acute inflammatory narrowing and thrombosis.
B. The gradual narrowing of arteries by chronic inflammation does not cause acute kidney failure.
C. GN is not a feature of Takayasu arteritis.
D. **Correct. Narrowing of main renal arteries by the arteritis causes renovascular hypertension.**
5.
A. Clinical trials have shown no difference in adverse events.
B. **Correct. Clinical trials have shown noninferiority between induction therapy with rituximab compared with cyclophosphamide.**
C. Clinical trials have shown noninferiority between induction therapy with rituximab compared with cyclophosphamide.
D. Rituximab has been approved by the FDA for induction therapy.

CHAPTER 27

1. D. She could be treated with belimumab alone.
2. A. Continue the current dose of MMF, follow patient for a complete renal remission, and when achieved reduce MMF to 2 g/day and continue for at least 36 months of total immunosuppressive therapy, with ongoing monitoring for any evidence of LN relapse.
3. E. Mycophenolate mofetil
4. B. Order a kidney biopsy to determine if there is any residual histologic activity.

CHAPTER 28

1. E. A major prognostic factor for patient survival
2. C. Frequently responsible for nondiabetic glomerulosclerosis
3. E. Electron microscopy
4. A. Kidney failure

CHAPTER 29

1. C. Lecithin–cholesterol acyltransferase deficiency
2. B. Bezafibrate
3. C. Idiopathic (primary) membranous nephropathy
4. D. Antiphospholipid antibody test

CHAPTER 30

1. A. Thrombocytopenia and nonimmune hemolytic anemia, with or without neurologic and/or kidney dysfunction

2. B. Shiga toxin E. coli–associated hemolytic uremic syndrome
3. C. *CFH* mutations
4. B. Eculizumab
5. C. TTP with anti-ADAMTS13 antibodies

CHAPTER 31

1. B. Glomerulosclerosis, tubular atrophy, and tubulointerstitial lesions are typical pathologic findings in diabetic nephropathy.
2. E. Type of diabetes
3. D. Acanthocytes in urine sediment
4. B. Inflammasome activation in the diabetic kidney

CHAPTER 33

1. C. Add liraglutide to current regimen.
2. A. History of recurrent severe hypoglycemia
3. B. Intensive blood pressure lowering in the SPRINT trial was associated with lower rates of eGFR decline.
4. D. The cardiovascular benefits of SGLT2i are largely related to reductions heart failure hospitalizations, whereas there is stronger evidence of reductions in atherosclerotic cardiovascular disease with GLP-1 receptor agonists.

CHAPTER 34

1.

A. Atrial natriuretic peptides can work quickly but generally have only small effects on blood pressure in normal humans.

B. Endothelin has variable effects on blood pressure in normal humans, but most effects occur over hours to days.

C. Although the kallikrein-kinin system can act relatively quickly, it is thought to contribute only in minor ways to regulation of blood pressure in normal humans.

D. Modulation of the renin-angiotensin-aldosterone system generally takes hours to days to affect blood pressure in normal humans.

E. **Correct. Catecholamines are heavily involved in modulation of blood pressure during hypovolemia and/or hemorrhage, especially in normal human subjects.**

2.

A. None of his three measurements falls into the <120/<80 mm Hg range.

B. According to the ACC/AHA 2017 US hypertension guideline, the term, "elevated blood pressure" is properly used to categorize in-office systolic blood pressures between 120 and 129 mm Hg, and diastolic blood pressures <80 mm Hg. All of this patient's blood pressure measurements are above these categories.

C. **Correct. HEDIS 2021 and its several predecessors have condoned the use of the lowest individual systolic and lowest diastolic blood pressures, even if measured separately, as "the blood pressure for this visit." As a result, his blood pressure for this visit would be 138/88 mm Hg, which is in the stage 1 hypertension range according to the ACC/AHA US hypertension guideline.**

D. Although four of his six numbers fall into the >140/>90 mm Hg range, HEDIS 2021 and its several predecessors recommend (or condone) the reporting of the lowest individual systolic and the lowest individual diastolic blood pressure, even if not part of the same measurement, as "the blood pressure for this visit." This process differs from most clinical trials, which most often used the average of the last two of three measurements.

E. This diagnosis is no longer part of the classification scheme for blood pressures in the ACC/AHA 2017 US hypertension guideline, although it continues to be used overseas, typically for systolic blood pressure >140 mm Hg and diastolic blood pressure <90 mm Hg.

3.

A. This recommendation leaves unanswered the question of chronic kidney disease, which needs to be confirmed or rejected, and which might prompt drug therapy if his reduced eGFR is confirmed after 3 months.

B. This is most appropriate for a healthy person with prehypertension according to JNC 7. But there is the unresolved issue of chronic kidney disease, which needs to be confirmed or rejected, and which might prompt drug therapy if his reduced eGFR is confirmed more than 3 months later.

C. **Correct. The diagnosis of chronic kidney disease hinges on a 3-month history of abnormal kidney function, which has not yet been established. Repeat testing to confirm the diminished estimated glomerular filtration rate is necessary.**

D. This was the JNC 7 recommendation for healthy people with initial blood pressures in the stage 1 hypertension range. It might be appropriate here, but there is the unresolved issue of chronic kidney disease, which also needs to be addressed. Rechecking kidney function in 2 more months might be appropriate, but doing so would not fulfill the diagnostic criteria for chronic kidney disease.

E. The US FDA does not recognize albuminuria as an indication for antihypertensive drug therapy, and he does not yet meet the diagnostic criteria for chronic kidney disease, If, in 3 months' time, his estimated glomerular filtration rate is ≥60 mL/min/1.73 m2, he would then fulfill the ACC/AHA 2017 US hypertension guideline criteria for uncomplicated stage 1 hypertension, but since his 10-year risk of a cardiovascular event is <10%, this guideline specifically exempts him from drug treatment until his blood pressure is ≥140/90 mm Hg. Many nephrologists would argue that even a little albuminuria is prognostically bad, but there are few, if any, randomized clinical trials involving patients with this level of albuminuria to demonstrate that giving an antiproteinuric drug improves the time to death, dialysis, or kidney transplantation.

4.

A. This is probably higher than the prevalence of pseudohypertension, which is said to be associated with a positive Osler maneuver. No such finding is described in the vignette; she is likely too young to have developed this condition.

B. This is the expected prevalence of secondary hypertension in the hypertensive population. Although it is possible that she has secondary hypertension, there are no clinical clues, and the description is more likely that of masked hypertension.

C. **Correct. This is the expected prevalence of masked hypertension, which fits the description in her case. It is likely that an ambulatory blood pressure monitor or home blood pressure monitoring will demonstrate elevated blood pressures, which might prompt treatment. Some have speculated that masked hypertension may occur more often in people with childcare responsibilities if they arrange for a caregiver during office visits.**

D. This is the expected prevalence of white coat hypertension, which does not fit her case history, in that she has target organ damage and normal office blood pressures.

E. This is the expected, age-adjusted prevalence of hypertension (defined as blood pressure ≥140/90 mm Hg) in the US over the last 20+ years. Yet her in-office blood pressures do not meet older diagnostic criteria (but the lowest diastolic was 80 mm Hg, which, in the ACC/AHA 2017 US hypertension guideline might qualify for this diagnosis, but if her estimated 10-year cardiovascular risk is <10%, she would not be mandated to receive drug treatment). It is likely that since NHANES also uses an automated oscillometric

sphygmomanometer, she would probably not be identified as hypertensive in national surveys.

5.

A. Renal biopsy is more often used to determine the cause of glomerulonephritis or nephrotic syndrome and is seldom useful in the diagnosis of hypertension.

B. Although iothalamate clearance is more accurate than calculations of estimated glomerular filtration rate, it is expensive; exposes staff, patients, and the environment to radioactivity; and was abandoned by the National Institutes of Health after the vanguard phase of the African American Study of Kidney diseases and hypertension (AASK). The CKD-Epi equation is more accurate (especially for those with eGFR >60 mL/min/1.73 m2) than the updated MDRD equation, which is widely used by most US laboratories.

C. A search for a secondary cause of hypertension is typically undertaken only when there is strong suspicion on clinical grounds, or when the blood pressure is resistant to treatment. The idea of screening all hypertensives for secondary causes has not been recommended by any US hypertension guideline.

D. The most likely diagnosis for him is white coat hypertension, which typically does not respond with a lowered office blood pressure after institution of antihypertensive drug therapy. It might be worth a try, but it is unlikely to improve his office blood pressures much, and puts him at risk for hypotension outside the office.

E. **Correct. The most likely diagnosis for him is white coat hypertension, but some people with this diagnosis progress to sustained hypertension, which can be detected by home blood pressure monitoring. If and when sustained hypertension is diagnosed, he would be a candidate for drug therapy. The threshold of 125/75 mm Hg is the expected home equivalent to an office blood pressure of 130/80 mm Hg.**

CHAPTER 35

1. B. Salt sensitivity increases with age.
2. E. The presence of transmural necrosis should prompt consideration of vasculitis, not primary hypertension.
3. E. Although coffee is not a risk factor, caffeine tablets, or high caffeine content such as in "power drinks," may be potential risk factors for hypertension.

CHAPTER 36

1. D. The guidelines do not recommend regular muscle-strengthening activity for all age groups.
2. B. 1 mm Hg
3. D. People younger than 40 years
4. B. Abstinence of from alcohol may reduce the risk of myocardial infarction.

CHAPTER 37

1. C. The recommended combinations of drug therapy for most patients with hypertension usually involve a RAS blocker combined with a CCB or diuretic.
2. A. Lowering BP to at least <140/90 mm Hg in all treated patients, if tolerated, is recommended by all guidelines.
3. E. Angiotensin receptor-neprilysin inhibitors are significantly more effective at lowering BP than ARBs alone.
4. E. RH is most effectively treated with further diuretic therapy.

CHAPTER 38

1. D. The patient has hypertensive urgency, not a hypertensive emergency. In the absence of target organ damage, the patient can be treated less aggressively. The key is rapid follow-up (within a week).
2. C. While the INTERACT2 trial does suggest reduction of BP to levels of 140/90 mm Hg in subjects with hemorrhagic stroke, nitroprusside is not a desired antihypertensive agent as it obliterates cerebral autoregulation; nicardipine is a superior agent. Reducing BP to 160/90 mm Hg remains the standard target for these patients.
3. B. For subjects with aortic dissection, reducing the BP to 100 mm Hg systolic is the goal. Labetalol is an effective antihypertensive agent for this purpose.

CHAPTER 39

1.

A. Mutations affecting the aldosterone synthase gene (CYP11B2) are present in FH-I. They are not a common cause, however, of APA.

B. Mutations in the mineralocorticoid gene are not a common cause of APA.

C. Mutations in the AT1 receptor are not a common cause of APA. Some evidence suggests, however, that activating autoantibodies directed against the AT1 receptor may be pathogenic in primary aldosteronism from bilateral adrenal hyperplasia.

D. **Correct. Mutations in the KCNJ5 gene are present in ~40% of APA.**

E. Mutations in ENaC occur in Liddle syndrome but not in APA.

2.

A. Eplerenone appears to have less effect to decrease BP in patients with primary aldosteronism.

B. The rate of side-effects and drug discontinuation appears to be similar between spironolactone and eplerenone.

C. **Correct. Spironolactone appears to decrease BP significantly more, by about two-fold, than does eplerenone in patients with primary aldosteronism.**

D. The rate of side-effects and drug discontinuation appears to be similar between spironolactone and eplerenone.

3.

A. Most patients with primary aldosteronism do not have hypokalemia.

B. Cannot differentiate between primary aldosteronism and secondary hyperaldosteronism and has significantly less sensitivity to identify primary aldosteronism.

C. Although a suppressed plasma renin activity is a hallmark of primary aldosteronism, by itself it cannot identify primary aldosteronism.

D. **Correct. This is the preferred first line test for primary aldosteronism.**

E. Cannot differentiate primary aldosteronism from other causes of hypertension.

CHAPTER 40

1. D. May present as hypertension resistant to multiple drugs
2. B. 1 mg dexamethasone suppression test
3. C. 30% to 40%

CHAPTER 41

1. B

After intravenous tPA administration AHA/ASA guidelines recommend maintenance of BP <180/105 mm Hg. Therefore, a diastolic BP of 110 mm Hg should be lowered to a target value of <105 mm Hg. In this case the patient presented with signs consistent with an acute ischemic stroke, and given that the CT scan shows no hemorrhage, acute cerebral ischemia is the most likely diagnosis. In that setting the correct first-line therapy in the absence of contraindications is intravenous tPA. In this patient the presenting BP is higher than the limit for tPA administration; thus administration of intravenous tPA after acute BP lowering to <180/110 mm Hg is appropriate (Answer A). In this patient IV labetalol or nicardipine would be the drug of choice. Sublingual nifedipine is proscribed since nifedipine can lead to a substantial reduction in BP (Answer C). In the setting of acute ischemic stroke there is no evidence-based data to support use of vasopressors to augment BP, especially in this case where BP is elevated and above the recommended thresholds for post tPA BP management (answer D)

2. E

This patient presents with an ICH without intraventricular extension or hydrocephalus and no impairment of consciousness. In this case clinically significant hematoma expansion is expected in about 40% of the patients. Additionally, hematoma expansion in hypertensive ICH is rare after the first 36 hours. Since the patient reportedly had the first presentation 2 days prior, it is unlikely that any further clinically significant expansion will occur (answer A). Lowering BP has not been conclusively proven to decrease the incidence of hematoma expansion (answer B). Since the patient is fully conscious with a relatively small hematoma, lack of decline after 2 days from the onset of symptoms and no associated hydrocephalus, there is no clinical evidence for increased ICP and no indication for ICP monitoring (answer C). Some studies had suggested that there may be perihematomal ischemia around an ICH but this theory has been largely discredited by more recent studies (answer D).

3. E.

All the options are features of carotid hyperperfusion syndrome.

CHAPTER 42

1. C. Peridialytic BP recordings are inadequate to assess BP control.
2. D. Hypertension in dialysis patients is best managed using nonpharmacologic strategies.
3. D. Intradialytic hypertension is often a sign of volume overload.

CHAPTER 43

1. B. CTA of renal arteries
2. B. Start ACE inhibitor and follow BP response and potassium and creatinine closely
3. D. Both A and B
4. A. MRA of RAs
5. C. CT with and without contrast
6. A. Cholesterol emboli

CHAPTER 44

1. B. Hypernatremia
2. A. Proteinuria 2 g/day
3. C. Hemolytic uremic syndrome
4. B. Placental growth factor concentrations
5. D. Aspirin
6. C. Interbirth interval less than 1 year

CHAPTER 45

1.

A. Women with ADPKD with hypertension have a higher risk for preeclampsia and preterm delivery than those without hypertension.

B. Preimplantation genetic testing can be offered, but many women with ADPKD prefer to conceive spontaneously.

C. **Correct. Aspirin should be offered to all women with chronic hypertension to reduce the risk for preeclampsia.**

D. Amlodipine has not been demonstrated to be teratogenic, but more experience of safety is needed with nifedipine, which could be offered as an alternative agent but requires twice or three times daily dosing. BP control before pregnancy should be optimized.

2.

A. Conception after transplantation is recommended to be delayed until at least 12 months posttransplantation to ensure graft stability. The optimal time to conceive remains unclear; however, in view of increased maternal age and graft stability in this case, it would not be unreasonable to switch MMF to azathioprine at 12 months, ensure graft stability, and then for the woman to attempt to conceive.

B. Breastfeeding should be encouraged in women with kidney transplants, particularly those with preterm deliveries with greatest infant benefit. Standard immunosuppression during pregnancy, that is, prednisolone, azathioprine, and tacrolimus, can be continued safely with lactation, and only minimal quantities of each drug have been identified in breast Milk.

C. There are no data regarding breastfeeding with MMF, and therefore it is not currently recommended. Azathioprine should be substituted for MMF. High-dose prednisolone may be associated with gestational diabetes, maternal infection, osteoporosis, and preterm delivery and therefore should be avoided.

D. **Correct. Women with lupus nephritis may continue to have anti-Ro or La antibody that is transferred by the placenta and may lead to neonatal lupus syndromes, including fetal heart block. Fetal cardiac monitoring from 16 to 18 weeks of gestation is recommended in those with positive antibody.**

3.

A. **Correct. At this early gestation, attempts should be made to prolong pregnancy to optimize neonatal outcomes.**

B. Fetal assessment will determine timing of delivery. If maternal compromise persists despite BP control, delivery may be needed, but a balance between maternal and fetal benefit needs to be considered by obstetricians, nephrologists, and neonatologists. This presentation also could be consistent with progression of underlying kidney disease, and placental and fetal ultrasound will help determine whether preeclampsia is evolving.

C. Intravenous magnesium should be used only if there is evidence of neurologic involvement such as brisk reflexes, scotoma, or HELLP syndrome (hemolysis, elevated liver enzymes, low platelet count) but not routinely in a woman with suspected preeclampsia.

D. Labetalol may be used to treat hypertension, but there is no evidence of benefit of aspirin to treat gestational hypertension and its associated complications.

CHAPTER 46

1. E. All options all been shown to contribute to the rate of progression of the kidney cystic disease in ADPKD.
2. C. Aneurysms in the posterior circulation of the circle of Willis have an increased risk for rupture compared with those in the anterior circulation. Although some authors argue that all patients with ADPKD should undergo presymptomatic screening for intracranial

aneurysms, there is no evidence to support the efficacy or cost-effectiveness of this strategy. Most intracranial aneurysms do not rupture. Screening for intracranial aneurysms by magnetic resonance angiography does not require administration gadolinium.

3. A. Hypocitraturia is a common metabolic abnormality in patients with ADPKD even before there is a decline in kidney function. Hypercalciuria, hyperuricosuria, and hyperoxaluria do not occur more frequently in these patients. Renal tubular acidosis is rarely associated to ADPKD.
4. D. The HALT PKD study showed that ACE inhibitor monotherapy is very effective in controlling BP in the majority of patients with ADPKD; however, superiority to β-blockers has not been proven in head-to-head studies. Rigorous BP control was found to be superior to standard control in young patients with ADPKD with a GFR >60 mL/min/1.73 m^2 in the HALT PKD Study A clinical trial, but rigorous BP control was not used in Study B with more advanced ADPKD.

CHAPTER 47

1. E. ARPKD has a diverse set of extrarenal complications that primarily involve the liver, less commonly impact growth, and very rarely involve intracranial aneurysms.
2. B. The term nephronophthisis derives from the Greek, meaning "progressive loss of nephrons"; nephron loss combined with fibrosis (another hallmark of NPHP) leads to small kidneys.
3. C. Angiomyolipomas are a major clinical feature of TSC and the most common kidney lesion in TSC patients.
4. D. VHL-associated disease clusters into two complexes based on the nature of the germ-line mutation.
5. A. MSK is generally considered to be a sporadic disorder, but familial clustering with autosomal dominant inheritance and evidence for genetic alteration in the RET-GDNF axis suggest a genetic basis for MSK in at least a subset of patients.

CHAPTER 48

1. B. His mother has AS.
2. E. All of the above
3. C. Hearing loss in AS initially targets high frequencies above the range of conversational speech.

CHAPTER 49

1. C. Bartter syndrome (types 1 and 2), as well as Liddle and Gordon syndrome are associated with hypercalciuria and Bartter syndrome types 3 and 4 with normocalciuria. While some patients with Bartter syndrome type 3 can phenocopy Gitelman syndrome and thus may have hypocalciuria, Gitelman syndrome is the only disorder listed that is consistently associated with hypocalciuria.
2. B. Prostaglandin synthesis inhibitors, also called cyclooxygenase (COX) inhibitors, such as indomethacin, ibuprofen or celecoxib, as well as salt and KCl supplementation, are usually the mainstay of treatment of Bartter syndrome. Potassium-sparing diuretics such as amiloride worsen the salt wasting and thus risk hypovolemia but may be helpful in cases with extreme electrolyte abnormalities, as long as they are cautiously used and supported with adequate salt supplementation.
3. B. Aldosterone deficiency, PHA1, and PHA2 are all characterized by hyperkalemic acidosis due to impaired Na transport through ENaC. In contrast, enhanced ENaC activity causes hypokalemic alkalosis, as it facilitates potassium and proton secretion in the collecting duct.
4. C. Whereas normally the kidney adjusts urine composition and volume to match intake and environmental stressors, this is impaired in tubular disorders such as NDI. In these disorders, maintenance of homeostasis is reversed and intake must be adjusted to the urine to maintain overall balance. In NDI, the kidneys lose water, thus intake should constitute of water. Administration of fluids with a higher sodium concentration than that of the urine, such as 0.45% or 0.9% saline and Hartman solution, will lead to hypernatremia.

CHAPTER 50

1. B. Cystinosis
2. A. Arginine, lysine, ornithine
3. B. Medications
4. E. SLGT2
5. D. ClC-5

CHAPTER 51

1. B. Have reduced urinary concentrating capacity
2. D. Have a higher rate of delayed graft function following kidney transplantation than patients with ESKD of other causes
3. C. Works by increasing fetal hemoglobin production

CHAPTER 52

1. A. Unilateral renal agenesis occurs in 1 in 3000 live births.
2. C. In prune-belly syndrome the ureters are grossly dilated.
3. B. Ureterosigmoidostomy may lead to hyperchloremic hypokalemic metabolic acidosis.
4. E. PUV only occurs in males.
5. B. Calcium phosphate stones are most often seen in augmented bladders.

CHAPTER 53

1. B. Ciprofloxacin
2. D. Periodic screening and treatment of asymptomatic bacteriuria
3. B. Nitrofurantoin
4. C. Pregnant patients and patients undergoing urologic instrumentation

CHAPTER 54

1. C. Immune reconstitution inflammatory syndrome (IRIS) is a pathogen-specific inflammatory response in HIV-infected patients that may be triggered after initiation, reinitiation, or change to more active antiretroviral therapy. It is a paradoxical phenomenon of apparent clinical and radiologic worsening occurring in HIV-infected patients who had TB, inactive cytomegalovirus retinitis, or quiescent cryptococcal infection. It is usually accompanied by an increase in CD4 cell count and/or a rapid decrease in viral load. It may occur in patients with HIV when treatment with antivirals is started together with specific chemotherapy. Higher incidence of IRIS has been observed if the load of organisms is higher.
2. D. In the usual doses, ethambutol is a bacteriostatic drug. It is bactericidal only if very high doses are used.
3. A. Painless macroscopic hematuria occurs in immunoglobulin A nephropathy, other glomerular diseases, and urinary TB. In other conditions, such as stone, tumor, trauma, and acute urinary tract infection, it is painful.

B. Acid sterile pyuria is unique to tuberculosis. The combination of persistent increase in urinary white cells, negative conventional cultures, and acidic pH of urine.
C. Sterility (in females) and epididymitis (in males) are a common genital involvement.
D. There is a characteristic lack of constitutional symptoms in urinary TB. Most symptoms are related to drug treatment.
E. **Correct. Icterus is not a manifestation of TB. If it occurs, it is due to drug therapy.**

4.
A. No dose change. The main route of excretion is by the biliary route.
B. **Correct. Dose should be modified. For streptomycin, increase dosing interval (over 45 years, 50% dose) and monitor for ototoxicity. For ethambutol, increase dosing interval and monitor visual acuity, field, and color vision.**
C. Pyrazinamide should be avoided in liver disease. Use carefully in the short term in kidney failure.
D. No dose change. The main route of excretion by the biliary route.

5. B. Rifampicin

CHAPTER 55

1. C. *C. albicans* is the species isolated most commonly in both UTIs and candidemia.
2. E. Pyuria is not a helpful sign for the diagnosis of a *Candida* UTI when a catheter is present or when there is a concomitant bacterial infection. If there is no catheter and no bacteriuria, pyuria is sometimes useful as a marker for UTI with *Candida* species.
3. B. Flucytosine is excreted in the urine, and serum levels rise when creatinine clearance is diminished. Toxic effects on bone marrow and liver and are directly related to serum levels greater than 100 μg/mL. The other drugs are metabolized in the liver or elsewhere in the body and do not accumulate with kidney failure.
4. B. Shown by placebo-controlled clinical trial (*Clin Infect Dis*. 2000; 30:19-24.)

CHAPTER 56

1. B. Schistosoma-associated *Salmonella* bacteremia
2. D. Infiltrative bladder cancer
3. D. Concomitant virus-induced cryoglobulinemia

CHAPTER 57

1. A. True
2. A. Low serum CH50 and C3 levels
3. A. True
4. A. Contraindicated in patients with active HBV infection and associated GN

CHAPTER 58

1. A. HIV-associated nephropathy (collapsing glomerulopathy) or focal segmental glomerulosclerosis
2. C. Tenofovir disoproxil
3. D. Giant mitochondria within the tubular cells

CHAPTER 60

1.
A. **Correct. Antibiotic therapy is important to reduce struvite stone growth and for stone prevention. Bacteria will remain in the stone interstices and stones will continue to grow unless chronic antibiotic suppression in maintained or the calculi are completely eradicated. Thus a short course of antibiotics is not sufficient.**
B. Struvite stones are composed of magnesium ammonium phosphate and calcium carbonate apatite. They form when urease production y certain bacteria that breaks down urea to ammonium and a carboxyl group.
C. Insoluble urinary phosphate forms a solid phase with magnesium, calcium, and ammonium.
D. With alkaline urine, urinary phosphate becomes insoluble and forms a solid phase with magnesium, calcium, and ammonium.
E. Bacteria will remain in the stone interstices after a short course of antibiotics until calculi are completely eradicated by surgical interventions.

2.
A. Dietary salt restriction is associated with decreased urine calcium excretion.
B. Animal protein ingestion increases the frequency of kidney stone formation by a number of mechanisms, including generation of sulfate ions, which render urinary calcium ion less soluble, and metabolic acidosis, which can cause calcium release from bone and a consequent increase in the filtered load of calcium.
C. **Correct. Several studies have demonstrated that there is a decrease in stone incidence when people consume adequate dietary calcium. This beneficial effect has been attributed to intestinal binding of ingested oxalate by dietary calcium.**
D. Most calcium stones are composed of calcium oxalate, either alone or in combination with calcium phosphate or uric acid. Thus dietary oxalate should be restricted.

3.
A. Uric acid stones are radiolucent and therefore poorly visible on plain radiographs.
B. **Correct. Uric acid stones often occur in patients with insulin resistance. The rising incidence of obesity and insulin resistance in the United States has led to a parallel increase in uric acid stones.**
C. Allopurinol should be prescribed if uric acid excretion remains high despite dietary intervention, to keep urinary uric acid excretion < 750 mg/day. This patient already had uric acid excretion < 750 mg/day.
D. Low urine pH is the principal metabolic disorder found in patients with uric acid stones. Potassium citrate can raise urine pH and prevent stone formation.
E. An increase in urine volume of more than 2 to 2.5 L/day has been proven to reduce the incidence of stones. This patient's urine volume was only 1.5 liter per day and thus inadequate.

CHAPTER 61

1.
A. **Correct. Hydronephrosis describes dilation off the upper urinary tract and can occur in the absence of functional obstruction.**
B. Urinary tract obstruction may affect neonates, children, and adults of both sexes, and the underlying causes and outcomes are therefore highly diverse, with most patients not developing ESKD.
C. Urinary tract obstruction may be associated with oliguria or even anuria if the obstruction is bilateral and complete. However, it is important to note that patients with a partial obstruction may report polyuria and nocturia as a result of an impaired ability of the kidney to concentrate the urine.
D. Urine dipstick analysis is highly variable in patients with urinary tract obstruction, and there are no "typical" findings. Microscopic

hematuria may be evident in patents with kidney calculi or tumors, but urinalysis is often negative for blood and protein.

E. **Correct. Urinary tract obstruction results in urinary stasis and is a risk factor for infection, with infections often being more difficult to eradicate if obstruction is ongoing.**

2.

A. Recent work suggests the opposite, with the development of marked diuresis (>7 liters per 24 hours) being associated with a very good outcome with preservation of kidney function.

B. **Correct. Examples include adynamic segments of the ureter that result in pelviureteral junction obstruction, and diseases such as multiple sclerosis and diabetes may be complicated by a hypertonic or atonic bladder, respectively.**

C. **Correct. Many inflammatory, degenerative, or neoplastic conditions may affect the retroperitoneum and involve the ureters, thereby causing urinary tract obstruction.**

D. **Correct. The obstructed kidney develops chronic inflammation that is associated with progressive scarring. Long-term obstruction leads to profound parenchymal damage and cortical thinning.**

E. Patients with IgA nephropathy may develop severe macroscopic hematuria. The red cells are of glomerular origin and may thus obstruct the nephron lumen and cause significant intrarenal urinary tract obstruction that is associated with acute kidney dysfunction.

3.

A. **Correct. Various aspects of tubular function may be abnormal, including urinary acidification, potassium handling, and urinary concentration.**

B. The blood flow of the obstructed kidney is also reduced, with kidney vasoconstriction associated with increased intrarenal levels of angiotensin II and thromboxane A2.

C. Renal tract ultrasound remains the first-line investigation for the majority of patients with suspected urinary tract obstruction because it does provide very useful information despite being operator dependent. Non–contrast-enhanced spiral CT scanning is useful for the primary assessment of patients with acute flank pain but, unlike ultrasound, does expose the patient to radiation.

D. A diuresis renogram is used to assess whether a dilated system is actually obstructed. The absence of functional obstruction is indicated by the rapid washout of the isotope after diuretic administration.

E. **Correct. Although unusual, urinary tract obstruction may occur in the absence of hydronephrosis, as in transplanted kidneys that are encased in dense fibrous tissue. In addition, retroperitoneal fibrosis or infiltrating tumors may surround the ureters and prevent dilation but still obstruct native kidneys.**

CHAPTER 62

1. B. Voiding cystourethrogram
2. D. 6-year-old female with grade IV reflux
3. D. Cefalexin
4. E. All the above

CHAPTER 63

1. C. Standard practice is to manage distal nonobstructing calculi conservatively for a period of 2 to 4 weeks, with a trial of medical expulsive therapy, given the high spontaneous passage rate.
2. D. Any patient with unexplained visible hematuria should undergo full urologic workup with flexible cystoscopy, renal function tests, and CT urogram, although local resources often dictate other imaging strategies such as intravenous urography and ultrasound as first-line interventions. Anticoagulation should not be considered an explanation for hematuria because underlying malignancy is common.
3. C. Partial nephrectomy has emerged as a favorable procedure when compared with radical nephrectomy because concerns over reduced oncologic clearance have been unfounded. If technically possible, this should be performed laparoscopically. Although cryosurgery and radiofrequency ablation are promising alternatives to partial nephrectomy, they should be considered experimental at present.

CHAPTER 64

1. A. Both NSAIDs and PPIs are among the classes of drugs most commonly responsible for AIN.

2.

A. This diagnostic procedure does not have a poor negative predictive value.

B. This diagnostic procedure does not have a poor negative predictive value.

C. Some drugs other than NSAIDs can induce AIN associated with heavy proteinuria, including ampicillin, rifampin, lithium, interferon, phenytoin, pamidronate, and d-pencillamine.

D. **Correct. A kidney biopsy is the only test that can be performed to reliably rule out or confirm the diagnosis of AIN.**

3. D. The course of drug-induced AIN is not always benign, and it leads to chronic kidney disease in at least 40% of cases.

CHAPTER 65

1. B. Vacuolation of the renal tubules
2. D. Autoimmune pancreatitis
3. A. Non–contrast-enhanced MRI

CHAPTER 66

1. B. Regions with a high prevalence of CKD that is unrelated to common causes such as hypertension and diabetes
2. A. A type of CKD of undetermined cause highly prevalent in the Pacific coast of Central America
3. B. Mostly asymptomatic, predominantly tubulointerstitial damage with low proteinuria, young workers from hot regions
4. E. All the above

CHAPTER 67

1. D. Light chain cast nephropathy
2. C. Acute interstitial nephritis
3. D. Lymphomatous infiltration of the kidneys

CHAPTER 68

1. C. Light chains
2. C. Cast nephropathy
3. E. Bortezomib
4. D. Serum free light chains

CHAPTER 69

1.

A. **Correct. The slowly falling glomerular filtration rate (GFR), the hypertension, and the bland urinalysis are all suggestive of chronic cyclosporine nephrotoxicity.**

B. A kidney biopsy is not considered urgent in the setting of bland urinalysis and a high pretest probability of cyclosporine toxicity, although It may be performed at some point for confirmation and prognostication purposes.

C. The combination of sirolimus + cyclosporine increases the risk for further kidney damage.

D. Cystic fibrosis of itself is not a contraindication to kidney transplantation.

E. Diltiazem will impair the metabolism of both cyclosporine and simvastatin, increasing their blood and tissue concentrations, which will increase the risks for acute kidney injury (AKI) and rhabdomyolysis.

2. C. The most likely process here given the risk factors (time frame, total body irradiation) and clinical and laboratory features (hypertension, low platelets, rising creatinine with proteinuria and hematuria) is thrombotic microangiopathy. Plasma LDH, serum haptoglobin, and blood film will confirm this suspicion. Membranous nephropathy tends to cause nephrotic (not nephritic) syndrome. Hematologic malignancies can infiltrate the kidneys, leading to AKI, but would not manifest with nephritic syndrome. Ultrasound is the preferred method for identifying obstructive uropathy (especially in the setting of kidney dysfunction, in which intravenous contrast could cause further kidney injury).

3. E. Clarithromycin increases cyclosporine levels (by reducing cytochrome P450 [CYP] 3A activity, which is involved in cyclosporine metabolism), giving rise to the typical manifestations of acute calcineurin inhibitor toxicity: tremor, AKI, hyperkalemia. Allopurinol and azathioprine should not be coadministered because of the risk for severe pancytopenia. Preemptive kidney transplant would be the best treatment for this patient because he is young, relatively healthy, and likely to withstand the stress of kidney transplant surgery.

4. B. Here, the baseline serum creatinine of 1.0 mg/dL likely reflects some degree of CKD, given the young age, female sex, and likely low muscle mass in the face of end-stage liver disease. Glomerulonephritis, although not uncommon in hepatitis C infection, tends to heave a more subacute presentation and—at least when acute—is characterized by hematuria and proteinuria. Simultaneous liver-kidney transplant is not currently indicated because her acute kidney dysfunction has been ongoing for 1 week only. Given her baseline CKD and current AKI, she has a significant risk for developing severe CKD over the long term.

5. D. Although severe heart failure is likely contributing to the kidney dysfunction, the hemodynamic insults at cardiac transplantation and the post-transplant nephrotoxic medications (without which outcomes are poor) make it more likely that the kidney function will further deteriorate. Furthermore, the proteinuria suggests there is also intrinsic kidney disease such as secondary focal segmental glomerulosclerosis (which can occur in cyanotic heart disease). Therefore, although not recommended because of her high risk for morbidity and mortality perioperatively.

CHAPTER 70

1. A

Acute tubular injury occurs in tubular regions due to an imbalance between blood supply and metabolic work. The proximal tubule (especially the S3 segment) and loop of Henle both lie within the outer medulla where blood supply is limited, and both have high metabolic requirements secondary to sodium reabsorption at these sites (Na-K-ATPase).

2. D

Reduction in left ventricular function triggers the release of potent vasoconstrictors (SNS, AII, ADH, endothelin) that can cause AKI by impairing kidney perfusion. NSAIDs inhibit the production of protective prostaglandins impairing compensatory afferent arteriole vasodilation in this setting. Note NSAIDs may also cause an acute interstitial nephritis (sometimes associated with heavy proteinuria), acute papillary necrosis and, rarely, AKI associated with minimal change disease.

3. B

Methotrexate may form intratubular crystal, which block tubular flow and cause an interstitial nephritis. Cisplatin inhibits mitochondrial ATP generation. Gentamicin accumulates in proximal tubular cells and interferes with cellular energetics and induces oxidative stress. Amphotericin punches holes in cell membranes. Tacrolimus causes kidney vasoconstriction leading to kidney ischemia in addition to direct tubular toxicity.

4. B

Contributing factors include kidney vasoconstriction (enhanced tubul-glomerular feedback due to increased delivery of chloride to the macula densa), obstruction from tubular cell casts (leading to increased hydraulic pressure in Bowman's space opposing filtration), and backleak.

CHAPTER 71

1. A. Viperidae and Elapidae
2. D. Leptospirosis
3. B. First *falciparum*, then *vivax*; less common *malariae, ovale,* and *knowlesi*
4. C. Dengue, yellow fever, and Hantavirus hemorrhagic fever

CHAPTER 72

1. A. Serum creatine kinase level
2. C. BUN of 34 mg/dL
3. D. Postvoid bladder catheterization

CHAPTER 73

1. D. Thyroid disorders are not associated with the risk of AKI.
2. C. The incidence of AKI in hospitalized patients has increased by approximately 13% per year over the last 3 decades.
3. D. All of the above appear to be consequences of AKI.
4. B. The incidence of stage 4 CKD or greater in AKI survivors is approximately 120 per 100,000 person-years.

CHAPTER 74

1. C. Detrimental for kidney function (increase in need for replacement therapy)
2. E. All the above
3. A. Urine output should be maintained around 300 mL/h until CK levels are lower than 1000 U/L.
4. B. Volume expansion should be maintained after major vascular surgeries unless patients develop evidence of pulmonary congestion.

CHAPTER 75

1.

A. False. The use of intermittent acute kidney replacement therapy as initial modality results in the same outcomes as the use of continuous KRT as initial modality, as long as one switches in a timely manner as best practice and clinical indications dictate. Early studies suggested that critically ill patients treated with continuous KRT or intermittent KRT may have better organ recovery than those treated with standard intermittent KRT. However, this has not demonstrated in a definitive manner.

B. False. While an individual's clinical situation might mandate more intensive treatment for any given case, high-quality evidence shows that thrice-weekly treatment is adequate for the majority of critically ill patients intermittent KRT modalities.

C. True. Delivering adequate dialysis is a core quality indicator for KRT programs and mandates routine and regular measurement of delivered dose. Because underdelivery of the prescribed dose is frequent, prescriptions frequently target 25 to 30 mL/kg/hr or a Kt/V of 1.3.

D. False. While cytokine removal via diverse variations of high-dose continuous KRT was theoretically very promising, studies have been unable to demonstrate any benefit of any of these modalities. This may be because these techniques can be quite difficult to sustain, cytokine removal is not achieved or beneficial, or because high-volume continuous KRT also removes beneficial substances (e.g., antibiotics, amino acids). These techniques are now largely abandoned as other methods of cytokine removal are being explored (e.g., adsorption filters).

2.

A. False. The combined IGFBP/TIMP2 biomarker test can help identify patients at risk of developing AKI, but it does not assist in the diagnosis of AKI (the KDIGO criteria are still the gold standard) nor do they predict who will progress to severe AKI or need KRT.

B. False. In general, the suboptimal sensitivity and specificity of biomarkers of AKI have limited their usefulness in guiding the therapy of AKI. Biomarkers that accurately identify progression to severe AKI or need KRT are also lacking. This remains an area of research with ongoing studies being performed to identify novel biomarkers, or biomarker panels that may assist in the therapy of AKI.

C. False. The furosemide stress test (FST) was initially found to identify patients who would progress to severe AKI (those requiring dialysis). However, the FST Trial found that the FST failed to identify 25% of patients assigned to a "late start" who never required KRT. While this was a significant improvement from previous studies, it did not prevent initiating KRT in patients who would not need it, nor did it have an impact on patient survival.

D. True. With the exception of the ELAINE trial, the available randomized control trials have not shown a benefit of starting KRT prior to the development of classic initiation criteria.

3. A. True. This is based on the findings of the CATHEDIA trials. However, it should be noted that this general finding did not hold true in the heaviest tertile of their population (BMI > 28). Thus, these results may not be applicable to other populations. Individual institutions should therefore monitor their own outcomes and establish local policies based on their results.

B. False. Temporary dialysis catheters are associated with less infection in chronic dialysis, but infection rates in acutely ill patients are not as well established. An observational study found better function, but this may have suffered from unaccounted for confounders. Current guidelines therefore recommend starting with a temporary nontunneled dialysis catheter rather than a temporary dialysis catheter.

C. False. Evidence-based guidelines and cumulative clinical experience both favor the use of arteriovenous access for intermittent hemodialysis. Catheters are only preferred for continuous therapies. While certain centers have used fistulas for KRT, this practice should be reserved for those with specialized expertise and specialized protocols aimed at protecting the integrity of the fistula/grafts.

D. False. Left-sided internal jugular and subclavian catheters provide flows that are more erratic and up to 100 mL/min lower than elsewhere. Femoral and right-sided internal jugular or subclavian catheters provide the best Qb. Overall, data support a recommendation for right-sided internal jugular catheters as the first choice for KRT, with femoral and left-sided internal jugular catheters as the second and third choices, respectively.

4.

A. Yes. Low rates of infection require both adherence to specific clinical guidelines and establishing a formal quality improvement framework. There is strong evidence that standardizing catheter insertion techniques to best practice results in a near-zero catheter-related infection rate. The relevant interventional bundles are contained in position statements of the Institute for Healthcare Improvement and the Centers for Disease Control and Prevention Healthcare Infection Control Practices Advisory Committee.

B. No. Topical antibiotic ointments are not recommended because of their potential to promote fungal infections and antimicrobial resistance.

C. The CDC recommends the use of antibiotic- or antiseptic-impregnated lines in patients whose catheters are expected to remain in place for longer than 5 days, and those at high risk for infection (e.g., extensive burn injury, neutropenia); however, there is scant good data establishing their efficacy in dialysis patients. KDIGO guidelines do not comment on this topic.

D. No. There is ongoing controversy around the risk for infection with different insertion sites, but on balance the internal jugular site is preferred, especially in those with a larger body mass index. However, it is likely that the way the catheter is handled is more important at preventing.

5.

Patients receiving systemic anticoagulation with heparin, have a lower incidence of circuit failure, but a higher incidence of significant bleeding complications.

False. Citrate anticoagulation has consistently been found to be more effective than heparin and is not associated with a higher bleeding risk.

Argatroban is the preferred approach in those with heparin-induced thrombocytopenia.

True. Patients on KRT with HIT are treated as those not on KRT. There are published protocols for using argatroban on continuous KRT.

C. False. Despite this complication being widely touted, it is very rare. In fact, metabolic alkalosis, hypernatremia, and hypocalcemia are the most common side effects; all of which are easily prevented with appropriate use of protocols.

D. False. Saline flushes are frequently used, but have not been definitively shown to enhance circuit life.

CHAPTER 76

1.

A. **Correct. Patients with HRS have vasodilation of the splanchnic circulation as a result of the activation of the vasodilator systems at this level.**

B. **Correct. In patients with HRS the heart cannot increase its output to compensate for a decrease in cardiac preload (secondary to the accentuation of splanchnic arterial vasodilation).**
C. **Correct. Systemic inflammation represents an important pathogenic factor for HRS.**
D. HRS is a functional kidney disorder. The presence of significant glomerular and/or tubular disease excludes the diagnosis.

2.

A and B. HRS is a functional kidney disorder with a diagnosis that is based on clinical criteria. Moreover, biopsy is risky in patients with liver disease with severe coagulopathy.
C. Activation of the vasoconstrictor systems (the renin-angiotensin-aldosterone system, the sympathetic nervous system, and vasopressin) is a key factor in the pathogenesis of HRS. Plasma renin activity/concentration is markedly increased in the majority of patients. However, its measurement is complicated and not useful in the clinical setting.
D. **Correct. The diagnosis of HRS is mainly one of exclusion and should be suspected in any patient with subacute or chronic liver disease with advanced liver failure and portal hypertension who develops progressive kidney impairment.**

3.

A. HRS should be suspected in any patient with subacute or chronic liver disease with advanced liver failure and portal hypertension.
B. **Incorrect. In the splanchnic circulation, there is marked arteriolar vasodilation resulting in reduction of systemic vascular resistance and arterial hypotension.**
C. Activation of the vasoconstrictor systems (the renin-angiotensin-aldosterone system, the sympathetic nervous system, and vasopressin) is a key factor int eh pathogenesis of HRS.
D. **Incorrect. HRS occurs in patients with advanced liver failure. The presence of ascites is mandatory.**
E. Infection is the most frequent trigger event of HRS.

4.

A. **Inorrect. Among the vasoconstrictor therapies, intravenous terlipressin, combined with daily albumin infusion, is the preferred therapy.**
B. **Incorrect. TIPS could be an alternative treatment of type 1 HRS in patients without response to terlipressin/norepinephrine plus albumin.**
C. Dialysis is not tolerated in patients with HRS (already hypotensive) and does not improve survival. It should be reserved for critically ill cirrhotic patients with severe uremia and volume overload.
D. **Inorrect. Some studies suggest that albumin dialysis may have beneficial effects in patients with type 1 HRS.**
E. In patients with HRS, the administration of midodrine, octreotide, and albumin is much less effective in improving kidney function than the combination of terlipressin plus albumin.

5.

A. **Correct. Primary prophylaxis of SBP with norfloxacin prevents SBP delays the development of HRS, and improves short-term survival in cirrhotic patients with advanced cirrhosis.**
B. **Correct. Albumin infusion prevents HRS in patients with SBP.**
C. Two randomized controlled trials have failed to show that albumin administration improves survival in infections other than SBP.
D. No study supports this contention.

CHAPTER 77

1. C. Fraction of normal dose = $1 - 0.8\ (1 - 0.25) = 0.4$. Therefore the dose should be reduced to 40% of the original dose.

2.

A. High-flux membranes have larger pore sizes and therefore increase removal.
B. Low protein binding allows a greater portion of unbound drug to be available for clearance.
C. A low volume of distribution indicates a larger portion f the drug dose that is in the plasma available for removal by dialysis.
D. **Correct. Large molecular sizes prevent drug removal because the drug cannot pass through the membrane pores.**

3.

A. **Correct. Renally cleared, although it has a wide therapeutic index and limited toxicity, so dose reduction usually is not clinically required for standard courses of oral doses.**
B. Extensively renally cleared with significant toxicity requiring significant dose reduction.
C. Extensively renally cleared with significant toxicity and narrow therapeutic index requiring significant dose reduction.
D. Extensively renally cleared with significant potential toxicity requiring dose reduction.
E. Extensively renally cleared with significant potential toxicity requiring significant dose reduction.

4.

A. Clarithromycin is a potent CYP3A4 and P-glycoprotein inhibitor significantly increasing sirolimus exposure.
B. Phenytoin is a potent enzyme-inducing agent that significantly increases the metabolism of coadministered hepatically cleared drugs such as prednisolone.
C. Fluconazole is a weak inhibitor of CYP3A4 and P-glycoprotein and may increase tacrolimus exposure, especially during prolonged combination use.
D. **Correct. Roxithromycin is a weak inhibitor of CYP3A4 and P-glycoprotein and rarely causes clinically significant increases in drug exposure, especially during typical 5-day courses of therapy.**
E. Verapamil is a strong inhibitor of CYP3A4 and P-glycoprotein and significantly increases everolimus exposure.

CHAPTER 78

1.

A. **Correct. Extensively renally cleared. Accumulation in kidney impairment increases the risk of bleeding.**
B. **Correct. Extensively renally cleared. Accumulation in kidney impairment increases the risk for adverse CNS effects.**
C. Significantly renally cleared, although accumulation is not clinically significant and dose reduction is usually not required.
D. Extensively hepatically cleared. Dosing is based on clinical response.
E. **Correct. Extensively renally cleared. Accumulation in renal impairment increases the risk of adverse CNS effects.**

2.

A. Weak CYP3A4 inhibitor. CNI concentration may increase. Base subsequent dose modification on measured CNI concentration changes.
B. **Correct. Strong CYP3A4 inhibitor. CNI concentration expected to increase. Avoid combination or significantly reduce CNI dose if combination is essential.**

C and D. Renally cleared and does not affect CYP3A4. No interaction expected.

3.

A. Hepatically cleared without active or toxic metabolites.
B. **Correct. Metabolized to oxypurinol, which can accumulate in kidney impairment.**
C. Renally cleared without active or toxic metabolites.
D. Hepatically cleared without active or toxic metabolites.
E. **Correct. Metabolized to toxic metabolite meperidine, which is renally cleared.**

4.

A. **Correct. Small molecule that is renally cleared and significantly removed by dialysis.**
B. Large volume of distribution so minimal amounts removed by dialysis.
C. **Correct. Small molecule renally cleared and significantly removed by dialysis.**
D. Significantly protein bound so minimal removal by dialysis.
E. **Correct. Small molecule renally cleared and significantly removed by dialysis.**

CHAPTER 79

1. B. Aristolochic acid nephropathy
2. C. Chronic tubulointerstitial nephritis (Balkan endemic nephropathy)
3. A. Cystine crystal
4. A. Acute rejection

CHAPTER 80

1. A. The KDIGO guideline on the classification of CKD recommends using a CGA staging system, including cause of disease, GFR, and level of albuminuria.
2. C. The presence of albuminuria has been linked to the development of albuminuria in many studies. Work by the CKD Prognosis Consortium found that low GFR remains a significant risk factor for morbidity (including ESKD) and mortality in older adults, and that there was little difference in the risk associated with albuminuria between men and women. Assays for proteinuria are less accurate than those for albuminuria.
3. B. *APOL1* risk alleles are almost solely present in persons of African descent. However, lower socioeconomic status and poor access to medical care is a big determinant of racial disparities in ESKD as well as other health outcomes.
4. C. Rates of new dialysis patients rise progressively with age, at least until approximately 75 to 80 years. They are highest in some Southeast Asian countries and the United States, among males, and among people with lower socioeconomic status.
5. D. Among patients with CKD, vascular mortality rates are higher than in general population; if rates of these were lower, a greater number of people would survive to reach ESKD. Issues of competing in other senses of the word are not relevant. Propensity score matching is a technique for dealing with potential confounders, not competing risks.

CHAPTER 81

1. B. Podocytes are damaged by excessive protein load after size selectivity is lost. Protein uptake by podocytes may occur through binding to megalin, a receptor for albumin and immunoglobulin light chains that is endocytosed after ligand binding, as shown in cultured murine podocytes. Excessive protein uptake by podocytes also incuses TGF-β production, which contributes to cell apoptosis, an additional cause of podocyte loss in proteinuric glomerulopathies.
2. A. Loss of podocytes secondary to protein-induced cell injury may lead to reduced production of VEGF, a molecule constitutively expressed and secreted by podocytes, influencing the formation of glomerular endothelial fenestrae and eventually promoting endothelial cell apoptosis.
3. B. Exposure of rat proximal tubular cells to excess autologous albumin, as in the case of proteinuric nephropathies, results in the formation of the N-terminal 24-residue fragment of albumin (ALB1-24). This peptide is taken up by dendritic cells, where it is further processed by proteasomes into antigen peptides. These peptides were shown to have the binding motif for MHC class I and to be capable of activating CD8+ T cells.
4. C. The progressive enlargement of cysts in the renal tubules in autosomal dominant polycystic kidney disease is largely attributable to the proliferation of mural epithelial cells and transport of fluid into cavities generated by accelerated epithelial cell growth.

CHAPTER 82

1. E. C and D
2. E. All the above
3. E. There will be an initial decline in kidney function (eGFR), which will be accompanied by a slower rate of eGFR decline over time, and slowing of progression to incident kidney failure.
4. E. All the above
5. E. All the above

CHAPTER 83

1. D. Cardiovascular disease
2. C. The CKD-EPI formula
3. B. Weight
4. B. Nocturia
5. D. Creatinine 13.5 mg/dL

CHAPTER 84

1. D. Hyperhomocysteinemia
2. E. The calcific aortic stenosis progression rate is only slightly higher in dialysis patients compared with the general population.
3. D. Stroke
4. C. Carvedilol

CHAPTER 85

1. D. Myocardial infarction
2. E. A history of atrial fibrillation
3. C. Less than 55 mg/dL
4. A. More and larger plaques

CHAPTER 86

1. E. The RBC life span is usually normal.
2. D. The defined upper dose limit of epoetin is 60,000 IU/wk because it is known that CV toxicity occurs above this dose level.
3. A. Patients receiving darbepoetin alfa were randomized to either a target hemoglobin (Hb) of 13 or a target Hb of 9 g/dL.
4. D. IV iron may improve the anemia of chronic kidney disease in up to 30% of patients not receiving ESA therapy who have a low ferritin level.

CHAPTER 87

1. D. Blood culture for bacteremia
2. A. HBV infection leads to chronic infection in the majority of affected CKD patients.
3. E. None of these
4. E. Clopidogrel

CHAPTER 88

1. C. Although the PTH value of this woman is in the desired range, her phosphate levels are too high. In particular in this situation, additional calcium loading should be avoided.
2. E. The very low PTH of this dialysis patient is almost diagnostic of low turnover bone disease. The key measure to improve bone turnover is avoidance of calcium loading.
3. E. Calcimimetics are not licensed for use in patients with stage 4 CKD stage. There is concern that in this situation calcimimetics lead to increases in serum phosphate.

CHAPTER 89

1. A. Use of gabapentin for neuropathic pain
2. F. A, B, and C are correct.
3. C. Iron overload and deposition in the basal ganglia

CHAPTER 90

1. B. Low predialysis urea and electrolytes along with low cholesterol may indicate a reduced protein and calorie intake and warrant further dietary investigation. The breathlessness also may indicate that although the target weight has been stable for months, dry weight has been lost over previous weeks (or months) and has been replaced by fluid, so reassessment of target weight is needed. It is a common mistake to see low blood urea nitrogen and electrolytes in a dialysis patient and reduce the amount of dialysis given. This can cause appetite to reduce further, exacerbating the problem. Serum albumin, with its relatively long half-life, does not always drop with a poor dietary intake and therefore is not a good marker of nutritional status on its own. Although one might consider starting a diuretic in a patient with some urine output, there is no indication to restrict fluids in this patient.
2. C. The patient is very enthusiastic about exercise and was found to be taking protein supplements. Protein intake works out to be 1.5 g/kg of body weight. If protein intake is high, a reduction toward 1 g/kg may reduce symptoms and also lesson the phosphate and potassium intake and the acid load. Although the BMI is 27, if the patient is exercising extensively, this higher BMI may reflect a higher muscle mass; a lower calorie intake is not necessarily indicated. In fact, if protein intake is being reduced, it will be important to ensure that advice is given to maintain calorie intake for weight maintenance. Sodium intake is high, and because the blood pressure is elevated, it would be very beneficial to advise on ways to reduce sodium in the diet. Potassium is at the top of the reference range, but reducing protein intake often leads to a reduction in the potassium intake, and the correction of acidosis with bicarbonate is likely to also have a beneficial effect on potassium.
3. D. The symptoms suggest reduced gastric emptying, possibly because of a combination of diabetic autonomic neuropathy and kidney failure. Reducing dialysis volumes would be wrong because having clearances above the minimum target does not exclude inadequate dialysis as a cause of his symptoms (and 2-L exchanges are not particularly large for this patient). It may even be appropriate, if other measures do not help, to increase the dialysis prescription in case there is a contribution of uremia to his symptoms. Attempting a weight reduction diet would be inappropriate in this patient, who is already losing weight and raising concerns about his nutrition. Initial forms of nutritional supplementation would be by oral means (dietary advice and supplements if needed) rather than amino acid dialysate as first-line treatment.

CHAPTER 91

1. B. A systemic disorder caused by uremia
2. E. In all patients
3. C. Is limited to patients with therapy failure
4. D. Warfarin and coumarins
5. B. Is related to exposure to linear gadolinium chelates

CHAPTER 92

1. B. A CKD is a common finding in patients on maintenance HD treatment and is a possible cause of hematuria.
2. E. Data from large registries reveals a nearly 10-fold increase in the risk for colorectal cancer in patients on HD treatment.
3. D. Bilateral nephrectomy is the treatment of choice for asymptomatic A CKD in kidney transplant recipients because malignant transformation occurs in almost 90% of cases.

CHAPTER 93

1. C. Crescentic glomerulonephritis
2. B. Her inability to ambulate, frailty, and depression will likely not improve with dialysis, and her condition is likely to continue to deteriorate over time.
3. B. He would likely benefit from transplantation, and he should consider living donation as the best option.

CHAPTER 94

1. A, D, and E. Survival on dialysis for elderly patients does not depend on dialysis modality, but is related to frailty and comorbidities.
2. C, D, E. Advance care planning is an outcome of shared decision making and is not a legal process. It involves sharing information between patient and health care team to arrive at an informed decision made by the patient
3. A and E. Dialysis withdrawal is withdrawal of life-sustaining treatment that is no longer effective in sustaining quality of life. In the absence of kidney function, patient survival is around 7 days, depending on comorbidities; survival can be considerably longer if the patient still has some residual kidney function.
4. A, D, and E. The decision for a patient to have conservative care is made after shared decision making. A number of retrospective studies have shown no survival advantage of dialysis compared with conservative care for patients older than 80 years and multimorbid patients older than 75 years. Conservative care is no dialysis but includes optimal management of kidney disease complications, comorbidities, and symptoms.

CHAPTER 95

1. B. In patients who are suitable for kidney transplantation, outcomes with a transplant are superior to any dialysis modality. Preemptive transplantation gives superior outcomes to transplantation after dialysis has been started. A living donor kidney gives superior outcomes to a deceased donor kidney.
2. D. The IDEAL study showed no improvement in outcomes with early initiation of dialysis, but health care costs were increased.
3. C. There is no single threshold of eGFR when dialysis should be started. Answers B and D can be managed without dialysis.
4. D. Physical and psychological preparation for dialysis or transplantation takes many months. The appropriate trigger for transferring a patient to multidisciplinary kidney care is therefore the time before

KRT is expected to be needed, rather than an arbitrary level of kidney function.

5. A. If a patient expresses a clear wish not to have dialysis, the physician is obliged to respect this because to treat patients against their will constitutes assault.
6. C. In the presence of a good performance status and little or no comorbidity, age alone does not indicate a poor prognosis on dialysis.

CHAPTER 96

1. C. The patient's ESKD Life-Plan and corresponding access needs (insertion/creation plan, contingency plan, succession plan, vessel preservation plan).
2. D. All the above
3. B. The DRIL procedure
4. D. Lower infection rate
5. A. Percutaneous transluminal angioplasty

CHAPTER 97

1. B. False
2. C. Less than 30% residual stenosis and resolution of physical indicators of stenosis
3. D. A and B
4.

A. An ultrasound of the kidneys should be performed in all patients with chronic kidney failure to rule out obstructive uropathy and polycystic kidney disease and to exclude advanced, irreversible disease (small kidneys with thin cortex) for which a biopsy will not be useful.

B. In many patients with acute kidney failure, the cause is apparent from the clinical picture (i.e., sepsis) and imaging is useful only when the cause is not apparent, the clinical picture suggests urinary obstruction, and it is not clear how much of the kidney failure is acute or chronic.

C. **Correct. Ultrasound is the modality of choice for diagnosing bladder outlet obstruction, with a negative study essentially ruling this out.**

D. Normal ureters are too small to be detected by sonography. Even when dilated, they are often not apparent because of overlying bowel gas.

5. E. All the above

CHAPTER 98

1. A. Endotoxin molecular weight is too high (~100,000) and thus cannot pass through dialysis membranes.
2. C. The bacterial microflora in the gut metabolizes some amino acids and other precursors into uremic toxins, for example, tryptophan into indoles, L-tyrosine into p-cresol, and choline into trimethylamine.
3. D. A large body of high-quality evidence indicates that a hemodialysate at a temperature below the patient's core temperature results in improved intradialytic hemodynamic stability.
4. A. A recent study showed an increased morbidity and mortality in HD patients with prolonged intradialytic hypoxemia.
5. B. Water preparation according to national and international guidelines is the foundation of dialysate preparation.

CHAPTER 99

1. C. Probably 3 hours of dialysis time because there would not be enough time to remove interdialytic volume without a dangerously high ultrafiltration rate. The other factors may not be optimal but are far less dangerous.
2. A. Use of antihypertensive drugs in large trials rarely reduce systolic BPs by more than 10 mm Hg. The other actions are more effective, particularly C and D together.
3. B. Application of abdominal pressure would not be useful in these circumstances. Decreasing dialysate temperature will cause arteriolar vasoconstriction, and reducing ultrafiltration will maintain circulating volume. Having an easier (higher) weight target to reach will indirectly result in lower ultrafiltration rates and maintenance of BP.
4. D. An increase in dialysate flow rate does not affect the convective volume in online HDF. All the other actions listed here, either individually or in combination with one or more of the other actions, are useful to increase convection volume.
5. C. This indicates the importance of apparently even small degrees of residual function (2.00 is the minimal standard KtV prescribed dose).

CHAPTER 100

1. B. Cardiac ischemia
2. D. Avoidance of excessive interdialytic weight gains
3. E. Heparin exposure
4. E. Peracetic acid
5. E. All the above

CHAPTER 101

1. B. The glucose molecules are smaller than the ICO molecules and therefore are relatively "inefficient" as osmotic agents in small pores, but relatively more efficient across AQP.
2. E. None of the catheters above shows significant clinical superiority.
3. C. Increases in small-solute transport (PETcreat) combined with no or only moderate increases in the UF coefficient (LpS).
4. D. They produce higher concentrations of the dialysate effluent marker CA-125.
5. E. Icodextrin is polydispersed, but with 30% of the molecules being larger than 3 kDa.
6. A. Small pores

CHAPTER 102

1. A and C. A is false because although there is some emerging evidence of the superiority of the laparoscopic technique, this is not a substitute for a well-audited and experienced surgical team. C is false because normal pH solutions should be considered if available. Note that E is true but occasionally is due to fluid tracking down the abdominal wall from a deep cuff leakage.
2. B and C. B is false because antifungals should be commenced intraperitoneally, but the catheter should be removed and treatment continued systemically. C is false because treatment should await cultures; the indications for immediate treatment are purulent discharge of clinical evidence of infection of the tunnel. Note that D is true for both exit site infections and peritonitis. E is true and remains the most common reason for PD-associated peritonitis death.
3. B and D. B is false because the target should take residual kidney function into account; an anuric patient obtaining less than 1 L should have their membrane and prescription examined. D is false; CT can be used to confirm that obstructive symptoms are a result of encapsulation but should not be used to screen for EPS in the absence of symptoms. Note that A is true because of both increasing solute transport and loss of osmotic conductance. For E, progressive loss of osmotic conductance is not treatable, and PD should be continued only in patients with otherwise low life expectancy.

CHAPTER 103

1. A. Ethylene glycol is metabolized to glycolic acid and oxalate by alcohol dehydrogenase. Its presentation is associated with oxalate crystals in the urine and a raised anion gap acidosis.
2. E. Acute kidney injury is not associated with a raised osmolar gap, whereas all of the other conditions are.
3. C. All the other drugs/poisons are effectively removed by intermittent HD.
4. A. Hemoperfusion remains the first choice treatment for removal of theophyllines.

CHAPTER 104

1. C. Should be started immediately while awaiting complement studies and possible use of eculizumab.
2. A. Should be started immediately while awaiting complement studies and possible use of eculizumab.
3. A. Good evidence for benefit of plasma exchange.

CHAPTER 105

1. E. PD-L1
2. E. A and D
3. C. Tubulitis, interstitial inflammation, arteritis
4. B. Siblings from the same parents are predicted to have a 50% chance of having zero HLA mismatches.
5. C. The MHC class I system is designed to present extracellular proteins taken up and processed by antigen-presenting cells.

CHAPTER 106

1. A. Nephrotoxicity
2. C. Blocks CD28 mediated costimulation of T cells
3. D. Mycophenolate
4. B. Basiliximab

CHAPTER 107

1. A. Active sepsis will likely worsen with immunosuppression, so it is important to have this resolved before transplantation. Responses B to E are no longer seen as contraindications, although special care must be taken to address the specific issue and potentially modify the immunologic, medical, and surgical approach to transplantation.
2. D. A normal stress echocardiography result does not necessarily exclude coronary heart disease, however the negative predictive value for myocardial infarction or cardiac death is in excess of 90% in patients with kidney failure.
3. D. Deceased donors over the age of 60 years without any other medical history of significance meet the definition for expanded criteria donors. If there is a history of hypertension or death from a cerebrovascular accident, the age for classifying a donor as meeting expanded criteria can be lower between 50 and 59 years old. Diabetes, smoking, vascular disease, and HCV are not factors used to classify donors as expanded criteria. The new KDRI/KDPI system is more detailed and does use donor age, diabetes, hypertension, HCV, and mode of death in the formula when deriving the donor score.
4. B. A colonoscopy would usually be considered only in donors with bowel symptoms, iron deficiency, or a family history of colon cancer. Urine microscopy and imaging are important tests in assessing underlying kidney conditions in the donor and defining anatomy before donation. Hepatitis serology is important in assessing the risk for disease transmission. An electrocardiogram will help define the donor's cardiac status and possible risks associated with the surgical procedure and anesthetic.
5. C. A positive T cell cytotoxicity-dependent crossmatch is likely to be indicative of a very high level of donor-specific antibodies against class I HLA, making the risk for hyperacute rejection extremely high. Additionally, this test is functional in that it uses T cells from the donor (therefore expressing antigens that also may be present on the allograft) to assess the recipient's immunologic reactivity to the allograft.

CHAPTER 108

1. A and D
2. A and D
3. C. von Willebrand disease
4. C and E
5. A. Transplant nephrectomy is mandatory for early graft failure caused by thrombosis.

CHAPTER 109

1. D. Peritubular capillary C4d deposition, circulating donor-specific antibodies, peritubular capillaritis (ptc2)
2. B. Lymphocyte-depleting agents are more effective in preventing acute rejection compared with IL-2 receptor antibodies in patients at high immunologic risk.
3. B. Tacrolimus, MMF, prednisone
4. C. rATG 1.5 mg/kg IV for 7 to 14 days

CHAPTER 110

1. D. Seasonal influenza vaccine is safe and effective, and no conclusive evidence exists for a link between vaccination and allograft dysfunction. The AST-IDCOP guidelines recommend that all transplant recipients receive COVID-19 vaccination irrespective of prior COVID-19 infection or evidence of humoral immunity. The CDC recommends that vaccination should be postponed for 90 days following COVID-19 infection or following receipt of convalescent plasma or monoclonal antibody. However, the ideal period for vaccination after infection remains to be studied. Inactivated vaccine should be completed by 2 weeks prior to transplantation to optimize immune response to vaccination and a minimum of 4 weeks should elapse between live attenuated virus vaccine administration and transplantation to minimize the possibility of live vaccine-derived infection in the posttransplantation period.
2. A. Quantitative CMV assays in patients with invasive colitis and gastritis or neurologic disease, including chorioretinitis, are often negative and diagnosis may require invasive testing and biopsies.
3. C. Rituximab is considered first-line treatment for CD20-positive PTLD that fails to respond to manipulation of immunosuppression alone. The use of acyclovir and ganciclovir are of unproven benefit. PTLD is the most common type of posttransplantation malignancy in children, whereas skin cancers are the most common de novo posttransplantation malignancy in adult kidney transplant recipients. The higher incidence of PTLD in children compared with adult has been attributed pretransplant EBV naive status in the pediatric population

CHAPTER 111

1. D. The American College of Cardiology/American Heart Association guidelines on blood pressure management advocate liberalizing the BP target to <160/90 mm Hg in the early posttransplantation period to maintain organ perfusion and avoid hypotension to reduce the risk of graft thrombosis. Beyond the first posttransplantation month, more stringent BP control to <130/80 mm Hg is recommended to prevent end-organ damage. The beneficial effect of ACE inhibitors or ARBs on patient or graft survival has not been consistently demonstrated. The KDIGO guidelines suggest a BP goal of <130/80 mm Hg for kidney transplant recipients irrespective of the level of albuminuria. Because of the lack of conclusive evidence that one class of antihypertensive agent is superior to another in transplant recipients, the choice of antihypertensive agents should be individualized based on efficacy, tolerability, concomitant comorbidity, and drug-drug interactions.
2. C. The concomitant use of statins and cyclosporine often results in a severalfold increase in statin blood level because CSA inhibits CYP450 3A4 enzyme, of which statins are major substrates. In addition, CSA inhibits OATP1B1/SLCO1B1-mediated hepatic uptake of statins, resulting in significant medication interaction. In patients receiving CSA immunosuppression, high dose statin should be avoided because CSA-induced increase in statin bioavailability can result in an increased risk for myopathy and rhabdomyolysis. In contrast, tacrolimus does not inhibit CYP3A4 to a significant extent and has no effect on OATP1B1/SLCO1B1 and thus drug-drug interaction with statins is not observed. However, rhabdomyolysis associated with tacrolimus and statin use may be seen in patients on concomitant diltiazem therapy because the latter is a moderate CYPA3A4 inhibitor.
3. D. Both calcineurin inhibitors and mTOR inhibitors are diabetogenic. Tacrolimus has been shown to be more diabetogenic than cyclosporine. Sirolimus or everolimus use is associated with the worst lipid profile (particularly hypertriglyceridemia) compared to cyclosporine and tacrolimus. Belatacept, mycophenolic acid derivatives, and azathioprine have not been shown to be diabetogenic.

CHAPTER 112

1. D. HLA alloantibodies
2. C. 1, 2, and 3 are correct
3. E. 1, 2, and 4 are correct

CHAPTER 113

1. A. Risk is approximately 5% to 10% within 10 years after transplantation for IgAN; less than 1% for B, C, and D; and E does not recur.
2. E. A histologic diagnosis pre- and posttransplantation is required for the diagnosis of recurrent disease.
3. D. Plasma exchange should be started once a diagnosis of recurrent FSGS is made, with a plan to complete approximately nine cycles of therapy.

CHAPTER 114

1. B. Statistical method of maximizing the information available for analysis of outcome from a group of patients and events
2. C. Acute rejection, graft failure, lost to follow-up, and patient death
3. C. Method of combining the results from all similar trials to gain statistical power

ClinicalKey®

Confidence is ClinicalKey

Evidence-based answers, continually updated

The latest answers, always at your fingertips

A subscription to ClinicalKey draws content from countless procedural videos, peer-reviewed journals, patient education materials, and books authored by the most respected names in medicine.

Your patients trust you. You can trust ClinicalKey.

Equip yourself with trusted, current content that provides you with the clinical knowledge to improve patient outcomes.
